Color Centers in Cadmium Fluoride

Martin Rubenstein[1] and Ephraim Banks

Department of Chemistry, Polytechnic Institute of Brooklyn, Brooklyn, New York

ABSTRACT

Single crystals of CdF_2, purified and containing additions of NaF, CeF_3, and equimolar quantities of NaF and CeF_3, were grown from the melt in graphite crucibles in a helium atmosphere.

Physical constants of CdF_2 were measured. Optical transmission spectra were obtained before and after x-irradiation on slices of single crystals (about 1.5 mm thick), at 28°, —78°, —190°C. Crystals containing 0.05-4 mole % NaF, when irradiated at 28° or at —78°C, showed a radiation-induced absorption near the fundamental absorption edge; this induced absorption is stable at 28°C. These same crystals, when irradiated at —190°C, showed another absorption which is unstable at —78°C. CdF_2, pure, and containing low concentrations of CeF_3, NaF, or equimolar CeF_3 and NaF, all showed one x-ray induced absorption band, unstable above —10°C. CdF_2 x-irradiated at room temperature showed a very stable absorption band.

Color centers in alkali halides (1, 2), and to a lesser extent in alkaline earth halides (3-5), have been and are being investigated extensively. Only limited data have been published on the compound CdF_2 (6, 7), and there have been no investigations on color centers in this compound.

The density, melting point, optical transmission spectrum, and lattice constant of CdF_2 have been reported (6, 7). These characteristics were reinvestigated and are reported here. Since no color centers had been reported in CdF_2, we obtained transmission spectra (200-1200 mμ and 2000-15,000 mμ) of single crystals of CdF_2, pure, and with various additions before and after x-irradiation at 28°C (room temperature), —78°C (acetone and solid CO_2), and —190°C (liquid nitrogen).

Experimental Procedures

Chemical compounds and materials.—"Standard luminescent" grade $CdCO_3$ powder[2] was purified by dissolving the carbonate in concentrated aqueous ammonia solution, filtering repeatedly, precipitating with concentrated aqueous hydrofluoric acid, and leaching this precipitate repeatedly with boiling concentrated aqueous hydrofluoric acid. The purified CdF_2 was dried and used in the preparation of single crystals with and without additives.

Cerium (III) fluoride (CeF_3) was prepared by dissolving ammonium hexanitratocerate (IV)[3] in water and reducing with 3% aqueous H_2O_2 solution; a gelatinous precipitate was obtained on acidification with aqueous hydrofluoric acid, washed repeatedly with doubly distilled water, centrifuged, and heated to dryness.

Growth of single crystals.—Single crystals of about 8 g in weight were prepared by placing CdF_2 powder, with or without additions, in covered graphite[4] crucibles; the crucibles were placed in vitreous silica tubes (one end closed); a flow of helium (purified) was maintained in the silica tube; the silica tube was placed in a furnace. The furnace temperature was raised to 1120°C and the setting of the furnace controller was lowered in a step-wise manner (cut down 10° in 2 min, held for 8 min, and then this cycle was repeated) until room temperature was reached. The additions of CeF_3 were prepared by mixing CeF_3, prepared by using the method mentioned in the previous section; the additions of NaF were prepared by mixing reagent grade NaF with CdF_2. The smaller concentration additions were made by using portions of solid solutions of larger concentrations.

Density measurements.—The density of CdF_2 was obtained by using a 10 ml solid pycnometer, fragments of melted CdF_2 (each fragment about 5 mm in diameter), and doubly distilled water as the immersion liquid. The water level in the pycnometer was reached by using a water bath maintained at 36.5°C.

Melting point.—The melting point of pure CdF_2 was determined by recording heating curves. The CdF_2 powder was placed in a graphite crucible with the same apparatus as used for crystal growth. The temperature was measured by a Pt-Pt 10% Rh thermocouple whose junction was positioned in the wall of the graphite crucible—the distance between the thermocouple junction and the melt being less than 1/32 in. The thermocouple was calibrated using gold (mp 1063°C). The furnace temperature was raised and the arrest in the plot of thermocouple temperature vs. time was noted as the melting point.

Lattice constants.—The lattice constants of pure CdF_2 and CdF_2 with additions were obtained by means of the Debye-Scherrer technique, using a 57.32 mm radius Straumanis-type camera with nickel-filtered copper radiation. Eight back-reflection lines of the x-ray diffraction diagram were measured and the precision lattice constants were

[3] G. F. Smith Chemical Co., certified grade. NaF was reagent grade.

[4] AUC grade from National Carbon Corp.

calculated by the Straumanis calibration (8) and the Bradley-Jay (9) extrapolations.

Crystal slices.—The single crystals grown were cylinders about 12.5 mm in diameter and 12.5 mm in height. These crystals were sliced with a diamond-impregnated saw on a milling machine. These slices were mounted in polystyrene, polished with emery papers, and the final polishing was accomplished on a metallurgist's wheel using a silk cloth, Linde "B" Alumina, and water as a lubricant.

Optical measurements.—The transmission measurements were obtained at 28°C by a Process and Instruments Co. recording spectrophotometer, and at other temperatures by a Beckman DU Spectrophotometer, using a modified cell described by Casler, Pringsheim, and Yuster (10). The primary modifications were: standard tapered joints were replaced by ball and socket joints to provide maneuverability, and the beryllium window was replaced by an aluminum foil (0.2 mm) window. Transmissions were measured against an air path.

Irradiation.—The crystal slices were x-irradiated by a Machlett OEG-50-6 x-ray tube. The tungsten target permitted the generation of a white radiation x-ray spectrum. The tube was run as a self-rectified tube at 26 ma and 42 peak kv.

Ultraviolet irradiation was accomplished by a Conte-Glo lamp (3650Å). Infrared irradiation was obtained by a commercial infrared lamp.

Results

Physical constants.—The density of CdF_2 as previously reported (6) was 6.33 ± 0.06 g/cm³. Our pycnometric value for purified CdF_2 was 6.40 ± 0.02 g/cm³. The density calculated from the lattice constant (5.3883Å) was 6.386 g/cm³. The pycnometric density of CdF_2 with 16 mole % CeF_3 in solid solution was 6.32 ± 0.02 g/cm³.

The melting point of CdF_2 as previously reported was $1049° \pm 2°C$ (6). Our value from melting point curves of purified CdF_2 was $1072° \pm 2°C$.

The lattice constant of CdF_2 (fluorite structure) previously was reported as 5.3880 ± 0.0005Å (6). Our value for the lattice constant of purified CdF_2 was 5.3883 ± 0.0005Å. The difference between these two values probably is not significant.

The lattice constants of CdF_2 with additions of NaF indicate that the limit of solid solution is at 3 mole % NaF; the lattice constants form a straight line function from pure CdF_2 to the limit of solubility of NaF in CdF_2, with lattice constants increasing with NaF concentration. Concentrations greater than 3 mole % NaF produced no further increase in lattice constant, but did produce a two phase system. The lattice constant of a sample with 3 mole % NaF in CdF_2 is 5.3897 ± 0.0005Å, which is an expansion

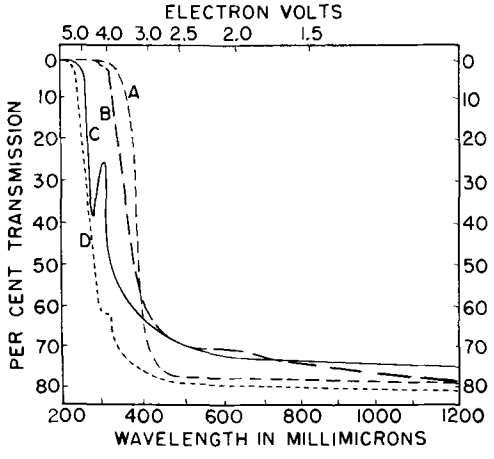

Fig. 2. Optical transmission spectra of CdF_2 with additions of CeF_3 measured at 28°C. A, CdF_2 with 10 mole % CeF_3; B, CdF_2 with 1 mole % CeF_3; C, CdF_2 with 0.01 mole % CeF_3; D, CdF_2 with 0.0005 mole % CeF_3.

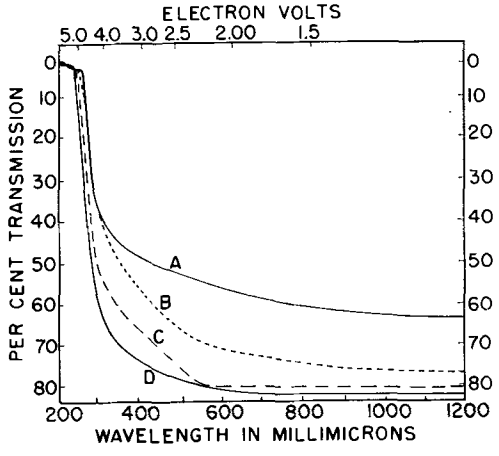

Fig. 3. Optical transmission spectra of CdF_2 with additions of NaF, measured at 28°C. A, CdF_2 with 5 mole % NaF; B, CdF_2 with 1 mole % NaF; C, CdF_2 with 0.05 mole % NaF; D, CdF_2 with 0.005 mole % NaF.

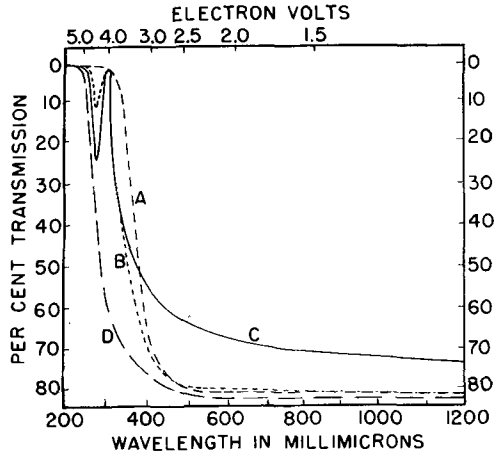

Fig. 4. Optical transmission spectra of CdF_2 with equimolar additions of NaF and CeF_3, measured at 28°C. A, CdF_2 with 5 mole % NaF and 5 mole % CeF_3; B, CdF_2 with 0.5 mole % NaF and 0.5 mole % CeF_3; C, CdF_2 with 0.05 mole % NaF and 0.05 mole % CeF_3; D, CdF_2 with 0.0005 mole % NaF and 0.0005 mole % CeF_3.

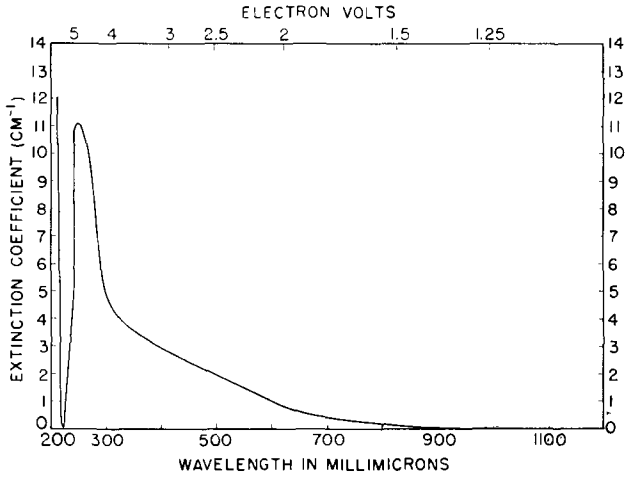

Fig. 5. Absorption spectrum of CdF_2 x-irradiated for 13 hr, x-irradiated and measured at 28°C.

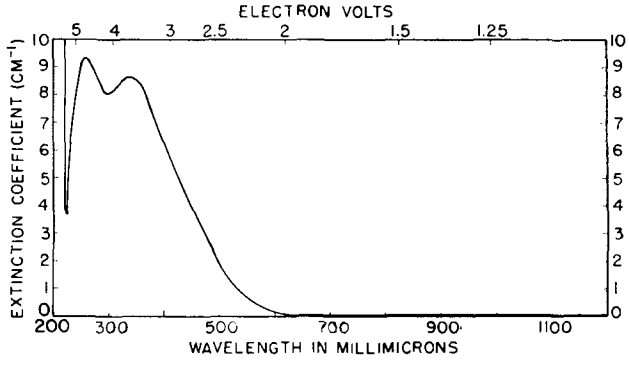

Fig. 6. Absorption spectrum of CdF_2 x-irradiated for 5 hr, x-irradiated and measured at —190°C.

of 0.0014 ± 0.0005Å. Similarly the lattice constants of CdF_2 with additions of CeF_3 indicate that the limit of solid solution is at 18 mole % CeF_3; this series also demonstrates a linear lattice expansion to 5.5032 ± 0.0005Å for the 18 mole % sample, which is an expansion of 0.0064 ± 0.0005Å per mole % CeF_3 in CdF_2. The lattice constant of a sample with 16 mole % CeF_3 in CdF_2 is 5.4890 ± 0.0005Å.

The maximum solubility of equimolar additions of NaF and CeF_3 in CdF_2 is 4.75 mole % NaF and CeF_3; this sample has a lattice constant of 5.4091 ± 0.0005Å. It should be noted that this lattice constant value would be attained in the solid solution containing no NaF at a composition of only 3.5 mole % CeF_3.

The optical transmission spectra from our data and from Haendler's (7) data are shown in Fig. 1. The fundamental absorption edge (the center of the portion of the transmission spectrum having the greatest slope before zero transmission) is at 265 mμ. Transmission spectra of polished crystal slices of CdF_2 with additions of CeF_3, NaF, and equimolar additions of CeF_3 and NaF are shown in Fig. 2, 3, and 4.

The transmission from 700 mμ to 10μ is almost constant with transmission of about 80%. At 10μ the transmission begins to fall and by 13.1μ there is no transmission; this edge is due to reststrahlen. In the range 2-15μ, crystals of CdF_2, purified, and with additions of NaF gave the same spectrum. However, CdF_2 crystals with CeF_3 and with equimolar additions of NaF and CeF_3, in addition to the reststrahlen edge, demonstrated another set of peaks around 4.40μ (2880 cm^{-1}). Two shoulders on both sides of the main peak at 4.17μ (2400 cm^{-1}), and at 4.64μ (2150 cm^{-1}) are observed in crystals of CdF_2 with CeF_3. In crystals with equimolar additions of CeF_3 and NaF, the main peak shifts to 4.45μ (2250 cm^{-1}) and the two shoulders appear at 4.18μ (2390 cm^{-1}) and 4.63μ (2160 cm^{-1}). The shoulder at the largest wave length is much more poorly defined with NaF plus CeF_3 in CdF_2 than with CeF_3 alone in CdF_2.

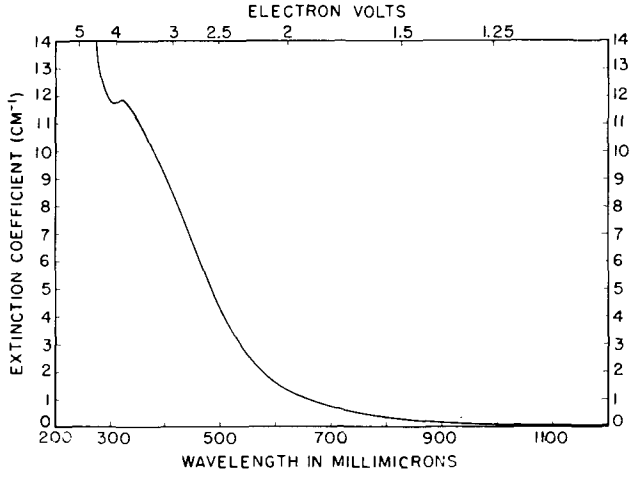

Fig. 7. Absorption spectrum of CdF_2 with 1 mole % NaF, x-irradiated 3.5 hr at 28°C, measured at —190°C.

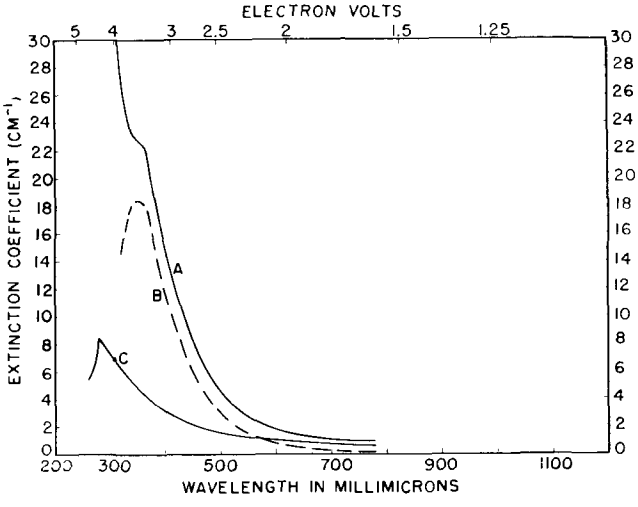

Fig. 8. Absorption spectra of CdF_2 with 1 mole % NaF. A, X-irradiated 2.6 hr at 28°C, measured at 28°C; B, Portion of Curve A bleached by heating 8 hr in 150°C oven; C, Portion of Curve A unbleached by heating 8 hr in 150°C oven.

X-radiation-induced absorption bands.—Four apparently independent x-ray-induced absorption bands were observed.

I. CdF_2 irradiated for several hours at room temperature causes an absorption band peaking at 255 mμ (see Fig. 5). This band does not bleach with heat (up to 150°C), ultraviolet radiation, or infrared radiation.

II. CdF_2, pure, and containing low concentrations of CeF_3 (less than 0.0005 mole % CeF_3), low equimolar concentrations of CeF_3 and NaF (less than 0.0005 mole % CeF_3 and NaF), and low concentra-

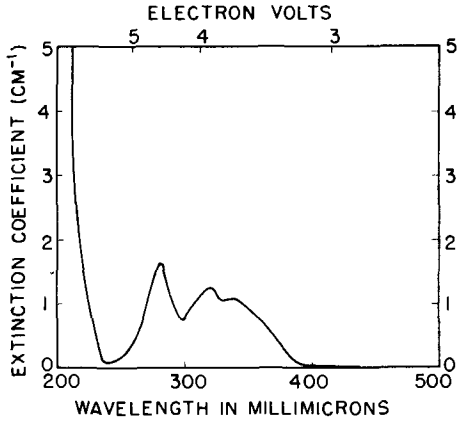

Fig. 9. Absorption spectrum of CdF_2 with 4 mole % NaF, x-irradiated 2.5 hr at —190°C, and measured at —190°C.

tions of NaF (less than 0.0005 mole % NaF) showed a double band (see Fig. 6). This band was produced by x-irradiation at —190°, or —78°C and was completely bleached by raising the temperature above —10°C. Irradiation with 3650Å at —190°, or —78°C, produced no bleaching.

III. CdF_2 with additions of NaF (in concentrations greater than 0.05 mole % NaF) when x-irradiated at —78° or 28°C produced an absorption band which could not be bleached completely. The band was relatively stable at 28°C. Partial bleaching could be accomplished by heating the crystal to 100° or 150°C in an oven, or by irradiating with 3650Å, or by irradiating with a commercial infrared lamp. The absorption band in Fig. 7 has a smaller extinction coefficient than that in Fig. 8A because the crystal in Fig. 7 was positioned further from the focal point and received a smaller dose of x-rays. Figure 8B shows that portion of A bleached by heating in an oven. Figure 8C shows the portion of A unbleached by this heating.

IV. CdF_2 with additions of NaF (also in concentrations greater than 0.05 mole % NaF) when x-irradiated and measured at —190°C produced the absorption bands in Fig. 9. This absorption was bleached by raising the temperature to —78°C or by irradiation with 3650Å at —190°C. This is a triple band.

To calculate the number of color centers per cubic centimeter, we assume that the expression derived by Smakula (11) applies. Smakula applied the theory of dispersion to F-center bands of alkali halide crystals to determine the density of F-centers. Among his assumptions were the following: the absorption transition is analogous to the 1s-2p transition in atomic hydrogen; the extinction coefficient of the bulk material is zero in the vicinity of the F-center bands. Since the bands are close to the absorption edge, this equation cannot apply exactly.

Table I summarizes some data on the above mentioned four primary x-ray induced absorptions.

Discussion and Conclusions

If one compares the transmission spectrum of 0.005 mole % NaF in CdF_2 (Fig. 3, curve D) and the spectrum of the CdF_2 without any additions (Fig. 1), one notices that the transmission of the CdF_2 with NaF is greater than that of the CdF_2 without any additions in the visible and in part of the ultraviolet. This difference of transmission is real and not instrumental. This apparent anomaly is probably caused by $S^=$ ions. If CdS is added to CdF_2 in a concentration of 1 ppm, the resulting crystal is quite yellow. The optical absorption at wave lengths less than 5000Å is total. The CdF_2 crystals prepared in this investigation undoubtedly had some $S^=$ ions but much less than 1 ppm. The addition of NaF to CdF_2, even at low concentrations of NaF, seemed to reduce the $S^=$ ion concentration.

CdF_2 with 16 mole % CeF_3 has a pycnometric density of 6.32 ± 0.02 g/cm³ and a lattice constant of 5.4921 ± 0.0005Å. A density of 6.335 g/cm³ may be calculated using this lattice constant, by assuming that a Ce (III) ion substitutes for a Cd (II) ion and an interstitial fluoride ion is present for charge compensation. If one uses a molecular weight assuming that two Ce (III) ions substitute for three Cd (II) ions, the calculated density would be 5.851 g/cm³. Therefore, it is concluded that a Ce (III) ion substitutes for a Cd (II) ion and the charge compensatory ion is an interstitial fluoride ion. This conclusion is consistent with the findings of Zintl and Udgard (12) on the CaF_2-YF_3 system and the findings of Ketelaar and Williams (13) on the SrF_2-LaF_3 system. Although the substitutional Ce (III) ion would tend to cause a small electrostatic contraction

Table I. Description of absorption bands

* The oscillator strength is assumed to be unity in these calculated values.

of the lattice, the larger size of the Ce (III) ion (ionic radius of Cd (II) = 0.97Å; ionic radius of Ce (III) = 1.07Å) would tend to cause an appreciable expansion of the lattice, and the interstitial fluoride ion (ionic radius = 1.33Å) would also cause an appreciable expansion of the lattice.

CdF_2 crystals with additions of NaF show a small lattice expansion: 0.0005Å/mole % of NaF. The expansion of CeF_3 in CdF_2 shows a much larger expansion of 0.0064Å/mole % of CeF_3. If the Na (I) ion were to enter the CdF_2 lattice interstitially in any way (either a fluoride ion could also enter interstitially or a Cd (II) ion vacancy could allow two interstitial Na (I) ions to enter the lattice) one would expect a larger lattice expansion than observed. Therefore, it has been assumed that on this basis and on the x-ray induced absorption band data (discussed in the next paragraphs), each Na (I) ion entering the CdF_2 lattice does so substitutionally for a Cd (II), and an anionic vacancy is present to achieve electrical neutrality.

In the case of solid solutions of NaF in CdF_2, both the substitution of Na (I) ion for Cd (II) ion and the formation of anionic vacancies would lead to an expansion of the lattice by virtue of the local decrease in charge density. The expansion is probably diminished by the decrease in overlap repulsion when a Cd (II) ion is replaced by a Na (I) ion and when fluoride ions are removed. This may account for the relatively small expansion actually observed. Since the ionic radius of Cd (II) ion is 0.97Å and the ionic radius of Na (I) ion is also 0.97Å, no expansion or contraction of the lattice would be expected because of a difference in ionic radii.

It seems quite apparent that the number of anionic vacancies has been reduced by a similar reduction of the number of interstitial fluoride ions in crystals of CdF_2 with equimolar additions of CeF_3 and NaF (the number of anionic vacancies here is compared to solid solutions of CdF_2 and NaF and the number of interstitial fluoride ions here is compared to solid solutions of CdF_2 and CeF_3), for the following reasons:

1. The crystals of CdF_2 with equimolar additions of CeF_3 and NaF (in concentrations greater than 0.05 mole % CeF_3 and NaF) did not show x-ray induced absorption stable at room temperature, while crystals of CdF_2 with NaF additions greater than 0.05 mole % demonstrate this absorption band (Fig. 7).

2. We have proved that CdF_2 with additions of CeF_3 has an interstitial fluoride ion for each substitutional Ce (III) ion. The lattice constant of such crystals of CdF_2 with equimolar additions of CeF_3 and NaF is less than if the same percentage of CeF_3 alone were incorporated (the expansion of CdF_2/mole % NaF is 0.0005Å, the expansion of CdF_2/mole % CeF_3 is 0.0064Å, and the expansion of CdF_2 with equimolar additions of CeF_3 and NaF is 0.0044Å/mole % of CeF_3 or NaF). Since we have indicated that CdF_2 with additions of NaF has an anionic vacancy for each substituted Na (I) ion, and since CdF_2 with additions of CeF_3 produces interstitial fluoride ions, the combination of NaF and CeF_3 incorporated together allows most of the interstitial fluoride ions to enter the anionic vacancies.

It has been proved (14) that the shoulder at about 4.18 μ (2400 cm^{-1}) is an artifact caused by CO_2 absorption in the beam path of the spectrophotometer. In using a double-beam spectrophotometer in this region of the spectrum, the response of the recording pen falls to zero since the CO_2 in the air is high enough to cause almost total absorption in both beams. In this region the electrical circuit becomes insensitive so that if the transmission is the same below and above this region, there is usually a small pip, which has been subtracted in Fig. 1A (the spectrophotometer is insensitive immediately about 4.18 μ, but is quite sensitive at wave lengths above and below this immediate region). In the case of solutions of CeF_3 in CdF_2, the absorption spectra of the crystal are rising to a peak in the region of 4.18 μ (Fig. 1B), and it could not be decided whether this was a separate peak or an artifact caused by the CO_2 absorption. Using a single-beam spectrophotometer and a nitrogen gas path for the beam instead of air, it was proved that this was not a separate peak but merely an artifact due to the CO_2 absorption (14). Mandel also obtained a value of 2×10^{-6} oscillators per atom from the calculated intensity of the absorption of the Ce (III) ion involving only a 4f shell transition. He has suggested, by analogy with other work on rare earth spectra, that this infrared absorption may be the $2_{F_{5/2}}$-$2_{F_{7/2}}$ transition.

The x-ray induced absorption band which is stable at 28°C could involve electrons trapped at anionic vacancies, since the crystals demonstrating this absorption do have a high concentration of anionic vacancies before x-irradiation. This band was resolvable into a bleachable and a difficultly bleachable(unbleached portion) band (see Fig. 8). Since bleaching by means of 3650Å irradiation was observed at temperatures as low as −78°C (but no bleaching was observed at −190°C), we must assume a thermal step is involved in the bleaching [Gurney and Mott indicate that a thermal step is necessary for the bleaching of F-centers in alkali halides (15)].The more difficultly bleached band may involve the absence of levels sufficiently shallow for the thermal step to be accomplished at the temperature at which the measurements were made.

Since the x-ray induced absorption band (Fig. 7) which is stable at room temperature is not observed when crystals of NaF in CdF_2 are x-irradiated at −190°C, one must conclude that a thermal step is involved in the production of the centers causing this band. The triple absorption band (Fig. 9) produced when NaF in CdF_2 is x-irradiated at −190°C is bleached by 3650Å irradiation or by warming to −78°C.

The absorption band (Fig. 6) common to pure CdF_2 and CdF_2 with low concentrations of cerium (III) fluoride, NaF, and equimolar additions of NaF and CeF_3 is not bleached by 3650Å at −78°C, or −190°C, but is bleached by warming to temperatures greater than −10°C. This band is independent of the impurities added to CdF_2. Apparently bleaching requires only a thermal step.

The increase in extinction coefficients at the high energy end of the spectra in Fig. 5, 6, and 9 is due to the logarithmic differences between the reciprocals

of small transmissions of questionable accuracy. Since the Beckman spectrophotometer is not as accurate at very low transmissions as it is at higher transmissions, the values of the transmissions at small transmissions are not very accurate, the differences between such small transmissions are less accurate, and the logarithms of such differences exaggerate the inaccuracy. Therefore, it is doubtful whether the increase in extinction coefficients at the high energy end of the spectra involved is real.

Acknowledgment

The authors wish to thank Henry F. Ivey for reading this manuscript.

Manuscript received Nov. 10, 1958. This paper is part of a thesis submitted by one of the authors (M.R.) in partial fulfillment of requirements for the Ph.D. degree to the Polytechnic Institute of Brooklyn. This paper was prepared for delivery before the Washington, D. C., Meeting, May 13-16, 1957.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

The Luminescent Center in Self-Activated ZnS Phosphors

J. S. Prener and D. J. Weil

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

A model for the ground state of the self-activated luminescent center in ZnS phosphors proposed by Prener and Williams in 1956 has been confirmed experimentally. It is shown that a Zn vacancy is involved in the blue luminescence and that the spectrum depends on whether the required coactivator can occupy a Zn or S site near the vacancy. The calculated energy levels of the center using a simple model are in qualitative agreement with the observed spectra.

If pure ZnS is heated to a high temperature in the presence of a halogen (e.g., NaCl or H_2S, HCl gas mixture) or with small amounts of Al or Ga (1), a blue emitting phosphor is obtained. The atomic nature of the defect responsible for this "self-activated" emission has been the subject of much discussion in the literature (2, 3). Recognizing that a neutral Zn vacancy may act as a double acceptor, Kröger and Vink (2) proposed that this defect was such a vacancy with one of the bound holes ionized. However, a concentration of such centers of about 2×10^{19} cm^{-3} or greater should have led to a measurable paramagnetic contribution to the magnetic susceptibility of this phosphor in the experiments of Bowers and Melamed (3); yet they failed to find such a contribution. More recently, Prener and Williams suggested that the defect in question consists of a Zn vacancy in which both the holes are ionized, leaving the vacancy doubly negatively charged, and an ionized donor impurity (Cl, Br, I, Al, or Ga) associated at nearest possible sites in the ZnS lattice (4). Such a center, in its ground electronic state, is not paramagnetic.

It is the purpose of this paper to present experimental evidence for such an associated center. The role of Zn vacancies in the formation of the center is shown by the expected variation in the intensity of the blue fluorescence with changes in the pressure of S vapor over the phosphor during preparation. That the coactivator is also part of the center is shown by the differences in spectral distribution of the fluorescence when halogens or group IIIB elements are used as coactivator impurities. Deductions based on a model for such a center are shown to be consistent with these observed differences.

In a series of papers Bube (5) and Addamiano (6) discussed the preparation of self-activated ZnS with blue fluorescence, by high-temperature firing in air or nitrogen without the use of any added coactivators. Their interpretation was that the center responsible for the fluorescence was a Zn vacancy which was formed thermally at high temperatures. Careful and numerous experiments performed in our laboratories have convinced us that previous observations were the result of faulty experimental techniques. If a "luminescent grade" of ZnS is carefully protected from dust and is fired in a stream of purified, dry H_2S in clean apparatus, first at low temperatures (400°C for several hours) and then slowly at increasingly higher temperatures until 1150°-1200°C is reached, no visible luminescence is found even at liquid nitrogen temperature! If, on the

other hand, the firing temperature is raised rapidly to 1150°C, very frequently bright blue luminescence is indeed observed. We presume that even the best ZnS available probably has some coprecipitated halide which can be volatilized or converted to sulfide by low temperature H_2S firing. At higher temperatures the halogen may diffuse into the ZnS lattice producing the characteristic blue luminescence. Our general conclusion is therefore that under conditions most likely to produce Zn vacancies (H_2S firing rather than nitrogen) no self-activated luminescence can be induced in ZnS without the use of coactivators.

Experimental and Results

Emission Spectra of ZnS:xCu:yAl as a Function of Atmosphere during Preparation

Many phosphors containing various amounts of Cu and Al were prepared by adding appropriate quantities of copper sulfate and aluminum sulfate solutions to pure ZnS and firing at 950°-975°C for 2 hr in a stream of purified and dry H_2S. Parts of these phosphors, all of which showed bright blue and green fluorescence under 3650Å excitation, were refired in oxygen-free, dry H_2 for an additional 2 hr at the same temperature. Emission spectra were taken at liquid nitrogen temperatures with 3650Å excitation (General Electric BH-4 high-pressure mercury lamp with a Corning 5840 filter) using a recording spectroradiometer. The powdered samples were contained in a holder which permitted us to position each sample accurately with respect to the exciting light and the entrance slit of the spectroradiometer and also to obtain spectra at low temperatures.

In Fig. 1 are shown emission spectra, typical of many obtained, for phosphors in which $x = 0$, $x < y$, $x = y$, and $x > y$. The results show the sensitivity of the "self-activated blue" emission to H_2 refiring and the absence of any such marked effect on the "copper green" emission and the "copper blue" emission always obtained when $x > y$. The different spectral distribution of the copper blue band at liquid nitrogen temperatures compared to the self-activated blue emission has been cited as evidence that two different types of centers are responsible for these two blue bands (7). The different behavior of the fluorescent intensity after H_2 refiring is further evidence for this.

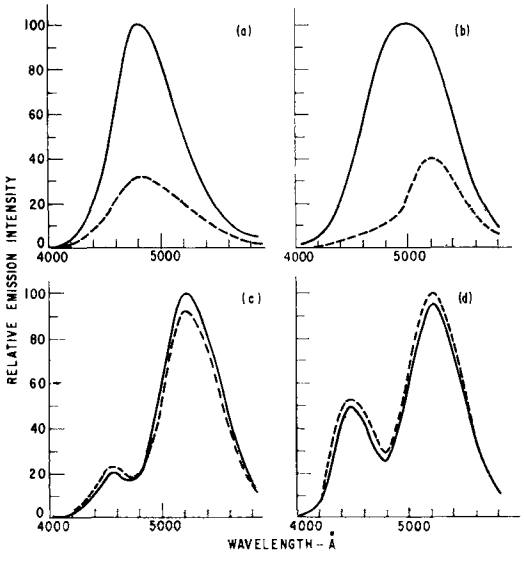

Fig. 1. Typical emission spectra at —196°C with 3650Å excitation of ZnS:xCu:yAl phosphors fired at 950°C in H_2S ——————; and refired at 950°C in H_2 - - - - - -. (a) $x = 0$; $y = 10^{-4}$; (b) $x = 2 \times 10^{-6}$; $y = 10^{-4}$; (c) $x = 10^{-4}$; $y = 10^{-4}$; (d) $x = 10^{-4}$; $y = 10^{-5}$.

To test the reversibility of this effect on the intensity of the blue self-activated emission after H_2 refiring, as well as its reproducibility, four phosphor samples were prepared, all of the composition ZnS:5 x 10^{-6} Cu:10^{-4} Al. These were then subjected to the following firing schedules at 975°C: (*a*) 2 hr in H_2S; (*b*) 2 hr in H_2S followed by 2 hr in H_2; (c) 2 hr in H_2S, 2 hr in H_2, 2 hr in H_2S; (*d*) 2 hr in H_2S, 2 hr in H_2, 2 hr in H_2S, and finally 2 hr in H_2. The emission spectra shown in Fig. 2 show again that there is a marked decrease in the intensity of the blue self-activated band on H_2 refiring. Furthermore, the effect is clearly reversible and reproducible. There appears also to be a small decrease in the green copper band intensity after H_2 refiring of those phosphors in which $y > x$. For $y = x$ and $y < x$, no such effect is observed within the limits of experimental reproducibility. The effect of H_2 refiring on the green band is very much smaller than on the self-activated blue band. The reason for this effect is not known at present but may very well be due to the increased association at nearest neighbor sites of the negatively charged copper acceptors with the larger concentration of available positively charged Al donors available at the high temperature when the phosphor is fired in H_2 and ionized Zn vacancies are destroyed. The effect of H_2 refining on the intensity of the self-activated blue emission described above for ZnS:Al has also been observed in ZnS:Ga phosphors. (See the third section of Discussion).

Spectral Distribution of the Self-Activated Emission in Cubic ZnS

ZnS:Al and ZnS:Ga phosphors were prepared as described in the previous section, except that the firing was carried out at 850°C. ZnS:Cl and ZnS:Br phosphors were prepared by firing ZnS in a stream of H_2S containing several per cent of anhydrous HCl or HBr at 850°C for 2 hr. Bright blue fluorescing materials were obtained in all cases. The low firing

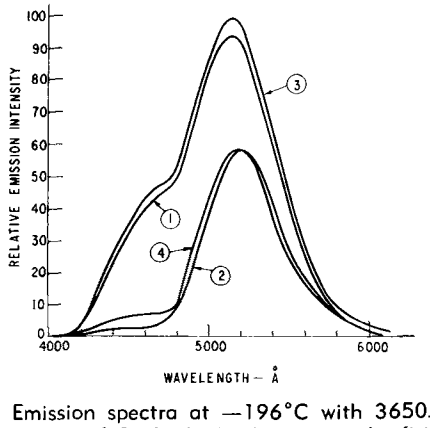

Fig. 2. Emission spectra at —196°C with 3650Å excitation of ZnS:5 x 10^{-6} Cu:10^{-4} Al subjected to the firing schedules described in the text.

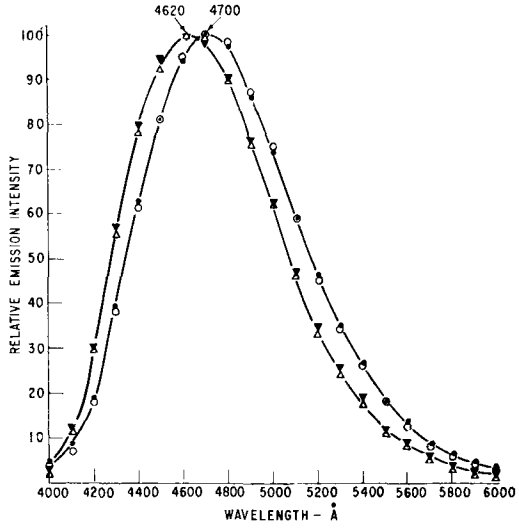

Fig. 3. Emission spectra at room temperature with 3650Å excitation of ZnS:10^{-3} Al, solid circle; ZnS:10^{-3} Ga, open circle; ZnS:Cl, open triangle; ZnS:B, solid inverted triangle; all fired at 850°C.

temperatures were used to assure the absence of any hexagonal phase in the ZnS phosphors, since it is known that the emission spectra are different for the cubic and hexagonal phases. The absence of any hexagonal phase was confirmed by obtaining long exposure x-ray diffraction patterns of the fired phosphors.

The emission spectra of four phosphors taken at room temperature are shown in Fig. 3. It is seen that the spectra of ZnS:Al and ZnS:Ga are identical as are the spectra of ZnS:Cl and ZnS:Br. However, the peak of the emission band of the latter two phosphors occurs at about 80Å toward shorter wave lengths than the peak of the first two phosphors. This effect of the coactivator impurity on the spectral distribution of the self-activated blue emission was also observed by Kröger and Dikhoff (1), although they placed no significance on this difference and indicated that the blue emission was independent of the coactivator. We believe this 80Å difference to be significant and this is discussed later in this paper.

The emission spectra of those phosphors containing halogen were also found to be independent of how the halogen was introduced. In Fig. 4, the emission spectra of halogen-containing phosphors prepared from HCl and H_2S, HBr and H_2S, NaCl, and NaI are compared to the phosphor ZnS:Al (10^{-3}) by plotting the ratios of the emission intensities (normalized to unity at 4700Å) at various wave lengths. The emission spectrum of the self-activated emission was found not to depend on the concentration of the coactivator. In Fig. 5, emission spectra of ZnS:Al (10^{-4}, 5 x 10^{-5}) and ZnS:Ga (10^{-3}, 10^{-4}) are compared to ZnS:Al (10^{-3}) by again plotting the ratios of emission intensities. Similar measurements of the emission intensity of various phosphors as a function of wave length compared to ZnS:Al (10^{-3}) also showed that the emission spectra were dependent neither on firing temperature so long as no hexagonal ZnS were formed, nor on the intensity of the exciting ultraviolet. The general conclusion is that

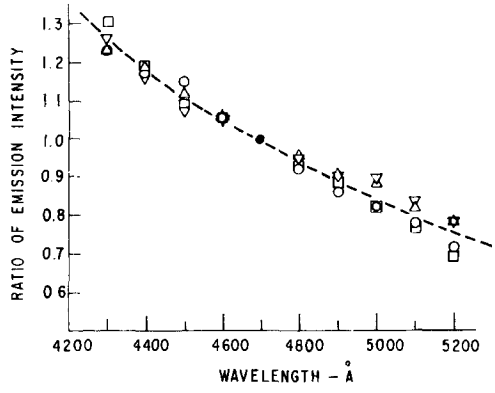

Fig. 4. Ratio of the emission intensity at room temperature and 3650Å excitation of the various phosphors given below to the emission intensity of ZnS:10^{-3} Al, as a function of wave length. (Intensities normalized to unity at 4700Å). Open circle, ZnS fired in H_2S containing HCl at 850°C; open square, ZnS fired in H_2S containing HBr at 850°C; open triangle, ZnS:5%NaCl fired in N_2 at 850°C; open inverted triangle, ZnS:2%NaI fired in N_2 at 925°C.

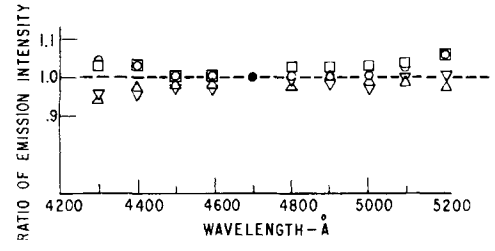

Fig. 5. Ratio of the emission intensity at room temperature and 3650Å excitation of the various phosphors given below to the emission intensity of ZnS:10^{-3} Al as a function of wave length. (Intensities normalized to unity at 4700Å). All phosphors were fired in H_2S at 850°C. Open circle, ZnS:10^{-4} Al; open square, ZnS:5 x 10^{-5} Al; open triangle, ZnS:10^{-3} Ga; open inverted triangle, ZnS:10^{-4} Ga.

the spectral distribution of the blue emission depended only on whether the coactivator used was one of the Group III or Group VII elements.

Discussion

Formation and Ionization of Zn Vacancies

ZnS phosphors prepared by firing at high temperatures will contain neutral Zn vacancies and S vacancies (V_{Zn}^0 and V_S^0) whose equilibrium concentration will depend on the temperature and pressure of S in the gas phase with which the solid is in equilibrium. The assumption will be made that lattice defects in ZnS are primarily vacancies, not interstitials. Work on CdS (8), CdSe (9), and other binary compounds has indicated that metal atom vacancies can behave as acceptors. Since the removal of a neutral Zn atom from ZnS removes two of the eight electrons in the four bonds to the neighboring sulfurs, a neutral Zn vacancy has two holes bound in its vicinity. These may be thermally ionized into the valence band as shown in Eqs. [1] and [2].

$$V_{Zn}^0 \rightleftharpoons V_{Zn}^{-1} + p - \epsilon_1 \quad [1]$$

$$V_{Zn}^{-1} \rightleftharpoons V_{Zn}^{-2} + p - \epsilon_2 \quad [2]$$

In these equations, p represents a hole in the valence band, and ϵ_1 and ϵ_2 are the thermal ionization energies. The energy released by the optical capture of a hole into V_{Zn}^{-1} can be computed approximately us-

ing a Bethe model (10). This energy would be equal to the ionization energy of a hydrogen atom in a polarizable medium whose static dielectric constant is that of ZnS. Similarly the energy released on capturing a hole optically into V_{Zn}^{-2} should be approximately the ionization energy of He^{+1} in a polarizable medium (11). For ZnS, with a static dielectric constant of 8, these energies are 0.21 e.v. and 0.84 e.v. These values can only be approximate for ZnS due to the fact that the holes move in small orbits around the charged Zn vacancies so that the details of the potential in the vicinity of the vacancy are important. Once the hole is captured in the center, the atoms surrounding the vacancy will move to new equilibrium positions, and the energy required for the optical ionization of the hole will be greater than 0.21 or 0.84 e.v. depending on the lattice polarization energy. The thermal ionization energies ϵ_1 and ϵ_2 will lie somewhere between these two limits (12).

Association of Charged Zinc Vacancies and Ionized Donor Impurities

Coactivator impurities such as Al or Cl in ZnS are donors and therefore constitute a single positively charged species when ionized (13). For the thermal ionization of Al we have

$$Al^0 \rightleftharpoons Al^{+1} + n - \epsilon_3 \qquad [3]$$

Here n is a conduction electron. These ionized centers interact coulombically with negatively charged Zn vacancies, and the equilibrium distribution of these two defects will therefore be a nonrandom one. Of particular interest is the strong interaction between V_{Zn}^{-2} and Al^{+1} or Cl^{+1}. For a concentration of each of 10^{-4}M at 1000°K, the fraction of V_{Zn}^{-2} and Al^{+1} associated into $V_{Zn}^{-2} - Al^{+1}$ pairs at neighboring Zn sites is about 0.9 (14). For $V_{Zn}^{-2} - Cl^{+1}$ the fraction will be even higher. At a large distance the associated pair appears as a single negative charge in ZnS and should therefore be capable of binding a hole in a localized orbital. This hole can be thermally ionized as follows

$$(V_{Zn} - Al)^0 \rightleftharpoons (V_{Zn} - Al)^{-1} + p - \epsilon_4 \qquad [4]$$

The energy released by the optical capture of a hole into the ionized acceptor can be estimated using a Bethe-type model in which the hole moves in the potential of a $-2e$ and a $+1e$ charge separated by a distance R in a polarizable medium. For cubic ZnS the distance R is 2.35Å when Cl, Br, or I are the donors and 3.84Å when Al or Ga are the donors. The particular group IIIB or VIIB impurity used would be expected to affect the position of the localized level only to a slight extent because the trapped hole moves in an orbit close to the doubly negatively charged Zn vacancy and therefore does not feel the inner potential peculiar to the donor impurity. Our primary interest is the difference in the binding energy of a hole to the two types of associated pairs characterized by the different distances R and particularly the sign of this difference. Therefore, the binding energy of a hole to such an associated pair embedded in a medium of dielectric constant 8 was calculated as a function of R. At very small or very large values of R the binding energy

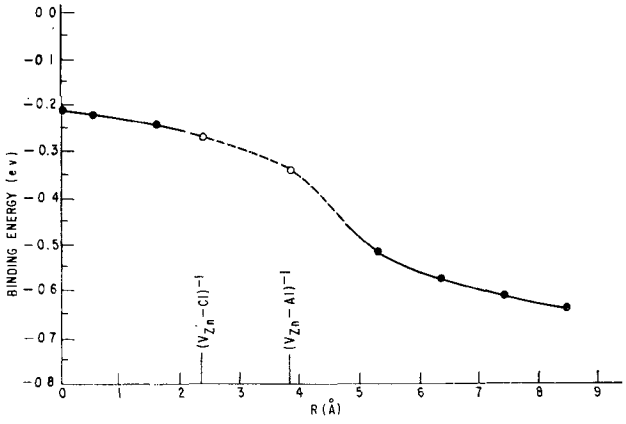

Fig. 6. Binding energy of a positive hole to fixed charges of —2e and +1e separated by a distance R (Å) in a polarizable medium of dielectric constant 8.

of a hole can be obtained by a perturbation treatment using hydrogen 1s wave functions. The binding energy in electron volts is:

$$E(\text{small } R) = -\frac{27.2}{2k^2} + \frac{27.2}{k^2R}\left[(0.529\,k - R) - (0.529\,k + R)\,e^{-2R/0.529\,k}\right] \qquad [5]$$

$$E(\text{large } R) = -\frac{54.4}{k^2} + \frac{27.2}{k^2R}\left[0.529\,k - (0.529\,k + 2R)\,e^{-4R/0.529\,k}\right] \qquad [6]$$

E is shown as a function of R in Fig. 6 for the dielectric constant $k = 8$. The two values of R of particular interest do not lie within the range where the simple perturbation treatment would be expected to be valid. Accordingly, for these two distances the energies were calculated using the continued fraction solutions given by Baber and Hassé for the ground state of the unsymmetrical hydrogen molecule ion (15). These two values are also given in Fig. 6 and are seen to differ by 0.07 e.v., the level due to $(V_{Zn} - Al; Ga)^{-1}$ lying higher above the valence band than the level due to $(V_{Zn} - Cl; Br; I)^{-1}$. This energy difference amounts to a 100Å difference at 4700Å and is therefore in accord with the observed difference of the emission spectra as shown in Fig. 3, both as to the direction and magnitude of the difference, provided that we assume that the lattice polarization energy following excitation of the phosphor is largely independent of the donor impurity making up the center. As was pointed out, the hole moves in an orbit close to the Zn vacancy so that it is not unreasonable to imagine that it is the vacancy which primarily governs the lattice polarization.

Concentration of Luminescent Centers $(V_{Zn} - Al)^{-1}$ as a Function of Sulfur Pressure

ZnS, heated for a sufficiently long time in a very slow stream of a gas, will attain a stoichiometry dependent on the composition of the gas (16). When H_2 is used as the gas atmosphere during firing we can show that the final effective sulfur pressure with which the solid phase is in equilibrium and which therefore determines the stoichiometry of the solid

is obtained by a solution of the equation (taking sulfur to be S_2 molecules in gas phase):

$$2p_{S_2}^{3/2} + K_d P_{H_2} p_{S_2} - K_p = 0 \quad [7]$$

P_{H_2} is the pressure of H_2, usually 1 atm, and K_d is the equilibrium constant for the dissociation of H_2S.

$$H_2 + \frac{1}{2} S_2 \rightleftharpoons H_2S \quad [8]$$

$$K_d = (p_{H_2S}/p_{S_2}^{1/2} \cdot p_{H_2}) \quad [9]$$

K_p is the equilibrium constant for the dissociation of ZnS molecules in the gas phase multiplied by the equilibrium pressure of ZnS molecules at the firing temperature:

$$ZnS \text{ (solid)} \rightleftharpoons ZnS \text{ (gas)}; \; p_{ZnS} = \text{constant} \quad [10]$$

$$ZnS \text{ (g)} \rightleftharpoons Zn \text{ (g)} + \frac{1}{2} S_2 \text{ (g)} \quad [11]$$

$$K_p = K_{ZnS} \cdot p_{ZnS} = p_{Zn} \cdot p_{S_2}^{1/2} \quad [12]$$

At 1000°K, Kelley (17) gives K_d as 144 $atm^{-1/2}$ and, according to Pogorelyi (18), $K_p = 1.63 \times 10^{-10}$ $atm^{3/2}$. With $P_{H_2} = 1$ atm, we get from Eq. [7] that $p_{S_2}^{1/2} = 1.06 \times 10^{-6}$ $atm^{1/2}$. On the other hand, if H_2S is used as the firing gas, we can show that p_{S_2} is obtained from:

$$2K_d p_{S_2}^2 + 2p_{S_2}^{3/2} - p_{S_2}^{1/2} (P_{H_2S} + K_p K_d) - K_p = 0 \quad [13]$$

With P_{H_2S}, the initial pressure of H_2S, equal to 1 atm, we get from Eq. [13] that $p_{S_2}^{1/2} = 0.15$ $atm^{1/2}$. These results show that firing ZnS phosphors for a sufficiently long time in a slow stream of H_2S at 1000°K followed by H_2 is equivalent to lowering the square root of the sulfur pressure by about five orders of magnitude.

We did not determine whether or not the gas flow rates we used were sufficiently slow to maintain equilibrium between the solid and gas phases. Thus in our experiments the ratio of effective values of $p_{S_2}^{1/2}$ might very well not have been as low as 10^{-5}. For this and, more important, for other reasons to be pointed out in the following paragraphs, only a qualitative comparison of experiment with calculations can be made at this time.

The method developed by Kröger and Vink (19) for calculating the concentrations of various defects as a function of sulfur pressure, can be applied to the system ZnS:Al (2.54×10^{18} cm^{-3}) by using the values of the equilibrium constants given in Table I.

If the concentrations of defects, impurities and charge carriers are expressed as number per cubic centimeter, then K_1 to K_4, which are the equilibrium constants for the reactions given in Eqs. [1] to [4], are taken to have the form $K = 2(2\pi mkT/h^2)^{3/2} \exp(-\epsilon/kT)$, the free electron mass being used. K_g is the equilibrium constant for the thermal production of electron-hole pairs.

$$ZnS \text{ (ground state)} \rightarrow n + p - \epsilon_g \quad [14]$$

$$K_g = [n]\,[p] \quad [15]$$

K_g is taken to be of the form $4\,(2\pi mkT/h^2)^3 \exp(-\epsilon_g/kT)$. Finally, the reciprocal of K_a is the equilibrium constant for the dissociation of the associated pair

$$(V_{Zn} - Al)^{-1} \rightleftharpoons V_{Zn}^{-2} + Al^{+1} \quad [16]$$

$$K_a = [(V_{Zn} - Al)^{-1}]/[V_{Zn}^{-2}]\,[Al^{+1}] \quad [17]$$

Neutral Zn vacancies are formed by the reaction

$$(1 - \delta)\; ZnS + \delta/2\; S_2 \rightleftharpoons Zn_{1-\delta}\; (V_{Zn}^{0})_\delta S \quad [18]$$

The application of the law of mass action for $\delta << 1$ gives

$$K_v = [V_{Zn}^{0}]\; p_{S_2}^{-1/2}\; cm^{-3}\; atm^{-1/2} \quad [19]$$

Since K_v is unknown for ZnS, the concentrations of all other defects and charge carriers were calculated as functions of $K_v\, p_{S_2}^{1/2}$ for ZnS:Al (2.54×10^{18} cm^{-3}) at 1000°K using the method of reference (19). The Schottky constant for ZnS, giving the equilibrium product of the concentrations of neutral Zn and S vacancies, is also unknown, so that we assumed that, in the range of sulfur pressures used, the concentration of ionized sulfur vacancies which can act as donors was much less than the concentration of Al^{+1}. After the high-temperature concentrations were determined, the concentrations at liquid nitrogen temperature were found by assuming that the total concentration of lattice defects and associated pairs is frozen in at 1000°K as the phosphor is cooled, whereas electrons and holes distribute themselves among the various available states in accordance with the equilibrium Eqs. [1] to [4] and [14] using the values of the equilibrium constants at 77°K also given in Table I. The results, shown graphically in Fig. 7, are to be taken only as an indication of the behavior of ZnS:Al because of the approximations used, some of which have been cited. Somewhat different approximations would still lead to the same general qualitative behavior with varying sulfur pressure. Nevertheless, it is of interest to note that the model used leads to the concentration of

$$(V_{Zn} - Al)^{-1}$$

Table I. Equilibrium constants for the system ZnS:Al

	Temp, 77°K		Temp, 1000°K		
	K_i	ϵ_i (e.v.)*	K_i	ϵ_i (e.v)*	Remarks
K_a	—	—	2.3×10^{-17}	—	From calc. deg. of assoc. (14)
K_1	2.1×10^{-20}	0.58	4.1×10^{17}	0.51	Assumed same as K_4
K_2	3.3×10^{-136}	2.32	7.6×10^{9}	2.0	ϵ_2 taken as four times ϵ_1

K_4	2.1×10^{-20}	0.58	4.1×10^{17}	0.51	From temperature quenching data (21)
K_g	1.6×10^{-204}	3.66	1.6×10^{24}	3.20	From optical band gap data applying a correction of -5×10^{-4} ev/deg (22).

* All levels assumed to decrease with temperature at the same rate as the optical band gap.

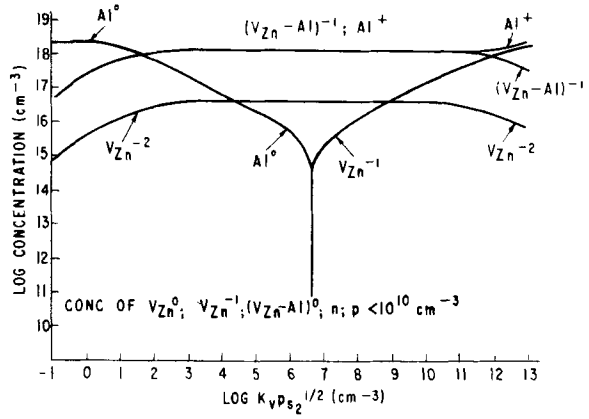

Fig. 7. Concentration of defects in ZnS:Al (2.54×10^{18} cm^{-3}) at —196°C after equilibration at 1000°K and various pressures of sulfur in the gas phase.

being practically constant at one-half the total Al concentration over a range of values of $p_{S_2}^{1/2}$ of about eight orders of magnitude. The indicated decrease in the concentration of this associated pair at low sulfur pressures is in accord with the experimental results given in this paper and the interpretation that a Zn vacancy is part of the luminescent center. The indicated decrease in the concentration of self-activated luminescent centers at high sulfur pressures was observed in CdS:Ga by Kröger, *et al.* (8), although the authors interpreted their results differently. Also, over a wide range of sulfur pressures the concentrations of Al°, V_{Zn}^0, V_{Zn}^{-1}, and $(V_{Zn} - Al)^0$ are less than 2×10^{16} cm^{-3}. Since these would be paramagnetic defects, it can be seen that only under special conditions of preparation would this phosphor be expected to have a measurable paramagnetic susceptibility.

Summary

Associated $(V_{Zn} - Al; Ga)^{-1}$ or $(V_{Zn} - Cl; Br; I)^{-1}$ pairs can form in ZnS containing Al, Ga, or a halogen as an impurity due to the strong coulombic interaction between ionized donor impurities and Zn vacancies. Calculations show their concentration can remain fairly constant at one-half the concentration of the donor impurity over a considerable range of sulfur pressures. At decreasing sulfur pressures the concentration of these pairs decreases. This is in accord with the observed decrease in the intensity of the blue luminescence after H_2 refiring of the self-activated phosphor.

The peak of emission spectrum of the blue luminescence depends on whether a group IIIB or group VIIB element is used as a coactivator indicating that the coactivator is a part of the luminescent center. Simple considerations suggest that the observed shift in peak position is in the right direction and of the correct order of magnitude.

On the basis of these results we conclude that the luminescent center in self-activated ZnS is a V_{Zn}^{-2} associated with the coactivator at a nearest possible site in ZnS. The associated pair gives rise to a localized acceptor level above the valence band just as do the usual activators such as Cu or Ag.

Acknowledgments

The authors acknowledge the help given them by Dr. F. J. Studer and Miss G. Lloyd in obtaining the emission spectra of the many phosphors prepared in the course of this study. Dr. B. Segall aided greatly in obtaining the solutions to the two-center problem used in this paper. Dr. D. T. F. Marple carried out the careful measurements of intensity ratio as a function of wave length of many phosphors containing Al, Ga, Cl, and Br. Finally the many discussions with Dr. F. E. Williams were instrumental in clarifying our ideas on the interpretation of the data and the model presented here for the self-activated luminescent center.

Manuscript received Oct. 27, 1958. This paper was prepared for delivery before the New York Meeting, April 27-May 1, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

A Double Diffused Silicon High-Frequency Switching Transistor Produced by Oxide Masking Techniques

J. F. Aschner, C. A. Bittmann, W. F. J. Hare, and J. J. Kleimack

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

The relative merits of two double diffused transistor structures are discussed, one of which employs a localized emitter. A process for producing the localized emitter structure is described employing the masking property of SiO_2 against the subsequent phosphorus diffusion. The dimensions of each emitter are controlled closely by etching away this oxide mask from only those regions not protected by a specially prepared photo resist coating. Transistors have been produced which switch 30 ma with a gain of 12, in times in which the sum of the turn-on, storage, and turn-off time is less than 0.1 μsec. Small signal alphas of 0.97, and alpha cut-off frequencies in the common base connection in excess of 300 mc have been achieved.

The need for high-frequency transistors, requiring extremely narrow base layers, has led to the development of new fabrication techniques. The adaptation of solid-state diffusion (1) has been found to permit a high degree of control of both the depth and concentration of an impurity necessary to produce such layers. In this paper an n-p-n silicon switching transistor is discussed, in which both the emitter and base layers are formed by diffusion. By making use of the masking properties of a specially prepared oxide layer, precise regulation of the geometry of the emitter region is attained. The electrical characteristics of transistors prepared by these techniques are presented.

Double Diffused Structure

In Fig. 1(a) the essential features of a transistor produced by a double diffusion process (2) are illustrated. A p-type impurity is diffused first into the n-type wafer to form a collector junction about 0.2 mils from the surface. An n-type emitter dopant having a much higher impurity concentration is then diffused into this layer. This overcompensates the original diffused impurity until such a depth is reached that their concentrations are equal. The emitter junction, so formed, is located at this depth. The separation of the two junctions, defining the base layer, can be reproduced to within 0.005 mils.

In this type of transistor, since the emitter layer entirely covers the base layer, a metallic base contact is alloyed through the emitter. Furthermore, the regrowth region around this contact must form a rectifying junction with the emitter layer, in order for the device to operate as a transistor; otherwise, the base would be shorted to the emitter. With a suitable choice of materials, this technique is quite feasible, and transistors have been built this way. However, certain limitations are imposed. In order to have a rectifying junction between the base contact and the emitter layer through which it passes, an upper limit is placed on the surface concentration of the emitter diffusant, thus limiting emitter efficiency. Alternatively, the highly doped portion of the emitter immediately surrounding the base contact may be removed by an etching process. The latter, in fact, is the preferred choice but suffers from control difficulties as the electrical characteristics of the transistor are quite sensitive to the depth reached by this etch.

The present paper is concerned with a process in which the masking properties of a silicon dioxide layer against certain diffusants have been exploited to circumvent these difficulties (3, 4). By removing the oxide from selected regions on the surface, the emitter diffusant can penetrate into the base layer only at each of these designated areas, leaving the base layer exposed to the surface everywhere else [Fig. 1(b)]. Contact to the base region thus may be made without difficulty after the remaining oxide has been removed. The elimination of any emitter etch and the freedom to make use of high emitter

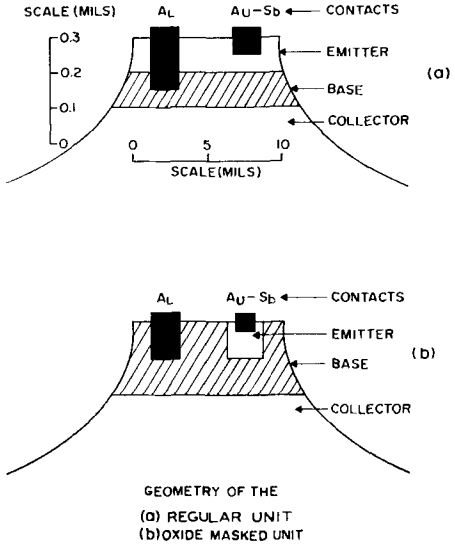

Fig. 1. Cross section of two double diffused transistor structures. Geometry of (a) regular unit, (b) oxide masked unit.

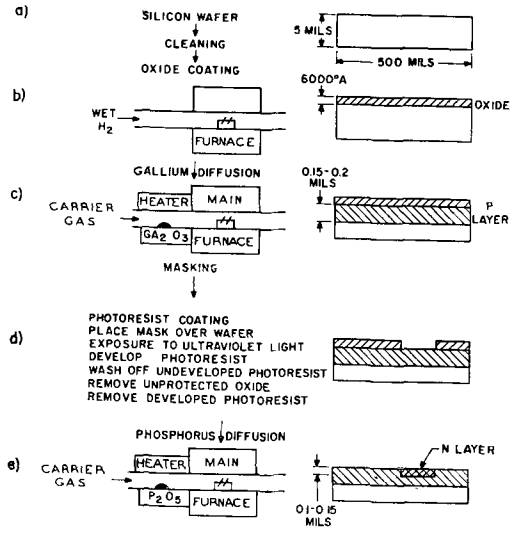

Fig. 2. Detailed diffusion and masking process.

concentrations are considerable advantages. In addition, limiting the emitter area results in a lower emitter capacity.

Oxide-Masking Technique

The masking process is illustrated in detail in Fig. 2. N-type silicon wafers of about 0.3 ohm-cm resistivity are cut into squares and lapped to obtain the highly polished surface essential to the production of uniform diffused junctions. A silicon dioxide layer is now grown over the surface; a simple method is illustrated, in which wet hydrogen is passed over the heated wafers to produce the 8000Å oxide layer required. Using the technique developed by Frosch (3, 4), the base layer dopant, gallium, is diffused into the wafer to a depth of about 0.2 mils. The oxide coating only slightly inhibits the rate of gallium diffusion.

The oxide now must be removed, selectively, from the 100 3 mil x 6 mil designated areas on the surface into which emitters are to be diffused. For clarity, only one emitter area, much enlarged, is shown in Fig. 2. To achieve this, the wafer is dipped into a photo resist solution,[1] dried in air, and exposed to ultraviolet light through a film mask which covers only those areas which are to be the emitters. The photo resist over these areas is not exposed to the light and, after the exposed portion is developed, is easily washed off in water. The oxide unprotected by the photo resist is removed in a slow etch. Finally, all of the photo resist is dissolved to give the structure in Fig. 2(d).

The second diffusion, with phosphorus as the impurity, is now carried out. In the time necessary to diffuse through the exposed regions to the required depth of about 0.1 mil, there is no diffusion through the oxide. To produce much deeper emitter junctions, thicker oxide layers would have to be prepared to insure complete masking. The final diffused structure of a single transistor is shown in Fig. 2(e).

To illustrate the control attained over the geometry of the emitters, an actual photomicrograph of

[1] Such as one made by the Eastman Kodak Co. A description of the general properties of this material is given in the pamphlet "Industrial Uses of Kodak Photo Resist," a manual prepared by Eastman Kodak Co., Rochester 4, N. Y.

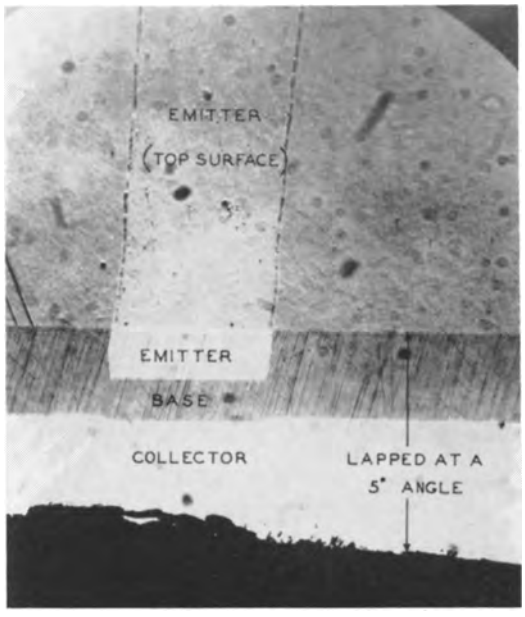

Fig. 3. Photomicrograph of an oxide masked double diffused unit. The junction has been exposed by beveling at a slight angle and staining the p-layer.

a unit is presented in Fig. 3. The transistor has been lapped at an angle of five degrees to the surface and the base layer stained with a hydrofluoric-nitric acid etch (5) to delineate the junctions clearly. Both collector and emitter junctions are seen to be quite straight, any imperfections being much less than the layer thicknesses.

In the next step, Au-Sb emitter contacts and Al base contacts are evaporated through masks. To insure that the former fall entirely within the emitter areas and that the latter are positioned accurately close to the emitter edges but within the base layer, the masks are indexed carefully with respect to the original film mask used to prepare the emitters. Again, considerable control is needed in the definition of the emitter areas on the surface to prevent emitter-to-base shorts. The unlapped part of the wafer in the photomicrograph of Fig. 3, showing one such emitter area prior to the evaporation of contacts, clearly illustrates the close control of the emitter geometry that can be achieved by this masking technique.

The subsequent fabrication process follows standard procedures of collector bonding, lead attachment, and encapsulation.

Results and Discussion

The electrical characteristics of n-p-n, silicon, switching transistors prepared using the above techniques are presented in Table I. The base layers are normally from 0.05 to 0.10 mils in width. As some of the electrical parameters are quite sensitive to this width, results from some experimental units with a much thinner base layer (0.029 mils) are also shown.

The static characteristics of the normal units show a high collector to emitter breakdown voltage, a low emitter junction breakdown due to the high impurity gradient at this junction, and the low reverse saturation currents expected with silicon devices.

Table I.

	Normal median values	Thin base median values	Units
Number of units	9	20	
Emitter thickness	0.09	0.04	mils
Base thickness	0.08	0.029	mils
BV_{CBO} at $I_{co} = 1\ \mu a$	65	27	volts
BV_{EBO} at $I_{eo} = 1\ \mu a$	3	8	volts
I_{co} at $V_{CB} = 4.5$ V	2×10^{-10}	9×10^{-9}	amps
C_c at $V_{CB} = 4.5$ V	5	6	$\mu\mu f$
hie at $V_{CE} = 5V$, $I_c = 10$ ma	400	450	ohms
Switching times			
at $I_c = 30$ ma, $I_{B_1} = 2.5$ ma			
$V_{B_2} = O$ V			
t_0	0.03	0.03	μsec
t_1	0.03	0.03	μsec
t_2	0.04	0.03	μsec
V_{CE} at $I_C = 30$ ma, $I_B = 2.5$ ma	0.5	0.9	volts
V_{BE} at $I_C = 30$ ma, $I_B = 2.5$ ma	0.9	1.1	volts
Small signal alpha			
at $V_{CB} = 4.5$ V			
$I_E = 0.1$ ma	0.927	0.939	
1 ma	0.960	0.976	
10 ma	0.973	0.987	
30 ma	0.972	0.985	
hfe at f = 30 mc, $V_{CE} = 5V$	14	21	db
$I_E = 5$ ma			

The small size of the unit is reflected in the low collector capacitance of 5 $\mu\mu f$. Base resistances of 200-300 ohms are encountered normally.

The electrical parameters of interest for switching applications also are summarized in Table I. In the circuit used for measuring the switching time, the units are usually in the ON or saturation condition, with 2.5 ma base drive and 30 ma collector current. They are turned off by a negative pulse to the base which thus is driven to ground potential. The total switching time is the sum of storage time t_1, turn-off time t_2, and turn-on time t_0. For switching 30 ma with a gain of 12, total switching times of the order of 0.1 μsec have been measured.

Finally, the gain characteristics are given. The low-frequency short-circuit current gain, alpha, is fairly high for this transistor and varies only slightly over the operating range. The variation both with emitter current and collector voltage is presented in Fig. 4. The fact that alpha is independent of the reverse collector voltage is of considerable advantage in the design of circuits using the unit. The advantage gained from the use of such a narrow base device is apparent from the current gain at high frequency (hfe). For the normal units, the measured gain of 14 db at 30 mc corresponds to an alpha cut-off frequency of approximately 150 mc.

An analysis of the data for the extremely thin base experimental units emphasizes the favorable high-frequency behavior. The gain has been measured as a function of frequency both for the common emitter and common base connection (Fig. 5) for a thin base unit. The alpha cut-off frequency of 350 mc is comparable to the best germanium transistors if the difference in mobility is taken into account. These units also show a small but significant

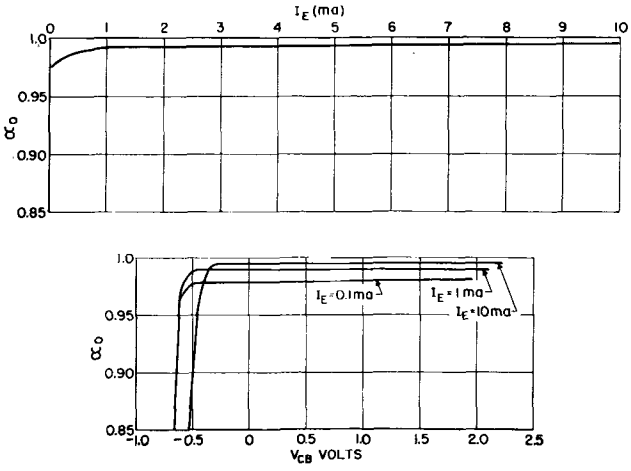

Fig. 4. The variation of alpha with emitter current and collector voltage for an oxide masked unit.

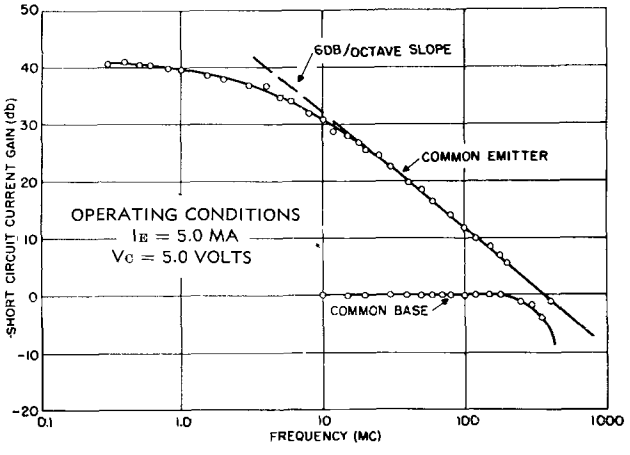

Fig. 5. The current gain vs. frequency for a thin base unit, both in the common emitter and common base connection.

improvement in the low frequency alpha. The collector to base reverse breakdown voltage is substantially lower than in the regular units due to reach-through effects; however, it is still high enough for many switching circuit applications.

Acknowledgments

The authors wish to acknowledge the contributions of W. C. Hittinger, who suggested this approach to the problem, M. Mandel (now at Stanford University), and D. L. Kushler. Thanks are also due to D. E. Thomas for making the frequency measurements.

Manuscript received July 18, 1958. This paper was prepared for delivery before the New York Meeting, April 27-May 1, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Equilibrium Reduction of Tungsten Oxides by Hydrogen

Robert C. Griffis

Refractory Metals Laboratory, General Electric Company, Cleveland, Ohio

ABSTRACT

A complete study has been made of the heterogeneous equilibrium involving the four tungsten oxides, water, and hydrogen, using a modified static equilibrium apparatus. These data show that the initial results, previously reported, are in error due to thermal diffusion. The new data were used to compute the standard heats of formation and entropies of the solid oxide species as follows:

WO_2, $\Delta H_f^\circ = -134.0 \pm 0.7$ kcal/g-atom W, $S^\circ_{298} = 19.7 \pm 1.0$ e.u./g-atom W
$WO_{2.72}(W_{18}O_{49})$, $\Delta H_f^\circ = -180.3 \pm 1.4$ kcal/g-atom W, $S^\circ_{298} = 25.0 \pm 1.4$ e.u./g-atom W
$WO_{2.90}(W_{20}O_{58})$, $\Delta H_f^\circ = -193.1 \pm 1.4$ kcal/g-atom W, $S^\circ_{298} = 23.6 \pm 1.4$ e.u./g-atom W
WO_3, $\Delta H_f^\circ = -202.8 \pm 1.4$ kcal/g-atom W, $S^\circ_{298} = 19.1 \pm 1.4$ e.u./g-atom W

Since the previous paper (1) there have been several significant developments in the literature which warrant notice. The high-temperature form (above 740°C) of WO_3 has been the subject of two more investigations (2, 3). Vasil'eva, *et al.* (3) have made a thermodynamic study of the series of suboxides formed from the high-temperature species of WO_3. They reported that the structure of the oxide formed by the reduction of WO_3 is determined by the structure of the WO_3. This gives rise to a series of heretofore unreported tungsten suboxides. In addition to this, some very interesting evidence as to metallic nature of beta tungsten has been presented (4, 5).

The purpose of this paper is to discuss the etiology of the thermal diffusion error in the initial results for the heterogeneous equilibrium involving H_2-W-WO_2-H_2, and to present new data for the heterogeneous equilibrium involving the complete reduction of WO_3 to W.

Experimental Procedure

All reagents were prepared as previously described (1). X-ray analyses of the products of the equilibrium reactions are discussed in the next section.

The extension of the reported experimental techniques to the higher oxide systems was found to be impracticable (1). The limiting H_2O vapor pressure resulted in large relative errors when the value of K_p was greater than one. It was experimentally difficult to thermostat the condensing bulb at higher than room temperature since provision had to be made for cooling the cold finger. There was also an indication of increased mass transfer of the oxides in the vapor phases, especially at high H_2O vapor pressures and temperatures. This increase in volatility in the presence of H_2O has been reported in the literature (6, 7). Effects encountered here were cumulative in nature only, and the amount of oxide lost in any one run was negligible, but the effects of 10-20 runs resulted in a visible oxide film at the exit of the reaction chamber. The original reaction chamber, due to its circular nature, could not be cleaned out in a reasonable time. The situation was aggravated also by accidental spillage inside the chamber.

Apparatus.—The design and construction of the new experimental apparatus closely followed the original work of Emmett and Schultz (8). The entire apparatus is present in Fig. 1. It should be noted that the hot reaction gases over the sample are pumped into the restricted section of the reaction chamber and thence to the H_2O vapor saturator. This design also facilitates removal of the chamber for periodic cleaning. The temperature of the water bath is regulated to within ±0.02°C by means of a mercury thermoregulator and zero current relay. The container is a Pyrex glass jar 12 in. in diameter and 18 in. high, holding approximately 7 gal of double distilled water. It is fitted with a plastic cover to minimize evaporation losses and to keep out dust. The supports for the water saturator and man-

ometer are fashioned from brass, copper, and Teflon.

The basic design for the gas solenoid pump was furnished by Seybolt (9) and is similar to that recently described by Bennett (10). A Teflon encased drill rod is used as a piston. This piston was machined to give a tight fit in ½ in. OD Pyrex glass tubing. This size of glass tubing was chosen so as to fit the readily available commercial solenoids. The piston was then hand lapped to give a smooth sliding action. A port is also provided for easy removal of the piston, if necessary. Small blocks of iron transformer core were placed on the upper part of the glass tube on the outside of the solenoids next to the vertical sections of the pump. When the solenoid is energized the iron blocks attract the iron core of the piston and tend to lengthen the stroke. This action results in a floating effect which enables the pump to run continuously for 8-10 hr at a temperature of 60°C without variation in pumping speed. The pumping frequency is 60 cycles/min and is obtained by a cam, synchronous motor, and breaker point assembly. The pumping capacity was measured as 250 cc/min by a water displacement method at atmospheric pressure. There was no evidence of decomposition of the Teflon piston at 60°C when it was operated in a vacuum.

All the glass tubing, including stopcocks, is heated with asbestos-covered resistance wire and wrapped with Al foil strips. The high vacuum stopcocks operate efficiently at 60°C if the proper greasing technique is used. Enough heat is conducted from the quartz reaction chamber to prevent condensation of H_2O in this section. The H_2O vapor pressure therefore is determined only by the temperature of the water bath which is carefully regulated. The same reaction furnace was used. The constant temperature zone (± 1°C) was increased to 4 cm due to increased end insulation and radiation shielding. The control thermocouple and recorder were rechecked against a Bureau of Standards Certificate Pt-Pt-10%Rh to ± 1°C for the entire temperature range. The mercury manometer readings were made with a precision cathetometer to ±0.03 mm.

This new experimental apparatus was used to determine once again the Fe-H_2O-H_2-Fe_3O_4 equilibrium over the temperature range 400°-550°C. Data were some 20% higher than those obtained with the initial apparatus, while data for the system H_2-W-WO_2-H_2O were slightly lower than the previous data. Vasil'eva and Gerasimov (11) suggested some changes in the experimental apparatus. They were of the opinion that the flow of the hot reaction gases was not great enough to eliminate thermal diffusion. At their suggestion the exit capillary of the reaction chamber was made 1 mm ID and most of the space in the reaction chamber was occupied by inserting a sealed quartz tube after the sample boat was inserted. This resulted in a much higher flow of gases through the hot reaction zone.

These improvements enabled data to be obtained for the system Fe-H_2O-H_2-Fe_3O_4 which agreed essentially with that obtained using the original apparatus (1); however, the K_p's now obtained for the system H_2-W-WO_2-H_2O were considerably lower than those obtained previously. The apparent paradox can be explained by examining the conditions under which the original apparatus was used. In the original apparatus the entire reaction chamber was insulated by Al foil guards. The auxiliary furnace was operated at about 300°C while the reaction furnace varied from 400° to 550°C for the reference Fe-H_2O-H_2-Fe_3O_4 system. Under these conditions the temperature gradient was not large enough over the closed tube chamber to bring thermal diffusion effects into play and/or convection circulation was sufficient to overcome this effect. In working with the tungsten oxide system, however, the temperature ranged from 500° to 1000°C. Under these conditions the effects of thermal diffusion evidently had a considerable influence on the data obtained.

Therefore, it is believed that thermal diffusion effects were eliminated in the system described above because; (*A*) the positive pressure action of the pump maintained a forced circulation of the reaction gases; (*B*) the velocity of the gases in the reaction chamber was increased by eliminating as much as possible of the dead space by means of the sealed quartz tube; and (*C*) the exit gases were conducted by means of a 1 mm capillary directly to the water vapor saturator.

X-ray studies.—The x-ray investigation was concerned with two areas of interest. The first area involved routine x-ray examinations of the solid phases in the equilibrium samples, using powder camera techniques. This study showed only the tungsten oxide phases as reported by Magneli, *et al.* (12).

The second area of interest concerned the new structures of the suboxides described by Vasil'eva, *et al.* (3). Samples in this study consisted of the pure tungsten oxides in contrast to the solid two-phase samples encountered in the equilibrium samples. A General Electric XRD-5 x-ray diffractometer was used to examine the quenched samples so as to obtain the data as soon as possible. Copper K radiation was used since the resolution achieved was sufficient for this study. It has been pointed out that reliable determination of angular position and intensities of the diffraction peaks requires considerable attention to the preparation and mounting of the sample powders (13). The samples were mounted according to the procedure as outlined by McCreery (14). Several samples were examined for each oxide in order to detect gross variations. The pure oxide samples were sealed in quartz tubes after careful evacuation at less than 0.1 μ pressure for a period of 8 hr. These capsules were held at 1000°C for approximately 18 hr. The samples were quenched to room temperature by dropping the hot capsule into a reservoir of water. The quenched powder which was still under vacuum was removed by breaking the capsule. Total time required for quenching and preparing the sample was 3 min. In one instance a sample of WO_3 was heated in air, quenched directly into water, filtered, washed with acetone for drying purposes, and then prepared for x-ray.

Results and Discussion

All of the data was obtained by alternate reduction and oxidation of the samples. The sample consisted of a mixture of the two solid phases concerned for the particular heterogeneous equilibrium being investigated. This is in contradistinction to the method of Vasil'eva, *et al.* (3) who prepared the phases *in situ* by the reduction of WO_3. The two phases were introduced in order to achieve equilibrium conditions as soon as was practicable and to avoid excessive sintering effects which sometimes invalidate the data obtained for experimental runs involving long times and/or high equilibrium gas ratios. The 2-g sample was evacuated to less than 0.1 μ and held there for at least 3 hr. Each sample was subjected to conditioning runs under oxidizing and reducing conditions before the final run was made. The system was evacuated after the final equilibrium measurements were made and the sample cooled to room temperature. All equilibrium samples then were examined by x-ray, using powder camera techniques, to identify the solid phases present. The temperature regions investigated were limited by the significant volatility of the higher tungsten oxides in the presence of water vapor, as was pointed out in the first paragraph.

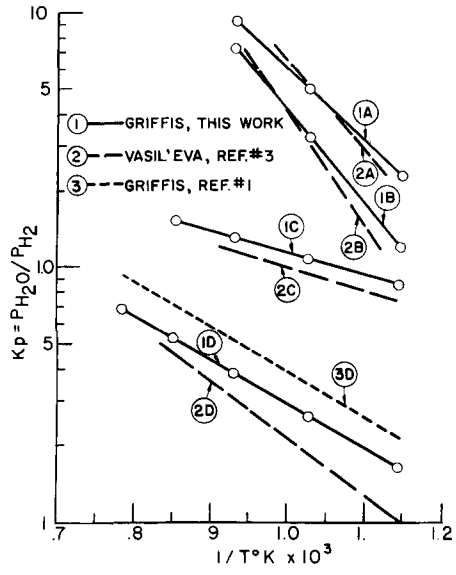

Fig. 2. Plot of log $K_p = \frac{P_{H_2O}}{P_{H_2}}$ vs. $\frac{1}{T°K}$ for the systems:

(1A)(2A)—WO_3-H_2-$WO_{2.90}$-H_2O
(1B)(2B)—$WO_{2.90}$-H_2-$WO_{2.72}$-H_2O
(1C)(2C)—$WO_{2.72}$-H_2-WO_2-H_2O
(1D)(2D)(3D)—WO_2-H_2-W-H_2O

The data are summarized in Tables I-IV, and Fig. 2.

C_p's for the equilibrium reactions were calculated on the basis of literature values for H_2, H_2O, WO_3 (15), W (16), and Kopp's rule for the tungsten oxides since no literature values are available. The equilibrium values in Tables I-IV were treated by means of sigma functions and the method of least squares. Literature values (17) of $\Delta F°_{298}$ (−109, 200 cal) and $\Delta H°_{298}$ (−115, 600 cal) for the reaction $2H_2 + O_2 \rightarrow 2H_2O$ were used to calculate $\Delta H°_f$ for each oxide. The standard entropy values of W and O_2 (18) were used to calculate the standard entropies of the oxides. The results of these calculations are tabulated in Table V.

The lack of reliable heat capacity data accounts for the large estimated error assigned to these values. The heats of formation reported here (Table VI) are compared with those obtained by direct combustion techniques (1).

(D) $\frac{1}{2}\ WO_2 + H_2 \rightarrow \frac{1}{2}\ W + H_2O$

$\Delta H^\circ = 10{,}125 - 3.48T + 1.08 \times 10^{-3} T^2 + 0.04 \times 10^5 T^{-1}$

$\Delta F^\circ = 10{,}125 + 3.48T\ln T - 1.08 \times 10^{-3} T^2 + 0.02 \times 10^5 T^{-1} - 30.7T$

$\Delta H^\circ_{298} = +9.2 \pm 0.5$ kcal

$\Delta F^\circ_{298} = +6.8 \pm 0.5$ kcal

$W + O_2 \rightarrow WO_2$

$\Delta H^\circ_{298} = 134.0 \pm 0.7$ kcal/g-atom W

$S^\circ_{298}\ WO_2 = 19.7 \pm 1.0$ e.u./g-atom W

Table VI. Heats of formation of tungsten oxides

Oxide	ΔH_f° kcal/g-atom W Combustion	Equilibrium
WO_3	-199 ± 1	-202.8 ± 1.4
$WO_{2.90}$	-193 ± 1	-193.1 ± 1.4
$WO_{2.72}$	-183 ± 1	-180.3 ± 1.4
WO_2	-137 ± 1	-134.0 ± 0.7

The x-ray examination of the equilibrium samples, as was previously pointed out, showed no evidence of the structure reported by Vasil'eva, *et al.* (3). The structure of the equilibrium oxide phases corresponded only to those reported by Magneli, *et al.* (12).

The x-ray examination of the pure oxides phases, as outlined under the second area of interest, was also unsuccessful in revealing any new structures for the tungsten oxides. All of the samples heated at 1000°C and quenched gave only the tungsten oxide patterns as previously reported (12). The tetragonal structure of WO_3 above 740°C had been confirmed by dilatometric (19), x-ray, and differential thermal analysis data (20-22). Perri, *et al.* (2) showed that there is a smooth transition from the monoclinic form of WO_3 to the orthorhombic form at about 300°C, and a sharp transition to the tetragonal form at 720°C. The high-temperature form (above 740°C) of WO_3 was described as orthorhombic by Vasil'eva on the basis of examination of rapidly cooled samples of WO_3. As stated above, this study failed to detect any "quenched-in" high-temperature form. The one sample of WO_3, which was cooled by pouring the hot powder into H_2O, did show some evidence of increase in the *d* values obtained from 001, 020, 200 reflections. This comportment indicates a shift to the orthorhombic structure. The peaks were recorded in their normal positions, however, after 15 min. The data obtained from the diffractometer, especially at slow scanning speeds, were sufficiently precise so as to show the possible shift in structure for all the tungsten oxides. The question as to whether the tungsten oxides prepared *in situ* by Vasil'eva and subsequently cooled rapidly have a different structure from those prepared by direct synthesis, using WO_3 and W, is difficult since the high-temperature structure for WO_3 was not reported by Vasil'eva. The equilibrium data certainly suggest that there is a distinct and measurable difference. Further work is planned in examining the phase transitions of each of the oxides by means of a high-temperature x-ray camera. The characteristics of those oxides prepared by reduction of WO_3 *in situ* and those prepared by direct synthesis of WO_3 and W (12) will be compared.

Acknowledgments

The author wishes to thank many members of the Refractory Metals Laboratory, and other divisions of the General Electric Company for their helpful assistance. He wishes to thank Dr. A. U. Seybolt for the gas pump design. He is especially grateful for the helpful discussion with Professor Gerasinov and Candidate Chem. Science Vasil'eva.

Manuscript received Nov. 5, 1958. This paper was prepared for delivery before the Buffalo Meeting, Oct. 6-10, 1957.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Polarographic Behavior of Nitro and Nitrosoguanidine

Gerald C. Whitnack and E. St. Clair Gantz[1]

General Research Branch, U. S. Naval Ordnance Test Station, China Lake, California

ABSTRACT

The general behavior of nitro and nitrosoguanidine at the dropping mercury electrode has been studied under various alkaline, neutral, and acidic conditions. Different mechanisms of reduction are postulated and discussed. Optimum conditions are specified, with other details, both for the determination of the nitroso compound in the presence of the nitro compound, and for the reduction of the nitro compound to either the amino or nitroso compound. Half-wave potentials, diffusion current constants, and n-values are reported for each compound in several media. The multiple waves obtained with these compounds at some *p*H values are discussed in terms of different ionic and molecular forms in solution.

The reduction of nitroguanidine has been a subject of considerable study for many years (1-5). Nitrosoguanidine has been established as the first product in the chemical reduction of nitroguanidine (1, 3). Thiele described the preparation of nitrosoguanidine by the careful reduction of nitroguanidine with tin and dilute hydrochloric acid. Steinbach (5) studied the chemical reduction of nitroguanidine in neutral, acidic, and alkaline solutions and the electrochemical reduction in acidic and alkaline solutions. He showed that the product of the chemical reduction depended mainly on the type of reducing agent and the amount of reductant present. Aminoguanidine and nitrosoguanidine were the end products. Smith and Sabetta, and Davis and Rosenquist (4, 23) proposed a method for the preparation of nitrosoguanidine by the reduction of nitroguanidine with zinc dust in an ammonium chloride solution. The oxidation potential for the half-cell, nitro-nitrosoguanidine, has been measured (4,6); however, very little fundamental information has been reported on the polarographic behavior of this very involved system.

Nitro and nitrosoguanidine exhibit amphoteric characteristics (7) and their different possible molecular and ionic forms have been the subject of considerable controversy (8-13). The dissociation constants of several derivatives of nitroguanidine (14) and the effect of substituents on the absorption spectrum of nitroguanidine have been determined spectrophotometrically (15). A hydroxylaminoguanidine intermediate has been proposed in the reduction of nitroguanidine by titanium (III) chloride (16).

In the fall of 1955, a paper on the polarographic behavior of nitro and nitrosoguanidine was published by Lanza, *et al.* (17). In addition, Namba and Suzuki (18) in 1955 published some work on nitrourea and nitroguanidine. In general, where their work overlapped with the work presented in this report, good agreement was obtained.

The present study was initiated so that additional fundamental knowledge about the mechanism and products of reduction and the general polarographic behavior of nitro and nitrosoguanidine might be obtained. It is the purpose of this report to present and discuss such data.

Experimental

Apparatus and materials.—A Sargent Model XXI recording polarograph and a Fisher "Elecdropode" were used in these studies. Mercury pool potentials and half-wave potentials ($E_{1/2}$) vs. the saturated calomel electrode (SCE) were determined with the "Elecdropode" (19). The $E_{1/2}$ values (vs. Hg pool) were calculated by the method of intersecting lines from polarograms obtained with the Sargent Model XXI polarograph. It is recognized that $E_{1/2}$ (vs. Hg pool) values do not have exact significance and are reported for relative comparison only. The potential of the mercury pool was fairly constant in a Britton and Robinson buffer system through the *p*H 3-7 range.

Solutions used in these studies had cell resistances of less than 500 ohms (as determined with a Wheatstone bridge) and the *iR* correction was negligible in computing the $E_{1/2}$ values (20). All *p*H measurements were made with a Beckman Model G *p*H meter.

Several dropping mercury electrodes were used in this work. The $m^{2/3}t^{1/6}$ values are reported in the tables.

Small borosilicate glass beakers (30 ml) were used as polarographic cells. A rubber stopper to which were attached the dropping mercury elec-

[1] Present address: Aircraft Gas Turbine Division, General Electric Co., Cincinnati, Ohio.

trode, contact electrode, and a glass tube with a fritted disk, was placed over the top of the small beakers. The current-voltage curves were obtained in a constant temperature bath at 30° ± 0.1°C.

Dissolved oxygen was removed from all solutions with pure nitrogen just prior to the polarographic examination. The nitrogen was passed through a portion of the solution being examined polarographically and finally through the solution in the polarographic cell.

Clark and Lubs' and Britton and Robinson buffer solutions (21, 22) were prepared double strength (2x), and then the buffer was added to varying amounts of aqueous stock solutions of nitro and nitrosoguanidine so that the final polarographic solutions were about 0.1M in buffer. Methyl red (0.001%) was used as a maxima suppressor in these studies, and redistilled mercury, C.P. grade, was used as the anode. The ionic strength of the polarographic solutions was controlled carefully by the addition of ionic strength agents whenever needed.

Nitrosoguanidine was prepared by the method of Davis and Rosenquist (23). The material was recrystallized once from water and analyzed 98.6% by a permanganate titration.

The nitroguanidine used in this work was a commercial grade known as "picrite." This material was recrystallized three time from distilled water and had a melting point of 234°-236°C.

Diffusion Coefficient and n-*Value Measurements*

The diffusion coefficient (D) for nitroguanidine was determined by a procedure adapted from that employed by Stokes (24). In this method, porous diaphragm cells were used, which embodied a magnetic stirring mechanism. The cells were calibrated by the usual method of allowing 0.1M potassium chloride to diffuse into water at 25°C until 25% had passed through the diaphragm. The diffusion constant of potassium chloride for these conditions is known to be 1.867×10^{-5} cm²/sec.

Since nitrosoguanidine decomposes in aqueous solutions (25), a more rapid method of determining its diffusion coefficient and n-value was needed. A millicoulometric method reported by Reynolds (26), and recently modified in this laboratory (27), was employed. In this method the polarograph served as a coulometer and a source of constant applied potential. The integration method was used in calculation. An n-value for nitroguanidine was also determined by this technique.

Results and Discussion

Effect of pH, mercury height, and concentration.— Nitro and nitrosoguanidine were investigated in ammonium chloride and ammonium sulfate solutions (pH 4.5). Only one wave was observed for nitroguanidine in these salt solutions, and the $E_{1/2}$ was more negative in the ammonium sulfate solution than in the ammonium chloride solution. However, in 1N HCl and H_2SO_4 solutions, two waves were observed. The $E_{1/2}$ values were more negative in the H_2SO_4 solution than in the HCl solution. Nitrosoguanidine gave two waves in the salt solutions but only one in the 1N acid solutions. Thus it appeared

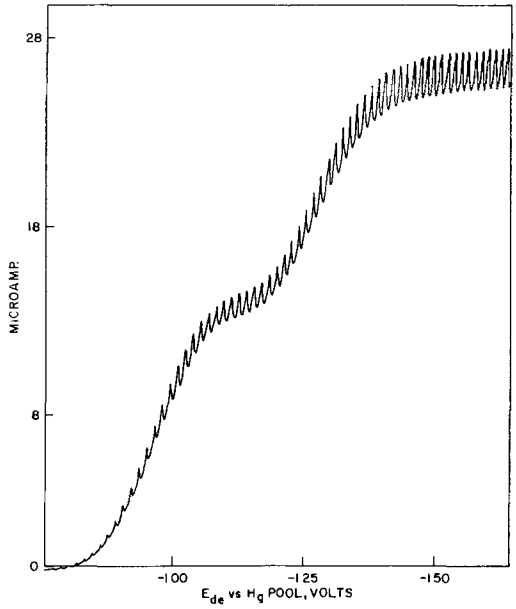

Fig. 1. Polarographic waves of 1.70 mM nitrosoguanidine solution. Britton and Robinson buffer (2X), pH 5.5, 0.001 % methyl red, $m^{2/3}t^{1/6} = 1.45$ mg$^{2/3}$ sec$^{-1/2}$.

that these waves were greatly dependent on the pH and the medium, Therefore, nitro and nitrosoguanidine solutions were studied in Clark and Lubs' and in Britton and Robinson's buffer solutions. The ionic strength of the polarographic solutions was maintained below 0.2M to minimize effects on half-wave potentials. In general, two well-defined waves were obtained over the acid and neutral pH range and one well-defined wave was obtained in alkaline solutions with a pH > 10. The definition of the waves appeared to be better in the Britton and Robinson buffer solutions and a typical polarogram is shown in Fig. 1 for nitrosoguanidine in this system. The first wave is referred to as the more positive in voltage. The effect of pH on the i_d values and the $E_{1/2}$ values of the two individual waves and the total waves, respectively, is shown in Tables I and II. The $E_{1/2}$ values of the first waves increased linearly with an increase in pH to about a pH of 4. The slope of

* 18 ml Britton and Robinson buffer solution with 2 ml of stock nitrosoguanidine solution.
† Total, refers to total diffusion current. pH 2.4-5.0 waves well defined, pH 5.7-8.7 waves ill-defined, pH 9.0-11.7 one well-defined wave.

the $E_{1/2}$ vs. pH plots for nitrosoguanidine (1st wave) is about ½ that for nitroguanidine in this pH range. The diffusion current constants become smaller for the first wave and larger for the second wave with an increase in the pH of the solution. It should be noted (Table II) that in the narrow pH range of 5.7-6.1 the diffusion current constants for each wave of nitrosoguanidine are nearly the same. It appears that nitro and nitrosoguanidine have nearly the same reduction potentials in acid solution with a pH < 2.5. Nitrosoguanidine appears to be slightly the better depolarizer ($E_{1/2}$ more positive) in solutions with a pH > 2.5, although the differences in the $E_{1/2}$ values are very small. Thus, it would seem that if one tried to reduce nitroguanidine electrochemically, any nitrosoguanidine that might form would be immediately reduced further. It should be noted also from the data in Tables I and II that a pH range of 5 to 6 appears to be best for a good separation between the first wave of nitrosoguanidine and the wave of nitroguanidine. Thus, a quantitative analysis of nitrosoguanidine in the presence of nitroguanidine should be possible in this pH range.

Data on the effect of the mercury column height on the diffusion current for each wave of nitro and nitrosoguanidine indicates diffusion controlled processes throughout the entire pH range studied; i.e., the limiting current varies with the square root of the corrected mercury height (Tables VII and VIII).

The effect of concentration on the $E_{1/2}$ and i_d values of nitro and nitrosoguanidine is shown in Table III and was obtained in a Clark and Lubs' buffer solution of pH 6. At this pH a double wave was observed with 1.0 mM solutions of the guanidines but only the total wave was defined well enough for accurate measurement. Over the concentration range of 0.5-6.0 mM the total wave appeared to be proportional to concentration ($i_d = KC$) for nitroguanidine. However, for the total wave of nitrosoguanidine,

Table III. Effect of concentration on $E_{1/2}$ and i_d of nitro and nitrosoguanidine, Clark and Lubs' buffer (2x), pH 6.0, 0.001% methyl red $m^{2/3}t^{1/6} = 1.92$ mg$^{2/3}$ sec$^{-1/2}$

Compound	Concentration, mM	i_d, μa	$E_{1/2}$ (vs. Ha pool), v
Nitroguanidine	0.5	8.15	—1.29
Nitroguanidine	1.4	24.20	—1.33
Nitroguanidine	4.0	66.60	—1.38

Nitrosoguanidine	0.5	7.29	—1.12
Nitrosoguanidine	1.7	20.20	—1.15
Nitrosoguanidine	4.0	39.90	—1.17
Nitrosoguanidine	6.0	50.70	—1.25

$i_d = KC$ over the shorter range of 0.5-2 mM solutions. Since the $E_{1/2}$ values depend on concentration and become more negative with increasing concentration for both nitroguanidine and nitrosoguanidine solutions, and since plots of log $i/(i_d - i)$ do not give a linear relationship, the over-all reduction process at the cathode appears to be irreversible for each compound.

With solutions containing two or more organic compounds, the possibility exists that one compound may affect the diffusion process of the other compound at a dropping mercury electrode. Table IV gives data on the effect of nitroguanidine on the first wave of nitrosoguanidine. Small amounts of nitrosoguanidine can be determined in the presence of nitroguanidine. However, when the ratio of these compounds exceeds 1:1 there is difficulty in precise measurement of the first nitrosoguanidine wave.

Effect of temperature, solvent, and acid concentration.—In a Clark and Lubs' buffer solution (pH 5.5), the total wave for each compound is lower at 5°C than at 30°C. This is what one would expect, as the diffusion coefficients depend on temperature and are larger at the higher temperatures. However, at the lower temperature the i_d of the first nitroguanidine wave decreased and the i_d of the second wave increased. This may indicate a change in state and concentration of the reducible species in solution with a change in temperature. With nitrosoguanidine solutions, the height of the first wave and the $E_{1/2}$ values, respectively, are nearly the same at 5°C as they are at 30°C. Only the second wave appears to be greatly affected by the change in temperature. This unusual behavior of the polarographic waves with a change in the temperature of the solution is difficult to explain. It may be due to the de-

gree of solvation of different reducible species in solution.

Ethyl alcohol was used to study the effect of a nonaqueous solvent on the waves of nitroguanidine (Table V). Although the separation of the waves is not as sharply defined in the presence of ethyl alcohol, there are two distinct waves for nitroguanidine in these solutions. The $E_{1/2}$ values and i_d values are dependent on the concentration of ethyl alcohol in the medium. It should be noted that the $E_{1/2}$ values are shifted to more negative potentials in the presence of ethyl alcohol, and the i_d value of the total wave appears to go through a minimum around 25% ethyl alcohol. With reducible metal ions an increase in the product $i_d\eta^{1/2}$, where η is the viscosity of the solution, is observed up to about 25% ethyl alcohol (28). However, it can be seen that a decrease in the product $i_d\eta^{1/2}$ is observed with solutions of nitroguanidine up to about 25% ethyl alcohol. Thus, it would appear that with up to 25% ethyl alcohol an increase in the size of the solvated reducible nitroguanidine ion occurred as the activity of water decreased; or that the decreasing dielectric constant favored and caused ion-pair formation and thus an increase in the size of the diffusing species. The increase of "apparent" pH of the final solution with increasing ethyl alcohol concentrations could account also for some difference in wave heights. As the percentage of ethyl alcohol is increased beyond 25% the wave heights of both the total and individual waves increase. The total wave is about the same height in a 70% ethyl alcohol solution as it is in a purely aqueous solution; however, the individual wave heights are just the opposite (first wave height larger and second wave height smaller) in alcohol. These data would seem to rule out ion-pair formation and suggest that the degree of solvation of nitroguanidine was about the same in 75% ethyl alcohol and purely aqueous pH 6.0 buffer solution. Since the first wave height is greater in the 75% ethyl alcohol solution than in the purely aqueous solution, it might also be suggested that nitroguanidine is more highly protonated in the 75% ethyl alcohol solution, and that the first wave is due to the reduction of a protonated species and the second wave is due to the reduction of the unprotonated molecule.

The effect of hydrochloric acid concentration on the $E_{1/2}$ and i_d values of nitroguanidine is shown in Table VI. Again two waves were observed. With a decrease in acid concentration the $E_{1/2}$ value of the first wave became more negative and the i_d value decreased. Only one well-defined wave was observed in 6*N* acid, although a very small second wave was found in 2*N* acid. In strong acid solution a highly protonated specie should predominate, and very little of the unprotonated molecule would be present. In acidic solution a shift of half-wave potentials to more negative values with an increase in pH sometimes can be thought of as a direct reaction of the compound with a proton to form an intermediate ion which is reduced more easily. At the higher pH values the molecule itself is reduced, followed by a reaction of the anion with water as hydrogen ions (29).

Nitro and nitrosoguanidine are weak ampholytes. For nitroguanidine pK_a = 12.20 and pK_b = 14.5, while for nitrosoguanidine pK_a = 11.70 and pK_b = 11.90 (30). As a consequence, different ionic and molecular species may exist in solution depending upon the pH. This fact suggests a possible explanation for the existence of two waves at some pH values and only one wave at other values. For simplicity in explanation of the observed polarographic waves, only the following ionic and molecular forms[2] need to be considered.

[2] Since nitro and nitrosoguanidine molecules may be considered as resonating among various hybrids (8), numerous other forms with various charge separations may also be written, but these are not important in the present discussion.

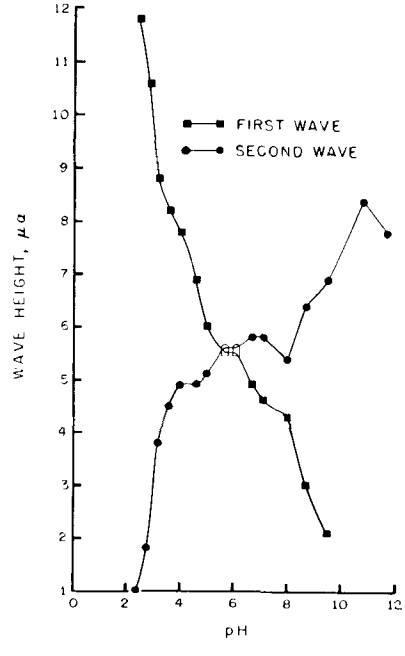

Fig. 2. Effect of pH on i_d of 1.043 mM solution of nitrosoguanidine. Britton and Robinson buffer system (2X).

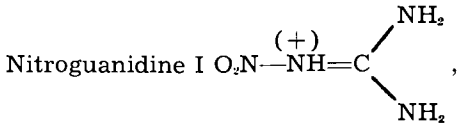

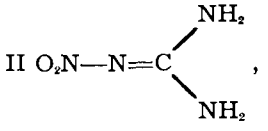

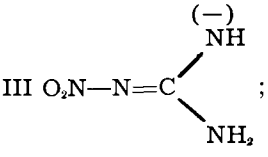

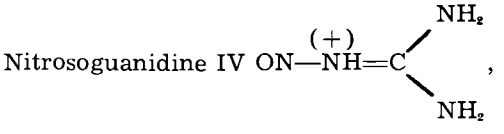

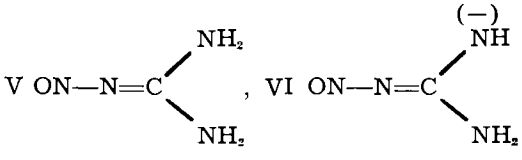

Thus, in 6*N* HCl, forms I and IV would be the predominant species; in *p*H from 1 to 4, I and II or IV and V; about *p*H 7, II and III or V and VI; and at *p*H 8-9 and above, III and VI should be the major forms present. Only one wave was observed in solutions more alkaline than *p*H 9 and more acid than 2*N* acid. In the Britton and Robinson buffer system, the two wave heights obtained with millimolar solutions of nitrosoguanidine vary greatly with *p*H and appear to be of equivalent height around a *p*H of 6 (Fig. 2). Both these waves appear to be diffusion-controlled (i_d varies as $h^{-1/2}$) (Tables VII and VIII) and the $E_{1/2}$ values vary with a change in *p*H. These data would suggest that if the existence of two waves for nitrosoguanidine in this medium is due to two reducible species in solution, then, at a *p*H of 6 forms IV and V probably give rise to the equivalent wave heights shown in Fig. 2 as first wave and second wave, respectively. The two waves obtained with

solutions of nitroguanidine were not as sharply defined and accurate measurements were not possible in the intermediate *p*H ranges of the buffered systems.

Determination of the n*-value and reduction mechanism.*—The porous diaphragm cell method with magnetic stirring has been used successfully in these laboratories for the determination of the diffusion coefficients (D) of some organic compounds (31). A D value of 2.37 x 10^{-5} cm^2 sec^{-1} was obtained for nitroguanidine by this method in a 2M ammonium sulfate solution. This value for D, when used in the Ilkovic equation ($n = i_d/607D^{1/2}Cm^{2/3}t^{1/6}$), gave an n-value of 3.48 electrons. From the Stokes-Einstein equation, $D(\text{cm}^2/\text{sec}) = 2.96 \times 10^{-7}/\eta(V_m)^{1/3}$ at 25°C, where η is the solution viscosity in dyne seconds per cm^2 and V_m is the molar volume, an n-value of 4.88 electrons was obtained. Since these values were not in agreement and since nitrosoguanidine decomposes rather rapidly in aqueous solutions, a direct and rapid method for the determination of n was thought desirable. With the direct and rapid method for n-values (millicoulometric) that was recently investigated and modified in these laboratories (26, 27), an n-value of 5 was obtained for nitroguanidine in a Clark and Lubs' buffer solution of *p*H 10 where one well-defined wave occurred. Nitroguanidine in a Clark and Lubs' buffer solution of n-value of 3. These values of 5 and 3 are repeatable, and, although the n-values are not 4 and 2 as expected, the 2 electron difference in values indicates that the reduction process of nitroguanidine passes through the nitrosoguanidine state in *p*H 10 buffered solutions (Fig. 3).

It is known that in strong acid solutions nitroguanidine is reduced directly to aminoguanidine (3, 32). In 6*N* hydrochloric acid solutions an n-value of 6 was obtained for nitroguanidine by the millicoulometric technique (26). However, in neutral and alkaline solutions the reduction mechanism appears to be complicated and n-values are of little help in elucidating the over-all process.

The n-value of 5 for nitroguanidine, obtained by millicoulometry in a pH 10 Clark and Lubs' buffer solution, may be explained by a coupling of the products of a 2 and 6 electron reduction respectively (Fig. 3). It has been shown that nitrosoguanidine and aminoguanidine can react to form a tetrazene (33), which should be further reducible. The n-value of 3.5, obtained in the 2M ammonium sulfate solution (pH 4.5) from an experimental D value, would seem to indicate the reduction of nitroguanidine to hydroxylaminoguanidine (Fig. 3) in weakly acidic or neutral solutions. This latter compound was suggested as the end product in the reduction of nitroguanidine in alkaline medium (pH > 12) by Lanza and co-workers (17). Hydroxylaminoguanidine has never been isolated. It would be expected to decompose rapidly to guanidine and hyponitrous acid. It appears that in neutral and alkaline solutions there is more than one process occurring at the dropping mercury electrode. These processes are probably occurring at different rates and the products may undergo "dearrangement." Thus, it is difficult to establish the over-all reduction mechanism of either nitroguanidine or nitrosoguanidine at a dropping mercury electrode in these solutions.

The authors prepared nitrosoguanidine at a mercury cathode in 20% yields by the large-scale electrolysis of nitroguanidine in a 2M-ammonium sulfate solution. Polarographic techniques were used to determine the optimum conditions for the preparation. The addition of nickel II ions to the solutions produced excellent yields of a red nickel-nitrosoguanidine complex salt. The complex salt is extremely stable and attempts to quantitatively recover the nitrosoguanidine from the complex were unsuccessful. The formation of this salt established nitrosoguanidine as the first step in the reduction of nitroguanidine in neutral or weakly acidic solution at a mercury cathode (Fig. 3). As fast as nitrosoguanidine is formed, it complexes with the nickel ions and a bright red precipitate appears in the electrolysis solution.

Acknowledgment

The authors wish to express their sincere appreciation and gratitude to G. B. L. Smith (deceased), Ronald A. Henry, and William G. Finnegan, for their invaluable help and encouragement during this work. The authors also wish to thank Robert D. Weaver for obtaining the n-value data.

Manuscript received March 10, 1958. This paper was prepared for delivery before the Pittsburgh Meeting, Oct. 9-13, 1955.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Electrodeposition of Adherent Titanium Coatings on Induction Heated Cathodes in Fused Salts

B. J. Fortin, J. G. Wurm, L. Gravel, and R. J. A. Potvin

Laval University, Quebec, Quebec, Canada

ABSTRACT

A new electrolytic method for the deposition of adherent coatings of titanium on steel cathodes is described. The procedure involves the use of fused alkali-halide baths composed of eutectic mixtures of lithium, potassium or sodium iodides, bromides, chlorides, and fluorides, with a high-frequency heated cathode and a soluble titanium anode. The bath composed of KI-KF performed best and deposited a very smooth and uniform titanium coating. Conversely, the bath composed of KI-NaI and TiI_4 (2 to 5%) yielded dendritic Ti and is therefore considered more suitable for an electrorefining process. Equipment and operating conditions are described and the microstructure of the coating produced is reported. A series of decomposition voltage curves is included and discussed, and the mechanism of the electrolytic reactions is studied in detail.

A complete literature survey of the electrodeposition of titanium from molten salts has been published recently by Steinberg (1). Ti diffusion coatings were obtained by Straumanis, *et al.* (2, 3) from fused baths containing dispersed Ti crystals or Ti salts. Much remains to be investigated, however, on the deposition of uniform and strongly adherent coatings of Ti.

The present work deals with an electroplating method involving the use of an induction-heated cathode and a soluble Ti anode in fused salt baths. The induction-heated cathode acts at the same time as a heating element to maintain the bath in a molten state. In this manner, the cathode is at a temperature appreciably higher than the surroundings. In fact, the anodic zone, far removed from the cathode area, may be kept much colder. This provides, therefore, means to control the rate of solution of the anode as well as volatilization losses and secondary reactions. The skin effect due to induction current creates a maximum temperature zone on the very surface of the cathode, speeding up degassing and facilitating diffusion of the deposited Ti. Furthermore, the electrolysis may be carried out in a Pyrex or transparent quartz cell which makes it convenient to see directly the phenomena taking place.

Description of Cells

Two types of cells are used. These cells are made up of a Pyrex or quartz tube closed at the bottom and covered at the top by a gas-tight asbestos lid which holds also the electrodes and inert gas ducts.

In the first type, as shown in Fig. 1, the anode is composed of Ti sponge which covers the bottom of the cell: a shielded W wire passing through the molten electrolyte is provided to carry current to the anode. The cathode, in this particular case, is made of steel wire 2-mm diameter and has the form of a ring which is located in the center of the high-frequency coil.

The second type of cell differs from the first one in that the relative positions of the anode and cathode are reversed: the anode is located in the upper portion of the bath and consists of either Ti wire or a cylindrical W grid filled with Ti sponge. The ring-shaped cathode reaches near the bottom of the cell and is held by means of a connecting wire shielded with a Pyrex glass tube. The design of the cell shown in Fig. 1 was found in practice to be preferable. In fact, in this cell, there exists a marked difference in temperature between the anode and the cathode zones, which cannot be obtained in the other type of cell where the cathode, close to the bottom, favors stronger convection resulting in a more uniform heat distribution.

A variety of cathode shapes made of iron or steel were used. These included massive pieces such as threaded rods, flat washers, or lighter pieces made of wire wound in different shapes.

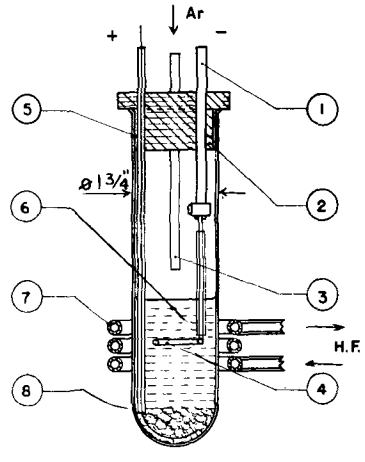

Fig. 1. Electrolytic cell with a heating cathode (Type 1). 1, Cathode holder; 2, asbestos stopper; 3, argon inlet; 4, heating cathode ring; 5, W wire in Pyrex tube; 6, electrolytic bath; 7, high-frequency coil; 8, Ti sponge anode.

Experimental Procedure

Electrolytic baths composed of low-fusing halides of lithium, sodium and potassium were selected. Each bath contained about 150 g of an eutectic mixture of these salts which were placed in the cell tube and melted in a separate furnace for dehydration while flushing with dry argon. Finally, the assembled cell was rapidly transferred to the high-frequency coil. An optical pyrometer was used to observe the cathode temperature, and a thermocouple introduced through the argon outlet tube served to determine the temperature of the bath at different depths. The temperature of the cathode during electrolysis was kept constant within 25°C and was approximately 200°C above the average temperature in the bath.

At the very first stage of electrolysis, the cathode became surrounded with a bluish-violet cloud which within a few minutes extended to the whole bath. At the end of the electrolysis, the cell was cooled rapidly in an air blast while maintaining a difference of potential of about 1 v between the electrodes in order to prevent any interaction between the bath and the deposited Ti. The cathode products and the remainder of the bath after solidification were submitted to a combined chemical and x-ray analysis. It was considered that rapid cooling of the bath after electrolysis minimized postelectrolytic reactions, and therefore it was assumed that analytical results obtained on the solidified melts could serve as a basis for proposing a probable explanation of the mechanism involved.

In some experiments, TiI_4 and K_2TiF_6 were injected into the molten eutectic during electrolysis.

Results

The first series of experiments reported in Table I dealt with electrolytic baths composed of mixtures of halides of eutectic composition, using a soluble anode and a ring-shaped cathode made of a 2-mm steel wire. Cathode current densities were kept fairly constant during the whole of the electrolysis: values from 0.42 to 1.0 amp/cm^2 were used. It was observed that the Ti deposit was mainly dendritic, nonuniform and poorly adherent when the temperature at the cathode was below 850°C, while it was more adherent for higher temperatures; in fact, it was found, in this first series of experiments, that at the start of the electrolysis a compact, adherent and shiny deposit of Ti appeared on the cathode. This deposit grew up regularly for about 10 min, after which some dendritic deposit showed up at various spots and continued to develop, forming an irregular surface or even bridging up to give rise to a spongy layer. This latter effect was more marked for the iodide and bromide baths. At the end of the electrolysis, the zone next to the cathode gave a definitely alkaline aqueous solution while that from the anode was acid. Furthermore, as the electrolysis proceeded the zone near the anode turned from a faint bluish-violet to a reddish-brown in the case of the bromide and iodide baths and to a pale green in the case of the chloride baths. The latter is ascribed to the formation of $NaTiCl_4$ described by Steinberg (1). The current efficiency was high, slightly above 90% in most of the experiments mentioned in Table I. On the other hand, the amount of Ti dissolved at the anode exceeded considerably the theoretical value; this may result in part from the formation of lower valence Ti compounds which have been detected in the bath.

In the second series of experiments, Nos. 9-12 in Table I, small proportions of TiI_4 were injected under argon in baths containing the eutectic mixture NaI-KI. One experiment also is reported on a bath containing KI-KF in which K_2TiF_6 was injected in the same manner. At the end of the electrolysis the baths containing only iodides had a reddish-brown color; as in the previous series, the salts surrounding the cathode gave a very strongly alkaline reaction while those surrounding the anode had a low pH when dissolved in water. The coatings in this series of experiments were in general of a heavier adherent type than in the previous; however, they had a rough and nonuniform surface as may be seen in Fig. 2a. When the temperature of the cathode was increased to 975°C, as in experiment No. 11, the surface became smoother and more uniform but it was found that the amount of anode dissolved during electrolysis was still greater than in the previous series, reaching 215% of the theoretical value based on Faraday's law. This is not surprising in view of the strong reaction between the injected TiI_4 and the anode at a high temperature.

The third series of experiments, Nos. 13-17 of Table I, concerned only baths composed of a KI-KF eutectic mixture using Ti anodes or Zr anodes in the

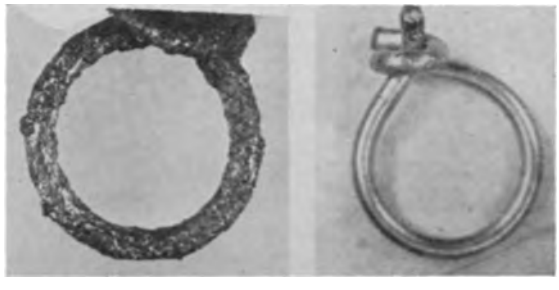

Fig. 2. (a) (left) Rough and nonuniform surface obtained in a KI-NaI bath with TiI_4 addition (Expt. 10, Table I). (b) (right) smooth and uniform coating obtained in KI-KF bath (Expt. 15, Table I). Approx. 2/3 size.

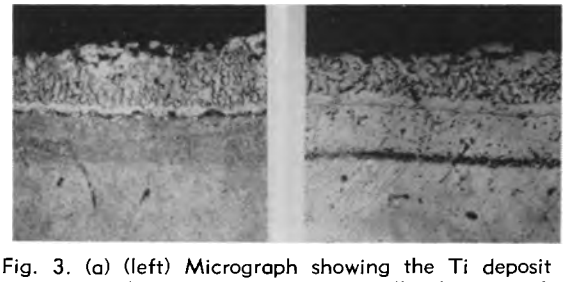

Fig. 3. (a) (left) Micrograph showing the Ti deposit obtained in a KI-NaI bath (Expt. 5, Table I). The HF etch has revealed the more or less granular deposit of Ti crystals separated by a clear white, compact and very hard intermediary zone from a darker etching zone. The Ti at the surface contained below 0.001% metallic elements as determined spectrographically, save for Fe, which reached a value of 11% near the interface. The darker zone is much harder than the low carbon steel of the base as shown by the microindentations in (b) (right), suggesting that Ti has diffused in that zone to the darker line limiting the soft steel and appearing in (b) after a Nital etch. Magnification 300X.

type of cell depicted in Fig. 1. The Ti coatings obtained with this type of bath were adherent, compact, smooth and shiny either on ring-shaped or flat pieces; in all cases, as may be seen in Fig. 2b, they showed no pitting or dark spotted or spongy areas. Contrary to the other two series, the salts surrounding the cathode and the anode both showed an alkaline reaction at the completion of the electrolysis and the bath had a pinkish color. In this latter series also, the inside wall of the Pyrex or quartz cell was free from any Ti mirror which always tends to form in the two other series of experiments; such mirrors have already been observed by Straumanis, *et al.*, on ceramic materials during titanizing experiments (4).

Metallographic examination.—Figures 2-5 illustrate some of the types of Ti coatings obtained with the main baths described above.

Decomposition Voltages and Mechanism of the Electrolytic Reactions

The decomposition voltages were determined for the main eutectic mixtures selected for the above experiments using first an insoluble anode, and then a soluble Ti anode. These decomposition voltages were obtained in the usual way by extrapolating the experimental current-voltage curves to zero current. All measurements were carried out under an argon atmosphere in a graphite crucible containing the molten salts held uniformly at 725°C. The use of a crucible heated in a resistance furnace eliminated the excessive variations brought about by the stirring action obtained in induction heating and, in particular, facilitated the determination of the needed data on the anodic phenomena under the same average bath temperature as in the electroplating experiments described in Table I. The steel cathode was spaced ¾ in. from the anode. Both electrodes were immersed 1 in. into the fused salts. The salts were always submitted to a preliminary electrolysis at 1.8 v for 30 min using graphite electrodes in order to remove the last traces of water. The curves in question are shown in Fig. 6-8. In these figures are also given the current-voltage curves when TiI_4 or, in one case, K_2TiF_6, were injected into the bath prior to measurements.

The extrapolation of curve A in Fig. 6 corresponds to the decomposition of NaCl (3.2 v), indicating that the electrolysis of a NaCl-KCl mixture yields Na as a primary product. On the other hand, when a Ti

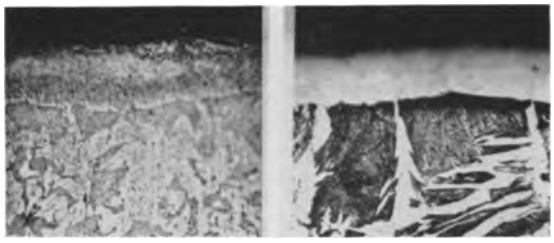

Fig. 4. (a) (left) Micrograph showing the 0.03 mm thick Ti coating built up on the steel cathode (sample appearing in Fig. 2b); the HF etch reveals that interdiffusion of Ti and Fe has taken place in the coating. (b) (right) Micrograph of a section similar to (a), but with a Nital etch to reveal with better contrast the Ti deposit which is left practically unetched and also the coarse Widmanstatten structure of the steel underneath. Magnification 300X.

Fig. 5. Micrograph of a section from a sample plated with Ti in a KI-KF bath (Expt. 15, Table I). The microindentations in the Ti deposit correspond to a hardness of about 180 Vickers which is of high order and possibly results from some diffusion of the steel constituents into the Ti coating at the temperature at which the cathode was held during the electrolysis (950°C).
1% HF + Nital etch Magnification: 500X

anode is used, there is a considerable drop in the decomposition voltage corresponding to 1.7 v as shown by comparison with the extrapolated voltage of curve B. Of the known Ti chlorides, $TiCl_2$ is the one the free energy of which corresponds the closest to the voltage drop mentioned above. It suggests, therefore, the possible following reaction as predominant:

$$Ti + Cl_2 \rightarrow TiCl_2 (E_{725°C} = 1.7 \text{ v}) \qquad [1]$$

It appears also from Fig. 6 that the addition of TiI_4 shifts the decomposition voltage to a slightly lower value for both W and Ti anodes.

Somewhat similar conclusions may be inferred from examination of the decomposition voltage curves of Fig. 7 dealing with KI-NaI baths. In this case, however, the extrapolation of curve A to zero current gives a decomposition voltage of 2.65 which falls between those of NaI and KI. It is therefore likely that K is formed to some extent along with Na as a primary reaction product. On the other hand, since the drop in the decomposition voltage, when using Ti as anode (see curve B), is 0.90 v, it seems that the Ti at the anode, as in the case of the NaCl-KCl bath, also forms a divalent salt; in fact, the voltage drop observed corresponds to the formation of $TiI_2 (E_{725°C} = 0.86 \text{ v})$ which is the Ti iodide having the highest decomposition voltage.

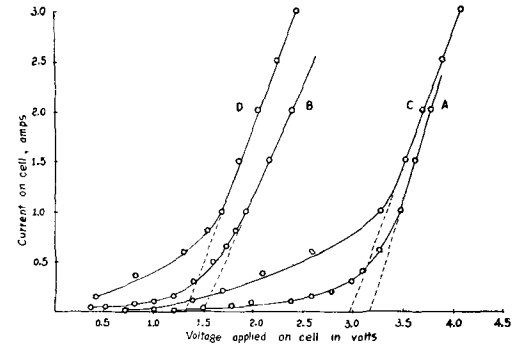

Fig. 6. Decomposition voltage curves of fused KCl-NaCl baths at 725°C with and without addition of TiI_4 using a Fe cathode. A, KCl-NaCl bath, W anode; B, KCl-NaCl bath, Ti anode; C, KCl-NaCl bath + TiI_4 (1.5%), W anode; D, KCl-NaCl bath + TiI_4 (1.5%), Ti anode.

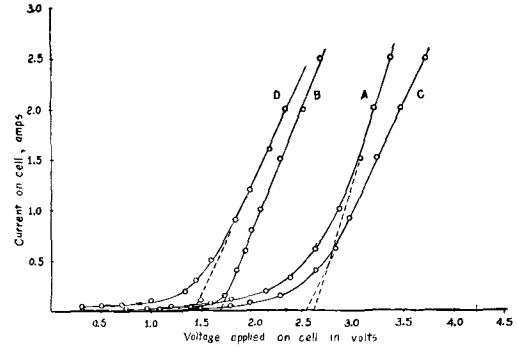

Fig. 7. Decomposition voltage curves of fused KI-NaI baths at 725°C with and without addition of TiI_4 using a Fe cathode. A, KI-NaI bath, Pt anode; B, KI-NaI bath, Ti anode; C, KI-NaI bath + TiI_4 (1.5%), Pt anode; D, KI-NaI bath + TiI_4 (1.5%), Ti anode.

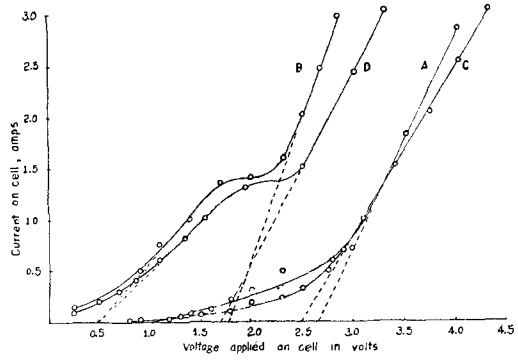

Fig. 8. Decomposition voltage curves of fused KI-KF baths at 725°C with and without addition of K_2TiF_6 using a Fe cathode. A, KI-KF bath, Pt anode; B, KI-KF bath, Ti anode; C, KI-KF bath + K_2TiF_6 (1.5%), Pt anode; D, KI-KF bath + K_2TiF_6 (1.5%), Ti anode.

The extrapolation to zero current of curve A in Fig. 8 indicates that, in the case of a mixed halide bath such as KI-KF, only KI is decomposed because the value of 2.7 v found for the decomposition voltage corresponds closely to the calculated value for KI. Otherwise, a much higher decomposition voltage would be observed (E for KF at 725°C = 4.7 v). When a Ti anode is used, the curve obtained exhibits two distinct branches which may be extrapolated to give two different decomposition voltages; this points to a double type of reaction at the anode. It appears in fact that at low voltage Ti forms only fluorides; formation of such fluorides is highly exo-

Table II. General mechanism of reactions

A—Primary steps

(a) At the Cathode: reduction of an alkali halide.
$M^+ + e^- \rightarrow M$ [7] (Primary cathode reaction according to decomposition voltage curves). where M^+ is an alkali ion in the form of a halide MX contained in the electrolyte and X is the most active halogen.

(b) At the Anode: Formation of Ti ions.
$Ti - ne^- \rightarrow Ti^{n+}$ [8]

B—Secondary steps

(a) At the Anode $Ti^{n+} + nX^- \rightarrow TiX_n$ [9]

(b) At the Cathode $TiX_n + nM \rightarrow Ti + nMX$ [10]

C—Over-all Electrolytic reaction

$$Ti + nMX \underset{b}{\overset{a}{\rightleftharpoons}} TiX_n + nM \quad [11]$$

1. Process: $\overset{a}{\rightarrow}$ The anodic dissolution (endothermic): the Ti anode is attacked and converted into halide.
2. Process: $\overset{b}{\leftarrow}$ The cathodic reaction (exothermic): the Ti halide is decomposed by the free alkali metal formed at the cathode as a primary product

thermic and, consequently, leads to the low decomposition voltage obtained by the extrapolation of the first branch of curve B shown in Fig. 8. The formation of TiF_3 is the most likely to be favored since this salt has a higher decomposition voltage than TiF_2 and TiF_4 and one which is closer to the experimental value inferred from the curves shown in Fig. 8. Furthermore, TiF_2 is not stable even at room temperature because of disproportionation to metal and TiF_3(5) according to the reaction

$$3TiF_2 \rightarrow 2TiF_3 + Ti \quad [2]$$

On the other hand, TiF_4, if formed in the molten bath, would be converted into trivalent fluoride as was shown in a previous paper (6).

When the voltage is increased to a point corresponding about to the extrapolation of the second branch of curve B to zero current, another anodic reaction starts and becomes predominant with increasing voltage, as may be inferred by the shape of the last portion of curve B. The difference between the decomposition voltages corresponding to curve A and the upper branch of curve B is 0.9 v, which is in agreement with the value mentioned in the above paragraph for the formation of TiI_2. It seems, therefore, that the formation of TiI_2 would take place predominantly at the surface of the anode at higher current densities. This TiI_2 would tend, however, to be transformed rapidly in presence of KF according to the reaction

$$TiI_2 + 2KF \rightarrow \underset{\downarrow}{TiF_2} + 2KI \quad [3]$$

TiF_3 (due to reaction [2])

In fact, reaction [3] is very exothermic, and furthermore it was found that the reddish-brown color of TiI_2 did not show up at the end of the electrolysis of the KI-KF bath. To prove reaction [3] by way of similitude, TiI_4 was added to a molten KF bath, and it was observed that the brown color of TiI_4 vanished to form KI as was established by x-ray diffraction analysis; the violet complex of TiF_3 and KF identified as K_3TiF_6 was also found. The following reactions occur

$$TiI_4 + 4KF \rightarrow TiF_4 + 4KI \quad [4]$$

$$TiF_4 + 2KF \rightarrow K_2TiF_6 \quad [5]$$

$$K_2TiF_6 + KF \rightarrow K_3TiF_6 + \tfrac{1}{2}F_2 \quad [6]$$

During the plating operations in the fused salt baths using Ti as anode, there is a transfer of the Ti from the anode to the cathode. As may be seen from the decomposition voltages, this transfer would involve, as a primary step, the reduction of an alkali halide at the cathode and the simultaneous formation of Ti halide at the anode; in turn, the alkali metal would reduce the Ti halide at the cathode where it is deposited (see Table II). As may be inferred from the decomposition voltage curves, the process of cathodic deposition of Ti cannot proceed before some alkali metal has been deposited at the cathode or before some Ti halide has been injected in the bath. This latter condition applies in the case of the experiments in Table I where the addition of Ti salts started earlier the cathode reaction [11](b), Table II.

It may be seen by comparing the curves in Fig. 6-8 that the decomposition voltages for KCl-NaCl or KI-NaI baths using a Ti anode are much higher and the slope indicating the anode polarization much steeper than for KI-KF baths at lower current densities. It results therefore that in the latter bath Ti may be deposited at very low voltages with relatively high current density; energy efficiency is therefore better as also the Ti deposited.

After the electrolysis was completed in the KI-KF baths using a Ti anode, the salt mixture left was submitted to x-ray diffraction analysis (7) and was found to contain besides KI and KF some unidentified compound not described in the available literature which was definitely not K_2TiF_6 nor K_3TiF_6 (6). This compound is most likely the result of the following reaction

$$TiF_3 + n\,KF \rightarrow n\,KF,\ TiF_3 \quad [7]$$

On the other hand, the absence of K_2TiF_6 in the electrolytic bath confirms the view that TiF_4 is not formed at the anode. It follows, therefore, that the reaction at the cathode would be in this particular case

$$TiF_3 + 3K \rightarrow Ti + 3KF \quad [8]$$

The reduced Ti obtained by reaction [8] under the conditions mentioned in Table I produces a smooth and uniform deposit. This is ascribed to the fluidity of the KI-KF bath and to the high temperature of

the cathode which therefore remains clean and free from any excess of K metal on account of its low boiling point (774°C). Conversely, this explains in part the dendritic formation observed in baths containing Li or even Na, the boiling points of which are higher.

Electrodeposition Behavior of Trace Amounts of Copper

Richard C. DeGeiso[1] and L. B. Rogers

Department of Chemistry and Laboratory for Nuclear Science, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

Deposition, onto inert electrodes, of copper in amounts insufficient to form a monolayer takes place more readily than predicted using the Nernst equation. The undervoltage is a function of the acidity, the anion present, and the amount of copper deposited. Examination of the literature for silver and for zinc indicated that, as the lattice dimension of the deposited element approached that of the electrode material, the undervoltage increased. Copper undervoltage appears to follow the same trend, but the observed differences are small and open to question.

The electrodeposition of less than a monolayer of an element onto an "inert" electrode sometimes takes place much more readily than one would predict using the Nernst equation (1). For example, deposition of silver from a 10^{-9}M solution onto a platinum electrode takes place at potentials about 0.5 v less cathodic than onto a silver electrode (2). Because silver and copper are quite similar in many chemical and metallurgical properties, a systematic study involving copper was made in the hope of obtaining more information about variables which affect the undervoltage. The fact that copper could be present in more than one valence state was a complication not encountered in the earlier work with silver.

Experimental

Apparatus and Solutions

Deionized water, with conductivity three times less than that of distilled water, was used for all dilutions. In order to insure a minimum of contamination from copper and other elements (as well as organic impurities), all solutions, except concentrated acids, were pre-electrolyzed overnight at —0.8 v vs. S.C.E. using a large platinum gauze cathode.

The concentration of copper in an electrolytic solution was between 10^{-7} and 10^{-9}M. The lower limit was set by the copper impurity in the zinc-oxide cyclotron target (Johnson, Mathey and Co. Ltd.). Copper —61, —63, and —64 produced in the bombardment were much smaller, each being about 10^{-12}M. An upper limit of 10^{-7}M was established by finding no copper in typical tracer solutions when a coulometric procedure, sensitive to somewhat less than 10^{-7}M, was used.

The radio-copper was a mixture of 3.0 hr copper —61 and 12.8 hr copper —64 as shown by half-life measurement, gamma-ray spectrometry, and aluminum absorption analysis. Usually, only 6-10 deposition runs could be completed in the three-day period following isolation of a tracer preparation before its activity became too low to permit precise measurements to be made. As a result, a large number of tracer preparations were used, each of which was undoubtedly somewhat different in concentration of total copper from the others.

Procedures involving electrolysis, anion exchange (3), and solvent extraction were compared briefly as methods for separating the radio-copper from the accompanying zinc and gallium activities. The dithizone extraction procedure, based on that of Haymond, *et al.* (4), was found to be the fastest. The procedure involved dissolution of the target material in concentrated hydrochloric acid, adjustment of the *p*H to 1.0-1.2 by dilution with deionized water, and extraction of the radio-copper using

[1] Present address: Experimental Station, E. I. du Pont de Nemours & Co., Inc., Wilmington, Del.

0.001% dithizone in carbon tetrachloride. The organic extract was washed with 0.1M sulfuric acid and then wet-ashed with a mixture of 1-2 drops of 18M sulfuric acid and 2 ml of 15M nitric acid. After evaporation to dryness, the radio-copper was taken up in 1M perchloric acid. Usually 2 ml of this solution were added to 200 ml of background electrolyte in preparing a solution designated as a "trace" concentration of copper. A pH of 2.0 was used in all depositions unless otherwise stated. Additional amounts of natural copper (II) salt were added if higher concentrations were to be studied.

The electrodes used in this study were of two types. Platinum gauze of approximately 80 cm^2 geometrical area, sealed into 6 mm lead-glass tubing, was used for most of the experiments. In addition, foil electrodes of platinum, palladium, gold, iridium, and rhodium were prepared and had, as nearly as possible, the same geometrical area, estimated to be 29.8 cm^2.

Several procedures for pretreatment of the electrodes were compared and found to give virtually the same results. The procedure finally chosen consisted of rinsing them in ethanol and allowing them to dry in air. They then were immersed in boiling 6*N* nitric acid, rinsed thoroughly with deionized water, and placed directly in the electrolytic cells.

Electrolyses were performed in lipless tall-form beakers, 20 cm tall and 6 cm in diameter. The beakers were covered with Plexiglass to protect the solutions from contamination by atmospheric dust. Salt bridges containing 2M sodium perchlorate connected the reference cell and the working anode with the main electrolytic cell. The ends of the bridges were plugged with unfused Vycor glass which had been previously soaked overnight in sodium perchlorate. The volume of solution in the electrolytic cells was 200 ml in all cases. Nitrogen was bubbled vigorously through the solutions prior to and during the electrolyses in order to keep the oxygen concentration to a minimum. Solutions were stirred by Teflon-covered bars driven by magnetic stirrers.

Immediately after the electrodes had been immersed, a 1-ml sample was removed from the cell. This sample was used as a standard against which all later samples were compared in order to correct for decay of the mixture of radio-copper nuclides. A potential was applied and regulated by potentiostats (5) for the time necessary for the amount deposited to reach a virtually constant value. (For the 80-cm^2 platinum gauze electrodes this time was 1 hr; for the 29.8 cm^2 foils, 3 hr.) At the end of that time, another 1-ml sample was taken and compared with the standard. From the relative difference in activity, the percentage of copper deposited at that potential was calculated. Then the potential usually was changed 0.05 v in the cathodic direction and the procedure repeated. In this manner, the percentage of copper deposited was obtained as a function of cathode potential. Stripping curves were obtained by changing the potential in the opposite direction.

A single-channel differential discriminator coupled through a linear amplifier to a 2-in. well-type, thallium-activated, sodium iodide crystal scintillator was used for measuring the gamma-ray spectrum to characterize the radio-copper. Coupled to an ordinary binary scaler, it was used to count the radio-copper samples in the deposition studies. Usually 3000-3500 counts above background (about 250 cpm) were obtained for each sample. Using the square root of the total counts as an estimate, the standard deviation was about 2%.

The reproducibility of the deposition data was primarily a function of the amount of copper present and the slope of the curve at the potential in question. At the millimolar level, the run-to-run reproducibility was ± 5 mv. Curves at the trace level were reproducible within ± 20 mv (corresponding to an estimated 3-7% variation in observed percentage of copper deposited), although for a given electrode and a particular batch of tracer, the reproducibility was ± 10 mv. Some variability was caused undoubtedly by variation in the copper contamination from one preparation to another.

Potentials for 50% deposition, $E_{50\%}$, in various media, were compared with half-wave potentials, calculated from formal potentials obtained from millimolar copper, using platinum microelectrodes and a Sargent polarograph, Model XXI. Half-wave values could usually be reproduced within ± 10 mv or less.

Results

Perchlorate media

Because a study of the deposition of silver (2) from dilute solutions indicated that the largest undervoltage was obtained in perchlorate medium, 0.1M sodium perchlorate was the first medium studied in the present investigation. Figure 1 shows the deposition behavior of copper in sodium per-

chlorate as a function of copper concentration. Undervoltage effects and changes in curve shape with increasing initial concentration of copper were reminiscent of those obtained for silver. Depositions of copper from 10^{-3}M and 10^{-2}M solutions agreed quite well with predictions based upon the Nernst equation.

The pH always was measured before and after a deposition study. Only in the deposition of millimolar copper from a solution initially at pH 5.0 was a change greater than 0.1 pH unit found, and then it was between 1 and 2 units higher.

Although a change from pH 2.0 to 0.0 had little effect on depositions at the millimolar level (Fig. 2), increased acidity facilitated deposition at the trace level just as it had for silver (2, 6), probably due to its effect on the platinum oxide surface film (Fig. 3). At pH 5.0, deposition appeared to be easiest but, unfortunately, sorption contributed substantially to the observed removal of copper as indicated by the stripping curve and by studies conducted at open circuit. At pH 2.0, however, sorption losses never exceeded 4%. Other effects of pH, particularly those encountered in halide media, are discussed below.

Other Media

A change from perchlorate to complexing media had resulted in lower undervoltages for the deposition of silver. However, Fig. 4 and Table I show the opposite effect for copper in that the ease of deposition increased in the order perchlorate, sulfate, bromide, chloride, and nitrate. The data for nitrate do not fit the trend although it is widely known from macro experiments that depositions from nitrate are difficult to reproduce in the absence of a substance to remove nitrous acid.

The undervoltage for silver had been studied as a function of acidity only in perchlorate medium (2, 6), so a brief study using copper in different media

seemed advisable. For 0.1M sodium perchlorate a change in acidity from *p*H 2 to 1M (in perchloric acid) produced only a 20 mv anodic shift, a change not much larger than the limits of reproducibility. Halide media, however, showed interesting differences. A 0.1M solution of sodium chloride, after being made 1M with hydrochloric acid, gave a cathodic shift of 0.1 v; a similar run in 1M sodium chloride (at *p*H 2) agreed with the 0.1M solution at *p*H 2 (i.e., no shift due to chloride alone). When a *p*H 2 solution of 0.1M sodium bromide was made 1M in hydrobromic acid, a cathodic shift of 0.2 v relative to 0.1M bromide at *p*H 2 was produced. These changes appear to be much too large to be accounted for by changes in activity coefficients or junction potentials. The important factor appears to be not the anion but the hydronium ion. Partial confirmation was obtained by making a 0.1M solution of sodium chloride 1M in perchloric acid and finding a 50 mv cathodic shift. The fact that this same acid produced a slightly anodic shift when added to sodium perchlorate would appear to rule out contamination with copper as the cause for the cathodic shift.

Because the largest undervoltage was observed for deposition from chloride medium, deposition behavior was examined as a function of concentration. Figure 5 shows that a distinct plateau, which extended for 0.2 v, appeared at copper concentrations of 5 x 10^{-6}M and 10^{-5}M. Depositions from 10^{-4}M and 10^{-3}M copper agreed within 0.02 v with the predictions based upon the Nernst equation.

Chloride is known to complex with platinum as well as with copper. It aids in removing oxide films and might also act as a bridging ion. However, preelectrolysis in chloride did not seem to affect the deposition of "trace" copper from 0.1M sodium perchlorate although it is possible that the oxide was first removed in chloride medium and then restored in perchlorate. The following experiment then was performed to study the effect of various amounts of chloride on the deposition of trace amounts of copper from 0.1M sodium perchlorate. The cathode potential was held at +0.15 v vs. S.C.E. in a solution of trace copper in 0.1M sodium perchlorate. At this potential only 21% copper deposited under ordinary conditions. After making this solution 10^{-5}M in chloride, the percentage of copper deposited increased to 24%, a small but possibly significant change. At 10^{-3}M, the per cent increased only to 26%. However, after an increase in chloride concentration to 0.1M, the per cent deposited increased to 38%. This increase, which corresponded to a 0.05 v shift of the entire deposition curve toward less cathodic potentials, seems greater than could be accounted for on the basis of a change in either activity coefficient or junction potential. The fact

that the chloride curve in the presence of perchlorate was displaced cathodically from the curve for chloride electrolyte alone may indicate competition for the platinum surface, interference with the discharge reaction, or possibly contamination.

Effects of Electrode Size and Material

Electrodes comparable in size and shape to the standard platinum gauze electrodes were not available for other elements so, in order to be able to make comparisons more easily, foils of platinum as well as gold, palladium, iridium, and rhodium were cut so as to have uniform geometric areas of 29.8 cm^2. As expected (2, 17), a comparison of the deposition curves for the gauze and foil of platinum showed a cathodic displacement for the smaller electrode. A brief comparison of a shiny and a dull platinum foil did not show a difference in behavior greater than the usual experimental error, although it might have on a more extended series of runs (2).

Figure 6 compares the behavior of trace copper using different metal foils. It is interesting that differences could still be observed at the millimolar level (Fig. 7) although, at 10^{-2}M, all experimentally significant differences had disappeared. Calculations show that complete deposition of 10^{-3}M copper would correspond to 1000 layers, assuming a roughness factor of unity. The fact that differences could be observed through many layers is consistent with observations (7) that the early layers of deposit assume the crystal structure of the substrate.

Electrolysis as an Isolation Procedure

Because carrier-free copper deposits so readily, electrolysis should be a suitable method for separating radio-copper from radio-zinc and radio-gallium. It was found that copper could indeed be deposited essentially completely on platinum without depositing zinc or gallium. The following procedure gave radiochemically pure copper activities. It is somewhat more time consuming than solvent extraction but should be adapted more easily to remote operation.

A platinum-gauze electrode was placed in a solution of the target material in 0.5M sulfuric acid. A potential of −0.5 v vs. S.C.E. was applied for 1 hr, following which the electrode was removed, without disconnecting the leads to the potentiostat, and carefully washed by submersion in a beaker containing deionized water. The electrode then was placed in fresh 0.5M sulfuric acid and electrolysis was continued for another hour. A total of three electrolyses were made and, after each one, estimates were made of the activity remaining in solution, the activity in the washings, and the activity on the electrode. The final activity on the electrode was pure radio-copper. Small amounts of zinc and gallium activities present in the washings were presumably carried over by entrainment.

Discussion

Qualitatively, undervoltage appeared to be greater when the lattice dimensions of the electrode material more nearly matched those of the deposited trace element. This was first noted in a re-examination of the data for silver (2) (see Table II and Fig. 8). It was found then that, although quantitative deposition data are not available, qualitative statements for zinc behavior indicate that it follows the same trend. The fact that zinc is normally hexagonal close-packed, while the other metals are face-centered cubes, is probably not as important as the lattice dimensions themselves (8). On that basis, predictions of the order in which the electrode undervoltages would fall were made for copper. Except for rhodium, which also gave anomalous results with silver, the electrode materials fell in the expected order (Fig. 8). Admittedly the differences are small, but they were observed consistently on many batches of copper, the uncertainty being less than ± 10 mv when repeated runs were made using a single preparation of tracer.

[d] $E_{50\%}$ remains constant with decreasing initial concentration.
[e] Shift of $E_{50\%}$ toward nobility is inversely proportional to decrease of initial concentration.
[f] Follows Nernst even at very low initial concentrations.
[g] If the value for zinc were 2.75Å (20), the difference in behavior between copper and platinum would be resolved.

On the silver diagram, the discrepancies for tungsten and rhodium are quite probably due to the presence of oxide films which led to anomalous dissolution behavior (2) as well. (Note: the points for rhodium and tungsten have been mislabeled in Fig. 4 of reference 2.) Such films would tend to minimize, or even eliminate (10), the effect of the substrate. While it might be attractive to believe that rhodium fell on a smooth curve, the large percentage of mismatch and the obviously discrepant behavior of rhodium in both the copper and silver series leads one to favor a linear decrease in undervoltage with an increase in mismatch (8).

Extrapolating to zero undervoltage, the silver data give a figure for critical mismatch of about 11%; copper, 23%. [Assuming the data of Yang, *et al.* (10) to be linear rather than curved, one can determine a minimum value of mismatch of about 30%.] Because other determinations of critical mismatch give values in the range from 10 to 20% (11-13) before a continuous film of deposit will fail to form, the limits extrapolated from trace deposition appear reasonable.

That a correlation should exist between mismatch and undervoltage seems plausible on the basis of electron-diffraction and microscopic studies of deposits which have shown that the first few layers tend to follow the structure of the substrate and that smoother deposits are obtained as the lattice parameters of the deposit and electrode approach one another. We are indebted to Taylor and Datz (9) for pointing out the existence of comparable data for the condensation coefficients of silver on different metals (10) and for alkali halides on one another (11, 12).

It is important to note that the undervoltage scale for copper in Fig. 8 is double that for silver. This was done to convert the observed values into slopes equivalent in terms of the decrease in activity of the deposit relative to the standard state. That is, a decrease of 0.060 v for silver corresponds to 0.030 v for copper due to the difference in number of electrons transferred. Even so, the slope for copper was only about half that for silver. Part, if not all, of the difference may be due to differences in surface coverage. The concentration of silver may well have been one hundred times more dilute than the copper, although the sixfold larger geometric area of the electrodes used in the present study would tend to counteract this factor. In any event, it is obvious that a study using the same set of electrodes and as nearly as possible the same concentrations of trace elements would be desirable. At the same time, a reinvestigation of the zinc system to obtain more nearly quantitative data would be valuable, particularly in view of an apparent difference in behavior between copper and platinum electrodes, both of which mismatch about 4%. Zinc falls halfway between the larger platinum lattice and the smaller copper lattice.

There seems to be little question that copper deposited as the element from solutions of perchlorate and sulfate. However, in chloride and bromide media, the respective copper (I) salts probably deposited initially even though their solubility products (particularly for the chloride) were not exceeded. First, the $E_{50\%}$ value for trace deposition corresponded almost exactly with the $E_{1/2}$ for copper (II) to (I) reduction. Second, if one assumes that the nearest neighbors in the copper (I) chloride and bromide are the sums of the radii, values of 2.77Å (0.96 + 1.81) and 2.91Å are obtained. (Platinum is 2.77Å.) Depositions on two batches of copper tracer using both platinum and gold electrodes in both chloride and bromide media indicated somewhat easier reductions in chloride at both electrodes and easier reduction using platinum than gold. The important feature is the qualitative correspondence between ease of deposition and the small mismatch. (Cu-Cl: Pt mismatch 0%; Au, 4.0%, Cu-Br:Pt, 5.1%; Au, 1.4%). If mismatch had been the only factor involved, deposition onto gold from bromide should have been easier than onto platinum, but it was not. Unfortunately, another major program would have been required to explore fully the effects of different electrode materials.

A consideration that has been ignored in the above discussion is the fact that complexing anions, particularly halides in acidic solution, would tend to dissolve oxide coatings, thereby increasing the effective surface area of the electrode. From studies in perchlorate media, an increase in geometric surface area is known to result in easier deposition of copper just as it did in experiments involving silver (14). Comparable studies in fused halide melts would therefore be desirable because oxide films should be virtually absent.

In order to refine the correlations, studies employing the same amount of tracer as well as the same

electrode area would be needed. These conditions might be approached much more closely by comparing several tracer elements using a given electrode at one potential. Such a study was beyond the scope of the present one which was designed to survey the suitability of copper for a comparison of that type.

Another precaution to observe would be the conservative use of lattice parameters, determined for carefully prepared crystals, in interpreting data obtained on foils whose surfaces will reflect, to a greater or lesser extent, the physical treatment encountered in their preparation. An outstanding example of the effect of electrode history has been cited already in an electrodeposition experiment with silver for which a gold crucible was used as an electrode (14). However, the differences incorporated by working a surface generally seem to be much smaller than those between any two elements used in the present comparison. Hence, the use of single-crystal parameters appears valid.

The concept of mismatch appears capable of extension by the use of lattice neighbors more distant than the nearest. For example, a collection of data (15) on the relative rates of volatility of thin metallic films from different substrates is given in Table III along with data on nearest and next-nearest neighbors, the latter calculated on the basis of a face-centered cubic structure. It is important to note, particularly for lead and bismuth, that the direction of change in mismatch using nearest neighbors is directly opposite to that using next-nearest. The latter trend, however, conforms to the concept of stronger sorption for smaller mismatch. The striking exception is nickel, for which the rationalization based on an oxide film seems unlikely because of the great care exercised to exclude air (16). The data for polonium are meager and, unfortunately, fall in a region of large mismatch on both bases. On any given surface, the interatomic distances undoubtedly vary widely and almost continuously so some sorption of any given substance will occur on any surface (8). However, lattice parameters will probably represent modes in a plot of the relative number of sites vs. interatomic distance.

Two other points are worth noting in the lead and bismuth data involving the noble metals. In the first place, although $T_{50\%}$ values for bismuth fall on a straight line when plotted against mismatch, values for lead show a sharp change in slope in going from platinum to palladium. The abrupt change occurs in going from 11 to 12% mismatch, values close to the critical 10% limit above which continuous films did not form in some studies (12, 13). Second, in spite of the fact that bulk bismuth boils 100°C lower than bulk lead, the smaller mismatch of bismuth raised its "50% volatilization" temperature as a thin film to values nearly identical with those for lead films.

The present study emphasizes the similarity between adsorption and trace deposition that has been pointed out earlier (13, 17). However, the presence of inert solute and solvent complicates the picture as they do in adsorptions from the liquid phase. As yet, the effect of changing the solvent remains to be explored, as does the effect of adding small amounts of adsorbable substances. The latter studies should provide a fruitful way of exploring the suggested leveling of activity of sites on an electrode (18), as well as supplementing data from polarographic and electrolytic studies in general.

Mechanisms of Hydrogen Producing Reactions on Palladium

VI. Atomic Hydrogen Overvoltage on an α Pd-H Bielectrode

Sigmund Schuldiner

U. S. Naval Research Laboratory, Washington, D. C.

ABSTRACT

An electrochemical system was evolved in which the only reactions occurring on the cathode and anode surfaces of an α Pd-H bielectrode were the formation and ionization of atomic hydrogen, respectively. The atomic hydrogen overvoltage on this bielectrode was determined. A kinetic analysis of the system was supported by the experimental results.

In this paper a bielectrode system is described in which the net reaction, on the cathode side, is the reduction of hydronium ions to hydrogen atoms and, on the anode side, the oxidation of hydrogen atoms to hydronium ions. The electrochemical system consists of two cells in series in which the first cell is connected to the second by means of an α Pd-H bielectrode. In the first cell, the anode reaction is the oxidation of hydrogen atoms, which have diffused through a palladium tube, to hydronium ions. The cathode reaction on the α Pd-H bielectrode is the reduction of hydronium ions to hydrogen atoms. The hydrogen atoms formed on this cathode surface are transported through the α Pd-H bielectrode to the anode surface where they are oxidized to hydronium ions in the second cell. The cathode reaction in the second cell is the reduction of hydronium ions to hydrogen atoms which diffuse through a Pd tube cathode to react with oxygen on the inner surface of the tube.

In such an electrochemical system, for every equivalent of atomic hydrogen oxidized to hydronium ions at the anode in the first cell, an equivalent of hydrogen ions is transported through the bielectrode, and an equivalent of hydronium ions is oxidized to hydrogen atoms which are removed from the system through the cathode in the second cell. Hence, the concentration of hydronium ions in both cells remains constant, atomic hydrogen is consumed as fast as it is produced, and the system can be kept free of molecular hydrogen.

On the cathode side of the bielectrode, the adsorbed atomic hydrogen concentration will increase with increasing current densities, whereas on the anode side of the bielectrode, the adsorbed atomic hydrogen concentration will decrease with increasing current densities. At a limiting current density, the transport of hydrogen through the bielectrode will not be fast enough to furnish enough hydrogen atoms to support the current density on the anode side of the bielectrode. At this point the potential will rise sharply and an oxygen producing reaction also will occur on this surface. No longer will there be a complete transfer of the hydrogen atoms formed on the cathode side to the anode side.

Experimental

The electrochemical system used in this investigation is shown in Fig. 1. It is a modification of a previously described double cell (1). In this system the anode in the right hand cell is a Pd tube with a sealed bottom, 5 cm long, 3 mm in diameter, and with a wall thickness of 0.2 mm. During a run hydrogen gas is circulated through the inside of this tube. Some of the hydrogen diffuses through the wall of the tube and exists as hydrogen atoms on the outer surface in contact with the 2*N* sulfuric acid solution. Virtually all of these hydrogen atoms are oxidized to hydronium ions under an applied current flow. If the flow of atoms to the surface is too slow to support the applied current, an oxygen forming reaction at a sharply elevated positive potential occurs. Hence a determination of the polarization of this electrode indicates whether the reaction is completely the ionization of hydrogen atoms or not. During the runs reported here the maximum

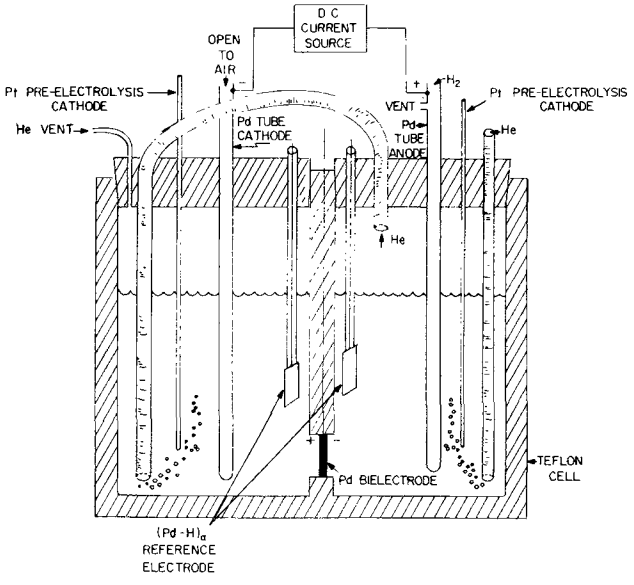

Fig. 1. Electrochemical system

polarization of the Pd tube anode was less than 0.1 v. This indicated that the diffusion of atomic hydrogen through the wall of the anode tube was fast enough to prevent an oxidation reaction other than ionization of atomic hydrogen. There is a possibility that at low current densities some molecular hydrogen could form on this surface of the Pd tube anode. However, even if this did occur the molecular hydrogen would be formed at a slow rate and, since the cells were swept continuously with a rapid stream of helium, the partial pressure of molecular hydrogen in the solutions would always be negligible.

The bielectrode consisted of a Pd diaphragm (0.004 in. thick with an apparent exposed area of 0.14 cm^2) charged to the maximum α phase (H/Pd atom ratio $\sim$ 0.03). During polarization the reaction on the cathode side consisted of the reduction of hydronium ions in the double layer to hydrogen atoms chemisorbed on the cathode surface. The hydrogen atoms formed on this surface are transported to the anode side of the bielectrode where they are oxidized to hydronium ions. A description of the transport mechanism already has been given (2).

The cathode in the left hand cell consisted of a Pd tube of the same dimensions as the anode in the right hand cell. This tube was open to the atmosphere. The reaction on the surface in contact with the solution was the reduction of hydronium ions to atoms which then migrated through the wall of the tube to react with oxygen on the inner surface. Polarization of this electrode for the maximum current applied was less than —0.05 v which indicated that virtually all of the atomic hydrogen formed on the outer surface did diffuse through the wall and react with oxygen on the inner surface of the tube.

The reference electrodes used in this investigation were $(Pd\text{-}H)_\alpha/H_3O^+$ electrodes of the maximum α composition (3).

A run was conducted in the following way. Using previously described techniques (4, 5) the double cell was cleaned thoroughly and about 5 ml of purified 2*N* sulfuric acid solution was added to each compartment. The solution was then "pre-electrolyzed" using the Pt wire electrodes shown in Fig. 1 as the pre-electrolysis cathodes. Purified hydrogen gas was circulated through the cells during the pre-electrolysis. During this treatment all of the Pd electrodes in the cells were anodically cleaned. After a minimum 16-hr pre-electrolysis, the Pt cathodes were removed from the cells (during current flow) by pulling them through the holes indicated in the Teflon stoppers in the cells. These wires then were cleaned by repeatedly dipping them in concentrated nitric acid and heating them white hot in a flame. The Pt wires then were reintroduced into the cells. Hydrogen gas was circulated through the cells until the potentials on the Pd bielectrode and reference electrodes were 0.05 v positive to the Pt/H_2 electrodes in each cell. This usually took from 4 to 6 hr. At this point the hydrogen flow was transferred to the anode tube electrode in the right hand cell and a purified stream of helium was passed rapidly through both cells. The open-circuit potential between the $(Pd\text{-}H)_\alpha/H_3O^+$ reference electrodes and each side of the α Pd-H bielectrode was equal to zero. Steady-state currents then were applied to the double cell in the circuit shown in Fig. 1. Overvoltages were determined under steady-state conditions at increasing current densities only, since at the highest current densities some oxygen formation reaction occurred on the anode side of the bielectrode. Current interrupter (6) measurements were made in order to verify surface cleanliness and to correct for the *IR* drop between the surfaces of the bielectrode and the reference electrodes. The temperature was 27° ± 1°C.

Results and Discussion

Four typical anodic and cathodic overvoltage curves are shown in Fig. 2. Actually about 15 runs

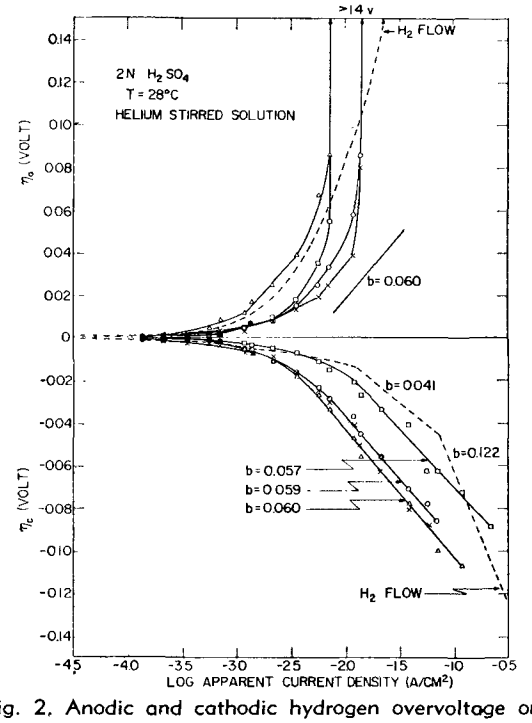

Fig. 2. Anodic and cathodic hydrogen overvoltage on an α Pd-H bielectrode. X, O, △, □ represent experimental points for four separate runs, and • represents the overlapping of three or more points of different runs. Broken line represents overvoltages in the presence of molecular hydrogen (2). The reference electrodes are $(Pd\text{-}H)_\alpha/H_3O^+$ (3).

were made, but the curves shown are representative. The curve with a broken line was taken from a previous investigation (2) and represents the overvoltage curves obtained for the same bielectrode system when molecular hydrogen is present in the system. As can be seen from Fig. 2 the presence of molecular hydrogen does markedly change the polarization behavior on both the anode and cathode sides of the bielectrode. Under open-circuit conditions the potential determining reaction on the α Pd-H electrodes was shown to be an equilibrium between hydronium ions in the solution and protons dissolved in the Pd (3). Upon polarization in a solution containing molecular hydrogen two simultaneous reactions occur on the bielectrode surfaces. The first reaction involves the reduction of hydronium ions to hydrogen atoms on the cathode side of the bielectrode, the transfer of part of the atoms through the bielectrode and the oxidation of the atoms to hydronium ions on the anode side of the bielectrode. The second simultaneous reaction involves the combination of those atoms, which do not migrate from the cathode to the anode sides of the bielectrode, to molecules on the cathode side and an equivalent amount of ionization of molecular hydrogen on the anode side to hydronium ions. Upon polarization in a solution which is free of molecular hydrogen, only the first reaction occurs. Hence all of the hydrogen atoms formed on the cathode side of the bielectrode are transferred to the anode side and there is no second reaction involving the formation or ionization of molecular hydrogen. Therefore, it is obvious that, in the case of the system free of molecular hydrogen, the overvoltage being observed is solely that of atomic hydrogen on the α Pd-H electrode of maximum hydrogen content.

The shapes of the curves shown in Fig. 2 were reproducible. However the effective exchange current density, i_o, values were only reproducible to the extent indicated. This most likely means that the atomic polarization was extremely sensitive to surface conditions. Since previous investigations (5) have shown that for the molecular hydrogen system the effective area remained fairly constant after the initial electrode treatment, this would indicate that the atomic hydrogen electrode in the absence of molecular hydrogen was more sensitive to active centers on the surface. It may be that molecular hydrogen exerts a buffering effect since there is an exchange between molecular hydrogen and hydrogen atoms adsorbed on the surface. When molecular hydrogen is eliminated from the system this source of atomic hydrogen is removed and the effect would be most marked in the low current density region. This would account for the poor reproducibility of i_o.

The rate constants $(-di/d\eta)$ for the over-all reactions found in the low current density overvoltage range in which the overvoltage is linearly dependent on current density varied from 0.14 to 0.33 mhos/cm^2. Since in the presence of molecular hydrogen, $-di/d\eta$ is 0.13 mhos/cm^2 (2), this indicates that the hydrogen transport through the bielectrode is somewhat faster than the surface H_2 evolution or ionization reaction. In the presence of molecular hydrogen 70% of the current was used in transporting hydrogen through the bielectrode and 30% was used forming and ionizing H_2 on the cathode and anode surfaces, respectively (2).

The rate of helium stirring made virtually no change in the overvoltage measurements. Stirring rates were reduced even to zero with no significant change in polarization potentials.

Overvoltage on the cathode side of the bielectrode. —During current flow the reactions occurring on the cathode side of the bielectrode are:

$$H_3O^+ + e^- = H_a + H_2O \qquad [1a]$$

$$H_a \xrightarrow{\text{slow}} H_i \qquad [1b]$$

$$H_i = H_i^+ + e^- \qquad [1c]$$

where H_a denotes hydrogen atoms chemisorbed on sites on the cathode side of the α Pd-H bielectrode; H_i, hydrogen atoms absorbed in the interior of the bielectrode; and H_i^+, protons in the interior of the bielectrode. Equation [1a] represents the formation of chemisorbed hydrogen atoms on the cathode surface. Equation [1b] represents the absorption of the adsorbed hydrogen atoms from the surface through the skin of the metal to some position in the interior of the metal. Equation [1c] represents the donation of hydrogen 1-s electrons to the d band of the metal. The atomic absorption step, Eq. [1b], is considered to be rate determining. Previous work (2) has indicated that the transfer of the hydrogen atoms through the skin of the metal is the rate-determining step in the migration of hydrogen atoms through a Pd bielectrode. The kinetic analysis which follows supports this conclusion since the experimental results are in accordance with the mechanism indicated in Eqs. [1a], [1b], and [1c].

Let us write the kinetic equations for the primary discharge step [1a].

$$\vec{i}_a = \vec{k}_a\,(H_3O^+)\,\exp\,(-\alpha\eta_c F/RT)$$

$$\overleftarrow{i}_a = \overleftarrow{k}_a(H_a)\,\exp\,[(1-\alpha)\eta_c F/RT]$$

where k_a is the rate constant; (H_3O^+), the concentration of hydronium ions; (H_a), the concentration of adsorbed hydrogen atoms on the cathode surface; α, the transfer coefficient; η_c, the cathodic overvoltage; F, the faraday; R, the gas constant; and T, the absolute temperature. Since step [1a] is considered to be virtually equilibrium, $\vec{i}_a = -\overleftarrow{i}_a$ and

$$(H_a) = (\vec{k}_a/\overleftarrow{k}_a)\,(H_3O^+)\,\exp\,(-\eta_c F/RT) \qquad [2]$$

For the rate-determining step [1b]

$$i_c = \vec{k}_a(H_a) + \overleftarrow{k}_a(H_i) \qquad [3]$$

Under conditions where the back reaction in the rate-determining step [1b] is negligible, the net cathodic current density is

$$i_c = \vec{k}_a(H_a), \qquad [4]$$

where $\vec{k}_a$ is the rate constant for the forward reac-

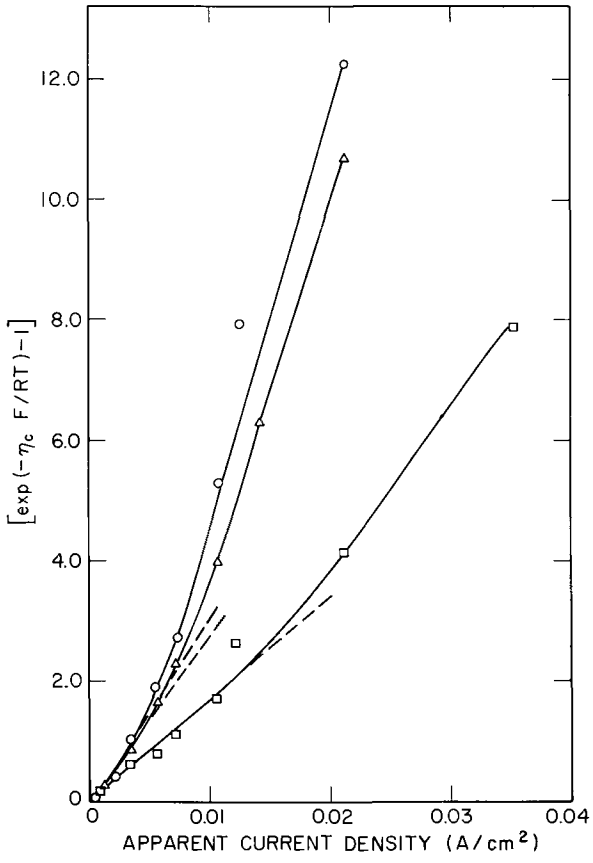

Fig. 3. Relationship between i_c and exp $(-\eta_c F/RT)-1$

tion of the atomic absorption step [1b]. Hence, substitution of Eq. [2] into Eq. [4] yields, after conversion to logarithms,

$$\eta_c = (RT/F)\ [-\ln i_c + \ln \text{const} + \ln (H_3O^+)] \qquad [5]$$

Since (H_3O^+) represents the bulk concentration of hydronium ion, which is constant, the Tafel equation can be written $\eta_c = a - b \log i_c$, where the Tafel constant $b = 2.3\ RT/F$; at 27°C, b = 0.059 v.

Since the Tafel lines found in the cathode overvoltage curves in Fig. 2 are near a 0.059 slope this confirms that the slow step in the hydrogen atom production reaction is the absorption (solution) of hydrogen atoms.

The data in Fig. 2 show that the Tafel lines commence at overvoltages of about −0.02 v. This means that the back reaction in Eq. [3] must vanish at a much lower overvoltage than one would expect. Similar low values for the start of the Tafel slope were found for platinum and palladium (4-6).

From Eq. [3] and [4] one obtains $i_c = K \exp (-\eta_c F/RT) - \overleftarrow{k}_a(H_i)$. From Eq. [1c], $\overrightarrow{i}_{1c} = \overrightarrow{k}_{1c}(H_i)$, and $\overleftarrow{i}_{1c} = \overleftarrow{k}_{1c}(H_i^+)$. Since step [1c] can be considered to be virtually at equilibrium and (H_i^+) is constant at low overvoltages, $(H_i) = K'$. Therefore the net cathodic current is

$$i_c = K \exp (-\eta_c F/RT) - K' \qquad [6]$$

At equilibrium, $i_c = 0$, $\eta_c = 0$, and $K' = K$, hence,

$$i_c = K\ [\exp (-\eta_c F/RT) - 1] \qquad [7]$$

Figure 3 shows a plot of exp $(-\eta_c F/RT) - 1$ vs. i_c for three separate runs which had about the maximum deviation from one another. These curves clearly show that Eq. [7] holds only up to overvoltages of about −0.02 v. This means that $K' = K$ near equilibrium only. The experimental shift to a Tafel slope at about −0.02 v could be accounted for by an increase in K and a decrease in K′ with increasing current density. This implies a larger increase in the forward reaction in the rate-determining step [1b] and a larger decrease in the back reaction. This is owing to the increase in concentration of H_a on the cathode surface.

Overvoltage on the anode side of the bielectrode. —Using a derivation analogous to that for Eq. [6], one finds for the anode side of the bielectrode

$$i_a = K'' - K \exp (-\eta_a F/RT) \qquad [8]$$

where $K'' = K$ at low overvoltages. Hence at low current densities $\eta_a = -\eta_c$. This is experimentally observed in Fig. 2.

The anodic polarization slopes shown in Fig. 2 do not show a clear region in which an 0.059 slope exists, although for a short current density range such a slope can be drawn. This is because in the higher current density range the depletion of adsorbed hydrogen atoms becomes such that it cannot support the current density flowing from the anode. Hence, as the concentration of adsorbed atomic hydrogen approaches zero, there is a sharp rise in potential. At higher potentials (>0.1 v) a secondary reaction involving an oxygen formation reaction occurs in the region shown in Fig. 2 where the anodic potential rises vertically. Equation [8] shows that as a limiting condition, $i_a = K''$. The atomic hydrogen supply on the anode surface is limited by the rate of the deabsorption of atomic hydrogen from the interior of the bielectrode, whereas the limiting step on the cathode surface of the bielectrode is the solution of atomic hydrogen through the skin of the metal. Hence on the cathode side the chemisorbed atomic hydrogen concentration can build up to a large value, whereas on the anode side the depletion of the atomic hydrogen will occur at a relatively low current density, since the atomic hydrogen concentration cannot be larger than that on an α Pd-H reversible electrode of maximum hydrogen concentration.

It should be noted that in the electrochemical system reported here, the interior of the Pd bielectrode is the maximum α Pd-H alloy. This is because this is the alloy at zero current density and this composition is maintained, except at the highest current densities, because hydrogen is dissolved into the interior of the bielectrode from the cathode side at the same rate it is removed from the interior of the bielectrode on the anode side.

In the high current density range a reaction involving oxygen occurs on the anode side of the bielectrode and only part of the current flowing in the interior of the Pd is protonic, the remainder is an electronic current. This would mean that not all of the hydrogen atoms formed on the cathode surface would be transferred through the bielectrode to the

anode side. Most of these excess atoms probably dissolve in the interior of the palladium to form β Pd-H which coexists with the α phase. During the time interval in which measurements were taken in this high current density range (usually less than 1 hr, although in several cases currents were maintained for several hours with no potential change) only a relatively small amount of the β phase would be formed. The atomic hydrogen overvoltage on the cathode side of this two phase alloy does not deviate significantly from the pure α alloy since the cathodic Tafel lines in Fig. 2 show no change in the high current density region.

The anodic curves shown in Fig. 2 indicate that beyond a potential of 0.06 v, the concentration of atomic hydrogen on the surface must be very small. Since the concentration of hydrogen atoms on the surface at zero overvoltage would not be more than ten times higher, it can be concluded that the atomic hydrogen coverage on the maximum α Pd-H alloy under open-circuit conditions is quite small. Also, inasmuch as the potentials on both sides of the bielectrode are dependent on (H_a), one can approximate the change in (H_a) on the cathode side at the maximum overvoltage by use of the Nernst potential equation. Thus, at the maximum measured η_c of about -0.10 v, (H_a) on the cathode side will increase $\sim$50 times. This means that the initial atomic hydrogen coverage must be less than 2%.

Technical Notes

Molybdenum Plating Inside of Large Bore Tubes

Paul L. Raymond

Metallurgical Department, National Research Corporation, Cambridge, Massachusetts

In early 1953 a program was initiated to develop equipment and procedures for coating the inside of alloy steel tubes with a uniform coating of molybdenum. The inside diameter of the tubes was about 1⅝ in. and the coated section was to be about 2 ft long. These tubes when coated were to be subjected to various tests for adhesion, wear resistance, corrosion resistance, etc.

Previous investigations (1, 2) had determined that: (*A*) high-purity molybdenum metal could be deposited at a high rate by the reduction of molybdenum pentachloride with hydrogen; (*B*) the temperature for this reaction ranged between 650° and 1100°C; and (*C*) excess hydrogen was necessary to yield complete reduction and to utilize efficiently the available pentachloride.

Work at this laboratory had shown further that: (*A*) the pressure at which reduction occurred most efficiently was approximately 20 mm Hg; (*B*) the plate followed surface contours without building up at discontinuities; and (*C*) high-purity molybdenum pentachloride required could be obtained by heating commercially pure $MoCl_5$ for an hour at a pressure of 1 mm Hg or less at 100°C.

With this general background it was proposed to coat the interior of tubes with molybdenum by hydrogen reduction of the pentachloride. The size of the tubes precluded the convenient use of an enclosed system for vacuum operation, and it seemed generally desirable to establish a system employing common engineering materials in order that tubes could be inserted rapidly for processing.

Equipment

Schematically, the equipment design for vapor plating is shown in the flow diagram, Fig. 1. Argon from high-pressure cylinders was heated and passed through molten molybdenum pentachloride.

It was then mixed as it passed through the lines with heated hydrogen. The mixture of hydrogen, argon, and molybdenum pentachloride vapor entered the reaction tube where it passed upward through a heated zone. Metallic molybdenum was deposited on the walls in this heated zone by the reduction of the pentachloride by the hydrogen. The reaction gases passed through a filter to remove solid by-products and the gases exhausted to atmosphere through a vacuum pump. The heated zone was

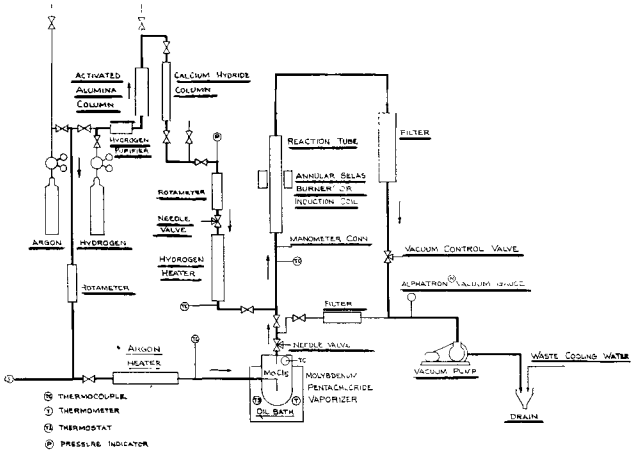

Fig. 1. Flow diagram

slowly moved downward throughout the length of the tube as the plating progressed.

Except for a series of stainless steel valves, the components containing molybdenum pentachloride and the products of the reaction were all mild steel, synthetic, or natural rubber. Operating temperatures of the vaporizer in use at the conclusion of the investigation did not exceed 250°C, so that only a slight amount of iron contamination was observed. A vacuum-tight vacuum system was developed with this equipment and an initial pump-down to 20 μ with the original mechanical vacuum pump was possible throughout the program. Rubber tubing was employed in some cases to facilitate connections to flowmeters and manometers. Experience indicated that the most suitable gasket material for hot connections at the reaction tube was compressed asbestos sheet packing. This material does not flow as do plastic materials and it will withstand high temperatures.

The flow diagram shows the sequence of equipment and operations, starting with the gas system.

Commercially pure water pumped hydrogen in high-pressure tanks was purified by a catalytic purifier followed by a column filled with activated alumina and one filled with calcium hydride lumps. Hydrogen from this system had a dewpoint below −70°C. Argon and helium used for purging and as carriers for molybdenum pentachloride vapor have extremely low dewpoints as-received and were used without further purification. Pressure regulators reduced gas pressures to approximately 1 atm. A manifold permitted the flow of either hydrogen or argon through rotameters to determine the flow rate. A pressure slightly above atmospheric was maintained in this system to preclude air leaking into the system. Needle valves reduced the gas pressure to 5-20 mm Hg and also controlled the flow. As this was generally a steady-state system, only slight adjustments during a plating run were required.

The gases were heated at atmospheric pressure by passing through a spiral finned resistance heater within an asbestos jacketed section of 1¼ in. iron pipe. Exit gas temperature was determined by thermocouples. Variable transformers were used to control power to the heating elements.

The molybdenum pentachloride vaporizer consisted of a 4 in. diameter cylinder about 8 in. long with a hemispherical base and flanged top. The vaporizing gas bubbled through the bath of molten molybdenum pentachloride and out through a pipe in the cover of the assembly. The entire assembly was immersed in a constant temperature oil bath to provide heat of vaporization and to control the vapor concentration.

Throughout the course of the investigation there probably were more changes in the vaporizer than in all other components concerned. In early experiments, heated hydrogen flowed past the molybdenum pentachloride suspended in a glass cloth bag while the outside of the vaporizer, which then consisted of a flanged section of pipe, was heated by gas burners. Poor control of vapor concentration and premature partial reduction of pentachloride resulted from this system.

Next, a mechanical screw-type feeder was employed to regulate the flow of pentachloride crystals to a heated plate where it was hoped that flash evaporation would occur, giving a controlled molybdenum pentachloride-hydrogen ratio. However, premature reduction and disproportionation were observed. Also, the feed screw became jammed frequently, resulting in no vapor flow at all.

The tank-type vaporizer was modified several times before the final model was developed. In the first model, heated hydrogen was passed over molybdenum pentachloride placed on trays in a vaporizer, which picked up the hydrogen vapor. It was hoped that a constant evaporation rate could be maintained throughout the duration of the run, but due to the changing surface conditions of the pentachloride crystals, the vapor concentration in the gas mixture decreased as the run progressed. After several attempts involving minor modifications of the system, it was decided to melt the molybdenum pentachloride before vaporizing. The $MoCl_5$ vapor was picked up in one hydrogen stream and diluted with a second hydrogen stream. Various amounts of partially reduced chlorides were observed in the reaction tube, and the system contained partially reduced chlorides in the form of dust, which at times caused either nonadherent coatings or nodules to be formed in the reaction zone. Through the use of heated argon as a vapor pick-up and carrier, the premature reduction of the pentachloride vapor was eliminated and much closer control of vapor ratio was obtained. In this case, hydrogen for the reaction was added after the argon had passed through the vaporizer and just prior to entrance into the reaction tube. In this way, it was not necessary to control closely the temperature of the diluent hydrogen gas but only to maintain the temperature of the resultant mixture above the dewpoint of the molybdenum pentachloride vapor present.

The use of argon as a means of picking up pentachloride vapor was extremely successful, as it was possible to control the hydrogen:pentachloride ratio sufficiently closely to permit uniform coating conditions throughout extended runs. In an effort to determine whether helium would work as well, two runs were conducted utilizing helium as a carrier

gas. In both of these runs, the coatings deposited were as good as those deposited when argon was utilized.

Measurements and Controls

With the vaporizer operating at approximately atmospheric pressure, near saturation conditions of $MoCl_5$ in argon existed. By varying the temperature of the oil bath or the temperature of the argon entering the vaporizer or both, it was possible to control closely the ratio of molybdenum pentachloride to argon. The diluting hydrogen stream was measured by a rotameter. Thus, the desired molybdenum pentachloride to hydrogen ratio could be maintained through an extended run.

During the project several schemes for actual measurement of the vapor concentration were attempted, but with poor success. Color comparison methods were of little value due to clouding of sight glasses and to variation of color with pressure. Considerable effort was expended in an attempt to develop a dewpoint type of measuring device, but here again, clouded sight glasses prevented precise measurements.

A tap at the reaction tube inlet was connected to a mercury manometer by means of copper tubing to determine the static pressure in the reaction tube. This arrangement functioned very satisfactorily throughout the project. The pressure in the system was maintained by a vacuum pump evacuating the system. The pumping rate was regulated by a globe-type vacuum valve to provide a controllable orifice. Solid products of the reaction frequently caused excessive friction to gas flow until a large area vacuum filter was installed ahead of the control valve.

Reaction Tubes

Most of the plating runs utilized tubes made from commercially drawn steel tubing with an approximate composition comparable to AISI 4620. The internal surface of the tubes was finished to a high polish. Initially, metallic "O" rings were used as gaskets at the tube ends, but experience proved that the asbestos sheet material provided a tighter seal.

The tubes were bored out to 1⅝ in. and were finished to a surface of better than 16 microinches rms. The tubes were approximately 36 in. long over-all permitting a coating length of about 30 in.

Various substrates were used as a basis for the molybdenum plate, in addition to cleaned but otherwise untreated steel. All tubes were carefully degreased with acetone. Electroplates of copper and of nickel and chemical plates of nickel and of cobalt were tested. Chemical plate was produced by the manner outlined by Brenner and Riddell (3) at the National Bureau of Standards. Since cobalt chemical coatings gave the best results in the early stages of development, all tubes used in the later stages were given this treatment.

Heating of the Reaction Tube

An induction heating coil was originally proposed for this study, but it was not possible to secure an adequate power supply in a reasonable time at the outset of the project. For the most part heating of the tube was accomplished by an annular high-temperature gas burner mounted on a moving platform. The burner was of the positive pressure, mixed air and gas type. It was capable of producing a narrow band of intense heat at the exterior of the tube and could be regulated within very close limits.

The burner was moved downward counter to the feed flow in order to allow the molybdenum to be deposited on a clean surface. With a plating run starting at the upper end of the tube, any partially reduced products of the reaction were deposited on the plated surface and could easily be removed.

During the final phase of the project, a 25 kw, 9600 cycle induction generator became available and it was decided to investigate the effect of an extended reaction zone on the process. A heated zone of from 8-10 in. was desired in place of the narrow 2-in. zone available from the gas burner. It was determined that about 2½-3 kw were required to maintain the tube at reaction temperature. This method of heating proved to be extremely successful, clean, easy to control, and produced less scaling on the outside of the tube than the gas burner. The temperature of the external tube surface was measured by a thermocouple and by a radiation pyrometer. Unfortunately, there was time for only four runs utilizing this equipment. Results are discussed later.

For all runs secondary heating by infrared lamps was utilized to maintain the temperature of the reaction tube above the condensation temperatures of molybdenum pentachloride in order to prevent a subsequent vaporization and enrichment of the vapor mixture as the burner traveled down the tube.

Effect of Variables on Plating Quality

Throughout the investigation, the effects of the following variables on plate quality and thickness were studied: total pressure, temperature of reaction zone, vapor concentration, hydrogen flow rate, surface preparation, and direction and rate of travel of the burner. The following were found to be the optimum conditions using the equipment described: (*a*) total reaction pressure 15-20 mm Hg; (*b*) tube temperature of 900°-950°C measured externally; (*c*) rate of travel of burner in the downward direction of 2 in./hr. (*d*) hydrogen flow of 7-9 liters/min measured at standard conditions.

When the pressure in the reaction tube rose above 20 mm, a vapor phase reduction occurred and the deposit became porous and nonadherent due to deposition of molybdenum particles which did not form a continuous coating. Below 10 mm total pressure it was impossible to obtain an adequate concentration of molybdenum pentachloride vapor to provide a sufficiently high rate of deposition. Most of the work was carried out at a pressure of 17 mm Hg.

The external temperature of the reaction zone as determined optically was usually between 875° and 975°C. These temperatures were correlated with measurements made by thermocouples to the internal tube temperature early in the project. Temperatures below 875°C were not high enough to produce a complete reduction at the existing gas velocities. Above 975°C there was an increased tendency to-

ward formation of large amounts of scale and toward decarburization of the exterior tube surface. No improvement in internal plate quality was gained by operating at temperatures in excess of 975°C.

While it was not possible to determine quantitatively the actual molybdenum pentachloride to hydrogen ratio, it was quite evident from the examination of the data that this was one of the fundamental variables of the process. When the vapor concentration was too low, an excessively long period was required to build up an adequate plate thickness. However, when very lean mixtures were used, the plate appeared to be dense and well bonded. With a high ratio of molybdenum pentachloride to hydrogen in the vapor a porous nonadherent coating was deposited. In the latter case there was a tendency for the coating to be much thicker, but because of side reactions, voids were apparent between the molybdenum and the base metal. The maximum plating rate for dense adherent coatings was 0.004 in./hr. When the plating rate was increased by increasing reactant rate or by increasing the vapor concentration, the deposit became less adherent, brittle, and less dense. When a low vapor concentration was used, the deposition rate was low but the quality of the deposit was excellent. Considerable effort was expended in an attempt to establish a means of determining quantitatively the molybdenum pentachloride-hydrogen ratio, but without success.

From the examination of a large number of plating runs, the conclusion was reached that downward travel of the burner consistently produced the best results; as the vapor mixture flowed through the heated zone, the reduction to metallic molybdenum was only partially complete. Some low molybdenum chlorides were also produced, which deposited on the internal tube surface in the cool zone. If the burner were moved concurrent with the flow, these lower chlorides might not be revaporized before they reached reduction temperature. This would result in a porous or powdery deposit with little or no adherence of the subsequent metallic plate. If on the other hand the heater were moved downward, incompletely reduced chlorides would be deposited on plate which had already been laid down and would be subjected to no additional heating. As the heater moved down, the plate would be deposited on fresh clean surface. When necessary, unreduced chlorides were removed with no difficulty by wire brushing.

Because of the reaction of the molybdenum and the carbon of the steel, it was determined early in the research that a barrier must be established to prevent this from taking place. Copper, nickel, and cobalt plates in various thicknesses were tried. The best results were obtained using a cobalt underplate of about 0.00025 in. This plate was easily applied nonelectrolytically and, once in place, provided excellent protection for the internal surface of the tube prior to molybdenum plating.

Time did not permit a more detailed study of the effect of increasing the width of the reaction zone. The results of the last four runs of the project were so much superior to all others that it appears that plating quality and rates could be improved greatly.

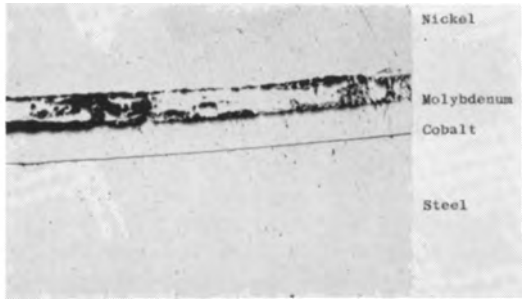

Fig. 2. Photomicrograph of molybdenum on cobalt on steel, unetched. Magnification 100X before reduction for publication. Photograph courtesy of Watertown Arsenal Laboratories.

Examination and Testing

Photomicrographs of coatings and base materials were made regularly to determine quality of the plate. Figure 2 shows the polished, but unetched, tube at 100X magnification (before reduction for printing). On the bottom is the base material of the tube. The line above is the cobalt substrate; next is the molybdenum deposit of about 0.004 in. The specimen was coated with electrodeposited nickel prior to metallographic examination, and the dark area between the molybdenum and the nickel is apparently due to the sample preparation.

Figure 3 shows the etched deposit at 500X. The base material, AISI 4620, is in the lower section, the cobalt interface and the molybdenum. The columnar structure of the deposited metal is readily observed. The protecting nickel coat is shown here as above.

The plated tubes have undergone utilization tests to determine resistance to abrasion and erosion. In addition to the metallographic examination of the coatings, several other tests were made to determine the efficiency of the plating process and the quality of the deposited molybdenum.

Samples of the coatings were subjected to various bend tests to determine the angle to which the plate and base material could be deformed before separation of the plate occurred. The specimen was bent with the plated surface out so that the plate was under tension. It was observed that the heavier the plate, the more readily it fractured. In all cases, the plate fractured when the bending angle exceeded 135° at a bending radius of ½ in. In several instances good plate showed failure at much lower bend angles because of the extreme columnar struc-

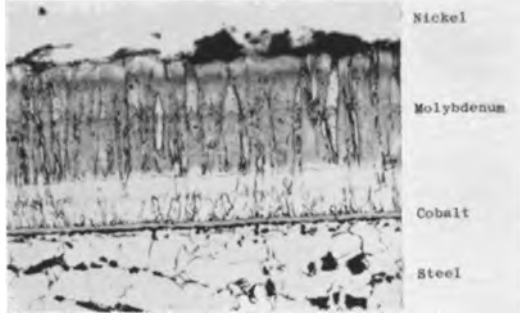

Fig. 3. Photomicrograph of typical molybdenum deposit, etched with alkaline $K_3Fe(CN)_6$. Magnification 500X before reduction for publication. Photograph courtesy of Watertown Arsenal Laboratories.

ture of the deposited material. When this type plate was examined under a low-power microscope, it was evident that the molybdenum failed by separation of the columnar grains as indicated by the many cracks extending from the base material to the outside surface of the plate. In spite of the failure of the molybdenum, it was evident that the cobalt plate below the molybdenum had remained intact during the bend test. Additional indications of quality of the molybdenum plate were obtained by observing the tube when it was sawed for sampling.

To further determine plate quality, various machining operations were performed on coated tubes. Sawing of a tube which had been plated with what was considered to be a high-quality plate produced a rolled-over edge of the coating at the edge of the cut. A poor coating would either flake off or chip away from the base material at the saw cut.

When a piece of coated tube was placed in a shaper and a strip of material removed lengthwise from the tube, good coatings would, as in the case of the sawed sample, remain attached to the section of base material removed from the tube. Poor quality coatings would flake and chip as the tool passed across the coating, and the coating would separate from the base material even though the base material were removed in a clean, even cut from the tube section.

Conclusions

A technique has been developed for the production of relatively heavy molybdenum plates inside of tubes. The best deposits were produced when the vapor concentration was held constant throughout the run. The wide hot zone produced by the induction coil proved superior to the narrow hot zone produced by the external gas burner. It was essential to maintain a large excess of hydrogen in the vapor stream to insure complete reduction, in order to produce dense deposits. Chemically clean surfaces for deposition were necessary to permit good bonding of the plate and substrate.

There should be uses for such plates in the chemical engineering field to take advantage of the mechanical strength and resistance to abrasion and erosion of molybdenum, as well as its high chemical and corrosion resistance. In the presence of air, at elevated temperatures, molybdenum undergoes catastrophic oxidation. However, for many uses in high-temperature, high-pressure reactors, this material could well be the answer to erosion problems where nonoxidizing conditions exist.

Effects of Impurities on the Crystallographic Modifications of Calcium Metal

J. F. Smith and B. T. Bernstein

Institute for Atomic Research and Department of Chemistry, Iowa State College of Agriculture and Mechanic Arts, Ames, Iowa

Previous work at this laboratory (1) has shown that above room temperature very pure calcium exists in only two allotropic forms: f.c.c. between room temperature and 464°C and b.c.c. between 464°C and the melting point. It is the authors' belief that these results represent the behavior of the purest Ca which has been examined to date. This point of view is substantiated by the rapidity and reversibility of the observed transformation since such behavior is representative of high-purity metal. Subtraction of the analyzed impurity content indicated this metal to be 99.96 wt % Ca. No analytical data were available, however, for hydrogen, oxygen, or carbon content.

Indication that these nonanalyzed impurities play an important role in the allotropic behavior of Ca was found in a subsequent examination of a later preparation of Ca. The analytical data for this latter Ca [herein referred to as calcium D (Ca D)] was comparable to that for the original Ca. The values for Ca D were: Mg, <0.01 wt %; N, <0.009 wt %; C, ~0.02 wt %; Si, <0.005 wt %; Mn, Fe, Al, Ba, Be, <0.001 wt %; and Cd, Cu, K, Li, <0.0001 wt %. The observed crystal structures in Ca D showed the low-temperature f.c.c. form and the high-temperature b.c.c. form but showed in addition a h.c.p. modification at intermediate temperatures. This sequence of structures has also been observed by Melsert, Tie-

Table I. Analytical data for those elements showing possible differences in concentration in the two Ca preparations

dema, and Burgers (2). The behavior of Ca D was such, however, that the Ca D must be concluded to be a less pure Ca preparation than the dimorphic Ca used in the original investigation. This conclusion is based on the observation of two-phase regions showing f.c.c. plus h.c.p. and h.c.p. plus b.c.c. The temperature ranges for the occurrence of these two-phase regions was a function of the thermal history of the sample, and indeed the appearance of a single-phase region of h.c.p. could be entirely eliminated after prolonged heating at elevated temperature. On the basis of the phase rule the occurrence of two-phase regions over a temperature range at constant pressure is precluded in a one-component system if the system is at equilibrium. It may be argued that the f.c.c. to h.c.p. transition is mechanistically difficult and that sluggish kinetics may defeat equilibrium; however, a similar argument is not valid for the h.c.p. to b.c.c. transition. In the latter case the transition is conceptually simple and may be visualized as occurring through a region of continuous strain. Such a transition should be rapid and reversible.

It seems evident, therefore, that the behavior of Ca D must be due to some contaminant present to a greater degree in Ca D than in the original Ca. In Table I are shown the analytical data for those elements exhibiting concentration differences in the two Ca preparations. These data were interpreted to mean that carbon or one of the nonanalyzed impurities was most probably responsible for the observed difference in behavior of the two Ca preparations. Substantiation of this point of view was made by re-examination of the only remaining sample of the original Ca preparation. This Ca had been stored for approximately 1½ years in a glass bottle with a plastic stopper. The bottle had been flushed with He and the glass-plastic juncture had been sealed with wax. Visual examination of the Ca taken from the bottle showed that the surface was discolored and obviously contaminated. Instead of the original dimorphic behavior, four structural modifications were observed: f.c.c., a low symmetry form originally reported by Graf (3), h.c.p., and b.c.c. The structural behavior was comparable to the least pure Ca (99.66%) examined in the previous investigation (1). By inference the change in behavior of the

* Behavior of Ca D in the temperature region 455°-560°C was a function of the thermal history of the sample since the single phase h.c.p. region could be eliminated by prolonged heating at elevated temperature.

high-purity Ca must have resulted from interaction with atmospheric components (O_2, N_2, CO_2, water vapor) which had diffused through the plastic stopper.

The present investigation was undertaken to determine which contaminants were associated with the appearance of the h.c.p. modification and which with the low symmetry structure. The low symmetry structure had already been shown to be a result of contamination (1) which result is corroborated by the recent work of Schottmiller (4).

Experimental Results

Any attempt to determine which contaminants were associated with the impurity phases by further purification studies seemed impractical because of the limitations of the analytical techniques. Therefore, it was decided to contaminate samples of Ca deliberately to see which impurities caused the appearance of the low symmetry and h.c.p. phases. Calcium D was considered to be satisfactory as a test material for the determination of the impurities associated with the low symmetry phase but, because the h.c.p. phase was already present, Ca D was not suitable for delineating the cause of the h.c.p. phase. Examination of other Ca preparations which were on hand showed one [herein referred to as calcium E (Ca E)] which exhibited the f.c.c., low symmetry, and b.c.c. phases but not the h.c.p. phase. Calcium E was, therefore, satisfactory for the determination of the impurity associated with the h.c.p. phase. Chemical analysis showed Ca E to be high in Mg content but otherwise of good purity: Mg, 0.027 wt %; C, 0.02 wt %; N, <0.009 wt %; Si, <0.005 wt %; Al, B, Ba, Be, Cu, Fe, <0.001 wt %; and Cd, K, <0.0001 wt %.

Oxygen, ethane, carbon, nitrogen, boron, and hydrogen were chosen as contaminants. Boron was included in the list in order to determine whether or not the structural effects were due simply to interstitial atoms. A summary of the diffraction results before and after contamination is shown in Table II. Diffraction patterns were taken with a modified Geiger-counter diffractometer (5) with the samples in the form of small bars. A slowly circulating atmosphere of purified He was maintained in the camera under a slight positive pressure. Temperatures were measured with a Pt-Pt 13% Rh thermocouple spot welded to the sample. It should be emphasized that the transition temperatures shown in Table II are approximate since diffraction patterns were taken at finite temperature increments, and no particular effort was made to precisely bracket a transition.

Gaseous contaminants were introduced into the experimental system by attaching to the system a 200-ml glass bulb filled with the gas. After first checking the sample to see that the structural behavior was typical and that inadvertent contamination had not occurred, the gas was vented into the system through a stopcock. Carbon and boron were added as powders, and contamination was accomplished in the following manner. The powder was sprinkled on a file, and the sample was inverted and lightly abraded across the file until a thin adherent film of the powder had collected on the calcium. The sample was then mounted in the camera and heated to ~500°C to allow reaction to occur.

In all cases the diffraction patterns were checked to determine that the sequence of phases was reversible in temperature. It was observed that in two-phase regions there was a general tendency for the intensity of the diffraction peaks of the low-temperature phase to decrease with increasing temperature with an accompanying inverse effect for the high-temperature phase.

It is evident from Table II that neither oxygen nor boron is responsible for the low symmetry or h.c.p. phases. However, both carbon and nitrogen were found to induce the appearance of the low symmetry phase. Since there might be some question with regard to adsorbed nitrogen on the graphite powder, carbon was also introduced in the form of ethane. Ethane contamination also caused the appearance of the low symmetry phase and, since contamination with hydrogen alone did not produce this result, the evidence indicates that carbon as well as nitrogen can cause the appearance of the low symmetry phase.

It is also evident from Table II that hydrogen is the impurity associated with the h.c.p. phase. Only hydrogen and ethane caused a significant change in the temperature range of stability of the h.c.p. phase in Ca D, and indeed hydrogen induced the appearance of the h.c.p. phase in Ca E. Although hydrogen does not cause the appearance of the low symmetry phase, the stabilization of this phase at lower temperatures in Ca E after hydrogen addition must indicate some degree of hydrogen solubility in the phase.

The effect of the thermal history of the samples on stability of the h.c.p. structure has been noted in the description of the behavior of Ca D. This effect is consistent with the conclusion that hydrogen is responsible for the occurrence of the h.c.p. phase since reduced stability of the phase after high-temperature annealing would be explicable on the basis of volatilization of hydrogen. Hydrogen would be expected to have an appreciable vapor pressure at elevated temperature, and volatilized hydrogen would be carried away by the slowly circulating helium atmosphere.

Discussion

On the basis of the results, there is little doubt that the free energy balance among the various structures is rather precarious and that small variations in the number and type of impurity atoms have significant effects. This sensitivity to nonmetallic impurities, readily available from the atmosphere, must be largely responsible for the disparity in results obtained by different investigators while measuring the physical properties of Ca metal and, in particular, for the diversity in reports concerning the allotropic behavior.

Calcium is known to be a highly reactive metal, especially so in the powdered form which has been used in other structural investigations. In the author's opinion the recent work of Schottmiller (4) on the Ca-Sr phase diagram illustrates this point.

Schottmiller found a marked difference between results obtained by x-ray diffraction using powder samples and results obtained by thermal analysis on massive samples of the same Ca metal. This occurred even though Schottmiller was particularly careful in the handling of his powder samples. The diffraction results showed a f.c.c. to h.c.p. transition at 342°-347°C and a h.c.p. to b.c.c. transition at 607°-612°C. In addition the low symmetry phase was found to exist in the temperature region 300°-345°C; it is not specified whether this was a single-phase or two-phase region. In comparison, the thermal data showed a transition at 281°-314°C which was attributed to the appearance of the low symmetry phase. But only one additional transition was found at 482°-516°C instead of the two transitions to be expected on the basis of the diffraction results.

It seems highly probable that the difference in results observed by Schottmiller was due to reaction of the Ca powder with some contaminant. Water vapor is the contaminant most difficult to exclude from an experimental environment since it adsorbs readily on most surfaces and in addition it will diffuse appreciably through many media.

Svec and co-workers (6, 7) have studied the reaction of Ca with water vapor and have found that the reaction occurs at the surface with the liberation of hydrogen. Hydrogen was found to have a high solubility in Ca and to diffuse rapidly into the metal, while the oxygen remained behind in a thin surface layer. The results provide a ready explanation for a source of hydrogen contamination and hence an explanation for the appearance of the h.c.p. phase in many Ca preparations. The degree of water vapor contamination which may occur before an oxide phase can be detected by x-ray diffraction is a function of the surface to volume ratio and is quite high in the case of powder samples.

In summary, the results of the present investigation show that nitrogen or carbon will induce the appearance of the low symmetry phase in Ca, and hydrogen will induce the appearance of the h.c.p. phase. In fairness, it should be emphasized that in neither case was the initial Ca completely pure and the observed results may have occurred because of a combined effect due to the added impurity plus impurities already present. Nonetheless, by inference the h.c.p. and low symmetry phases are both impurity-stabilized. This leaves f.c.c. and b.c.c. as the allotropic modifications of pure Ca with a transition temperature of ~450°C. The present investigation thus corroborates the results of the previous investigation and, in addition, provides an explanation for the occurrence of the low symmetry and h.c.p. phases. The transition temperature is also in reasonably good agreement with a thermal transition at 440°C listed by Kubaschewski (8) and for which he reports an averaged value for the enthalpy of transition of 0.24 ± 0.04 kcal/mol. Kubaschewski's value is based on a critical survey of available data, and he notes that only one transition is found consistently although an additional transition at lower temperature is also found by some investigators.

Acknowledgments

The authors wish to express their appreciation to Dr. O. N. Carlson for providing the calcium used in this investigation and to Mr. E. D. Gibson for his assistance in the initial stages of the investigation.

The Synthesis of Some Pyridyl Glycols by Electrolytic Reduction

M. J. Allen and H. Cohen

Research Department, CIBA Pharmaceutical Products Inc., Summit, New Jersey

The synthesis of the pinacone, 3,3-di(p-aminophenyl)butanone - 2 - dihydrochloride (Amphenone B) (1) with subsequent elucidation of its interesting biological activities (2) led us to continue our investigations in an attempt to find pinacones analogous to Amphenone B which would retain the adrenal inhibitory effect of this compound but not its undesirable side effects.

It was decided to investigate the biological properties of the pinacones (3) prepared from the pinacols of 2-, 3-, and 4-acetylpyridine, but first it was necessary to prepare the respective pinacols. The electrolytic method was chosen for this purpose as it had proved itself quite satisfactory for the preparation of 2,3-bis(p-aminophenyl)-2,3-butanediol, the Amphenone B intermediate (4), as well as for other pinacols (5).

The pinacol of 3-acetylpyridine has been previously described (6). However, the experimental conditions which involved the use of an acidic medium resulted at times in difficulty in isolation of the pinacol with desired purity. Therefore as there is always the possibility of side reactions when using an acidic medium for a cathodic reduction of a ketone to its pinacol, it was decided to utilize basic conditions in our investigation. Although a potassium hy-

droxide medium was found to be quite satisfactory for the 2- and 4-acetylpyridines, the 3-acetylpyridine when electrolyzed in this medium gave extremely poor yields with an excessive amount of tarry material. In this instance a less basic medium, i.e., one containing potassium acetate, proved more satisfactory.

Experimental

The apparatus used for controlled potential electrolysis has been described (7) as has the 1500-ml cell used for the reductions of 2- and 4-acetylpyridine, except a regular paddle stirrer was used instead of a magnetic stirrer (6). The mercury cathode area in this cell was 111.3 cm^2. The reflux-type cell (8) used in the preparation of the 3-acetylpyridine pinacol had a mercury cathode area of 17.2 cm^2. In all the experiments reported the anode chamber contained a nickel anode and an aqueous 40% potassium carbonate solution.

2,3-Bis-(2-pyridyl)-2,3-butanediol. — The catholyte consisted of 100 g 2-acetylpyridine dissolved in 460 ml 1*N* KOH in 50% aqueous ethanol. At a reference potential of —1.6 v vs. S.C.E. the initial current was 5.6 amp and the applied voltage 16 v. The temperature was maintained at 23°-25° throughout the course of the reaction. After 256 min the current plateaued at 1.2 amp at which time the applied voltage was 4.5 v. The heavy precipitate which began to appear 40 min after onset of electrolysis, was filtered, washed with 25% ethanol, and dried. Yield 69 g (68.4%), mp 134°-137°, current efficiency 74.2%. Recrystallization from 50% aqueous methanol mp 138°-139°; anal. found: C, 69.06; H, 6.65; N, 11.77%. $C_{14}H_{16}N_2O_2$ requires, C, 68.82; H, 6.60; N, 11.46%.

2,3-Bis-(3-pyridyl)-2,3-butanediol. — A solution of 6 g 3-acetylpyridine in 35 ml ethanol, 15 g potassium acetate, and 17 ml distilled water was placed in the cathode compartment and the whole maintained at reflux throughout the course of the electrolysis. At a reference potential of —1.5 v the initial current was 8.9 amp and applied voltage, 11.4 v. After 25 min the current plateaued at 0.5 amp with an applied voltage of 2.1 v. The catholyte was distilled to a small volume under reduced pressure and, after chilling, the aqueous phase separated from the solid residue. This solid upon trituration with 20% acetone yielded 4.13 g (68.4%), mp 220°-224°, current efficiency 80.3%. Recrystallization from ethylene glycol gave mp 244°-245° (5).

2,3-Bis-(4-pyridyl)-2,3-butanediol. — The catholyte in this instance contained 100 g of the 4-acetylpyridine in 460 ml aqueous 1*N* KOH. At a reference potential of —2.2 v the initial current was 7.8 amp and applied voltage 12.5 v. After 176 min the current plateaued at 4.2 amp and the applied voltage was 7.0 v. The temperature throughout the course of this reaction was maintained at 23°-25°. The precipitate which had formed during the electrolysis was filtered, washed with water, and dried. Yield 99 g (98.2%), mp 209°-212°, current efficiency 97%. Recrystallization from methanol-ethyl acetate gave mp 219-220; anal. found: C, 68.51; H, 6.63; N, 11.33%. $C_{14}H_{16}N_2O_2$ requires C, 68.82; H, 6.60; N, 11.46%.

Technical Review

The Silver Oxide Electrode

T. P. Dirkse

Calvin College, Grand Rapids, Michigan

ABSTRACT

A review has been prepared of the electrochemistry of the silver oxide electrode. The discussion covers the structure and electrochemistry of the oxides of silver and their behavior in batteries.

With respect to the battery family, silver and its oxides are relatively new arrivals. There was some interest in these oxides for battery use around the turn of the century. In 1910 Morrison was issued several patents (1) covering various phases of the construction of a storage battery using silver oxides as positive plate materials. However, so far as is known, no commercial application was made of these patents.

Around the beginning of World War II interest was again aroused. Andre (2) once again suggested the use of silver oxides in a storage battery. To overcome the problem of a short shelf life he advised the use of a membrane as a sheath around the silver oxide plates. Some work at the National Bureau of Standards showed that silver oxides could serve well in a primary battery. The silver-zinc-alkali system was found to have a relatively high watt hour per pound value. At present this system is available both as a primary and as a secondary battery.

Because of this relatively short history of interest in the silver oxides as active materials for alkaline batteries, there is in the literature of silver and its oxides very little material dealing with the chemical problems peculiar to or associated with the battery industry.

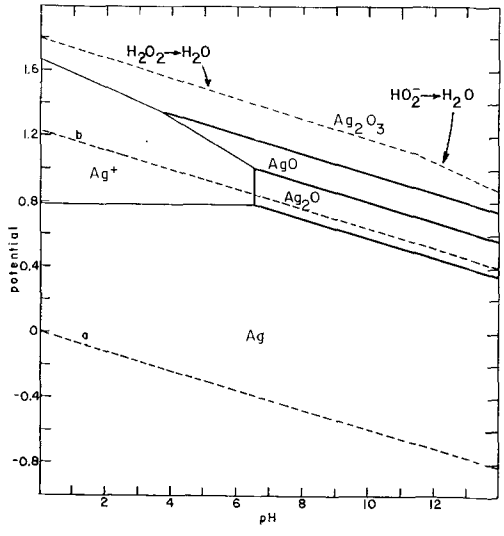

Fig. 1. Potential-pH diagram for silver and its oxides

There are several oxides of silver and, although their use as active materials in batteries has been limited to alkaline electrolytes, there is a good deal of literature dealing with the problem of silver oxides in acid solutions. Figure 1 is a modification of the diagram of Delahay, Pourbaix, and Van Ryssel-berghe (3). It gives a good survey of the relationship of silver to its oxides in a rather wide *p*H range. This diagram, of course, represents equilibrium conditions, and such conditions may not prevail at all areas of electrode-electrolyte interface during the operation of a battery. The areas of Ag, Ag^+, Ag_2O, and AgO seem fairly well defined, but there is uncertainty about the existence of oxides in which silver apparently has an oxidation number greater than two. Line a represents the reduction of H^+ to H_2 and line b the reduction of O_2 to water. For alkaline batteries the region of high *p*H is most significant. Here we find Ag, Ag_2O, and AgO as the thermodynamically stable phases.

Silver

Generally, the oxides used in these batteries are formed by the electrolytic oxidation of silver. Metallic silver is a good electrical conductor, having a specific resistance of 1.59×10^{-6} ohm-cm (4). During discharge, these oxides are reduced to silver, which then makes the plates better electrical conductors.

An interesting characteristic of silver is its ability to allow oxygen to diffuse through it (5). It has been suggested that this is done by the formation of Ag_2O (6).

The crystal structure of silver has been the subject of much investigation. It appears that there is only one crystal form, a face-centered cubic arrangement. The edge of a unit cube has a length of 4.078Å, and the distance between the centers of the nearest silver atoms is 2.884Å (7).

Although the crystal lattice seems fairly well established, there is some question about the electronic

configuration of the silver atoms. The K, L, and M orbits of the silver atom are complete, as are the 4s and 4p orbitals. This leaves 11 electrons to be allocated. One possibility is to assign 10 of these electrons to the 4d orbitals, completing them and leaving one electron for the 5s orbital. This is in agreement with the fact that silver is ordinarily univalent. However, Kaplan (8) contends that the 4d shell does not have the stability of the rare gas shells, and suggests the presence of 3 free electrons per atom in the lattice. This would account for the various oxides and valence states.

When the potential on a silver electrode in alkaline solution is raised, the first product formed is Ag_2O. This reaction proceeds efficiently and can be carried out with a polarization of less than 50 mv. However, only a thin film of Ag_2O is formed. It has been estimated to be of the order of 3 molecules in thickness (9).

Silver(I) Oxide

Silver(I) oxide, Ag_2O, is a rather well-defined substance. It has a deep brown color and gives a definite x-ray pattern. At one time it was suggested that there are two crystal modifications of this substance (10) with different electrode potentials. However, other investigators found no warrant for this (11).

The crystal structure of this oxide is basically the cubic type, the length of an edge being 4.72Å (12). It has a face-centered cubic arrangement of silver atoms or ions interpenetrated by a body-centered cubic arrangement of oxygen ions (13). Consequently, each oxygen ion is in the center of a tetrahedron of silver ions. Apparently then, the formation of Ag_2O does not alter the basic structure of silver but spreads it out a bit, increasing the length of the cube edge. If the basic lattice be divided into octants, the oxygen ions then occupy two octants of the unit cube. The distance between centers of nearest silver ions is 3.336Å and that between silver and oxygen is 2.043Å.

The electrochemical formation of Ag_2O can be represented by Eq. [1]. The variation of E_{Ag-Ag_2O} with hydroxyl ion

$$2Ag + 2\,OH^- \rightarrow Ag_2O + H_2O + 2\,e \qquad [1]$$

concentration is in agreement with this equation. The exact value of E° for this reaction appears to be in some doubt. Hamer and Craig (14) have reviewed the situation, and point out that the lack of reproducibility of the potential of the Ag-Ag_2O couple in alkaline solution is not due to changes in the Ag_2O. They suggest that it is due to a chemisorbed film of oxygen on the silver, which film could be passive. They point out further that no value of E° has been determined for this change by measurement against a hydrogen electrode.

Two properties of Ag_2O limit its effectiveness as the positive active material in an alkaline cell. The first of these is its high electrical resistance. Le Blanc and Sachse (15) give the specific resistance as about 10^8 ohm-cm. This high resistance, or low conductivity, indicates the absence of mobile or unpaired electrons in the Ag_2O lattice. It naturally affects the conductivity of the electrodes in which it is found, and may be the reason why only a thin film of Ag_2O is formed on the Ag. The resistance of this film results in a rise of the applied voltage when such an electrode is charged by a constant current process.

The other property is the solubility of Ag_2O in alkaline solutions. This solubility, at least in the more dilute solutions, is a function of the hydroxyl ion and not of the cation. The solubility product at 25°C is of the order of 2×10^{-8} (16), and it increases with increasing temperature (17). The solubility is due to reaction [2]. A part of the dissolved

$$Ag_2O + 2\,OH^- \rightarrow 2AgO^-\ [\text{or } Ag(OH)_2^-] + H_2O \qquad [2]$$

Ag_2O in alkaline solutions may also be in the form of $Ag_2(OH)^+$. This solubility of Ag_2O is at least partly responsible for the poor shelf life characteristics of the silver cell (18).

Silver(II) Oxide

Silver(II) oxide, AgO, has been investigated in numerous ways and has been studied both in alkaline and acid solutions. It is a grayish black substance and is now available commercially. It can be prepared in many ways, e.g., by the oxidation of silver or silver salts with ozone, persulfate, or permanganate. It is also prepared electrochemically by anodic treatment of silver or Ag_2O in alkaline solutions.

The latter reaction is an efficient one and the polarization is of the order of 100 to 150 mv. Luther and Pokorny (19) state that it proceeds reversibly as well. Jones, Thirsk, and Wynne-Jones (20), however, state that this process is irreversible. They used as their criterion the assumption that the discharge is an efficient process. This, however, is not necessarily the case. On discharge, particularly at appreciable current densities, only a part of the capacity of the AgO is delivered at the higher potential. There is still AgO present at the beginning of the lower voltage level during discharge (Fig. 2). The kinetics or mechanism of this reaction have not been established, but the equilibrium condition is likely represented by Eq. [3].

$$Ag_2O + 2\,OH^- \rightarrow 2AgO + H_2O + 2e \qquad [3]$$

This reaction is similar to [1]. Accordingly, the relation of the potential of [3] to hydroxyl ion con-

centration is the same as that for reaction [1] (Fig. 3).

The layer of AgO formed in these electrochemical processes is thicker than that of Ag_2O. On Fig. 4, for example, the plateau for the formation of AgO is longer than that for the formation of Ag_2O. At moderate current densities both processes are about 100% efficient (21). Therefore the length of the plateaus is a relative measure of the depth of formation of the oxides. A constant potential charging process can give a product that is completely converted to AgO. In fact, we have produced in this manner products that on analysis appear to be Ag_2O_3. Yet these products have the same electrode potential (Fig. 3) and x-ray pattern that AgO has. It is possible that these products are the AgO plus adsorbed oxygen.

There has been some disagreement as to the mechanism of the transformation of the lower oxide to a higher one. The second plateau of the charge curve is preceded by a small peak (Fig. 4). This peak has been interpreted differently. Hickling and Taylor (9) consider it to represent the formation of Ag_2O_3 which then decomposes to AgO. Jones, *et al.* (20) suggest that this peak is due to the difficulty of forming nuclei of AgO. This could be somewhat similar to a resistive effect of Ag_2O which is decreased as soon as the better conducting higher oxide is formed (22).

Within the past year or so the structure of AgO has been clarified. The work of Scatturin, *et al.* (23) shows AgO to have a monoclinic structure, and the cell parameters have been evaluated. More recently Graff and Stadelmaier (24) have reached the same conclusions. Thus, when Ag_2O is oxidized to AgO the cubic arrangement of the silver atoms or ions is distorted or destroyed.

However, there still are questions concerning the structure of this substance. The material produced from the product obtained by anodizing a silver nitrate solution between platinum electrodes and that produced by extensive ozonization of silver gives a different x-ray diffraction pattern than the monoclinic form of AgO (24, 25). The monoclinic form is the one produced on a battery plate. Jones and Thirsk (26) have interpreted the nonmonoclinic x-ray pattern as revealing a face-centered cubic form of AgO. Graff and Stadelmaier (24) suggest that this may possibly be a higher oxide such as Ag_2O_3. This matter is as yet unresolved.

Various properties of AgO have been studied and the results of the several investigations have differed significantly. Some of this may be due to the fact that many data reported for AgO have been obtained by measurement and study of the nonmonoclinic variety (27, 28). The condition of the silver in the AgO has not been clarified. It has been suggested that there may be two Ag — O distances, and the bonding may be partly ionic and partly covalent (23). The specific resistance of AgO has been reported as 0.012 ohm-cm (26), 15 ohm-cm (29), and 10 ohm-cm (15). In any event, the conductivity is considerably better than that of Ag_2O and this indicates that there are unpaired or mobile electrons present in the solid material. The magnetic susceptibility per mole has been given as $+40 \times 10^{-6}$ (paramagnetic) (30) and -19×10^{-6} (diamagnetic) (29). The latter value was used as evidence for the conclusion that the bonding in the AgO lattice is covalent or metallic and the silver is trivalent. Two of these valences are used for bonding the oxygen atom and the other one for bonding with other silver atoms.

It is generally agreed that the silver in AgO has an oxidation number of +2. Klemm (30) used several criteria to establish this. He considered analytical evidence, oxidative ability, and isomorphism with CuO. To this may be added the fact that electrochemical reduction of this oxide yields two Faradays per mole (31). Addition of acids to this oxide yields oxygen but no hydrogen peroxide. This indicates that AgO is not a peroxide (26).

AgO dissolves in nitric acid to give a dark brown solution which is fairly stable in the cold. This solution has strong oxidizing powers. The color disappears on warming or on dilution. Barbieri (32) suggested that this dark colored solution contained tri-

valent and monovalent silver. However, later work showed that the dissolved silver is primarily bipositive (33). This was determined by a solubility method and by a determination of magnetic susceptibility. The magnetic moment corresponded closely to that calculated on the assumption of one unpaired electron. This then is a 4d electron.

For use in a battery it is necessary that a substance be fairly stable in the electrolyte, in this case an aqueous solution of NaOH or KOH. Denison (31) reported that the oxide is stable in 20-40% KOH solutions. However, pure AgO does decompose very slightly in alkaline solutions at room temperature. At higher temperatures this decomposition is more rapid (34). Practically, in a battery, pure AgO is never produced on charging, and the presence of unoxidized silver in such a plate further hastens the decomposition of the AgO (34).

Because of the higher oxidation state of silver, one would expect the AgO to be more soluble than Ag_2O in alkaline solutions. Some solubility data have been reported (34,35), and it appears that the solubilities of Ag_2O and AgO are not far different from each other in alkaline solutions. The solubility passes through a maximum with time but equilibrium is reached within a few hours (34).

Higher Oxides

Of the various higher oxides of silver mentioned, Ag_2O_3 is the most popular formula. The evidence for the existence of this oxide is, in the main, indirect. It is doubtful whether a pure sample has been isolated. Jirsa (36) claims that Ag_2O_3 can be prepared but cannot exist alone. Furthermore, it is readily decomposed by heating. Braekken (37) attempted to determine the structure by means of x-ray diffraction measurements but reached no conclusion other than that it had a cubic structure. However, the cube edge length seemed to vary with the method of preparation.

Three methods have been used to prepare this material. (*A*) Luther and Pokorny (19) were able to oxidize silver nitrate or sulfate anodically and obtain a product which appeared to be a mixture of AgO and Ag_2O_3. This couple had a potential about 200 mv higher than that of the Ag_2O-AgO couple. They were not able to produce this substance by anodic treatment of AgO in alkaline solutions. Somewhat similar work was done later (38) and it was concluded that Ag_3O_4 or Ag_4O_5 was formed. However, these oxides were not pure but contained $AgNO_3$ or Ag_2SO_4. Later Weber (39) prepared this same material and determined transference numbers of it in a nitric acid solution. On the basis of his results he concluded that at least some of the dissolved silver was trivalent.

(*B*) Yost (40) oxidized silver salts with peroxysulfuric acid and obtained a product which appeared to be $Ag_2O_3 \cdot x\,Ag_2(SO_4)_3$. De Boer and van Ormondt (41) also used acid solutions of persulfates as oxidizing agents and obtained a black precipitate which they considered to be a mixture of Ag_3O_4 and $Ag_2(SO_4)_2$ or $Ag_2S_2O_8$. However, the use of persulfates in alkaline solutions gave only the AgO.

(*C*) The third method for preparing this oxide involves the treatment of silver or Ag_2O with ozone (42), or the treatment of silver salts in acid solution with ozone (43). However, here the trivalent silver, AgO^+, had but a transient existence in solution.

In summary, there seems to be some evidence for the existence of a trivalent state of silver, e.g., Ag_2O_3. However, much of the evidence may also be interpreted in other ways (44). The potential value given for the AgO-Ag_2O_3 couple is very close to that for the formation or reduction of the HO_2^- ion in alkaline solutions or H_2O_2 in acid solutions (Fig. 1). Whatever the interpretation, this higher valence state is of little significance for use in alkaline batteries. This conclusion is substantiated by recent work at the Battelle Memorial Institute (45). Samples of Ag_2O_3 were prepared and used as the positive active material in an alkaline cell. The voltage curves and the ampere-hour capacity obtained from such plates were essentially those of AgO.

Conclusions

Although silver oxides are being used in commercial batteries, the performance of these batteries could stand improvement. Some of the troubles encountered are inherent in the system, e.g., the solubility of the oxides in the alkaline electrolyte. Others are due to or are aggravated by the method of assembly of the components. In order to understand this system better there are at least two areas that need to be more thoroughly investigated.

1. The higher voltage level on discharge, (AgO, Fig. 2), is rather unpredictable, particularly in a secondary battery. The capacity delivered at this voltage is sensitive to a variety of conditions, and it disappears on stand without a loss in total capacity. The latter phenomenon can be accounted for by reaction [4] which can take place readily (34). More work

$$Ag + AgO \rightarrow Ag_2O \qquad [4]$$

is necessary to determine precisely what conditions do affect this part of the discharge curve. It is necessary also that work be carried out to determine the polarization of these various processes, particularly the reduction of AgO to Ag_2O.

2. In a secondary battery the charge acceptance is erratic (44). While the current efficiency is high and the discharge capacity is equal to the charge capacity, the amount of charge capacity varies from cycle to cycle and tends to decrease during the life of the battery. Some of this may be due to design, but it is also possible that there are physical changes in the silver during cycling. This is an area in need of more investigation. Allied with this may be the problem of aging of the oxides during long periods of stand.

The Performance of Zinc, Magnesium and Aluminum Primary Cell Anodes. A Review

R. Glicksman

RCA Laboratories, Radio Corporation of America, Princeton, New Jersey

ABSTRACT

In this paper some of the factors involved in the operation of a primary cell anode are presented. The effects of such variables as alloy composition, inhibitors, pH, electrolyte composition, current density, and type of service, on the performance characteristics of zinc, magnesium, and aluminum anodes are discussed.

The number of metals which can be used in a galvanic cell is large in theory, yet in practice only a few have proved satisfactory. The anode materials which are in common use today are those which have standard potentials of an intermediate value and high hydrogen overvoltages such as zinc, cadmium, and lead. Of these, Zn is used most widely in primary cell systems, finding use in both acidic and alkaline cells (1-5). Attempts have been made to use Mg (6, 7) and Al (8) in dry cells, and considerable success has been achieved with Mg anodes.

The requirements for secondary cell anodes are somewhat more stringent than for primary cell anodes in that the electrode reactions have to be reversible. Thus, Mg and Al are unsuitable for use in rechargeable cells. Lead and cadmium, which form insoluble compounds at the anode surface during discharge, find extensive use for this application (9-11). The use of Zn has also proved quite feasible in alkaline cells (12) despite the solubility of $Zn(OH)_2$.

In this paper some of the factors involved in the

Table I. Theoretical data for Mg, Al, and Zn anodes

Metal	Density, g/cc	Reversible electrode potential, v $E°$ acid	$E°$ base	Electrochemical equivalent, amp-hr/g
Magnesium	1.74	2.37	2.69	2.20
Aluminum	2.70	1.66	2.35	2.98
Zinc	7.14	0.76	1.245	0.82

operation of a dry cell anode are discussed, and in particular the performance of Zn, Mg, and Al anodes is considered.

Theoretical

Theoretically, the suitability of a metal for use as a galvanic anode can be ascertained simply from its position in the electrochemical series (13) and its electrochemical equivalent, as shown in Table I. The electrochemical equivalent provides a measure of the quantity of electricity (ampere-hours) contained in a unit weight of the metal and is defined by Faraday's law. On this basis, Mg and Al are more attractive anodes than Zn.

However, because of their protective oxide film, the high reversible potentials of Mg and Al are never achieved. In practice, Mg has anode potentials only 0.3 to 0.6 v higher than those of Zn, while Al is cathodic to Zn in neutral or acidic electrolytes, as evidenced by the data in Table II (14).

Effect of Current Density

The current density affects the anode in two ways: through its effect on the potential and on the current efficiency of the electrode.

Most electrodes used in battery applications are characterized by low polarization as a whole at reasonable current densities. Active metal anodes generally have large activation polarization with respect to hydrogen discharge and, hence, a low self-corrosion, but very little polarization with respect to the oxidation of the metal. Notable exceptions to the latter are Mg and Al in many electrolytes (15). For example, Robinson (16) showed that current density had relatively little effect on the potential of Mg anodes in aqueous chloride and sulfate electrolytes; however, when the electrolyte contains a high concentration of an anion capable of precipitating Mg^{++} ion, e.g., OH^-, $SO_3^=$, anodic polarization occurs. Thus the polarization characteristics of Mg in these electrolytes nullifies an otherwise acceptable electrode potential.

As one might expect from the results of dissolution studies of metal anodes and viscosity studies of cell electrolytes, at low temperatures there is a large increase in polarization with increasing current density and decreasing temperature (17). In order to minimize polarization at the low temperatures, the trend is toward increased electrode area for low-temperature batteries.

Another important index of anode performance which must be considered is the anode efficiency. This indicates how much of the stored electricity is recoverable as useful energy under service conditions. Although theoretically the consumption of Mg per ampere-hour should be only 0.37 times that of Zn, it actually is about 0.6 times. This has been explained by the fact that 40% of the consumed Mg is dissolved by wasteful corrosion during the discharge of the cell as compared to 5-10% for the Zn cell (18).

The effect of a polarizing current on the dissolution rate of a magnesium AZ10A[1] alloy in 2*N* $MgBr_2$ is shown in Fig. 1 (19). When the specimen is made anodic, the observed dissolution rate is the sum of the rate due to the external current and the rate due to local action. It is seen that the local corrosion rate increases with increasing anodic current density. This is known in the theory of corrosion as the negative difference effect. For Mg the magnitude of this effect has been found by Robinson (16) to be dependent on both the electrolyte and anode composition including alloy ingredients and level of impuritites.

[1] This alloy consists principally of magnesium but contains in addition 1% aluminum and 0.5% zinc.

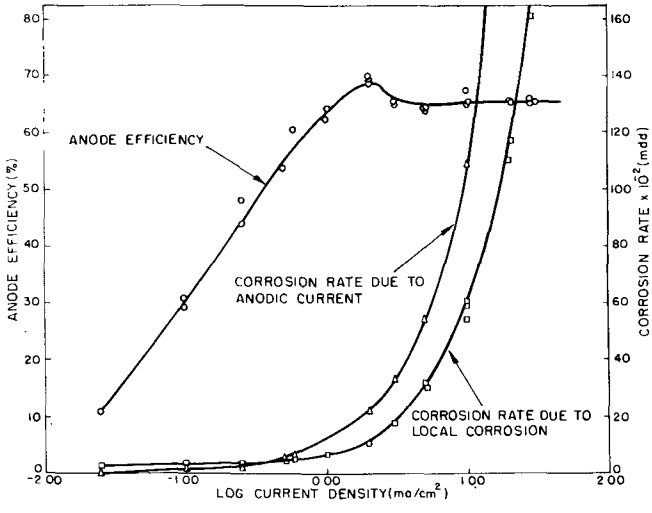

Fig. 1. Effect of current density on the local corrosion rate and anode efficiency of a MgAZ10A alloy dissolving in 2N $MgBr_2$ electrolyte [saturated with $Mg(OH_2)$]. [Glicksman 19)].

Table II. Electrode potentials* of Mg, Al, and Zn in various electrolytes (potentials referred to a standard hydrogen electrode) [Mears and Brown (14)]

Metal	1.0M NaCl	1.0M Na_2SO_4	1.0M Na_2CrO_4	1.0M HCl	1.0M HNO_3	1.0M NaOH	1.0M NH_4OH	St'd $Ca(OH)_2$	St'd $Ba(OH)_2$
Mg	1.38	1.41	0.62	1.34	1.15	1.13	1.09	0.61	0.54
Al	0.52	0.16	0.37	0.46	0.15	1.16	0.46	1.20	1.19
Zn	0.81	0.85	0.33	0.80	0.72	1.17	1.16	1.06	1.15

* Potentials originally reported were referred to a 0.1*N* calomel electrode. They are here corrected to the standard hydrogen electrode scale without making correction for the liquid junction potential.

This type of effect has also been observed on Mg corroding in a 3% NaCl solution (20) and is usually found with very active anode metals covered by a protective layer. The positive effect is found in the absence of a protective layer as in the case of Mg dissolving in HCl (21). Similarly, Al anodes show positive difference effects in certain corrosive electrolytes such as NaOH (22) and HF (23) which can dissolve the protective film, while the negative effect shows up in HCl (23) because of the presence of a film on the metal.

Thus one of the difficulties associated with the use of Al and Mg anodes is their poor current efficiencies, especially at low current densities. Moreover, the efficiency at any given current density has been found to decrease with a more intermittent type of discharge. This increase in corrosion on intermittent discharge is attributed to a change in the surface condition of the anode with alteration of current density. An example of this can be seen in Fig. 2, which shows the change in terminal voltage of Mg/$MgBr_2$/MnO_2 and Zn/NH_4Cl-$ZnCl_2$/MnO_2 dry cells as current pulses of 10 and 50 ma are withdrawn (24). It is seen that the Mg-MnO_2 cells undergo a greater instantaneous voltage fluctuation than the conventional Leclanché cells. (Oscillographic measurements of an Al/$AlCl_3$/MnO_2 cell showed a behavior quite similar to that of the Mg cells.) For Mg cells, the large initial drop is believed due to the resistance of the oxide film on Mg, the voltage rising as the oxide layer is being removed, reaching a steady-state value. When the circuit is opened, the cell voltage rises above the original open-circuit value and then gradually returns to its original voltage.

Thus, immediately after decreasing the current or breaking the circuit, the surface of the Mg is seen to be in a more active form than in its steady state under these same conditions. The question is, then, whether this change in the surface condition influences the over-all rate of hydrogen evolution. Presented in Fig. 3 is a comparison of the rate of hydrogen evolution from two magnesium AZ10A alloy samples in 2*N* $MgBr_2$ electrolyte in the absence of an external anodic current. Prior to the measurements, sample A was discharged for an hour at a current density of 5 ma/cm² and then allowed to corrode normally, while sample B was not discharged at all. The difference in corrosion rates of the two samples for the first 3 hr is attributed to a less effective oxide coating for the previously discharged Mg. At the end of 4-5 hr, there is little or no difference in the corrosion rates, and apparently the oxide coating on sample A is just as protective as that on the undischarged Mg, i.e., sample B. It is thus apparent that the change in surface condition with current density influences the rate of hydrogen evolution at a Mg anode. For Zn, no such problem arises, and it functions at high anode efficiencies for normal current drains and discharge tests.

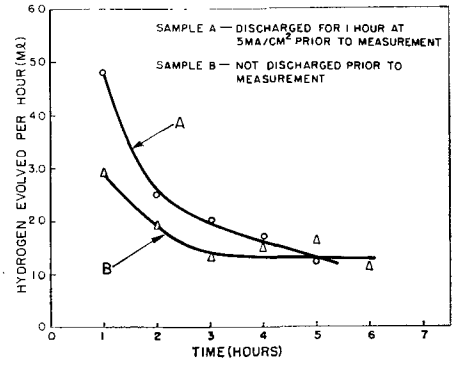

Fig. 3. Corrosion rate of a magnesium AZ10A alloy in 2N $MgBr_2$ electrolyte saturated with $Mg(OH)_2$ (Area 19.6 cm²).

As a consequence of the oxide film, two other problems are encountered in Mg dry cells when current is withdrawn, namely, "delayed action," and impedance. Delayed action is defined as the number of seconds required for the cell voltage to reach a minimum of 1.0 after the circuit is closed. At present this delay is less than 1 sec and apparently is no longer a problem (25). For Al cells using an $AlCl_3$ electrolyte inhibited with potassium chromate, a 1-sec delayed action is found (8).

When a primary cell is considered for use in powering electronic equipment, its impedance values

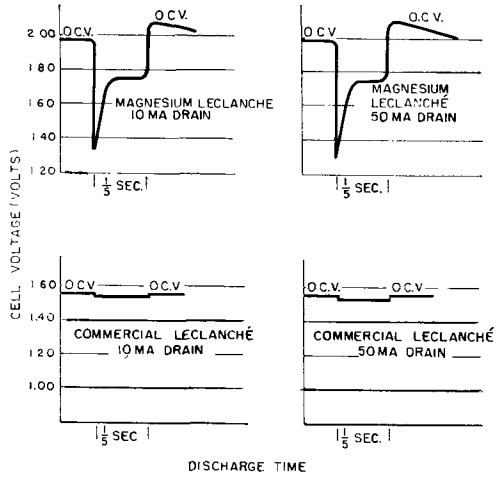

Fig. 2. Oscillographic measurements of change in voltage of AA-size Mg and Zn Leclanche type cells, subjected to 10 and 50 ma constant current drains. [Glicksman and Morehouse (24)].

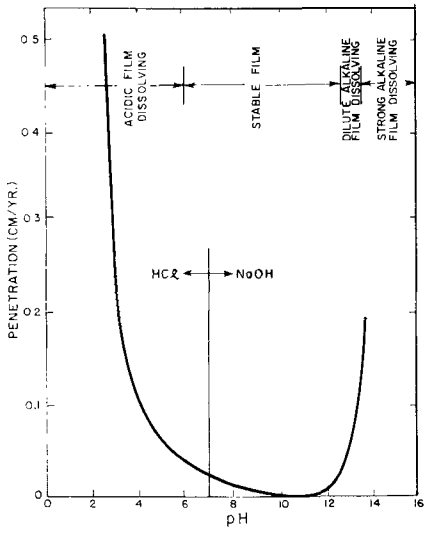

Fig. 4. Effect of pH on the corrosion of Zn by NaOH + HCl [Roetheli, Cox, and Littreal (27)].

under a variety of conditions must also be considered. Impedance measurements (26) for AA-size Mg-MnO_2 and Zn-MnO_2 cells show that the a-c impedance decreases with increasing current density and increasing frequency. At 400 cps the impedance of Mg cells is similar to that of Leclanché cells, whereas at 30 cps the impedance of the Mg cells becomes much greater than that of Leclanché cells at the lighter current drains. The high impedance of the Mg cells and their instantaneous voltage fluctuations with variations in power output, presents a problem as to the use of these cells in some electronic applications. Similar problems would be expected for Al dry cells.

Effect of Electrolyte

The influence of an electrolyte on the electrode potential and corrosion of a metal anode often depends on the nature of the protective film formed on the metal. In the corrosion process these films serve as barriers for the attack of the metal by the corrosive electrolyte. Frequently they are so effective that rapid corrosion proceeds for only a short time, and when the action of the films becomes a predominantly controlling factor, further corrosion is either prevented or the rate is reduced to a small value. Since the pH of the electrolyte has a marked effect on the solubilities and physical characteristics of this film, it is of great importance in choosing a particular electrolyte.

The influence of pH on the corrosion rate of Zn in mixtures of NaCl with NaOH and HCl (27) is shown in Fig. 4. It is seen that Zn is rapidly corroded by solutions whose pH is less than 6 or greater than 12.5 owing to the high solubility of the corrosion product formed. In solutions having pH values from 6 to 12.5 the low corrosion rates are attributed to the presence of adherent protective corrosion-product films. These films are precipitated probably because of the production of high pH's by the corrosion process in the liquid film adjacent to the metal.

In the Leclanché cell, with its NH_4Cl-$ZnCl_2$ electrolyte, the wasteful corrosion of Zn becomes a problem only on long-time intermittent use. For this electrolyte, which has an initial pH [2] of 4 to 5 depending on the concentration of the NH_4Cl and $ZnCl_2$, the corrosion of Zn can be expressed by

$$Zn + 2NH_4Cl = ZnCl_2 \cdot 2NH_3 + H_2 \qquad [1]$$

which represents the over-all reaction.

In alkaline dry cells, it would be expected that the corrosion of Zn would be much faster as the metal is shifted to more anodic potentials due to the low activity of metallic cations brought about by complex ion formation. For example, Zn exists in a sodium zincate solution as $[ZnO_2]^=$, or if the solution is less alkaline, as $[HZnO_2]^-$. However, in strongly alkaline solutions the Zn anodes owe their stability in large part to the addition of zincate salts to the electrolyte in substantially saturating concentration (4). The presence of the zincate ion decreases the rate of corrosion of the Zn anode by the mass action effect.

[2] The pH of the electrolyte increases during cell discharge, attaining values as high as 8 to 10 during heavy continuous service (28).

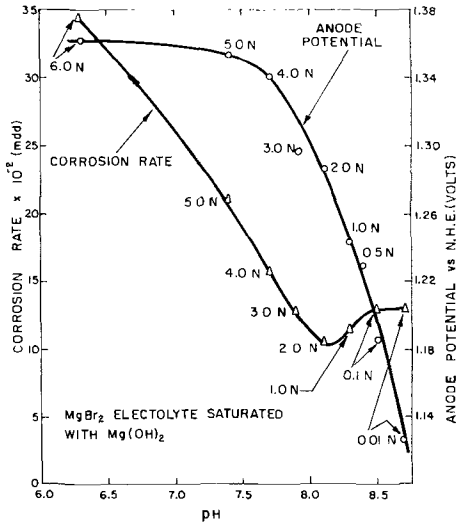

Fig. 5. Effect of pH on the corrosion rate and anode potential of a Mg AZ10A alloy dissolving anodically in various $MgBr_2$ electrolytes [saturated with $Mg(OH_2)$] at a current density of 2.0 ma/cm² [Glicksman (19)].

Aluminum is similar to Zn in that its oxide is soluble in both acid and alkali, and it is attacked by liquids of very high or very low pH value. Analogous curves to that of Zn in Fig. 4 have been obtained for Al, with a minimum near pH 7 (29).

The effect of pH on the corrosion rate of Mg in solutions of NaOH, HCl, and distilled water has been studied by Akimov and Rozenfeld (30). They report that, from pH 3 down, there is a sharp increase in the corrosion rate, while from pH 3 to 11 the corrosion curve slopes smoothly. At pH's of 11 and higher the protective film increases strongly in stability so that corrosion ceases above pH 11.5.

The effect of pH on the corrosion rate and electrode potential of a magnesium AZ10A alloy dissolving anodically in various magnesium bromide electrolytes is shown in Fig. 5 (19). The corrosion rate decreases approximately linearly with increasing electrolyte pH over the range of 6.3 to 8.1 pH units and, at pH's greater than 8.1, approaches a constant value, corresponding to an anode efficiency of 63%. In the weakly acidic solutions the potential varies very slightly with pH, while in the basic pH range the anodic potential falls rapidly with increasing pH and decreasing bromide ion concentration.

These results have been explained in terms of a MgO film on the anode surface, which is more easily penetrable at low pH values because the OH^- ion concentration is too low to maintain an effective oxide film. Thus, at low pH values, high corrosion rates and high anode potentials are observed. At high pH values the OH^- ion concentration controls the precipitation of the Mg^{++} ions produced at the anode, which according to Robinson (16) are precipitated so close to the anode as to stifle the anodic reaction. This results in lower potentials, a decrease in local corrosion, and excessive polarization of the anode.

In an intermediate pH range precipitation of $Mg(OH)_2$ occurs at a sufficient distance from the active anode areas to permit the anodes to function normally. It is in this pH range that other properties

Table III. Electrode potentials of Mg, Al, and Zn in typical electrolytes (potentials referred to a standard hydrogen electrode) [Akimov and Clark (33)]

Metal	3% NaCl		0.1N HCl		0.1N HNO_3		0.1N NaOH	
	1 min	rubbing	1 min	rubbing	1 min	rubbing	1 min	rubbing
Mg	1.418	1.500	1.622	1.596	1.270	1.220	1.086	1.484
Al	0.577	1.221	0.493	0.916	0.320	0.804	1.403	1.386
Zn	0.772	0.818	0.769	0.752	0.688	0.643	1.126	1.123

of the electrolyte, such as the anion present, exert a greater influence over the local corrosion rate and the anode potential.

The effect of the anion present in an electrolyte is often of great importance in dealing with anodes having a protective film. For Al in a solution containing 0.001M K_2CrO_4 and various potassium salts, it was found that small ions show the highest penetration of the oxide film, the order of penetration being Cl^-, Br^-, I^-, F^-, $SO_4^=$, NO_3^-, and $PO_4^{\equiv}$ (31). Evans points out that these differences may be connected not only with size but with solubility and diffusivity as well. What this means in terms of corrosion is seen by the corrosion measurements of Akimov and Glulskova (32) of Al in solutions of NaCl, Na_2SO_4, and $NaNO_3$. Measurements were made over the *p*H range of 0 to 14, and the *p*H being adjusted with NaOH or the acid according to the anion present. In the strongly acid and strongly alkaline regions the rate of corrosion was of the same order, but in neutral or acid solutions the rate of corrosion in the presence of chloride ions was as much as one thousand times greater than in the presence of the sulfate ion.

With metals coated with a protective film, such as Mg and Al, more anodic potentials may be produced by ions which can easily penetrate through this protective film. The fact that aluminum chloride has proved to be the most satisfactory electrolyte for aluminum-manganese dioxide cells (8) is no doubt due to the ability of the chloride ion to penetrate the oxide film and activate the electrode. However, because of their high penetrating power, chlorides are not acceptable for use in conjunction with Mg anodes, and a magnesium bromide electrolyte is used instead.

From an examination of the data in Table II, it is seen that variations in the *p*H of the solution have a pronounced effect on the magnitude of the electrode potential. For the Zn electrode which behaves reversibly except at very high current densities (3), these variations generally follow the Nernst equation. For Al and Mg the influence of *p*H on the electrode potential is essentially due to its effect on the oxide film. Thus, the potential of Al is most anodic in electrolytes of high *p*H in which the oxide film is soluble, but the rate of corrosion is excessive since Al owes its stability in electrolyte to its oxide film.

The influence of protective films on the electrode potentials of Mg and Al is illustrated in Table III (33). Measurements were made by first determining the electrode potentials of the metals in a conventional manner and then during a continuous cleaning of the surface by means of a carborundum rod, which removed much of the original protective film. It is evident that protective films are preserved or formed on metals only when the electrolytes have appropriate characteristics. Thus, a good protecting film is preserved on Al immersed in solutions of NaCl, HCl, and HNO_3, while the film dissolves in NaOH. On the other hand, good protecting films are formed on Mg in NaOH.

Effect of Anode Composition

When hydrogen evolution is the controlling factor in the rate of attack on a metal anode, the effect of low hydrogen overvoltage impurities are important. They produce cathodes from which hydrogen can be evolved rapidly without too much shift in anode potential, so that the conditions for continued corrosion are favorable. The effect of such impurities on the attack of Zn and Al in acid solution is described by Evans (34) while the work of Hannawalt and his co-workers (35) stresses the importance of certain impurities and alloy metals on the corrosion characteristics of Mg alloys in aqueous salt solutions.

For this reason, high-purity Zn (with respect to low hydrogen overvoltage metals) is used in the various zinc-alkaline and Leclanché dry cells. In the case of Mg, although the potential of pure commercial Mg is about 0.04-0.10 v more anodic than the Mg-Al and Mg-Al-Zn alloys, it has been found to be a less efficient anode material than the high-purity alloys (19). It is for this reason that the Mg anodes

Table IV. Electrode potentials* of Al-Zn alloys in various solutions (potentials referred to a standard hydrogen electrode) [Mears and Brown (14)]

Metal	1.0M NaCl	St'd Na_2SO_4	1.0M HCl	1.0M NaOH	1.0M Na_2CO_3	1.0M Na_3PO_4	St'd $Ca(OH)_2$	St'd $CaCO_3$	St'd $CaSO_4$
Al (2S)	0.51	0.16	0.54	1.13	1.01	0.98	1.20	0.70	0.43

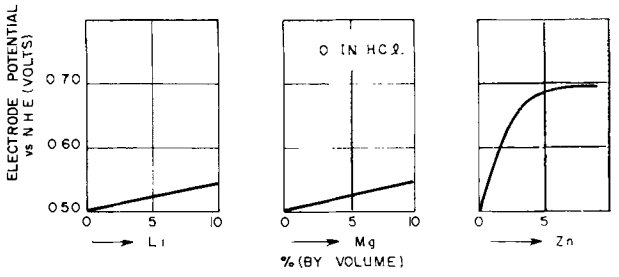

Fig. 6. Electrode potentials of the solid solutions Al-Li, Al-Mg, and Al-Zn. [Akimov and Clark (37)].

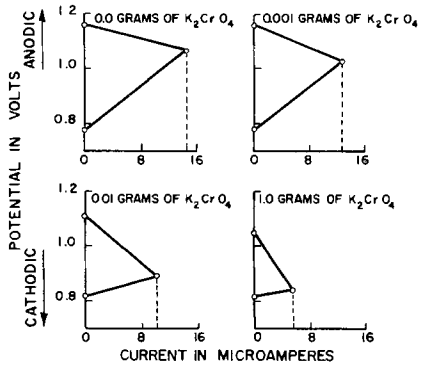

Fig. 7. Effect of concentrations of chromate on local cells on Al in 10% NaCl solution. [Mears and Brown (39)].

used in dry cells have been alloys such as AZ31 and AZ10, the former containing principally 3% Al and 1% Zn, while the latter consists of 1% Al and about 0.5% Zn. The effect of the various alloying ingredients on the anode efficiency of Mg has been reported in detail by Robinson (16). Essentially, the addition of Al permits the removal of the major cathodic impurity, Fe, by precipitation with Mn, while the addition of Zn results in better corrosion distribution and more uniform anode consumption. The latter effect is quite important, for a galvanic anode may operate quite efficiently, but, unless the corrosion is distributed uniformly, segregation losses may be so large as to make operating efficiency a matter of minor concern (36). Recently, it has been found (6) that the addition of small amounts of Ca to the Mg-Al-Zn alloys aids greatly in minimizing "delayed action."

Aluminum dry cells have been fabricated (8) using an Alclad anode which contains an Al 3S alloy on the outside and a 1% Zn-Al alloy on the inside. The effect of Zn is to increase the potential by about 0.1 v. The outer part of the Alclad anode is less anodic than the inner part and serves to prevent pin-hole perforations during normal cell service life and storage. The effect on the electrode potential of alloying Zn to Al has been studied by Mears and Brown (14). They measured the potentials of a series of Al-Zn alloys in various electrolytes and found that in alkaline solutions the potential of Al is high and is not raised greatly by the addition of Zn. However, from the data in Table IV, it is seen that in neutral solutions the addition of Zn raises the potential of Al, and in neutral solutions containing chlorides, the potentials of the Al-Zn alloys approach those of Zn. It was also found by Mears and Brown that, for equal quantities of current supplied by electrodes of such alloys, the Al-base alloys generally lost less than one-third as much weight as did the Zn. Therefore, from the standpoint of metal consumed, the Al-base alloys appear definitely superior to Zn.

Akimov and Clark (37) have made an extensive study of the electrode potentials of solid solutions and have classified them into groups according to the relationship between the potential of a solid solution and its composition. The typical group to which a given system of alloys belongs is defined principally by the nature of (*a*) the components and their interaction, (*b*) the solution, and (*c*) the protective film. They also found that no relationship existed between the potential of a component and the effect on potential produced by this component. Figure 6 presents the influence of three components, Li, Mg, and Zn, on the potential of a corresponding solid solution with Al. It is apparent that Zn shifts the potential of the solid solution in the anodic direction the most and Li the least. This effect is in the reverse relation to the potentials of these three metals.

Corrosion Inhibitors

The corrosion of an anode may be represented as consisting of two parts, an anodic reaction [2], and a cathodic reaction [3].

$$M \rightarrow M^{++} + 2e^- \qquad [2]$$

$$2H^+ + 2e^- \rightarrow H_2 \qquad [3]$$

As long as no external current is present to accept or supply electrons, the two reactions must occur at the same rate. Thus the problem of finding corrosion inhibitors which can retard the corrosion reaction may be accomplished by inhibiting either reaction [2] or [3].

In a dry cell it is desirable that the corrosion of the anode be inhibited by altering the cathodic reaction and not the anodic one, which is necessary for the production of electrical energy in the cell. For example, although organic compounds such as furfural and quinaldine were found to be effective in retarding the corrosion of Zn in dry cell electrolytes, dry cells made with them did not have the expected increase in shelf-life or electrical output (38). The inhibitors either reacted with the paste wall of the cell and decreased its strength or formed a high-resistant film on the Zn. In the latter case, these compounds probably form an insoluble precipitate over the entire surface of the Zn, which stifles not only the undesirable corrosion reaction but also the cell discharge reaction.

The use of soluble chromates, which function as anodic inhibitors, in the electrolyte has proved beneficial for cells during storage. However, they apparently become ineffective when current is drawn from the cell. For Zn the presence of $K_2Cr_2O_7$ in the electrolyte probably passivates the Zn with a very thin chemically resistant film, which, however, breaks down rapidly when current is drawn from the cell. According to Mears and Brown (39) the inhibiting action of sodium chromate on the corrosion of Al in NaCl solution is due to the polarization of local anodes. Chromate functions as an in-

hibitor because it increases anodic polarization in spite of the fact that it decreases cathodic polarization. The latter effect, which is illustrated by the polarization curves in Fig. 7, is to be expected because of the oxidizing properties of the chromate ion.

For Al dry cells which have an aluminum chloride electrolyte, ammonium and alkali chromate inhibitors are used. With potassium chromate a 1-sec delayed action is found, while the Al anode shows no delay with an ammonium chromate inhibitor (8). In general, the concentration of chromate required for protection becomes greater at high chloride concentrations than at low ones and becomes greater still if the temperature is raised (40).

In Mg dry cells, a lithium chromate inhibitor is used in the electrolyte and a small reservoir of an insoluble chromate e.g., barium chromate, is incorporated in the cathode mix to furnish additional soluble chromate as it is used up at the anode. For Mg the lowest chromate concentration which will give adequate corrosion protection is preferred, since delayed action increases with increasing chromate concentration. However, care must be taken since anodic inhibitors like the chromates are dangerous inhibitors when not added to the electrolyte in sufficient quantities. The reason for this is that the area undergoing anodic attack is greatly cut down. If corrosion velocity is controlled exclusively by the anodic reaction, then the anodic attack is cut down in the same ratio, and the intensity of corrosion remains the same. If, however, the velocity is controlled even in part by the cathodic reaction, the corrosion rate will be diminished to a less extent than the corroded area, and the intensity of the attack will be increased (41). In dry cells this localized corrosion causes perforation of the anode can, resulting in loss of electrolyte by leakage and evaporation.

On the other hand, cathodic inhibitors such as mercury are safe in general, as they decrease the total corrosion rate without causing the anodic area to become smaller. For Zn, amalgamation produces an electrochemical couple in which Zn is the anode, but the activation overpotential of hydrogen on mercury is so high as to inhibit the cathodic reaction [3], and thus the corrosion reaction is greatly curtailed. The quantities of mercury than can be used effectively are very limited, seldom exceeding 0.25% because of the embrittlement and loss of strength of the amalgamated metal (1).

For Mg and Al, amalgamation changes both the hydrogen overvoltage and the anodic polarization for the active metal dissolution. The high potentials observed with amalgamated Al and Mg anodes are attributed to the partial removal of the oxide film by amalgamation. For Al this results in a greatly increased rate of corrosion and is therefore undesirable; however, results in this laboratory for Mg dry cells show that the effect of mercurous salts in the electrolyte may be beneficial, especially at low current drains. The use of mercury has a further advantage in that it reduces cell impedance by its interference with the protective oxide coating.

The shelf life of a cell can be considerably increased by storage below ordinary temperatures. The main reasons for this are the lower rates of the corrosion reactions and the increased hydrogen activation overpotential which are associated with decreased temperature. For example, assuming the temperature coefficient of hydrogen activation overpotential at a mercury cathode to be −2.5 mv/°C, Potter (42) calculates that for an amalgamated Zn anode, decreasing the temperature from 40° to 9°C should decrease the current density at the mercury cathode approximately 4.5 times. Thus the shelf life of a cell should be at least 4.5 times as great at 9° as at 40°C. This is in agreement with experimental results.

Cathode Performance

The advantage to the use of a particular anode-electrolyte combination often lies in the effect of the electrolyte on cathode performance. An example of this is illustrated by the coulometric data in Fig. 8 for an electrolytically prepared manganese dioxide.[3] In the more acidic aluminum chloride electrolyte the MnO_2 operates at a potential 0.4-0.5 v higher than in the NH_4Cl-$ZnCl_2$ electrolyte and gives twice the ampere-minute capacity to an end voltage of +0.25 v. This capacity corresponds to a theoretical two-electron change per molecule of MnO_2, indicating that reduction takes place in accordance with the following equation:

$$MnO_2 + 4H^+ + 2e^- = Mn^{++} + 2H_2O \qquad [4]$$

It is also seen that the gain in anode potential derived from the use of a strongly alkaline electrolyte with Zn is offset by the lower operating potential of MnO_2 in this electrolyte. Assuming an end voltage of −0.40 v[4] for MnO_2, the ampere-minute capacity

[3] 85% manganese dioxide.

[4] The potential of Zn is approximately 0.75 v in acidic electrolyte and 1.3 v in strongly basic electrolyte, so that to allow for end voltages of 0.90 v in actual dry cells, half-cell end-potentials of +0.25 and −0.40 v are taken.

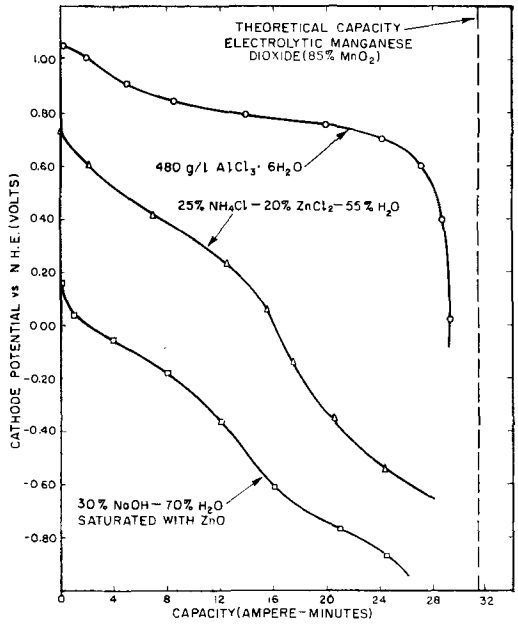

Fig. 8. Effect of electrolyte on the performance characteristics of an electrolytic MnO_2 cathode material.

obtained corresponds to a one-electron change per molecule of MnO_2 in accordance with the following equation:

$$2MnO_2 + H_2O + 2e^- = Mn_2O_3 + 2OH^- \quad [5]$$

It is interesting to note that, under these conditions of discharge, comparable capacities are obtained from MnO_2 in the NaOH and NH_4Cl-$ZnCl_2$ electrolytes. For the use of cathode materials such as mercuric oxide and cupric oxide, however, strongly alkaline electrolytes are necessary because of the solubility of these oxides in acidic solutions.

Conclusions

On the basis of watt-hour capacity per gram, Al and Mg are more attractive anode materials than Zn. The important progress which has been made in the development of Mg dry cells indicates the potential advantages of this anode. However, there are several problems associated with the use of Mg. These are: cost, "delayed action," high impedance, and loss in cell capacity on light intermittent tests. These problems are gradually being solved, and it is predicted that Mg dry cells will achieve commercial significance in the near future. For Al dry cells more research is needed to improve the performance on intermittent tests, as well as to ascertain the shelf life characteristics.

Acknowledgments

The author wishes to express his appreciation to G. S. Lozier and C. K. Morehouse for their helpful suggestions.

Manuscript received Nov. 3, 1958. This paper was prepared for delivery before the Ottawa Meeting. Sept. 28-Oct. 2, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Technical Feature

Current Problems in the Production of Magnetic Ceramics

George Economos

Laboratory for Insulation Research, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

Reproducibility of the electrical and magnetic properties while adhering to mechanical tolerances is still the main difficulty in quantity production of magnetic ceramics. This problem is discussed from a developmental viewpoint with suggestions for improving present methods. Older production schemes are compared with newer techniques.

The field of magnetic ceramics has grown by tremendous proportions since its rebirth after World War II. The work by Hilpert (1), Kato (2), Snoek (3), and others came at a time when the need for such materials was not urgent. Television and other high-frequency applications have now brought these materials to the forefront. One of the major difficulties, as in any young industry, is the lack of sufficiently trained technical personnel and of the required "skill in the art." The picture is improving, however, because of the trend in modern ceramics toward a more scientific basis.

The innumerable variables involved in the fabrication of a useful ceramic, from the basic raw materials to a finished electronic component, make it a formidable task to acquire the needed control throughout the production scheme. It must be borne in mind that it is necessary not only to make a product with the proper electrical and magnetic properties, but one that will also meet rather rigid mechanical tolerances of size and shape. The complexity of the problem requires the pooling of many talents. Co-ordination of research and production activities is necessary to utilize the varied skills of the electrical engineer, physicist, chemist, mechanical engineer, ceramist, chemical engineer, crystallographer, and the industrial engineer. There is still considerable inertia in the industry which keeps it from discarding some of the older methods. Present difficulties show the necessity for employing newer and even novel techniques without regard to what is the generally accepted practice.

Achieving reproducibility in the final sintered product necessitates accurate control in all the processing steps. By giving a generalized picture of the various factors involved in the manufacture of these shapes, a critical evaluation of the techniques can be made with suggestions for possible substitutions.

Processing Techniques

General Survey

The "compounding" of ferrites, magnetoplumbites, and other magnetic ceramic materials involves the reaction between various components in the solid state to yield a homogeneous product suitable for forming and sintering into a dense form. A simple outline of the steps required is given below:

1. *Powder preparation*: analysis of the raw materials, weighing the components, mixing, and calcining (reacting).
2. *Ceramic body preparation*: grinding of the calcine, addition of the lubricant and binder, granulating, and drying.
3. *Specimen preparation*: molding, firing (sintering), and testing. An examination of the various steps will give a better insight into the types of problems encountered.

Raw Materials

The choice of raw materials is important in the successful preparation of a homogeneous compound. Extensive information has been compiled on the reactivity between solids (4), which shows that the nature of the reacting species often governs the rate of compound formation. With but few exceptions, the commercial practice is to react the constituent oxides at high temperatures. High-purity oxides are available at relatively low cost, but in using them the manufacturer can defeat one of the prime requisites for high reactivity: high surface area and high-defect crystal structure. Precipitation techniques (5) are available to achieve this end, but they are not competitive at present and find only limited use.

The oxides generally used are products of some decomposition process. Why use the oxide when the original material offers better opportunity for mixing and reacting? This possibility has not been exploited to any extent, even though it could be competitive with the oxides. The result would be a reduction of the calcining temperature and the production of a more friable material for easy grinding.

Comminution Processes

Grinding of the calcine is a major operation in the ceramic body preparation. Ball mills have long been

used, but not until recently have newer type units found extensive use. The attritor and the vibratory ball mill cut the time to a fraction of that needed before. The micronizer (high velocity interparticle impact by air or steam pressure) has not received extensive attention in this field. This unit could accomplish in the dry state what the other methods do in the wet, thus eliminating the expensive dewatering step usually needed.

Dry-Press Body Preparation

The effort expended in the preparation of the dry-press body pays dividends in the behavior of the materials at the presses and in the sintering steps. Lubricants and binders (one or both) are added to the milled material to impart the needed flow properties to this nonplastic material. This is generally done by blending-in these additives in the semiplastic state. For a given amount of additive, the pressing behavior is related to how well each particle is coated by the blending process. The most obvious method is one in which the additives can be dispersed effectively and brought into intimate contact with the solid material. Emulsions are highly dispersed systems, but a molecular or ionic solution is even more so. Using lubricants and binders which are soluble in a liquid medium permits wetting of the solid particles and, on subsequent evaporation of the solvent, a film of the solute remains on the particles.

A word of caution is needed here. In the evaporation of the solvent, it is essential that agitation be continued until evaporation is complete, otherwise capillary activity brings the solute to the surface and destroys the highly dispersed condition originally present. The most effective method to achieve this is to dry the wet mix quickly in as highly divided state as possible. Spray drying effectively accomplishes this. This unit eliminates the dewatering and the binder-blending step after grinding and produces granules suitable for pressing.

Pressing

Most of the problems in the pressing operation usually can be traced to flaws in one of the previous processes. Proper die design and loading, pressing pressure and speed, and other mechanical effects must be worked out for each shape and composition. Most of the difficulties at this stage of manufacture will be overcome by the proper choice of ceramic body preparation.

Firing

The firing or sintering of the molded shapes can be regarded as a three-stage process: (*a*) heating, (*b*) soaking, and (*c*) cooling. The initial stage of the heating period is the careful removal of the additives by evaporation or by burning. The evaporation is not affected by the furnace atmosphere, whereas the burning requires oxidizing conditions. Obviously, the choice of binder will be critical because the mode of its removal can be detrimental to the body, depending on the composition and its behavior in various furnace atmospheres. This initial portion of the heating cycle progresses at a slower rate compared to the rate which follows, generally at more than 300°C.

The proper regulation of the remainder of the heating cycle, the soak period, and the cooling rate will be governed by the size and shape of the pieces, and by the desired end properties. The usual difficulties, such as cracks due to too rapid burn-out and specimen shattering caused by sharp thermal gradients during heating and cooling, must be overcome. Added to this is concern for the oxygen stoichiometry in the fired piece. No set rule can be made on the optimum firing conditions, because these vary widely with the type of material and its properties. Each composition must be treated separately. Tunnel kilns are most efficient for large volume production; however, for special heating and cooling cycles and atmospheres, batch-type kilns are more suitable.

Comparison of Some Production Schemes

Having considered some of the more critical processes and their associated problems, a few typical production flow sheets may be examined and compared. The "dry-process" (Fig. 1) is the most common (5). Two dewatering steps are required: the first is essential for proper mixing of the component oxides, but the second can be eliminated by using the micronizer. This speeds the process and, in the long run, reduces costs. Figure 2 shows the flow sheet of a "wet-process" plant (5) in which the second wet milling could be replaced also. Use of decomposable salts of the cations can be incorporated at the beginning of both these arrangements.

Highly specialized schemes, such as that using the atomizing burner (6) (Fig. 3), cut down the re-

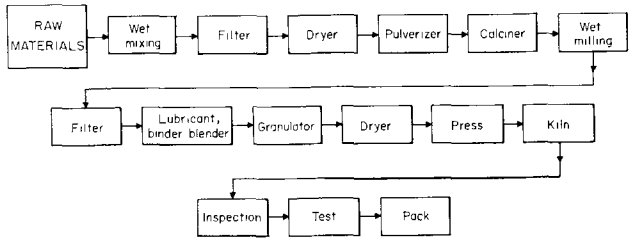

Fig. 1. "Dry-process" flow sheet

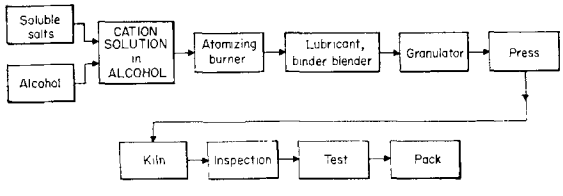

Fig. 3. Atomizing-burner flow sheet

quired number of steps. At present, this technique has found application only where its high cost and low yield can be justified by the special properties of the end product, such as microwave ferrites.

Not to be omitted from this discussion is the present status of the evaluation of the final product. Numerous organizations (Institute of Radio Engineers, Metal Powders Association, American Society for Testing Materials, etc.) have committees which draw up evaluation parameters with acceptable test procedures for these materials. Such factors as shape, size, application, measurement technique, and so on, enter into the picture. Because of the multitude of these factors, no one choice can be expected to win wide acceptance. Some tentative agreements have been reached, but much has to be done before the field is properly covered.

Manuscript received Dec. 1, 1958. This paper was prepared for delivery before the New York Meeting, April 27-May 1, 1958. Work was sponsored by the U. S. Office of Naval Research, the Army Signal Corps, and the Air Force.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Brief Communications

The Ubiquity of Localized Corrosion

R. B. Mears

Applied Research Laboratory, United States Steel Corporation, Monroeville, Pennsylvania

For decades localized corrosion has appeared to be considered more mysterious than uniform or general attack. Many papers have been written pointing out various causes of localized attack, usually implying that uniform corrosion was the expected form and that localized corrosion was exceptional and, therefore, required a special explanation. It now appears that this viewpoint should be changed. Localized corrosion is the form to be expected and uniform corrosion is the form that requires explanation.

Even single crystals of very pure metals contain crystal imperfections. Read and Shockley (1) proposed that localized corrosion (etch pits) occurred at edge dislocations in high-purity aluminum. They stated, "We have proposed that each etch pit originates at a dislocation, where the free energy of the stressed material is somewhat higher than elsewhere; the pit then grows to large size so that it can be observed optically."

Later Vogel, Pfann, Corey, and Thomas (2) showed that etch pits developed in high-purity single crystals of germanium and that the measured spacing of these pits correlated well with spacings predicted from x-ray diffraction. They concluded that individual etch pits are nucleated by single dislocations, with the pit being formed where the dislocation singular line intersects the surface.

Etch pits at dislocation sites have been observed on several other high-purity metals, including iron (3, 4). It now appears that all commercially available metals contain dislocations and that, under appropriate conditions, localized corrosion (etch pits) can develop at dislocation sites. The reason generally given for the formation of these etch pits is still essentially that proposed by Read and Shockley as quoted earlier. However, it should be pointed out that very specific corroding solutions (etchants) must be used to reveal dislocation sites. The majority of corrodents do not give this type of attack. Thus, although following Read and Shockley, we can explain satisfactorily the localized corrosion that occurs in carefully selected etchants, it is much more difficult to explain the more commonly encountered uniform attack.

To complicate matters still further Boswell (3, 4) has pointed out in a private communication that, with the specific etchant he used to reveal dislocation sites in high-purity iron, it was necessary to have between 0.001% and 0.01% carbon in the iron or proper resolution of the dislocation sites did not occur. [Apparently impurity segregation is also necessary for etch pits to be revealed in high-purity Al (5) and Zn (6).]

Metallographers have known for years that grain boundaries, different crystal faces, and dissimilar phases in polycrystalline metals or alloys can be corroded or etched at different rates. Use is made of this "localized corrosion" in examining polished metallic specimens under the microscope.

All metals or alloys used in quantity by industry are polycrystalline and contain dissimilar phases to a greater or lesser extent. The expectation would be, therefore, that all metallic articles when exposed to corrodents would develop localized corrosion.

A New Separator for the Aluminum Dry Cell

N. C. Cahoon[1] and M. P. Korver

Research Laboratories, National Carbon Company, Division of Union Carbide Corporation, Cleveland, Ohio

ABSTRACT

A new and improved separator medium for the aluminum dry cell is described. It provides an adhesive contact with the anode and a satisfactory electrolytic contact with the cathode. The method by which this separator is prepared involves a new technique which is described. The separator layer significantly improves the keeping quality and delayed service performance of the aluminum-manganese dioxide cell.

Aluminum as an anode for primary batteries has received periodic attention during the past 30 years. Recent studies with renewed interest by Stokes and Ruben have shown greater progress (1, 2). As an anode for a battery system, aluminum looks particularly attractive for several reasons. Electrochemically, the aluminum anode theoretically consumes only 0.336 g of metal per ampere hour of electrical output, or about 27% of that consumed by the zinc anode. In addition, drawn aluminum cans offer attractive economic features.

Since any new system imposes many problems, a considerable amount of study was required with this particular system because of the very acidic nature of the altogether new electrolyte employed. Stokes has reported considerable progress on studies of the anode, the cathode, and the electrolyte. These studies have yielded the "Alclad"-type anode and the chloride-chromate type electrolyte (1, 3).[2] Our studies have been concerned primarily with the selection of an improved separator for this system. An effective separator medium is essential if a battery is to operate satisfactorily and to possess acceptable keeping quality.

Experimental

This study has followed a pattern somewhat similar to that previously described for separator studies in the Leclanché cell (4, 5). As in the Leclanché cell, it was deemed advisable to select a separator which would possess the following properties: (*a*) A medium which would contact the cathode satisfactorily and form a positive adhesive contact with the anode; (*b*) A medium which would be compatible with the battery components and nonreactive for a reasonable period of time, i.e. at least one to three years; (c) A separator which would possess adequate wet strength to allow ease of cell assembly.

It has been shown (4) that the usual cereal paste does not meet these requirements satisfactorily, since both starch and flour hydrolyze and break down in an acid electrolyte. The choice of possible separators, therefore, must be made from the field of other natural or synthetic colloids.

First, one must select one or more colloids which satisfy items (*a*) and (*b*) above. Since the depolarizer is the same in both systems, with the background knowledge of the stability of various colloids with manganese dioxide, one may choose colloids which might satisfy item (*a*) when used with an aluminum anode. This group included water soluble methyl cellulose, two types of hydroxypropyl methyl cellulose, Lytron X-887,[3] polyacrylamide 50, locust bean gum, and gum Karaya. Self-supporting films of all colloids of this group except Lytron X-887, locust bean gum, and gum Karaya were prepared. These three materials were difficult or impossible to prepare as self-supporting layers. Therefore, a new technique was used to incorporate the gums into an acceptable separator layer. It involves the suspension of the powdered colloid in a resin solution and is thereby designated the resin-bonded separator. The resin, e.g., polyvinyl acetate, is dissolved in a volatile solvent, e.g., acetone. The colloidal material chosen is then dispersed in this solution. The suspension may be coated onto a paper possessing high wet strength, an anode metal, film, or other support, and dried. In this application high wet strength paper was used.

These prepared films were exposed to the chloride-chromate electrolyte solution, the composition of which is presented in Table I. Periodically they were examined to determine their behavior in the electrolyte. Those materials which absorbed electrolyte to become gel-like and tacky to the touch were locust bean gum, gum Karaya, and polyacrylamide 50. At the end of one week these same materials appeared to have the same bibulous characteristics. The other materials appeared only slightly damp and did not appear to be bibulous enough to act as satisfactory separator media.

Experimental cells were made evaluating these three separators and also, as a direct comparison, a filter-paper separator.[4] A 5:1::manganese dioxide: acetylene black mix ratio was used with the electrolyte formulation given in Table I. Natural manganese dioxide ore from the African Gold Coast was the depolarizer used. D-size experimental units were assembled which possessed equal weights of the same mix so that the only variable introduced was the different separators. A cross-sectional view of the construction used appears in Fig. 1. In addition, one group of cells was made with manganous chloride electrolyte (2) and assembled with the locust bean gum separator. Comparison of these formulations appears in Table II.

Discussion of Results

Comparative service data on these experimental batteries are presented in Table III. It may readily be seen from these data, especially on delayed and longer term tests, such as intermittent, that the improved separators show a significant advantage. These data show that, although the cells made with manganous chloride give somewhat better initial service than those with the chloride-chromate electrolyte, they do not maintain this service level. The

chloride-chromate electrolyte, because of the chromate present, would be expected to possess better keeping quality. With the improved separator medium present to maintain adequate anode contact coupled with satisfactory stability of the separator, it is evident that the aluminum dry cells will operate satisfactorily even after 12 months shelf storage at 21°C.

The mechanism by which the resin-bonded separator operates is twofold. As the separator absorbs electrolyte the polyvinyl acetate bond hydrolyzes to form polyvinyl alcohol which absorbs electrolyte of the composition, given in Table I, to a very limited extent. This action releases the colloid present, e.g., locust bean gum, which then absorbs electrolyte. This combination provides a stable adhesive mass which readily contacts the aluminum anode, allowing the battery to have both good keeping quality and delayed service characteristics. The paper serves a dual purpose. It serves as a carrier for the resin-bonded film and as a barrier layer to maintain the colloid layer at the anode.

Although only a limited number of batteries was available with the polyacrylamide film, which was not of the resin-bonded type, the data show that it is a satisfactory film separator for this system. These data show that it is not completely the equivalent of the resin-bonded gum separator but could be employed if less stringent service requirements are demanded.

Conclusions

It is believed that these studies have contributed materially to the improvement and advancement of the aluminum dry cell. The establishment of a satisfactory separator medium removes one additional limitation of this system. The discovery of a separator which will provide adequate stability and improved keeping quality should permit further progress and study of the other phases of the aluminum-manganese dioxide system.

Manuscript received Dec. 5, 1958. This paper was prepared for delivery before the Ottawa Meeting, Sept. 28-Oct. 2, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

On the Internal Resistance of Dry Cells

A New Pulse Method

Ralph J. Brodd

National Bureau of Standards, Washington, D. C.

ABSTRACT

The internal resistance of Leclanché cells of various sizes and manufacture was measured by imposing a current pulse on the cell and observing the instantaneous *IR* drop in the cell. The internal resistance of Leclanché cells was determined also as cells were discharged on various standard tests and on continuous or momentary current drains. The increase in internal resistance of the cells on discharge depended on the type of discharge, cell size, and manufacture. The use of the internal resistance of a Leclanché cell to estimate the life expectancy of the cell is suggested.

The internal resistance of Leclanché cells and its measurement have been controversial subjects for many years. In one of the oldest and probably the most universal method (1) the internal resistance of a cell is determined by employing the equation:

$$\text{Internal resistance} = \frac{V - V'}{I} \qquad [1]$$

where V is the open-circuit voltage of the cell and V' is the voltage when current I flows in through the cell. The resistance measured in this fashion is a sum of the resistances of all parts of the cell plus the resultant of any emf including polarizations generated in the cell. Also the resistance depends on the current, age of the cell, temperature, and degree of exhaustion of the cell. In a similar method in wide use today (2) the short-circuit current (SCC) is measured with a critically damped ammeter having a total resistance including the leads of 0.01 ohm. In this instance the ratio V'/I in Eq. [1] is replaced by 0.01. The Wheatstone bridge and the method of charging capacitor are other d-c methods that have been used to measure the resistance of a cell.

Recently, a new d-c method for measuring the internal resistance of dry cells has been reported (3). The *IR* drop of a cell occurring in 10^{-3}-$^{-4}$ sec was measured on an oscilloscope when current pulses were drawn from the cell. The internal resistance of the cell could be calculated by applying Ohm's law, knowing the current in the pulse. In recent years a-c bridge techniques (4-6) for measuring resistance have been employed in an effort to eliminate errors caused by polarization of the electrodes of a cell.

A method for measuring the internal resistance of

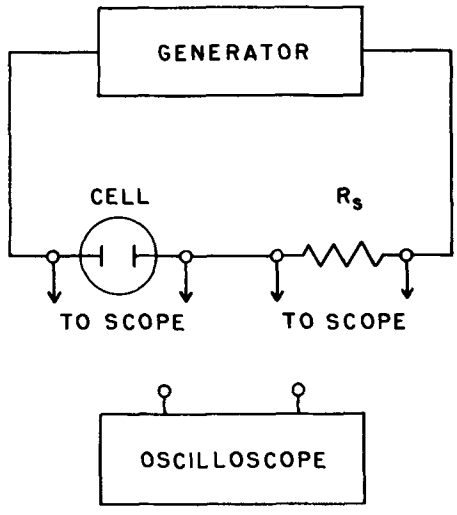

Fig. 1. Schematic diagram of circuit

dry cells is described below wherein the errors caused by polarization of electrodes are reduced to a minimum. The usefulness of this method will be illustrated by measuring the internal resistance of Leclanché cells as they are discharged on momentary drains, on various standard tests, and through constant resistance.

Experimental

A schematic diagram of the circuit used to determine the internal resistance of Leclanché cells is shown in Fig. 1. The pulse generator was a Hewlett-Packard Model 212. The oscilloscope was a Tektronix Model 532. The resistance standard was a deposited carbon resistor of known value. To measure the internal resistance of a Leclanché cell, the oscilloscope leads were connected across the dry cell in Fig. 1 and the instantaneous *IR* drop measured at the trailing edge of the pulse. The instantaneous drop of the oscilloscope pattern occurred in 10^{-7} sec or less. The oscilloscope was connected across the resistance standard, the instantaneous *IR* drop of the resistor was noted, and the current in the pulse was calculated by applying Ohm's law. From this value of the current in the pulse, the resistance of the dry cell was calculated by applying Ohm's law to the *IR* drop in the cell in the first measurement. Typical oscilloscope traces for these measurements are shown in Fig. 2.

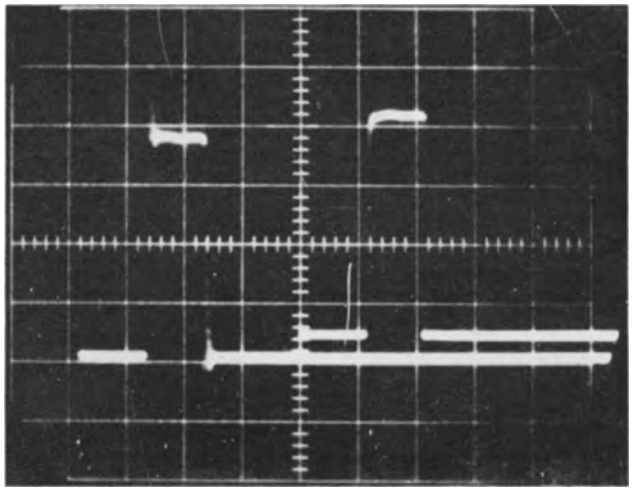

Fig. 2. Typical oscilloscope traces: trace of current pulse through cell on left (0.05 v/cm), trace of current pulse through standard resistor (10 ohms) on right (5.0 v/cm), pulse length 3 μsec.

The effects of both momentary and continuous current drain (in addition to the constant drain by the generator of about 10^{-4} amp) on the internal resistance of Leclanché cells were also investigated. In these cases a loading resistor was connected across the cell. The current drain was calculated by measuring the voltage drop in the resistor with a potentiometer and applying Ohm's law. The internal resistance of the cells was determined in the fashion described above. However, in this case the loading resistor and cell were in parallel. In investigating the effect of momentary drain, measurements of the internal resistance and current drain were made as rapidly as possible so the capacity of the cell would remain essentially unchanged. Measurement of the highest drain was made first; the lowest drain was made last. This procedure was then reversed. The internal resistance with no load was measured after each current drain.

The internal resistance of Leclanché cells was determined also as the cells were discharged on the general purpose 4-ohm intermittent test (4-ohm test), the general purpose 2.25-ohm test (2.25-ohm test), and the light industrial flashlight test (LIF test) (7).

Results and Discussion

When the resistance of a circuit, in this case a Leclanché cell, is determined it is necessary to ascertain whether the measured resistance includes other impedance components than the purely resistive component. In order to establish that the resistance of Leclanché cells measured by the pulse technique had the characteristics of a purely resistive element, the effects of varying various experimental parameters on the value of the measured internal resistance of the cells was investigated first. The current in the pulse was varied from 0.008 to 3.96 amp with no change in the internal resistance of the cell. Likewise there was no change in the internal resistance of the cell when the direction of the pulse was reversed or when the repetition rate of the pulse was altered from 100 to 5000 pulses per second. The measured internal resistance of the cell did not change when the pulse length was varied from 1 to 10 μsec. Thus, the measurement of the internal resistance of Leclanché cells by this method appears to fulfill the conditions for the measurement of the resistive portion of the cell; that is, the current pulse and the voltage pulse have the same shape and the ratio *E/I* is independent of variations in magnitude and sign of the current, repetition rate, and length of the pulse.

The internal resistance of fresh undischarged AA-, C-, and D-size cells (R_i) is found in Table I. The group number has no significance from one cell size to the other. Also reported in Table I are the open-circuit voltage (OCV), the short-circuit current

(SCC), the performance on test (P.T.), and the internal resistance at the cutoff voltage (R_f) of the cells when discharged on the LIF, 2.25-ohm, and 4-ohm tests. All values in Table I are the arithmetic mean of three or more cells. The values of the R_f should be considered only as an indication of the internal resistance of the cell at the cutoff voltage as some of the cells were discharged past the cutoff voltage before their internal resistance could be measured. An examination of Table I fails to reveal a general relation between R_i and R_f of a cell and its performance on test. In general, the SCC increases as the internal resistance decreases. It is also noted that the internal resistance of all the cells increased on discharge. The internal resistance computed from the SCC and OCV is always larger than the internal resistance measured by the pulse method.

The effect of current drain of momentary duration on the internal resistance of an undischarged cell is shown in Table II. After each drain, the internal resistance of the cell with no load was measured. The internal resistance with no load remained constant. The internal resistance of the cells in Table II remained essentially constant at all current drains with a slight tendency to increase at the highest current drain. These results do not confirm the work of other investigators (3, 8) who reported that the internal resistance of Leclanché cells decreased as the momentary current drain increased.

These investigators interpreted their results by postulating an adsorbed film of hydrogen on the zinc electrode. It is possible that the oscillations observed at the leading edge of the pulse in Fig. 2 are caused by the destruction of an adsorbed film of hydrogen on the zinc electrode. If this is the case, there is no conflict in results.

The discharge behavior of AA, C, and D cells from one manufacturer was determined. The typical behavior of AA- and C-size cells as they were discharged on the 4-ohm test is shown in Fig. 3 and 4, respectively. The typical behavior of D-size cells as

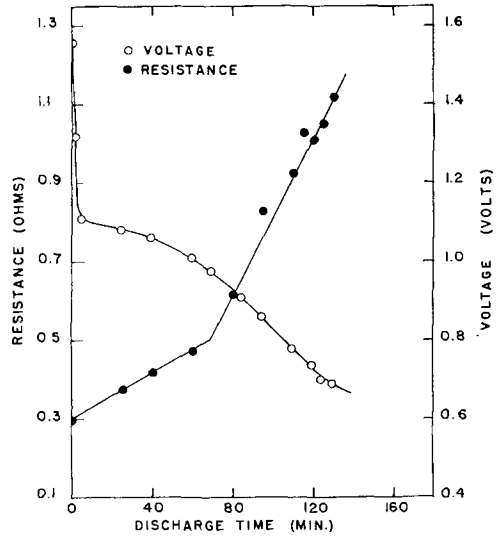

Fig. 3. Behavior of AA-size cell on the 4-ohm test.

they were discharged on the LIF test is shown in Fig. 5. A summary of the results of discharges of 6 cells of each size is given in Table III, where the arithmetic mean, A.M., and the standard deviations, σ_s, are given for P.T., R_i, R_f, the change in resistance during discharge, ΔR, the slope of the plot of discharge time vs. internal resistance, S. In the case of AA- and C-size cells the discharge time, T_b, internal resistance, R_b, and voltage, V_b, are given at the point of departure from initial linear behavior of the internal resistance-discharge time plot. D-size cells were discharged past 0.6 v on the LIF test with no change in the slope, S. P.T. for control samples of each size cell was within 3% of the values in Table III.

In Fig. 6 the behavior of the internal resistance of AA-size cells is shown as they were discharged continuously through the fixed resistances noted in the figures. The arrows indicate the point at which the cell voltage was 0.8 v. If the discharges were stopped at any point, the internal resistance of the cell remained constant even though the cell voltage recovered to its normal value. C-size cells exhibit behavior similar to that for AA-size cells shown in Fig. 6.

A common feature of the discharges through fixed resistances or on the standard tests was the increase in the internal resistance of the cells as the discharge continued. In general, it was found that the lower values of R_i corresponded to the lower values of R_f. One of the most interesting possibilities that the data in Table III suggest is the use of the internal resistance of a cell to estimate life expectancy for a particular test or use. Unfortunately, the variation of the internal resistance of Leclanché cells with group found in Table I makes impossible any general statements. It appears possible, however, to make a calibration for each group of cells, as Table III and Fig. 3, 4, and 5 illustrate, and then to use the calibration for predictions of life expectancy. For instance, if the internal resistance of D-size cells of the same group as those in Table III increased 0.113 ohms from R_i (refer to Table III and Fig. 5) it would have a life expectancy of 324 min on the LIF test. Similar predictions can be made for the C-and AA-size cells allowing for the change in slope of the plot of time on discharge vs. internal resistance. Of

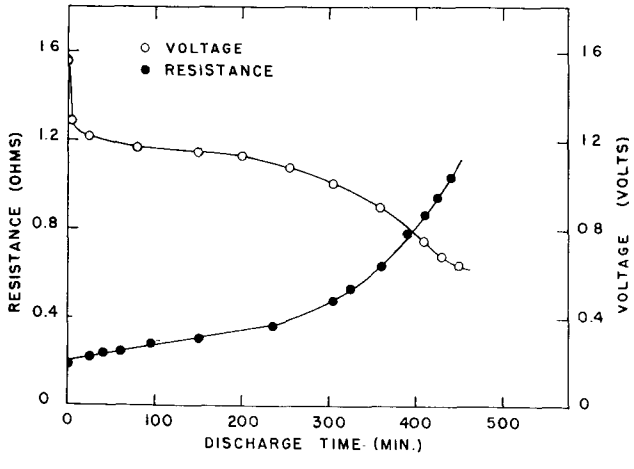

Fig. 4. Behavior of C-size cell on the 4-ohm test.

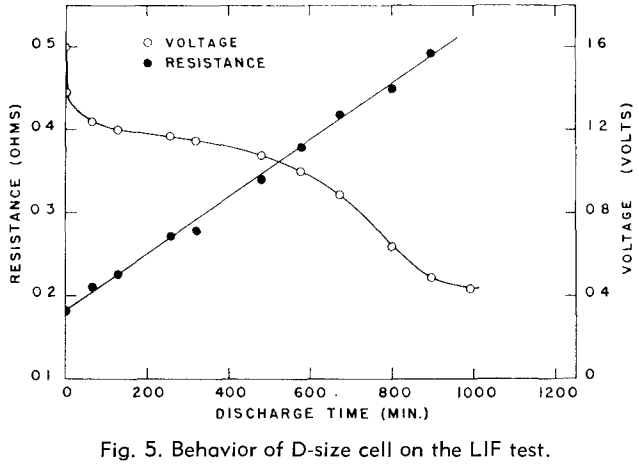

Fig. 5. Behavior of D-size cell on the LIF test.

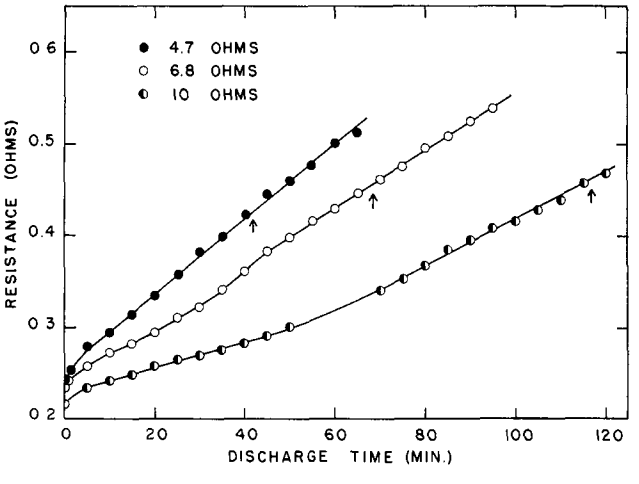

Fig. 6. Behavior of AA-size cells discharged continuously through 4.7, 6.8, and 10 ohms.

course, the predictions are subject to the same statistical errors as the calibration. Investigations are under way to determine if the decrease in life expectancy with age can be predicted from measurements of the internal resistance of the cell. Recently (9) a method for predicting the capacity of a battery has been reported. It is based on repeated short discharges measuring the current and voltage of the battery during discharge.

Iodine-Activated Solid Electrolyte Cell for Use at High Temperature

Joseph L. Weininger

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

Iodine-activated miniature cells, Ta(I_2)/AgI/Ag, with solid silver iodide as the electrolyte, have been studied at 150°-550°C. In this range of temperatures the cells have the following characteristics: complete conversion of the consumable silver anode into its electrical equivalent, open-circuit voltage of 0.67 v, short-circuit currents up to 18 ma, capacity of 10 ma-hr, energy output up to 5 mw-hr/cell, a definite activation temperature obtained by selecting a suitable source of iodine vapor, and indefinitely long shelf life below that temperature. The size of the smallest cells is 0.15 cm in diameter and 0.5 cm in length.

Recently halogen-activated solid-electrolyte cells were discussed from a general viewpoint with regard to their history, mechanism, and applications (1). They have the advantage of simpler construction over cells with liquid electrolytes. By reducing the size and weight of individual cells, batteries can be miniaturized. However, solid electrolyte cells have high internal impedance which limits the short-circuit currents to a few microamperes at room temperature. The high-temperature modification α-AgI, which is stable in the range of 146°-552°C is one of the few ionic compounds with large ionic conductivity. Therefore, a study was made of primary cells with an α-AgI electrolyte in that temperature range.

Tantalum-Tube Cells

Figure 1 is a schematic drawing of the cell. The cathode is a tantalum tube containing a "cathode mix," which is a source of the cathode reactant, iodine vapor. The cathode mix may be itself iodine or a suitable chemical system which will produce iodine at a definite elevated temperature. In the course of assembly, the tube is sealed with silver iodide in a stream of dry nitrogen. A silver anode is imbedded then in the iodide, the source of iodine is added, and the other end of the tube is sealed by cold-welding under vacuum. A photograph of one of the first models, which was about 9 mm long, indicates the possibility for miniaturization (Fig. 2). The silver anode can be seen as it protrudes out of

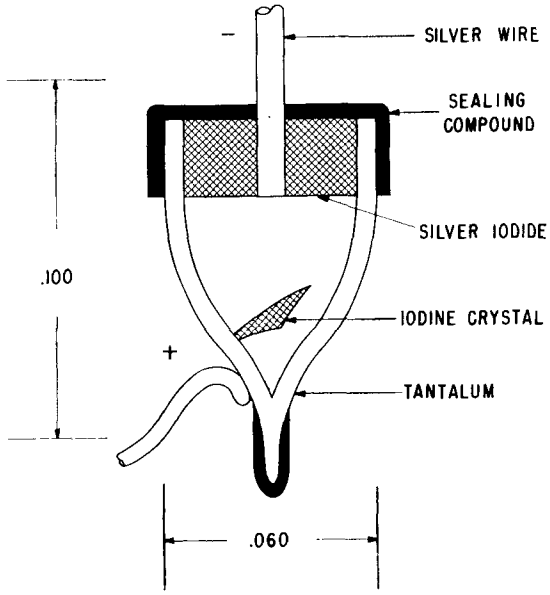

Fig. 1. Schematic of Ta-tube cell

Fig. 2. Photograph of Ta-tube cell

the electrolyte located in the tube. Most of the cell volume is taken up by the iodine reservoir which can be reduced considerably.

The electrode and cell reactions are:

At the anode	$Ag = Ag^+ + e^-$	[1]
At the cathode	$\frac{1}{2}I_2 + e^- = I^-$	[2]
Cell reaction	$Ag + \frac{1}{2}I_2 = AgI$	[3]

Thus, the silver anode is consumed with formation of additional electrolyte, AgI, as the product of the cell reaction.

Preliminary Experiments with Iodine Depolarizer

In preliminary experiments, cells with elemental iodine as the cathode mix as well as cathode reactant were investigated. The following is a typical performance of such a cell, which was 0.477 cm (3/16 in.) long and had an outside diameter of 0.159 cm (1/16 in.): Current-voltage curves at room temperature and at 170°C resulted in the data of Fig. 3. The internal resistance at 170°C was only 40 ohms; hence short-circuit currents were larger than 5 ma. Theoretical open-circuit voltage (0.67 v) also was achieved. With a load of 10 kΩ, 0.11 ma-hr were obtained. This and other cells failed as high temperature was approached because boiling iodine (bp 188°C) burst the cathode tube. For complete cell reaction each cubic centimeter of silver would require the equivalent amount of 1.9 liters of iodine vapor at 1 atm and 200°C. Thus, in the preliminary experiments the cell volume was too small to contain all the iodine vapor. Generally, if maximum capacity, high-temperature operation, and miniaturization are desired, then iodine must be introduced and remain in the cell, as far as possible, in a condensed state.

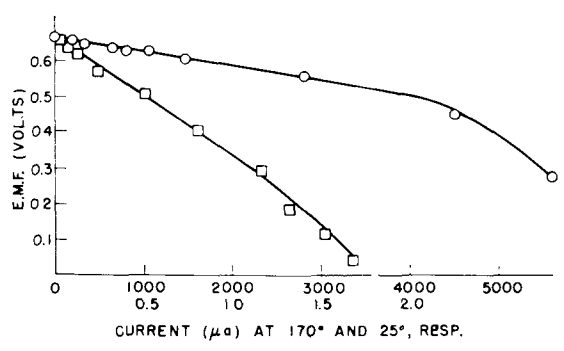

Fig. 3. Current-voltage curves for a cell with iodine as the cathode reactant at 25° (lower curve) and 170°C (upper curve).

Methods of Activating Cells

Two methods were employed to achieve high-temperature stability and gradual evolution of iodine, so that iodine could be used in the cell without building up undue vapor pressure. First, a polyiodide was used which was in thermodynamic equilibrium with iodine over a fairly wide temperature range. In the case of cesium polyiodides, a very thorough study was made by Briggs and co-workers for cesium iodide + iodine + water (3), and for iodine + cesium iodide (4). Second, certain oxidation-reduction reaction mixtures, e.g., Cu_2I_2 + $KMnO_4$, evolved iodine slowly at high temperatures. These systems were investigated by thermogravimetric analyses.

Activation by Decomposition of Iodine Compounds

The following compounds were suitable sources of iodine above the boiling point of iodine: CsI_4, CsI_3, BiI_3, I_2O_5, and CHI_3. In the present work, emphasis was placed on cesium polyiodides as sources of iodine because they decompose at temperatures consistent with their use in tantalum-tube cells.

Preparation of CsI_3 *and* CsI_4

Precipitation from aqueous solutions and crystallization from the melt (in the case of CsI_4) were used to prepare the compounds. As starting material CsI C. P. was added to an aqueous solution of iodine from which precipitation of CsI_3 or CsI_4 took place. Another method involved mixing in stoichiometric ratio 2 mole CsI and 3 mole I_2. This mixture was sealed in a quartz tube under vacuum and raised to 235°C. It was cooled slowly to 135°C and equilibrated at that temperature for 16 hr. Samples were checked for iodine content by wet analysis on a routine basis, and the existence of the tri-iodide and tetraiodide was established in this manner. Samples were also analyzed by x-ray diffraction. The Debye-Scherrer pattern of CsI_4 was not known. In fact, crystals of CsI_4 were identified as I_2O_5. A literature check showed that the pattern given by Hanawalt, *et al.* (5) for I_2O_5, which is accepted as the ASTM standard, also matched the pattern of our sample of CsI_4. To prove our sample as CsI_4, the cesium content was also determined by wet analysis (Table I).

Table I. Analysis of CsI_4 prepared by crystallization from the melt

	Theor.	wt (%)	Found
Iodide content	79.3		78.2
Cesium content	20.7		22.7

Table II. Thermolysis data for decomposition of iodine compounds

Sample	Atmosphere	Primary temp. range, °C	Other temp. ranges, °C	Mechanism	Weight loss	
					Theoretical, %	Experimental (thermobalance), %
I_2O_5	Dry N_2	350-430	—	$I_2O_5 \rightarrow I_2\uparrow + 2\frac{1}{2} O_2\uparrow$	100	98.8
MgI_2	Dry N_2	145-250	300-400	$MgI_2 \rightarrow Mg + I_2\uparrow$	91.1	89.5

* This weight loss determined on analytical balance.

Application of Phase Diagram $CsI-I_2$ *to Solid Electrolyte Cells*

By means of the phase diagram, one can choose a suitable cesium polyiodide as the source of iodine. A composition is required which in the desired temperature range will have a vapor pressure of iodine smaller than 1 atm.

Traces of iodine would be sufficient to produce an appreciable open-cell voltage of the cell $Ta(I_2)/AgI/Ag$, but they could not sustain any current output. Hence, the phase diagram of $CsI-I_2$ may be used to estimate the temperature ranges in which sufficient iodine will be produced to maintain appreciable current density. Thus, iodine first should appear on heating at about 138°C in the case of CsI_4, and at 210° in the case of CsI_3. If it is desired to avoid melts rich in iodine, one can shift the composition of the $CsI-I_2$ mixture toward more CsI, e.g., an over-all composition of 60 mole % CsI and 40 mole % I_2. Such a source of iodine would form less iodine vapor below 306°C than others described previously which also contain CsI_4. The phase diagram of reference (4) refers, however, to the open system $CsI-I_2$ at a pressure of 745 mm, whereas in the cells the polyiodide is in a closed system. In the latter system the iodine pressure increases from vacuum to 1 atm below 306°C as the decomposition reaction proceeds. This difference in the atmospheric environment of the polyiodide will lead to slightly different values for transition temperatures and vapor pressures of the cell as compared to the phase diagram.

Thermolyses of Iodine Compounds

The results of thermobalance measurements of iodine compounds are shown in Table II. Samples were tested in dry oxygen or dry nitrogen to detect any oxidation reactions. In the case of BiI_3 and CsI_4 the oxide was not formed, but decomposition took place in steps. This is indicated in Table II by primary and other temperature ranges. The primary range refers to the temperature interval in which the major part of the decomposition occurred. The other temperature ranges of the next column are those in which smaller weight changes took place. Weight losses to 560°C were considered as final and are compared with calculated values based on the reactions indicated in the table. In each case agreement was very good so that with these compounds the existence of the required iodine-producing reaction is proved.

Activation by Oxidation of Iodides

Mechanism

The second mechanism of activation of tantalum-tube cells is based on the oxidation of an iodide to iodine vapor, e.g.

$$Cu_2I_2 + O_2 \rightarrow 2CuO + I_2\uparrow \qquad [4]$$

This reaction takes place at 240°C, which is the temperature of activation for a cell with Cu_2I_2 as the iodine-source, if oxygen or air is present. If it is desired to achieve a higher activation temperature, one may introduce oxygen chemically bound in compounds such as $KMnO_4$ or KIO_3. These decompose at a higher temperature, and the oxygen formed in the initial decomposition step will react then with Cu_2I_2 above 240°C to produce the necessary iodine vapor, e.g.

$$KIO_3 \rightarrow KI + 3/2\ O_2\uparrow \qquad (\leqq 330°C) \qquad [5]$$

followed by reaction [4] at a temperature above 240°C. Thus, the temperature of activation of tantalum-tube cells may be increased by finding a compound which will give off oxygen at the desired temperature.

Cuprous iodide was used as the source of iodine. When oxygen was added in the form of $KMnO_4$ or KIO_3, the tube was sealed under vacuum. When molecular oxygen was the oxidizing agent, the tube likewise was closed off, but without evacuation. This caused leaks to develop in the cell on heating because of the expanding air. The leaks were necessary to provide a fresh supply of oxygen as the original amount was used up.

Thermolyses of Reaction Mixtures

The thermogravimetric data of iodine-reaction mixtures are listed in Table III. Figure 4 shows the thermobalance curves for cuprous iodide in the presence and absence of oxygen. In dry nitrogen there was 0.6% weight loss at 550°C, which is negligible. The curve of Cu_2I_2 + dry O_2 confirms the temperature of 240°C as the temperature at which reaction [4] takes place (6). In the experiment, 92.2% of the theoretical weight loss corresponding to this reaction had occurred.

Table III. Thermolysis data for iodine-reaction mixtures

Sample	Atmosphere	Primary temp. range, °C	Other temp. range, °C	Mechanism	Weight loss: Theoretical, %	Weight loss: Experimental (thermobalance), %
Cu_2I_2	Dry N_2	No reaction				
Cu_2I_2	Dry O_2	249-330	—	$Cu_2I_2 + O_2 \rightarrow 2CuO + I_2 \uparrow$	58.2	54.0
2.5 Cu_2I_2 + KIO_3	Dry N_2	262-330	332-550	$KIO_3 \rightarrow KI + 3/2\ O_2 \uparrow$ $3/2\ O_2 + 3/2\ Cu_2I_2 \rightarrow 3CuO + 3/2\ I_2 \uparrow$	67.4	66.5
KIO_3	Dry N_2	480-540	540 up	$KIO_3 \rightarrow KI + 3/2\ O_2 \uparrow$	77.6	Reaction not complete at high-temperature limit (620°C)

Figure 5 is the thermobalance curve of a mixture of 2.5 Cu_2I_2 + KIO_3 in dry nitrogen. It shows two separate reaction steps at 260° and 330°C. The weight loss is the result of the oxidation of Cu_2I_2 by oxygen (cf. Fig. 4), but the two steps indicate the successive loss of oxygen from KIO_3, first a partial decomposition to KIO_2, then an accelerated decomposition to KI. This is in agreement with the thermolysis of pure KIO_3, which also takes place in two steps, but at temperatures about 200° higher than in the presence of Cu_2I_2. This lowering of the reaction temperature by a catalyst has been observed in a similar system, that of $KClO_3$ catalyzed by CuO (7). A limitation to a thermogravimetric study of this type is that the oxygen formed would not react entirely with the Cu_2I_2. However, the comparison of the two curves of Fig. 5 and the evidence of the thermolysis of Cu_2I_2 + dry nitrogen, in which Cu_2I_2 did not decompose below 500°C, confirm that KIO_3 decomposes first and then reacts with Cu_2I_2 in the cathode-mix of the solid electrolyte cell.

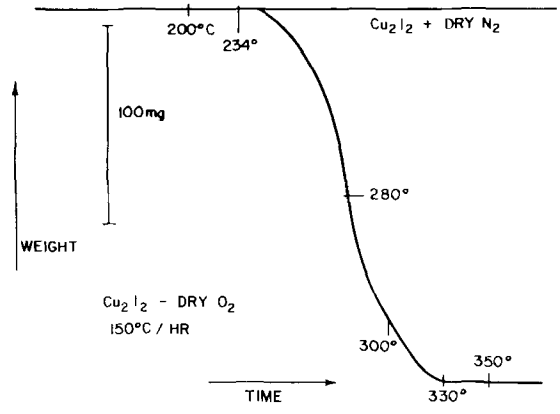

Fig. 4. Thermobalance curves of Cu_2I_2, heated in dry O_2 and N_2, respectively, at 150°/hr (initial wt: 0.3531 g and 0.3205 g, respectively).

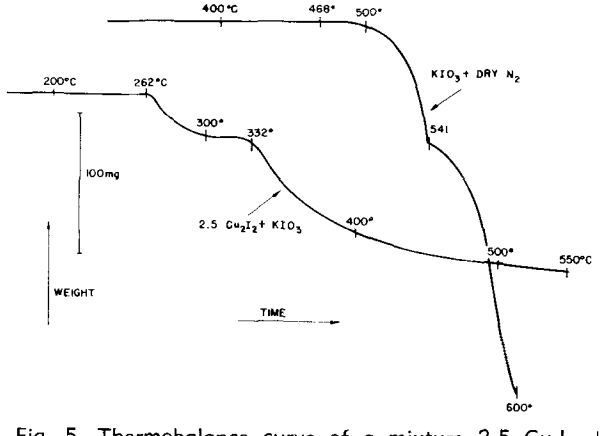

Fig. 5. Thermobalance curve of a mixture 2.5 Cu_2I_2 + KIO_3, (initial wt = 0.3921 g) and KIO_3 + pure N_2 (initial wt = 0.8822 g), heated at 150°/hr.

Another interesting aspect of the thermobalance curve of the mixture Cu_2I_2 + KIO_3 is the weight loss of the mixture, which proceeds quite slowly. This indicates, in comparison with the thermolyses of the individual components, that the production of oxygen is likewise slow. This makes it possible to reach the high-temperature limit of the cell if oxygen is not evolved too rapidly. The reaction mixture of 2.5 mole of Cu_2I_2 per mole of KIO_3 contains an excess of 40% iodide. Assuming that all of the oxygen originally present in KIO_3 is used up in the formation of I_2 from Cu_2I_2, the thermobalance curve shows that at 550°C the reaction was 98.8% complete. This supports the proposed mechanism of decomposition and oxidation.

Results

Performance data.—Cells with the first type of iodine source behaved similarly once the characteristic decomposition of the iodine donor was reached. Besides the iodides listed in Table II, the following compounds were tested successfully as sources of iodine at elevated temperatures: CsI_3, CsI_3 + CsI, Cu_2I_2, CHI_3, and CI_4. Cu_2I_2 reacted with oxygen or oxidizing agents. The organic compounds, CHI_3 and CI_4, were intended primarily as radiation-sensitive iodine compounds which would decompose and trigger off a solid electrolyte cell. For this application CHI_3 and also CBr_4, with the corresponding AgBr electrolyte, are promising, but CI_4 is too unstable at room temperature to act as a radiation detector. Instead, it has a good response to thermal activation in the range 145°-169°C.

In the second type of iodine source, i.e., oxidation couples of iodides, Cu_2I_2 was tested with O_2, $KMnO_4$, and KIO_3, respectively. Results obtained with both types are discussed below.

Temperature response can be obtained from 145° to 500°C. Thus, CsI_4 or CI_4 depolarize satisfactorily at the lower temperature limit; BiI_3, CsI_3, and mixtures of CsI_3 and CsI can be used up to about 320°, and finally, by means of the oxidation couples, e.g., Cu_2I_2 + $KMnO_4$, one can reach the high-temperature limit. Shelf life is unlimited below the activation temperature, because free iodine is absent before

thermal activation of the depolarizer. Capacity and energy-output of cells, whether in series or separately, were as high as 14.4 ma-hr for a single cell of $Cu_2I_2 + KIO_3$ depolarizer or 7.12 ma-hr and 3.62 mw-hr for a battery (four CsI_4 cells in series). Conversion of active cell materials by the cell reaction into their electrical equivalent was nearly complete. The capacity of the cells was limited either by the amount of iodine or silver available to the cell, but generally it is the quantity of silver present as the consumable anode which is limiting. Only in the case of one cell (cathode-mix $Cu_2I_2 + KIO_3$) was the capacity limited by the amount of available iodine. There, 78% of the iodine was converted into its electrochemical equivalent (chemically, into AgI). The open-circuit voltage (OCV) of 0.67 v, equal to the calculated emf of the AgI system based on thermal values at 25°C, was obtained with most cells, although the cells were operated at high temperature. This can be explained qualitatively by the decrease in the free energy of formation of AgI with increasing temperature which is counterbalanced by an increase as a result of higher iodine pressure. This was not the case with oxidation couples. The OCV usually dropped to a lower value after prolonged loading of the cells, but occasionally it recovered to its original value. Complete recovery of OCV was again a question of proper cell design. Likewise, the short-circuit current and internal impedance of cells depended on their structure. Best values of 18 ma and 11 ohms were obtained with a cell of flat tube design (CI_4 depolarizer), but in that case the capacity was only 3.6 ma-hr. It is difficult to estimate a current density for this cell because the dimensions of the silver anode change with time, but at least in its initial operation the surface of the wire anode is known. If 0.159 cm (1/16 in.) is immersed in the solid electrolyte, then the short-circuit current of 18 ma corresponds to about 290 ma/cm^2. The response to activation also depends on the design of the cell. On heating the cell above 145°C from room temperature, the attainment of open-cell voltage required about 1 min or less, whereas proper current response required several minutes of activation.

Tables IV and V show performance data characteristic of the two different sources of iodine. There was considerable variation from cell to cell with regard to internal resistance and capacity, but this is to be expected from the dimensions of the cells, in which the silver anode was a wire 0.127 cm long, imbedded in a solid electrolyte within a tube with inside diameter of about 0.23 cm. The electrochemical equivalent of 0.159 cm (1/16 in.) length of such a silver wire is 5.32 ma-hr. The conversion of silver into the equivalent number of coulombs is described, for brevity, below and in the figures as "percent yield of Ag." Complete utilization of silver can also be demonstrated by microscopic examination of the original locus of the silver anode which has been converted completely into silver iodide. The difference in texture between the original AgI electrolyte and that formed in the course of the experiment gives a clear picture of the cell reaction. A lower but steady output is obtained when one uses smaller diameter tubing. Thus, Fig. 6 shows the discharge

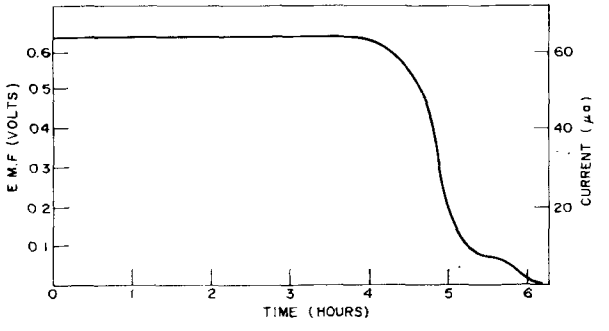

Fig. 6. Ta-tube cell on 10 kΩ load at 300°C; source of iodine: CsI_4; capacity 0.370 ma-hr, theoretical 0.435 ma-hr.

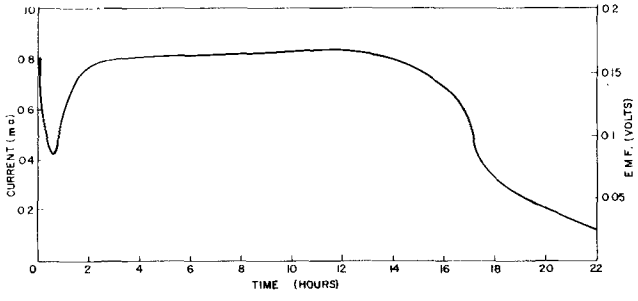

Fig. 7. Ta-tube on 200 Ω load at 258°C; cathode mix: $Cu_2I_2 + KIO_3$; output 14.43 ma hr, 2.32 mw-hr.

Table IV. Performance of AgI cells with thermally activated iodine compounds as iodine sources

No. of cells	OD of Ta-tube, cm	Depolarizer	Temp. of operation, °C	Open-cell voltage, v	Short-circuit current, ma	Internal resistance, ohms	Capacity, ma-hr	Notes
1	0.159	CsI_4	300	0.65	4.0	140	—	
1	0.318	CsI_4	250	0.675	1.5	440	5.23	Discharge at 1 kΩ.
1	0.159	CsI_4	300	0.63	0.5	1510	0.37	3 ma at 0.25 v, per cent yield: 85% Ag, see Fig. 6.
4	0.318	CsI_4	225	2.55	5.8	250	7.19	Energy output 3.62 mw-hr.
1	0.318	CsI_4	265	0.60	11.0	55	3.76	Operated also at 520°C.
5	0.318	CsI_3	250	3.25	6.0	540	0.85	Failure caused by bad contact.

Table V. Performance of AgI cells with Cu_2I_2 plus oxidizing agent as iodine sources

Oxidizing agent	Temp. of operation, °C	Open-cell voltage, v	Short-circuit current, ma	Internal resistance, ohms	Capacity, ma-hr	Notes
Air	450	0.95	~34	28	8.58	Two cells in series.
Air	422	0.45	~12	35	5.23	
$KMnO_4$	450	0.60	3.0	120	2.6	
$KMnO_4$	330	0.56	1.2	625	5.5	
$KMnO_4$	450	0.45	—	—	0.53	
KIO_3*	258	0.55	~2.5	200	14.43	Energy output, 2.32 mw-hr.
KIO_3	287 and 360	0.66	>10	11	5.22	1.56 mw-hr. At 360°C obtained capacity of 4.80 ma-hr compared to 0.42 ma-hr at 287°C.
KIO_3	275	0.655	1.2	1320	7.78	Consumed 78% of total iodine present in Cu_2I_2.

* See Fig. 7.

of a cell with small outside diameter across 10-kΩ load. Figure 7 gives the performance of a larger cell. The minimum near the beginning of this discharge curve can be attributed to the relatively low temperature of operation (258°C) for the $KIO_3 + Cu_2I_2$ cathode mix of this cell. The minimum is not a characteristic of the cathode mix or the cell. In other cases, the current terminated abruptly, which indicated that all of the silver anode had been used up.

Comparison of cell performance with thermobalance experiments.—The cells could be operated in definite temperature ranges which were somewhat lower than the temperature of decomposition of the iodine donor obtained from thermobalance curves. This can be explained by the temperature lag between the recording thermocouple and the sample, which would give slightly higher temperature readings in the thermolyses. Also, in the decomposition mechanism an equilibrium or steady-state reaction occurs at constant temperature at which the iodine donor decomposes. The equilibrium may be displaced toward lower temperatures if iodine is removed constantly by the cell reaction.

Thermoactivation current and emf.—By employing a technique similar to that of the thermobalance one can use the solid electrolyte cell as a halogen detector. The cell output is recorded while the temperature is increased in the same manner as the weight is recorded with the thermobalance. This is shown for a cell with CsI_4 in Fig. 8. It is seen that the current rose rapidly starting at about 246°C from 0.3 to 2.9 ma, the steady-state value for this cell at 200 Ω load. Similar curves were obtained for cells with other iodine donors.

Comparison of cell performance with phase diagram of the system CsI-I_2.—On the basis of the phase diagram, it was predicted that a cell with CsI_4 as iodine source should be operable at 190°-245°C, with full activation at the higher temperature. This observation has been confirmed by the thermoactivation current illustrated in Fig. 8. The fact that full current output was not obtained until 257°C was reached can again be explained, as above, by the temperature lag between the recording thermocouple and the cell. It is the temperature at which the increase of current begins that is characteristic of full activation. Below 190°C a current of 0.3 ma is also appreciable for a Ta-tube cell, but the increase in current demonstrated the decomposition of the iodine source. Thus, there is qualitative agreement of cell performance and its prediction from the phase diagram of the open system. The correlation must not, however, be pushed too far, because in the cell we deal with a closed system.

To evaluate different iodine donors, a series of cells was chosen for initial room temperature similarity in structure (0.318 cm OD Ta-tube cells) and internal room temperature impedance (280-500 kΩ). The cells were filled with different iodine sources, namely, iodine, CsI_4, CsI_3, and the mixture of 4 mole CsI_3 + 1 mole CsI, which was discussed previously. The polarization of the cells then was measured at increasing temperatures. Specific values obtained

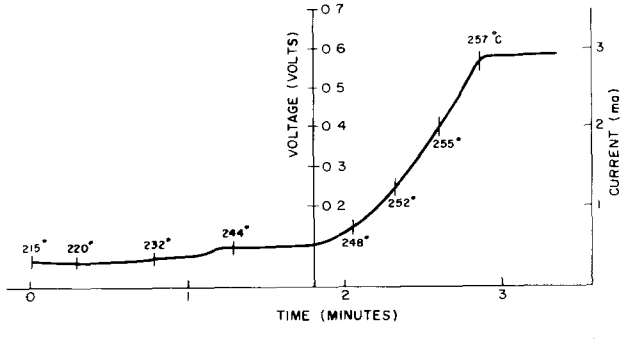

Fig. 8. Thermal activation of a Ta-tube cell, iodine source: CsI_4. Cell on 200 Ω load.

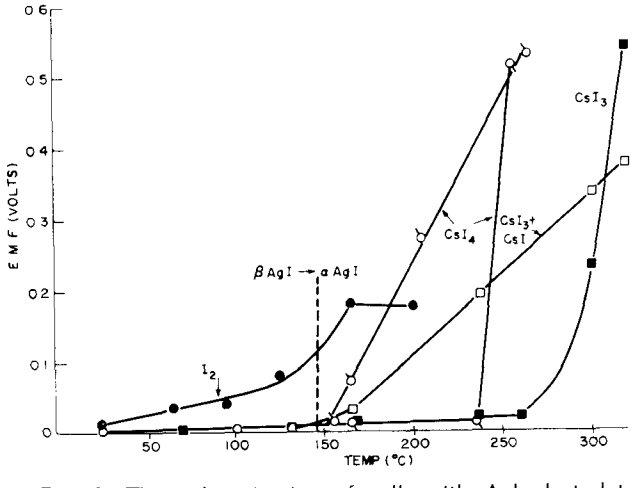

Fig. 9. Thermal activation of cells with AgI electrolyte (emf at 25 kΩ load).

with an external load of 25 kΩ are shown in Fig. 9. Where iodine crystals were the source of iodine vapor the cell responded even below the transformation temperature and broke down at 200°C. This is to be expected because iodine has a boiling point of 188°C. The cell with CsI_3 was not activated fully until 320°C was reached. Two cells with CsI_4 behaved differently; one was activated slowly over the temperature range 155° to 245°C, and the other one attained full output abruptly between 235° and 255°C. Finally, the mixture of $4CsI_3 + CsI$ also was activated slowly from 150°C up and had not reached full activation at 320°C. Despite the discrepancy in the two CsI_4 runs, these curves qualitatively agree with the interpretation of the phase diagram.

Acknowledgments

The author is indebted to D. L. Douglas, W. T. Grubb, A. E. Newkirk, and E. L. Simons for very helpful discussions. Miss I. Aliferis performed the thermolyses, and P. R. Schmidt assisted in the preparation of cells. The x-ray analysis of CsI_4 was performed by the metallography group of the Research Laboratory.

Manuscript received June 25, 1958. This paper was prepared for delivery before the Ottawa Meeting, Sept. 28-Oct. 2, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Studies of the Structure of Anodic Oxide Films on Aluminum, I

D. J. Stirland and R. W. Bicknell

Caswell Research Laboratories, Towcester, Northants, England

ABSTRACT

The influence of the formation voltage on the structure of nonporous anodic aluminum oxide films has been studied by electron microscope and electron diffraction methods. It has been shown that low formation voltages (<100 v) produce an amorphous oxide layer, whereas high formation voltages produce amorphous oxide together with some crystalline γ'-alumina. The location of this crystalline oxide within the anodic layer is discussed.

In general the so-called direct methods for examination of thin films (such as optical and electron microscopy, x-ray and electron diffraction) can provide information regarding the "structure of the films," but it is necessary to define carefully what is meant by this phrase. Conventional microscopical methods can show details of the topography of both surfaces of the film and, providing the film is sufficiently transparent either to light or to electrons, may also reveal bulk physical features within the film. Diffraction methods can be used to determine the crystallographic structure either of a thin surface layer of the film or of the bulk material. These methods thus give two structural parameters, the physical and the crystallographic.

A number of workers (1-5) have investigated these parameters in the case of films formed on aluminum by electrolytic oxidation and have shown that anodic aluminum oxide films can be divided into two classes, determined by the solvent action of the forming electrolyte on the oxide. Electrolytes which dissolve the oxide produce porous coatings whose thickness depends primarily on both formation current and time, whereas electrolytes which do not attack the oxide appreciably produce thin nonporous coatings, whose thickness depends mainly on formation voltage. Although the electrical properties of nonporous films have led to a wide application in the industrial field of electrolytic capacitors, most fundamental investigations of the structure of anodic coatings have dealt with the porous types of oxide only.

This paper presents and discusses the results of electron microscope and electron diffraction studies on both the physical and crystallographic structures of nonporous anodic oxide coatings.

Methods of Examination of Anodic Films

A systematic x-ray investigation of the crystallographic structure of anodic coatings has been made by Taylor, *et al.* (6). Oxide films were formed on 99.8% pure aluminum foil in a variety of electrolytes (giving both porous and nonporous coatings) under differing conditions of temperature and formation voltage. X-ray examination of the oxide films showed that some crystalline alumina was obtained in all cases where the formation voltage exceeded 100 v, and that the amount of crystalline oxide increased with increase in formation voltage. This was determined by comparing the relative intensities of the x-ray diffraction lines given by each specimen.

Taylor, *et al.* do not discuss the significance of the x-ray pattern in detail and, as Burwell (7) has

pointed out, the excessive line broadening of the pattern does not permit conclusive identification of the crystallographic structure of the oxide. We have found that in general only two lines are clear enough for measurement, and these are very broad. A typical x-ray diffraction pattern obtained from an anodic film formed at 525 v on 99.99% pure aluminum (see next section for preparative details) shows two such broad reflections which have d-spacings of 1.97 and 1.39Å. If the observed line broadening is due to the small crystallite size of the alumina, then it might be expected that the smaller equivalent wave length of an electron beam (as compared with an x-ray beam) would give a sharper diffraction pattern suitable for a complete identification of the structure, but it is found that the specimen is then too thick to give any transmission electron diffraction pattern at all. In fact, using a diffraction camera operating at a beam voltage of 50 kv, the practical upper limit to the specimen thickness will be ~400Å, and since for nonporous anodic films the thickness formation voltage ratio is almost constant at ~14Å/v (8), this limits the maximum permissible anodic formation voltage to ~30 v.

However, it is possible to examine higher voltage films in the electron diffraction camera if their thickness can be reduced by some suitable method. It was found that a phosphoric-chromic acid mixture, previously used (9) to dissolve anodic films from aluminum, would also serve to thin down the thick coatings to an appropriate thickness for transmission diffraction. Thus films formed over a wide range of voltages could be examined. Furthermore, these thinned specimens were also suitable for electron microscope examination, providing a direct method of observing the stripping action of the acid mixture on the anodic coatings.

Experimental Details

Aluminum foil of 99.99% purity was used for all the experiments, and in each case the specimens were cleaned prior to anodization by a 3-min immersion in a 3% NaOH solution. They then were washed thoroughly in distilled water and dried in a warm air stream. The anodizing electrolyte consisted of a 3% boric acid-0.05% borax aqueous solution used at 20°C. All specimens were anodized at constant voltage for a set period of 5 min. The acid mixture used to thin down the anodic coatings consisted of 35 cc of 85% phosphoric acid and 20 g of chromic acid per liter of solution used at 80°C.

The investigation was carried out in two parts. (*a*) *Action of the acid mixture.*—Specimens were anodized at 500 v, 20°C, and then immersed for 1, 3, 10, and 20 min, respectively, in the acid mixture. Then they were washed thoroughly and re-anodized at 10 v. One reason for this second anodization was to provide a thin (~150Å) supporting film to hold in position fragments of the original anodic coating which had survived the acid treatment. This 10-v film only formed on the aluminum surfaces exposed by the dissolution of the original coating. Examination of specimens in the electron microscope showed that the second anodization was unnecessary for the lightly attacked films, but the same procedure was adopted for all specimens in order to standardize conditions. The composite film was stripped in small squares from the aluminum by the usual mercuric chloride method (10), washed, and picked up on electron microscope specimen grids for subsequent examination.

(*b*) *Effect of differing formation voltages on the structure of the oxide.*—Specimens were anodized over a range of voltages between 12 v and 500 v at 20°C. They then were immersed in the acid mixture for various times, sufficient in each case to reduce the oxide thickness to less than ~400Å. For example, specimens anodized at 12 and 25 v did not need to be treated at all, the 200-v specimen was immersed for 2 min, and the 500-v specimen for 5 min. The treated specimens were then re-anodized at 10 v and oxide squares prepared for examination as before.

Besides providing a coherent supporting membrane for the remaining parts of the original anodic film, the 10-v oxide film also acted as a normal oxide replica (10) of the exposed parts of the underlying aluminum surface. Thus it was possible to examine, on the same specimen, both the partially dissolved original anodic coating together with an oxide replica of the metal surface from which the coating had been dissolved completely. Since this aluminum had been exposed to the acid mixture, however, it was necessary to investigate whether any reaction had occurred.

A cleaned sheet of aluminum foil was placed in the acid bath for 20 min, and then oxide replicas of its surface were prepared and examined. These showed that the only observable effect of the acid mixture was to produce a small number of easily identifiable etch pits (dimensions ~0.05μ) in the aluminum surface. Since the size of these pits was considerably smaller than that of the surface detail which was being studied, and since the 20-min acid attack was the maximum period employed during the dissolution of the anodic films, it was considered that the effects of the reaction between the acids and the aluminum could be ignored.

Finally, it was found that all the low voltage anodic films (<100 v) dissolved quickly and completely in the acid mixture. For example, squares of oxide removed from foil anodized at 25 v dissolved completely in ~1 min.

Interpretation of Results

Figures 1-7 show typical areas of the anodic layers after different times of immersion in the acid mixture. Figures 1 and 2 demonstrate at once the nonuniformity of the acid attack, which has dissolved the oxide preferentially in cylindrical pores. With a longer attack the pores increase in size and number, and the less soluble parts eventually become thin enough to enable some fine structure to be visible in them (Fig. 3-5, with finely structured areas arrowed on Fig. 4). Figures 6 and 7 show areas in which the high voltage oxide has been dissolved almost completely, and therefore consist mainly of 10-v oxide replicas of the surface beneath the original anodic layer. Micrographs of oxide replicas do not differentiate between identically shaped raised or depressed features, but by metal-shadowing (11) it

has been shown that the features on Fig. 6 and 7 represent shallow craters in the aluminum surfaces.

Electron diffraction examination of specimens containing the areas shown in Fig. 3-5 gave the sharp ring pattern of Fig. 8. Table I gives the indexed reflections, together with their estimated relative intensities, for this pattern. It agrees very closely with x-ray diffraction results obtained by Verwey (12) from anodic aluminum oxides. He identified the material as a face-centered cubic structure of cell-size $a_o = 3.96$Å, and called the oxide γ'-alumina. This is not to be confused with the aluminum oxide which can be prepared by the thermal decomposition of alumina hydrates and has a deficient spinel structure ($a_o = 7.89$Å). In the English nomenclature this oxide is called γ-alumina (13); in American literature it is known as η-alumina (14). Both γ'-alumina and γ (or η)-alumina have in their diffraction spectra two strong lines with d-spacings of 1.97 and 1.39Å; in the case of γ'-alumina these are from (200) and (220) reflections, and in the case of γ (or η)-alumina they are from (400) and (440) reflections. These two may be the only lines capable of measurement on an x-ray pattern, and thus the identification of the oxide structure is not certain. However, the sharp electron diffraction pattern conclusively identified the crystalline oxide as γ'-alumina.

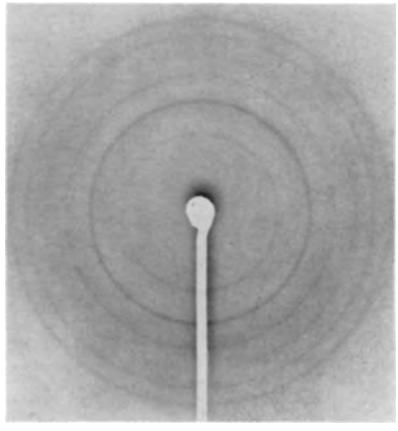

Fig. 8. Electron diffraction pattern from finely structured material present in high voltage anodic oxide films.

Exactly the same diffraction pattern was obtained from all the anodic films formed at voltages greater than 100 v, thus confirming the results of Taylor, *et al.* (6). Films formed below 100 v gave patterns consisting of two broad diffuse rings, typical of those obtained from amorphous materials. Amorphous in this sense is defined as a structure whose crystallite size is less than ~10Å. Electron micrographs of these films appeared to be normal oxide replicas, showing surface detail which could be correlated with that observed by optical examination of the unformed aluminum specimens.

Location of the Crystalline Oxide within the Anodic Layer

It was possible to deduce theoretically and confirm experimentally that the finely structured areas shown in Fig. 3-5 could be identified with the crystalline γ'-alumina. On each micrograph three types of area can be seen; black areas, light gray areas, and the finely structured areas. The black areas cannot give a diffraction pattern since they represent partially dissolved oxide which is still too thick to be penetrated by the electron beam. The light gray areas cannot give a ring pattern because they con-

sist of the 10-v amorphous film. Hence the remaining areas must be responsible for the γ'-alumina diffraction pattern.

Experimentally this was confirmed by the "selected area diffraction technique." A variable aperture in the electron microscope was adjusted so that only a restricted area of the specimen was visible, and the diffraction pattern from this area was then obtained. On scanning the specimen it was found that the thin film replica areas gave two broad diffuse rings, and the black areas gave no transmission pattern at all. Only the finely structured gray areas produced the γ'-alumina pattern, and hence they indicate the disposition of the γ'-alumina within the anodic layer. These areas are most probably agglomerates of crystallized alumina.

Discussion

The first conclusion which can be drawn from a study of the micrographs is that a short attack by the phosphoric-chromic acid mixture does not dissolve the high voltage anodic coatings uniformly. Instead, a selective dissolution of thin cylindrical columns of material takes place. It was found by examination of the lightly attacked oxide specimens before they had been anodized to give the 10-v replica support film that, in fact, no material was present within the columns after a 3-min immersion in the acid mixture. This means that there is a variation in solubility of the anodic coatings, which in turn implies a variation in their composition. It has been mentioned previously that all the low voltage (that is, amorphous) films dissolved quickly and completely in the acid mixture, and so it is reasonable to propose that the very soluble part of the film consists of amorphous oxide.

Altenpohl (15) used a weighing method to study the action of the phosphoric-chromic acid mixture on nonporous anodic films formed in hot aqueous boric acid electrolytes. From the experimental results he suggested that these anodic films consisted of at least two different types of oxide; an outer layer readily soluble in the acid mixture, and an insoluble layer beneath this. He also found that the relative proportion of insoluble oxide increased with increase of formation voltage. Since the results described in the present paper are not strictly comparable with those obtained by Altenpohl because of the difference in electrolyte temperatures, some preliminary experiments using the boric acid-borax forming electrolyte at 100°C may be mentioned. These showed that 500-v anodic coatings could not be thinned down sufficiently to give any transmission diffraction pattern, even after 30 min in the acid mixture, although in every case of formation at 20°C it was possible to dissolve the oxide completely.

The results obtained with electrolyte at 100°C agree with Altenpohl's observations, but with electrolyte at 20°C it has been shown that all the oxide is removed from the metal. It is not certain whether this is because the cold formation oxide eventually is dissolved completely, or whether dissolution of part of the anodic layer (i.e., the amorphous oxide columns) weakens the adherence of the remainder. Figure 4 suggests that the latter explanation may hold in some cases, since the black fragments on this micrograph have been unattacked during the dissolution of the rest of the film, and yet a further treatment in the acid mixture would result in a film free surface (e.g., Fig. 6 and 7). It is difficult to imagine that these unattacked fragments dissolve completely during the second treatment, if they have already resisted the initial attack, and it seems more likely that they eventually become detached by a weakening of their adherence to the aluminum. The micrographs do demonstrate, however, that the distribution of readily soluble oxide and insoluble (or slowly soluble) oxide is very much more complex than the simple double layer arrangement proposed by Altenpohl.

The electron micrographs also provide information regarding the physical structure of the anodic films. At any instant during its formation the anodic layer is in intimate contact with the aluminum surface beneath it, and so the aluminum must reproduce every topographical detail of the oxide surface. Hence, replicas of the aluminum surface are also replicas of the oxide surface at the metal-oxide interface. This provided Keller, *et al.* (9) with a method of examining the oxide surface of porous anodic coatings, and by using low formation voltages they were also able to examine the stripped films in transmission. From these observations they derived a structure for the porous anodic films. The

* Data obtained from ref. 9.

basis of this derivation was that the oxide contained a uniformly spaced array of tiny pores surrounded by close-packed hexagonal columns of oxide. These oxide cells had bases with the shape of a spherical section somewhat less than a hemisphere. Measurements of the pore spacings showed that they corresponded with the cell sizes (spacing between cell-base centers) measured from replicas of the aluminum surfaces beneath the coatings. Since the essential feature giving rise to this structure was assumed to be the existence of pores through the anodic films, it is surprising to find that micrographs of the metal-oxide interface of nonporous anodic films (Fig. 6 and 7) are almost identical in appearance with those shown by Keller, *et al.* for the same interface of porous anodic films (Fig. 8 of ref. 9, p. 415). Furthermore, it was possible to show that the similarity between the two structures is also quantitative.

Keller, *et al.* used four different electrolytes, all producing porous films. They found that over a voltage range of 20-120 v a linear relationship existed between cell size and formation voltage. By assuming that this linear relationship continued for higher voltages and by making a large extrapolation, the cell sizes which might be expected for a 500-v formation in each of the four electrolytes could be calculated. These values, compared with the cell size measured directly from micrographs of the 500-v nonporous formation, are shown in Table II.

This remarkably close agreement between the cell-base sizes for both porous and nonporous oxides is indicative of a similarity in physical structure. Franklin (16) has described some aspects of anodic oxidation and suggested that, since nonporous oxide films have a pronounced cell-type of structure, similar growth processes may occur for both types of oxide.

Conclusions

It has been shown that anodic oxide films formed in a boric acid-borax electrolyte contain some crystalline γ'-alumina provided that they are formed at voltages in excess of 100 v; otherwise they consist entirely of an amorphous oxide. The amorphous oxide dissolves more readily in a phosphoric-chromic acid mixture than does the crystalline oxide, and it appears to be present in cylindrical columns penetrating right through the anodic coating. Finally, the nonporous oxide structure is found to be similar in some ways to a structure previously proposed for porous anodic films.

Aqueous Uranium Corrosion at 100°C

J. B. Schroeder,[1] D. A. Vaughan, and C. M. Schwartz

Battelle Memorial Institute, Columbus, Ohio

ABSTRACT

The mechanism of aqueous uranium corrosion has been studied using weight loss and hydrogen evolution measurements. Microscopic x-ray diffraction and chemical analyses were made of the corrosion product. The results indicate that uranium corrodes by forming an oxide of the type UO_{2+x}. The lack of chemical balance reported by earlier workers is explained by the existence of metallic uranium in the oxide layer.

Many of the atomic reactors in existence today use a metallic, natural uranium fuel which is cooled with either heavy or light water. The design of some fuel elements is discussed by Gurinsky and Dienes (1) in their review of the first Geneva conference on atomic energy. All of these designs overcome the high corrosion rate of uranium by providing some protective container to prevent the coolant from coming in direct contact with the uranium fuel. The fabrication of reactor fuel elements would be greatly simplified and the potential hazard of contamination resulting from a cladding failure reduced if a corrosion-resistant uranium alloy were available. This study was undertaken to provide information about the mechanism of the aqueous corrosion of alpha uranium to aid in the development of corrosion-resistant alloys.

Previous work on the corrosion of uranium has been summarized in the Reactor Handbook (2) and by Gurinsky and Dienes (1). The early work showed that the uranium corrosion rate below 100°C was lower for oxygen-saturated water than for hydrogen-saturated water. In aerated water, uranium corroded slowly at first and then assumed the higher linear rate for hydrogen-saturated water. The mechanism proposed to account for these observations was that the oxide formed in water containing oxygen was self-healing and, therefore, protective. When the dissolved oxygen was depleted from the water, uranium hydride was believed to form beneath the oxide and break the oxide film. Hydride was identified on samples corroded in steam and water in the temperature range between 150° and 180°C. The formation of UH_3 also was considered necessary in order to account for the small quantity of hydrogen liberated during corrosion.

In the work reported here no evidence was found of either form of UH_3. The observations are explained on the basis of metallic uranium being present in the corrosion produced oxide.

Experimental

The samples were rectangular coupons (½ x ½ x ⅛ in.) of selected, center-cut ingot.[2] Before fabricating into samples the uranium was reduced 50% by rolling in the high alpha region.

Preliminary tests showed that the corrosion rate of uranium in water at 100°C was linear and varied between 2.70 and 3.50 mg/cm²/hr, with an average value of 3.28. Three methods of surface preparation were investigated: electropolishing,[3] abrading through 600 grit paper, and abrading followed by a HNO_3 pickle. Corrosion rates were independent of the method of surface preparation. After this preliminary work all of the samples were electropolished, rinsed in distilled water and alcohol, and tested in boiled, deionized water.

Rate measurements.—Weight loss measurements were made by weighing the sample prior to testing and again after the corrosion-produced oxide had been removed by pickling in concentrated HNO_3. The final weight was corrected for the amount of uranium lost in the pickling step by repeating the pickling step, which was usually of 45-sec duration, and reweighing. The weight lost during the second pickling was added to the final weight in order to calculate the corrosion rate. The average corrosion rate was found to be 3.28 mg/cm²/hr by this method.

Hydrogen evolution during corrosion was measured by bubbling tank argon through the corrodant and drying the gas stream in a $Mg(ClO_4)_2$ train, converting the H_2 to water by passing it through hot CuO, and measuring the weight gain in a $Mg(ClO_4)_2$ absorption tube. The system was flushed until a constant weight was obtained for the absorption tube both before and after the test. The average amount of hydrogen evolved during four 24-hr and four 8-hr tests was 91.5 ± 1.2% of the amount calculated from the weight loss using Eq. [1].

$$U + 2H_2O \rightarrow UO_2 + 2H_2 \qquad [1]$$

Analysis of the Corrosion Product

Microscopic examination.—The oxide produced during corrosion was not adherent after the first few minutes at temperature. Figure 1 is a photomicrograph of the oxide layer after a 24-hr test. Metallographic examination of the metal-oxide interface did reveal some hydride; however, no more hydride was present at the interface after corrosion than was observed in the interior of the sample both

[3] The electropolishing bath was 40% H_2SO_4, 40% H_2O, 10% H_3PO_4, and 10% C_2H_5OH. The open-circuit voltage was 10 v. A more uniform polish was obtained when the bath temperature was maintained below 15°C.

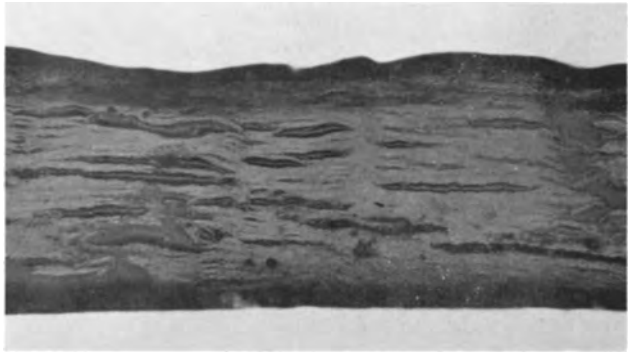

Fig. 1. Oxide layer formed on uranium metal during a 24-hr corrosion test at 100°C.

before and after testing. Vacuum-fusion analysis also failed to detect any increase in the hydrogen content of the metal as corrosion progressed.

X-ray diffraction.—Using copper radiation, diffractometer traces were obtained of the wet sample surfaces after various times during the corrosion tests. These showed alpha uranium and UO_2. After the oxide had grown to such a thickness that it was no longer possible to obtain the diffraction pattern of the metal, the oxide was removed by directing a stream of alcohol or water against the surface. Using this treatment it was possible to remove enough of the oxide to make the metal the most intense phase in the pattern. A hydride phase was not detected.

In both the diffractometer traces and Debye-Scherrer patterns the corrosion produced oxide gave very broad lines, due to extremely small particle size. For this reason it was not possible to obtain accurate lattice parameters of the oxide.

When the corrosion product was reacted with dilute HNO_3 (5%) the UO_2 was attacked preferentially leaving feather shaped particles. These particles were identified by x-ray diffraction as being metallic uranium.

After metallic uranium was detected in the corrosion product, tests were performed which showed that both the metal and the beta hydride could withstand the dilute HNO_3 cleaning and would probably be detected, if present in the corrosion product. Samples which showed no oxide were oxidized to such an extent that only oxide could be seen in the diffraction pattern. This "oxide" was then treated with dilute HNO_3 and the residue examined by x-ray diffraction. The patterns showed a mixture of UO_2 and either the metal or UH_3, depending on the starting material.

Oxygen-to-uranium ratio.—Uranium dioxide, prepared by the hydrogen reduction of higher oxides, is frequently unstable, resorbing oxygen (3-5). This was found to be the case with the corrosion product when it was vacuum dried. The apparent oxygen-to-uranium ratio of the air-dried corrosion product was found by ignition to be 2.40.

The oxygen-to-uranium ratio of oxide samples generally is determined by measuring the weight gain when the sample is ignited to U_3O_8 by heating it in air to 750°C and holding it at that temperature for 15 min. This type of analysis cannot distinguish between oxygen, hydroxyl, or water. Therefore, the valence of the uranium is not necessarily twice the oxygen-to-uranium ratio.

Because of the instability of the dry corrosion product, wet samples were loaded into a controlled atmosphere, differential thermal balance. They were dried overnight in vacuum (5×10^{-5} mm Hg), weighed, heated to constant weight at 750°C, and then ignited to U_3O_8. Three samples lost 3.2, 1.6, and 4.2% of their weight during the drying operation and were found to have oxygen-to-uranium ratios of 2.19, 2.24, and 2.19, respectively. A sample of commercial oxide was placed in a simulated corrosion test and then run through the differential thermal analysis. It was found to lose 0.3% of its weight during the drying cycle and have an oxygen-to-uranium ratio of 2.04, which is in excellent agreement with other measurements.

Mean valence.—The mean valence of the uranium in the corrosion product was determined by a modification of an analytical method developed by Melton (6). It consists of dissolving the sample in a solution of $AgNO_3$ and NH_4F, 1*N* with respect to each. The silver ion acts as an oxidizing agent and produces hexavalent uranium and a precipitate of free silver. The silver is filtered off, dissolved, and measured gravimetrically as silver chloride, and the uranium content determined by a weight-volumetric method employing ceric sulfate.

The mean valence of uranium in the corrosion product was found to be 3.70, which is in good agreement with the hydrogen-evolution experiments. However, when the loose corrosion product was allowed to drop into a cool zone (approximately 25°C), rather than remain in the proximity of the metal, the mean valence was found to be 3.16. A sample of the corrosion product which remained in the boiling solution 24 hr after the metallic sample had been removed gave a mean valence of 3.87.

In order to obtain independent data on uranium valence the x-ray absorption spectrum of the bulk corrosion product was compared with that of UO_2 and UO_3. Spectrometer data were obtained over the range of x-ray wave lengths extending above and below the L_{III} absorption edge of uranium. The powders were briquetted in absorption cells of about the same x-ray density. The corrosion samples were coated with water soluble resin before drying in an attempt to minimize air oxidation. The curve of intensity vs. wave length in the region of the absorption edge was analyzed for maximum, minimum, and point of inflection. The results for the three materials are given in Table I. By each criterion char-

Table I. Characteristic points on the L_{III} x-ray absorption edge of uranium for uranium dioxide, uranium trioxide, and uranium corrosion product

Sample	Maximum absorption, A	Inflection point, A	Minimum absorption, A
UO_2	0.7267_9	0.7226_1	0.7184_1
Corrosion product	0.7263_4	0.7223_2	0.7183_1
UO_3	0.7263_1	0.7222_7	0.7182_4

Note: The absorption-edge wave length was calculated on the basis of a LiF analyzing crystal with an assumed 2d spacing of 4.0275Å.

acteristic values for the corrosion product are intermediate between those of UO_2 and UO_3. These results tend to verify the oxygen-to-uranium ratio measurements and to indicate that the oxide phase should not be considered as stoichiometric UO_2, as written in Eq. [1], but that the valence state of the uranium is somewhat greater than 4.

Solubles.—Samples of the corrodant were filtered and analyzed for solubles. The uranium content of the solid obtained by evaporating the filtered corrodant to dryness was 16%. Spectrographic analysis showed that the major constituents were calcium, magnesium, and chromium. All of these elements were present in the original metal.

The uranium content of the corroding water was measured as a function of time during tests carried out at 60°C. After 50 days the uranium concentration attained a value of 5×10^{-5} mole/l. This is an order of magnitude higher than the solubility data reported (7) for $U(OH)_4$ and is probably due to the formation of complexes. This was considered to be unimportant in the over-all mechanism because samples tested in water containing the dissolved uranium exhibited the same corrosion rates as those run in fresh water.

Effect of Surface Treatments

Oxide films.—Metal samples were heated in low oxygen pressures to form coherent oxide films prior to corrosion testing for study of the protective properties of uranium oxide. Table II presents the results of short term corrosion tests and the heat treatment employed. These data show that the protection of these films increases as the temperature of film formation is increased to 650°C. When the oxide film was removed by electropolishing, the corrosion rate was the same as that for unannealed samples. This demonstrates that the increased corrosion resistance was due to a surface effect and not a bulk effect. When the films were formed at temperatures above the alpha-beta transformation (663°C), deep cracks appeared in the metal, producing discontinuities in the oxide film. All of the samples heated above the alpha-beta transformation corroded at the same rate as untreated samples. Figure 2 shows the results of longer tests on oxide-coated samples. All of the samples used in this test were held for 2 hr at 650°C in an oxygen atmosphere at a pressure of 5×10^{-4} mm Hg. Oxide films were put on only two samples at a time in order to keep them well separated in the furnace. The samples that were coated together are enclosed by one circle in Fig. 2. The spread observed is probably due to minor uncontrolled variations in the conditions used in forming the films. The oxide films failed after approximately 20 hr by developing a few small pits and undercutting. No inclusions were detected at the site of the original failure. X-ray diffraction patterns of the material formed in these pits showed that no hydride was present. Line broadening of the x-ray diffraction pattern showed that the coherent oxide films may have been highly stressed. The failure possibly occurred where the local stress level was sufficient to rupture the film.

Table II. Corrosion results on uranium

Sample No.	Condition of oxide film formation Temp., °C	Pressure, mm Hg	Time in corrosion test, hr	Rate, mg/cm²/hr
90	100	5×10^{-5}	4	2.93
91	100	5×10^{-5}	4	3.04

124	600	1×10^{-3}	21	0.21

* Electropolished after film formation.

It seems likely that the stresses in the oxide film resulted from the difference between the thermal expansion coefficients of the oxide and the metal. In an attempt to reduce the stress and thereby increase the life of the film, samples were run at lower temperatures and, when necessary to obtain a reaction, at higher pressures (10^{-3} to 10^{-2} mm Hg). Above 400°C no change was observed in the line broadening. Below 400°C a mixture of UO_2 and a higher oxide was formed which did not provide protection against aqueous corrosion.

Cathodic charging.—In order to test the effect of surface hydride on corrosion behavior, a hydride layer was produced by cathodic charging in weakly acid (0.5%) solution. By varying the temperature, the structure of the coating could be changed. At

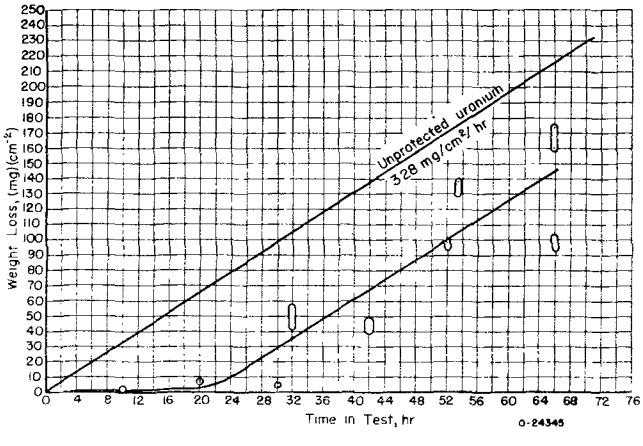

Fig. 2. Effect of oxide film on corrosion of uranium. Samples were held 2 hr at 650°C in oxygen atmosphere at 5×10^{-4} mm Hg. Two samples were coated together and are enclosed by one circle.

temperatures above 80°C only the beta form of UH_3 was produced, while at lower temperature a mixture of alpha and beta UH_3 was formed. No pure alpha coatings were produced.

Corrosion tests were run on samples coated with the beta UH_3 and with the mixture of alpha and beta. When corrected for the amount of uranium in the hydride layer no difference in corrosion rate could be detected between the charged and the uncharged samples.

Discussion of Results

The corrosion product formed when uranium reacts with 100°C water at atmospheric pressure does not offer protection to the underlying metal. In contrast, UO_2 films produced on the metal at temperatures above 400°C in oxygen, temporarily protect the base metal against corrosion in 100°C water. Ignition analyses of the water corrosion product indicate that its composition may be as high as $UO_{2.2}$, and increases to $UO_{2.4}$ after exposure to air at room temperature. Some confirming evidence that the valence state of uranium in the bulk corrosion product is greater than 4 was obtained from x-ray absorption spectroscopy.

This high oxygen-to-uranium ratio is in apparent contradiction to that from hydrogen-evolution measurement which indicates a composition of $UO_{1.9}$. The latter value is in good agreement with valence determination by chemical analysis. However, it is obvious that the oxygen-uranium ratio and the mean-valence and hydrogen-balance measurements are in error, being low by the amount of unattacked metal particles present in the samples. The metal content, although significant in explaining the low values of mean valence, must be considered an extraneous constituent of the corrosion product.

Thus the oxidized product is a phase or phases giving a UO_2-type x-ray pattern. It cannot be concluded from the oxygen-uranium ratio that the material is indeed UO_{2+x}, since, under conditions of reaction in the presence of water, hydrous oxide or the phase $U(OH)_4$ is a likely alternative indistinguishable from UO_{2+x}, by ignition analysis, in the presence of free metal. The solubility of $U(OH)_4$ is known (5), and its powder pattern has been reported to be very similar to that of UO_2 (9). It is possible that the decrease in the oxygen-to-uranium ratio of air-dried corrosion product from 2.40 to 2.21, during vacuum drying, may represent the partial decomposition of $U(OH)_4$. The product cannot be $U(OH)_4$ alone, since this phase would lose weight on ignition, requiring excessive amounts of free metal to compensate. Furthermore, its valence state is not consistent with the x-ray absorption-edge data. Thus, it is suggested that the corrosion product is a mixture of UO_{2+x} and $U(OH)_4$.

Although no hydride was detected in the present investigation, its stability under the conditions of the present tests was verified, and, therefore, it is likely that previous observations (1) of a hydride phase in the corrosion layer were due to hydrogen overpressure in the reaction vessel. It would be of interest to determine the hydrogen pressure required to form hydride in the presence of water and the effect of pressure on the corrosion rate of uranium.

Measuring Equipment for Polarization Studies in Distilled Water

J. E. Draley, W. E. Ruther, F. E. DeBoer, and C. A. Youngdahl

Argonne National Laboratory, Lemont, Illinois

ABSTRACT

A technique of measuring polarization in distilled water is described. The Luggin capillary and the a-c–d-c bridge methods are discussed and judged inapplicable. The decay of polarization voltage (of aluminum) is shown to be relatively slow in this environment. A recording voltmeter and current interrupter suitable for making polarization measurements in low conductivity solutions are described. The important design features of the electrolytic cell are discussed, and polarization data for aluminum in boiling water are given as an experimental example.

A number of articles (1) have discussed the theoretical analysis of metal potential vs. applied current curves for corroding metals. In those cases in which a specific experiment is described, the corroding medium has been of relatively low electrical resistance. Extending these potential-current analyses to a high-resistance medium such as distilled water modifies several of the usual measurement problems and introduces certain new ones.

The most serious problem in high-resistance solutions is that of the solution *IR* drop. Three methods are known for overcoming the solution resistance problem (Fig. 1): (*a*) by use of the Luggin capillary, (*b*) by balancing out this potential with an appropriate bridge circuit, and (*c*) by measuring the metal potential when no current is flowing (the interrupter technique). The Luggin capillary cannot be used in pure water because it shields the metal and because the small leak of the conducting salt at the metal surface would change the results entirely. Furthermore, the Luggin capillary would not eliminate the *IR* drop in so high a resistance medium.

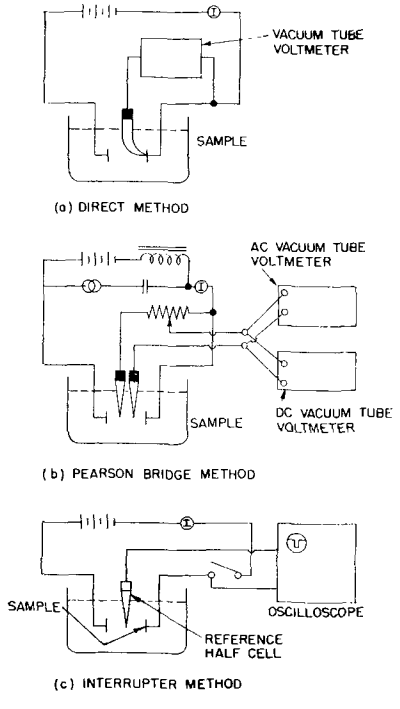

Fig. 1. Methods of overcoming solution IR drop in polarization measurements.

Initially the bridge technique appeared more promising since the circuitry was comparatively simple and the instruments (a-c and d-c vacuum tube voltmeters, etc.) were available from commercial sources. After preliminary experimentation several serious sources of trouble due to the high-resistance solution became apparent. As a result, attention was directed to the third or interrupter technique. A brief description of the experimental difficulties encountered with the bridge circuit is presented before the detailed discussion of the interrupter equipment to illustrate some of the unusual aspects of the problem.

Bridge Circuit

Various modifications of the Pearson (2) circuit were tried. It is assumed that the large specimen-solution pseudocapacitance effectively bypasses the electrode resistance for alternating currents, leaving only the solution resistance. Various impedance bridge circuits may then be devised, using a.c., to balance the solution *IR* drop with an equivalent external *IR* drop. Thus, when the current is changed to d.c., only the polarized potential of the specimen is measured in the previously balanced arm of the bridge. In distilled water at least two serious complications were encountered. First, the capacitative portions of the impedances between bridge members in the polarization cell were the same order of magnitude as the resistive component of the impedance in the solution. Balancing the a-c bridge under these conditions required a Wagner ground connection and multiple adjustments. Since a relatively large total d-c voltage (5-20 v) was required to drive the desired small polarizing currents, the a-c bridge had to be set with extreme precision to reduce the d-c error voltage (due to unbalanced *IR* drop) to within a few millivolts. Another difficulty was experienced with the reference electrodes. Since

most reference electrodes contaminated the pure water (a possible, but cumbersome, exception was the platinum-hydrogen electrode in hydrogen saturated water), the area of contact between the solution of the reference electrode and the pure water was deliberately made quite small. This small area resulted in a high-resistance contact shunted by a capacitative reactance. As a result, a-c and d-c impedances through the reference cell were not equal, whereas the analysis of the bridge circuits used demanded that they be equal. Because of these difficulties the work on bridge circuits was suspended.

Interrupter Technique

High solution resistance also complicates the interrupter type of measurement (Fig. 1c). The electronic detector must be sensitive to millivolts with the polarizing current off and yet not be overloaded by solution *IR* drops of up to 20 v with the current flowing. The high impedance of the measuring path between the reference electrode and the specimen makes it susceptible to stray a-c pickup (usually 60 cycles). Also, the input capacitance of the measuring circuit must be minimized to prevent relatively long RC decay times from introducing spurious polarization voltages.

Many circuits have been described for making quantitative measurements during the current interruption period (3). The recent, more complicated circuits have been required for precise measurements in the microsecond range. However, in the case of corroding specimens in distilled water, examination of current interruptions with a Model 531 Tektronix oscilloscope indicated several favorable features. For example, pure aluminum in 100°C distilled water and the simple circuit of Fig. 1c gave the trace shown in Fig. 2. A low resistance reference cell (platinized Pt, H_2 gas) and a special input circuit to the oscilloscope were used to permit viewing in the short time range. Even so, the period up to 60 μsec was obscured by the decay of the *IR* voltage. A very rapid polarization decay reaction, essentially complete in this time, may have occurred, but in view of the subsequent slow decay this seems unlikely. Since the direct method is not feasible we know of no way to eliminate this possibility.

It was also noted that the polarization decay in this preliminary experiment (with hydrogen gas) was about three times more rapid than that obtained in boiling distilled water without deliberate gaseous additions. In the latter more common case with the above polarizing conditions, the polarization voltage (about 300 mv at 0.2 msec) decayed about 6% in 1 sec, 63% in 33 sec, and 86% in 108 sec. It was obvious that this was not a simple RC decay.

The decay time for polarization voltages in distilled water thus appeared longer than that measured in the usual solutions. It was not similar to the usual rapid decay of the overpotential of a reversible system (3b). Since a smooth platinum sample behaved in approximately the same fashion in hydrogen-free water, the slow decay was not associated with the aluminum oxide film. The slow decay was not caused by the particular form of the reference electrode as is evidenced by the fact that the results with aluminum samples were not changed by interchanging reference electrodes (Pt-H_2 and calomel). It is not intended in this paper to discuss the theoretical implications of the observed values; it is hoped that a future publication will cover this aspect of the subject.

While the oscilloscope is an excellent method of obtaining a single piece of polarization data it is not well suited to the recording of complete curves in which both the *I* and *E* vary with time. A special piece of equipment was designed for this purpose.

Electronic Equipment

A thyratron tube with constant plate voltage fires nearly instantly whenever the grid-cathode voltage is more positive than a constant critical firing voltage. Hickling (4) devised a potentiometer circuit for determining the polarization voltage during a brief current interruption using this principle (Fig. 3a). The potentiometer is connected so that the voltage due to the solution resistance drives the grid negative with respect to the cathode (Fig. 3c). Manual adjustment of P_2 to the threshold of oscillation was required for each reading. However, the thresh-

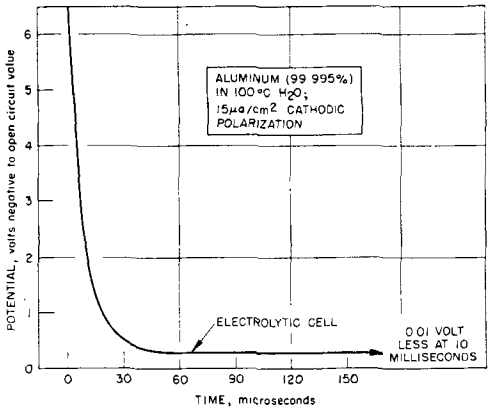

Fig. 2. Oscilloscope trace of current interruption

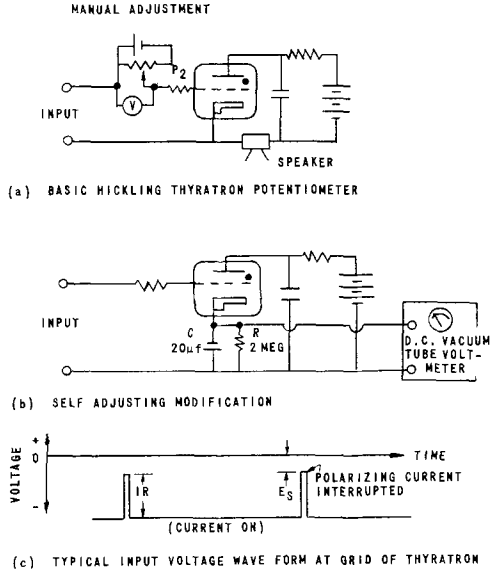

Fig. 3. Basic circuit of self-adjusting polarization voltmeter.

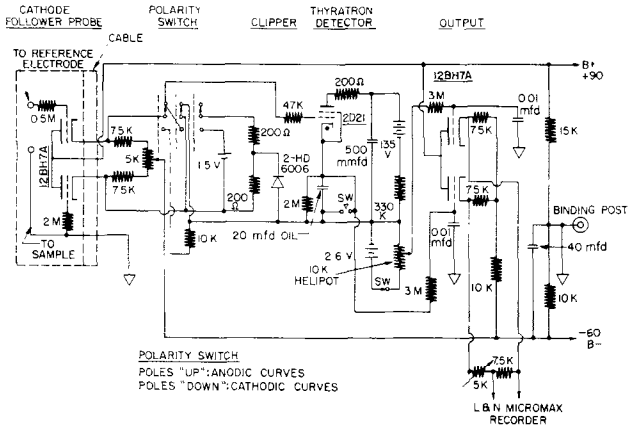

Fig. 4. Circuit diagram of polarization voltmeter

old adjustment can be performed automatically by the RC circuit of Fig. 3b. As the circuit operates as a saw-tooth oscillator, the current through the thyratron charges the condenser C until the grid-cathode potential is just equal to the critical firing potential for the thyratron. If the input voltage to be measured (E_s) changes, the condenser C is charged automatically by renewed oscillation or discharged by leakage through R until the total grid-cathode voltage again equals the critical firing potential. The change in potential across RC (measured with a d-c vacuum tube voltmeter) is therefore the change in the input voltage. This type of detector measures the most positive excursion of the grid potential during the interruption period.

In Fig. 4 the circuit diagram of the complete detector is shown. The cathode follower (12BH7A) provides high input resistance and isolates the sample from voltage pulses generated by the firing of the thyratron detector (2D21). The output circuit (12BH7A) prevents the loading of the RC self-balancing circuit by the L&N recorder. The range of polarization voltage of the specimen that can be handled by the peak detector itself is about 0.6-0.7 v. An adjustable bucking potential arrangement permits extension of this basic range, when it is necessary.

Certain precautions in construction will improve the performance of the instrument materially. The 12BH7A tube used in the cathode follower probe is selected for low grid current. The test is performed by applying +15 v (with respect to ground) to the "reference electrode" connection of the instrument with a galvanometer in series. A maximum of 10^{-9} amp should be drawn by the grid under these conditions.

Permitting the tubes to age for 5-10 days with their filaments operating tends to stabilize their performance, especially the 2D21 thyratron. The 135-v battery in the plate circuit of the 2D21 should be isolated from the instrument chassis to avoid stray leakage currents and large capacitance to ground. The usual care should be taken to isolate signal leads from those carrying 60 cps currents.

The polarizing current is supplied in the normal manner from a multiturn potentiometer and dry cells. The potentiometer may be motor driven, and a large resistance may be in the circuit to provide a

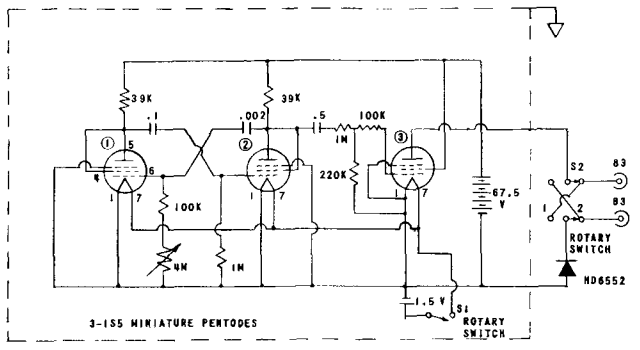

Fig. 5. Battery operated current interrupter

linear rate of change of polarization current when desired. An adjustable, battery operated multivibrator provides the interruption pulses (Fig. 5). The frequency of interruption is about 10 cps. Period of current interruption is adjustable from 1 to 20 msec. A silicon diode in the output lead is used to prevent capacitatively coupled spurious pulses. Reversing switches provide a maximum of flexibility in operation.

Cell Design

The commonly used stop off materials (Bakelite, Lucite, and various waxes) contaminate pure water. As shown in Fig. 6, the sample is clamped tightly against the side of the chamber in a manner similar to that described by Sheff, *et al.* (5) and covers a 1-cm² hole. Only the edge of the thin polyethylene washer is exposed to the solution. The specimen-polyethylene-glass assembly is heat sealed (3 min, 150°C oven) to define the corroding area sharply. Experiments with and without the polyethylene gasket produced identical results within the experimental error.

Contamination of the pure water was also a consideration in choosing materials for construction of the cell. Tygon and Neoprene parts in the water feed line were found to be unsatisfactory where the temperature was high. Teflon parts were difficult to clean properly. Stainless steel appeared to contami-

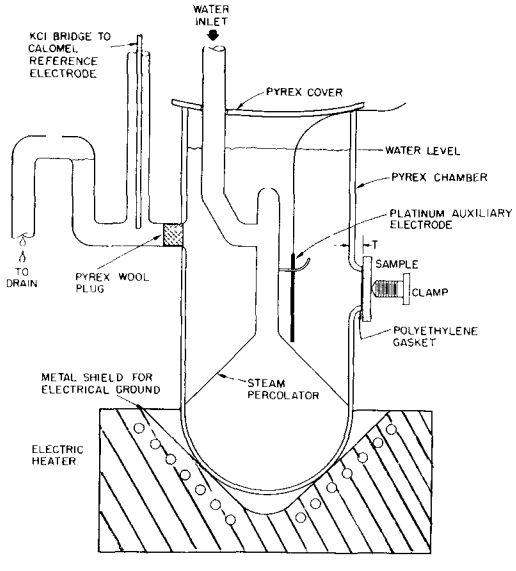

FIGURE 6
TEST CELL USED WITH BOILING DISTILLED WATER

Fig. 6. Test cell used with boiling distilled water

nate the hot water to some extent as judged by its influence on polarization curves. In the present design platinum and Pyrex glass are used throughout, except for the polyethylene gasket.

The 1-cm² hole permits the use of small samples. Any metal which can be ground or otherwise worked to expose one flat surface can be used. These considerations are important when an investigation of a wide range of metals is desired.

A relatively large ratio of water volume (250 cc)/sample area (1 cm²) reduces contamination of the solution by a corroding sample, as does a substantial rate of solution refreshment (10 cc/min).

In order to avoid a stray electrical ground the solution is allowed to form discrete drops at the end of the exit tube and drip into the drain. Also, the cell to ground capacitance is minimized to permit rapid decay of the *IR* voltage pulses.

The calomel cell is used because of its convenience. The slowly leaking salt bridge is constructed by fusing a strand of "Refrasil" insulation in Pyrex. The sweep of distilled water through the cell and the glass wool plug prevent chloride contamination of the sample chamber. On several occasions a portion of the flow was syphoned slowly from the chamber and collected for analysis. No chloride was found (sensitivity better than 0.1 ppm Cl^-).

Dimension T (Fig. 6) should be controlled. If it is made too small, the current distribution is nonlinear to a significant extent. If it is too large, the solution *IR* voltage can exceed +20 v. Under these conditions the grid of the input tube draws current and spurious polarization in the reference path occurs.

To evaluate the problem of nonuniform current distribution a Pt test probe was made by mounting a piece of 2.8 mm OD rod through a piece of Teflon and grinding the exposed face flush with the surface. This probe was mounted on the test cell in place of the usual specimen, and the resistance between the Pt working electrode in the cell and the small probe face was measured with an a-c impedance bridge as the probe was moved from edge to center of the 1 cm² opening. A maximum variation of 4% was found for 100°C distilled water with $T = 1.5$ mm. If greater uniformity were desired, T could be varied so that the maximum *IR* drop did not exceed 20 v or alternatively the input stage to the polarization voltmeter could be operated with higher plate voltage. Experiments have shown that up to 100 v *IR* can be tolerated using this latter technique.

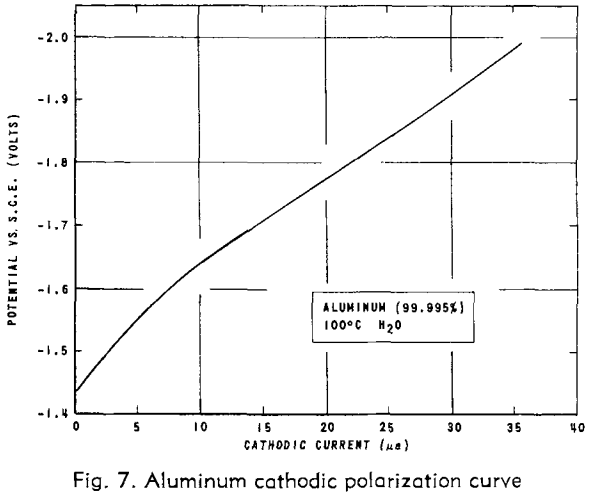

Fig. 7. Aluminum cathodic polarization curve

Annoying fluctuations in the current and voltage measurements were traced to steam bubbles moving across the face of the specimen. The present percolator design provides good temperature distribution, aids in degassing the replenishing water, sweeps the corrosion product away from the sample, and eliminates the steam bubble problem.

Experimental Example

The distilled water (resistivity —1.1 to 1.5 x 10^6 ohm-cm at 28°C) is usually slightly electrolyzed between Pt plates prior to its entry into the polarization chamber. When high-purity Al is used as the sample, this pre-electrolysis causes a slight decrease in the initial slope of the E vs. I cathodic curve and also prevents a sharp bend in the E-I curve at about 30 μa of cathodic polarization current. It is usually thought (6) that this pre-electrolysis takes some impurities out of the solution, but it is not clear that this mechanism applies here. The design of the pre-electrolysis cell and the amount of current do not seem to be critical.

Figure 7 is a trace of the recording of one experiment of potential (vs. saturated calomel electrode at room temperature) against applied cathodic current for high-purity Al in boiling water. The current was increased linearly with time ($\Delta I/\Delta t = 0.08$ μa/sec). This rate had little effect on these curves within the range investigated (0.04 to 0.11 μa/sec) and was controlled easily within this range. A 5-msec interruption period was used. The curve of Fig. 7 is one of thirteen similar curves. For this group of curves the average deviation at $I = 0$ is 0.006 v, that at 35 μa is 0.027 v; the maximum deviation at $I = 0$ is 0.011 v, that at 35 μa is 0.054 v. The slope of the straight line part (15 μa to 30 μa) is 14.4 x 10^3 v/amp with an average deviation of 1.1 x 10^3 v/amp. Samples were prepared by wet grinding pieces of a single stock of rolled and annealed sheet. They were exposed to the boiling water for about 20 hr (to an approximately constant value of open-circuit potential) before these measurements. Great care must be exercised to exclude impurities, since a small amount of contaminant corresponds to a large percentile change in the impurity level of the solution.

Reproducible E-I curves are being obtained for a variety of metals in distilled water at 100°C. Certain other variables of sample preparation are yet to be evaluated before a theoretical interpretation of the data is made.

Electroplating of Nickel from the Pyrophosphate Bath

S. K. Panikkar and T. L. Rama Char

Electrochemistry Laboratory, Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore, India

ABSTRACT

The pyrophosphate bath has been found to be satisfactory for the plating of nickel. It gives good quality deposits over a wide range of operating conditions and has some advantages over the Watts bath.

Nickel is commonly plated from the sulfate-chloride or choride baths, and the fluoborate and sulfamate types have been established recently for industrial work. These solutions are all right in most respects, but they have a poor throwing power and are not suitable for direct plating on zinc. A complex salt bath suggests itself as an alternative. Brockman and Nowlen (1) have plated nickel on zinc from the triethanolamine bath. Langbein (2) cites an alkaline nickel pyrophosphate solution, and there is a patent (3, 4) on the zialite bath, containing nickel in the form of ammoniacal pyrophosphate and citrate complexes, for plating the metal on zinc. In view of the meager information available in literature, the plating of nickel from the pyrophosphate bath was studied in detail. The initial work has been reported briefly from this laboratory (5, 6), and a general review of plating metals and alloys from the pyrophosphate bath was made recently (7, 8).

Experimental

Plating solutions were prepared in the early work (5) by the addition of alkali pyrophosphate to a wet precipitate of nickel pyrophosphate obtained from nickel sulfate and pyrophosphate. Alkali chloride was then added to facilitate anode corrosion. It was necessary to add at least 6 g/l potassium chloride to the solution; otherwise the anode efficiency was zero. The bath preparation was therefore altered, potassium pyrophosphate being added to nickel chloride. The potassium salt was chosen in place of the sodium in view of the beneficial effects of the former as in other plating solutions. The pyrophosphate content of the bath was always in excess of that required for complex formation. Physicochemical measurements have shown (9) that the molar ratio of pyrophosphate to nickel in the complex is 2 as well as 1, the instability constant as determined from spectrophotometric data being of the order of 10^{-4}. There was no immersion deposition of nickel on zinc.

In solutions containing more than 0.3M nickel there was a tendency for precipitation after electrolysis. Ammonium citrate was added as a bath constituent since it was beneficial from the viewpoint of stability and buffering of the solution, quality of the deposits, cathode efficiency, and limiting c.d. (current density). Solutions with 0.3M nickel were titrated electrometrically with alkali using the glass electrode. Figure 1 shows that the precipitation pH is raised slightly by citrate, the best buffering action being imparted by 20 g/l of the salt. It was not advisable to increase the citrate content of the solution, thereby making it a mixed bath. The concentration of citrate was proportional to the nickel content of the solution, the ratio being 66.6 g/l ammonium citrate for 1M (58.7 g/l) nickel. Figure 2 shows that the resistivity of the solution is slightly decreased by citrate.

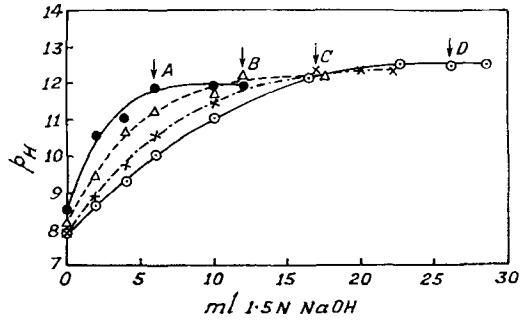

Fig. 1. Electrometric titrations. Ni 0.3M, ratio (i.e., ratio of pyrophosphate to metal by weight) 8. (A) am.citrate nil, (B) am.citrote 10 g/l, (C) am.citrate 20 g/l, (D) am.citrate 30 g/l. Each arrow shows the precipitation point for a curve, and the letter above it refers to the curve.

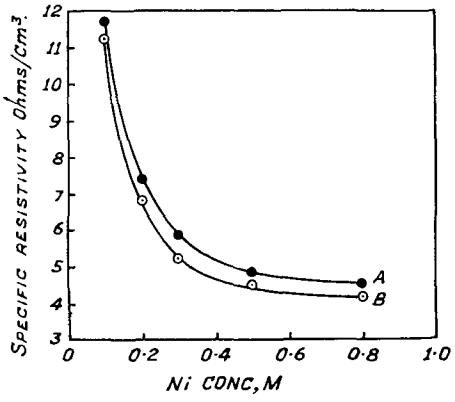

Fig. 2. Specific resistivity. Temp. 60°C, ratio 8. (A) am.citrate nil, (B) am.citrate 66.6 g/l for 1M Ni.

Fresh solutions, 200 ml, were taken for each experiment. Nickel anodes[1] (3 x 1 x ⅛ in.) and copper sheet cathodes (3 x 1 x 1/32 in.) were used, the inter-electrode distance being 1 in. and the immersed area of each electrode 2 in.^{2}; plating time for an experiment was 10-45 min. The experimental details concerning cleaning of electrodes, plating equipment, current efficiencies, temperature, agitation, pH, resistivity, and electrode potentials were the same as described before (10). The pH was varied by the addition of potassium hydroxide or hydrochloric acid. Conditions were carefully controlled to obtain electrode potential values (hydrogen scale) to the accuracy of ± 0.005 v.

The throwing power of the plating solution was measured under optimum conditions with a modification of the Haring-Blum throwing power box (11). The object was to obtain a relative idea of the throwing power of different plating solutions. A cylindrical glass cell 15 cm long and 4.5 cm in diameter was used, with 2 copper cathodes and a perforated nickel anode in between. The distance between the cathodes was 12 cm. The cathodes were weighed after electrolysis and cathode potentials and resistivity of the solution determined. The throwing power was calculated from the Field formula (12) and also from the equation of Gardam (13) for a linear relationship between cathode potential and log c.d., there being no variation of the cathode efficiency with c.d.

Photomicrographs of a thick coating (0.001 in.) of the surface of nickel deposit were taken with a Leitz projection microscope. X-ray powder patterns of the deposit were obtained from a Rich Seifert 13 unit with 57.3-mm diameter camera. Hardness measurements were made on the surface of the deposit with Leitz 1151 Durimet Midget hardness tester.

Experimental Results

Electrodeposition was carried out under the following conditions: nickel concentration 0.05, 0.1, 0.2, 0.3, 0.4, 0.5, and 0.8M; ratio of pyrophosphate (P_2O_7) to metal (weight) 6, 7, 8, and 10 (3.375 molar ratio); pH 7.8, 8.5, 9, 9.5, and 10.5; temperature 30°, 50°, 60°, and 70°C. Results are presented in Fig. 3-14 and in Tables I-III. All the results have not been covered to avoid overlapping. For the same reason, points corresponding to static potentials have not been marked. The data recorded correspond to good quality deposits. The decomposition potential for the plating solution was 1.8-1.9 v, and the bath voltage 0.9-3.0 v.

Nature of deposit.—The bath gave smooth, white, bright, fine-grained, and adherent deposits of nickel on copper (brass or zinc) cathodes over a wide range of plating conditions. Table I shows the effect of beneficial addition agents on cathode efficiency, potential (where there was a significant change), and quality of the deposit. Among other substances tried, diphenylamine had no effect, and selenium dioxide resulted in a deterioration. Plates 1 to 5 (Fig. 3) show the photomicrographs of the surface of nickel plates obtained under different conditions. Addition of ammonium citrate made the deposit finer grained and brighter, and there was no indication of escape of gas from the surface (plates 1 and 2). Increase of c.d. or temperature (not shown) or addition of cobalt chloride gave a brighter deposit; in the last case there was gas evolution and stress (plates 3-5). X-ray studies showed that the deposit has a f.c.c. structure, with $a = 3.516$Å.

Current efficiencies.—The cathode efficiency was increased by the addition of ammonium citrate, increase of nickel content, or pH of the solution. There was a slight increase with increase of temperature, and decrease with agitation. Most of the addition agents increased the efficiency at higher

Table I. Effect of addition agents on cathode efficiency, potential, and quality of the deposit

Bath composition: Ni 0 5M, ratio 8, ammonium citrate 33.3 g/l; pH 9.5; temperature 60°C, still plating. The first figure under c.d. gives the cathode efficiency % and the second (in parentheses) gives the cathode potential (-ve sign) in volts in H scale. Quality of deposit: A—marked improvement, B—slight improvement.

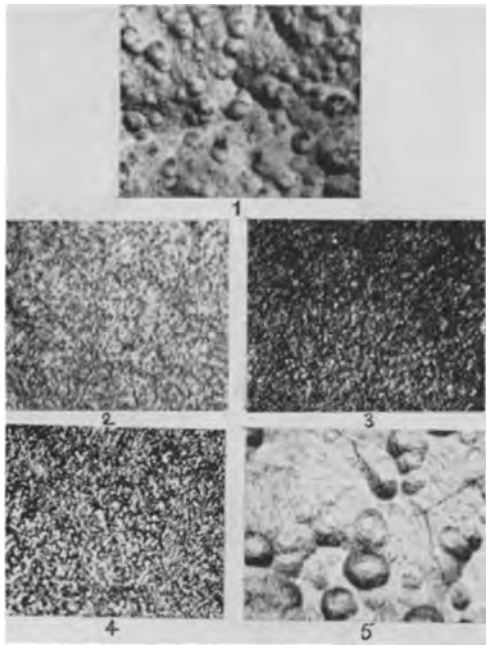

Fig. 3. Phatomicrographs of deposits. Temp. 60°C, Cu cathode, magnification 1 x 700. Plate 1—Ni 0.3M, ratio 8, 1 amp/dm²; Plate 2—Ni 0.3M, ratio 8, am.citrate 20 g/l, 1 amp/dm²; Plate 3— Ni 0.5M, ratio 8, am.citrate 33.3 g/l, 2 amp/dm²; Plate 4—Ni 0.5M, ratio 8, am.citrate 33.3 g/l, 4 amp/dm²; Plate 5—Ni 0.5M, ratio 8, am.citrate 33.3 g/l, cobalt chloride 4.8 g/l, 2 amp/dm².

c.d. In the majority of cases the values were from 80 to 94% (Table I and Fig. 4-8). The deposits were satisfactory even though the efficiency was less than 100%. It was possible to work the bath up to 10 amp/dm² with addition agents. The anode efficiency was about 100% throughout, and the values have therefore not been recorded under different conditions (Fig. 8). There was some sludge formation at the anode. The corrosion was, however, quite normal even beyond the limiting cathode c.d.

Potentials.—The cathode potential decreased[2] with increase of nickel or citrate content of the solution, temperature or agitation, and decrease in the ratio or pH (not shown). However, the potential changes were not very marked. The values were decreased by the addition of lead acetate, thiourea, beta-naphthol, and selenium dioxide (0.15 v decrease), and increased by gelatin (Table I and Fig. 9-11). The effect of the variables on the anode potential was in general similar to that on the cathode side (not recorded). Figure 12 shows that the chloride ion promotes anode corrosion.

[2] "Decreased" means that the potential has become more noble, i.e., has shifted toward the potential of a gold electrode.

Throwing power.—Table II gives the results on throwing power measurements for the pyrophosphate, Watts (4), and chloride (14) baths under optimum conditions. The throwing power decreased with increase of c.d., and increased to some extent with increase in the linear ratio. There was reasonable agreement between the values calculated from the Field and Gardam equations. The reciprocal of the slope of the plot of the metal ratio against linear ratio, called the throwing index (15), gives a direct measure of the throwing power. Figure 14 gives this plot for the three baths; the index values are given in Table II.

Table II. Throwing power

Control and maintenance of bath.—The bath was quite stable under the conditions of operation. In a typical case with a solution containing 0.5M nickel, ratio 8, and ammonium citrate 33.3 g/l, the cathode and anode efficiencies were 92 and 96%, respectively. The changes before and after electrolysis for 1 hr at 4 amp/dm² and 60°C were: nickel 29.8, 29.9; total pyrophosphate (P_2O_7) 234.6, 234.5 g/l; pH 9.50, 9.52; specific resistivity 4.51, 4.50 ohm/cm³; orthophosphate nil. A freshly prepared solution could be used for several runs with consistent and satisfactory results. Ageing of the electrolyte up to six months had no effect on the performance.

Testing of deposits.—Satisfactory coatings of any desired thickness from 0.0003 in. onward, calculated from area and weight, could be obtained. Bending and breaking tests indicated excellent adherence of the electroplate to the copper base. Deposits were free from porosity as shown by the electrographic method. A filter paper moistened with a 5% solution of sodium nitrite is applied to a coating of nickel on brass, and a sheet of platinum is placed on top. The test specimen is made the anode and the metal plate the cathode while a current of 2 ma/in.² is passed for 3 min. The paper is then developed for 1 min in a solution of 50 g/l potassium ferrocyanide and 30 g/l glacial acetic acid. Porosity is shown by brown spots on the paper. The hardness of deposits, 0.001 in. thick, increased with increase of c.d. from 1 to 6 amp/dm²: 380 to 450 Vickers, and decreased with increase of temperature from 50° to 80°C: 470 to 240.

Comparison of pyrophosphate and acid baths.—Table III gives the plating characteristics under optimum conditions for the pyrophosphate, Watts, and chloride baths for nickel plating. Data for the last two have been obtained experimentally for typical commercial compositions (4, 14).

The pyrophosphate bath is comparable to the acid baths in all important characteristics. The advantages of this bath over the others are: low metal content, high throwing power, and ability to plate directly on zinc.

Discussion

Experimental results show that the pyrophosphate bath is satisfactory for the plating of nickel. The solution mentioned by Langbein (2) contains nickel pyrophosphate 19.5 and sodium pyrophosphate 79.4 g/l; it is operated at 0.5 amp/dm², the bath voltage being 3.5 v. The zialite bath (3) consists of nickel in the form of pyrophosphate and citrate complexes, sodium and ammonium sulfates, chlorides, and free ammonia. It has been used for plating on zinc at 21°-35°C, pH 7.5-9.0, and current densities up to 2.5 amp/dm². The current efficiency

is 92% at 1.5 amp/dm², the values decreasing with increasing c.d. Solutions used in the present investigation are simple in composition, and even at 30°C the limiting c.d. is 4 amp/dm².

Most of the addition agents given in Table I act as brighteners in the Watts bath. Sodium sulfite and bisulfite have also been used in the zialite bath (3) and the pyrophosphate (16) and cyanide (4) baths for copper. The beneficial effects of ammonium citrate are similar to those obtained in the deposition of copper (16) and zinc (17) from the pyrophosphate bath. Brighteners in other baths include: gelatin and beta-naphthol in zinc (17) and tin (10) pyrophosphate, and lead acetate, sodium beta-naphthalene sulfonate and triethanolamine in copper (16) pyrophosphate baths. Cobalt, lead, and zinc codeposit with nickel from this bath. All these

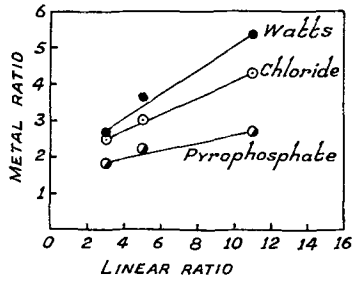

Fig. 14. Throwing index. L and M values at 1 amp/dm² from Table II.

substances belong to three broad types from the viewpoint of the current theories of addition agent action (18): complex formation, codeposition, and the formation of compounds which may exist as adsorbable colloids in the cathode film or function as brighteners on the analogy of their acid pickling inhibiting tendency.

The nickel electrode did not give reproducible potentials; this has been observed by other workers. It appears to be due to a passive film on the metal surface, giving a more noble potential. The passage of nitrogen or a freshly deposited nickel surface

changed the static potential in a negative direction, and a combination of these two gave the most satisfactory value. In a 0.5M nickel solution the potential values were: —0.1 under normal conditions, —0.4 for deposited surface, and —0.5 v for deposited surface under nitrogen. Taking the last value the instability constant for the complex (molar ratio of pyrophosphate to metal 2) was of the order of 10^{-9}, indicating a fairly stable complex. The static potential values including those given in Table I correspond to the deposited condition.

Cathode polarization was high, as in the deposition of other metals from this bath (7). Polarization is considerable during the deposition of nickel from the sulfate and sulfamate (19) baths; in the former case it is about 0.2 to 0.3 v. In the pyrophosphate bath the polarization was in the range 0.4 to 0.9 v. The relationship between cathode potential and log c.d. is linear under optimum conditions for the pyrophosphate, Watts, chloride (Fig. 13), and sulfamate (19) baths, and fine-grained deposits are obtained. This is in accordance with the views of Gardam (20) that the logarithmic relationship is an indication of frequent formation of new nuclei. Similar results have been obtained in the plating of tin (10), zinc (17), and copper (7) from the pyrophosphate bath. The slope of the potential-log c.d. straight line was 0.55, much greater than the values for the Watts and chloride baths (Fig. 13 and Table II). For the pyrophosphate bath the slope of the plot of polarization under agitation, against log c.d., was 0.34 (from Fig. 10, curve D). Calculations from the Tafel equation gave a value of the order of 10^{-4} amp/cm^2 for the exchange current density, and 0.1 for alpha under these conditions. The corresponding values reported in literature (21) for nickel from sulfate bath are 10^{-9} amp/cm^2 and 0.5, respectively.

The bath possesses good throwing power. In view of the greater slope of the potential-log c.d. lines and the lower resistivity the throwing power of this bath is much better than that of the acid baths. The throwing index is also greater.

The anode potentials of nickel in pyrophosphate solutions indicate the phenomenon of passivity (Fig. 12). The passive anode shows a potential of 1.2 v., close to the oxygen evolution value. Increasing additions of potassium chloride change the potentials to more negative values, and finally at the chloride concentrations used for plating the potential is 0.4 v, the active value. Unlike the partial passivity in acid solutions, the nickel anode is totally passive in the pyrophosphate bath. Addition of chloride raises the efficiency from 0 to 100%. Anode polarization was rather high, 0.8-0.9 v, but the values cannot be regarded as accurate in view of the sludge formation.

The electrodeposition of alloys of nickel with tin, copper, zinc, cobalt, iron, manganese, tungsten, and molybdenum from this bath has been reported elsewhere (8, 22-24).

Acknowledgment

Our thanks are due to Professor K. R. Krishnaswami, Head of the Department, for his keen interest in the work. One of the authors (S. K. Panikkar) is grateful to the Government of India for the award of a Senior Research Scholarship during the period of the investigation.

Manuscript received May 20, 1958. This paper was prepared for delivery before the Ottawa Meeting, Sept. 28-Oct. 2, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Phase Equilibria and Fluorescence in the System $Zn(PO_3)_2$-$Mg(PO_3)_2$

J. F. Sarver and F. A. Hummel

Department of Ceramic Technology, College of Mineral Industries, The Pennsylvania State University, University Park, Pennsylvania

ABSTRACT

The equilibrium diagram for the system $Zn(PO_3)_2$-$Mg(PO_3)_2$ was established as a solid solution type by quenching and solid-state methods. About 10 mole % $Mg(PO_3)_2$ was found soluble in β-$Zn(PO_3)_2$ at 850°C, but less than 2 mole % was soluble in α-$Zn(PO_3)_2$ at 650°C. Solid solution of $Zn(PO_3)_2$ in $Mg(PO_3)_2$ was extensive, ranging from approximately 35 to 100 mole % $Mg(PO_3)_2$.

The cathodoluminescence of compositions in the three solid-solution series was examined for peak emission and brightness when activated with manganese. A shift in the position of the emission peak from 6000 to 6200Å in the magnesium metaphosphate solid-solution series has been interpreted in terms of the difference in influence between magnesium and zinc ions on the polarizability of oxygen ions in the neighborhood of the manganese activator.

Equilibrium relationships in the system $Zn(PO_3)_2$-$Mg(PO_3)_2$ were established as an aid to the identification and understanding of the host lattices which are responsible for the luminescence of preparations in the system ZnO-MgO-P_2O_5. It is well known that the ortho-, pyro-, and metaphosphate compounds of zinc and magnesium are bases for several phosphors which emit in the red portion of the visible spectrum and a few others which emit in the orange or green portion.

Two previous papers have dealt with the phase relationships in the system ZnO-P_2O_5 (1) and the emission characteristics of the manganese-activated zinc phosphate compounds under cathode ray excitation (2).

Berak (3) has established the melting points and eutectic compositions and temperatures in the system MgO-P_2O_5. The fluorescence of the magnesium phosphate compounds has not been explored as extensively as that of their zinc phosphate counterparts, probably due to the generally low brightness obtained with manganese activation. No equilibrium data have been published for the ternary system ZnO-MgO-P_2O_5.

Experimental Procedure

Compositions Used for Determination of Equilibrium Relationships

Ten-gram batches of the compositions shown in Table I (weighed to 0.0001 g) were made from C.P. ZnO, C.P. basic magnesium carbonate, and C.P. $(NH_4)_2HPO_4$ and were melted to glasses in platinum crucibles for use in quench determinations.

To minimize P_2O_5 volatilization during melting, the batch materials were reacted in the solid state at about 800°C for 24 hr. The batches were melted then in platinum crucibles for 10 min between 900° and 1200°C. The glasses were air quenched, crushed in a steel mortar, and passed through 100 and 120 mesh sieves. The fraction retained on the 120 mesh screen was reserved for index of refraction measurements, and the minus 120 mesh material was used for quench experiments after magnetic removal of traces of metallic iron introduced by the crushing process.

Heat Treatment and Physical Measurements

The melting, quenching, solid-state reactions, phase identification, differential thermal analyses, and measurement of emission spectra were carried out as described in previous papers (1, 2). Calibration of thermocouples used in the quench work was done using Li_2SiO_3 (1201°C), Au (1063°C), and Ag (961°C); the accuracy of temperature measurement was generally ±2°C.

CuKα radiation was used for x-ray identification

of crystalline materials. Petrographic microscope determinations of refractive indexes of glasses and crystals were accurate to ±0.001 using index oils which had been calibrated with an Abbé refractometer. Cathodoluminescent emission spectra were determined on a demountable tube using an electron beam with a current density of 2.0 μamp/cm² and an accelerating potential of 16 kv.

Results and Discussions

Magnesium Metaphosphate

Although it was already known that ortho-, pyro-, and metaphosphate compounds of magnesium exist, the system was briefly re-examined by solid-state reactions and the three compounds were confirmed. Then further work was carried out on the thermal behavior of $Mg(PO_3)_2$ to check for possible inversions and the nature of melting. The congruent melting point was determined by quenching experiments to be 1165° ±5°C which agrees well with that reported by Berak (3).

No inversions were detected after extensive solid-state, quenching, D.T.A., and dilatometric experiments. Crystals prepared by devitrification of $Mg(PO_3)_2$ glass were found to be biaxial negative with $n_\beta = 1.585$ and 2 v equal to about 30°C. The x-ray diffraction data for $Mg(PO_3)_2$ and the two forms of $Zn(PO_3)_2$ are given in Table II.

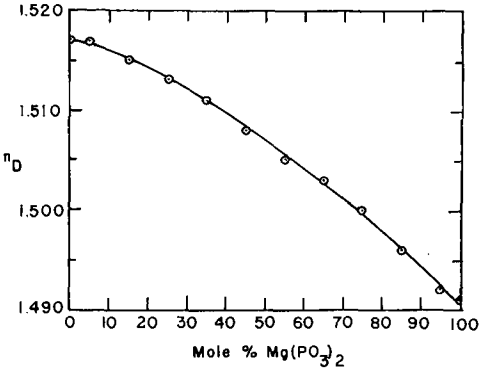

Fig. 1. Indexes of refraction of metaphosphate glasses

Phase Equilibrium Relationships in the System $Zn(PO_3)_2$-$Mg(PO_3)_2$

The refractive index curve for the metaphosphate glasses is shown in Fig. 1. These data were used extensively during the petrographic examination of the many quenches made in the system. The important quench data are summarized in Table III and the equilibrium diagram based on these data is shown in Fig. 2. The starting material for the quench work was a glass, and all phase identifications were made with the petrographic microscope, except for composition No. 16. In this case the starting material was batch which had been reacted below 650°C and the phase identifications were made by x-ray diffraction.

The system is characterized by two small regions of solid solution near the $Zn(PO_3)_2$ compound, a large region of $Mg(PO_3)_2$ solid solutions, and a mis-

* G, glass; ZP, $Zn(PO_3)_2$; MP, $Mg(PO_3)_2$; ss, solid solution.

cibility gap involving β-$Zn(PO_3)_2$ and $Mg(PO_3)_2$ solid solutions. At 850°C, the two-phase region extends from about 10-35 mole % $Mg(PO_3)_2$.

Further confirmation of the nature and extent of solid solution was obtained on a series of well-crystallized compositions which had been prepared by devitrification of glasses at 800°C for 24 hr. Diffraction patterns shown in Fig. 3 were obtained with a rotating specimen holder and a goniometer speed of 1°/min. An examination of the patterns of compositions containing 100-35 mole % $Mg(PO_3)_2$ showed that there was practically no change in peak positions, but only a change in intensity for certain 2θ reflections, notably those at 14.5°, 19.5°, 21°, and 27.8°.

A more detailed examination of the $Mg(PO_3)_2$ solid-solution series was made by obtaining diffraction patterns at a goniometer speed of ¼° (2θ)/min. When the patterns of the end members of the solid-solution series (Fig. 3a) were compared [$Mg(PO_3)_2$ vs. $(Mg_{0.35}Zn_{0.65})(PO_3)_2$], the maximum shift in position of any particular high angle reflection was 0.05°, indicating a very low order of magnitude of change in lattice dimensions. With increasing amounts of zinc in solid solution, the small shift was toward lower angles, indicating only the slightest increase in lattice dimensions.

When attention is focused on the patterns of compositions containing 30-10 mole % $Mg(PO_3)_2$ (Fig. 3b), it is evident that two solid solutions are present in this range. The strong lines of $Mg(PO_3)_2$ at 29.9°

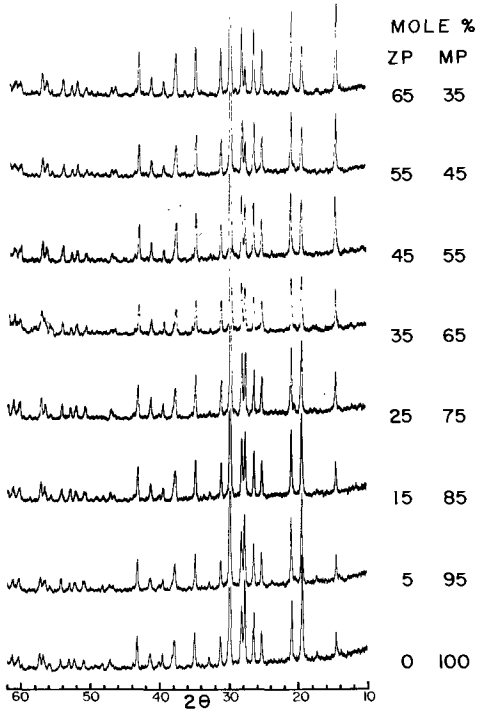

Fig. 3a. X-ray diffraction patterns of $Mg(PO_3)_2$ solid solutions.

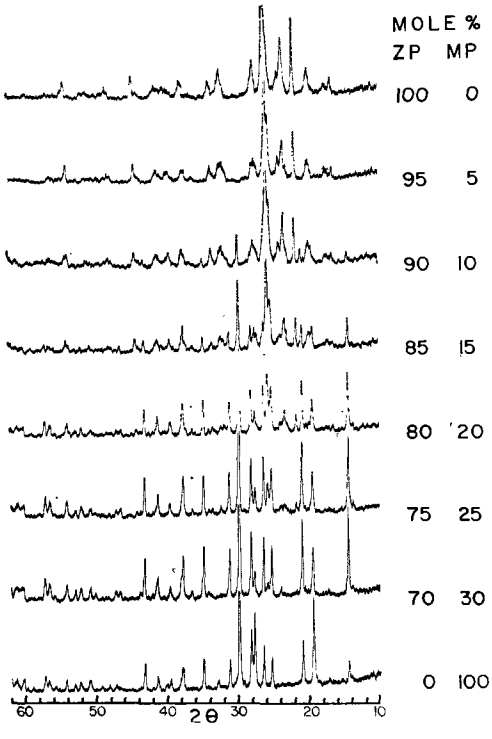

Fig. 3b. X-ray diffraction patterns of β-$Zn(PO_3)_2$ solid solutions and mixtures of β-$Zn(PO_3)_2$ solid solution and $Mg(PO_3)_2$ solid solution.

and 21.0° persist in this region as do the characteristic 25.8° and 21.8° lines of β-$Zn(PO_3)_2$. The relative intensities of the reflections of each of the two solid solutions do not change in this range, indicating constancy of composition.

Finally, it should be noted (Fig. 3b) that only the relative intensities in the 5 mole % $Mg(PO_3)_2$ pattern change when compared to the pattern for pure $Zn(PO_3)_2$, indicating that it is a solid solution having the structure of the beta form of zinc metaphosphate.

Table IV. Peak emission and brightness of metaphosphate phosphors

Comp., mole % ZP	Comp., mole % MP	°C/hr	Phases	Peak emission, Å	Brightness (f-L)

45	55	850/24	MP_{ss}	6100	23.3
35	65	850/24	MP_{ss}	6100	23.0
25	75	850/24	MP_{ss}	6100	21.1
15	85	850/24	MP_{ss}	6100	18.9
5	95	850/24	MP_{ss}	6200	12.1
0	100	850/24	MP_{ss}	6200	9.8
NBS standard β-$Zn_3(PO_4)_2$				6380	36.0

Note: In the MP_{ss} series, one would expect the peak emission to vary systematically and continuously rather than in steps as shown (6200, 6100, 6000). However, the spectroradiometer curves could not be read with greater accuracy than that listed in the table.

It is conceivable that the brightness values listed above may have been affected by the method of preparation (settling in an aqueous medium) since metaphosphates are known to have relatively poor chemical durability.

It had been shown previously that pure α-$Zn(PO_3)_2$ could never be obtained by devitrifying a glass (1). A mixture of α and β forms always resulted from the crystallization. Likewise, from the glass containing 5 mole % $Mg(PO_3)_2$, a mixture of the α and β forms of $Zn(PO_3)_2$ and a $Mg(PO_3)_2$ solid solution always resulted from devitrification below 700°C. Quench work with this crystalline mixture showed that this assemblage could be converted to β-$Zn(PO_3)_2$ plus a $Mg(PO_3)_2$ solid solution between 716° and 725°C. Due to the uncertainties about the increase in the α and β inversion temperature with increase in Mg $(PO_3)_2$ in solid solution, the phase boundaries in this region of the diagram are showed in dashed lines.

Luminescence Studies

On the basis of the phase relationships determined above, the compositions shown in Table IV were selected for the preparation of manganese-activated phosphors. To each composition 0.01 mole MnO/mole (ZnO + MgO) was added, and heat treatments were carried out at subsolidus temperatures as listed in Table IV. The constitution of the phosphors was checked by x-ray diffraction patterns as shown in the fourth column of Table IV.

β-$Zn(PO_3)_2$ solid solutions.—The β-$Zn(PO_3)_2$ phosphors did not show any shift in their peak emission positions (5700Å). However, there was a noticeable decrease in brightness with increasing magnesium content. In the composition 85 $Zn(PO_3)_2$, a second phase was present, a $Mg(PO_3)_2$ solid solution. Its emission dominated that of the β-$Zn(PO_3)_2$ phosphor, raising the apparent brightness, and causing the peak emission to lie at 5900Å.

An interesting observation was made regarding the brightness of the β-$Zn(PO_3)_2$ phosphor. Katnack (2) prepared this phosphor by additions of 1 wt % MnO to preformed $Zn(PO_3)_2$ and obtained a brightness of 4.8 ft-L as compared with 33.9 obtained in this work. His preparation was fired 50°C lower than

the β-$Zn(PO_3)_2$ listed in Table IV, but the greatest part of the difference probably was due to starting materials.

α-$Zn(PO_3)_2$ *solid solutions.*—These phosphors do not exhibit a shift in the position of peak emission (6300Å) with increasing magnesium content. Magnesium seems to lower the brightness (Table IV), and with as little as 5 mole %, $Mg(PO_3)_2$ solid solution appears as a second phase.

The α-$Zn(PO_3)_2$ phosphors had a second emission band with a peak around 4000Å, but of much lower intensity than that at 6300Å.

$Mg(PO_3)_2$ *solid solutions.*—This is the most interesting series, since the $Mg(PO_3)_2$ lattice accommodates 65 mole % $Zn(PO_3)_2$ in solid solution without appreciable change in dimensions. However, there is a significant shift in peak emission from 6200Å for pure $Mg(PO_3)_2$ to 6000Å for the $(Zn_{0.55}Mg_{0.45})(PO_3)_2$ solid solution (Table IV).

Fonda (4) recently reviewed the influence of activator environment on the spectral emission of isomorphous compounds and solid solutions and indicated that lattice dimensions and polarizability of the ions are major factors which determine the position of the peak emission.

Since changes in cation to anion distances in this series of solid solutions are apparently extremely small, an explanation of the shift in peak emission might be based on the polarization of oxygen ions in the structures.

Unfortunately, the crystal structure of $Mg(PO_3)_2$ is not known. However, it is reasonable to assume that some kind of P-O unit forms the basic network and that zinc isomorphously replaces magnesium in MO_6 groups in the $Mg(PO_3)_2$ structure. If there were no difference in polarizing power between Zn^{2+} and Mg^{2+} and the ions acted as rigid spheres, some increase in lattice dimensions would be expected with increasing substitution of zinc (0.83Å) for magnesium (0.78Å). However, due to its 18 electron shell, the zinc ion distorts the oxygen ion, resulting in a Zn-O distance which gives essentially the same effective size for ZnO_6 and MgO_6 groups. Addition of manganese results in MnO_6 groups which are adjacent to MgO_6 groups in $Mg(PO_3)_2$ and to an increasing number of ZnO_6 groups as one proceeds to the $(Zn_{0.55}Mg_{0.45})(PO_3)_2$ solid solution. The electron density distribution in the oxygen around the manganese ion is controlled by the relative amount of zinc and magnesium in the solid solution. Substitution of zinc for magnesium apparently lowers the electron density around the Mn^{2+}, causing a change in the energy of electronic transitions and a resultant shift toward shorter wave lengths.

The change in energy required for the electronic transitions due to substitution of Zn^{2+} ions for Mg^{2+} ions is attended by an increase in brightness of these phosphors from 9.8 ft-L for $Mg(PO_3)_2$:Mn to 25.2 ft-L for $(Zn_{0.55}Mg_{0.45})(PO_3)_2$:Mn.

Summary

1. The solid solubility of $Mg(PO_3)_2$ in β-$Zn(PO_3)_2$ increases from about 3 mole % at 725° to about 10 mole % at 850°C. Increasing solubility of $Mg(PO_3)_2$ decreases the cathodoluminescent brightness of manganese-activated solid solutions which have a peak emission at 5700Å.

2. The solid solubility of $Mg(PO_3)_2$ in α-$Zn(PO_3)_2$ is very low, probably less than 2 mole % at 700°C. Manganese activated α-$Zn(PO_3)_2$ solid solutions have a very low cathodoluminescence brightness with a maximum at 6300Å.

3. Solid solubility of $Zn(PO_3)_2$ in $Mg(PO_3)_2$ is very extensive, ranging from 100-35 mole % Mg $(PO_3)_2$. The peak emission of manganese-activated cathodoluminescence varies from 6200Å for pure $Mg(PO_3)_2$ to 6000Å for a $(Zn_{0.55}Mg_{0.45})(PO_3)_2$ solid solution. Brightness increases with increase in Zn $(PO_3)_2$ in solid solution.

Chemical Etching of Silicon

I. The System HF, HNO_3, and H_2O

Harry Robbins and Bertram Schwartz

Hughes Semiconductors, Newport Beach, California

ABSTRACT

The kinetics of the etching of silicon in the system HF, HNO_3, and H_2O was studied as a function of the composition of the etchant at 25°C. A triaxial plot of the etch rate vs. composition of the etchant shows two extreme modes of behavior. In the region of high nitric acid compositions, etch rates are functions only of the hydrofluoric acid concentration. In the region of high hydrofluoric acid compositions, nitric acid concentration determines the etch rates. The kinetic behavior in the latter region is complicated by autocatalysis in which the reduction products of nitric acid are involved.

The reaction proceeds by an oxidation step followed by the dissolution of the oxide. In the high hydrofluoric acid region the oxidation step is rate limiting. In the high nitric acid region the dissolution step is rate limiting. In both regions the flow of reagent to the surface by diffusion determines the etch rates. A plot of the etch rates as a function of the concentration of the rate-limiting reagent indicates an exponential relationship between the etch rates and the concentration. This relationship has been explained qualitatively on the basis of a second, nonchemical autocatalytic factor, the heat of reaction.

This study was undertaken for the purpose of elucidating the physical and chemical processes that determine the behavior of an acid etching solution. The system HF, HNO_3, H_2O was chosen for study because it is the simplest, from the point of view of composition, of all the acid etching systems used on silicon. It was felt that an understanding of the simple system was a prerequisite for the understanding of the more complicated systems containing additives such as acetic acid, bromine, or heavy metal salts.

Experimental Procedure

The kinetics of the etching system was studied as a function of the composition of the etchant at constant initial temperature (25°C), and data were taken over the composition range where the decrement in die thickness exceeded 0.1 mil/min. Silicon specimens were ⅛ x ⅛ x 0.025 in. n-type dice of approximately 3 ohm-cm resistivity. The two large surfaces of the die were 111 oriented with an accuracy of about 90 min, while the remaining four surfaces were not oriented with respect to any crystal plane. All surfaces had been lapped with an abrasive grit and were work damaged to a depth of about ¼ mil.

The dice were etched, one at a time, in 10 cc of solution in a small Teflon beaker. Agitation was provided by an electric stirring motor equipped with a polyethylene paddle. The reaction was quenched at the proper time with a large volume of water. The dice were then rinsed in distilled water, dried, and measured with a micrometer.

All dice were etched three times, and each etch was performed in a fresh portion of the same solution. Since each etching period had been selected to remove from 4 to 6 mils from the specimen, it may be assumed that the work damage had been removed after the first etch. The third etch was performed in the presence of a few milligrams of $NaNO_2$, for reasons which will be explained later.

All etching was performed in a Teflon beaker immersed in a constant temperature bath regulated at 25°C. The heat transmission of the beaker was so poor, however, that the temperature of 25°C could not necessarily be maintained in the etch solution. Since the etching period was generally shorter than 1 min, and quite often of the order of only several seconds, it is extremely unlikely that thermal equilibrium was maintained, and the reaction may be considererd to have been run under essentially adiabatic conditions.

A triangular coordinate system was set up to represent the composition of the etchant. One vertex was arbitrarily chosen to represent the composition of the stock HNO_3 used to make up the solutions, and another vertex was similarly used to designate the stock HF. The third vertex, therefore, represents only the amount of added water, not the total amount of water present. This normalization of the axes results in a representation of the data valid only for one particular set of concentrations of reagents. However, the representation of the data in mole fraction units, which is free from this objection, led to identical conclusions.

In the preparation of the etching solutions, HF was weighed out to ±0.01 g. The weights of HNO_3 and water were converted to volumes and measured out in a buret to ±0.01 cc. Control of the composition of the etching solutions was established by analysis of the stock acids from which the solutions were to be made and adjustment of these stock acids to the proper concentration, which was arbitrarily taken as the analysis of the initial batch of reagents.

In order that the effect of crystal orientation and

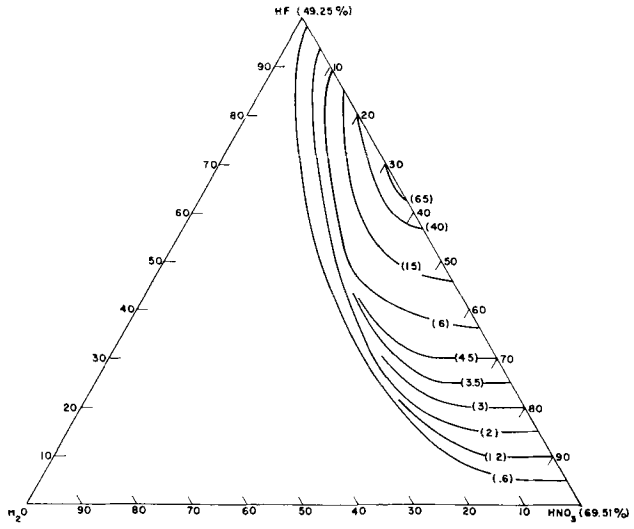

Fig. 1. Curves of constant rate of change of die thickness (mils per minute) as a function of etchant composition (weight per cent in the system 49.25% HF, 69.51% HNO_3, and water).

resistivity type on the etch rates might be checked, specimens of both p-type and n-type Si oriented along the 111, 110, and 100 planes, as well as small Si spheres, were etched in several compositions chosen at random.

Results and Discussion

Figure 1 is a plot of the etch rate (numbers in parentheses are the decrement in die thickness in mils per minute) as a function of the composition of the etchant. The reagents used in this study were the normally available concentrated acids, i.e., 49% HF and 70% HNO_3. It will be shown later that the range of compositions accessible through the use of these reagents was insufficient to clarify the mechanism in the HF-rich region, so that it was necessary to extend the range by employing more concentrated reagents, i.e., 60% HF and 90% HNO_3. Data corresponding to this system are plotted in Fig. 2.[1]

[1] Note that the 20%-added-water line of Fig. 2 corresponds approximately with the no-added-water line of Fig. 1.

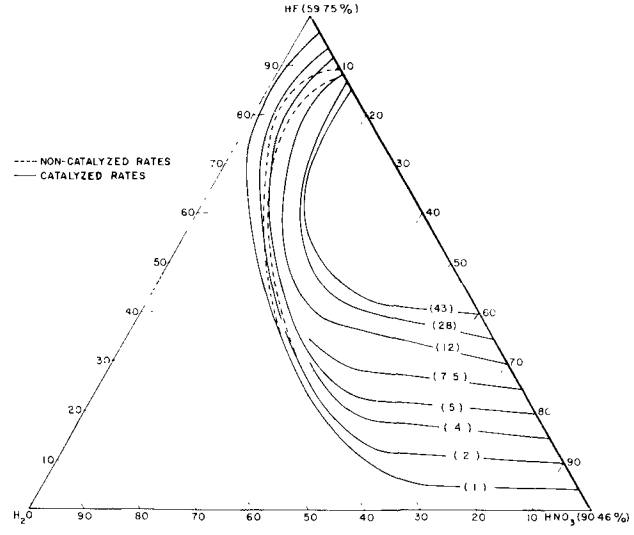

Fig. 2. Curves of constant rate of change of die thickness (mils per minute) as a function of etchant composition (weight per cent in the system 59.75% HF, 90.45% HNO_3, and water).

Rate-Limiting Reagents and Autocatalysis

The contours shown are lines of constant etching rate. In the high HNO_3 compositions the contours run parallel with lines of constant HF concentration, indicating a dependence of the rates only on the HF concentration. The slight inclination of the contours with respect to lines of constant weight per cent HF does not indicate a slight dependence of the rates on HNO_3, as a plot of the same data in mole fraction units results in an inclination of the contours in the other direction. In either case the inclination can be shown to be in the direction of constant molarity, which is kinetically a more significant unit, but which cannot be represented on a triaxial plot.

In the upper region of Fig. 2 there is a strong tendency for the contours to run parallel with lines of constant HNO_3 concentration, indicating that in this region only the HNO_3 concentration determines the rates. However, the behavior of the system is complicated by a second factor, autocatalysis. Rates shown by the dotted curves are second etch rates. They represent the action of fresh solution on a surface from which the work damage has been removed. The solid curves represent what shall be called catalyzed third-etch rates. These etches were performed in the presence of a trace of $NaNO_2$. Sodium nitrite decomposes in acid solution to yield oxides of nitrogen which are apparently catalysts for the reaction (1), as shown by the displacement of the solid contours in the direction of decreased HNO_3 concentration. At all compositions within the area bounded by the innermost dotted contour the added catalyst had no effect on the measured rates. The reaction is believed to require the presence of catalyst throughout the entire composition range. For the majority of compositions, however, the rates are sufficiently high that adequate catalyst is generated to assure its availability for the reaction, and other factors come into play to mask the effect of the catalyst concentration on the etch rates. It is only when the rates are very slow and HNO_3 dependent that the amount of generated catalyst is a prime factor in rendering the reaction self-sustaining.

Many etchant compositions have been found that attack a work-damaged surface readily but fail to re-etch the specimen after the work damage has been removed. This is another manifestation of the influence of the generated catalyst. Etch rates are initially more rapid on a work-damaged surface. The catalyst is either generated in adequate amounts or trapped in surface crevices, and the reaction rate can build up to the steady-state value. When the surface is free from work damage the initial reaction rate is very slow, and it is possible for the reaction products to be dispersed before they can become involved in the propagation of the reaction. The addition of oxides of nitrogen to the solution by any means, such as the addition of $NaNO_2$ or even a chip of work-damaged Si, will supply sufficient impetus to get the reaction started, and once it is started it will usually attain the same steady-state rate as a damaged specimen.

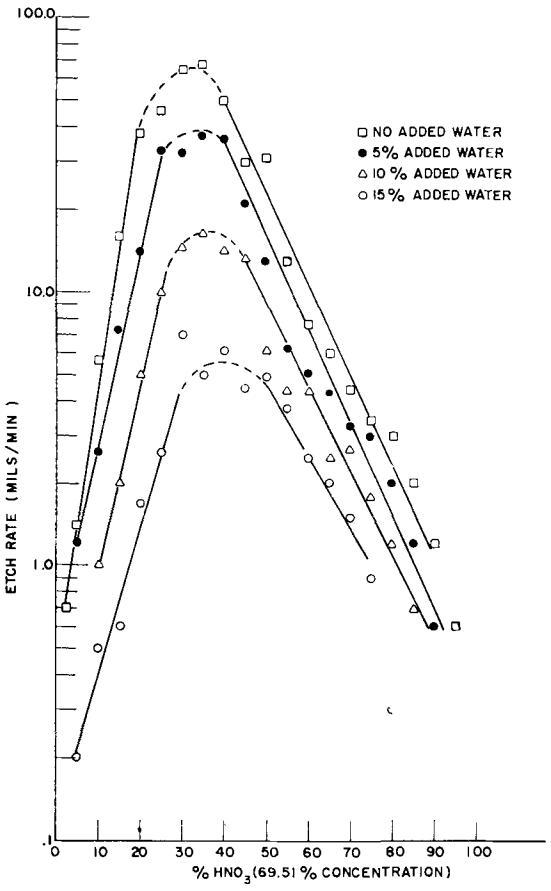

Fig. 3. Logarithm of the rate of change of die thickness as a function of the concentration of HNO_3.

In Fig. 2 the etch rates are initially insensitive to the addition of substantial amounts of water in both the high HF and the high HNO_3 regions, provided that the concentration of the rate-determining species in the region under consideration remains constant. However, at a fairly definite composition the system suddenly becomes critical with respect to the addition of water, and the etch rates rapidly vanish with a slight increase in the water concentration. It will be shown below that the etch rates are determined by the rate of diffusion of the kinetically important species to the Si surface in the regions where the system is insensitive to the addition of water. For this reason the etch rates do not respond to the concentration of added catalyst or to changes in the oxidizing potential of the HNO_3 resulting from the addition of the water. However, at the critical concentration of water, the oxidation potential of the solution has been reduced to the extent that the surface of the Si is no longer a nearly perfect sink for the HNO_3, and the etch rates decrease slightly. At this point the catalyst concentration begins to play a kinetic role. A slight decrease in the etch rates is amplified by the decreased production of the catalyst so that on further addition of water the etch rates rapidly vanish, even though the rate-determining reagent remains at the same concentration. It should be pointed out that the regular concentrated HF contains just the critical amount of water, so that the slope of the etch-rate contours in the very high HF region is just beginning to turn parallel with lines of constant HNO_3 concentration (see Fig. 1). It is for this reason that it was necessary to go to the more concentrated system, where the amount of water is less than critical.

Reaction Mechanisms

Figure 3 is a plot of the logarithm of the etch rate as a function of the concentration of HNO_3 for various levels of added water, i.e., in a direction parallel with the HF-HNO_3 axis of Fig. 1. A similar family of curves may be plotted for the more concentrated acid system. In the latter system the curves corresponding to compositions containing 0-20% added water and to the left of the maximum would coincide. To the right of the maximum the curves for both systems would coincide throughout if the data were plotted as a function of the HF concentration. In this region the displacement of the curves is the result of the varying amount of water in the etchant, which does not permit the simultaneous representation of the concentration axis in terms of both HF and HNO_3.

To the left of the maximum the etch rates are dependent on the HNO_3 concentration and on the amount of added water. Hydrofluoric acid is present in considerable excess, and decreasing amounts of that reagent are still sufficient to sustain increasing rates. The surface of the Si may be considered to be essentially stripped of oxidized Si until the composition corresponding to the maximum etch rate is approached. Then the rate of the reaction becomes sufficiently great, and the concentration of HF sufficiently reduced that a skin of oxidized Si begins to form. This skin renders the surface less accessible to HNO_3 so that the rate of the reaction decreases as the concentration of HNO_3 is increased still further. Beyond this point the rates are dependent only on the rate at which HF can attack the oxidized film.

The kinetics suggest a two-step process. In the first step the Si is oxidized by the HNO_3. This step is followed by a metathesis-type reaction in which the oxidized Si is attacked by the HF. In the composition region to the left of the maximum the oxidation step plays a rate-limiting role, and in the composition region to the right of the maximum the metathesis reaction plays a rate-limiting role.

The conformance of the data to a straight-line relationship indicates that the rates are possibly exponential functions of the concentration of the type $R = e^{ac+b}$. It is interesting to note that the logarithms of the maximum etch rates, when plotted against the concentration of water, also give a straight-line relationship. The constants a and b remain constant only as long as the etch rates are strictly diffusion limited. Thus the curves to the left of the maximum in the weaker acid system do not have the same slopes, although the exponential form of relationship is retained.

The exponential relationship between the etch rates and the concentration of the rate-limiting reagent suggests autocatalysis. As we have indicated above, the chemical catalyst cannot be expected to enhance the rate of a diffusion-governed process, and so we are obliged to postulate the existence of a physical factor which is capable of operating on the

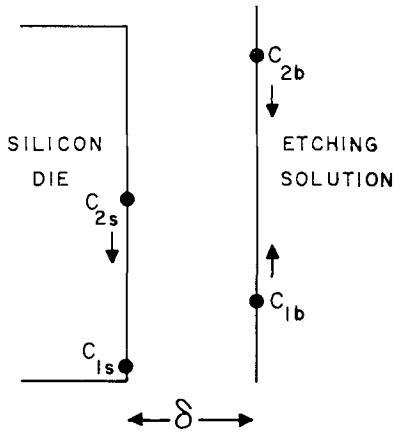

Fig. 4 Model used to explain the diffusion mechanism of the reaction.

diffusion mechanism. This factor is the heat of reaction, which sets up a thermal gradient in the vicinity of the specimen and therefore causes the diffusion coefficient to become a function of the distance from the reacting surface.

In favor of diffusion-governed kinetics is the evidence that differently oriented surfaces, as well as p- and n-type silicon of different resistivities, all appeared to etch at the same rate, whereas large differences in the etch rate of these surfaces are generally observed in other etching systems. Furthermore, the fact that the etch rates are insensitive to the concentration of added catalyst or to the variation of the oxidation potential of the solution, as explained above, supports the theory. The heterogeneous nature of the reaction also requires the consideration of transport phenomena as being kinetically important (2).

In Fig. 4 is shown schematically the surface of a Si specimen immersed in an etching solution under the condition of violent agitation. A thin layer of relatively immobile liquid of thickness δ adheres to the specimen as the solution moves past it. Since the amount of reaction is negligible relative to the total amount of reagents in solution, the bulk solution provides a constant source for reagents. The surface of the Si provides a nearly perfect sink for one of the reagents, the one that is rate limiting. The flow of the other reagent adjusts itself to the stoichiometric requirements of the reaction. Thus, if the stoichiometry of the reaction is assumed to be

$$3Si + 12HF + 4HNO_3 = SiF_4 + 4NO + 8H_2O$$

then the flow rate of HF will have to be three times that of the HNO_3.

In addition to the concentration gradients across δ there will exist a thermal gradient, because of the flow of the heat of reaction away from the surface. Our calculations show that the temperature profile across δ is linear, and the slope is proportional to the amount of heat dissipated, i.e., to the reaction rate. In the absence of the temperature gradient the concentration gradients across δ would also be linear, because of the assumption of the steady state. However, the temperature gradient causes a distortion of the concentration profile toward steeper gradients and thus enhanced reaction rates.

Let us now identify subscript 1 with HNO_3 and subscript 2 with HF, and let us consider the change in the reaction rate as the proportion of HF to HNO_3 is decreased at a given constant level of added water. As C_{1b} increases, the concentration gradient, and thus the reaction rate, also increases. C_{2b} falls because the sum of the two reagents $C_1 + C_2$ is constant. C_{2s} will also fall in a manner that takes into consideration both the fall of C_{2b} and the stoichiometry of the reaction, and will approach C_{1s}, which remains stationary. The finite surface concentration C_{2s} reflects the condition that the HF is present in excess, for the flow rate can be increased by a decrease in C_{2s}. As the maximum etch rate is approached, C_{2s} approaches C_{1s}, and the rate of the dissolution of the oxidized Si can no longer keep ahead of the rate of oxidation. The oxide coating thus impedes the HNO_3 reaction, and the decreased flow rate of HNO_3 is reflected in a rise in C_{1s}. The point where the two surface concentrations cross over marks the transition from a HNO_3 dependent rate to a HF dependent rate. Further increase in the proportion of HNO_3 causes a decrease in the reaction rate by virtue of the resultant decrease in C_{2b}, which is now rate determining.

It is interesting to speculate that if the diffusion coefficients of the two reagents are equal and if the stoichiometry indicated above is correct, then the composition of the fastest etching solution at a given level of added water would have to contain 3 molecules of HF per molecule of HNO_3. On the HF-HNO_3 axis, this composition corresponds to 56 wt % HF, which is not much removed from the observed 65%.

Acknowledgment

The authors wish to express their indebtedness to S. Pryor for her assistance in the experimental work and to F. Ludwig, S. Watelski, and P. Walker for most stimulating discussions and many helpful comments.

Preparation of Crystals of InAs, InP, GaAs, and GaP by a Vapor Phase Reaction

G. R. Antell and D. Effer

Research Department, Metropolitan-Vickers Electrical Co. Ltd., Manchester, England

ABSTRACT

Small crystals of InAs, InP, GaAs, and GaP have been grown from a vapor composed of the monochloride or mono-iodide of the metal and phosphorus or arsenic. Crystal growth took place at from 100° to 300°C below the melting points of the compounds. Whiskers of InAs up to 2 cm long also have been grown.

Indium monochloride tends to disproportionate in some of its reactions forming the trichloride and a compound of indium. The reaction of indium monochloride and arsenic vapors to form InAs therefore seemed a practical possibility. $AsCl_3$ would not form as it is unstable at the temperatures of such a reaction.

The reaction was of practical interest especially as we had established that chlorine had little or no effect on the electrical properties of InAs. Crystals of InAs in fact were deposited by this reaction and the principle was extended to the preparation of crystals of GaAs, InP, and GaP, even though the solubility of chlorine or iodine in these latter compounds is not yet known.

Theory

From the free energies of formation of the indium halides at 298°C the free energy change of reactions [1] and [2] are small but negative.

$$3InCl \leftrightarrows InCl_3 + 2In \qquad [1]$$

$$2InCl \leftrightarrows InCl_2 + In \qquad [2]$$

As the temperature rises the free energy change becomes more positive and the reactions tend to go from right to left.

If arsenic vapor is added to reaction [1], the following becomes possible:

$$3InCl + \tfrac{1}{2}As_4 \leftrightarrows InCl_3 + 2InAs \qquad [3]$$

The decrease in free energy due to the formation of InAs should lead to a reasonable yield of InAs crystals.

Equation [3] is strictly applicable only if the pressure of arsenic equals the dissociation vapor pressure of InAs at the temperature of the reaction. For arbitrary pressures of arsenic vapor, the InAs formed might be expected to be associated with an indium or arsenic-rich liquid as shown in the phase diagram (1, 2). Hence, a more general description of the reaction in Eq. [3] is:

$InCl + As_4$ (arbitrary pressure) in equilibrium with $[InCl_3 + (InAs + liquid)]$

It should be noted that Eq. [1]-[3] have been used merely to illustrate the principle and that the actual reaction is not known.

Arguments similar to the above can be applied to the bromides and iodides of indium and to the chlorides, bromides, and iodides of gallium together with the cases where phosphorus replaces arsenic.

Crystal Growth

All the crystals were grown in evacuated silica reaction tubes approximately 20 cm long and having volumes of about 50 cm^3.

Method 1.—The reaction tube containing the reactants on the left hand side of Eq. [3] was heated uniformly. Initially the temperature was maintained high enough to prevent any crystals forming and was lowered gradually until nucleation occurred.

Method 2.—The reaction tube contained a small amount of chloride or iodide of gallium or indium or only iodine itself, together with a sample of the appropriate $A_{III}B_V$ compound. The tube was placed in a furnace which had a temperature gradient of between 40° and 70°C over the length of the tube, the sample of the compound being at the hotter end. As the temperature of the whole furnace was lowered slowly, crystals nucleated at the cool end. The furnace was held at this temperature, and it was possible to transport the whole of the sample of the compound from the hot to the cool end of the tube.

This result follows from the fact that Eq. [3] is a

Table I

Reaction number	Initial reactants	Temp. of growth, °C	Pressure of atmospheres: Halide	Pressure of atmospheres: As_4 or P_4
1	InCl, As_4	725	8	1.2
2	InI, As_4	690	8.2	1.65
3	$InCl_3$, As_4	No growth	3.1 (800°C)	1.8 (800°C)
4	InI_3, As_4	No growth	3.1 (800°C)	1.35 (800°C)
5	GaI, P_4	1050	5.0	2.6

Table II

Reaction number	Initial reactants	Temp. of sample, °C	Temp. of growth, °C	Press. atm of halide
6	InAs, $InCl_3$	890	840	1.6
7	InAs, InI_3	875	830	1.6
8	InP, InI_3	915	860	1.65
9	GaAs, I_2	1070	1030	2.15

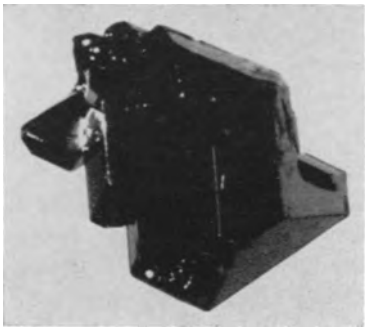

Fig. 2. GaAs crystals grown by reaction 9. Magnification 27X.

reversible reaction. At the hot end of the reaction tube the reaction tends to go from right to left and is reversed at the cool end.

Results

Table I gives a list of experiments that were performed according to method 1. The pressures that are listed are the partial pressures that the reagents would have at the temperature of growth but before they have reacted. Table II covers experiments that were performed by method 2. The pressure of the halide has been calculated as that which it would have been if the tube were at a uniform temperature equal to that of the cool end.

Crystals that have been grown by the reactions listed in Tables I and II are shown in Fig. 1-4.

Growth of InAs *Whiskers.*—Conditions under which whisker growth may be expected are not entirely clear, but it appears that there must be a low pressure of halide present in the tube and also a fairly rapidly falling temperature.

The whiskers always seemed to grow from what appeared originally to have been a molten globule.

The whisker shown in Fig. 4 was grown by reaction 6, Table II when the density of $InCl_3$ molecules was about $10^{18}/cm^3$. Whiskers up to 2 cm in length were grown by a combination of reactions 2 and 4 in Table I. The iodide vapor consisted of InI_3 at a pressure of about 3 atm at 800°C together with a trace of a lower iodide.

X-ray and electron diffraction data.—InAs crystallized mainly as flat plates which in many cases

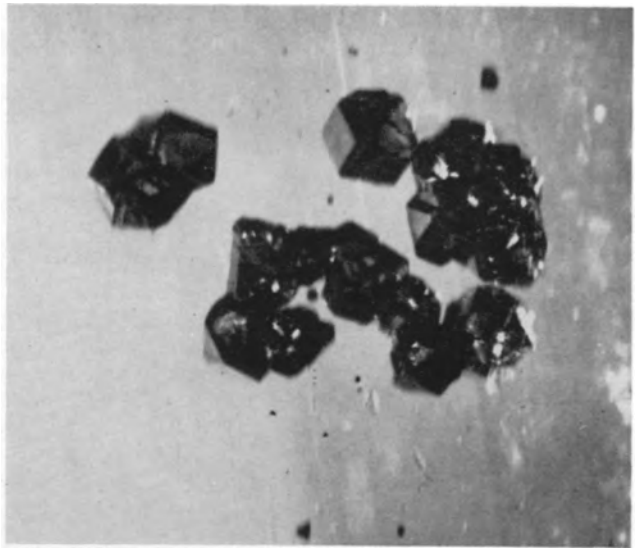

Fig. 3. GaP crystals grown by reaction 5. Magnification 40X.

Fig. 4. InAs whiskers grown by reaction 6. Magnification 40X before reduction for publication.

were up to 5 mm across. A sample was mounted in an electron diffraction camera and a "Kikuchi line" pattern was obtained by reflecting an electron beam at a glancing angle from the flat face of the crystal. From this it was deduced that the flat face was a (111) plane. This also was found to be the case with two other crystals.

The edge of the elementary cell was measured for each compound by the x-ray powder method using a copper anode and a nickel filter. The determinations are listed below together with other published results in brackets.

InAs	$a_o = 6.058_5$Å	[6.058$_4$Å] (1)
InP	$a_o = 5.868_8$Å	[5.869Å] (3)
GaAs	$a_o = 5.654_1$Å	[5.653$_4$] (4)
GaP	$a_o = 5.451_4$Å	[5.450$_5$] (4)

The close agreement between these determinations and previously published values shows that the various compounds have indeed been formed in all cases.

Acknowledgments

The authors are indebted to Mr. P. Worthington for his electron diffraction measurements, and to Miss K. Whitehead and Mr. L. Brownlee for the determination of unit cell sides.

We should also like to thank Dr. R. W. Sillars and Mr. R. P. Chasmar for their helpful criticisms of the manuscript and to Sir Willis Jackson, Director of Research and Education, and Dr. J. M. Dodds, Manager of Research Department, Metropolitan-Vickers Electrical Co. Ltd., for permission to publish this paper.

Manuscript received Nov. 3, 1958.

Oxide Nucleation and the Substructure of Iron

E. A. Gulbransen and K. F. Andrew

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh Pennsylvania

ABSTRACT

Electron optical studies were made of the initial stage of reaction of oxygen with pure iron. Oxidation occurred in a discontinuous manner with the oxide structure orienting to the metal grain. The sites for oxide nucleation depend on the initial pretreatment atmosphere. Thus, a vacuum annealing treatment showed a random arrangement of nucleation sites, while a hydrogen annealing treatment showed a highly ordered arrangement of nucleation sites.

Since iron was embrittled by annealing in dry and moist hydrogen and not by vacuum annealing, the nucleation sites probably show the substructure of iron responsible for embrittlement.

The theory of oxidation as developed by Wagner (1, 2), Mott (3), and others is based on the diffusion of metal or oxygen atoms and ions through interstitial sites or through cation and anion defects in the oxide film. The oxide film is assumed to be uniform while the metal underlying the oxide is assumed to be structureless over a particular grain. Recent developments in metal physics have shown that crystal orientation, dislocations, and other defects determine the mechanical properties of the metal. These factors also may determine the nature of chemical reactions on metal surfaces. The purpose of this paper is to show the effect of annealing environment on the oxide nucleation pattern for pure iron and to indicate a possible relation between the nucleation pattern and the mechanical properties of the metal.

The fact that iron reacts with oxygen in a nonuniform manner is well known. Early electron optical work was reviewed by Phelps, Gulbransen, and Hickam (4). These authors, in addition, studied the structure of oxide films formed on mechanically polished specimens of pure iron using electrochemical stripping methods for removal of the oxide film. Electron optical studies showed the oxide to consist of many small crystals several hundred to a thousand angstroms in size. The oxide crystals were nearly randomly oriented with respect to the metal grain.

Bardolle and Bénard (5) used carefully polished and annealed specimens of Armco iron to study oxide nucleation processes at temperatures between 650° and 850°C at low pressures of oxygen. At 850°C and a vacuum of 10^{-3} mm Hg, a few well oriented oxide nuclei of definite crystal habit were formed. Many nuclei were formed at pressures of 10^{-2}-10^{-1} mm Hg. Light micrographs of thick oxide films formed under these conditions showed the oxide film on a single metal crystal to consist of many similarly oriented crystals. In no case was a single crystal of oxide observed to form on a single crystal of iron.

Gulbransen, McMillan, and Andrew (6) extended the work of Bardolle and Bénard (5) by controlling conditions of oxidation and by use of electron optical methods. The latter method makes possible observation of finer details of the crystal habit.

Thermodynamic conditions for oxidation.—Since the formation of an oxide film, as well as its crystal habit, depends on the relative importance of one or more chemical reactions, it is necessary to consider the thermodynamic equilibria of these reactions. For iron at 650°-850°C, the more important reactions are the following: (*a*) direct oxidation of iron to FeO, (*b*) reaction of carbon in the metal with the surface oxide to form carbon monoxide and the metal, and (*c*) solution of oxygen in the metal.

Calculations show the dissociation pressure of oxygen over FeO and Fe to be $10^{-17.6}$ atm at 850°C (6). The extent of the oxygen reaction is limited only by the oxygen available and the time of reaction.

Under conditions of low pressure, carbon in the metal reacts with the surface oxide. To minimize this reaction, the concentration of carbon should be less than 0.005% by weight (6). The kinetics of this reaction has been shown by Gulbransen and Andrew (7) to be feasible above 610°C.

Several recent values exist for the solubility of oxygen in alpha-iron. Seybolt (8) found a value of 0.022 wt % at 850°C. Sifferlen (9) has shown that for iron recrystallized by a rigorous thermal treatment the solubility does not exceed 0.002 wt % at 850°C. Considering the low values for the solubility and that oxygen pressures of 10^{-2}-10^{-3} mm Hg were used, we feel that the amount of oxygen dissolving in the metal is small.

Good conditions for studying the initial nucleation process and the effect of pretreatments on iron are as follows: (*a*) carbon content of less than 0.005 wt %, (*b*) oxygen pressures of less than 0.01 mm Hg, (*c*) electropolished and annealed metal, and (*d*)

low concentration of other impurities such as Mn, S, P, Si, etc.

Structural factors in matter.—Four factors are important in discussing structural factors in the oxide nucleation process. These are as follows: (*a*) crystal structure or atomic geometry of the unit cell, (*b*) crystal size and shape, (*c*) particle size and shape, and (*d*) orientation of the oxide particles with respect to the underlying metal crystal.

The crystal structure is studied by electron diffraction while crystal size and shape and orientation factors are studied by the electron microscope.

Experimental

Samples.—"Puron" [1] iron was used for all of the experiments. The iron contains about 0.001% metallic impurities. Of nonmetallic impurities there exists about 0.04% oxygen, 0.005% C, and virtually no sulfur, phosphorus, or nitrogen.

The following steps were used in the preparation of specimens for this study: (*a*) mechanical polishing using polishing papers up to 4/0 under purified kerosene, (*b*) cleaning with soap and water, distilled water, petroleum ether, and absolute alcohol, (*c*) electrolytic polishing using Jacquet's solution, (*d*) washing in distilled water and absolute alcohol.

The following pretreatments were used: (*a*) annealing at 875°C for 24 hr in vacuum of 10^{-7} mm Hg plus 1-hr annealing in hydrogen passed through a palladium tube at 2.4 cm Hg pressure to remove any oxide formed in vacuum annealing, cooled in vacuum, (*b*) annealing at 850°C for 20 hr in 1 atm of hydrogen purified by passing over hot copper and dried with $CaCl_2$, cooled in hydrogen, (*c*) annealing at 850°C for 23 hr in tank hydrogen passed over a dry ice trap at −78.5°C at 59 cm Hg, cooled in vacuum, (*d*) annealing at 875°C for 21 hr in hydrogen passed through a palladium tube at 59 cm Hg pressure, cooled in vacuum, (*e*) same as (*d*) except with an additional annealing for 20 hr in vacuum of 10^{-7} mm Hg plus 1 hr in palladium purified hydrogen at 2.3 cm Hg pressure to remove any oxide formed, cooled in vacuum, and (*f*) annealing at 875°C for 23 hr with hydrogen passed through a palladium tube at 59 cm Hg plus 0.2 cm Hg of pure nitrogen, cooled in vacuum.

Reaction with oxygen.—Strips of 0.013 cm thick iron weighing about 0.1 g and having a surface area of 2.5 cm^2 were reacted in the microbalance system. Specimens were introduced singly and the system pumped overnight. A vacuum of better than 10^{-6} mm Hg was obtained. The furnace at the desired temperature was raised around the Mullite furnace tube. A given quantity of oxygen was introduced by means of a gas handling system. Weight changes were followed with the microbalance. Although the oxygen reacted very rapidly with the metal, the metal was kept in contact with the gas atmosphere for 25 min. Following reaction the residual gases in the system were evacuated, the furnace lowered, and the specimen allowed to cool in the vacuum.

The following facts were observed or calculated for each nucleation experiment: (*a*) weight of oxygen reacting, (*b*) average thickness of oxide film, (*c*) color of oxide, (*d*) crystal structure of oxide, (*e*) size and shape of oxide crystallites, and (*f*) crystal habit and orientation of oxide with respect to the metal grain.

Examination of crystal habit and structure.—The crystal structure of the oxide crystallites was studied by transmission electron diffraction while the crystal habit was studied by electron microscopy of the stripped oxide film. Electron diffraction patterns were taken with the electron diffraction adapter of the EMB-4 electron microscope. Polystyrene-silica replicas shadowed with chromium were prepared in the conventional manner. Stripped oxide films were prepared in an electrochemical stripping apparatus similar to one previously described (4). To support the oxide crystallites, the oxidized surface was covered with a Parlodion film.

Several modifications were made in the electron microscope to obtain large fields at low magnifications. A special internal screw mechanism was used for removing the projector-pole piece for carrying out studies in the range of 400X to 1600X. Most of electron micrographs were made at 1080X to 1600X and enlarged two to eight times.

Results and Discussion

Vacuum pretreatment.—Table I and Fig. 1 and 2 show the pretreatment and nucleation conditions and results. Figure 1A shows a typical electron micrograph of the stripped oxide film formed by low pressure oxidation at 850°C using oxygen at a pressure of 5 x 10^{-3} mm Hg. For this condition a blue-gray film was formed having an average film thickness of 453Å. The electron diffraction pattern shown in Fig. 1B shows a highly oriented oxide film of FeO and Fe_3O_4. The electron micrographs suggest that, although the oxide is highly oriented to the metal, the sites at which oxide nucleation takes place are nearly random.

Figure 2, A, B, C, and D, shows the effect of the amount of oxidation on the nucleation and growth processes. The average oxide film thickness varies from 64 to 453Å. The oxide crystal size increases with the amount of oxidation. In each experiment electron diffraction patterns showed oriented oxide crystals while the electron micrographs showed a random arrangement of the oxide nucleation sites.

Figures 1 and 2 show several interesting facts about the mechanism of oxidation when the specimen was annealed in high vacuum. (*A*) Single crystals of oxide do not form on a single crystal of metal. This confirms the results of a light micrograph study of Bardolle and Bénard (5) for a later stage of the reaction. The fact that many nucleating centers exist on a metal surface may be related to dislocations and defects in the structure of the metal. (*B*) The oxide structures were oriented to the metal structure. (*C*) Except for the grain boundaries, nearly random distribution of nucleation sites were observed. (*D*) The grain boundaries of the metal were not preferentially attacked.

Pretreatment with tank hydrogen passed over hot copper.—Table II shows details of pretreatment and oxide nucleation conditions together with information on the thickness and color of the oxide crystallites. Fig. 3, A and B, shows electron micrographs of the oxide film formed at 850°C by dosing with O_2 at 2 x 10^{-3} mm Hg and the oxide film formed at 750°C by dosing with O_2 at 1 x 10^{-3} mm Hg. Figure 4, A and B, shows similar results for the film formed at 650°C. A surface replica was included to check the film stripping technique.

Electron micrographs of specimens pretreated in partially purified hydrogen and cooled in hydrogen showed some similarities with and some differences from the results of vacuum annealing. For both pretreatments, a discontinuous oxide film was formed.

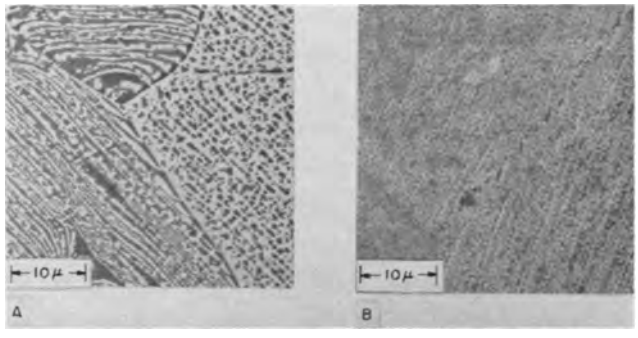

Fig. 3. Oxide film stripped from Puron annealed in hydrogen passed over hot copper. H_2, 850°C, 20 hr, cooled in H_2. A, 752Å thick oxide, 850°C; B, 322Å, thick oxide, 750°C.

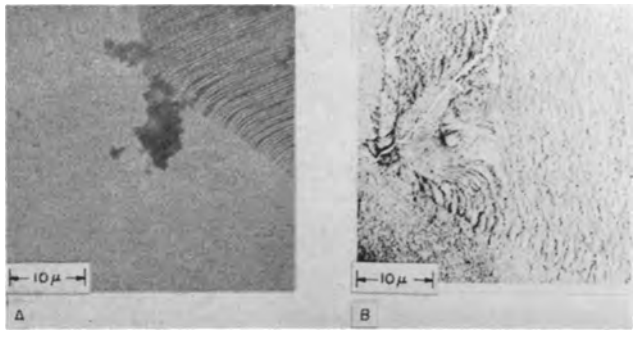

Fig. 4. Oxide film stripped from Puron annealed in hydrogen passed over hot copper and surface replica. H_2, 850°C, 20 hr, cooled in H_2. A, 252Å thick oxide, 650°C; B, surface replica.

Electron diffraction studies of the oxide films in both cases show orientation of the oxide structure to the metal. In addition, the particle size of the oxide crystals for the same degree of oxidation was nearly the same.

Several major differences were observed: (*a*) nucleation sites were not random but highly ordered in certain directions determined by the orientation of the metal grain; (*b*) spacings of these lines of nucleation sites were relatively constant over a given distance; (*c*) lines of nucleation were usually bent at the grain boundaries and join with lines of oxide growth of other metal grains, and (*d*) circular growth patterns were frequently seen. This is shown in Fig. 5. The circular growth patterns probably were related to inclusions or other local defects in the metal structure.

To test the influence of annealing in dry hydrogen, tank hydrogen was dried by passing through a dry ice trap at —78.5°C. Details of the experiment were

Table II. Summary of hydrogen pretreatments, tank hydrogen passed over hot copper

1 atm, 850°C, 20 hr, cooled in H_2	O_2 at 1 x 10^{-3} mm Hg, 750°C, 25 min	4.59	322	Blue spots	0.5	Same
1 atm, 850°C, 20 hr, cooled in H_2	O_2 at 1 x 10^{-3} mm Hg, 650°C, 25 min	3.60	252	Blue spots	0.3	Same
56 cm, 850°C, 23 hr, cooled in vacuum dew point—78.5°C	O_2 at 5 x 10^{-3} mm Hg, 850°C, 25 min	6.35	451	Blue	1.0	Partially directed nucleation pattern, oriented growth

given in Table II. Figure 6, A, B, and C, shows three electron micrographs, while Fig. 6D shows an electron diffraction pattern of the oxide crystals. Although an ordered pattern of oxide nucleation was observed, the amount of order was smaller than that shown in Fig. 3, 4, and 5. The electron diffraction pattern showed oriented oxides of FeO and Fe_3O_4 were formed.

Pretreatment with hydrogen passed through palladium.—Table III and Fig. 7, 8, and 9 show details of pretreatment and nucleation conditions together with a summary of the results.

Figure 7, A and B, shows an electron micrograph and an electron diffraction pattern of a specimen pretreated in hydrogen passed through palladium and cooled in vacuum. The sample was oxidized at 850°C in O_2 at 5.0 x 10^{-3} mm Hg. The electron diffraction pattern shows a highly oriented structure while the electron micrograph shows a partially ordered oxide nuclei. Ordering of nucleation sites was not as well developed as for specimens annealed and cooled in less pure hydrogen.

Figure 8 shows an electron micrograph and an electron diffraction pattern of a specimen pretreated in palladium purified hydrogen and then held in a vacuum for 20 hr at 875°C before cooling. The electron micrograph shows a partial ordering of oxide nucleation sites.

Figure 9, A and B, shows electron micrographs of a specimen treated in palladium purified hydrogen plus a small amount of pure nitrogen. Nucleation sites show only a small amount of ordering. Nitrogen, as an impurity in the hydrogen, does not have an important influence on the ordering process.

We conclude from these experiments that water vapor in hydrogen is primarily responsible for ordering of nucleation sites for oxide formation.

Discussion

It is of interest to note that the density of oxide crystallites in Fig. 1 is of the same order of magnitude as the density of dislocations in a well annealed metal crystal, i.e., of the order of $10^8/cm^2$. The growth of oxide nuclei may be related to the number and arrangement of dislocations in the metal crystal. Normally, these nucleation centers are random in arrangement. However, if iron is annealed

in impure hydrogen, these nucleation centers become ordered along definite crystallographic directions. The mechanism of ordering is not clear. However, low pressure oxidation offers a new method for the study of the fine structure of iron not observable by light microscopic studies of low temperature etched surfaces.

These results may lead to an understanding of the effect of annealing treatments on the mechanical properties of Puron and other pure irons. Stanley (10) has made a thorough study of the embrittling of Puron when heated in high vacuum and in dry and moist hydrogen atmospheres at temperatures of 700°-1100°C. Puron is embrittled in dry hydrogen atmospheres at a dew point of −65°C in 10 hr for the temperature range of 700°-1150°C. In moist hydrogen, Puron was embrittled in about an hour. Vacuum annealing did not lead to embrittlement. Light micrographic studies showed only minor changes in metal structure.

Stanley's observations on the embrittlement of iron at 700°C and our studies on the effect of hydrogen and its impurities on the oxide nucleation pattern at 700°C appear to be related. Atmospheres which embrittle iron give ordered nucleation sites for oxide growth while atmospheres which do not embrittle iron give random nucleation patterns for oxide growth.

The Separation of Hydrogen and Deuterium by the Reaction of Iron with Water

Hilton A. Smith, Carl O. Thomas,[1] and John C. Posey[2]

Department of Chemistry, University of Tennessee, Knoxville, Tennessee

ABSTRACT

In the decomposition of water by reaction with iron, as in the electrolysis of water, the residual water is enriched in deuterium. Since the separation factor is an inverse function of the temperature, an attempt was made to increase the reaction rate at low temperatures. Introduction of cathodic surfaces by partial plating of cathodic impurities on steel increased the reaction rate by a factor of 2 to 4 at 98°-100°C. Separation factors from 4.8 to 6.1 were observed for the chemical reaction of these partially plated samples with water. In electrolysis experiments vigorous agitation of the electrolyte caused an increase in the separation factor.

An important part of the development of nuclear power is the procurement of heavy water which is used as a moderator in some types of nuclear reactors (1). Since the natural concentration of deuterium in water is approximately 1 part in 7000 and since separation factors are generally small for isotope separation processes, it is necessary in the initial concentration stages to process very large quantities of water (2). One of the largest separation factors is obtained in the electrolysis of water. However, the energy cost is high, and the method is practical economically only when a market exists for electrolytic hydrogen or when the method is used for the final concentration of water which has been enriched by a less expensive process (2).

Separation of the isotopes is obtained in the direct chemical reaction of a variety of metals with water or steam (3-5). Smith and Posey (6) reported separation factors of 3.2 to 1.4 for the reaction between iron and steam at 118°-340°C. The reaction rate in this temperature range is low for a practical production technique. Moreover, the commercial production of hydrogen by the reaction between iron and steam requires temperatures of 800°-1000°C (7).

Since the separation factor is an inverse function of the temperature (8), temperature requirements for a useful separation factor and a useful rate in the reaction of metals with water or steam appear to be mutually exclusive. The principle of sacrificial corrosion protection suggested the possibility that the reaction rate might be increased without increasing the temperature, so that the advantage of the larger separation factor at the lower temperatures could be retained. The present paper discusses reaction rates and separation factors in the direct chemical reaction of water with iron samples some of which had plated on a portion of their surfaces a variety of cathodic materials. The effect of vigorous stirring on the concentration gradient at the cathode also is discussed.

Experimental

Reaction rates.—Reaction rate data were obtained by measuring the rate of hydrogen evolution at constant volume or at constant pressure. The constant volume apparatus is shown in Fig. 1. The liquid and gas-phase volumes were approximately 10 ml each. Since the apparatus is very simple and compact, as many as ten runs could be conducted simultaneously in a 5-gal thermostat. Constant-pressure apparatus is shown in Fig. 2. The volume of the reaction flask was approximately 500 ml. Before each run the receiving flask was evacuated. The check valve was set to operate at 85 cm Hg.

The electrolyte was ferrous chloride which was prepared by the reaction of hydrochloric acid with an excess of iron powder. In order to conserve heavy water, reaction rates were investigated using ordinary water only.

Iron samples were prepared from the following materials: Merck and Company iron powder (re-

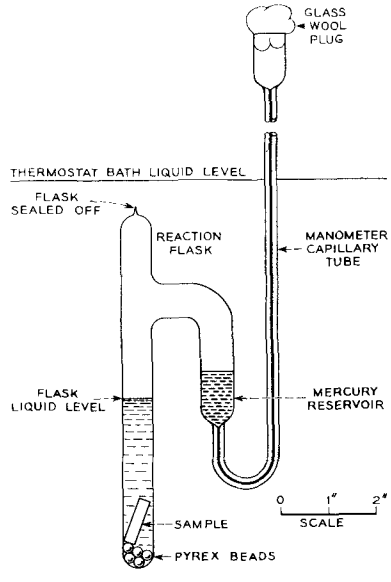

Fig. 1. Constant volume apparatus for measuring rate of hydrogen evolution.

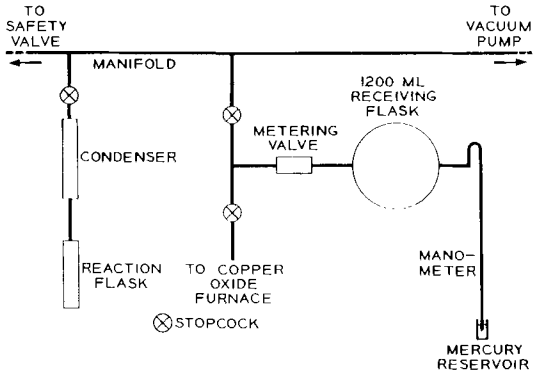

Fig. 2. Constant pressure apparatus for determining separation factors and rates of hydrogen evolution.

duced by hydrogen); J. T. Baker's and Baker and Adamson's reagent grade iron wire (size AWG-36); extremely pure bulk iron (9) provided by the Bell Telephone Laboratories and the Battelle Memorial Institute; and ordinary low-carbon steel plate, rod, and tubing. Iron powder was used as received. Wire samples approximately 1 meter in length were wound into spirals approximately 5 mm in diameter and 3 cm in length. Rectangular and cylindrical samples of the remaining materials were prepared by machining.

All of the samples except the iron powder were cleaned by washing with hot C.P. toluene and then by sulfuric acid pickling. Following cleaning, the absence of hydrophobic contaminants was verified by the wetting properties of the surface as exhibited by the contact angle of water droplets at the surface.

The surface area of the iron powder was measured by the BET-nitrogen-adsorption method and the krypton-adsorption method. The values found by these two methods were 3.5 $m^2\ g^{-1}$ and 3.4 $m^2\ g^{-1}$, respectively. In order to obtain a comparison between the reaction rates observed with powder and with bulk samples, the rate of hydrogen evolution was calculated in cm^3 atm of gas per cm^2 of substrate per minute, corrected to 30°C. For all of the samples, except the iron powder, the reaction rate was constant throughout the runs. Since the surface roughness of the bulk samples changed visibly during the runs, the rate per unit area for the bulk samples was calculated from their physical dimensions, arbitrarily assuming unit roughness factor.

For all of the samples, except iron powder, runs were made with a cathodic surface plated onto approximately 50% of the sample surface. Plating was accomplished by displacement, thermal decomposition, and electroplating.

Table I summarizes the reaction-rate data for a variety of conditions. It can be seen that the rate of hydrogen production may be increased by the application of cathodic metals to a portion of the surface of the iron samples. The data presented in Table I include rate values obtained with both types of apparatus. This suggests that the difference in the reaction rates at constant pressure and at constant volume is not significant.

Some measurements of the reaction rate, not included in Table I, were made with samples of wire, Bell Telephone iron, Battelle iron, and low-carbon

steel which were partially plated by displacement with mossy deposits of platinum, palladium, and copper. In general, the initial rates were several times larger than those which were obtained with unplated samples. However, the hydrogen evolution rates dropped off rapidly and approached the values which were obtained with the unplated samples. The mossy deposits had a tendency to become detached from the iron, and they collected a layer of reddish-brown oxide very quickly. The oxide layer eventually turned black. The reproducibility of the rate measurements with this type of cathode surface was very poor.

Rates with iron powder were initially relatively rapid but decreased rapidly, presumably due to stifling by the reaction products. Prereduction of the powder, coating with copper, or use of other salts such as sodium chloride, ammonium chloride, sodium sulfate, ferrous sulfate, and zinc sulfate did not prevent the decrease in rate as the reaction proceeded.

Separation factors.—Ferrous chloride solutions of twice the desired strength were prepared as described above. A calculated amount of heavy water was added in order to produce a salt solution of the appropriate concentration which also contained approximately 45 mole % of heavy water. The heavy water[3] was reported to be 99.8% pure.

The reaction was carried out in the apparatus shown in Fig. 2. The hydrogen-deuterium mixture which was collected in the receiving flask was subsequently oxidized by copper oxide at 300°C in a Pyrex-tube furnace. The water which was produced by this reaction was collected in a cold trap. The method has been described in detail by Posey (6).

Approximately 130 ml of salt solution was used in each of the runs. The amount of water which was consumed in the reaction was small in comparison to the total amount of water present. However, the change in the composition of the residual water during a run was large enough to affect the calcu-

* By electroplating on 50% of surface.
† Average error.

lation of the separation factor. Therefore, the arithmetical average of the compositions at the beginning and at the end of the run was used for the calculation of the separation factor. A small sample of the salt solution was taken before and after each run. The samples were vacuum distilled, and the water was collected in a cold trap. The isotopic compositions of the various water samples were determined by the falling-drop method of Combs, Googin, and Smith (10).

Steel tubing was used for these runs since it provided the most convenient form for plating, for obtaining a large surface area, and for physically supporting the samples in the reaction flask.

Table II lists the separation factors which were obtained in the reaction of 1*M* ferrous chloride solutions (45 mole % heavy water) at 98°-100°C with unplated and with partially plated samples of steel tubing. Separation factors were calculated by means of Eq. [1]

$$\alpha = (D/H)_e/(D/H)_g \qquad [1]$$

where D and H are the mole fractions of deuterium and of hydrogen, the subscript *e* refers to the electrolyte, and the subscript *g* to the gas produced by the reaction.

Separation factors also were determined in a series of electrolysis experiments with an external emf of 4 v and a current density of 0.06 to 4 amp cm^{-2}. All electrolysis experiments were conducted in 1*M* ferrous chloride solutions containing approximately 45 mole % heavy water. The only heating was that produced by the electrical-power dissipation in the cell, which established an operating temperature of 30°-45°C. The purpose of these runs was to determine the effect of vigorous stirring on the separation factor. Three levels of stirring were investigated: that provided by hydrogen evolution at the cathode, that provided by vigorous mechanical agitation, and that provided by ultrasonic agitation. The mechanical agitation was obtained in the apparatus shown in Fig. 3. The cathode, to which an off-balance weight was attached, was rotated at 1800 rpm, with consequent vigorous vibration. The ultrasonic generator[4] produced sufficient energy to create a Nujol-water emulsion in a test tube in approximately 1 min.

[4] Manufactured by the Crystal Research Laboratories, Hartford, Conn.

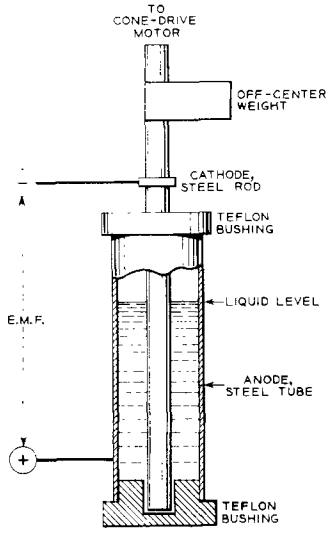

Fig. 3. Electrolysis cell with rotating off-balance cathode

A much larger fraction of the water was decomposed in the electrolysis runs than in the direct chemical reaction runs. Therefore it was not necessary to collect the hydrogen and deuterium. Instead, the separation factor was determined from the initial and the final concentrations of the reacting water by means of Eq. [2]

$$\alpha \ln (H_o/H) = \ln (D_o/D) \qquad [2]$$

where H_o and D_o are the initial concentrations, and H and D are the final concentrations of hydrogen and deuterium in the reacting material. The separation factors for the three types of electrolysis experiments are presented in Table III.

Discussion

The rate of hydrogen production per unit surface area of unplated sample was approximately the same for all of the materials, except iron powder. Therefore, for reasons of convenience, steel was chosen as the substrate material for the investigation of plated cathodic surfaces.

The increase in the reaction rate which was produced by the artificial introduction of galvanic couples was lower than expected. It is possible that cathodic polarization prevented the rates from being much larger. Since hydrogen was the desired product, it was not possible to take advantage of oxidative depolarization of the cathode in order to increase the rates. In fact, the preparation and handling of the salt solutions was done in such a manner as to minimize the amount of dissolved air, and the

Table III. Separation factors in the electrolysis with steel electrodes of stirred 1M ferrous chloride solutions at 30°-45°C

ferrous chloride solutions were continually in contact with excess metal. The solutions were always blue-green in color.

Separation of hydrogen and deuterium by chemical or electrical decomposition of water depends on differences in the reaction rates of the two species. Therefore, the kinetic separation factor normally should be calculated by use of Eq. [2]. This was done in the electrolysis experiments where a relatively large fraction of water was decomposed. Since a very small fraction of the water was decomposed in the direct chemical reaction between iron and water, steady-state conditions were approximated, and it was possible to calculate the separation factor by use of Eq. [1].

The average values of the separation factors in the chemical reaction of iron with water vary from 4.8 for a brass cathode to 6.1 for uncoated steel. The values of the separation factors are not sufficiently precise to show conclusively any variation due to the nature of the cathode. From the data in Table II a composite separation factor of 5.7 may be calculated with an average error of ± 0.2.

No variation in the separation factor could be observed in the electrolysis experiments as a function of current density.

Topley and Eyring (11) discussed in detail the effect on the observed separation factor of a concentration gradient in the thin film of liquid at the cathode surface. They concluded that the effect should be small. The data in Table III show that efficient stirring can increase the separation factor.

The direct chemical reactions and the electrolysis experiments were performed at different temperatures and cannot be compared directly. In Fig. 4 the separation factors obtained in this investigation are compared with selected values from the literature. Figure 4 also includes the theoretical curve of separation factor vs. temperature which was calculated by Eyring and Cagle (8).

The Role of the Electrokinetic Potential in Some Surface Tension Phenomena

Lawrence Baylor Robinson

Space Technology Laboratories, Inc., Los Angeles, California

ABSTRACT

The Wagner-Onsager-Samaras theory (without adjustable constants) allows one to calculate the surface tension of an aqueous electrolyte solution as a function of concentration. It predicts that an electrolyte added to water would increase the surface tension. Precise measurements of the surface tension by the capillary rise method give an initial decrease and a minimum in the surface tension-concentration wave. Theory and experiment can be reconciled by taking the electrokinetic effects into account.

The available evidence indicates that a knowledge of the electrokinetic (commonly called zeta) potential is required for an interpretation of surface tension measurements of electrolyte solutions made with the capillary rise technique. The basic contributions to the theory of the surface tension of (Debye-Hueckel) electrolytes were made by Wagner (1) and by Onsager and Samaras (2). The quantitative discussions were limited to 1-1 electrolytes such as KCl. An extension of the theory to the case of asymmetrical electrolytes has been carried out by Thacher (3), and numerical results are given for 2-1 (e.g., $BaCl_2$) electrolytes and 3-1 (e.g., $LaCl_3$) electrolytes. More drastic approximations in the theory, used by Robinson (4), gave results for 2-1 and 3-1 electrolytes not too different from those obtained in Thacher's more refined treatment. The essential result in all of the cases is that the surface tension turns out to be an increasing monotone function of the concentration; the addition of any amount of a neutral salt to water will increase the surface tension according to theory.

Meanwhile, the theory of surface tension had received a serious challenge by the precise measurements of Jones and Ray (5) with a capillary rise apparatus which gave the ratio of the surface tension of an electrolyte solution to that of water. Their measurements indicated that the surface tension of water decreased sharply as a result of the addition of a small amount of a salt; the surface tension-concentration curve passed through a broad minimum at about 0.001 equivalents per liter for all electrolytes tested. Following this, the curve increased with concentration at a rate about that predicted by theory.

Jones and Ray initially interpreted the decrease in the surface tension as resulting from the interaction of the polarized water molecules (dipoles) with the ions of the electrolyte. They pointed out that these forces are neglected in the usual theoretical treatments, in which the principal effect is attributable to the presence of a boundary (so-called image forces). They postulated that the addition of ions to water would disturb the systematic arrangement of water dipoles. The electric forces among the water molecules, opposing this disturbance, would tend to thrust the disturbing ions into the surface. This initial positive adsorption was taken as the cause of the decrease in surface tension in the extremely dilute range.

Several other proposals were put forward by various theoreticians to account for the observed minimum in the surface tension-concentration curve. The interpretation given by Irving Langmuir (6) attracted more attention; it is subject to quantitative checks. Langmuir advanced the suggestion that the results obtained by Jones and Ray represented an instrumental effect rather than a pure surface tension property. He contended that the film of the liquid in the capillary above the meniscus was not of negligible thickness as was generally assumed, but could assume thicknesses which would be appreciable when compared with the radius of a tiny capillary. The thickness of the wetting film was postulated as being dependent on the nature and concentration of the electrolyte and especially on the potential existing at the interface between the capillary wall and the solution. This is essentially the so-called zeta-potential, the potential existing at the boundary between a flowing liquid and the layer of liquid attached to the wall. The film was supposed to be much thicker for water than for solutions of electrolytes of moderate concentrations, and the film evidently becomes negligible for concentrated solutions. Jones and Frizzell (7) developed the theory more rigorously so that the original surface tension data of Jones and Ray could be corrected in the manner proposed by Langmuir.

A significant result is that a connection is established between the surface tension and the electrokinetic potential. In principle, one can invert the problem and calculate the zeta potential from a static phenomenon. At the time of Langmuir's suggestions, reliable zeta potential measurements were very few. At present, reliable results have been made on a variety of electrolytes by Rutgers and De Smet (8) and by Jones, Wood, and Robinson (9). The results of these two groups of workers are in complete agreement.

The application of the correction, as suggested by

Langmuir, puts the results of Jones and Ray in substantial agreement with the theory.

Surface Tension by Capillary Rise

The method employed by Jones and Ray measured the ratio of surface tensions of solutions to that of water, by measuring relative rises in a capillary tube. The surface tension is given by

$$\sigma_c = h\ (d_c - \beta)\ gr_c/2 \qquad [1]$$

where d is the density of the solution, h is the height to which the liquid rises in the capillary, β is the density of air, g is the acceleration of gravity, and r_c is the radius of the capillary containing the liquid. The relative surface tension is

$$\sigma = \frac{\sigma_c}{\sigma_o} = \frac{h_c}{h_o}\,\frac{(d_c - \beta)}{(d_o - \beta)}\,\frac{r_c}{r_o} \qquad [2]$$

where the subscript zero refers to water. Jones and Ray assumed that $r_c = r_o$. Langmuir's suggestion that a wetting film (of significant dimensions) forms in the capillary requires that the original data of Jones and Ray be multiplied ("corrected") by a factor of $(r - \Delta r_c)/(r - \Delta r_o)$ where Δr is the thickness of the film.

The wetting film is established from the equilibrium of various forces at the meniscus. For films which are thick in comparison with the diameter of the water molecule, one may neglect short range forces. The other forces considered have their origin as follows:

1. The hydrostatic pressure exerted by the main body of the liquid in the capillary exerts a downward force (per unit area) on the film which tends to make this film thinner; this pressure has magnitude $-(d - \beta)\ hg$, where d is the density of the solution, β the density of air, h the capillary rise, and g the acceleration of gravity.
2. The surface tension in the inner surface of the annular wetting film tends to contract the entire inner surface, and hence make the film thicker; the pressure exerted has magnitude $p = \sigma/r = (d - \beta)\ hg/2$.
3. The difference between the osmotic pressure in the bulk solution and at the air-solution interface tends to make the film thicker in attempting to dilute the solution comprising the film; this pressure has magnitude

$$\Sigma_i\, n_i\, kT\left\{\exp\left(-\frac{Z_i \epsilon \Psi}{kT}\right) - 1\right\}$$

where n_i is the number of ions per cubic centimeter of the ith species in the main part of film (assumed to be the same as that in the bulk solution), Z_i is the number of electronic changes on the ion, and the other symbols have their usual significance. The above expression is a result of Vant Hoff's simple law that the osmotic pressure is $P = nkT$ (where n is the total number of ions per cubic centimeter), and from the assumption that the ions in the wetting film are in a Boltzmann distribution governed by the potential Ψ. At equilibrium, the sum of all of these pressures is zero, and therefore

$$\Sigma_i\, n_i\, kT\left\{\exp\left(-\frac{Z_i \epsilon \Psi}{kT}\right) - 1\right\} - (d - \beta)\ hg/2 = 0 \qquad [3]$$

where the potential Ψ is evaluated at the air-film interface. It is also assumed that at the air interface

$$\nabla \Psi = 0 \qquad [4]$$

The above two boundary conditions, plus the Poisson-Boltzmann equation

$$\nabla^2 \Psi = \frac{d^2\Psi}{dr^2} + \frac{1}{r}\,\frac{d\Psi}{dr} = \Sigma_i\, n_i\, \epsilon Z_i \exp\left(-\frac{Z_i \epsilon \Psi}{kT}\right) \qquad [5]$$

constitute the problem to be solved. The problem is to find the Δr consistent with the boundary conditions and the specified potentials.

Equations [3] and [4] provide a means of determining both the function Ψ and its slope, respectively, at the air-solution boundary. Some refinements have been offered at various times to improve the theory, especially as far as Eq. [4] is concerned; the evidence suggests that the theory as proposed is substantially correct as long as the potential at the film-quartz interface (i.e., the zeta potential) is large in comparison with the potential at the air-film interface. This condition prevails in the cases of KCl and $BaCl_2$, but is not so for $LaCl_3$. In fact, in two of the $LaCl_3$ solutions studied, the air-film interfacial potential (as calculated) turned out to be larger than the zeta potential. Presumably, the wetting film thickness is zero in such cases; in any circumstance this film thickness would have to be calculated in some other way. Evidently the results for $LaCl_3$ are not as reliable as those for KCl and $BaCl_2$.

Electrokinetic Potentials

In order to carry out the corrections as suggested by the wetting film theory, one must have reliable values of the zeta potential. Recently significant gains have been made in regard to the experimental knowledge concerning this potential. Hitherto there has been no agreement among the various experimenters (10) in this field, and the reliability of much of the data is open to question. Many experimenters have not characterized their methods and instruments adequately and, therefore, a valid evaluation of their results is difficult. A hopeful indication that reliable information has been obtained concerning these potentials is furnished in the work of Rutgers and De Smet (8) at Ghent (Belgium) and Jones, Wood, and Robinson (9) at Harvard. This is perhaps the first time that systematic agreement has been obtained by different investigators, using different experimental techniques. Rutgers and De Smet, using both the method of electroendosmosis and of streaming potentials, studied the ζ-potential of solutions of a great variety of salts in contact with Jena 16 III glass, whereas the Harvard experimenters studied solutions of metallic chlorides in contact with quartz. The latter group used only the streaming potential method. It is remarkable that the results were practically identical.

An interesting regularity was observed in both sets of data. Instead of the curves passing through maxima, as shown in most textbooks (11), the potentials decreased in a more or less linear fashion

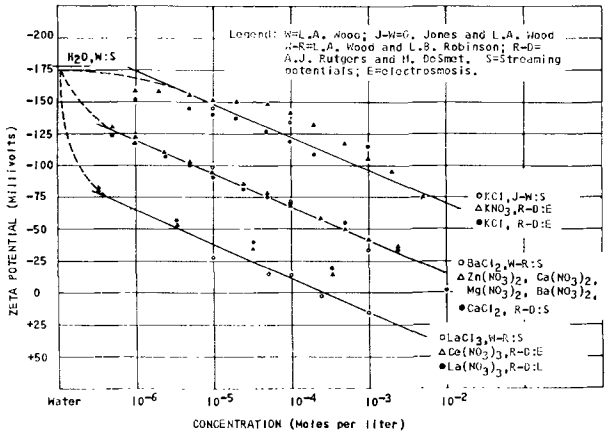

Fig. 1. Zeta potentials of neutral electrolyte solutions

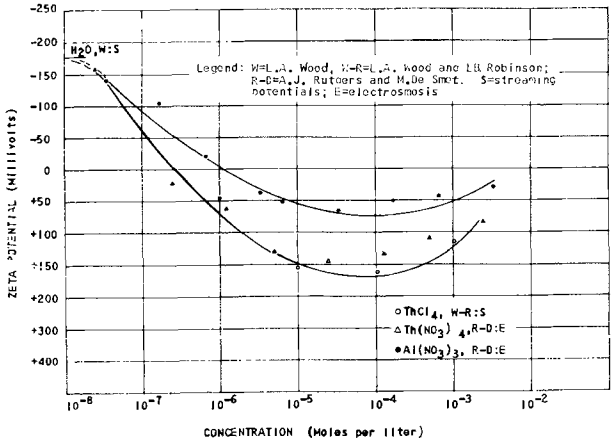

Fig. 2. Zeta potentials of hydrolyzable electrolyte solutions

with the logarithm of the concentration. Both groups of workers found out that thorium salts did not fit the general behavior pattern. This is also true of aluminum chloride. Hydrolysis and other effects with these salts gave their solutions properties not common to the other electrolytes.

Typical results for neutral electrolyte solutions are given in Fig. 1. One observes that all of the data of both groups of workers can be correlated very simply. Actually, only one slope and one intercept are needed to correlate all of the phenomena. The broken lines in the figure are used to give some indication of the expected behavior of the zeta potential in the very dilute range. The three solid lines represent the following equation:

$$\zeta(\text{mv}) = -336 + 55.0\, Z_+ + 26.3 \log c \qquad [6]$$

where Z_+ is the number of charges on the positive ion, and c is the concentration of the salt in moles per liter. The above formula describes the results accurately to about ±10 mv, which is the order of the experimental accuracy. Many times, reversing the direction of flow of the solutions gives an asymmetry potential of this order. In Eq. [6], the symbol c could represent the concentration of the anions (well within the experimental accuracy). There is perhaps some significance in that Eq. 6 can be rewritten as

$$2.27\,\zeta\ (\text{volts}) = \zeta' = -0.760 + 0.1235\, Z_+ + 2.303\,\frac{kT}{\epsilon}\log c \qquad [7]$$

where k, T, and ϵ have their usual significance.

The above equation makes ζ' immediately amenable to an electrochemical interpretation in which the ratio of the viscosity to the dielectric constant (η/D) in the double layer has been increased by a factor of 2.27 over this ratio in pure water. The zeta potential, as calculated both from streaming potential data and from electroendosmosis (electroosmosis) involves this (unknown) ratio as well as experimentally evaluated parameters. Remarks similar to this were made by Robinson (5) some time ago. It seems as though some independent determination of this ratio would be a very worthwhile contribution to the subject of electrokinetic phenomena.

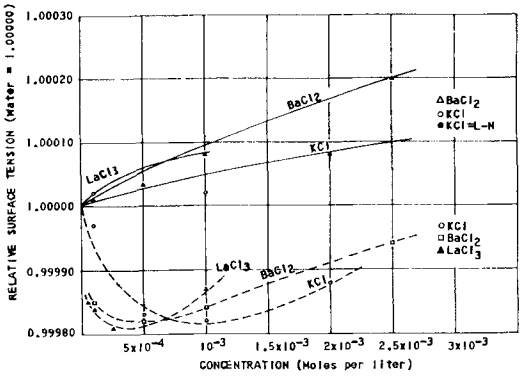

Fig. 3. Relative surface tension of some electrolyte solutions. Solid lines are calculations by H. C. Thacher, Jr.; broken lines connect experimental points of G. Jones and W. A. Ray. Points above 1.00000 (except the one solid circle) are the "corrected" experimental points. The one solid circle is an experimental point of F. A. Long and G. C. Nutting.

Figure 2 shows a different type of behavior for electrolytes which hydrolyze. An interesting problem here would be an attempt to determine the degree of hydrolysis of these salts from the data given

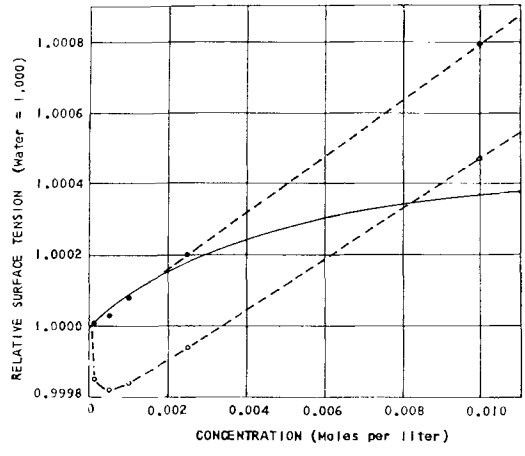

Fig. 4. Comparison of surface tension data of solutions of barium chloride with theories. Open circles are the measurements of Jones and Ray; solid circles are the "corrected" experimental points. The solid line is an approximation to the limiting law of Onsager and Samaras by L. B. Robinson. The upper broken line coincides with a linear extrapolation of the calculations of H. C. Thacher, Jr.

Table I. Wetting film thickness in the Jones-Ray capillary apparatus

Concentration $BaCl_2$	Δr (A)	
	Reported previously	New
2.50×10^{-3}	87	88
1.00×10^{-3}	112	110
5.00×10^{-4}	152	135
1.00×10^{-4}	223	240
$LaCl_3$		
1.00×10^{-3}	56	277
1.00×10^{-4}	18	78

by Rutgers and De Smet for HCl and KOH and a formula similar to Eq. [6]. It is interesting to note that one single curve can represent the streaming potential data for $ThCl_4$ as well as the electroosmosis data for Th $(\eta O_3)_4$. Such all around agreement as exhibited in Fig. 1 and 2 increases confidence in the reliability of both sets of measurements.

Results

Numerical results for the thickness of the wetting film as a function of the zeta potential have been reported by Jones and Frizzell and by Jones and Wood for 1-1 electrolytes, by Wood and Robinson for 2-1 electrolytes, and by Robinson for 3-1 electrolytes. In every case, the approximation was made that one could replace the Laplacian for a region of cylindrical symmetry by the one dimensional Laplacian operator. When this is done, the solution of the problem for the case of 1-1 and 2-1 electrolytes can be obtained in terms of elliptic function. For the case of 3-1 electrolytes, in addition to the approximation of the one-dimensional case, another approximation of a computational nature has to be made; the solution involves hyperelliptic integrals and these were approximated in terms of elliptic integrals. Since the publication of these results, a numerical analysis group at the Ramo-Wooldridge Corporation has assisted Robinson in obtaining numerical integrations of the differential equation involving the Laplacian in cylindrical coordinates. These new results show that the one-dimensional approximation is entirely justified for the 2-1 case; for the 3-1 case, the new wetting film thicknesses are larger by a factor of about four or five than those previously reported. The larger wetting films, however, made no significant difference in the qualitative behavior of the "corrected" surface tension-concentration curves. Table I shows the old and new results for $BaCl_2$ and $LaCl_3$ as well as the old results for KCl. No additional calculations have been made for KCl.

Figure 3 shows the original data of Jones and Ray, the theoretical curves as given by Thacher, and the "corrected" data of Jones and Ray for KCl and $BaCl_2$ solutions. The agreement between various aspects of theory and experiment is good for these two cases. One data point is given from the work of Long and Nutting; they did not have points at lower concentrations (12).

Figure 4 shows the results for $BaCl_2$ in more detail. In the very high dilution range, the calculations of Thacher and Robinson agree. Thacher's calculations were carried up to a concentration of 2.5×10^{-3} moles/l of $BaCl_2$. Figure 5 shows the corresponding results for $LaCl_3$. The only specific thing one can say in regard to the corrected data is that none of these corrected relative surface tensions is less than that of water.

The evidence suggests that the theory of the surface tension of electrolytes is satisfactory, and the minimum in the surface tension-concentration curve is an instrumental effect.

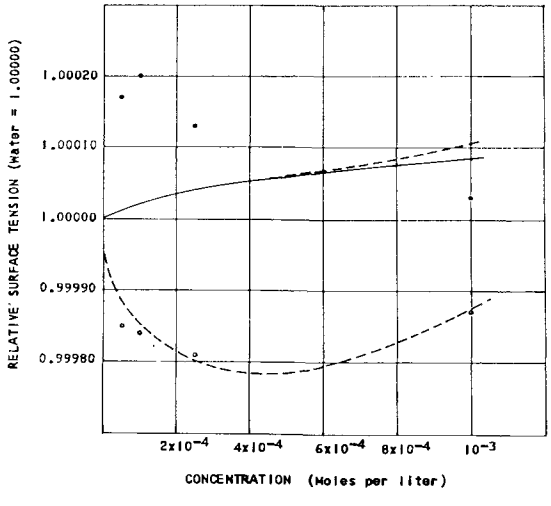

Fig. 5. Comparison of surface tension data of solutions of lanthanum chloride with theories. Open circles are the measurements of Jones and Ray; solid circles are the "corrected" measurements; solid line is the calculation given by H. C. Thacher, Jr. The calculation given by L. B. Robinson coincides with this below 6×10^{-4} moles/l; the broken line continues Robinson's results beyond this point.

Acknowledgment

The author is indebted to Dr. Henry C. Thacher, Jr. for allowing him to make use of the results of his thesis.

Manuscript received June 17, 1958. This paper was prepared for delivery before the New York Meeting, April 27-May 1, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Technical Notes

Enhanced Surface Reactions

IV. The Adsorption of Hydrogen on $ZnO \cdot Cr_2O_3$

M. J. D. Low and H. A. Taylor

Nichols Laboratory, New York University, New York, New York

Recent experiments on gas-solid interactions (1-3) were explained in terms of a mechanism (4) intimately connected with the Elovich equation (4)

$$dq/dt = ae^{-\alpha q}$$

q being the amount of gas adsorbed at time t. It was thought of interest to study the change of the constants a and α with initial gas pressure, P_o, and temperature. The adsorption of hydrogen on $ZnO \cdot Cr_2O_3$ was measured using previously described techniques (3-6). The unreduced catalyst (33.4 g) (7) was reduced in flowing hydrogen at 1 atm at 450°C for 20 hr. Between runs the catalyst was degassed at 450° for 16 hr to $\leqq 10^{-6}$ mm Hg.

Most q-log t plots showed isothermal discontinuities (4) and were described precisely by the Elovich equation. At 147° and 200°C the change in slope corresponded to a decrease in α; at 257°, to an increase in α. Table I summarizes the data, numbered according to the order of their execution. The subscripts 1 and 2 refer to the a and α values calculated (8) before and after the break at time t_b and adsorption amount q_b.

Plots of $\alpha_1 - P_o$ show breaks, α_1 varying more rapidly with a change in P_o at low temperature, less rapidly at higher pressures. In contrast to previous studies, this break seems to be temperature dependent, changing from 16 cm at 147° to 20 cm at 257°C. Conversely, the breaks in q-log t plots occur approximately at $q = 8$ ml regardless of P_o or temperature. Further, the break occurs at $q = 8$ ml, whether the change in slope corresponds to an in-

crease or decrease in α. Such behavior is similar to that found by Decrue and Susz (9) in part for the same system, but even more so for the system H_2-WS_2. A peculiar effect of initial pressure is discernible in the earlier work with hydrogen on zinc chromite by Taylor and Strother (10). At ¼ atm of hydrogen they calculated energies of activation which increase monotonously with the amount of hydrogen adsorbed over the range 80°-218°. At ½ and at 1 atm the change in the calculated energy of activation is different for the ranges 80°-110° and 110°-184°. The adsorption isobar showed a maximum around 184°. No energies of activation at temperatures higher than 184° at ½ or 1 atm are given. Kubokawa and Toyama (11) have called attention to this effect as different from their findings, remarking that "the reason for the difference is not yet clear." That they did not observe the effect is no doubt to be attributed to the low pressure, 6 cm, in their work. The low pressure would account also for the absence of breaks in the q-log t plots of their data, since none was found at the lowest pressures at 147° in the current study. Their data satisfy an Elovich treatment, Table II listing the calculated parameters. The value q_1 is the amount adsorbed after 1 min, obtained by extrapolation of the data given, and used to calculate the initial rate a from the integrated Elovich equation, $q = (2.3/\alpha) \log (1 + a\alpha t)$. From 0° to 80°C a increases steadily, but from 80° to 200°C a decreases. If the Arrhenius equation is applied to these values the energy of activation so calculated is 37 kcal in the first temperature interval, and −26 kcal in the second interval. If the a_1 values in Table I are similarly treated, an average energy of activation of −63 kcal is found. Similar negative activation energies have been pointed out by Decrue and Susz. The numerical discrepancy can undoubtedly be attributed to a difference in the catalytic activity of the adsorbent. At 140° Kubokawa and Toyama found 21 ml hydrogen adsorbed on 12.37 g catalyst at ≈6 cm pressure; the α value was ≈1.0. In the present study at 147° 33.4 g adsorb only 10 ml at that pressure, while α_1 is 2.1.

The a_2 values in Table I decrease in going from 147° to 200°C but increase from 200° to 257°C. It is obvious that the temperature dependence of the adsorption after the break is completely different from that before the break. Patently, at least two types of adsorption are involved, and much more kinetic data from other adsorbent-adsorbate systems are required to unravel the complexity. It may be noted, parenthetically, that the activation energies calculated from the times required to adsorb definite amounts of gas, in the ranges 3-4 or 7-13 ml found by Taylor and Strother and also by Kubokawa and Toyama, do not have the significance which these authors claim.

The Elovich equation shows adsorption to be a decelerating process, to an extent dependent on the value of α, which is itself temperature and initial-pressure dependent. To apply the Arrhenius equation to rates at constant amounts adsorbed disregards whatever is responsible for the parameter α. In view of the previously discussed mechanism the deceleration is the result of spontaneous site decay and hence, for the adsorption of a constant amount of gas, a different proportion of the surface sites has decayed at different temperatures, and thus the stages of reaction are not comparable.

Formation of Silicon Carbide Crystallites

Allen H. Smith

Research Division, Raytheon Manufacturing Company, Waltham, Massachusetts

A unique approach to the problem of growing silicon carbide crystals has produced free falling crystallites. This SiC "snow" is transparent and clear in typical hexagonal or triangular platelet form. The snow forms in a pressurized furnace containing an argon atmosphere.

Silicon carbide is known to sublime at elevated temperatures. Near 2700°C (1) decomposition takes place forming an atmosphere of silicon vapor and a solid residue of graphite. This experiment utilizes decomposition rather than sublimation. The Lely process (2,3) employs sublimation as the principal mechanism. The argon pressure of about 80 psi was established empirically. This pressure controls the diffusion rate of the silicon vapor rather than operation at some arbitrary point on a phase vs. pressure diagram.

Figure 1 shows the apparatus for this experiment in a schematic drawing. The essential parts include the pressure envelope of steel, with water cooling coils soldered on; graphite heater tube with graphite piston sliding fit; thermal insulation of lampblack; and a viewing port at the bottom through which the temperature is taken and events viewed. A neoprene "O" ring and a lavite washer electrically isolate the top electrode. The "O" ring also serves as the pressure seal around the water-cooled electrode. Argon circulates throughout the furnace for flushing and gives a supporting upward draft for the flakes at the point of entry. The furnace uses about 4 kw of power at 600 amp to maintain 2700°C. A saturable core reactor with a stepdown transformer supplies the power. Manual control regulates the power for temperature changes. The temperature remains at a constant value for a given power setting, as determined by a L&N optical pyrometer.

The operating zone, ¾ x 4 in., contains the graphite capsule with its supply of silicon carbide (see Fig. 2). A dense form of graphite[1] must be used for this capsule to prevent breakage when the silicon vapors react with it. The silicon vapor does not attack other parts of the system as much as the capsule. Spectroscopic grade[2] graphite works well for the piston, base, and heater sleeve. The capsule support with three thin legs minimizes heat loss by conduction to the base. A radiation shield above the capsule cuts radiation losses from the capsule top to the much cooler piston.

A simple concept of this experiment assumes the equilibrium reaction:

$$Si + C \rightleftarrows SiC$$

Silicon combines with carbon from 1600°C up to the decomposition temperature. As silicon carbide is very stable, the silicon remains localized until released at the decomposition temperature. As the silicon vapor builds up in the capsule, it streams out

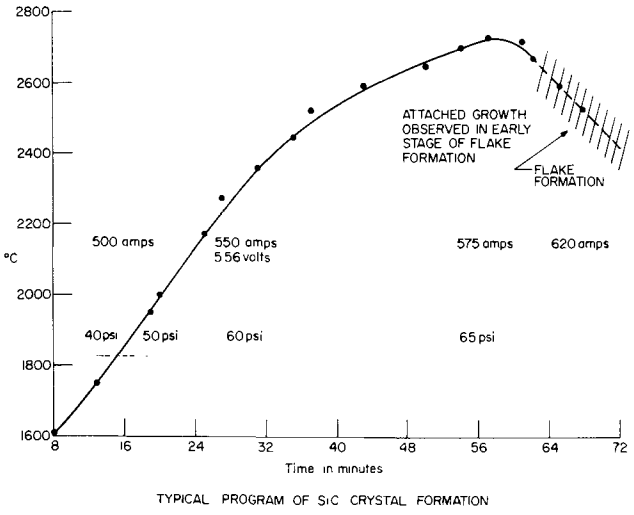

Fig. 3. Typical program of SiC crystal formation

a small hole in the cover. In the upper part of the reaction zone the silicon combines with carbon at a temperature just below decomposition. The inner wall of the support becomes coated with silicon carbide crystals. However, a thinned zone in the heater sleeve creates a "hot spot" from which carbon atoms evaporate readily. This carbon can react with silicon before it reaches the side walls of the reaction tube. When this happens free falling crystals occur.

The actual mechanism of the reaction has not been studied. Possibly intermediate carbides form before a silicon carbide crystal develops. A clear understanding of the reaction would help make a more efficient process. Three important observations lead to the mechanism suggested. The release of silicon from the silicon carbide has been abrupt enough to separate the cover from the capsule. The shape of the original sintered mass of silicon carbide remains in the soft, spongy, graphitic mass. The flutter of flakes visible in the pyrometer occurs abruptly about 2750°C at 80 psi. Those runs in which conspicuous erosion of the heater sleeve takes place, are most productive of silicon carbide crystals.

A run lasts for a little over an hour as shown in the typical program, Fig. 3. The drop in temperature at the end of the run comes from the masking effect of the silicon carbide snow, between the pyrometer and the reference surface. An upward flow of argon

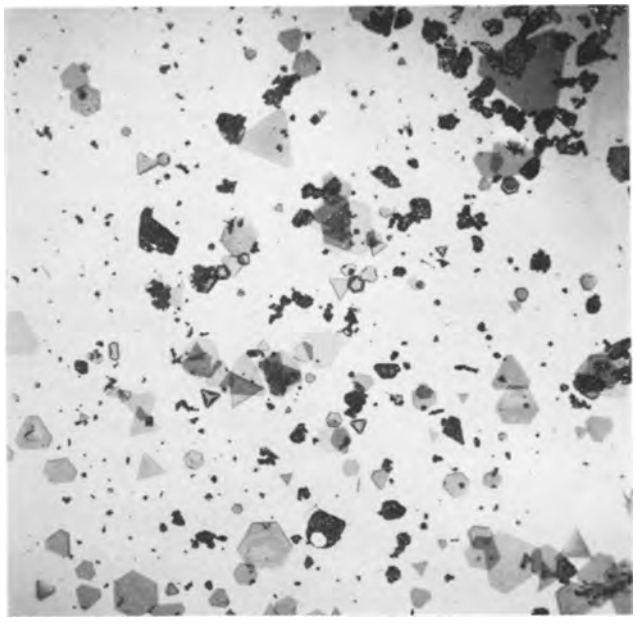

Fig. 4. Display of SiC crystallites as they fell in the furnace. Graphite dust and silicon spheres are also present. One inch equals 40 mils.

maintains the flakes in the reaction zone until they become large enough to fall under gravity. Typical shapes are shown in the display of Fig. 4. The largest dimensions observed are between 20 and 30 mils. Measurements on these crystals are very difficult because of their extreme thinness (~0.3 mil). The size of the crystals is limited largely by the small size of the reaction zone. Crystals which hit the side walls adhere and are no longer free falling. Further work on these free falling crystals is planned with a larger reaction zone so that larger crystals can form.

Manuscript received Nov. 18, 1958. This paper was prepared for delivery before the Ottawa Meeting, Sept. 28-Oct. 2, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

The Diffusion Coefficient of Lead Ion in Fused Sodium Chloride-Potassium Chloride Eutectic

Richard B. Stein[1]

Ecole Nationale Supérieure d'Electrochimie et d'Electrométallurgie, Grenoble, France

Work in progress in this Laboratory (1) has indicated that the fused sodium chloride-potassium chloride eutectic displays an ideal behavior; the molten bath is completely ionized and solvation is absent. Electrode reactions taking place in this fused electrolyte are being investigated at present by the method of oscillographic polarography. The diffusion coefficient of the discharging metal ion can be measured directly by this method.

In the case of oscillographic polarography the discharge current is given by (2)

$$i = \pi^{1/2}\, n\, F\, A\, \beta^{1/2}\, D^{1/2}\, C^{\circ}\, \phi\, (\beta t)$$

where A is the surface of the electrode, D is the diffusion coefficient, C° is the bulk concentration of the diffusing species, and $\phi(\beta t)$ is a complex function relating the discharge current, electrode potential, and rate constant. Once the electrode surface and bulk concentration are known, the diffusion coefficient can be obtained from the polarographic wave and the above equation.

Experimental

The polarographic reduction of Pb^{++} in the fused electrolyte was followed by means of a polarograph especially conceived for this system. The reduction cell consists of a cathode in the form of a microelectrode, made from a 0.5 mm platinum wire sealed into a quartz tube ($A = 1.89 \times 10^{-3}$ cm^2), and the Ag/AgCl electrode of Coriou, Dorian, and Hure (3).

The preparation and purification of the solvent bath have already been described (1). The lead chloride used to make up the electrolyte was purified by a flash distillation under vacuum. The dissolution of the lead chloride in the purified solvent was accomplished under a rigorously controlled inert atmosphere, and the resulting solution was electrolyzed immediately in such a manner that no impurities were introduced from the atmosphere. The polarographic cell was placed in a graphite resistor furnace where the temperature was regulated to $\pm\frac{1}{2}$ °C. Polarograms were taken at four different temperatures for a solution ($C^{\circ} = 2.187 \times 10^{-2}$ mmole Pb^{++}/g solvent) in order to determine the energy of activation of the diffusion process.

[1] Present address: 219 Grace Dr., South Pasadena, Calif.

Table I. Diffusion coefficient of Pb^{++} ion in fused NaCl-KCl eutectic

Temp, °C	Diffusion coefficient x 10^5, cm^2/sec
701	2.4±0.3
746	3.1±0.4
777	3.8±0.5
807	4.4±0.6

Discussion

If the solvent is considered as being a continuous medium in which the laws of classical hydrodynamics are applicable, then the diffusion coefficient can be calculated from the Stokes-Einstein equation. For the diffusion of the lead ion having a radius of 1.21Å, and using the viscosity data of Smithells (5), the diffusion coefficient is calculated at 780°C as $D = 4.6 \times 10^{-5}$ cm^2/sec. From Table I it is seen that the measured and calculated values for the diffusion coefficient are approximately equal, and it can be concluded that the solvent possesses the structure of a simple ionic fluid.

The energy of activation for the diffusion process as obtained from the experimental values is 12.5 kcal/mole. This value can be compared with the value of 13 kcal found by Nachtrieb and Steinberg (6) for the diffusion of Pb^{++} in a complex nitrate bath.

Brief Communications

Rectification by Zircaloy 2 in High-Temperature Water

J. N. Wanklyn and R. Aldred

Atomic Energy Research Establishment, Harwell, Berkshire, England

Recent corrosion tests of Zircaloy 2 under heat transfer in water at pH 10.5, 280°C, were vitiated by rectification effects. Strips of the material were heated by the passage of a large 50 cps alternating current, and this involved a voltage of about 12 v rms between the specimen and the wall of the apparatus. Corrosion was unexpectedly great, white oxide forming in less than 200 hr, and much hydrogen was taken up by the Zircaloy 2.

Polarization experiments with unheated Zircaloy 2 specimens in the same apparatus at 250°C, and in simpler apparatus at 20°C, showed that, as expected from work by Carmody (1), rectification occurred, producing a cathodic direct current. As shown in Fig. 1, there was a "barrier" voltage below which no significant d.c. flowed, and above this the curve rose to a final linear portion. At room temperature, curves for unalloyed zirconium lay to the right of those for Zircaloy 2, but had the same linear slope. Experiments in solutions of different concentrations showed the slope to be predominantly controlled by the electrolyte resistance. The "barrier" value was virtually unaffected by changing from a 1 g/l KOH solution to 50 g/l KOH and to a dilute Na_2SO_4 solution. The lower barrier for Zircaloy 2 (which contains iron among other additions) is interesting in view of Carmody's finding (1) that the addition of Fe^{++} to his electrolyte (H_2SO_4) lowered the barrier for unalloyed zirconium.

Similar curves were obtained at 250°C, but the currents were more variable, and the curves changed appreciably with time when sufficient polarization was applied to cause white oxide to form. Analysis after 100 hr at 12 v rms showed that the hydrogen entering the metal was about 15-25% of that equivalent to the charge passed cathodically. Micrographs showed precipitated hydride throughout the material and, generally, a "case" of massive hydride at the surface. The increased corrosion accompanying cathodic charging with hydrogen is presumably related to the similar effect of d-c polarization of zirconium alloys in high-temperature water (2).

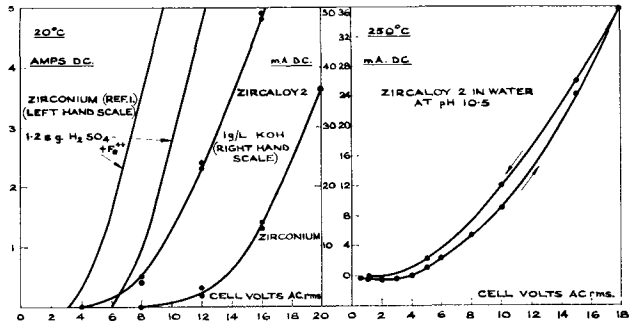

Fig. 1. Rectificotion curves of zirconium and Zircaloy 2

In contrast, virtually none (<1%) of the cathodic hydrogen entered zirconium and Zircaloy 2 polarized at 12 v rms at room temperature.

Provided the conductivity was at least several hundred μ mho/cm, variation of it, at 20°C, merely altered the linear slopes; but if it fell below roughly 100 μ mho/cm, little or no d.c. flowed even up to 50 v rms although, considering only the electrolyte resistance, there was sufficient voltage to produce a measurable current. Likewise, in neutral water at 250°C the currents were low, and the curves, although rather irreproducible, suggested that the barrier was raised to about 10-15 v rms and that the linear slopes were lower than corresponding merely to the reduced conductivity, compared with that at pH 10.5. No hydrogen was taken up in 100 hr at 12 v rms. In dilute solutions behavior appears to be determined by complex phenomena, probably in the oxide/solution interface.

Manuscript received Feb. 19, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Heater Cathode Breakdown

R. J. Jaccodine

Allentown Laboratory, Bell Telephone Laboratories, Inc., Allentown, Pennsylvania

This communication concerns a method of studying heater-cathode insulation breakdown (1). It further proposes a mechanism for this breakdown.

In some electron tubes, the heater is a helix of tungsten wire coated to several mils thickness by spraying with fine Al_2O_3. These heaters are then baked at high temperature prior to being inserted into the cathode sleeve. During use this insulating coating degrades allowing leakage, and in extreme cases a short develops between heater and cathode.

In order to study these phenomena under more controlled conditions, the following method is used. A regular sprayed heater is mounted vertically in a standard tube press. Coiled about this heater is another uncoated tungsten heater or a thin strip of metal (Fig. 1). This outside heater acts in the same manner as the cathode sleeve in an actual tube. This arrangement allows the environmental condition of a portion of the insulation to be controlled. If the effects of various metals or impurities are to be tested, they are applied on thin strips and wound in place of the uncoated heater. The current in each heater can be controlled separately and a d-c potential can be applied between the two heaters. This allows a wide range of temperature, potential and environmental conditions to be studied.

Using the above technique, breakdown was shown to occur only under the wound outside heater (Fig. 1); the appearance of the alumina varied from light gray to black. Under conditions where the heater voltage was 15% higher than normal rated voltage and the heater-cathode potential was 10% higher, breakdown was accelerated. Shorts occurred which caused a glassy, cratered appearance in the insulator probably due to large amounts of current passing through degraded spots raising the local temperature of these spots to the melting point.

In the course of studying factors influencing this breakdown, it was found that oxygen, in the form of metal oxides, caused the degradation process to occur in a fraction of the normal time. The alumina in tubes in which either of the tungsten heaters was oxidized broke down in a short time. In still other tubes, a source of oxygen was included in the form of a separate tungsten filament coated with cupric oxide. Heating this filament gently released oxygen. The alumina in these tubes, after the oxygen was released, broke down in the same order of time as

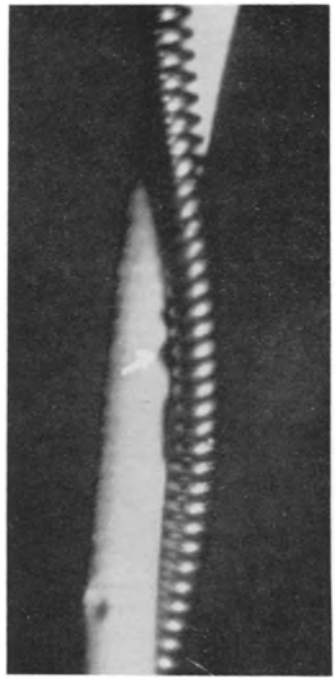

Fig. 1. Experimental arrangement showing "breakdown" region under outside tungsten heater.

the previous group. Heaters subjected to three and five times the normal processing time in dry hydrogen however have not degraded and are still on life.

It is proposed that in an actual tube, a metallic oxide is formed either of nickel or of tungsten depending in part on the polarity of heater-cathode potential. The oxide reacts with the Al_2O_3 to form a spinel (aluminum tungstate in the case of tungsten oxide).[1] It is this product that degrades the insulating quality of the alumina and allows leakage and eventually a short.

[1] In a paper by Rodinhuis, *et al.* (2), they mention that identification of the breakdown product has been made as aluminum tungstate.

Discussion Section

This Discussion Section includes discussion of papers appearing in the JOURNAL of The Electrochemical Society, 104, No. 5 (May 1957), and 105, No. 1, 5, 6, 7, and 11 (January, May, June, July, and November, 1958). Discussion not available for this issue will appear in the Discussion Section of the December 1959 JOURNAL.

Throwing Index; A New Graphical Method for Expressing Results of Throwing-Power Measurements

R. V. Jelinek and H. F. David (pp. 279-281, Vol. 104)

S. A. Watson[1]: One point which is not made clear in the experimental details given by the authors is that the distance between the anode and the nearer of the two cathodes must be kept constant if the metal distribution ratio at a given average current density is to be a linear function of the linear or primary ratio.

At a fixed average current density, the relationship between the metal distribution ratio, M, and the linear ratio, L, was found by the authors to be of the form $L = kM + C$ where k = Throwing Index and C is some constant. From this, it follows that throwing power expressed by Field's formula,

$$T^F = \frac{(k-1)+C}{(k+1)+C-2} = \text{a constant.}$$

But Gardam[2] showed that

$$T^F = \frac{1}{1+\frac{2dl_2}{N}}$$

where d is the average current density, l_2 is the distance from the anode to the nearer cathode, N is a constant related to solution resistivity and cathode polarization, and clearly T^F is constant at a fixed current density only if l_2 is constant. Therefore, Throwing Index is constant only if l_2 is constant.

The dependence of Throwing Index on the value of l_2 can be shown using data published by Wesley and Roehl[3] by taking advantage of the fact that $M = 1$ at $L = 1$. In Fig. 1 of this discussion, values of M determined at current densities of 0.01, 0.02, and 0.04 amp/cm^2 in a nickel chloride/boric acid solution are plotted against linear ratio and the lines for $l_2 = 10$ cm are extrapolated. Throwing Index is seen to be higher when $l_2 = 2.9$ cm than when $l_2 = 10$ cm at all three current densities. From similar data of Wesley and Roehl obtained with a hard nickel solution and a Watts solution (pH 2.0) at a current density 0.04 amp/cm^2, it can be shown that Throwing Index increases as l_2 decreases with these solutions, too, though the effect is smaller than in the chloride bath.

Although the influence of l_2 on the results obtained by Jelinek and David cannot be estimated from the data given in their paper, the data published by Pan[4] which they quote does show the effect of change in l_2. Pan's data for a cadmium cyanide solution at a current density 0.01625 amp/cm^2 are plotted in Fig. 2 of this discussion. Throwing index is seen to increase as l_2 is decreased. Throwing index can also be shown to vary with l_2 for the acid-zinc and nickel baths which Pan used.

The plots of Wesley and Roehl's data in Fig. 1 show that a threefold increase in l_2 may affect Throwing Index as much as a fourfold increase in current density, which emphasizes that l_2 must be kept constant during determinations of Throwing Index.

R. V. Jelinek: We certainly appreciate Mr. Watson's interest in our paper and his effort to offer constructive criticism. Unfortunately, his mathematical argument is rendered invalid by what appears to be an error in algebra. Using Mr. Watson's symbols, if we substitute the linear Throwing Index relationship

[4] L. C. Pan, *Trans. Electrochem. Soc.*, 58, 423 (1930).

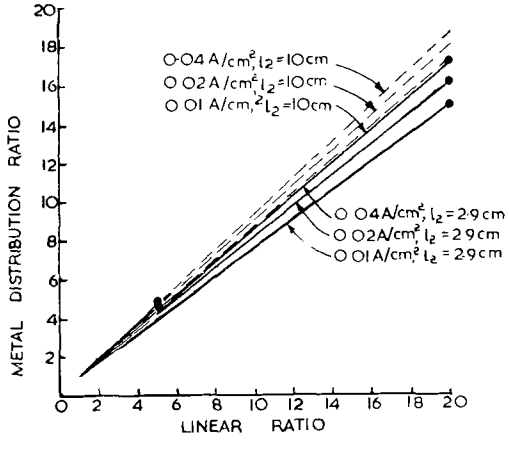

Fig. 1

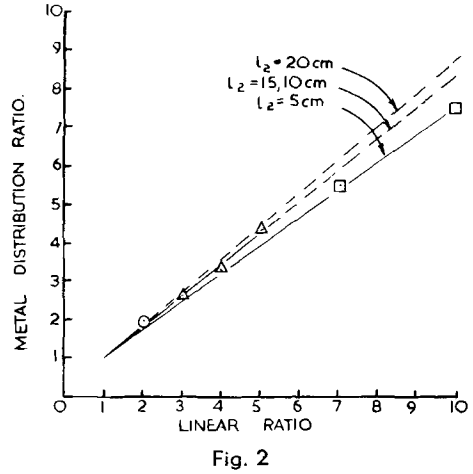

Fig. 2

[2] G. E. Gardam, *Trans. Faraday Soc.*, 34, 698 (1938).
[3] W. A. Wesley and E. J. Roehl, *Trans. Electrochem. Soc.*, 86, 79 (1944).

$$L = kM + C$$

into Field's formula [Eq. (III) of our paper], the correct result is

$$T_F = \frac{kM + C - M}{kM + C + M - 2} = \frac{M(k-1) + C}{M(k+1) + C - 2}$$

and not the equation stated by Mr. Watson. Since M remains in the equation T_F is clearly not a constant.

The data of Wesley and Roehl and of Pan, as interpreted by Mr. Watson, do appear to indicate some dependence of Throwing Index on electrode spacing. However, his rather ambitious extrapolation of some of the points is questionable at best. When we originally examined Pan's results, we noticed some drift in the cadmium cyanide data, but in preparing our Fig. 2 we thought it best to draw a single line through the points. We do not believe that the three separate lines in Mr. Watson's second figure are really justified. Also, we question seriously the 10-cm lines on his first figure.

Our own results were obtained by keeping the cathodes fixed at the ends of the throwing-power box and moving the anode. Thus, in successive runs, the spacing between the anode and both of the cathodes was varied; i.e., Mr. Watson's 1_2 was definitely not kept constant in our measurements.

Perhaps a careful evaluation of geometric factors and their influence on Throwing Index would be an interesting subject for study. However, we should remember that the rectangular throwing-power box is simply a convenient empirical device with many theoretical limitations. Throwing Index is offered principally as an interpretive tool, which we believe more convenient in practice than the various Throwing Power formulas in the literature, for the reasons stated in our paper.

The Anodic Oxidation of Cadmium, I. Mechanism of Film Formation

P. E. Lake and E. J. Casey (pp. 52-57, Vol. 105)

Indra Sanghi[5]: I was deeply interested in the paper by Lake and Casey as we also happen to be carrying on some investigations on the constant current polarization of Cd in our laboratory. Preliminary results were presented at the XLV Indian Science Congress Session.[6]

During our studies, we found that the behavior of Cd was more complicated than appears from the paper of Lake and Casey. The time-voltage curves obtained during anodic polarization with constant current show more than one arrest. The method adopted by us was similar to that already reported in connection with our studies on Zn[7] and generally resembled the procedure adopted by Lake and Casey. Cd rods or sheets (electrolytic 99.99% purity) were machined out and all the surface except the experimental portion was stopped off with suitable plastic coatings. The prepolarization preparation of the surface consisted of successive mechanical polishings with 0 to 6/0 grades of emery moistened with ethanol. Hg/HgO/KOH was used as the reference electrode and Philips GM 6010 type VTVM to read the potential variations. Both stirred and unstirred solutions were studied at room temperature (35°C) but no attempts were made to keep the solutions air free. Various current densities and concentrations of KOH solutions ($N/5$ to $5N$) were tried and some of the curves obtained are reproduced in Fig. 1 published here.

From these figures, it will be seen that sudden or single-step passivation, similar to that of Zn[7] and as reported by Lake and Casey, was not observed by us in the case of Cd. Also, if only one oxidation compound, CdO, is electrochemically formed and effective, then the reasons for the observed arrests in the neighborhood of −0.6 v with reference to the Hg/HgO/KOH electrode are not clear. Also, a uniform gradual variation of potential, as is observed with Al and other barrier layers, is not to be expected in the case of Cd. Moreover, the potential at which the polarization curve becomes horizontal appears to vary considerably from 0.2 to 1.2 v with different concentrations and current densities, more than can be accounted for on the basis of $(OH)^-$ concentration. All these points could be checked only if the authors had given actual detailed polarization curves obtained by them.

The authors do not give the order of variations in t_p experimentally observed by them. General experience has been that good reproducibility of t_p is obtained only when t_p is small and not greater than a few minutes.[8] There may be risks in taking average values for quantitative calculations, and we were not successful in getting satisfactory reproducibility in similar experiments, either with Zn or Cd. Accordingly, the discussed paper, based almost entirely on It_p measurements, appears to depend on rather uncertain grounds for deriving final conclusions. It would have been helpful if the authors had specifically mentioned the actual method of measuring t_p in cases of prolonged polarization wherein the curves would not steeply rise, clarifying particularly whether the determining criterion was a low slope or atttainment of a particular potential (say 1.1 v). Also in Table I of the discussed paper, measured It_p value for KOH is shown to be 0.52; but the concentration of the electrolyte and the current density are not clearly mentioned. If a low slope determines t_p, then, in our experiments, It_p varies from 0.004 to 0.20 in KOH depending on current density and concentration.

Quantitative calculations and electrometrics depend on the assumption that all oxide films are reduced before hydrogen evolution starts. But it has been suggested, and some evidence adduced, that in some cases hydrogen is actually liberated even on thin oxide films,[9] and hence it is necessary to check this point in the particular case of Cd. It is possible that metals like Zn and Cd are never completely free of oxide films in aqueous solutions, as suggested also by Huber.

The authors have presented only the derived

graphs and have not reported the direct measurements. This has resulted in some loss of clarity. For example, in Fig. 1 of the discussed paper, the dotted gas evolution curve appears to indicate that oxygen is discharged in the negative region of potential itself and that as much as 40% of current goes toward oxygen evolution at as low a potential as 0 v with respect to Hg/HgO/KOH. This is not possible in view of the high oxygen overvoltage on Cd and in view of the definite minimum potential required for the reaction $2\overline{OH} \rightarrow H_2O + O$. Also, on page 54 of this paper, the full significance of Fig. 5a and b in connection with the depassivating reaction is not quite clear. Some average rate of depassivation R_2 has been discussed, and probably what the authors imply is that $R_2 = \frac{I\,t'_p}{t_s\,t'_p}$. Similarly, on page 56 (bottom of column 1), it is stated that "if $R'_2 >> R_1$ initially, the CdO film may build up even before supersaturation is reached." This does not appear to be correct, and perhaps there is a typographical error and it should read "$R'_2 << R_1$."

Ionic conduction through very thin oxide films is governed by the high field theory[10] and would be expected to assist the oxide film growth. However, correct ideas about this can be had only by measuring current growth and decay transients or by applying square wave polarization.

Stirring appears to have very interesting effects in the present case. Generally, stirring is expected to delay the passivation considerably, but we find that stirring decreases t_p for 0.2N and N-KOH but increases it for 2N and 5N-KOH. This aspect has perhaps not been considered by Lake and Casey. Also, there appear to be certain difficulties and limitations in evaluating the kinetics of electrode processes and in measuring the rate of film thickening or growth by constant current polarization alone. It has been suggested that potentiostatic measurements are more fruitful[11, 9] and are, therefore, being carried out in these laboratories.

P. E. Lake and E. J. Casey: *Potential arrests.*— Preliminary work showed that extra prolonged potential arrests exist if the current density distribution through the electrode is not uniform and/or constant. In all of the electrometric work reported, a cylindrical cell of which the electrodes formed the ends was used and, within the limits of sensitivity of the multipoint recorder used (±0.005 v, 4 points per min), the extra steps were no longer present. Dr. Sanghi's instrumentation may have detected a real "fine structure." However, if this fine structure is not reproducible, one must consider that the current distribution may be changing from run to run.

Reproducibility of the value of It_p was not as good as could be desired, as was reported in the paper. Best reproducibility was obtained by us if the surface was first cleaned with nitric acid and then prereduced. The possibility that all oxide was not removed was suggested in the paper but accepted as a possible small constant error. When parallel-plate geometry was used, the determination of the value of It_p was usually reproducible to ±10% in experiments done within the fiftyfold range of current densities reported. If successive experiments disagreed by a larger amount, some extraneous factor, such as peeling of the stop-off lacquer, could usually be found to be the reason. However, at Dr. Sanghi's room temperature of 35°C (if this is indeed not a misprint!), the conversion reaction would be expected to be more rapid than at the temperatures (≦25°C) used in the study reported by us, and would probably lead to irreproducible passivation. This comment is strengthened by the further facts that the solubility of $Cd(OH)_2$ in KOH is much higher[12] than is usually supposed, even at 25°C, and

[10] N. F. Mott and N. Cabrera, *Repts. Progr. in Physics*, 12, 163 (1948); D. A. Vermilyea, *This Journal*, 104, 426 (1957).

[12] P. E. Lake and J. M. Goodings, *Can. J. Chem.*, 36, 1089 (1958).

that the electrolyte can supersaturate during the oxidation. The effect of the supersolubility on potential is simply not known because there are no activity data available.

For the above reasons, the use of It_p as a quantitative measure of the depth to which Cd is oxidized before passivation is certainly justified on the basis of reproducibility. Its variation, as OH^- is replaced by $CO^=_3$ at constant $[K^+]$, is real and can be described in terms of the mechanism proposed in the paper. An interesting further fact, the one which suggested the reported study, is that the changes in It_p with experimental conditions are amplified, sometimes up to tenfold, in the sintered negative plate of the Ni-Cd battery. We are driven to the conclusion that the amplification is due to an important factor not usually considered, *viz.*, the effective volume of the reaction product. It is considered that the product could, in favorable circumstances, seal off at the neck the pores which contain still-unoxidized Cd.

Passivation.—The criterion for choosing t_p was low value of $d\,E/dt$ following the onset of oxygen evolution. To choose a definite potential over so wide a range of experimental conditions would have been meaningless, as Dr. Sanghi's graph testifies. However, it is necessary to restate that sharp passivation depicted in Fig. 1 of the original paper is typical of the behavior of pure Cd at 25° and below.

Dr. Sanghi has simply misinterpreted Fig. 1 in his discussion of gas evolution rate. It is the time base which is common to both the potential and the O_2 evolution rate. What the graph shows, for example, is that a small fraction of the current goes into O_2 evolution while the average potential of the electrode is still below 0 v w.r.t. Hg/HgO (this is not surprising because the potential distribution on the actively corroding metal is probably not completely uniform), and that gas evolution accounts for 40% of the current by the time the rapidly rising potential has reached 1.1 v. What is interesting is the fact that, in the experiment reported in Fig. 1, for some hours *after* passivation a small fraction of the current continued to split off to oxidize Cd and to keep in repair the CdO film which is continually etched away by the conversion reaction.

New work.—A study of the decay of overpotential before, during, and after passivation has recently been completed and will be submitted shortly. At any time after passivation, the decay is of the form usually found for gas electrodes and referred to as activation overpotential decay. However, at times before passivation, after an *IR* drop has been separated the first part of the decay is *exponential* in time. The exponential part is not described by activation theory and is tentatively interpreted as the decay of an inner double layer of $O^=/OH^-$, of fixed dimensions, in the CdO layer at the CdO-electrolyte interface. Passivation occurs when the field strength across this inner double layer increases to the value at which OH^- discharge to OH occurs more easily than the ionization reaction $OH^- \rightarrow O^= + H^+$.

The role of adsorption of OH^- on the CdO surface thus becomes quite important, and is manifested through unexpected variations of overpotential with activity of KOH. In general, the new work supports and extends the mechanism of passivation already proposed:

$$\mathrm{Cd} \xrightarrow{R_1} \mathrm{CdO} \xrightarrow{R'_2}$$

$$\text{Soluble Complex} \xrightarrow{R_2''} \begin{matrix}\mathrm{Cd(OH)_2}\ \text{or}\\ \mathrm{CdCO_3}\end{matrix}$$

where R_1 refers to the oxidation process, and R_2 to the conversion.

In fact, the proposed mechanism, which incidentally has been strengthened by recent work of Huber,[13] has proven to be quite versatile. For instance, poor reproducibility at high temperatures and low currents is predictable when considered in terms of the role of the conversion reaction and the new information on solubility. At high temperatures, the conversion reaction is fast; a thick and probably loose layer of product is built up on the surface before passivation occurs. The first evolution of oxygen may simply undermine the protecting film of product, and force the process to start over again. At very low currents, the solubility is high enough that the product can actually be transported to and plated out on the negative electrode, and the passivation time will be longer than expected, probably will be irreproducible, and indeed the electrode may never passivate. Stirring will obviously have its greatest effect at low current densities, by aiding dissolution of the CdO layer and aiding transport of complex to the negative where it can be plated out.

The supposed role of adsorption of OH^- on the CdO layer predicts longer passivation times for increasing a_{KOH}, because the decrease in pH in the pores of the conversion product will be less the higher the a_{KOH}. Stirring should shorten t_p in low concentrations by raising the pH in the pores. On the other hand, increased a_{KOH} increases the rate of the conversion reaction and, once the CdO surface is saturated with OH^-, stirring should lengthen t_p as the a_{KOH} is further increased. It is encouraging that Dr. Sanghi has observed that t_p is shortened in low concentrations of KOH and lengthened in high concentrations.

General.—The conditions under which the values in Table I were obtained could have been approximated from Fig. 4a; they were 0.07 ma/cm^2 and 7.2*N* electrolytes.

As Dr. Sanghi has kindly pointed out, on page 56, line 15, the misprint should read $R_2' << R_1$.

We agree with Dr. Sanghi's comment that the reaction is a complicated one on which further work is necessary.

Uncommon Valency Ions and the Difference Effect

M. E. Straumanis (pp. 284-286, Vol. 105)

Ph. Brouillet, I. Epelboin, and M. Froment[14]: In his article, Dr. Straumanis expresses surprise that the Δ-effect has not been considered to explain the deviations from faradaic yield in the anodic dissolution of certain metals. However, examination of experiments carried out in recent years shows that the Δ-effect cannot explain the anomalous yields obtained in certain electropolishing procedures.

[13] K. Huber, *Z. Elektrochem.*, **62**, 675 (1958).

[14] Laboratoire de Physique, Faculté des Sciences de Paris, Paris, France.

The Δ-effect supposes that in the absence of current there is a protective film on the metal, and that this film is disrupted in certain spots on passing anodic current.

We have observed the surface of metals undergoing anodic dissolution with a noninverting metallographic microscopic whose objective was immersed in the electrolyte. Examination was made in two ways: (*a*) with an interferometric arrangement using two polarized waves (Nomarski system), and (*b*) with ordinary polarized light. The first method gives a resolution of a few dozen angströms; the second makes evident the existence of crystalline layers as they are formed at the anode surface. The results have been observed visually, and recorded by means of microphotography and microcinematography.[15-17]

We have established that during electropolishing the surface becomes more and more uniform and can become perfectly smooth within a few dozen angströms. If polishing is continued on such a surface, its appearance does not change. The homogeneity of the dissolution seems to contradict the Δ-effect, heterogeneous by definition.

The polishing sometimes can be accomplished without the appearance of a layer on the anodic surface. But, if it appears (and it is clearly visible in polarized light), it is quite homogeneous, and an important fact is that it disappears on interrupting the current. Optical examination, as well as chemical analysis,[16] shows that this film has nothing in common with the oxide film which is formed when the anode is just below the polishing potential; this oxide film disappears when the polishing range is attained.

From a chemical point of view, the reactions involved in the mechanism of the Δ-effect raise additional difficulties.

In the experiments to which we refer, for example the anodic dissolution of pure Al in solutions containing ClO_4^- ions,[18-22] the electrode does not undergo any "spontaneous" dissolution when there is no applied current. In electropolishing, no gas evolution is apparent. If, according to the argument of Straumanis, a "spontaneous dissolution" occurs on parts of the metal made bare by anodic dissolution, one must indeed consider the possibility of unusual chemical reactions, for example the reduction of perchlorate to chloride on the metal surface. According to authors who have studied this question,[23] the reduction is difficult, even if the surface has been "made bare" by amalgamation.

We have explained the appearance of reduction products in the electrolyte by the return to their stable valence of ions formed at the anode in a lower and unstable valence state. Quantitative analysis has confirmed this hypothesis, [10,21,22,24] and the work of others with quite different solutions[25] has shown that the reduction products can be formed at some distance from the electrode.

In addition, we have described[22,26] the precise measurement of the electrode potential with respect to a reference electrode. The anodic overpotential is considerable, and it is difficult to postulate a reasonable mechanism of reduction at the electrode surface. Even if this chemical reaction exists, we do not see how it could explain the constancy of the yield when such parameters as time of electrolysis and current density are varied. We have observed a yield constant to about 1% as both parameters were varied over a range of 1 to 20.[22,24]

On the other hand, the importance of the "spontaneous dissolution" ought to vary if the potential of the electrode is changed, with a consequent change in the yield. Now, experiment has shown that the anomalous yield is not modified by change in the polishing potential.[16,24,27] Even on changing the potential by incorporating the metal studied in an alloy, for example Al-Ni,[16,24,27] the Al retains the same abnormal valence. In this case, the electrochemical potential is changed as much as 500 mv, without any external polarization. Again, we do not see how the Δ-effect can explain these results.

Finally, we wish to point out, in response to a question of the author, that we have measured the yield of anodic dissolution during electropolishing of most of the common metals.[10,22,24] With certain metals, the valence calculated from these measurements has been the lowest customary value: Mo^{3+}, Bi^{3+}, V^{2+}, Mn^{2+}, Zr^{2+}, Fe^{2+}, Cd^{2+}, Co^{2+}, Ni^{2+}, Sn^{2+}, Pb^{2+}, Ga^{+}, In^{+}, Hg^{+}, Ag^{+}, Cu^{+}, Li^{+}. With others, we have found a valence lower than the lowest accepted values: La^{+}, Ce^{+}, Ti^{+}, Zn^{+}, U^{+}, Mg^{+}, Al^{+}, Be^{+}. The values found are in no case greater than a known valence, and they are never less than unity.

M. E. Straumanis: The negative difference effect is found when the rate of *self-dissolution* of a metal electrode increases while under an anodic current, and the positive Δ-effect—when under the same conditions this rate decreases. From the loss of weight of the electrode and from the time and strength of the current passing the anode, the valency of the metallic ions pushed into solution can be calculated. If, now, the difference effect (that is, the increase or decrease of self-dissolution rate during the flow of current) is disregarded, one will calculate in the first case a decrease in the valency of ions going anodically into solution (because the weight of the metal which dissolved outside the faradaic current was not taken into consideration), and, vice versa, an increase in the ionic charge in the second case.

Both effects were studied by the author[28] and they also were observed by others, e.g., the negative effect by Heumann and associates during the anodic

passivation of Cr[29] and on stainless steel by Tomaschow.[30] Both effects are proportional to the current density, meaning that the ratio of the rate of self-dissolution and of enforced rate (through current) is constant, and independent of the *p*H of the solutions.

In the case of Al corroding in KCl, the increase in rate of self-dissolution while the anodic current was on could be directly observed. Besides, it could be seen that the protective (oxide) layer on Al broke down under the impact of anodic current. Thus, the increase in self-dissolution could be attributed to the scale breakdown. It is not said that the latter should in all cases be an oxide scale; it can be a salt layer as well. Even a metal without any scale at all could produce a Δ-effect if the metal in the surface becomes activated by the anodic current. The same effect could be produced by a decreasing thickness of the scale while under anodic current. If in the experiment with Al in KCl the increase in self-dissolution is disregarded, a valency lower than 3 can be calculated for Al ions from the experimental data. This, in the opinion of the author, happened in the work of Drs. Brouillet, Epelboin, and Froment.

Although the discussors state that in an electrolyte containing ClO_4^- there was no gas evolution (at the anode) during electropolishing, and that the reduction of ClO_4^- is difficult by the metal, they nevertheless write in the next paragraph that there are reduction products present but produced by the Al ions of lower valency. Is it not simpler to write: $Al + 3H^+ \rightarrow Al^{3+} + 3H$ (self-dissolution while under anodic current, Δ-effect) and then $ClO_4^- + 8H \rightarrow Cl^- + 4H_2O$?[31]

The (active) hydrogen has a certain solubility in water and may act at some distance from the electrode; no lower valency Al-ions are necessary for the reduction. In addition, no such ions were obtained by the discussors when electropolishing was made in solutions containing phosphoric acid, chlorides, or fluorides.[32] It is clear that there was no negative Δ-effect, but probably a positive one during the passage of current, as it is well known that the effect may change its sign if a metal is anodically dissolved in different electrolytes.[33]

Furthermore, in the last paragraph of the discussion, two series of metal ions are given. Is it not surprising that the metals which supposedly produce ions of lower valency during electropolishing all are *the most active metals* (Zr^{2+} should be transferred into the second series because its most common valency is 4)? These metals react with the electrolyte (self-dissolution) as soon as the protective layer is removed or changed (e.g., by the anodic current, Δ-effect). Even ions with a valency lower than 1 can be found by calculation in such cases.[34] More noble metals exhibit only very slight Δ-effects[30] and, therefore, no ions of unusual valency (1st series) were found by the discussors with such electrodes.

Finally, the assumption of the discussors, that during anodic polarization ions of lower valency are going into solution, is contrary to experience gained in passivation experiments. For instance, Fe or Cr,[29] as it, e.g., follows from the recent work of Pourbaix,[35] at small current densities go into solution with low but normal valencies and with the valency increasing at higher current densities (or potentials), which is in accordance with our theoretical considerations.

Of course, if the discussors can show that there is absolutely no change in the rate of self-dissolution of an anode made of an active metal during polarization (no Δ-effect), then their conclusions should be regarded as correct (or *see* last sentence in the discussed paper).

Studies of Natural Convection at Vertical Electrodes

N. Ibl and R. H. Müller (pp. 346-353, Vol. 105)

G. Wranglén[36]: This paper is of great interest since it shows that the velocity profiles obtained in the rigorous numerical solutions of the boundary layer equations by Ostrach and by Sparrow and Gregg can be realized also in electrolysis experiments under ideal flow conditions just as they already have been realized in experiments on thermal boundary layers. In addition, a new contribution is the application in the approximate analytical treatment, according to von Kármán, of velocity profiles that are in agreement with theoretical expectations and experimental findings. The method adopted by the authors is to vary certain parameters in the velocity and concentration functions so that the calculated values of u_m and τ fit the experimental data. However, this method will not admit a comparison between a purely theoretical solution and experimental results. This comparison can be made if the functions introduced are adapted instead to the profiles obtained by a rigorous numerical treatment. It should further be emphasized that any functions will give results that are correct dimensionally. Only the numerical coefficients in the expressions for maximum flow velocity, limiting current density, diffusion layer thickness, concentration difference, etc., will differ. However, exact values of these coefficients can easily be obtained by comparison with the rigorous numerical solutions for the appropriate Schmidt (or Prandtl) number.

According to these principles, the discussor has performed calculations, the main results of which were recently published in a short communication.[37] While the concentration profiles used were the conventional ones, corresponding to Eq. (V) of the paper discussed, the following approximation was used for the velocity profile, *viz.*,

$$u = 3.375\, u_m \frac{y}{\delta}\left(1 - \frac{y}{2\delta}\right)^2 \qquad [1]$$

for

$$0 \leqq y \leqq 2/3\ \delta$$

Table I

Quantity	Constant liquid density A.A.	Constant liquid density R.N.	Constant current density A.A.	Constant current density R.N.
u_m	1.18	0.98	1.33	1.1
$\delta_{0.99}$	3.48	3.54	3.00	3.09
τ	2.32	2.69	2.00	(2.1)
i_{11m}	0.575	0.499	—	—
$/c_o - c_e/$	—	—	1.50	1.59

Fig. 1. Transition from laminar to turbulent flow in the electrode film in electrodeposition of Cu under free convection conditions.

and

$$u = 0.070\, u_m\, Sc^{-1/3}\left(1.5\, Sc^{1/3} - \frac{y}{\delta}\right) \qquad [2]$$

for $2/3\ \delta \leqq y \leqq 1.5\ Sc^{1/3}\ \delta$. In these expressions, $\delta = \delta_{0.99}$ is defined as the value of y for which $/c - c_e/ = 0.99/c_o - c_e/$. This definition also allows an exact meaning to be assigned to δ. Eq. [1] implies that u_m is reached at 2/3 δ, which is approximately true for high Schmidt numbers. Eq. [2] takes into account the fact that the thickness (1) of the hydrodynamic boundary layer is a function of the Schmidt number. Generally, $1 \simeq \delta \cdot Sc^{1/3}$.

For the numerical constants of interest here, the results listed in Table I were obtained. They refer to Sc = 1000, which is a good mean value for aqueous electrolytes, particularly if higher temperatures are also considered.

A.A. means approximate analytical solution and R.N. rigorous numerical solution. The table shows that the approximate profiles introduced, although comparatively simple, are a satisfactory substitution for those obtained in the rigorous numerical treatments. This can also be shown by plotting the respective profiles in the same diagram. In a comparison with experimental results, the constants derived from the numerical solutions should be used. Experimental values for the coefficients are: 1.04 for u_m, 1.63 for τ (at constant c.d.), and 0.505 for the limiting c.d.[38]

The fact that the flow becomes turbulent at relatively low values of the Grashof number is illustrated by Fig. 1 published here which was obtained by a schlieren technique without lenses.[39] A cathode in a 1M $CuSO_4$-solution was placed in a beam of parallel light and the shadow was photographed. The electrode, filling the whole cross section of the electrolyte, was 180 mm high and the photograph was taken between $x = 80$ and $x = 140$ mm. The current density was 1.5 amp/dm² and the temperature 20°C. While laminar flow on the lower part of the cathode is evident from the constant deviation of light and a regular vertical motion in the bright band, the conditions on the upper part of the cathode are clearly turbulent. The transition from laminar to turbulent flow under the conditions mentioned occurs at $x \simeq 100$ mm both at the cathode and the anode. The same result was obtained with electrodes, 1000 mm in height. These results seem to agree with those reported in the paper under discussion. They obviously imply that in full-scale electrolysis (e.g., copper refining) the free convective flow is turbulent over the main part of the electrodes. Calculations, based on an assumption of laminar flow, are then of qualitative value only. This situation stresses the need for at least empirical relations for mass transfer under turbulent free convection conditions.

N. Ibl: The interesting results reported by Wranglén on the onset of turbulence in natural convection are in agreement with the findings of R. Müller. In our optical experiments, the flow became turbulent[40] for instance at a height of 8 cm with a current density of 20 ma/cm² and at a height of 14 cm with a current density of 4 ma/cm². This corresponds to a Rayleigh number, Ra (Ra = Sc x Gr) of roughly 4×10^{11} (compared to a Ra of 2×10^9 reported by Saunders[41] for the transition to turbulence in heat transfer). As Wranglén points out, the question arises as to how far the relations hitherto derived are still valid with tall electrodes, of the kind used in technical cells. M. G. Fouad has studied experimentally in our laboratory the mass transfer by natural convection at Rayleigh numbers above 10^{11}. His unpublished experiments show that the limiting current has a tendency to become almost independent of the height with tall electrodes. The slope of the line log Nu vs. log Ra is somewhat larger than ¼. In this investigation, the cathodic limiting current was measured in the usual way with electrode heights up to 100 cm and $CuSO_4$-solutions acidulated with H_2SO_4, the concentration of the $CuSO_4$ ranging from 0.01 to 0.73M.

Concerning the question of the profiles as discussed by Wranglén, there is no doubt that the results obtained by von Kármán's method should become better with increasing accuracy of the profiles employed. However, it is interesting to note that the profiles hitherto commonly used in the application of von Kármán's method to natural convection [Eq. (V) and (VII) of the discussed paper], although they are far from true, yield limiting currents which differ by only 2%[42] from those derived from the rigorous treatment given by Ostrach. In the case of the maximum flow velocities, the agreement is less good but

[40] R. H. Müller, Dissertation No. 2668, Swiss Federal Institute of Technology, Zurich (1956).
[41] R. Saunders, *Proc. Roy. Soc. (London)*, **A157**, 278 (1936).
[42] C. R. Wilke, C. W. Tobias, M. Eisenberg, *Chem. Eng. Progr.*, **49**, 663 (1953); S. Ostrach, *Nat. Advisory Comm. Aeronaut., Technote Note 2635* (1952).

the difference is still not very large, the numerical coefficient in the equation for the flow velocities being 0.98 for the rigorous method[43] and 0.77 in the case of von Kármán's approximation using the above profiles (Table I of the discussed paper). It was thus felt worth while to study in some more detail the influence of the assumed profiles on the results obtained with von Kármán's method. This was achieved by varying the parameters of Eq. (VIII) to (X) of the discussed paper. It was found that the results depend greatly on the assumption made on the relative location of the velocity maximum and the shape of the velocity profile up to the maximum, but, within a wide range, they are almost not affected by a variation of the slope of the velocity profile beyond the maximum. This might help to understand how it is possible that Eq. (V) and (VII) give good results in spite of the fact that they are quite wrong in the outer parts of the boundary layer. It might be noted that, with velocity profiles of the type used by Wranglén, the results are also practically independent of the slope beyond the maximum. This slope is in this case inversely proportional to $Sc^{1/3}$, which is roughly 10 in aqueous solutions. However, if a value of 5 or 20 is used instead of 10, the calculated maximum of the flow velocity at constant liquid density, for instance, is changed by less than 2%.

In the discussed paper, the measured velocities were not compared with the values obtained by the rigorous method, since the extrapolation to high Schmidt numbers of the velocity distributions shown graphically by Sparrow and Cregg[44] for a few Prandtl numbers between 0.1 and 100 appeared inaccurate. It is encouraging that the figure of 1.1 given in Wranglén's discussion for the numerical coefficient of the equation for the flow velocity (which was extrapolated to Sc = 1000 from more accurate values of the rigorous solution communicated by Sparrow and Cregg) is in very good agreement[45] with the experimental value of 1.04.

A Contribution to the Theory of Stress Corrosion in Al-4% Cu Alloys

W. H. Colner and H. T. Francis (pp. 377-384, Vol. 105)

G. J. Schafer and T. Marshall[46]: The comments regarding H_2O_2 concentration variability during tests are of great interest. Partly for this reason, we have much greater confidence in the acid chloride gas evolution test for intercrystalline corrosion susceptibility than in the salt-peroxide test. It has been shown[47] that important composition variables remain constant during the former test.

We do not entirely agree with the interpretation of some of the results presented by the authors. The polarization curves in Fig. 7 and 8 of the discussed paper indicate mixed rather than cathodic control. Cathodic control implies a large difference in polarization curve slopes with the cathode polarization curve being relatively much steeper. Again, in Fig. 6, current is only influenced by cathode area at large cathode: anode ratios, which indicates mixed control.

The area effect demonstrated in Fig. 2 of the paper does not necessarily support the contention that the grain boundary-grain center corroding cell is under cathodic control. In the case of the specimens not connected to auxiliary electrodes, the ratio of grain-center to grain-boundary areas is constant. Therefore, the failure time vs. exposed area curve must be explained purely on the basis that, when a larger specimen area is exposed, more grain-boundary trenches are formed in the stressed metal surface, and the time required for a given deflection is therefore shorter.

The disappearance of the area effect when auxiliary electrodes were used is not very relevant. It is shown in Fig. 8 that stressed 2024 is anodic to unstressed 2024 (this effect of stress has been observed on other materials),[48] so, when a stressed specimen is electrically coupled to an unstressed specimen, the system under consideration is equivalent to a bimetallic couple and has no simple relation to a stressed specimen by itself. Auxiliary electrodes of any more noble metal having appropriate polarization characteristics would have a similar effect on times to failure of the stressed specimens.

We would appreciate the authors' comments on our interpretation of their data.

H. T. Francis and W. H. Colner: It is conceded that Fig. 7 and 8 could be interpreted as indicating mixed control rather than cathodic control. In the couples of Fig. 6, however, the current was determined by the total cathode area when the anode area was held constant (C curves). Conversely, the current was unaffected by changes in anode area when the cathode area was held constant (A curves). This we interpret as cathodic control.

With regard to the area effect demonstrated in Fig. 2, we agree that the ratio of grain-center area to grain-boundary area is constant in any given specimen. For small specimens, however, we contend that the cathodic area is insufficient to produce enough total anodic attack to promote cracking. With larger specimens, the total cathodic area promotes rapid enough attack on *some* of the anodic zones to permit cracking. Reference is made to the work of Mears, Brown, and Dix on this point.[49]

We agree that coupling to other suitable cathode material would cause small-area specimens to crack. The question then remains: Why do small-area specimens not fail by themselves? We know they possess anodic grain-boundary zones, since they crack readily when coupled to auxiliary cathodes. The conclusion then must be that they cannot in themselves provide sufficient cathodic action to cause cracking.

[43] The K value of 0.98 indicated on the third line of Table I of the discussed paper is equal to the rounded numerical coefficient in Wranglén's equation for the flow velocity at constant liquid density along the interface [*Acta Chem. Scand.*, 12, 1143 (1958)]. The figure of 0.98 was directly obtained from the value of F' (η) given by Ostrach for a Prandtl number of 1000, the method used in the derivation being probably very similar to that employed independently by Wranglén (G. Wranglén, *Trans. Roy. Inst. Technol., Stockholm*, In press).

[44] E. M. Sparrow and J. L. Cregg, *Trans. Am. Soc. Mech. Engrs.*, 78, 435 (1956).

Fundamentals of the Theory of Electrodes and Galvanic Cells

E. Lange and P. Van Rysselberghe (pp. 420-428, Vol. 105)

Patrizio Gallone[50]: I would like to take the liberty to submit some very modest considerations about some particular points of this paper, which deserves the most careful study by all electrochemists wishing to keep abreast with the fundamentals of their subject.

[2.3] About the last statement made by the authors in this paragraph of their paper one may object that "if chemical forces were alone effective" the "corresponding reaction" could only be spontaneous, so that in this hypothetical case A would only be positive.

[2.7] The electrochemical affinity is defined as the sum of the chemical affinity and of a term derived from the galvanic tension. This term, which also has by consequence the dimension of an affinity, is, among all the physical quantities considered by the authors, the only one that has not been given its own name. From the concepts underlying the definition of the Galvani tension, one may deduce that such nameless quantity should be called *Galvani affinity*, or *inner electric affinity*, or *electrostatic affinity*.

[2.9] With regard to the sign of the reversible Galvani tension of a given electrode, one may note that the way in which this quantity has been defined under [2.5] is clearly based on the spontaneous reaction, *viz.*, either α or β, as the case may be, irrespective of considering the electrode x or its reverse y. This is the reason for the change in sign when considering the reverse electrode. Consequently, the statement that the Galvani tension "is the same whether the electrode reaction is regarded as being α or β," instead of adding any further clarification, may seem to be at variance with the definition of the Galvani tension itself, which is based on the consideration of the spontaneous reaction only.

These same considerations essentially apply also to the sign of the corresponding chemical tension.

[4.11] As to the mutual interdependence of the cell tension U and the electromotive force E, may it be emphasized that we "always" have $U = -E$ provided that the equilibrium conditions of the reversible process are satisfied. For a better understanding of the reciprocal behavior of U and E, as well as of their different nature, it can be noted that these two tensions are in the same relationship as an acting and a reacting force in a mechanical system. The chemical tension, or electromotive force, E of the Galvanic cell can be compared to a static pressure exerted by a fluid against the wall of its container, and the electrostatic tension U is comparable to the reaction force opposed by the vessel. Whenever the reaction force is decreased, e.g., by establishing a metallic connection between the two cell electrodes, or by opening an aperture through the wall of a fluid-containing vessel, a new equilibrium of a dynamic sort comes about, with a flow of electric charges or of fluid and the consequent appearance of forces having a dissipative nature.

A mechanical comparison such as the above may sound somewhat trivial at the higher stages of theoretical standing, but it is extremely helpful at the lower ones in giving more concreteness to the fundamental concepts expounded by the authors.

E. Lange and P. Van Rysselberghe: The authors appreciate Dr. Gallone's interest in their paper.

The statement made about paragraph [2.3] is erroneous. The chemical affinity of an electrode reaction will be positive or negative according to the direction in which the reaction is written.

In connection with paragraph [2.7], we agree that an expression such as *electric affinity* could well be used. This has, in fact, been suggested in the 1958 version of the report on Electrochemical Nomenclature and Definitions of the International Committee of Electrochemical Thermodynamics and Kinetics (C.I.T.C.E.).

The statement made about paragraph [2.9] is erroneous. Paragraph [2.5] defines the chemical tension, not the electric or Galvani tension. Moreover, the direction in which these tensions, chemical and electric, are taken corresponds to the manner in which the phases are counted and not to the direction in which the electrode reaction may be spontaneous.

We agree that the analogy developed by Dr. Gallone in connection with paragraph [4.11] may be of some help in an elementary discussion of electrochemical equilibrium and of the departure from this equilibrium.

The Mechanism of Passivating-Type Inhibitors

M. Stern (pp. 638-647, Vol. 105)

H. H. Uhlig[51]: The electrochemical mechanism for passivation of metals by oxidizing passivators, as outlined by Dr. Stern, is a reasonable proposal and, in my opinion, fits the facts as we now know them. In a paper by Dr. King and myself, presented at this same meeting (ECS, Ottawa, September 1958), we have arrived at essentially the same mechanism. Dr. Stern appears to lean toward a definition of passivity which excludes nonoxidizing passivators. I concur in the advantages of such a definition, especially if the metal admitted to be passive exhibits a Flade potential. But many investigators have traditionally defined passivity on the basis of a low corrosion rate (Definition II, "Corrosion Handbook") which includes as passivators nonoxidizing substances like pickling inhibitors, Na_3PO_4, Na_2SiO_3, and carbon monoxide. Perhaps we are now at the point where a clearer definition of passivity can be formulated, and, in this regard, Dr. Carl Wagner has already moved in this direction.[52]

Of course, oxidizing property is not the only factor that enters passivation even in the presence of a

[51] Corrosion Lab., Massachusetts Institute of Technology, Cambridge 39, Mass.

[52] C. Wagner, International Symposium on Passivity, Jugenheim, West Germany, September 1957.
A metal is called passive if: (*a*) on increasing the electrode potential toward more noble values, the rate of anodic dissolution in a given environment as a function of electrode potential under steady-state conditions is found to be less than the rate at a lower, less noble potential; or (*b*) if, on increasing the concentration of an oxidizing agent in an adjacent solution or gas phase, the rate of oxidation without flow of external electrical current under steady-state conditions is found to be less than the rate at a lower concentration of the oxidizing agent.

strong oxidizer. In an experiment we did some years ago, 18-8 stainless steel in 10% ferric chloride was found to corrode by pitting at a very high rate, but, on addition of 3% sodium nitrate, the corrosion rate fell to less than one millionth its original value. It is not possible that the nitrate ion contributed to the cathodic depolarizing action of the ferric ion; instead, the nitrate ion probably adsorbed on anodic areas displacing chloride ion and thereby reduced the critical current density required for passivity of 18-8. This mechanism fits in with the general picture outlined by Dr. Stern. Incidentally, it is difficult in this instance to conceive of any mechanism involving build-up of thick oxide films as cause of the tremendous decrease in corrosion rate.

With regard to Fig. 2, it is unfortunate that point E is described in the text as the Flade potential. This potential is not the same as the critical potential observed on decay of passivity first described by F. Flade, and after whom the Flade potential is named. Point E includes an unknown increment of potential caused by concentration polarization and *IR* drop through temporary thick films of anodic corrosion products. Such films are not present and do not cause error in measurement of the true Flade potential when passivity decays.

Whether a critical concentration of passivator exists with accompanying sudden shift of potential to the passive value, or instead the shift in potential is more gradual on increasing the passivator concentration, depends on the rapidity with which the passivator can be cathodically reduced. If reduction is slow, as is apparently the case with chromates, chromate can adsorb increasingly on the metal surface (thereby producing more cathodic area) in accord with the Langmuir adsorption isotherm. If reduction is rapid, a critical concentration should be found above which, but not below, passivity is observed. For the latter case, a Langmuir adsorption behavior of potential vs. passivator concentration may then be found only on a surface already passive. This situation probably obtained in the course of Geary's measurements showing a Langmuir relationship for 18-8 and titanium in sulfuric acid in presence of Cu^{++} and Fe^{+++}. It is my conclusion that the passive film in presence of ferric or cupric sulfate is essentially an adsorbed film of oxygen in accord with the ideas described in the paper by Dr. King and myself, on top of which Cu^{++} or Fe^{+++} is adsorbed in amount dependent on concentration.

It is not entirely clear what experimental conditions of Okamoto led to a constant corrosion potential of iron short of 10^{-3} moles chromate/liter and a passive potential thereafter. Careful work of Heyn and Bauer[53] shows a gradual change of potential on increase of chromate concentration more nearly in accord with data of Geary.[54,55] The lower purity iron used by Okamoto is not the cause,[56] and it is not certain whether Okamoto's use of beeswax-rosin to shield a portion of his electrode surface reduced some chromate at the wax-metal interface and produced a passive-active cell which disturbed the potential.

It is true that Fig. 4 indicates that the corrosion rate in a passivator solution should be the same as that which occurs when the metal is passivated by anodic polarization to the same potential, but with one important provision. This provision is that the anode to cathode ratio should be the same in the passivator solution as during anodic polarization. This situation may or may not prevail in practice, depending on the metal and the passivator.

From data of Fig. 8, it is probable that chemical equivalents of passive film substance on Ti are less than 0.02 coulomb/cm^2 in view of the fact that Ti corrodes rapidly in boiling sulfuric acid before passivity is achieved. The calculated coulombs under these conditions partly include those measured in forming an insulating reaction product film preceding build-up of the true passive film. The situation is analogous to Fe where the measured coulombs in sulfuric acid are found to be 1.6/cm^2 [57] which includes build-up of ferrous sulfate or similar film before passivity is achieved. But as Weil[58] observed, the true passive film accounts for only about 0.008 coulombs/cm^2 of the 1.6 coulombs/cm^2. It well may be, therefore, that the chemical equivalents of passive film substance on Ti are also consistent with the value of about 0.01 coulomb/cm^2 for Fe, which is the value found for the passive film on Cr-Fe and 18-8 stainless steels.[57,59]

With respect to Fig. 6, Dr. Stern states that, when the redox system is essentially at equilibrium on the passive surface, there is no net reduction of inhibitor. Thermodynamically, of course, the total system still tends to react and hence some corrosion undoubtedly occurs. The actual situation is probably one in which the net reduction of the redox system is finite, but nevertheless so small that the conditions of equilibrium are not appreciably upset.

The effect of oxygen on passivity of Fe in presence of molybdates and tungstates (and also on the rate of passivation in presence of chromates), in addition to factors mentioned by Dr. Stern, is a probable increase in the cathode to anode ratio favoring anodic passivation of the smaller anodic areas. This factor is mentioned in our paper.

Finally, I should like to mention that Dr. Stern's paper helps clarify our understanding of passivity and passivation, and is a welcome contribution. It comes at a time when serious effort is being made, as was evident at the International Symposium on Passivity held at Jugenheim, West Germany, in September 1957, to arrive at a more satisfactory knowledge of the structure and composition of passive films in general in metals and alloys.

E. E. Nelson[60]: This paper is another example of Dr. Stern's excellent discussions of previous publications and of his original work on electrode processes. The explanations of the roles of the reversible poten-

tials, the exchange currents, and concentrations of oxidizing agents will aid greatly in the eventual complete understanding of passivity.

In this discussion, the relationship of Stern's arguments to particular anode-cathode reactions will be considered. It is believed that this supports Stern's conclusions and develops some additional information. The particular reactions were discussed by Pryor and Evans[61] and were named "autoreduction" by them. Later, they have been studied by Oswin and Cohen,[62] Buob, Beck, and Cohen,[63] and Nelson.[64]

"Autoreduction" is the combination of reactions (I) and (II) given below.

$$Fe_2O_3 + 6H^+ + 2e \leftrightarrows 2Fe^{++} + 3H_2O \qquad (I)$$

$$Fe \leftrightarrows Fe^{++} + 2e \qquad (II)$$

Pourbaix[65] shows that in the pH range of about 2 to 8, the equilibrium potential of reaction (II) is negative to the equilibrium potential of reaction (I). Therefore, when ferric oxide is in metallic contact with Fe in solution, reaction (II) will be mostly in the anodic direction and reaction (I) will be mostly in the cathodic. Footnotes 61, 62, and 63 give proof that this actually does occur. Many writers have felt that passivation is due to a covering of ferric oxide over the metallic Fe. The theory of "autoreduction" indicates that an extensive film of ferric oxide can not start forming until the Fe anode is polarized to the equilibrium potential for reaction (I).

Some authorities feel that passivity is due to absorbed oxygen rather than to an oxide. The arguments here could apply also to absorbed oxygen, but the work on autoreduction seems to favor the oxide theory.

Referring to Fig. 2 of Dr. Stern's paper, the corrosion rate of Fe increases along the curve from A to B. The reduction of ferric oxide would predominate over its formation at point A. These two rates would approach each other and become equal at point B. As the potential becomes more positive, the formation of the oxide increases and its reduction decreases. In the region from B to E, the coverage of the oxide increases. This decreases the anode area and also the total corrosion rate. The corrosion rate per unit of active anode is probably increasing in this area. This would account for the tendency for steel to pit in an inhibitor solution of a concentration below a safe minimum. At point E, the film development is completed and maximum protection is achieved.

In many of the figures of Dr. Stern's paper, current is plotted rather than current density. This has the advantage of showing the decrease in anodic current (and the total amount of corrosion) as passivity is developing. However, it fails to show that the current density on the active anode is probably increasing up to the establishment of a complete film. If current density is considered, the curve would look more like Fig. 1 of the original paper. This would avoid the multiple intersections between the polarization curves for the oxidizing agent and for the Fe anode. It seems probable that only one of these intersections represents an electrochemical state. The other is due merely to the method of plotting the data. The current density of the Fe anode, of course, cannot be plotted since we do not know the true anode area. This does not alter the above reasoning, however, At least if this concept is kept in mind, the curves in the original paper are no longer ambiguous.

The Discussion indicates that, for passivity to start, the cathodic curve for the oxidizing agent must intersect the anodic curve for Fe at a potential more positive than the oxidation-reduction potential of Fe_2O_3. For complete passivity, the intersection must be more positive that the abrupt break in potential (E in Stern's Fig. 2). This agrees with Dr. Stern's conclusions.

The combination of Dr. Stern's position with autoreduction" correlates well with certain known facts about inhibitors. For instance, at room temperature, sodium hydroxide requires dissolved oxygen in order to reduce corrosion. According to Pourbaix,[65] the difference between the equilibrium potential of reactions (I) and (II) decreases with increasing pH. Adding sodium hydroxide increases the stability of any ferric oxide that forms, but it does not produce any ferric oxide. For Fe_2O_3 to result, there must be some oxidizing agent, such as dissolved oxygen, present. At higher temperatures, water alone can probably oxidize iron to Fe_2O_3.

Sodium nitrite acts as an oxidizing agent to produce the higher Fe oxide. Also, the reduction of sodium nitrite provides a cathodic reaction so that a high anodic current is possible on the Fe anodes. This polarizes the Fe anodes to a more positive potential than the equilibrium potential of Fe_2O_3. At this more noble potential, a protective film of ferric oxide can develop.

Chromate ions probably have an additional action. They produce an oxide film and also permit a high anodic current to flow and polarize the Fe anode. Additionally, the reduction product of chromate has an oxidation-reduction potential more negative than that of bare Fe.[65] Therefore, chromate can form a stable film even though the Fe anode is not greatly polarized. This stable film reduces the anode area and aids in producing a condition where ferric oxide becomes stable.

D. M. Brasher[66]: We have read with much pleasure Dr. Stern's illuminating exposition of the electrochemical principles underlying the passivity of metal surfaces brought about by oxidizing inhibitors.

In his reference to the amount of inhibitor associated with the passivated surface, the author states that the amounts reported have "varied considerably from system to system." With regard to surfaces passivated in chromate, it is probable that this variation in the amount of Cr^{51} found (by radiometric means) is due to the fact that some workers have determined Cr^{51} on the surface without reference to the variation of this quantity both with time of immersion of the specimen, and also with "age" of the

surface oxide film before immersion. In this laboratory, in work on steel, we have shown that adsorption of the inhibitor (presumably as $CrO_4^=$ ions) is followed by "logarithmic" growth of a film containing Cr_2O_3.[67] The work has also demonstrated the logarithmic growth of an oxide film on steel, both in air[68] and also in other inhibitive solutions such as sodium nitrite, aerated fenzoate, phosphate, etc.,[69] at rates comparable to that occurring in chromate solution.

The logarithmic nature and similarity in rates of film growth in all these environments has led us[70] to suggest a common mechanism, based on theories of Mott, and Hauffe and Ilschner,[71] whereby electron transfer through the film is the rate-controlling step in the growth of the film. It would be of much interest to know whether this logarithmic growth can be alternatively accounted for on the electrochemical principles set forth in Dr. Stern's paper.

Milton Stern: Before commenting on the above discussion, it should be mentioned that the description of passivity in the subject paper was devised in order to obtain a *useful* description of passivity. The mechanism proposed is kinetic in character and relies on simple, measurable parameters which determine the corrosion rate and electrode potential of the system. Descriptions of passivity which embrace films of one type or another are still embryonic in character and do not promise utility for some time.

I heartily agree with Professor Uhlig's suggestion that a clearer definition of passivity is in order. Dr. Wagner's definition appears quite reasonable and is consistent with the mechanism of passivity in the subject paper. I further agree that it is unfortunate that point E in Fig. 2 is described as the Flade potential—not necessarily for the reasons given by Professor Uhlig, since the figure is schematic, but rather because of the special nature of Flade's experiments. I would prefer to let the term "Flade potential" decay to nonexistence and believe point E would best be called the critical potential for passivity. This point, then, divides the potential scale into active and passive regions.

Since "oxidizing" is a relative term, it should be clear that a passivating-type inhibitor must exhibit a redox potential more noble than the critical potential for passivity of the metal. This is why a metal like Fe, which exhibits particularly noble critical potentials for passivity, requires rather strong oxidizing agents, whereas a metal like Ti, which exhibits relatively active critical potentials for passivity, is passivated by only mildly oxidizing solutions. As described in the text, many factors other than the oxidizing nature of the inhibitor are also pertinent to determining whether passivity is achieved.

The subject description of the mechanism of passivating inhibitors requires that a critical concentration of passivator exist which is accomplished by a sudden shift of potential from active to passive values. The data of Geary are not consistent with this since they show a gradual change of potential with inhibitor concentration. However, since the data do not appear to traverse the critical potential for passivity, they cannot be considered a test of the theory since the electrochemical picture also shows a gradual change of potential with inhibitor concentration in either the active or the passive potential region.

Miss Brasher's interesting work with Cr[51] deserves considerable attention and careful study. The electrochemical description of passivating inhibitors is consistent with her observation that Cr associated with the surface is in the reduced form. It is also consistent with the observation that the amount of Cr found on the surface is not dependent on the concentration of the chromate solution provided the mixed potential is between points E and F of Fig. 2. The mechanism further predicts that in the presence of oxygen the amount of Cr associated with the surface should be less than that found in the absence of oxygen.

There is some evidence that current in the potential region between E and F (Fig. 2) is time dependent and actually decreases in magnitude in a manner which is logarithmic with time.[72] This has been observed for stainless steel. If it is also true for Fe, then Miss Brasher's observations and this electrochemical description (modified to consider time effects) may be considered completely compatible.

Mr. Nelson's suggestion that current density be substituted for current is not clear, since it is necessary to plot polarization diagrams on a current basis in order to have the intersection of anodic and cathodic curves represent the mixed potential. I believe it is not only correct to show multiple intersections between polarization curves, since this is a characteristic of passive systems, but also that this is highly desirable and represents one of the characteristic features of this description. Note, for example, that the diagram in Fig. 10 shows an abrupt change in potential would occur when the limiting diffusion current for reduction of inhibitor exceeds the critical current for passivity. Fig. 9 illustrates this behavior experimentally.

The introduction of area effects into the electrochemical description of passive systems could probably be accomplished in the manner described for systems controlled solely by activation polarization.[73] However, this additional complexity was not introduced (along with possible time effects) because it was believed it would mask the more elementary and equally important features of the description and because these effects could not (at the time) be handled in a quantitative manner.

A New Experimental Technique for the Study of Films Produced at Electrochemical Interfaces

B. D. Cahan and P. Rüetschi

Research Center, The Electric Storage Battery Company, Yardley, Pennsylvania

ABSTRACT

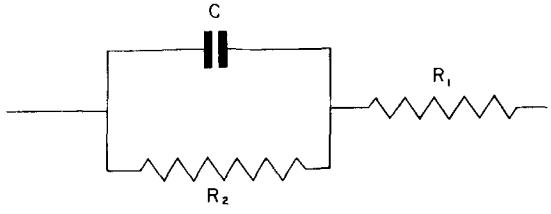
A new experimental technique for the study of the corrosion films at electrochemical interfaces has been developed. It consists of applying a square wave current superimposed on a constant d-c current. The a-c current charges and discharges the double layer capacity at a high frequency. From the voltage transients produced by this current, as observed with an oscilloscope, the nature of the electrode interface can be studied. The instrumentation is described in detail, and experimental results for corrosion films on lead are presented. Capacities were measured with a precision of better than 3% and voltages to 1 mv during transients lasting only a few seconds.

The formation or precipitation of films at electrochemical interfaces occurs in many systems. A good example is found in the behavior of lead in sulfuric acid. During constant current anodization a film of lead sulfate is built up. If the current exceeds a critical value, the electrode passivates and the potential rises quickly to very high values and arrives finally at a steady-state oxygen overvoltage value. The characteristics of electrochemical interfaces have been studied in the past by a variety of different techniques. These characteristics include the electrode potential, electrode double layer capacity, and ohmic resistance.

The oldest technique used in electrochemical investigations is the measurement of the steady-state voltage-current relation (1, 2). This procedure naturally ignores any initial transients. Initial transients have been studied by the application of a single current step function (3). In this manner ohmic resistance and electrode capacity can be determined. However, this procedure permits the determination of only one value in a particular state requiring many measurements for the study of one transient phenomenon. This applies also to experiments based on a constant voltage step function (4, 5).

On the other hand, a-c techniques allow continuous measurements during a transient (6-8). The use of an a-c bridge permits precise, but not necessarily accurate, determinations of electrode capacities and resistances. This technique involves the superposition of a small sine wave on the polarizing d.c. The bridge is balanced by using an equivalent RC network. Capacities and resistances are generally found to be frequency dependent and nonlinear. The balancing operation takes a certain amount of time, and it is difficult to obtain measurements in the short times involved in some transient phenomena.

A very useful technique is the application of a current interrupter (9-12). The polarizing d.c. is interrupted periodically for very short periods of time and the potential decay is followed with an oscilloscope. The ohmic drop, due to R_1 in series with R_2C network of the electrode interface,



is separated out and easily determined by this technique. For this reason, the interrupter is useful in overvoltage measurements at high current densities. If the electrode interface is represented rigorously by the network shown above where R_2 and C are assumed linear, then a plot of the logarithm of the electrode potential vs. time would be a straight line. Experimentally, this is not always the case. Moreover, only the product R_2C can be evaluated from this plot. A complicating factor is that, if faradaic currents and strongly adsorbed species are involved, the potential decay becomes logarithmic with time. This is due to the fact that the discharge current of the capacitor C is then an exponential function of potential (13).

At high frequencies the reactance of the double layer capacity C is much smaller than the parallel resistor R_2 and the latter can be neglected. In the present investigation, an a-c coupled square wave current is superimposed on the polarizing d.c. The double layer capacity is charged and discharged by the square wave current. The initial portion of the square wave represents high-frequency harmonics of the base frequency, and the initial slope of the voltage-time trace gives then a direct measure for the effective double layer capacity, since one measures effectively the charge and discharge of the capacitor at constant current.

Experimental Technique

Figure 1 shows the electrolytic cell used in our investigation. The body of the cell is constructed from two sections of a 1½-in. glass pipe. Two

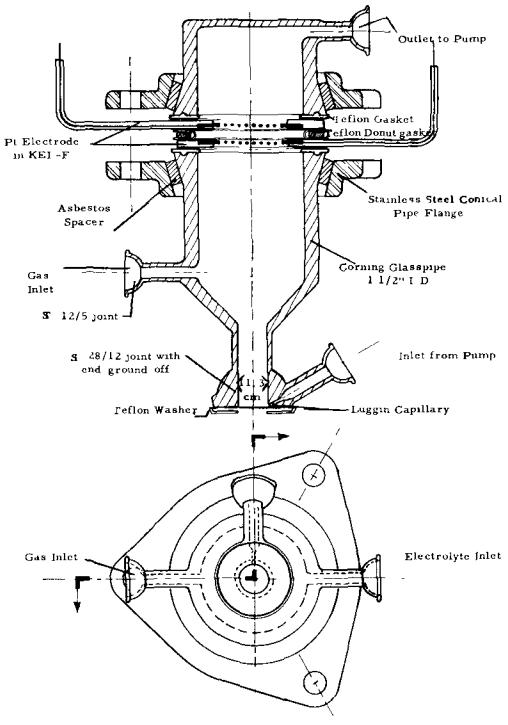


Fig. 1. Electrolytic cell

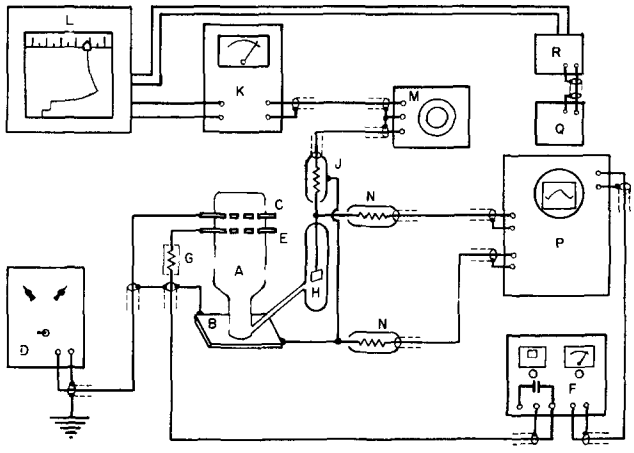

Fig. 2. Block diagram of electronic circuit: A, electrolytic cell; B, sample; C, upper platinum electrode; D, constant current supply; E, lower platinum electrode; F, square wave generator; G, noninductive resistor; H, reference electrode; J, 9mΩ scope probe; K, electrometer; L, high speed recorder; M, bias box; N, 4mΩ scope probes; P, oscilloscope; Q, camera; R, relay.

platinum gauze electrodes, imbedded at the edges in Kel F, are gasketed with Teflon between the two sections of the cell. Kel F coated platinum wires are used as current connectors. Inlets for gas bubbling and electrolyte are provided with ball joints. The electrode sample to be investigated is pressed with a clamp against an opening in the bottom of the cell and gasketed with a thin Teflon washer. The bottom of the cell is ground flat and a Luggin capillary to the reference electrode intersects the wall in the immediate vicinity of the electrode surface. In this manner ohmic drops are minimized. The electrode area exposed to the electrolyte is 1 cm^2. The narrowed section at the bottom of the cell provides a uniform current density. The samples investigated were of pure lead and were microtomed at the exposed surface as described in previous publications (14).

Figure 2 shows a block diagram of the instrumentation used. The electrolytic cell is shown at A with the sample B pressed against the bottom of the cell. A constant d-c current is applied between the sample and the upper platinum electrode C by the constant current supply D. An a-c square wave current is applied between the sample and the lower platinum electrode E. The constant voltage output of the square wave generator F is converted to constant current by a noninductive resistor G. The electrode potential is measured against a reference electrode H which was in our particular case Hg/Hg_2SO_4 in the same solution. The d-c component of the electrode potential is measured through a 9mΩ scope probe J with an electrometer amplifier K. This electrometer amplifier drives a high-speed recorder L. A bias box M is used to adjust the zero level of the d-c voltage. The a-c component of the electrode potential is measured through two 4mΩ scope probes N with a high-gain, wide-band differential input oscilloscope P, which is synchronized externally with the square wave generator F. A robot camera Q is mounted on the oscilloscope. A side marker pen on the recorder L is synchronized to the camera by an electronic relay R, triggered by the flash contacts of the camera.

The use of a square wave signal has, as pointed out before, the advantage that the capacities can be measured accurately, independent of frequency.

It is necessary to avoid carefully any ground loops in the circuit. Any portion of the circuit where currents or voltages may pass through two separate paths in parallel, in particular paths through ground, must be eliminated; otherwise spurious a-c voltages may be generated by inductive or capacitive pick up. All connecting wires in the circuit must be shielded to eliminate hum and noise. The shields of the coaxial cables used can be grounded only at one point. For the input of the electrometer amplifier, amphenol noise-free cables were used. This eliminates spurious noises due to flexing of the cables.

All coaxial cables have a natural resonant frequency and if a square wave is applied, the cable will produce a damped oscillation called ringing which distorts the desired signal. Pick up of a.c. in the cable to the d-c generator is minimized by the use of the upper platinum electrode rather than the lower one. In this manner the d-c supply electrode is kept outside of the a-c field in the electrolyte. In the cables to the electrometer amplifier and to the oscilloscope, ringing is minimized by the use of the scope probes.

The square wave frequency is adjusted for the particular electrode capacity range to be investigated. A high frequency is desired to minimize the voltage swing of the electrode and the frequency dependence. The upper limit is set by the response of the oscilloscope and by the available output current of the generator. The square wave current is set by the choice of the noninductive resistor and using the maximum output voltage of the generator,

which in our case, was 50 v. A low leakage capacitor is used to block out the d-c component. This capacitor must be large enough to pass the lowest frequencies involved with a drop of less than 2%.

The differential input of the oscilloscope assures rejection of any stray pick-up. The two scope probes must be a matched pair to preserve the differential characteristics of the scope. The trimming of the frequency compensating capacitors and the differential balance controls in the oscilloscope must be done with the probes connected to achieve the lowest noise level and best resolution.

The constant current generator has been described in an earlier paper (14). It is capable of delivering currents from 1 μa to 10 ma with a regulation better than 0.5%. The shield of the output cable is the common ground for the whole circuit. The bias box consists of a helipot potentiometer across a 5-v mercury battery. The desired bias voltage is obtained between one end of the pot and the slide contact. This voltage is in series with the input voltage of the General Radio 1230-A Electrometer. The electrometer output drives a Minneapolis-Honeywell ½ second Recorder. The electrode potential can be followed in this manner with an accuracy of 1 mv or 0.25%, whichever is greater.

The square wave generator is a Hickok model 710. The rise time of the generated square wave is 0.1 microsec, and the frequency range is 20 cycles to 1 M cycle. The maximum output voltage is 50 v peak to peak, and the maximum current output 50 ma. In the experiments to be described, the current limiting resistor was 10,000 Ω which adjusted the square wave current to 5 ma. The d-c blocking capacitor was 5 μF.

The oscilloscope is a Textronic model 535 with a 53/54 D plug-in preamplifier. The camera was a DuMont model 352. This is a Robot camera which is able to take up to 6 pictures per second. In our experiments, the camera was triggered manually, but a solenoid was provided which allowed remote or automatic triggering. The flash contact available on the camera was used to trigger a marker pen on the recorder through a sensitive transitorized relay. In this way the time of each exposure was exactly correlated to the voltage recordings.

Results and Discussion

Figure 3 shows a selection of oscilloscope traces obtained during an anodization run on pure lead in 4.40M H_2SO_4 at 30°C. The anodizing d-c current was 1 ma/cm^2. The square wave current was 5 ma peak to peak with a frequency of 6250 cps. The sweep speed of the oscilloscope was 20 μsec/cm, or 200 μsec full screen. The voltage scale factor was varied from 5 to 25 mv/cm, depending on electrode capacity. The initial slope of the traces is a measure of the electrode capacity. The capacity C is determined by the equation

$$C = \frac{i}{(\delta V/\delta t)}$$

where i is the square wave current and $\delta V/\delta t$ the voltage time slope.

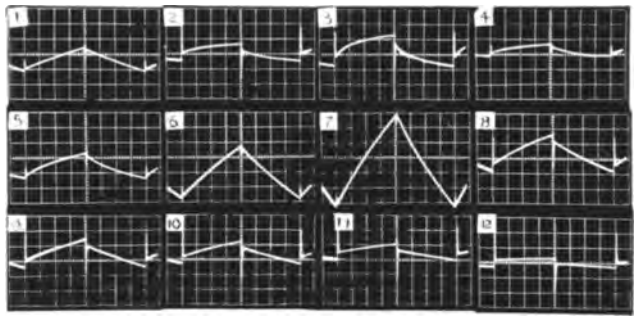

Fig. 3. Selection of oscilloscope traces. DC current 1 ma. Square wave current 5 ma peak to peak. Frequency 6250 cps. Sweep speed of oscilloscope 20 μsec/cm (before reproduction of photograph). Photograph 1: hydrogen evolution, at scale factor 25 mv/cm; 2: after 15 sec anodizing, scale factor 5 mv/cm; 3: after 47 sec, 5 mv/cm; 4: after 53 sec, 25 mv/cm; 5: after 54 sec, 25 mv/cm; 6: 55 sec 25 mv/cm; 7: 105 sec, 25 mv/cm; 8: 122 sec, 5 mv/cm; 9: 126 sec, 5 mv/cm; 10: 129 sec, 5 mv/cm; 11: 137 sec, 5 mv/cm; 12: 129 sec, 5 mv/cm.

The first trace was taken during cathodization with hydrogen evolution, at 1 ma/cm^2 at 25 mv/cm. The steepness of the slope shows that the capacity here is fairly small, amounting to about 10 μF/cm^2. Trace 2 is taken 15 sec after reversal of the current. At this point metallic lead is being converted to lead sulfate, a reaction which proceeds with extreme ease. The capacity, as determined from the initial slope, is 40 μF/cm. It is interesting to observe that the trace is highly curved indicating a nonlinearity in the apparent electrode capacity. This shows that at this point the electrode does not behave like an ideal condenser, but that a faradaic current is also flowing. The "exchange current" of the conversion of lead to lead sulfate is large, so that even with a small polarization a large faradaic current is produced. The curvature accounts for the frequency dependence usually observed with a-c bridge techniques. The initial portion of the trace is representative of the high-frequency range, whereas the later portions correspond to the lower frequency range.

Trace 3 is taken further along the lead-sulfate plateau and shows that the capacity is now decreasing, which is due to a blockage of the surface with lead sulfate. Traces 4, 5, 6, and 7 are taken during the rise of the electrode potential toward the oxygen evolution value. In this portion, the capacities are extremely small, in the range from 1 to 3 μF/cm^2. Film resistance, on the other hand, is increased considerably as shown by the ohmic drop. The electrode is substantially covered with a passivating layer of lead sulfate. Traces 8, 9, 10, 11, and 12 show the gradual build up of capacity as a surface film of PbO_2 is built up and oxygen is evolved. It is interesting to note that the traces are quite straight in this region, indicating a small faradaic component which means that the exchange current is small.

At the points where the current reverses, small peaks are observable on the oscilloscope traces. These peaks result from high-frequency pick-up by the unshielded capillary to the reference electrode. They could have been eliminated by proper shield-

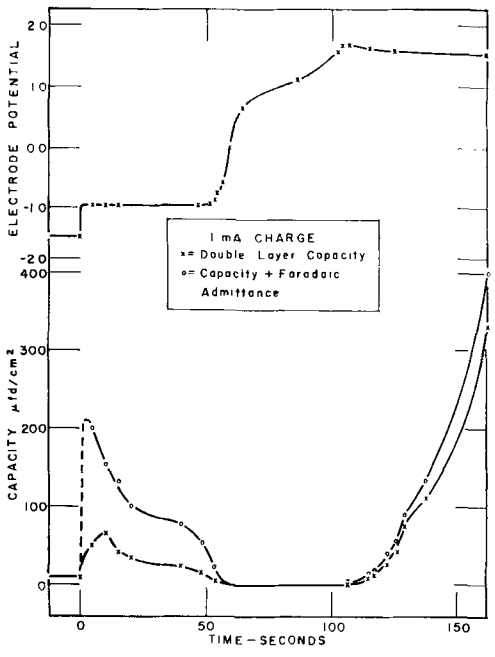

Fig. 4. Electrode potential and double layer capacity as function of time during build-up of an anodic corrosion layer on lead at 1 ma/cm².

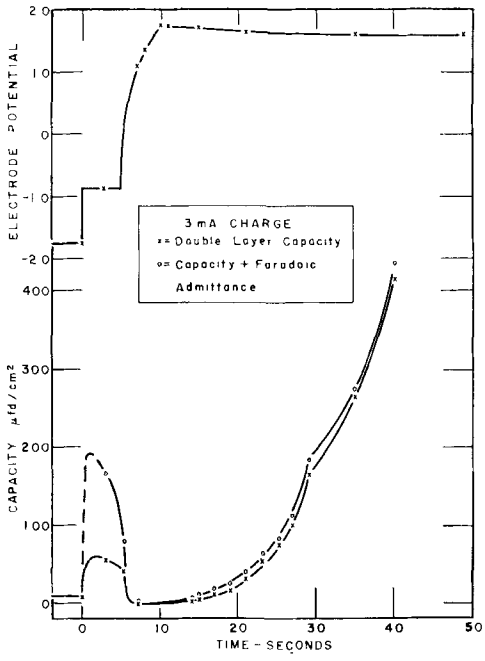

Fig. 5. Electrode potential and double layer capacity as a function of time during build-up of an anodic corrosion layer on lead at 3 ma/cm².

ing, but they did not interfere with the accuracy of the measurements. In fact, they turned out to be quite useful in checking the particular voltage scale factor used.

Figure 4 shows a plot of the electrode potential vs. the Hg/Hg_2SO_4 reference electrode and of the capacities as a function of time during anodization at 1 ma/cm². The lower curve with the crosses is the capacity as determined from the initial slope of the traces, and the curve with the circles shows the capacity including a faradaic component, as determined from the average slope of the traces and shows the regions where this component is large. In particular, it is seen that the faradaic component is large during the reversible oxidation of lead to lead sulfate. The first voltage plateau corresponds to this reaction. As the electrode is covered with lead sulfate, the capacity decreases and drops sharply to a very small value at the point where the potential starts to rise. As the oxidation of lead sulfate to PbO_2 proceeds and oxygen is evolved, the electrode potential drops somewhat and the capacity gradually increases to very high values. A hump in the capacity curve is observed at a point where the potential stops falling and could possibly correspond to the completion of the oxidation of lead sulfate to β PbO_2 and the start of oxygen evolution and production of α PbO_2 from the metallic lead.

The resistance of the electrolyte path from the electrode to the Luggin capillary is about 0.3 ohm in the electrolyte used. Such a low value could not be achieved with an arrangement whereby the a-c potential is measured between the electrode and a much larger platinum counter electrode in the same solution (15).

Figure 5 shows similar curves for an anodization at 3 ma/cm². Again, one observes a large faradaic component during the conversion of lead to lead sulfate, the low capacity during passivation where the ohmic drop is high, in the order of 1 ohm, and the hump at the end of conversion of $PbSO_4$ to β PbO_2.

Figure 6 shows the electrode potential and capacity curves during discharge at 1 ma/cm² of the PbO_2 layers formed after 180 sec of anodization at 1 ma/cm². On the potential plot one recognizes the $PbO_2/PbSO_4$ plateau, the $PbSO_4/Pb$ plateau, and a

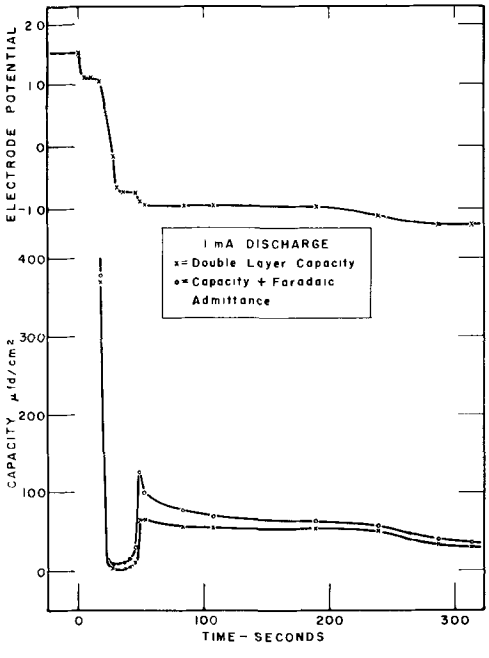

Fig. 6. Electrode potential and double layer capacity as a function of time during discharge of an anodic film on lead at 1 ma/cm².

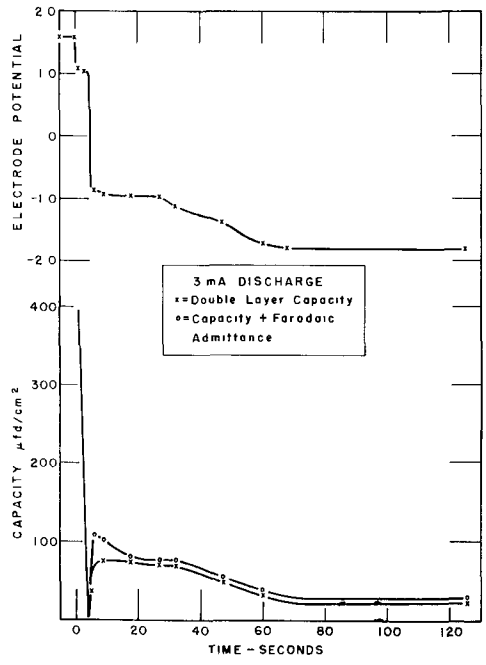

Fig. 7. Electrode potential and double layer capacity as a function of time during discharge of an anodic corrosion layer on lead at 3 ma/cm².

slow decrease of potential toward the hydrogen overvoltage value. During the PbO_2 step the capacity is extremely high, 500-1000 μF/cm, but decreases rapidly toward the end of the plateau to a very low value. This indicates a passivation of the PbO_2 film as it is covered by $PbSO_4$. During the $PbSO_4$/Pb plateau the capacity is again much higher and decreases again toward the end of the plateau. It is interesting to note that there exists a potential plateau at about −0.73 v vs. Hg/Hg_2SO_4 during which the capacity remains quite small. This could correspond to the formation of a discharge product underneath a partially protecting sulfate layer, for instance PbO, or polarized α PbO_2.

Figure 7 shows a discharge curve at 3 ma/cm after 300 sec of anodization at 3 ma/cm². Quite similar phenomena are observed. The ohmic resistance again increases sharply at the end of the PbO_2 discharge step, indicating passivation.

These results show the usefulness of this technique in studying transient film phenomena on electrodes. The capacities can be measured with a precision of better than 3% and the voltages to 1 mv during processes lasting only a number of seconds.

Manuscript received Dec. 22, 1958. This paper was prepared for delivery before the Ottawa Meeting, Sept. 28-Oct. 2, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Oxygen Overvoltage and Electrode Potentials of Alpha- and Beta-PbO_2

P. Rüetschi, R. T. Angstadt, and B. D. Cahan

Research Center, The Electric Storage Battery Company, Yardley, Pennsylvania

ABSTRACT

Buildup and decay of oxygen overvoltage on α- and β-PbO_2 has been studied. Layers of the two PbO_2 modifications were electrodeposited on Pt wires, sealed at both ends into glass. Initial buildup of oxygen overvoltage at constant current is linear with time, and decay on open circuit is logarithmic with time. The results are explained on the basis of a generalized theory of overvoltage. Electrode potentials of α- and β-PbO_2 have been measured as a function of pH.

Lead dioxide exists in two modifications, the tetragonal β-PbO_2 and the orthorhombic α-PbO_2. The latter was identified only a few years ago by Zaslavsky, *et al.* (1). Previously, an unidentified oxide of lead had been described by several authors (2, 3). Bode and Voss (4) and Rüetschi and Cahan (5), found α-PbO_2 independently in battery and corrosion research. Recently, other authors have mentioned the occurrence of α-PbO_2 (6-8).

The exact electrode potentials of α- and β-PbO_2 in

H_2SO_4 have been determined recently (9) by the authors.[1] The potentials of the α-PbO_2-$PbSO_4$ and the β-PbO_2-$PbSO_4$ couples are 1.7085 ± 0.0005 v and 1.7015 ± 0.0005 v, respectively, vs. H_2 in 4.4*M* H_2SO_4 at 31.8°C. This value of the β-PbO_2 electrode is in good agreement with that reported by Hamer. Other measurements of electrode potentials of α-PbO_2 have also been reported (10).

In spite of the fact that the potentials of the PbO_2 electrodes are much higher than the potential of the oxygen electrode and that the PbO_2 electrodes must, therefore, thermodynamically oxidize water to oxygen, the PbO_2 potentials can be measured over long periods of time with good reproducibility. Thus, PbO_2 electrodes have a very high degree of metastability, which is the reason that these electrodes can be used in the lead-acid battery.

Experimental

Electrodes of α- and β-PbO_2 have been prepared by electrodeposition onto a platinum rod, sealed at both ends into glass. The exposed length of the platinum rods was 20.0 mm and the diameter 1.30 mm.

The plating solution for the α-PbO_2 electrode was prepared by making up a stock solution of lead plumbate (500 cc of saturated sodium acetate, 100 cc of saturated lead acetate, 1000 cc of carbonate-free saturated KOH and 500 cc of water). Prior to plating, the solution was diluted 1:1 with water. Triple-distilled water was used throughout the experiments.

For the β-PbO_2 electrode, the plating solution was lead perchlorate-perchloric acid. A stock solution was prepared by dissolving 500 g of PbO in 1000 cc of 30% perchloric acid. The PbO was obtained by precipitating from a lead nitrate solution at slightly alkaline *p*H, adjusted by the addition of KOH. The precipitate was dried at 170°C. Prior to plating, the stock solution was diluted 4 parts to 1 part H_2O. The plating of both electrodes was performed in a two-compartment cell, joined at the bottom with a capillary, in a water bath held at 30°C. The plating current was 1 ma, the plating time 6 days. The plating bath was renewed every two days. PbO_2 was deposited to a depth of 0.1 mm.

Certain precautions must be observed when making PbO_2 electrodes. For instance, during the electrodeposition of α-PbO_2 it was observed that a too strongly alkaline solution would permit the growth of red Pb_3O_4 crystals on the electrode. Further, at the end of the plating period, the electrodes must be washed carefully so as to be free of Pb^{++} ions, which would otherwise form deposits of $PbSO_4$ which can rupture the electrodeposits physically or form passivating layers. Also, particular care must be taken that during washing temperature fluctuations are kept to a minimum. Rapid evaporation of water by a stream of air might chill the electrode sufficiently to cause cracking, and even the smallest crack or exposure of the underlying platinum to the solution results in rapid deterioration of the electrodes.

Electrodes prepared in this manner, and for which the above precautions were observed, were stable over extended periods of time (up to one month) and their potentials were reproducible to within 1 mv.

Constant currents were obtained by a generator described earlier (5).

Electrode potentials were measured against hydrogen and Hg/Hg_2SO_4 in the same solution. Electrode potentials were followed with a precision of 1 mv, current drains less than 10^{-11} amp and with a response of 1 mv in 20 msec.

Figure 1 shows a photograph of two electrodes prepared in the described manner. This picture was taken at the end of all the measurements reported herein and after a surface film of the electrodes had been stripped off in ammonium-acetate solution. The texture of the α electrode is quite smooth and shiny, whereas the surface of the β electrode appears polycrystalline.

Results

Figure 2 shows the dependence of the α- and β-PbO_2 electrode potentials on *p*H. The first point

[1] Since this paper was submitted for publication, electrode potential measurements on α-PbO_2 electrodes by S. J. Bone, Battery Symposium, Signals Research and Development Establishment, Ministry of Supply, Christchurch, Hampshire, England, Oct. 21 to 23, 1958, have been brought to the attention of the authors by M. Barak.

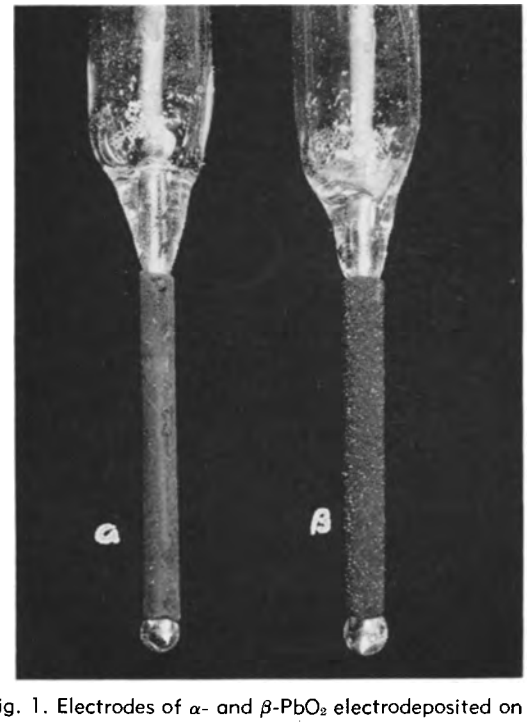

Fig. 1. Electrodes of α- and β-PbO_2 electrodeposited on Pt

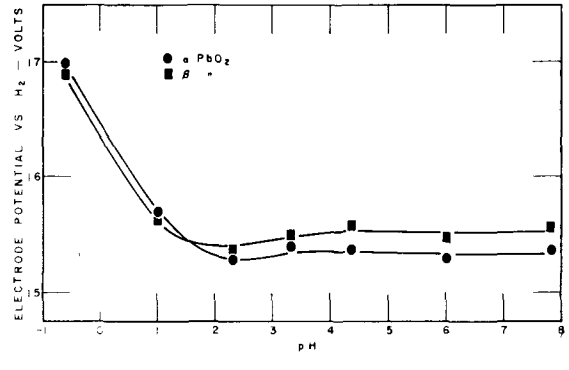

Fig. 2. Electrode potentials of α- and β-PbO_2 as a function of pH vs. a hydrogen electrode in the same solution at 30.0° ± 0.02°C.

(at pH −0.6) was measured in 4.4*M* H_2SO_4. Subsequent measurements were made in solutions where the ($SO_4^=$) concentration was maintained at 1/10M. For pH 1, a 1/10M solution of H_2SO_4 was used. For other pH values, various amounts of a solution, which was 1/10M in KOH and 1/10M in K_2SO_4, were mixed with a 1/10M solution of H_2SO_4. In this manner, the sulfate ion concentration was kept at 1/10M in all the experiments. After mixing, the solutions were saturated with $PbSO_4$, and pH values were determined accurately with a glass electrode. Figure 2 shows that above pH 2 the potentials tend to vary only little with pH. This behavior is, of course, in contradiction to the normally written electrode reaction involving hydrogen ions. However, one has to remember that $PbSO_4$ starts to become soluble at high pH values. Soluble lead species might set up a mixed electrode potential. Also, the H_2SO_4-K_2SO_4-KOH system is not a very good buffer, and in the pH range from 2 to 9 the hydrogen ion concentration is not well stabilized.

Figure 2 shows that in strongly acid solutions the α-PbO_2 has a potential 7 mv above that of the β-PbO_2, but that there is a crossover in the region between pH 1 and 2 where the β-PbO_2 becomes more positive than the α-PbO_2. The electrode with the lower potential is naturally the more stable one, hence it follows that in solutions more alkaline than pH 2, α-PbO_2 is formed in preference to β-PbO_2. The crossover point might be influenced by the particular anion of the solution. In our case only $SO_4^=$ and OH^- were present.

The crossover in electrode potentials is of practical importance in lead-acid battery manufacture. The interior of positive plates is known to remain basic during the initial periods of formation, providing one condition conducive to the formation of α-PbO_2. It is also known that corrosion of metallic lead at elevated potentials tends to form α-PbO_2. This might also be due to a pH effect underneath a protecting sulfate layer. The combination of the two conditions provides an explanation for the observation that newly formed positive plates usually show more α-PbO_2 in their interiors than in their surface layers.

After measuring the potentials through the pH series, the electrodes were replaced in 4.40*M* H_2SO_4, and the potentials were observed to return to within 1 mv of their previously observed values. This was repeated with the same result, demonstrating the stability of the electrodes. Also, concerning stability, on occasion the electrodes were polarized slightly below their open-circuit values for very short time periods whereby some lead sulfate was formed; after removing the polarizing current the electrodes returned slowly to their original open-circuit values.

After prolonged open-circuit stand of these electrodes in 4.40*M* H_2SO_4, the slow oxidation of water, as mentioned earlier, produced some self-discharge and the buildup of some lead sulfate on the surface. If the electrodes are subsequently anodized at an appreciable rate (where the electrode potential is raised substantially), this lead sulfate is oxidized to β-PbO_2. This treatment, therefore, does change an α-PbO_2 electrode into an electrode containing a mixture of α- and β-PbO_2. During open-circuit periods an exchange current is always maintained. A finite amount of PbO_2 is converted into $PbSO_4$ and *vice versa*. This exchange establishes the reversible potential. In the case of an α-PbO_2 electrode, this means that $PbSO_4$ must convert back to α-PbO_2 at the rate of the exchange current even in acid solution. The fact that α-PbO_2 is formed rather than β-PbO_2 must be explained in that the activation energy required for the nucleation of β-PbO_2 must be greater than the activation energy required for the deposition of α-PbO_2 on α-PbO_2. During anodization, the electrode potential is raised sufficiently that the activation energy for the formation of β-PbO_2 is exceeded and the β phase can be formed. Without anodization, the electrodes maintain their particular structures over extended periods of time. This has been determined both by their maintenance of distinctly different and reproducible potentials and by x-ray diffraction analysis. The difference in electrode potentials between α- and β-PbO_2 in the same solution must be a measure of the difference in free energy of the two crystalline modifications. The crossover of the potentials could mean that the free energies of the two materials are a function of the hydrogen (or hydroxyl) ion concentration of the electrolyte. The oxygen deficiency and/or possibly the OH^- or H^+ content of either crystalline form of PbO_2 can change with the pH of the solutions with which they are in equilibrium. In other words, the free energy (or electrode potential) varies with the oxygen deficiency and/or OH^- or H^+ content in the crystals.

This becomes particularly evident in oxygen overvoltage studies. Figure 3 shows the buildup of oxygen overvoltage on the β-PbO_2 electrode at constant current. The electrode had been anodized previously at 10 μa over a prolonged period of time and then left on open circuit for 24 hr prior to the curve identified 20 μa. After each anodization the electrode was allowed to decay to a value slightly above the reversible potential and then anodized at the next higher current. In this manner no $PbSO_4$ was allowed to be formed on the electrode. The formation of lead sulfate would have changed the surface area of the electrode upon subsequent anodization. The currents in Fig. 3 refer to the total electrode area.

The buildup of oxygen overvoltage at constant current involves four processes which proceed at

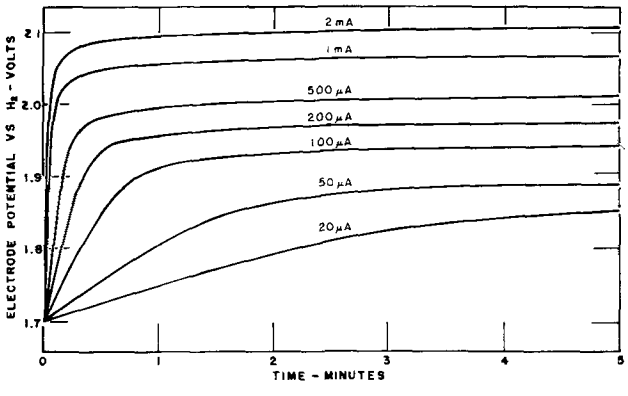

Fig. 3. Buildup of oxygen overvoltage on β-PbO_2 at constant current in 4.40M H_2SO_4 at 30.0°C.

different rates. The fastest process occurs first and is the buildup of a double layer, whereby only free electrons of the electrode and hydrated ions of the solution are displaced. This process occurs during the initial few microseconds and was observed using an oscillographic technique. The apparent double-layer capacity of this first process is of the order of 100 μF/cm^2 of the true surface area.

The buildup of the double layer is paralleled by the much slower process of oxygen deposition onto the surface of the electrode. This process becomes predominant after the initial few milliseconds and after a rise of potential of 5-10 mv. During this second step (which is shown in Fig. 3) the potential rises linearly with time. The process involves the buildup of a layer of adsorbed, negatively charged oxygen species. This can be expressed again as an apparent capacitance. Also, this capacity is apparently constant over a considerably potential region. If the current density is divided by the slope of the linear portion of the curve, one obtains a value for this apparent capacity of 20,000 to 30,000 μF/cm^2 of apparent geometric area. This capacity is independent of the charging current.

As the oxygen content on the surface continues to increase, two further processes become apparent. Oxygen molecules are formed from the activated adsorbed species and oxygen is removed by evolution as a gas. The process of oxygen removal becomes increasingly faster with the number of adsorbed species and finally approaches asymtotically the rate of oxygen deposition onto the surface.

Consideration has been given to a fourth process: oxygen may diffuse into the bulk of the PbO_2 electrodes and slowly saturate it. Because of the relatively slow rate of the last process, the steady-state value of oxygen overvoltage on PbO_2 electrodes is reached slowly.

Figure 4 shows the steady-state oxygen overvoltage on α- and β-PbO_2 in 4.4*M* H_2SO_4 at 30°C. The Tafel slope of the α electrode is 0.07 and that of the β electrode is 0.14. This would indicate a different mechanism of oxygen evolution on the two electrodes. The slopes were quite reproducible and were measured several times with increasing and decreasing currents. The values of the slopes remained constant after anodization periods of up to 5 days which demonstrates the absence of any changes in modification during anodization. It is of interest to note that the absolute overvoltage value of β-PbO_2 is higher than the value for α, although the reverse is true of the reversible potential on open circuit. Tafel slopes for oxygen overvoltages on α- and β-PbO_2 reported earlier (9) were obtained without thoroughly saturating the electrodes by previous anodization.

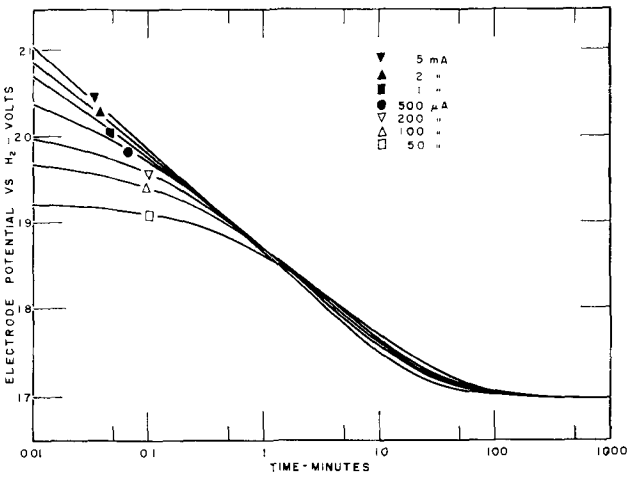

Fig. 5. Decay of oxygen overvoltage on open circuit of a β-PbO_2 electrode at 30.0°C in 4.40M H_2SO_4.

The decay of oxygen overvoltage on open circuit is shown in Fig. 5.

The decay tends to become logarithmic with time, and the slope of the voltage-log time plot is (within experimental errors) the negative of the Tafel slope.

Figure 6 shows the plot of the open-circuit decay of potential vs. log time for the α electrode.

That the slopes of the potential vs. log time plot are the negatives of the Tafel slopes can be explained by the following: The electrode potential is a linear function of the surface concentration of oxygen (11-13). The rate of oxygen evolution and desorption is an exponential function of the electrode potential; therefore one obtains

$$i = K_1 \cdot \exp\left(-\frac{V\alpha Ze_0}{KT}\right) = \text{const.} \cdot \frac{d[O^=]}{dt} = K_2 \frac{dV}{dt} \quad [1]$$

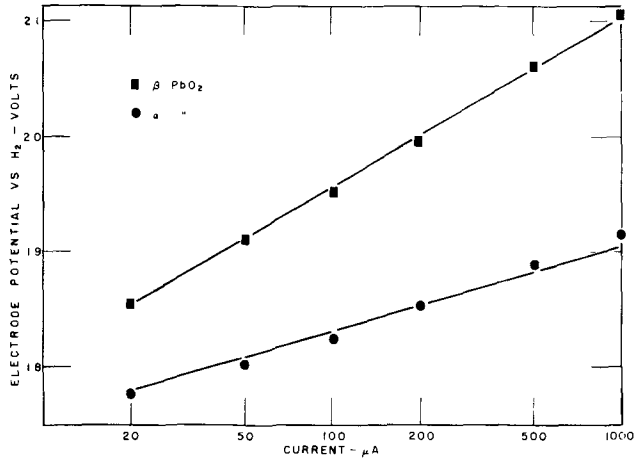

Fig. 4. Steady-state Tafel curves for α- and β-PbO_2 electrodes at 30.0°C in 4.40M H_2SO_4.

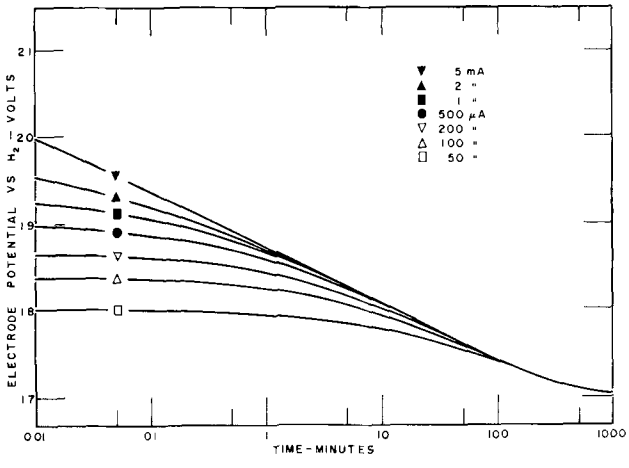

Fig. 6. Decay of oxygen overvoltage on open circuit of α-PbO_2 electrodes at 30.0°C in 4.40M H_2SO_4.

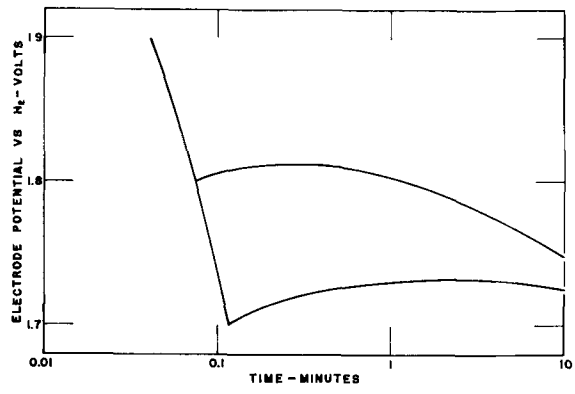

Fig. 7. Recovery of overvoltage after discharge to a lower potential value.

where i is the current density, V the electrode potential, $[O^=]$ the oxygen concentration on the surface, and K_1 and K_2 are constants.
Integrating, one obtains

$$t = \frac{K_2}{K_1} \cdot \frac{KT}{\alpha Ze_0} \left[\exp\left(\frac{V\alpha Ze_0}{KT} \right) - \exp\left(\frac{V_0 \alpha Ze_0}{KT} \right) \right] \quad [2]$$

After the potential has decayed about 50 to 100 mv, the second exponential may be neglected and one obtains:

$$V = \frac{KT}{\alpha Ze_0} \cdot \ln t - \frac{KT}{\alpha Ze_0} \cdot \ln \frac{K_2}{K_1} \cdot \frac{KT}{\alpha Ze_0} \quad [3]$$

or

$$\frac{dV}{d(\ln t)} = \frac{KT}{\alpha Ze_0} \quad [4]$$

which is the negative of the Tafel slope (11).

The presence of the adsorbed (activated) oxygen on and/or in the PbO_2 lattice was demonstrated by the following experiment. The oxygen overvoltage of the β electrode at 2 ma was forced down toward the open-circuit potential by application of a reversed current of 2 ma. The current was interrupted after the potential reached a given value. Figure 7 shows the voltage-time curves for two different runs. In the first one the potential was forced to 1.8 v and in the second to 1.7 v (that is, the reversible open-circuit value). At the point where the electrode reached these potentials, the current was interrupted. The voltage-time curve showed a recovery of overvoltage of more than 30 mv after interruption of current before the potential slowly decayed to the open-circuit value. At higher reversal currents, the recoveries observed were much greater, in the order of 100 mv. This phenomenon, which has not been described previously, shows that the electrode potential is maintained by the strongly adsorbed or absorbed species. A reversal of current would definitely destroy a diffuse ionic type double layer.

On an Ion-Exchange Property of Manganese Dioxide

Akiya Kozawa

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Nagoya, Japan

ABSTRACT

When manganese dioxide is shaken with an electrolyte solution, the cation is adsorbed and hydrogen ion is released: an ion exchange reaction takes place on the surface of the manganese dioxide. A simple method based on zinc ion exchange reaction is proposed to measure the ion exchange capacity of various manganese dioxides. Results have been compared to the surface area of those samples measured by the B.E.T. method based on nitrogen gas adsorption, and a fairly good proportionality was found between them. The mechanism of the ion exchange is correlated with the structure of a surface complex.

If manganese dioxide is shaken with a salt solution, some cations are adsorbed on the dioxide, and simultaneously hydrogen ions are released to the solution. This ion-exchange property of MnO_2 has been known since 1926 (1, 2). Sasaki (3) and Johnson and Vosburgh (4) have emphasized the importance of this ion-exchange property in conjunction with measurements of the electrode potentials of MnO_2, since the potential depends on the *p*H of the solution. The ion-exchange capacity of MnO_2 varies widely from sample to sample and also is affected by various factors which determine the suitability of certain manganese dioxides for dry-cell use. The ion-exchange capacity of MnO_2 usually is known as "the *p*H of the manganese dioxide." In Japan this statement is taken to mean the change in the *p*H value of a salt solution after shaking it with the dioxide. The *p*H values can be used to evaluate manganese dioxides for dry cell use (5) and have a close relationship with the corrosion of the zinc anode. Up to the present time only water and ammonium chloride solution (3) have been used for the determination of the *p*H value.

In the present paper, a new method is proposed for comparing the ion-exchange capacities of various manganese dioxides. Manganese dioxide is shaken with an NH_4Cl solution in which ZnO is dissolved, and the solution then is analyzed for zinc and hydrogen ion by volumetric methods. The results for various samples of manganese dioxide are compared with the surface areas of these samples as obtained by the B.E.T. method. In addition, in order to clarify the mechanism of the ion-exchange reaction, several additional experiments have been carried out.

Special Property of Ammonium Chloride Solution in Which Zinc Oxide Is Dissolved

In preliminary experiments it was found that the adsorption of cations on MnO_2 depends on both the *p*H of the salt solution and the concentration of the cation. Therefore, these conditions must be kept constant if the relative ion-exchange capacities of manganese dioxides are to be measured. Ammonium chloride solution in which ZnO is dissolved has a *p*H of about 7 and, in addition, has very good buffer action. When this solution is titrated with HCl, a nearly constant *p*H is maintained until the point where the same number of equivalents of HCl are added as that of ZnO added to the solution. At this point the *p*H changes suddenly. Two moles of NH_4Cl and about 0.1 mole of ZnO were dissolved in a liter of water. The zinc content was determined by the E.D.T.A. method: 5 ml of the solution was titrated with a 0.02 m/l E.D.T.A. (ethylenediaminetetracetic acid disodium salt) standard solution using Eriochrom Black T as the indicator (before titration, the *p*H was adjusted to about 9.5 using an NH_4Cl-NH_4OH buffer).

Figure 1 shows the titration curves for the zinc solution (2 m/l NH_4Cl, 0.1073 m/l ZnO) using 0.100*N* HCl as the standard solution. It is evident from the titration curves that the zinc solution has a remarkable *p*H buffer action. At the point where exactly the same number of equivalents of HCl is added as that of zinc in the solution, the *p*H changes suddenly from 5 to 2.8. This feature of the zinc solution makes it possible to determine the zinc ion adsorption on MnO_2 at a constant *p*H of 7 and also to measure the released hydrogen ion by titration of the resulting solution with HCl.

This property also can be used to determine a small amount of ZnO existing in $ZnCl_2$ as an impurity. In most cases, $ZnCl_2$, even the analytical reagent, contains a small amount of ZnO. A concentrated $ZnCl_2$ solution (7.63 m/l from zinc analysis)

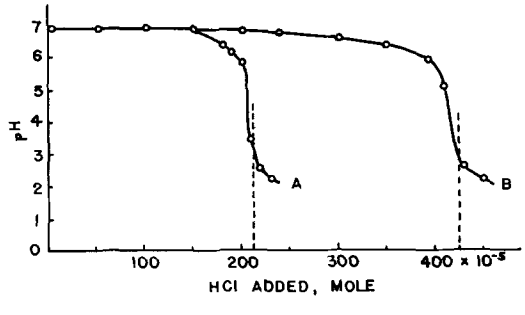

Fig. 1. Titration curves of the Zn solution (2 m/l NH_4Cl, 0.1073 m/l ZnO). 10 or 20 ml of the Zn solution was titrated, corresponding to curve A or B, respectively. Broken lines indicate the points where the ratio of the amount of HCl to that of Zn^{++} is $H^+ : Zn^{++} = 2:1$.

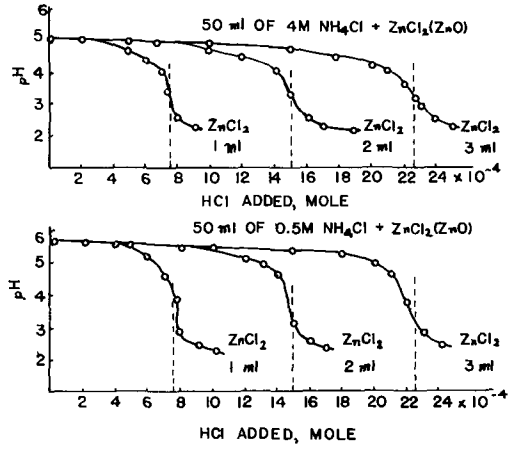

Fig. 2. Titration curves of the solutions of NH_4Cl (0.5 and 4.0 m/l), into which 1 to 3 ml of $ZnCl_2$ (7.63 m/l) solution containing ZnO were added. Broken lines indicate the points where mole ratio H^+ added: ZnO contained in the $ZnCl_2$ = 2:1.

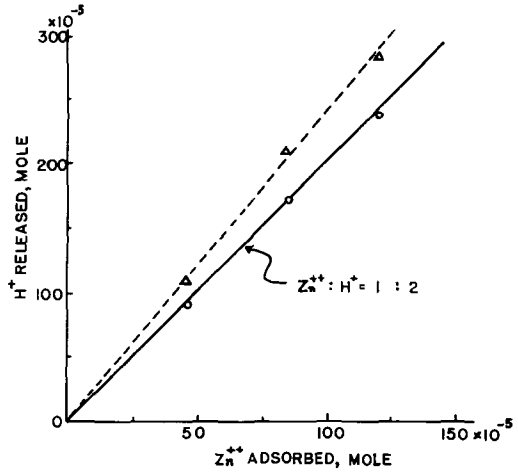

Fig. 3. Zn^{++} adsorbed and H^+ released by the ion-exchange reaction on electrolytic MnO_2. The three points correspond to 1, 2, and 3 g of MnO_2 taken as samples. △, experimental values; O, experimental results corrected for free acid in the MnO_2.

containing a small amount of ZnO was prepared. One to five ml of this solution was added to 50 ml of 0.5, 2.0, and 4.0 m/l NH_4Cl solution. These solutions then were titrated with a standard solution of HCl, using a *p*H meter to measure *p*H values. Results for the 0.5 and 4.0 m/l solutions are shown in Fig. 2. In spite of the large difference in NH_4Cl and $ZnCl_2$ concentration, an abrupt *p*H change was noted and, as more of the $ZnCl_2$ solution containing ZnO was taken, proportionally more HCl was consumed.

From very careful analysis of the $ZnCl_2$ solution the ratio Zn:Cl = 1:1.900 was determined. Therefore, the original $ZnCl_2$ contained ZnO in the amount of 1/20 of the total zinc. Dotted lines in Fig. 2 indicate the equivalent amounts of HCl as calculated from this analysis.

From the previous studies (6,7) of the $ZnCl_2$-NH_4Cl-H_2O system, the above described behavior of the zinc solution can be understood. In the zinc solution containing 2 m/l NH_4Cl and 0.1 m/l ZnO, the species $[ZnCl_4]^{2-}$, $[Zn(NH_3)Cl_3]^-$, $[Zn(NH_3)_2Cl_2]$, $[Zn(NH_3)_3Cl]^+$, $[Zn(NH_3)_4]^{2+}$ are present, with $[Zn(NH_3)_2Cl_2]$ being the predominant complex at *p*H 7. The equations describing the formation and dissociation of this complex ion (neglecting intermediate species) are:

$$ZnO + 2NH_4Cl \rightarrow [Zn(NH_3)_2Cl_2] + H_2O \quad [1]$$

$$[Zn(NH_3)_2Cl_2] + 2H_2O + 2Cl^- \rightleftharpoons [ZnCl_4]^{2-} + 2OH^- + 2NH_4^+ \quad [2]$$

When HCl is added to the zinc solution the OH^- is neutralized and all the $[Zn(NH_3)_2Cl_2]$ is converted to $[ZnCl_4]^{2-}$.

Proposed Method for Determination of the Ion-Exchange Capacity of MnO_2

If MnO_2 is shaken with the zinc solution described above, zinc ion is adsorbed and hydrogen ion is released, but the ion-exchange reaction proceeds at a nearly constant *p*H value. A portion of the supernatant solution (or the filtrate) then is titrated with a standard solution of HCl (0.100*N*) using methyl orange as the indicator. The difference between the amount of HCl consumed in this procedure and that consumed by the original solution corresponds to the amount of hydrogen ion released by the ion-exchange reaction. Another portion of the supernatant solution is analyzed by the E.D.T.A. method to determine the zinc ion adsorption.

Samples of 1, 2, and 3 g of MnO_2 (prepared by electrodeposition and ground so as to pass through a 100 mesh sieve) were added to 50-ml portions of 2 m/l NH_4Cl + 0.1 m/l ZnO solution contained in 100-ml flasks fitted with rubber stoppers. The resulting suspensions then were shaken for 6 hr by machine and allowed to stand overnight. Then 5-ml portions of the supernatant liquid were analyzed for Zn^{++} and H^+ as described above. Thus, the amount of adsorbed Zn^{++} and released H^+ were determined. Results are shown in Fig. 3. The MnO_2 used contained some free H_2SO_4. Therefore, the released H^+ value must be corrected. After complete decomposition of the dioxide by concentrated HCl, the $SO_4^=$ in the solution was determined as $BaSO_4$. The correction is shown in Fig. 3. The corrected values show that the ratio adsorbed Zn^{++}:released H^+ is very nearly equal to 1:2, and that the ion-exchange values are proportional to the amount of MnO_2 used. Thirty minutes shaking followed by filtration gave the same results within 5%.

To measure the Zn adsorption of a very small sample of MnO_2 (15-50 mg), a more dilute Zn solution (0.5 m/l NH_4Cl, 0.005 m/l ZnO; *p*H about 7.2) is recommended. In this case 0.01-0.005 m/l E.D.T.A. standard solution should be used. This micromethod for the zinc adsorption measurement has been shown to give the same results as that of the above method within a few per cent. The micromethod has been applied to MnO_2 electrodeposited on graphite rods (8).

Since the Zn adsorption value is not affected by free acid, NaOH, or Na_2CO_3 present in the sample, it, rather than the amount of H^+ released, may be taken as a measure of the ion-exchange capacity of MnO_2. If the MnO_2 sample has heavy metal ions adsorbed on the surface, these should be washed off

Table I. Various samples of MnO_2 (ground to pass through 100 mesh sieve) for measurement of ion-exchange capacity

	x in MnO_x	MnO_2, %
No. 1 prepared by electrodeposition from $MnSO_4$ bath at 97°-98°C with a current density of 1.74 amp/dm²	1.98	84.94
No. 2 No. 1 treated with Na_2CO_3 solution	1.98	87.58
No. 3 No. 2 washed with 6N H_2SO_4 at 60°C, then with water	1.94	89.23
No. 4 cryptomelane prepared by autoclaving No. 2 with NH_4Cl solution at 170°C	1.95	89.31
No. 5 Mn_2O_3 prepared by heating No. 2 at 630°C for 5 hr	1.50	50.01
No. 6 No. 5 heated at 250°C with dilute NaOH solution followed by washing with water	1.53	55.95
No. 7 prepared by thermal decomposition of $Mn(NO_3)_2$	2.00	100.07
No. 8 natural ore (pirica)	2.00	86.05
No. 9 natural ore (kawai)	1.96	76.88

by dilute H_2SO_4 prior to the ion-exchange capacity measurement.

The method for obtaining the ion-exchange capacity described above was applied to various samples of MnO_2, including natural ores, artificial manganese dioxides, and a series of heated manganese dioxides (see Table I). Some of the results were corrected for free acid. Results shown in Fig. 4 indicate that ion-exchange capacities thus measured are distributed over a very wide range depending on the origin of the dioxide, the electrolytic manganese dioxides having the largest capacity.

In Fig. 4, most of the points are above the theoretical line of $Zn^{++}:H^+ = 1:2$. There are two causes for this: free acid and impurities such as Ca and Mg, the ions of which behave like Zn^{++} in the E.D.T.A. method. Natural ores especially contain the latter impurities. The effect of these impurities is to decrease the apparent adsorption of Zn^{++}.

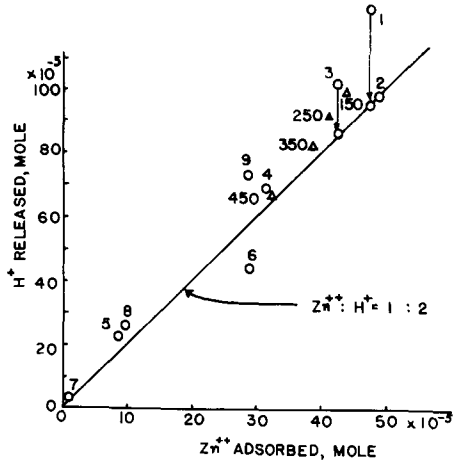

Fig. 4. Ion-exchange capacities of 1.00 g of the various manganese dioxides listed in Table I. The numbers near the points correspond to the ones in Table I. The triangles show the results for sample 1 on heating at the various temperatures indicated in the figure for 3 hr. Samples 1 and 3 were corrected for free acid, the length of the arrows indicating the amount of the correction.

Sasaki (5) and Johnson and Vosburgh (4) have shown that MnO_2 is able to exchange NH_4^+. For the case under consideration here, however, any contribution of NH_4^+ need not be taken into consideration, since the amount of H^+ released can be explained experimentally by the amount of Zn^{++} adsorbed. Therefore, in the competitive adsorption of Zn^{++} and NH_4^+, divalent Zn^{++} seems to be far superior to monovalent NH_4^+ in spite of the large difference in the bulk concentrations.

Relation between Ion-Exchange Capacity and Surface Area

The surface areas of various manganese dioxides including electrolytic MnO_2 heated at various temperatures have been measured by the B.E.T. method using nitrogen gas adsorption at liquid nitrogen temperatures. In these experiments, prior to the gas adsorption, out-gasing of all the samples (except the unheated and 90°-heated samples) was carried out by heating at 165°C for 2 hr under evacuation in the adsorption vessel followed by 4-hr evacuation at room temperature. The unheated and 90°-heated samples were evacuated to 2×10^{-4} mm Hg for 24 hr at room temperature.

As shown in Fig. 5, the surface area of the electrolytic MnO_2 decreases with heating temperature above 250°C. Although the surface areas for the unheated and 90°-heated samples appear to be slightly smaller than that for the 160°-heated sample due to their greater water content (several per cent), the surface areas per net MnO_2 content remain constant up to 160° heating.

The relationship between the surface areas and the Zn ion-exchange values of the various kinds of MnO_2 is shown in Fig. 6. In spite of the variety of samples, there is a fairly good proportionality between the surface area and the Zn adsorption value. The adsorption of 1×10^{-3} mole Zn^{++} corresponds to 140 m² of the surface of MnO_2 with an approximate error of 10-15%. These results suggest a method for determining the approximate surface area of MnO_2 by the Zn adsorption method described above.

In a previous paper (9) it was reported that heat-treatment of MnO_2 forms lower oxides on the surface of the sample. Thus, the cause of the decrease of the Zn^{++} ion-exchange of MnO_2 on heating can be consid-

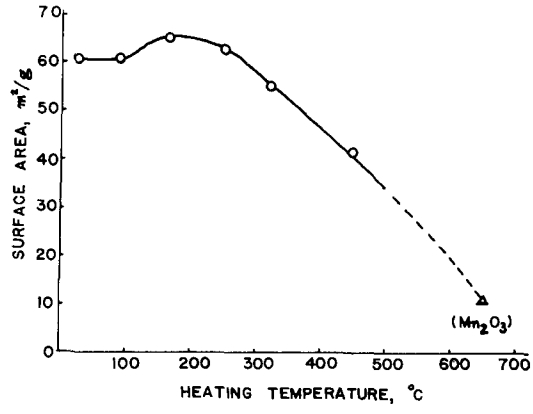

Fig. 5. Surface-area change of electrolytic MnO_2 on heating. Each sample was heated at the temperature indicated for 3 hr under air in an electric furnace.

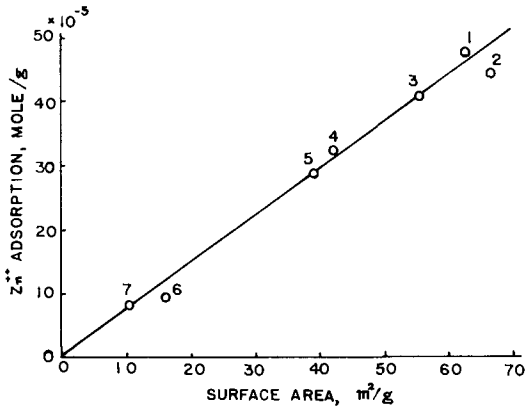

Fig. 6. Relation between the surface area measured by the B.E.T. method and the Zn adsorption from the 2 m/l NH_4Cl, 0.1 m/l ZnO solution: 1, electrolytic MnO_2; 2, No. 1 heated at 165°C; 3, No. 1 heated at 320°C; 4, No. 1 heated at 450°C; 5, natural ore; 6, natural pyrolusite; 7, Mn_2O_3 prepared from electrolytic MnO^2 by heating at 650°C for 6 hr.

ered as twofold: change of the surface area and change of the surface oxidation state of the manganese dioxide. The former factor appears to predominate, since points for Mn_2O_3 and 450°-heated MnO_2, which has considerable lower oxide on its surface, fall on the straight line shown in Fig. 6.

If the pore size of electrolytic MnO_2 is extremely small, the zinc adsorption method might not give the true surface area. Therefore, the pore size distribution of electrolytic MnO_2 was measured using the mercury method (10, 11). The results (see Fig. 7) show that the sample has a fairly homogeneous pore size with a predominant pore radius of 180Å and with no extremely fine pores. This is in accord with the fact that the Zn ion-exchange reaction attains equilibrium within a short period of time.

Mechanism of the Ion-Exchange Reaction

The following five experimental facts are important for consideration of the mechanism of the ion-exchange reaction occurring on MnO_2:

1. The ratio of the adsorbed Zn^{++} to the released H^+ is 1:2 (Fig. 3 and 4).

2. The Zn^{++} adsorption isotherm on MnO_2 was measured as follows: 2:00-g samples of electrolytic MnO_2 were washed with dilute H_2SO_4 and shaken at 25° ± 1°C with various concentrations of the zinc solution (0.01-0.1 m/l ZnO in 2 m/l NH_4Cl, *p*H 7.0) using enough solution to furnish 5×10^{-3} mole of total zinc ion.

The results, shown in Fig. 8, seem to indicate a typical chemi-adsorption process. The ratio of the number of Mn^{IV} atoms present on the surface of the MnO_2 to the number of Zn ions adsorbed on the surface for the highest concentration in Fig. 8 is Mn^{IV}: $Zn^{++} = 5.9 \times 10^{20}$ *: 3.0×10^{20} * = 2:1.

The number of Mn^{IV} atoms on the surface was calculated using the formula, number of atoms = $(d \times N/MnO_2)^{2/3} \times 100^2 \times S$, where d is the density of the MnO_2 (4.4 for this sample), S is the surface area as measured by the B.E.T. method using N_2 adsorption (60.7 m^2/g for this sample), N is the Avogadro number, and MnO_2 is the formula weight.

* Refer to 1 g MnO_2.

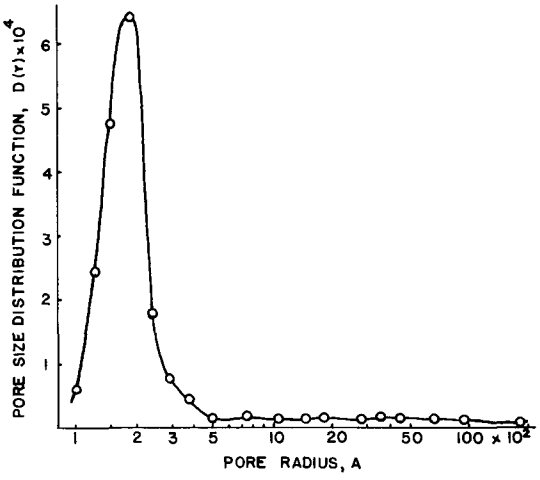

Fig. 7. Pore size distribution of electrolytic MnO_2 (No. 2 in Table I).

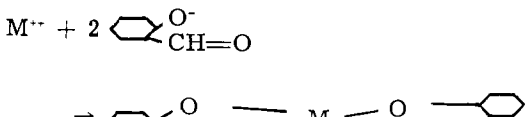
3. The ion exchange of various metal ions on MnO_2 was examined by shaking the electrolytic MnO_2 with various divalent metal sulfate solutions, 2×10^{-3} m/l in $M^{II}SO_4$, buffered to *p*H 5.5 with a sodium acetate-acetic acid buffer solution. Results are given in Table II. In the formation of divalent metal chelate compounds, for example:



$$K = \frac{(MKe)}{(M^{++})(Ke)^2}$$

there is a well-established order in the stability constant (or log K) for the divalent metal ions (12), Cu > Ni > Co > Zn > Mg. Adsorption values for MnO_2 show a similar order, although the position of Ni is slightly different.

4. Combined water molecules (13) and OH groups contained in the MnO_2 samples might be expected to be the source of the released H^+. However, the electrolytic MnO_2 loses almost all H_2O when heated above 300°C: the original H_2O content is 8.7% and after heating above 300°C it is only 0.4% or less (13). Nevertheless, this heated MnO_2 has a

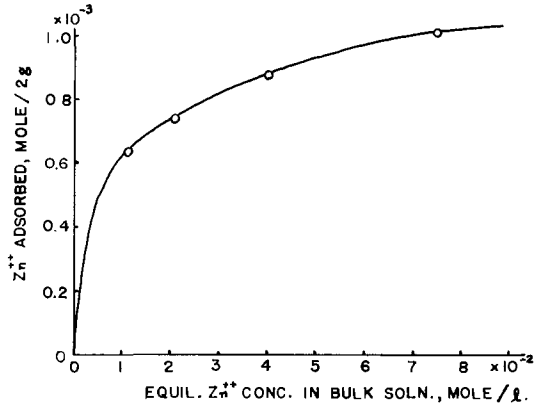


Fig. 8. Zn^{++} adsorption isotherm. Zn^{++} adsorption by 2 g of the electrolytic MnO_2 in the zinc solution.

Table II. Adsorption of various divalent ions on MnO_2 in the solution of pH 5.5 buffered with HAc and NaAc

Cu^{++}	88×10^{-5} Mole/2 g MnO_2
Co^{++}	37
Zn^{++}	26
Ni^{++}	19.5
Mg^{++}	0.5

considerable ion-exchange ability, or in other words a considerable amount of H^+ ion is released. Thus, the source of the released H^+ may be H_2O molecules from the solution adsorbed on the surface of the MnO_2. This is supported by the fact that the amount of H^+ ion released is proportional to the surface area of the MnO_2.

5. Wadsley (14) has considered the ion-exchange reaction of various hydrous MnO_2 samples. Sodium contained in the hydrous oxides was irreversibly replaced by various metal ions. However, the electrolytic MnO_2 used in the above experiments was found by using a flame photometer to be free from Na and K. Also, it was found that the adsorbed Zn can be desorbed reversibly by lowering the pH of the solution. Figure 9 shows the reversibility. The pH of the Zn solution was raised by adding NH_4OH and then lowered by HCl. For each experimental point the mixture of MnO_2 and Zn solution was shaken for a few hours in order to attain the ion exchange equilibrium.

In conclusion, the author would like to propose the mechanism shown in Fig. 10 for the ion-exchange reaction occurring on the surface of MnO_2. This mechanism satisfies all five of the experimental facts described above. In order for the complex ions in the zinc solution to be adsorbed preferentially on the MnO_2, it is necessary that the adsorbed forms be more stable than the form existing in the solution. In the proposed mechanism, the adsorbed zinc forms a six-membered ring with the MnO_2 surface with adsorbed water. It is a well-known fact of chelate chemistry that 5- or 6-membered rings are more stable than complex ions having groups such as Cl^-, OH^-, NH_3, and H_2O as the ligands.

Acknowledgment

The author would like to thank Professor K. Sasaki for his valuable suggestions during the course of this work. The author is indebted to Dr. H. Saito, Nagoya University of Japan, for the pore size distribution measurement. Thanks are also due to Professor E. Yeager, Western Reserve University, and Professor W. C. Vosburgh, Duke University, for their encouragement and comments.

The Significance of the Flade Potential

M. J. Pryor

Metallurgical Laboratories, Olin Mathieson Chemical Corporation, New Haven, Connecticut

ABSTRACT

Previous explanations of the Flade potential have been reviewed critically. A new explanation based on a single phase passive film of γ-Fe_2O_3 having non-uniform defect concentration and type is advanced. The potential determining reaction is considered to be that between excess oxygen in the outer p-type layers and hydrogen ions and electrons. The inner n-type oxide is destroyed by reductive dissolution in acid media and by exchange of oxygen ions with hydroxyl ions in solution having pH values higher than 3.0.

Previous Explanations of the Flade Potential

If iron is polarized at progressively more noble potentials in sulfuric acid, the onset of passivity will be observed at a reproducible potential. If the potential of iron which has been passivated either by anodic means or by inhibitors is permitted to decay by switching off the passivating current, or by adding corrosive agents to the passivating solution, a similar well-defined potential arrest is again often observed. This potential arrest was first observed by Flade (1) whose name it now bears. Later workers (2) in the field have characterized the pH dependency of the Flade potential by the equation

$$E = 0.58 - 0.059\ pH \qquad [1]$$

Since the early work of Flade, Weil (2) has proposed that the Flade potential is an equilibrium potential when no current is passing through the film and when no oxidation-reduction system is available in the electrolyte. This view has been supported by Cartledge (3) following a study of the formation of passive films in osmium (VIII) oxide.

If the postulate that the Flade potential is an equilibrium potential is accepted, its pH dependency, under conditions of potential decay (with no external current passing), implies that the basic reaction involved is an electrochemical reduction of the type

$$O + 2H^+ + 2e = H_2O \qquad [2]$$

Depending on the state of association of the oxygen, ferric ions in an iron oxide film also may be reduced to the ferrous condition.

The main problem lies in the fact that the oxygen would appear to be necessarily contained in or otherwise associated with an oxide of iron on the passive surface. Attempts to reconcile a value of $E_F = 0.58$ (Eq. [1]) with the standard state free energies of reduction of known bulk oxides of iron to an intermediate state or to the metal have been unsuccessful. In order to reconcile this difficulty "sandwich" oxides often possessing unusual properties have been suggested almost universally. Investigators favoring a thermodynamically reversible reaction have pictured the reaction giving rise to the Flade potential as occurring within such sandwich films.

For instance, Cartledge (3) postulated the formation of a duplex passivating oxide on iron immersed in osmium (VIII) oxide. He assumed, consistent with past electron diffraction investigations (4-6), that the outer layer was composed of γ-Fe_2O_3. He also assumed that an inner two dimensional layer of "abnormal" ferrous oxide existed between the γ-Fe_2O_3 layer and the iron. By assigning arbitrarily an unusual value of free energy of formation of -73.6 kcal mole^{-1} to the inner layer of abnormal "FeO" (the free energy of formation of bulk FeO is actually -58.4 kcal mole^{-1}) he was able to derive a potential determining reversible electrode process in the film as follows

$$Fe_2O_3 + 2H^+ + 2e = 2\text{"FeO"} + H_2O \qquad [3]$$
$$\Delta F_o = -26.7 \text{ kcal}$$

A fit with the $E_F = 0.58$ v for the Flade potential is obtained only because of the assumption of the unusual free energy of formation for abnormal "FeO". This is somewhat similar to the approaches used by several investigators of passivation mechanisms of iron who have postulated the presence of layers of energy-rich and unknown oxides of iron (7, 8).

Vetter (9, 10), Weil (2), and Gohr and Lange (11) also pictured the passive layer on iron as being duplex, with a Fe_3O_4 layer next to the metal interface being overlayed by a second layer of γ-Fe_2O_3. Using this model Vetter (10) proposed that the Flade potential was, in fact, an irreversible potential. He suggested that the reaction

$$Fe + 4Fe_2O_3 = 3Fe_3O_4 \qquad [4]$$

occurs irreversibly and completely giving rise to a potential difference of 0.66 v in the resulting magnetite layer. This is the difference between the theoretical and experimental values which is otherwise difficult to explain. Vetter proposed that the destruction of the duplex layer involved the slow dissolution of the γ-Fe_2O_3 film. He considered that once the γ-Fe_2O_3 was consumed it was succeeded by an extremely rapid dissolution of the magnetite layer during which the iron became spontaneously activated.

Past explanation of the Flade potential have all been based on Eq. [1] in which $E_F = 0.58$ v. Recently, however, Uhlig and King (12) have shown that the values of the Flade potential in inhibitive solutions such as nitrite, chromate, tungstate, molyb-

date, and ferrate are constant in that they do not vary with time, but that the absolute values vary by up to 0.14 v with the passivating medium. Using these facts, Uhlig and King have reasoned that the Flade potential observed during passive potential decay is an equilibrium potential due to the reduction of chemisorbed oxygen atoms and molecules ($0 \cdot O_2$) on the surface of iron or on a nonprotective oxide covering the iron surface.

Critical Examination of Previous Models of Passive Films on Iron and Their Relation to the Flade Potential

One of the most fundamental questions left unresolved by previous considerations of the Flade potential is whether this is a thermodynamically reversible or an irreversible potential. Direct experimental proof of either concept has so far not been obtained. Consequently, it appears that one procedure based on existing knowledge involves obtaining a suitable model for the reactions occurring during passive potential decay and from this determining the magnitude of the local-cell currents involved in these reactions. The magnitude of these currents then may suggest whether or not the overall reaction occurs at a potential close to the equilibrium value. The first part of this approach involves setting up the most reasonable model for the reactions involved during passive potential decay on iron. In order to achieve this a critical consideration of previous suggested models is in order.

Previous models of duplex passivating films proposed by investigators of the Flade potential fall primarily into the following classes:

(*a*) $Fe/Fe_3O_4/\gamma\text{-}Fe_2O_3$ (2, 9-11)

(*b*) Fe/"FeO"/Fe_2O_3 (3)

(*c*) The model of Uhlig and King (12) involving chemisorbed oxygen atoms and molecules on the iron surface.

Model (*a*) as stated by its supporters appears difficult to maintain for passive potential decay in acid electrolytes. Here it has been shown (13-15) that films of γ or α Fe_2O_3 formed on iron by exposure to air at different temperatures are destroyed rapidly by reductive dissolution according to the equations

$$Fe = Fe^{++} + 2e \qquad [5a]$$

$$Fe_2O_3 + 6H^+ + 2e = 2Fe^{++} + 3H_2O \qquad [5b]$$

$$Fe + Fe_2O_3 + 6H^+ = 3Fe^{++} + 3H_2O \qquad [5]$$

The rate of reaction [5] is very great so that up to 800Å of film may be destroyed in 1-2 sec in either 1*N* HCl or 1*N* H_2SO_4. The reaction proceeds by fairly uniform inward thinning from the oxide-solution interface. Similar films, when detached from the iron, are virtually unattacked for prolonged periods by similar acid electrolytes.

In examining model (*a*) it is first necessary to determine why the outer portion of the duplex film has apparently greater stability toward H_2SO_4 solutions than γ-Fe_2O_3 films formed by exposure of iron to air. One possible reason might lie in a higher electronic resistance which might make reaction [5*b*] slower or in higher ionic resistance which would make reaction [5*a*] slower. Either factor would tend to decrease the rate of over-all reductive dissolution of the film.

However, it has been pointed out previously (16) that the passive films on iron are good electronic conductors and that they cover the surface of the metal completely. Therefore, enhanced electronic resistance cannot provide the reason for the greater stability of the thin (100Å) passive films. Values of leakage current determined during anodic passivation of iron in H_2SO_4 (2) show that the initial ionic resistance of the passive films so formed is fairly high. However, if the passivating conditions are disturbed, the ionic resistance of thin oxide films on metals can be reduced very rapidly, even at 25°C, by n-type defects introduced into the oxide film by exchange between O" in the oxide lattice and monovalent anions such as OH' (17) and by the introduction of H^+ into the lattice. Therefore, it also appears that enhanced ionic resistance cannot account for the relative stability of the outer γ-Fe_2O_3 layer in H_2SO_4 electrolytes. This greater stability is presumably the result of special properties or structural characteristics not described to date by the supporters of model (*a*).

The suggestion that an inner layer of Fe_3O_4 is present in the passive films formed anodically in H_2SO_4 is also hard to reconcile with previous work on thermal films unless unusual properties are again ascribed to it. If the structure of the film was duplex as suggested by Lange (11) and Vetter (10), the initial destruction of a conventional γ-Fe_2O_3 film by reductive dissolution would be fast in acid solution. Magnetite as formed in duplex thermal Fe_3O_4/Fe_2O_3 films cannot easily be cathodically reduced by local-cell corrosion currents in acid solutions or by impressed cathodic currents of the order of 15 $\mu a/cm^2$ in neutral or slightly alkaline electrolytes (18). Therefore, the subsequent direct dissolution of magnetite would be slower than the reductive dissolution of the outer γ-Fe_2O_3 layer. This is exactly opposite to the mechanism suggested by Vetter (11). Therefore, it appears that the applicability of model (*a*) to passive potential decay in H_2SO_4 logically requires the postulation of radically different characteristics both for the γ-Fe_2O_3 and to the Fe_3O_4 layers than are experienced in thermal films.

Model (*b*) and Eq. [3] as put forward by Cartledge also lack experimental support. Certainly in solutions having *p*H values lower than 3.0 the reaction shown in Eq. [3] has not been observed experimentally. A considerable volume of experimental evidence (15, 19) shows that reduction of thermal ferric oxide films proceeds completely to soluble ferrous ions rather than to "FeO" (normal or abnormal) whose existence, even in transient form, has never been detected during cathodic reduction of oxide films on iron. Recent precise and successive quantitative cathodic reduction of duplex Fe_3O_4/Fe_2O_3 thermal films on iron (18) at *p*H = 7.65 has revealed in turn α-Fe_2O_3, γ-Fe_2O_3, and Fe_3O_4 in that order but with no suggestion of any "FeO" compound either normal or abnormal. Again successful application of model (*b*) requires the description of the Fe_2O_3 layer in markedly different terms to those normally attributed to thermal films. If it was at-

tempted to apply the Cartledge model to acid solutions, it would suffer the same additional disadvantage experienced above by model (*a*).

The mechanism suggested by Uhlig and King (12) appears to be more consistent with previous knowledge of the reactions of iron oxide films than those outlined above. Doubtless, adsorbed oxygen is present on the surface of many passive films, and it would appear necessary to reduce this in some manner before further reactions involving the film could occur. The time factor for one seems to argue against this mechanism being primarily responsible for the Flade arrest. For instance, Evans (21) in his early work on anodic passivation showed that a layer of oxygen absorbed on the surface of an iron oxide film[1] prevented its reductive dissolution but only for a fraction of a second. Therefore, it is evident that a certain period of immunity toward reductive dissolution of the film may be obtained by virtue of oxygen supersaturation on its surface; supersaturation of this type could result from the formation of the oxide by the anodic discharge of oxygen or by the action of strong oxidizing agents. It is also equally clear that this short period of immunity against reductive dissolution observed earlier by Evans is not sufficient to account for the rather long periods of metastable passivity observed by many investigators. The model of Uhlig and King also fails to account for the slow appearances of ferric ions in sulfuric acid electrolytes during the early stages of passive potential decay (25). Further it implies that passivation processes in the inhibitors studied are invariably associated with the layer of adsorbed oxygen atoms and molecules ($O \cdot O_2$) which is generally contrary to the existing direct experimental evidence.

Proposed Model for Passive Layers on Iron

It is believed that the subsequent model reconciles many of the difficulties outlined above and is more consistent with known experimental facts on the properties of thermal oxide films on iron. It postulates structural differences between thermal and passive oxide films which can account for their different behavior in many electrolytes and for the Flade potential. The passive films on iron have been shown in many cases to consist largely of γ-Fe_2O_3 (4-6). Accordingly, it is most consistent with past experimental evidence to propose that the passive films are crystallographically single phase. These films may, of course, contain minor inclusions of hydrated oxide (5, 6) when formed in nearly neutral inhibitors, but these compounds in small amounts of less than a few per cent do not affect the arguments advanced below.

Whereas the gross crystallographic structure of passive films is held to be uniform, the defect concentration of passive films having thicknesses of the order of 100Å will be far from uniform and will result in marked departure from stoichiometry. For instance Fig. 1 shows schematically the effect of a metal interface on the concentration of metal excess, n-type, defects in the oxide near to the oxide-metal interface. The investigations of Grunberg and Wright (20) on photosensitized electron emission strongly suggest that the excess metal concentration in this interfacial region is due to considerable numbers of oxygen ion vacancies where electrons are trapped. Defect concentrations at the oxide-metal interface may presumably approach values of 10^{20}-10^{21}/cc. The strong effect of the oxide-metal interface largely disappears at a distance of around 50Å. Thereafter, the film is capable of assuming a more conventional defect structure and concentration (10^{14}-10^{17}/cc) except at the outer interface between the oxide and the passivating medium. Here, if strongly oxidizing conditions exist, it is reasonable to propose that the surface layers of oxide contain excess oxygen. By similar reasoning to that above this is probably due to metal ion deficiency resulting in a p-type structure although the existence of interstitial excess oxygen cannot be ruled out.

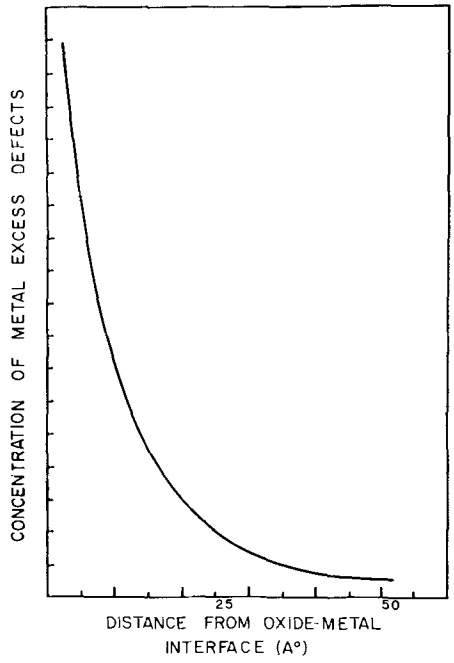

Fig. 1. Schematic representation of the concentration of metal excess defects in an oxide film on iron as a function of distance from the metal interface.

The concentration of excess oxygen ions plus bound positive holes in the outer portion of the film usually should distinguish passive from thermal films. In the former case films are produced at low temperatures when cation diffusion is relatively slow and also under conditions where the concentration of oxidant is high. Such conditions seldom apply to thermal films since appreciable thickening must be the result of raising temperature in which case cation diffusion is speeded. The chance of producing a high concentration of excess oxygen plus bound positive holes in the outer portion of a thermal film is thus greatly reduced. Here, therefore, it appears possible to use the new model to account for logical differences in defect structure between air-formed and passive films as will be shown below. This can

[1] Oxygen dissolved in the bulk electrolyte cannot depolarize reaction [5b] at pH values less than 3.0 because the local cell corrosion currents are sufficiently high that O_2 depletion occurs at the cathode surface and because the reduction of dissolved molecular oxygen is a gas electrode reaction which suffers from high activation polarization. These effects offset the more favorable free energy considerations involved.

in turn relate to differences in behavior on immersion in certain electrolytes.

The resulting model of a p-n semiconductor has many aspects in common with the duplex oxides postulated by Cartledge and Vetter. However, it does not involve gross crystallographic changes throughout the oxide and provides a means of eliminating many of the difficulties encountered with the other models.

Application to the Flade Potential

Using this model it is first necessary to explain why such a single phase film of p-n γ-Fe_2O_3 will resist rapid reductive dissolution when exposed to electrolytes more acid than pH 3.0. The explanation should rely logically on factors other than an adsorbed layer of oxygen to retard reductive dissolution of the film.

The most probable means by which reductive dissolution of γ-Fe_2O_3 could be prevented involves the excess oxygen contained in the outer p-type portion of the passive film. This excess oxygen which consists of oxygen ions plus bound positive holes could be reduced by the following electrochemical reaction:

$$O'' + \boxed{+\atop +} + 2H^- + 2e = H_2O \qquad [6]$$

crystal lattice; bound positive holes

with the electrons being supplied by the anodic passage of ferrous ions through the film.

By employing the new model outlined above in conjunction with reaction [6] a ready distinction is obtained between the electrochemical characteristics of passive and thermal oxide films on iron based on the concentration of excess oxygen ions plus bound positive holes in the outer layers. It has been suggested above that passive films on iron contain a much higher concentration of excess oxygen than thermal films due to their formation at lower temperature often under strongly oxidizing conditions. Consequently, the higher concentration of excess oxygen may confer substantial periods of immunity against reductive dissolution (Eq. [5]) which would not be experienced with thermal films of similar crystallographic structure.

An equilibrium potential may be written for reaction [6] as follows

$$E = E_0 + \frac{RT}{2F} \log (H^-)^2 (O'') \left(\boxed{+\atop +}\right) \qquad [7]$$

where (O") and $\left(\boxed{+\atop +}\right)$ are the activities of excess oxygen ions and bound positive holes, respectively, in the outer p-type layer. Reaction [6] is considered to be potential determining during the thinning of the outer p-type γ-Fe_2O_3. Therefore, the relationship between the equilibrium potential of reaction [6] and the Flade potential may now be considered with a view to determining how closely the two will approach.

It is known from past work on the reductive dissolution of oxide and sulfide films on iron (13), copper (19), and silver (22) that cathodic removal of oxygen and sulfur from the oxide and sulfide lattices is accompanied by a high degree of polarization. However, calculation of local-cell currents during reductive dissolution of thermal oxide films on iron in 1N H_2SO_4 shows that these are of the order of 50 ma/cm^2. Currents of the order of 0.5 to 1.0 ma/cm^2 often have been employed for the quantitative cathodic reduction of oxide films on iron and copper in neutral electrolytes. Severe cathodic polarization of the reductive dissolution at these high current densities normally would be anticipated. However, Price (23) has pointed out that as the applied current density is reduced the reduction potential will approach the calculated equilibrium value asymptomatically.

Typical values of local-cell current flow may be calculated for reaction [6]. Assuming the outer p-type layer of γ-Fe_2O_3 is 50Å thick, that it contains an average of 0.1 at. % of excess oxygen, and that it is subjected to a combination of reduction (Eq. [6]) and dissolution as described later for 100 sec, local cell currents of the order of only 0.2 μa/cm^2 are required to reduce the excess oxygen by reaction [6]. The extremely small current flow involved when combined with Price's observation (23) strongly suggests that the degree of polarization of reaction [6] should be very small. Consequently, the Flade potential and the equilibrium potential for reaction [6] may be regarded as being identical to the first approximation. Of course, the Flade potential must always be somewhat less noble than the E value in Eq. [7] and the difference between the two will be related to the film structure and the length of the Flade arrest. Based on the calculations above, the differences appear to be very small so that the Flade potential will be regarded through the rest of the paper as approximately representing the equilibrium potential of reaction [6].

The success of the new model, therefore, depends to a considerable degree on the accuracy with which it represents experimental observations on the Flade potential and the behavior of oxides of iron exposed to aqueous solutions. If Eq. [7] is compared with Eq. [1] it may be deduced that

$$E_F = E_0 + \frac{RT}{2F} \log (O'') \left(\boxed{+\atop +}\right) \qquad [8]$$

Using this model it becomes erroneous to treat E_F as a standard state thermodynamic potential because it is uncorrected for the activities of the components of the excess oxygen. Equation [8] also implies that reproducible values of the Flade potential will be obtained only if the method of formation of the oxide film is such that a relatively reproducible defect structure is formed in the outer layers. The considerable variation in E_F found by Uhlig and King (12) when passive films were formed in different inhibitors can be ascribed logically to variations in the defect structure of the outer layers of passivating oxides formed under different conditions.

The potential determining step outlined in Eq. [6] fits well with previous work concerning the mechanism of direct dissolution of bulk ferric oxide (24).

Here it was found that direct solution of α-Fe_2O_3 occurred rapidly only at surface defects associated with oxygen vacancies. Once these had been "leached out" further attack on more perfect portions of the oxide was very slow. It is reasonable, therefore, to picture a slow reduction of excess oxygen at a surface layer resulting in conditions where apparent stoichiometry is approached by the production of surface layers which contain missing ferric and oxygen ions in approximately equal proportion. By analogy with previous mechanism of direct solution of ferric oxide (24) the disruption of the electric field within the oxide lattice accompanying removal of oxygen ions should permit the more rapid removal of remaining oxygen ions by combination with hydrogen ions adsorbed from solution. The latter is a direct dissolution process with iron entering solution in the ferric condition rather than a reduction process. Some iron should enter solution in the ferrous condition since the electrons in reaction [6] presumably are supplied by the anodic formation of ferrous ions. Calculation of the amount of ferrous ions so produced, using the assumptions put forward previously for calculation of local cell currents required for reduction of excess oxygen, indicates that this is only of the order of 5×10^{-9} g Fe^{++}/cm^2. This accords well with the recent observations of Weil (25) who demonstrated that iron found in solution during the initial stage of the potential decay in 1.0N H_2SO_4 decay was in the ferric condition with any ferrous ions being below the limit of detection of the ferricyanide test.

The sequence of reduction followed by direct solution of the defective surface layer outlined above may occur until such a time as the depolarizing influence of excess oxygen in the p-type surface layer is exhausted. When the p-type oxide has been removed as outlined above, the reaction proceeds on the n-type metal-excess oxide which can be destroyed almost instantaneously in acid solutions by reductive dissolution as shown in Eqs. [5a & b]. Here the product of both the anodic and cathodic reactions is ferrous ion as has also been observed by Weil (25). Since it has been pointed out previously that local-cell corrosion currents involved during the rapid reductive dissolution of n-type γ-Fe_2O_3 films to soluble ferrous ions are of the order of several milliamperes per square centimeter, reaction [5b] is highly polarized. Therefore, on exposure of the n-type γ-Fe_2O_3 and on initiating reaction [5b] an immediate and substantial shift in potential in the active direction must be observed. This, of course, coincides with the end of the Flade plateau.

The pH dependency of reaction [6] is clearly consistent with the Flade potential. Furthermore, the over-all reaction is consistent with past work on the direct and reductive dissolution of iron oxides. However, the value of $E_F = 0.58$ v for the Flade potential, with or without the deviations observed by Uhlig and King (12), is still a problem which defies precise solution. If the above model is accepted, it is clearly meaningless to attempt to calculate E_F in terms of free energies of formation of bulk oxides. This is because no reliable estimates of free energy of formation of energy rich, highly defective oxide films have been developed, and because E_F cannot be corrected to the standard state without a knowledge of the activity of excess oxygen in the outer p-type layer. However, the latter problem is one that can be investigated experimentally using semiconductor techniques. If the activity of the excess oxygen ions in the outer layers was known, it would then be possible to calculate the E_0 value for Eq. [8]. Subsequent calculation from this value and from the free energy for the reduction of molecular oxygen would give the standard state free energy for the reaction

$$\tfrac{1}{2}\,O_2 \rightarrow \underset{\text{crystal lattice}}{O''} + \underset{\text{bound positive hole}}{\boxed{+\\+}} \quad \Delta F = 110 \text{ kcal} \quad [9]$$

i.e., the partial ionization of gaseous oxygen into a different dielectric and would throw light on the bond energy between the excess oxygen ions and the bound positive holes. This in turn would assist the understanding of the structure of defect and energy rich surface oxides on iron.

The mechanism outlined above proposes that the Flade potential should be observed only if an oxygen excess p-type layer of γ-Fe_2O_3 is formed during passivation. Formation of films of γ-Fe_2O_3 less than around 50Å thick would appear to preclude the possibility of this type of outer layer defect structure. It is, therefore, of interest to note that thin films formed by very short time anodic passivation of iron in H_2SO_4 appear to be destroyed almost instantaneously once the passivating current is switched off. No evidence of a Flade arrest is found in this case and it is probable that the film is destroyed by reductive dissolution in a similar manner to thermal oxide films.

Whether the same sequence of passive film breakdown can occur in p-n γ Fe_2O_3 films at pH values higher than 3.0 is less certain. It is known that the inner n-type oxide could not undergo reductive dissolution due only to the flow of local-cell corrosion currents (13). Instead it is probable that the ionic resistance of the n-type inner layer is reduced progressively by hydroxyl ion exchange which will be more rapid at the higher pH values.

However, there appears no reason why the reduction and dissolution of the outer p-type layer of oxide, which is believed to give rise to the Flade potential, should not proceed by the same mechanism as that outlined above. At the same time it must be borne in mind that the higher electrolyte pH magnifies the importance of exchange between oxygen ions in the oxide and hydroxyl ions from solution. This exchange will be accompanied by a decrease in ionic resistance since each exchange creates an n-type defect. A decrease in ionic resistance due to this reaction will be accompanied by a shift in potential in the active direction similar to that which accompanies activation of the iron in acid electrolytes by reductive dissolution of the n-type inner layer. These two processes, therefore, have a similar total

effect, differing only in rate. On occasion, however, the exchange reaction could presumably occur before the outer p-type oxide was completely removed by reaction [6] and the accompanying dissolution reaction. In this case, the decrease in ionic resistance accompanying the exchange reaction may well mask the Flade potential. Therefore, it is of interest to note that well-defined Flade arrests do not always occur at the higher pH values (26). Instead, there is sometimes a range of erratic potentials spreading over as much as 400 mv. From these, it is impossible to typify a well-defined Flade potential.

Rapidly fluctuating potentials such as these are characteristic of the nonuniform reduction of ionic resistance and accompanying increase in local-cell currents such as would accompany oxygen-hydroxyl ion exchange. Potential-time curves of this type are, therefore, believed to be characteristic of the exchange reaction masking the true effect of the Flade potential.

Potential Studies on Passivity to Corrosion Induced by Pretreatment Processes

II. Comparative Study of Chromate Treatment and Chromate Inhibition

K. S. Rajagopalan and K. Balakrishnan

Central Electrochemical Research Institute, Karaikudi, South India

ABSTRACT

The mechanism of passivation of zinc by chromate treatment is compared with that of chromate inhibitor in this paper. The part played by soluble chromate in enhancing passivation by chromate treatment is elucidated in terms of the kinetic approach made in a previous paper.

It was shown earlier (1) that potential and polarization studies are very helpful in elucidating the mechanism of passivation of aluminum by chemical oxidation processes. The present paper attempts to throw more light on the mechanism of inhibition of corrosion of zinc by chromate treatment as well as chromate inhibitor.

Experimental

Commercially pure zinc (1/16 in. thick) was cut into 1 x 1 in. and 3 x 2 in. specimens. The metal specimens were abraded with 120 emery until a uniform finish was obtained, degreased with methanol, hot benzene, and hot acetone, and subjected to chromate treatment, where necessary, in Cronak (2) composition (200 g of potassium dichromate + 6 cc of H_2SO_4/l) at room temperature for 30 sec. Specimens were rinsed in cold water and dried by cold compressed air after treatment.

Sodium chloride solutions of various concentrations were used. The chloride solutions were air-saturated by bubbling air through solution for 15

Table I. Initial and steady potentials* of chromate-treated and untreated zinc in sodium chloride solutions

Condition of metal	Conc. of NaCl, %	Initial potential[α] vs. SCE	Form of potential time curve	Steady potential[β] vs. SCE
Untreated	0.001	—0.94	Becomes 50 mv more negative and recovers to initial potential after 2 weeks	—0.94
Untreated	1.0	—1.02	Same as above	—1.01
Chromate-treated	0.001	—1.05	Rises slowly over 2 weeks to a potential 100 mv more positive	—0.95
Chromate-treated	1.0	—1.03	Rises slowly over 2 weeks to a potential 40 mv more positive	—0.99

* Mean of duplicate determinations which did not differ from each other by more than ±20 mv. α—measured after 5 min; β—measured after 2 weeks.

min before each test and were exposed to air afterward. All inhibition experiments were done using 500 ppm sodium chromate in the solutions.

Methods.—These have been described (1). All experiments were carried out at 35°C. The potential values are given the negative sign according to the European convention (3). The potential decreases in anodic polarization curves and increases in cathodic polarization curves.

The 3 x 2-in. specimens were suspended in triplicate in 1 liter of solution contained in a tall form beaker such that the upper edge of the specimen was 3 in. below liquid level. At the end of test period, the specimens were taken out, cleaned in 20% sulfate-free chromic acid at 80°C (8), and reweighed. Weight of film was deducted from the initial weight for calculation of the loss in weight due to corrosion in the case of treated metal. The mean of the triplicate determinations made in each solution did not differ from the individual values by more than 20%. Mean values are given in Table II.

Results

Potential-time studies.—Initial and steady potentials of untreated and chromate-treated zinc in 0.001% and 1% NaCl solutions and the forms of the potential-time curves are shown in Table I. It is seen from Table I that the potential of untreated zinc varies little with time and that its potential in 0.001% NaCl is 70 mv more positive. Nearly the same potential as that of untreated metal is recorded by chromate-treated zinc after it is allowed to reach a steady value. The potential obtained immediately after immersion is, however, about 100 mv more negative in 0.001% NaCl solution. As compared to these, rapid changes are observed in the potential of untreated metal in the presence of chromate inhibitor (see Fig. 1). At the lowest chloride concentration, viz., 0.001% NaCl, the initial potential becomes immediately more positive by

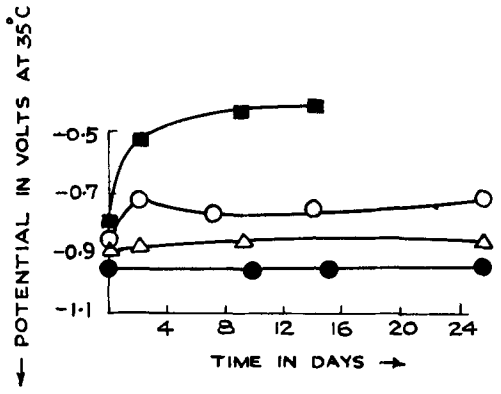

Fig. 1. Potential-time curves of untreated zinc in NaCl solutions containing 500 ppm chromate. ■ in 0.001% NaCl; ○ in 0.01% NaCl; △ in 0.1% NaCl; • in 1% NaCl. Potentials were measured against saturated calomel electrode.

nearly 200 mv, and this increases in the next few days to a value of 500 mv more positive. The ennobling effect is observed again in 0.01% NaCl but to a lesser extent. In the case of 0.1% NaCl, the initial potential is slightly more positive to start with, but there is hardly any change with time. In 1% NaCl solution, the behavior of untreated zinc is reproduced.

Polarization studies.—Potential-current density curves obtained with untreated and chromate-treated zinc, a few hours after immersion, in solutions containing different concentrations of chloride ions are shown in Fig. 2 and 3. Figure 4 gives poten-

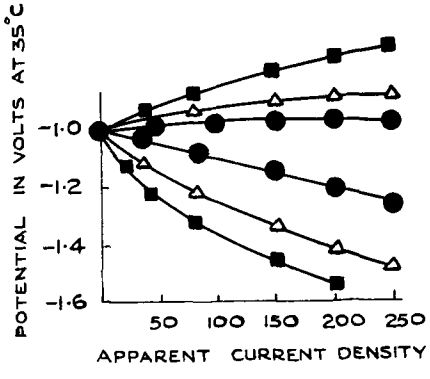

Fig. 3. Potential-current density curves of chromate-treated zinc in NaCl solutions. ■ In 0.001% NaCl; △ in 0.01% NaCl; • in 1% NaCl.

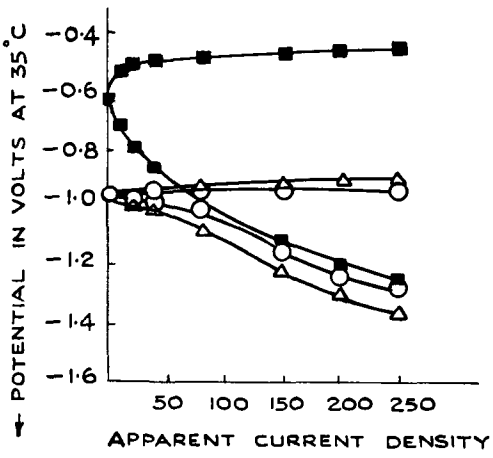

Fig. 4. Potential-current density curves of untreated zinc in NaCl solutions containing 500 ppm of chromate. ■ In 0.001% NaCl, △ in 0.1% NaCl; O in 1% NaCl.

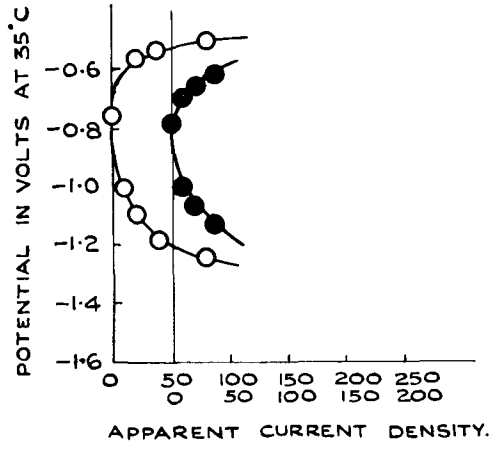

Fig. 5. Potential-current density curves of chromate-treated zinc. • After immersion for a week in 0.001% NaCl; O in 0.001% NaCl + 500 ppm chromate immediately after immersion. Potentials were measured against saturated calomel electrode. Current densities are given in $\mu a/in.^2$.

tial current density curves for untreated zinc in chloride solutions to which chromate has also been added. A common initial potential has been taken where the potentials do not differ from each other considerably to avoid overlapping of the curves and to compare the slopes.

The points given in the curves, therefore, indicate only the observed shifts. It is seen from Fig. 2 that at the highest concentration of chloride, i.e., 1% and 0.1%, there is practically no polarization of untreated metal. Slight polarization is observed in 0.001% NaCl solutions. The initial potential is itself changed considerably (c.f. Fig. 1) in 0.001% solution containing inhibitor, and the metal shows considerable cathodic as well as anodic polarization with externally applied current. Chromate-treated metal shows slight polarization in 1% solution. This increases considerably as the concentration falls to 0.01%. This is further increased at 0.001% concentration when the metal is polarized both anodically and cathodically to a much greater extent than untreated metal. Slopes of the polarization curves suggest that cathodic polarization is somewhat greater than anodic polarization at all concentrations.

Table II. Rate of corrosion of treated and untreated zinc in NaCl solutions in the presence and absence of chromate

Solution	Whether untreated or treated	Loss in weight in mg/dm² (16 in.²) of metal at the end of: 2 days	4 days	11 days
1% NaCl	Untreated	58	86	183
1% NaCl	Treated	22	39	34
1% NaCl + $CrO_4^=$	Untreated	49	60	57
1% NaCl + $CrO_4^=$	Treated	16	36	35
0.1% NaCl	Untreated	35	—	109

* Below 0.5 mg.

Figure 5 compares the potential-current density curves obtained with treated metal after immersion in 0.001% NaCl solution for a week with that given by treated metal immersed in solution containing chromate in addition to chloride immediately after immersion. The close resemblance in the shapes of the two curves may be noted.

Corrosion tests.—Losses in weight of untreated and chromate-treated zinc in the various solutions considered are given in Table II. It is seen from Table II that, at all concentrations, chromate treatment gives better protection than inhibitor and the corrosion rate falls to a negligible value in 0.01% and 0.001% solutions. It is also seen that even at 1% concentration of NaCl, corrosion rates of both treated metal and untreated metal in the presence of inhibitor fall with time. The combined effect of inhibitor and chromate-treatment is greater than that of either.

From the loss in weight data given in Table II, the current flowing through the local cells was calculated. The calculation shows that at the highest chloride concentration of 1% this current is of the order of 10 $\mu a/in.^2$ in the case of chromate-treated metal and 30 $\mu a/in.^2$ for untreated metal. In the other solutions, it is much less. Polarization studies thus have been carried out at similar and greater current densities.

Discussion

A comparison of Fig. 1 and Table I shows that, while the presence of chromate inhibitor in solution is accompanied by considerable shifts in potential in the nobler (positive) direction, no such shift in potential is observed in the case of chromate-treated metal. On the other hand, the initial potential of chromate-treated zinc is slightly more negative than that of untreated metal. But it is seen from Table II that, in both cases, the corrosion rate becomes almost negligible in chloride solutions of low concentration, i.e., 0.01% and 0.001%. The irreversible character of these potentials thus is

brought out. An understanding of such potentials has, however, been facilitated by the mechanism of inhibition put forward by Mears (4) based on local cell theory of corrosion and Evans' diagram. According to Mears, corrosion inhibition will be accompanied by shifts of the over-all electrode potentials such as those measured here in the nobler (positive) direction when the polarization of the local anodes alone is increased, in the negative direction if only cathodic polarization is increased, and no shift in potential will take place when the polarization of both anodes and cathodes is increased. That this approach is very helpful is readily seen in the case of chromate treatment where the treated metal shows more cathodic as well as anodic polarization. When we come to polarization curves in the presence of chromate inhibitor, however, we find that there is marked cathodic polarization and the anodic polarization is not very significant unless we take into account the initial shifts also. Mears' mechanism does not, therefore, lend itself to an explanation of the changes in potentials with time, as has been pointed out (1). The other drawbacks of this approach, viz., the need for reproducing the local cell by indirect methods which themselves are suspect and the lack of quantitative relationship between changes taking place on the metal surface and potential, were also referred to earlier (1). It was also shown that the behavior of aluminum subjected to a wide variety of passivation treatments could be explained satisfactorily if a kinetic approach based on the theory of rate processes is made. This approach was shown to result in an equation which enabled changes in potentials being interpreted in terms of log ratio of the anodic and cathodic areas on the metal surface under identical experimental conditions (5, 1). A similar equation has also been derived by other workers (6, 7). It will be shown presently that this approach is equally helpful in explaining the behavior of zinc and that it also enables us to get an intimate knowledge of the mechanism by which chromate ions inhibit corrosion in the present case, information which may be of use in other cases of chromate inhibition as well.

No appreciable shift in potential following chromate treatment is explained on this basis as arising from a reduction in the anodic as well as cathodic areas. Polarization data given in Fig. 2 confirms this conclusion. A much lower anodic and cathodic polarization observed at higher chloride concentration shows that, due to the penetrating effect of chloride ions, both anodic and cathodic areas are increased. This is also reflected in the increased corrosion rate. No appreciable change in potential with time is expected in the case of treated zinc, as both anodic and cathodic areas are increased by the chloride ions. This is what is observed (see Table I). Similarly, no change in potential is expected with time in the case of untreated zinc as it does not form a protective oxide film (cf. aluminum). Coming to untreated zinc in solution containing chloride and chromate, the smaller rise in potential with increase in chloride concentration is to be attributed either to the breakdown of the film covering the anodic area, if a film is formed, or due to the greater solubility of insoluble zinc chromate formed at the anodic areas in the higher chloride concentrations. The first rapid rise in potential immediately after immersion in 0.001% NaCl is followed by a slow rise for several days. It is likely that in the presence of the inhibitor the following reactions take place at the anodes and cathodes which result in the diminution of both the anodic and cathodic areas.

$$3Zn + 3CrO_4^{=} \rightarrow 3ZnCrO_4 \text{ (insoluble)} + 6e^- \quad [1]$$

$$6e^- + 2CrO_4^{=} + 5H_2O \rightarrow Cr_2O_3 + 10(OH^-) \quad [2]$$

Thus, the chromate ion may be expected to act like oxygen both as a depolarizer at the cathode and as a suppressor of the anodic reaction. According to the above mechanism, the first rapid rise in potential indicates the preponderating coverage of the anodic areas by the reaction of adsorbed chromate ions at the anodic points, and the later slow rise is to be attributed to the coverage of the cathodic areas also according to Eq. [2]. Potential-current density data for untreated zinc in 0.001% NaCl solution containing chromate confirms this view. Considerable anodic polarization is indicated by the rapid rise in potential in the presence of chromate even without application of current. But increase in cathodic polarization is also observed indicating that, in the presence of the chromate ion, the cathodic areas also are affected. It may be seen from Table II that, in 1% NaCl, corrosion of the metal is suppressed to some extent in the presence of the inhibitor when the test is prolonged to 11 days. The potentials of the two systems, however, remain nearly the same (cf. Table I and Fig. 3). This is also to be attributed to partial coverage of both anodic and cathodic areas by the formation of insoluble reaction products. Figure 5 compares the potential-current density curves obtained with treated metal after immersion in 0.001% solution for a week with that given by treated metal immediately after immersion in solution containing 500 ppm of sodium chromate in addition to chloride. A close resemblance in the shape of the two curves is observed. This similarity arises from the fact that the two systems are nearly identical since the former system also contains hexavalent chromium ions in solution at the end of one week due to its getting leached out from the film. Since, as already pointed out, the treatment predominantly diminishes cathodic areas and addition of chromate predominantly diminishes anodic areas, increased anodic and cathodic polarization is observed in the above two systems. It may, therefore, be expected that under these conditions, the corrosion rate will also be further reduced. Corrosion resistance data given in Table II confirms this view.

Conclusions

According to the local cell theory of corrosion and the equation derived earlier (1), inhibition of corrosion will be most satisfactory when both anodic and cathodic areas are diminished. This condition is

obtained satisfactorily when zinc is chromate-treated and immersed in an aqueous solution containing hexavalent chromium.

Anodic Behavior of Aluminum at Low Potentials

J. V. Petrocelli

Research Laboratory, The International Nickel Company, Inc., Bayonne, New Jersey

ABSTRACT

Electrode potentials, differential capacities, and anodic polarization curves have been determined for aluminum in sulfuric acid solutions. It is shown that the anodic behavior in the region of low potentials (—1.0 v to +3.0 v, S.C.E. scale) follows the relationship $i = \alpha \exp [\beta F]$. Differential capacity measurements show that the capacitance is inversely proportional to the potential. The analysis of the experimental data indicates the existence of a very thin film on the aluminum in this low potential region. It is suggested that the passive behavior of aluminum is due to the presence of a thin, compact, and continuous "oxide like" film on its surface. This film is formed and/or modified by the electrochemical action which takes place between the aluminum and the electrolyte.

The role played by films, especially oxide films, on metal surfaces in electrode processes is of increasing technical and scientific interest. The greatest advances have perhaps been made in the study of the oxidation of metals in air. The foundation of these advances was the idea introduced by Wagner (1) that metal ions and electrons diffuse through the oxide layer and react with the oxygen at the oxide-gas interface.

Verwey, Mott, and others (2-7) have extended the theories of dry oxidation to the formation of anodic films by electrolytic action. The rate of both types of processes are supposed to depend on the kinetics of the movement of ions, usually metallic ions, into and through the film under the influence of an electrostatic field. Experimental work and theoretical developments have been concerned primarily with the so called "valve" metals such as tantalum, aluminum, hafnium, niobium, titanium, vanadium, and zirconium. Most of these studies have dealt with the formation of relatively thick oxide films, circa 2000Å or more, formed at 100-600 v (8-16). The work of Guntherschulze and Betz (17) contains an excellent compilation of results up to 1936. Johansen, *et al.* (18) give a comprehensive bibliography for the more recent work on anodization.

Although under certain conditions of formation some thick anodic coatings may be porous, there are strong indications that many of them are relatively compact and nonporous and that even the thicker porous coatings have a compact, nonporous "barrier" layer film underneath which may be from 10Å to 200Å thick (15, 19, 20).

It has been suggested that the above "valve" metals as well as chromium, nickel, and iron, which exhibit passive behavior at relatively low voltages, have a compact, nonporous film on their surface under conditions usually encountered in corrosion and finishing (21-23, 24). These metals exhibit passive behavior in that they do not react or react extremely slowly with aqueous solutions despite the extremely favorable thermodynamic conditions. Although there are several schools of thought as to the nature of these films which exist on passive metals (25), it is very likely that they are similar, if not identical, to the barrier layer type which form during anodization of the metal in question (10, 11, 27).

In some cases the film is formed in air, hence preexists prior to exposure to the aqueous medium. For other cases the entire film forms after immersion in the electrolyte. In either case the final thickness of the film will be governed by the electrochemical action which occurs in the electrolyte. On open circuit, without external polarization, film growth is promoted by an electrostatic field set up across the film by the local electrochemical action. The anodic reaction consists of the migration and diffusion of ions (the metallic ions in many cases) through the film while the cathodic reaction involves the reduction of oxygen, hydrogen, or other reducible substance present in the solution. The kinetics and mechanism are very similar to that which occurs

during anodization by application of an external current.

It is the object of this work to determine the presence of such a film on Al on open circuit and in the low voltage region, −1.0 to +2.0 v. Previous work on the behavior of Al with oxidation-reduction systems strongly suggested the presence of such a film on this metal (21).

Some investigators have explored this low voltage region for some of the film forming metals. Vermilyea (26) has shown that it is possible to form a film on Ta even when its electrode potential is negative to the hydrogen electrode in dilute solutions of HNO_3 and NaOH. Young (10) studied the anodization of Nb in the 0.0 to 10 v range in Na_2SO_4 and H_2SO_4. He found that in this voltage region films ranging from about 20Å to a few thousand angstroms thick formed on the metal. Johansen, *et al.* (18) studied anodic film formation on Ta, Al, Ti, Hf, V, Nb, and Cr in boric acid-ammonia solutions in the potential region below oxygen evolution. Except for Cr and V they found that films did form and determined some of the electrolytic parameters involved.

Experimental Technique

Differential capacity measurements, strictly speaking impedance measurements, were adopted in this work for detecting and studying the film on Al. Measurements of the capacity of electrodes covered by anodic oxide films have been used successfully for obtaining an estimate of film thickness (10, 13, 17). The oxide film functions as the dielectric of a parallel plate condenser of which the basis metal and the solution form the plates. It is likely that this model is oversimplified and Young (10) has treated some of the possible complicating factors which may be involved.

It is well known, however, that the capacity of clean metallic surfaces in electrolytes varies with the electrode potential in such a manner that the minimum capacitance is about 16 $\mu F/cm^2$ and that this value is that characteristic of the double layer (28, 29). It is reasonable to assume that the presence of a thin film on the surface will yield lower capacity values and that the capacity should decrease as the film thickens. The results obtained do in fact strongly indicate that the capacity values measured at high frequencies are very close to, if not identical with, the capacity of a barrier layer film.

The apparatus was practically identical to that used by Grahame (29) and Robertson (30). A mercury-mercurous sulfate half-cell was used as a reference electrode, and a glass tube filled with the solution being studied served as a salt bridge. One end of this tube was drawn down to a fine capillary which was pressed close to the back of the Al electrode. An H-type electrolysis cell with two separate compartments was used. One compartment contained the Al electrode, the capillary tipped tube, and a large (75 cm^2) platinized Pt electrode which functioned as an auxiliary electrode for the a-c measurements. The other portion of the cell contained a Pt electrode which served as a cathode in the d-c circuit.

All experiments were performed at constant temperature of 25.0°C. Although no appreciable difference was observed between results obtained in air-free solutions and air-saturated solutions, purified nitrogen was used in most of the experiments. The data presented were obtained with stationary electrodes and unstirred solutions.

The values of the electrode potentials, E, are given with reference to the saturated calomel electrode, increments in the electrode potential, ΔV, are referred to the open-circuit potential of Al in any given experiment.

Pure Al (99.99) sheet, 0.25 mm thick was used, and all solutions were made up from redistilled water and reagent grade sulfuric acid.

Generally the experimental procedure was as follows: The sheet aluminum was thoroughly cleaned and then polished with No. 0000 metallographic paper. It was then cleaned in hot acetone and thoroughly rinsed in distilled water, alcohol, and dried. All but a defined rectangular area, 0.10 cm^2 to 1.0 cm^2, was coated with an inert resin. The electrodes were then stored in a desiccator for one or two days prior to use.

Polarization experiments were conducted by making the Al the anode of a d-c circuit and impressing a predetermined current density. Unless noted otherwise, each potential reported is a steady-state value. The a-c impedance bridge could be connected to the Al and the platinized Pt auxiliary electrode at any time for the measurement of the a-c impedance. The impressed a-c voltage never exceeded 10 mv and was usually less.

The a-c impedance was measured on the bridge as a capacitance ,C_s, in series with a resistance, R_s. The impedance at the metal-solution interface is probably best represented by a capacitance in parallel with the film resistance (14). Therefore the values C_s and R_s obtained on the bridge were converted to the corresponding values C_p and R_p as shown in Fig. 1 where R_L is the resistance of the electrolyte. This choice does not effect the results reported because C_s and C_p are identical at the higher frequencies used in this work (10-15 kc).

The resistance due to the electrolyte was obtained by extrapolating R_s to infinite frequency. The values so obtained were checked in the following manner: a small platinized Pt electrode having the same shape, size, and exposed area as the Al was substituted for the Al electrode and the conductivity of the system measured with the a-c bridge in the conventional manner. The resulting values compared very well with those obtained above. The electrolyte resistance is designated by R_L.

Many exploratory experiments showed that neither the electrode potential nor the capacitance was appreciably sensitive to the exact position of the capillary tip and/or the auxiliary Pt electrode. Sev-

eral experiments were performed without the use of an insulating resin in order to determine if this resin had an effect on the capacitance values. No significant effect was ever found.

Experimental Results

The potential of Al on immediate immersion was about −0.2 v and changed to more anodic values with time, becoming fairly steady in about 1 hr. The steady-state value was about −0.9 v in all solutions. While any given specimen maintained a steady-state potential within a few centivolts, the steady-state potential of different specimens varied within 0.1 v.

When anodically polarized, Al reaches a steady potential at any given current density in about 15 min. The actual time required depends on the previous current density as well as the current density in question. The behavior is that generally found for film forming metals.

The curves shown in Fig. 2 and 3 show typical behavior in H_2SO_4. Curves obtained with many different specimens all had about the same general shape. Variation in potential for any given current density was about ±0.2 v.

The polarization at any one current density could be prolonged for 1 or 2 hr without changing the form of the curve to any appreciable extent.

No visual evidence of gas evolution was detected throughout the voltage range investigated.

If the Al is polarized rapidly (each reading taken within 30 sec), subsequently depolarized, and the process repeated several times, the following behavior, shown in Fig. 4, is observed. The first polarization curve lies somewhat above the remaining curves, curve A in Fig. 4. The subsequent curves,

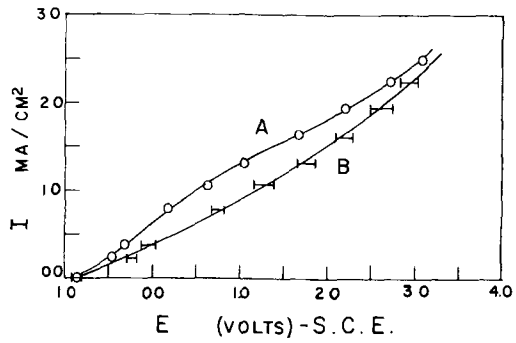

Fig. 4. Rapid anodic polarization in 5.0N H_2SO_4 hysteresis effect.

as well as the steady-state curve, lie within the brackets of curve B in Fig. 4. After the first rapid polarization all subsequent curves including the steady-state one are identical within the experimental error.

Although instrument limitations did not allow accurate readings for times less than about 30 sec, indications were obtained that if depolarization potentials were obtained in very short time intervals a considerable hysteresis effect would be noted. A specimen which had been polarized at steady-state values up to about 1.0 ma/cm^2 showed a pronounced hysteresis on rapid depolarization. The potential retained its noble value for several seconds while the current diminished to very low values.

An Al specimen which had been polarized up to +1.0 v in 5N H_2SO_4 and removed from the solution without interrupting the current exhibited noble behavior in a weaker, 1N H_2SO_4, solution. The open-circuit potential was about −0.6 v, and the anodic polarization obtained in the latter solution had a higher slope, (dV/di).

Several specimens were polarized at various current densities for 30 min in 5.0N H_2SO_4 and tested in the dry state for the presence of an insulating film. A metallic probe was pressed against the surface, and 1.0 v d.c. was applied across the probe and the Al.

Insulating films were obtained on specimens which had been polarized at more noble potentials than +1.0 v. The conduction did not depend on the polarity of the probe.

The anodic behavior described above strongly indicates that Al forms a film on the surface and that its thickness depends on the potential and current density.

The differential capacitance varied with the frequency as shown in Fig. 5. In all cases it became constant at about 8 kc. It may be assumed that the C_p measured at 10 kc or greater is the true, or very close to the true, value of the parallel plate capacity of the oxide (10). Unless otherwise noted, all values reported were measured at 15 kc.

At any given current density the capacitance changed with time in about the same manner as the potential. On open circuit the capacitance increased in value as the potential became more anodic (negative with respect to S.C.E.). At any given current density the capacitance decreased with time as the potential became more noble, both values becoming fairly steady at about the same time.

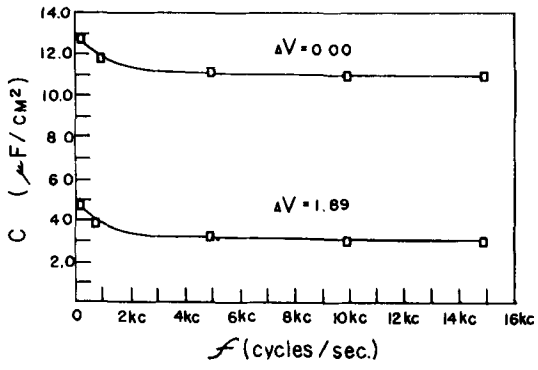

Fig. 5. Variation of capacitance with frequency in 1.0N H_2SO_4.

In any one experiment the capacitance varied from about 13 $\mu F/cm^2$ on open circuit to about 2 $\mu F/cm^2$ at $\Delta V = +3.0$ v. On open circuit the maximum variation from one specimen to another was about 1 $\mu F/cm^2$; this variation decreased with applied current to a few tenths of a microfarad per square centimeter. It is very likely that variations in capacitance values were predominately due to variations in the surface roughness factor, since this probably approached unity as the surface film thickened (9).

Generally the capacitance was lower in 1N H_2SO_4 than in the 5N and 10N acid. No significant differences were observed in 5N and 10N H_2SO_4.

A fairly well-defined linear relationship was found between $1/C$ and ΔV. Typical results are shown in Fig. 6.

Assuming that an oxide film is present on the surface we may follow the ideas of Mott and Cabrera (5) and others (8, 9) and express the current density as follows:

$$i/Ar = \alpha\, e^{\beta F} \qquad [1]$$

where α and β are constants and F is the field strength across the film.

If we let $F = V/x$, where V is the potential difference across the film and X the film thickness, we obtain

$$i/Ar = \alpha\, e^{\beta V/x} \qquad [2]$$

Expressing the current density in terms of the current per unit of apparent area, A, we have

$$i/A = \frac{Ar}{A}\,\alpha\, e^{\beta V/x} \qquad [3]$$

where Ar/A is the roughness factor.

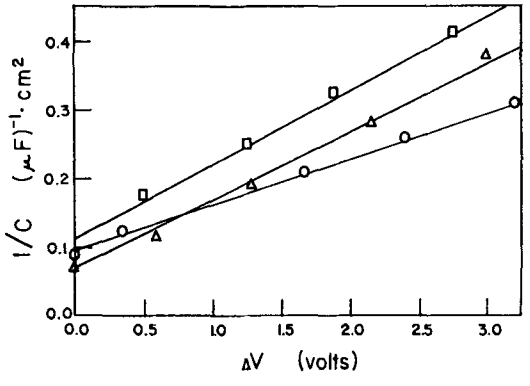

Fig. 6. Variation of the reciprocal capacitance with potential. □—1.0N H_2SO_4; ○—5.0N H_2SO_4; △—10.0N H_2SO_4.

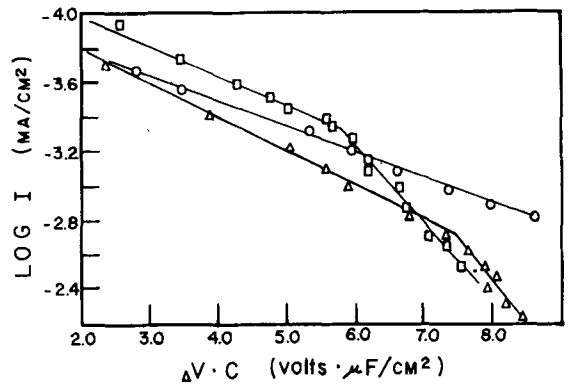

Fig. 7. Variation of the product $\Delta V \cdot C$ vs. log of current density. □—1.0N H_2SO_4; ○—5.0N H_2SO_4; △—10.0N H_2SO_4.

Since the measured electrode potential of the Al will differ from the actual electrical potential difference at the Al-solution interface by some constant, we will, for purposes of convenience, refer most of our potentials to that of the Al on open circuit, V^0.

$$i/A = Ar/A\ \alpha \exp\left[\beta(V^0 + \Delta V)/x\right] \qquad [4]$$

Assuming that the roughness factor is one, we finally have:

$$\Delta V/x = \frac{2.3}{\beta}\log i/A - \frac{2.3}{\beta}\log \alpha - V^0/x \qquad [5]$$

If the film on the surface acts as the dielectric of a parallel plate condenser, the capacity should be related to the film thickness as follows:

$$C = \frac{D\,Ar}{4\pi x} \qquad [6]$$

or

$$C = k/x \qquad [7]$$

where C is the capacitance and D the dielectric constant.

Substituting the above into Eq. [5], we have

$$\Delta V \cdot C = 2.3\ k/\beta \log i/A - 2.3\ k/\beta \log \alpha - V^0 \cdot C \qquad [8]$$

If we assume that α and β do not differ appreciably from the values found for thick films, where $\alpha \cong 5 \times 10^{-18}$ amp/cm² and $\beta \cong 5 \times 10^{-6}$ cm/v (8, 9), it is reasonable to expect that the relatively small variations in the product $V^0 \cdot C$ will not affect expression [8] to any appreciable extent. Hence if our concepts and assumptions are correct, $\Delta V \cdot C$ should be a linear function of log i/A.

Figure 7 shows that the product $(\Delta V \cdot C)$ plotted vs. log i/A yields straight lines as predicated by Eq. [8].

The data obtained in 5N H_2SO_4 always resulted in one line, whereas those obtained in 1N and 10N H_2SO_4 invariably showed a break with two straight lines of different slopes. This tendency for the current to increase more rapidly at high field strengths has been observed by others for both Al and Ta (8, 9), and a "heating effect" was suggested as the possible cause.

It is difficult to understand why this phenomena was not observed in 5N H_2SO_4, and no satisfactory explanation can be offered at this time. It is possible, of course, that the proper conditions of current and solution composition for producing a heat effect were encountered in 1N and 10N acid and not in the 5N H_2SO_4.

The average value of the slope $d(\Delta V \cdot C)/d \log i$

obtained on several different specimens in 5*N* H_2SO_4 was 6.0, with an average deviation of 5%. The slopes in 1*N* acid were 6.0 and 2.1 and in 10*N* acid 4.3 and 2.3. The average deviation was about 10% in both cases.

Discussion

Since the capacity of the auxiliary platinized Pt electrode was about 2000 μF, we may assume that the measured capacitance is very close to the true value of the capacitance of the Al electrode. The experimental results may be interpreted, at least in a qualitative manner, as indicating the presence of a film on the Al surface. The film is present at all potentials including open-circuit conditions and apparently thickens as the potentials are made more noble.

A quantitative interpretation of capacitance in terms of a film thickness is complicated because of the following factors. The true capacity of the film is somewhat greater than the measured value because of the capacitance of any diffuse double layer at the oxide-solution interface. While the film is probably fairly uniform in thickness, it is not entirely so, and our measurements correspond to some average thickness. The surface roughness factor is not known, although as previously mentioned, it probably approaches unity as the film increases in thickness. Finally, we do not know the exact composition nor the dielectric constant of the film.

However, the data do strongly indicate a film thickness which varies linearly with the potential, and it is interesting to obtain at least some qualitative idea of the probable thickness.

If we rewrite Eq. [6] as

$$C = \frac{8.84\ D}{x \cdot 10^{8}} \qquad [9]$$

where C is in μF/cm^2 and x in centimeters, we see from Eqs. [7] and [8] that the slope, S, of the $\Delta V \cdot C$ vs. log i curve is

$$S = \frac{20 \times 10^{-8}\ D}{\beta} \qquad [10]$$

If we take the value of $\beta \cong 0.5 \times 10^{-6}$ cm/v as calculated by Verwey (2), we obtain a value for the dielectric constant, D, of about 15 which is the right order for Al_2O_3.

Higher values of β as reported for thick films (4, 8, 9) would yield values of D which are unreasonably high.

If we take $D \cong 15$, and calculate x we obtain film thickness of the order of about 10Å on open circuit to about 50Å at +3.4 v in 5*N* H_2SO_4; and in 1*N* and 10*N* acid in lower voltage region.

Since it is not known whether β, D, or both change to cause lower values of the slope at the higher voltages no attempt will be made to calculate thicknesses in these cases. It should be noted, however, that a change in β from 0.5×10^{-6} to about 1.5×10^{-6} is all that is necessary to account for the change in the slope with the same dielectric constant.

The results obtained on Al in this study and on some of the other film forming metals mentioned in the introduction strongly indicate that, at least for these metals, the presence of a very thin, compact, and continuous "oxide-like" film on the surface is responsible for their passive behavior. The film thickness and characteristics will be governed by the electrochemical action which occurs between the metal and the electrolyte. This action exists on open circuit and does not differ in kind from that induced by external anodic polarization.

It is, in fact, a self-anodic polarization. The electrons are removed by the cathodic reduction of some reducible substance present in the solution.

Kinetic Studies on Corrosion Systems

I. Polyelectrodes under Activation Control

Franz A. Posey

Oak Ridge National Laboratory, Oak Ridge, Tennessee[1]

ABSTRACT

Electrochemical kinetics has been applied to the case of corroding polyelectrodes under activation control for the situation where the rates of partial processes vary over the surface of an electrode. Explicit expressions have been derived for rate and potential in the simplest polyelectrode systems. The kinetics of galvanic couples under activation control has been derived with emphasis on the significance of measurable quantities. The use of steady-state polarizability measurements, potentiostatic measurements, and galvanostatic measurements in the study of polyelectrode systems has been outlined.

Numerous investigators have contributed to the foundations[2] and experimental applications of electrochemical kinetics and comprehensive reviews of this work have been published (4-6). Much of the existing theory treats the case of a single over-all reaction under activation control[3] at an electrode-solution interphase [e.g., a metal-metal ion equilibrium, or a redox reaction at an inert electrode (8)], and one of the most general treatments of such a system[4] has been presented by Parsons (9). Wagner and Traud (10), Kimball (11), and Audubert (12) have been among the few to examine corrosion systems from a systematic kinetic viewpoint. However, in the study of some of the more complex electrochemical situations, such as those occurring in many corrosion systems, there appears to be a need for a more extensive treatment suitable for interpreting the phenomenology. In the present report, an elementary electrochemical kinetic treatment of two-phase polyelectrode systems[5] and galvanic couples under activation control has been developed, and the application of the theory to the analysis of corroding polyelectrodes has been outlined for several types of steady-state measurements. The results of an experimental investigation on a particular polyelectrode system will be presented in a subsequent report.

[1] Operated by Union Carbide Corporation for the U. S. Atomic Energy Commission.

[2] The source equations of electrochemical kinetics may be found in the works of Butler (1), Bowden and Rideal (2), and Erdey-Gruz and Volmer (3).

[3] Use of the term, activation control, here corresponds to the sense of the designation, "Durchtrittsüberspannung," as employed by Vetter (7) to distinguish between cases where the charge transfer step in an electrochemical reaction or partial process is rate-determining and those where the higher activation energy of a precursor step or a subsequent step in the reaction determines the rate.

[4] The designation, system, is used here to refer to an electrode plus its liquid environment.

[5] The term, polyelectrode, as used here, refers to the situation where more than one chemically distinct individual or partial process is occurring at the same electrode-solution interphase. The term, two-phase polyelectrode system, denotes a metallic polyelectrode in contact with a nonmetallic environment in the liquid state. The case of intervention of a third phase (e.g., an oxide film) between metal and solution is not considered explicitly, although the kinetics of some three-phase systems is indistinguishable from that of the two-phase systems treated here. This latter situation may occur if all rate-determining charge transfer steps in a three-phase system proceed at the same interphase (e.g., an oxide-solution interphase).

Definitions and Fundamental Relations

The present theory, in addition to treating the case where several partial processes under activation control occur at the same electrode-solution interphase, attempts to take account (at least in a formal manner) of the experimentally demonstrable fact that the rates of each of the partial processes may vary over the surface of the electrode. As a consequence of these variations, three current quantities present themselves for consideration in a kinetic analysis. The first of these quantities is given by the equation:

$$j_i = \lambda_i F \overline{k_i} \pi (C_i^{p_i}) \qquad [1]$$

wherein the current density, j_i (units of amp/cm^2), of the i^{th} charge transfer step at a very small (differential) element of area, dS, on the surface of an electrode is related to the absolute value of the number of charges transferred across the interphase (λ_i) during the i^{th} charge transfer step, Faraday's constant (F), an electrochemical specific rate constant ($\overline{k_i}$), and the product of the concentrations of the reactants (symbolized by $\pi(C_i^{p_i})$, where p_i denotes the kinetic order of the i^{th} charge transfer step with respect to the species of concentration, C_i).[6]

Since the energy barrier of a charge transfer step may be traversed in either direction, it is pertinent

[6] In this definition, the significance of the current density of a charge transfer step is assigned to j_i, instead of the current density of a partial process. This is done so that Eqs. [2], [3], and [7] will be general in that they include all the charge transfer steps of any two-phase polyelectrode system. However, the current density of a charge transfer step is not necessarily identical to the current density of the associated partial process, except for partial processes under pure activation control (cf. footnote 3) having a mechanism with only one charge transfer step. A partial process may involve several steps (i.e., the surmounting of several energy barriers), of which at least one step will be a charge transfer step. Furthermore, the charge transfer step(s) of a partial process may or may not be rate-determining (viz., the "slow recombination" mechanism of the hydrogen evolution reaction), but each charge transfer step will obey Eq. [1] in which $\overline{k_i}$ is the electrochemical specific rate constant of the charge transfer step and $\pi(C_i^{p_i})$ involves all species participating in the step, whether they be identifiable reactants or products of the partial process or intermediates of transitory existence. In general, the current density of a partial process which has a mechanism with m energy barriers involving charge transfer is equal to m times the net current density crossing each of the energy barriers. In applying Eqs. [1], [2], [3], and [7] to the cases discussed in the rest of the report, however, it will be assumed that all partial processes are under pure activation control and involve only one charge transfer step; in other words, only the simplest electrode processes will be assumed present in the system.

to define the anodic and cathodic current densities, $j_{i,a}$ and $j_{i,c}$.[7] With this convention, a second current quantity is given by the equation:

$$j_\sigma = \sum_i (j_{i,a} - j_{i,c}) \qquad [2]$$

This is the net current density (j_σ) at a differential element of area (dS) on an electrode surface and is the difference between total anodic and total cathodic current densities at dS. It will be shown later that the sign and magnitude of j_σ depend on the kinetics (i.e., on the energetics and on the number of reactive particles) of the various processes occurring both at dS and over the rest of the electrode surface, as well as on the sign and magnitude of any current applied to the electrode from an external source.

The third important current quantity is the applied current, i_P, which for steady-state conditions is given by:

$$i_P \equiv \int_S j_\sigma \, dS = \int_S [\sum_i (j_{i,a} - j_{i,c})] dS \qquad [3]$$

on integrating j_σ over the surface area, S, of the electrode. The applied current, of course, is an experimentally measurable quantity.

Further consideration of polyelectrode systems necessitates the assignment of a particular form to the electrochemical specific rate constants, $\overline{k_i}$. It will be assumed that the rate constants are given (13) by:

$$\overline{k_i} = \tau_i \left(\frac{kT}{h}\right) e^{-\frac{\overline{\Delta\mu_i}^\ddagger}{RT}} \qquad [4]$$

where (kT/h) has its usual significance of the decomposition frequency of activated complexes (14), τ_i equals $\kappa_i \dfrac{\pi(\gamma_i^{p_i})}{\gamma_i^\ddagger}$ (in which κ_i is the transmission coefficient of the i^{th} charge transfer step (15), $\pi(\gamma_i^{p_i})$ symbolizes the product of the activity coefficients of the reactants, and $\gamma_i^\ddagger$ is the activity coefficient of the activated complex), and $\overline{\Delta\mu_i}^\ddagger$ is the change in the electrochemical potential of the system required for the formation of one mole of activated complex from reactants. $\overline{\Delta\mu_i}^\ddagger$ is a partial molar quantity in the usual thermodynamic sense.

The rate constants for anodic and cathodic charge transfer steps may be obtained from Eq. [4] on introducing the definition of electrochemical potential due to Lange (16, 17), $(\overline{\mu_n})_\beta = (\mu_n)_\beta + Z_n F \phi_\beta$ (in which $(\overline{\mu_n})_\beta$ is the electrochemical potential of species n in phase β, $(\mu_n)_\beta$ is the chemical potential of n in β, Z_n is the charge on n, and ϕ_β is the inner or Galvani potential of the phase β), in a manner similar to the procedure used by Parsons (9) in deriving the rate constant of a partial process. The electrochemical specific rate constants become:

$$\overline{k_{i,a}} = \tau_{i,a} \left(\frac{kT}{h}\right) e^{-\frac{\Delta\mu_{i,a}^\ddagger}{RT}} e^{+\frac{\alpha_{i,a}\lambda_{i,a}F}{RT}\Delta\phi_H} \qquad [5]$$

$$\overline{k_{i,c}} = \tau_{i,c} \left(\frac{kT}{h}\right) e^{-\frac{\Delta\mu_{i,c}^\ddagger}{RT}} e^{-\frac{\alpha_{i,c}\lambda_{i,c}F}{RT}\Delta\phi_H} \qquad [6]$$

for anodic and cathodic charge transfer steps, respectively. Here, $\Delta\mu_{i,a}^\ddagger$ and $\Delta\mu_{i,c}^\ddagger$ are the changes in the chemical potential of the system required for the formation of one mole of activated complex from reactants for anodic and cathodic steps, respectively. $\alpha_{i,a}$ and $\alpha_{i,c}$ are the symmetry factors of the charge transfer steps while $\Delta\phi_H$ is the inner potential difference between the interior of the metallic element of volume, dv (one surface of which is the element of area, dS, in contact with the solution), and the innermost portion of the diffuse double layer in the solution.[8,9] Many of the preceding definitions are offered mainly to establish a nomenclature for the treatment of polyelectrode systems rather than as new propositions, and the presentation resembles Parsons' derivation (9) of similar expressions for partial processes. For convenience in reference, a list of frequently used symbols and their definitions is appended to this report.

From Eqs. [1], [3], [5], and [6], the current applied to a polyelectrode system in a steady state is given by:

$$i_P = F\left(\frac{kT}{h}\right)\int_S \sum_i \Big[\lambda_{i,a}\tau_{i,a}\pi(C_i^{p_i})_a \, e^{-\frac{\Delta\mu_{i,a}^\ddagger}{RT}} e^{+\frac{\alpha_{i,a}\lambda_{i,a}F}{RT}\Delta\phi_H} - \lambda_{i,c}\tau_{i,c}\pi(C_i^{p_i})_c \, e^{-\frac{\Delta\mu_{i,c}^\ddagger}{RT}} e^{-\frac{\alpha_{i,c}\lambda_{i,c}F}{RT}\Delta\phi_H} \Big] dS \qquad [7]$$

Equation [7] is the fundamental expression of the present model of two-phase polyelectrode systems; it includes all the charge transfer steps occurring at an electrode-solution interphase, whether rate-determining or not. Since $\Delta\phi_H$ of Eq. [7] is not an experimentally measurable quantity, it is appropriate to modify this equation to a form containing a measurable potential difference. Figure 1 shows a typical circuit for the measurement of cell or electrode potentials. Here, the measurable potential difference, V, is the potential difference corresponding to the difference in the electrochemical potential of electrons in the two ends of a potentiometer slidewire of uniform composition, i.e., $V = (\phi_{l'} - \phi_{l''})$. Hence, $V = (\phi_{l'} - \phi_M) + (\phi_M - \phi_S) - (\phi_{l''} - \phi_R) - (\phi_R - \phi_S)$, where $(\phi_{l'} - \phi_M)$ is the potential difference due to electronic equilibrium between one potentiometer lead (l') and the metallic volume element, dv, at the surface of the electrode, $(\phi_M - \phi_S) = \Delta\phi = \Delta\phi_H +$

[7] Here and elsewhere, subscript a refers to an anodic charge transfer step, entailing a transfer of positive charge from electrode to solution or of negative charge in the reverse direction; likewise, subscript c refers to a cathodic charge transfer step, with transfer of negative charge from electrode to solution or of positive charge in the reverse sense. Current densities are denoted by j, currents by i. Currents and current densities of charge transfer steps are considered as positive quantities, and positive or negative signs are affixed according to whether the particular charge transfer steps are anodic or cathodic, respectively. The signs of all other current quantities and derived functions, such as that of the externally applied current, are fixed by this procedure.

[8] If ϕ_M is the inner potential of the metallic volume element, dv, and ϕ_S is the inner potential at the outermost portion of the diffuse double layer in the solution, $\Delta\phi \equiv \phi_M - \phi_S$ is the over-all inner potential difference between metal and solution at dS. However, the specific rate constant of a charge transfer step is a function of the potential difference across the Helmholtz double layer, $\Delta\phi_H \equiv \phi_M - \phi_H$, where ϕ_H is the inner potential at the outermost portion of the Helmholtz or "fixed" double layer or (we shall assume also) at the innermost portion of the diffuse double layer. The inner potential difference of the diffuse double layer is then $\psi \equiv \phi_H - \phi_S$, and it follows that $\Delta\phi \equiv \phi_M - \phi_S = \Delta\phi_H + \psi$.

[9] The inner potential of electrochemistry should not be confused with the inner potential of electron diffraction theory. For the distinction, see Parsons' article in reference (4).

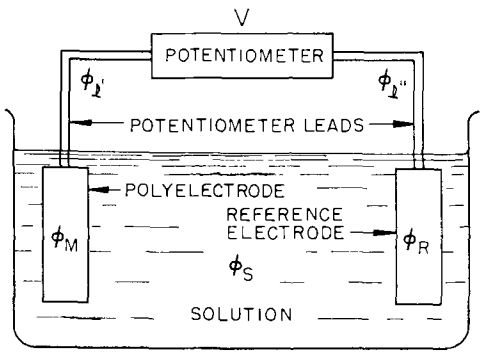

Fig. 1. Schematic diagram of typical circuit for the measurement of electrode potentials of polyelectrodes.

ψ (cf. footnote 8) is the electrode-solution potential difference at dS, $(\phi_{l''} - \phi_R)$ is the potential difference due to electronic equilibrium between the other potentiometer lead (l'') and the reference electrode, and $(\phi_R - \phi_S)$ is the potential difference between the reference electrode and the solution. If $(\phi_{l''} - \phi_R) + (\phi_R - \phi_S) = (\phi_{l''} - \phi_S)$ is denoted by $\Delta\phi_{\text{ref.}}$, and $(\phi_{l'} - \phi_M)$ is replaced by $\frac{1}{F}[(\mu_e)_{l'} - (\mu_e)_M]$, $\Delta\phi_H$ of Eq. [7] is given by $\Delta\phi_H = V - \psi + \Delta\phi_{\text{ref.}} + \frac{1}{F}[(\mu_e)_M - (\mu_e)_{l'}]$. Here, $[(\mu_e)_M - (\mu_e)_{l'}]$ is the difference in the chemical potential of electrons in the metallic volume element, dv, and in the potentiometer lead (l'). Equation [7] then becomes:

$$i_P = F\left(\frac{kT}{h}\right)\int_s \sum_i \left[\lambda_{i,a}\tau_{i,a}\pi(C_i^{p_i})_a\, e^{+\frac{\alpha_{i,a}\lambda_{i,a}F}{RT}(\Delta\phi_{\text{ref}} - \psi)} \right.$$

$$e^{-\frac{(\Delta\mu_{i,a}^{\ddagger} - \alpha_{i,a}\lambda_{i,a}[(\mu_e)_M - (\mu_e)_{l'}])}{RT}}\, e^{+\frac{\alpha_{i,a}\lambda_{i,a}F}{RT}V}$$

$$- \lambda_{i,c}\tau_{i,c}\pi(C_i^{p_i})_c\, e^{-\frac{\alpha_{i,c}\lambda_{i,c}F}{RT}(\Delta\phi_{\text{ref}} - \psi)}$$

$$\left. e^{-\frac{(\Delta\mu_{i,c}^{\ddagger} + \alpha_{i,c}\lambda_{i,c}[(\mu_e)_M - (\mu_e)_{l'}])}{RT}}\, e^{-\frac{\alpha_{i,c}\lambda_{i,c}F}{RT}V} \right] dS \quad [7']$$

Two assumptions are implicit in Eq [7']. First, it is assumed that currents flowing in the electrode, whether externally applied or existing as a result of variations in the rates of processes over the electrode surface, can have no significant effect on $[(\mu_e)_M - (\mu_e)_{l'}] = F(\phi_M - \phi_{l'})$. This assumption is surely an excellent approximation since it is well known that metals and metallic contacts are quite unpolarizable; certainly the assumption will be valid for currents encountered in systems having partial processes under activation control. Second, it is assumed that ϕ_S is constant everywhere in the solution, and hence that the measured value of V will be independent of the position of the reference electrode (or its Luggin capillary) with respect to the corroding polyelectrode (i.e., no significant "IR drop" exists in the solution). For systems under activation control, this condition usually can be met experimentally by employing a large excess of an indifferent electrolyte in the solution. The presence of a large excess of inert electrolyte is advantageous also in that the diffuse double layer potential difference (ψ) is suppressed, is approximately independent of the overall electrode-solution potential difference ($\Delta\phi$) at potentials sufficiently far from that of the electrocapillary maximum and is approximately independent of the concentration of reactive species.

It should be noted that $\Delta\phi$ (or ϕ_M) has not been presumed to be constant over the polyelectrode surface. Constancy of $\Delta\phi$ is expected only when the polyelectrode is a metal of uniform composition, although even in this case the rates of processes may vary over the surface because of, for example, the presentation of various crystal faces to the solution. Measurements of V do not necessarily give any information on the variation of $\Delta\phi$ over a polyelectrode surface, although a change in V corresponds to an identical change in $\Delta\phi$ everywhere on the surface, under the conditions of validity of the two assumptions mentioned above. The terms, $\Delta\mu_{i,a}^{\ddagger}$ and $\Delta\mu_{i,c}^{\ddagger}$, of Eq. [7'] frequently are not independent of $(\mu_e)_M$ since electrons must be considered as reactants in some charge transfer steps; the exact dependence is a function of the particular charge transfer step.

In applying Eq. [7'] to cases of practical interest, several further assumptions will be made. First, it is assumed that all partial processes are under pure activation control and that each has only one rate-determining charge transfer step. Second, it will be presumed that concentrations of solution species which enter into the terms, $\pi(C_i^{p_i})_a$ and $\pi(C_i^{p_i})_c$, are approximately the same as the concentrations of the same species in the bulk of the solution. Third, a large excess of an indifferent electrolyte will be presumed present, so that the diffuse double layer potential difference (ψ) is suppressed. And fourth, it will be assumed that the electrochemical transfer coefficient ($\alpha_i\lambda_i$) of the i^{th} charge transfer step does not vary significantly over the polyelectrode surface, even though the energetics of the step may vary greatly, as from one metallic crystal face to another.[10] With these assumptions, Eq. [7'] may be modified to give:

$$i_P = \sum_i \left[Q_{i,a} I_{i,a} e^{+\frac{\alpha_{i,a}\lambda_{i,a}F}{RT}V} - Q_{i,c} I_{i,c} e^{-\frac{\alpha_{i,c}\lambda_{i,c}F}{RT}V} \right] \quad [8]$$

where

$$Q_{i,a} \equiv F\left(\frac{kT}{h}\right)\lambda_{i,a}\tau_{i,a}\pi(C_i^{p_i})_a\, e^{+\frac{\alpha_{i,a}\lambda_{i,a}F}{RT}(\Delta\phi_{\text{ref.}} - \psi)}$$

$$Q_{i,c} \equiv F\left(\frac{kT}{h}\right)\lambda_{i,c}\tau_{i,c}\pi(C_i^{p_i})_c\, e^{-\frac{\alpha_{i,c}\lambda_{i,c}F}{RT}(\Delta\phi_{\text{ref.}} - \psi)}$$

$$I_{i,a} \equiv \int_s e^{-\frac{(\Delta\mu_{i,a}^{\ddagger} - \alpha_{i,a}\lambda_{i,a}[(\mu_e)_M - (\mu_e)_{l'}])}{RT}} dS$$

$$I_{i,c} \equiv \int_s e^{-\frac{(\Delta\mu_{i,c}^{\ddagger} + \alpha_{i,c}\lambda_{i,c}[(\mu_e)_M - (\mu_e)_{l'}])}{RT}} dS$$

In Eq. 8, $Q_{i,a}$ and $Q_{i,c}$ are considered independent of dS, whereas the exponential terms under the integral signs of $I_{i,a}$ and $I_{i,c}$ are functions of dS. Remembering the approximate nature of the assumptions which led to the development of Eq. [8], it is possible to proceed with a derivation of formulas which

[10] See, however, the work of Busing and Kauzmann (18), who consider the possibility of a rather large variation of the electrochemical transfer coefficient over an electrode surface.

describe the behavior of certain of the simpler polyelectrode systems satisfying the conditions discussed above.

Rate and Potential in Simple Polyelectrode Systems

Frequently, and especially in corrosion systems, the situation is encountered where only two chemically distinct partial processes, one anodic and one cathodic, contribute a significant portion of the total current crossing an electrode-solution interphase. Such might be the case for the hydrogen-evolution-type corrosion of a metal. From Eqs. [5]-[8] it is seen that $\Delta\mu_{i,a}^{\ddagger}$ and $\Delta\mu_{i,c}^{\ddagger}$ are most important factors in determining rates of partial processes, and the effect of variations in these quantities over a polyelectrode surface is of interest. Variations in $\Delta\mu_{i,a}^{\ddagger}$ and $\Delta\mu_{i,c}^{\ddagger}$ are expected to occur on a real polyelectrode surface because of a number of well-known structural factors, e.g., the presence of impurities and lattice imperfections in the metal, the presentation of various crystal faces to the interphase, the existence of grain boundaries, etc. If Eq. [8] holds for such a system with two distinct partial processes, the measurable potential (V) for the case of no externally applied current ($i_P = 0$, "spontaneous" corrosion) is given by:[11]

$$V = \frac{RT}{(\alpha_a\lambda_a + \alpha_c\lambda_c)F}\left[\ln\left(\frac{Q_c}{Q_a}\right) + \ln\left(\frac{I_c}{I_a}\right)\right] \quad [9]$$

Equation [8] is soluble explicitly for V (for arbitrary values of $\alpha_a\lambda_a$ and $\alpha_c\lambda_c$) only for the present case where $i_P = 0$, but various workers have reported solutions for other specialized cases (19-21). The potential (V) of this simple corroding polyelectrode system is not related directly to the rates of the partial processes (except through the condition that $i_a = i_c$) but, apart from concentration terms, is a function primarily of the difference in the "activation energies" of the two partial processes, $\Delta\mu_a^{\ddagger} - \Delta\mu_c^{\ddagger}$. Thus, if $\Delta\mu_a^{\ddagger}$ and $\Delta\mu_c^{\ddagger}$ were constant over the polyelectrode surface, $\ln(I_c/I_a)$ would contain a term in $(\Delta\mu_a^{\ddagger} - \Delta\mu_c^{\ddagger})/RT$. If, in addition, both partial processes referred to the same over-all chemical reaction, Eq. [9] would reduce to the familiar Nernst equation of thermodynamics.

The corrosion current of this polyelectrode system, which is a measurable quantity, is given by:

$$i_a = i_c = Q_a^{\theta_c} Q_c^{\theta_a} I_a^{\theta_c} I_c^{\theta_a} \quad [10]$$

on substituting the result of Eq. [9] into the appropriate rate equations for i_a and i_c expressed in terms of V. Here, $\theta_a \equiv \dfrac{\alpha_a\lambda_a}{\alpha_a\lambda_a + \alpha_c\lambda_c}$ and $\theta_c \equiv \dfrac{\alpha_c\lambda_c}{\alpha_a\lambda_a + \alpha_c\lambda_c}$

The integrals, I_a and I_c, determine the effect of the variations in activation energies of the partial processes on the observable kinetics. Terms in $(\Delta\phi_{ref} - \psi)$, which appear in the definitions of Q_a and Q_c (cf. Eq. [8]), in order to relate the rates of partial processes to the measurable potential (V), cancel out in the result of Eq. [10]. The symmetry of this equation and the interdependence of the kinetic parameters of the two partial processes in determining rates is rather striking. Whereas the potential, V, was found to be a function primarily of the difference in the activation energies of anodic and cathodic processes, the corrosion current is a function primarily of the sum of the activation energies. Thus, if $\Delta\mu_a^{\ddagger}$ and $\Delta\mu_c^{\ddagger}$ were constant over the polyelectrode surface, i_a would be proportional to $e^{-\frac{(\theta_c\Delta\mu_a^{\ddagger} + \theta_a\Delta\mu_c^{\ddagger})}{RT}}$

When Eq. [9] is solved for $e^{+\frac{\alpha_a\lambda_a F}{RT}V}$ and $e^{-\frac{\alpha_c\lambda_c F}{RT}V}$ and these quantities are substituted into the appropriate form of Eq. [2], the net current density at dS (j_σ) is given by:

$$j_\sigma = Q_a^{\theta_c} Q_c^{\theta_a}\left[\left(\frac{I_c}{I_a}\right)^{\theta_a} e^{-\frac{(\Delta\mu_a^{\ddagger} - \alpha_a\lambda_a[(\mu_e)_M - (\mu_e)_{i'}])}{RT}} - \left(\frac{I_a}{I_c}\right)^{\theta_c} e^{-\frac{(\Delta\mu_c^{\ddagger} + \alpha_c\lambda_c[(\mu_e)_M - (\mu_e)_{i'}])}{RT}}\right] \quad [11]$$

This interesting relation shows that the net current density at dS is a function not only of the anodic and cathodic activation energies at dS but also of the kinetic variables over the rest of the polyelectrode surface. Depending mainly on the values of I_a, I_c, $\Delta\mu_a^{\ddagger}$, $\Delta\mu_c^{\ddagger}$, and $(\mu_e)_M$, j_σ may be either positive or negative. j_σ is the kinetic counterpart of the "local cell currents" of classical corrosion theory. For the case of a polyelectrode consisting of a metal of uniform composition, but with various crystal faces exposed to solution, $(\mu_e)_M$ and $\Delta\phi$ are expected to be constant over the electrode surface, whereas j_σ is free to follow the variations of $\Delta\mu_a^{\ddagger}$ and $\Delta\mu_c^{\ddagger}$ of Eq. [11]. Equation [11] provides a kinetic basis for a definition of "anodic" and "cathodic" areas on an electrode surface. At anodic areas, j_σ is positive, whereas at cathodic areas, j_σ is negative. In this definition no reference is made to the value of $\Delta\phi$ at anodic as compared to cathodic areas. It will become evident in the kinetic treatment of galvanic couples (to be discussed later) that, in fact, $\Delta\phi$ at anodic areas may be more positive, more negative, or the same as $\Delta\phi$ at cathodic areas. This may be seen also from Eq. [11] on replacing the term $[(\mu_e)_M - (\mu_e)_{i'}]$ by $F[\Delta\phi - (\phi_{i'} - \phi_S)]$, so that j_σ (and its variation over the surface) is not determined uniquely by $\Delta\phi$ (and its variation over the surface), but is a function of $\Delta\mu_a^{\ddagger}$, $\Delta\mu_c^{\ddagger}$, and $\Delta\phi$. Thus, there is no kinetic necessity for variations in the net current density (or the "local cell current") to follow (or to be "in phase" with) variations in $\Delta\phi$ over a polyelectrode surface.

As a corollary of Eq. [11], if the actual distribution of $\Delta\mu_a^{\ddagger}$, $\Delta\mu_c^{\ddagger}$, and $(\mu_e)_M$ were specifiable in algebraic form, so that I_a and I_c could be evaluated, the locus[12] of all elements of area on the electrode surface where $j_\sigma = 0$ could be obtained from:

$$(\Delta\mu_a^{\ddagger} - \Delta\mu_c^{\ddagger}) - (\alpha_a\lambda_a + \alpha_c\lambda_c)[(\mu_e)_M - (\mu_e)_{i'}] = RT\ln\left(\frac{I_c}{I_a}\right) \quad [12]$$

[11] Subscript i will be dropped in the presentation of equations pertaining to systems with only one anodic and one cathodic partial process.

[12] If $\Delta\mu_a^{\ddagger}$, $\Delta\mu_c^{\ddagger}$, and $(\mu_e)_M$ are expressed in Cartesian coordinates as functions of x and y, the values of these quantities at the point (x, y) will be considered as referring to those at the rectangular element of area dS, two adjacent sides of which have the lengths, $(x + dx) - x$ and $(y + dy) - y$. Hence, the coordinates of the point (x, y) are defined as the locus of the element of area, $dS = dxdy$.

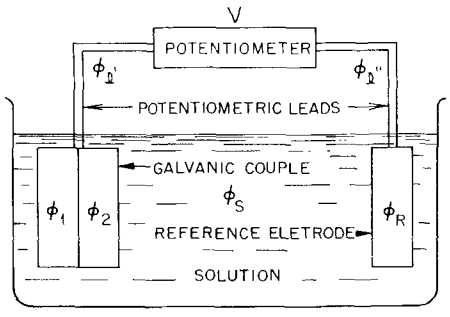

Fig. 2. Schematic diagram of typical circuit for the measurement of electrode potentials of galvanic couples.

In the more general case of externally applied current ($i_P \neq 0$), values of j_a, and thus the locus of elements of area where $j_a = 0$ (hence also the ratio of anodic to cathodic areas, defined as above), are functions of i_P. For purposes of illustration, a numerical example based on a continuous distribution of activation energies of partial processes over a polyelectrode surface is presented in the appendix to this paper.

Kinetics of Galvanic Couples under Activation Control

The kinetics of a special case of a polyelectrode system wherein two metallic electrodes may be connected together (shorted) in the same solution as a galvanic couple can be derived on the basis of propositions discussed above. An appropriate circuit for electrode potential measurements on a galvanic couple is presented in Fig. 2. Here (cf. Fig. 1), the measurable potential difference is $V_n = (\phi_{l'} - \phi_{l''}) = (\phi_{l'} - \phi_n) + (\phi_n - \phi_S) - (\phi_{l''} - \phi_R) - (\phi_R - \phi_S)$, where subscript n refers to metal 1 or metal 2. On setting $(\phi_{l'} - \phi_n) = \frac{1}{F}[(\mu_e)_{l'} - (\mu_e)_n]$ because of electronic equilibrium between one potentiometer lead (l') and the metal n, setting $(\phi_n - \phi_S) \equiv \Delta\phi_n$, and setting $(\phi_{l''} - \phi_R) + (\phi_R - \phi_S) \equiv \Delta\phi_{ref}$, it follows that $V_n = \frac{1}{F}[(\mu_e)_{l'} - (\mu_e)_n] + \Delta\phi_n - \Delta\phi_{ref.}$.

It will be assumed that only two partial processes under activation control, one anodic and one cathodic, occur at each electrode, and that all the assumptions considered in the derivation of Eqs. [9]-[12] apply here also. In addition, it is assumed that the rate constants of the partial processes are constant over the surface of each of the electrodes (although different rate constants will be assumed for each electrode). With these conventions, it is possible to derive formulas for quantities of interest for the cases in which each electrode is isolated and in which both electrodes are shorted together. The anodic (corrosion) current ($i^0_{n,a}$) and the cathodic current ($i^0_{n,c}$) of the metals in the unshorted state[13] are given by:

$$i^0_{n,a} = S_n K_{n,a} e^{+\frac{\lambda F}{2RT}\Delta\phi^0_n} \qquad [13]$$

and

$$i^0_{n,c} = S_n K_{n,c} e^{-\frac{\lambda F}{2RT}\Delta\phi^0_n} \qquad [14]$$

[13] Superscript zero refers to quantities pertaining to the unshorted electrodes, while superscript asterisk pertains to the shorted state.

Here, S_n is the area of metal 1 or metal 2, $K_{n,a}$ and $K_{n,c}$ include activation energies and concentrations of reactants,[14] and $\Delta\phi^0_n$ is the metal-solution potential difference of metal 1 or metal 2 in the unshorted state. It is assumed that the symmetry factors and the electrochemical transfer coefficients of all partial processes in the system are identical; specifically, α equals ½ and λ is common to all partial processes. Since $i^0_{n,a} = i^0_{n,c}$ for metals 1 and 2 when unshorted, it follows from Eqs. [13] and [14] that:

$$\Delta\phi^0_n = \frac{RT}{\lambda F}\ln\left(\frac{K_{n,c}}{K_{n,a}}\right) \qquad [15]$$

The measurable electrode potential (V^0_n) of the unshorted metals is given by:

$$V^0_n = \frac{1}{F}[(\mu_e)_{l'} - (\mu_e)_n] - \Delta\phi_{ref.} + \frac{RT}{\lambda F}\ln\left(\frac{K_{n,c}}{K_{n,a}}\right) \qquad [16]$$

When the result of Eq. [15] is substituted into Eqs. [13] and [14], $i^0_{n,a}$ and $i^0_{n,c}$ are given by:

$$i^0_{n,a} = i^0_{n,c} = S_n(K_{n,a}K_{n,c})^{1/2} \qquad [17]$$

From Eqs. [15] and [16], the difference in the measurable potentials of the unshorted metals is related to the difference in the interfacial potential differences or to the K's by:

$$(V_2^0 - V_1^0) = \frac{1}{F}[(\mu_e)_1 - (\mu_e)_2] + (\Delta\phi_2^0 - \Delta\phi_1^0) = \frac{1}{F}[(\mu_e)_1 - (\mu_e)_2] + \frac{RT}{\lambda F}\ln\left(\frac{K_{1,a}K_{2,c}}{K_{2,a}K_{1,c}}\right) \qquad [18]$$

It is apparent from Eq. [18] that the sign of $(V_2^0 - V_1^0)$ is not necessarily the same as the sign of $(\Delta\phi_2^0 - \Delta\phi_1^0)$ and that, in fact, measurements of $(V_2^0 - V_1^0)$ alone give no information about $(\Delta\phi_2^0 - \Delta\phi_1^0)$. If $(V_2^0 - V_1^0)$ is positive, then $(\Delta\phi_2^0 - \Delta\phi_1^0)$ may be negative provided $\frac{1}{F}[(\mu_e)_1 - (\mu_e)_2]$ is sufficiently positive. On the basis of Lange's definitions (16, 17) and on the condition that the metals be nonpolarizable, the term $[(\mu_e)_1 - (\mu_e)_2]$ depends only on the composition and structure of the two metals in contact and is independent of the environment and of the events occurring at the metal-solution interphases.

When the two electrodes are connected together, the measurable electrode potential of the resulting galvanic couple (V^*)[13] is given by:

$$V^* = V_1^* = V_2^* = \frac{RT}{\lambda F}\ln \frac{\left[S_1(K_{1,a}K_{1,c})^{1/2}e^{+\frac{\lambda F}{2RT}V_1^0} + S_2(K_{2,a}K_{2,c})^{1/2}e^{+\frac{\lambda F}{2RT}V_1^0}\right]}{\left[S_1(K_{1,a}K_{1,c})^{1/2}e^{-\frac{\lambda F}{2RT}V_1^0} + S_2(K_{2,a}K_{2,c})^{1/2}e^{-\frac{\lambda F}{2RT}V_2^0}\right]} \qquad [19]$$

[14] In terms of previously defined quantities,

$$K_{n,a} = F\left(\frac{kT}{h}\right)\lambda\tau_{na}\pi(C_i^{p_i})_{n,a}e^{-\frac{\Delta\mu^{\ddagger}_{n,a}}{RT}}e^{-\frac{\lambda F}{2RT}\psi_n}$$

and $K_{n,c} = F\left(\frac{kT}{h}\right)\lambda\tau_{nc}\pi(C_i^{p_i})_{n,c}e^{-\frac{\Delta\mu^{\ddagger}_{n,c}}{RT}}e^{+\frac{\lambda F}{2RT}\psi_n}$. $K_{n,a}$ and $K_{n,c}$ have the dimensions of current density and, from Eqs. [13] and [14], are merely the current densities of the respective partial processes when $\Delta\phi_n = 0$.

Equation [19] gives the electrode potential of a galvanic couple in terms of the electrode potentials of the unshorted metals and the currents crossing the interphases of the metals when unshorted (cf. Eq. [17]). If metals 1 and 2 were both reversible electrodes when unshorted, the terms $S_1(K_{1,a}K_{1,c})^{1/2}$ and $S_2(K_{2,a}K_{2,c})^{1/2}$ would be merely the exchange currents of the respective systems. If $S_1(K_{1,a}K_{1,c})^{1/2} > S_2(K_{2,a}K_{2,c})^{1/2}$, V^* will have a value nearer to V_1^0 than to V_2^0. In the limit, if $S_1(K_{1,a}K_{1,c})^{1/2}$ is much larger than $S_2(K_{2,a}K_{2,c})^{1/2}$, then V^* will be approximately the same as V_1^0.

The total anodic (corrosion) current or total cathodic current of both electrodes in the shorted state is given by:

$$i_a^* = i_{1,a}^* + i_{2,a}^* = i_c^* = i_{1,c}^* + i_{2,c}^* =$$

$$\left[S_1^2 K_{1,a}K_{1,c} + S_1S_2\{K_{1,a}K_{1,c}K_{2,a}K_{2,c}\}^{1/2}\left\{ e^{+\frac{\lambda F}{2RT}(V_2^0 - V_1^0)} + e^{-\frac{\lambda F}{2RT}(V_2^0 - V_1^0)} \right\} + S_2^2 K_{2,a}K_{2,c} \right]^{1/2} \quad [20]$$

In terms of $(\phi_1^* - \phi_2^*)$, the difference in the inner potentials of metals 1 and 2 in the shorted state, Eq. [20] becomes:

$$i_a^* = i_c^* = \left[S_1^2 K_{1,a}K_{1,c} + S_1S_2\left\{ K_{1,a}K_{2,c}\, e^{+\frac{\lambda F}{2RT}(\phi_1^* - \phi_2^*)} + K_{2,a}K_{1,c}\, e^{-\frac{\lambda F}{2RT}(\phi_1^* - \phi_2^*)} \right\} + S_2^2 K_{2,a}K_{2,c} \right]^{1/2} \quad [20']$$

The term $(\phi_1^* - \phi_2^*)$ of Eq. [20'] is equivalent to $(\Delta\phi_1^* - \Delta\phi_2^*)$, the difference in the interfacial potential differences of the two shorted metals. For the case that $V_1^0 = V_2^0$, no change would occur in the system on shorting the metals, and Eq. [20] reduces to $i_a^* = i_c^* = S_1(K_{1,a}K_{1,c})^{1/2} + S_2(K_{2,a}K_{2,c})^{1/2} = i_{1,a}^0 + i_{2,a}^0 = i_{1,c}^0 + i_{2,c}^0$. In the limiting case where $S_1(K_{1,a}K_{1,c})^{1/2}$ is very much greater than $S_2(K_{2,a}K_{2,c})^{1/2}$, Eq. [20] reduces to $i_a^* \cong S_1(K_{1,a}K_{1,c})^{1/2} = i_{1,a}^0$, in which case the corrosion rate of metal 1 would be scarcely changed on shorting to metal 2. The term $F(\phi_1^* - \phi_2^*)$ of Eq. [20'] may be replaced by $[(\mu_e)_1 - (\mu_e)_2]$, which is a constant depending only on the composition and structure of the two metals in contact.

In the shorted state, the net current crossing the interphase of metal 1 ($i_{1,N}^*$) is equal but of opposite sign to the net current crossing the interphase of metal 2 ($i_{2,N}^*$). These net currents are given by:

$$i_{1,N}^* = i_{1,a}^* - i_{1,c}^* = -i_{2,N}^* = i_{2,c}^* - i_{2,a}^* = \text{(see below)}$$

In terms of $(\phi_1^* - \phi_2^*)$, Eq. [21] becomes: (see [21'])

$$\frac{S_1S_2\left\{K_{1,a}K_{1,c}K_{2,a}K_{2,c}\right\}^{1/2}\left\{ e^{+\frac{\lambda F}{2RT}(V_2^0 - V_1^0)} - e^{-\frac{\lambda F}{2RT}(V_2^0 - V_1^0)} \right\}}{\left[S_1^2 K_{1,a}K_{1,c} + S_1S_2\left\{K_{1,a}K_{1,c}K_{2,a}K_{2,c}\right\}^{1/2}\left\{ e^{+\frac{\lambda F}{2RT}(V_2^0 - V_1^0)} + e^{-\frac{\lambda F}{2RT}(V_2^0 - V_1^0)} \right\} + S_2^2 K_{2,a}K_{2,c} \right]^{1/2}} \quad [21]$$

Equation [21'] shows that, for a galvanic couple, the sign of the net current $i_{1,N}^*$ (which is equivalent to the "local cell current" of classical theory) is a function of, but certainly is not uniquely determined by, the sign of $(\phi_1^* - \phi_2^*)$, or its equivalent $(\Delta\phi_1^* - \Delta\phi_2^*)$, the difference in the interfacial potential differences of the shorted metals. If $i_{1,N}^*$ is positive, $\Delta\phi_1^*$ may be more positive than $\Delta\phi_2^*$ provided the K's have appropriate values, even though V_2^0 is more positive than V_1^0. If $V_1^0 = V_2^0$, then obviously $i_{1,N}^* = -i_{2,N}^* = 0$. For the case where $S_1(K_{1,a}K_{1,c})^{1/2}$ is very much greater than $S_2(K_{2,a}K_{2,c})^{1/2}$, then from Eq. [19] metal 2 is polarized nearly to the potential of unshorted metal 1 and Eq. [21] reduces to $i_{1,N}^* \cong S_2(K_{2,a}K_{2,c})^{1/2}\left\{ e^{+\frac{\lambda F}{2RT}(V_2^0 - V_1^0)} - e^{-\frac{\lambda F}{2RT}(V_2^0 - V_1^0)} \right\}$, so that the net current here depends primarily on the current crossing the interphase of unshorted metal 2 and the difference in the unshorted potentials.

$$i_{1,N}^* = -i_{2,N}^* = \frac{S_1S_2\left\{K_{1,a}K_{2,c}\, e^{+\frac{\lambda F}{2RT}(\phi_1^* - \phi_2^*)} - K_{2,a}K_{1,c}\, e^{-\frac{\lambda F}{2RT}(\phi_1^* - \phi_2^*)}\right\}}{\left[S_1^2 K_{1,a}K_{1,c} + S_1S_2\left\{K_{1,a}K_{2,c}\, e^{+\frac{\lambda F}{2RT}(\phi_1^* - \phi_2^*)} + K_{2,a}K_{1,c}\, e^{-\frac{\lambda F}{2RT}(\phi_1^* - \phi_2^*)}\right\} + S_2^2 K_{2,a}K_{2,c} \right]^{1/2}} \quad [21']$$

From Eqs. [20] and [21], the ratio of the current flowing between the shorted metals to the total anodic (corrosion) current is given by:

$$\frac{i_{1,N}^*}{i_a^*} = -\frac{i_{2,N}^*}{i_a^*} = \frac{i_{1,N}^*}{i_c^*} = -\frac{i_{2,N}^*}{i_c^*} = \text{(see [22] below)}$$

The value of this ratio may lie anywhere between 0 and 1, depending on the values of the various kinetic parameters. A similar expression in terms of $(\phi_1^* - \phi_2^*)$ is derivable from Eqs. [20'] and [21'].

The anodic (corrosion) current of metal 1 in the shorted state is given by:

$$i_{1,a}^* = S_1(K_{1,a}K_{1,c})^{1/2} \frac{\left[S_1(K_{1,a}K_{1,c})^{1/2} + S_2(K_{2,a}K_{2,c})^{1/2} e^{+\frac{\lambda F}{2RT}(V_2^0 - V_1^0)} \right]^{1/2}}{\left[S_1(K_{1,a}K_{1,c})^{1/2} + S_2(K_{2,a}K_{2,c})^{1/2} e^{-\frac{\lambda F}{2RT}(V_2^0 - V_1^0)} \right]^{1/2}} \quad [23]$$

From Eqs. [17] and [23], the ratio of the corrosion current of shorted metal 1 to the corrosion current of the same metal in the unshorted state is:

$$\frac{S_1S_2\left\{K_{1,a}K_{1,c}K_{2,a}K_{2,c}\right\}^{1/2}\left\{ e^{+\frac{\lambda F}{2RT}(V_2^0 - V_1^0)} - e^{-\frac{\lambda F}{2RT}(V_2^0 - V_1^0)} \right\}}{\left[S_1^2 K_{1,a}K_{1,c} + S_1S_2\left\{K_{1,a}K_{1,c}K_{2,a}K_{2,c}\right\}^{1/2}\left\{ e^{+\frac{\lambda F}{2RT}(V_2^0 - V_1^0)} + e^{-\frac{\lambda F}{2RT}(V_2^0 - V_1^0)} \right\} + S_2^2 K_{2,a}K_{2,c} \right]} \quad [22]$$

$$\frac{i_{1,a}^*}{i_{1,a}^0} = \frac{\left[S_1(K_{1,a}K_{1,c})^{1/2} + S_2(K_{2,a}K_{2,c})^{1/2} e^{+\frac{\lambda F}{2RT}(V_2^0 - V_1^0)}\right]^{1/2}}{\left[S_1(K_{1,a}K_{1,c})^{1/2} + S_2(K_{2,a}K_{2,c})^{1/2} e^{-\frac{\lambda F}{2RT}(V_2^0 - V_1^0)}\right]^{1/2}} \quad [24]$$

For the limiting case where $V_2^0 >> V_1^0$, Eq. [24] becomes:

$$\frac{i_{1,a}^*}{i_{1,a}^0} \simeq \left[\frac{S_2(K_{2,a}K_{2,c})^{1/2}}{S_1(K_{1,a}K_{1,c})^{1/2}}\right]^{1/2} e^{+\frac{\lambda F}{4RT}(V_2^0 - V_1^0)} \quad [25]$$

Equation [25] shows how the corrosion current of metal 1 increases on shorting to a metal of much higher (measurable) electrode potential. For the limiting case where $V_1^0 >> V_2^0$, Eq. [24] becomes:

$$\frac{i_{2,a}^*}{i_{1,a}^0} \simeq \left[\frac{S_1(K_{1,a}K_{1,c})^{1/2}}{S_2(K_{2,a}K_{2,c})^{1/2}}\right] e^{-\frac{\lambda F}{4RT}(V_1^0 - V_2^0)} \quad [26]$$

This case corresponds to "cathodic protection" of metal 1 on shorting to another metal of much lower (measurable) electrode potential.

For the case, $V_2^0 >> V_1^0$, the corrosion current of shorted metal 1 ($i_{1,a}^*$) is found from Eq. [23] or from Eqs. [17] and [25] to be:

$$i_{1,a}^* \simeq (S_1S_2)^{1/2}(K_{1,a}K_{1,c}K_{2,a}K_{2,c})^{1/4} e^{+\frac{\lambda F}{4RT}(V_2^0 - V_1^0)} \quad [27]$$

It may be seen also from Eqs. [20] and [21] that, for this same assumption ($V_2^0 >> V_1^0$), $i_{1,a}^* \simeq i_{1,N}^* \simeq i_a^*$. That is, provided the kinetic parameters have suitable values and metal 1 is shorted to a second metal of much higher electrode potential, the corrosion current of shorted metal 1 is virtually identical to both the net current flowing from metal 1 and the total corrosion current of both electrodes. This limiting case apparently corresponds to situations which led to the development of the classical "local-cell" hypothesis of the corrosion of metals in solution. It should be noted that Eqs. [19]-[27], containing V_1^0 and V_2^0 (which are measurable quantities), also contain the factors, $S_1(K_{1,a}K_{1,c})^{1/2}$ and $S_2(K_{2,a}K_{2,c})^{1/2}$. These latter factors may be replaced by their equivalents, $i_{1,a}^0$ and $i_{2,a}^0$ (cf. Eq. [17])[15]. The quantities $i_{1,a}^0$ and $i_{2,a}^0$ (the corrosion currents of the respective metals in the unshorted state) are measurable in principle by either direct chemical or electrochemical means. Hence all these equations may be expressed in terms of measurable quantities.

The equations derived above may be considered as special cases of the more general treatment discussed earlier. In particular, appropriate forms of Eqs. [9], [10], and [11] are equivalent to Eqs. [19], [20], and [21], respectively. It should be remembered that the expressions derived in this section pertain only to one of the simplest possible cases of a galvanic couple and that drastic assumptions about the values of particular kinetic parameters were invoked in order to obtain explicit equations for the various quantities of interest. However, it is expected that systems of greater complexity will behave in a manner qualitatively similar to that predicted by the present analysis.[16,17] In this sense, it is hoped that the ideas presented will prove to be useful as a kinetic basis for interpreting studies on galvanic couples.

[15] For example, in terms of $i_{1,a}^0$ and $i_{2,a}^0$, Eq. [20] assumes the simple form: $i_a^* = \left\{(i_{1,a}^0)^2 + (i_{1,a}^0)(i_{2,a}^0)\left\{e^{+\frac{\lambda F}{2RT}(V_2^0 - V_1^0)} + e^{-\frac{\lambda F}{2RT}(V_2^0 - V_1^0)}\right\} + (i_{2,a}^0)^2\right\}^{1/2}$.

Polarizability of Polyelectrode Systems

The remainder of this paper is concerned with the interpretation of some types of steady-state measurements on polyelectrode systems under activation control. It is often convenient to perform three complementary operations on a system; these are: (*a*) polarizability measurements, (*b*) potentiostatic measurements, and (c) galvanostatic measurements. The equations presented below which describe these operations are expressed in terms of the surface average current densities of the respective partial processes, $\overline{j_i} \equiv \frac{1}{S}\int_s j_i dS$ (see Eq. [1] for definition of j_i). With this convention, and the assumptions leading to Eq. [8], the applied current of a polyelectrode system is given by $i_P = S\sum_i[\overline{j_{i,a}} - \overline{j_{i,c}}]$ and the applied current density is $j_P = \sum_i[\overline{j_{i,a}} - \overline{j_{i,c}}]$.[18]

The "polarizability" of an electrode will be defined here as the derivative of the (measurable) electrode potential, V (cf. Fig. 1), with respect to any one of the four quantities: (*a*) the applied current (i_P), (*b*) the applied current density (j_P), (c) the logarithm of the applied current, and (*d*) the logarithm of the applied current density. Differentiation of Eq. [8] for the above cases and substitution of the definitions of $\overline{j_{i,a}}$ and $\overline{j_{i,c}}$ lead to the equations:[19]

$$\left(\frac{\partial V}{\partial i_P}\right) = \frac{RT}{F}\left[S\sum_i\{\alpha_{i,a}\lambda_{i,a}\overline{j_{i,a}} + \alpha_{i,c}\lambda_{i,c}\overline{j_{i,c}}\}\right]^{-1} \quad [28]$$

$$\left(\frac{\partial V}{\partial j_P}\right) = \frac{RT}{F}\left[\sum_i\{\alpha_{i,a}\lambda_{i,a}\overline{j_{i,a}} + \alpha_{i,c}\lambda_{i,c}\overline{j_{i,c}}\}\right]^{-1} \quad [29]$$

[16] See, in this connection, the interesting analysis of Shultin (22) on the relative importance of the several factors (e.g., activation and diffusion control of partial processes and ohmic resistance of the solution) which influence the corrosion rate of a galvanic couple.

[17] The preceding analysis should hold also for the appropriate case where an active metal (two-phase system) is shorted to a passive metal (three-phase system) if all the rate-determining charge transfer steps in the passive metal system occur at the same interphase (e.g., the oxide-solution interphase).

[18] Using the nomenclature of Eq. [8] $\overline{j_{i,a}} = \frac{1}{S}Q_{i,a}I_{i,a}e^{+\frac{a_{i,a}\lambda_{i,a}F}{RT}V}$ and $\overline{j_{i,c}} = \frac{1}{S}Q_{i,c}I_{i,c}e^{-\frac{a_{i,c}\lambda_{i,c}F}{RT}V}$. The assumptions of Eq. [8] equated the current density of a charge transfer step, j_i, to the current density of the associated partial process. However, Eqs. [28]-[30], subject to the assumption that the electrochemical transfer coefficients of charge transfer steps are invariant, also describe the more general case where mechanisms of partial processes involve several charge transfer steps. In this case, $\overline{j_{i,a}}$ and $\overline{j_{i,c}}$ may be interpreted as the surface average current densities of the respective charge transfer steps.

[19] $\left(\frac{\partial V}{\partial \ln i_P}\right)$, of course, is equal to $\left(\frac{\partial V}{\partial \ln j_P}\right)$, and the electrode area, S, cancels out in the derivation of Eq. [30].

$$\left(\frac{\partial V}{\partial \ln i_P}\right) = \left(\frac{\partial V}{\partial \ln j_P}\right) = \frac{RT}{F} \frac{\sum_i [\overline{j_{i,a}} - \overline{j_{i,c}}]}{[\sum_i \{\alpha_{i,a}\lambda_{i,a}\overline{j_{i,a}} + \alpha_{i,c}\lambda_{i,c}\overline{j_{i,c}}\}]} \quad [30]$$

Polarizability measurements usually find importance in the determination of the rates and the electrochemical transfer coefficients ($\alpha_i\lambda_i$) of partial processes. If, in some range of electrode potentials, the rate of one partial process ($\overline{j_x}$) greatly exceeds those of all other processes occurring at the same interphase, Eq. [30] reduces to:

$$\left|\left(\frac{\partial V}{\partial \ln j_P}\right)\right| = \frac{RT}{F} \cdot \frac{1}{\alpha_x\lambda_x} \quad [31]$$

Equation [31] is just the differential form of the well-known Tafel relation. Generally, however, for systems with several partial processes of comparable rates, there may exist no accessible range of electrode potentials where the rate of one process predominates, so that the more general relationship, Eq. [30], must be used.

A relationship between the polarizability of a corroding polyelectrode and its corrosion rate, $\overline{j_{corr}}$, at the steady-state corrosion potential ($V_{corr.}$) is derivable from Eq. [29]. If it is assumed that all anodic processes are corrosion processes, and ξ_a and ξ_c are dimensionless constants such that $\sum_i \alpha_{i,a}\lambda_{i,a}\overline{j_{i,a}} \equiv \xi_a \cdot \sum_i \overline{j_{i,a}}$ and $\sum_i \alpha_{i,c}\lambda_{i,c}\overline{j_{i,c}} \equiv \xi_c \cdot \sum_i \overline{j_{i,c}}$, then, on recognizing that $\overline{j_{corr.}} = \sum_i \overline{j_{i,a}} = \sum_i \overline{j_{i,c}}$ at V_{corr}, Eq. [29] can be rearranged to give:[20]

$$\overline{j_{corr.}} = \frac{RT}{F} \cdot \frac{1}{(\xi_a + \xi_c)} \cdot \frac{1}{\left(\frac{\partial V}{\partial j_P}\right)_{V_{corr.}}} \quad [32]$$

Here, the term $(\xi_a + \xi_c)$ has a value which is of the order of magnitude of unity for corroding polyelectrodes under activation control. For a simple polyelectrode system having only one anodic and one cathodic partial process, $(\xi_a + \xi_c) = (\alpha_a\lambda_a + \alpha_c\lambda_c)$. The exact value of $(\xi_a + \xi_c)$ is a function of the particular system, depending both on the identity of the metal and on the composition of the solution. Equation [32] may be used to estimate corrosion rates from polarizability measurements to an accuracy of a small numerical factor for corroding polyelectrode systems under activation control. Alternatively, in studying relative corrosion rates of a series of alloys of similar compositions, it may be possible to determine the factor $\frac{RT}{F} \cdot \frac{1}{(\xi_a + \xi_c)}$ experimentally and to use the resulting value in Eq. [32] to estimate corrosion rates for the series in a constant environment.[21]

Potentiostatic Measurements on Polyelectrode Systems

This section and the following one are concerned with the information obtainable from electrical measurements on polyelectrode systems when the concentration of one of the reactants in the system can be varied. One of the important parameters of electrochemical kinetics is the kinetic order (p_x) of a partial process with respect to the concentration of one of its reactants (C_x).[22] For a situation in which V is held constant while the concentration of one of the reactants (C_x) in the system is varied, it can be shown from Eq. [8] that p_x is given by:

$$\left(\frac{\partial \ln |\, i_P - i_{P,0}\,|}{\partial \ln C_x}\right)_V = p_x \quad [33]$$

Here, i_P is the current applied to the polyelectrode which is necessary to maintain the (measurable) electrode potential (V) constant in the presence of some amount, C_x, of the reactant under study. $i_{P,0}$ is the applied current at the same potential before additions of x (or for a known amount of x already present). Precautions are necessary that additions of x do not change appreciably the ionic strength of the solution or the structure of the double layer at constant V; i.e., experiments should be performed in an excess of an inert electrolyte. The procedure embodied in Eq. [33] is equivalent to the method of isolation long used to determine reaction orders in ordinary chemical kinetics.

An assumption implicit in Eq. [33] is that electrode processes other than x proceed independently of C_x, at constant V. It is in providing an experimental test of this assumption that potentiostatic experiments find considerable value. Plots of $\ln |\, i_P - i_{P,0}\,|$ vs. $\ln C_x$ can exhibit linearity only if $i_{P,0}$ is independent of C_x; i.e., linearity will be obtained if the processes initially present in the system proceed with unchanged rates regardless of the value of C_x. Nonlinearity of the plots does not necessarily obviate the model for a given electrode system but may merely indicate that new paths are being provided for the reactions initially present in the system on the introduction of x.[23] A series of potentiostatic experiments conducted at various potentials yields a spectrum of relations among V, C_x, and $\overline{i_x}(\equiv |\, i_P - i_{P,0}\,|)$. These data lead immediately to the same information ($\alpha_x\lambda_x$ and $\overline{i_x}$ as a function of V) obtainable from the usual procedure of direct analysis of the rates of partial processes and use of the Tafel relation, Eq. [31].[24]

[20] An expression similar to Eq. [32] has also been derived by Stern (23) for the case of a simple corroding polyelectrode with one anodic and one cathodic partial process

[21] An inverse relationship between corrosion rate and polarizability at V_{corr} was noted by Bonhoeffer and Jena (24), Simmons (25), and Skold and Larson (26). The data of Bonhoeffer and Jena on the corrosion of iron and carbon steels in acid environments are described well by Eq. [32]. The systems studied by Skold and Larson apparently were not under pure activation control (and probably were not simple two-phase systems), and Eq. [32] describes their data only qualitatively.

[22] Subscript x will be used in this section and the following one to denote both the reactant and the partial process in which it participates. C_x and p_x are as defined in the discussion of Eq. [1].

[23] Conceivably the situation may arise where more than one new partial process is encountered on additions of x (e.g., x may react by alternative paths of comparable rates). In this case, Eq. [33] will contain additional terms (as can be verified by solving Eq. [8] for such a situation) which may cause plots of $\ln|i_P - i_{P,0}|$ vs. $\ln C_x$ to consist of two (or perhaps more) linear portions, if the new, alternative paths possess different orders (p_x) with respect to C_x. If, in addition, the alternative paths possess different electrochemical transfer coefficients ($\alpha_x\lambda_x$), the projection of the point(s) of intersection of the linear portions of these plots on the concentration axis will vary with V, the potential chosen for observation.

[24] Equation [33] holds also in the event that the reaction of x proceeds by alternative and/or consecutive charge transfer steps (if each step has the same value of p_x). However, two (or perhaps more) linear portions in the Tafel-type plot of V vs. $\ln \overline{i_x}$ (at constant C_x) may then be obtained, and for this case the observed value of $\frac{F}{RT}\left|\left(\frac{\partial V}{\partial \ln \overline{i_x}}\right)\right|$ on any one linear portion may not equal the electrochemical transfer coefficient ($\alpha_x\lambda_x$) of a single step in the partial process (cf. Eq. [31]) but may be a function of the values of the electrochemical transfer coefficients of two (or more) charge transfer steps of the partial process, as has been demonstrated by workers in the field of hydrogen overvoltage.

Galvanostatic Measurements on Polyelectrode Systems

It is known that the addition of oxidizable or reducible substances to polyelectrode systems affects the electrode potential. It has been found in some cases (27, 28) that the electrode potential of a corrosion system increases linearly with the logarithm of the concentration of the added (reducible) constituent, at least at higher concentrations. This behavior is predictable for polyelectrode systems under activation control. Let the current density applied to a polyelectrode be given by the expression, $j_P = \sum_i \bar{j}_{i,a} - \sum_i \bar{j}_{i,c} \pm \bar{j}_x$, where $\bar{j}_x$ is the (surface average) current density of the added constituent[18,22] and plus or minus signs denote an anodic or cathodic partial process, respectively. Then the slope of the relationship between V and $\ln C_x$ at constant applied current density (j_P) is given by:

$$\left(\frac{\partial V}{\partial \ln C_x}\right)_{j_P} = \pm\frac{RT}{F}\left[\frac{\bar{p}_x \bar{j}_x}{\sum_i\{\alpha_{i,a}\lambda_{i,a}\bar{j}_{i,a} + \alpha_{i,c}\lambda_{i,c}\bar{j}_{i,c}\} + \alpha_x\lambda_x\bar{j}_x}\right] \quad [34]$$

Here, the minus or plus sign is employed according to whether the additional partial process is anodic or cathodic, respectively. Generally, the magnitude of the slope, $\left(\frac{\partial V}{\partial \ln C_x}\right)_{j_P}$, is a function of C_x, but for certain important special cases, it may be a constant; some of these special cases are noted below.

Consider the case of a simple polyelectrode system having only one anodic and one cathodic partial process, but in which a third cathodic process is introduced by the addition of a reducible constituent (x). Equation [34] then becomes:

$$\left(\frac{\partial V}{\partial \ln C_x}\right)_{j_P} = \frac{RT}{F}\left[\frac{p_x\bar{j}_x}{\alpha_a\lambda_a\bar{j}_a + \alpha_c\lambda_c\bar{j}_c + \alpha_x\lambda_x\bar{j}_x}\right] \quad [35]$$

As C_x is increased, $\bar{j}_x$ may become much larger than $\bar{j}_c$, so that j_P is given approximately by $j_P \simeq \bar{j}_a - \bar{j}_x$, and Eq. [35] becomes:

$$\left(\frac{\partial V}{\partial \ln C_x}\right)_{j_P} \simeq \frac{RT}{F} p_x\left[\alpha_x\lambda_x + \alpha_a\lambda_a\left(1 + \frac{j_P}{\bar{j}_x}\right)\right]^{-1} \quad [36]$$

It can be seen from Eq. [36] that, for zero applied current, $\left(\frac{\partial V}{\partial \ln C_x}\right)_{j_P=0}$ is independent of C_x when $\bar{j}_x >> \bar{j}_c$ and is a function only of $\alpha_a\lambda_a$, $\alpha_x\lambda_x$, and p_x. However, both $\alpha_x\lambda_x$ and p_x are obtainable from a series of potentiostatic measurements, as noted in the previous section. Hence, the electrochemical transfer coefficient of the anodic partial process ($\alpha_a\lambda_a$) is calculable from Eq. [36] and potentiostatic data on the same system. If the applied current is large and negative ($j_P << 0$), for the case $\bar{j}_x >> \bar{j}_c$, then $\bar{j}_P \simeq -\bar{j}_x$, and Eq. [36] becomes:

$$\left(\frac{\partial V}{\partial \ln C_x}\right)_{j_P} \simeq \frac{RT}{F}\cdot\frac{p_x}{\alpha_x\lambda_x} \quad [37]$$

Under these conditions, the galvanostatic measurements can provide a check on the results of potentiostatic measurements on the same system.

The preceding kinetic analysis has been limited to two-phase polyelectrode systems in a steady state having partial processes under pure activation control. As such, it obviously is not applicable quantitatively to every polyelectrode system or galvanic couple which may be encountered in the laboratory, since no account has been taken of the influence of diffusion or other situation of mixed rate control of partial processes. It can be expected to serve as a starting point for the treatment of systems of greater complexity, however, and as a kinetic basis for the qualitative interpretation of observations on corrosion systems. The results of an experimental investigation on a particular corroding polyelectrode system, using the theory and techniques outlined here, will be presented in a subsequent report.

APPENDIX I

Numerical Example of Polyelectrode with Continuous Distribution of Partial Process Activation Energies

Consider the case of a two-phase simple polyelectrode system with one anodic and one cathodic partial process. For the particular case that $\alpha_a\lambda_a = \alpha_c\lambda_c = \alpha\lambda$, explicit expressions are derivable from Eq. [8] for various quantities of interest as a function of the applied current (i_P). These are given by the equations below in which the function, Z, appears. Z takes account of the influence of the integrals, I_a and I_c, and of the applied current on the system, and the use of Z leads to simple forms of the equations for the various quantities of interest. The electrode potential of the system may be derived from Eq. [8] as:[25]

$$V = \frac{RT}{\alpha\lambda F}\ln Z$$

where

$$Z \equiv \left(\frac{i_P + \sqrt{i_P^2 + 4Q_aQ_cI_aI_c}}{2Q_aI_a}\right) \quad [38]$$

The total anodic and cathodic currents in the system are given as a function of Z and thus of i_P by:

$$i_a = Q_aI_aZ \quad [39]$$

$$i_c = \frac{Q_cI_c}{Z} \quad [40]$$

The net current density at dS (j_σ) is given by:

$$j_\sigma = Q_aZ\,e^{-\frac{A_a}{RT}} - \frac{Q_c}{Z}e^{-\frac{A_c}{RT}} \quad [41]$$

where A_a and A_c are given in the nomenclature of Eq. [8] by $A_a \equiv \Delta\mu_a^\ddagger - \alpha\lambda[(\mu_e)_M - (\mu_e)_{i'}]$ and $A_c \equiv \Delta\mu_c^\ddagger + \alpha\lambda[(\mu_e)_M - (\mu_e)_{i'}]$, so that $I_a \equiv \int_s e^{-\frac{A_a}{RT}}\,dS$ and $I_c \equiv \int_s e^{-\frac{A_c}{RT}}\,dS$. Finally, the equation of the locus of elements of area on the electrode surface[12] where $j_\sigma = 0$ follows from Eq. [41] as:

$$A_a - A_c = RT\ln\left(\frac{Q_a}{Q_c}Z^2\right) \quad [42]$$

[25] The minus sign is omitted before the square root symbol in the function, Z, of Eq. [38] since $Z = e^{\frac{\alpha\lambda F}{RT}V}$ must be a positive quantity for all values of V.

Table I. Certain quantities pertaining to numerical example

i_P (applied current), amp	V, v	i_a (corrosion current), amp	$i(+) \equiv \int_S j_\sigma(+)dS$, amp	$\frac{i_a}{i(+)}$	Locus where $j_\sigma = 0$, cm
$+6 \times 10^{-3}$	+0.307	6.72×10^{-3}	6.00×10^{-3}	1.12	—
$+1 \times 10^{-3}$	+0.261	2.75×10^{-3}	1.45×10^{-3}	1.90	0.504
±0.00	+0.249	2.20×10^{-3}	8.09×10^{-4}	2.71	0.371
-1×10^{-3}	+0.237	1.75×10^{-3}	3.47×10^{-4}	5.05	0.237
-3×10^{-3}	+0.216	1.16×10^{-3}	0	$+\infty$	—

When $i_P = 0$, Eqs. [38]-[42] become the appropriate cases of Eqs. [9]-[12], respectively.

In the construction of the present model, $\alpha = \frac{1}{2}$, $\lambda = 1$, $T = 25°C$, $Q_a = Q_c = 6 \times 10^{17}$ (amp/cm²), and the electrode area (S) is 1 cm². A_c is taken to be constant over the electrode surface and equal to 25 kcal/mole. It is assumed that A_a is of the form, $A_a = A_{a,0} + B_a \cdot x$, where $A_{a,0} = 30$ kcal/mole, $B_a = 2$ kcal/mole-cm, and x is one of the coordinates of the set (x, y) which describe the locus of elements of area on the electrode surface ($0 \leqq x \leqq 1; 0 \leqq y \leqq 1$). A_a thus varies linearly from 30 kcal/mole at $x = 0$ to 32 kcal/mole at $x = 1$ cm. From the previous information and Eqs. [38]-[42], it is possible to calculate the properties of this simple polyelectrode system.

Table I lists the values of some of these quantities as a function of the applied current. Figure 3 shows the rather enormous variation of j_σ over the electrode surface as a function of the applied current. The fourth column of Table I lists values of $i(+)$, the net positive current flowing from the electrode, obtained by integration of j_σ over that region of the electrode where it has positive values. When $i_P = 0$, it is noteworthy that the total corrosion current of the electrode (i_a) is about a factor of three greater than would have been estimated from $i(+)$, the current flowing between anodic and cathodic areas (as defined by Eq. [11]). Column six of Table I shows how the "boundary" between anodic and cathodic areas on the electrode varies with applied current; for large positive applied currents, no cathodic areas exist on the surface, while for large negative applied currents, no anodic areas exist. Because of the 1 cm² area of the electrode, the values recorded in column six are also equal to the fraction of the surface area which is anodic. The relatively large variation of j_σ over the surface corresponds to a variation in A_a of only 6-7%, so that the importance of variations in the activation energies of partial processes over the surface of a polyelectrode is evident.

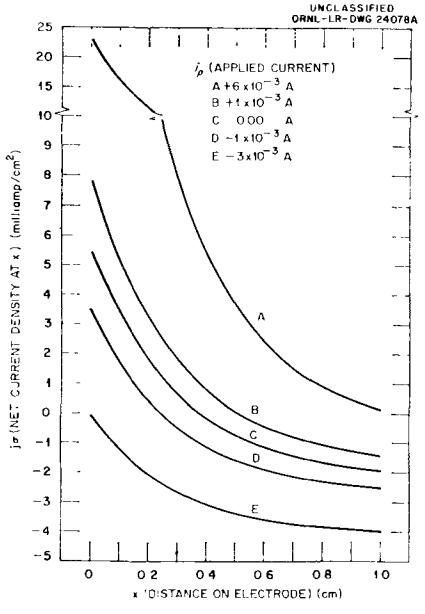

Fig. 3. Plot of j_σ vs. position on electrode surface for model of numerical example (see Appendix I for description of model).

APPENDIX II

List of Frequently Used Symbols

j_i = current density of i^{th} charge transfer step at element of area, dS, on polyelectrode surface.

λ_i = number of charges transferred across interphase during i^{th} charge transfer step.

$\overline{k_i}$ = electrochemical specific rate constant of i^{th} charge transfer step.

$\pi(C_i^{p_i})_a, \pi(C_i^{p_i})_c$ = product of reactant concentrations raised to appropriate kinetic orders for anodic and cathodic charge transfer steps.

j_σ = net current density at element of area, dS.

i_P = current applied to polyelectrode from external source.

τ_i = equal to transmission coefficient of i^{th} charge transfer step (κ_i) times product of activity coefficients of reactants raised to appropriate kinetic orders ($\pi(\gamma_i^{p_i})$) divided by activity coefficient of activated complex ($\gamma_i^{\ddagger}$).

$\Delta\mu_i^{\ddagger}$ = "activation energy"; change in chemical potential of polyelectrode system required for formation of one mole of activated complex from reactants for i^{th} charge transfer step.

$\Delta\phi$ = interfacial inner potential difference at dS, between metallic volume element dv at polyelectrode surface and outermost portion of diffuse double layer in solution ($\Delta\phi = \Delta\phi_H + \psi$).

$\Delta\phi_H$ = inner potential difference across Helmholtz double layer at dS.

ψ = inner potential difference across diffuse double layer at dS.

α_i = symmetry factor of i^{th} charge transfer step.

$\phi_{l'}, \phi_{l''}$ = inner potentials of potentiometer leads, l' and l'' (cf. Fig. 1).

V = measurable cell or electrode potential; $V = \phi_{l'} - \phi_{l''}$.

ϕ_M, ϕ_R, ϕ_S = inner potentials of metallic volume element, dv, on polyelectrode surface, of reference electrode, and of solution, respectively.

$(\mu_e)_M, (\mu_e)_{l'}$ = chemical potentials of electrons in metallic volume element, dv, on polyelectrode surface and in potentiometer lead, l', respectively.

$\Delta\phi_{ref}$ = equal to $(\phi_{l''} - \phi_R) + (\phi_R - \phi_S)$.

$Q_{i,a}, Q_{i,c}$ = contain decomposition frequency of activated complexes, concentrations of reactants, reference electrode potential ($\Delta\phi_{ref.}$), and other quantities presumed independent of dS; defined in Eq. [8].

$I_{i,a}, I_{i,c}$ = exponential integrals containing chemical potentials (which may vary over polyelectrode surface); defined in Eq. [8].

i_a, i_c = total anodic (corrosion) current and total cathodic current of polyelectrode.

$\theta_a, \theta_c =$ equal to $\frac{\alpha_a\lambda_a}{\alpha_a\lambda_a + \alpha_c\lambda_c}$ and $\frac{\alpha_c\lambda_c}{\alpha_a\lambda_a + \alpha_c\lambda_c}$; occur in treatment of simple polyelectrode system.

$V_1^0, V_2^0 =$ measurable electrode potentials of metals 1 and 2 (cf. Fig. 2) when disconnected from each other; occur in treatment of simple galvanic couple.

$\Delta\phi_1^0, \Delta\phi_2^0 =$ netal-solution potential differences of metals 1 and 2 when disconnected.

$i_{1,a}^0 = i_{1,c}^0, i_{2,a}^0 = i_{2,c}^0 =$ anodic and cathodic currents of metals 1 and 2 when unshorted.

$S_1, S_2 =$ areas of metals 1 and 2 of simple galvanic couple.

$K_{1,a}, K_{1,c}, K_{2,a}, K_{2,c} =$ include activation energies and concentrations of reactants for anodic and cathodic partial processes on metals 1 and 2 of galvanic couple; defined in footnote 14.

$(\mu_e)_1, (\mu_e)_2 =$ chemical potentials of electrons in metals 1 and 2 of galvanic couple.

$V^* = V_1^* = V_2^* =$ measurable electrode potential of galvanic couple formed by shorting metals 1 and 2.

$i_a^* = i_c^* =$ total anodic (corrosion) and cathodic currents of galvanic couple.

$\phi_1^*, \phi_2^* =$ inner potentials of metals 1 and 2 when shorted as a galvanic couple.

$i_{1,N}^* = -i_{2,N}^* =$ net currents from metals 1 and 2 when shorted as a galvanic couple.

$i_{1,a}^*, i_{1,c}^*, i_{2,a}^*, i_{2,c}^* =$ anodic and cathodic currents of metals 1 and 2 when shorted as a galvanic couple.

$\bar{j}_{i,a}, \bar{j}_{i,c} =$ surface average current densities of anodic and cathodic partial processes.

$\bar{j}_{corr.} =$ corrosion current density of polyelectrode (surface average).

$V_{corr.} =$ steady-state (measurable) electrode potential of corroding polyelectrode with no externally applied current.

$Z =$ function taking account of effect of i_P, I_a, and I_c on properties of simple polyelectrode system; defined in Eq. [38] of Numerical Example.

$A_a, A_c =$ functions of activation energies of anodic and cathodic partial processes of Numerical Example.

Kinetic Studies on Corrosion Systems

II. The Reduction of Cupric Ion on Passive Stainless Steel Electrodes

Franz A. Posey, G. H. Cartledge, and R. P. Yaffe[1]

Oak Ridge National Laboratory, Oak Ridge, Tennessee[2]

ABSTRACT

The reduction of cupric ion on the surface of passive stainless steel electrodes in aerated, dilute sulfuric acid medium has been investigated using potentiostatic, galvanostatic, and tracer techniques. The independent simultaneity of the electrode reactions has been demonstrated. A mechanism is advanced for the reduction of cupric ion on the oxide surface. The data are interpreted on the basis of electrochemical kinetics.

The first paper in this series (1) (hereinafter referred to as I) treated two-phase polyelectrode systems under activation control, including corrosion systems, on the basis of electrochemical kinetics. It was shown in I that the results of steady-state potentiostatic and galvanostatic measurements can be interpreted in terms of the rates, the kinetic reaction orders, and the electrochemical transfer coefficients of the individual partial processes proceeding at the metal-solution interphase of a polyelectrode system under activation control. The present report deals with the results of some measurements of these types on a real corroding polyelectrode system. Specifically, the effect of additions of cupric ion to solution on the electrode potential and the rates of the partial processes of the system, passive stainless steel in aerated, dilute sulfuric acid solution, has been examined and compared with theoretical expectations.

The effect of additions of oxidizable and reducible substances to solution on electrode potentials and corrosion rates of metals has been studied by several workers in recent years (2-9). Numerous exploratory experiments, performed in this laboratory, have been concerned with the effect of additions of reducible ions (and some uncharged species) on the electrode potential of passive stainless steel in dilute sulfuric acid solution (3, 4, 9). A summary of these results is presented in Table I. Here the addition slope, $\left(\frac{\partial V}{\partial \log C_x}\right)$, refers to the slope of the linear portion of plots of the stainless steel electrode potential (for zero applied current) against the logarithm of the additive concentration for those ions causing significant potential changes (> 40-50 mv for concentrations up to about 10^{-3} M) and for which the linear $V - \log C_x$ relation holds (cf. Part A). Part B lists ions of "noble" metals which, even at low concentrations ($10^{-7} - 10^{-6}M$), cause large changes in electrode potential. However, in this concentration region, it appears that steady states are not attained with the ions of Part B. Electrode potentials may increase with time for long periods, and the observations suggest that the specific rate constants of one or more partial processes change markedly with time. The reduction rates of ions in Part B are large (much larger than the reduction rates of ions in Part A) and at higher concentrations ($10^{-5} - 10^{-4}M$) it appears that a metallic phase is soon produced on the electrode surface. Following the appearance of a metallic phase, potentials no longer

Table I. Summary of the effect of additions of various ions to solution on the electrode potential of passive stainless steel in aerated, 0.10N H_2SO_4 at 85°C*

A. List of ions (and uncharged species) which cause significant potential changes and for which linear plots of electrode potential vs. logarithm of additive concentration are obtained.

Added group	Addition slope, $\left(\frac{\partial V}{\partial \log C_x}\right)$ (V)	Number of experiments averaged
BrO_3^-	0.072	1
Cu^{++}	0.051 ± 0.004	12
Fe^{+++}	0.104 ± 0.012	9
$HCrO_4^-$	0.098 ± 0.008	10
H_2O_2	0.139 ± 0.005	4
IO_3^-	0.080	1
IO_4^-	0.160 ± 0.005	2
OsO_4	0.137 ± 0.003	3
$S_2O_8^=$	0.035	1

B. List of ions which cause significant potential changes but for which, at low concentrations, steady states are not attained and which, at high concentrations, produce a metallic phase on the electrode surface:
Ag^+, Au^{+++}, Hg_2^{++}, Hg^{++}, Pd^{++}, $PtCl_6^=$

C. List of ions which cause slight potential changes:
La^{+++}, Sn^{++}, UO_2^{++}, Zr^{++}, Zn^{+2}

D. List of ions for which no appreciable effect is detected:
AsO_4^{-3}, BiO^+, Ca^{++}, Cd^{++}, Ce^{+3}, Cr^{+3}, Cl^- (caused loss of passivity at high concentrations), ClO_3^-, ClO_4^-, F^-, $Co(NH_3)_6^{+3}$, I^-, Mn^{++}, Na^+, Ni^{++}, NO_3^-, PO_4^{-3}, ReO_4^-, Tl^+, TcO_4^-

* Medium: 150-400 ml of 0.10N H_2SO_4 at 85°C stirred at ca. 600 rpm; pO_2 = 0.2 atm. Electrodes: flag-shaped type 347 stainless steel sheet electrodes (abraded surface) of 2-4 cm^2 geometrical area, stems lacquered with baked G. E. Glyptal. Initial electrode potentials, before additions, occupied region + (100-200) mv vs. S.C.E. at 25°C and were sensibly constant (±3 mv/hr). 2.303 RT/F at 85°C = 0.071 v.

[1] Present address, Department of Chemistry, San Jose State College, San Jose, Calif.

[2] Operated by Union Carbide Corporation for the U. S. Atomic Energy Commission.

change with time, steady states are attained rapidly, and the addition slopes, as well as the potentials, correspond closely to those expected for equilibrium between oxidized and reduced (metallic) forms of the additives. Part C lists ions which cause very slight potential changes (< 10-20 mv for concentrations up to about $10^{-3}M$) and, finally, Part D lists those ions which cause no detectable change in stainless steel electrode potential.

In order to inquire further into the significance of the addition slopes, one of these systems was chosen for more detailed examination by the methods outlined in I. The effect of additions of cupric ions to the chosen stainless steel electrode system was studied potentiostatically at a number of potentials in the passive region. From the resulting information the kinetic order of the reduction reaction with respect to the concentration of cupric ions was determined as well as the (electrode potential)-(current density) relationship for the reduction of Cu^{++} as a function of concentration. In addition, the independent simultaneity of the electrode processes was demonstrated. The results of galvanostatic experiments, together with the results of the potentiostatic experiments, permitted a calculation of the (electrode potential)-(current density) relationships for the anodic oxidation reaction of passive stainless steel and for the cathodic reduction reaction of oxygen dissolved in solution, these being the interphase reactions present in the system before additions of Cu^{++}. Tracer experiments were performed with labelled cupric sulfate (using isotope of atomic weight 64) which yielded information of interpretive value. The results of these experiments are reported below and analyzed on the basis of an electrochemical kinetic model.

Experimental

The experimental vessel was a five-necked spherical reaction flask of 500-ml capacity fitted with a short, vertical condenser to which was attached a mercury-seal stirrer operated by a Bodine motor (type KYC-23) with a step-up gear at 600 rpm. Standard taper (24/40) entry ports provided space for a thermometer, the entry of air, an auxiliary platinum polarizing electrode, and for the insertion of a stainless steel electrode. A vigorous supply of air was effused into the solution through a sintered glass disk. Standard taper joints and glass apparatus were used throughout the experimental assembly. Temperature was controlled by means of a Glascol heating mantle operated from a Variac supplied with regulated a.c. The constancy of the ambient temperature permitted control of the solution temperature by this means from room temperature up to the boiling point to within $\pm 0.5°C$. The efficiency of the condenser was such that no significant change in solution volume occurred for many hours, even at temperatures close to the boiling point.

Measurements of electrode potentials were performed using a L&N *p*H Indicator (No. 7664) as a potentiometer coupled with a Brown recorder. The input impedance of this instrument is very large compared to the polarizability of stainless steel electrodes under almost any conditions. Potentials were measured and recorded with time by the direct method, using a Luggin capillary bridged (with $0.10N$ H_2SO_4) to a Ag/Ag_2SO_4 (sat'd. in $0.10N$ H_2SO_4) reference electrode maintained at room temperature. Currents were measured with time by recording the voltage drop across precision resistors in the polarizing circuit. Current-interrupter and other incidental studies proved ohmic potential drops in solution between the stainless steel electrode and the tip of the reference electrode capillary to be negligible even at the highest externally applied currents employed. External polarizing current was provided through high resistances by means of high voltages supplied by an Oregon Electronics Variable Voltage Regulated Power Supply (model A3A).

Experiments were performed using abraded[3] electrodes of 4 cm^2 geometrical surface area prepared from a type 347, Ta-stabilized stainless steel sheet of 20 ml thickness. Stainless steel electrodes were attached to a stainless steel rod lead and all portions of the rod, the junction of the rod with the electrode, and a part of the electrode (except 4 cm^2) were covered with an insulating coat of G.E. Glyptal Clear Baking Varnish No. 1202 which was baked at 110°C to a tough, acid-resistant finish. Electrodes were allowed to passivate for many hours in the environment, 400 ml of aerated, $0.10N$ H_2SO_4 (prepared from redistilled water) at 85°C, until constancy (± 3 mv/hr) of electrode potential was observed. The choice of the experimental temperature, 85°C, rested on the fact that steady states are attained very much more readily here than at room temperature as a consequence of the higher rates of the partial processes at the higher temperature.

In the potentiostatic experiments, following the attainment of a steady-state potential, the electrode potential was maintained constant ($\pm$ 1 mv) at any desired value with an electromechanical potentiostat (10) or with a sensitive manual device. Additions of aliquots of a concentrated stock solution of $CuSO_4 \cdot 5H_2O$ in $0.10N$ H_2SO_4 were made to the solution by micropipettes and the externally applied current necessary to maintain the chosen potential constant was recorded with time. In the galvanostatic experiments, a similar procedure was followed except that the electrode potential was recorded continuously with time at constant externally applied current.

For the tracer experiments, previously irradiated[4] $CuSO_4 \cdot 5H_2O$ was dissolved in $0.10N$ H_2SO_4 to form a stock solution, and aliquots of this were added to the stainless steel electrode system. In these experiments, eight stainless steel electrodes, each of 2 cm^2 area and prepared as above, were present in the dilute acid environment. Electrodes were removed periodically from solution at various cupric ion con-

[3] Abrasion as a method of electrode surface preparation is subject to obvious objections from the standpoint of distortion of the surface structure of the metal. However, for use with the stainless steels, the method was found to permit a good degree of reproducibility among different electrode specimens with respect to initial steady-state potentials in the passive region and polarizability in the environment used here. These are characteristics of considerable importance in a series of galvanostatic experiments using different electrodes. However, it should be made explicit that current quantities measured here pertain only to the real electrode surface used.

[4] The authors are indebted to G. W. Leddicotte of the Analytical Chemistry Division of this Laboratory for his kind cooperation in irradiating samples of $CuSO_4 \cdot 5H_2O$ in the graphite reactor for use in this work.

centrations, rinsed thoroughly in distilled water, dried in a jet of air, and assayed for ^{64}Cu in a standard well-type scintillation counter. Specific activity of the experimental solution at the end of an experiment was found by counting small aliquots of the solution which had been evaporated to dryness on an abraded stainless steel surface.

Results and Discussion

Potentiostatic Experiments

It was shown in I that potentiostatic measurements permit the determination of the kinetic order of an individual partial process in a polyelectrode system with respect to the concentration of a reactant in this process, provided the reactant concentration can be varied without affecting the concentrations of other reactants in the system and provided two (or more) partial processes of the system have no common kinetic orders with respect to the reactant under examination. Thus, the kinetic order (p_x) of a reaction (denoted by subscript x) with respect to the concentration of one of its reactants (C_x) is given by:

$$\left(\frac{\partial \ln \mid i_P - i_{P,0} \mid}{\partial \ln C_x}\right)_V = p_x \qquad [1]$$

Here, i_P is the externally applied current in the presence of an amount, C_x, of the reactant and $i_{P,0}$ is the initial applied current at the chosen electrode potential (V) before additions of the reactant (or for a known amount of reactant already present). Figure 1 presents graphically the results of experiments of this type on the addition of Cu^{++} to a passive stainless steel electrode system. From the unit slopes obtained in Fig. 1, it is evident that the reduction reaction is first order with respect to (Cu^{++}) over the whole potential range investigated (−158 to +283 mv vs. S.C.E.) and over a thousandfold variation in (Cu^{++}).

The ionic strength of the solution was essentially constant at $\mu = 0.15$ throughout the experiments except for the very highest concentrations, hence changes in activity coefficients have been neglected in the interpretation of the results. Two observations attest to the independent simultaneity of the electrode reactions (i.e., the presence of the additional partial process due to the reduction of Cu^{++} does not significantly affect the rates of the initial partial processes in the system): (*a*) i_P does not vary with time at the various (Cu^{++}), except for the very highest concentrations at the lowest potentials studied;[5] (*b*) the measured values of $i_{P,0}$, for each potential, are exactly the current quantities necessary to confer linearity on the plots of log $\mid i_P - i_{P,0} \mid$ vs. log (Cu^{++}).

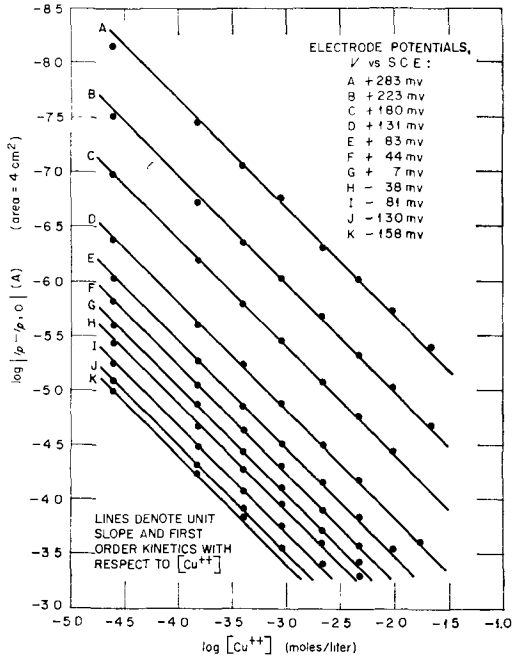

Fig. 1. Results of potentiostatic experiments on the reduction of cupric ion at the surface of passive stainless steel in aerated, 0.1N H_2SO_4 at 85°C.

In Fig. 2, a Tafel-type plot, experimental points corresponding to log $\mid i_P - i_{P,0} \mid$ at constant (Cu^{++}) from Fig. 1 have been plotted against electrode potential, V. Solid lines are drawn through experimental data referring to constant (Cu^{++}). Lines of slope $-RT/F$ and $-4RT/F$ have been provided for comparison with theoretical expectations. The present system is limited with respect to the experimentally accessible potential region. At higher potentials than those studied, currents due to the reduction of Cu^{++} are small and difficult to measure accurately except for very high (Cu^{++}), where changes in ionic strength become important. At lower potentials than those in Fig. 2, Cu^{++} is reduced so rapidly that the electrode surface cannot long be

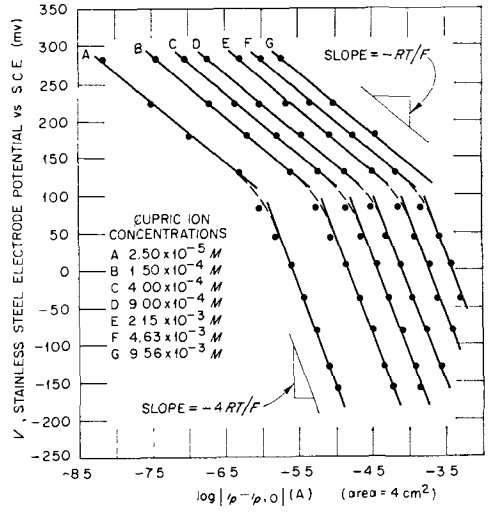

Fig. 2. Electrode potential-current density curves for the reduction of cupric ion at the surface of passive stainless steel in aerated, 0.1N H_2SO_4 at 85°C.

[5] Variations of i_P with time were observed at the lowest potentials at high (Cu^{++}); i_P became more negative linearly with time at constant (Cu^{++}). If, following the onset of this behavior, the (cathodic) applied current was interrupted, the electrode potential was observed to assume very rapidly the value of the reversible Cu^0/Cu^{++} potential for the environment and to maintain that value for periods of the order of minutes before changing to more noble potentials characteristic of passive stainless steel in the presence of Cu^{++}. This phenomenon was not observed at potentials much above S.C.E. even for the highest (Cu^{++}) studied and did not occur at lower potentials unless i_P was observed to change with time at constant (Cu^{++}). For electrodes held at still lower potentials than those of Fig. 2, the addition of Cu^{++} soon produced a visible metallic copper phase, and on release of applied current, these electrodes also showed the above behavior. Precautions were taken in studies at the lower potentials of Fig. 1 to minimize the effect of this additional complication by conducting experiments as rapidly as possible and the data of Fig. 1 contain no significant error from this source.

considered that of passive stainless steel, i_P changes very rapidly with time, and a metallic copper phase is soon produced, the properties of which are not of primary interest here. For partial processes under pure activation control and involving a single charge transfer step, such plots of V vs. log $|i_P - i_{P,0}|$ ($\equiv$ | current due to added constituent |) yield straight lines of slope $\left|\frac{RT}{F}\cdot\frac{1}{\alpha_x\lambda_x}\right|$ (cf. Eq. [31] in I). Here, α_x is the symmetry factor of the energy barrier in the charge transfer step of the partial process, and λ_x is the number of charges transferred across the interphase during the charge transfer step.

The change of slope of the curves in Fig. 2 implies the existence of alternative and/or consecutive charge transfer steps in the mechanism for the reduction of Cu^{++} on the electrode surface.[6] Numerous mechanistic schemes have been examined for the purpose of finding one or more which predict the type of behavior observed in Fig. 2. Mechanisms involving partial diffusion and partial activation control (assuming Fick's first law and linear diffusion) or partial "reaction" (12) and partial activation control, with a single charge transfer step, were found to be inconsistent with experiment in that they do not allow a constant slope at lower potentials, but predict an asymptotic approach to a limiting current as $V \to -\infty$. It can be shown that when the slope of the (electrode potential) - (logarithm of current density) curves for these mechanisms is twice that of the upper portion, where activation is effectively rate controlling for a cathodic partial process, the current at this point equals half the limiting current. Inspection of Fig. 2 shows that at the lowest potential studied the current is already a factor of about ten larger than that at the point where the slope is twice the slope of the high potential region, with no indication of an approach to a limiting current. Furthermore, a calculation of the expected effect of concentration polarization on the results at the lowest potentials of Fig. 2, using probable values of the diffusion coefficient of cupric ion and of the thickness of the Nernst diffusion layer (13), shows that little error is involved in neglecting changes in cupric ion concentration at the electrode surface for the currents used here. A mechanism consisting of two simultaneous simple reaction paths (e.g., a "two-electron" path simultaneous with a "one-electron" path) is incapable of explaining the data, for it requires that the slope of the higher potential region of the (electrode potential) - (logarithm of current density) relation be greater than that of the lower potential region, whereas the reverse is observed here.

Without discussing additional mechanisms examined in relation to this problem, one mechanism is presented which is consistent with the data. This reaction sequence is given by:

$$Cu^{++}(\text{d.l.}) \underset{\overline{k_2}(-e^-)}{\overset{\overline{k_1}(+e^-)}{\rightleftharpoons}} Cu^{+}(\text{d.l.}) \xrightarrow{\overline{k_3}(+e^-)} Cu^{\circ}\,(\text{oxide}) \qquad [2]$$

[6] R. Parsons (11), among others, has discussed cases of simultaneous mechanisms for the hydrogen evolution reaction.

The symbol Cu^{++}(d.l.) refers to cupric ions at the innermost portion of the diffuse double layer at the interphase, the concentration of which, for the experimental conditions of this work (large excess of inter electrolyte), must be essentially equal to the concentration in the bulk of the solution. Because of the well-known multivalency of copper in aqueous solutions, it does not seem unreasonable to presume that the cuprous state is energetically accessible as an intermediate in the over-all process for the reduction of Cu^{++}, and the symbol Cu^{+}(d.l.) refers to the postulated intermediate at the interphase. Cu^{+} (d.l.) is produced from Cu^{++}(d.l.) by the "one-electron" step of electrochemical specific rate constant $\overline{k_1}$ and (surface average) current density $\overline{j_1}$. It may react further either by reoxidation back to Cu^{++}(d.l.) (via the "one-electron" anodic step of rate constant $\overline{k_2}$ and current density $\overline{j_2}$) or by moving across the interphase to a position in the stainless steel oxide lattice. This latter cathodic step is characterized by rate constant $\overline{k_3}$ and current density $\overline{j_3}$. The product of the partial process is symbolized in Eq. [2] by Cu° (oxide), although the observable kinetics gives no information on the identity of the species, which may be Cu^{+}(oxide).

Designating the over-all (surface average) current density of the reduction process by $\overline{j_x}$, $\overline{j_x}$ is given as a function of $\overline{j_1}$, $\overline{j_2}$, and $\overline{j_3}$ by:

$$\overline{j_x} = \overline{j_1} - \overline{j_2} + \overline{j_3} \qquad [3]$$

Denoting the concentration of Cu^{++}(d.l.) (or the equivalent concentration of Cu^{++} in the bulk of the solution) by (Cu^{++}), and denoting the concentration of Cu^{+}(d.l.) by (Cu^{+}), Eq. [3] becomes:

$$\overline{j_x} = \overline{k_1}(Cu^{++}) - (\overline{k_2} - \overline{k_3})\,(Cu^{+}) \qquad [4]$$

Assuming that (Cu^{++}) is constant with time, that (Cu^{+}) very soon reaches a steady-state value, and that the reaction product on the oxide surface builds up continuously with time (i.e., no back reaction), the steady-state concentration of Cu^{+}(d.l.) is given by:

$$(Cu^{+}) = (Cu^{++})\,\frac{\overline{k_1}}{\overline{k_2} + \overline{k_3}} \qquad [5]$$

The over-all current density of the reduction process is given from Eqs. [4] and [5] by:

$$\overline{j_x} = (Cu^{++})\,\frac{2\overline{k_1}\overline{k_3}}{\overline{k_2} + \overline{k_3}} \qquad [6]$$

The electrochemical specific rate constants of the respective steps in the mechanism of Eq. [2] are assumed to be given by:

$$\overline{k_1} = k_1\, e^{-\frac{\alpha_1\lambda_1 F}{RT}V} \qquad [7]$$

$$\overline{k_2} = k_2\, e^{+\frac{\alpha_2\lambda_2 F}{RT}V} \qquad [8]$$

$$\overline{k_3} = k_3\, e^{-\frac{\alpha_3\lambda_3 F}{RT}V} \qquad [9]$$

The terms, k_1, k_2, and k_3 are presumed independent of the value of V, the measurable electrode potential, α_1, α_2, and α_3 are the symmetry factors of the steps in the mechanism of Eq. [2], and λ_1, λ_2, and λ_3 are the numbers of charges transferred across the interphase during the respective charge transfer steps ($\lambda_1 = \lambda_2 = \lambda_3 = 1$ is assumed in the mechanism of Eq. [2]). Substitution of Eqs. [7], [8], and [9] in Eq. [6] and differentiation of the resulting expression for $\overline{j_x}$ with respect to V, with use of the relations $\frac{d\overline{k_1}}{dV} = -\frac{\alpha_1\lambda_1 F}{RT}\overline{k_1}$, $\frac{d\overline{k_2}}{dV} = \frac{\alpha_2\lambda_2 F}{RT}\overline{k_2}$, $\frac{d\overline{k_3}}{dV} = -\frac{\alpha_3\lambda_3 F}{RT}\overline{k_3}$, and $\frac{dV}{d\ln \overline{j_x}} = \overline{j_x}\cdot\frac{dV}{d\overline{j_x}}$, leads to:

$$P_x \equiv \left(\frac{\partial V}{\partial \ln \overline{j_x}}\right)_{(Cu^{++})} = -\frac{RT}{F}\left[\frac{\overline{k_2} + \overline{k_3}}{(\alpha_1\lambda_1 + \alpha_2\lambda_2 + \alpha_3\lambda_3)\overline{k_2} + (\alpha_1\lambda_1)\overline{k_3}}\right] \quad [10]$$

The behavior of the function, P_x, depends on the ratio of $\overline{k_2}$ to $\overline{k_3}$; this ratio increases rapidly with increasing V. Thus, when $\overline{k_2} >> \overline{k_3}$ at high potentials, P_x becomes $P_x^+ = -\frac{RT}{F}\cdot\frac{1}{(\alpha_1\lambda_1 + \alpha_2\lambda_2 + \alpha_3\lambda_3)}$; and when $\overline{k_2} << \overline{k_3}$ at low potentials, P_x becomes $P_x^- = -\frac{RT}{F}\cdot\frac{1}{\alpha_1\lambda_1}$. The former slope ($P_x^+$) corresponds, in the present set of experiments (cf. Fig. 2), to that in the potential region from +100 to +300 mv vs. S.C.E., while the latter slope (P_x^-) corresponds to that in the region from +100 to −200 mv vs. S.C.E.[7] Equations [6] and [10] adequately describe the present data on the reduction of Cu^{++} at the surface of passive stainless steel in the chosen environment.

Before calculating values of electrochemical transfer coefficients from the results of Fig. 2, on the basis of the mechanism of Eq. [2] and the kinetic deductions of Eqs. [6] and [10], it is necessary to recognize the existence of three phases in the present passive metal system. The over-all electrode-solution potential difference may be considered to be composed of three parts: (*a*) the metal-metal oxide potential difference; (*b*) any potential difference existing between the inner and outer boundaries of the oxide on the passive metal; and (c) the oxide-solution potential difference. In the absence of a quantitative kinetic theory of the passive state which takes into account all the above potential differences, a theoretically exact interpretation of the system studied here does not seem possible at the present time. However, the values of the electrochemical transfer coefficients calculable from the present data and Eq. [10] do find a reasonable interpretation on the basis of a model developed in collaboration with Meyer of this laboratory (14).

In the model it is assumed that the rate constants for the transport of positive ions and oxide ions through the passive oxide layer on stainless steel are quite large compared to the rate constants for the transfer of positive ions from metal to oxide and from oxide to solution. Hence it is assumed that any potential difference between the inner and outer boundaries of the oxide is negligible compared to the potential differences at the metal-metal oxide interphase and at the oxide-solution interphase. It is assumed also that the concentration of metal ions is essentially constant everywhere in the oxide. The current density for the transfer of positive ions from metal to oxide is assumed to be given by:

$$\overline{j_M} = K_M e^{+\frac{\alpha_M\lambda_a F}{RT}\Delta\phi_M} \quad [11]$$

Here, $\overline{j_M}$ is the (surface average) current density of the transfer step, K_M contains the potential-independent portion of the specific rate constant of the charge transfer step and the concentration of ions in the metal, α_M is the symmetry factor of the energy barrier at the metal-oxide interphase, λ_a is the charge of the metal ions, and $\Delta\phi_M$ is the inner potential difference between metal and oxide. The current density for the transfer of positive ions from oxide to solution ($\overline{j_S}$) is given by:

$$\overline{j_S} = K_S e^{+\frac{\alpha_S\lambda_a F}{RT}\Delta\phi_S} \quad [12]$$

Here, K_S is analogous to K_M of Eq. [11], α_S is the symmetry factor of the energy barrier at the oxide-solution interphase, λ_a is as defined in Eq. [11], and $\Delta\phi_S$ is the oxide-solution potential difference. It is assumed that the back reactions corresponding to Eqs. [11] and [12] can be neglected. Since it has been presumed that the potential difference through the oxide is negligible, the total metal-solution potential difference ($\Delta\phi_T$) is given by:

$$\Delta\phi_T = \Delta\phi_M + \Delta\phi_S \quad [13]$$

Equations [11], [12], and [13] may be solved simultaneously and, for steady-state conditions ($\overline{j_M} = \overline{j_S}$), lead to the current density of the anodic process ($\overline{j_a}$), which is given by:

$$\overline{j_a} = \overline{j_M} = \overline{j_S} = (K_M)^{\frac{\alpha_S}{\alpha_M+\alpha_S}}(K_S)^{\frac{\alpha_M}{\alpha_M+\alpha_S}} e^{\left(\frac{\alpha_M\alpha_S}{\alpha_M+\alpha_S}\right)\frac{\lambda_a F}{RT}\Delta\phi T} \quad [14]$$

Furthermore, the current density of a cathodic partial process ($\overline{j_r}$) under pure activation control with one charge transfer step and proceeding at the oxide-solution interphase may be written as:

$$\overline{j_r} = K_r e^{-\frac{\alpha_r\lambda_c F}{RT}\Delta\phi_S} \quad [15]$$

Here, K_r is analogous to K_M and K_S of Eqs. [11] and [12], α_r is the symmetry factor of the barrier at the oxide-solution interphase, and λ_c is the charge trans-

[7] No evidence was found in this system for the existence of a significant direct "two-electron" reduction path for Cu^{++}. If a path of this type is included in Eq. [2], it is found that P_x (cf. Eq. [10]) can then possess four constant values in four ranges of potential, and the plot of V vs: log $\overline{j_x}$ for the mechanism possesses the aspect of an inclined "W", in which the two inner portions (or "legs") are described by Eqs. [6] and [10] and the two outer portions refer to the additional "two-electron" path. Thus either the experimentally accessible range of electrode potentials for this system does not permit observation of regions at very high and very low potentials corresponding to predominance of a "two-electron" path, or else such a path is nonexistent.

ferred across the interphase during the cathodic charge transfer step. Equation [15], together with the value of $\Delta\phi_S$ obtained by simultaneous solution of Eqs. [11], [12], and [13], leads to:

$$\bar{j}_r = K_r \left(\frac{K_S}{K_M}\right)^{\frac{\alpha_r\lambda_c}{(\alpha_M+\alpha_S)\lambda_a}} e^{-\left(\frac{\alpha_r\alpha_M}{\alpha_M+\alpha_S}\right)\frac{\lambda_c F}{RT}\Delta\phi_T} \quad [16]$$

It is evident that, for this case, the "over-all" symmetry factor for the anodic partial process is given by $\frac{\alpha_M\alpha_S}{\alpha_M+\alpha_S}$, so that, if the energy barriers are symmetrical (i.e., $\alpha_M = \alpha_S = \frac{1}{2}$), the over-all symmetry factor is $\frac{1}{4}$, instead of the $\frac{1}{2}$ observed frequently for two-phase polyelectrode systems. Likewise, the over-all symmetry factor for the cathodic partial process, $\frac{\alpha_r\alpha_M}{\alpha_M+\alpha_S}$, is also $\frac{1}{4}$ if $\alpha_r = \alpha_M = \alpha_S = \frac{1}{2}$.

If it is assumed that the preceding model holds for the case of passive stainless steel, and that α_1, α_2, and α_3 of Eqs. [7]-[10] are "over-all" symmetry factors having values of $\frac{1}{4}$, while $\lambda_1 = \lambda_2 = \lambda_3 = 1$ in accord with the mechanism of Eq. [2], the values of P_x calculated from Eq. [10] for the higher and lower potential regions of the (electrode potential)-(logarithm of current density) plot (cf. Fig. 2) are $P_x^+ = -1.33\ RT/F$ and $P_x^- = -4\ RT/F$, respectively, compared with the observed values of $-1.14\ RT/F$ and $-3.71\ RT/F$. The agreement seems satisfactory since exactly symmetrical energy barriers are not necessarily expected. The slope of the higher potential region in Fig. 2 (P_x^+) is $P_x^+ = -0.082\ (V)$; hence it follows that $(\alpha_1\lambda_1 + \alpha_2\lambda_2 + \alpha_3\lambda_3) = 0.87$. The slope of the lower potential region is $P_x^- = -0.263\ (V)$, leading to a value of $\alpha_1\lambda_1 = 0.27$; and if λ_1 is presumed equal to unity as in the mechanism of Eq. [2], $\alpha_1 = 0.27$, in good agreement with the assumption of two fairly symmetrical energy barriers for the anodic process in the system. From the values of $\alpha_1\lambda_1$ and of P_x^+, it follows that $(\alpha_2\lambda_2 + \alpha_3\lambda_3) = 0.60$, and if λ_2 and λ_3 are also equal to unity, $(\alpha_2 + \alpha_3) = 0.60$, also in reasonable agreement with the mechanistic conceptions outlined above. No further separation of $(\alpha_2 + \alpha_3)$ into its constituents appears possible from these data.

Galvanostatic Experiments

An elementary theory of the effect of additions of a reducible constituent to solution on the electrode potential of a polyelectrode system with only one anodic and one cathodic partial process initially present was presented in I. There it was shown that the slope of the (electrode potential)-(logarithm of additive concentration) plot is given by:

$$\left(\frac{\partial V}{\partial \ln C_x}\right)_{j_P} = \frac{RT}{F}\left[\frac{p_x \bar{j}_x}{\alpha_a\lambda_a\bar{j}_a + \alpha\lambda_c\bar{j}_c + \alpha_x\lambda_x\bar{j}_x}\right] \quad [17]$$

Here, $\bar{j}_a$ and $\bar{j}_c$ are the (surface average) current densities of the anodic and cathodic partial processes initially present in the system; in the system studied here these are the oxidation of stainless steel constituents and the reduction of molecular oxygen dissolved in solution. The current density of the added reducible constituent is denoted by $\bar{j}_x$, where $\bar{j}_x$ is defined for the present system by Eq. [3], $\alpha_x\lambda_x$ is given from Eq. [10] by $-\frac{RT}{F}\cdot\frac{1}{P_x}$, and p_x is as defined in Eq. [1]. The appropriate values of α_a, α_c, and α_x for use in Eq. [17] are the "over-all" symmetry factors of the respective processes, as discussed in the previous section. The applied current density is given by $\bar{j}_P = \bar{j}_a - \bar{j}_c - \bar{j}_x$, so that when $\bar{j}_x >> \bar{j}_c$ (at higher concentrations of the added reducible constituent), $j_P \simeq \bar{j}_a - \bar{j}_x$, and Eq. [17] reduces to:

$$\left(\frac{\partial V}{\partial \ln C_x}\right)_{j_P} = \frac{RT}{F} p_x \left[\alpha_x\lambda_x + \alpha_a\lambda_a\left(1 + \frac{j_P}{\bar{j}_x}\right)\right]^{-1} \quad [18]$$

Equation [18] predicts a constant slope when $j_P = 0$, in accord with experimental observations. The potentiostatic experiments have shown that p_x equals unity for the reduction of Cu^{++} on the surface of passive stainless steel.

Figure 3 presents the results of galvanostatic experiments on the present system and Fig. 4, constructed from the data of Fig. 3, shows how the slope, $\left(\frac{\partial V}{\partial \log C_x}\right)_{j_P}$, varies with C_x for various values of j_P. For comparison with theory, the analogous behavior of an idealized system is shown in Fig. 5 and 6. For the construction of these theoretical diagrams,

a model was used having the following electrochemical kinetic parameters. k_1, k_2, and k_3 of Eqs. [7]-[9] were assumed to be given by the relations: $k_1 = 44.3$ and $k_2/k_3 = 8.59 \times 10^{-9}$. In accord with the mechanism of Eq. [2] and with the dual barrier model discussed in the previous section, $\alpha_1 = \alpha_2 = \alpha_3 = \frac{1}{4}$ and $\lambda_1 = \lambda_2 = \lambda_3 = 1$. The current density of the anodic process was assumed to be of the form of Eq. [14]; specifically, $\overline{j_a} = 1.21 \times 10^{-15}\, e^{+\frac{\alpha_a \lambda_a F}{RT} V}$ with $\lambda_a = 2$ and α_a (the over-all symmetry factor equal to $\frac{\alpha_M \alpha_S}{\alpha_M + \alpha_S}$ of Eq. [14]) $= \frac{1}{4}$. Likewise, the current density of the cathodic process was assumed to be of the form of Eq. [16]; specifically, $\overline{j_c} = 9.55 \times 10^{-3}\, e^{-\frac{\alpha_c \lambda_c F}{RT} V}$, with $\lambda_c = 1$ and α_c (the over-all symmetry factor equal to $\frac{\alpha_r \alpha_M}{\alpha_M + \alpha_S}$ of Eq. [16]) $= \frac{1}{4}$. These parameters were selected to correspond closely, except for temperature ($T = 25°C$), with those calculable from the results of the potentiostatic experiments on the reduction of Cu^{++} and with those calculable from the polarizability of the system before additions of Cu^{++}. The agreement between the forms of the curves for theoretical and experimental systems seems satisfactory.

The linearity, at high (Cu^{++}), of curve A in Fig. 3 is evidence for the independent simultaneity of the two partial processes, oxidation of steel constituents and reduction of Cu^{++}, in agreement with evidence from the potentiostatic experiments. In this linear region, the reduction current of dissolved oxygen is negligible compared to that for the reduction of Cu^{++}, hence the latter current very nearly equals the current for the oxidation of the steel constituents. Therefore, from the results of Fig. 2 and 3, the (electrode potential)-(logarithm of current density) relationship for the anodic (corrosion) reaction can be calculated. This is found to be linear and to exhibit a slope of $\left(\frac{\partial V}{\partial \log \overline{j_a}}\right) = 0.164$; hence it follows that $\alpha_a \lambda_a = 0.43$. This result is consistent with a value of λ_a (an average value since stainless steel is composed of three important oxidizable species) in the vicinity of two and slightly asymmetrical energy barriers for the anodic process (cf. Eq. [14] with $\alpha_a = \frac{\alpha_M \alpha_S}{\alpha_M + \alpha_S}$).

Knowledge of $\alpha_a \lambda_a$ and $\overline{j_a}$ as a function of V permits a calculation of the corresponding quantities for the reduction reaction of dissolved oxygen from the polarization curve for passive stainless steel in the absence of Cu^{++}. The (electrode potential)-(logarithm of current density) plot for this reaction was found to possess a slope of $\left(\frac{\partial V}{\partial \log \overline{j_c}}\right) = -0.275$; hence $\alpha_c \lambda_c = 0.26$, in agreement with a "one-electron" process for the reduction of oxygen and an over-all symmetry factor for the process of approximately $\frac{1}{4}$. The values of $\alpha_a \lambda_a$ and $\alpha_c \lambda_c$ are seen to be consistent with the dual barrier model discussed above which was invoked to interpret the potentiostatic experiments on the reduction of Cu^{++}. If the values of $\alpha_a \lambda_a$ and $\alpha_x \lambda_x$ reported above are substituted into Eq. [18], $\left(\frac{\partial V}{\partial \log C_x}\right)$ has the value 0.054 (V) when $j_P = 0$. This value is identical to that observed experimentally, as seen in Fig. 3 and 4. If the values of $\alpha_a \lambda_a$ and $\alpha_x \lambda_x$ found in this work are substituted into Eq. [18] for the temperature, 25°C, a slope of 0.046 (V) is predicted. This value compares favorably with that [0.048 (V)] obtained on plotting data [in a V vs. log (Cu^{++}) diagram] of other workers (5) on the effect of Cu^{++} on the electrode potential of 18-8 stainless steel in 0.2N H_2SO_4 at 25°C. An increase in cupric ion concentration from zero to $10^{-2}M$ in this system, with $j_P = 0$, increases the corrosion rate of passive stainless steel from 2.9×10^{-8} amp/cm² to 3.0×10^{-7} amp/cm².

Part A of Table I lists those ions for which a linear relationship between electrode potential and logarithm of additive concentration is observed for zero applied current. The model of the passive stainless steel interphase outlined above also assists in the interpretation of the values of the addition slope, $\left(\frac{\partial V}{\partial \log C_x}\right)$, for some of these systems. Thus, as-

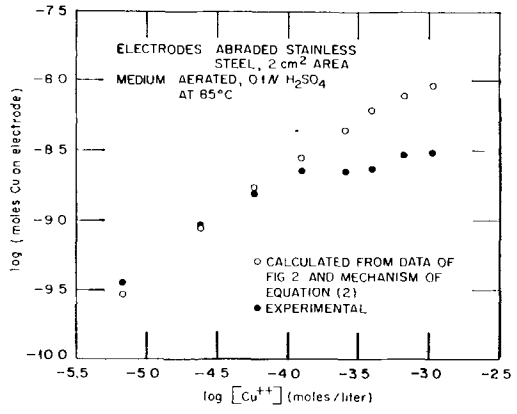

Fig. 7. Typical results of tracer experiments using $^{64}Cu^{++}$—relationship between amount of copper retained by electrode surface and $[Cu^{++}]$ in solution.

suming over-all symmetry factors of $\alpha \simeq 1/4$ for the reduction processes of each of the additives and the value of $\alpha_a\lambda_a$ reported above, the following approximate values of λ_x are calculable from the addition slopes and Eq. [18] for $j_P = 0$: $Fe^{+++} = 1$; $HCrO_4^- = 1$; $BrO_3^- = 2$; and $IO_3^- = 2$. These values seem in reasonable agreement with known facts about the solution chemistry of these ions. The other groups in Part A, consisting of peroxy species and ions of high oxidation state, may involve complicated reaction sequences for reduction, instead of simple one-step mechanisms necessarily assumed in the calculations for the above ions ($HCrO_4^-$ may also belong in this category).

Tracer Experiments

A typical set of tracer results is shown in Fig. 7. Calculated values of the amount of copper reduced by the path of specific rate constant $\overline{k_3}$ of the mechanism suggested in Eq. [2], as a function of (Cu^{++}) in solution, are included for comparison. Calculated and experimental values are in good agreement below $(Cu^{++}) = 10^{-4}M$; at higher concentrations, the order of magnitude is still correct, but the numerical agreement is poorer (theoretical and experimental values differ by a factor of about three at $(Cu^{++}) = 10^{-3}M$).[8] Although the results of the tracer experiments offer some support for the mechanistic conceptions outlined above, the quantity measured is not particularly well defined, as the procedures followed in rinsing and drying electrodes for assay of radioactivity may have involved unknown errors. Nevertheless, these tracer experiments and some other tracer studies on the amount of copper retained by the electrodes as a function of time at constant (Cu^{++}) do support the contention that the product of the final reduction step, the path of specific rate constant $\overline{k_3}$ in Eq. [2], builds up continuously with time on the oxide surface. Further tracer studies have demonstrated the "irreversibility" of the final step in the mechanism of Eq. [2]. If galvanostatic experiments at zero applied current are performed with $^{64}Cu^{++}$, in which the solution is subsequently replaced with fresh, copper-free solvent, the electrode potential returns to its initial value observed before additions of Cu^{++}. However, the amount of copper retained by the electrodes in the copper-free solution is identical, within expected experimental error, to that retained by similar electrodes withdrawn from solution before changing solvents.

The potentiostatic, galvanostatic, and tracer experiments, together with the mechanism of Eq. [2] and a dual barrier model for the anodic (corrosion) reaction of passive stainless steel, offer a self-consistent picture of the present polyelectrode system and afford a mechanistic basis for interpreting the results of experiments like those reported in Table I. There seems little doubt that similar studies, involving the theory and techniques outlined in I and used here in a concerted study of a single system, would prove valuable in analyzing other corroding polyelectrode systems.

Manuscript received Jan. 16, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

[8] The discrepancy between theory and experiment in Fig. 7 at higher (Cu^{++}) may be removed by assuming additional paths for the destruction of the cuprous intermediate in the mechanism of Eq. [2], such as diffusion of the intermediate away from the interphase before it can react at the surface or reaction of the intermediate with molecular O_2 from the solution. The additional paths are not included in Eq. [2], however, since this would complicate the analysis unduly.

Effects of Chloride on the Orientation of Nickel Deposits

B. C. Banerjee and A. Goswami

National Chemical Laboratory, Poona, India

ABSTRACT

The effects of chloride ions in a nickel bath have been studied. Chloride ions generally counterbalance the outgrowth condition due to impurities and favor lateral growth; this is attributed to the desorption of the impurities from the cathode, which facilitates the electron-transfer process.

In a series of papers (1-3) Goswami and his coworker have shown that the preferred orientation of an electrodeposit can be altered by an appropriate change in the bath conditions such as *p*H, current density (c.d.), temperature, rate of stirring, bath compositions, additives, etc. Finch, *et al.* (4, 5) first recognized that the crystal orientations were related to the modes of ways in which crystals were growing and these were loosely termed as (*a*) out growth deposits, when the most densely packed atom rows of deposit crystals were normal to the substrate-surface, (*b*) lateral growth deposits, when a densely packed lattice plane containing the most densely packed lattice rows was parallel to it, and (*c*) other types of growth exhibiting complex orientations. In f.c.c. metals, out growth deposition condition is denoted by the appearance of {110} orientation, whereas lateral growth is denoted by {100} or {111}. The last orientation was never observed during electrodeposition of nickel but was observed (6) during chemical reduction from a nickel hypophosphite bath. The mixed {211} + $\{10\bar{1}0\}_{hex}$ which come primarily from the initial {100} orientation have also been shown (7, 2) to be of lateral growth type.

In preliminary experiments it was observed that the out-growth condition of nickel deposition in presence of impurities as reported (8) earlier can be modified to lateral growth type by addition of sodium chloride. Since chloride ion is known to increase the bath conductivity (9-11) and also facilitate electron transfer process (12, 13) at the cathode, it was deemed necessary to study its effect on the structure of nickel deposited from impure baths and gain an insight into the mode of cathodic crystal growth process.

Experimental

Nickel was deposited on mechanically polished brass substrates from baths containing $NiSO_4$, $7H_2O$ 280 g/l and H_3BO_3 31 g/l in presence of varying amount of aluminum sulfate, chromium sulfate, chromic acid, benzaldehyde, nitrobenzene, glycine, gelatine, benzene disulfonate, and 1:3:6 sodium salt of naphthalene trisulfonate at constant c.d. ($\simeq$10 ma/cm^2) and temperature ($\simeq$24°C).

Deposition was carried out to well beyond the stage where polycrystalline deposits developed preferred orientations characteristic of bath conditions. The *p*H of the solution was adjusted so that the deposits were lateral growth type in the absence of impurities (8). After each addition of impurities or sodium chloride the deposit orientation was determined by electron diffraction (reflection method) in the usual way. Other experimental conditions such as *p*H adjustment, method of deposition, etc., were similar to those already described (1-3).

Results and Discussion

Electron diffraction studies revealed that the polycrystalline deposits, which were initially unorientated, developed one or another orientations depending on the amount and also on the nature of the additives. The results (Table I) showed that with increasing amount of impurities, at high *p*H region, the deposit crystals favored {110} orientation, but {210} at low *p*H values. This later orientation has been ascribed to hydrogen adsorption (2, 3) by the deposit crystals. The addition of sodium chloride suppressed these orientations and eventually led to {100} or {211} + $\{10\bar{1}0\}_{hex}$ or a mixture of them. This, however, signifies that the crystal growth process was considerably modified to give lateral growth deposits (2, 7). Both the out-growth or lateral growth conditions of deposition could be induced by the alternate addition of suitable amount of impurities or sodium chloride. This is demonstrated clearly with chromic sulfate and gelatine in the results marked with asterisks (Table I) and is likely to be true for others also.

Factors which control the crystal growth process at the cathode have been described by various workers (1-5). An important feature in the growth process in the present cases is the adsorption of basic salts or hydroxides of the inorganic impurities (8) or of the organic compounds which are good surface active agents (14, 15). The deposition will, however, be influenced both by the extent of equilibrium coverage of the cathode surface area and also by the rate of adsorption/desorption process (16). In any case, the result will be the out-growth deposition condition either due to depletion of metal ions at the cathode surface region as discussed in the previous paper (8) or to an increase in c.d. resulting from the decrease in surface area. That high c.d. favors {110} orientation even at different *p*H and bath composition is evident from Table II. Increase in c.d. also raises the cathode polarization. The interdependency between modes of crystal growth process or the preferred orientation and cathode polarization in presence of or-

ganic brighteners in nickel baths has been pointed out by one of us (A.G.) in a recent paper (2).

Sodium chloride seems to suppress completely or at least minimize the effect of factors such as (*a*) adsorption of compounds at the cathode, (*b*) film formation in the catholyte resisting the supply of ions and hindering the electron transfer process, (c) complex ion formation, etc., which contribute to out-growth deposition condition. Hoar (17) has emphasized that adsorption is essentially a dynamic process and equilibrium may be shifted by altering additives. That sodium chloride facilitates the desorption process is clearly shown from the results with naphthalene trisulfonate. The deposits were highly lustrous with this additive, but did not yield any clear diffraction patterns which were only ill-defined and

diffuse. By the addition of sodium chloride, the deposit crystals became less and less lustrous and finally became dull and even blackish, similar to those obtained from a chloride bath (3). Such surfaces yielded clear diffraction patterns, revealing that the deposits had developed $\{211\} + \{10\bar{1}0\}_{hex}$ orientations. That the loss of details of electron diffraction pattern in the above was not due to non-crystallinity, but due to adsorption of organic compounds, was shown from x-ray pattern of the stripped films, which consisted of rings indicating the crystalline nature of deposits. X-rays, because of their higher penetrating power, are scattered by the underlying metals, whereas electrons are scattered by surface layers which in the present case contained adsorbed additives. The alternate addition of naphthalene trisulfonate and sodium chloride made the deposits bright and dull, with their characteristic surface structures as discussed above.

These results suggest that chloride ions facilitate the desorption process of the surface active compounds at the cathode surface and produce more sites for depositions, thus reducing the current density and hence contributing to lateral growth. The depolarization of cathode potential in a gelatine-copper sulfate bath with halide ions has been explained similarly (18). In the competition between chloride ions and surface active agents or other impurities to get adsorbed at the growing cathode surface, it is likely that the former, because of its polarizability (19), prevails over the others. This will also help the electron transfer process and favor lateral growth condition. The observation that chloride ions facilitate the deposition of metals (9-11) and the suggestion that the formation of chloro or aquo-complexes helps the electron transfer process during nickel deposition (12, 13) are also in agreement with our results.

On the Jet Etching of N-Type Si

Paul F. Schmidt and David A. Keiper

Research Division, Philco Corporation, Philadelphia, Pennsylvania

ABSTRACT

The rate of jet electropolishing of low resistivity n-Si is controlled by two factors: supply of injected minority carriers and rate of dissolution of the SiO_2 film. The current through the oxide changes from ionic to electronic, i.e., the silicon becomes passive, if the oxide thickness increases beyond a critical value. The hole supply determines the amount of etching which can occur when the Si is not passivated by a thick oxide layer.

A general description of this process has been given before (1). The present paper is concerned with the mechanism of the etching process and with the rate and quality of etching, which is important from the economic point of view; not only is it necessary to etch fast, but the resultant surface also must be polished completely for subsequent device applications.

Anodic dissolution of a metal involves the removal of positive ions from the metal lattice under the action of the applied electrostatic field. In n-type semiconductors having an appreciable width of the forbidden gap there are no positive ions, except the few donor atoms and the very few lattice ions corresponding to holes in the valence band. In principle, the hole concentration can be increased by raising the temperature of the system. However, this approach is of no help on heavily doped n-Ge because of the very small hole concentration in this material at room temperature. The hole concentration at 100°C has not increased sufficiently to maintain any appreciable etching currents. (For 0.1 ohm-cm n-Ge the electron concentration is $n = 2.0 \times 10^{16}$ cm^{-3}. The intrinsic product for Ge at room temperature is $n_i^2 =$

$n \cdot p = 6.25 \cdot 10^{26}$, so that $p = 3.7 \times 10^{11}$ cm^{-3}. At 100°C the intrinsic product has increased to 2.6×10^{29} cm^{-3}. Assuming that $n_{25°}$ is approximately the same as $n_{100°}$, $p_{100°}$ would be approximately 1.3×10^{18} cm^{-3}.) With increasing bias, therefore, either discharge of anions in the electrolyte or breakdown of the surface barrier of the n-Ge must occur. This breakdown is usually very undesirable because it does not occur evenly over the anode surface and thus leads to pitting. Use of higher boiling electrolytes than water is not readily possible because of the low solubility of the reaction products in nonaqueous electrolytes. Also viscosity problems are troublesome. On Si with its wider gap appreciable thermal generation of hole-electron pairs is almost out of the question for jet operation.

For these reasons hole-electron pairs are generated by optical excitation of electrons from the valence band, and strong illumination is employed in the etching of both n-Ge and n-Si. This need for strong illumination is a common feature in the etching of n-Ge and n-Si. Differences in behavior are caused on one hand by the smaller gap of Ge and on the other by the relatively good solubility of GeO_2 in water as compared to SiO_2.

Mechanism of electropolishing.—Electropolishing proceeds under conditions of strong polarization. Differences in work function of the individual crystal faces, or due to degree of crystal perfection, or differences in conductivity of semiconductor material, must be small compared to the overpotential of the process; otherwise preferential etching would result.

On metals which form very stable oxides, the necessary polarization during electropolishing can be provided by an oxide having such a rate of dissolution in the given electrolyte that rate of anodic film growth and rate of dissolution of the film can be balanced.

The applied electric field pulls ions through the film, cations from the metal, and anions from the electrolyte interface; they combine to form more oxide [the older theory of anodic oxide growth by Mott and Cabrera regards only the cations as mobile: recent evidence favors the mobility of both cations and anions, at least for some systems (2, 3)]. At the same time the oxide dissolves in the electrolyte; under steady-state conditions the oxide thickness does not change. The differences in work function[1] of the individual crystal faces are small compared to the activation energy for migration through the oxide film,[2] which in turn is small compared to the activation energy necessary for migration through the oxide at a point not favored by the presence of a vacancy or other defect.

An increase in current density at any spot would increase the rate of film growth there; the rate of dissolution by the electrolyte would not increase as readily (it may increase somewhat because of a local rise in temperature and greater disorder of the film structure; cf. however, discussion on "Characteristics of SiO_2 films"). For a given applied bias, the field strength in the oxide decreases very rapidly with increasing thickness. The rate of reaction at this spot must therefore decrease to its old value. Thus there results a complete masking of local differences in etch rate of the metal surface itself.

It is hoped to present here evidence that an oxide film is present on Si during electropolishing in aqueous solvents, but it has not been shown that the oxide film must be present and that other anions, e.g., halides, cannot play the same role as oxygen.

Electropolishing of N-Si

The jet electropolishing of Si is possible in aqueous or alcoholic solutions containing fluoride ions. Prior to this investigation the jet etching of n-Si was done with a 0.2*N* solution of NaF + 5 cc 48% HF/1000 ml H_2O. Under illumination with a Bausch and Lomb reflector lamp electropolishing currents not higher than 3.0 ma were possible with a 10 mil jet. A further increase in light intensity did not increase the etch rate.

This limitation of the etching currents could be due to (*a*) an insufficient hole supply, or to (*b*) a slow chemical step, or to both.

In order to check the first possibility, it was necessary to know (*a*) the absolute intensity of illumination expressed in number of photons of energy greater than the gap width, and (*b*) what fraction of this number is available for the etching process, allowing for the unavoidable losses by reflection and by bulk and surface recombination.

Experimental Methods

The intensity of illumination was determined by shining the focused beam of a 1 kw projector lamp through a narrow opening in the lid of a Dewar flask into a dilute solution of india ink in water. A water filter of 2 cm thickness inserted in the path of the beam cut off wave lengths greater than 1.2 μ which do not create hole-electron pairs in Si. The lid of the Dewar consisted of cork, covered with reflecting aluminum foil both on the inside and the outside. The india ink solution was stirred gently to obtain a uniform temperature distribution. The rise of temperature with time of illumination was measured, as was the drop of temperature with time after switching off the light. The total energy absorbed thus could be calculated from the known heat capacity of the solution and could be corrected for heat losses during illumination. The latter correction proved to be very small.

Knowing the color temperature of the tungsten filament, approximately 3200°K, the total energy input, and assuming that the energy distribution vs. wave length for the tungsten filament is essentially the same as for a black body radiator, the total number of photons of wave lengths shorter than 1.2μ can be calculated. This also gives the number of photons/cm^2 x sec for a given size of the illuminated area.

Knowing the reflectivity of the Si the number of photons is obtained which penetrate into the Si and create hole-electron pairs.

The next step was to determine experimentally the fraction of the injected holes that are lost by bulk or surface recombination before they can be collected by the anode process. Since the rate of

[1] Work for removal of a positive ion from the crystal.

[2] At least in the "high field" case which is realized in jet etching (2).

recombination could change at very high light intensities, it was also necessary to determine the hole flux that could be collected as a function of light intensity. This was done by shining light of a known intensity on the front surface of a photodiode on n-Si, while maintaining a reverse bias of 0.25 v across the diode. Light intensity was varied by inserting Kodak-Wratten neutral density filters in the path of the light beam.

Since illumination introduces a forward bias of the diode, the applied reverse bias had to be increased in order to maintain the effective bias at 0.25 v. This procedure does not take into account the change in voltage drop with current across the base contact and across the bulk of the diode; it is, therefore, only a rough approximation. However, the current under illumination does not depend strongly on the magnitude of the applied reverse bias for the given resistivity of the Si.

Before the hole current collected can be compared to the hole current injected a further correction must be applied because the diode collects holes not only from the area directly in front of it but also from the surrounding area by lateral diffusion of holes.[3] The absolute amount of this contribution to the current increases with the circumference of the contact. The relative importance, however, depends on the ratio of contact radius to diffusion length for holes. For the photodiode employed it will increase the current by a factor of about 2. Collection of holes by the jet also differs from collection of holes by the photodiode in that the concentration of injected holes is greatest immediately underneath the Si surface; it must be expected therefore that the jet will be a more efficient collector than the photodiode. Thus the experiments with the photodiodes only give a lower limit for the supply of holes which may be expected to be available for the anode process.

Results

Determination of light intensity.—Total energy input into calorimeter by 1 kw projector lamp, with water filter inserted, was equal to 0.70 w. The light beam was focused uniformly over an area of 0.08 cm^2. For this setting, which also was used in the experiments with the photodiodes and during jet etching, a total number of photons of 5×10^{19}/sec x cm^2 in the wave-length region 0.3-1.2μ is calculated from the color temperature of the tungsten filament (3200°K).

Corrections for reflection losses and for collection of holes by lateral diffusion.—Table I gives the pertinent data for the n-Si photodiodes employed. For the diode area of 1.9×10^{-4} cm^2 the photon flux is 9.5×10^{15} sec.

[3] Provided the illuminated area is larger than the diode area, as was the case in our experiment.

Table I

Bulk lifetime after alloying, μ sec	Material	Resistivity, ohm-cm	Base thickness in front of recrystallized region, μ	Area of contact
9	n-Si alloyed Al contact	0.7 to 1.3	5.0	1.9×10^{-4} cm^2

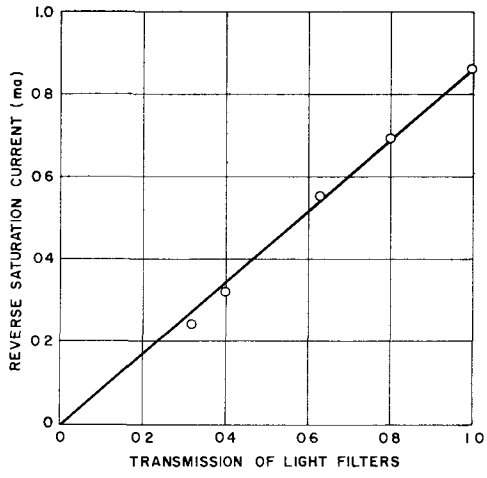

Fig. 1. Response of photodiode on n-Si vs. light intensity

The reflectivity of Si as a function of wave length in the visible has been given by Coblentz (4). Taking into account the change of reflectivity with wave length it was found that for the energy distribution of the tungsten filament an average reflectivity of 29% can be employed for the spectral region 0.3-1.2μ.

An average reflectivity[4] of 29% converts the number of 9.5×10^{15} photons/sec incident on the diode area to 6.8×10^{15} photons penetrating into the silicon, equivalent to a hole current of 1.1 ma.

Due to the above mentioned affect of lateral diffusion, however, a current of about 2.2 ma may be expected.

Diode response vs. light intensity.—Figure 1 shows diode current vs. light intensity and also indicates the transmission factors of the filters used.

The diode response is practically linear. As already mentioned, this can be only an approximation because the change in voltage drop with current across bulk of the diode and base contact has been neglected.

At the highest light intensity the diode response was 0.87 ma, i.e., about 40% of the injected holes reached the collector.

Correction for reflection losses during jet etching.—Since under our experimental conditions of jet etching the light was not perpendicularly incident on the Si surface but within 15° of the perpendicular, and because additional reflection losses are introduced by the jet stream, the above figure needs a further correction before it can be used to estimate the expected etch rate. It was found that the diode current decreased by about 40% when an electrolyte jet was directed against the front surface of the diode and the light was incident within 15° of the perpendicular.

Applying the above corrections indicates that at least 1 out of every 3 incident photons should be available to the etching process, based on the etched area.

Discussion

From the fact that there is no levelling off of the photodiode response at very high light intensity, and

[4] Actually, the reflectivity may also depend somewhat on intensity of illumination (5, 6).

from the fact that there is a definite correlation between low light intensity and etching currents below 3 ma/10 mil jet, it may already be concluded that the limitation of 3 ma is imposed by a slow chemical step and not by an insufficient hole supply (at very high light intensities).

As a check, we can now compare the hole supply and therefore also the expected etching current under illumination with the 1 kw projector lamp to the highest etching current obtained experimentally (with 10 mil ϕ jet and 0.2*N* NaF + 5 cc 48% HF/liter solution).

At low current densities (3 ma) the diameter of the etch pit is normally about twice the jet diameter (it increases to about 4 times the jet diameter at large current densities, i.e., the current density does not increase as rapidly as the jet current.)

The photon flux on an area of 2×10^{-3} cm^2 (= 20 mil ϕ) is 1×10^{17} sec^{-1}, equivalent to a hole current of 16 ma. Reflection losses under actual jet-etching conditions reduce this figure to 6.8 ma. Two corrections must again be applied: increase of the available number of holes due to lateral diffusion, and decrease because of surface and bulk recombination. It can be estimated that the first factor will increase the current by about 60% of its value in the absence of lateral diffusion.[5] Recombination losses ought to be considerably less than in the case of the photodiode, because the holes are generated in the space charge region of the surface barrier and are immediately collected by the strong field. The two factors should at least balance. It is therefore justified to assume a hole supply sufficient to maintain an etching current of at least 6 ma. Experimentally, however, the electropolishing current was found to be limited to 3.0 ma.

It must therefore be concluded that the hole supply under intense illumination is sufficient to maintain quite large etching currents, but that a slow chemical step controls the etch rate for the given electrolyte.

Dissolution of SiO_2 *Film as the Rate-Controlling Process During Jet Etching of* N-Si *Under Intense Illumination*

Characteristics of SiO_2 *films.*—Slow dissolution of a SiO_2 layer appeared as the most likely cause of slow etching under the above mentioned conditions. In work on the anodic formation of oxide films on Si in inert electrolytes it had been found (7) that the current through the SiO_2 during forming is mostly electronic and not ionic (e.g., 99% electronic at 7 ma/cm^2). The same is true apparently also for the SiO_2 film present during electropolishing; thus if for a given electrolyte the rate of formation of SiO_2, i.e., the current density, is higher than the rate of dissolution of the SiO_2 by the electrolyte, the oxide film will increase in thickness, and the silicon will become passive because the current through the SiO_2 changes from ionic to electronic.

It might be thought that the chemical dissolution of the oxide would continue at the same rate after passivation so that the Si must again become active. This, however, is not the case: once the silicon has become passive, it remains passive at the given current density. An explanation for this phenomenon may be sought either along the lines of passivation of iron, which dissolves rapidly as long as the surface is covered by Fe_3O_4 only, but becomes passive when a layer of Fe_2O_3 appears in addition (8), or along the lines of the work of Engell (9) who showed that the dissolution rate of bulk oxides like FeO or Fe_3O_4 depends strongly on an applied potential. But it may also be that the enormous electrostatic pressure on the SiO_2 film at the very high current densities of the jet process is of importance. The oxide is strongly disordered while ionic current is flowing through it (10). Any strongly disordered structure will have a higher rate of dissolution than an ordered structure. When the Si passivates, ionic current flow through the SiO_2 stops almost completely. According to Le Chatelier's principle the electrostatic pressure should decrease the number of interstitials and vacancies, thus decreasing the volume and leading to a decreased rate of dissolution.

If the slow dissolution of an SiO_2 film is indeed rate determining, an increase in acidity and in temperature should permit faster etching (under intense illumination).

Effect of acidity and temperature on etching speed.—In order to accelerate the dissolution of the SiO_2 both the temperature and the HF content of the electrolyte were increased. A solution containing 30 cc of 48% HF + 8.4 g NaF/1000 H_2O, heated to 70°C, was found suitable for electropolishing at 30 ma with a 10 mil jet under the above quoted high light intensity. The resulting etch pit had a diameter of 0.1 cm. The photon flux on the area of the etch pit, 7.8×10^{-3} cm^2, is equivalent to a hole current of 26.8 ma, allowing for reflection losses. For the relatively large area of the etch pit (radius $> L_p$) the contribution by lateral diffusion of holes is becoming less important and may be estimated to amount to about 14%, which increases the expected electropolishing current to 30.5 ma. This good agreement between expected and experimentally determined electropolishing current may be somewhat accidental (compensation of errors), but essentially it means that surface and bulk recombination of holes are suppressed by the strong field of the jet contact. Another solution, 40 g NH_4HF_2 + 8 g NaF/liter, proved very satisfactory at room temperature.

Shape of etch pits.—Assumption of slow dissolution of an SiO_2 film as the rate-determining step permits understanding of the factors governing the shape of the etch pit. Si, in contrast with Ge, usually yields very flat-bottomed etch pits. The current density should be highest in the center of the etch pit if potential distribution alone were decisive. However, as was shown above, a very high current density leads to a thickening of the SiO_2 film, which in turn increases the electronic current component. The center region also cannot collect as many holes as the periphery which profits from lateral diffusion of holes. Thus a balance can be achieved with the periphery etching at about the same rate as the center. Mounds

[5] These estimates are based on the assumption that the number of laterally collected holes decreases to $1/e$ at distance $\chi = L_p$ from the geometric edge of the diode.

formed in the center of the etch pit can be explained by the same reasoning. Typically, it was found that under conditions of high HF content and high light intensity the resulting etch pits are rounded. Thus, a delicate balance of all contributing factors is required to obtain flat-bottomed etch pits at high etch rates.

What causes the pitting at too high current density is not yet completely clear. Crystal defects are an obvious possibility, but it seems that other causes like dielectric breakdown of insulating layers or removal by the electric field of positively charged donor atoms, aggregated at dislocations, and thus causing a catastrophically high local etch rate, may also be involved. Correlation between pitting and dislocation density is, of course, very pronounced.

Pitting is reduced markedly when the light intensity, current density, and pH of the solution are correctly adjusted; it is also possible to add certain complexed cations (such as K_4 [Fe(CN)6]) in their lower valence state to the electrolyte; apparently they are then oxidized to a higher valence at a lower field strength than is required for the production of "pin-holes."

Valence state of dissolved Si.—No lattice structure is revealed by the anodic electropolishing of Si; the same holds true for the anodic electropolishing of Ge. On the other hand, the cathodic jet etching of Ge[6] (reaction product GeH_4) results in etch pits corresponding to the given orientation, i.e., formation of distorted hexagonal etch pits on the {100} plane. Clearly sufficient polarization is absent in the cathodic etching of Ge but is present in the anodic polishing of Si (and Ge). The polarization factor could be either a thin oxide layer on the Si or diffusion control in the electrolyte, specifically diffusion of fluoride ions through the diffusion layer to the interface (12). Actually the two mechanisms may describe the same physical picture, namely, the presence of a thin oxide layer on the Si. This question can perhaps be decided if the current efficiency during jet electropolishing of Si is known. In the absence of an oxide layer one would expect the Si to go into solution initially in the divalent state. If a layer of SiO_2 were present, then the Si should definitely go into solution in the quadrivalent state. A third possibility is suggested by the work of Bockris (to be published) who has shown by galvanostatic measurements that the surface of Ge during anodic polarization is covered by a monolayer of GeO; yet the Ge ions which have gone into solution are found to be in the quadrivalent state. Results of related studies (11) show that the Si dissolves in the quadrivalent state in the high current density region. This, together with the high potential values observed, with the need for free HF in order to electropolish, and with the passivation of the Si at too high current densities for a given HF content seems to establish definitely the presence of a thin SiO_2 film during electropolishing in aqueous solutions. In order to obtain the best polish, the dissolving power of the electrolyte must be neither too low nor too high.

Uniform Resistivity p-Type Silicon by Zone Leveling

E. D. Kolb and M. Tanenbaum

Bell Telephone Laboratories, Inc., Murray Hill, New Jersey

ABSTRACT

Silicon single crystals nominally 1 cm in diameter and 16 cm long have been grown with aluminum doping in a floating zone apparatus. Crystals have been prepared with nominal p-type resistivities of 0.3 and 5 ohm-cm with variations of 5% or less along the crystal length. Variations of resistivity with rotation rate, growth rate, ambient gas flow rate, and other growth variables have been studied. Zone volume variations were also measured.

The wide use of diffusion techniques for the production of silicon devices has led to a need for large quantities of single crystalline Si of uniform resistivity. Past experience with germanium zone refining and leveling (1) demonstrated that this is a practical method of obtaining large quantities of uniform resistivity single crystals.

By the use of the floating zone technique (2) Si single crystals can be grown and zone refined. The process can be adapted easily to zone leveling. Figure 1 illustrates a typical zone leveling experiment. A zone of molten semiconductor, A, is formed between a single crystal seed, B, and a pure polycrystalline ingot, C. The impurity is added to the molten zone. The molten zone is moved to the right freezing out impurity doped semiconductor onto seed B and melting pure polycrystalline semiconductor from ingot C. The newly grown single crystal will contain a concentration of impurity kC_L, where k is the effective distribution coefficient of the impurity, and C_L is the impurity concentration in the molten zone. If k is very small (e.g., < 0.01), the amount of impurity frozen into the single crystal is sufficiently small so that C_L is not significantly altered even after several zone lengths have been traversed.

In addition to having a small k, a suitable doping element must be nonvolatile if a uniform concentration is to be maintained. It must be of high purity since trace elements having a larger distribution coefficient would have a detrimental effect on the leveling process. Further, since control is often desirable over several orders of magnitude of impurity concentration, it is desirable to be able to use both alloys of the impurity with the semiconductor as well as the elemental impurity itself. Aluminum fulfills these requirements and was used for these experiments.

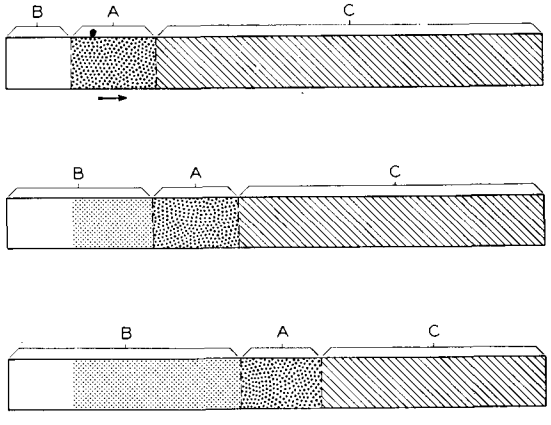

Fig. 1. Typical zone leveling experiment

Experimental

The floating zone machine used for the experiments has been described by Buehler (3). It is necessary to keep the zone volume constant during zone leveling to keep C_L constant. In order to minimize zone volume changes, the zone volume was monitored during the leveling operation. This was done by measuring the zone length with a cathetometer, assuming that the zone diameter and liquid-solid interface shape remain essentially constant, and manually adjusting the rf induction heater to compensate for any observed changes. Zone length variations did not exceed ±7% for the growth conditions studied.

Zone leveling was studied with crystals that ranged from 14 to 18 cm in length, were between 0.9 and 1.2 cm in diameter with diameter variations in individual rods of ±3% or less. They were all p-type with resistivities at the seed ends in the range from 80 to 175 ohm-cm and 30 to 165 ohm-cm at the opposite ends.

Crystals were doped to nominal resistivity levels of 0.3 and 5 ohm-cm. The 0.3 ohm-cm crystals were grown by doping with elemental Al. A small piece of 99.998% Al weighing approximately 0.5 mg was placed in a 0.025 cm slot, cut at approximately a 45° angle in the seed end of the pure crystal, where the starting zone was to be established (Fig. 2a).

The 5 ohm-cm rods were grown by doping with cylinders of floating zone leveled Al doped Si of approximately 0.038 ohm-cm resistivity. These were placed between the seed and the undoped starting rod where the starting zone was to be established (Fig. 2b). It was important to assure that the seed, the doping cylinder, and the starting rod were coaxially aligned prior to the zone-leveling operation. Any eccentricity tended to increase the diameter variations during zone melting and thus increase the uncertainty in the zone volume. It was possible to achieve conditions where the diameter fluctuations increased from an original average of ±3% to final values of ±7% or less.

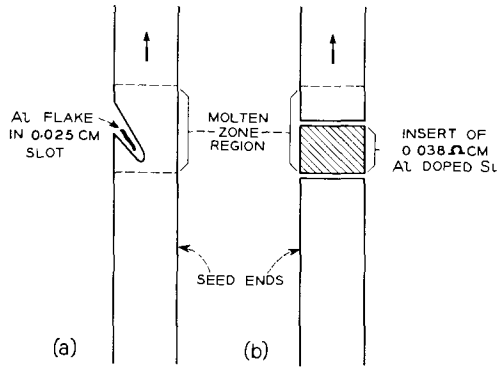

Fig. 2. Aluminum doping schematic

All the experiments were performed in a hydrogen atmosphere. Oxygen was removed from the hydrogen by passing through a Deoxo purifier and the hydrogen dried to a dew point of $< -100°C$ by passing over Linde molecular sieves (No. 5A) at liquid nitrogen temperature. This purification was necessary to insure a minimum loss of aluminum from the molten zone by oxidation.

The resistivity of the zone leveled crystals was measured on bars 0.625 cm by 0.625 cm in cross section cut from the center of a crystal. Current electrodes were rhodium and copper plated on the ends of the bars, and a constant current was passed along their length. Two movable points spaced 0.025 cm apart were driven mechanically along the length of the rod and the potential difference between the points was plotted on a L&N Speedomax recorder. Resistivities were calculated from the potential profiles. These measurements showed a background noise level which appeared as the points were dragged along the surface of the crystal. By repeating the measurements several times on a particular crystal, it was determined that the measurements were reproducible but, due to the noise, variations in resistivity less than ±3% could not be determined.

Results

The following variables were studied: stirring of the molten zone, growth rates, loss of Al from the molten zone, and ambient gas flow rate.

The molten zone is stirred by rotating the seed crystal while holding the undoped portion of the rod stationary. The effect on resistivity of seed rotation speeds between 40 and 110 rpm was determined to be negligible at the 0.3 ohm-cm level. A crystal was grown at both 0.0021 and 0.0058 cm/sec with rotation speeds of 40 and 110 rpm. Figure 3 is a resistivity profile obtained from a typical stirring experiment. Distance along the crystal axis in centimeters is plotted along the vertical coordinate while resistivity in ohm-cm is plotted along the horizontal coordinate. It can be seen that the resistivity is virtually unchanged by changing the rotation rate at either growth rate. A closer comparison of the resistivities at the 0.0021 cm/sec growth rate showed the 110 rpm region to be ~7% higher than the 40 rpm region. Since this increase occurred gradually, and there was no abrupt change when the stirring rate was changed, it is believed that this is not a result of stirring but is due to some unknown variable.

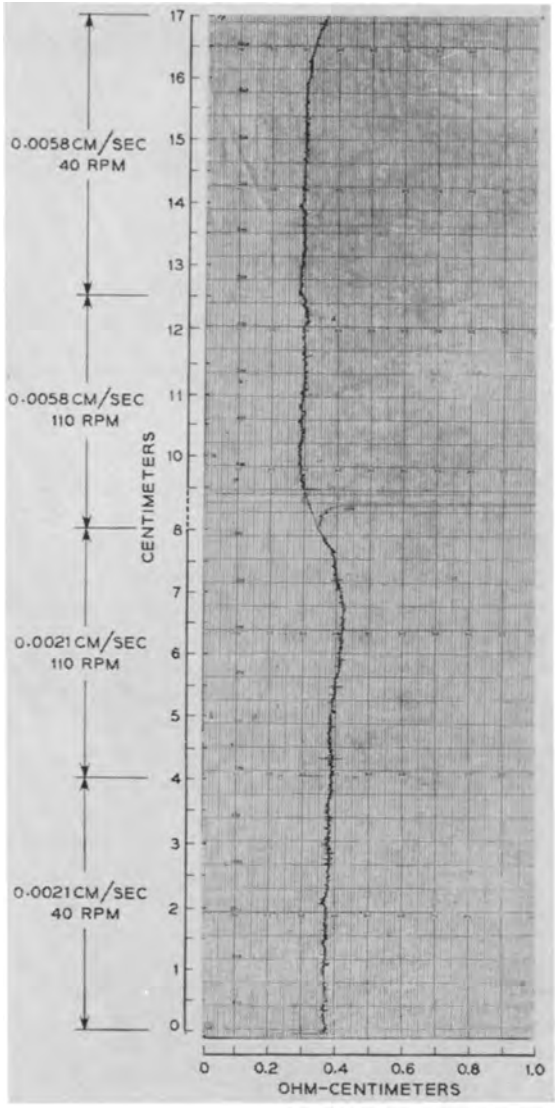

Fig. 3. Resistivity profile of 0.3 ohm-cm stirring and growth rate experiment.

Changing the growth rate produced the largest effect of any of the variables studied. Increasing the growth rate from 0.0021 cm/sec to 0.0058 cm/sec decreased the resistivity approximately 25% at the 0.3 ohm-cm level and 35% at the 5 ohm-cm level. Measurements of zone length and crystal diameter indicated that the maximum change in zone volume between the above growth regions was not more than ±3%. Figure 3 is the resistivity profile of a typical 0.3 ohm crystal. The decrease in resistivity is in the direction expected from the Burton-Prim-Slichter (4) diffusion layer theory. At the faster growth rate, less of the rejected impurity is able to diffuse away from the growing interface, and the effective distribution coefficient increases.

It is interesting to note that a comparison of uniformity of resistivity vs. growth rate shows that at resistivity levels of 5 ohm-cm and growth rates of approximately 0.0021 cm/sec the resistivity variations are ±10%. In the region grown at 0.0058 cm/sec the resistivity varied less than ±5%. Zone volume changes as measured by the cathetometer readings between the slow and fast growth rate regions did not exceed ±3% for each region and cannot ac-

count for the observed resistivity variations. It appears that at the higher resistivity levels the resistivity is more uniform at the faster growth rates. At the lower resistivity levels, the resistivity uniformity is not affected over the range of growth rates studied. The reason for this difference is not known.

Loss of Al from the molten zone by evaporation or reaction with the protective atmosphere was studied by stopping the zone travel approximately halfway through the pass, holding the zone stationary for an hour with the seed rotating (puddling), and then proceeding at the original growth rate. Loss of Al from the molten zone would produce higher resistivity after puddling. By comparing the resistivity measurements in the first half of a 0.3 ohm-cm crystal with those in the second half it was observed that the resistivity level upon resuming growth is equal to that prior to the puddling interval within the measurement error. Thus the loss of Al from the molten zone at the 0.3 ohm-cm level is negligible. Two additional puddled crystals doped to 1.5 and 5 ohm-cm resulted in resistivity levels upon resuming growth that were 5% and 12% higher, respectively, than the levels prior to the puddling, indicating some loss of Al. The loss of Al may be due to variations in the control of the H_2 dew point resulting in oxidation of Al from the molten zone. In this case the total loss of Al would depend only on the water content of the ambient hydrogen atmosphere and would be independent of the Al concentration in the molten zone. At higher resistivity levels the loss of a constant amount of Al from the molten zone would be more noticeable since it is a larger fraction of the total Al concentration added initially to the molten zone.

Finally, the effect of the H_2 gas flow rate between 100 and 1000 cc/min on resistivity level was determined to be negligible at the 0.3 ohm-cm level. A crystal was grown at 0.0028 cm/sec. The resistivity in the region of 100 cc/min of H_2 was within measurement error of $\pm 3\%$, while the resistivity varied $\pm 8\%$ in the 1000 cc/min region. The reason for this difference is not known.

Measurements of the resistivity variations through the cross sections of the zone leveled crystals were made on rods 0.0125 cm by 0.0125 cm in cross section cut diagonally from the 0.625 cm cross section of the square rods that had been used for the longitudinal measurements. Maximum resistivity variations through the cross section were $\pm 7\%$ and seldom exceeded $\pm 5\%$ in any of the growth conditions studied.

Values for the effective distribution coefficient of Al in Si at the concentration levels and with the growth variables studied ranged between 2.0×10^{-3} and 9.0×10^{-3}. Burton (5) has reported an equilibrium distribution coefficient value for Al in Si at the melting point of Si $> 4.0 \times 10^{-3}$. The values obtained from the present work are based on Al concentrations in the molten zone calculated from the concentration of Al added and corrected for zone volume changes measured along the crystal length. The concentration of Al in the leveled crystals and in the doping alloys was obtained from the respective resistivity measurements using mobility data of Prince (6).

There is some uncertainty in Prince's mobility data below 1.0 ohm-cm, and an extrapolation was made to the 0.038 ohm-cm level. Calculations of the effective distribution coefficient were also made using the recent values of hole mobility determined by Backenstoss (7). These resulted in distribution coefficients as large as 1.5×10^{-2}. These values are much larger than any previous estimate of the distribution coefficient of aluminum. Furthermore, if the distribution coefficient was this large, zone leveling with Al should not be as effective as is actually observed. This indicates that the mobilities reported by Backenstoss may be too low at low resistivities.

Minority carrier lifetime determined by photoconductivity decay measurements (8) ranged from 10-20 μsec at the 0.3 ohm-cm level, and from 50-200 μsec at the 5 ohm-cm level.

Conclusions

For the growth parameters studied, changes in growth rate have the largest effect on resistivity level. Increasing the growth rate from 0.0021 cm/sec to 0.0058 cm/sec produced a decrease in the resistivity level of approximately 25% at the 0.3 ohm-cm level and 35% at the 5 ohm-cm level. Changes in stirring rate or gas flow rate do not produce significant effects on resistivity level over the range that was explored. Also aluminum evaporation is not significant. This suggests that satisfactory zone leveling of Al in Si requires close control of growth rate while moderate variations in rotation rate and ambient gas flow rate can be tolerated.

Crystals doped with Al can be grown in the present apparatus with resistivity variations along the length of $\pm 5\%$ or less at the 0.3 ohm-cm level at growth rates between 0.0021 cm/sec and 0.0058 cm/sec and at the 5 ohm-cm level at 0.0058 cm/sec. Crystals doped to the 5 ohm-cm level and grown at approximately 0.0021 cm/sec have variations along the length of $\sim 10\%$. Resistivity variations through the cross section of all crystals studied were less than $\pm 7\%$.

Acknowledgments

The authors wish to express their appreciation to Miss A. D. Mills who made all the resistivity and lifetime measurements.

Simple Method of Determining Crystal Perfection

H. K. Herglotz

Pigments Department, E. I. du Pont de Nemours & Company, Inc., Wilmington, Delaware

ABSTRACT

An optical analogy leads to a simple x-ray method of determining crystal perfection. Although furnishing only semiquantitative information at present, this can be developed into a quantitative method. For some applications it is considered superior to existing techniques such as etch pit counts or x-ray rocking curves. This method is combined with the determination of the crystal orientation since it is based on a slightly modified Laue back reflection method.

It is not necessary to stress the importance of crystal perfection for semiconductor devices since it has been emphasized by several authors (1, 2). Many of the properties of the solid state can be understood only if a deviation from the regular arrangement of matter in crystals is assumed (3). The status of this knowledge has been summarized (4, 5).

The methods commonly used for the determination of single crystal perfection are etch pit counts (6), copper precipitation (7), and x-ray rocking curve measurements (8, 9). These procedures have limitations with respect to ease of handling, reproducibility, or interpretation.

This paper describes a simple x-ray method which eliminates some of the drawbacks of the methods mentioned above. The objective of this method is an over-all characterization of the crystal with respect to reticular orientation (Ref. 4, p. 411) but not to lattice defects of atomic dimensions. Other x-ray methods of perfection studies are available (10-12).

This part of the publication presents a qualitative description of the method, an outline of the evaluation procedure, and some preliminary results. Part II will deal with some quantitative considerations and more examples of application.

Experimental Procedure

A model with visible light is helpful in explaining this x-ray method (13). The reference article shows a well grown rock salt cube which, although far from being an ideal single crystal, might represent here a single crystal. It is completely transparent which means that no internal surfaces reflect light from a light source into the eye of the observer. However, it became dull and opaque after it had been deformed by exercising some pressure on it in a hand press. The crystal has kept its external shape, but the deformation has created internal reflecting surfaces. This rock salt cube with internal surfaces might serve as a model for a mosaic crystal.

Consider an analogous experiment using x-rays, for which practically all materials are to some extent transparent, particularly silicon or germanium. X-rays are also a more sensitive probe due to their short wave lengths. The inherent differences between x-ray diffraction and optical reflection must be kept in mind in spite of the frequent informal use of the expression "x-ray reflection."

Due to the selectivity of x-ray diffraction a stationary single crystal permits reflections by the lattice planes only if a variety of wave length (bremsstrahlung) is used so that the crystal can select those which satisfy Bragg's equation: $n\lambda = 2d \sin \theta$.

Monochromatic radiation, however, has a chance for reflection only if a variety of angles are used so that the crystal can select those very few which satisfy Bragg's equation. It is well known that this is achieved by rocking or rotating a single crystal. In the case of a powder or polycrystal without preferred orientation, a large variety of lattice planes is present, whose normals point to all directions of radii of the sphere around the crystal. This large number of planes offers such a variety of incident angles that in any case a sufficient number of planes are in glancing position. The geometrical shape of all rays reflected by one type of planes forms a cone with an apex of 4θ or $360\text{-}4\theta$, respectively. The polychromatic bremsstrahlung is in the case of a powder reflected in all directions because of the variety of both λ and θ and contributes to the background only.

The oriented polycrystals such as rolled sheets or electrolytically grown whiskers, to name two of many examples, hold a position between the well grown single crystal and the irregular powder, which mark the extremes. Also, a place between, although closer to the single crystal, must be attributed to the distorted single crystal (mosaic crystal) as represented by the opaque rock salt cube.

Since the mosaic crystal, the most common form of "single crystal," is a hybrid between the perfect monocrystal and a polycrystal, a method should be available to determine how much of each component is present. One possible way is to take an x-ray pattern under conditions for both mono- and polycrystal and find out what traces of polycrystallinity it contains.

As stated previously, it is proper to use the bremsstrahlung to obtain a pattern of a stationary single crystal (Laue pattern). A tungsten target x-ray tube serves best for this purpose, since the radiation from such a tube consists almost exclusively of the polychromatic x-ray spectrum.

For powder patterns, however, the bremsspectrum is not only useless, but even adverse, since it gives rise to excessive background. The radiation of a copper target is used mostly for this case since it com-

bines a very intense characteristic radiation with little bremsstrahlung due to the relatively low atomic number of copper. To make Debye-Scherrer diagrams even clearer, other wave lengths besides the desired Kα-doublet are suppressed or eliminated by filters, monochromators, or pulse height discriminators.

However, the purpose is served best by the unfiltered radiation of a copper target, since it offers a certain amount of a polychromatic radiation plus a strong monochromatic component. Thus, conditions for both single and polycrystal are met simultaneously. Furthermore, the unfiltered radiation from a copper target is obtainable in the simplest fashion.

Registration by counters (Geiger, proportional, scintillation), which offers tremendous advantages in many cases in comparison to photographic methods, is not very suitable in this case because the scanning nature of these devices makes registration of a Laue pattern of a single crystal uneconomical. A recorder should register a maximum of diffracted rays and offer an over-all view of the crystal. The ideal situation would be to have a spherical film around the crystal. The closest approximation to this, which permits rolling off the film into a plane, is the double cone suggested by Regler (14, 15).

The appearance of undeformed and deformed rock salt in double cone patterns is illustrated by Fig. 1 and 2, respectively. The film from regular cones has the shape of a semicircle and permits simple evaluation of the readings on the film.

Figure 1 shows a Laue pattern of a single crystal with spots from the bremsstrahlung and hardly any diffraction of the copper radiation. This corresponds to the reflectionless appearance of the crystal in visible light. Distortion of the crystal lets monochromatic reflections appear in the form of lunates on the back reflected part and causes the Laue spots on the transmitted part to degenerate to curves, (Fig. 2). This is closely related to the multiple reflections of the visible light which make the crystal appear dull.

In using these facts for crystal perfection studies,

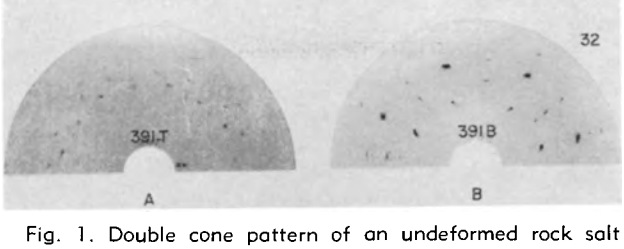

Fig. 1. Double cone pattern of an undeformed rock salt crystal: (A) transmitted part, (B) back-reflected part. The figure next to the back reflected pattern indicates the perfection value in arbitrary units (see Fig. 7).

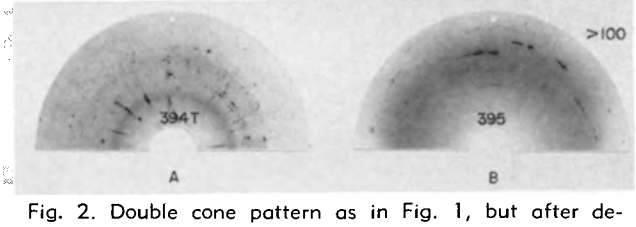

Fig. 2. Double cone pattern as in Fig. 1, but after deformation of the rock salt crystal.

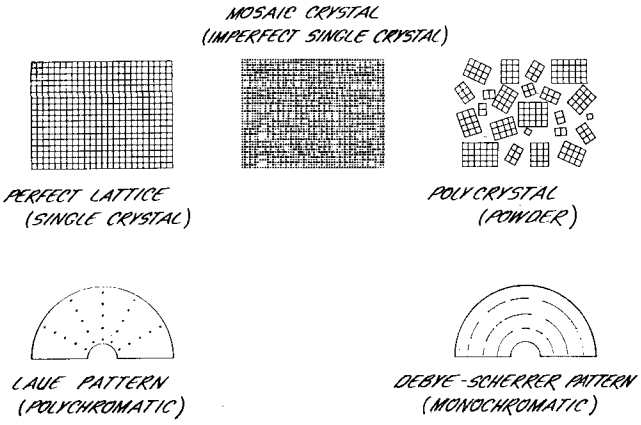

Fig. 3. Summary of perfection method

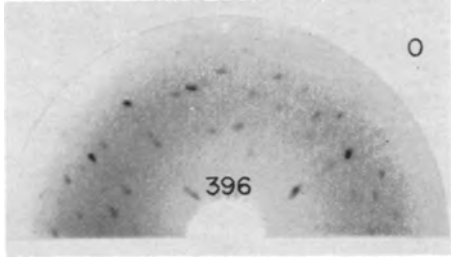

Fig. 4. Cone back reflection pattern of a diamond (perfection value 0).

it is found the back reflected cone furnishes all the information we need and permits nondestructive testing. Restriction to the back reflected part of the diffraction pattern is, therefore, no disadvantage since it offers simplicity with no sacrifice of information. This is the reason all routine work on perfection studies has been carried out with the single cone back reflection method only.

As compared to the plane film method, the advantages of the cone back reflection method for the task under consideration consist of: (a) focusing, which reduces exposure time by making use of a wider aperture; (b) recording of all glancing angles $45 < \theta < 90$ on the entire circumference of the diffraction cones.

Figure 3 summarizes the situation. A perfect lattice, symbolized by an undistorted network (left), furnishes only a Laue pattern from the bremsstrahlung. A completely irregular polycrystal with small sized crystallites furnishes only Debye-Scherrer circles, the bremsstrahlung disappearing in the continuous background. The mosaic crystal, symbolized by an irregular network, is a hybrid between the two.

Even with the small divergence of the primary beam which offers a small variety of angles to the crystal, no traces of Debye-Scherrer lines should be found on the Laue back reflection pattern of an ideal single crystal. This is proved by Fig. 4, a pattern from a 3 x 3 mm clear diamond chip. Diamond is known to have the most nearly perfect lattice. In spite of the divergence of about 5° of the primary beam, no reflection from the copper K radiation can be observed. The diamond chip was not cut in a major crystallographic direction; therefore, no simple symmetry relations can be seen on its Laue pattern.

To demonstrate the opposite extreme from this diamond lattice, a pattern taken under the same con-

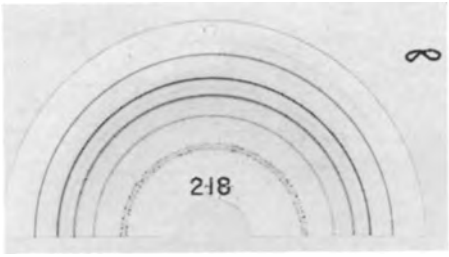

Fig. 5. Cone back reflection pattern of a polycrystalline piece of silicon (perfection value ∞).

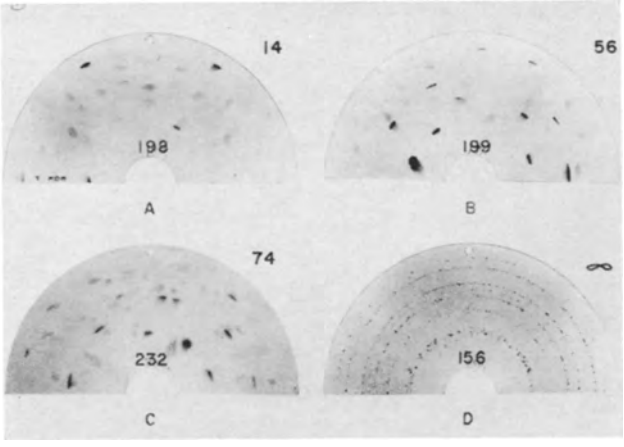

Fig. 6. Various degrees of "singularity" between the extremes of Fig. 4 and 5. A, B, Czochralski crystals with perfection values of (14) and (56), respectively; C, floating zone crystal, twinned (74); D, silicon needle from the zinc reduction of silicon tetrachloride (∞).

ditions as for Fig. 4 was obtained with a piece of silicon (Fig. 5). The silicon was obtained by vapor decomposition of its chloride. It is an example of a finely polycrystalline aggregate without any preferred orientation furnishing full Debye-Scherrer circles (degenerated into half circles after rolling off the film). No Laue spots from the bremsspectrum can be observed.

Between these two extremes belong the photographs of Fig. 6 (A-D). Figure 6A is taken from a well grown Si-Czochralski crystal, "B" from a less perfect Si single crystal, "C" is the pattern from an early unsuccessful attempt to grow a float zoned single crystal, and "D" stems from a silicon needle deposited from the vapor phase. The latter approaches Fig. 5, but the crystalline individuals are large enough to furnish Laue spots instead of continuous background from the bremsspectrum. A necessary consequence of this is that the Debye-Scherrer circles are broken into single reflections and are not continuous as in Fig. 5.

Evaluation of Perfection Numbers

These experiments make it clear that conclusions about the perfection of the single crystal can be drawn by counting the number of monochromatic reflections and by taking into account the size of the lunates, in other words, estimating the fraction of the Debye-Scherrer circle which is blackened. This leads to semiquantitative results in arbitrary units, good for comparison of crystals but not of significance in an absolute sense. A scale for arbitrary units is suggested in a later part of this paper (Fig. 7).

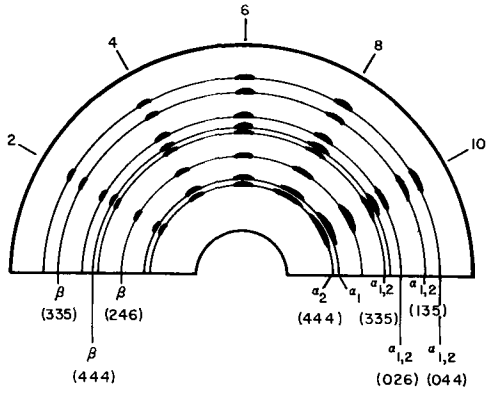

Fig. 7. Scheme of a rough scale for evaluation in arbitrary units. The size of the lunates is rated from 2-10. The reflecting planes are marked (in parentheses) from both Kα and Kβ. If the doublet appears, the number should be doubled. The β-reflections are weaker than the α-reflections because of the lower intensity of the β wave length.

Perfection numbers measured in these arbitrary units are shown for the back reflection patterns of Fig. 1, 2, 4-6, 13. This figure in arbitrary units is derived from the planes (111), (013), (011), (135), (335), (123), which appear on the back reflection pattern of silicon with the radiation from a copper target (see Fig. 7).

The method applied in this way is semiquantitative and does not take strict account of several factors such as, for example, the divergence of the primary beam and the intensity of the Debye-Scherrer lunates (correlated with each other). The method, however, furnishes a very dependable relative measure of perfection as demonstrated by a few examples below. A chip of a clear industrial diamond serves as a standard marking the zero point of the scale. A perfect single crystal represents the value 0 in this scale, while the powder or polycrystal with continuous Debye-Scherrer circles is designated as infinity. The method can be developed into a quantitative one leading to the stereographic projection of the poles of all planes appearing on the back reflection pattern. The number of planes registered can be increased by using alloyed targets (14). This development will be described in a future paper. For almost all practical purposes encountered with semiconductor single crystals, evaluation in arbitrary units yields adequate information and is preferred because of the rapidity of the method.

A few more detailed instructions about this proposed semiquantitative scale in arbitrary units is given below to facilitate its application.

Figure 7 is a rough sketch of a cone back reflection pattern of silicon with copper radiation. The full semicircles, pictured in thin lines, are the Debye-Scherrer reflections from the following planes (111) IV. Order, (335), (013) II. Order, (135), (011) IV. Order, (335), and (123) II. Order. These reflections are obtained by the α_1, α_2 doublet and/or by the β line of the characteristic copper K spectrum. At glancing angles near 90°, the α-doublet is clearly resolved into its components (444 reflection). In the case of an imperfect single crystal, fractions of these Debye-Scherrer circles appear on the pattern on the place of a Laue spot. Fractions from all possible

Debye-Scherrer circles can appear. This is verified for example in Fig. 13B, where practically every Debye-Scherrer circle is represented by a fraction. There is a correlation between the peripheral width of the lunate, its glancing angle θ, and the fluctuation of the normal vector of the reflecting plane. This will be covered in more detail in Part II of this paper. A small fraction on any of the Debye-Scherrer circles points to a relatively small misorientation of the lattice. A number of 2 is arbitrarily attributed to such a small lunate pictured on the left side of Fig. 7. Increasing size of the lunate points to larger misorientation and is represented on subsequent rows, from left to right, Fig. 7, by increasing "imperfection values" ranging from 2-10. A double lunate of both α_1 and α_2 radiation indicates a rather serious misalignment of the crystal since the probability of reflection of a monochromate radiation by a single crystal is small; to reflect two monochromatic wave lengths of 4 XU wave-length distance is still more improbable. If it happens, the crystal must be significantly distorted. Therefore, such a double lunate should be counted double. The reproductions do not give all the details visible on the originals, particularly with respect to these double lunates. In Fig. 13, a full evaluation of these patterns is carried out, leading to the "perfection" values at the right side of the patterns.

The significance of the intensity of a lunate should also be considered when evaluating the photographs. A very intense lunate of small peripheral width evidently stems from a small fluctuation of the normal vector of a "shattered plane," but spread over a large part of the crystal. On the other hand, one occasionally finds large fractions of the Debye-Scherrer circle of very weak intensity (Fig. 6C, clearly visible on the original photograph). Such a case points to a serious misorientation with large fluctuations of the normal vector but only in small areas of the crystal.

Admittedly, the perfection figures are dependent on some individual judgment varying from person to person. However, it has been established empirically

that a laboratory assistant, after proper instruction, will assign figures differing not more than a few points from those of the writer in most cases. A deviation of several points is rare. It is significant that the relative values assigned by a given observer are self-consistent, based on numerous cases, although the absolute figures may vary slightly.

Crystal Orientation

The method furnishes crystal orientation simultaneously. If the direction of the x-ray beam is a major direction of the lattice, for example the [111]-direction, the Laue spots of zones with zone axes perpendicular to the x-ray beam intersect in the center of the cone (Fig. 1b). If the crystal direction is a few degrees off, the intersection does not occur in the center of the film (Fig. 13). If the crystal is fixed on a support as demonstrated in Fig. 8, correction values can be derived with respect to a direction of reference. Whereas the monochromatic reflections are used for evaluation of the perfection, the polychromatic Laue spots are an excellent means of determining how much a crystal grown in a certain crystallographic direction deviates from this direction. Figure 9 shows a mask which enables one to read correction values with respect to the reference direction of Fig. 8. These corrections can be incorporated when the support shown in Fig. 8 is fastened on the diamond saw. The mask is derived from the geometry of the particular cone camera and a definite sample distance (see Fig. 10).

If the starpoint (intersection of spots from zones with zone axes perpendicular to the x-ray beam) is at the position marked in Fig. 9, a movement of the R-direction (Fig. 8) 2° upward and 3° to the right will bring the crystal into a position such that the x-ray beam is in accord with the [111]-direction of the lattice, which was the direction of growth in this case.

Figures 10-12 illustrate more in detail how the mask of Fig. 9 and the correction values are obtained. Consider a Laue plane film back reflection pattern, the more familiar case. It is then easy to change to the less common cone film.

The macroscopic axis of the crystal might be the [111]-direction and the x-ray beam may impinge perpendicularly to the (111)-plane (Fig. 10A). Then we obtain the Laue pattern sketched in Fig. 11A. If the [111]-direction does not coincide with the macroscopic crystal axis but is inclined by the angle ϕ (Fig. 10B), we obtain the Laue pattern of Fig. 11B or C, respectively, depending on whether the deviation is vertical or horizontal. The [111]-direction can deviate in an arbitrary manner, of course, but this case can be resolved into a vertical plus horizontal deviation.

The mirror can be used as an analogy. To bring the crystal (or mirror, respectively) of Fig. 11B or C into a position to furnish a Laue pattern of Fig. 11A, turn it by the angle ϕ_V in the vertical or ϕ_H in the horizontal direction, respectively. Use of a mask facilitates evaluation of the films (Fig. 12). This mask or the one for the cone film can be obtained by geometrical construction using Fig. 10 for a given distance, d, and varying angles, ϕ.

Figure 12 shows a Laue plane film back reflection pattern on top of the mask. The crystal from which this diagram stems could be oriented by a movement of the R direction (Fig. 8) 2° upward and 2° to the left.

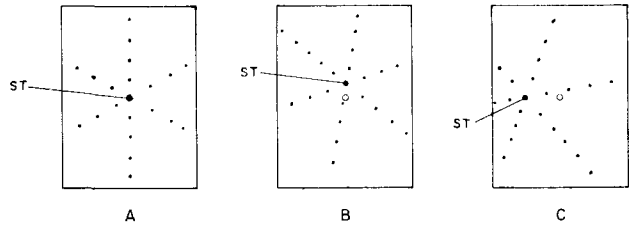

Fig. 11. Schematic Laue plane film patterns from a perfectly oriented crystal (A), a vertically misoriented crystal (B), and a horizontally misoriented crystal (C); ST, star point.

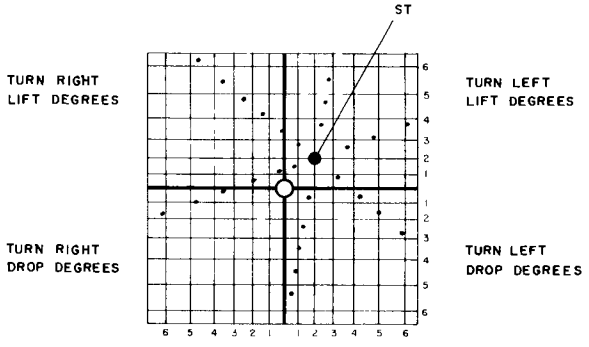

Fig. 12. Evaluation mask for a plane film at a given distance d (Fig. 10). On top of mask, a sketched Laue pattern from a misoriented crystal.

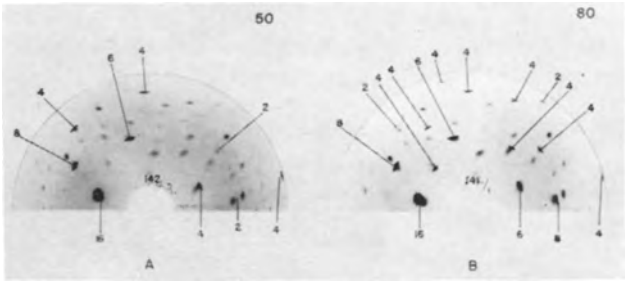

Fig. 13. Cone back reflection pattern of the top (A) and bottom (B) of a Czochralski crystal. The crystal axis is about 9° off the [111]-direction. Degree of perfection evaluated according to Fig. 7.

The shift from these plane film considerations to the case of a cone is very simple. The symmetry of the photograph is unchanged. Rolling off the film cone, however, compresses the 360° picture of the plane film into the 180° of a semicircle. It also compresses the mask of Fig. 12 to our mask of Fig. 9. Simple geometrical considerations show that the starpoint of Fig. 11 and 12 is split in two when the cone film is rolled off into a semicircle, but only the one lying within the film semicircle is realistic and can be used for evaluation purposes.

In this discussion, no consideration has been given to orientation of the crystal by rotation about its axis of growth. This is evident from the random direction of radii of the star in Fig. 11 A-C. If orientation with respect to rotation about the crystal axis of growth is desired, this can readily be done by measuring the angle necessary to rotate the star in order to bring it to the desired position.

No attention has been paid to the attainable precision of this orientation method. The accuracy of the cutting tool for which the orientation figures were used was inferior (±1°). Therefore, no need existed for more accurate x-ray orientation, which can be achieved easily.

Results of Perfection Studies

Results of the new method generally agree with information obtained by etch pit counts (see Table I). Disagreement, however, was experienced in some cases, where the etched plane did not coincide with the (111) plane nor with any other low indices plane.

The decrease in perfection of a Czochralski crystal from top to bottom is demonstrated in Fig. 13. Whereas the part next to the seed can be characterized by a number in arbitrary units of 50, the bottom represents a number of 80. The same or a similar observation was made in many other cases. However, this rule appears to be invalid in cases of crystals

Table I. Comparison of etch pit counts with x-ray values

Crystal slice	Etch pits	Perfection No. (Fig. 7)
A	$1 \times 10^4/cm^2$	30
B	$2 \times 10^4/cm^2$	46
C	$1 \times 10^4/cm^2$	32

with good orientation and good perfection.

The influence of sawing and sanding on the x-ray picture was demonstrated in another experiment. A large crystal disk sawed from a Czochralski crystal was covered with wax. The wax was successively removed from different quarters and the crystal leached every time so that the 4 quarters were exposed 0, 1, 2, 5 min to the etchant (HF, HNO_3, COOH, equal parts, about 40°C). The thickness change of the four sectors was: 0, 0.04, 0.06, 0.1 mm. X-ray patterns taken from each of the 4 sectors demonstrated that, after removal of 0.04 mm, the pattern did not change by further removal. In other words, the thickness of the damaged layer was less than 0.04 mm. Higher intensity of the pattern from the unleached part of the crystal, clearly visible on the photographs, is another criterion of distortion (secondary extinction) (3, 4) but can be observed only in a case like this where photographs were taken under identical conditions before and after removal of the damaged surface layer.

Other conclusions from corresponding experiments were:

(*A*) The average crystal grown in good accord with a major lattice direction is of better perfection than the average crystal poorly oriented during growth.

(*B*) Pictures taken before and after heat treatment showed only slight differences which were not consistent from crystal to crystal. The heat treatment consisted of heating the crystal in argon and holding at 1100°C for 30 min, cooling in the furnace to 700°C, and removing from the furnace.

(*C*) The average perfection of large diameter crystals is better than the one of small diameter crystals. This rule was found true in the range $\frac{3}{8}$ in. $< d < 1$ in. (d = diameter). Different results, however, have been reported in the case of germanium crystals. Since the perfection of Czochralski crystals depends on many factors such as geometrical arrangement, gradient of supercooling, and skill of the operator, a rather complex correlation might be obtained if other variables besides the diameter in the limited range between $\frac{3}{8}$ in. and 1 in. are varied.

(*D*) A multipass float zoned crystal from which all impurities other than boron had been removed was of very high perfection. Whether this is a general rule could be established only after a series of experiments, but it appears to be very logical.

(*E*) A Czochralski crystal grown with poor heat control due to failure of the automatic heat control was of very poor perfection. What has been said in the former example about establishing this as a general rule applies here.

It is inherent in the method that it integrates over the whole volume of the crystal hit by the slightly divergent beam. Therefore, localized imperfections such as those close to the surface can be detected only under certain conditions.

The photographs were taken almost exclusively under the following conditions: radiation: Cu-target, 35 kvp, 20 ma; exposure time: 10 min; size of pinhole: 0.6 mm.

Manuscript received Nov. 12, 1958. This paper was prepared for delivery before the Ottawa Meeting, Sept. 28-Oct. 2, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

The Anodic Oxidation of Zinc and a Method of Altering the Characteristics of the Anodic Films

H. Fry and Marjorie Whitaker

The British Non-Ferrous Metals Research Association, London, England

ABSTRACT

Preliminary work on anodizing zinc in a variety of alkaline solutions led to some smooth white or gray films. A detailed study was made of the anodic oxidation of zinc and zinc alloys in one electrolyte the results of which suggest similarities but also some differences between anodic films on aluminum and on zinc. Autoclaving in silicate solutions improved the resistance to corrosion and abrasion and changed the chemical composition of the anodic films without altering their appearance greatly.

Systematic work previously has been done on the kinetics of the oxidation of zinc in air (1) and of the initial stages of the anodic oxidation of zinc in sodium hydroxide solutions as well as on the characteristics of films on zinc produced by anodic oxidation at low voltages in a variety of solutions (2-7). Considerable variations in the properties of the films were observed in the earlier work. It was therefore of interest to study some aspects of the nature and growth of a wider variety of anodic films on zinc, including particularly films formed at higher field strengths. In view of the poor chemical resistance which zinc oxide films were expected to have, the possibility was examined of converting the films to zinc silicate by reaction of the anodic film with a silicate solution at elevated pressure and temperature.

Experimental

The following materials were used: high-purity Zn strip (99.95%), 4.3 mm thick, main impurity 0.02% Pb; die-cast flat plates of Mazak 3,[1] 2.8 mm thick; chill-cast Zn-4% Al and Zn-12% Al alloys, made from 99.99% pure metals. Their grain size and microstructure were coarser than those of the die-cast alloy. In the 4% Al alloy the primary phase is the Zn-rich β solid solution, containing about 1% Al (light gray in Fig. 1A). In the 12% Al alloy the primary phase is the α solid solution, and it separates on cooling to a mixture of α and β phases; this is the slightly darker constituent in Fig. 1B. The electrolytes were made up with demineralized water using "Analar" chemicals if available or purest commercial grade of chemicals.

Preparation of specimens.—Strips of the material to be anodized (1 x 8 cm) were bolted to copper strips. An area of 3 x 1 cm of polished surface on one side was left exposed for anodizing and the remainder coated with an insulating lacquer. The zinc was electropolished in a solution of 250 g/l chromic acid, 12 g/l boric acid, and the alloys were buffed.

Anodizing procedure.—Fresh electrolyte at 20°C was used for each experiment, unless otherwise stated, and stirred during anodizing. Specimens were immersed for 15 sec before applying the potential. Temperature rises of up to 3°C were observed during anodizing. The anode potential relative to a saturated calomel electrode was measured as a function of time.

[1] Zamak 3 in U.S.A. High purity Zn-4.1% Al-0.04% Mg.

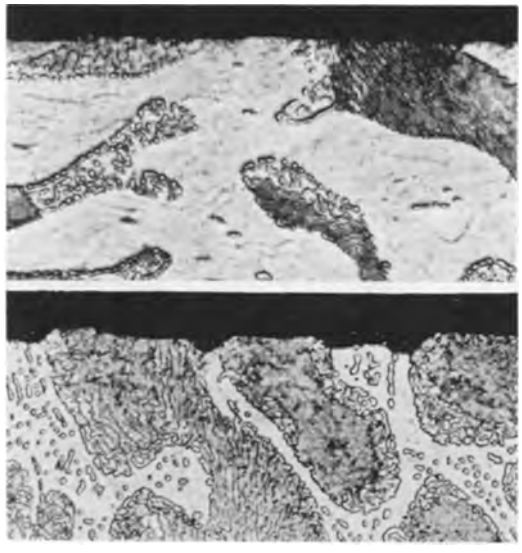

Fig. 1. Microsections through the anodized surface of chill-cast alloys showing (A) (top) even attack on Zn-4% Al and (B) (bottom) preferential attack on the eutectic in Zn-12% Al. Both etched nital. (The films, which are about 5 mm thick at this magnification, are not visible in the photographs.) Magnification X100.

In constant-current tests the selected current density was reached almost instantaneously and was maintained to within 1%. In constant-anode-potential tests the selected potential was reached in about 10 sec and was maintained to within 1%. In some tests the mains voltage was applied across the cell in series with a fixed external resistance.

After-treatment.—Anodized specimens were autoclaved in various solutions in a stainless steel autoclave.

Isolation of films and density measurements.—Film thicknesses were measured on microsections to $\pm\frac{1}{4}\mu$ at a magnification of 1000. The apparent density was determined by weighing isolated films of known area (6). The method involved an experimental error of about $\pm 10\%$.

Abrasion resistance.—The abrasion resistance of the films was measured by a method due to Schuh

and Kern (8) in which a stream of 60 mesh fused alundum particles falls on to the film from a height of 1 m through a tube of 0.5 cm internal diameter. The film was judged to be worn through when electrical contact could be made with the basis metal over an area which was just sensibly greater than a single point with a hardened steel probe having a radius of curvature of 1/16 in. Results of abrasion tests, expressed in terms of the volume of abrasive required to penetrate the coating, appear to be reproducible to within ±10%.

Results

Preliminary Work

Dark films and white films.—Black coatings were obtained by anodizing zinc in *N* NaOH solution at a current density of about 200 ma/cm² and a cell voltage of about 5 v. These coatings were smooth and uncracked and in this respect differed from those prepared by Huber at a cell voltage of 2.5 v (4).

In various solutions containing Na_2CO_3 and NaOH, dark films were formed at low anode potentials and white films at higher potentials. Films formed under the latter conditions were transparent when thin.

Formation of smooth anodic films.—Using a constant voltage source and constant external resistance, zinc was anodized in a series of mixtures made from 0.2*N* NaOH and one other 0.2*N* solution. When the second solution was sodium borate or sodium succinate, translucent and smooth opaque white films were obtainable. The latter type of film was obtainable when the second solution was sodium carbonate or sodium oxalate and the former type when it was sodium hydrogen phosphate.

Some of the white films had areas with small, partly or wholly detached flakes. Flaking depended on the solution composition and on conditions and duration of formation of the film. From NaOH-Na_2CO_3 solutions smooth white films were obtained only when the composition was 0.146*N* NaOH, 0.054*N* Na_2CO_3, but the films flaked if, under certain conditions of anodizing, the time exceeded a certain maximum or if the solution had been used previously.

The tendency to form flakes increased with increasing temperature, voltage, and current density. For example, at 0°C incipient flaking occurred only in samples anodized at a constant voltage of 120 v, whereas at 50°C flaking occurred even at 15 v.

Electrical breakdown of anodic films in the electrolyte.—In experiments at constant current, the anode voltage rose until there was an arrest or reversal of the original current-voltage trend accompanied by audible and sometimes visible sparks. Experiments usually were stopped at this stage. The sparking voltage depended on the composition of the electrolyte, a maximum voltage of about 170 v being reached in certain alkaline borate electrolytes while about 110 v was typical for NaOH-Na_2CO_3 solutions.

In the experiments in a solution of 0.146*N* caustic soda 0.054*N* sodium carbonate the sparking voltage in constant current tests was about 130 v at 0°C and 120 v at room temperature, independent of current density under both conditions, while at 50°C it was 3 v at 50 ma/cm² and about 80 v at 183 ma/cm². In later experiments, described below, the mean sparking voltage was about 100 v for zinc anodized in the same solution at an initial temperature of 20°C.

Abrasion resistance of smooth anodic films.—The abrasion resistance of smooth films on zinc varied from about 300 to about 3500 ml of abrasive, i.e., by a factor of about 10. The values for anodized aluminum lay between 8000 and 9000 ml for a 4μ thick sealed anodic film. The abrasion resistance of films formed under one set of conditions increased with thickness, but in general the abrasion resistance per unit thickness was found to depend in a complex manner on the anodizing conditions and on the composition of the solution.

Chemical resistance of anodic films.—A few tests were made of the corrosion resistance provided by anodic films on zinc under humid conditions and the results were invariably poor, white corrosion product appearing after about 1 day's exposure. The anodic films also were attacked by several dye solutions acidified with oxalic acid to pH values lying between 6.4 and 3.2.

Systematic Study of Anodic Oxidation of Zn *and* Zn-Al *Alloys in a Solution of 0.146N Sodium Hydroxide, 0.054N Sodium Carbonate*

Constant current experiments.—When the current flowing through the cell was kept constant during anodizing, smooth white films were formed on zinc and Mazak 3 at current densities in the range 50-200 ma/cm². Curves of anode potential against time are reproduced in Fig. 2A (zinc) and 2B (Mazak 3). They show that after an initial period the anode potential increased linearly with time. The shape of the curve suggests that the initial period, which became shorter as the current density increased, is associated with the formation of black films.

The mean rate of increase of the anode potential with time, obtained by measuring the slope of the straight part of the curve, became greater as the

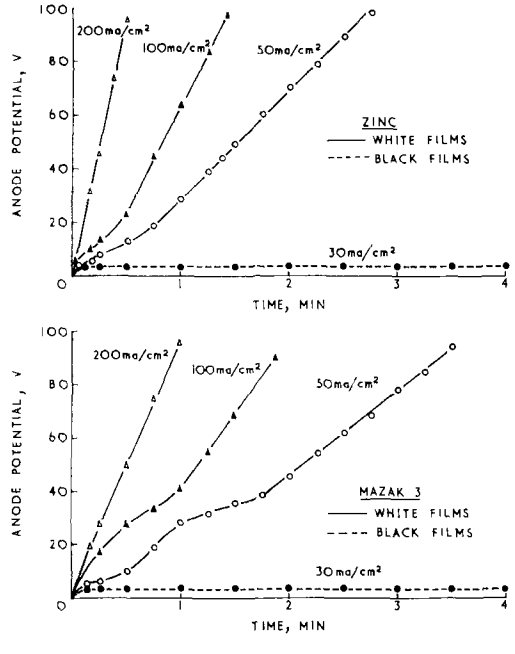

Fig. 2. Anode potential as a function of the time during the formation of black and white films at constant current density (A) (top) zinc, (B) (bottom) Mazak 3.

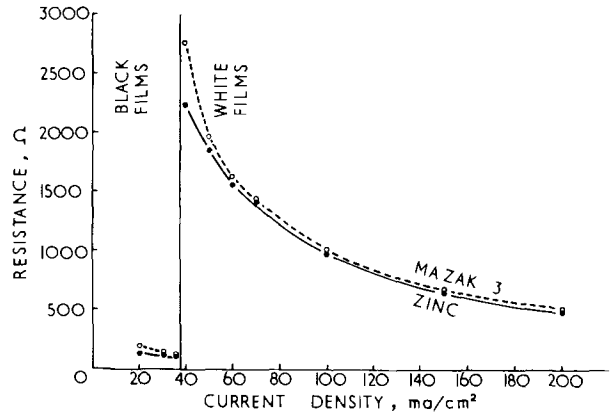

Fig. 3. Effective wet resistance per unit area of a completely formed film as a function of current density in constant-current tests.

current density increased, but the rate of increase of the effective wet resistance (the anode potential divided by the current) was nearly independent of current density. The rate of increase of the effective wet resistance at each current density was greater for zinc than for Mazak 3. Although the reproducibility was low (±20% for zinc and ±25% for Mazak 3 in five tests) the corresponding results for the two materials did not overlap.

There was a spread of about 20 v in the potential at which conditions became unsteady in replicate tests, and the mean was about 100 v, independent of current density for both zinc and Mazak 3 anodes. The effective wet resistance of the complete film was approximately inversely proportional to the current density as shown by the hyperbolic shape of the curves in Fig. 3.

At low current densities, 20 to 35 ma/cm², the anode potential reached a maximum in the range 1.8 to 4 v after several minutes and then fell slightly. The films on both materials were black. Curves showing the relationship between anode potential and time at 30 ma/cm² are given in Fig. 2. The effective wet resistance of completely formed black films, i.e., at the maximum voltage, decreased slowly as the current density was increased within the range 20 to 35 ma/cm² and it was greater for Mazak 3 than for zinc (Fig. 3).

At current densities between 35 and 50 ma/cm² the results were unpredictable. Some films remained dark, some quickly became white, and others remained dark for several minutes and then became white, a fairly sudden increase in resistance being associated with the change.

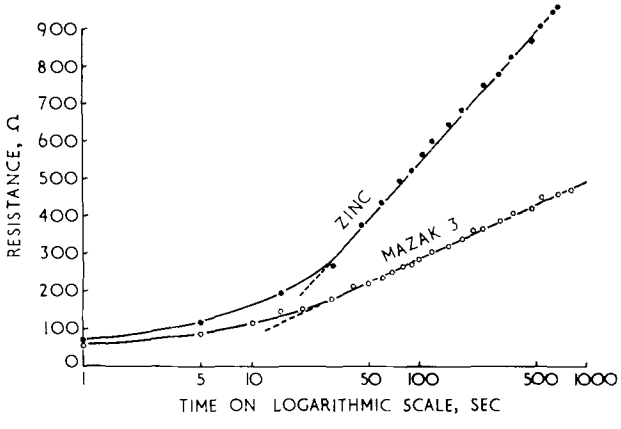

Fig. 4. Typical curves showing the effective wet resistance per unit area of film as a function of the logarithm of time in constant-voltage tests. Zinc and Mazak 3 at 16 v.

With chill-cast Zn-4% Al alloy the rates of increase of anode potential at constant current were close to the corresponding values for Mazak 3, and it was concluded that the results were not influenced by the difference in grain size and microstructure of these two materials.

The Zn-12% Al alloy formed a black film at 30 ma/cm², with effective wet resistance (110 ohm/cm²) similar to that of films on zinc and Mazak 3. Smooth white films were obtained at 70 and 150 ma/cm² but the anode potential did not increase linearly with time; after a continuous rise at a rate which decreased with time the potential became unsteady at a value between 50 and 80 v.

Constant-voltage experiments.—When the anode potential was kept constant during anodizing smooth white films were obtained on zinc and Mazak 3 at anode potentials in the range 4 to 60 v. The point at which fluctuations first occurred in the resistance of the film was taken as indicating the completion of film growth. Figure 4 shows that the effective wet resistance increased linearly with the logarithm of the time after an initial period of slower growth which is probably associated with the formation of black films. The current density at the point of completion, taking the mean of several tests, is plotted against anode potential in Fig. 5, and the effective wet resistance is plotted against anode potential in Fig. 6. At each anode potential in the white-film region the completely formed films on zinc had greater resistance than films on Mazak 3. The scatter of the resistance values was within ±30% in replicate tests, six at each voltage, but the probability that the difference between the two materials at each anode potential (Fig. 6) could have arisen by chance was 2 in 100, which is conventionally accepted as indicating that the difference is significant.

Black films were formed on both materials at anode potentials 1.5-3.5 v. The current reached a minimum after several minutes and then increased, sometimes only slightly. The minimum current is plotted against anode potential in Fig. 5. The effective wet resistance of films on Mazak 3 increased by about 40% at the boundary between dark and white films, and the corresponding increase for zinc was about 100% (Fig. 6).

Relative rates of anodic attack on the different constituents in zinc-aluminum alloys. — Metallographic examination of sections through anodized Mazak 3 and chill-cast Zn-4% Al mounted in a cold-setting acrylic resin revealed no differential attack or penetration at the surface (Fig. 1A). At the surface of the Zn-12% Al alloy, however, the eutectic was attacked more rapidly than the primary dendrites[2] (Fig. 1B). The primary dendrite areas (the slightly darker gray constituent) remained flat in the center during anodizing and did not project through the film at any point.

Thickness of white films on zinc and Mazak 3.—

[2] The buffed surface (before anodizing) was flat.

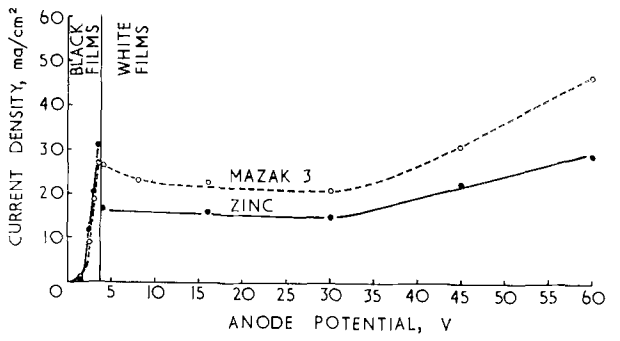

Fig. 5. Current density on completion of film formation as a function of anode potential in constant-voltage tests.

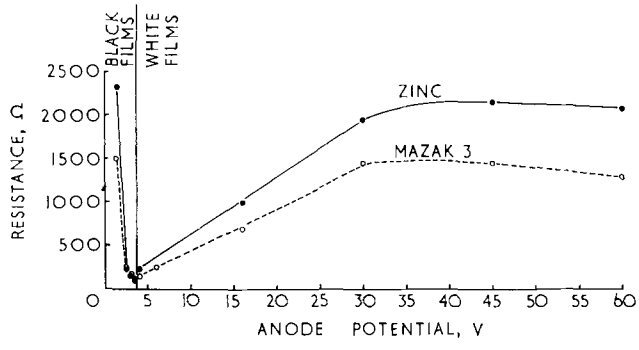

Fig. 6. Effective wet resistance of a completely formed film as a function of anode potential in constant-voltage tests.

Specimens were anodized at 20°C until just before the resistance of the film was known to become unsteady. The thickness of films on zinc (see Table I) appeared to be largely independent of current in constant-current tests (mean about 4μ) and independent of anode potential in constant-voltage tests (mean about 2.5μ). Films on Mazak 3 were thicker than those on zinc. Films on the chill-cast Zn-4% Al alloy were not significantly different in thickness from those on Mazak 3. Exceptionally thick films on Mazak 3 (7-8μ) were formed at 40-50 ma/cm^2 in constant-current tests and at 16-30 v in constant-voltage tests. These films took much longer to form than any of the others.

Rather thicker films were formed at 0° than at 20°C both at constant voltage and constant current, but the thicknesses of films formed at 50°C were the same as those of films formed at 20°C.

Analysis.—Specimens were dried over silica gel for several days. On ignition at 700°C films produced by anodizing zinc at 60 ma/cm^2 lost about 15% by weight. This was mainly water, including combined water, and it probably included a trace of carbon dioxide. The zinc content of these films before ignition, determined microchemically by a titrimetric dithizone procedure, was equivalent to 84% zinc oxide.

The x-ray diffraction pattern of films removed from zinc indicated the presence of zinc oxide in the film; the lines were diffuse, suggesting that the crystal size was small, possibly between 10^{-5} and 10^{-6} cm. No further information was obtained from electron diffraction examination although the diffraction pattern was less diffuse.

Porosity and cell structure of white films on zinc:

Table I. Thickness and porosity of films formed at 20°C

Anodizing conditions	Films on Mazak 3 Thickness,* μ	Films on zinc Thickness,* μ	Films on zinc Porosity,* %
Constant current density, ma/cm^2			
40	7.5	3.8	45
50	6.3	4.3	43
60	5	5.6	43
70	4	4	45
100	3.3	3.5	38
150	5	4.3	54
200	4.5	3.1	40
Constant voltage, v			
16	6.9	2.2	50
30	6.6	2.3	—
45	3.8	2.5	48
60	4	2.4	45

* Mean of duplicate tests.

Electron microscopy.—In many cases carbon replicas of the outer surfaces of anodic films on zinc could not be interpreted, but some evidence of an hexagonal cell structure was obtained from a film formed at 45 v as shown in Fig. 7, the cell width being about 3000Å.

Very thin films examined by direct-transmission appeared to be porous (see Fig. 8). Three constant-current films formed by anodizing zinc for 1 sec and 2 sec at 60 ma/cm^2 and for 0.6 sec at 200 ma/cm^2 were examined in this way; the distance between the pores was about 500Å in each case, with no detectable difference between the two current densities.

Determination of porosity from the apparent density.—Apparent densities were in the range 1.8-3.5 g/cm^3. In calculating the porosity a correction was made for the presence of 15% water in the films, and the density of zincite (5.60 g/cm^3) was taken to be the density of the nonporous oxide. The porosities of duplicate films from zinc anodized at a range of constant-currents and constant-voltages are given in Table I. Within the limits of the experimental error (±15%) the porosity, with a mean value of 45%, appeared to be independent of anodizing conditions.

After-treatment of anodic films on zinc: Composition of autoclaved films.—The films for analysis were made by anodizing in a solution of 0.146*N* sodium hydroxide, 0.054*N* sodium carbonate to just before the sparking voltage and they were autoclaved in a solution of 200 g/l sodium silicate "Q79" containing 8.8% Na_2O, 29% SiO_2, 62.2% H_2O for 30 min at 150°C. The films were isolated (6) and then analyzed in the same way as anodized films. Silica was determined spectrophotometrically as reduced silicomolybdate.

The total water content of films produced at constant current density was about 10%. The ZnO:SiO_2 ratio increased from 2:1 to nearly 3:1 as the current density was increased from 60 to 200 ma/cm^2, although films formed to completion at 60 ma/cm^2 and 200 ma/cm^2 resembled each other closely in thickness and porosity.

Only lines corresponding to zinc oxide were identified in x-ray and electron diffraction photographs.

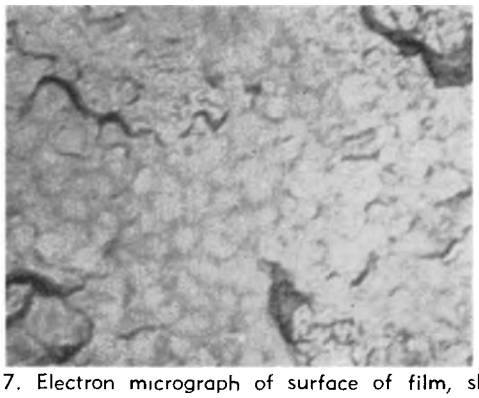

Fig. 7. Electron micrograph of surface of film, showing cell structure. Zinc anodized 1 min at 45 v. X 10,000

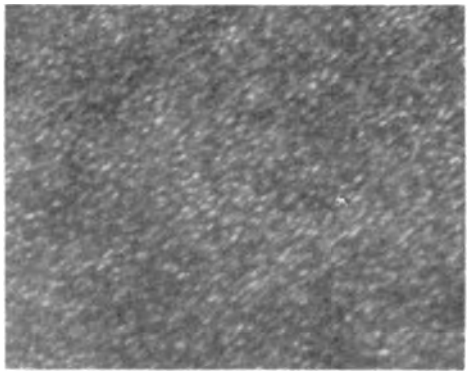

Fig. 8. Direct transmission electron micrograph of film, showing pores. Zinc anodized 2 sec at 60 ma/cm^2. X 32,500

In view of the change of the chemical properties of the film on autoclaving it would be surprising if silica had not entered into chemical combination with zinc oxide to some extent.

Properties of autoclaved films:

Appearance and abrasion resistance.—Films were generally smooth and off-white after autoclaving in a variety of different silicate solutions at 150°C for 30 min. For a given autoclave treatment the abrasion resistance of the films depended in a complicated way on the anodizing conditions, the ratio of abrasion resistances before and after autoclaving varying from 1 to 7. For a given set of anodizing conditions, e.g., 0°C and 50 ma/cm^2, the abrasion resistance of the autoclaved samples increased roughly linearly with the thickness, the duration of the anodic treatment, and the maximum anodic voltage. The highest values of abrasion resistance (about 7000 ml of abrasive) were obtained by using an autoclaving solution with a relatively high SiO_3:Na_2O ratio (about 3.3-3.6) at a relatively high concentration of about 400 g/l sodium silicate (water glass).

The autoclaved films accepted some dyes from acidified solutions, the intensity of the color produced generally increasing as the *p*H of the dye decreased. Dyeing was aided by boiling autoclaved samples in a solution of chromium oxalate the *p*H of which had been adjusted to 7.4 with NaOH.

Corrosion resistance.—Anodized and autoclaved samples suffered hardly any deterioration after 1 week's exposure to humid conditions in contrast to unautoclaved samples which corroded quickly. After 96 hr in an atmosphere of 95% relative humidity containing 3% sulphur dioxide the samples were attacked strongly as were some samples of chromated zinc and of anodized aluminum.

After treatment of anodized zinc alloy die-castings.—Films on zinc alloy were affected adversely during autoclaving in some solutions in which the corresponding films on pure zinc remained intact. The adverse effects included flaking and darkening which occurred particularly when anodizing had been carried out in solutions containing borates. By adding phosphoric acid to the normal autoclaving solutions or by using solutions of lower alkaline content, flaking, but not darkening could be avoided. In some cases a fine mottled effect was observed; the pattern of flow marks was usually found on treated commercial die-castings. Smooth, almost white films were obtained when certain anodized films were autoclaved in a solution of 400 g/l sodium silicate "Q79" (*p*H 11.1) but not for all conditions of anodizing.

The abrasion resistance of anodized and autoclaved samples of zinc alloy was about 3500 ml of abrasive for samples anodized in a NaOH-Na_2CO_3 solution with a fixed external resistance of 1000 ohms and autoclaved in water glass containing phosphoric acid, but this value was not accurately reproducible.

The ability of treated zinc alloy to accept dyes is similar to that of treated zinc.

A few tests suggest that the corrosion resistance of treated zinc alloys resembles that of treated pure zinc. Some anodized and autoclaved zinc alloy die-castings were attacked considerably when exposed to an industrial atmosphere for several months.

Discussion

Composition, Structure, and Color of Anodic Films on Zinc

The results of chemical and x-ray diffraction analysis indicated that the white anodic films consisted essentially of zinc oxide. The same result was obtained by Huber for a white film formed under different conditions (6).

Huber found that loose white coatings were formed when zinc was anodized at cell voltages up to 2 v in *N* NaOH solution and that white or dark films were formed and oxygen was evolved at voltages between 4 and 6 v, the color of the film depending on composition and *p*H of solution. The present results show that continuous white films are formed at still higher voltages in a variety of similar solutions.

The dark appearance of certain films is due to the presence of finely divided zinc (4); such films turn white if heated in air because the free zinc is oxidized. The resistivity of normal zinc oxide, an excess metal semiconductor, is of the order of 10 ohm-cm, and this increases to 10^7 ohms when the oxide is kept for 30 hr at 900°C in 120 atm pressure of oxygen (9). Dried white anodized films on zinc had a resistivity of more than 10^{10} ohm-cm indicating that the composition of such films approaches still more closely that of stoichiometric zinc oxide, ZnO.

The transmission electron micrograph in Fig. 8 demonstrates the porosity of films about 100Å thick

whose structure was probably that of black films. The distance between pores was independent of current density. Huber and Bieri (5) found that films formed in *N* NaOH solution did not develop any porosity till they were about 2000Å thick. In thick anodic films on aluminum the distance between pores was also independent of current density (11), but thin anodic films on aluminum appear to be different, in that the distance between pores increased with the forming voltage (10, 11).

The porosity of thick anodic films on zinc calculated from measurements of the apparent density (Table I) was about 45% independent of electrical conditions of formation, while that of anodic films on aluminum has been calculated from data on the number and diameter of pores to vary from about 50% at 10 v to less than 2% at 100 v (10). Some evidence has been found for a hexagonal cell structure similar to that on certain anodic films on aluminum, the cell size of about 3000Å in a film formed at 45 v being of the same order as that of the largest cells observed in films on aluminum.

In view of the large porosity of the films the resistance of the electrolyte in the pores is small and in order to account for the relatively high effective wet resistance it is necessary to postulate a nonporous barrier layer adjacent to the basis metal.

The Barrier Layer

The wet resistance of the black films is seen in Fig. 6 to drop rapidly with increasing voltage. This suggests that the concentration of metallic zinc in the barrier layer of the black film increases with increasing voltage, rapidly at first and then more slowly.

The slope of the curves of resistance vs. voltage and vs. current density changes its direction at 4 v and at 40 ma/cm^2, respectively. The change in the nature of the barrier layer which is responsible for this reversal is presumably the same as that which is known to take place at this stage in the porous part of the layer, viz., the oxidation of metallic zinc. This change is accompanied by a change in the mechanism of conduction which, in white films, is dependent on the presence of interstitial zinc ions.

The changes in the wet resistance of the film cannot, however, be interpreted solely in terms of changes in the thickness of the barrier layer, i.e., without taking into account the changes in resistivity which probably occur. The resistivity is influenced by the concentration of interstitial zinc ions, and, since this concentration may be expected to increase with increasing field strength the resistivity probably falls as the field strength increases (12). Another factor, which also tends to cause a fall in the resistivity of the barrier with increasing field strength, while it is being formed, is the increasing amount of heat evolved (13, 14).

For these reasons the rate of increase of the thickness of the barrier layer of white films with increasing voltage is probably greater than the rate of increase in the wet resistance of the film (Fig. 7).

In constant-current tests the increase in resistance at any given current density (directly proportional to the increase in voltage in Fig. 2A and 2B) may be a fair measure of the increase in thickness, since the concentration of interstitial zinc ions is presumably constant and a mean equilibrium will be quickly established. Fig. 2A and 2B suggest that the thickness of the barrier layer increases linearly with time after an initial period during which it appears to increase more slowly.

Influence of Aluminum on the Barrier Layer

In the anodizing of Mazak 3 the linear and logarithmic rates of increase of the effective wet resistance were less than the corresponding rates for zinc.

It seems likely that aluminum enters the barrier layer and changes its properties and its rate of growth. The presence of aluminum in zinc reduces the rate of atmospheric oxidation—0.1 at. % Al reducing the rate of oxidation 100-fold at 390°C (15), and Wagner's theory of oxidation attributes this to the displacement from the lattice of interstitial zinc ions whose diffusion is the rate-controlling process in atmospheric oxidation. It is reasonable to suppose that the rate of growth of the barrier layer in anodic oxidation is controlled by the same process, and it would follow that the layer should grow more slowly on Mazak 3 than on zinc.

In entering the zinc oxide lattice aluminum ions also increase its conductivity by increasing the concentration of electrons in the conduction band—1 mole % Al_2O_3 increasing the conductivity of zinc oxide 1000-fold at 394°C (16). Although the concentration of aluminum in the barrier layer of anodized films on Mazak 3 is not known, it seems likely that the conductivity of the layer is considerably greater than that of the corresponding layer on zinc.

These two factors explain the lower rate of increase of the resistance of the barrier layer on Mazak 3 in all experiments and the lower resistance of the layer in completely formed films in constant-voltage tests.

Manuscript received June 5, 1958. This paper was prepared for delivery before the New York Meeting, April 27-May 1, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

A Study of the Silver (I) Oxide-Silver (II) Oxide Electrode

James F. Bonk and Alfred B. Garrett

McPherson Chemical Laboratories, The Ohio State University, Columbus, Ohio

ABSTRACT

A reproducible emf of the cell Ag(c), Ag_2O(c)/NaOH (1M)/AgO(c), Ag_2O (c), Pt is found to be 0.262 v at 25°C. From this value and the known potential of the Ag, Ag_2O electrode, the standard oxidation potential of the Ag_2O, AgO electrode is —0.604 v. The temperature coefficient of the cell is $+2.20 \times 10^{-4}$ v/deg. The free energy, enthalpy, and entropy changes for the cell reaction are —6049 cal, —4537 cal, and 5.07 cal/deg, respectively. From these values and the existing thermodynamic data on Ag and Ag_2O, values of 3463 cal, —2769 cal, and 13.81 cal/deg are calculated, respectively, for the free energy and enthalpy of formation and for the entropy of AgO at 25°C.

The purpose of this research is to present data on the electrode potential of the silver (II) oxide electrode over the temperature range 20°-30°C. Various investigators (1-5) have established in studies of the silver (II) oxide-zinc-alkali battery that a cell having an AgO cathode has twice the capacity of a similar cell having an Ag_2O cathode, but at high current drains the discharge of an AgO cathode to free silver takes place in a single step at a potential corresponding to that of an Ag_2O cathode. At low current drains, however, there occurs a two step reduction in voltage (1) which would be expected in view of the results of a number of earlier studies involving AgO.

Marsh (6) determined the potential of Ag_2O against AgO to be 0.15 v. From this datum and the known oxidation potential for the Ag, Ag_2O electrode of —0.342 v (7),[1] a value of —0.49 v can be calculated for the Ag_2O, AgO oxidation potential. Early studies by Luther and Pokorny (8) indicated a stepwise reduction of $AgO \rightarrow Ag_2O \rightarrow Ag$ at electrode potentials of 0.57 v and 0.344 v, respectively. The preceding values were determined from cells using Hg, HgO reference electrodes and samples of AgO prepared by the anodic oxidation of Ag in alkali. Unfortunately, conflicting values of 0.927 and 0.962 v are given in the original reference for the emf of the cell

$$Hg, HgO/NaOH(1N)/H_2(1\ atm) \qquad [A]$$

The difference of 0.035 v may have led to conflicting values for the Ag_2O, AgO potential. Latimer (9) accepts the oxidation potential obtained directly from Luther and Pokorny's data (—0.57 v). Hickling and Taylor (10), however, correct the original data by 0.04 v so as to produce a value of —0.61 v for the Ag_2O, AgO oxidation potential. No explanation of this 0.04-v correction is given by Hickling and Taylor, but Jones, Thirsk, and Wynne-Jones (11) suggest that the correction may be connected with the potential of the cell

$$H_2/OH^-(N)/calomel \qquad [B]$$

which Hickling and Taylor used in their study. It is also possible that a 0.04-v correction can be made for the 0.035-v inconsistency in the reported emf of cell [*A*]. From studies of Jirsa (12) and Jirsa and Jelinek (13) on cells of the type

$$H_2/NaOH(M)/Ag_2O,Ag \qquad [C]$$

a value of about —0.60 v can be calculated for the Ag_2O, AgO oxidation potential at 25°C.

In view of the inconsistencies which exist with regard to the potential of the couple

$$Ag_2O + 2\ OH^- \rightarrow 2AgO + H_2O + 2e^- \qquad [1]$$

it was deemed advisable to reinvestigate the emf associated with the Ag_2O, AgO electrode. Such an investigation also makes possible the evaluation of some important thermodynamic functions of AgO which at present have not been determined reliably.

Experimental

In this study of the Ag_2O, AgO electrode, cells of the following type were employed

$$Pt,Ag(c),\ Ag_2O(c)/NaOH(1M)/AgO(c),\ Ag_2O(c),\ Pt \qquad [D]$$

The reactions occurring in the cell would be

$$(Cathode)\quad 2AgO + H_2O + 2e^- \rightarrow Ag_2O + 2\ OH^- \qquad [2]$$

$$(Anode)\quad 2Ag + 2\ OH^- \rightarrow Ag_2O + H_2O + 2e^- \qquad [3]$$

Thus, the over-all cell reaction for 1 faraday may be considered to be

$$AgO(c) + Ag(c) = Ag_2O(c) \qquad [4]$$

As this reaction indicates, it is not practical to replace the platinum contact by a silver contact in this cell since reaction [4] can then occur completely at the cathode. Confirmation of this was obtained in a preliminary study of the cell

$$Ag,\ Ag_2O/NaOH(1M)/AgO,\ Ag_2O,\ Ag \qquad [E]$$

In less than 1 min the voltage of cell [*E*] dropped from about 0.25 v to less than 0.01 v. In a half hour

[1] Signs given for oxidation potentials in this paper are consistent with those used by Hamer and Craig (7) in their study of the Ag, Ag_2O electrode and with those of Latimer's (9) oxidation potentials. The electrode potential, as defined by The Electrochemical Society and by the IUPAC Stockholm convention, has the opposite algebraic sign.

the voltage had dropped almost to zero. Therefore, it is necessary to use an inert substance such as platinum in the construction of the Ag_2O, AgO electrode.

In constructing cell [*D*], reproducible and highly stable Ag, Ag_2O electrodes, prepared as directed by Hamer and Craig's method number two (7), were used as reference electrodes. The Ag_2O used in the preparation of the electrodes was of certified reagent grade.[2] Two different sources of AgO were employed in the preparation of electrodes: (*a*) "Divasil"[2] and (*b*) AgO prepared from reagent grade chemicals by Kleinberg's method (14), in which $AgNO_3$ was oxidized by $K_2S_2O_8$ in NaOH at 90°C. The resulting AgO was washed numerous times, filtered, and allowed to dry in an atmosphere of nitrogen in a desiccator. Analyses of AgO samples, carried out iodimetrically by Dutta's method (15), averaged 98% AgO for samples of "Divasil" and 99.0 to 99.5% AgO for preparations carried out by Kleinberg's method.

In assembling the cell, an H-type Pyrex glass container was used. The legs were 1.5 cm in diameter by 12.5 cm long and were connected near the top by a cross-tube 5 cm long and 0.8 cm in diameter. In one leg was placed the sample of AgO which had been thoroughly mixed with a small amount of Ag_2O and then repeatedly washed with the 1M NaOH which was to be used in filling the cell. After filling the cell with 1M NaOH, a rubber stopper, through which extended a 5 mm soft glass tube with a Pt-helix sealed into one end, was inserted into the leg of the H-tube in such a way that the Pt-helix was completely covered by the oxide slurry. Into the other leg of the H-cell, the reference electrode was inserted and held in place by means of a rubber stopper. The assembled cell was then placed in a bath in which a desired temperature could be maintained within 0.02°C. All temperature measurements were made with a National Bureau of Standards certified thermometer graduated in 0.02°C intervals in the range from 18° to 30°C. Measurements of emf were made by means of a L&N type K-2 pontentiometer which was calibrated against a Rubicon potentiometer of known accuracy. The standard cell employed was calibrated against a standard cell certified by the National Bureau of Standards.

Average value of $dE/dT = 2.20 \times 10^{-4}$ v/deg at 25°C.

In Table I are given the emf's found at 25°C for cell [*D*]. New samples of AgO were prepared freshly by Kleinberg's method (14) for each of the first four cells. The average value for the emf of these cells is 0.2623 ± 0.0002 v. Using 23,060.5 cal/abs volt. g-eq for the faraday (16) in the relation $\Delta F^\circ = -n\mathbf{F}E^\circ$, the standard free energy change for cell reaction [4] is −6049 ± 5 cal at 25°C.

For comparison, four cells (No. 5 through 8) were prepared in the same manner using Merck's "Divasil" instead of our own preparation of AgO. As can be seen in Table I, "Divasil" produces a slightly lower emf of 0.2613 ± 0.0004 v at 25°C. For further comparison, slurry-type reference electrodes prepared by Hamer and Craig's method No. 1 (7) were used in the preparation of two cells, No. 9 and 10. Comparison of the data in Table I for the two types of reference electrodes shows good agreement between them.

The stability of cell No. 4 was investigated by taking emf measurements over a period of ten days at 25°C (Table II). As can be seen, the emf slowly decreases from 0.2625 v to 0.2610 v in this period of time. Aged AgO and "Divasil" seem to produce slightly lower and more stable potentials than freshly prepared AgO.

The effect of temperature on the emf of cells No. 1, 2, and 3 is given in Table III. Readings were taken at each temperature when a constant emf value had been maintained for at least 1 hr. No appreciable emf-temperature hysteresis occurred as is clearly shown by the reproducibility of 25°C emf's in cells No. 2 and 3. The average value for the coefficient at 25°C is $+2.20 \times 10^{-4}$ v/deg which gives ΔS° for cell reaction [4] as 5.07 ± 0.02 cal/deg since $\Delta S^\circ = n\mathbf{F}(dE^\circ/dT)$. The enthalpy ΔH° of cell reaction [4] is −4537 ± 11 cal at 25°C since $\Delta H^\circ = \Delta F^\circ + T\Delta S^\circ$.

Thermochemistry

From the standard value −2586 cal for the free energy of formation of Ag_2O (16) and our value of

-6049 ± 5 cal for the standard free energy of cell reaction [4], a value of 3463 ± 5 cal is calculated for the standard free energy of formation of AgO. The entropy of reaction [4] is given by

$$\Delta S^\circ = S^\circ(Ag_2O) - S^\circ(Ag) - S^\circ(AgO) \quad [5]$$

The values for $S^\circ(Ag_2O)$ and $S^\circ(Ag)$ are, respectively, 29.09 and 10.21 cal/deg (16). From these values and our value of 5.07 ± 0.02 cal/deg for ΔS°, a value of 13.81 ± 0.02 cal/deg is calculated for $S^\circ(AgO)$.

In a similar manner, our value of -4537 ± 11 cal for the enthalpy of reaction [4] together with -7306 cal for the heat of formation of Ag_2O (16) leads to a value of -2769 ± 11 cal for the heat of formation of AgO at 25°C. Latimer (9) gives -6.0 kcal/mole for this heat of formation of AgO which he attributes to the National Bureau of Standards. Actually, Circular 500 (16) gives -6.3 kcal/mole as the heat of formation of Ag_2O_2 (not AgO) from which the heat of formation of AgO would be -3.15 kcal/mole. This value is obtained from thermochemical measurements made by Jirsa (12). Jirsa's studies involved the determination of the heats of solution of Ag_2O and AgO in acids. Taking $HClO_4$ as an example

$$2AgO + 2HClO_4(aq) \rightarrow 2AgClO_4(aq) + H_2O + \tfrac{1}{2} O_2 + 10964 \text{ cal}$$

$$Ag_2O + 2HClO_4(aq) \rightarrow 2AgClO_4(aq) + H_2O + 9964 \text{ cal}$$

By subtraction

$$2AgO \rightarrow Ag_2O + \tfrac{1}{2} O_2 + 1000 \text{ cal}$$

However, Jirsa found that the difference between the two heats of solution was not a constant 1000 cal but varied from 1197 cal to 1956 cal as the acid strength varied from 20% to 70%, respectively. The 1000-cal difference was obtained by a questionable extrapolation of these data to zero concentration of acid. Using 1000 cal as the approximate difference between the heats of solution of the oxides and the known heat of formation of Ag_2O (16), an approximate value of -3.15 kcal/mole can be calculated for the heat of formation of AgO. Thus no great discrepancy exists between Jirsa's value of -3.15 kcal/mole and our more accurate value of -2.769 kcal/mole. The discrepancy becomes even smaller when Jirsa's actual calorimetric values are substituted for his extrapolated value.

Electrode Potential

From our value of 0.262 v for the emf of cell [D] and the value -0.342 v (7) for the oxidation potential of half-reaction [3], a value of -0.604 v can be calculated for the standard oxidation potential of couple [1]. The standard electrode potential of this couple is, therefore, 0.604 v.

Our value of -0.604 v is in poor agreement with -0.49 v calculated from Marsh's data (6). Since no experimental data are given in the reference, it is not possible to make a further evaluation of this discrepancy. Our oxidation potential does agree well with the value -0.60 v calculated from Jirsa's work (12, 13) and with Hickling and Taylor's (10) correction of Luther and Pokorny's (8) data. Although the corrected value does agree well with our data, such a correction does not seem justifiable for a number of reasons.

First, applying a 0.04-v correction to the other data obtained by Luther and Pokorny would give a value of $+0.38$ v for the standard electrode potential of Ag, Ag_2O and a value of $+0.78$ v for the AgO, Ag_2O_3(?) electrode potential. These values are both 0.04 v higher than other determinations (7, 9, 13).

Second, using samples of AgO prepared by a variety of methods, Luther and Pokorny obtained data from which values of -0.56 to -0.60 v can be calculated for the standard oxidation potential of the Ag_2O, AgO electrode. Since the same Hg, HgO reference electrode was used in all these determinations, it seems reasonable to attribute the variation in the standard potential to the method of preparation of AgO. The cell from which the highest oxidation emf value (-0.56 v) was obtained by Luther and Pokorny contained AgO prepared by the anodic oxidation of silver in dilute sulfuric acid. Due to the lack of experimental details, it is not possible to determine the exact method of preparation of the AgO electrode used in their study. However, in view of a later x-ray study (17) it is probable that the AgO electrode contained some free silver or silver in some oxidation state other than +2, which produced the higher oxidation emf value of -0.56 v. Luther and Pokorny's accepted oxidation emf of -0.57 v was determined from samples of AgO prepared by the anodic oxidation of silver in alkali. Denison (1), however, has shown by x-ray studies that this electrolytic method produces AgO which still contains some free silver. Jones, Thirsk, and Wynne-Jones (11) also suggest the presence of a "suboxide" in AgO prepared by this electrolytic method. The lower oxidation emf of -0.60 v was obtained by Luther and Pokorny from cells containing AgO prepared both by the anodic oxidation of $AgNO_3$ and Ag_2SO_4 solutions. This same value can be obtained from Jirsa's (13) data on AgO prepared by the ozonization of powdered silver and from our data on AgO prepared by the alkaline oxidation of Ag(I) by $K_2S_2O_8$.

Thus it would appear that early electrolytic preparations of AgO from silver resulted in high standard oxidation potentials for the Ag_2O, AgO electrode. The other major methods of preparation produce a lower oxidation potential of about -0.60 v. In the case of AgO prepared by the alkaline oxidation of Ag_2O by $K_2S_2O_8$, we have accurately determined this lower oxidation potential to be -0.604 v for couple [1].

In conclusion it is of interest to consider the observations made on the commercial silver(II) oxide-zinc-alkali battery. Most interesting of these is the fact that the emf of the commercial cell on high current drains is the same whether AgO or Ag_2O is used as the cathodic material, but the capacity of a cell containing an AgO cathode is twice that of a similar cell containing an Ag_2O cathode. In light of our study it seems possible to explain this observation in the same manner as Schumacher and Heise (18) explained a similar phenomenon involving the corre-

sponding oxides of another coinage metal, Cu_2O and CuO. The discharge may be considered to be represented by the following reactions

$$2AgO+2KOH+Zn+H_2O=K_2Zn(OH)_4+Ag_2O \quad [6]$$

$$Ag_2O + 2KOH + Zn + H_2O = K_2Zn(OH)_4 + 2Ag \quad [7]$$

Reaction [6] predominates until the amount of Ag_2O builds up at which point reaction [7] predominates. This would be consistent with the observation that a higher voltage is observed for a short time on low current drains (1). The fact that the AgO electrode has twice the capacity of an Ag_2O electrode may be explained by reference to reaction [4]. The Ag_2O used in reaction [7] is regenerated by means of reaction [4] until all the AgO has been consumed. In this way AgO can contribute to the total capacity of the cell without contributing to the potential, once reaction [7] becomes the predominant reaction.

Manuscript received Nov. 10, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

The Temperature Coefficients of Electrode Potentials

The Isothermal and Thermal Coefficients—The Standard Ionic Entropy of Electrochemical Transport of the Hydrogen Ion

A. J. deBethune, T. S. Licht, and N. Swendeman

Chemistry Department, Boston College, Chestnut Hill, Massachusetts

ABSTRACT

The temperature coefficient of the potential of an electrode can be defined experimentally by reference to (*a*) the potential of the SHE at the same temperature, (*b*) the potential of the same electrode at some fixed temperature. These two definitions give rise to the "isothermal" and "thermal" temperature coefficients of electrode potentials. The isothermal coefficient is $\Delta S/n\mathbf{F}$ where ΔS is the reaction entropy of the "SHE//Electrode" cell. The thermal coefficient is $S^*/n\mathbf{F}$ where S^* is the entropy transported from the hot to the cold heat reservoir by the passage of n faradays of positive electricity through the cell from the cold to the hot electrode (before the onset of thermal diffusion). The entropy S^* is divided into an entropy S^*_E of electrochemical transport which determines the electrode temperature effect, and an entropy S^*_M of migration transport which determines the thermal liquid junction potential.

By assuming that S^*_M is negligible in a saturated potassium chloride bridge, we have deduced that the thermal temperature coefficient of the SHE is +0.871 mv/°C [hot electrode (+) terminal] at 25°C. The standard ionic entropy $S^{*\circ}_E$ of electrochemical transport of hydrogen ion is —4.48 cal/deg. Thermal temperature coefficients are computed for calomel, silver chloride, and copper sulfate electrodes and are compared with experiment. Thermal and isothermal temperature coefficients are computed and tabulated for nearly 300 standard electrode potentials.

The temperature coefficient of electrode potentials[1] can be defined experimentally in two ways, either as an "isothermal" or as a "thermal" temperature coefficient. The isothermal temperature coefficient $(dV/dT)_{isoth}$ is the derivative dE/dT of the emf[2] E of the isothermal cell

$$\text{SHE // Electrolyte / Electrode} \qquad [1]$$

where the left electrode is a standard hydrogen electrode (SHE). In cell [1], the temperature of the two electrodes is varied in the same way.

The thermal temperature coefficient $(dV/dT)_{th}$ is the derivative dE/dT_2 of the emf E of the thermal cell

$$\text{M}(T_1) \,/\, \text{Electrode}(T_1) \,/\, \text{Electrolyte}(T_1) \,/\, \text{Electrolyte}(T_2) / \text{Electrode}(T_2) / \text{Electrode}(T_1) / M(T_1) \qquad [2]$$

in which T_1 is fixed and T_2 varies. When the thermal coefficient, as defined here, is positive, the hot electrode is the (+) terminal of cell [2]. Cell [2] can also be modified by the introduction of salt bridges across the liquid thermal boundary.

The Gibbs-Helmholtz equation (5, 7, 8) yields an expression for the isothermal temperature coefficient in the form

$$(dV/dT)_{isoth} = \Delta S/n\mathbf{F} = (\Delta H - \Delta G)/n\mathbf{F}T \qquad [3]$$

where ΔS, ΔH, and ΔG are the entropy, enthalpy, and free enthalpy (Gibbs free-energy), respectively, of the reaction which transfers n faradays of positive electricity through cell [1] from left to right.

Thermal Temperature Coefficients

Thermal temperature coefficients of electrode potentials have been studied by many investigators (9-36) since the pioneering work of Bouty (9). Much of the early work was reviewed by Lange (10). The electromotive force of a thermal cell (in its initial state) is the resultant of three effects: (*a*) the metallic thermocouple effect, (*b*) the electrode temperature effect, and (c) the thermal liquid junction potential. Effect (*a*) can be eliminated by keeping all metal-metal junctions isothermal, as in cell [2], a technique used by Richards (13), or it can be corrected for, as in the work of Carr and Bonilla (31). Effect (*a*) has a magnitude of the order of 1% of the sum of (*b*) and (c) and will be considered eliminated in what follows.

With the passage of time, a thermal cell is subject to thermal diffusion in the electrolyte (Soret effect) (18) as demonstrated experimentally by Agar and Breck (33). Thermal diffusion tends to concentrate strong electrolytes in the cold region. The resultant concentration gradient further changes the two electrode potentials, and the cell eventually reaches a new stationary state after thermal diffusion has become fully developed. However, most thermal cell

[1] The sign convention to be followed in this paper for single electrodes is that of the Gibbs-Stockholm electrode potential V (1-4) which is positive if the electrode in question is the (+) terminal of a cell whose other electrode is a standard hydrogen electrode (SHE).

[2] The sign convention followed for whole cells is that of the Lewis-Stockholm cell emf E (2-6) which is positive when positive current tends to flow through the cell as written from left to right.

measurements have been conducted under experimental conditions unfavorable to the development of the Soret effect, and the initial state of the cell then has been found to be stable for extended periods of time (up to 24 hr) (13, 30). Only the initial state of thermal cells is considered here.

Thermodynamics of Thermal Cells

The driving force of a thermal cell is the transport (or flux) of entropy from a high-temperature heat reservoir (at T_2) to a low-temperature heat reservoir (at T_1) as is the case for any heat engine. Let the entropy transported in a Carnot engine be S^*. The product $S^*(T_2 - T_1)$ is the useful work output of the engine. This work, divided by the electrical charge transported $n\mathbf{F}$, gives the electromotive force E of the cell, i.e.,

$$E/(T_2 - T_1) = dE/dT = S^*/n\mathbf{F} \qquad [4]$$

The electromotive force is positive for that direction of the current flow which transports entropy reversibly from the hot to the cold heat reservoir. The quantities of heat absorbed by the cell from the hot heat reservoir, and evolved to the cold heat reservoir, are T_2S^* and T_1S^*, respectively (Peltier heats).

The above analysis is too simple, since a thermal cell is the seat of two entropy fluxes: (*a*) a flux of entropy by heat conduction, and (*b*) a flux of entropy accompanying the flux of electricity. The former is irreversible while the latter can be made reversible by the use of a potentiometer. Consider cell [2] connected with a potentiometer. Let $T_2 = T_1 + dT$ where dT is positive. The electrical potentials of the left and right terminals are V and $V + dV$, respectively. Let the current I be positive when it flows through the cell from left to right. The entropy flux J is positive from the hot (right) to the cold (left) heat reservoir.

The irreversible rate of production of Clausius' uncompensated entropy (37, 38) from these two fluxes is

$$\dot{S} = I(-dV/T) + JdT/T \geqq 0 \qquad [5]$$

Following the methods of irreversible thermodynamics (39), one may write the phenomenological equations for the two fluxes:

$$I = L_{II}X_I + L_{IJ}X_J \qquad [6]$$

$$J = L_{JI}X_I + L_{JJ}X_J \qquad [7]$$

where $X_I = -dV/T$ and $X_J = dT/T$. The L's are phenomenological coefficients. By Ohm's law, L_{II} is T/r where r is the total resistance of the circuit. The heat conductance of the system, at zero current, is given by $L_{JJ} - L_{JI}L_{IJ}/L_{II}$, a quantity which must be positive. The interaction coefficients L_{IJ} and L_{JI} serve to measure, respectively, the flow of electricity caused by a thermal gradient when the cell is short-circuited and the flow of entropy caused by an applied emf when the cell is at uniform temperature. By the Onsager relations (40), the conjugate interaction coefficients are equal, i.e., $L_{IJ} = L_{JI}$.

Equation [6] shows the current I as the resultant of two emf's: (*a*) an externally applied emf $-dV = TX_I$ determined by the potentiometer, and (*b*) a thermal emf $dE = TL_{IJ}X_J/L_{II} = L_{IJ}dT/L_{II}$ determined by the applied temperature difference. At the balance point ($I = 0$), the potential difference dV equals the emf dE and

$$-X_I/X_J = dE/dT = L_{IJ}/L_{II} \qquad [8]$$

By the Onsager relations, this becomes

$$dE/dT = L_{JI}/L_{II} \qquad [9]$$

Suppose now that the cell is brought to uniform temperature and a small external emf applied (dV negative). The current flowing is $I = L_{II}X_I = n\mathbf{F}/t$ if t is the time required for the passage of n faradays. At the same time, the entropy flux is $J = L_{JI}X_I = S^*/t$ if S^* is the entropy transported from the right heat reservoir to the left heat reservoir, by the transfer of n faradays of positive electricity through the cell from left to right. And therefore

$$dE/dT = (dV/dT)_{I=0} = (J/I)_{dT=0} = S^*/n\mathbf{F} \qquad [10]$$

an expression derived from the Onsager relations which coincides with Eq. [4], obtained above from a consideration of a thermal cell as a quasi-Carnot engine. The entropy S^* is seen to be the entropy transported from one heat reservoir to the other, by the flow of electricity, in the absence of a temperature gradient.

The entropy S^* is the sum of two terms: (*a*) an entropy S^*_E absorbed by the reaction at the right electrode from its heat reservoir and evolved by the reaction at the left electrode to its heat reservoir (S^*_E will be referred to as the entropy of electrochemical transport); and (*b*) an entropy S^*_M transported through the cell from right to left by electrolytic migration. An equal quantity of entropy then enters the cell from the right heat reservoir and leaves the cell at the left heat reservoir, in order to keep the temperature constant (S^*_M will be referred to as the entropy of migration transport).

Consider cell [2] with two reversible iron-ferrous ion electrodes and a ferrous sulfate salt bridge. For the passage of 2 faradays through the cell from left to right, the reaction at the right electrode is $Fe^{++} + 2e^- = Fe$ and the entropy S^*_E becomes

$$S^*_E = S(Fe) - S^*_E(Fe^{++}) \qquad [11]$$

where $S(Fe)$ is the entropy of metallic iron while $S^*_E(Fe^{++})$ is the ionic entropy of electrochemical transport of the ferrous ion. The entropy S^*_M is

$$S^*_M = t_-S^*_M(SO_4^=) - t_+S^*_M(Fe^{++}) \qquad [12]$$

where the t's are transference numbers, and the S^*_{Mi}'s are ionic entropies of migration transport, of the two ions. The two transport entropies S^*_{Ei} and S^*_{Mi} for an ion[3] do not coincide with its ordinary ionic entropy (based on the standard $S^\circ(H^+) = 0$ at all temperatures) and neither do they coincide with one another. S^*_{Ei} is the entropy transported by an

[3] S^*_{Ei} has been referred to (18, 29, 41) as the "absolute ionic entropy," and S^*_{Mi} as the "entropy of transfer." Agar and Breck (33) have referred to $S^*_{Ei} + S^*_{Mi}$ as the "transported entropy" and to S^*_{Mi} as the "molar entropy of transport." See Temkin and Khoroshin (33).

ion when it sheds its hydration sheath in one place and picks up a new hydration sheath in its new place. S^*_{Mi} is the entropy transported by the ion when it drags its hydration sheath with it across the cell (35, 36). The ionic entropy S^*_{Mi} is equal, in ideal solutions, to $-RT$ times the Soret coefficient of the ion.

The thermal temperature coefficient of the iron-ferrous ion electrode, with a ferrous sulfate salt bridge, should therefore be given by

$$(dV/dT)_{th} = S^*_E/2\mathbf{F} + S^*_M/2\mathbf{F} \qquad [13]$$

where S^*_E and S^*_M are given by [11] and [12] above.[4] The first term in Eq. [13] measures the electrode temperature effect, the second term the thermal liquid junction potential. The separation of a measured thermal emf into these two terms is, strictly speaking, impossible. This separation can be accomplished only with the help of certain arbitrary assumptions.

An estimate of the thermal liquid junction potential.—One such assumption, which we shall make now, is that the thermal liquid junction potential of a saturated potassium chloride salt bridge, as used in the experimental work of Fales and Mudge (14), is zero. This assumption, while arbitrary, can be looked upon as reasonable and approximately valid for the following reasons.

In 1928, Eastman (42) estimated entropies of migration of the ions of hydrogen, and alkali chlorides, in 0.02*N* solutions from measurements on electrolytic thermocouples. From his estimates, the following entropies of migration, and thermal liquid junction potentials (tljp), can be calculated.

0.02M solution	HCl	LiCl	NaCl	KCl	RbCl
S^*_M (cal/deg)	−7.7	−0.03	−0.36	−0.49	−0.54
tljp (mv/deg)	−0.33	−0.001	−0.016	−0.021	−0.023

(23.06 cal/deg = 1 mv-faraday/deg). The negative sign means that the hot end of the thermal liquid junction dipole is negative. While the tljp of hydrochloric acid is significant, the tljp's of dilute alkali chlorides are estimated to be not larger than 0.03 mv/deg.

With the assumption that the tljp of saturated potassium chloride is zero, Fales and Mudge's (14) measurements lead to a value of the entropy of electrochemical transport S^*_E of the hydrogen ion, as will be shown below. This in turn yields the S^*_E values of other ions, and from them, the thermal temperature coefficients of reversible electrodes (without tljp). When these calculated thermal coefficients of electrodes are compared with experimental values, the difference may be used as an estimate of the tljp in the experimental bridge. This study, which is still in progress, will be reported in detail in a companion paper (36). It is possible at this stage, however, to present certain tentative conclusions. The estimated tljp's of a variety of salts, in concentrations ranging from 0.001*N* to 1*N*, fall within +0.08 to −0.08 mv/deg that of a saturated potassium chloride bridge. For potassium chloride solutions, the estimated tljp's are +0.03 to −0.03 mv/deg; for sodium chloride, +0.02 to −0.02 mv/deg; for lithium chloride, +0.05 to +0.07 mv/deg. For strong acids, the estimated tljp's are around −0.3 to −0.4 mv/deg. For strong alkalies, they are around +0.5 mv/deg. The latter two are consistent with the Soret effect in that the cold end of the thermal liquid junction dipole takes on the charge of the faster ion (H^+ or OH^-). Thus it seems probable that our assumption of zero tljp in a saturated potassium chloride bridge will not be in error by more than about 0.03 mv/deg.

Since the saturated potassium chloride salt bridge is used widely in electrochemistry as method of "eliminating the liquid junction potential," since it has been proposed by Scatchard (60) as a practical tool for the definition of single ion activities, since it is part of every cell that measures pH (61) or pCl (62), we felt justified in adopting it as a means of exploring further the subject of thermal temperature coefficients. In particular, our assumption opens up an avenue to the evaluation of the two transport entropy terms which appear in Eq. [13].

Thermal temperature coefficient of the 0.1N hydrogen ion saturated hydrogen gas electrode.—Fales and Mudge (14) investigated the emf of the isothermal cell

Pt/H_2(satd, total pressure 1 atm),

$$0.1M\ HCl/\text{satd KCl}, Hg_2Cl_2/Hg \qquad [14]$$

in the temperature range 5°-60°C. We have calculated the least squares expression

$$E\ (\text{cell [14] at } t°C, \text{mv}) = 310.0 - 0.46793(t\text{-}25) - 0.0020617(t\text{-}25)^2 \qquad [15]$$

which fits their data within the experimental scatter of a few tenths of a millivolt. In addition, Fales and Mudge investigated the emf's of the thermal cells H/C, C/H, H/H, and C/C, where H and C denote the two electrodes of cell [14], with one electrode at 25° and the other at 5°-60°, and with the thermal liquid junction located in a saturated potassium chloride bridge. From their observations, we have calculated least squares expressions for the electrode potential V_t referred to the potential V_{25} of the same electrode at 25°, as follows:

$$(V_t - V_{25})\ (Pt/H_2(\text{satd 1 atm}), 0.1M\ HCl/\text{satd KCl}, \text{mv}) = +0.67273(t\text{-}25) + 0.0018351(t\text{-}25)^2, \qquad [16]$$

$$(V_t - V_{25})\ (Hg/Hg_2Cl_2, \text{satd KCl}, \text{mv}) = + 0.21692(t\text{-}25) - 0.0010547(t\text{-}25)^2 \qquad [17]$$

[4] Equation [13] has been referred to as the Eastman thermocell equation (29) and applies to a thermal cell in its initial state, before the onset of thermal diffusion. Wherever the Soret effect is allowed to develop, it can be shown, by introducing solute diffusion into the set of Onsager fluxes [6-7], that the cell reaches a final steady state in which $2\mathbf{F}(dV/dT)_{th,final} = S^*_E[11] - \frac{1}{2}[S^*_M(Fe^{++}) + S^*_M(SO_4^=)] - \frac{1}{2}[S^*_M(Fe^{++} - S^*_M(SO_4^=)]$. Here the second term gives the effect of the thermally induced concentration gradient on the difference of the two electrode potentials, and the third term gives the final value of the liquid junction potential as a resultant of both temperature and concentration gradients. The whole expression for the final state reduces to $S^*_E[11] - S^*_M(Fe^{++})$. The corresponding equation [13] for the initial state takes the comparable form $S^*_E[11] + S^*_M[12]$.

For an electrolyte which dissociates into $\nu_+ + \nu_- = \nu$ ions, and for the passage of $\nu_i|z_i|$ faradays through electrodes of the metal Me reversible to the positive ion, the molal and ionic entropies are replaced by $\nu_i S(Me)$ or $\nu_i S^*_E(i)$ or $\nu_i S^*_M(i)$ in all of these expressions. The first $\frac{1}{2}$ in the expression for the final state is replaced by ν_+/ν; the second $\frac{1}{2}$ is replaced by ν_-/ν for the positive ion and by ν_+/ν for the negative ion.

Both expressions fit the data well within the experimental scatter of a few tenths of a millivolt.[5] At 25°, the thermal temperature coefficients are +0.217 mv/deg for the saturated calomel electrode, and +0.673 mv/deg for the 0.1*N* hydrogen electrode. Their difference, −0.456 mv/deg, is consistent with the isothermal coefficient −0.468 mv/deg observed for cell [14] (Eq. [15]). The uncertainty of these 25° values appears to be no more than 0.02 mv/deg. Over the temperature range 5°-60°, the isothermal temperature coefficient of cell [14] calculated from Eq. [15] agrees with the difference of the two thermal temperature coefficients calculated from Eq. [16] and [17] within ±0.045 mv/deg.

Correction to unit activity of hydrogen gas.—Fales and Mudge's 0.1*N* hydrogen electrodes were saturated with hydrogen gas under total pressures of 755-770 mm Hg. To correct to the standard state of hydrogen gas (partial pressure equal to 760 mm Hg), the term $(RT/2\mathbf{F}) \ln [p(H_2, \text{mm})/760]$ must be added algebraically to the hydrogen electrode potentials as measured in any of their cells. The partial pressure of hydrogen can be computed by subtracting the vapor pressure of water (which holds very nearly in 0.1*M* hydrochloric acid) from their recorded barometric data. When this correction is applied to their individual data, Eq. [15] is modified as follows

$$E \text{ (cell [14] corrected to } H_2 \text{ p.p. 1 atm, mv)} = 310.3 - 0.43520(t\text{-}25) - 0.00089234(t\text{-}25)^2 \quad [18]$$

while Eq. [16] becomes

$$(V_t - V_{25}) \text{ (Pt/H}_2\text{(p.p 1 atm), 0.1}M \text{ HCl/satd KCl, mv)} = +0.64023(t\text{-}25) + 0.00064334(t\text{-}25)^2 \quad [19]$$

At 25°C, the thermal temperature coefficient of the 0.1*N* hydrogen electrode is +0.640 mv/deg, after correction to unit activity of hydrogen gas.

Correction to unit activity of hydrogen ion.—The Nernst equation for a reversible hydrogen electrode is

$$V = V^\circ + (RT/\mathbf{F}) \ln [(H^+)/(H_2)^{1/2}] \quad [20]$$

The temperature derivative of this equation can be applied to both isothermal and thermal temperature coefficients of electrode potentials. When applied to the thermal coefficient, it yields[6]

$$(dV/dT)_{th} = (dV^\circ/dT)_{th} + (R/\mathbf{F}) \ln [(H^+)/(H_2)^{1/2}] + (RT/\mathbf{F})(d \ln [(H^+)/(H_2)^{1/2}]/dT) \quad [21]$$

[5] Neither of these expressions has been corrected for the thermocouple effect. The status of the correction is not clear from Fales and Mudge's paper. However, the emf's of Hg/Cu and Pt/Cu thermocouples (43) amount to +0.0120 and +0.0068 mv/deg at 25° [hot Cu terminal (+)]. These values fall within the experimental uncertainty of Fales and Mudge's data of about 0.02 −0.04 mv/deg.

[6] Applications of equations such as [20] and [21] come up against the thorny problem of defining the single ion activities which they involve. A practical rule is that of Scatchard (60): "We will define single ion activities as those measured with a use of a saturated potassium chloride bridge. 'Such a definition does not contradict any measurements or theories which do not involve single ion activities.' " A convenient rule for computation applicable to uni-univalent salts is to take the single ion activity equal to the measurable mean ion activity of the electrolyte (7). For multiply charged ions of binary salts, an extension of this rule, consistent with the Debye theory (44), is to take single ion activity coefficients as $\gamma_+ = \gamma_\pm^{-z_+/z_-}$ and $\gamma_- = \gamma_\pm^{-z_-/z_+}$ where z_+ and z_- are the valences (with sign) of the cation and anion, respectively. These rules will be adopted in the present paper.

Fales and Mudge (14) reported their 0.1*M* hydrochloric acid as 0.1003*M*. If one takes $\gamma_+ = \gamma_\pm = 0.7967$ (45), the second term in Eq. [21] becomes equal to (0.1984 mv/deg) log (0.1003 × 0.7967) = −0.218 mv/deg, when $(H_2) = 1$. At constant molality, $d \ln (H^+)/dT$ can be replaced by $d \ln \gamma_\pm/dT$. From data of Bates and Bower (45, Eq. [5] in their paper), $d \log \gamma_\pm/dT = -0.0002181$ deg^{-1}, and the third term in Eq. [21] is equal to (59.16 mv)(−0.0002181 deg^{-1}) = −0.013 mv/deg.

Thermal temperature coefficient of the standard hydrogen electrode.—By taking $(dV/dT)_{th} = +0.640$ mv/deg in Eq. [21], one can obtain the thermal temperature coefficient of the standard hydrogen electrode (SHE) as (+0.640) − (−0.218) − (−0.013) = +0.871 mv/deg at 25°C.

An independent experimental check of this value can be made as follows. The potential of the saturated potassium chloride calomel electrode (SCE) has been deduced from buffer measurements of (*a*) MacInnes, Belcher, and Shedlovsky (46) and of (*b*) Baxter (47) to be: 10°C, +0.2540*b*; 12°, 0.2530*a*; 15° 0.2508*b*; 18° 0.2489*b*; 20° 0.2476*b*; 25° 0.2446*a*, 0.2443*b*; 30° 0.2410*b*; 35° 0.2376*b*; 38° 0.2375*a*, 0.2356*b*; 40° 0.2342*b*. The isothermal temperature coefficient of the SCE at 25°C is obtained as −0.60 mv/deg from set (*a*) and −0.66 mv/deg from set (*b*). These may be contrasted with Clark's (61) earlier estimate of −0.76 mv/deg and Vellinger's (48) of −0.66 mv/deg. The thermal temperature coefficient of the SCE has been observed as +0.217 mv/deg, Fales and Mudge (14); +0.21, Ewing (15); +0.20, Cary and Baxter (25); +0.22, Bjerrum and Unmack (20); +0.234, Wingfield and Acree (23).

The difference thermal minus isothermal coefficient for the SCE should yield the thermal temperature coefficient of the SHE. When this is done, extremes ranging from +0.80 to +1.0 mv/deg are obtained. However, if −0.66 mv/deg is adopted as a preferred isothermal value and +0.22 mv/deg as a median thermal value, for the SCE, the thermal value +0.88 mv/deg is obtained for the SHE, which is very close to our own. The experimental uncertainty in these and other observations still amounts to a few hundredths of a millivolt per degree. It seems best to assign a precision measure of not less than ±0.02 mv/deg and we shall therefore adopt, for the SHE at 25°C:

$$(dV^\circ/dT)_{th}(H_2/H^+) = +0.871 \pm 0.02 \text{ mv/deg} \quad [22]$$

Standard ionic entropy of electrochemical transport of the hydrogen ion.—For the standard hydrogen electrode, the entropy of electrochemical transport $S^{*\circ}_E$ is given by

$$S^{*\circ}_E = S^\circ(H_2) - 2S^{*\circ}_E(H^+) \quad [23]$$

for 2 faradays, and is equal to +0.871 mv/deg × 2**F** = +1.742 mv**F**/deg = 40.17 cal/deg. Since the molal entropy of hydrogen gas is 31.211 cal/deg (6), the standard ionic entropy $S^{*\circ}_E$ of H^+ is computed as −4.48 cal/deg ±0.5 cal/deg. This value may be contrasted with estimates ranging from −1.5 to −6.3 cal/deg reported by several authors (28, 29, 41).

Since the entropy transported by a neutral sub-

stance should be independent of the particular way its entropy is divided into constituent ionic entropies, the standard entropies of electrochemical transport $S^{*\circ}_{Ei}$ of other ionic species can be obtained from their tabulated standard entropies S°_i (referred to $S^\circ(H^+) = 0$ at all temperatures) by the equation

$$S^{*\circ}_{Ei} = S^\circ_i + z(-4.48 \text{ cal/deg}) \quad [24]$$

where z_i is the ionic charge (with sign).

Calomel electrodes.—For the calomel electrode: $2Hg + 2Cl^- = Hg_2Cl_2 + 2e^-$, $V^\circ = +0.2676$ v, the entropy of electrochemical transport S^*_E is

$$\begin{aligned} S^{*\circ}_E &= 2S^\circ(Hg) + 2S^{*\circ}_E(Cl^-) - S^\circ(Hg_2Cl_2) \\ &= 2(+18.5) + 2(13.2 + 4.48) - (46.8) \\ &= 25.56 \text{ cal/deg} = 1.108 \text{ mv}\mathbf{F}/\text{deg} \end{aligned} \quad [25]$$

Division by 2 faradays yields

$$(dV^\circ/dT)_{th}(Hg/Hg_2Cl_2, Cl^-) = +0.554 \text{ mv/deg} \quad [26]$$

The Nernst equation for this electrode and its temperature derivative (applied to the thermal coefficient), are

$$V = V^\circ - (RT/\mathbf{F}) \ln (Cl^-) \quad [27]$$

and

$$\begin{aligned} (dV/dT)_{th} &= (dV^\circ/dT)_{th} - (R/\mathbf{F}) \ln (Cl^-) \\ &\quad -(RT/\mathbf{F})(d \ln (Cl^-)/dT) \end{aligned} \quad [28]$$

By means of Eq. [26] and [28], we have calculated the thermal temperature coefficients of 0.01, 0.1, 1.0, 3.5, and 3.8N potassium chloride calomel electrodes and compared them with experimental observations on thermal cells in which the salt bridge contained the same concentration of potassium chloride as the electrodes (Table I). The second term in Eq. [28] is equal to $+(0.1984 \text{ mv/deg})$ pCl where $pCl = -\log (Cl^-)$, a quantity which can be equated to $-\log m\gamma_\pm$ (62). In the third term, the derivative $d \ln (Cl^-)/dT$ can be replaced, at constant molality, by $d \ln \gamma_\pm/dT$. The latter quantity can be evaluated from data in Harned and Owen (49), the estimates for the two highest normalities are uncertain and have been put in parentheses in Table I. The third term in Eq. [28] amounts to +0.002, 0.000, −0.021, (−0.07), and (−0.075) mv/deg for the five normalities studied. For the first three normalities, the third term could have been neglected without significant error while, for the last two, it is significant but uncertain. For the first three normalities, agreement between calculation and experiment falls by and large within ±0.02 mv/deg, and no deviation exceeds 0.04 mv/deg. For the two highest normalities, better agreement is attained when the third term is neglected. Inclusion of the third term (values in parentheses) leads to calculated values that are about 0.06 −0.07 mv/deg low.

The potential of the saturated potassium chloride calomel electrode (SCE) can be calculated from Eq. [27] with the chloride ion activity set equal to the square root of the activity of the saturated potassium chloride electrolyte. The latter in turn is equal to $\exp(-\Delta G^\circ/RT)$ where ΔG° is the standard free enthalpy (Gibbs free energy) of solution of potassium chloride according to the reaction: $KCl(c) = K^+(aq) + Cl^-(aq)$, and is equal to −1.224 kcal = −0.0532 v-faraday (6). The potential of the SCE is therefore equal to $V(SCE) = V^\circ + \Delta G^\circ/2\mathbf{F} = +0.2676$ v + (−0.0532 v$\mathbf{F}$/2$\mathbf{F}$) = +0.2410 v, a value which is consistent with observed values 0.2446 (46) and 0.2443 (47) at 25°C after correction for the liquid junction potential by means of the Henderson equation. The thermal temperature coefficient of the SCE potential is then given by $(dV/dT)_{th}(SCE) = (dV^\circ/dT)_{th} - \Delta S^\circ/2\mathbf{F}$ where ΔS° is the standard entropy of solution of potassium chloride, and is equal to 17.94 cal/deg = 0.778 mv$\mathbf{F}$/deg (6). We can therefore calculate

$$(dV/dT)_{th}(SCE) = +0.554 - (0.778/2) = + 0.165 \text{ mv/deg}$$

at 25°C. The comparable experimental values already have been quoted above as: +0.217 (14), +0.21 (15), +0.20 (25), +0.22 (20), and +0.234 mv/deg (23). The calculated value here seems to be about 0.05 mv/deg low.

Silver chloride electrode.—For the silver chloride electrode: $Ag + Cl^- = AgCl + e^-$, $V^\circ = +0.2223$ v, the entropy of electrochemical transport S^*_E is

$$\begin{aligned} S^{*\circ}_E &= S^\circ(Ag) + S^{*\circ}_E(Cl^-) - S^\circ(AgCl) \\ &= (10.206) + (13.2 + 4.48) - (22.97) \\ &= 4.92 \text{ cal/deg} = 0.214 \text{ mv}\mathbf{F}/\text{deg} \end{aligned} \quad [29]$$

Division by 1 faraday yields

$$(dV^\circ/dT)_{th}(Ag/AgCl, Cl^-) = +0.214 \text{ mv/deg} \quad [30]$$

This value may be compared with experiments of Tyrrell and Hollis (28) who deduce a value of +0.205 mv/deg for the standard thermal coefficient,

from their observations in sodium chloride solutions.

For several nonstandard silver chloride electrodes, thermal temperature coefficients can be computed (neglecting the slight discrepancy between normality and molality of chloride) and compared with experiment (Table II). The temperature effect on activity coefficients was estimated from data in Harned and Owen (49) or from the Debye theory (44). Agreement between calculation and experiment is within ±0.02 mv/deg, the largest deviation is 0.04 mv/deg.

From the calculated values in Table II, the Peltier heat of the silver chloride electrode can be computed as $TS^*_E = Tn\mathbf{F}(dV/dT)_{th} = 4.27$ and 2.98 kcal, in 0.01N and 0.1N potassium chloride, respectively. Lange and Hesse's calorimetrically observed values are 4.52 and 3.32 kcal, respectively (22).

Copper-copper sulfate electrode.—The standard potential of the copper electrode, $Cu = Cu^{++} + 2e^-$, has been assigned values ranging from $V° = +0.3448$ to +0.337 v (5-7, 51-53) at 25°C. In general, the amalgam electrodes proved about 5 mv more noble than the pure metal. Tragert and Robertson (53) investigated the dependence of potential on crystal face orientation. For the most stable (111) plane, they found a potential of +0.3419 v. For unstable (110), (100), and (210) planes, the potential was about 4 mv more active and reverted in time to the (111) value.

The entropy S^*_E of electrochemical transport for the copper electrode is

$$\begin{aligned} S^{*\circ}_E &= S^\circ(\mathrm{Cu}) - S^{*\circ}_E(\mathrm{Cu^{++}}) \\ &= (7.96) - (-23.6 - 2 \times 4.48) \\ &= 40.52 \text{ cal/deg} = 1.757 \text{ mv}\mathbf{F}/\text{deg} \end{aligned} \quad [31]$$

Division by 2 faradays yields

$$(dV°/dT)_{th}(\mathrm{Cu/Cu^{++}}) = +0.879 \text{ mv/deg} \quad [32]$$

Bonnemay (32) has reported a value of +0.81 mv/deg for the standard thermal coefficient from his experimental observations.

For unsaturated copper sulfate electrodes, the thermal temperature coefficient should be given by $+0.879 + (R/2\mathbf{F}) \ln (Cu^{++})$ plus a third term involving the temperature dependence of activity coefficients which will be neglected here. This coefficient was measured by Meyer (12), Burian (21), Ewing (24), and other observers [see Lange (10)]. The bulk of the values, for copper sulfate concentrations from 0.02 to 1M, fall in the range +0.5 to +0.8 mv/deg. The following approximate calculations can be carried out and compared with selected experimental values (Table III). Agreement between calculation and experiment falls here within about ±0.05 mv/deg.

The saturated copper sulfate electrode is a popular reference electrode in corrosion field work (24, 34). Its potential at 25°C is given by $V(\mathrm{Cu/satd\ CuSO_4}) = V° + (RT/2\mathbf{F}) \ln (Cu^{++} \text{ in satd } CuSO_4)$. The activity of cupric ion in saturated copper sulfate solution may be set equal to the square root of the activity of saturated copper sulfate electrolyte. The latter is equal to $\exp(-\Delta G°/RT)$ where $\Delta G°$ is the standard free enthalpy of solution of copper sulfate according to the equation $CuSO_4 \cdot 5H_2O(c) = Cu^{++}(aq) + SO_4^=(aq) + 5H_2O$ and is equal to +4.04 kcal = +0.1752 v$\mathbf{F}$ (6). The potential of the saturated copper sulfate electrode is therefore equal to $V(\mathrm{Cu/satd\ CuSO_4}) = V° - \Delta G°/4\mathbf{F} = +0.3419 \text{ v} - (0.1752 \text{ v}\mathbf{F}/4\mathbf{F}) = +0.2981$ v at 25°C. The latter is in good agreement with data of Hall (54) who observed values ranging from +0.302 to +0.317 on uncleaned copper, and +0.296 to +0.303 after nitric acid etch.

The thermal temperature coefficient then is given by $(dV/dT)_{th}(\mathrm{Cu/satd\ CuSO_4}) = (dV°/dT)_{th} +$

Table III. Thermal temperature coefficients of unsaturated copper sulfate electrodes

Molarity of $CuSO_4$	0.08	0.1	0.5	1.0	1.4
$\gamma_\pm$	0.17	0.16	0.068	0.047	0.04 (est)
pCu	1.86	1.80	1.47	1.33	1.25
$(dV/dT)_{th}$ mv/deg					
Calc.	+0.694	+0.700	+0.733	+0.747	+0.755
Obs.	+0.64[a]	+0.72[b]	+0.75[c]	+0.69[a] +0.79[b]	+0.75[c]

[a] Meyer (12); [b] Burian (21); [c] Ewing (24) found no variation when copper sulfate bridge was replaced by a potassium chloride bridge. Coefficients observed in range 28.5°-51°C. In 0.5M $CuSO_4$, observed value drops to +0.55 mv/deg at 0°C.

$\Delta S°/4\mathbf{F}$ where $\Delta S°$ is the standard entropy of solution of copper sulfate pentahydrate and is equal to -8.92 cal/deg $= -0.3868$ mv**F** (6). We can therefore calculate

$$(dV/dT)_{th}(\text{Cu/satd CuSO}_4) = +0.879 + (-0.3868/4) = +0.782 \text{ mv/deg}$$

This calculated value may be compared with the observed values: Ewing's +0.895 mv/deg (24) observed in the temperature range 0°-50°C with a copper sulfate bridge, and Scott's +0.97 mv/deg (34) observed under field conditions with a soil bridge and a polarized steel structure as the constant temperature reference electrode. Ewing observed a distinct hysteresis in the behavior of the saturated copper sulfate electrode with temperature changes, Scott apparently did not. Although the agreement between calculation and experiment is only within 0.1-0.2 mv/deg, it is sufficiently striking to confirm the validity of the ionic entropies of electrochemical transport deduced in this paper from Fales and Mudge's observations (14) on the 0.1*N* hydrogen electrode together with the assumption that their saturated potassium chloride bridges eliminated the thermal liquid junction potential.

Isothermal Temperature Coefficients

Isothermal temperature coefficients of electrode potentials have already been defined above in terms of cell [1] and Eq. [3]. Consider cell [1] with a reversible iron-ferrous ion electrode at the right-hand end. The entropy ΔS of the reaction which transfers 2 faradays of positive electricity through cell [1] from left to right is

$$\Delta S = S(\text{Fe}) - S(\text{Fe}^{++}) + 2S°(\text{H}^+) - S°(\text{H}_2) \qquad [33]$$

If the iron and ferrous ion are in their standard states, their standard molal entropies are 6.49 and -27.1 cal/deg, respectively, at 25°C (6). Given the standard entropies of hydrogen gas and hydrogen ion as 31.211 cal/deg and zero, respectively, the standard reaction entropy of cell [1] is $\Delta S°[33] = +2.38$ cal/deg $= +0.1032$ mv**F**/deg. Division by 2 faradays yields

$$(dV°/dT)_{isoth}(\text{Fe/Fe}^{++}) = +0.052 \text{ mv/deg}$$

The thermal temperature coefficient of the iron-ferrous ion electrode is determined by the electrochemical transport entropy S^*_E already given in Eq. [11]. If we take $S^{*\circ}_E(Fe^{++}) = -27.1 + 2\ (-4.48) = -36.06$ cal/deg, the standard transport entropy $S^{*\circ}_E$ [11] becomes +42.55 cal/deg $= +1.845$ mv**F**/deg. Division by 2 faradays yields

$$(dV°/dT)_{th}(\text{Fe/Fe}^{++}) = +0.923 \text{ mv/deg}$$

The difference thermal minus isothermal coefficient for the iron-ferrous ion electrode becomes $[S^*_E[11] - \Delta S[33]]/2\mathbf{F} = [S(\text{Fe}^{++}) - S^*_E(\text{Fe}^{++}) - 2S°(\text{H}^+) + S°(\text{H}_2)]/2\mathbf{F} = [-2S^{*\circ}_E(\text{H}^+) + S°(\text{H}_2)]/2\mathbf{F}$, i.e., this difference is equal to the thermal temperature coefficient of the SHE. For the standard iron-ferrous ion electrode, this difference is equal to $+0.923 - (+0.052) = +0.871$ mv/deg, i.e., the numerical value assigned above to the SHE thermal coefficient.

Thus the thermal temperature coefficient of any (standard or nonstandard) electrode potential, when computed according to the methods of this paper, can be converted to the corresponding isothermal temperature coefficient by subtraction of the numerical constant 0.871 mv/deg.

Table of Temperature Coefficients

Table IV lists a number of electrodes, their standard electrode potentials, the thermal temperature coefficients computed according to the methods of this paper, and the isothermal temperature coefficients computed from Eq. [3]. The data refer, except where noted, to 25°C. The entropy data were taken largely from Latimer (6). Whenever entropies were given only to the nearest cal/deg, the coefficients were rounded off to the nearest hundredth of a millivolt per degree. Direct experimental observations, in addition to those discussed above in the text, are noted in parentheses. The agreement is usually within a few hundredths of a millivolt per degree for both thermal and isothermal temperature coefficients.

The temperature coefficient of the emf[2] of any isothermal cell can be computed from the temperature coefficients given in Table IV by taking the algebraic difference of the values listed for the two electrodes in the order: thermal right minus thermal left, or isothermal right minus isothermal left.

Acknowledgment

The authors wish to express their gratitude to those corrosion engineers who persistently asked them the question "What is the effect of temperature on electrode potentials?" They take pleasure in acknowledging their indebtedness to Dr. W. A. Mudge of the International Nickel Company for calling their attention to his experiments (14) on the thermal temperature coefficient of the 0.1*N* hydrogen electrode which have proved basic to this entire study. They also wish to thank the International Nickel Company for a Grant-in-Aid in support of this work.

Manuscript received Aug. 8, 1958. This paper was prepared for delivery before the Philadelphia Meeting, May 3-7, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Table IV. Thermal and isothermal temperature coefficients of the standard electrode potentials at 25°C

The electrode potential V° is given a positive value if the electrode is the (+) terminal of a cell whose second electrode is the SHE. The thermal temperature coefficient $(dV°/dT)_{th}$ is given a positive value if the hot electrode is the (+) terminal in a thermal cell. The isothermal temperature coefficient $(dV°/dT)_{isoth}$ is given a positive value if the electromotive force of the isothermal cell: SHE // Electrode, increases with the temperature.

Electrode	V°, v	$(dV°/dT)_{th}$, mv/deg	$(dV°/dT)_{isoth}$, mv/deg

Transport Numbers in Pure Fused Salts

The Alkali Metal Chlorides

Frederick R. Duke and Allen L. Bowman[1]

Institute for Atomic Research and Department of Chemistry, Iowa State College, Ames, Iowa

ABSTRACT

The transport number of the chloride ion has been determined in fused alkali chloride salts by a radiochlorine tracer technique, using a membrane cell. Values obtained (Table I) are compared with theoretical predictions of Mulcahy and Heymann, and of Sundheim.

The transport numbers of the fused alkali metal chlorides have been estimated from comparisons of electrical conductivity data (1, 2) and from purely theoretical considerations (3, 4). Mulcahy and Heymann (1) compared the equivalent conductivities at a corresponding temperature defined as three-fourths of the boiling point. They found that the data could be approximated by the equation $\lambda = K(1/r_A + 1/r_C)$. Bloom and Heymann (2) concluded that the electrical conductance of the alkali halides is due primarily to the small cation. This was based on the fact that the equivalent conductivity changes strongly with change of cation but very little with change of anion. Frenkel (3) suggested that only one of the ions in a molten salt should be responsible for electrical conductance, and that this would in general be the cation because of its smaller radius. Sundheim (4) proposed that the transport numbers in a pure fused salt should be expressed by the equation $t_A = M_C/(M_A + M_C)$ where the M's are the masses of the anion and cation. Sundheim derived this equation by requiring a balance of momentum in a simplified model, assuming no momentum transfer to the apparatus.

If the transport number of an ionic species in a fused salt is defined as the fraction of the current carried by those ions which are moving relative to the bulk of the liquid (5), then this number can be determined by holding a quantity of salt in a thick membrane of very fine porosity where its motion is restricted, and measuring the movement of the ions through this membrane under the influence of an electrical potential. The transport numbers of several pure fused salts have been determined by measuring the volume changes in the electrode compartments resulting from the movement of the ions through the membrane (5-7). The movement of one of the ions can also be measured by the use of a radioisotope (8). This method is particularly convenient for the measurement of the transport number of the chloride ion in any fused chloride.

Experimental

Reagent grade salts were used; they were kept in a drying oven at 150°C and cooled in a desiccator before weighing, except for lithium chloride which was fused and held in this condition in a dry atmosphere for several hours. The chloride isotope, Cl^{36}, was obtained from Oak Ridge National Laboratory as an aqueous solution of hydrochloric acid. The alkali metal salts containing Cl^{36} were prepared by dissolving the salt in water, adding HCl^{36}, and evaporating the solution to dryness. Reagent grade silver wire and granulated lead were used for electrodes.

A 16-in. Marshall Tube Furnace was used with a Brown Indicating Controller to provide the high-temperature region. A d-c power supply capable of delivering up to 350 ma at 35 v was used for electrolysis. The quantity of charge was determined by measuring the fairly constant current with a milliammeter and the time of electrolysis with a Precision "Time-It".

The cells were made from 10 mm ID quartz, in the form of a square U-tube, 2.5 in. wide and 1.5 in. high, with a small bubble on the bottom of each vertical tube to hold the liquid metal electrodes. A membrane of fused quartz, 1.5 mm thick, porosity No. 4, Engelhard Industries, Amersil Quartz Division, was sealed into the center of the horizontal section. The porosity of the membrane was reduced by depositing silica within it. This was done by alternately running ethyl silicate and hydrochloric acid through the membrane and dehydrating the resulting silica gel by baking at 800°C. This treatment was repeated until more than 2 hr was required for 1 ml of water to flow through the membrane under suction. The cathode was a pool of molten lead, with electrical contact through a nichrome wire sealed into a glass tube. The anode was either lead or a silver wire. The same results were obtained with both anodes.

To carry out a run, the cell was filled with solid salt, radiotracer salt was added to the catholyte, the electrodes were inserted, the ends of the cell were capped, and the cell was placed in the furnace at the temperature of the run. As soon as thermal equilibrium was attained and the cell was conducting, a metered d-c current was passed for a measured time (usually 300 ma for 400 sec). The cell was then withdrawn, frozen, and split at the membrane to separate anolyte and catholyte. The two halves of the cell were dissolved in aqueous ammonia. The Cl^{36} was precipitated from the ammoniacal solutions with excess silver nitrate and counted as silver chloride.

[1] Present address: Los Alamos Scientific Laboratory, University of California, Los Alamos, N. Mex.

In order to obtain a smooth, fine-textured precipitate, it was necessary to keep the solution ammoniacal during the precipitation. All samples were corrected to a common weight by the use of a self-absorption curve. The weight of anolyte salt was obtained by weighing the anode portion of the cell before and after the salt was dissolved.

To obtain a relation between experimental quantities and the transport numbers, consider a cell whose anolyte and catholyte are separated by an ideal membrane which permits passage of current-carrying ions only. The number, m, of current-carrying chloride ions which pass through the membrane is equal to (tZ/e) where t is the transport number of the chloride ion, Z is the quantity of charge passed during electrolysis, and e is the electronic charge. Let the catholyte initially contain $(N^*)^\circ$ radioactive chloride ions and a total number N° of chloride ions. After m chloride ions have passed through the membrane during electrolysis, $(N^*)_m$ radioactive chloride ions are found in the anolyte. Then $m = [(N^*)_m/(N^*)^\circ]N^\circ = [(N^*)_m/(N^*)]N$, where N^* and N are the numbers of radiochloride and total chloride ions, respectively, in the catholyte at the end of the run. The second relation follows, since the initial and final ratio of Cl^{36}/Cl in the catholyte must remain the same, if no isotopic fractionation occurs. If the radioactivity found in anolyte and catholyte at the end of the run, C_A and C_C, are expressed in (counts per minute) per milligram, then $(N^*)_m = C_A W_A$, and $(N^*) = C_C W_C$, where W_A and W_C are the total weights of anolyte and catholyte, respectively, in milligrams. This assumes that the samples used for counting are identical in size and composition. But $N = (W_C/M) N_A$, where M is the milliequivalent weight of the salt and N_A is Avogadro's number. Then m can be expressed by $m = (C_A/C_C)(W_A/M)N_A$, and the transport number t of chloride ion by

$$t = em/Z = \mathbf{F}C_A W_A/ZC_C M \qquad [1]$$

where $\mathbf{F}$ is the faraday.

The assumed condition that only current-carrying ions pass through the membrane can be realized in effect by carrying a parallel blank run with no passage of charge, and subtracting the $(C_A)_{blank}$ from the observed values of C_A. It was found experimentally that the blank correction was essentially zero if the membrane was sufficiently fine.

Table I. Transport numbers of chloride ion in fused alkali metal chlorides

Salt	Temp, °C	Observed values (This investigation)	Calculated values	
LiCl	600	0.25±0.03	0.25*	0.16†
NaCl	860	0.38±0.04	0.34	0.41
KCl	830	0.38±0.04	0.42	0.52
RbCl	785	0.42±0.04	0.45	0.71
CsCl	685	0.36±0.04	0.48	0.79

* $t = r_C/(r_A + r_C)$ Mulcahy and Heymann (1).
† $t = M_C/(M_A + M_C)$ Sundheim (4).

Results and Discussion

The values of t obtained in the alkali metal chlorides by following the migration of Cl^{36} are given in Table I and are compared with values calculated from the estimates of other workers.

It is apparent that the transport numbers do not agree with Sundheim's equation (4) nor with the predictions of Bloom and Heymann (2) and Frenkel (3). With the exception of cesium chloride, the experimental values do agree, within experimental error, with the radius dependence of Mulcahy and Heymann (1). However, the latter authors require that the mobility of the chloride ion should be constant at corresponding temperatures. Using the conductivity data of Yaffe and Van Artsdalen (9), the mobility of the chloride ion in these salts at 5% above their melting points varies from 2.9×10^{-4} $(cm^2/sec)/v$ for cesium chloride to 5.6×10^{-4} for sodium chloride. Thus it would appear that the transport numbers of these salts cannot be expressed as any simple function of the mass or radius of the ions.

Technical Notes

Glow Discharge Spectra of Copper and Indium above Aqueous Solutions

Dwight E. Couch and Abner Brenner

Chemistry Division, National Bureau of Standards, Washington, D. C.

An unusual glow discharge was produced between a tungsten electrode and an aqueous solution of cupric or indium salts. This glow was somewhat lambent and almost filled the containing flask. It was not produced with solutions of the other metallic salts which we tried ($BaClO_4$, $CuCN \cdot 3KCN$, H_2SO_4, LiCl, LiI, $LiClO_4$, NaCl, $SrCl_2$ U (VI) Acetate). However, occasional flashes of color were produced with solutions of lithium and sodium chloride. Many studies of the chemical effects of the glow discharge between an electrode and a solution have been made (1-3), but the phenomenon which we observed has not been reported. The glows were characteristic of the spectra of copper and indium. Production of spectra in this manner is unique since spectra are usually obtained by vaporizing the metal or compound at high temperatures.

In these experiments, saturated solutions of cupric perchlorate, chloride, or sulfate or indium(III) chloride were placed in a round, three-necked flask, one- or two-liters in volume, and the flask evacuated through a side neck to 5 or 10 cm Hg. One lead of a high-voltage d-c power supply was attached to a tungsten rod which passed through the center neck of the flask and terminated about 1 in. above the solution level. The other electrode which passed through the remaining neck of the flask was shielded along its length by a glass tube except at the end where the electrode dipped into the solution. A current of 0.05-0.2 amp, which required about 500 v, produced a continuous glow discharge. After a period of about 15 min of discharge a soft green or blue glow developed around the central discharge, depending on the salt used, and grew until it almost completely filled the containing flask. The glow was more easily produced with copper salts than with indium salts. The spectra of the glow were photographed and examined.[1] The atomic lines were excited at about the same intensities as those produced by flame spectra. Spectral lines of OH were also present.

These experiments were repeated using a fused salt bath of lithium chloride, potassium chloride, and

cupric chloride, but no similar copper spectra could be produced. Therefore, it was concluded that there was something unique about the aqueous cupric salt solution that caused this green glow around the central discharge. Table I shows the wave lengths of the lines observed.

The first attempt to explain the glow discharge was on the basis of spray or particles being thrown between the electrodes. If this is the explanation, the glow should have been produced with aqueous solutions of other metal salts. To test this hypothesis specifically an apparatus was constructed which consisted of a rotating device which threw a sheet of electrolyte into the space between the two electrodes. This procedure did not lead to results as good as were obtained in the simple equipment consisting of a three-necked flask with electrodes. Further experiments showed that the glow was not caused by salts coating the electrodes, as coated electrodes did not yield a spectrum until they became hot enough to volatilize the deposited salt.

Our explanation of the phenomenon is that a volatile copper or indium compound is formed in the solution. This evaporates into the evacuated space and is responsible for the spectra. This explanation is in accordance with the observations that the glow is less pronounced with chilled solutions and becomes stronger as the solutions become warmer; also it fits with the observation that the glow is not always given immediately with a fresh solution, but may require a brief period of electrical discharge. A somewhat stronger glow was obtained when the solution was cathodic, but, since the glow could be produced also when the solution was anodic, this indicates that the phenomenon was not likely caused by the migration of charged cations into the gaseous space.

Manuscript received Jan. 22, 1959.

Determination of Activities in Multicomponent Metallic Solutions

Rudolph Speiser and George St. Pierre

Department of Metallurgy, The Ohio State University, Columbus, Ohio

It is generally difficult to determine phase equilibria at high temperatures. Attempts at retaining the high-temperature situation by rapid quenching to low temperatures at which examination is easier are not entirely satisfactory. Diffraction studies are performed at high temperatures with considerable success; however, no knowledge of the activities of the components is obtained from such investigations. The present method allows for the simultaneous determination of activities and phase equilibria at high temperatures.

Thermodynamic Treatment

The vapor pressure and vapor composition over a condensed phase can be used to determine phase equilibria and activities. A direct measurement (static) of the vapor pressure can be made only when the vapor pressure is at least 10^{-2} mm Hg. At lower pressures dynamic methods must be employed. It will be shown that it is not necessary to determine the vapor pressure at all.

The general form of the Gibbs-Duhem (1) equation may be written in the following form:

$$S^q\,dT - V^q\,dP_T + \Sigma_i N_i^q\,d\mu_i = 0 \qquad [1]$$

where N^q_i is the mole fraction of component i in any condensed phase, q, and μ_i is the chemical potential of component i in the system. For each phase, q, there is an equation of form [1]. The first term in Eq. [1], $S^q\,dT$, disappears under isothermal conditions and is not considered further in this paper. The second term, $V^q\,dP_T$, is negligible because the absolute variation of P_T with the composition of the condensed phase is very small. Therefore, Eq. [1] is reduced to

$$\Sigma_i N_i^q d \ln a_i = 0 \qquad [2]$$

(constant T and P_T)

The activity of each component in the condensed phase is related to the vapor phase by the following equations:

$$a_i = \frac{f_i}{f_i^\circ} \cong \frac{P_i}{P_i^\circ} \qquad [3]$$

where f_i° and P_i° designate the fugacity and partial pressure of component i for a standard state of the condensed system. If the vapor is assumed to obey ideal gas laws, then

$$P_T = \frac{P_i}{N_i^v} = \frac{P_1}{N_1^v} = \frac{P_2}{N_2^v} = \ldots \qquad [4]$$

where N_i^v is the mole fraction of component i in the vapor phase. The partial pressure of any component may be expressed in terms of the partial pressure of any other component by the relation

$$P_i = \frac{N_i^v}{N_j^v} \cdot P_j \qquad [5]$$

and the activity of each component may be related to the vapor composition and the relative vapor pressure of one component.

$$a_i = \frac{N_i^v}{N_j^v} \cdot \frac{P_j}{P_i^\circ} \qquad [6]$$

Combination of Eq. [2] and [6] results in the following modification of the Gibbs-Duhem equation

$$\sum_i N_i^q \, d \ln \frac{N_i^v}{N_j^v} P_j = 0 \qquad [7]$$

Solving for P_j in Eq. [7]

$$d \ln P_j = -\sum_i N_i^q \, d \ln \frac{N_i^v}{N_j^v} \qquad [8]$$

which reduces even further to

$$d \ln P_j = d \ln N_j^v - \sum_i N_i^q \, d \ln N_i^v \qquad [9]$$

The integration of Eq. [9] from $N_j^{v(1)}$ to $N_j^{v(2)}$ yields the ratio of the activities in the corresponding condensed mixtures.

$$\ln \frac{a_j^{(2)}}{a_j^{(1)}} = \ln \frac{N_j^{v(2)}}{N_j^{v(1)}} - \sum_i \int_{N_i^{v(1)}}^{N_i^{v(2)}} N_i^q \, d \ln N_i^v \qquad [10]$$

The path of integration in Eq. [10] is of no significance because only exact differentials are involved. If the starting condensed mixture is the standard state ($a_j^{(1)} = 1$), then Eq. [10] gives the a_j at any composition in the system. The integrations involved may be obtained graphically from a plot of N_i^q vs. $\ln N_i^v$ or the integral may be modified as follows,

$$\int N_i^q \, d \ln N_i^v = \int \frac{N_i^q}{N_i^v} \, dN_i^v \qquad [11]$$

Equation [11] has the obvious advantage that both $\frac{N_i^q}{N_i^v}$ and N_i^v do not become infinite.

Equation [10] allows for the determination of activities from a study of vapor composition corresponding to condensed phase composition without any need for the measurement of vapor pressures. There is an equation of form [10] for every component in the system. Before pursuing this aspect any further, attention will be directed at phase equilibria within the condensed system.

Phase Equilibria

Equation [10] indicates that it is necessary to follow the variation in vapor composition caused by variation in the composition of the particular condensed phase, q. If this were so, the method would lose much of its value because it would require sampling and examination of multiphase condensed systems. As previously noted the Gibbs-Duhem equation may be applied to each equilibrium phase in the system. Therefore, from Eq. [9] it follows that

$$\sum_i N_i^\alpha d \ln N_i^v = \sum_i N_i^\beta d \ln N_i^v = \sum_i N_i^\gamma d \ln N_i^v = \ldots = . \qquad [12]$$

where α, β, γ designate particular equilibrium condensed phases. From the above equalities, the following set of equations may be written:

$$\sum_i (N_i^\alpha - N_i^\beta) d \ln N_i^v = 0 \qquad [13a]$$

$$\sum_i (N_i^\beta - N_i^\gamma) d \ln N_i^v = 0 \qquad [13b]$$

$$\sum_i (N_i^\gamma - N_i^\delta) d \ln N_i^v = 0 \qquad [13c]$$

$$\vdots$$

$(p\text{-}1)$ equations

If p designates the number of phases, then there are $(p\text{-}1)$ equations of the above type. From material conservation

$$N_i^T = n_\alpha N_i^\alpha + n_\beta N_i^\beta + n_\gamma N_i^\gamma + \ldots + . \qquad [14]$$

where N_i^T is the mole fraction of i in the system taken as a whole and n_α, n_β, are the fractions of the total moles of the system included in each stable phase. Equation [14] may be modified to

$$N_i^T = n_\alpha (N_i^\alpha - N_i^\beta) + (n_\alpha + n_\beta)(N_i^\beta - N_i^\gamma) + \ldots + N_i^P \qquad [15]$$

and

$$N_i^T - N_i^P = n_\alpha (N_i^\alpha - N_i^\beta) + (n_\alpha + n_\beta)(N_i^\beta - N_i^\gamma) + \ldots + (1 - n_P)(N_i^{P-1} - N_i^P) \qquad [16]$$

If each equation in set [13] is now multiplied by the appropriate factor, [13a] by n_α, [13b] by $(n_\alpha + n_\beta)$, etc., and their sum is taken, it follows that

$$\sum_i (N_i^T - N_i^P) d \ln N_i^v = 0 \qquad [17]$$

and

$$\sum_i N_i^T d \ln N_i^v = \sum_i N_i^P d \ln N_i^v = \sum_i N_i^\alpha d \ln N_i^v = \ldots \qquad [18]$$

The necessity of designating a particular condensed phase in Eq. [10] is, therefore, removed and the general solution becomes

$$\ln \frac{a_j^{(2)}}{a_j^{(1)}} = \ln \frac{N_j^{v(2)}}{N_j^{v(1)}} - \sum_i \int_{N_i^{v(1)}}^{N_i^{v(2)}} \frac{N_i^c}{N_i^v} \, dN_i^v \qquad [19]$$

N_i^c designates the mole fraction of i in either a particular phase or in the condensed system taken as a

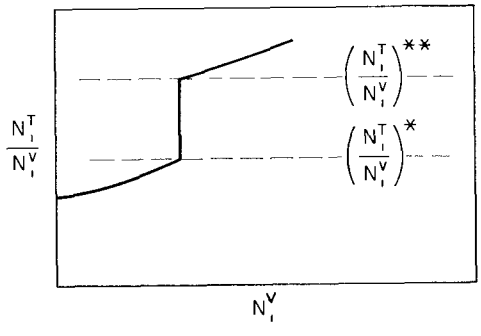

Fig. 1. Schematic representation of vapor composition variation in a binary system.

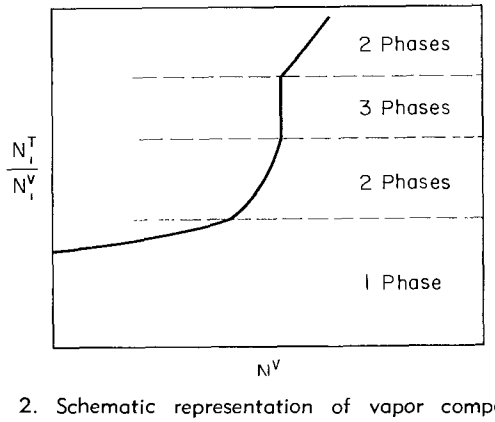

Fig. 2. Schematic representation of vapor composition variation in a ternary system.

whole. The question now arises as to the possibility of detecting phase boundaries from the experimentally determined plots of N_i^v/N_i^v vs. N_i^v. The answer can best be obtained by examination of special systems.

Binary and Ternary Systems

For a two-component system with immiscibility a plot of N_i^T/N_i^v vs. N_i^v would appear as schematically represented in Fig. 1. Within the two-phase region the activities and, therefore, the vapor composition must be invariant and the slope of the curve must become infinite. The composition limits of the region of immiscibility are defined clearly. Thus binary phase diagrams may be determined by isothermal cuts of the variation of vapor composition with total composition.

For a three-component system the situation is similar; however, the vapor composition does not become invariant in a two-phase field except when the total composition varies along a tie line. In a three-phase field the vapor composition is independent of total composition without exception. A traverse of a ternary system could appear as schematically illustrated in Fig. 2. In moving from a one-phase field to a two-phase field a change in slope must occur. If, by coincidence, the total composition varies along a tie line in the two-phase field, then the slope of the curve in the two-phase region will be infinite. This coincidence could be readily detected; however, because the total composition at either end of the two-phase field would then correspond to a boundary between a one-phase and a two-phase field. By several different traverses an isothermal section of the phase equilibria may be determined from plots like Fig. 2.

Experimental Application

Speiser, Jacobs, and Spretnak (2) have applied the method to liquid Fe-Ni alloys at temperatures between 1510° and 1600°C. Analyses of the condensed vapor effusing from a Knudsen cell enabled them to apply a special form of Eq. [19]. Iron and nickel are completely miscible at the temperatures employed so that no phase equilibria were involved. The activity data on Fe-Ni alloys has also been determined by Zellars and Morris (3) at the U. S. Bureau of Mines by a transpiration method which obtained vapor pressures directly. The agreement between the two methods was outstanding.

Formation of Hydride Films on Ti, Zr, Hf, Th Dissolving in Hydrofluoric Acid

W. J. James and M. E. Straumanis

Departments of Chemical and Metallurgical Engineering, School of Mines and Metallurgy, The University of Missouri, Rolla, Missouri

During studies on the dissolution of nuclear metals in dilute hydrofluoric acid in our laboratories, the formation of gray to black films on the surface of the dissolving metals has been noted (1). The presence of a black film on the surface of Zr dissolving in HF has also been reported by Baumrucker (2) and by Johnson and Hill (3); and on Ti by Ogawa (4) and Rüdiger, *et al.* (5). Suggestions as to the nature of these films have been made (4) but not corroborated by experimental data.

Small pieces of low Hf content Zr and Ti metal, in separate beakers, were immersed in approximately 0.1*N* HF for about 1 hr. The films were removed with the aid of a rubber squeejee and the black smut washed onto a watch glass. In the case of Zr, immersion of the sample in saturated NH_4F for a short time facilitated the removal of the film. The films were dried and crushed to a powder. Powder diffraction pictures were taken using Cu $K\alpha$ radiation with a Ni filter.

The "d" values of the patterns were compared with data from many sources and were found to agree very well with hydride patterns corresponding to approximately ZrH_2 and TiH_2. The comparison with the three principal "d" values of the hydrides are shown in Table I. Additional lines were also in good agreement with the standards.

In addition to the identification above, the authors have previously reported the formation of ThH_2 on Th dissolving in dilute HCl (6).

A thin grayish film was observed also on Hf dissolving in dilute HF, but attempts to remove the film were unsuccessful. In light of the foregoing the film is probably HfH_2.

These observations appear to indicate that sufficient atomic hydrogen is generated under conditions

Some Morphological Studies of Silver Crystals Electrodeposited from LiCl-KCl Eutectic Melt Containing AgCl

Ling Yang, Chien-yeh Chien, and Robert G. Hudson

Metals Research Laboratory, Carnegie Institute of Technology, Pittsburgh, Pennsylvania

Study of the morphology of metal crystals electrodeposited from molten salt baths is of both fundamental and practical interest. Information available on this subject, however, is very limited (1-7). This note reports some observations made on silver crystals electrodeposited from LiCl-KCl eutectic melt containing AgCl at 500°C.

The electrolyte was made by melting known amounts of AgCl and LiCl-KCl eutectic mixture under dry argon atmosphere in a Pyrex cell shown in Fig. 1 and was purified by electrolysis with dummy silver electrodes according to procedures described previously (8). When electrolysis was carried out with the cathode remaining stationary, the metal pulley shown in the figure was removed, and the iron rod holding the silver cathode was connected to the glass sleeve by a rubber tubing seal, similar to that shown for the anodic side. However, if it was desired to rotate the cathode during electrodeposition, the arrangement shown in Fig. 1 was used, with the metal pulley resting on top of the glass sleeve. The latter fitted closely to the iron rod and acted as a bearing. Any leakage of air into the cell during rotation was prevented by maintaining a slow flow of argon through the space between the iron rod and the glass sleeve. After the electrolysis, the cathode was raised out of the melt to the upper part of the cell and cooled in argon. The silver crystals deposited were freed of occluded electrolyte by washing in dilute (6*N*) NH_4OH, dried, and examined under a microscope.

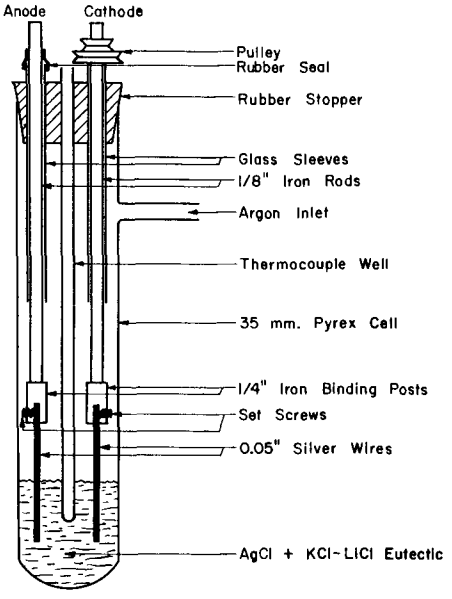

Fig. 1. Cell arrangement for electrodeposition

When the cathode was stationary, the deposits were always dendritic [Fig. 2 (a)], irrespective of the current density (10-1000 ma/cm^2 of original cathodic area) and the concentration of AgCl (3-14 wt %) used. Figure 2(h) and 2(k) are microphotographs taken of these dendrites. It can be seen that the main axis of the dendrite is 60° from the branches at one side and 90° from the branches at the other side. The 60° branches stretch out much farther than the 90° branches which terminate with the formation of definite facets [Fig. 2(k)]. All dendrites examined showed this unsymmetrical feature. X-ray back reflection Laue patterns obtained from these dendrites indicate that the plane of the dendrite is of the most densely packed {111} type, and the main axis of the dendrite is parallel to the <211> directions. The 60° branches are also parallel to the <211> directions, while the 90° branches are parallel to the <110> directions, each being a densely packed atom row in the {111} planes. Thus, the growth of the dendrite is fastest along the <211> directions and slowest along the <111> directions. Since the flow of current is perpendicular to the

(h) same as (a), (i) same as (b), (j) same as (d), all oblique illumination (k) same as (a) but for a very large dendrite, vertical illumination, (l) triangular etch pits on the (111) plane of the dendrite shown in (k), vertical illumination.

equal potential surfaces, any crystal grain on the surface of the silver cathode with the <211> directions perpendicular to the equal potential surfaces between the electrodes is a favorable site for starting a dendrite. As the dendrite nucleus grows outward, more metal ions are attracted to its tip and edge where the electric field is more concentrated and thus help the formation of branches. The actual current density on the flat {111} planes is thus very small and the growth along the <111> directions probably has to rely on the screw dislocation mechanism.

Close examination of Fig. 2(k) reveals the existence of triangular pits with pipes (some triangular shaped) running down at their centers. On the surfaces of other dendrites, round pits have been observed [Fig. 2(h)]. These pits were probably formed by etching while these dendrites were being freed of the occluded electrolytes by washing in NH_4OH. The favorable locations of these pits are regions in between the dendritic branches [Fig. 2(k)] and along the midrib of the dendrite [Fig. 2(h)], although more drastic etching does produce pits elsewhere. The regions between the dendritic branches are places where large amounts of impurities and imperfections are concentrated. The two sides of the dendrite, grown out of its midrib, may not exactly align with each other crystallographically. These may be the reasons why pits are more likely to form at these places. The fact that some of these pits are triangular and some are round is probably due to the difference in the rate of etching and the presence of different amounts of impurities at these pits. When the impurity contents are high, preferential adsorption on certain faces would lead to the formation of pits showing crystallographic symmetry. On the other hand, if the impurity contents are low and the rate of etching fast, round pits are formed. Figure 2(l) shows the triangular pits at a bigger magnification. The large size of the pipe at the center of the pit is probably associated with the presence of large amounts of impurities along the line defect pointing downward.

If the cathode was rotated during the electrolysis, both the macroscopic and the microscopic appearances of the deposits were modified. When the speed of rotation was low (e.g., 400 rpm, and current density equaled 50 ma/cm²), the branches of the dendrites grew thicker and shorter in the form of polyhedrons showing well-defined facets, although the deposits in general still retained the dendritic shape [Fig. 2(b) and 2(i)]. With the increase of the speed of rotation to 2000 rpm (current density still equaled 50 ma/cm²), the dendritic structures broke up further, and the deposits became granular, each grain being a single crystal polyhendron exhibiting mostly the low index planes [Fig. 2(c), 2(j)]. Since these grains usually were not located in one plane, it was impossible to obtain well-focussed pictures. Rotation continuously moves the dendrite nuclei away from the positions favorable to their growth along the <211> directions. It also helps to even up the current density distribution over the various parts of the dendrite and thus the rate of growth along the different crystallographic directions. High current density and high AgCl concentration were found to favor the dendritic growth, as shown by comparing Fig. 2(d) with Fig. 2(e), 2(f), and 2(g). Periodic reversal of the current (2-sec deposition, 1-sec dissolution; or 20-sec deposition, 10-sec dissolution) did not appear to affect appreciably the macroscopic appearance of the deposit on the cathode. In all cases studied, both the cathodic and the anodic current efficiencies were close to 100%, as determined from the weight loss of the electrodes with the aid of a silver coulometer.

Acknowledgments

The authors wish to thank Dr. G. Derge and Dr. G. M. Pound of Carnegie Institute of Technology and Mr. Frank Kerze, Jr., of the U. S. Atomic Energy Commission, for their interest in this work. We also are indebted to Dr. John P. Hirth and Dr. W. H.

Robinson of Carnegie Institute of Technology for stimulating discussions and to Mr. R. T. Keelan for the x-ray work involved.

Manuscript received March 5, 1959. This work is part of a program sponsored by the U. S. Atomic Energy Commission under Contract No. AT(30-1)-1432.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

The Silver/Silver Chloride/Chlorine Solid Electrolyte Cell

Donald M. Smyth

Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

A $Ag/AgCl/Cl_2$ solid electrolyte cell has been developed in which the chlorine is furnished by the dissociation of potassium tetrachloroiodide, $KICl_4$. These cells can be assembled into batteries which are extremely stable and compact and which deliver currents in the microampere range. The dissociation characteristics of the cathode salt influence the shelf-life, temperature dependence of the open-circuit voltage (OCV), and the change of OCV with aging. The ionic conductivity of the AgCl electrolyte controls the internal resistance of the battery and its temperature dependence. The shelf-life, OCV, and temperature dependence of OCV are strongly dependent on the cathode atmosphere since this can influence the electronic conduction of the electrolyte.

The development of electronic devices which can operate on currents in the microampere range has given rise to considerable interest in electrochemical cells with solid electrolytes. Such cells have potential shelf-lives many times those of conventional systems and lend themselves to extreme miniaturization. This paper describes a cell system with an indicated shelf-life in excess of 20 years and which is easily constructed in sizes of the order of 0.03 cm^3/v.

The choice of a solid electrolyte cell system is based on several factors: (*a*) the electrolyte should have a high ionic conductivity for current delivery and an infinitesimal electronic conductivity for long shelf-life; (*b*) the electrolyte must have suitable mechanical properties for the formation of strong, thin films; (*c*) the component parts must be chemically compatible; and (*d*) a high emf is desirable.

Requirement (*b*) excludes a large majority of ionic salts from consideration as electrolytes. The silver/silver halide/halogen systems meet these requirements quite well, and batteries based on the $Ag/AgI/I_2$ and $Ag/AgBr/Br_2$ systems have been described previously (1-3). The $Ag/AgCl/Cl_2$ system has the advantages of a higher emf [$Ag\text{-}Cl_2$, $E_o = 1.133$ v; $Ag\text{-}Br_2$, $E_o = 1.008$ v; $Ag\text{-}I_2$, $E_o = 0.788$ v (4)], an electrolyte with a smaller electronic conductivity (based on the evidence of silver-halogen tarnishing reactions), and an electrolyte with excellent mechanical properties. Use of potassium tetrachloroiodide, $KICl_4$ as a low pressure source of chlorine vapor has made possible the development of a $Ag/AgCl/Cl_2$ cell which is extremely stable. The cells have an open-circuit voltage (OCV) of 1.04 v at 25°C, and this does not vary more than ±5% over the temperature range +75° to −40°C. The theoretical shelf-life predicted by tarnishing experiments and the shelf-life obtained by extrapolation of accelerated aging data are both of the order of decades of years. The cells have an internal resistance of about 10^5 ohms/cm^2 area at 25°C and this increases by a factor of 60 as the temperature is reduced to −40°C.

Cell Structure

For a system such as the $Ag/AgCl/Cl_2$ cell which contains a corrosive vapor phase, the stability of the cell system depends on the extent to which this vapor can be sealed within the cell and, for this reason, a sealed cup structure has been developed. The cell is constructed from a small silver can which serves as the anode and as the main structural unit. An electrolyte film of AgCl a few microns thick is formed over the anode by exposure to Cl_2 at 200°-300° for about 30 min. The cathode is a conducting mixture of $KICl_4$ and carbon black in 6:1 weight ratio mixed with Kel-F #90 grease[1] to give a putty-like consistency. The cathode is extruded into the anode can which is then sealed with a compression fitted Teflon plug through which extends a tantalum wire that provides electrical contact to the cathode.

Open-Circuit Voltage (OCV)

The emf of the $Ag/AgCl/Cl_2$ system is related to the temperature, T, chlorine pressure, P_{Cl_2}, and the standard free energy, $\Delta F°$, of the reaction

$$Ag + \tfrac{1}{2}\, Cl_2 = AgCl \qquad [1]$$

by the familiar expression

$$E = \frac{-\Delta F°}{F} + \frac{RT}{2F} \ln P_{Cl_2} \qquad [2]$$

This expression yields a theoretical emf of 1.04 v at 25°C using thermodynamic data compiled by Quill (4) for $\Delta F°$ and the data of Smyth and Cutler (5) and Cornog and Bauer (6) for P_{Cl_2}. The observed OCV is in exact agreement with this theoretical value. If Eq. [2] is differentiated with respect to temperature, neglecting the variation of $\Delta F°$ with temperature and assuming that the chlorine pressure over $KICl_4$ can be expressed in the form

$$P_{Cl_2} = Ae^{-B/T} \qquad [3]$$

we obtain an expression for the temperature dependence of the emf,

[1] A product of M. W. Kellogg Co., Jersey City, N. J.

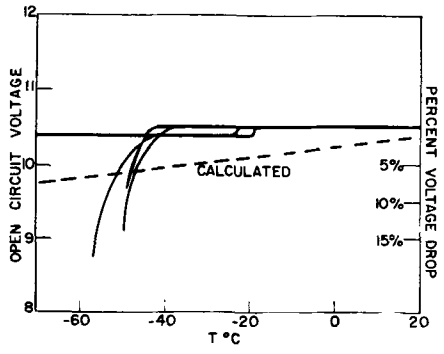

Fig. 1. Temperature dependence of open-circuit voltage. Behavior of several ten cell batteries compared with calculation from Equation IV.

$$\frac{dE}{dT} = \frac{R}{2F} \ln A \qquad [4]$$

in which R is the gas constant in coulombs per mole °K and A is a constant evaluated from the dissociation pressure data (5, 6). Evaluation of this relation gives a predicted temperature variation of OCV of 0.00092 v/°C assuming that the chlorine vapor is always in equilibrium with the solid phase. Figure 1 shows the actual temperature dependence of the OCV of several batteries together with the calculated dependence. It is seen that the observed OCVs lie above the predicted value down to about —50°C. In the vicinity of this temperature, the voltages start to drop off rapidly in many cases, although a few batteries show very little voltage drop even at —70°C. The rapid drop in OCV at very low temperatures is probably related to a relatively increasing importance of the electronic conductivity of the electrolyte with decreasing temperature.

The discrepancy between the observed and calculated temperature dependence of the OCV can be related to the nonreversible dissociation of the polyhalide cathode salt. It has been observed that equilibrium dissociation pressures are obtained only in the direction of increasing temperature for these salts (5). After a decrease in temperature, halogen pressures several times the equilibrium value may be maintained for several days. This is probably related to the formation of a film of solid recombination product over the decomposition residue, with the result that further recombination is hindered. Thus the assumption that the chlorine vapor is in equilibrium with the solid cathode phase is not valid when the temperature is decreased.

Attempts have been made to return the OCV to its equilibrium value by consuming the excess halogen pressure by current drain. The number of electrochemical equivalents of excess pressure is surprisingly high, however, and exceeds that estimated from the cell volume by more than a factor of ten. It is believed that the grease cathode binder and the carbon black act as reservoirs of excess halogen by dissolving and adsorbing large amounts of vapor. This fact reduces the hazard that a slight drop in OCV may result after a small amount of current has been drawn from the cell.

The full, theoretical emf of the electrochemical system will be observed across the cell terminals only for systems in which electronic conduction through the electrolyte phase is negligible compared with the ionic conduction. This requirement is always satisfied in aqueous electrolyte cells, since water solutions have immeasurably small electronic conductivities. Ionic crystals range all the way from essentially pure ionic conductors to essentially pure electronic conductors, however, and the relative magnitudes may depend on the purity and crystallinity of the material, the composition of the ambient atmosphere, and the nature of the electrodes.

As a result of the early work of Tubandt (7), the silver halides were long considered to be classic examples of materials having almost purely ionic conductivity. Wagner was able to show, however, that in the presence of 0.23 atm of bromine at 200°C the total conductivity of AgBr films formed by reaction of silver with bromine is 17% electronic, and that the electronic contribution increases rapidly with decreasing temperature (8). In recent years, Pfeiffer, Hauffe, and Jaenicke have shown that single crystal AgBr is an essentially pure electronic conductor and that the ionic contribution increases with the concentration of grain boundaries (9). Luckey and West (10) and Shamovskii, Dunina, and Gosteva (11) have shown that, in the presence of bromine vapor, single crystal AgBr has an "additional" conductivity which is proportional to the square root of the bromine pressure and which is thus considered to be due to the injection of electron holes into the AgBr in agreement with the theories of Wagner. These properties of AgBr and their possible extension to AgCl and AgI raise a question as to the suitability of the silver halides for electrolytes in solid-state cells of the silver-halogen type. It has been known for several years that such cells do have open-circuit voltages close to the theoretical emf (1-3), and it is necessary to reconcile this fact with the known electrical properties of the electrolytes. The following experiments clarify this point.

It has been found that a Ag/AgCl/Cl_2 cell with a cathode phase consisting of 1 atm of dry chlorine has an equilibrium OCV of about 0.75 v, whereas the theoretical emf is 1.13 v. The OCV also decreases rapidly with temperature. This indicates that a substantial electronic conduction through the AgCl electrolyte is partially short-circuiting the emf and that the relative electronic contribution is increasing with decreasing temperature. When undried chlorine is used, however, the OCV is the same as the thermodynamic emf, and the change of OCV with temperature is greatly reduced. The cell voltage changes rapidly and reversibly with changes in the moisture content of the chlorine. It appears that the moisture content of the chlorine atmosphere is suppressing the electronic conduction through the AgCl. Measurements of the internal resistance of the cell in wet and dry chlorine show that the water vapor has very little effect on the ionic conduction through the electrolyte. These findings led to an investigation of the effect of foreign

vapors on the tarnishing rate of silver in halogen vapor; this work is described in a separate publication (12). It was found that very small partial pressures of water or carbon tetrachloride vapor suppress the reaction rates drastically and that the rate-determining process is an interface phenomenon, since the reaction rate is independent of tarnish film thickness. The suppression of the reaction rate may be taken as an upper limit of the suppression of the electronic current.

It has since been found that cells made with cathodes consisting only of carbon black and $KICl_4$ have voltages less than the theoretical emf, and very poor low-temperature properties. Cells in which the cathode contains a hydrated salt as a source of water vapor or Kel-F grease have the theoretical emf and greatly improved low temperature properties. Thus the Kel-F grease binder used in the cathode serves to stabilize the cell voltage and to extend the theoretical shelf-life by decreasing the electronic conduction through the electrolyte. Tarnishing experiments indicate that the stabilizing vapor is not consumed during the formation of more silver halide.

The stability of the OCV with time as a function of temperature is of great interest for such a potentially long shelf-life item. The shelf-life under ideal conditions will be determined by the rate of consumption of the active materials by the internal tarnishing reaction whose rate is limited by the electronic leakage through the electrolyte. Thus a maximum attainable life of such a system can be estimated from tarnishing data and the amount of active materials in a cell. The reaction rates of silver foils of different purities with the equilibrium halogen atmosphere over $KICl_4$ at 60°C are shown in Fig. 2, in which the square of the weight increase is plotted against time. The two cadmium doped samples appear to follow a parabolic tarnishing expression, whereas high-purity and commercial purity silver have an even greater dependence of reaction rate on film thickness.

Chemical analyses of these films indicate a chloride:iodide atomic ratio of about 19.5:1 whereas the equilibrium dissociation vapor of $KICl_4$ at 60° has a Cl:I ratio of 14.5:1 (5). Thus there may be a slight preferential reaction of chlorine, and the films

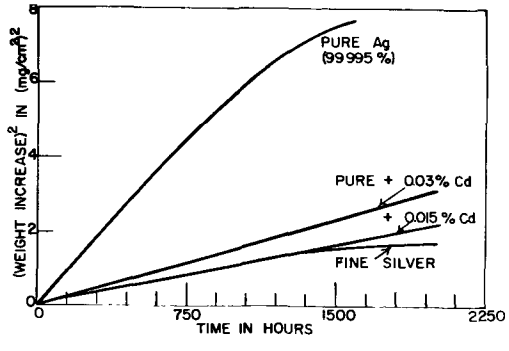

Fig. 2. Tarnishing rates of various silver samples with the dissociation vapor over $KICl_4$ at 60°C. Square of weight increase plotted against reaction time. (Fine silver is nominally 99.9% silver.)

may be considered as a dilute solution of AgI in AgCl.

A calculation based on the assumption that the commercially pure silver reacts according to a parabolic rate expression gives a theoretical shelf-life of 25 years for continuous storage at 60°C for typical cell dimensions and an initial electrolyte thickness of 13 μ. This is a conservative estimate, since the actual reaction rate is decreasing with time more rapidly than indicated by a parabolic expression and also because the reactions were carried out in the room atmosphere without the presence of any rate-depressing vapors such as are present in actual cells. The initial electrolyte film of pure AgCl will also depress the reaction rate to a greater extent than would the same thickness of Ag-$KICl_4$ tarnishing product.

In actual practice, the shelf-life of a solid electrolyte cell is limited by the leakage of active cathode vapor from the cells and by electrical leakage through and over the surface of the encapsulating material. The magnitude of these effects may be determined from accelerated life tests carried out at elevated temperatures. Such tests have been performed with groups of 4-cell batteries stored at 125°, 110°, and 100°C. The end of the battery life has been defined arbitrarily as the time at which the room temperature open-circuit voltage of half the batteries in a group has dropped 5%. Results are summarized in Fig. 3, in which the shelf-life has been plotted logarithmically against the reciprocal absolute storage temperature. The relationship is merely an intuitive guess which seems to fit the extremely strong temperature dependence of shelf-life reasonably well. Although the extrapolation of these data to ordinary storage temperatures cannot be considered accurate, the indication is that satisfactory stability has been attained.

The aging characteristics of a typical battery are shown in Fig. 4, in which the room temperature voltage of a 4-cell battery stored at 100°C is plotted against storage time. It is seen that there are two stable voltage levels: an initial voltage of about

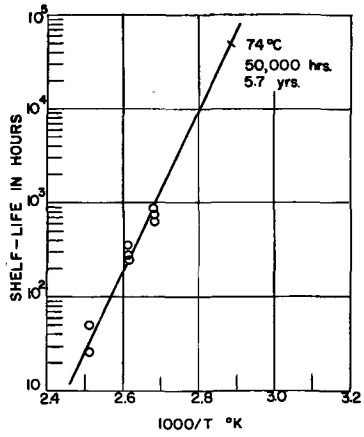

Fig. 3. Accelerated aging data of four-cell batteries, and a possible extrapolation to lower temperatures. Shelf-life defined as time prior to a 5% drop in open-circuit voltage (measured at room temperature) for half of the batteries in a group. The line was fitted to the data by the method of least squares.

1.05 v/cell which is related to a $Ag/AgCl/Cl_2$ cell in which the Cl_2 is furnished by the dissociation of $KICl_4$, and a subsequently stable plateau at 0.89 v/cell. It has been shown that this latter voltage is that of a Ag/AgCl/ICl cell in which the ICl is furnished by the dissociation of $KICl_2$. An earlier publication (5) has shown that $KICl_4$ dissociates in two steps:

$$KICl_4 \rightarrow KICl_2 + Cl_2 \qquad [5]$$

$$KICl_2 \rightarrow KCl + ICl \qquad [6]$$

and that the equilibrium vapor is predominantly chlorine which is thus consumed or lost faster than the ICl. When the chlorine has all been lost, there is still sufficient $KICl_2$ left to maintain the voltage at 0.89 v/cell for a period which is generally longer than the duration of the initial voltage. Note that this second voltage plateau has not been included in the shelf-life definition and thus represents a substantial safety factor for applications that can tolerate a 15% voltage drop. The internal resistances of the cells do not increase appreciably until near the end of the second voltage plateau.

The Internal Resistance

The internal resistance, R_o, is defined here by the expression

$$V = E_o \frac{R}{R+R_o} \qquad [7]$$

in which E_o is the OCV and V is the terminal voltage with load R. The relatively small ionic conductivity of the AgCl electrolyte determines the general magnitude of the resistance and also its temperature dependence. Data reported by Compton (13) show a conductivity of about 3×10^{-9} to 2×10^{-8} ohm^{-1} cm^{-1} at 25°C for undoped AgCl. For a cell area of 0.24 cm^2 and an electrolyte thickness of 0.0013 cm, this gives a calculated resistance range of 2.7×10^5 to 1.8×10^6 ohms which is to be compared with an observed range of 5×10^5 to 5×10^6 ohms for cells with these dimensions. The single-crystal conductivity data reported by Compton may contain an unknown electronic contribution which could account for the observed resistances being slightly higher than the calculated values. The conductivity data predict a resistance increase by a factor of 60 between 25° and −40°. Seventeen 10-cell batteries selected at random showed an average increase by a factor of 57 over this range although there was considerable variation among the group (average deviation of factor = 20).

Compton's conductivity data lie in the impurity-sensitive range below 100°C rather than in the intrinsic range, and the correlation between the temperature coefficients of resistance and resistivity indicate that the cell behavior should also be typical of the impurity-sensitive range. Thus small additions of impurities to the AgCl electrolyte might have considerable influence on the resistance. It is well established that the principal ionic charge carriers in silver halides in this temperature range are silver ion vacancies and that the cation vacancy content of the silver halides can be enhanced by the addition of divalent metallic halides such as those of cadmium or lead. The divalent foreign cation enters the lattice in place of a monovalent silver ion, and another silver ion position is left vacant to maintain electrical neutrality. It has also been established that the impurity content of halide films formed by tarnishing reactions is related to the metallic impurity content of the base silver. Cells have been made from silver anode cans containing various amounts of cadmium, and it was found that a cadmium content of 0.02% causes a reduction in the cell resistance by a factor of three to five over the entire temperature range of battery operation. Larger amounts of cadmium cause the AgCl film to become brittle and less adherent. Aging characteristics, low temperature properties, and other operating characteristics are as good or better for these batteries as for the undoped cells.

In addition to the ionic conductivity of the electrolyte, other factors may influence the apparent resistance of cells during long periods of heavy current drain. The rate of dissociation of the polyhalide salt and the rate of diffusion of the liberated halogen to the electrolyte-cathode interface may eventually limit the current. The importance of these secondary factors may be surmised from a comparison of heavy current drain data with ideal behavior, which takes into account only conductivity effects. In particular it is necessary to allow for the fact that the electrolyte thickness increases with current drain due to the formation of additional AgCl.

The rate of increase in electrolyte thickness with current drain may be expressed as

$$\frac{dx}{dt} = \frac{V}{\mathbf{F}} \frac{\sigma E}{x} \qquad [8]$$

where x is the thickness of the electrolyte, t the time, V the volume of AgCl per equivalent weight, $\mathbf{F}$ Faraday's constant, σ the ionic conductivity of the AgCl, and E the voltage drop across the electrolyte (essentially the emf for near short-circuit conditions). It has been assumed that the current can be expressed as

$$i = \frac{\sigma A E}{x} \qquad [9]$$

where A is the active electrolyte area, and that the product of current drain is essentially pure AgCl.

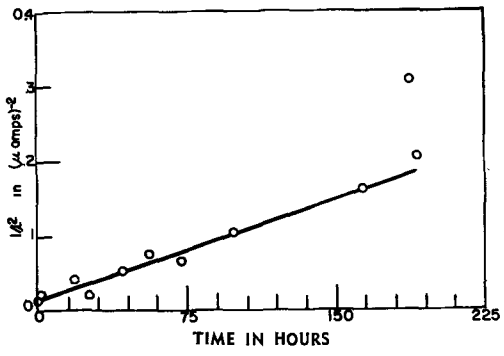

Fig. 5. Short-circuit current of a ten-cell battery at room temperature plotted according to Eq. [10].

Integrating [8] and using [9] to relate thickness to current and expressing σ in terms of i_o and x_o (the initial current and electrolyte thickness) gives

$$\frac{1}{i^2} = \frac{2V}{\mathbf{F}x_o A i_o} \cdot t + \frac{1}{i_o^2} \qquad [10]$$

Thus a plot of $1/i^2$ vs. t should give a straight line of slope $2V/\mathbf{F}x_o A i_o$ and an intercept of $1/i_o^2$, if the electrolyte conductivity is the principal determining factor. An example of this type of treatment is shown in Fig. 5. It is seen that ideal behavior is followed for about 150 hr, after which the current decreases quite abruptly. The scatter of the data is due mainly to fluctuations in room temperature; smoothed discharge data give precise linearity. At the end of 150 hr, the cell had delivered a total of 2 coulombs; after 265 hr of continuous drain the load was removed from the cell and its OCV returned to 85% of its original value in 3 sec and to 95% of its original value in 25 min. When current drain was resumed the current was 5.5 μa, decaying after about a day to the 1.5 μa level reached prior to the initial removal of the load. A more detailed study of the first few minutes of discharge discloses a brief period of high current which amounts to about 0.005 coulombs of charge more than would correspond to a linear $1/i^2$ vs. t plot extrapolated to $t=0$. An evaluation of the slope of this plot gives $x_o = 11.6$ μ and $\sigma = 3.7 \times 10^{-8}$ ohm^{-1} cm^{-1} which agrees remarkably well with the x_o of 13 μ estimated from the time and temperature of the chlorination of the silver cans and with the conductivity range previously quoted from the work of Compton. This correlation is a good indication that the current drain is conductivity controlled even in the near short-circuit range for periods up to about a week.

Typical current drain performance of 10-cell batteries at room temperature and —40°C are shown in Fig. 6 and 7. Voltage recovery after removal of the load is almost instantaneous.

Surface to Volume Considerations in the Palladium-Hydrogen-Acid System

James P. Hoare

Scientific Laboratory, Ford Motor Company, Dearborn, Michigan

ABSTRACT

The open-circuit potential against a Pt/H_2 electrode in the same $2N$ sulfuric acid solution of a series of palladium electrodes of different sizes and shapes was recorded as a function of time. The electrical resistance in certain cases was also followed as a function of time. It is shown that the time required for charging the palladium with hydrogen is sensitive to the surface-to-volume ratio of the electrode. Charging mechanisms are discussed.

It has been shown (1) that pure palladium metal, when placed in an acid solution saturated with hydrogen gas, will absorb the hydrogen until the maximum α-Pd concentration ($\sim$0.03 H/Pd atomic ratio) has been reached and will exhibit a potential of 50 mv more noble than a Pt/H_2 electrode placed in the same solution. It was stated also that under open-circuit conditions the Pd would not absorb additional hydrogen beyond this maximum α-Pd limit and that the 50-mv potential could be maintained indefinitely in the absence of impurities. The potential of 50 mv has been associated with an atomic-hydrogen potential-determining reaction (2) on the Pd as opposed to the molecular hydrogen reaction on the Pt/H_2 electrode. The solubility limit at H/Pd atomic ratios of about 0.03 has been described (3) in terms of a blocking mechanism due to a variation in the point of zero charge of the Pd as hydrogen was absorbed.

Recently, Ratchford and Castellan (4) have reported that Pd electrodes made from thin metal wires or foils behaved somewhat differently. Such electrodes did not give open-circuit-potential-vs-time curves with a plateau at 50 mv of indefinite length; instead, the plateau at 50 mv was less than 10 hr long after which the potential dropped to a steady value of zero volt. Another interesting feature about these curves is the initial overshooting of the 50 mv value with an immediate return to the 50 mv plateau, analogous to a supercooling curve. Electrodes, which had gone to zero potential vs. a Pt/H_2 electrode, were analyzed for the hydrogen content with ceric sulfate (5) and found to have absorbed hydrogen to the β-phase concentration of about 0.6 H/Pd atomic ratio.

It is the purpose, then, of this investigation to study possible surface to volume effects important to the solution of hydrogen by palladium.

Experimental

Electrodes were made from Pd foil and wire 99.5+% pure. In the first set of experiments the following electrodes were used: (*a*) a 1 cm^2 piece of Pd foil 2 mils thick; (*b*) a 1 cm^2 piece of foil 4 mil thick; (c) a 1 cm^2 piece of 4 mil foil whose surface was nine-tenths covered with a polyethylene film; (*d*) a 3 cm length of wire, 5 mil in diameter; and (*e*) a Pd bead 0.057 in. in diameter and half way covered with polyethylene so that a hemisphere was exposed to the solution.

The Teflon cell was similar to those used before (6). All electrodes were cleaned in hot concentrate HNO_3 and the cell was rinsed repeatedly with water triply distilled in an all-quartz still as described before (6). All measurements were made in $2N$ H_2SO_4 solution made with triply distilled water and saturated with hydrogen purified by a standard multistage purification-train. The hydrogen flow was maintained approximately at a constant rate night and day. Final purification of the solution and electrodes was done by pre-electrolysis overnight with an auxiliary Pt electrode which was removed while the pre-electrolysis current was flowing. The open-circuit potential between the test electrode and a Pt/H_2 electrode in the same solution was recorded as a function of time. At no time in this complete investigation was any electrode cathodized.

A second series of experiments was done in which wires of approximately the same length but of varying diameters were used. These wires were about 11 cm long and had diameters of 5, 10, 15, 20, and 25 mils. Each wire was cleaned as described above and mounted diagonally in a virgin polyethylene cell 19 cm long and 2.5 cm in diameter from the top on one side to the bottom on the other side. Platinum leads were welded to the Pd wire and the weld area as well as about 3 or 4 mm of Pd wire penetrated through the cell wall and was well covered with polyethylene. This was done to assure adequate protection against contact between the weld area or the Pt and solution and against contact between Pd and the external atmosphere. It is to be noted that in all cases throughout this investigation the entire Pd electrode was maintained submerged beneath the solution level so that the Pd was never in contact with the external atmosphere. After a given wire was cleaned electrolytically overnight, the hydrogen stirring was begun and the open-circuit potential vs. a Pt/H_2 electrode in the same solution as well as the electrical resistance of the wire was recorded as a function of time. Zero time is taken when hydrogen flow is begun. The resistance was measured

with a General Electric Portable Double Bridge which is designed to measure resistance from 0.0001 to 22Ω.

These same experiments were repeated with these same wires wound in the form of a toroid on a polyethylene ring and placed in the Teflon cell. The results of this series of experiments were similar to those done in the polyethylene cell.

Results and Discussion

Figure 1 shows the open-circuit potential vs. a Pt/H_2 electrode in the same $2N$ H_2SO_4 solution for a series of Pd electrodes having different values for the ratio of the exposed apparent surface area to the total volume of the Pd as a function of time. The surface area was determined by geometric measurement and the volume by weight measurements using a value of 12.01 g cm^{-1} for the density of Pd. As was observed by Ratchford and Castellan, the open-circuit potential falls from the high positive value produced by anodization to a very flat plateau at about 50 mv. After a time, the potential falls along a sigmoid curve to zero and remains there. The length of the 50 mv plateau and the transition time from the 50 mv plateau to the zero volt plateau are found to be sensitive to the ratio, area/volume (A/V).

In Fig. 2 and 3 are shown the relative resistance-vs.-time curves for a series of Pd wires. Figure 3 shows the initial part of the curves in greater detail. It is seen that a plateau of varying length occurs at about a value of R/R_0 of 1.05. Using Fischer's expression (7), $R = R_0(1.0292 + 0.000668\ V)$, where V is the relative volume of the dissolved hydrogen, this resistance value corresponds to about 31 relative volumes or a H/Pd atomic ratio of about 0.03, the upper limit of the α-phase (1, 7, 8).

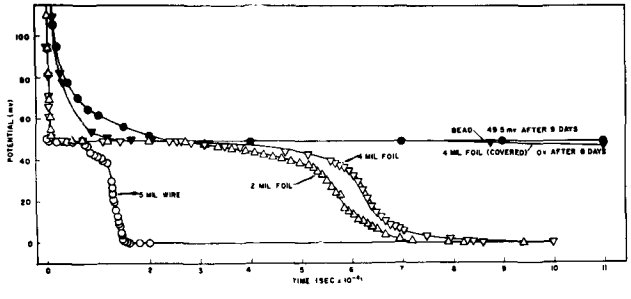

Fig. 1. Open-circuit potentials of Pd electrodes of various sizes in 2N H_2SO_4 solution plotted as function of time. Potential measured with reference to Pt/H_2; temperature, 24°±1°C.

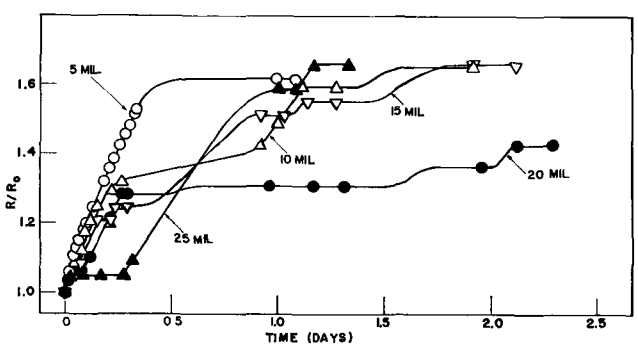

Fig. 2. Relative resistance-vs.-time curves for Pd wires of different diameter; temperature, 24°±1°C.

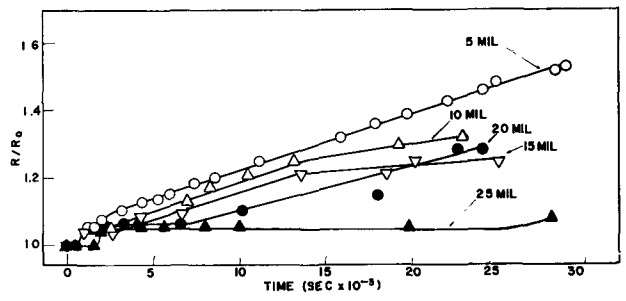

Fig. 3. Initial part of relative resistance-vs.-time curves of Fig. 2 for Pd wires on open circuit in H_2-saturated acid solution.

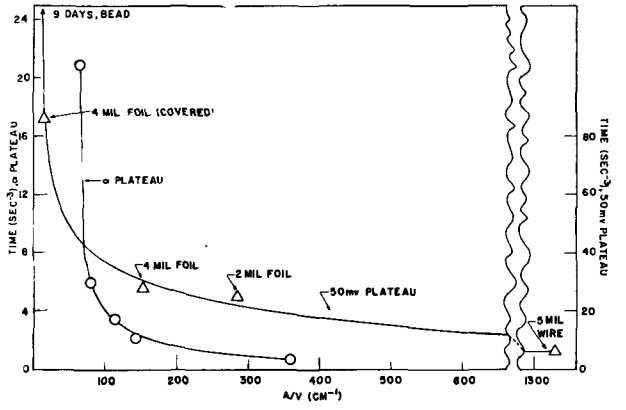

Fig. 4. Length of α plateau found on resistance-time curves for Pd wires is shown by circles and is plotted vs. surface-to-volume ratio. Length of 50 mv plateau found on potential curves for Pd electrodes of various shapes is shown by triangles and also is plotted as function of surface-to-volume ratio.

In general after the α-phase-plateau the resistance increases uniformly to about a value of 1.27 for R/R_0 which corresponds to a H/Pd atomic ratio of 0.29. In Fig. 5 is shown the potential-time curve with the accompanying relative resistance-time curve for only the 5 mil wire case, for the sake of simplicity. Similar curves were obtained for all the other wires. When the relative resistance reaches a value of about 1.35, corresponding to a H/Pd atomic ratio of 0.37, the potential begins to drop away from the 50 mv plateau in all cases. This is in good agreement with the data reported when the wire was charged with hydrogen cathodically (1, 2). When the potential finally reaches a steady value of zero volts, the resistance has come to a steady value somewhat over 1.6 for R/R_0. This is a higher value than was reported for a wire charged with hydrogen cathodically (1, 2) and corresponds to a H/Pd atomic ratio near 0.7.

In order to check the hydrogen content of a wire which had reached zero volts, the amount of hydrogen absorbed was determined using ceric sulfate solution and was found to contain about 0.6 H/Pd atomic ratio.

A plot of the length of the 50 mv plateau vs. A/V is found in Fig. 4. The curve is hyperbolic. Although the experiment with the bead was terminated for convenience after 9 days, it is believed that the potential would have fallen to zero after a sufficiently long time.

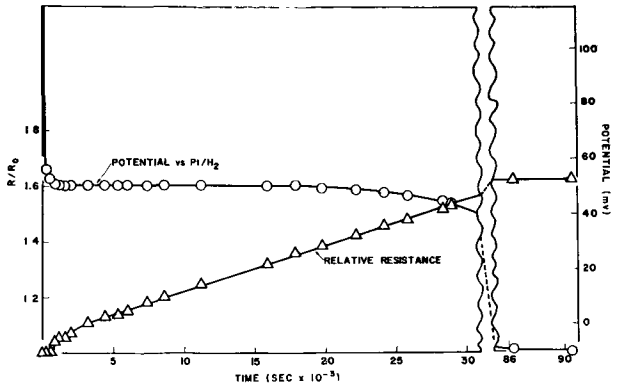

Fig. 5. Potential vs. time and R/R_0 time curve recorded simultaneously for 5 mil wire; temperature, 24°±1°C; solution, hydrogen saturated 2N H_2SO_4.

The length of the α-Pd plateau for the wires is plotted in Fig. 4 as a function of A/V. This plot is also hyperbolic. If the data in Fig. 4 are plotted as a function of V/A instead of A/V, indeed, straight lines are obtained. This indicates that the length of the plateau is directly proportional to the volume and inversely proportional to the area. It is to be noted, though, that the values for the bead and for the 25 mil wire deviate from the respective straight lines toward higher values.

One may conclude from the data in Fig. 5 that hydrogen does not enter the Pd metal until the oxide is removed from the surface. This is indicated by the fact that the resistance does not change until the potential drops from a high positive value to that of 50 mv which is the potential associated with the exposed α-Pd surface of maximum concentration. This same behavior was found in all cases. Once the surface is clear the hydrogen is dissolved by the Pd.

The potential remains at 50 mv until an H/Pd atomic ratio of about 1.37 is reached. At this point, the amount of β-Pd has increased at the expense of the α-phase until now the mixed potential (2), which had, up until now, been dominated by the α-phase potential-determining reaction, is beginning to be dominated by the β-phase reaction. Of course, when the wire reaches a potential of zero volt, it is now a β-phase electrode and the potential determining reaction is the same as that on Pt.

Because of the fact that both the length of the plateau of 50 mv on the potential curves and the length of the α-phase plateau on the resistance curves are sensitive to the ratio, A/V, it is suggested that the penetration of the surface skin of the metal is the rate-determining step in the solution of hydrogen by Pd. This proposal is also supported by the lack of a thickness effect in the transport of hydrogen through a Pd bielectrode (9). Once the hydrogen enters the interior of the metal, it is quite mobile as shown by the nuclear magnetic resonance work of Norberg (10) and spreads evenly throughout the metal. It is postulated here that the β-phase cannot nucleate until the entire body of Pd is converted to the α-phase of maximum hydrogen concentration (H/Pd at ratio ~0.03). It is interesting to note that the resistance makes a very rapid jump to an R/R_0-value of about 1.05 and remains at this value for a length of time dependent on the value of A/V according to the curve shown in Fig. 4. It would appear, then, that the resistance is not a linear function of the hydrogen content until the maximum α-phase concentration is reached throughout the metal. As a matter of fact, Fischer makes this statement, and it appears in the intercept value of 1.0292 in his equation. It is assumed here that the length of the α-phase plateau is the time it takes to change the entire bulk of Pd to the α-phase of maximum concentration and that the resistance is not a linear function of hydrogen content until at least some β-phase is present.

After the α-phase plateau the resistance increases at the same linear rate of 1.67×10^{-5} units sec^{-1} up to a value of about 1.27 for R/R_0 in all cases regardless of the value of A/V. From then on, as shown in Fig. 2, the resistance increases in steps, increasing in length with decreasing values of A/V, except for the 25 mil case. This would seem to suggest that the β-phase nucleates at various centers throughout the metal and then grows according to a domain-type mechanism at the expense of the α-phase. The steps in the resistance may be due to a coalescing of these domains. The rate at which the β-phase nucleates and grows seems to be a function of the history of the electrode preparation as exemplified by the rapid charging of the 25 mil wire. Such steps are not found in the open-circuit potential curves for these wires. These curves are not shown here, but they are similar to the smooth curves shown in Fig. 1. This may have been expected since the resistance is a bulk quantity while the potential is a function of a surface quantity and surface conditions may not necessarily vary linearly with those occurring in the bulk material.

In the case of a very small wire, these effects are at a minimum because of the high surface area and consequently the high rate of penetration of the hydrogen to the interior of the metal. It is with this type of electrode, one with a very high value of A/V, that Ratchford and Castellan worked and so they worked on the right-hand branch of the hyperbolas shown in Fig. 4. On the other hand, Schuldiner and Hoare worked on the left-hand branch by using small beads and pieces of foil

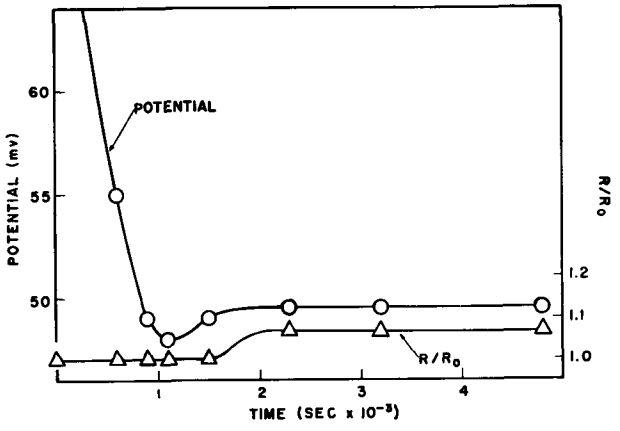

Fig. 6. Potential and resistance curves for 20 mil wire that exhibited overshoot in potential. Potential is measured against Pt/H_2 electrode in same solution.

highly covered with polyethylene films. In this way it is possible to resolve the differences between the two investigations. Even though it is not necessary to resort to a change in the point of zero charge to explain the α-phase plateau, it is still held that the hydrogen enters the metal by way of a hydrogen atom in the double layer being transported to the metal surface through an adsorbed water molecule as described before (3).

It was observed neither by Schuldiner and Hoare nor in this investigation that an electrode made from Pd foil or bead gave a potential time curve with a minimum similar to a supercooling curve. This effect was not observed for the wires stretched along a straight line in the polyethylene cell nor for the same wire wound as a toroid on a polyethylene ring in the Teflon cell. However if the wire was wound in the form of a loose air-cored helix, a minimum may be found as shown in Fig. 6. It is important to note that the resistance does not change from the original hydrogen free value of R_0 until the potential has returned to the 50 mv value. It would appear, then, as the hydrogen removes the oxygen from the surface, by some chance condition of the surface film brought about by an accidental stage in the history of its preparation the surface becomes more platinum-like, that is, a noble metal that does not dissolve hydrogen readily and the potential strives toward zero volt. However, the potential never reaches zero because the hydrogen gradually destroys this unusual surface film. After the film is destroyed and the true Pd surface exposed, the hydrogen begins to dissolve, the resistance increases and the potential returns to the 50 mv plateau. Although the nature of this surface film has not been determined at this time, it is seen that it is reduced by hydrogen, it is conducting, it is a catalyst for the hydrogen reaction, and it most likely contains oxygen since it occurs only after strong anodization.

In view of the results presented here it may be necessary to differentiate between three types of hydrogen-charging mechanisms in the Pd-H system. In previous work (3), it was shown that hydrogen-charged Pd that was obtained from dry Pd exposed to dry hydrogen gas had different properties from that obtained by the cathodic charging of a Pd electrode in an acid solution. A difference was in the hydrogen content of the final stable product which seemed to be a function of the amount of lattice distortion. In the first case the H/Pd atomic ratio was about 0.6 while in the second case it was about 0.36. In the present work, the final product contains hydrogen at 0.6 H/Pd atomic ratio but which exhibits a relative resistance which seems to be much too high and does not lose hydrogen as in the cathodized case. This may indicate that in this case the lattice is distorted in a different manner in absorbing a quantity of hydrogen necessary to raise the H/Pd atomic ratio to 0.6 than in the two previous cases cited above. Apparently the domain-like charging process described here was not permitted in the cathodically charged Pd due to the forcing of the hydrogen into the Pd by electrochemical means as shown by the linear curve in Ref. (1).

One may say, then, that Pd charged with hydrogen to the β-phase by standing on open circuit in a hydrogen-stirred acid solution gives a final result more similar to the dry Pd-H charging than to the cathodic charging. Also, if one wishes to study the properties of α-phase Pd one must use an electrode configuration (e.g., beads) in which the A/V value is such that the rate of change to the β-phase is very slow.

Manuscript received Feb. 20, 1959. This paper was prepared for delivery before the Philadelphia Meeting, May 3-7, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

The Growth of Barrier Oxide Films on Aluminum

W. J. Bernard and J. W. Cook

Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

The growth of anodically formed barrier oxide films on aluminum has been followed by weight, capacitance, and rate measurements. The increase of film thickness at constant voltage has been calculated and compared to the values obtained by optical measurements. The results have been shown to obey the law $i = \alpha e^{\beta F}$.

Several papers in recent years (1-6) which have dealt with the thickness of anodically formed barrier oxide films on aluminum lead to the conclusion that the thickness is determined precisely by the voltage impressed on the oxide film. This conclusion ignores the generally accepted theory of anodic ox-

ide growth first advanced by Mott (7) and covered more specifically in the case of aluminum by Charlesby (8) and by Nagase (9). It is the purpose of the present paper to show that the relationship between current and field $i = \alpha e^{\beta V/s}$, where α and β are constants, correctly expresses the dependence of the thickness, s, of the oxide film on both ionic current density, i, and the applied voltage, V. It is probably the failure to define the current density in the cited papers, rather than the use of different electrolytic solution, which has led to the variations in reported values of oxide thickness, ranging from 12.7 to 16.5 Å/v. Although it is pointed out by van Geel and Schelen (2) that film growth may continue at constant voltage, they suggest that it is sufficient only to permit the current to decrease to a low (but unspecified) value in order to define the thickness.

In this investigation we have calculated oxide film thicknesses by measurement of the weight of oxide and by the direct measurement through the use of interference fringes. This latter method has been employed previously by Nagase (1).

Barrier films can be formed on Al in any of several different aqueous solutions, most commonly in solutions of boric acid or alkali borates. However, aqueous solutions are characterized by generally poor current efficiency of oxide formation, as a result of oxygen evolution and anodic dissolution of Al. These effects make it difficult to examine only that component of the current which leads to film growth, and we have, therefore, found it convenient to work with solutions of ammonium pentaborate in ethylene glycol. The particular composition chosen by us (30% by weight of salt) is not useful for oxidizing Al to high voltages, but it is characterized by a high current efficiency of formation up to 150 v; within the error of the measurements the efficiency is 100%. The films found in this solution appear to be identical to those found in aqueous solutions of boric acid, as shown by the capacitance of films formed under the same conditions of temperature, voltage, and current density in the two electrolytes.

In order to determine the thickness of a formed film by weight measurements, the density of the oxide and the surface area of the formed metal must be known. The density of such films of Al_2O_3 is not necessarily the same as that of the bulk oxide, and values varying from 3.0 to 5.0 g/cm^3 have been reported. We have, therefore, also carried out a determination of this quantity. The "roughness factor" of the metal surface has been estimated by comparing the formation charge required for foil to that of highly polished Al surfaces where the true area is assumed to be equal to the geometrical area. We have verified the equation for oxide growth by obtaining straight-line plots of log i vs. $1/W$ (W = oxide film weight), and log i vs. capacitance, over the current density range of 10^{-3} to 10^{-7} amp/cm^2 for films maintained at a constant voltage of 150 v.

Experimental

Formations were carried out at 25°C on Alcoa foil of 99.99% purity, with an apparent surface area of 97 cm^2. Before forming the foil was cleaned briefly with cold potassium dichromate-sulfuric acid cleaning solution and washed thoroughly with high-purity water, rinsed in methanol, and dried. The negative electrodes of the formation cell, which were platinized, also served as the subsidiary electrodes for capacitance measurements of the formed films.

The roughness factor of the foil was measured by comparing its formation charge to that of electrodes which were assumed to have a factor of unity. These latter electrodes were prepared by machining high-purity Al plates in the form of disks 2 in. in diameter. One face of each disk was drilled and tapped to accommodate a brass rod which served as an electrical contact. The opposite face was polished, cleaned, and then formed, along with the cylindrical surface, to 400 v in aqueous boric acid. The formed face was repolished to a mirror finish and then given a brief chemical polish in Alcoa "R-5 Bright Dip" solution. The heavy formation on the cylindrical surface of the electrode protected that portion from chemical attack and defined the area for subsequent formation. Several such electrodes were formed to 150 v at 1.0 ma/cm^2, and from the charge passed it was determined that the roughness factor of our foil specimen was 1.03. This low roughness factor is probably not a true measure of the state of the surface before formation but is a result of the smoothing effect of anodizing. This effect has been discussed by Lewis and Plumb (10).

Oxide films were detached from the underlying metal by dissolving the Al in a methanol-bromine solution (11), filtered, washed, and dried at 105°C. All weighings were made on a Brinkmann-Sartorius microbalance.

Density measurements were made by hydrostatic weighing in toluene. About 100 mg of sample was sufficient to give the desired accuracy.

Capacitance readings were made 10 min after removal of voltage, at which time the change in capacity with time is negligible.

Direct determinations of the thickness of films were made by the measurement of the displacement of interference fringes produced by a standard air wedge. Detached flakes of oxide, prepared by Strohmaier's method (12), were mounted on an optical flat and covered with an evaporated layer of silver about 600Å thick. Since the step thus produced on the surface of the optical flat is the same height as the thickness of the oxide film, the observed displacement is the same as that which would be due to the film itself. The displacement was measured at a magnification of 32X with a traveling microscope which was calibrated to read to 0.001 mm. The light source was the Hg 5460Å line.

A constant-current generator[1] was used for the measurement of formation rates at constant current. The range of current of this instrument limited the measurements to between 2.0×10^{-6} and 2.0×10^{-4} amp/cm^2. During the period of measurement the current could be held constant to better than 0.5%.

Calculated wt. of oxide, μg/cm²	68.4	64.0	59.6	56.0	52.8

Results

The validity of the results is dependent on a knowledge of the current efficiency of oxide formation, i.e., the fraction of the total current which is ionic. Preliminary work with the glycol-borate electrolyte showed a linear rise in voltage with time to slightly higher than 150 v when a constant current of 10^{-3} amp/cm² was maintained. Therefore, an end voltage of 150 v was chosen as a convenient value for our formations. Formations were made at a constant current density with a silver coulometer in series with the cell, the voltage being adjusted manually during formation. At the end voltage, the voltage was held constant, and the current was allowed to decrease to the desired value. Therefore, in each formation 0.299 coulomb/cm² (see Table I) was passed at 10^{-3} amp/cm², the remainder of the charge being passed at a constantly decreasing current density. The measured weight gain of the anode was compared to that calculated from the amount of charge passed, assuming that the production of Al_2O_3 was the only anodic process. In addition, the oxide was removed from the foil, and its weight was also compared to the calculated value. Table I shows that the agreement between the two values is generally within 1%, which is the estimated error of the experiments.

Heating of the oxide to 600°C resulted in no change in weight, indicating that the film contained neither water nor glycol, and the presence of borates could not be detected by chemical analysis. Furthermore, there was no apparent oxygen evolution at any time during formation, nor did the electrolyte contain Al after formation. On the basis of these analyses, we have concluded that the anodic product was solely Al_2O_3 and that the conditions of formation led to 100% current efficiency of oxide formation.

Figure 1 is a plot of log i vs. $1/W$ (the reciprocal of the weight of oxide per unit area), where each point represents the average value of at least three separate measurements. The data at the higher current densities were corrected for iR losses in the electrolyte so that each point corresponds to an applied anodic voltage of 150 v. The slope of the line is $150\beta\,\rho/2.303$ where ρ is the density of the anodic oxide. Four separate density measurements resulted in an average value for ρ of 3.17 ± 0.03 g/cm³. β is then calculated to be 4.8×10^{-6} cm/v. A similar plot of log i vs. capacitance per unit area measured at 120 cps is given in Fig. 2. The slope in this case is equal to $150\beta/2.04 \times 10^{-13}\epsilon$. From the thickness measurements, ϵ is calculated to be 8.4 ± 0.2, and β from this plot has a value of 5.4×10^{-6} cm/v. Extrapolation of the two plots permits an estimation of α, giving 10^{-22} and 10^{-24} amp/cm² in Fig. 1 and 2, respectively. Charlesby (8) reported $\beta = 3 \times 10^{-6}$ and $\alpha = 10^{-18}$, while Nagase (9), who obtained his values from rate measurements, is in better agreement with our figures, giving 4.3×10^{-6} and 10^{-20} for β and α.

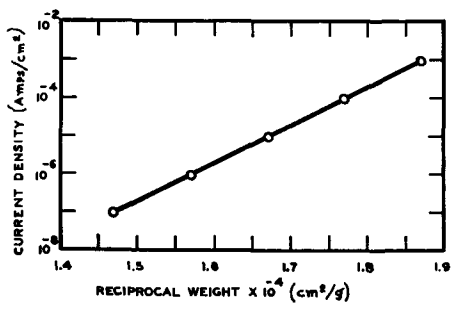

Fig. 1. Current density vs. reciprocal weight of aluminum oxide films maintained at a constant potential of 150 v at 25°C.

Table II shows the thickness, s, calculated for some of the points and compared with those obtained from interferometric measurements, the latter being reliable to about 30Å. Satisfactory agreement was obtained between the two methods.

The increase in oxide thickness which is possible at constant voltage explains the variation in the reported values for anodic aluminum oxide. In the range of currents discussed here, a 150-v film may vary in thickness from 11.3 to 14.4 Å/v. Clearly, then, both voltage and ionic current density must be defined if the value of thickness at some specified voltage is to be significant.

In a recent paper, Winkel, Pistorius, and van Geel (13) suggest a modification of the existing theory for anodic growth. Support for their view is given by their observation that the constant β apparently varies with field. However, the aqueous electrolyte used in their experiments required them to correct the total current for the electronic component, and large corrections of this nature lead to an appreciable degree of uncertainty in the final results. We, on the other hand, have measured these rates in our electrolyte of high current efficiency and plotted in the same manner as Winkel, *et al.*, as shown in Fig. 3. A straight line is produced as predicted by theory. From the slope β may again be calculated and gives the value 4.4×10^{-6}, in good

agreement with the values obtained from weight and capacitance measurements.

Rates at all current densities were measured in the voltage range of 120-150 v by first forming at 10^{-3} amp/cm² to 120 v and then reducing the current to the desired level. In this way all rates were measured under the same conditions of surface roughness since nearly the same thickness of oxide was present before the initial readings were taken.

All the work presented here is based on the assumption that even at the lowest current densities used we are dealing solely with ionic current. It may be argued that since the experiments which led to this conclusion were based on formations during which the major portion of the charge was passed at 10^{-3} amp/cm², an appreciable contribution by electronic current would have been unnoticed at the lower currents. If such were the case, however, we would not expect such a good fit to the plots over the whole range. Furthermore, the rate curve (Fig. 3) would then be expected to have the shape obtained by Winkel, *et al.*, rather than a straight line.

Acknowledgments

The authors wish to acknowledge the assistance of Mr. Stanley Szpak, who prepared the special electrodes for surface roughness measurements, and Mrs. Concetta Duval, who carried out the density determinations.

Kinetics of the Dissolution of Copper in Oxygen-Containing Solutions of Various Chelating Agents

J. Halpern,[1] H. Milants,[2] and D. R. Wiles[3]

Department of Mining and Metallurgy, The University of British Columbia, Vancouver, British Columbia

ABSTRACT

The kinetics of the dissolution of copper in stirred oxygen-containing solutions of ethylenediamine and several amino acids have been examined and compared with those found earlier for ammonia. In each case, provided that the partial pressure of oxygen exceeds a critical value (below which its transport to the copper surface may be rate limiting), the rate was found to be zero-order in oxygen and first-order in the complexing agent. The rate-determining process is believed to be the chemical attack of the oxygen-covered copper surface by the complexing agent. At 25°, the rate constants for dissolution by ethylenediamine, glycinate, α-alaninate, and β-alaninate were found to be 2.3×10^2, 49, 59, and 11 mg Cu cm^{-2} hr^{-1} M^{-1}. These follow the same order as the stability constants of the corresponding cupric complexes. In each system there is also another reaction path, independent of the first, which involves the protonated species, i.e., the ethylenediaminium ion and the neutral amino acids. The corresponding rate constants are 5.1×10^2, 31, 36, and 3.5 mg Cu cm^{-2} hr^{-1} M^{-1}.

A kinetic study of the dissolution of copper in oxygen-containing aqueous solutions of ammonia and ammonium salts was described earlier (1, 2). It was shown that the reaction proceeded by two independent paths whose rate-determining steps are the chemical attack on the oxygen-covered copper surface by an NH_3 molecule and an NH_4^+ ion, respectively. Both rates are independent of the oxygen concentration above a critical value when the transport of oxygen to the surface is no longer rate-limiting. Under these conditions the kinetics are of the form

$$\text{Rate} = k_A[NH_3] + k_{AH}[NH_4^+] \qquad [1]$$

At lower oxygen partial pressures a different rate law, first-order in oxygen and independent of the concentrations of ammonia or ammonium salts, was observed; this was attributed to rate control by oxygen transport.

The present paper describes similar measurements using several other complex-forming reagents, notably the chelating agents ethylenediamine, glycine, α-alanine, and β-alanine. These were selected with a view to providing further insight into the role of complex formation in the mechanism of the dissolution process and to correlating the rate of dissolution with the structure and stability of the complexes formed.

Experimental

The apparatus and experimental procedure were similar to those employed earlier (1, 2) with the following minor variations: Agitation was effected by means of a turbine-type impeller whose blades, generally rotating at 770 rpm, swept a cylindrical volume of 8 cm diameter. The exposed surface (generally about 2 cm^2) of the Bakelite-mounted copper specimen was positioned in a vertical plane tangential to this cylindrical volume.

Most of the measurements were made using conductivity-grade (99.97%) copper; no difference in the rate of dissolution was noted when Johnson-Matthey high-purity (99.999%) copper was used instead. Different annealing pretreatments, which resulted in grain sizes ranging from 0.035 to 0.12 mm, were also without effect on the dissolution rate. Before each experiment the copper surface was etched lightly with an ammonia-ammonium persulfate solution, but this procedure also did not appear to be critical.

Ethylenediamine (99%) was obtained from Carbon and Carbide Chemicals Corp. Purification by fractional distillation did not affect the dissolution rate. Glycine, α-alanine, and β-alanine, of Reagent Grade, were obtained from Nutritional Biochemical Corp.

Dissolution rates were determined by analyzing the leaching solution periodically for copper using the carbamate colorimetric method (3). All experiments were performed at 25.0° ± 0.1°C. To avoid the complications due to salt effects found in the previous study (1), the total electrolyte concentration of all the solutions was adjusted (in most cases to 0.1M) with sodium perchlorate.

Results

The chelating agents used and their properties are listed in Table I. Typical rate plots for the various complexing agents are shown in Fig. 1. In all cases these were found to be linear, and the dissolution rates, corresponding to the slopes of the plots, were generally reproducible to about ±2%. It was established that the total dissolution rates were proportional to the copper surface area and independent of the solution volume (generally 2 liters). No cuprous species could be detected in the solutions, the dis-

solved copper apparently being predominantly in the form of the tetracoordinated cupric chelate complex, e.g., $Cu(en)_2^{++}$, $Cu(gl)_2$, etc.

For each of the complexing agents, the dependence of the rate of dissolution on the concentration of the reagent and on the oxygen partial pressure (shown for ethylenediamine in Fig. 2) was found to conform qualitatively to the same pattern as observed previously for ammonia. This pattern is characterized by two distinct kinetic regions. At low oxygen pressures, the rate is first order in oxygen and independent of the concentration of the complexing agent. In the case of ammonia, evidence was found that the rate in this region is determined by transport of oxygen to the copper surface. While this interpretation also may apply to the present systems, it appears superficially at variance with the observations that the rate for ethylenediamine in this region (as well as in the region of high oxygen pressure) was unaffected by varying the stirring rate from 550 to 810 rpm and that the rates for solutions of different complexing agents (e.g., ethylenediamine and glycine) differed by as much as 25%. This point was not investigated further, and all the kinetic results to be considered here refer to the region of higher oxygen pressure, where the rate was found to be zero-order in oxygen and first-order in the complexing agent. In this region the rate-determining step is obviously chemical in nature.

In the ethylenediamine system, kinetic measurements extended over ethylenediamine (en) concentrations of 0.05 to 0.5M, ethylenediaminium (enH^+) perchlorate concentrations of 0.00 to 0.03M and oxygen partial pressures of 0 to 7.5 atm. The results are summarized in Table II and Fig. 2 to 4 and, in the high oxygen pressure region, conform to a rate-law analogous to Eq. [1], i.e.,

$$\text{Rate} = k_A[\text{en}] + k_{AH}[\text{enH}^+] \qquad [2]$$

Values of k_A and k_{AH}, given in Table I, were computed from the data in Table II.

Addition of sodium hydroxide to a solution of ethylenediamine resulted in a slight decrease in the rate of dissolution (Table II). This is attributed to passivation of the copper surface by oxide or hydroxide films.

In the glycine, α-alanine, and β-alanine systems, kinetic measurements were made at concentrations ranging from 0.0 to 0.3M each of the free amino acid (AH) and of the corresponding anion (A^-). The results are summarized in Table II. Both

species are apparently active in promoting dissolution and the oxygen-independent rate law in each system was found to be of the form

$$\text{Rate} = k_A[A^-] + k_{AH}[AH] \qquad [3]$$

Values of k_A and k_{AH}, computed from these data, are listed in Table I. By analogy with the interpretations accorded to the ammonia and ethylenediamine system it may be concluded that these are the rate constants for the independent attack of the anion and acid species, respectively, on the oxygen-covered copper surface, either process leading to the dissolution of a cupric ion.

The neutral amino acids are present in solution in two forms (5), the zwitterion (e.g., $^+NH_3CH_2COO^-$) and the molecular form (e.g., NH_2CH_2COOH). Since the ratio of the concentrations of the two forms is constant for each acid, the kinetic data provide no information about the relative contributions of the two species to the rate. However, in view of the predominance of the zwitterion form, it is reasonable to conclude that k_{AH} refers essentially to the reaction of this species.

No passivation effect was evident with solutions containing appreciable concentrations of the free amino acid and/or the anion. However, the addition of an excess of H^+, resulting in formation of some protonated amino acid, H_2A^+, was found to inhibit dissolution completely. This is attributed to passivation of the copper surface by an oxide film due to suppression of complex formation in the solution

$$CuA_2 + 2H_2A^+ \rightleftharpoons Cu^{++} + 4AH \qquad [4]$$

[Similarly it was found (2) that copper does not dissolve in a solution containing NH_4^+ if the free NH_3 concentration is very low, despite the fact that the rate constant for the reaction of NH_4^+ is higher than for NH_3 when both are present.] Because of this restriction, measurements could be made only in solutions in which the concentration of the pro-

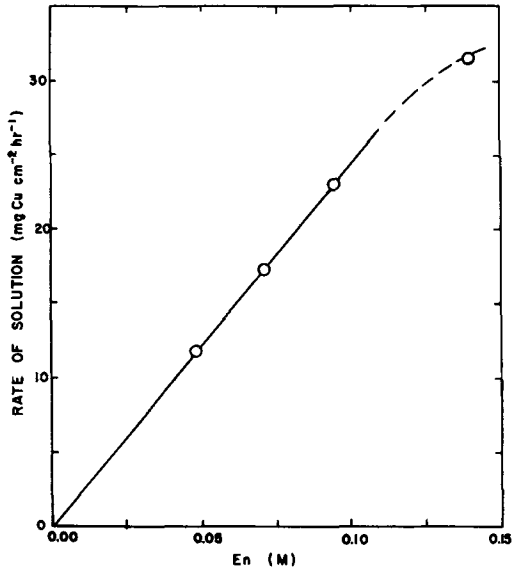

Fig. 3. Dependence of the rate at 7.8 atm O_2 on the ethylenediamine concentration.

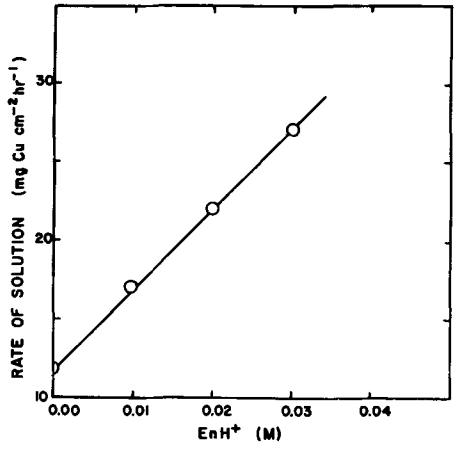

Fig. 4. Dependence of the rate at 7.8 atm O_2 on the ethylenediaminium perchlorate concentration. Solutions also contain 0.048M free *en*. Ionic strength held constant at 0.1M with sodium perchlorate.

tonated amino acid (e.g., $^+NH_3CH_2COOH$) was very low and the rate constant for the reaction of this species could not be determined.

Under the conditions employed in these studies (25°, 6.5 atm O_2) the dissolution of copper in solutions of acetic acid and/or sodium acetate was found to be very slow. This is probably also due to passivation of the copper since the *p*H of these solutions is relatively high and the complexing of Cu^{++} weak.

Conclusions

The same type of mechanism as proposed earlier for the dissolution of copper by ammonia also appears to be applicable to the present systems. This mechanism involves the following sequence of steps

$$\text{(i)}\quad Cu + \tfrac{1}{2}O_2 \xrightarrow{\text{fast}} Cu\ldots O$$

$$\text{(ii)}\quad Cu\ldots O + NH_2R \xrightarrow{\text{slow}} \left[\begin{array}{c} NH_2R \\ \diagup \\ {}^{++}Cu \\ \diagdown \\ O^{=} \end{array}\right]$$

$$\xrightarrow[\text{fast}]{HOH} Cu(NH_2R)^{++} + 2\,OH^- \qquad [5]$$

or

$$Cu\ldots O + {}^+NH_3R \xrightarrow[\text{slow}]{} \left[\begin{array}{c} NH_2R \\ \diagup \\ {}^{++}Cu \quad H^+ \\ \diagdown \\ O^{=} \end{array}\right]^{\cdot}$$

$$\xrightarrow{\text{fast}} Cu(NH_2R)^{++} + OH^- \qquad [6]$$

Examination of the data in Table I reveals the following points of interest:

1. The reactivities of the amines (NH_3 and en) in dissolving copper appear to be significantly higher than those of the amino acids.

2. The higher reactivities of ethylenediamine relative to ammonia, and of α-alanine relative to β-alanine suggest the influence of a chelate effect in the rate-determining step. This implies that both coordinating groups of the chelating agent interact with the metal surface in this step.

3. The rate constants for the four chelating agents follow approximately the same order as the stability constants of the corresponding cupric complexes.

4. In the case of both ammonia and ethylenediamine the protonated species is more reactive than the neutral base ($k_{AH^+} > k_A$). This has previously (1) been attributed to stabilization of the activated complex in the dissolution process by interaction between the extra proton and the incipient oxide ion (Eq. [6]). However, this explanation does not accommodate the present observation that the reactivities of the amino acids are enhanced by *removal* of a proton (i.e., $k_{A^-} > k_{AH}$). It may be of significance that in both cases the higher reactivity is associated with the ionic species.

5. A comparison of the rates of reaction of α- and β-alanine fails to reveal any indication that the presence of a methyl group on the α- position of the amino acid interferes sterically with the reaction.

6. Somewhat unexpectedly, the ratio $k_{NH_4^+}/k_{NH_3}$ (18.5) is much greater than k_{enH^+}/k_{en} (2.1). A possible explanation of this is that dissolution by ethylenediamine involves concerted interaction with the surface of both amine groups and hence is assisted only slightly by protonation of one of the groups.

Electrodeposition of Amorphous Selenium

A. K. Graham, H. L. Pinkerton, and H. J. Boyd

Graham, Savage & Associates, Inc., Jenkintown, Pennsylvania

ABSTRACT

Amorphous selenium coatings have been electroplated in thicknesses up to 30 μ (1.2 mils) on bright nickel cathodes (and thicker coatings can be prepared). Data are given for studies leading to the selection of the optimum bath and operating conditions for the formation of reproducible, uniform, and adherent deposits. It is shown that the plating baths employed and the amorphous deposits obtained are extremely sensitive to a variety of conditions, thus emphasizing the need for further study of the electrodeposition of selenium in the amorphous form.

During recent years an electrophotographic process called xerography (1) has been developed. It is used for the rapid reproduction of photographs. As a photographic process, xerography employs a reusable plate consisting of a thin layer of a photoconductive material, having a high dark resistivity, on an electrically conductive base. The plate is sensitized by electrostatic charging immediately before use and an electrical image formed by exposure of the plate to a light image. The electrical image then is transformed to a powder image by subjecting the plate to an electrically charged powder dispersed in air. Prints are made by transferring the powder image to paper or other material suitable for handling or use.

The photographic plates in use today are composed of a 50 μ (2.0 mils) thick layer of amorphous selenium on an aluminum base. The selenium layers are deposited on the basis metal by a vacuum evaporation process.

This paper presents the results of a research investigation undertaken to produce by electrodeposition amorphous selenium films having the required properties for use as electrophotographic plates.

Both electronegative and electropositive ions of selenium can exist together in alkaline solutions. Crystalline allotropes of selenium include two monoclinic forms and one hexagonal form. The monoclinic variety consists of 8-membered ring molecules (2), and the hexagonal form is built up from chain-molecule spirals (3). The amorphous and monoclinic forms of selenium are nonconductors and are dark red to black and red, respectively. The hexagonal modification is a semiconductor and is generally gray in color.

The semiconducting hexagonal form of selenium has reportedly been electrodeposited both cathodically (4) and anodically (5). However, there is little information concerning the formation of uniform, dense, and adherent amorphous selenium electrodeposits. Von Hippel and Bloom (4) in their work on the electrodeposition of metallic selenium stated that under certain conditions nonconductive selenium was formed which interrupted current flow. They also reported that the electrodeposition of amorphous selenium practically ceases in the dark but could be continued under strong illumination until a thickness of about 0.12 μ was reached. Sella (6) reported obtaining, by electrodeposition, the allotropic forms of selenium by varying the deposition temperature with low temperature (0° - 62°C), apparently producing the amorphous form of the element.

The baths previously reported for electrodepositing selenium ranged from alkaline (for anodic deposition) to strongly acid and, except for anodic deposition, were solutions containing Se IV. It appears from polarographic evidence (7) that Se VI is not reduced in acid media.

Experimental

Plating solutions were prepared in distilled water, using selenium dioxide of high purity.[1] When a wetting agent was used, it was important to follow the sequence of adding the agent to the water first, and then adding the desired amount of selenium dioxide in order to obtain satisfactory reproducibility. The solution was digested 30 min at 80°C, cooled, and filtered through a cellulose filter aid.

The range of spectrographic analyses of three lots of selenium dioxide is shown in Table I.

Except in the preliminary work, the plating so-

lutions were contained in a Lucite Haring cell provided with a ceramic diaphragm. The anolyte was placed in the smaller section; for acid plating baths, 10% (vol) H_2SO_4 was used with lead anodes; stainless steel anodes were used in NaOH solution of bath strength when alkaline plating baths were being studied. Most of the work was done in a cell 17.7 x 10 x 11 cm deep, although a smaller, geometrically similar cell also was used.

The plating solutions were circulated through Tygon tubing by means of a Sigmamotor pump, providing mild agitation of the catholyte. Temperature control was obtained by immersing a considerable length of the Tygon tubing in a constant temperature bath. Storage batteries were used as the current source to provide direct current with zero ripple.

Provision was made for varying the degree of illumination of the cathode from very strong to complete darkness. The very strong illumination was obtained by focusing three 500-w photospot lamps on the cathode surface from a distance of 12½ in. Under these conditions, considerable cooling was required to maintain bath temperatures, especially those below room temperature.

Temperatures from 5° to 40°C were investigated; no higher temperature was studied, since it was deemed inadvisable to approach the transformation temperature amorphous → crystalline too closely.

Exploratory work was done on a beaker scale with a Pt cathode and with the anodes in porous cups. Deposits were made with normal illumination and no agitation at room temperature. In one series, the solution contained 211 g/l SeO_2 and the *p*H, originally about 0.8, was raised successively to 1.5, 2.6, 7.8, 12.8, and 13.7 with NaOH. At the two higher *p*H values, little or no deposit was obtained. From the other baths, at moderate current densities of 0.1 to 0.2 amp/dm², uniform, adherent, glossy deposits were obtained ranging from glossy slate or black below *p*H 3 to dark red above this *p*H. In another series, 350 g/l SeO_2 was dissolved in water or in 1, 2, or 5*N* H_2SO_4. Deposits made in the same way showed the solution without added acid to be the most promising. Further work was confined to the *p*H region of 0.8 to 8.0.

Solutions of selenious acid attack a great many metals, including lead, silver, and gold. Platinum is not attacked, and the attack on rhodium or chromium, if any, is slow. The rate of attack diminishes, naturally, as the *p*H is raised. In all the work reported here, the cathode was connected to the current source before immersion in the plating solution to minimize the effect of the chemical attack.

Using the two baths at the extremes of the selected *p*H range, the limiting current densities on platinum were found to be as shown in Table II. Above these current densities, the deposits became redder, pulverulent, and nonadherent.

Alkaline bath.—Because of its higher limiting current density and the reduced attack on metals other than platinum, the alkaline bath of Table II was chosen initially for evaluation in the Haring cell. The temperature was varied from 5° to 25°C, the current density from 0.05 to 0.25 amp/dm², and strong illumination of the cathode was used. The character of the deposit, as judged by appearance, was extremely sensitive to the cathode material used, which included buffed sheet copper, and electrodeposits thereon of lead, Watts nickel, bright nickel, bright chromium, black chromium, rhodium, and gold. Generally speaking, the limiting current density was lower (about 0.4 amp/dm²) on these cathodes than on platinum. The deposits were redder, with a tendency to be pulverulent, and on copper a black, nonadherent deposit was obtained. With the sole exception of the deposit on platinum, which was amorphous, all deposits from this bath were crystalline, by x-ray diffraction.[2] The addition of wetting agent, the addition of citrate ion, and/or the substitution of ammonium ion for sodium were without effect. No further work was done with alkaline baths.

Table II. Preliminary work with selenium deposits on Pt cathodes for 15 min at 25°C with normal illumination

	Bath	Composition	*p*H	Limiting C. D., amp/dm²	Deposit description below limiting C. D.
A	Acid	350 g/l SeO_2	0.7-0.9	0.4	Amorphous,* uniform dark red to black
B	Alkaline	211 g/l SeO_2 in 2.6*N* NaOH	7.5-8.0	0.85	Amorphous,* uniform, red

* By x-ray diffraction.
Note: The deposits tended to be pulverulent, the more so at the higher current densities.

Acid bath.—From various modifications of the acid bath of Table II, a large number of deposits were obtained which were amorphous according to x-ray diffraction. These varied widely in appearance, and surprisingly, deposits up to 30 μ (1.2 mils) thick were obtained, with no indication that this was an upper limit. Spectrographic analysis of two such deposits showed contamination with copper, nickel, and lead, minor in one case and in major amounts in the other. Possibly because of such contamination, none of the amorphous deposits would retain an electrical charge, and were therefore unsuitable for xerographic purposes. The physical character of many such deposits, however, was excellent, being smooth, glossy black, and adherent. Because of this it is considered worth while to report on their preparation.

The best deposits were obtained from a solution of 350 g/l SeO_2 in distilled water, containing 1 g/l Duponol ME (sodium lauryl sulfate) prepared as described above. The cathode was plated with an undercoat of bright nickel about 0.25 mil thick and was introduced into the bath with the current on, at a current density of 0.1 to 0.4 amp/dm². Room temperature up to 40°C was found to be the best range. Moderate to strong illumination favored the formation of glossy black deposits; the deposits were less glossy and grayer in normal illumination or in total darkness.

[2] Since the authors were interested only in amorphous selenium, the existence of any crystalline diffraction pattern at all amounted to a rejection. No attempt was made to characterize the actual structure of the crystalline deposits from the diffraction data.

Results

At acidities varying between 5*N* H_2SO_4 up to *p*H 1.5, over temperatures from 5° to 40°C, with illumination varying from total darkness to very strong white light, amorphous deposits were obtained, varying only in appearance, on bright nickel-plated cathodes from baths containing wetting agent from 0.01 to 10 g/l. From baths without wetting agent, deposits were sometimes amorphous and sometimes crystalline, for causes not clearly established.

None of these amorphous deposits would retain an electrical charge. Seeking the reason for this, two of the best-looking amorphous deposits and two samples of vacuum-deposited selenium suitable for xerography were sent out for spectrographic analysis, with rather startling results:

	Spec. A	Spec. B	Vacuum-deposited
Ni	0.5	>10.0	nd*
Cu	0.5	>10.0	0.005-0.5
Pb	0.01	1-10	nd-0.0002
Fe	0.001	nd*	0.005-0.01
Ag	0.02	<0.01	nd-0.01

Notes:

1. Specimen B was analyzed by a different laboratory, and the results are believed to be order-of-magnitude only, rather than quantitive.
2. Specimen A was produced in a bath without wetting agent at *p*H 0.7; Specimen B was produced under similar conditions of temperature, current density, and illumination, but the bath contained wetting agent.
* nd, not detected.

An attempt was made to obtain purer deposits by purifying the bath before use and by taking extra precautions to avoid accidental contamination of the bath. Graphite anodes were substituted for the lead anodes previously used; the porous diaphragm of the cell was replaced by a fresh one, and all metallic connections close to the bath were coated heavily with stop-off lacquer, leaving the face of the nickel cathode as the only exposed metal. The freshly prepared bath was carefully neutralized with ammonium hydroxide. The white precipitate which was obtained was filtered off and the *p*H was readjusted to 0.8 with H_2SO_4. Another portion of fresh bath was passed through a bed of Amberlite IR-120,[3] a strong acid cation exchange resin. Baths with and without wetting agents were treated thus. After plates were prepared under conditions presumed to be optimum, the purified baths were purposely contaminated with 10 mg/l each of Cu and Ni and 30 mg/l of Pb as soluble salts, and further plates were made. Plates also were made from a freshly prepared control bath (i.e., untreated) with and without additions of contaminating metals. Generally speaking, the appearance of the deposits from purified baths was less satisfactory than from the control; those from the contaminated baths were slightly improved. Time was not available for x-ray or spectrographic analyses, but retention-of-charge tests showed some very weak ability to hold a charge in about half the plates, but in an entirely haphazard and inconsistent manner from which no conclusions could be drawn.

[3] Rohm & Haas Co. analytical grade.

Effect of substrate.—It has already been observed that from the alkaline bath deposits on platinum were amorphous, but on all the other basis metals tried, they were crystalline. Except on copper, the deposits were dense, uniform, and dark red to reddish black. Copper was so reactive that good deposits could not be obtained.

From the acid bath, deposits on lead and dull nickel were smooth and black; glossy black on bright nickel, but orange-red and pulverulent over chromium and bright nickel that had been passivated by a dichromate dip. All these deposits were amorphous. Black deposits were obtained on platinum, which were amorphous when prepared at room temperature, but crystalline when prepared from the bath at 5°C.

Defective Deposits.—All the remarks above apply to deposits which were not visibly defective. Especially in the early work, good deposits were difficult to obtain reproducibly. During the long plating runs necessary to obtain the thicker deposits, a defect frequently occurred which at the onset appeared like pitting in nickel but as plating progressed, these pits erupted into large crater-like areas of powdery red selenium. These areas invariably gave x-ray evidence of crystallinity, although the good black areas remained amorphous. It was surmised that hydrogen evolution was responsible for the pitting and likewise for the chemical reduction of selenious acid to the metal. Addition of the wetting agent improved the situation and it was found that, if the fresh bath was made up in the manner which has been described, good deposits could be obtained reproducibly until the bath had been operated for no more than about 6 amp-hr/l, when the defect reappeared. All attempts to determine the cause and cure for this behavior were futile. There had been no measurable loss of wetting agent, and depletion of the selenium content of the bath was insignificantly small. During plating, a certain amount of red selenium invariably formed in the bath; when no wetting agent was present, this could be removed by filtration, but in the presence of wetting agent some of it must have been in colloidal form, since even after heavy carbon treatment and filtration through filter aid, the bath had a red tinge. This treatment, followed by replacement of the wetting agent, also failed to restore the bath's ability to produce good plates. Considering what was later learned of the presence of impurities in the deposits, it is thought possible that the depletion by deposition of some of these impurities from the bath may have been responsible. The results of the later attempts to purify the bath in part support this explanation, although replacement of the three major impurities did not again cause good plates to be produced. Time did not permit a fuller exploration of this problem.

Summary

1. Although the production of relatively thick amorphous selenium electrodeposits with photosensitive retention-of-charge properties was not achieved, thick, sound, amorphous deposits were obtained from a bath containing 350 g/l SeO_2 and

wetting agent at current densities of 0.05 to 0.2 amp/dm^2 and temperatures of 20°-40°C.

2. Spectrographic analysis of two of the best-looking amorphous deposits showed metallic contamination, in one case serious, but relatively minor in the other. It was not determined whether this contamination occurred in all cases.

3. A serious drawback was the short life of the bath before defective deposits were obtained. More work needs to be done to discover the cause and cure for this behavior.

4. Equally sound crystalline deposits were obtained from a bath containing 211 g/l SeO_2 and wetting agent in 2.6*N* NaOH (8.0 pH) under similar conditions, but this area was not as extensively investigated.

5. Illumination varying from zero to very strong had no very profound effect.

6. The nature of the cathode material exerts a profound influence on the appearance and structure of the deposits. Bright nickel plating was the best of the substrates examined, which also included lead, silver, gold, rhodium, copper, dull nickel, bright chromium, and black chromium electrodeposits and sheet platinum.

Acknowledgment

The authors wish to express their appreciation to Dr. Harold J. Read, Pennsylvania State University, University Park, Pa., under whose direction the x-ray diffraction and spectrographic analyses were performed, and personnel of the Fort Monmouth Laboratory for several spectrographic determinations.

Manuscript received Oct. 20, 1958. Project carried out under Contract DA-36-039-SC-71228 with U. S. Army Signal Corps, Fort Monmouth, N. J.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Electroclad Aluminum on Uranium

John G. Beach and Charles L. Faust

Battelle Memorial Institute, Columbus, Ohio

ABSTRACT

Electroplating of aluminum was studied at Battelle in 1953-55 as an alternative method for aluminum cladding of uranium fuel elements. Uranium electroclad with 12 mils of aluminum over a 0.5-mil nickel or nickel-plus-copper electroplate resisted corrosion for more than 100 hr in boiling water. Hot pressing the electroclad composite improved the corrosion resistance. Many of the results obtained with aluminum electrocladdings paralleled those obtained with wrought aluminum claddings on uranium.

One method of cladding uranium fuel elements with wrought aluminum involves an intermediate braze layer of aluminum-12.5% silicon alloy (AlSi) or a nickel plate. The purpose of the intermediate layer is to aid bonding, to prevent rapid interdiffusion, and/or to provide a secondary barrier to rapid corrosion by hot water in case of penetration of the aluminum cladding. However, during dip brazing excessive solution of the aluminum cladding in the molten AlSi and selective penetration of the AlSi into the cladding may result if the temperature and time of AlSi dip brazing are not carefully controlled, and porosity of the AlSi brazing layer and unbonded area can also result in an inferior cladding.

This research was undertaken at Battelle to evaluate the possibilities of electrocladding uranium with aluminum. The electrodeposition of aluminum had been developed to the point where commercial applications were technically feasible, but electrocladding of reactor materials had not been explored. New techniques for preparing metal surfaces to be plated with adherent aluminum were needed. The principal characteristics of the electrocladding investigated were the diffusion and the corrosion protection afforded by aluminum plated directly on uranium and also over intermediate coatings plated on uranium. The studies were useful in showing the role of barrier-metal electroplates in preventing deleterious diffusion of uranium with the aluminum and the importance of good bonds between the barrier metal, the uranium, and the aluminum.

Selection of an Aluminum Plating Process

Two types of aluminum electroplating baths were available: fused salt (1) and organic. In this work, the need for deposits thicker than 10 mils (0.010 in.) obviated more than a few cursory tests with fused-salt baths. Two organic-type baths, the ethyl pyridinium bromide bath and the hydride bath, were investigated.

The ethyl pyridinium bromide-aluminum chloride-toluene bath was discovered by Weir and Hurley (2, 3, 4) and developed by Safranek, Schick-

ner, and Faust (5, 6). The following plating bath and conditions are recommended: *bath composition*: Ethyl pyridinium bromide-aluminum chloride fusion product, 32%; toluene (sp gr 0.866), 67%; methyl t-butyl ether, 1%; *plating conditions*: temperature, 86° ± 2°F; current density, 10-20 amp/ft^2 (superimposed a.c.); agitation nitrogen diffuser.

The lithium hydride-aluminum chloride-ethyl ether bath (composition and operating conditions are given later) was discovered by Couch and Brenner (7-9). The hydride bath is relatively easy to prepare. The ether content makes the bath flammable and safety precautions must be followed rigorously. Although explosions with systems containing lithium hydride and ether have been reported (10, 11), the presence of aluminum chloride tends to suppress the volatility of the ether and thus reduces the fire hazard.

Both nonaqueous organic processes produce smooth, dense, mat-type deposits, but electroformed foils, prepared for this work from the hydride bath, were more resistant to boiling water than those made in the ethyl pyridinium bromide bath. After 8 days' exposure to boiling distilled water, 2S aluminum foils and foils deposited in the hydride bath gained about 0.4 mg/cm^2 in weight. The absence of appreciable lithium in the hydride-bath deposit, in view of the high lithium content of the bath and the low weight change, suggests little or no occlusion of the bath constituents in the electrodeposited aluminum. On the other hand, foils deposited in the ethyl pyridinium bromide bath gained 2.0 mg/cm^2 in weight after exposure to distilled water. This greater weight gain is attributed to the hydration of occluded organic matter. Table I shows the results of spectrographic analyses of the aluminum deposits from the two organic plating baths. The aluminum produced in the hydride bath was of somewhat higher purity than that produced in the other bath.

Based on the ease of plating-bath preparation and operation and the higher purity and greater corrosion resistance of the electrodeposited aluminum, the hydride bath was selected for these studies of electrocladding aluminum on uranium.

Adherent Plating of Aluminum on Various Metals

Good adhesion between the aluminum and the uranium is an important factor for satisfactory claddings. But, as shown later, the good as-plated adhesion of aluminum directly on uranium is degraded by diffusion. Thus, adherent plating of aluminum on metals other than uranium was investigated. Adherent plating of aluminum on wrought metals was done preparatory to electrocladding aluminum over intermediate coatings plated on the uranium.

Treatment of clean metal surfaces by rinsing in alcohol, dipping in oleic acid (12), and plating with aluminum produced fairly adherent aluminum deposits on many metals. Wrought metal surfaces were first cleaned and activated by conventional means for aqueous plating and then treated by rinsing in alcohol and oleic acid.

Fatty acids other than oleic acid, such as linoleic acid and ethereal solutions of palmitic acid, were also successfully used to promote adherent plate of aluminum. Since pelargonic acid was not effective, a fatty acid with carbon chain longer than nine carbon atoms apparently is necessary.

Solutions of stearato chromic chloride[1] in isopropyl alcohol were even more effective than oleic acid in promoting adhesion of aluminum to iron and nickel. However, the stearato chromic chloride carried into the plating bath shortened the bath life. Subsequently rinsing in oleic acid was helpful in preventing bath contamination. Oleic acid per se did not shorten the life of the aluminum plating bath noticeably.

Preparation of Metal Surfaces for Plating with Adherent Aluminum

Aluminum.—Preparation of aluminum surfaces was by application of a conventional zincate replacement film and rinsing in water before rinsing in alcohol and oleic acid. The adhesion of the aluminum electroplates on 3S aluminum was tested by peening and by soldering. Peening of the surface was done by a rounded tip tool mounted in a vibrating marking tool. In the second test, the aluminum electrodeposit was copper plated, and a rod was soldered perpendicular to the surface and then pulled loose. Neither peening nor solder testing broke the aluminum-zincate-aluminum bond. The distortion of the peened aluminum plate is apparent in Fig. 1.

Copper.—Clean copper surfaces were activated in a sodium cyanide solution and then rinsed in water before rinsing in alcohol and oleic acid.

Nickel.—Nickel was activated by electropolishing[2]

[1] Quinol, E. I. du Pont de Nemours and Company, Inc.

or anodic etching and strike plating in the high-chloride "Woods" nickel bath and then rinsed in water prior to rinsing in alcohol and oleic acid.

Stainless steel.—Stainless steel was activated by anodic etching and nickel strike plating in the high-chloride "Woods" nickel bath and then rinsed in water before rinsing in alcohol and oleic acid.

Carbon steel.—Carbon steel, Type 1020, was electropolished and then rinsed in water prior to rinsing in alcohol and oleic acid. Chemical etching in hydrochloric acid or anodic etching in sulfuric acid was less satisfactory than electropolishing. Aluminum on carbon steel is shown in Fig. 2.

Electroplating of Aluminum over Metals Electroplated on Uranium

Electroplating of aluminum over electroplated metals on uranium was complicated by the fact that uranium was exposed through discontinuities in the intermediate plated layers which prevented optimum activation of the surface. Nickel, copper, and iron electrodeposits, ½ mil thick, plated adherently on uranium, were not impervious. The thickness of the intermediate metal coating was limited in this study to about ½ mil because of the higher thermal-neutron cross section of nickel, copper, and iron as compared with aluminum.

The best methods for activating solid nickel and steel specimens prior to the organic activation steps were not applicable to nickel- or iron-plated uranium, because these acid treatments attacked the underlying uranium. Therefore, aluminum was electroplated directly on nickel- or iron-plated uranium following rinsing in alcohol and oleic acid. The method for activating clean copper surfaces by immersion in a cyanide solution prior to the organic activation steps was effective in promoting adherent aluminum electroplating over uranium plated with copper or nickel.

The as-plated bond of the aluminum to the nickel or iron plates was inferior to that of aluminum to electroplates of copper or copper over nickel on uranium. Subsequent hot pressing or vacuum heat treating of electroclad specimens having aluminum on nickel- and copper-plated uranium improved the as-electroplated bonds. However, hot pressing of aluminum plate on iron-plated uranium produced brittle alloys that resulted in doubtful adherence.

Electrocladding Uranium with Aluminum

Uranium samples.—Alpha-rolled uranium plate was cold rolled to 90-mil sheet and cut into samples ¾ by ¾ in. square. The edges and corners were rounded to minimize edge buildup. Surfaces were cleaned by grinding or by grit blasting to remove scale. Samples were held in racks made of stainless steel with two point-type contacts on opposite edges. The contact areas were not plated, and thus there were discontinuities in the electrocladding. The racks were coated with Synthetasine,[3] a synthetic resin preparation, which was inert in the bath.

Aluminum-Plating Bath

Preparation.—The lithium hydride-ethyl ether bath was prepared under nitrogen atmosphere in a three-neck flask provided with a stirrer and a cooling bath of dry ice and acetone. Ethyl ether was stirred in the flask while $AlCl_3$ was added through a gooch rubber tube. Next, the LiH was added similarly. Considerable heat was liberated during these additions; however, the temperature was maintained between −25° and −10°C to minimize ether evaporation. The final composition was 400 g $AlCl_3$, 6 g LiH, and ether to make 1 liter.

Baths of 2.5 liters were contained in glass jars and covered with an aluminum dry box into which dry nitrogen gas was bled slowly. Two sets of doors were provided in the dry box for insertion and removal of the cathodes. Figure 3 shows the electroplating setup.

Bath life.—The longest time a hydride type of aluminum bath was operated was 30 days, or 190 amp-hr/liter. About 160 g of aluminum had been deposited from the 2-½-liter bath, or 80% of the amount in the original $AlCl_3$. The bath was then discarded because the electrodeposited aluminum had become brittle, nodulated, and spongy. The cathode current efficiency had increased to 115%. No attempt was made to recondition the bath.

Generally, at the beginning of their use, aluminum plating baths produced ductile, mat aluminum. As the baths grew older the plates tended to become smoother. In some cases, the smoothness was accompanied by small cracks and fissures in the plates. As the plates became smoother they usually tended to loose ductility. Finally, many baths began to produce dark, streaky deposits when they had outlived their usefulness.

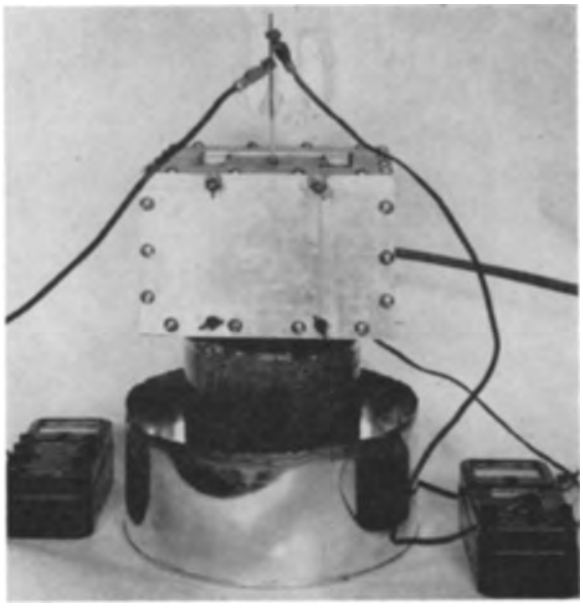

Fig. 3. Aluminum plating bath with dry box and plating rack in place.

Fig. 4. Surface view of crystalline electrodeposited aluminum. Magnification approx. 1000X before reduction for publication.

In some cases the aluminum tended to become satin surfaced, due to aluminum crystals. Figure 4 shows one of these flat surfaces. The tendency to form regular hexagons was outstanding. In Fig. 4 cubic crystals can be seen also.

Aluminum Plated Directly on Uranium

The preparation of uranium for aluminum plating was the same as for conventional aqueous plating, as discussed later. An extra requirement for aluminum plating was that after activation the uranium was dried in alcohol and ether before being immersed in the anhydrous plating bath. As-plated aluminum on uranium is shown in Fig. 5.

Heat treatment of aluminum-plated uranium easily diffused the two metals. The extent of diffusion occurring in 24 hr at temperatures of 200°, 250°, and 300°C is illustrated in Fig. 6, 7, and 8. The diffusion in 24 hr at 300°C was enough to destroy the as-plated bond.

Diffusion of aluminum and uranium at 250°C, and possibly at 200°C, was unexpected based on the observed diffusion between wrought aluminum and uranium. The interface of aluminum plated on uranium probably has less oxides than mechanically

Fig. 5. Aluminum electroplate on uranium as-plated (aluminum thickness, 12 mils). As-polished. Magnification 500X before reduction for publication.

Fig. 6. Aluminum electroplate on uranium after 24-hr diffusion at 200°C (aluminum thickness, 12 mils). As-polished. Magnification 500X before reduction for publication.

Fig. 7. Aluminum electroplate on uranium after 24-hr diffusion at 250°C (aluminum thickness, 12 mils). As-polished. Magnification 500X before reduction for publication.

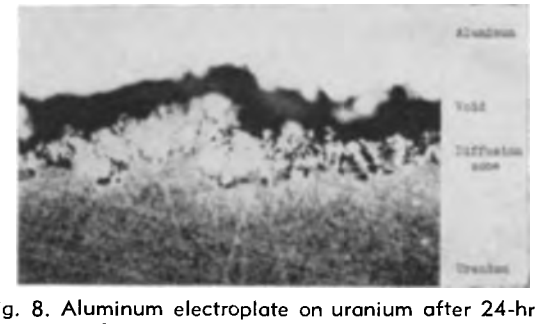

Fig. 8. Aluminum electroplate on uranium after 24-hr diffusion at 300°C (aluminum thickness, 12 mils). As-polished. Magnification 500X before reduction for publication.

prepared diffusion samples, and this difference could explain the difference in diffusion across the aluminum-uranium interface.

Aluminum Plated over Electroplated Metals on Uranium

The observed deleterious diffusion of electroplated aluminum and uranium in 24 hr at 250° and 300°C pointed out the need for an interfacial diffusion barrier. A barrier metal was desired that would prevent diffusion, would be well bonded to both the aluminum and the uranium, and would provide secondary corrosion protection to the uranium when exposed to boiling water through discontinuities in the aluminum. Nickel, copper, and iron electroplates were tried as barrier layers.

The procedure for activating and plating on uranium was as follows:

Descale uranium: (a) surface grind, (b) abrasive blast, or (c) chemical pickle.

Alkaline clean: immersion for 2 min at 180°F.

Rinse

Nitric pickle: 8*N* HNO_3, 80 ± 10°F, 5-10 min.

Rinse

Anodic pickle: 22*N* H_3PO_4, 0.2*N* HCl, 100°F, 50 amp/ft², 10 min

Cold rinse

Nitric pickle: 8*N* HNO_3, 80° ± 10°F, 3-5 min.

Electroplate: (a) Copper (0.5 mil), copper sulfate, $CuSO_4 \cdot 5H_2O$, 210 g/l; sulfuric acid, H_2SO_4, 82.5 g/l; molasses, 2.5 g/l; 20° ± 10°F, 50 amp/ft², 1 min, 25 amp/ft², 20 min.

(b) Iron (0.5 mil), ferrous sulfate, $FeSO_4 \cdot 7H_2O$, 300 g/l; ferrous chloride, $FeCl_2 \cdot 4H_2O$, 40 g/l; sodium formate, NaCOOH, 15 g/l; ammonium sulfate, NH_4SO_4, 15 g/l; boric acid, H_3BO_3, 30 g/l; wetting agent, DuPonol M. E.,[4] 1 g/l; pH 4.1 ± 0.1, 140°F, 60 amp/ft², 1 min, 30 amp/ft², 19 min.

Activate: (a) ethyl alcohol rinse, (b) oleic acid rinse.

Aluminum plate (12 mils), aluminum chloride, $AlCl_3$, 400 g/l; lithium hydride, LiH, 6 g/l; ethyl ether, balance; 75° ±5°F, 10 amp/ft², 24 hr.

Rinse and dry.

Treatment after electrocladding.—Heat treating of aluminum-electroclad samples for 5 min at 950°F and hot pressing for 5 min at 950°F with ram pressures up to 5.1 tsi were done to promote diffusion and improve the as-plated adhesion. Heat treating was done in a vacuum tube furnace with a pressure of less than 10 μ.

Hot pressing was done in a closed die. The hot-press assembly, Fig. 9, consisted of a frame and two cover plates of 3S aluminum in which the electroclad sample was encased. A 1-½-mil iron foil was included as a parting compound. The 1-7/16-in.-diameter by ⅜-in. thick assemblies were hot pressed in a tubular die with the ram pressure applied on one face. The 3S aluminum deformed under pressure and heat to fill the contours of the aluminum-electroclad sample. After being hot pressed, the aluminum-electroclad core was peeled off the 3S aluminum casing. A small hydraulic press[6] furnished the pressure.

Corrosion Testing of Aluminum-Plated Uranium

Samples of aluminum-plated uranium were immersed in boiling distilled water for 24-hr intervals or less. The corrosion trend was followed by the weight change and the progressive change in appearance. The relative corrosion resistances of the various cladding systems were based on the hours in test before a weight change of ± 1 mg/cm² was noted. Corrosion for the most part occurred only at contact areas in the aluminum electrocladding. If the bond of the aluminum cladding was not good, corrosion also occurred over the barrier-coated uranium because of penetration of water along the aluminum-barrier metal interface. The best samples

Ni + Fe	0.4 + 0.1	Passive	2.6-4.5	36-1	(18)

* *Active* uranium was that which was pretreated for good as-plated adherence. *Passive* uranium was just pickled in nitric acid and plated with an envelope of the barrier metal. Bonding of the electroplated metal to the uranium depended on the diffusion that occurred during hot pressing.

† Hours in boiling water until weight change of ±1 mg/cm² occurred. Number in parentheses is average of two samples.

showed slight corrosion only at the electroplating contact areas.

Tables II and III show the relative corrosion resistance of uranium electroclad with various barrier metals plus 12 mils of aluminum. The best corrosion resistance was observed for uranium that was plated with adherent 0.4 mil of nickel plus 0.1 mil of copper plus aluminum and hot pressed at 950°F with a ram pressure of 5.1 tsi. This system provided the best adhesion of the aluminum cladding and also provided desirable alloying of the uranium with the nickel as a secondary corrosion barrier. Samples that were not hot pressed nor heated after electrocladding corroded rapidly (within a few hours) along the uranium-electroplate interface.

ABSTRACT

Conditions for electrolytic deposition of iron powder from a slurry of iron III oxide in caustic soda solutions were investigated. The variables that influence the deposition the most were temperature (90°C), caustic soda concentration (600-800 g/l), and low current densities. Results from pilot-plant studies were in good agreement with laboratory findings. Several photomicrographs of the deposits are included. Physical and chemical properties of the powders are listed. Results show that a ductile, dendritic deposit was obtained that could be ground up easily. The size of the dendrites was influenced greatly by conditions of deposition. Particle size distribution, particle shape, ductility, flow rate, purity, and compactability of several powders were examined. Tensile strength and elongation of sintered compacts were also studied.

Iron III hydroxide is soluble to a limited extent in strong caustic soda solution from which metal powder may be deposited in a dentritic and ductile form. The solution is kept saturated by employing an excess of finely divided iron oxide maintained in suspension by agitation.

Estelle (1) first patented such a process in which he recommended a bath consisting of 30% iron III hydroxide, 35% sodium hydroxide, and 35% water, maintained at 100°C. He stated that a gray metallic deposit can be obtained from this solution. Angel (2) showed that finely divided iron ore could be used in place of the pure hydroxide in the same type of medium. Estelle's and Angel's patents defined very few conditions for electrodepositing the iron and did not describe the characteristics of the powder produced. Little attention has been given to this method of producing iron powder. Ljungberg (3) described it in a review of electrolytic methods for making powders and concluded that further work would be necessary to change it from the status of a laboratory curiosity. He considered the method attractive, since the powder is obtained directly from the ore. Mehl (4) stated that a brittle deposit, suitable for crushing, is obtained by Estelle's process, and patented a process (5) in which soluble iron anodes were employed in 50% caustic solution at 100°C. A very fine, dentritic powder was obtained.

The experimental work described in this paper was undertaken to determine conditions of electrolysis, yields, and characteristics of the iron powder produced in an alkaline iron oxide medium.

Experimentation

Laboratory Electrolytic Studies

A bath was prepared consisting of equal parts of water, caustic soda, and finely divided C.P. iron III oxide. This was electrolyzed at cathode current densities ranging from 30 to 90 amp/ft^2 and a tem-

perature of 120°C in an iron container used as the anode. Gray, metallic deposits were formed from which it was difficult to remove all of the adhering oxide, so that the current efficiencies calculated from the gain in weight were 120%. A photomicrograph of the cross section of a typical deposit is shown in Fig. 1a. Oxide inclusions are evident, except near the surface, where they were washed out. However, if a rotating cathode was used, the calculated current efficiency was reduced to 92%. Figure 1b is a photomicrograph of this deposit, and the amount of oxide occluded is seen to be less than previously. If, in addition, a high-speed impeller was used to agitate the viscous bath, oxide inclusions were further eliminated, as shown in Fig. 1c, and a current efficiency of 70% was obtained.

In addition to its tendency to give deposits containing occluded oxide, the bath was so viscous that drag out was excessive. The viscosity was considerably reduced by decreasing the amount of suspended oxide, and deposition at high current efficiency was still possible if the bath was vigorously agitated. Further experiments were carried out in 1- and 4-liter containers. Nickel or iron anodes 0.5 in. in diameter or larger and 6-7 in. long were used. The iron anodes were corroded slowly during electrolysis. The cathodes consisted of mild-steel sheets that had been slightly roughened. The deposits adhered well to the surface but were easily removed from the electrode by flexing or scraping. The removed chips were reduced to powder by mild grinding. Air agitation was tried in a few experiments but had the disadvantages of producing a large amount of spray and introducing carbon dioxide into the bath. Agitation with a 2.5 in. diameter impeller revolving at about 700-800 rpm was found to be more satisfactory.

Bath stability during electrolysis.—The cathode current efficiency of a freshly prepared bath was found to decrease upon continued electrolysis. In a typical experiment a current efficiency of 90% was obtained during the first few hours of electrolysis, but after 24 hr the current efficiency had decreased to a steady value in the range of 60-80%. The high current efficiency of a freshly prepared solution may be due to the fact that the iron oxide contains an easily soluble fraction that dissolves shortly after the addition to the caustic soda solution.

The character of the deposits also changed during the stabilization period. Deposits from freshly prepared baths were loose and powdery but became more compact as electrolysis was continued. In the progress of the experimental work, successive experiments were run until the bath had reached a stable state.

Table I. Effect of bath temperature on current efficiency. Fe_2O_3-50 g/l; current density, 40 amp/ft²

Temp, °C	NaOH, g/l	Cathode current efficiency, %
30	400	30
35	600	45
50	600	75
60	400	45
70	600	85
80	600	90
90	400	60
90	600	90-95
120	400	70

Effect of temperature.—The effect of temperature was investigated in a bath containing 200-600 g/l of caustic soda and 25-75 g/l of iron III oxide. Electrolysis was carried out at a cathode current density of 40 amp/ft² over a temperature range from 30° to 120°C. The highest temperature was still below the boiling point of the bath.

Results are shown in Table I and indicate a current efficiency of well over 80% in several instances. The effect of temperature was investigated before the need for extensive electrolysis to obtain a stable condition was realized. While the results are generally consistent with one another, some of the values are inconsistent with later work.

The best current efficiency was obtained at the highest temperature for any given caustic concentration. The nature of the deposit also changed with the temperature. As the temperature increased the deposited dendrites increased in size, as shown in Fig. 2a to 2d inclusive. These figures are photomicrographs of polished cross sections of the deposits. The deposit made at 60°C was dispersed somewhat when mounted prior to polishing.

The variation in dendrite size with temperature was even more clearly shown by grinding deposits to −325 mesh, mounting in Lucite, and polishing.

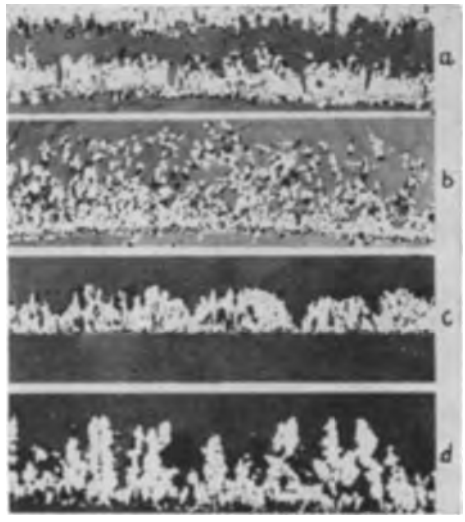

Fig. 2. Influence of temperature on cathode deposits: a, 35°C; b, 60°C; c, 90°C; d, 120°C. Magnification 100X before reduction for publication.

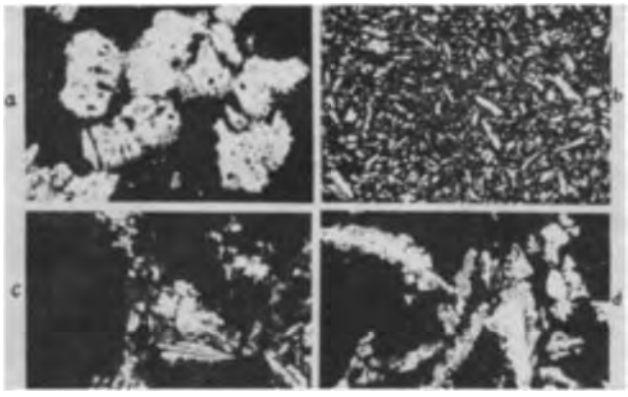

Fig. 3. Effect of bath temperature on iron deposit (caustic soda, 400 g/l; Fe_2O_3, 50 g/l): a, 35°C; b, 60°C; c, 90°C; d, 120°C. Magnification 500X before reduction for publication.

Photomicrographs of the specimens are shown in Fig. 3a to 3d. The large particles appearing in the photomicrograph of the powder deposited at 35°C are not individual dendrites but rather clumps made up of many smaller dendrites. This powder had very poor flow characteristics and balled up on the screen rather than passing through it. The dendrites from the 60°C deposit easily passed a −325 mesh screen. At higher temperatures some of the dendrites were too large to pass a −325 mesh screen and had to be distorted first, requiring a much more severe grinding treatment. However, the flow properties of the powder tended to improve as the temperature of deposition increased.

In all of the photomicrographs, except that of the powder produced at 35°C, fragments with a hexagonal symmetry can be observed, resulting from sectioning through the width rather than the length of the dendrite. Therefore, the dendrites consist of six longitudinal ridges spaced around a longitudinal axis with hexagonal symmetry.

Effect of caustic concentration.—Electrodeposition of iron from iron III oxide slurries in caustic soda solutions of varying concentrations showed that a high caustic soda concentration, in excess of 400 g/l, is required to obtain a current efficiency of over 50%. Representative results are shown in Table II. A bath containing 200 g/l of caustic soda and 50 g/l of iron III oxide was held at a temperature of 90°C and electrolyzed at 36 amp/ft². The first deposits from this bath were obtained at a current efficiency in excess of 60%, but the current efficiency dropped continually as more ampere-hours were put through the bath. Apparently, caustic soda present in a concentration of 200 g/l is not able to solubilize all of the iron oxide.

Table II. Effect of caustic soda concentration. Fe_2O_3-50 g/l; temp, 90°C; current density, 40 amp/ft²

200 g/l NaOH		465 g/l NaOH		765 g/l NaOH	
Amp-hr/l	C.E., %	Amp-hr/l	C.E., %	Amp-hr/l	C.E., %
3.1	68	3.1	91	4.7	80
15.6	40	15.6	86	17.2	85

50.0	13	47.0	54	36.0	68
59.5	13	50	52	39.2	67

With 465 g/l of caustic soda in the bath, a stable current efficiency of about 55% was obtained. With 765 g/l of caustic soda in the bath, deposits were produced at a current efficiency of 70%.

Effect of iron III oxide concentration.—The slurry concentration of iron III oxide in caustic soda solution was varied to determine whether its concentration affected the current efficiency of electrodeposition and the type of deposit produced. A finely divided, chemically pure iron oxide was selected for use in the bath. Baths containing 25, 50, and 75 g/l of iron oxide and 400-765 g/l of caustic soda were operated at 90°C and a cathode current density of 35-40 amp/ft². The results in Table III indicate that the concentration of oxide could be varied without significantly affecting the electrolysis.

Use of commercial hematite ores containing as high as 86% Fe_2O_3 in place of pure iron oxide gave somewhat inconsistent results. However, the current efficiencies were generally 20-30% lower than with the pure oxide. The use of a magnetite ore (Fe_3O_4) gave current efficiencies below 5%.

Effect of current density.—The effect of increasing the current density was to decrease both the current efficiency of deposition and the size of the dendrites deposited. Current efficiency values are given in Table IV. The decrease in the average size of the dendrites deposited is evident from the photomicrographs of deposit cross sections shown in Fig. 4a to 4g. At 2400 amp/ft² the deposit appears to have been torn off by the hydrogen evolved, except for a thin layer.

As expected, the effect of increasing the current density is opposite to the effect of increasing the temperature. Increasing the current density decreases the concentration of iron in the cathode film, leading to a decrease in the current efficiency and

more nucleation. Thus, finer dendrites are formed. An increase in temperature increases the rate of diffusion in the cathode film and probably increases the solubility of the oxide. The result is a higher current efficiency and a tendency to deposit on dendrite surfaces already established, rather than to start new ones.

Conclusions

The experimental results have shown that it is possible to prepare iron powder with an average particle size that can be varied over a wide range. The variables that most influence the electrodeposition of iron from an alkaline bath are temperature, caustic soda concentration, and current density. High temperatures of the order of 90°C are desirable for maintaining current efficiency and producing coarser dendritic deposits. Similarly low current densities, in addition to producing high current efficiencies, bring about coarse dendrites. High caustic soda concentrations in excess of 400 g/l and preferably between 600-800 g/l effect the best current efficiencies. The laboratory scale experiments established the feasibility of depositing dendritic iron from a caustic soda-iron oxide medium.

It is probable that the iron was deposited by the reduction of the soluble sodium ferrite in the solution. The solubility of the ferrite is rather low and deposition would soon cease without constant replenishment of the solution by the suspended oxide. The presence of more oxide particles than are needed to maintain the ferrite ion concentration should not change the results, which explains why the oxide concentration is not critical, at least above a certain minimum value.

Pilot-Plant Electrolytic Studies

On the basis of the laboratory findings establishing the feasibility of the deposition process, pilot-plant studies were undertaken. Pilot-plant studies were to aid in determining the best conditions for continuous electrolysis, to verify efficiencies, to furnish a basis for an economic study of the process, and to make available sufficient quantities of iron powder for chemical and physical property studies, commercial applications and evaluations.

Large-scale studies also offered the possibility for investigating other sources of iron oxide in place of the chemically pure material used in the laboratory. They further aided in determining the technical advantages and disadvantages of the electrodeposition process and gave some knowledge on the design of the cell, grinding equipment, and the over-all production process.

Equipment and procedure.—The cell was constructed of 0.125 in. nickel sheet with base dimensions 18 x 9 in. and a height of 29 in., and had a 20-gal capacity. An inlet and outlet were provided on the side of the cell for the introduction and removal of liquor. Agitation was provided by a high-speed impeller rotating from 1000 to 1500 rpm. The solution was heated from the outside by strip heaters. The walls of the cell served as one anode, and a second anode was hung in the center of the cell. Two cathodes 10 x 24 in. made of 0.25-in. steel plate were inserted on either side of the center nickel anode. The total cathode area was 5.5 ft². D.C. current was supplied by a selenium rectifier.

Caustic soda flakes were dissolved in water to make 16.5 gal of 50% liquor. This electrolyte was used throughout a run, which sometimes extended from 6 to 8 days, with only periodic additions of water to replace evaporation loss. The iron was added as 9 lb of C.P. iron oxide or commercial ores. Periodic additions of approximately 2 lb of oxide were made every 4 hr throughout the run, assuming a current efficiency of 85%.

The cell was operated at 275 amp with an average cell potential of about 2.3 v. The bath temperature was maintained at 85°-90°C, and the solution was agitated to assure intimate mixing of the iron oxide and the alkaline bath.

After each 24 hr of operation the cathodes were removed from the cell. The deposited iron was washed thoroughly with water to remove any excess alkali and metallic oxides adhering to the surface and then scraped off. After the iron was ground in a ball mill, the oxide was removed. The powder was oven dried, sifted through a U. S. Standard 120 screen, and weighed. Samples of each day's production were analyzed for hydrogen loss, total iron, and particle size distribution according to standard MPA methods.

Process evaluation.—Pilot-scale runs were made at conditions which had proven most successful in the laboratory. The correlation between the laboratory work at Battelle Memorial Institute and Dia-

mond Alkali Company and the pilot-plant runs made at Diamond Alkali was excellent. As shown on Table V, using C. P. Fe_2O_3 as a raw material, current efficiencies were in the range of 75-80% and were not appreciably affected by the age of the bath as long as the Fe_2O_3 concentration was maintained by the addition of ore. The chemical quality of the product was excellent, analyzing 99.57% iron and 0.43% hydrogen loss. The type of deposit is shown in Fig. 5, which is similar to that found in bench scale work.

Pilot operation verified that a very simple cell design was sufficient. It was shown that a bath could be used for several days without detrimental effects. It was also shown that after several days of operation the cell could set dormant for several days and be put back in operation without a reduction in current efficiency.

The use of oolitic hematite in place of C.P. ore reduced the current efficiency to approximately 50%. The product quality was also reduced, showing 2% hydrogen loss. The nature of the deposit was altered slightly, and although it was easily removed while fresh, it became difficult to remove if allowed to cool and dry. This was probably due to the presence of silicate, which cemented the deposit. It is possible that with some additional work to improve the technique and by selection of a more suitable natural ore results could be considerably improved.

Fig. 5. Iron deposited on pilot plant cathode, cross section of cathode deposit. Magnification 90X before reduction for publication.

In general, it was shown that the electrodeposition of dendritic iron from a caustic soda bath containing a suspended Fe_2O_3 is chemically and economically feasible. The raw materials are low in cost and can be handled easily. The electrolysis proceeded as planned. And finally, the product could be removed from the cathodes with a minimum of effort, yielding a deposit that could be easily ground in a ball mill.

Physical and Chemical Properties of Iron Powders

A determination of the physical and chemical properties of powders made under all of the conditions tried would be extremely laborious, since there are so many properties of significance in powder metallurgy and other powder uses. However, many of the properties are related inherently to the shape and size distribution of the powder. Therefore, detailed determinations could be restricted to a few representative powders covering the shapes and size distributions encountered during the experimental production of powders. In most of the deposition experiments on a laboratory scale less than 30 g of powder were produced. This amount of material is insufficient to determine several important properties, such as flow rate. Therefore, most of the powders that were examined in detail were made on a

pilot-plant scale. In several cases the operations of stripping from the starting sheet and washing with vigorous agitation were sufficient to reduce most of the deposit to powder. The product is referred to as "unground" powder as distinct from "ground" powder resulting from further comminution in a ball mill or mortar.

Analytical data.—Determinations were made of powders prepared from baths containing either C.P. iron oxide or a commercial iron oxide ore (hematite). Typical results of several experiments are shown in Table VI. Little difficulty was experienced in obtaining a hydrogen loss[3] (oxygen content) of less than 1% when pure oxide was used. However, with oolitic hematite ore the oxygen content was as high as 2%.

Ductility.—All deposits and powders were extremely ductile. When struck with a hammer a deposit was easily deformed without fracture. It was difficult or impossible to fracture particles by grinding. Even a relatively mild grinding deformed the particles as evidenced by the photomicrographs, Fig. 6a-6f, of the same powder, before and after milling. Extensive grinding caused severe deformation. Evidence that the powder is fully ductile as formed and that an annealing treatment does not increase the ductility was obtained as follows: A green compact prepared from powder No. 1 had a density of 5.51 when pressed at 38.7 t.s.i. A green compact made from powder No. 1 annealed in hydrogen at 1,000°C for 1 hr had a density of 5.57, or essentially the same value as the unannealed powder. Had the annealing increased the ductility to any extent, the density of the corresponding compact should have increased.

[3] The term "hydrogen loss" is the loss due to the removal of oxygen during the heating of the specimen in an atmosphere of hydrogen. Procedure in MPA-Standard 2-48 was followed.

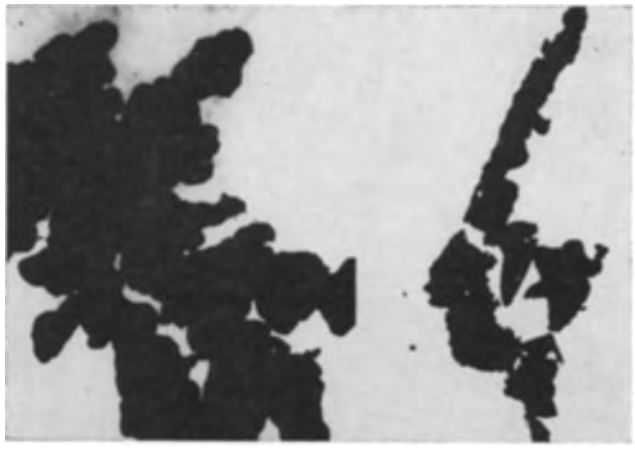

Fig. 7. Electron micrograph showing pattern of growth. Magnification 24,750X before reduction for publication.

Comminution.—The deposits were adherent, and, after they were removed from the bath, excess electrolyte and oxide could be eliminated by spray rinsing. The size of the dendrites and their adherence to each other increased with the temperature of deposition. Many of the 90°C deposits were converted to powder by the stripping and washing operations, particularly the deposits prepared on a pilot-plant scale. A further mild grinding treatment separated the few remaining dendrite agglomerations except for the large nodules formed at the corners and edges of the cathodes. The deposits prepared at 120°C in the laboratory showed a different behavior than the lower temperature deposits. Dendrites were generally too large to pass a 100 mesh screen, and the agglomerates tended to deform under the impact in the ball mill rather than to separate into individual dendrites.

Particle shape.—The dendrites as formed tended to be needle-like, and the particles appeared to become narrower and longer as the current density and temperature were lowered. Powder particles of No. 12, as shown in Fig. 6e, had perhaps the largest length to width ratio of any of the samples examined. Even mild grinding tended to flatten the particles, and extensive grinding distorted the particles into flattened platelets. Individual particles were also examined at higher magnifications. Electron-micrographs in Fig. 7 show the pattern of growth. Growth appears to take place by budding off from a parent stalk.

Particle size distribution.—Sieve analyses were made of powders prepared in both the laboratory and pilot plant. The laboratory results are shown in Table VII. A high proportion of fines was found in all the powders. As the temperature of deposition was increased, more grinding was required to break up the deposit, and the amount of fines became less. At 120°C a firm deposit was obtained that required extensive grinding and resulted in powder particles having a flat, disk-like shape. Similar results were obtained with pilot-plant powders as shown in Table VIII. Again the powders were on the fine side. The results for −325 mesh fractions would appear to be erratic, and this is related to the deformability of the particles on grinding. Table IX indicates this effect clearly. In four of the five examples the frac-

Notes:
No. 1. Deposits average 0.1 in. in thickness and were ground wet for 2 hr with 1-in. diameter steel balls. Several large pieces from edges and corners of the deposits were not broken up. The large pieces account for most of the 100 mesh material.
No. 2. Deposit loose and crumbly. Ground for 5 min with ½-in. diameter steel balls. Particles were needle-like and tended to agglomerate so that particle size is probably much finer than indicated by sieve analysis.
No. 3. Ground with 0.5 in. diameter ceramic balls, sizing after 5, 15, 30, and 45 min and returning 100 mesh material to the ball mill. Powder definitely dendritic but less so than No. 2.
No. 4. Deposit was firm and adherent but easily ground in a mortar. Particles dendritic but considerably less so than No. 2 and No. 3.
No. 5. More grinding required than with lower temperature deposits and particles were more irregular in shape.
No. 6. Deposit very firm and compact. Ground with 0.625 in. diameter steel balls for 3 hr, removing −100 mesh material frequently. Particles were severely deformed and flattened.
No. 7. Deposit very firm and compact and required over 10 hr of grinding to reduce the bulk to −100 mesh powder. Particles severely deformed and flattened.

* Part of the fines were removed so that the powder would flow.

tion of fines is decreased by grinding, as the needle-shaped particles are flattened and unable to pass through as fine a screen. Therefore, the amount of grinding is very critical in determining size distribution, since breaking up of agglomerates, tending to reduce screen size, and flattening, tending to increase screen size, occur simultaneously.

The −325 fraction of a laboratory sample was further analyzed by air elutriation (infrasizer) with the results shown in Table X. The results can be considered only very approximate, since the instrument is calibrated for spherical rather than needle-like particles. The average nominal diameter for the particles in the fines appears to be in the range of 20-40 μ, with less material below 10 μ.

Flow rate.—Flow rate tests were carried out on sized fractions of powders prepared in the pilot plant with the results shown in Table XI. None of the powders flowed prior to screening, but all the −325 fractions flowed after screening. Powder No. 14 originally contained much more than 39% fines, but when the fines above this amount were removed, the powder flowed with a standard time of 35 sec, which is commonly accepted in powder specifications.

Apparent density.—The apparent densities of powder No. 8 and No. 14 were 2.29 g/cc and 2.47 g/cc, respectively. The higher value for the latter powder may be because a part of the fines were removed. The values for apparent density are acceptable for metallurgical powders.

Compactability.—Green compacts were made in a single plunger die with a 0.5 in. diameter cylinder. Unless otherwise stated, the pressure used was 30 t.s.i., and 0.5-1% of zinc stearate was added to the powder as a lubricant. In most cases the green density was in the range 5.5-6.0 g/cc (Fig. 8). A

3.5	3-15

green density of at least 6.5 would be preferable to meet existing specifications, although tensile tests indicated that such a high density is not necessarily required for strength and ductility.

Green strength.—The standard MPA rattler test was carried out with green compacts of powder No. 8. The value was 2.29% loss, well above minimum requirements.

Tensile strength and elongation of sintered compacts.—Tensile specimens were compacted, sintered,

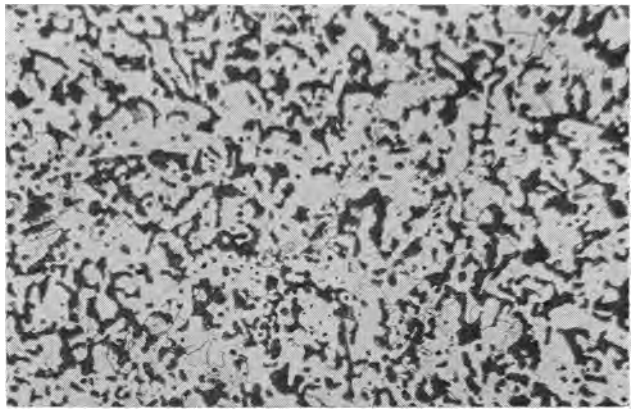

Fig. 9. Sintered powder compact. Magnification 250X before reduction for publication.

and tested according to MPA standard 10-50 T. Results for two experimental powders are shown in Table XII and are compared with several commercially available materials. Powder No. 12 had very long, jagged particles and did not flow. Its sintered compacts had strengths and ductilities comparing favorably with much higher density compacts from other powders. The results with powder No. 14 illustrate the risk in using a standard evaluation test. At a pressure of 30 t.s.i., commonly used for evaluation, results were very poor, but at 50 t.s.i., which is still a practical pressure, much higher strength and ductility were obtained.

A photomicrograph of a sintered compact made from an experimental powder is shown in Figure 9.

Electric Field Enhancement of Cathodoluminescence (Cathodoelectroluminescence)[1]

Philip M. Jaffe

Research Department, Westinghouse Electric Corporation, Bloomfield, New Jersey

ABSTRACT

The application of an alternating electric field to certain cathode-ray excited ZnCdS:Mn,Cl powder phosphors causes the cathodoluminescence to be enhanced. Enhancement is a function of the frequency and strength of the applied field, the beam current density, and the accelerating potential. The indications are that the effect is in reality cathode-ray induced electroluminescence. Similar testing of a ZnCdS:Mn,Au,Cl phosphor results in either enhancement or quenching depending upon the exciting conditions.

Destriau has shown that the Roentgenoluminescence of certain ZnCdS:Mn,Cl (1) and ZnCdS:Mn,-Au,Cl(2) phosphors is enhanced by the application of an alternating electric field. Since then, several similar enhancement effects have been reported (3-14). One of these, described by Cusano (3-5), utilizes a thin film of ZnS phosphor activated by either manganese, arsenic, or phosphorus and coactivated by chlorine. On exciting the film with 3650Å radiation, x-rays, or cathode-rays, the simultaneous application of a d-c field produces an increase in the light output. A similar effect has been reported by Thornton using a wide variety of powdered ZnS phosphors with u.v. radiation and either a-c (6) or d-c (7) fields and by Woods (8) using single crystals. Halsted's enhancement effect (9) has been observed using a-c fields and 2537Å excitation of ZnS:Cu,Al and ZnS:Ag,Cl and 3650Å excitation of ZnCdS (35, 50, 85% Cd): Ag,Cl and ZnSSe (20%Se): Cu,Al phosphor powder samples. Gobrecht and Gumlich (10) have studied the effect of a-c fields on u.v.-excited ZnS:Mn,Cl powder phosphor, while Mattler (11) investigated the same phosphor using excitation by α particles. Neumark (12) has studied the enhancement of thermoluminescence by electric fields. Mention also should be made of the work of Woods and Wright (13) on the enhancement of the cathodoluminescence of MgO by the application of a d-c field.

The present paper deals with a-c field enhancement of the cathodoluminescence of certain ZnCdS:Mn,Cl, and ZnCdS:Mn,Au,Cl powder phosphors. The simultaneous effect of a-c fields and cathode-rays on ZnS:Cu,Al and ZnS:Mn powder phosphors has been reported on by Gobrecht and co-workers (14).

Experimental

The composition of the phosphor mainly used in this work was (70Zn·30Cd)S:0.14Mn,0.5NaCl[2] and is similar to that used by Destriau in his studies on x-ray enhancement (1). Some observations also were made with a (50Zn·50Cd)S:0.5Mn,10^{-4}Au (added as the respective chlorides) phosphor, supplied by Destriau, which shows greater x-ray enhancement than the phosphor without gold (2). In addition, silver-activated ZnS and ZnCdS(30,-70, 85 wt % Cd), Zn_2SiO_4:Mn and a good electroluminescent ZnS:Cu,Cl phosphor were tested. The silver-activated phosphors generally showed quenching of the cathodoluminescence on application of the field. No field response was found for the willemite phosphor, i.e., no enhancement or quenching.

[1] The sections of this paper which deal with the ZnCdS:Mn, Cl phosphor were presented at the Washington, D.C., Meeting of The Electrochemical Society, May 1957, under the title "Electrocathodoluminescence." F. E. Williams in his keynote speech before the Luminescence Symposium of this Society in 1955 suggested that in phenomena of this sort the first prefix indicate the controlling source and the second prefix the power source. As will be shown later, the experimental results indicate that the effect reported on here should be called "Cathodoelectroluminescence" in keeping with Williams' suggestion.

[2] All compositions are on a weight basis. Normally Destriau adds the activators as the chlorides but the presence of the halide is not necessary, at least for Mn alone. He finds, however, that the phosphors without chlorine are not as good as those containing chlorine.

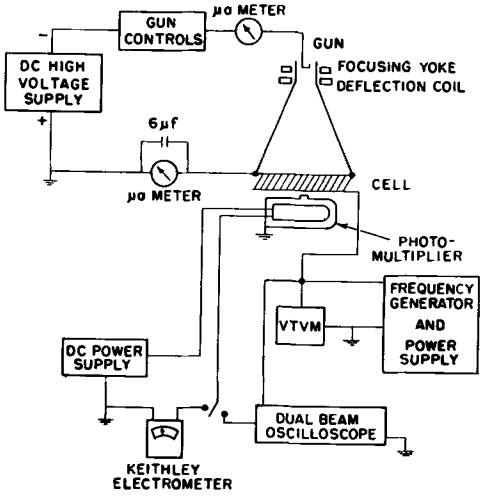

Fig. 1. Block diagram of the circuit used in the cathodoelectroluminescent studies.

The phosphors were made into cells 1 x 1 in. and approximately 2 mils thick using Nylon (DuPont FM6501) as the dielectric. The cells were prepared by coating the conducting surface of tin oxide-coated glass with a clear coat of Nylon, 0.5 mil thick (as measured with a micrometer), on which was superimposed a 1 to 1.5 mil thick layer of Nylon plus phosphor in a volume ratio of 1:1. The cell was completed by evaporating an approximately 1500Å thick layer of aluminum on the Nylon-phosphor layer. The cells were first tested under x-rays for uniform enhancement. The satisfactory cells then were examined in a continuously pumped, demountable cathode-ray tube. The tube was operated with the gun at negative high voltage while the aluminum electrode of the cell and the internal conducting coating of the tube were connected to ground. The gun was of the magnetically focused type, and a constant raster of approximately 5 cm² was used in all the measurements. The light output from the cell was detected with an RCA 1P22 photomultiplier and a Keithley electrometer. Provisions also were made for visual observations of the photomultiplier output on a dual-beam oscilloscope in order to study phase relationships. A block diagram of the test circuit is shown in Fig. 1.

Results

Studies of the enhancement effect were made as a function of accelerating potential, beam current density, and the frequency and strength of the applied field. The results of these measurements as well as several miscellaneous measurements and observations are given below. The results are reported in terms of the enhancement factor, ρ, which is defined by the expression

$$\rho = B/B_{cl} + B_{el}$$

where B is the light output under the action of both cathode rays and the field, B_{cl} is the normal cathodoluminescence and B_{el} is the electroluminescence, if any.

Enhancement as a function of frequency.—The enhancement effect was studied extensively over the range of 60-6000 cps; some measurements were also made between 20 and 60 cps using the ZnCdS:Mn,-Cl phosphor. With the Mn,Cl phosphor, ρ goes through a maximum around 30 cps and decreases toward a limiting factor of unity with increasing frequency (Fig. 2). Also, ρ decreases with increasing frequency for the Mn,Au,Cl phosphor, and, depending on the beam current density and field strength, may be less than unity, i.e., the output is quenched (Fig. 3).

Enhancement as a function of field strength.—The enhancement effect was studied over the range of approximately 10,000 to 60,000 v/in. since the use

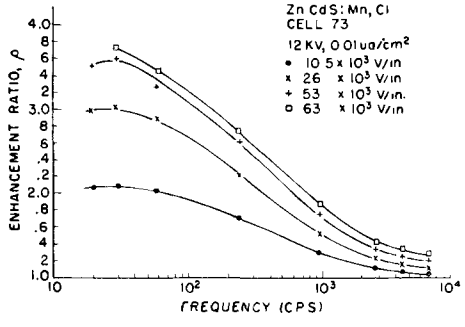

Fig. 2. Enhancement ratio, ρ, as a function of frequency for the (70Zn·30Cd)S:Mn,Cl phosphor at different field strengths.

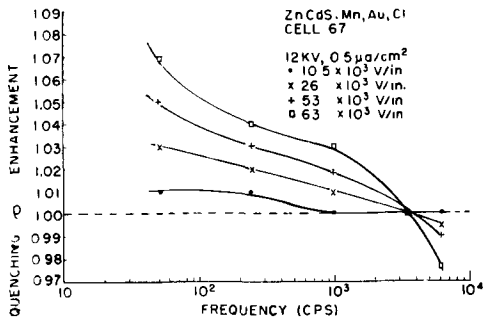

Fig. 3. Enhancement ratio, ρ, as a function of frequency for the (50Zn·50Cd)S:Mn,Au,Cl phosphor at different field strengths. At 12 kv, 0.5μa/cm² and field strengths between 26,000 and 63,000 v/in., quenching is found at frequencies above 3600 cps. Quenching is also found at 4 and 8 kv as discussed in the text.

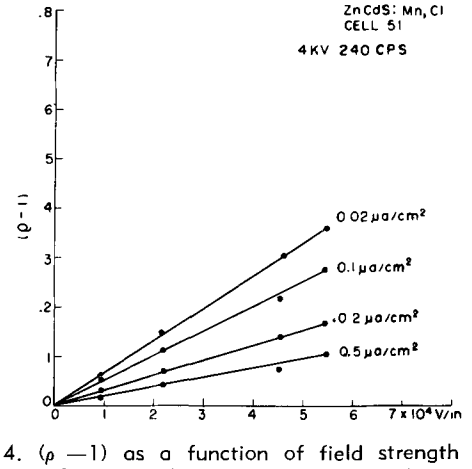

Fig. 4. $(\rho - 1)$ as a function of field strength for the (70Zn·30Cd)S:Mn,Cl phosphor. Notice the decrease in ρ with increasing beam current density over the range 0.02-0.5 μa/cm².

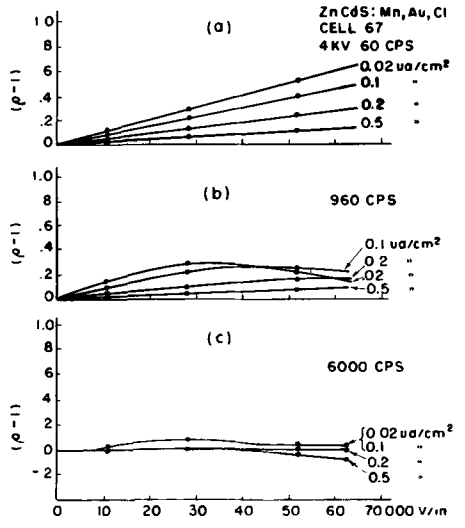

Fig. 5. $(\rho - 1)$ as a function of field strength for the (50Zn·50Cd)S:Mn,Au,Cl phosphor. Note the decrease in ρ with increasing frequency, field strength, and beam current density.

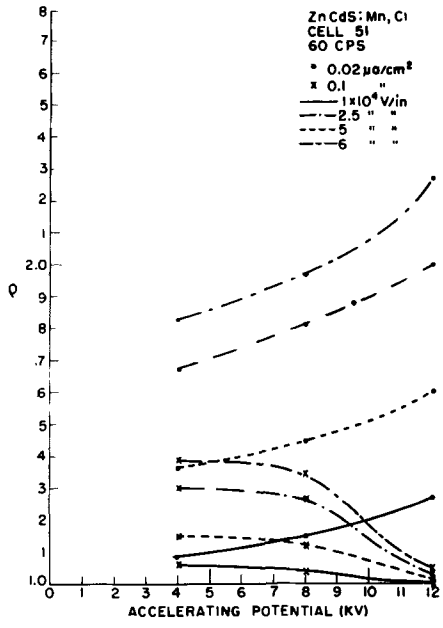

Fig. 6. Enhancement ratio, ρ, as a function of accelerating potential for the (70Zn·30Cd)S:Mn,Cl phosphor. At low beam current densities ρ increases with increasing accelerating potential over the range 4-12 kv; at high beam current densities ρ decreases with increasing accelerating potential. The value of the beam current density at the cross-over point between the two kinds of behavior varies from cell to cell. A similar behavior is observed for the (50Zn·50Cd)S:Mn,Au,Cl phosphor.

of higher fields resulted in arcing which deteriorated the cells. With the Mn,Cl phosphor the quantity $(\rho-1)$ increases linearly with field strength (Fig. 4). The quantity $(\rho-1)$ also increases linearly with increasing field strength for the Mn,Au,Cl phosphor at low frequency (60 cps) and 4 kv. As the frequency increases there is a negative deviation from linearity; the curves obtained at 0.02 and 0.1 μa/cm^2 first show the deviation, but as the frequency increases the 0.2 and 0.5 μa/cm^2 curves also deviate. In the frequency range of 3800-6000 cps there is quenching at high field strengths. This behavior is shown in Fig. 5. At 8 and 12 kv the quantity $(\rho - 1)$ is linear except at 6000 cps where quenching is observed at a beam current density of 0.2 and 0.5 μa/cm^2 and high field strengths.

Enhancement as a function of beam current density.—The effect of beam current density on the enhancement factor was studied over the range of 0.01 to 0.5 μa/cm^2 for the Mn,Cl phosphor and 0.02 to 0.5 μa/cm^2 for the Mn,Au,Cl phosphor. At higher current densities, or for long times of bombardment at the lower current densities there is some decomposition of the Nylon as evidenced by its acquiring a brown discoloration. Because of this, measurements at high current densities were taken after those at lower densities. Between measurements, the current was either lowered or turned off.

The enhancement factor is strongly dependent on the beam current density as can be seen in Fig. 4 and 5. Maximum enhancement occurs at the lower densities and decreases with increasing current density. This decrease in enhancement with increasing incident energy is not limited to the present studies but also is found with several of the other enhancement effects mentioned earlier (3-7, 9).

Enhancement as a function of accelerating potential.—The effect of accelerating potential was studied over the range of 4-12 kv. The results are a little erratic and depend on the beam current density, field strength, and frequency. In general the enhancement factor increases with increasing accelerating potential for low current densities and decreases for high current densities (Fig. 6). The value of the beam current density at the cross-over point between the two kinds of behavior varies from cell to cell, the range being from 0.1-0.5 μa/cm^2.

Brightness waves.—Brightness waves from cells made with the Mn,Cl phosphor were observed on a dual-beam oscilloscope. These were displayed in two different ways. In one method, the photomultiplier output was fed into one set of vertical deflection plates and the alternating voltage across the cell into the other set. The two channels were locked together so that the signals were synchronized. This resulted in a linear trace that showed the time relationship of the two curves. In the second method a trace similar to a Lissajous figure was obtained. This was accomplished by connecting the photomultiplier output to one set of vertical plates and the alternating voltage across the cell to both sets of horizontal plates. The two channels were locked together and the horizontal traces superimposed. In this way one channel, the one having only the horizontal signal, acts as a zero reference while the other shows the brightness wave form as a function of voltage.

The study of the wave form was made at beam current densities of 0.01 and 0.02 μa/cm^2 at variable frequency, field strength, and accelerating potential. The brightness waves show two peaks per cycle of applied voltage, with one peak generally larger than the other (Fig. 7 and 8). The brightness peaks appear after the voltage maxima, as can be seen in the figures. This is similar to the brightness waves obtained during the electroluminescence of Mn-

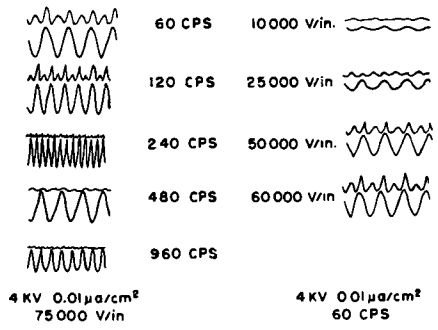

Fig. 7. Linear display of brightness and voltage wave forms for the (70Zn·30Cd)S:Mn,Cl phosphor. The curves on the left showe the influence of frequency and those on the right the influence of field strength. The bottom curve of each pair of curves is the voltage wave form.

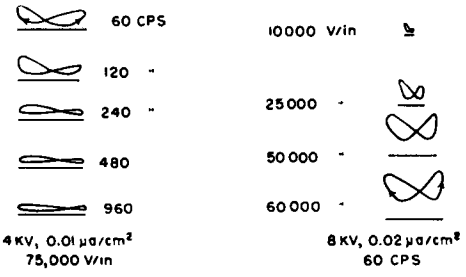

Fig. 8. Lissajous-type of display showing, on the left, the influence of frequency and, on the right, the influence of field strength on the brightness waves of the (70Zn·30Cd)S:Mn,Cl phosphor. The transparent conducting electrode is negative to the left and positive to the right. The direction of the trace is shown by arrows.

activated zinc sulfide phosphors (15). On increasing the field strength both peaks generally increased proportionally. In general the larger peak occurred after the transparent electrode became positive. On increasing the frequency of the applied field, the brightness waves shift slightly to later times, the magnitude of the shift varying from cell to cell. There also appears to be some field strength dependence of the brightness peaks, but the dependence is very erratic. The shift with increasing field strength is also to later times. Variations in beam current density and accelerating potential seem to have little, if any, effect on the waveform relationships.

Examination of the wave form shows the presence of two components, an a-c component superimposed upon a d-c component (Fig. 8). On increasing the field strength, at constant frequency, both the a-c and the d-c components increase, with the amplitude of the former increasing the faster. On increasing the frequency at constant field strength, the d-c component decreases slightly while the amplitude of the alternating component decreases fairly rapidly.

Miscellaneous observations.—In addition to the enhancement effect there is also a Gudden-Pohl effect. Immediately after the application of the field to a cell under cathode-ray excitation there is a rapid increase in brightness to some maximum value followed by a rapid decrease to a constant value which is higher than the initial cathodoluminescence. This permanent increase in light output here has been called the enhancement effect. Removal of the field also causes a transient brightness increase which decreases rapidly to the original field-off value. Both the magnitude and the decay time of the transient component increase with increasing field strength. Equilibrium was usually obtained within 5 sec after the application or removal of the field.

Relative brightness obtained with the enhancement effect.—In order to compare the relative brightness obtained with cathodoelectroluminescence with that of the usual P4 phosphor,[3] cells were prepared using a P4 phosphor (RCA #33Z259). Table I shows the results of brightness measurements (no field) for different beam current densities and accelerating potentials. An RCA 1P22 photomultiplier corrected for eye sensitivity was used in making these measurements. The enhancement ratio used for a given exciting condition is the maximum that was obtained under those conditions, i.e., for any value of frequency. The brightness with field acting was obtained by multiplying the brightness of the ZnCdS:Mn,Cl phosphor, no field acting, by the selected value of the enhancement ratio. As can be seen from Table I, depending on the exciting conditions,

[3] The phosphor used in black-and-white television, designated P4, is in reality a mixture of two phosphors, one (ZnS:Ag) having a blue emission and the other (ZnCdS:Ag) a yellow emission.

the P4 phosphor is approximately 5-35 times brighter than the field-enhanced ZnCdS:Mn,Cl phosphor.

Discussion

An increase in light output is observed when an alternating electric field is applied to a 2-mil thick cell made with (70Zn·30Cd)S:Mn,Cl phosphor or, under certain conditions, with (50Zn 50Cd)S:Mn,-Au,Cl phosphor which is under cathode-ray excitation. As can be seen from Fig 9, the total light output (B) is greater than the sum of the electroluminescence (B_{el}) and the cathodoluminescence (B_{cl}). The enhancement ratio, ρ, is found to depend on several factors, the most important being the frequency and strength of the applied field, the accelerating potential, and the beam current density. The Mn,Cl phosphor has the brighter cathodoluminescence and also the larger enhancement factor (Table II).

In many respects the behavior of the ZnCdS:-Mn,Au,Cl phosphor is similar to the ZnCdS:Mn,Cl phosphor. The major differences are: (a) quenching occurs with the former phosphor at 4, 8, and 12 kv at high beam current densities, high field strengths, and high frequencies. (b) The quantity (ρ -1) as a function of field strength is linear for the Mn,Cl phosphor but may have a negative deviation from linearity at 4, 8, and 12 kv for the Mn,Au,Cl phosphor depending on the frequency, field strength, and beam current density.

Several characteristics of this effect are similar in nature to ordinary electroluminescence, i.e., the shape and number of brightness waves per cycle of applied field, the increase in ρ with field strength, the effect of frequency on the a-c component of the light output, and the possible shift of the brightness peaks with frequency (16). There are also some dissimilarities, the main ones being the decrease in ρ with increasing frequency and the apparent shift of the brightness waves to later times with increasing field strength.

This new enhancement effect is somewhat similar to some of the other enhancement effects in that there is a decrease in enhancement with increasing high exciting intensity (3-7, 9). The x-ray and

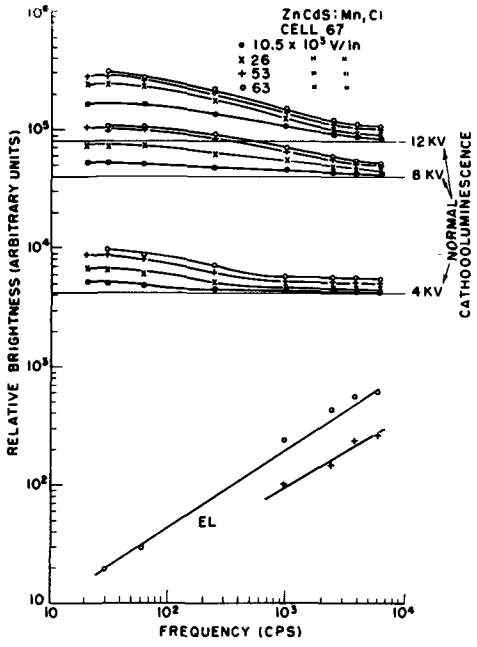

Fig. 9. Relative brightness of the enhanced cathodoluminescence and the electroluminescence of (30Zn·30Cd)S:Mn,Cl phosphor. Beam current density 0.01 $\mu a/cm^2$.

cathode-ray enhancement effects differ with respect to frequency in that there appears to be little frequency dependence for x-ray enhancement. This may be related to the difference in penetration between x-rays and cathode-rays.

Because of the preliminary nature of this work no conclusive theory can be developed at this time for the cathodoelectroluminescent effect. From the general behavior of this effect and the similarity to ordinary electroluminescence, it would appear that the effect is fundamentally radiation-controlled electroluminescence and is similar to the mechanism proposed by Williams for Cusano's and Destriau's enhancement effects (17). Recently, however, Curie (18), Destriau, (19), and Ivey (20) have concluded that the field-enhancement effect observed by Destriau does not have the same mechanism as that observed by Cusano. This presumably can be extended to the effect reported on here. Because of the complexity of cathodoluminescence in general and of the present effect, it may be extremely difficult to elucidate the enhancement mechanism.

Acknowledgments

The writer would like to thank Mr. E.G.F. Arnott and Dr. H. F. Ivey for suggesting this project (21) and Professor G. Destriau for supplying the information relating to the preparation of the ZnCdS:Mn,Cl phosphor and for the sample of the ZnCdS:Mn,Au,-Cl phosphor. Thanks also are due to Mr. G. Scanlon for his help in cell preparation and for obtaining some of the measurements. Acknowledgment should also be made to Drs. H.F. Ivey and W.A. Thornton for their advice and aid in solving some of the circuit problems and for the many valuable discussions held with them.

Manuscript received Dec. 15, 1958. This paper was prepared for delivery before the Washington Meeting, May 12-16, 1957.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Influence of Hydrogen on the Red ZnS-Cu Fluorescence

W. van Gool and A. P. D. M. Cleiren

Philips Research Laboratories, N. V. Philips' Gloeilampenfabrieken, Eindhoven, Netherlands

ABSTRACT

Self-coactivated ZnS-Cu phosphors were made by firing in different atmospheres. When H_2S/H_2 mixtures were used, the red fluorescence decreased with increasing amounts of hydrogen. With A/S_2 or with N_2/S_2 atmospheres no red fluorescence was obtained. These experimental results can be summarized by stating that, in order to obtain the red fluorescence, hydrogen must be incorporated into the phosphor and the sulfur pressure must be sufficiently high. The hydrogen either forms a part of the red center or it destroys or replaces a killer center that prevents the occurrence of red fluorescence when hydrogen is absent. In connection with the high sensitivity of the red fluorescence to small amounts of impurities it is suggested that the concentration of the red centers is much smaller than the amount of incorporated copper.

Some years ago Froelich (1) made an extensive study of the red fluorescence obtained by activating ZnS with Cu without coactivators such as chlorine or trivalent ions. Recently new data on the preparation of these powders and their properties were reported by Aven and Potter (2). In spite of this work it is as yet not possible to give a model of the structure of the centers which would account for this red fluorescence.

In our own investigations, which confirmed the more important facts given by the above-mentioned authors, we wanted to make sure that hydrogen had no influence on the red fluorescence. In view of the fact that most powders had been in contact with an atmosphere containing hydrogen in one way or another, the role of hydrogen should not be disregarded entirely. The experiments indicate that indeed hydrogen must be incorporated into the lattice in order to obtain the red fluorescence, as is described in the next sections.

Preparation of Powders and Firing Conditions

Several phosphors were made in gas atmospheres containing H_2S, S_2, and H_2. A fluorescent grade ZnS, precipitated from an acid $ZnSO_4$ solution, was used. By chemical analysis about 0.4% SO_4 and 0.003% Cl were found in the starting material. Spectrographical analysis showed 0.0005-0.0010% Pb and the other impurities were below their detection limit (all percentages are given by weight). The ZnS was wetted with a $CuSO_4$ solution, dried at 90°C, and mixed. The concentration in these phosphors was 10^{-4} gram atom Cu per mole ZnS.

The H_2S was taken from tanks. In the earlier stages of this research the H_2S was washed with an acid $CrCl_2$ solution to eliminate O_2 (3), with a solution of NaHS to eliminate HCl, and then dried over P_2O_5. At a certain stage of this investigation the red ZnS-Cu emission could not be reproduced. A careful investigation of the working conditions indicated that a change-over from one tank of H_2S to another was the cause of this failure. Further investigation showed that some tanks contained only small amounts of CO_2, whereas others contained about 1% CO_2. For this reason the H_2S was also washed with $Ba(OH)_2$ solution in the later stages of this research. The H_2S gas may contain small amounts of methylene chloride that are not removed by the purification technique used in these experiments. There was, however, no indication from the fluorescence of the powders that this impurity interfered with the result.

Hydrogen, nitrogen, and argon were taken from tanks and were of the purest quality available. In some experiments they were washed with an acid $CrCl_2$ solution, with a KOH solution, and then dried over P_2O_5. In other cases traces of oxygen were re-

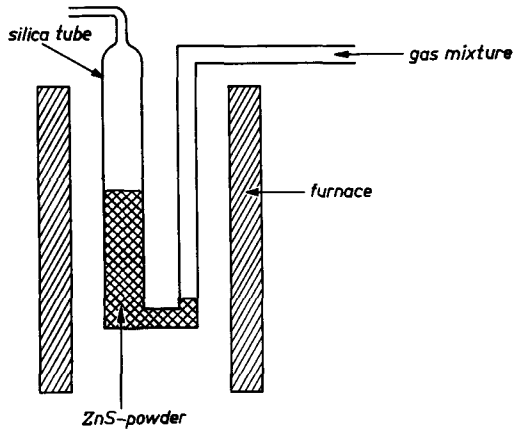

Fig. 1. Firing method used normally

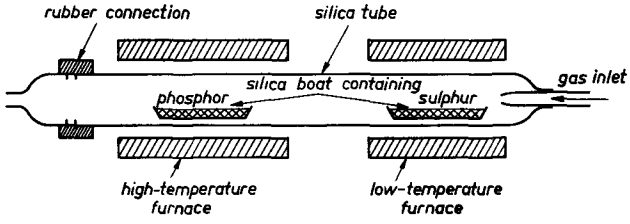

Fig. 2. Firing method used for producing sulfur-containing atmospheres.

moved from the nitrogen by means of a copper oven. When necessary the gases were mixed first and then passed through one purifying set. The sulfur used was of high purity: the only impurity found by spectrographical analysis was 0.00003% (by weight) of Cu.

Two different firing techniques were used. The first one, which was used in most of our experiments, is shown in Fig. 1. The second one, shown in Fig. 2, was used when addition of sulfur to the gases was necessary. By changing the temperature of the sulfur-containing part of the silica tube and the gas-flow rate, different sulfur pressures were obtained. In both firing techniques the tubes with powder were placed in the furnace after the furnace had reached the required temperature; thus the powders reached the firing temperature within a few minutes.

All powders were cooled as rapidly as possible. In the first firing technique this was done by immersing the firing tube in water; in the second one the outside tube was flooded with water.

Several cross experiments were made. Some powders were fired with both setups in order to make sure that no unexpected factors were important. Except for the case already mentioned, no significant differences were found.

AC 531	Fig. 1	H_2 purified	100	44/56

Three powders were fired in pure H_2S; some details of the firing conditions are given in Table I.

A second set of fluorescent powders was obtained by firing in H_2S/H_2 mixtures, as detailed in Table II.

A third series of phosphors was made by firing in H_2S/S_2 mixtures (Table III; AC 535, AC 536, and AC 537).

One single phosphor was made by passing pure H_2 over sulfur (Table III, AC 543).

In a fourth series nitrogen or argon were used as carrier gases. Powders AC 528, AC 529, AC 530, and AC 550 were obtained by passing the nitrogen over sulfur. AC 549 was fired in argon carrier gas (Table IV). The powders AC 533 and AC 534 were made by passing a N_2/H_2 mixture over sulfur.

In order to eliminate the effect of contaminations originating from the silica walls, ZnS-10^{-4} Cu was fired in two new vessels (Fig. 1). In each tube four firings were made in purified hydrogen. One tube was cleaned in the normal way after each firing. The second tube was not cleaned between the firings, the powder was merely shaken out (AC 551-AC 557).

Observations and Measurements

The fluorescence of the powders described in the preceding section was studied with 3650Å excitation. Although the relative brightness of the powders could be established easily by visual inspection of the powders, the measurement of the red fluores-

cence was difficult owing to the weakness of the red light emitted. The best method was to compare the luminance of a phosphor layer with that of a mat surface by means of a Lommer-Brodhun photometer containing a Schott red RG1 filter in the eyepiece. The mat surface was illuminated by an incandescent lamp, and the lamp voltage was varied so as to match the luminance of both surfaces. Every measurement was repeated two or three times, and the average of the lamp voltages was used in the calculation. The red luminance (as seen through a Schott red RG1 filter) of the mat surface at different voltage settings was calibrated with a laboratory luminance meter. The luminance of one phosphor layer (AC 538) arbitrarily was given the value 100. Calculated values of the luminance of the phosphor layers are summarized in Table V.

Phosphors made in low sulfur pressure or made in atmospheres without hydrogen did not show any red fluorescence; this corresponds to the values below the minimum value detectable with the luminance meter (about 6 units). They had a weak green or green-blue fluorescence. This fluorescence was killed when infrared light was shone on the phosphors together with the u.v. at room temperature. No stimulation of an afterglow was found with infrared radiation. At low temperature (77°K) these phenomena were reversed: the fluorescence was not influenced by infrared, but a stimulation of the afterglow was found. During the stimulation, the emitted light had the same color as during u.v. excitation, and not the slightest indication of any red fluorescence was found.

It is well known that the red Cu-fluorescence has the important property that it is much more sensitive to impurities than the fluorescence of normally activated ZnS powders; small amounts of O_2, CO_2, or H_2O all disturb the red fluorescence (1, 2). When adding aluminum in the order of 10 mole % of the added amount of Cu, one finds a blue emission as strong as the red emission. We have confirmed these observations.

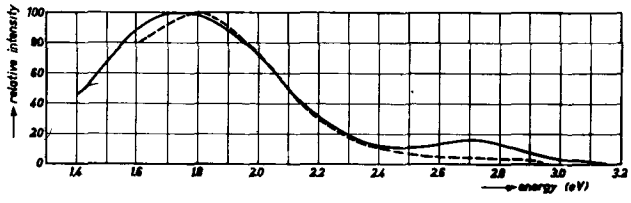

Fig. 3. Spectral distribution of red ZnS-Cu phosphor. ——— AC 538; measured at room temperature; - - - - - spectral distribution measured by Aven and Potter (2), Fig. 3 (x=0).

The spectral energy distribution was measured with the aid of a Leiss (Berlin) double mirror-monochromator with sodium chloride prisms. The 800 cps chopped radiation of the phosphor was imaged on the entrance slit of the monochromator. The output of the detector, amplified by a tuned a-c amplifier with synchronous detection, was recorded automatically as a function of the wave length.

The phosphor was excited by the radiation of a high-pressure mercury discharge lamp (the inner part of a Philips HP 125W lamp with stabilized discharge) from which the long wave length u.v. radiation was isolated by a combination of Schott filters UG11 and BG18. The BG18-filter was used to remove the transmission of the UG11 filter in the red part of the spectrum.

As a detector for the spectral region from 3.5 about to 1.65 ev a selected RCA photomultiplier (type IP28) was used with very high sensitivity in the red. For radiation of lower frequencies a Philips photomultiplier type 51CVP with Cs-O-Ag photocathode was used.

The relative emitted power of the phosphor was found from the recorded photocurrent by calibrating the equipment with the aid of a tungsten ribbon lamp with known spectral distribution. In Fig. 3 the spectral distribution of AC 538 is reported together with one of the distributions given by Aven and Potter (2).

Discussion

In describing the equilibrium system ZnS-sulfur vapor, the sulfur pressure is sufficient to define the oxidation-reduction state of the ZnS crystal. In that case the zinc pressure can be derived from the sulfur pressure according to the equation

$$p_{Zn} \cdot p_{S_2}^{1/2} = K_{ZnS} \qquad [1]$$

When hydrogen is also present in the atmosphere and when hydrogen is incorporated into the ZnS, the value of the hydrogen pressure must also be known in order to define the state of the ZnS powders. In equilibrium it is unimportant whether the presence of the hydrogen is defined by the hydrogen pressure itself, by the H_2S pressure, or by the pressure of some other hydrogen compounds, because these pressures are correlated by a relation of type [2]

$$\frac{p_{H_2}^2 \cdot p_{S_2}}{(p_{H_2S})^2} = K_{H_2S} \qquad [2]$$

A third equation is obtained from the condition that the total pressure is 1 atm, thus

$$p_{Zn} + p_{H_2} + p_{H_2S} + p_{S_2} = 1 \qquad [3]$$

A fourth equation is obtained from the relative amounts of gases or sulfur used during the experiment. In the case of pure H_2S this equation is

$$p_{H_2} = 2p_{S_2} \qquad [4a]$$

When 1 mole gas mixture, introduced in the firing vessel, contains p moles H_2 and $(1-p)$ moles H_2S and when, after establishment of the equilibrium, x moles S_2 have been formed, then we have

$$p_{H_2} = \frac{p + 2x}{1 + x}$$

$$p_{S_2} = \frac{x}{1 + x}$$

Thus, after elimination of x

$$p_{H_2} = p + (2 - p) \cdot p_{S_2} \qquad [4b]$$

In the same way a similar additional equation can be formulated for every experiment. We used $K_{H_2S} = 17 \cdot 10^{-3}$ atm (4) at 1100°C.[1]

The value $K_{ZnS} = 5.4 \cdot 10^{-5}$ atm$^{3/2}$ at 1100°C was calculated from reference (6). Recent measurements by Spandau and Klanberg (7) and Neuhaus and Retting (8) do not permit the calculation of the dissociation constant K_{ZnS}. The total pressures of ZnS, as measured by Spandau and Klanberg, deviate from the values used in (6), but there is no important influence on the main aspects of these calculations. Calculated pressures are given in Table VI.

p_{Zn} is always so small that one can use the equation

$$p_{H_2} + p_{H_2S} + p_{S_2} = 1 \qquad [3a]$$

instead of [3] when only H_2, H_2S, S_2, and Zn are present in the atmosphere. The relation obtained by eliminating p_{H_2S} from Eq. [1] and [3a] is represented by the heavily drawn line in Fig. 4. In the same figure the pressure points of the fired powders are indicated. All pressures were calculated with the assumption that all equilibria were actually established. In some cases the sulfur pressure was lower than the minimum sulfur sublimation pressure of ZnS ($9.1 \cdot 10^{-4}$ atm) and thus the zinc pressure higher than the minimum zinc pressure. Then the question arises whether the gas flow is slow enough to provide sufficient time for the equilibria to be established (9). If this is not the case, the pressure will be stabilized on the minimum sublimation line. This has been indicated in Fig. 4 by arrows pointing to some powders (AC 499, AC 532, AC 511, AC 551-AC 557, and AC 528). As none of these powders has any red fluorescence (see below), the question of the exact localization of the firing conditions in the pressure diagram is not important.

[1] From the tables of (5) a value of $K_{H_2S} = 18.5 \cdot 10^{-3}$ atm was calculated. The difference between this constant and the one we used results in a relatively unimportant change in the pressure calculations.

Table VI. Calculated H_2 and S_2 pressures under equilibrium conditions, $T = 1100$°C

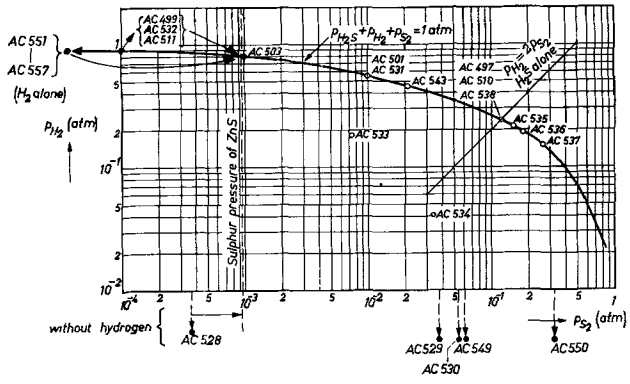

Fig. 4 Sulfur and hydrogen pressures used during preparation of the powders at 1100°C.

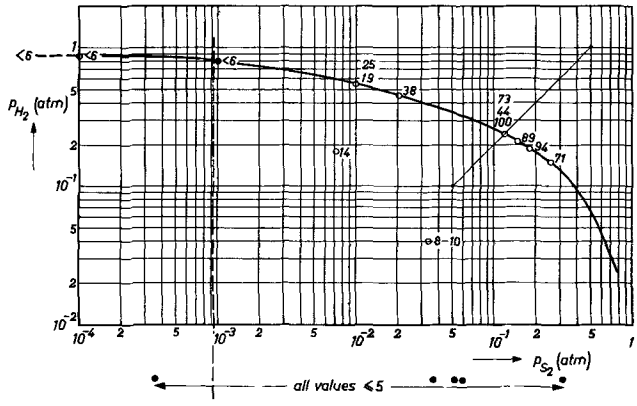

Fig. 5. Measured red fluorescence (in arbitrary units). The location in the pressure diagram corresponds with Fig. 4.

In order to facilitate the review of experimental results, the measured red fluorescence of the powders is inscribed at the respective pressure points in Fig. 5. From this figure it is immediately clear that two conditions had to be fulfilled in order to obtain the red fluorescence: (*a*) there must be hydrogen in the atmosphere, and (*b*) the sulfur pressure must be sufficiently high.

Unless these results are caused by impurity effects (see below), the first condition means that hydrogen is incorporated into the ZnS powders. At this time it is not possible to decide whether the hydrogen forms really a part of the red fluorescent center. The other explanation would be that without hydrogen the red centers would be present but that some other center kills the red fluorescence. Adding hydrogen then would transform the killer center into a harmless one. As there is, however, no evidence in our

work for the presence of the red centers in the powders fired without hydrogen, we prefer the first explanation.

Some doubt may be thrown on this conclusion on the basis of a few experiments described by Aven and Potter (2). They reported that firing ZnS-Cu in hydrogen first gave a blue fluorescence, but that repeated firings in the same vessel finally gave a red fluorescence. The authors interpreted their results with the transfer of a certain impurity (for instance aluminum) from the silica wall to the powder. We have found in some cases that the outside of the sintered powders did show a different fluorescence than the core, but this was restricted to a thin outer shell and the bulk of the powders was always homogeneous. Firing in hydrogen alone produced no red fluorescence, although the firings were repeated four times in the same vessel. Moreover, comparison of the powders AC 499, AC 503, AC 501, AC 543, and AC 497 (Table II) shows that the change in hydrogen pressure is rather small (by a factor of 4), but that the sulfur pressure changes at least by a factor of 100. The red fluorescence disappears completely at lower sulfur pressures in this series, and it seems improbable that a large change in impurity transfer should be brought about by a rather small change in hydrogen pressure. Therefore we believe that in the interpretation of our results we have to assume a direct influence of the sulfur pressure on the formation of the red fluorescence centers.

An important cross experiment is represented by the powders AC 533 and AC 534. With nitrogen no red fluorescence was found and with hydrogen the red fluorescence is decreased, as has been described above. Considering the great sensitivity of the red fluorescence to impurities it would be possible for some harmful impurity to have been introduced by each gas individually. But in using both gases together the red fluorescence was present again and thus the assumption about harmful gas impurities is made very improbable.

Some of the red fluorescent powders mentioned in (1) were made in a CS_2 atmosphere. This result is in conflict with the interpretation given in this paper. However, the experiments in (1) and (2) were not performed with the thought in mind that hydrogen in any form had to be removed carefully, and the experimental details necessary to settle this question are lacking in these papers.

Although the weakness of the red fluorescence as compared with that of strong red phosphors (for example color television phosphors) can be explained by assuming a small recombination coefficient in the kinetic mechanism, the assumption seems more probable that the concentration of the red centers is much smaller (by a factor of 10 to 100) than the added amount of Cu. Hence the occurrence of the red fluorescence centers results only in a minor change in the mechanism by which Cu is built into the lattice without hydrogen. This has three consequences. In the first place, the red fluorescence as such does not provide much useful information about the incorporation of Cu. In the second place, it is difficult to say anything definite about the structure of the red fluorescence centers so long as we do not know exactly the built-in mechanism of Cu. The diamagnetism of these ZnS-Cu phosphors, as found by Bowers and Melamed (10), can be interpreted as a diamagnetism of the majority of the built-in copper atoms. As long as we do not know the concentration of the red fluorescence centers the possibility that these centers are paramagnetic can not be excluded. Finally, this assumption can explain the high sensitivity of the red centers to impurities in a simple manner.

Perhaps one conclusion about the structure of the red fluorescence centers can be reached by comparing the red ZnS-Cu fluorescence with that of ZnS-Ag. According to the results published by Aven and Potter the red silver fluorescence has a spectral distribution different from that of Cu. Since hydrogen is also necessary for the red silver fluorescence the center must contain at least one metal (Ag or Cu) and one hydrogen atom or ion. As to the real nature of the center several possibilities arise depending on whether the impurities occupy substitutional or interstitial positions and on the valencies of these impurities.

In spite of the careful control of the preparative conditions a rather large spread in the luminance of the red phosphors was found, as can be seen from the powders fired in pure H_2S alone. Therefore it is impossible to give quantitative relationships between this luminance and the pressures used. Further investigations are necessary in order to find these quantitative relationships. In our opinion it is premature to give models for the red fluorescent centers as long as the experimental material is scarce and even partly contradictory.

Acknowledgments

The authors wish to express their thanks to Mr. H. J. M. Heyligers for his aid in the gas purifications and furnace construction. The assistance of Dr. P. M. van Alphen and Mr. A. H. C. Vliegen with the luminance measurement and of Dr. A. Bril with the measurement of the spectral distribution is gratefully acknowledged.

Manuscript received Jan. 7, 1959. This paper was prepared for delivery before the Philadelphia Meeting, May 3-7, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

The Fluorescence of Binary and Ternary Germanates of Group II Elements

H. Koelmans and C. M. C. Verhagen

Philips Research Laboratories, N. V. Philips' Gloeilampenfabrieken, Eindhoven, Netherlands

ABSTRACT

The fluorescence of binary and ternary germanates of Ca, Sr, Ba, Mg, and Zn with different activators was investigated. Germanate phosphors activated with Pb, Ti, and Mn are described. The ternary composition triangles are given together with the x-ray powder-diagrams of 23 hitherto unknown germanates.

A great deal of the research on inorganic phosphors has been concentrated on silicates. In contrast to this the germanates, which are closely related to the silicates, have drawn little attention. Only the orthogermanates of Mg, Zn, and Be have been investigated to some extent (1). For this reason it seemed worth while to investigate the fluorescence of germanates, also because nowadays pure GeO_2 is commercially available.

The work described in this article was done along the same lines and in close connection with the work of Klasens, Hoekstra, and Cox (2) on binary and ternary silicates. Most of the new germanates found are isomorphous with the corresponding silicates.

Preparation.—The starting materials used were reagent grade $CaCO_3$, $SrCO_3$, $BaCO_3$, $MgCO_3$, ZnO, and GeO_2. The activators, which included Pb, Ti, Mn, Sn, Ce, Bi, and Re, in form of solutions of their salts, were added in the required amounts to the raw materials. The suspension formed was evaporated to dryness and milled in a runner mill for 15 min. The blends were then heated in alundum crucibles in air at 1050°-1250° for 1 or 2 hr. In all cases 2 or 4% of the Ca-, Sr-, or Ba-carbonates used as base materials were substituted by the corresponding fluorides.

X-ray diagrams showed that this fluoride substitution greatly aided in quickly completing the reaction. It was shown by chemical analysis that after firing only a negligible amount of the fluoride was retained in the phosphors. The activator content was usually about 0.5 mole %. In order to prepare efficient phosphors an excess of free GeO_2 had to be avoided because GeO_2 absorbs u.v. radiation below 3150Å without giving any appreciable luminescence. The same is true for several of the germanates, especially those with a high GeO_2 content. This complication necessitated a careful choice of the composition with the aid of the phase diagrams to be discussed in section 3. X-ray diagrams of the fired powders were made with a North American Philips Geiger counter x-ray diffractometer using Co-K_α radiation.

Binary germanates.—The binary germanates found are listed in Table I together with the known binary silicates. The compounds labeled with the same letter in Table I are isomorphous. Our x-ray powder diagrams of the orthogermanates (2-1) of Ca, Sr, Ba, and Mg essentially correspond to those published by Ludekens (3). In contrast to Ludekens, who obtained only orthogermanates irrespective of the ratio of basic to acid oxides, we also found other compounds. Our mixtures were probably more reactive, especially because of the fluoride flux. The x-ray powder diagrams of the new 1-1, 2-3 and 1-2 germanates are given in Table II.

Ternary germanates.—The ternary germanates found are given in Table III together with the known ternary silicates. Table III shows that with the exception of the 2-1-2 BaMg- and BaZn-germa-

* $BaZn_2Ge_2O_7$ and $SrZnGe_2O_6$ are rather unstable. Lines of other compounds, especially of Zn_2GeO_4, also occur in the x-ray diagrams of these powders.

nates all corresponding germanates and silicates are isomorphous. This was confirmed by the formation of uninterrupted series of solid solutions. The x-ray powder data of the new ternary germanates are given in Tables IV-VII. The 2-1-2 germanates (Table IV) are all isomorphous with $Ca_2ZnSi_2O_7$ (hardystonite) and $Ca_2MgSi_2O_7$ (akermannite) which are tetragonal. The diagrams could readily be indexed. Cell dimensions are given in Table VIII in which it is seen that the corresponding Zn- and Mg-compounds have practically the same cell dimensions.

The 3-1-2 compounds occur only in the systems containing magnesium. $Sr_3MgGe_2O_8$ and $Ba_3MgGe_2O_8$ are isomorphous with $Ca_3MgSi_2O_8$ (merwinite) which is orthorhombic. With this knowledge the x-ray diagrams could be indexed (Table V) and the unit cell dimensions could be calculated.

$Sr_3MgGe_2O_8$	a = 5.5	b = 9.6	c = 7.3
$Ba_3MgGe_2O_8$	a = 5.7	b = 10.0	c = 7.4

$CaMgGe_2O_6$, $CaZnGe_2O_6$, and $SrMgGe_2O_6$ (Table VI) are isomorphous with $CaMgSi_2O_6$ (diopside), which is the only compound with this structure in the ternary silicate systems. $SrZnGe_2O_6$ and $BaMgGe_2O_6$ are isomorphous but have no diopside structure.

Sufficient firings were made to construct the composition phase triangles shown in Fig. 1. The final phases produced by the firing of compositions falling on conjugation lines are given by the compounds at the end of the lines. The final phases produced by the firing of compositions falling within the triangles are given by the compounds at the apexes of the triangles.

Activation with Pb.—The binary germanates did not give efficient phosphors with Pb activation. Of the ternary compounds the 2-1-2 BaMg-, SrMg-, BaZn-, and SrZn-germanates gave u.v. emitting phosphors. The emissions are given in Fig. 2 together with those of the corresponding silicates. The phosphors are excited strongly only with 2537Å. It is

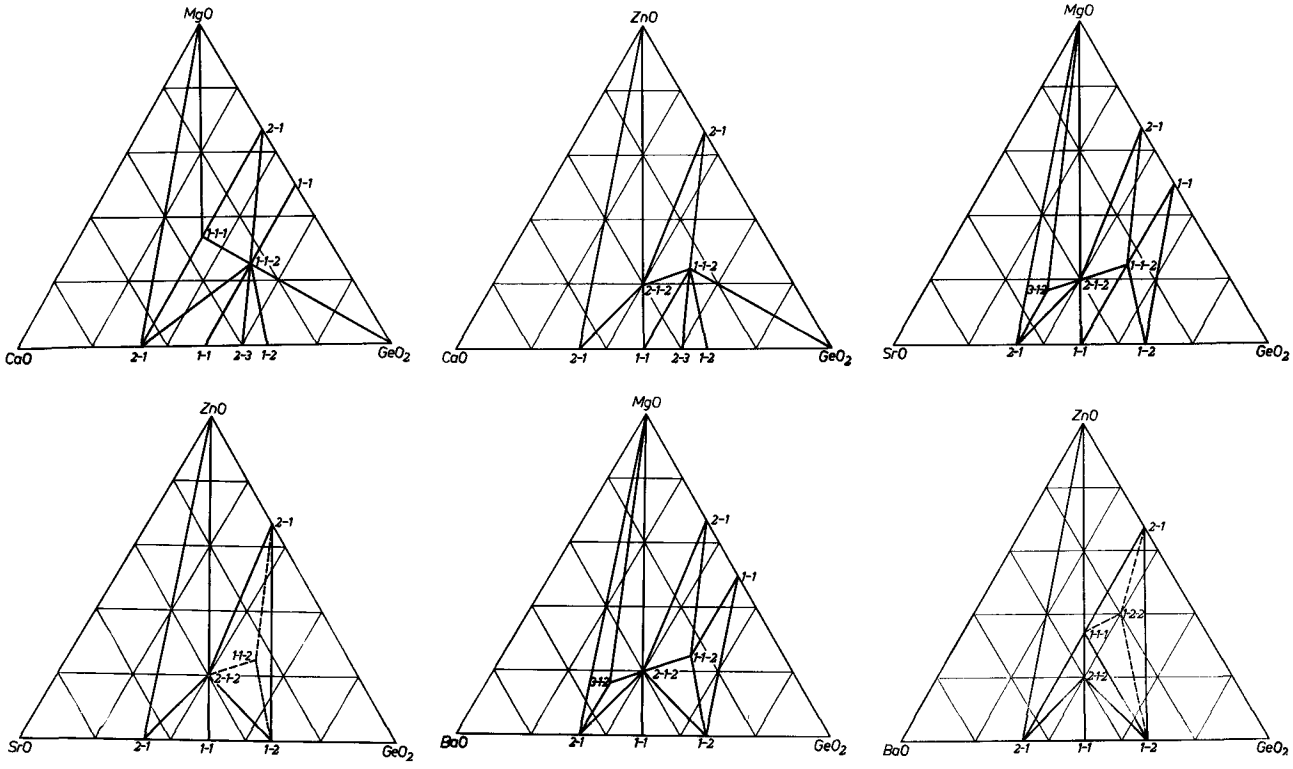

Fig. 1. Composition phase diagrams of the ternary germanate systems.

seen from Fig. 2 that the peak of the Pb emission in the germanates is at several hundred Å longer wave lengths than it is in the silicates. The 2-1-2 Pb-activated BaMg- and SrMg-germanates can be made with about the same efficiency as the corresponding silicates. The efficiency of the Pb-activated 2-1-2 BaZn-, SrZn-, and CaZn-germanates is much lower. An explanation for this can be given easily with the aid of Fig. 3, where the shaded parts are the triangles which contain one or more phases with an inefficient u.v. absorption. These phases are given by circles at the apexes. This means that compositions falling in the shaded areas have a low efficiency due to the presence of those undesired phases. It is also seen from Fig. 3 that in the Zn-containing compounds the whole area around the 2-1-2 com-

position is shaded. Since in our firing experiments the reaction was never entirely complete, nonluminescent absorbers could not be avoided in these cases. In the systems containing Mg there are unshaded triangles around the 2-1-2 composition. In fact the efficient Mg-containing phosphors were made by firing compositions falling within these favorable triangles.

Activation with Ti.—Of the binary and ternary germanates only $Ca_2Ge_3O_8$ gave an efficient emission with Ti. The spectral distribution with 2537Å excitation is given in Fig. 4 which shows that the emission of the $Ca_2Ge_3O_8$-Ti closely corresponds to that of blue-emitting, Sb-activated calcium halophosphate (Cl/F = 1). The quantum efficiency of the germanate phosphor is the same as that of the halophosphate or slightly better. The activator was added from a solution of $TiCl_4$ in a mixture of alcohol and water. The intensity of the emission does not vary much between 0.05 and 0.5 mole % of Ti, a concentration of about 0.1 mole % being the optimum. In the preparation of the phosphor a slight excess of GeO_2 was taken, because the occurrence of small amounts of the 2-1 germanate (cf. Fig. 1), which also gives a fairly strong emission, is less harmful than the occurrence of the 1-1 compound which does not give an appreciable emission with Ti. The phosphor was made in one single firing at 1150°C for 1 hr. The $Ca_2Ge_3O_8$-Ti is not efficiently excited by cath-

ode rays or long-wave u.v. In samples activated with Ti and Mn no sensitization of a Mn emission by the Ti was found. The temperature dependence of the Ti emission is shown in Fig. 5. The reflection spectrum of the unactivated and activated phosphor together with the excitation spectrum of the Ti emission are given in Fig. 6.

Activation with Mn.—Of the other activators tried in the binary and ternary germanates, e.g., Mn, Sn, Ce, Bi, and Re, only Mn gave a noticeable emission in $Ca_2Ge_3O_8$ with cathode-ray excitation. The peak of the emission is in the orange-yellow region; the en-

ergy efficiency is about 2%. The optimum Mn concentration is about 0.8 mole %. In order to obtain proper incorporation of the Mn the phosphors had to be fired in N_2.

Conclusions

The fluorescence of binary and ternary germanates of group II elements has been investigated. $Sr_2MgGe_2O_7$-Pb and $Ba_2MgGe_2O_7$-Pb proved to be good u.v. emitting phosphors. $Ca_2Ge_3O_8$-Ti was found to be a good blue emitting phosphor.

Thermoluminescence and Shallow Traps In ZnS:Cu:Co

B. Goldstein[1] and J. J. Dropkin

Polytechnic Institute of Brooklyn, Brooklyn, New York

ABSTRACT

Trapping states of the hexagonal ZnS:Cu 10^{-4}:Co 10^{-6} phosphor were investigated by thermoluminescence as functions of the time and temperature of ultraviolet (u.v.) excitation and of the time and temperature of spontaneous or *IR* induced decay. The main copper (chloride) and cobalt peaks are complex, and retrapping takes place in both.

In connection with some work on photoconductivity, quenching, and stimulation of the ZnS:Cu-10^{-4} mole %:Co 10^{-6} mole % phosphor, we found it advisable to investigate the shallow trap structure and used thermoluminescence as one of the methods(1-4). This paper reports the results of the glow curve work on the nature of the shallow trap distribution. Some estimate of the trap energies is obtained from the initial slope of the glow curves (4). The presence of retrapping was shown by temperature recycling experiments(3). Some of the properties of the *IR* sensitivity of the traps were studied. A measure of the complexity of the trap distribution was obtained by varying the time and temperature of excitation as well as by introducing a delay time for decay of the trap population before running the glow curves.

Experimental Details

The apparatus used in our glow curve work is illustrated in Fig. 1. This was a metal-glass Dewar with a thin layer of the phosphor powder mounted in the vacuum in contact with a brass block which was cooled or heated by liquid nitrogen or a nichrome heater. The heating rate was 3.6°C/min.

The Dewar was so situated that the phosphor and a photomultiplier were located at conjugate foci of a spherical mirror. The phosphor was excited by 3650Å u.v. radiation or stimulated by *IR* from a monochromator through a hole in the mirror. The luminescence reaching the photomultiplier first was filtered so that only the characteristic green Cu emission was measured.

The phosphors used were prepared by firing at 1100°C with NaCl flux in an atmosphere of H_2S to eliminate the effect of oxygen on the trap structure (4).

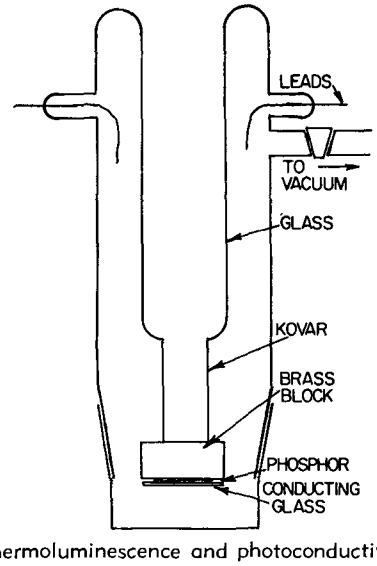

Fig. 1. Thermoluminescence and photoconductivity Dewar

Results

Effect of time and temperature of excitation.— Figure 2 shows some typical glow curves taken under saturation conditions of excitation for excitation at −178° and at −60°C. Curve A is the glow curve after 30-min excitation and 13 min of decay at −178°C. The low-temperature peak, attributable to copper (3) or to chloride (4),[2] is at −123°C and seems simple as in Hoogenstraaten's work (4). The high-temperature peak, attributable to Co (5), is at + 60°C and shows some structure. The activation energies derived from the initial rising portions of these peaks under the assumption either of trap saturation or of no retrapping are 0.16 ev and 0.20 ev, respectively. With the phosphor excited at −60°C, cooled to −178°C, and then warmed, curve

[2] In what follows, we will refer to the lower temperature glow peak found in ZnS:Cu (NaCl flux) as the Cu peak.

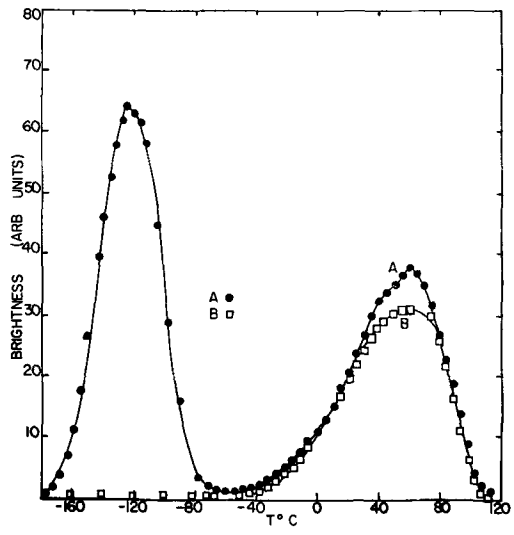

Fig. 2. ZnS:Cu:Co glow curves. A, Excitation: —178°C for 30 min, decay of 13 min at —178°C before glow curve run; B, excitation: —60°C for 30 min, cooled to —178°C before glow curve run.

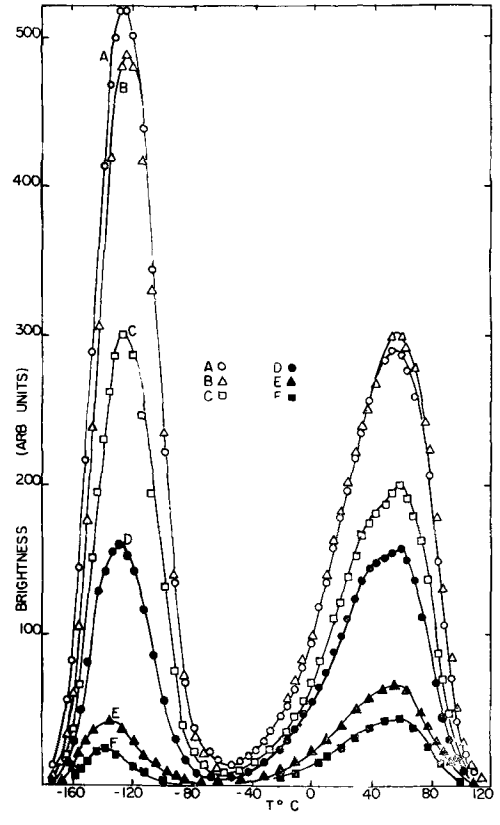

Fig. 3. Effect of time of excitation on ZnS:Cu:Co glow curves: A, 60 min; B, 5 min; C, 1 min; D, 10 sec; E, 5 sec; F, 2 sec (all at —178°C).

B is obtained. The first peak has disappeared, and now with no interference from the trailing edge of the lower temperature peak, the rising portion of the Co peak gives an activation energy of 0.38 ev.

When we studied how this trap or group of traps fills under excitation and empties under decay or *IR* stimulation, the simple structure apparent in the smooth shape of the Cu peak turned out to be nonexistent.

We investigated first the trap filling process by exciting the phosphor at — 178°C for various lengths of time from 2 sec to 60 min. The results are given in Fig. 3. Saturation is seen to occur in approximately 5 min. We note that, as the excitation time was reduced, the Cu peak shifted to lower temperatures and the ratio of the Cu peak area to the Co peak area decreased.

The latter point seems to indicate either that the Co trap has a larger cross section for u.v. excited electrons than the Cu trap or that Co traps retrap electrons released from Cu traps. The former suggests that the Cu glow peak is due to a trap distribution rather than a single trap. A single trap which did not retrap liberated electrons would produce an unchanged glow peak. A single trap which did retrap liberated electrons would have a *higher* temperature glow peak when only partly filled than when completely filled. Activation energies obtained from the initial portions of the respective glow curves vary from 0.11 ev for 2-sec excitation to 0.16 ev for saturation.

The Co peak does not shift with excitation time. Activation energies obtained from the leading edge do vary from 0.21 ev for saturation to 0.23 ev for 2-sec excitation, but the effect of the trailing edge of the Cu peak could not be eliminated in any of these cases.

In order to study the trap distribution of the Cu peak by another means, the phosphor was excited at successively higher temperatures and then cooled to — 178°C before warming. Figure 4 shows the glow curves obtained with excitation at — 178°, — 140°, —120°, and — 100°C before running the glow curves from — 178°C. These glow peak temperature shifts could be consistent with the behavior of a partly filled set of traps all of the same energy if they could retrap released electrons. However, in view of the previous results these

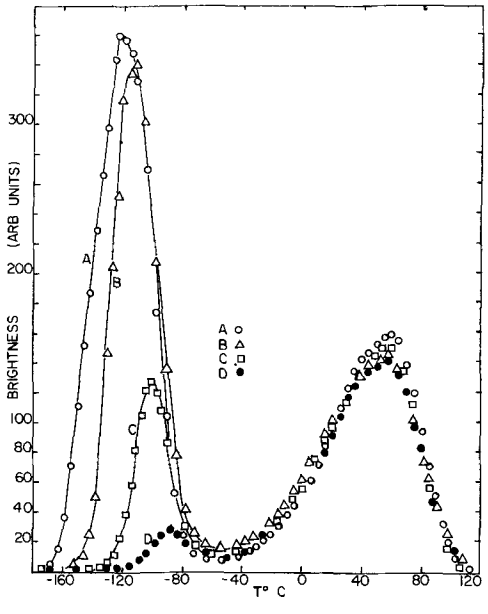

Fig. 4. Effect of temperature of excitation on ZnS:Cu:Co glow curves. Temperature of excitation for: A, —178°C; B, —140°C; C, —120°C; D, —100°C (all glow curves run from —178°C).

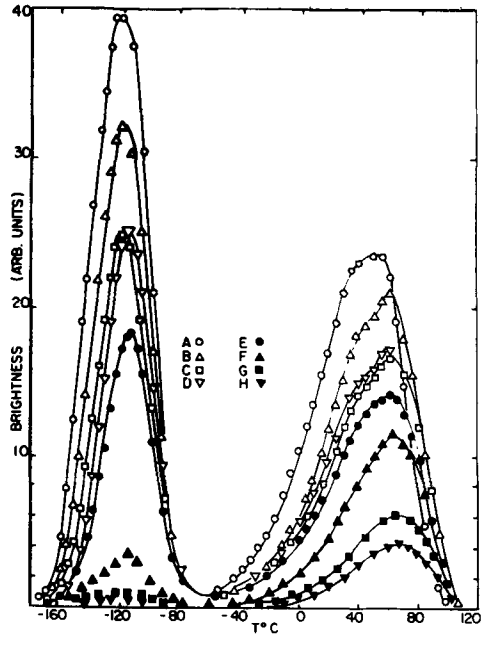

Fig. 5. Effect of infrared radiation on ZnS:Cu:Co glow curves. Wave length of IR for: A, No IR; B, 1.6μ; C, 1.4μ; D, 1.2 μ; E, 1.0 μ; F, 0.9 μ; G, 0.8 μ; H, 0.7 μ.

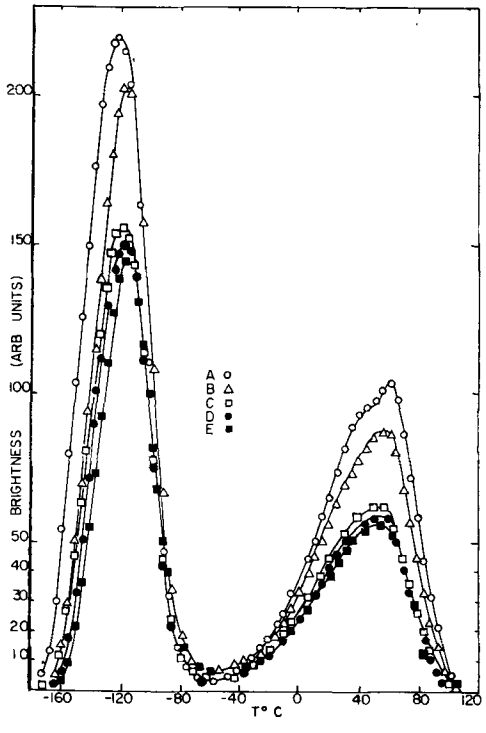

Fig. 6. Effect of decay time on ZnS:Cu:Co glow curves. Decay time at —178°C for: A, 11 min; B, 21 min; C, 36 min; D, 64 min; E, 122 min.

curves are better interpreted by the presence of a distribution of traps of different energy. The effect of higher temperatures of excitation is to leave occupied only those deeper traps of the distribution which are relatively more stable at the higher temperatures. The Co peak is unchanged throughout.

Effect of infrared radiation.—The wave-length dependence of the effect of *IR* on the thermoluminescence curves was studied by exciting the phosphor to saturation with u.v. for 30 min at —178°C and then irradiating the phosphor for 5 min with *IR* of a particular wave length at —178°C prior to running the glow curve. This was repeated for a number of *IR* wave lengths, keeping the incident *IR* intensity constant. Results are shown in Fig. 5. These curves seem to indicate that electrons trapped in either the Cu or the Co traps may absorb *IR*. All we observe, however, is the decrease of luminescence. The actual emptying of either or both traps may be an absorption of *IR* by the electron or alternatively may be part of an indirect process (such as one involving the luminescent center).

Effect of time of decay.—In the thermoluminescence obtained by allowing the phosphor to stand for a time after excitation before running the glow curves, we observed an interesting anomaly which also may indicate that both traps are linked to the luminescent center. Figure 6 shows the glow curves obtained by allowing the phosphor to decay for successively longer times at —178°C after excitation for 30 min at —178°C. The Cu peak temperature shifts slightly from —123°C after 11 min decay to —119°C after 21 min decay, and remains unchanged thereafter, except for a decrease in area for all longer decay times. There is little change in area from 36-min decay time to 120-min decay time. What is unusual, however, is that, although the decay takes place at —178°C, the Co peak, which should be stable, decreases in area also. In fact, the ratio of Cu peak area to Co peak area remains constant to within 2% over the entire decay time interval. This ratio was also found to be constant for these same decay times after excitation of 1 min, i.e., below saturation. This effect is not consistent with the removal of electrons from traps, but more likely with the filling of ionized luminescent centers by electronic transitions to these centers.

Effect of CdS.—We repeated the work of Hoogenstraaten (4) and found that both glow peaks shifted linearly to lower temperatures as CdS was added.

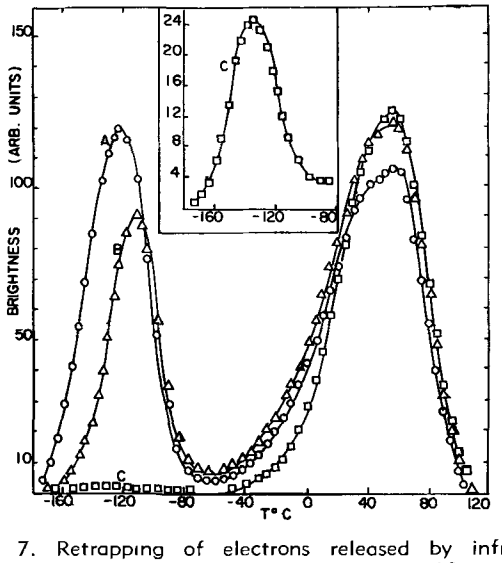

Fig. 7. Retrapping of electrons released by infrared. ZnS:Cu:Co glow curves: A, u.v. 1 min at —178°C, no IR; B, u.v. 1 min at —178°C, IR 1 min at —178°C; C, u.v. 1 min at —60°C, IR 1 min at —178°C. Insert: Portion of curve C replotted with enlarged scale.

In addition, the emission during thermal glow shifted to longer wave lengths with increased CdS content.

Retrapping.—After exciting at −60°C so that the Cu traps were empty (see Fig. 2), and for only 1 min so that the Co traps were only partially filled (see Fig. 3), the phosphor was cooled to −178°C and then irradiated with intense 1.2-μ radiation.[3] Results shown in Fig. 7 indicate that retrapping can occur in either the Cu or the Co trap. The insert shows the retrapping in the Cu peak on a larger scale. A comparison of curve A with curve B shows that retrapping occurs in the Co traps as well. It should be noted that this increase in the Co peak by retrapping of electrons released from the 1.2-μ deep trap occurs over and above the *IR* sensitivity of the Co traps shown in Fig. 5.

Summary

The shallow trap structure of ZnS:Cu 10^{-4}:Co 10^{-6} which produces thermoluminescence consists of two different groups of traps, one associated with copper or chloride, the other with cobalt. Each of these is capable of retrapping electrons that are released. The copper traps have a distribution of energy levels.

[3] In connection with photoconduction studies, we have found a 1.2-μ sensitive storage center in ZnS:Cu:Co. (See final report N6onr 26313, "Photoconduction in Phosphors.")

Acknowledgment

The authors wish to thank Professor E. Banks and his assistant, A. Ferretti, of the Chemistry Department of the Polytechnic Institute of Brooklyn, for the preparation of the samples used in this work.

Manuscript received Jan. 19, 1959. This paper was prepared for delivery at the Chicago Meeting, May 2-6, 1954, and is part of the Ph.D. dissertation of one of the authors (B. G.). Work on this paper was supported by the Office of Naval Research Contract N6onr 26313.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Arrays of Inorganic Semiconducting Compounds

A. J. Cornish

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

Arrays of compounds related to the periodic chart of the elements can be prepared. These arrays aid in estimating the physical and chemical properties of compounds, including semiconducting properties. Many compounds included in the arrays may not exist; however, if the compound does exist, the value of its melting point, energy gap, and electron mobility generally fit into a uniform pattern related to adjacent compounds. The crystal structure of semiconducting compounds is shown to be of only second-order importance. Grouping semiconducting compounds by crystal types loses the over-all relations that exist between many compounds.

Braun (1) observed the rectifying action of metallic sulfides, and since then many attempts have been made to relate the phenomena of semiconductivity to chemical bonds and structure for the purpose of discovery of new semiconducting compounds. In 1925 Wherry (2), using a copper cat's whisker, a simple crystal set, and a mineral collection, found 75 minerals capable of being used as radio detectors. Since 1925 numerous tables of inorganic semiconducting compounds have been published (3-5); however, the number of compounds has not increased materially. Winkler's (3) list published in 1955 contains slightly under 100 inorganic semiconducting compounds. The reason for the lack of greatly expanded tables of semiconducting compounds is not because workers in the field are unaware of the large number that exist, but rather the lack of experimental work confirming the existence of a large number of suspected semiconducting compounds.

The recent expansion of semiconductor materials into the infrared detector, thermoelectric device, and other fields of application has led to a new interest in expanding the list of available compounds. Such an expansion involves the selection of compounds likely to be semiconductors, the careful preparation, and the measurement of properties of these compounds. Arrays of compounds, related to the periodic chart of the elements, serve a very useful purpose in the selection, preparation, and estimation of properties of semiconducting compounds. With these arrays, it is possible to estimate melting points, energy gaps, and possibly electron mobilities.

Crystal structure.—The idea that semiconductivity is found in only a few different types of crystal structures has been disproved during the past few years. Table I lists over 35 crystal structures containing inorganic semiconducting compounds. Many more are known to exist. Fischer and Pearson (6) and Mooser and Pearson (7) have shown relation-

Table I. Structures of semiconducting compounds

* "Strukturbericht" symbols.

ships between many of the different structures. It now appears that semiconductivity could be found in any crystal structure except the close-packed, high coordination number structures. In the latter structures, the large number and nearness of neighboring atoms generally insures an overlapping of the bands and therefore metallic characteristics.

Too much emphasis has been placed on the relationship between semiconductivity and crystal structure. The crystal structure which a compound assumes is a minimum energy orientation of atoms in space satisfying a particular bond scheme. The bond scheme is determined by the distribution of electrons between atoms in the compound; this same distribution determines the position of the valence and the conduction band. Although it is true that certain crystal structures commonly exhibit semiconductivity, the more basic property is the nature of the bonds. As the bonds change in a series of compounds, different crystal structures become preferred. In some examples an increase or decrease in ionic contribution to the bond changes the structure; in other examples radius ratio rules forbid certain orientations. However, in a chemically related series of compounds, even these structural changes form a more or less continuous spectrum, the crystal structures of adjacent compounds being the same as, or related to, the crystal structure of its neighbors. Thus listing and discussing semiconductors by crystal structure types hides the over-all relationships of properties that exist between structure types.

Melting points.—Attempts have been made to correlate the melting points of semiconducting compounds with bond strength and energy gap. Considerable caution should be taken in such work. The melting point of a compound may or may not be related to the strength of the bonds providing semiconducting properties. When germanium melts, covalent bonds are broken and the liquid becomes a denser metallic material. In tin, metallic properties appear following a solid-state phase change. The melting point is a transition from a metallic solid to a metallic liquid. Weak van-der Waal bonds are broken at the melting point of selenium; the covalent bonds giving rise to semiconductivity exist at temperatures well above the melting point. Compounds frequently behave like tin or selenium. The occurrence of phase changes and low melting points greatly reduce the number of usable semiconducting compounds. For chemically related compounds we expect melting points to decrease as the molecular weight increases. When this trend is reversed we look for a complicated bond structure.

Energy gaps.—At the present time it is not possible to predict satisfactorily the energy gap of a compound chosen at random. For related compounds, however, Pauling and Goodman have provided us with a means of understanding many of the measured values. Pauling (8) proposed that bond energies were inversely proportional to the equilibrium interatomic distance for the Group IVB elements C, Si, Ge, and αSn as well as groups using covalent bonds other than sp^3.

Goodman (9), in a speculative paper, assumed that the bond energy was proportional to energy gap. He also assumed the measured energy gap was the sum of two terms: a covalent contribution which is a function of the interatomic distance, and an ionic contribution which is a function of the electronegativity differences. The Group IVB elements, having no ionic contribution, gave values of the "covalent" energy gap as a function of interatomic distance. Values of the second term can be obtained for Group III-V compounds knowing the interatomic distance and the measured energy gap. Goodman was then able to show that an increase in the ionic contribution to the energy gap was proportional to an increase in the ionicity. When a series of chemically related compounds are compared the energy gap increases when: (*a*) the compounds become more ionic or less metallic, (*b*) the covalent bond length decreases, (*c*) the molecular weight decreases.

Electron mobilities.—The experimental values of electron mobilities are so sensitive to crystal perfection that it is difficult to put much faith in the present values. They appear to increase with increasing molecular weight and reach a maximum value in compounds possessing a small ionic component to the binding.

Periodic Arrays of Compounds

Knowing only the general trends of the melting points, energy gaps, and electron mobilities as the molecular weights, ionicities, and bond lengths change, we should look for some method of tabulat-

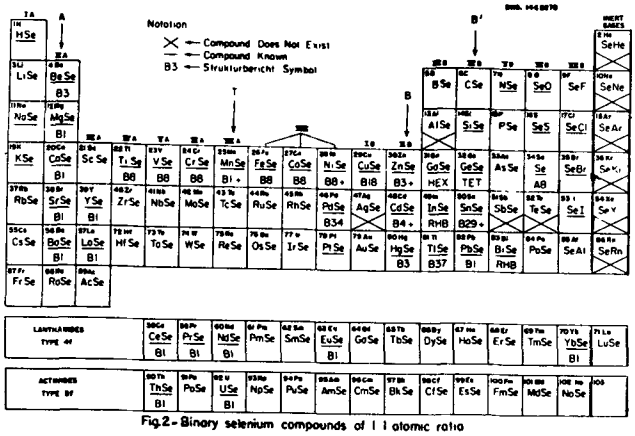

Fig. 1. Binary selenium compounds of 1:1 atomic ratio

ing or arranging compounds in order to make maximum use of this knowledge. The periodic chart of the elements is such an arrangement for the elements. Similar charts can be constructed for compounds. One such chart, a periodic chart of binary selenium compounds of 1:1 atomic ratio is shown in Fig. 1. The complete chart illustrates the principles involved but does not conveniently permit the listing of physical properties. Reduced charts or arrays of compounds including crystal structures, melting points, energy gaps, and electron mobilities will be used to discuss semiconducting compounds. Obviously many charts similar to Fig. 1 may be drawn considering that there are 102 elements and a large number of common stoichiometric ratios. The number of possible arrays increase rapidly when ternary and higher component systems are considered.

Figure 1 is similar to the elemental periodic chart in many ways. Cations occupy their normal positions as in the periodic chart of elements. The number of electrons increases as it does for the elements, and electronegativity differences between positions in the table are the same as for the elements. Definite trends in properties should and do exist as adjacent compounds in the same group (column) or period (row) are compared. These trends are more uniform in an array of binary compounds, such as Fig. 1, than in the periodic chart of elements. The common element, selenium, in this chart tends to moderate the effect of a change in the cation. In higher component systems where more than one atom is constant throughout the table this moderating effect is even more pronounced.

The compounds underlined in Fig. 1 are known to exist. Many not underlined probably exist, but sufficient work has not been done to establish the compound. When the phase diagram is known and a compound of 1:1 atomic ratio does not occur an x is placed in the appropriate square.

Relationships between crystal structures of adjacent compounds can be shown. In the alkaline earth column (IIA) the Bl (NaCl) structure occurs except for BeSe where the radius ratio forces a lower coordination number structure. The hexagonal B8 (NiAs) structure taken by many transition metals acts as a bridge structure, adjusting its c/a ratio in such a manner that it forms an almost continuous transition between adjacent compounds. Many compounds lying close to the tetrahedrally bonded B3 and B4 structures have related structures such as the B37 (TlSe) and B18 (CuSe). Similar relations exist between other physical properties which depend primarily on the bond between the cation and nearest selenium atoms.

Since selenium requires two electrons to fill its outer shell, selenium compounds are most stable when the element forming the cation can, by losing or sharing two electrons, form a stable kernel. This occurs whenever the element possesses two electrons above a stable electron configuration such as a filled or half-filled shell. Most semiconductors are compounds which obey this rule of stability and can conveniently be written as normal ionic compounds. A few important exceptions do exist, e.g., CuSe and BiSe. These would be missed if we limited ourselves to the abbreviated arrays that follow. They do appear on a periodic chart of compounds of the type shown in Fig. 1.

Columns A, T, B, and B′ in Fig. 1 indicate some of the places where this maximum stability occurs. Elements in Column A can lose 2 electrons and leave a stable filled p-shell (an s-shell in the case of Be). These elements form compounds which are largely ionic as their outer electrons are easily lost. Elements in Column T are transition metals. They are able to lose two electrons and have remaining a stable half-filled d-shell. Column B contains the usual B Group elements which tend to share two electrons leaving a filled d-shell, the two shared electrons being s-electrons. The B′ column elements are capable of losing two electrons leaving filled s- and d-shells. Many elements in other columns show a valence of two, but only those in columns designated A, T, B, and B′ are discussed in this paper.

The arrays that follow are, therefore, portions of periodic charts of compounds. The other anions in each anion group are included in such a manner that maximum use can be made of the relations that exist between chemically similar compounds.

It is obvious from Fig. 1 that, if we were forming compounds with a Group VB anion (N, P, As, Sb, or Bi) which require three electrons to fill their outer shells, the column marked A, T, B, and B′ would move one space to the right. In like manner, columns of other valence can be designated.

Table II shows an array of Group II-VI compounds with melting points, crystal structures, energy gaps, and electron mobilities taken from the literature. Compounds of beryllium, radium, and carbon have been omitted since they are not at present of great interest as semiconductors. Using the general relations discussed in the previous section, estimates can be made to fill in many of the missing experimental values. In the A column we generally expect the melting points to decrease with increasing molecular weight thus mp MgO > mp MgS > mp MgSe > mp MgTe and mp MgO > mp CaO > mp SrO > mp BaO. Similar series should

exist for the T column. Occasionally in the B column and more frequently in the B' column we find deviations from this general rule. These deviations are attributed to a more complicated bonding picture than simple cation-anion interaction. The B' group elements, and to some extent, the B group elements are capable of forming covalent bonds between themselves. This means a competition between bonding types exist in the solid. Many of these compounds melt to give covalent liquids. Their melting points are irregular.

Energy gaps follow the general rules already discussed. The gaps in the A group of Table II are too large to be classed as semiconductors; they are ionic insulators. The decrease in energy gaps with increasing molecular weights leads to predictions such as 6 ev > Eg (CaO) > Eg (SrO) > 4.2 ev, and 3.6 ev > Eg (BaSe) > Eg (BaTe). In the T group the gap of MnO of about 0.5 ev indicates that all the other compounds that exist in that group will have a gap of less than 0.5 ev. In fact it might indicate the ReSe and ReTe, if they exist as compounds, could be metallic. In the B group, the gaps are quite regular with the exception that ΔEg (ZnO) < ΔEg(ZnS). This inversion of the general rule could possibly be the 2nd order effect of crystal structure. In the B group the measured gap of 1.8 ev for GeS indicates that 1.8 ev > Eg GeSe > Eg GeTe and also 1.8 ev > Eg SnS > 0.34 ev.

Mobilities of compounds in Table II follow the rules except for the high value of ZnO and the low value of CdTe. It should be pointed out again that electron mobilities are so dependent on crystal perfection that all measured values are open to question. The large mobilities of HgSe and HgTe confirm the statement that maximum mobilities occur with slight ionicity.

Table III shows an array of Group III_2VI_3 compounds; boron and nitrogen compounds have been omitted. The trends in melting points and energy gaps are similar to those for the Group II-VI compounds. The value of 2.3 ev for the energy gap of Fe_2O_3 and 2.5 ev for Al_2O_3 indicates that the remaining compounds in both groups will have energy gaps below 2.3 and 2.5 ev, respectively. The energy gap of As_2Se_3 should be above 1.2 ev, the value for Sb_2Se_3, and below 2.2 ev, the value for As_2Se_3. It is expected that higher mobilities will be found, especially in the lower portion of the B group of compounds.

Ternary compounds and higher component systems require elaborate arrays if all possibilities are to be included. Figure 2 shows the possible substitutions that can be made to form compounds of the type I III VI_2. All possibilities do not exist, however many of the compounds do occur. In a single array, the effect of having more than one atom in

common moderates the trends in properties to a greater degree than in the binary systems.

Table IV shows an array of Group I III VI_2 compounds in which copper is used as the Group I element. Similar arrays exist for each of the other Group I elements. The few measured properties shown in Table IV confirm in general the trends expected. A similar chart with the Group I element silver instead of copper should have very similar properties with slightly lower melting points, energy gaps, and higher mobilities.

Similar arrays can be drawn up for other stoichiometric ratios of binary, ternary, and higher component systems following a pattern similar to that shown in Fig. 2.

One guide to other possible arrays could be a list of semiconducting compounds similar to Table I. For example Zn_3P_2 suggests II_3V_2, $ZnGeP_2$ suggests II IV V_2 and $HgIn_2Te_4$ suggests II III_2 VI_4. Goodman (10) has outlined a procedure which would aid in the selection of types of compounds which could be expanded into arrays. If the properties of some of the compounds in an array are known, the properties of others can be estimated.

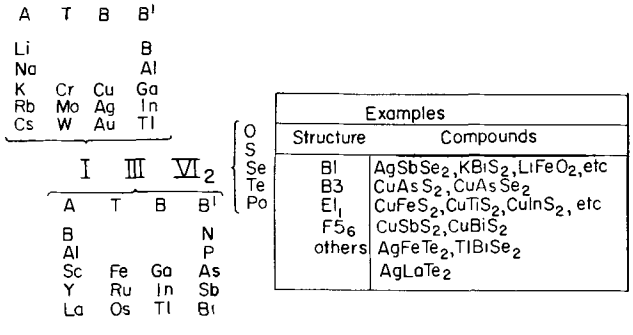

Fig. 2. Possible Group I III VI_2 semiconducting compounds

Glycerol Baths for the Electrodeposition of Molten Indium or Indium-Cadmium Alloy

A. J. Certa, T. J. Manns, G. L. Schnable, and H. S. Segal[1]

Lansdale Tube Company, Division of Philco Corporation, Lansdale, Pennsylvania

ABSTRACT

Plating baths employing glycerol as a solvent are described, from which ellipsoidal beads of molten indium or indium-cadmium alloy of approximately eutectic composition are electrodeposited onto whisker wires used as leads to electrodes of transistors. The In-Cd eutectic consists of 75% In and 25% Cd by weight and melts at 123°C. The glycerol baths for electrodepositing molten In-Cd alloy, which are solutions of $InCl_3$, $CdCl_2$, and NH_4Cl (and in some cases ethylenediaminetetraacetic acid) in glycerol, are usually operated at 140°C. Carbon anodes are used. With 24 v d.c. applied, a 15 μg ellipsoidal bead of In-Cd alloy of approximately eutectic composition can be electrodeposited on the end of a 0.05-mm nickel wire in about 2 sec. The effects of bath composition and of plating conditions on alloy composition, plating rate, and bath life are discussed. The plating baths are capable of serving as effective fluxes during soldering of whisker wires to electrodes of transistors.

In the manufacture of many types of semiconductor devices, electrical connections must be made to the electrodes. Indium metal, mp 156°C, is a convenient solder for devices where a soldering temperature of about 170°C can be employed.

In the fabrication of surface-barrier transistors, electrical connections must be made to indium emitter and collector electrodes. Indium-cadmium eutectic alloy (75% In, 25% Cd, by weight), which melts at 123°C (1), can be used to solder whisker wires to emitter and collector electrodes without melting the In metal. Soldering temperatures of about 140°C are employed. Indium-cadmium alloys in the approximate range from 50% In-50% Cd to 80% In-20% Cd by weight have been found to flow at temperatures below 130°C and thus are considered satisfactory solders for In metal. The advantages of In-Cd alloys as solders for semiconductor devices have been described previously (2).

Electrodeposition of Molten Solders

Metals electrodeposited in molten form are smooth, dense, and nonporous (2, 3). When molten metal or alloy is electrodeposited on a small wire, a bead forms at the end of the wire in a location highly suitable for a subsequent soldering operation (3). Deposition can be very rapid since high current densities can be used. Such current densities would generally cause dendritic growths in ordinary aqueous electroplating solutions.

The glycerol baths for electrodepositing molten In or In-Cd alloy are particularly suitable for rapidly plating small amounts of metals or alloys which may readily be used as solders. In contrast to the fused salt bath described previously (2), the glycerol bath is capable of acting as a soldering flux in the temperature range from room temperature to about 200°C. Thus in some applications, for example, on the automatic whisker attacher machines (4), the coating of plating solution which remains on plated whiskers withdrawn from the bath serves as a satisfactory flux during a subsequent soldering operation.

Experimental Results

Glycerol solvent.—In the electrodeposition of molten metals, a solvent is required which has a boiling point above the liquidus temperature of the metal or alloy electrodeposited. While it was found possible to electrodeposit molten In metal from solutions of anhydrous indium trichloride in a wide variety of polar organic compounds including ethylene glycol, 1, 2-propanediol, 1, 2, 4-butanetriol, N, N, N′, N′-tetrakis (2-hydroxypropyl) ethylenediamine, phenol, d-sorbitol, acetamide, ethylene glycol monobutyl ether, benzoic acid, phthalic anhydride, diethylene glycol, triethanolamine and ammonium formate, glycerol was the most suitable solvent. Glycerol, which has a boiling point of 290°C, is relatively nonvolatile at the usual operating temperatures of the plating baths, and its thermal decomposition rate at these temperatures is comparatively low. Glycerol fumes are nontoxic.

Materials.—Materials used in the preparation of In and In-Cd alloy plating baths are: glycerol (assay 95%, sp. gr. 1.25), A.C.S. reagent; cadmium chloride, anhydrous, powder, minimum assay 99%, A.C.S. reagent; indium trichloride, powder, anhydrous, minimum assay 96%, 0.02% maximum metallic impurities;[2] ammonium chloride, granular, A.C.S. reagent; ethylenediaminetetraacetic acid (EDTA), powder, reagent grade.[3]

Preparation of solutions.—Formulations of the glycerol solutions for electrodeposition of molten

In or In-Cd alloy are given in Table I. Solutions are prepared by stirring a mixture of the constituents for 30 min, breaking up any lumps, and then heating the resulting slurry with continuous stirring at 140°C for 10 min, or at 160°C for 10 min in the case of Solution III, to form a clear solution. The solution is allowed to cool to 100°-120°C and vacuum filtered through a coarse-porosity sintered glass filtering funnel.

While it is possible to dissolve all of the indium trichloride, cadmium chloride, and ammonium chloride in the glycerol at 25°C, the EDTA is only slightly soluble. Rapid dissolution of the solids is not possible below 135°C.

The glycerol baths are clear, light amber solutions which are somewhat more viscous than glycerol. Densities average roughly 1.35 g/ml at 25°C. The baths, which are prepared, stored, and operated in Pyrex or Kimax glass vessels, are stable for years at room temperature.

The reproducibility of numerous batches of plating solutions made by several different operators was quite satisfactory in terms of specific conductance at 140°C and in terms of plating rate (with 18 or 24 v applied) at 140°C, both initially and after 5 hr at 140°C.

Glycerol baths for Electrodeposition of Molten In *and* In-Cd *Alloy*

Properties and typical operating conditions of the various solutions are given in Table I.

Ammonium chloride increases the electrical conductivity of the plating solutions considerably and improves wetting by making the solutions more effective fluxes for the base metal to be plated (for example, nickel) as well as for the molten metal being deposited. (The specific conductivity at 140°C of a solution consisting of 13% $InCl_3$ and 87% glycerol was roughly 0.001 mho/cm, compared to 0.035 mho/cm for Solution I.) Cadmium chloride and indium trichloride are present in Solutions II and III in the ratio of 1:3.54 by weight, so that the ratio of Cd to In (as metal) in the baths is 1:3 by weight. Sufficient EDTA is present in Solution III to complex all In and Cd (assuming one mole of either metal per mole of EDTA) with 35% EDTA in excess.

Inert anodes of carbon (spectroscopic graphite) were used in all experiments. During electrolysis bubbles of oxygen and/or chlorine are evolved at the anode. The carbon anode should have sufficient area so that there is no appreciable polarization or local heating at the anode during electrolysis. One or more carbon rods 1/8 in. in diameter are used as anodes. The distance between cathode and anode is generally on the order of 1 cm.

In all of the experiments described, nickel wire 2 mils (0.05 mm) in diameter was used as a cathode. Under typical operating conditions the wire was immersed 1 to 2 mils (0.025 to 0.05 mm) below the plane of the surface of the plating solution. The hot plating baths normally wet the whisker wires far above the level of immersion. For example, a 2-mil nickel whisker wire immersed 1 to 2 mils below the plane of the surface of a glycerol plating solution at 140°C is wetted and plated along approximately a 10-mil length at the tip.

Under normal electrodeposition operating conditions, some hydrogen gas is evolved at the cathode during electrolysis of the solution.

The cathode area of immersed wires increases rapidly with the growth of the electrodeposited ellipsoidal beads of molten metal. For example, under typical operating conditions an ellipsoidal bead of molten In-Cd alloy 5 mils in diameter and 10 mils long is deposited on a 2-mil wire in about 2 sec. At the end of the 2-sec plating period, the surface area of the molten In-Cd alloy is several times

as great as the original immersed area of the wire. As the surface area of the molten solder increases during electrolysis, the current drawn at constant applied voltage also increases. For this reason, operating conditions are specified in terms of applied voltage rather than current density. Approximate current densities are given in Table I for several operating conditions.

Operating temperature and voltage of the baths are not particularly critical. Samples plated from Solution II at 120°C with 6 to 36 v applied, and at 160°C with 12 to 36 v applied, flowed at 130°C or less. The flow temperature of In-Cd alloys plated from Solution III at 140°C using 1.5 to 30 v was 130°C or less.

Bath life.—The average amount of In-Cd alloy deposited on the 2-mil nickel wires used in the fabrication of surface-barrier transistors is of the order of 10 to 20 μg. Under ordinary operating conditions, bath life is limited by decomposition reactions which occur in the bath at the operating temperature, usually 140°C; depletion of Cd and of In is negligible.

Since the ratio of Cd to In both in the plating baths and in the eutectic alloy is 1:3 by weight, the ratio of Cd to In in the bath remains essentially unchanged even when large amounts of alloy are electroplated from the bath.

Although thousands of whiskers can be plated from a 25-ml sample of plating bath without any evidence of decomposition of the plating solution due to anodic oxidation, prolonged electrolysis of these baths at high currents can accelerate decomposition reactions considerably.

Normally the principal limitation of bath life arises as a result of increase in viscosity with time at operating temperature. Increased viscosity results in lower electrolytic conductance and thus lower plating rates (with a constant plating voltage applied). Eventually, baths operated at 140°C become sufficiently viscous that plating rates are significantly lower than they had been initially, and the plated deposit tends to be somewhat erratic in size or location.

Tests have shown that these solutions frequently lose several per cent of their weight during 3 hr at 140°C due to volatilization.

No changes have been observed in flow temperatures of In-Cd alloys plated from solutions held at operating temperature for various periods of time up to 16 hr.

Effects of Bath Composition and Plating Conditions on Plating Rate and Bath Life

In a series of experiments to determine the effect of variations in bath composition, the relative amounts of $CdCl_2$, $InCl_3$, and EDTA were kept constant and were in the mole ratio of 1:2.94:5.36, respectively. The independent solution composition variables were thus per cent by weight ($CdCl_2$+$InCl_3$+EDTA) as a constant mole ratio group, and per cent by weight ammonium chloride, the remainder of the bath being glycerol. Specific conductance measurements at 100°C indicated that solutions consisting of the group ($CdCl_2$+$InCl_3$+EDTA) and glycerol in the weight ratio of 1 to 3 or 4 had a maximum specific conductivity. Decrease in the concentration of such solutions resulted in less ions available for electrolytic conductance and thus lower specific conductivity. Increase in the concentration of such solutions decreased the specific conductivity because the viscosity of these solutions increased considerably with concentration. [Generally, dissolved electrolytes increase the viscosity of glycerol solutions (5).] The viscosity of the glycerol solutions increased considerably with increase in concentration of the group ($CdCl_2$+$InCl_3$+EDTA); change in the concentration of the ammonium chloride had little effect on the viscosity of the solution.

Baths which were more concentrated than Solution III had a rather sharp decrease in specific conductivity with evaporation of glycerol and thus had a limited bath life. Solution III, which has approximately the concentration at which maximum specific conductivity is obtained, is relatively insensitive to changes in specific conductivity resulting from evaporation of glycerol. Solution III has an operating life at 140°C of approximately 8 hr whereas a more concentrated bath, consisting of 2.5% $CdCl_2$, 8.9% $InCl_3$, 21.4% EDTA, 6.1% NH_4Cl, and 61.1% glycerol, by weight, had an operating life of 2-3 hr at 140°C.

Increase in the ammonium chloride content of the bath increased the specific conductance and thus increased the plating rate at a given applied voltage. However, the solubility limit of ammonium chloride in the bath at about 20°C cannot be exceeded if the bath is to be stored at room temperature.

In some cases a small amount of surface-active agent is added to glycerol baths for plating molten metals and alloys. This addition lowers the surface tension of the solution, causing the bubbles formed at the cathode during electrolysis to be smaller. For example, 0.05% by weight of decyl benzene sodium sulfonate is effective in considerably reducing the surface tension of the Solution II at 140°C. The presence of a surface-active agent, by making the bubbles smaller, results in steadier plating currents and thus more reproducible plating rates.

Composition of Electrodeposited In-Cd *Alloys*

Flow temperatures were determined by immersing whiskers, on which the beads of In-Cd alloy had been flattened, into a flux such as 9% ammonium chloride in glycerol at 130°C. If the alloy flowed at 130°C or less, the bead returned to an ellipsoidal shape.

The composition of electrodeposited In-Cd alloys was determined by quantitative spectrographic analysis. Weighed samples of clean, dry, plated whiskers were treated with about 0.6 ml of 4*N* HCl to dissolve the In-Cd alloy. The stripped whiskers were rinsed, dried, and reweighed. The solution was diluted to a concentration of 0.50 mg of In-Cd alloy/ml and analyzed spectrographically by comparison with solution standards. About 50 plated

whiskers were used to prepare each sample solution for analysis. Generally duplicate determinations were made.

Local Heating at the Cathode during Electrolysis

In some cases considerable local heating occurs at the cathode during electrolysis. For example, molten In-Cd alloy was plated on a 2-mil nickel wire immersed in Solution III, operated at a temperature of 70°C, using 18 v for electrolysis. In this case, the temperature at the cathode rose more than 50°C above the operating temperature of the bath. In one experiment, with 90 v applied to a 2-mil wire immersed about 5 mm, molten In-Cd alloy was electroplated from Solution III at room temperature (25°C), indicating a temperature rise of approximately 100°C at the cathode.

Molten In metal can be deposited on 2-mil nickel wire from Solution I operated at 140°C with 18 v applied or at 120°C with 24 v applied. Molten In-Cd alloy can be plated on 2-mil nickel wire from Solution II operated at 100°C with 24 v applied.

The principle of employing local heating at the cathode to plate molten metals or alloys from a solution operated at a temperature considerably below the liquidus temperature of the metal or alloy is of interest in applications where long bath life or minimum fuming is desired.

Chemical Plating

Small pieces of Cd and of In metal were added to both Solution II and Solution III at 140°C. With both solutions the Cd became coated with a molten alloy, indicating that chemical plating of In had occurred. The In metal was etched by both solutions but no visible deposition of Cd occurred.

Conclusions

The chemical plating experiments indicate that In is more noble than Cd at 140°C in both the complexed and the uncomplexed solutions for plating molten In-Cd alloy. Such a result might be expected from a comparison of the single electrode potentials of In and of Cd in the acid electromotive series of the elements (in aqueous solution), where $E^\circ = -0.34$ v for In and $E^\circ = -0.40$ v for Cd (6).

Increase in plating solution viscosity with time at operating temperature is believed to be due to evaporation of glycerol and/or water and to condensation polymerization of glycerol to form polyglycerides, which are more viscous than glycerol (7). Since formation of polyglycerides appears to be catalyzed by anhydrous indium trichloride, the solutions listed in Table I are less susceptable to this type of degradation than more concentrated solutions.

Both Solution II and Solution III are used in the production of semiconductor devices. Solution II deposits In-Cd alloy more than twice as fast as Solution III, but the latter is less volatile at 140°C and electrodeposits In-Cd alloys of suitable solder composition over a wider range of operating conditions than the uncomplexed solution (8).

Acknowledgment

The authors wish to express their thanks to M. Sadowsky for his interest and encouragement, to E. Murt, who performed the spectrographic analyses, and to W. Hillegas, Jr., for excellent assistance in the experimental work on the uncomplexed In-Cd plating solution.

Manuscript received July 9, 1958. This paper was prepared for delivery before the Buffalo Meeting, Oct. 6-10, 1957.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Potential Measurements during Jet Etching of P-Type Ge and P-Type Si

Paul F. Schmidt and Maire Blomgren

Research Division, Philco Corporation, Philadelphia, Pennsylvania

ABSTRACT

Potential measurements have been made during jet etching, and the feasibility of the method has been established. Potentials during jet etching have been compared with those obtained in bath operations by other authors.

Jet etching and plating have become increasingly important for the fabrication of semiconductor devices. The current densities employed are well beyond the usual range of bath operation. Thus it appeared very desirable to investigate jet etching and plating by potential measurements. Development of special techniques was required for the peculiar geometry of the jet method. The method has been applied to p-Ge and p-Si so far, but should be applicable also to other systems.

Experimental

Jet-etching apparatus.—The apparatus consisted of a transparent plastic enclosure with removable lid; the jet and anode were inserted into the plastic chamber from opposite sides, both making an angle of 45° with the perpendicular (Fig. 1). The jet was rigidly fixed in its position. The anode consisted of a Ge or Si wafer mounted on a nickel or stainless steel disk, which in turn was screwed into a holder. Three micrometer screws permitted the movement of the holder perpendicular and parallel to the jet axis. In the direction parallel to the jet axis the accuracy was 0.2 mil, in the two perpendicular directions the accuracy was about 1 mil.

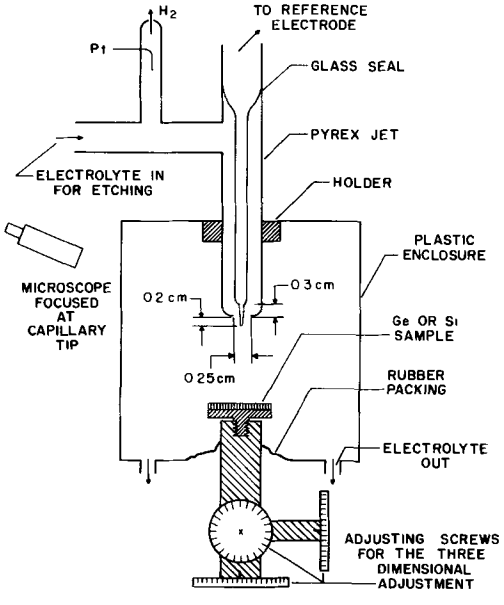

Fig. 1. Schematic of jet etching apparatus

A pocket microscope was mounted in such a fashion that it could always be brought to exactly the same position and could be focused simultaneously on the jet nozzle and on its mirror image at the shiny Ge or Si surface. Magnification by the microscope was 60X. Two drainage tubes at the bottom of the plastic chamber permitted the withdrawal of the electrolyte during etching. A lid was placed on the plastic chamber when large jet sizes were used.

The jet.—Two sizes of jet nozzles were employed: 30 and 100 mil diameter (7.6×10^{-2} and 2.5×10^{-1} cm). Inserted in the center of the jet, by means of a glass seal, is a smaller tube which tapers off to a capillary, about 0.5 cm long, 2.5 mil (6×10^{-3} cm) OD, and 1.5 mil (3.7×10^{-3} cm) ID. The capillary is located accurately in the center of the jet nozzle and extends 0.15 to 0.2 cm beyond it. The inner tube is connected to a saturated calomel electrode. The electrolyte in the outer tube was used for jet etching. The electrolyte in the inner tube, connected to the reference electrode, was usually the same as that in the outer tube except for those experiments which involved the use of free HF for jet etching. In this case the *p*H of the electrolyte in the inner tube was kept neutral in order to avoid excessive attack on the capillary. Only capillaries without any faults could be used; if the tip of the capillary was damaged in any way, the electrolyte from the inside would form droplets at the tip thus making it impossible to position the Ge or Si sample accurately (compare below). Also the potential values would be quite erratic with faulty capillaries.

The electrolyte for jet etching was introduced into the outer tube of the jet through a side arm. The latter in turn was connected to a small tube partially open at the tip. Inserted in this small tube was a Pt wire which served as the auxilliary electrode. Any hydrogen bubbles forming at the wire were swept out at the tip and thus did not enter the main jet stream.

Anode set up —The anode, as already mentioned, consisted of a Ge or Si wafer mounted on a nickel or stainless steel disk which in turn could be screwed into the sample holder. When positioning the sample, the anode was moved toward the jet nozzle by means of the micrometer screws until

both the tip of the capillary and its mirror image were simultaneously in the focus of the microscope. In this fashion it was possible to make the distance between the tip of the capillary and the semiconductor surface less than 1.2×10^{-3} cm.

Preparation of Ge *and* Si *samples.*—Ohmic base contacts to the p-Ge wafers (resistivity 1 ohm-cm, lifetime about 100 μsec, thickness 0.05 cm) was obtained by sand blasting the whole back surface of the wafer and soldering pure tin to the sand blasted area. The stainless steel disk was then pressed against the tin while heating. This resulted in a good electrical and mechanical contact. In the case of p-Si (ρ about 1 ohm-cm, τ about 20 μsec, thickness = 0.05 cm), Al was evaporated onto the back surface of the chemically polished wafer and was then alloyed by heating at 850°C for 30 sec. The Al was then painted with silver paste, which again resulted in a good contact when mechanically pressed against the metal disk.

In order to check that the contact was truly ohmic, the front surface of some wafers was given the same treatment as the back surface and I.V. curves were taken. Figure 2 shows that completely ohmic contacts were obtained both on p-Ge and on p-Si. The contact resistance for each contact is about 0.2 ohm on p-Ge, and 2.3 ohm on p-Si.

In order to obtain a homogeneous current density during jet etching it was necessary to mask the Ge or Si surface except for a hole of the same size or smaller than the jet employed. The hole had to be a perfect circle without fuzzy edges; otherwise, the resulting etch pit would be of very poor quality. The masking material must also meet the requirements of being quite inert to the electrolytes employed, and of being so thin that it would not obstruct the view of the mirror image of the capillary tip when the sample is brought into position. For measurements of current efficiency it was also essential that the masking material should be easily removable without changing the weight of the Ge or Si wafer. All these requirements were met by a Teflon tape with pressure sensitive silicone adhesive.[1] The tape was applied to the chemically polished surface of the semiconductor.

[1] Produced by the Minnesota Mining and Manufacturing Co. (pressure sensitive tape No. 549).

Potential measurements.—A voltage regulator supply, model 3-150 L, of the Dressen-Barnes Corporation served as a power source. The voltage was applied between the auxilliary electrode in the side arm of the jet and the ohmic base contact of the Ge or Si wafer. A standard resistor was inserted in the circuit and the voltage across this resistor applied to one axis of a Moseley X-Y recorder. The voltage between the reference electrode and the ohmic base contact was applied to the input of a Keithley electrometer, model 210, and from there to the other axis of the X-Y recorder. Use of the Keithley electrometer was necessary because of the high resistance in the capillary (about 10^9 ohm). The response time of the recorder is 1 sec full scale on either axis.

It was found that the potential values did not depend on the speed with which the curves were taken, i.e., for times of the order of a few seconds, except, of course, for the additional *RI* drop introduced if the etching process at high current densities increased the distance between capillary and Ge surface by an appreciable amount. Usually the current was increased to its maximum value in 10 sec and decreased to zero in the same time.

Owing to the small distance between the tip of the capillary and the semiconductor surface, the *RI* drop in the electrolyte up to current densities of about 0.1 amp/cm^2 is negligible ($\leqq$ 10 mv). This was checked by experiments in which the distance between capillary and Ge surface was increased successively in steps of 0.5 mil (1.3×10^{-3} cm).

At high current densities, however, this *RI* drop must be taken into account. It is then necessary to consider the distance by which the Ge or Si surface has receded from the capillary due to the etching action. Knowledge of the current efficiency over the current range investigated, of changes in the resistivity of the solution due to heating effects, and of the total amount of charge passed at each point of the curve would be required in order to apply an accurate correction. The amount of charge passed could be determined if the current had been increased linearly with time. The current in our experiments was increased manually and therefore not quite linearly with time. Therefore it is not justified to apply a correction in this manner.

No corrections have been applied to any of the curves shown in this paper, except those applied to Fig. 3; they are stated below in the text. However, from the known resistivities of the electrolytes employed it can be calculated that the additional *RI* drop introduced by recession of the semiconductor surface during etching is less than 1 v (at 10 amp/cm^2) if the etching current is raised linearly with time over a period of 10 sec from 0 to 10 amp/cm^2. When comparing this value to the potentials obtained at 10 amp/cm^2, roughly 10 v, it can be seen that the error even at the largest current densities is less than 10%. It can be shown that the additional *RI* drop under the above conditions increases with i^2; the error at lower current densities is therefore much smaller. The *RI* drop due to the original distance between the tip of the capillary

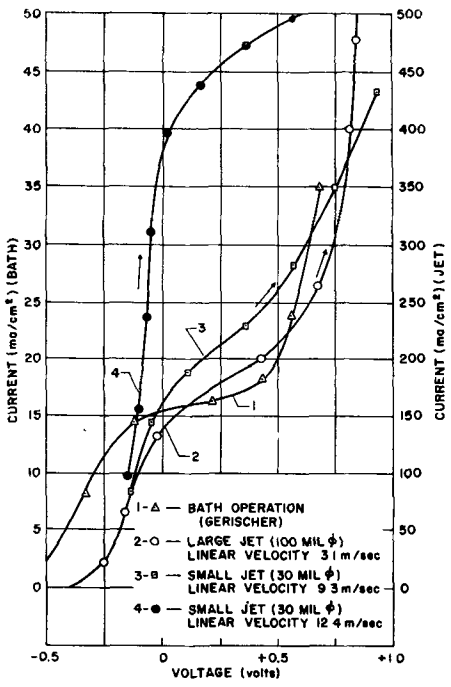

Fig. 3. Current-potential curves on p-Ge for bath operation (Gerischer and Beck) and for jet-operation using the same electrolyte. 1 ohm-cm p-Ge, 0.1M $NaClO_4$ + 0.02 M NaOH; flow rate: 3.1 m/sec.

and the semiconductor surface is about 0.5 v at 10 amp/cm^2.

The curves shown are typical of a very large number of experiments; the reproducibility was quite good. The potentials always refer to the saturated calomel electrode, except in Fig. 3 where they have been referred to the N-calomel electrode. All measurements were done at room temperature.

Since the experiments were performed on p-type material only, saturation effects inside the semiconductor are not expected to occur, and except for their appreciable resistivity Ge and Si can be treated in this respect much like metals.

Measurements of current efficiency.—These measurements were done in parallel to the potential measurements. The weight of the Ge or Si sample before and after etching was determined with a Mettler microbalance, sensitivity ± 1 μg. Before weighing, the samples were kept in a dessicator for 1 hr. It was again necessary to mask the Si or Ge wafers except for a small hole facing the jet in order to deal with a defined current density. In control runs it was found that applying the masking tape to the sample, exposing it to the electrolyte stream (without applying a bias), removing the tape and washing the sample with chloroform or CCl_4 did not change the weight of the wafer by more than ± 10 μg. The amount of charge passed during each run was chosen so as to remove 400 μg. It is believed therefore that the result of the weighings should be accurate to at least ± 5%. However, the amount of charge passed was obtained simply from the product time x constant current. This reduces the accuracy somewhat more. For accurate determinations a coulometer should be employed.

The electrolytes.—The electrolytes used had the following composition and resistivity (at room temperature):

On p-Ge: 0.1M $NaClO_4$ + 0.02M NaOH; ρ = 79.3 ohm-cm
0.2N H_2SO_4; ρ = 21 ohm-cm
0.2N H_2SO_4 + 1 cc Hyamine/1; ρ = 24.9 ohm-cm.
On p-Si: 40 g NH_4F + 8 g NaF/1; ρ = 16.4 ohm-cm
0.2N NaF + 5 cc 48% HF; ρ = 61.8 ohm-cm

The electrolyte was forced through the jet by pressure from a nitrogen tank. In separate experiments it was shown that removing dissolved oxygen from the electrolyte did not effect the potential measurements within the limit of accuracy except close to zero current.

The nitrogen pressure was 2 psig when the 100-mil jet was employed, and either 2.5 or 5 psig when the 30-mil jet was used. The corresponding linear jet velocities were 3.1 meters/sec (100-mil jet, 2 psig), 9.3 meters/sec (30-mil jet 2.5 psig), and 12.4 meters/sec (30-mil jet, 5 psig). The flow rate of the electrolyte has a very marked effect on the I.V. curves as would be expected.

Results

1. *Potentials during jet etching of p-Ge with 0.1M $NaClO_4$ + 0.02M NaOH solution, and comparison to the potential values obtained by Gerischer and Beck (1) with the same electrolyte in a stirred bath.*—Figure 3 shows the current potential curves for three different jet flow rates. For the sake of comparison the curve obtained by Gerischer and Beck is also shown. Unfortunately, the stirring rate for this curve is not given in the preliminary publication by Gerischer and Beck.

The jet curves in Fig. 3 are corrected for the total *RI* drop between base contact and tip of capillary in the following way: (*a*) From the experiments on contact resistance (Fig. 2) the resistance of the base contact is known to be about 0.2 ohm. (*b*) For the contact jet/Ge the spreading resistance inside the Ge is calculated from the formula (2): $R = \frac{1}{4a\sigma}$ (where a = radius of the contact, σ = conductivity of the Ge) to be 4.0 ohm for the large, and 6.5 ohm for the small jet. (In the experiments with the large jet the unmasked area of the Ge was 50 mils ϕ = 0.13 cm ϕ.) (*c*) From the resistivity of the solution (79.3 ohm) and an assumed distance of 1.3 x 10^{-3} cm, the resistance of the electrolyte layer between the tip of the capillary and Ge surface is calculated to be 23.1 ohm for the small jet (30 mil ϕ), and 8.1 ohm for the large jet (effectively 50 mil ϕ). (No correction has been applied for increase of the distance with etching because the curves were taken so rapidly that the additional distance is negligible compared to the original distance.)

It can be seen from Fig. 3 that the shapes of the curves are quite similar. However, the current

plateaus occur at much higher values for the jet operation, and the plateaus are not so flat.

It is evident that the vigorous stirring action of the jet causes a decrease in thickness of the Nernst diffusion layer. The fact that the position of the current plateaus depends strongly on the jet speed shows that concentration overpotentials are very pronounced in jet operation in this current density range.

The current plateaus obtained with the jet are not as horizontal as in the bath. This is due to the fact that the current density is not exactly homogeneous over the etching area, as can be seen from the slightly rounded bottom of the etch pit obtained with prolonged etching.

The current plateaus of curve 2 (100 mils ϕ jet, 50 mils ϕ etching area, 3.1 m/sec linear jet velocity) and of curve 3 (30 mils ϕ jet, 30 mils ϕ etching area, 9.3 m/sec linear jet velocity) occur at not greatly different current densities, whereas the current plateau of curve 4 (30 mils ϕ jet, 30 mils ϕ etching area, 12.4 m/sec linear jet velocity) is shifted to a much higher current density.

The thickness of the Nernst diffusion layer, which determines the position of the current plateau, is apparently smaller in the case of curve 2 than would be expected from the average flow rate of the jet (measured as volume/time). This must be due to the fact that the 50 mils ϕ etching area is exposed to the higher flow velocity in the center of the 100 mils ϕ jet. The small distance between jet nozzle and Ge surface (2 mm = 80 mils) is apparently not sufficient to suppress the velocity profile of the jet stream.

A rough calculation indicates that the thickness of the Nernst diffusion layer is about 25 times smaller for curve 4 than for curve 1.

The agreement between curve 1 (bath operation) and curves 2-4 (jet operation) is satisfactory when considering the deviations from ideal conditions mentioned above and shows that essentially the same electrode process takes place in jet etching as in bath operation.

As to the interpretation of the curves, reference is made to the publication by Gerischer and Beck (1). According to these authors the anode reaction

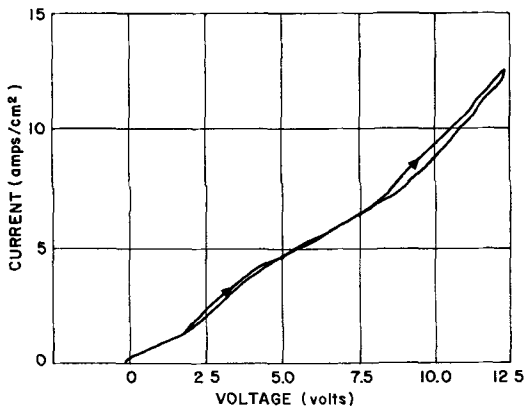

Fig. 4. Current-potential relationship at high current densities. Same electrolyte as in Fig. 3. 1 ohm-cm p-Ge, 0.1M $NaClO_4$ + 0.02M NaOH; flow rate: 12.4 m/sec.

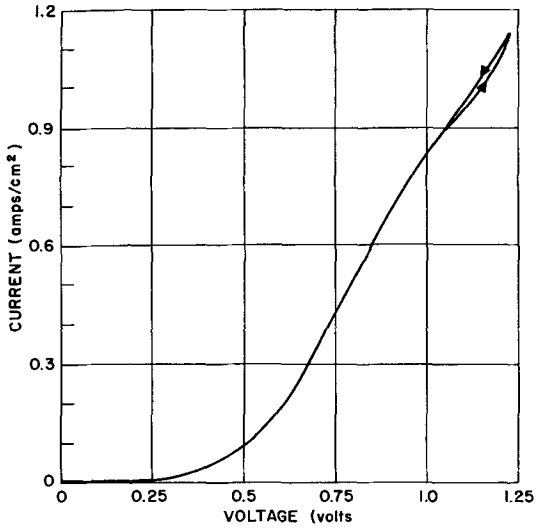

Fig. 5. Current-potential relationship in dilute H_2SO_4 at low current densities. 1 ohm-cm p-Ge, 0.2N H_2SO_4; flow rate: 9.3 m/sec.

on the first ascending branch is between Ge and OH^- ions, and on the second ascending branch between Ge and H_2O molecules. The current plateau indicates depletion of OH^- ion supply at the surface.

This solution (0.1M $NaClO_4$ + 0.02M NaOH) is not an electropolishing solution on Ge. It does not reveal crystal structure, but neither does it remove any surface structure present prior to jet etching.

Figure 4 shows an experiment (with the 30 mil ϕ jet at a flow rate of 12.4 m/sec) in which the current density was increased to 13 amp/cm^2. The additional *RI* drop caused by etching at high current densities is clearly seen on this graph from the difference of the potentials on the way up and down. In addition, a second levelling of the current is observed at about 5 amp/cm^2. This levelling marks the beginning of oxygen evolution (as indicated by current efficiency measurements), and is probably connected with the buildup of an oxide layer. At current densities much below 5 amp/cm^2 there is no indication of an increase in thickness of a hypothetical oxide layer with time: the current can be held constant without causing an increase of potential within a reasonable length of time. Above 5 amp/cm^2 an increase of potential with time at constant current is observed but cannot be distinguished easily from an additional *RI* drop caused by etching unless transient techniques were to be employed.

These remarks also apply to the current levels observed at very high current densities with the other electrolytes employed in this investigation.

2. *Current-potential curves obtained with a 0.2N solution of* H_2SO_4.—Figure 5 shows the curve obtained with 0.2*N* H_2SO_4 at low current densities, and Fig. 6 at high current densities. A second levelling of the current is again observed in Fig. 6, but it is remarkable that in the region of the levelling the current for a given potential is larger on the way down than on the way up. At higher current densities the curve taken upward coincides with

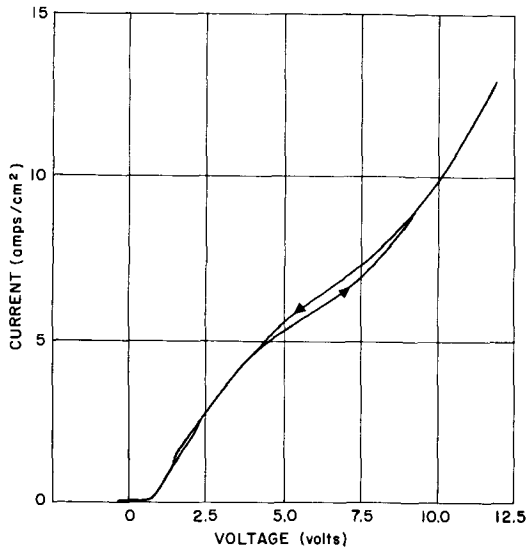

Fig. 6. Current-potential relationship in dilute H_2SO_4 at high current densities. 1 ohm-cm p-Ge, 0.2N H_2SO_4; flow rate: 9.3 m/sec.

the downward curve. This suggests that in this region the additional *RI* drop caused by etching is compensated by a decrease of potential with time at constant current. The shape of the curve in the region of low potentials is markedly different from the one obtained with the $NaClO_4$/NaOH solution and gives evidence that differences in electrode processes can be observed by potential measurements with the present jet technique.

Sulfuric acid has distinct electropolishing properties on Ge, but it still takes time for initially present surface structures to disappear.

3. *Current-potential curves obtained with 0.2N H_2SO_4 with the addition of a wetting agent.*—Figure 7 shows the current-potential curves obtained with a 0.2 *N* H_2SO_4 + 1 cc/liter of Hyamine 2389 [Alkyl (C_9-C_{15}) tolylmethyltriethyl ammonium chloride

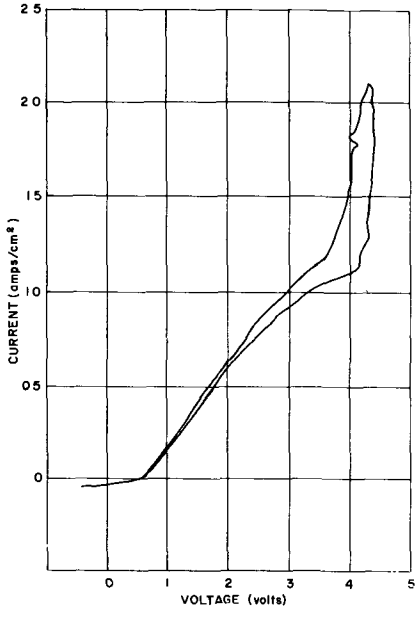

Fig. 7. Effect of addition of hyamine to dilute sulfuric acid. 1 ohm-cm p-Ge, 0.2N H_2SO_4 + 1 cc hyamine/liter; flow rate: 9.3 m/sec.

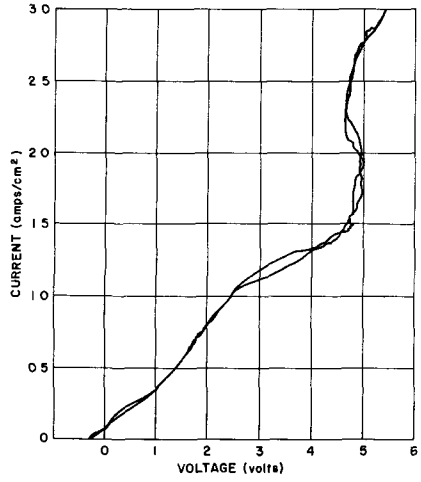

Fig. 8. Current-potential curves on p-Si in acidic fluoride solution. 1 ohm-cm p-Si, 8 g NaF + 40 g NH_4HF_2/liter; flow rate: 9.3 m/sec.

50%, H_2O 50%; Rohm & Haas Company]. The high anode potentials are remarkable. It is known that aromatic amines are adsorbed to an appreciable extent also on an anodic surface, and that they are desorbed at high anode potentials (3). The sudden jump in current at + 4.2 v suggests that the organic agent is partially desorbed at this potential, causing the current to approach the value for a clean Ge surface.

4. *Effect of crystal orientation.*—No difference in potential values was observed for the {111} and the {110} plane.

5. *Current-potential curves during jet-etching of p-Si with a solution of 40 g NH_4HF_2 + 8 g NaF/liter H_2O.*—Figure 8 shows a typical current-potential curve in the low, and Fig. 10 in the high current density range. In the region between 4 and 5 v the potential varies irregularly and rather violent fluctuations occur if the current in this region is held constant. The amplitudes of the oscillations are damped if the curves are taken with higher

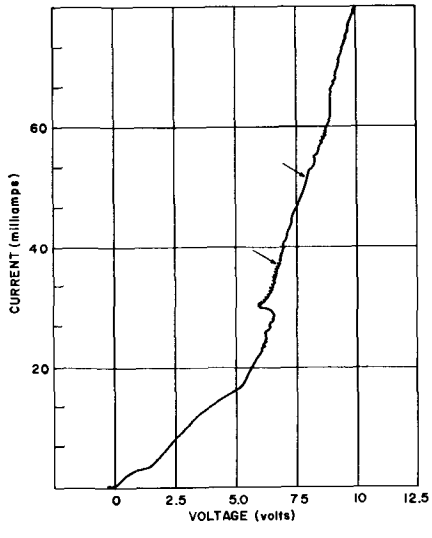

Fig. 9. Increasing size of etched area relative to jet size does not affect the general shape of the curve. 1 ohm-cm p-Si, 8 g NaF + 40 g NH_4HF_2/liter; flow rate: 12.4 m/sec; etching area 16 times jet size.

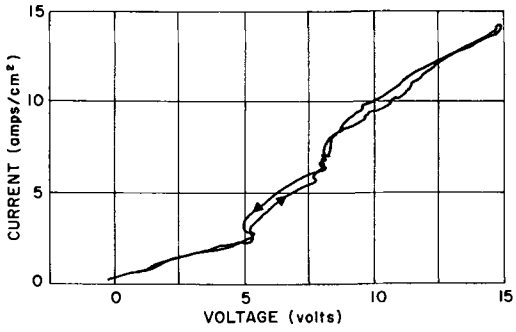

Fig 10. Current-potential curves in the same electrolyte at high current densities. 1 ohm-cm p-Si, 8 g NaF + 40 g NH_4HF_2/liter; flow rate: 12.4 m/sec.

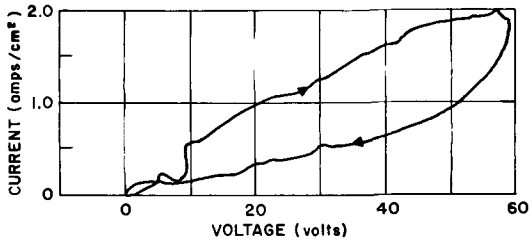

Fig. 11. Current-potential curves in an electrolyte containing less acid. 1 ohm-cm p-Si, 8 g NaF + 5 cc 48% HF/liter; flow rate: 9.3 m/sec.

speed. Also the jet flow rate has some influence. It was of interest to find out whether the fluctuations are caused by phenomena occurring at the edges of the masking tape. In Fig. 9 the diameter of the unmasked Si surface was 4 times the jet diameter; the contribution by phenomena at the periphery may therefore be expected to be less. The fluctuations nevertheless show up very clearly. Also in Fig. 9 two points are marked at which the current was held constant for 5 sec each without causing oscillations. Under the conditions of this experiment the oscillations are confined to the region between 16 and 31 ma.

A similar region of current-potential instability in the anodic oxidation of Si has been reported by Turner (5). No "run-away" region of decreasing potential with increasing current as noted by Turner was observed in our experiments presumably because the resistance of the electrolyte jet is so high (several K-ohms) that variations in electrode potential do not affect the current noticeably.

Potentials below 1 v were not very reproducible; this is probably connected with the ability of Si to form a thick oxide film in contact with air. Thus potentials in this region depend on the previous history of the sample, especially on the time elapsed since the wafer was polished chemically (with CP 4).

A thick air-formed film will not etch away rapidly before a critical potential is reached, as can be seen from the following experiment. Photodiodes on n-Si which had been exposed to air for a long time after their manufacture were biased reversely (+ 0.25 v), and light was shone through the running electrolyte jet aimed accurately at the front surface of the photodiode. (The diode area in these experiments was 30 square mils, the jet diameter was 20 mils, and the front surface of the Si had not been masked; the diode contact on the reverse side was, of course, insulated against contact with the electrolyte.) The saturation current of the photodiode increased to a value determined by the light intensity. An increasing anodic current was now applied between the Si base contact and an auxiliary electrode in the jet, so that the jet should now also act as a collector for the holes injected by the light. Until a current of 7 ma was reached, the current of the diode was quite independent of the jet current, proving that up to 7 ma the discharge of oxygen, i.e., the injection of majority carriers (electrons) was the main anodic process. Beyond 7 ma the diode current decreased abruptly to near the reverse saturation current in darkness, the jet now collecting practically all the injected holes.

If the electrolyte jet (same NH_4HF_2/NaF composition as above) is aimed at the Si surface without application of a current, a thin, semitransparent white film is formed, but the reaction is very slow and the Si is not attacked appreciably within 20 min. It is therefore more likely that the air-formed SiO_2 film rather than the formation of this whitish compound is responsible for the poor reproducibility of the potentials below 1 v. In our experiments the current density range 0-25 ma/cm² was usually traversed within 1 sec or less.

If, on the other hand, jet etching is done on purpose at a constant current density of 25 ma/cm² for a prolonged period of time, the Si is etched deeply and the surface becomes covered with a firmly adherent colorless compound, which is not soluble in water, slowly in CP 4, and dissolves slowly in strong NaOH with evolution of a gas, presumably hydrogen. The substance is thus similar to but not identical with the one described by Turner (5).

At large current densities (about 6 amp/cm²) oxygen evolution occurs as a side reaction, as shown by the current efficiency measurements (see below).

6. *Current-potential curves obtained with a solution of 8.4 g* NaF + *5 cc 48%* HF/*liter.*—This solution had been used extensively in practice but was satisfactory only at very low current densities. Figure 11 shows convincingly that at high current densities a high resistance SiO_2 film is formed which does not disappear quickly even when the current density is lowered.

7. *Measurements of current efficiency in the jet etching of p-Ge and p-Si.*—When etching p-Ge with dilute sulfuric acid the current efficiency based on a valency of +4 is usually close to 100% or just below, regardless of whether the Ge surface is masked or not. Up to moderately high current densities the current efficiency does not seem to depend much on current density; at high current densities oxygen is discharged as a side reaction and the current efficiency drops.

In solutions containing halide ions, more complex phenomena occur if the surface is not masked. Cur-

Table I

Electrolyte: 40 g NH_4HF_2 + 8 g NaF/liter; Flow rate: 3.1 m/sec

% Current efficiency	>>160	485-115	115-95	95-75
Remarks	Etched area covered with adherent white deposit, actual loss of Si therefore much greater, i.e., current efficiency >> 160%. Surface badly pitted under the deposit.	Shiny but not polished surface; at higher current densities transition to electropolishing.	Good electropolish at higher current densities	Electropolishing concommitant with O_2 evolution

rent efficiencies as high as 120% can be observed in HCl solution. This may well be due to the "edge-effect" described by Jirsa (4) who found that Ge goes into solution +4 valent over the whole current density range and in all electrolytes investigated by him (HCl, H_2SO_4, KOH, NH_4OH), but that at the interface solution/air/Ge divalent Ge ions are formed by the reaction: $Ge^{4+} + Ge \rightarrow 2\ Ge^{2+}$.

In contradistinction to the behavior of Ge very large deviations from a current efficiency of 100% were observed on Si. Table I summarizes the results.

It is very remarkable that apparent current efficiencies > 400% are obtained at low current densities. This rules out any explanation based on dissolution of Si as ions of lower valency. It seems in fact that an explanation must be sought along the lines of the negative difference effect investigated by Straumanis (6). A corresponding effect is not found on Ge which is more noble than hydrogen. This lends support to the assumption that current efficiencies > 200% are caused by current flow between local anodes and cathodes. The local cathodes are evidently created by an impressed anodic current in the manner described by Straumanis (6). The effect disappears at larger anodic potentials because the hydrogen evolution reaction is then suppressed on the Si surface.

At very large current densities oxygen evolution occurs but in the given electrolyte Si does not passivate, at least not below 20 amp/cm², the highest current density investigated.

Acknowledgments

The authors are greatly indebted to Dr. E. Blomgren of the University of Pennsylvania for valuable discussions and advice, and to Professor J. O'M. Bockris of the University of Pennsylvania for valuable discussions of semiconductor electrode kinetics. Our thanks are also due Mr. Larson at the University of Pennsylvania for solving the difficult task of preparing the Haber-Luggin capillaries and inserting them in the jets.

Manuscript received Sept. 24, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Junction Delineation on Silicon in Electrochemical Displacement Plating Solutions

D. R. Turner

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Antimony, copper, silver, platinum, and gold can be deposited on silicon by electrochemical displacement. The displacement plating process induces potential differences between abraded and polished n- and p-type silicon. This results in metal being deposited at different rates on the four types of silicon surfaces which in turn produces p-n junction delineation. The process also shows up abrupt changes in the impurity concentration at the surface. The maximum resolution between junctions in a multiple junction crystal is about 2 microns.

A number of chemical treatments have been developed to show up p- and n-regions on the surface of silicon single crystals. The first was devised by Fuller (1) and consisted of treating the Si in HF solutions containing a small amount of HNO_3. This solution stains p-type regions darker than the n-type. Silverman and Benn (2) were able to portray junctions on Si with Au deposited by electrochemical displacement from a gold cyanide plating solution in the presence of light. Recently Whoriskey (3) has improved on the reproducibility of the HF stain method by eliminating the HNO_3 and illuminating the junction with white light. He also reports good junction delineation using white light and a copper nitrate solution containing a small amount of HF. Iles and Coppen (4) obtained junction delineation on Si in a dilute silver-fluoride solution. They reported that Ag deposited preferentially on the lower conductivity material regardless of conductivity type in the dark or with room light.

The purpose of this paper is to describe a method of obtaining very sharp p-n junction delineation on Si in acid fluoride displacement plating solutions without the aid of light. Waltz (5) and Wang (6) have deposited metals on Si by electrochemical displacement from acid fluoride solutions for the purpose of making ohmic contacts. Their solutions are not suitable for junction delineation.

Electrochemical displacement plating on Si.—One metal plates on another by electrochemical displacement when the depositing metal is more noble (electropositive) than the metal receiving the deposit. Plating is literally by displacement, for each milligram-equivalent of metal depositing on Si at cathodic sites, 1 mg-equivalent of Si dissolves at anodic sites. The total anode current, therefore, equals the total cathode current. The rate of metal deposition by displacement can be controlled by regulating the rate of the anode reaction. Silicon dissolves anodically by first forming an oxide. Unless the electrolyte is capable of dissolving the oxide, the anode reaction will stop after the oxide becomes a few atom layers thick. Displacement plating also will stop under these conditions. Silverman and Benn (2) were able to deposit Au on Si by displacement from a gold cyanide plating solution because hot strongly alkaline solutions dissolve silicon dioxide forming a soluble silicate complex:

$$SiO_2 + 2KOH \rightarrow K_2SiO_3 + H_2O$$

For the same reason, Cu can be deposited on Si by displacement in a hot alkaline Cu plating solution.

Hydrofluoric acid dissolves SiO_2 by forming a soluble silicofluoride complex:

$$SiO_2 + 6HF \rightarrow H_2SiF_6 + 2H_2O$$

The rate of Si dissolution at anodic sites, and therefore the metal deposition rate at cathode sites, in acid fluoride displacement plating solutions can be regulated by controlling the rate of mass transfer of HF from the solution bulk to the anode sites. This is done easily by adjusting the bulk HF concentration in the plating solution.

Experimental Methods and Results

Five different metals were deposited on Si by electrochemical displacement: Sb, Cu, Ag, Pt, and Au. The aqueous solutions contain simple metal salts plus different amounts of HF as shown in Table I. They are all used at room temperature. The metals in Table I are arranged according to the electromotive series. Antimony is the most electronegative of the group while Au is the most electropositive. The amount of HF used in each solution is believed to be optimum for the sharpest junction delineation. A 2-min treatment is usually sufficient to portray p-n junctions in the solutions of Table I. At lower HF concentrations, the time required for delineation increases, and the deposit often is not uniform. Higher HF concentrations result in rapid metal deposition on both sides of the p-n junction so that delineation is poor or impossible. At a given HF concentration, the rate of metal deposition by displacement on Si increases the more electropositive the metal. Therefore, Au will deposit faster than the other metals. Rates of metal deposition may be equalized, however, by decreasing the HF concentration as the metal becomes more electropositive as shown in Table I.

Table I. Solutions for junction delineation on Si

Metal deposited	Metal salt	g/l	cc 48% HF/l
Sb	SbF_3	400	500
Cu	$CuSO_4 \cdot 5H_2O$	200	10
Ag	$AgNO_3$	40	4
Pt	$H_2PtCl_6 \cdot 6H_2O$	3	2
Au	$AuCl_3$	10	0.3

Experiments were carried out with single crystal bars of n- and p-type Si, half-sections of crystals with pn junctions, and bars with either single or multiple rate-grown junctions. The surface was prepared by either lapping with No. 600 SiC on glass or bright etching in an acid mixture containing HNO_3, HF, and acetic acids.[1] Silicon samples are used immediately after lapping or etching.

Adhesion of metals deposited by electrochemical displacement is relatively poor as compared to electroplated deposits. This is due, at least in part, to the undermining action of the anodic reaction which tends to dissolve Si from under the metal deposited by displacement. As expected, the adhesion of displacement plated metals is better on abraded than on polished Si surfaces. The most adherent deposits were obtained with Sb and Cu on abraded surfaces. The relative adhesion of displacement plated metals on Si is lower the more noble the metal. Gold deposits have the poorest adhesion and on polished surfaces the deposit is usually pulled off by the surface tension of the solution as the sample is removed. Adhesion of the other metals deposited on chemically polished silicon was adequate for the purpose of portraying junctions.

The best resolution of pn junctions was obtained with Cu and Ag. Most of the experimental work was done with the aqueous solution containing 200 g/l $CuSO_4 \cdot 5H_2O$ and 10 cc 48% HF/l. For the remainder of the paper, it will simply be called the Cu solution.

The solutions in Table I will deposit metal uniformly on n- or p-type Si specimens with either abraded or polished surfaces. If the Si contains a p-n junction and the surface is either all abraded or all chemically polished, metal again deposits fairly uniformly, and junction delineation is poor if discernible at all. This can be improved if the p-n junction area is illuminated with white light (2-4).

In order to obtain sharp p-n junction delineation on Si in the displacement plating solution without using light, it is necessary that the surface be partly polished[2] and partly abraded. An example of the results obtained is shown in Fig. 1. The photograph at the left shows a slice of a single crystal of Si about 2 x 2 x 0.2 cm thick, containing a grown p-n junction. The junction is visible as an inverted U with p-type on top. First, the entire slice was chemically polished and then the left half was abraded by rubbing with No. 400 Aloxite paper. The sample was immersed in the Cu solution for 2 min after which it

[1] The exact composition of the chemical polishing solution is: 5 parts by vol. conc. HNO_3, 3 parts by vol. 48% HF, and 3 parts by vol. glacial acetic acid. This is identical with the etching solution known as C.P.-4 except no bromine is added.

[2] Either a chemically or a mechanically polished surface is satisfactory. A chemically polished surface was used in most of the work to be described here.

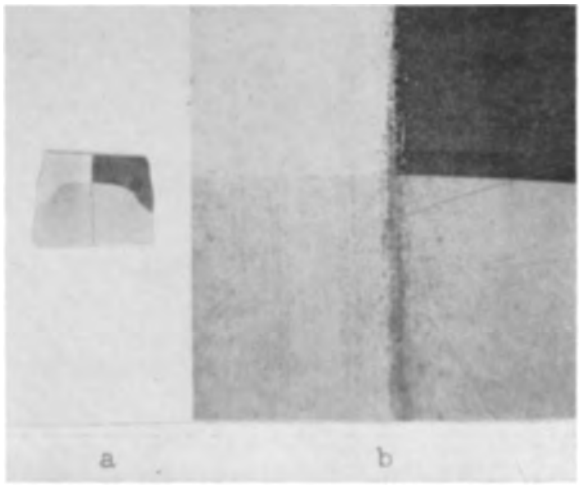

Fig. 1. P-N junction delineation on Si in the $CuSO_4$-HF solution with partly abraded and partly polished surfaces; p-region is the top half of crystal; left side is abraded while the right side is chemically polished. (a) View of large slice 2 cm x 2 cm; (b) magnified view of central region of (a).

was rinsed in water and air dried. The heaviest Cu deposit appeared at the top left on abraded p-Si while the least amount was on polished p-Si. An intermediate amount of Cu deposited on both abraded and polished n-Si. An enlarged view of the center of the specimen is shown in Fig. 1b. Good junction delineation is evident on both abraded and polished surfaces, but the greatest contrast is on polished Si.

If the junction area is illuminated with a strong light in the displacement plating solution, the results on abraded surfaces are about the same as without light. On the polished side of the crystal, however, the pattern is reversed and more Cu deposits on p-Si than on n-Si but only where the surface is illuminated. Polished areas that are not strongly illuminated behave as shown in Fig. 1. Whoriskey (3) and Iles and Coppen (4) reported that, under strong illumination, metal deposits more rapidly on n- than p-type Si. These results are obtained only when the Si is covered with a thin layer of plating solution. If the Si is immersed in a large volume of solution, a heavier deposit appears on p- than on n-Si with illumination as described previously. The reason for this reversal is not understood at present.

There is another way of obtaining sharp junction delineation on polished Si without using light or abrading part of the surface. This method requires a metal electrode connected to the p-type Si by means of an ohmic contact. The metal electrode should be the same as the metal deposited by displacement and is immersed in the plating solution along with the Si. An example of junction delineation obtained by this process in the Cu solution is shown in Fig. 2. This is a highly magnified view of the surface of a Si bar containing multiple rate-grown p-n junctions. Copper has deposited on the n-regions but not on p-type Si. This example also demonstrates the high resolution of junction delineation which is possible in displacement plating solutions. The narrow n-region in the center of the photograph is about 10 μ wide at the extreme left and is clearly visible down

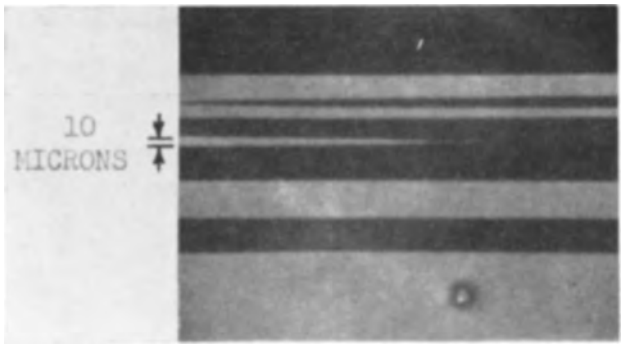

Fig. 2. An example of the high resolution of junction delineation on polished Si in the $CuSO_4$-HF solution. Surface of sample contains multiple rate-grown pn junctions. Copper deposit appears only on n-Si (light areas).

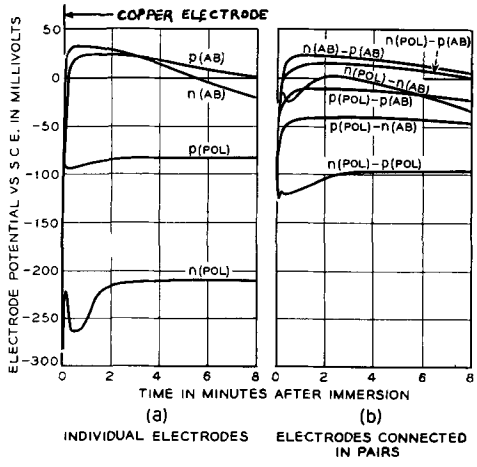

Fig. 3. Electrode potential-time curves of abraded and polished n- and p-type Si in the $CuSO_4$-HF solution.

to about 2 μ as it tapers to the right. The process also shows up abrupt changes in the impurity concentration at the surface of a Si crystal.

Junction Delineation on Germanium

Attempts were made to produce sharp pn junction delineation on Ge in the same displacement plating solutions used for Si. The results on Ge were not good as the junction was poorly defined if detectable at all. Some improvement was obtained with higher HF concentrations. The inherent differences in the electrochemical and semiconductor properties of Ge and Si probably make it impossible to obtain as sharp junction delineation on Ge as is obtained on Si in displacement plating solutions.

Mechanism of Junction Delineation

Electrochemical displacement plating on Si involves Si dissolution as well as metal deposition. It has been found that, if Si is attacked by an electrolyte, a large excess of holes and electrons is produced at the surface (7). These excess holes and electrons diffuse into the Si and change the concentration gradient of the minority current carrier between the surface and the Si bulk. The net result is to shift the measured potential of p-type Si toward more positive values while n-type Si changes in the negative direction. A similar effect is observed if excess holes and electrons are produced at the Si with illumination. The magnitude of the potential change is a function of the resistivity of the Si and the minority carrier lifetime.

The potentials of individual electrodes of n- and p-type Si with abraded and polished surfaces were measured against a saturated KCl calomel reference electrode (SCE) in an unstirred Cu solution. The electrodes were single crystal 0.7 ohm-cm n-type and 1.5 ohm-cm p-type Si. Number 400 Aloxite paper was used to prepare abraded surfaces while the polished electrodes were obtained by etching in the modified C.P.-4 solution previously described.

The recorded potentials vary with time as shown in Fig. 3a. The results show that there are considerable potential differences between abraded and polished Si and also between polished n- and p-type Si in the Cu solution. The potential of a Cu electrode in the Cu solution vs. SCE is also included in Fig. 3a for the purpose of comparison. A Cu electrode was used instead of abraded Si to bring out the junction in the experiment illustrated in Fig. 2.

All four Si electrodes exhibit large initial transients in potential. The two polished electrodes appear to reach steady potentials about 130 mv apart after 3 min immersion in the Cu solution. After the initial maximum, the potential of the abraded electrodes gradually became more negative and approached the steady potential values of polished Si electrodes. The reversal in potential between abraded n- and p-type Si after about 3 min is reproducible and is consistent with experimental results. On abraded Si, metal begins to deposit more rapidly on the n-side of a pn junction but later the rate of metal deposition becomes greater on p-Si than on n-Si.

In a voltaic cell, the negative electrode is the anode. Then according to the results of Fig. 3a, polished n-type Si is anodic to all the other electrodes. If all four types of Si electrodes are connected together in a single crystal, one would expect the least amount of Cu deposited on polished n-type Si. In actual practice, as demonstrated in Fig. 1, the least amount of metal is deposited on polished p-Si. The reason for this apparent anomaly is indicated by the results of connecting the electrodes of abraded and polished n- and p-type Si together in pairs as shown in Fig. 3b. The mixed potentials obtained are recorded as a function of time after immersion in the Cu solution. The three voltaic cells involving polished n-Si as the anode have mixed potentials very near the individual potentials of the cathode. This means that the current flowing between the electrode pairs is controlled by a polarizing effect at the polished n-Si. The effect is illustrated more clearly in Fig. 4 which shows the potential-current density relation of polished n-Si as the anode and polished p-Si as the cathode of a voltaic cell in the Cu solution. These curves were obtained by connecting the two electrodes together through a variable known resistance. The current between the electrodes was determined by measuring the *IR* drop across the shunting resistor while the electrode potentials were measured against the saturated calomel reference electrode. Initially a large resistance was placed be-

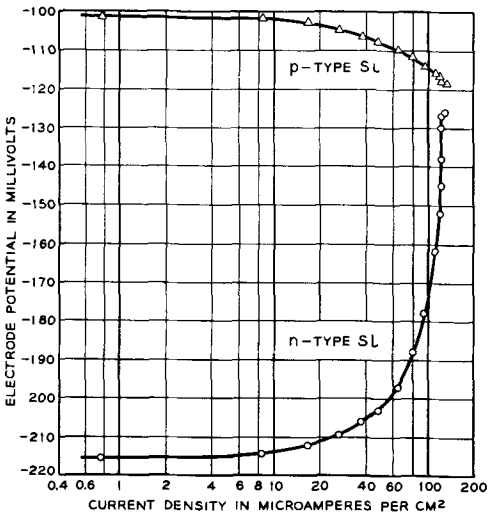

Fig. 4. Electrode potential-current density curves of polished n-Si anode and polished p-Si cathode of a voltaic cell in the $CuSO_4$-HF solution.

tween the two electrodes so the current flowing between them was small and the potentials were essentially those at open circuit. As the current between the electrodes was increased, by decreasing the shunting resistance, the potential of n-type Si acting as an anode changed more rapidly than p-type Si acting as a cathode. The maximum current flowing between the two electrodes therefore is determined primarily by the anodic polarizing effect on n-type Si.

Brattain and Garrett (8) and others have shown that holes are required to carry out anode processes on semiconductors. There is also evidence that cathodic processes on semiconductor electrodes require electrons (8-10). If the only source of holes and electrons at the surface of n- and p-type Si, respectively, is by diffusion from the bulk, then the saturation current of n-Si made anode and p-Si made cathode should be only a few microamperes per square centimeter. The results shown in Fig. 4 indicate that there must be another source for holes and electrons at the surface. As described earlier, holes and electrons are produced as a result of displacement plating. The additional holes available at the surface of the polished n-type Si electrode studied in the Cu solution allowed a maximum anode current density of about 130 $\mu a/cm^2$ when connected with a suitable cathode such as: polished p-Si, abraded Si, or a Cu wire. The maximum or saturation anode current density in the dark is a function of the equilibrium hole density and the diffusion length for holes in the surface region of the n-type Si electrode (9). This current flowing between n- and p-type Si should tend to deposit more Cu on p-Si than on n-Si. There are two electrolytic currents involved, however; one is between n- and p-type regions as just described and the other is between local anode and cathode areas that result in displacement plating. The reason that junction delineation is not obtained on an all polished Si crystal in the absence of strong light is that the rate of Cu deposition over all surfaces by electrochemical displacement is much greater than the deposition of Cu at different rates on n- and p-Si as a result of the potential difference. The displacement plating current density can be estimated from the total weight of Cu deposited in a given time. The amount of Cu deposited in 2 min from the Cu solution corresponds to an average current density of about 1.5 ma/cm^2, assuming equal anode and cathode areas and a Si dissolution valence of 4. This current density is about ten times the maximum current density between polished n-Si and polished p-Si when connected together as shown in Fig. 4. Shining light on the junction provides more holes on n-Si which increases the current flowing between n- and p-areas. This results in more Cu being deposited on p and less on n, thereby increasing the sharpness of junction delineation.

Polished p-type Si is cathodic to polished n-Si but is anodic to both abraded n- and p-Si and Cu as shown in Fig. 3a. Since holes are the majority current carrier in a p-type Si electrode, it can function as an anode up to relatively high current densities without the surface becoming depleted in holes. The current between polished and abraded p-type Si, therefore, can be about the same as the displacement plating current which results in a heavier Cu deposit on abraded p-Si and a corresponding lighter amount on polished p-Si. A Cu electrode, connected to polished p-type Si by means of an ohmic contact, behaves in the same manner as abraded p-Si in contact with polished p-Si in the Cu solution.

On the basis of the individual electrode potential measurements, abraded n-type Si should be as good a cathode in the Cu solution as abraded p-Si with respect to polished p-Si. However, current must flow between abraded n-Si and polished p-Si in the Si across the pn junction in the blocking direction to complete the electrical circuit. This limits the current between the two regions to a few microamperes and explains why the amount of Cu deposited on abraded n-Si is not as heavy as that obtained on abraded p-Si.

Summary and Conclusions

Electrochemical displacement of metals such as Cu and Ag and to a lesser extent, Sb, Au, and Pt can be used to delineate Si p-n junctions. Junction delineation is possible because of potential differences that are established between abraded and polished n- and p-type Si in displacement plating solutions. On the basis of these potential differences alone, the least amount of metal should deposit on polished n-type Si. This is not confirmed experimentally. Instead, polished p-type Si receives the least amount of metal. This is because polished n-Si cannot function as an anode at a high enough current density in the voltaic cell between n- and p-areas relative to the displacement plating current density. Shining light on the junction improves the junction portrayal because additional holes are produced by the light in n-type Si which increases the current in the voltaic cell between n- and p-surfaces.

Polished p-Si is capable of sustaining an anode reaction at relatively high rates without the aid of light. If connected to a suitable cathode, such as abraded p-Si or a Cu electrode in the Cu solution,

very little if any Cu deposits on polished p-Si while a substantial amount deposits on n-Si due to displacement plating. This produces a sharp junction delineation between n- and p-type Si.

Diffusion of Radioactive Antimony in Silicon

J. J. Rohan, N. E. Pickering, and J. Kennedy

Radiochemistry Section, Electronic Material Sciences Laboratory, Electronics Research Directorate, Air Force Cambridge Research Center, Air Research and Development Command, Bedford, Massachusetts

ABSTRACT

The diffusion coefficient of radioactive Sb-124 in Si has been investigated in the temperature range 1190° to 1398°C, with use of a technique involving measurement of the residual integrated activity of the 0.602 Mev gamma before and after removing successive 2- to 4-μ layers perpendicular to the diffusion path. Results are compared to literature data obtained via p-n junction measurements. The diffusion coefficients are on the average about 85% higher than the literature values, while the activation energies are essentially the same. The temperature dependence of the diffusion coefficient is given by $D = 12.9 \exp(-91{,}700/RT)$ cm^2 sec^{-1} with an average error of ±12%. Surface concentrations of Sb were in the range of 10^{19} to 10^{20} atoms cm^{-3}.

Studies of the diffusivities of donor and acceptor elements in semiconductors by means of radiotracers have been supplanted largely in recent years by methods involving the measurement of p-n junction distances. These methods (1, 2) which depend on the formation and location of p-n junctions within the crystals are faster and far less tedious than methods employing radiotracers. Up to the present, no comparison of results obtained by the two techniques appears to exist for diffusion in silicon. In germanium a radiotracer method gave diffusion coefficients for Sb which were 20 to 40% higher than those given by a p-n junction method (1, 3). Some indication that this might be the case for Sb in Si was noted in this laboratory in a study of the effect of various pressures of Sb_2O_3 vapor on the surface concentration of Sb on Si during diffusion anneals. With use of the data and techniques of Fuller and Ditzenberger (4), it was found in all cases that p-n junction measurements gave much larger values for the surface concentration, C_o, of Sb than radioactivity measurements when similar amounts of diffusant were heated in evacuated quartz tubes containing p-type single-crystal Si slabs. In these and the following experiments, boundary conditions were such that diffusion proceeded according to the error function complement equation. From p-n junction measurements then, the surface concentration, C_o, in atoms cm^{-3}, was calculated from:

$$C_x = C_o \operatorname{erfc} \frac{x}{2\sqrt{Dt}} \qquad [1]$$

where C_x is the concentration in atoms cm^{-3} of Sb at a junction located x cm from the surface of Si; D is the diffusion coefficient in cm^2 sec^{-1}, and t is the time in seconds at constant temperature. The diffusion coefficient, D, was presumed to be only temperature dependent and the surface concentration, C_o, presumed to be constant. Radioactivity measurements, described more fully later, gave C_o in terms of the total number of atoms N_T of Sb which diffused through one face of the Si slab. This is given by integration of Eq. [1] so that

$$N_T = GR_T = A\,C_o \int_0^\infty \operatorname{erfc} \frac{x}{2\sqrt{Dt}}\,dx = 1.13\,AC_o\sqrt{Dt} \qquad [2]$$

where R_T is the total activity, A is the area of the diffusion plane introduced here to account for the total number of diffused atoms, and G is a factor which relates activity to the number of atoms of Sb.

An example of the large discrepancies noted for values of C_o as found by both methods is given for a

diffusion anneal at 1380°C. From radioactivity measurements a value of $C_o = 4.3 \times 10^{19}$ atoms cm^{-3} was obtained while p-n junction measurements gave $C_o = 3.4 \times 10^{21}$ atoms cm^{-3}. The latter is consistent with a mean value obtained by Fuller and Ditzenberger (4) at the same temperature with similar amounts of Sb_2O_3, but is inconsistent with the expected solid solubility of Sb in Si even if saturation had been reached. The binary alloy system Sb-Si belongs to a class whose liquid phases are "regular" solutions and whose solid phases exhibit the phenomenon of retrograde solubility, as has been shown by Thurmond and Struthers (5). They have also shown that the logarithm of the distribution coefficient k of the solute (Sb in this case) between the solid and liquid phases of such systems is a linear function of the reciprocal of absolute temperature near the melting point of the solvent. Extrapolation of this line to the k corresponding to the melting point of the solvent (Si) gives the maximum value or segregation coefficient. The latter has been found by direct measurement to be 0.04 for Sb in the Sb-Si system (6). However, a value of 1.4 is calculated for the distribution coefficient of Sb in Sb-Si at 1380° from the C_o obtained by p-n junction measurement and the solubility of Sb in the liquid phase at this temperature (5, 7).

Apparently then C_o values for Sb in Si calculated from p-n junction measurements and the values of D given by Fuller and Ditzenberger can be too high by one or two orders of magnitude. One explanation for this is that too low values of D were used in the calculation. In the preliminary work and in much of Fuller's, the quantity $x/2\sqrt{Dt}$ had a numerical value of 2 or greater; relatively small changes in the value of erfc in such cases can lead to very large changes in C_o as calculated from Eq. [1], which is apparent on examination of tables of the error function. For example, a 50% increase in D at constant x and t can effect a tenfold reduction in C_o as calculated by Eq. [1] (p-n junction), whereas with Eq. [2] (radiotracer) the effect is to reduce C_o by only 20%. In view of the foregoing observations, it was decided to re-examine the diffusion of Sb in Si using radiotracer Sb-124 exclusively.

Discussion of Methods

Where the concentration of radioactive diffusant does not change appreciably over short distances (several microns) along the diffusion path, a method based on counting the activity in thin parallel segments of the matrix ground onto emery paper, or similar abrasive, has been used successfully for the determination of diffusion coefficients in highly impenetrable single crystals. Such concentration profiles require that the penetration parameter $\sqrt{Dt}$ be of the order of 10^{-3} cm, or greater, to insure any degree of precision and were accomplished in the case of Sb in Ge with anneal times of less than 10 days (3). However, in the case of Si in which Sb is one of the slowest diffusing elements, it would take up to 100 days to produce comparable penetrations; hence, a more suitable procedure was desired.

An alternate method for the radioassay of diffused Sb-124 in Si is to count the integrated gamma activity of a crystal following removal of thin layers parallel to one surface. On decay of Sb-124, beta particles and gamma rays are emitted. Of the several gamma rays emitted the principal one has an energy of 0.602 Mev and is virtually unabsorbed by the small thicknesses of Si encountered here. The count rate of the 0.602 mev gamma rays is therefore directly proportional to the total number of Sb atoms at all depths within the Si crystal. When the edges and one face of the crystal have been removed by grinding to depths below which the concentration of Sb is negligible, only unidimensional diffusion need be considered. The number of residual Sb atoms, N_x, in the crystal lapped down to a plane x cm below and parallel to the remaining original surface is

$$N_x = GR_x = A\,C_o \int_x^\infty \operatorname{erfc} \frac{x}{2\sqrt{Dt}}\,dx$$

$$= A\,C_o \sqrt{Dt}\left[\frac{2}{\sqrt{\pi}} \exp\left(-\frac{x^2}{4Dt}\right) - \frac{x}{\sqrt{Dt}} \operatorname{erfc} \frac{x}{2\sqrt{Dt}}\right] \qquad [3]$$

where R_x is the residual 0.602 Mev gamma activity.

If C_o is known, D can be obtained directly from Eq. [3] by successive approximations using tables of the error function and its first derivative (8), (the first term inside the bracket). Since C_o is usually not known, the integral count rates, R_1 and R_2, at two depths, x_1 and x_2 may be combined to give:

$$\frac{N_1}{N_2} = \frac{R_1}{R_2} = \frac{\phi_1}{\phi_2} \qquad [4]$$

where ϕ represents the terms inside the bracket of Eq. [3], and is a function of x only. Again, by successive approximations, a value for D is found which satisfies the ratios of Eq. [4].

Experimental

Samples of single-crystal Si, 200 ohm-cm n-type, 8 mm on a side and 1 mm thick, were prepared by hand lapping on glass through 3200-mesh abrasive suspended in water. They were then brought to a semi-mirror finish by a short final lapping with ¼-μ Diamet Hyprez on a silicon flat; in all cases the flatness of the samples, measured optically, was at least ± 0.1 μ out to the edges. After cleaning, the samples were washed successively in conc HNO_3 and conc HF. Two such specimens were sealed at 10^{-5} mm of air in quartz ampules containing 200 to 500 μg of radioactive Sb_2O_3. In the latter, obtained by neutron irradiation at Brookhaven National Laboratory, about 1 at. in every 10^5 at. of Sb was Sb-124. Before irradiation, the impurity content of the oxide was determined by spectroscopic analysis; the impurity content was low enough not to give rise to undesirable extraneous radioactivity. The samples were annealed in a graphite-resistor vacuum furnace which was maintained at constant temperature by a Minneapolis-Honeywell Radiamatic unit. This unit was calibrated against the melting points of Cu, Si,

and Ni contained in quartz ampules. Temperature measurement and control was ±4°C. Temperature rise and decay times in this furnace were such that no time correction was needed for samples diffused over 24 hr. At the highest temperature investigated (1398°C), the anneal was done in a globar-heated tube furnace where the samples could be introduced and withdrawn quickly. In nearly all cases, times were chosen so that the value of $\sqrt{Dt}$ would be at least 5 x 10^{-4} cm, in order to insure that count rates would not change by over three orders of magnitude while lapping through a depth of 15 μ or more.

After removal from the furnace, the samples were washed in 48% HF to remove possible oxides. The edges and one of the faces were ground off to a depth far below that at which no change in count rate was observed and autoradiographs of the active faces were taken. The samples were then weighed to constant weight on a microbalance and an initial count rate for each sample was determined. A layer of uniform thickness (2 to 4 μ in most cases) was then ground off each sample by hand lapping with 3200-mesh abrasive on glass. This process effects a clean separation between matrix and ground-off material; no extraneous activity on the matrix due to adhesion of ground-off layers was noted.

The process of grinding, weighing, and counting was repeated until the activity dropped to a value below which further processing would be impractical. All counting was done in a well-type gamma scintillation detector coupled to a single-channel spectrometer. All sample count rates were compared to the count rate of a standard of known total Sb content; backgrounds were determined at least twice a day. In most cases total counts were collected so as to give a counting error of 1% or less with 95% confidence.

Results

Evaluation of D.—The thickness of sample layers removed at each cut was calculated from the weight loss and the cross-sectional area of the sample using a density of 2.33 for Si[9]. All of the data from six temperature anneals are too bulky to reproduce here; however, an example of the basic data used in calculating D for the run at 1330°C is given in Table I.

The ratio of successive count rates and the corresponding values of x were substituted from Table I into Eq. [4] and D's were calculated for successive combinations as shown in Table II. The mean value of the D's thus calculated was taken as the final value for each sample.

Evaluation of C_o.—The surface concentration C_o was calculated from Eq. [2], substituting the mean value of D found for each sample and the corresponding total number of Sb atoms. This could be done in all cases where no extraneous surface activity was found on the samples as checked by autoradiography.

The results of six temperature anneals are summarized in Table III.

The temperature dependence of the diffusion coefficient of Sb in Si found in these experiments is expressed by the following equation:

$$D = 12.9 \exp(-91{,}700/RT) \text{ cm}^2 \text{ sec}^{-1} \quad [5]$$

which is the least squares equation of the data in Table III, omitting the data from the run at 1355°C. The solid line in Fig. 1 is a plot of Eq. [5]; the experimental points represent the mean D value of the two samples at each temperature. The latter fall on or are close to the line except the point correspond-

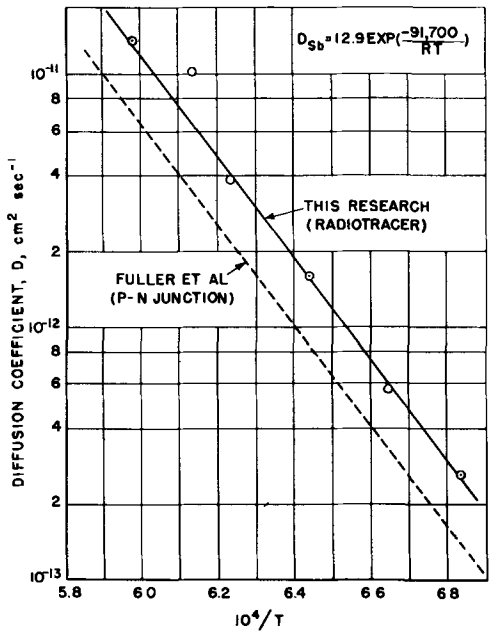

Fig. 1. Diffusion coefficients of Sb in Si plotted against reciprocal of absolute temperature.

ing to the 1355°C run. It is probable that this deviation was caused by the temperature being much higher than recorded, since some difficulties were experienced with the temperature controller during that run. For comparison a plot of the temperature dependence of the diffusion coefficient of Sb in Si as given by Fuller and Ditzenberger's equation (4),

$$D = 5.6 \exp(-91{,}000/RT) \text{ cm}^2 \text{ sec}^{-1} \quad [6]$$

is shown (dashed line). It can be seen that, whereas both tracer and p-n junction methods gave ΔH values which are in essential agreement, the values of D obtained by the tracer method averaged about 85% higher than those by the p-n junction method in the temperature range studied.

Discussion of Results

It is difficult to analyze quantitatively the effect of all possible errors on the values of D, C_s, and ΔH reported here. The error in counting has been mentioned previously; however, this error is based on the statistics of random process. A more practical error to consider here is that of reproducibility. In our counting assembly, count rates were reproducible to ±2% which leads to errors of ±4% in the ratio of Eq. [4]. Cumulative weighing errors of ±2 μg lead to errors in the estimation of lapping depths of ±0.02 μ; such precision, however, means little in view of the fact that parallel lapping was assumed but not proved.

The most serious errors in the value of D could be due to nonparallel lapping; the effect of misalignment of the plane of lapping with respect to the plane of the original crystal face can result in a value for D which is high compared to the true value in all cases. By assuming various geometries of misalignment it is possible to estimate the error in D due to this source. This was done for various geometries and degrees of misalignment, and it was found that the worst conceivable situation would produce an error in D of about +25%. However, toward the end of this work it was possible to check the geometry and degree of misalignment by means of a Zeiss optimeter capable of measuring thicknesses with an accuracy of ±0.2 μ. These measurements indicated that the degree of misalignment was indeed small and that confidence in the inherent simplicity of hand lapping was justified. Experiments with various machines and jigs led to the conclusion that these could introduce systematic errors which would be more serious than the random errors produced by hand lapping.

Errors might also accrue due to loss of sample surface by evaporation. It was felt that such losses would be small in a closed system; this was confirmed both by micrometric measurements and by the fact that the original semi-mirror finish of the samples was preserved (although some pitting was noticed). The question of whether the diffusion coefficients obtained are truly representative of bulk diffusion has not been fully resolved. This question arises from the fact that the samples were not etched after grinding flat. It is possible that the worked surfaces and the layers immediately below might provide an easier path for diffusant penetration than would the bulk material. Indeed it was found that values of D calculated from the data of cut combinations 0-1, 0-2, etc., were much higher than the mean value in all cases. Such values for D, therefore, were not included in calculating the mean; however, it will be noted from the representative data of Tables I and II that this effect was not noticeable beyond a depth of a few microns. Samples were left in the ground state because even the most rigorously controlled etching always produced uneven surfaces that would be very poor planes of reference for such relatively shallow diffusion penetrations.

The over-all effect of all the possible errors, as well as the assumptions made in carrying out these experiments, may be illustrated by comparing the experimental diffusion of Sb into Si with that predicted by Eqs. [2] and [3]. These equations may be combined to express the fraction of total diffused atoms remaining in the crystal, i.e., after grinding down to a plane x cm below the surface, as follows:

$$\frac{N_x}{N_T} = \frac{R_x}{R_T} = \frac{\phi}{1.13} \quad [7]$$

Figure 2 is a plot of theoretical residual atom fractions at various depths calculated from Eq. [7], substituting for $\sqrt{Dt}$ the value 8.26×10^{-4} cm corresponding to the mean value found from the diffusion anneal at 1330°C (Table II). The points are the experimentally determined count rate ratios; it is apparent that these follow the theoretical curve within experimental error. For the sake of clarity only one such curve is shown in Fig. 2, viz., that which may be verified by the data given; however, for other temperature anneals the fit of the experimental penetration with the theoretical was even more striking. Despite the fact that the rms deviations in the value of D's of the two samples in any temperature run varied considerably between samples, it

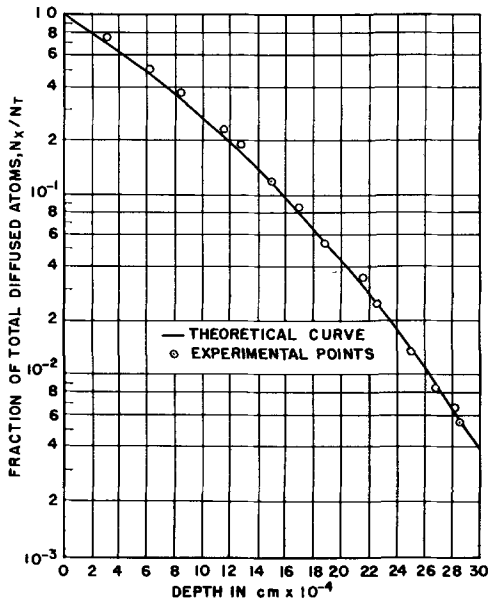

Fig. 2. Plot comparing experimental with theoretical diffusion of Sb in Si at 1330°C.

should be noted that the mean D values of both samples were in very close agreement (Table III). Such agreement, coupled with the good fit of the experimental penetration with the theoretical, seems to indicate that all of the assumptions made were vindicated and that the D's represent true bulk diffusion with an average error of ±12% which represents the mean of all the individual sample errors. From this and the closeness of the experimental points to the log D vs. $1/T$ line in Fig. 1, the estimated error in ΔH is about 1%.

Errors in C_o reflect the errors in D and the conversion factor G. The latter, from a series of calibrations, is estimated to be about ±5%. Thus, the error in C_o is about 12%.

Conclusion

Diffusion coefficients of Sb in Si measured by a radiotracer technique were found to be considerably higher than those reported in the literature where a p-n junction technique was used. The results confirmed the belief that p-n junction measurements gave too low values for D, since abnormally high values for the surface concentration of Sb on Si are calculated when p-n junction values of D are used. Surface concentrations calculated from the diffusion coefficients found in this investigation were found to be within the range expected for unsaturated Si surfaces. No explanation is offered at this time for the disagreement between the results as obtained by the two methods pending the completion of further studies using tracer acceptor elements as diffusants.

Since this work was completed, it has come to the attention of the authors that the diffusion of Sb in Si has been investigated using Sb-124 (10). Details of these experiments are insufficiently explicit to warrant comment; however the results of the work, expressed by the equation $D = 0.112 \exp(-66{,}000/RT)$ cm^2 sec^{-1} is in complete disagreement with both the authors' results and those of Fuller and Ditzenberger.

Acknowledgments

The authors are indebted to Mrs. Thelma B. Salmas for assistance in sample preparation and checking calculations; to Henry M. DeAngelis for stimulating discussions; and to Joseph R. O'Connor for furnishing the single-crystal silicon.

Manuscript received Feb. 2, 1959. This paper was prepared for delivery before the New York Meeting, April 27-May 1, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

The Relation of Gas Composition to Current Efficiency in an Aluminum Reduction Cell

T. R. Beck

Metals Division Research, Kaiser Aluminum & Chemical Corporation, Permanente, California

ABSTRACT

Experience with a 10,000-amp aluminum reduction cell indicates that the previously accepted equation relating current efficiency and cell gas CO_2 concentration is an oversimplification. A modified equation, % CE $= g[50 + \frac{1}{2}(\%\ CO_2)] - Z$, fits the data more satisfactorily. The new terms, g and Z, respectively, account for: (*a*) less than 100% initial CO_2 and/or reaction of CO_2 with carbon, and (*b*) a certain percentage of current inefficiency by oxidation or loss of some cathode products without involvement of CO_2. The experiments showed g to be somewhat larger than unity and to vary with the bake temperature of the anodes and Z to be somewhat larger than 3.5%.

This paper describes work done on a 10,000-amp experimental aluminum reduction cell. The cell was established for studying process variables that could not be studied satisfactorily in any other way. It was of such a size that results could be scaled up to apply directly to the present commercial cells. Although it was only 1/6 to 1/10 the size of present commercial cells, it was comparable in size to the commercial cells of three decades ago (1). Because it was operated as an independent unit with its own power supply and was not tied to a production schedule, experiments and measurements could be made and an accuracy obtained that would be virtually impossible to attain under plant conditions. Significantly smaller self-sustaining cells operating at commercial current densities are difficult to operate because of proportionately higher heat losses for their greater surface-to-volume ratio. Scale-up from still smaller externally heated bench scale cells to full scale plant cells is open to question.

In construction and dimensions it was equivalent to placing the two ends of a commercial prebaked-anode cell together after removing the center section. Dimensions of the cavity were approximately 43 in. x 65 in. cross section by 14 in. deep. Plant anodes and superstructure hardware were used. Anode dimensions were 15½ in. x 19½ in. cross section by 12 in. high.

Early in the program a test was made to evaluate the effect of anode-bake temperature on carbon consumption. Routine cell gas analyses for CO_2 and CO were made in order to determine what fraction of the carbon consumption could be attributed to the electrochemical reaction. Correlation of these gas analysis data with current efficiency was the basis for this paper.

Experimental

Anodes for use in this study were pressed and baked at the Corporation's Mead Works near Spokane, Washington. Thermocouples were installed in the baking pits to determine the maximum temperatures reached during the bake. From these data maximum-temperature-isotherms were drawn for the pits, and anodes were segregated into suitable bake temperature ranges for use in the 10,000-amp cell tests.

Each test lasted four weeks and consumed approximately 19 anodes. Each of the four anodes in the cell was changed every six days on a regular schedule. A one-week transition period between tests was used to install a new complement of anodes.

Cell conditions were held as constant as possible during the test series. Anode-cathode distance was maintained at 2 in. for all but the last three runs at which it was 1½ in. Bath composition was 89% cryolite at 1.5 NaF: AlF_3 ratio, 8% calcium fluoride, and 3% alumina. Bath temperature was maintained at 975°-985°C. Current varied from 9500 to about 11,000 amp during the course of the experiments because the power input was increased to compensate for increased heat losses as bath penetrated the insulation and because the last three runs were made at a lower anode-cathode distance.

Gas composition was measured with an Orsat gas analyzer at 2-hr intervals half way between hourly feedings of alumina. The cell gas was collected through a steel bell placed on the crust of the cell as shown in Fig. 1. The gas was drawn through Inconel and rubber tubing to the gas analyzer. The

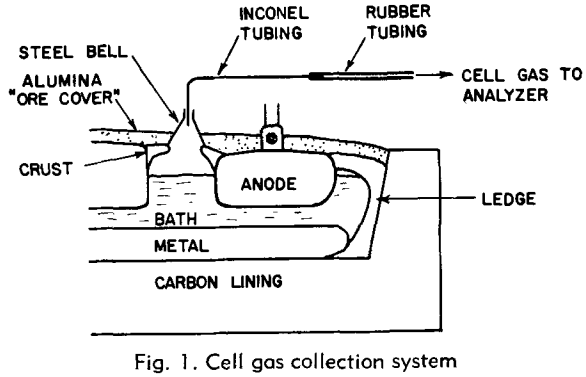

Fig. 1. Cell gas collection system

Table I. Experimental data for various bake temperature anodes. Each point represents one four-week test

	Current eff.	% CO_2	Avg. est. anode bake temp, °C	
Low-bake-temperature anodes	85.5	69.3	946	959
	86.9	71.8	972	
Medium-bake-temperature anodes	86.7	77.4	1071	1070
	88.9	79.7	1070	
High-bake-temperature anodes	86.8	80.7	1142	Approx. 1150
	85.5	78.5	1110-1190	
	86.4	79.0	1110-1190	
	88.2	81.1	1110-1190	
	86.5	78.7	1110-1190	
	84.4	77.4	1110-1190	
	84.1	75.9	1110-1190	

crust, composed of frozen cryolite, was continuous except for the single vent which was used for feeding and gas collection so there was a negligible leakage of air into the system. Reaction of the cell gas within the Inconel sample tube appears unlikely because the measured gas composition did not vary with the rate that the gas was sampled. The gas was cool before it entered the rubber tubing.

Results

The experimental data are presented in Table I and Fig. 2. Current efficiency did not vary significantly with anode-bake temperature, but per cent of CO_2 in the cell gas increased with increasing bake temperature. The low-bake-temperature-anode data are above the previously accepted Pearson and Waddington correlation (1, 2), and the high-bake-temperature-anode data are below it. There is a certain scattering of the data, but there is an unmistakable trend with anode bake temperature. For a given bake temperature, the data roughly parallel the Pearson and Waddington correlation although the slope appears to be slightly steeper.

The first four groups of anodes were run in random order to cancel the effect of cell aging. The remaining seven groups were run in the order listed.

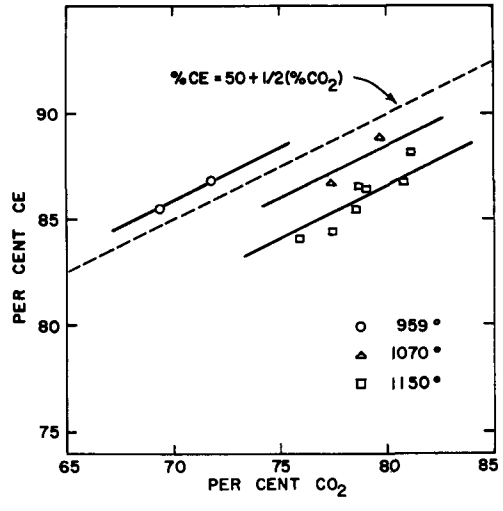

Fig. 2. Experimental data for various bake temperature anodes. Each point represents one 4-week test.

The range of current efficiency from 85.5 to 88.9% can be attributed to small changes in the operating conditions, unavoidable in an aluminum reduction cell. The 84% current efficiency in the last two runs was the result of the lower anode-cathode distance. Despite some variations in cell conditions the data for each bake temperature fell on its characteristic line. The regular deviation suggested that there were some factors ignored in the original derivation of the Pearson and Waddington equation so a more comprehensive equation was derived.

Discussion

The Pearson and Waddington equation

$$\% \text{ CE} = 50 + \tfrac{1}{2}(\% \text{ CO}_2)$$

is based on the following assumptions: (*a*) initial anode product is 100% carbon dioxide, and (*b*) carbon monoxide is produced by reduction of carbon dioxide by cathode products, i.e.,

$$CO_2 + \left\{\begin{matrix}2Na,\\ Al^{+},\\ 2/3Al,\\ \text{etc.}\end{matrix}\right\} \rightarrow CO + \left\{\begin{matrix}2Na^{+},\\ Al^{+++},\\ 2/3Al^{+++}\\ \text{etc.}\end{matrix}\right\} + O^{=}$$

A plot of the Pearson and Waddington equation is shown in Fig. 3 with the directions of the deviations due to errors in the assumptions.

Case I is a decrease in per cent CO_2 without a change in current efficiency. This can result from primary and/or secondary formation of CO. These are inseparable in the data presented here but could perhaps be separated using a radio-carbon technique. It must be borne in mind that there is always the possibility of introduction of air during sampling which will give a low apparent CO_2, especially with plant cells which often do not have a continuous solid crust. It is felt that this error is not significant in the work with the Permanente cell because of the continuous solid crust. The nitrogen content of the samples was usually less than 1%. Small amounts of other gases have been found in reduction cell gas but not in sufficient amount to affect the results presented here significantly. Hydrogen, hydrogen sulfide, and carbonyl sulfide have been found in concentrations of a few tenths of a per cent or less (3). Formation of fluorocarbons appears to be limited to periods of anode effect (3).

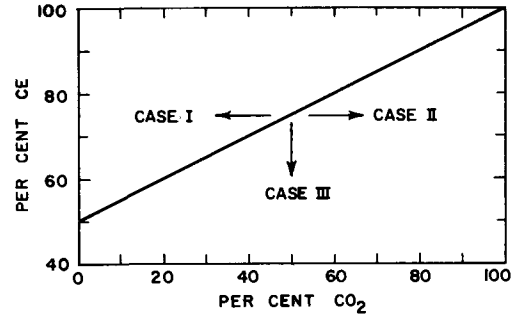

Fig. 3. Deviations due to errors in derivation assumptions for Pearson and Waddington equation.

Case II is an increase in per cent CO_2 without a change in current efficiency. A possible reaction is the formation of free carbon and CO_2 by disproportionation of CO as the pot gas temperature is reduced. No measurable amount of this free carbon formation was found with the Permanente cell.

Case III is a decrease in current efficiency without a change in the gas composition. There are a number of mechanisms that can lead to this condition. The more important possibilities are as follows. (*a*) escape of sodium from the cell or oxidation of sodium by air (Pockets of sodium metal are frequently found in the crust of the Permanente cell, substantiating this mechanism.); (*b*) direct oxidation of sodium, monovalent aluminum, or "metal fog" at the anode without the intervention of CO_2; (*c*) electronic conduction through the bath or through short circuits between anode and cathode by metal splashing or accumulated carbon "dust;" (*d*) formation of sodium and/or aluminum carbides with the lining; and (*e*) oxidation of aluminum during tapping.

Case IV, an increase in current efficiency without a change in gas composition, is not possible because it would require more than Faraday's equivalent of metal formed at the cathode.

The deviations of the experimental data in Fig. 2 can be explained by these reactions. For all three sets of data, the deviation below the Pearson and Waddington line due to Case III would be expected to be about the same. Anode quality would hardly be expected to affect significantly the factors that make up Case III. The shift in the lines to the left with lower-bake-temperature anodes can be explained by Case I.

The more general relation between current efficiency and gas composition is derived as follows:

Initial cell reaction

$$2Al_2O_3 + (6-n)\,C \rightarrow 4Al + nCO_2 + (6-2n)\,CO \quad [1]$$
$$0 \leqq n \leqq 3$$

Equivalent inefficiency reaction

$$2/3Al + CO_2 \rightarrow 2/3Al^{+++} + CO + O^{=} \quad [2]$$

Reaction of CO_2 with carbon

$$CO_2 + C \underset{y_2}{\overset{y_1}{\rightleftarrows}} 2CO \quad [3]$$

$$\% \text{ CE} = \frac{A - C - D}{A + B} \times 100 \quad [4a]$$

where A = equivalents of Al (or Na, etc.) initially formed; B = equivalents of electrons carried by electronic conduction; C = equivalents of Al reoxidized by CO_2; and D = equivalents of Al lost or reoxidized without CO_2.

To simplify the derivation the following transformation is made

$$A' = A + B$$
$$E = D + B$$
$$\therefore \% \text{ CE} = \frac{A' - C - E}{A'} \times 100 \quad [4b]$$

* The subscript *p* represents material produced, subscript *r* indicates material reduced, and the numerical subscripts refer to Eqs. [1], [2], and [3].

$$\% \text{ CO}_2 = \frac{CO_{2(p,1)} - CO_{2(r,2)} - CO_{2(r,3)}}{CO_{2(p,1)} + CO_{(p,1)} - CO_{2(r,2)} + CO_{(p,2)} - CO_{2(r,3)} + CO_{(p,3)}} \times 100 \quad [5]^*$$

Per each Eq. [1], assume x Eq. [2] and y Eq. [3]. (Note: y is the net number of CO_2's lost, i.e., $y = y_1 - y_2$ since the reaction is reversible.) $\therefore A' = 4$, $C = (2/3)\,x$, and $E = 4Z/100$, where Z is percentage of current lost by Case III.

$$\therefore \% \text{ CE} = 100\left(\frac{4 - (2/3)x - 4Z/100}{4}\right) \quad [6a]$$

and

$$\% \text{ CO}_2 = 100\left(\frac{n-x-y}{n+6-2n-x+x-y+2y}\right) = 100\left(\frac{n-x-y}{6-n+y}\right) \quad [6b]$$

Eliminating x from [6*a*] and [6*b*] gives

$$\% \text{ CE} = \frac{6-n+y}{3}\,[50 + \tfrac{1}{2}(\% \text{ CO}_2)] - Z \quad [6c]$$

The fraction of the initial CO_2 reacting by Eq. [3] is $f = y/n$

$$\therefore \% \text{ CE} = \frac{6-n+nf}{3}\,[50 + \tfrac{1}{2}(\% \text{ CO}_2)] - Z \quad [7]$$

$$\% \text{ CO}_2 \text{ in primary gas} = 100\left(\frac{n}{6-n}\right) \quad [8]$$

Substituting the value for n [Eq. 8] in Eq. [7]

$$\% \text{ CE} = 2\left[\frac{1 + f\left(\frac{\text{initial } \% \text{ CO}_2}{100}\right)}{1 + \frac{\text{initial } \% \text{ CO}_2}{100}}\right][50 + \tfrac{1}{2}(\% \text{ CO}_2)] - Z \quad [9]$$

Because it is difficult to separate the effect of initial anode gas composition and the reaction of CO_2 with carbon, Eq. [9] may be simplified by letting

$$g = 2\left[\frac{100 + f(\text{initial } \% \text{ CO}_2)}{100 + \text{initial } \% \text{ CO}_2}\right]$$
$$\therefore \% \text{ CE} = g[50 + \tfrac{1}{2}(\% \text{ CO}_2)] - Z \quad [10]$$

This equation reduces to the Pearson and Waddington equation for 100% initial CO_2, no reaction of CO_2 with carbon, and no loss of cathode products other than by reaction with CO_2.

The theoretical limits for g are $g = 1$ to 2. A value of $g = 1$ means initial $CO_2 = 100\%$ and no reaction of CO_2 with carbon. A value of $g = 2$ means that undiluted gas leaving the cell is pure CO and no CO_2 reduction by metal has occurred. Except when the cell is on anode effect, the value of g appears to be closer to unity. The value of g would be less than 1 for Case II in Fig. 3, but Case II appears to be negligible for the Permanente experimental cell.

The theoretical limits for Z are $Z = 0$ to 100.

The preceding sections show that (*a*) less than 100% initial CO_2 or reaction of CO_2 with carbon, and (*b*) loss of metal without reacting with CO_2 tend to shift actual pot data to opposite sides of the Pearson and Waddington line. It appears that the relation of per cent CO_2 to current efficiency found by prior investigations (2, 4) was due to a fortuitous combination of these two effects.

In Fig. 2 it is seen that the line for the highest bake-temperature anodes is about 3.5% below the Pearson and Waddington line within the range of the experimental data. Since even the highest bake-temperature anodes used probably gave a g value greater than one, Z must have been greater than 3.5%. The lines through the data in Fig. 2 were drawn as an example with a value of $Z = 5.0$. The corresponding values of g are as follows:

Anode bake temp, °C	g
959	1.070
1070	1.040
1150	1.020

In future tests it is hoped that Z can be evaluated, or at least its variation with cell variables determined. While the value of Z was probably relatively constant in these tests, there are indications from later tests that it varies significantly with bath NaF/AlF_3 ratio.

Measurement of the per cent CO_2 in cell gas has been advocated as a means of determining instantaneous values of current efficiency (4). Results in this work indicate that this is a very questionable practice.

Summary and Conclusions

Current efficiency and cell gas composition were measured on a 10,000-amp experimental aluminum reduction cell for operation with groups of anodes baked at temperatures from 950° to 1190°C. The following are the conclusions from this work:

1. Current efficiency did not vary significantly with anode bake temperature.

2. The percentage of CO_2 in the cell gas varied with anode bake temperature, increasing with increasing bake temperature.

3. This produced deviations from the previously accepted equation:

$$\% \text{ CE} = 50 + \tfrac{1}{2}(\% \text{ CO}_2)$$

4. The data could be correlated by a new equation:

$$\% \text{ CE} = g\,[50 + \tfrac{1}{2}(\% \text{ CO}_2)] - Z$$

5. Some oxidation or loss of cathode products by other than reaction with CO_2 is indicated by a value of Z that is at least 3.5%.

6. The value of g was greater than unity and increased for low-bake-temperature anodes, which indicates less than 100% initial CO_2 and/or reaction of initially formed CO_2 with carbon in cell.

7. Use of the oversimplified equation, $\% \text{ CE} = 50 + \tfrac{1}{2}(\% \text{ CO}_2)$, to calculate current efficiency from gas analyses is a questionable practice.

Acknowledgment

The author wishes to thank Bernard Porter and other members of the Research staff for helpful criticisms and Kaiser Aluminum & Chemical Corporation for permission to publish this work.

Manuscript received Dec. 22, 1958. This paper was prepared for delivery before the San Francisco Meeting, April 29-May 3, 1956.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

December 1959 Discussion Section

A Discussion Section, covering papers published in the January-June 1959 JOURNALS, is scheduled for publication in the December 1959 issue. Any discussion which did not reach the Editor in time for inclusion in the June 1959 Discussion Section will be included in the December 1959 issue.

Those who plan to contribute remarks for this Discussion Section should submit their comments or questions in triplicate to the Managing Editor of the JOURNAL, 1860 Broadway, New York 23, N. Y. *not later than September 1, 1959.* All discussions will be forwarded to the author(s) for reply before being printed in the JOURNAL.

Electromotive Force Series of Metals in Fused Salts and Activities of Metal Chlorides in 1:1 Molar KCl-NaCl Solutions

S. N. Flengas and T. R. Ingraham

Mines Branch, Department of Mines and Technical Surveys, Ottawa, Ontario, Canada

ABSTRACT

The potentials of a series of metal-metal chloride systems in an equimolar mixture of molten potassium and sodium chlorides have been measured against a silver-silver chloride reference electrode. An electromotive force series of metals at different temperatures has been established for this particular solvent. Experiments with a chlorine electrode have shown that the solutions of silver chloride in the KCl-NaCl solvent are ideal, and hence, deviations from ideality of the other chlorides in this solvent can be attributed directly to the formation of complexes in the melts. Three types of behavior have been observed for the salts studied in this solvent: ideality, and positive and negative deviations from ideality. The theoretical aspects of complex formation in melts are discussed.

The work reported in this paper is the culmination of experiments begun in 1956 for the purpose of establishing electromotive force series of metal-metal chloride systems in a solvent consisting of 1:1M KCl-NaCl, at temperatures between 650° and 900°C. In the initial experimental work, a thermodynamically reversible, diffusion-free, silver-silver chloride reference electrode (1) was developed. This electrode was used to obtain the standard potentials of several systems (2-5). In this paper, the data have been used to establish emf series of metals at various temperatures.

A theoretical interpretation of these data required the definition of an "ideal" reference standard state. By choosing the pure metal chlorides at the temperatures of experiment as the standard state, it was observed that the experimental standard cell potentials showed pronounced deviations from ideality. To resolve the differences, a chlorine-chloride ion electrode was constructed, and the properties of the silver-silver chloride electrode were investigated in detail. Having established the properties and thermodynamic functions of the silver chloride solutions, the activity coefficients and other related thermodynamic properties of the remaining chlorides were calculated.

Standard Electrode Potentials in Fused Salts

Experimental

The preparation of materials and the detailed experimental procedure for electrode potential measurements in fused salts has been described in detail in previous publications (1-5). The potentials of the systems Mn-$MnCl_2$, Zn-$ZnCl_2$, Cr-$CrCl_2$, Tl-TlCl, Cd-$CdCl_2$, Fe-$FeCl_2$, Pb-$PbCl_2$, Sn-$SnCl_2$, Co-$CoCl_2$, Ni-$NiCl_2$, and Cu-CuCl were investigated with cells of the type

M	$MCl_n(x_2)$			
(-)	KCl-NaCl (1/1 Mole)			
	(Indicator electrode)			
Asbestos	$AgCl(x_1)$			Ag
fiber	KCl-NaCl (1/1 mole)			(+)
	(Reference electrode)			

[*A*]

A typical design of the all-silica cell is given in Fig. 1. In this cell the reference electrode solution is

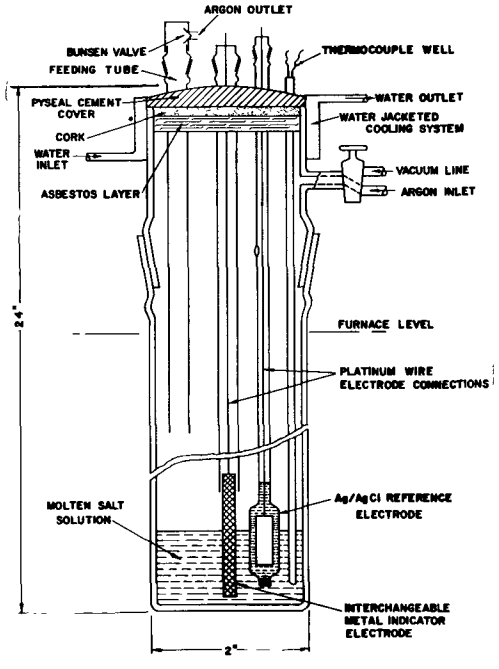

Fig. 1. Cell design for metal electrode potential measurements: Cell [A]

M	$MCl_n(x_2)$		Asbestos		$AgCl\ (x_1)$	Ag
(—)	KCl-NaCl	‖	fiber	‖	KCl-NaCl	(+)
	(1/1 mole)				(1/1 mole)	

separated from the solution in the indicator electrode by a small asbestos fiber sealed into the end of the silica tubing of the reference electrode. The fiber absorbs the salts and makes a good electrical contact between the two solutions while hindering diffusion. Analysis of the solutions from both electrode compartments indicated that this method of separation was effective. For dilute salt solutions, the presence of a large excess of the same ionic melt on both sides of the junction effectively eliminated junction potentials.

The reaction for a cell of the type shown above is:

$$M\,(s) + n\,Ag^+(AgCl \text{ in KCl-NaCl}) = M^{n+}(MCl_n \text{ in KCl-NaCl}) + nAg(s) \quad [A']$$

The relationship between the cell potential and salt concentrations in the melt is given by the Nernst equation in the expanded form

$$E(\text{cell A}) = E^\circ(Ag/Ag^+) - E^\circ(M/M^{n+}) + (RT/n\mathbf{F}) \ln \frac{x_2}{x_1^n} - (RT/n\mathbf{F}) \ln \frac{\gamma_2}{\gamma_2^n} \quad [1]$$

where $E^\circ(M/M^{n+})$ is the *standard electrode potential* [with the IUPAC Stockholm sign convention (16)] of M in the metal chloride MCl_n and $E^\circ(Ag/Ag^+)$ is the *standard electrode potential* of Ag in AgCl. The γ and x are, respectively, the mean activity coefficients and mole fractions of the metal chlorides taking part in the cell reaction. If the E° are referred to the standard chlorine-chloride electrode at the same temperature (see below), they become equal to *minus the formation potentials* of MCl_n and AgCl, respectively, in their standard states (pure salt at the temperature of the experiment) as defined by Hamer, Malmberg, and Rubin (6). Mole fractions are defined in the usual way, which is

$$x_i = n_i/\Sigma n_j \quad [2]$$

where n_i is the number of moles of the i^{th} constituent.

From Eq. [1], assuming that the activity coefficients for dilute solutions are constant, it is possible to calculate a cell potential which proved to be independent of concentration. This is done simply by subtracting the term $(RT/n\mathbf{F}) \ln (x_1^n/x_2)$ from the experimentally obtained potential, E (cell A). The potential thus derived is constant over the range of concentrations for which the activity coefficients are constant and will be called the "apparent standard cell potential," $E^{\circ\prime}$ (cell A). From Eq. [1], the apparent standard cell potentials are given by

$$E^{\circ\prime}(\text{cell A}) = E^\circ(Ag/Ag^+) - E^\circ(M/M^{n+}) + (RT/n\mathbf{F}) \ln (\gamma_1^n/\gamma_2) \quad [3]$$

The standard cell potential E°(cell A) would be given by Eq. [3] without the activity coefficient term.

Apparent standard cell potentials can be obtained in either of two ways: by the graphical method, which involves the interpolation (or extrapolation) of the log x_2/x_1^n vs. E(cell A) curve to zero log-value (Fig. 2), or by calculation from the Nernst equation. In the latter method the Nernst curves must be linear, and the slopes of the straight lines must be identical with the theoretical values of $(2.303\ RT/n\mathbf{F})$. From Eq. [3] it is seen that the experimentally derived apparent standard cell potential $E^{\circ\prime}$(cell A) includes, in addition to the standard electrode potentials, the dilution effect as an activity coefficient term. Since standard electrode potentials are known (6), Eq. [3] can be used to calculate activity coefficients in melts.

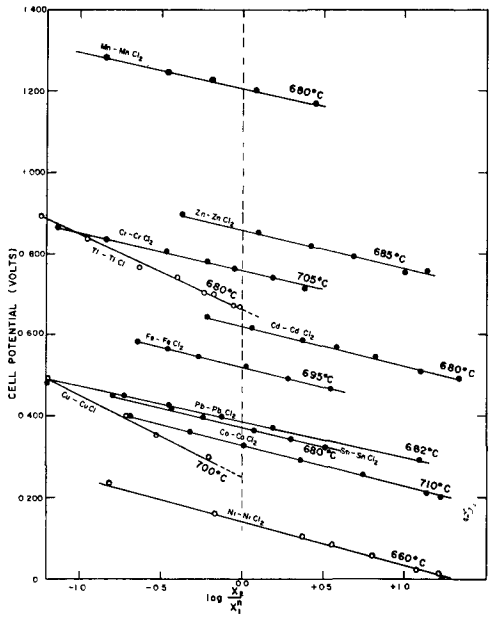

Fig. 2. Electromotive force of Cell [A] for different metals as a function of log (x_2/x_1^n) at constant temperature. ($x_1 = 6.235 \times 10^{-2}$).

Results

The results of potential measurements with these cells at different salt concentrations are given in Fig. 2. In this graph the experimentally obtained cell potentials E(cell A) are plotted vs. the logarithm of the mole fraction ratio in the two half-cells, following the Nernst equation [1]. It will be observed that the relationship is linear, which justifies the assumption made for the definition of the apparent standard cell potential $E^{\circ\prime}$(cell A) of Eq. [3]. This linearity indicates that the activity coefficients of the metal chlorides are either unity or constant for the concentration range of the experiments. The apparent standard cell potentials for each system, obtained by graphical interpolation or extrapolation at zero log-term, are indicated by the intercepts with the dotted line in the center of Fig. 2.

The slopes of the straight lines are in most cases in good agreement with the Nernst equation, with the exception of the Ni-$NiCl_2$ system in which a slope of 0.107 is obtained instead of 0.096. Cell potentials in Fig. 2 are corrected for small thermoelectric forces. These were measured separately on the bimetallic systems of the electrodes (with their connections) and are given in Fig. 3.[1]

[1] Potentials given in some of our previous publications (1-4) have not been corrected for thermoelectric effects. For such corrections, reference should be made to Fig. 3.

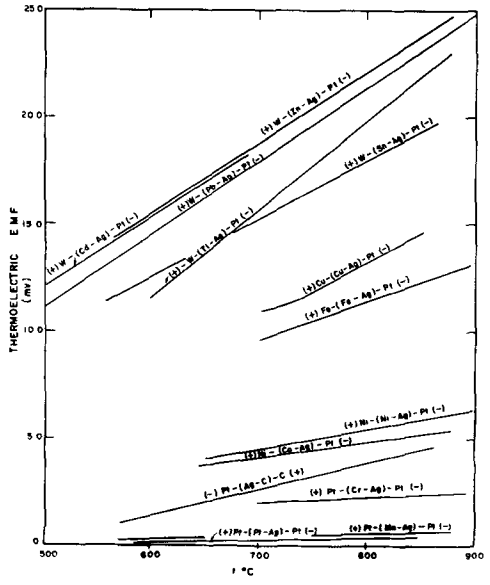

Fig. 3. Thermoelectric electromotive forces of the bimetallic systems of the various types of electrodes used in this study.

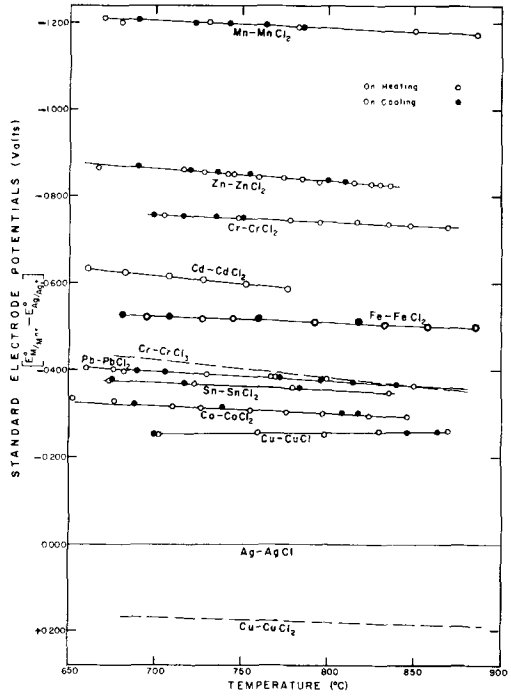

Fig. 4. Variation of standard electrode potentials with temperature.

The effect of temperature change on the apparent standard cell potentials $E^{o\prime}$ (cell A) was also measured; the results are summarized in Fig. 4. It is seen that between 650° to 900°C the relationship of temperature and apparent standard cell potential is linear and the temperature coefficient is small. Standard cell potentials for the systems Cu-$CuCl_2$ and Cr-$CrCl_3$ are shown in the graph by dotted lines to indicate that these values were not obtained experimentally but were calculated using a process described previously (4). In fact, neither of these potentials could be measured directly because of a spontaneous reduction of the higher valency chlorides by the corresponding metal electrodes.

The emf series derived in the present investigation at temperatures of 700°, 800°, and 900°C are given in the first three columns of Table I from our observed values of $E^{o\prime}$ (cell A). In the same tabulation are also included the standard potentials, calculated from E^{o} (cell A) values derived from thermal data by Hamer, Malmberg, and Rubin (6). A third set of data is included to demonstrate the agreement between the standard electrode potentials obtained in this study in the presence of 1/1M KCl-NaCl solvent and those published recently by Laitinen and Liu (7) in the KCl-LiCl eutectic solvent. Since the latter were determined at 450°C, it was necessary to extrapolate our values to this temperature.

[a] It will be noted that the sign of the electrode potentials is in accord with the recommendations of the IUPAC Stockholm Convention [See Licht and deBethune (16)]. The potentials are referred to Ag/AgCl.
[b] Standard potentials calculated from thermal data.
[c] Extrapolated values from our experimental data obtained at temperatures between 650° to 900°C in 1:1 KCl-NaCl.
[d] Values obtained by Laitinen and Liu (7) in KCl-LiCl at 450°C.

From Table I, it is readily seen that both the sequence and the magnitude of the potentials in the experimentally derived emf series of metals are different from those calculated by Hamer, Malmberg, and Rubin (6). These differences are due to the effects of solvent on the salts, as expressed by the γ term in Eq. [3]. On the other hand, standard potentials obtained experimentally in this study and by Laitinen and Liu (7) are in substantial agreement. The small differences in the magnitude of the potentials should be attributed to the difference in solvents and to the error in extrapolating our data to 450°C. It should also be noted that standard potentials determined by Laitinen and Liu are given without thermoelectric force corrections. The corrections are probably a few millivolts only and should be added to the measured potentials. The agreement should therefore be, in most cases, even better than that shown in Table I.

Thermodynamic Properties of Solutions of Silver Chloride in 1/1M KCl-NaCl

The standard cell potentials obtained in cell [A] represent the difference between the individual standard electrode potentials of the reference and indicator electrode systems. Consequently, it is not possible to calculate individual activities of the metal chlorides in solution unless the thermodynamic properties of one species are known. Although preliminary results (1) indicated ideality of the AgCl (KCl-NaCl) system, it was necessary to confirm this by determining the activities of silver chloride in solution. The thermodynamic properties of pure silver chloride have been studied by several investigators (8-10, 17), using silver-chlorine cells of various designs. The agreement between the different data is quite good. On the other hand, there is little information on the properties of solutions of silver chloride in fused salt solvents. Stern (11, 12) investigated the systems AgCl-KCl and AgCl-NaCl, at 800°C and showed that, whereas the former deviates from ideality positively, the latter deviates negatively. Takahashi (13) investigated the system AgCl(KCl-LiCl) and found a small deviation from ideality. In these studies the pure silver chloride state was also chosen as the standard state for reference.

In the present investigation, a cell consisting of silver-silver ion and chlorine-chloride ion electrodes was developed and used to measure the thermodynamic properties of solutions of silver chloride in the 1/1M KCl-NaCl solvent at temperatures varying between 650°-900°C.

Experimental

The cell used to measure the potentials of silver chloride in the molten salt solution was of the following type:

Ag (-)	AgCl (x) KCl-NaCl (1/1 mole)	‖		
Asbestos fiber	KCl-NaCl 1/1 mole	‖	Cl_2 (1 atm) C (graphite)	(+) [B]

The cell consisted of a chlorine-chloride ion reference electrode and a silver-silver ion indicator electrode. The cell reaction is simply the formation of silver chloride in solution, i.e.:

$$Ag(s) + \tfrac{1}{2}Cl_2(g) = Ag^+Cl^-(\text{in KCl-NaCl}) \quad [C]$$

The relationship between the cell potential and the mole fraction of silver chloride (x), is given by the Nernst equation in the expanded form:

$$E(\text{cell } B) = E^\circ(Cl^-/Cl_2) - E^\circ(Ag/Ag^+) - (RT/\mathbf{F}) \ln (x\gamma) \quad [4]$$

where the E° are the *standard electrode potentials* in pure silver chloride (which is the standard state), and x and γ are, respectively, the mole fraction and mean activity coefficient of silver chloride in solution in the potassium-sodium chloride solvent.

The actual cell design is shown in Fig. 5. The lower part of this cell was constructed from silica tubing and the upper part from Pyrex tubing. The two parts were joined by a graded seal. The over-all dimensions of the cell were 2 in. x 20 in. The silver electrode was a rod of pure silver wire (99.99%) connected to the potentiometer by platinum wire.

The inert electrode for the chlorine-chloride ion system was a ¼ in. diameter rod of spectrographically pure graphite. A 20,000-ohm resistance in series with the electrodes was used as an additional precaution to reduce the potentiometric current and prevent any polarization phenomena. One of the features of this cell is the activation of the graphite electrode before use. The end of the rod was coated with a concentrated sucrose solution and then carbonized in a chlorine atmosphere at 800°C for 24 hr. The result was a thin, porous, and highly absorbent carbon deposit. This cell, like all the others used in this investigation, was fitted with a small asbestos fiber to separate the two solutions. It will be noted

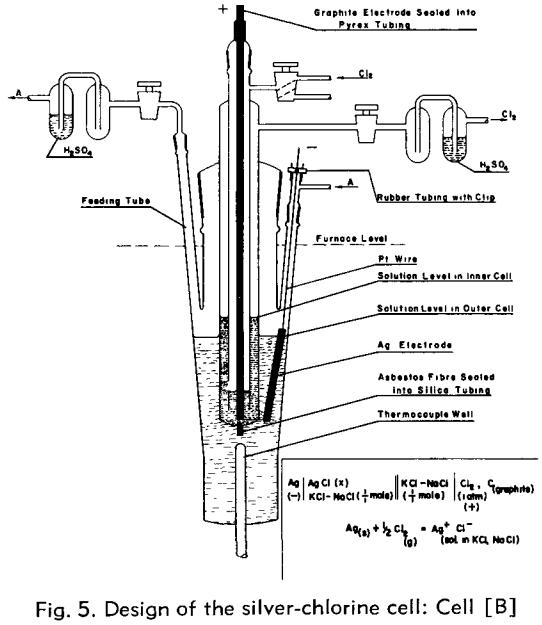

Fig. 5. Design of the silver-chlorine cell: Cell [B]

Ag (—)	AgCl (x) KCl-NaCl (1/1 mole)	‖	Asbestos fiber	‖	KCl-NaCl (1/1 mole)	Cl_2 (1 atm) (+) C (graphite)

that the main significant differences between this cell and those used by other investigators (8, 9) are (*a*) the effective separation between the two half-cells by the asbestos fiber, and (*b*) the simple method of activating the carbon electrode.

Prior to a run, the dry potassium-sodium chloride mixture was added to both the inner and outer half-cells, the amounts being arranged so that when the contents were molten the height in the inner cell would be greater than that in the outer cell. After the salts had melted, the graphite electrode was placed in position, and dry pure chlorine gas was introduced into the cell and permitted to escape after bubbling through the melt. To obtain steady and reproducible potential measurements, it was necessary to leave the cell in operation for about 24 hr before taking potential readings. A sulfuric acid outlet trap prevented air from leaking into the cell and also provided a means of estimating the chlorine gas flow. It was found that the cell potential was independent of the rate of chlorine gas flow, and the cell was operated normally under a very slow flow (about 30 cc/min).

Solutions of silver chloride were prepared *in situ* by adding weighed amounts of silver chloride to the molten salt solvent and mixing well with a small electrically-operated platinum stirrer. To insure that true equilibrium had been attained after each addition of solute, the cell was allowed to stand for about 24 hr during which the potentials were checked several times. It was observed that with vigorous stirring, equilibrium was attained in a short time and that afterward the potentials remained practically unchanged. Small fluctuations of the potentials, of the order of ±0.4 mv, did actually occur and were attributed to local temperature changes in the cell. Thus, a complete run lasted several days, during which the chlorine electrode was in continuous use. The silver electrode was immersed in the solution only while potential measurements were being made. It was then withdrawn into the space above the solution. Purified argon was used to provide an inert gas protection for the silver electrode compartment.

The chlorine-chloride ion electrode may be regarded as a standard reference electrode for potential measurements in fused chloride salts. Unfortunately, in comparison with the silver-silver chloride electrode, it has the disadvantage of being rather fragile and complicated in design.

Results

The results of the experiments in which the electromotive forces of the silver-chlorine cell were measured as a function of temperature at various mole fractions of silver chloride, are shown in Fig. 6. All potentials have been corrected for small thermoelectric effects. It is apparent that the cell potential varies linearly with temperature over the temperature range between 650° to 900°C.

The variation of E(cell B) with log x, according to the Nernst equation [4], is shown in Fig. 7, for 700°, 800°, and 900°C. The relationship over most of the curves is linear, and the slopes of the straight

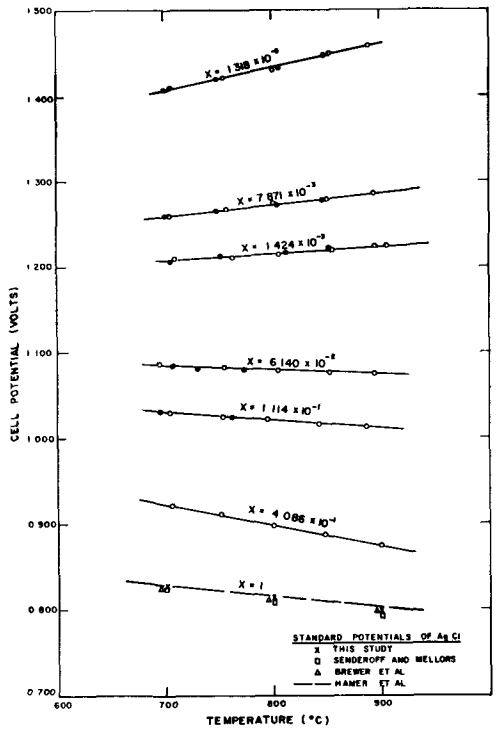

Fig. 6. Variation of emf with temperature for Cell [B]

lines agree very well with the calculated slopes from the Nernst equation at these temperatures for a one-electron electrode reaction. The standard cell [B] potential is obtained by graphical extrapolation of the straight lines in Fig. 7, to zero log x. These potentials, according to Eq. [4], would include the activity coefficient term of the Nernst equation, if any. It will be observed, in Fig. 7, that one of the experiments was continued to higher concentrations of silver chloride than the others. At a mole fraction of about 0.5, which corresponds to a log x term of about −0.2, the curve deviates from linearity. This is attributed mainly to the generation

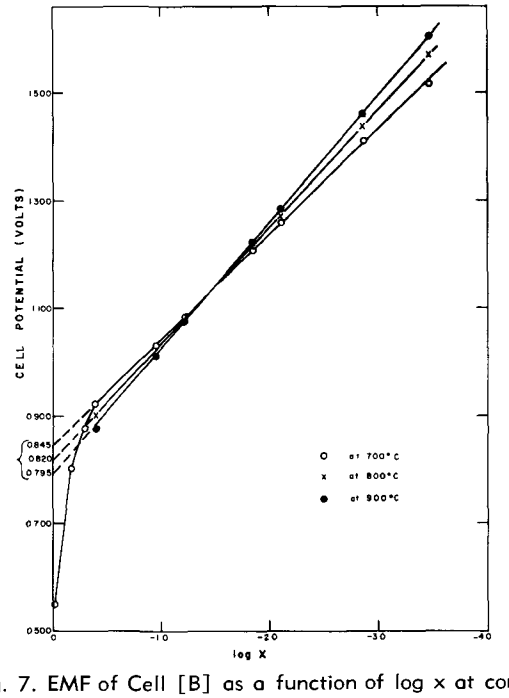

Fig. 7. EMF of Cell [B] as a function of log x at constant temperature.

of a junction potential at high silver chloride concentration. On this basis, it can be calculated that the junction potential between pure silver chloride and the potassium-sodium chlorides is about 300 mv. This junction potential decreases rapidly as soon as some of the potassium-sodium chloride mixture has been added to the silver chloride side, and at a mole fraction of about 0.5 it disappears completely.

However, it should be pointed out that part of this potential, which is termed a junction potential, could be due to a difference in the chloride ion activities in the two half-cell solutions. The activity of chloride ion in the potassium-sodium chloride half-cell, is equal to the activity of chloride ion in the silver chloride half-cell only for dilute silver choride solutions.

To investigate the combined effects of chloride ion activity and junction potential, a silver-chlorine cell without transference was operated. This was done by simply removing the asbestos fiber that separated the two half-cells and thus permitting free mixing of the solutions. The observed electromotive force initially was only 2 mv less than in the corresponding cell of the closed type, for the same chloride ion concentration (0.32*M*). After a short time, however, the potential of the open cell became erratic and this was attributed to the chemical depolarization of the silver electrode caused by small amounts of chlorine gas dissolving and migrating in the molten mixture. Hence, further experiments with this type of cell were discontinued. However, the initially observed difference of 2 mv, which is almost within the area of experimental error for the method, indicates that the effects of chloride ion activity coefficient had almost disappeared even in this rather concentrated silver chloride solution.

In Fig. 6 the dashed line at a mole fraction $x = 1$ indicates the formation potential of pure silver chloride at different temperatures, as calculated from thermal data by Hamer, Malmberg, and Rubin(6). The triangular and square points along this line represent the experimental results obtained by Senderoff and Mellors (9), and the potentials calculated from the free energy functions as tabulated by Brewer, *et al.* (10) for the Ag-AgCl system. It is evident from Fig. 6 that the potentials calculated by Hamer and co-workers are a little larger than the experimental ones, although the agreement with the calculations of Brewer is good. Deviations between the potential data are probably due to the uncertainty of the thermal data. The crosses along this line represent standard formation potentials derived experimentally in the present study, in the presence of solvent, and the agreement between the experimental data by the different methods is striking.

From the data in Fig. 6, using the well-known equations,

$$\Delta F^\circ = -E^\circ \mathbf{F} = -RT \ln K \qquad [5]$$

$$d \ln K/dT = \Delta H/RT^2 \qquad [6]$$

$$\Delta F = \Delta H - T\Delta S \qquad [7]$$

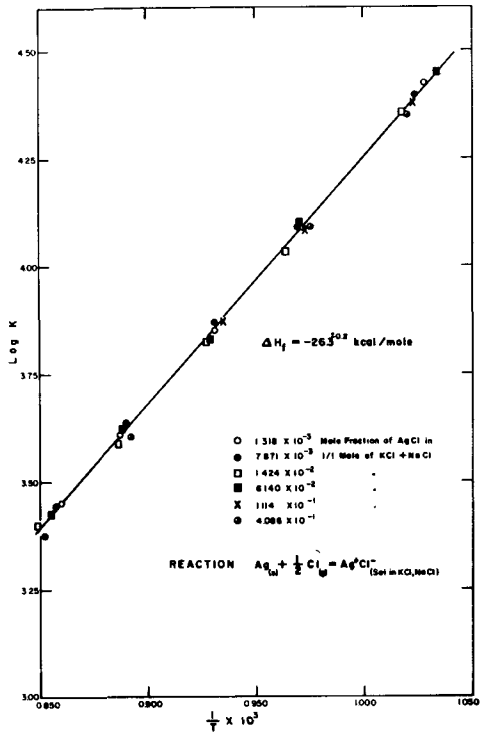

Fig. 8. Variation of log K with the reciprocal of absolute temperature of the reaction:

$$Ag(s) + \tfrac{1}{2}Cl_2(g) = Ag^+Cl^- \text{ (in KCl-NaCl)}$$

it is possible to calculate the enthalpies and entropies of formation of silver chloride in the presence of solvent. The results of the calculations are shown in Fig. 8, in which the logarithm of the equilibrium constant for the formation reaction of silver chloride is plotted against the reciprocal of absolute temperature. It will be noted that the agreement between the different sets of data from which these points were calculated is very good. The relationship is linear for the range of temperature, i.e., between 650°-900°C. From the slope of the straight line the heat of formation of silver chloride is calculated as: $\Delta H_f = -26.3 \pm 0.2$ kcal mole^{-1}. The summary of all thermal data for silver chloride is given in Table II.

From Table II it can be readily derived that the standard partial molal free energy of mixing of silver chloride with the potassium-sodium chloride

molten salt solvent is of the order of only −0.05 to −0.15 kcal mole^{-1}, a value surprisingly low and well within the area of experimental error of the data used for comparison. Accordingly, for all practical purposes, the activity coefficient of silver chloride in the 1/1M KCl-NaCl solution is unity ($\gamma = 1.0$). From the data in Table II, it can also be derived that the standard partial molal entropy of mixing is of the order of −0.9 to −0.3 cal/deg mole, the value again depending on the data used for the comparison. The indication is that the standard entropy change accompanying the process of solution is very small and in the area of experimental error of these measurements. Thus, the solution of silver chloride will be considered to be ideal over the temperature range of 650°-900°C and for the range of concentrations from very dilute up to 0.5*M*.

Discussion

By taking the state of the pure metal chlorides at the temperature of the experiments as the standard state, Eq. [3] can be applied to measure the activity coefficients of the metal chlorides in the fused salt solution. By setting the activity coefficient of silver chloride (γ_i) equal to unity, Eq. [3] can be rearranged to read

$$\log \gamma\,(MCl_n) = ({}_n\mathbf{F}/2.303RT)\,[E^\circ - E^{\circ\prime}] \quad [8]$$

where $E^{\circ\prime}$ is the apparent standard cell [A] potential experimentally obtained in this study, and E° is the calculated standard cell [A] potential from tabulated formation potentials given by Hamer, Malmberg, and Rubin (6) (cf. Table I).

Hence, the activity coefficients can be readily calculated by using Eq. [8] and the data given in Tables I and II. The accuracy of the values thus obtained depends on the accuracy of our observed potentials and on the accuracy of the thermal data from which Hamer's standard potentials have been calculated. The results of these calculations are given in Table III. Also shown in Table III are the range of concentration, for which the activity coefficients were found to be constant and the variation of activity coefficient with temperature. It is obvious from the table that only the solutions of silver chloride and thallous choride in this solvent behave ideally. For all the other metal chloride solutions studied, a marked deviation from ideality is observed.

For metal chloride solutions such as $MnCl_2$, $ZnCl_2$, and all the others for which the activity coefficients are less than unity, the formation of complexes can be postulated. It would appear that these salts in solution are complexed to the extent that only about 1/100 to 1/1000 of the amount present is free to contribute to the electrode potential. For these chlorides the activity coefficients show the expected behavior, i.e., they increase with increasing temperature. The constancy of the activity coefficients in dilute solutions, for the range of concentrations investigated, indicates that in these solutions the complex species remain unchanged.

Two notable exceptions to the general pattern of complex formation are represented by chromic and stannous chloride. For these salts the activity coefficients are larger than unity. On the assumption that no phase changes are involved, this behavior would indicate that the solvent has a bond-loosening effect on the solute.

In Table III, the standard partial molal free energies of mixing are calculated from the data, using the equation:

$$\overline{\Delta F^\circ}_{mix} = RT \ln \gamma = + n\mathbf{F}\,[E^\circ(\text{cell A}) - E^{\circ\prime}(\text{cell A})] \quad [9]$$

The quantity defined by Eq. [9] represents the difference between the free energy of the salt in its hypothetical standard state as a solute [i.e., a solution containing unit mole fraction of the salt but having in all other respects the thermodynamic properties of the state of infinite attenuation of the solute, as defined by Lewis and Randall (18)] minus the free energy of the salt in its actual standard state as the pure salt. It is of interest to note that the effect of temperature on the standard partial molal free energies of mixing is, in most cases, very small. Only in the cases of stannous chloride and chromic chloride is the change significant. For chromic chloride the "ideality" of the solutions is closely

related to temperature. At about 800°C the solutions are almost "ideal," but with increasing temperature a positive deviation from ideality is evident.

From the dependence of the standard partial molal free energies of mixing on temperature, the standard partial molal enthalpies and entropies of mixing can be calculated for the systems shown in Table III. The latter are also given in this table.

The standard partial molal entropies of mixing, as shown in the last three columns of Table III, also suggest that complex ions are present in all of these systems. It is necessary here to define the term "complex" as used throughout this study. In a very broad sense a "complex" in an ionic melt should be defined as a group of atoms for which the binding forces are stronger than the forces tending to separate them. The latter type of forces obviously includes the interactions between similar groups of atomic aggregates and also the interactions with the solvent. In terms of structure, a "complex" in solution should be a group of atoms in which the immediate neighbors of any atom are arranged in some orderly way, but the arrangement becomes more random gradually with increasing distance from the center of the complex. The definition is almost that on a liquid, with the difference that there is a distinction between the random distribution of atoms or ions in the solvent, and the locally more ordered distribution of atoms in a complex.

Although the presence of finite complexes in melts has been demonstrated both by potentiometric (14) and by spectrophotometric measurements (15), it seems reasonable that in ionic metals there should exist several intermediate states of aggregation between the so-called "noncomplexed" ionic state and the type of finite complexes found in aqueous solutions.

The actual values of the activity coefficients, and of other thermodynamic functions which characterize these complexes in solution will depend entirely on the definition of a noncomplexed state. A completely different set of data would be obtained if, instead of choosing the pure metal salt as the standard state, the state of infinite dilution were chosen. In fact, only the existing differences between any two states are measured directly, and a thermodynamic definition of a noncomplexed state is quite arbitrary. Even the "ideal solution" appears to arise from cancelling out of opposing effects in the binding forces within the complex itself.

In support of this view is the behavior of the solutions of silver chloride in alkali chlorides. Stern (11,12) found that the partial molal free energy of mixing of silver chloride in potassium chloride is negative, and that of silver chloride in sodium chloride is positive. In the present investigation it was found that in a solution of silver chloride in 1/1M mixture of potassium and sodium chlorides, the standard partial free energy of mixing is zero and the solutions are "ideal." It is apparent that by regulating the composition of the solvent and temperature it is possible to obtain solutions with positive, negative, or zero deviation from ideality. Thus, one may conclude that what is theromdynamically an "ideal" state is not necessarily a noncomplexed state.

Acknowledgment

The authors wish to acknowledge the help of Mr. P. Hernandez, Mines Branch glassblower, in constructing the silica apparatus used in the foregoing experiments.

The Oxygen-Evolution Reaction at Gold Anodes

I. Accuracy of Overpotential Measurements

Sidney Barnartt

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

The oxygen-evolution reaction at gold anodes was studied in 0.1M H_2SO_4 at 25°C. The factors affecting the accuracy of overpotential measurements and a new cell design for improved accuracy with a Luggin-Haber capillary are described. Current distribution in the cell, limitations imposed by competing reactions and by the *IR* drop included in the measurement, overpotential-time curves at constant current density, and the accuracy with which Tafel's equation is obeyed are presented. The current density range for accurate measurements was found to be 3×10^{-6} to 10^{-2} amp cm^{-2}. Overpotential measurements taken with decreasing and increasing currents were reproducible to ±1 mv, and deviations from the Tafel line were within this variation. At constant current density the gold anodes oxidized to hydrated Au_2O_3 following the linear law, and the current density dependence of the oxidation rate indicated a blister mechanism.

The steady-state overpotential measurements necessary for distinguishing possible rate-determining steps in anodic oxygen evolution have been compiled by Bockris (1). Data reported to date, however, have shown little consistency. Inherent experimental difficulties are probably greater than, and certainly have not been as intensively investigated as, those for the hydrogen evolution reaction (2, 3).

Platinum anodes have been studied in greatest detail (2). For this electrode there is general agreement that anodic oxygen evolution follows Tafel's equation (4):

$$\eta = a + b \log i \qquad [1]$$

where η is the steady-state overpotential at the applied current density (c.d.) i. The Tafel constants a and b reported by various authors are discrepant. Recently Bockris and Huq (5) investigated platinum in sulfuric acid solutions under conditions of extreme purification. Greater consistency in the Tafel plots was reported; the slope b was reproducible to ±12% or better. In the absence of applied current, a reversible oxygen electrode was apparently obtained for the first time.

This paper reports a detailed study of the accuracy attainable for oxygen overpotential measurements at gold anodes in 0.1M H_2SO_4 at 25.0°C. The various sources of error in overpotential measurements are evaluated, a new cell design for uniform current distribution described, and the c.d. limits determined for measuring η to ±1 mv. It will be seen that Tafel's equation is obeyed within this deviation.

Sources of Error

The following is a general outline of the sources of error involved in the experimental measurement of steady-state overpotential.

Current distribution.—When measurements are made by the direct method (while current is flowing) with a Luggin-Haber capillary (6), the current distribution over the test electrode should be uniform (7). With cell geometries having nonuniform distribution, the c.d. at the point of measurement generally will not be a constant and known fraction of the average c.d. at all values of overpotential (8-10). Even when interrupted currents are used and the potential is measured very rapidly after the interruption, it is desirable to use a cell having uniform current distribution (11).

It is recognized that a mechanically polished electrode surface will contain fine scratches and a large number of sharp micro peaks. In the primary current distribution (that in the absence of electrode polarization) the current density approaches infinity at sharp peaks. When the electrode is polarized, however, the distribution (secondary) is more uniform. The greater the ratio of Wagner's characteristic length parameter $\kappa \left| \partial\eta/\partial i \right|$, where κ is the solution conductivity, to the average scratch depth λ, the more uniform the current distribution (10). If Tafel's equation applies, $\left| \partial\eta/\partial i \right|$ decreases and the distribution becomes less uniform as the c.d. is increased, since

$$\partial\eta/\partial i = \pm 0.4343\ b/i \qquad [2]$$

where the plus sign refers to anodic and the negative sign to cathodic reactions. For even roughly polished electrodes in most electrolytes, the ratio of Wagner's characteristic length to average scratch depth is expected to be sufficiently large that the current distribution over the surface will be essentially uniform. The surface roughness, however, must be taken into consideration in calculating the true current density.

Shielding by the capillary.—It has been shown that large errors in overpotential can result from shielding of the electrode at the point of measurement, unless the capillary tip is either sufficiently far removed from the electrode surface (12, 13) or is

against the electrode and has a properly designed opening (14-16). For an open tip capillary of diameter d, negligible shielding will occur if the distance between the tip and electrode surface is $2d$ or greater.

IR-drop corrections.—Where a Luggin-Haber capillary with open tip is used, correction must be made for the IR voltage drop (V_{IR}) in the electrolyte between the tip and the electrode. These corrections can be appreciable, even in solutions of moderately high conductivity. For example, at 10^{-2} amp cm^{-2}, the following values of V_{IR} in 0.1M H_2SO_4 ($\kappa = 0.046$) were calculated for a capillary tip of diameter d positioned a distance $3d$ from a plane electrode:

d(cm):	0.5	0.1	0.02
V_{IR}(v):	0.290	0.058	0.012

These values were obtained from the equation:

$$V_{IR} = (3d - d/3)\, i/\kappa \qquad [3]$$

which is based on the observation (12, 13) that the potential inside the capillary is equal to that at a distance $d/3$ closer to the electrode in the undistorted field.[1] The above example illustrates the general requirement of positioning the capillary very close to the electrode and, hence, for using a capillary with small outer diameter in order to avoid shielding errors.

Where a coating forms on the electrode surface, as often occurs during anodic overpotential measurements, the resistance of the coating must be evaluated. This is done by actual measurement of the total IR drop included in the overpotential measurement, from which the IR drop in the electrolyte, calculated as above, is subtracted to obtain the IR drop within the coating.

Roughness factor.—For an electrode surface with roughness factor q (ratio of true area to apparent area), Tafel's equation may be written in the form

$$\eta = a + b \log(i'/q) = a' + b \log i' \qquad [4]$$

where i' is the apparent c.d. and $a' = a - b \log q$. If q remains constant throughout the measurements, the correct slope b is obtained when η is plotted against log i'. The apparent a-value from this plot, however, is the value a'; this is too small, as compared with the true a, by the amount $b \log q$.

For systems in which the roughness factor changes with changing c.d., the measurements may appear to follow a Tafel line, but both the slope and the a-value will be in error. This type of error should be revealed by a drift of the apparent Tafel line when determined with decreasing, then with increasing, current densities.

There is evidence that the roughness factor of a polished metal may vary by an order of magnitude, depending on subsequent treatments (17, 18). Therefore, where the electrode surface undergoes change, e.g., by oxidation during anodic oxygen evolution, prepolarization to a stable surface should precede the overpotential measurements.

[1] This observation refers (12) to a capillary tip with ID = 2/3 OD; the capillaries used in the apparatus to be described conformed to this geometry.

Impurities.—Trace impurities, present in the electrolyte or adsorbed on the electrode surface, may produce large errors in overpotential (5, 19-21). The observable effects of impurities on η-measurements include: (*a*) prolonged potential drift with time, (*b*) irreproducibility of steady-state potentials, and (c) depolarization accompanying increased agitation, particularly at low c.d., resulting from competing reactions involving impurities.

Competing reactions.—Any competing reaction depolarizes the electrode reaction under study, i.e., the measured overpotential corresponds to a current smaller than the observed total current. Competing reactions may occur even in highly purified systems; during anodic oxygen evolution, for example, metal dissolution and oxide formation often proceed simultaneously. Soluble products of the cathode reaction can diffuse to the anolyte and depolarize the anode reaction, and vice versa.

Potential-time variations.—The use of arbitrary polarization times has often resulted in failure to attain the steady-state η-values, as has been emphasized for anodic oxygen evolution by the work of Hickling and Hill (22). In general it is preferable to approach the steady state from two directions, e.g., with increasing and with decreasing current density, in order to avoid errors resulting from slow drifts or temporary potential arrests.

Concentration polarization.—Concentration changes at the electrode surface impose an upper limit to the c.d. range over which accurate overpotentials can be measured. The maximum permissible c.d. will generally be considerably lower than the so-called limiting current (at which the current efficiency begins to fall). An appreciable concentration change of any dissolved substance which affects the electrode potential will contribute to concentration polarization. In most cases the accompanying potential changes will be complex and not amenable to accurate calculation. Therefore, the fractional concentration change at the electrode should be maintained small by the use of increased agitation, a more concentrated solution, or a lower c.d. range.

From the mathematical theory of diffusion, the concentration at the electrode, C_e (mole cc^{-1}), of any solution constituent under steady-state conditions is given by the relation (23-25):

$$C_e - C_o = f\, l/D \qquad [5]$$

where C_o is its bulk concentration, l the thickness of the diffusion layer (cm), D its diffusion coefficient (cm^2 sec^{-1}), and f its flux at the electrode boundary (mole cm^{-2} sec^{-1}). The flux is equal to the rate at which the constituent is added at the electrode surface by the electrode reaction and by electrical transference.

In most practical systems involving forced convection of a complex nature, Eq. [5] is applied as a first approximation, with the assumption that the only effect of convection is a decrease in the parameter l. Quantitative theoretical predictions for convective effects in several simplified systems have been reviewed (26).

Experimental Procedure

Materials.—Reagent-grade sulfuric acid was distilled in an all-Pyrex still. Distilled water was treated with small amounts of KOH and $KMnO_4$ and redistilled in an all-Pyrex still. In each case the first portion of the distillate was rejected and the middle fraction used.

Oxygen gas was purified by passage through a column of cupric oxide heated to 700°C in a Vycor tube, then into an all-Pyrex system through bubblers containing 1M NaOH and 1M H_2SO_4, and finally through a fritted Pyrex tube to trap droplets. The purified gas was led into the cell through a short length of flexible, unplasticized polytrifluorochloroethylene (Kel-F) tubing.

Anodes of solid gold and of gold-plated copper were used. The solid electrode was machined from pure gold rod (99.98% Au, principal impurities Ag and Pt metals). The plated electrode was prepared by electroplating gold at 2 ma/cm^2 and 70°C from the following solution (reagent-grade chemicals): 0.05M K $Au(CN)_2$, 0.2M, KCN, and 0.1M K_2CO_3. The surface was alternately plated and polished until a gold layer 75 μ thick was achieved. Diamond polishing compound with a particle size of 3 μ was used for the final polish on each electrode.

The following surface treatments of the gold electrodes, prior to insertion in the cell, were standardized. Precleaning involved degreasing in solvents, treatment cathodically in hot 3M NaOH, then immersion in 10M HNO_3. The final treatment of the plated electrode consisted in electroplating an additional 3 μ thickness of gold to produce a smooth, matte surface. The solid gold electrode was made anodic in 1M H_2SO_4 at 5 x 10^{-2} amp cm^{-2} for 5 min to produce a very thin brown oxide, then the latter was dissolved in 5M HCl; the final surface remained almost mirror bright.

Two saturated calomel electrodes (SCE), of the type having a Pyrex salt-bridge junction tube containing a controlled diffusion crack (27), were used to follow potential changes. These were checked periodically with each other and with a third electrode; the voltage between any two never exceeded 0.1 mv.

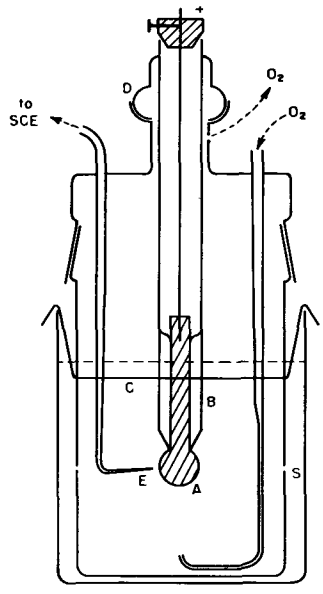

Fig. 2. Cell I

Cell design.—Two cells were used, both designed for uniform current distribution and based on concentric spherical geometry with conical sectioning (7), as indicated in Fig. 1. The following two distortions were introduced in the actual cells. (*A*) The insulator was shortened, as shown in Fig. 1 by the broken vertical lines, so that the 60° angle was maintained only for a distance r_o, where r_o is the radius of the inner electrode. In the cells used the inner electrode was the anode with $r_o = 0.50$ cm. (*B*) It was assumed that, provided the cell diameter exceeded 10 r_o, the outer spherical electrode (cathode) could be highly distorted with little effect on current distribution at the anode. For this reason the cathode was removed to an external compartment, and the diameter of the anode compartment was made 12 r_o in cell I (Fig. 2) and 16 r_o in cell II (Fig. 3). These distortions were expected to produce relatively small non-uniformities of current distribution at the anode A.

The cells were constructed of Pyrex glass. The 60° conical insulator was ground from precision-bore tubing B, and the rod portion of the anode was machined to fit snugly into the bore. The ball joint D

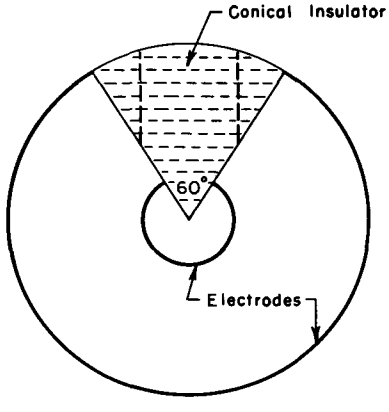

Fig. 1. Conical sectioning of concentric spheres

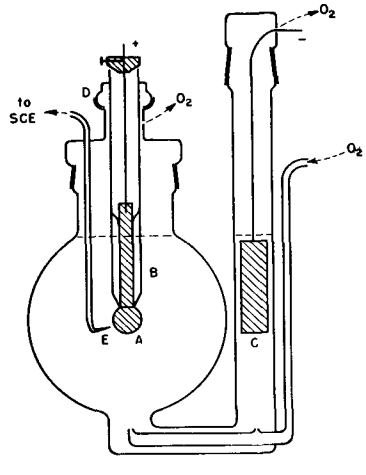

Fig. 3. Cell II

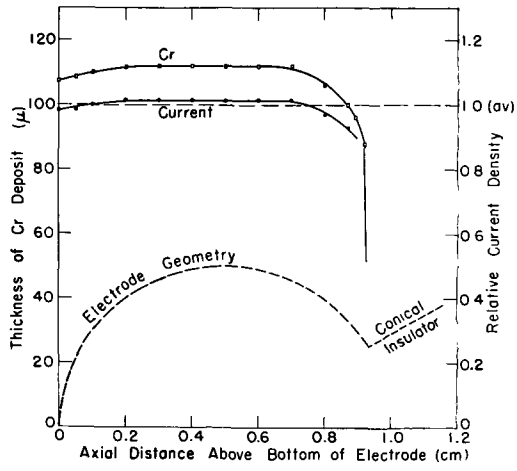

Fig. 4. Current distribution over the anode determined by electrodeposition of chromium.

permitted accurate positioning of the anode with respect to the fixed capillary tip E. A tip of diameter $d = 0.20$ mm was used and was positioned at a distance of about $3d$ from the anode.

In cell I the anolyte boundaries were cylindrical, 12 r_o in diameter and 12 r_o in height. Contact with the catholyte was made through a slot S, 0.5 mm wide, which was concentric with the anode. The cathode C was a platinum wire ring situated near the top of the catholyte. The primary current distribution over the electrode surface in this cell was obtained by measuring the distribution of chromium, electroplated under conditions shown previously (28) to yield good agreement with the primary distribution as measured by the potential-mapping method. Figure 4 shows the measured distribution of chromium over a copper electrode, and the current distribution calculated from it using the current efficiency data of Dubpernell (29). It may be concluded that the current distribution in this cell is sufficiently uniform for overpotential measurements, and that negligible error is incurred when one uses the average c.d. instead of that directly opposite the capillary tip.

In cell II the anolyte was approximately spherical in shape, of diameter 16 r_o. This cell incorporated the following improvements over cell I. (*A*) Both compartments were covered, with only a small hole for escape of oxygen. (*B*) The cathode, a platinized-platinum cylindrical gauze, had much larger surface area. (*C*) Oxygen was bubbled around the cathode as well as the anode, thus tending to sweep out any hydrogen formed at high c.d. The uniformity of current distribution was not measured in cell II, but was assumed to be just as satisfactory as in cell I. Cell II with the solid gold anode was used for measurements reported below except where otherwise stated. The reference compartment of each cell was, of course, filled with the solution under study. Traces of KCl entering this compartment from the reference electrode had a long diffusion path to the capillary tip.

Measurement of overpotential.—Polarizing current was drawn from a 30-v lead-acid battery source, through a resistance box designed to allow a sudden change in current to a preselected value without breaking the circuit. The anode-SCE voltage, E_{obs}, was measured with a shielded potentiometer (L&N Co. model K3) and a current-sensitive galvanometer having sensitivity of 1.3×10^{-9} amp/mm. The sensitivity-selecting switches of the potentiometer were replaced by four push-button switches in an external shielded circuit, by means of which a resistance of 10^9, 10^8, 10^7, or 10^6 ohms was inserted in series with the voltage being measured. With this circuit it was possible to prevent the out-of-balance current drain from exceeding 10^{-9} amp during a voltage measurement.

The reversible voltage E_1 between the SCE and a hydrogen electrode of the Hildebrand type was measured in the solutions used in the present study and the overpotential for the oxygen-evolution reaction was then given by:

$$\eta = E_{obs} + E_1 - 1.229 \qquad [6]$$

where 1.229 v represents the reversible emf between the oxygen and hydrogen electrodes in a given solution at 25°C (30).

Results and Discussion

Oxide formation.—In dilute sulfuric acid, gold anodes become covered with hydrated Au_2O_3 (31, 45). At very low c.d. Au_2O first forms, then converts through AuO to Au_2O_3 before oxygen evolution commences (32). The color of the oxide changes from yellowish brown to reddish brown as it thickens.

A coating was prepared at 10^{-2} amp cm^{-2} for 23 hr and was carefully flaked off the electrode. Chemical analysis for Au and H_2O (and oxygen by difference) indicated $Au(OH)_3$; some change in hydration could have occurred, however, during removal of the coating. X-ray diffraction patterns of the oxide were attempted with a Guinier focusing camera (33); no diffraction lines were obtained, although the instrument had high sensitivity and gave good patterns for evaporated gold films 100Å thick.

The kinetics of oxide growth at constant c.d was investigated at 10^{-3} and 10^{-4} amp cm^{-2} apparent anodic c.d. It was found that the amount of oxide on the spherical anode could be determined by dissolving it in 10 ml of 5M HCl, then analyzing the solution for Au spectrophotometrically (absorption peaks in the ultraviolet at 226 and 314 mμ). Oxide layers 1Å in average thickness are detectable by this method.

Figure 5 presents the oxidation rate measurements. Linear oxidation curves were obtained, corresponding to constant current efficiency for oxide formation. In 0.1M H_2SO_4, the oxidation rates at 10^{-3} and 10^{-4} amp cm^{-2} are 143 and 6.8 Å/hr, respectively, corresponding to current efficiencies for oxide formation of 1.13% at 10^{-3} amp cm^{-2} and 0.53% at 10^{-4} amp cm^{-2}. Such low current efficiencies would have negligible depolarizing effects. Measurements were made also in 0.05M H_2SO_4 at 10^{-3} amp cm^{-2}; as seen in Fig. 5, the change in acid concentration had no appreciable effect on the oxidation curve.[2]

[2] Armstrong, Himsworth, and Butler (44) found linear oxidation curves for gold in 0.1M H_2SO_4, as determined by cathodic reduction of the oxide, with a current efficiency of 0.9% independent of c.d.

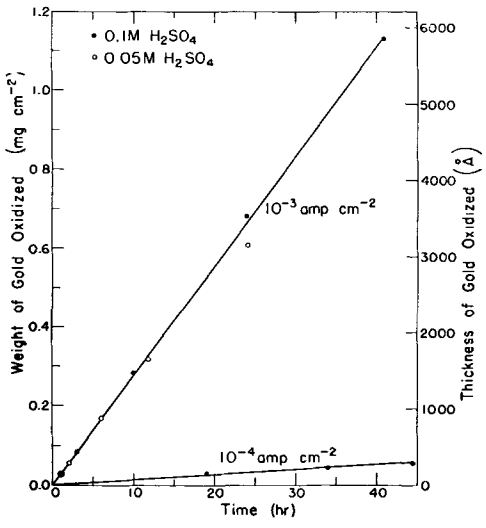

Fig. 5. Anodic formation of gold oxide in sulfuric acid solutions, 25°C.

Linear oxidation curves may be interpreted as resulting from a blister mechanism, in which local separation occurs at the oxide-metal interface in a manner similar to that postulated for gas-metal reactions (34). In support of this mechanism, it was noted that the oxide exhibited poor adhesion, and the thicker coatings could be readily flaked away from the gold substrate.

The blister mechanism may be used to explain the increase in current efficiency for oxide formation with increasing c.d. According to this mechanism, localized interfacial separation occurs when the oxide layer has grown to a critical thickness, such that the local adhesive force is exceeded by the compressive force in the oxide at that point. A blister forms, the distorted oxide cracks, the electrolyte then contacts the exposed metal surface, and rapid oxidation begins there again. In the absence of gas evolution, the oxidation rate should increase with c.d.; it would tend to be roughly proportional to c.d. if the critical oxide thickness for blistering is very small, as appears to be the case for gold anodes where linear oxidation occurs even at low film thicknesses (Fig. 5). The effect of simultaneous gas evolution, however, is to increase the oxidation rate by causing increased rate of blistering. Gas pressure can build up within the blisters, because the surface tension of the liquid tends to prevent the escape of gas through the small cracks in the blistered oxide layer. The gas pressure within a local blister helps to overcome the adhesive force at adjacent areas, thus increasing the rate of blistering and decreasing the critical oxide thickness. Since the rate of gas evolution is proportional to c.d., the higher the c.d. the greater the increase in oxidation rate resulting from this gas-evolution effect. Thus the blister mechanism is qualitatively consistent with the observed fact that the current efficiency for oxidation increased with c.d.

Potential-time variations.—In 0.1M H_2SO_4, oxygen-saturated but before any electrolysis, a clean gold electrode assumes a potential of 0.83 v vs. RHE,[3]

[3] Single electrode potentials refer to the reversible hydrogen electrode in the same solution.

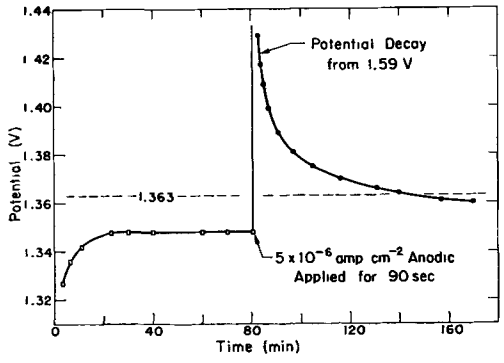

Fig. 6. Potential behavior of a fresh gold electrode in pre-electrolyzed 0.1M H_2SO_4, 25°C. Potential referred to reversible hydrogen electrode (RHE) in same solution.

which is 0.4 v less than the reversible oxygen potential. After prolonged electrolysis of the solution (roughly 0.2 coulomb/ml), however, the typical behavior of a clean gold electrode is that shown in Fig. 6. Upon immersion (zero time) the potential rises quickly to a value higher than the reversible oxygen potential and approaches the reversible Au/Au_2O_3 (hydrated) potential, 1.363 v (35, 36), indicating that gold tends to oxidize in the electrolyzed solution. After the electrode is made anode for a short time at very low c.d., the potential decay curve tends to arrest at the same value.

When a clean gold surface was made anode at 10^{-3} or 10^{-4} amp cm^{-2}, the potential increased to a value 3 to 5 mv higher than the steady-state value, then decreased to the steady value after passage of about 1 coulomb cm^{-2}. The potential was followed for an additional 40 hr, and remained constant to ±0.5 mv as the oxide layer thickened. It was concluded that no deleterious impurities were diffusing into the cell from the reference compartment.

In the procedure that was adopted for determining the η-i relationship, a relatively heavy oxide coating was first formed at a c.d. near the upper end

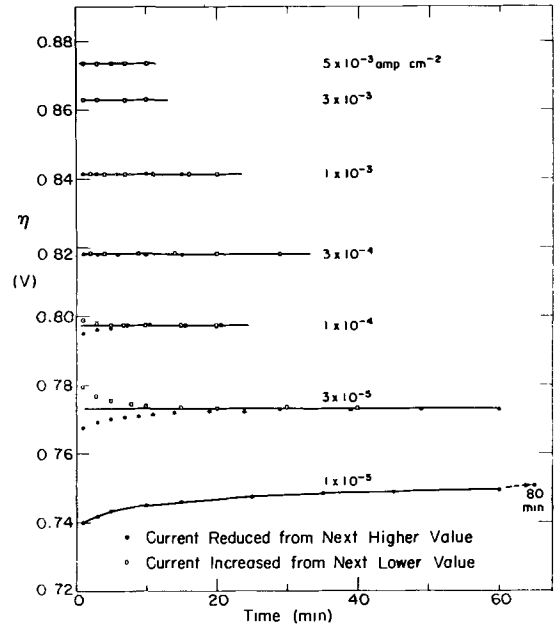

Fig. 7. Overpotential vs. time for oxygen evolution at gold anode in 0.10M H_2SO_4, 25°C.

of the range (at least 40 coulomb cm^{-2} passed). Then the current was decreased in steps to the minimum value and finally increased in steps to the maximum value. A typical set of η vs. time curves are shown in Fig. 7. The steady-state overpotentials obtained with decreasing or with increasing current were the same within ±0.5 mv. One experiment was continued through a second cycle of decreasing followed by increasing current densities, and the steady-state overpotentials remained the same within ±1 mv. Preliminary electrolysis of the solution with an auxiliary anode produced no appreciable change in the steady-state η-i curve.

The constant current curves of Fig. 7 exhibit a time effect at low current densities. When the current is decreased from a higher value the overpotential is initially lower than the steady-state value, and when the current is increased from a lower value η exceeds the steady-state value initially. This is a reproducible effect.

At 10^{-5} amp cm^{-2} the potential drift with time was prolonged (Fig. 7). The value of η after 1 hr was still 3 mv below the extrapolated η-log i curve. This behavior was characteristic of all runs, hence $i = 3 \times 10^{-5}$ was chosen as the lower limit for steady-state overpotential measurements. The interpretation of this time effect is considered in the next section from the standpoint of competing reactions.

Competing reactions.—The reversible single electrode potentials, referred to the standard hydrogen electrode (SHE), at 25°C for possible reactions at gold anodes, and for possible cathodic reactions, in dilute sulfuric acid solids are given in Table I.

Table I. Reversible electrode potentials at 25°C referred to SHE*

(a) $O_2 + H^+ + e^- = HO_2$; $E = -0.13 - 0.0592\ pH + 0.0592 \log [O_2]/[HO_2]$

(b) $2H^+ + 2e^- = H_2$; $E = -0.0592\ pH - 0.02\% \log [H_2]$

(c) $O_2 + 2H^+ + 2e^- = H_2O_2$; $E = 0.682 - 0.0592\ pH - 0.0296 \log [O_2]/[H_2O_2]$

(d) $O_2 + 4H^+ + 4e^- = 2H_2O$; $E = 1.229 - 0.0592\ pH + 0.0148 \log [O_2]$

(e) $Au(OH)_3 + 3H^+ + 3e^- = Au + 3H_2O$; $E = 1.363 - 0.0592\ pH$

(f) $Au^{+3} + 3e^- = Au$; $E = 1.50 + 0.0197 \log [Au^{+3}]$

(g) $Au^+ + e^- = Au$; $E = 1.7 + 0.0592 \log [Au^+]$

(h) $HO_2 + 3H^+ + 3e^- = 2H_2O$; $E = 1.7 - 0.0592\ pH + 0.0197 \log [HO_2]$

(i) $H_2O_2 + 2H^+ + 2e^- = 2H_2O$; $E = 1.77 - 0.0592\ pH + 0.0296 \log [H_2O_2]$

(j) $S_2O_8^{-2} + 2e^- = 2SO_4^{-2}$; $E = 2.01 + 0.0296 \log [S_2O_8^{-2}] - 0.0592 \log [SO_4^{-2}]$

(k) $O_3 + 2H^+ + 2e^- = O_2 + H_2O$; $E = 2.07 - 0.0592\ pH + 0.0296 \log [O_3]/[O_2]$

(l) $OH + H^+ + e^- = H_2O$; $E = 2.8 - 0.0592\ pH + 0.0592 \log [OH]$

* Standard electrode potentials are from Latimer (30), except for reaction (e) (35, 36). Potentials follow the IUPAC-Stockholm sign convention. [ ] denotes activity.

Reactions (a) to (c) are possible cathodic processes which yield products that would depolarize the oxygen evolution reaction at the anode. Of these, H_2O_2 is expected to be the primary depolarizer produced at low currents, hydrogen gas at high currents. The latter tends to be swept out of the solution by oxygen bubbling and has been shown to have no appreciable depolarizing effect at moderate current densities (37). Hydrogen peroxide was detected in the solution, at the end of an η vs. i run, with titanium sulfate reagent; spectrophotometric analysis indicated a concentration of 5×10^{-6}M. The maximum c.d. for H_2O_2 oxidation at the anode, corresponding to this concentration, can be computed from Eq. [5]; thus with $l = 5 \times 10^{-3}$ cm for gas-bubbling conditions (38), $D \approx 10^{-5}$ cm^2 sec^{-1}, and $C_e = 0$, one obtains $f = 1 \times 10^{-11}$ mole cm^{-2} sec^{-1}. This corresponds to a diffusion current density, $i_d = 2\mathbf{F}f$, of 2×10^{-6} amp cm^{-2}, which would result in measurable depolarization at an applied c.d. of 3×10^{-5} amp cm^{-2} or less. Actually the measured H_2O_2 concentration was determined soon after electrolysis at high c.d.; after prolonged electrolysis with gradually decreasing currents the H_2O_2 concentration would be less than the measured value, and the c.d. for observable depolarization would be less than 3×10^{-5} amp cm^{-2}. The typical potential-time curves in Fig. 7 indicated depolarization beginning at 1×10^{-5} amp cm^{-2}, hence this may be attributed to the presence of cathodically produced H_2O_2.

Of the possible simultaneous anodic reactions which could lower the current efficiency, (e) to (l) in Table I, oxide formation (e) and metal dissolution (f) tend to occur at low overpotentials. The rate of the former reaction has already been shown to be insignificant. The metal dissolution rate is expected to be small because of the relatively low solubility of the oxide in dilute acids (30):

$$Au(OH)_3 = Au^{+3} + 3OH^- \quad K = 8.5 \times 10^{-45} \quad [7]$$

This was confirmed in 0.1M H_2SO_4; the average current efficiency for gold dissolution at 10^{-3} amp cm^{-2} over a 24-hr period was found to be 0.007%.

At high values of η water tends to oxidize anodically to H_2O_2 and HO_2 by reactions (i) and (h), but these substances are very unstable with respect to further anodic oxidation, i.e., reactions (a) and (c). Peroxidisulfuric acid can be produced by reaction (j) and ozone by reaction (k); these products have greater stability in the anolyte, as shown by the fact that they can be generated at the anode in large quantities in more concentrated H_2SO_4 solutions (39, 40).

Thermodynamically, either of the latter two products is capable of oxidizing a fresh gold electrode, as indicated by the reactions:

$$2Au + 3H_2S_2O_8 + 6H_2O = 2Au(OH)_3 + 6H_2SO_4, \quad \Delta G^\circ = -90 \text{ kcal} \quad [8]$$

$$2Au + 3O_3 + 3H_2O = 2Au(OH)_3 + 3O_2, \quad \Delta G^\circ = -98 \text{ kcal} \quad [9]$$

where the values of ΔG°, the standard free energy change at 25°C, were calculated from the standard electrode potentials of Table I. Hence one of these substances might have produced the effect shown in Fig. 6, in which a fresh gold electrode in a used solution assumes a potential higher than the reversible oxygen potential and approaching that of the $Au/Au(OH)_3$ electrode. It may be noted that H_2O_2, which accumulated in the solution as found above, would not produce such high potentials (41). Attempts to detect $H_2S_2O_8$ in the solution after prolonged electrolysis, by the use of $Ni(OH)_2$ reagent (sensitivity approximately 5 ppm), were negative. More significantly, it was found that the potential of a clean gold surface in un-electrolyzed 0.1M H_2SO_4 remained constant at about 0.83 v when $K_2S_2O_8$ was added to the solution, even in concentrations as high as 0.002M.

The effect of ozone was determined qualitatively in the following manner. A platinum wire was placed inside a small Pyrex tube through which the purified oxygen gas passed before entering the cell. An induction coil (laboratory leak tester) was used to produce sparking to the platinum wire for a period of 9 min, thus introducing a little ozone into the oxygen gas bubbling around the electrode. At the end of this period the potential of the gold electrode had risen to 1.30 v, which is above the reversible oxygen potential but below the $Au/Au(OH)_3$ potential. Thus oxidation of an appreciable fraction of the gold surface was indicated.

From the above evidence it was concluded that ozone is an anodic by-product at the higher current densities, and is responsible for the marked change in potential behavior of a fresh gold electrode produced by pre-electrolysis of the solution.

IR-drop measurements.—An upper limit to the c.d. range may be imposed by the accuracy with which the *IR* drop included in the overpotential measurement is determined. To calculate the *IR* drop within the solution for a capillary of diameter d positioned at a distance $3d$ from the electrode, Ohm's law in the form $i = -\kappa dV/dn$ was integrated for concentric spheres, from $n = r_o$ to $n = r_o + 3d - d/3$, to give the equation:

$$V_{IR} = (ir_o^2/\kappa)\ [1/r_o - 1/(r_o + 3d - d/3)] \quad [10]$$

This assumes that the potential inside the capillary is equal to that at a distance $d/3$ closer to the electrode in the undistorted field, as was observed for parallel planes (12), a good approximation for concentric spheres with $3d << r_o$. The maximum allowable magnitude of V_{IR} was taken to be 10 mv for experimental error ±1 mv. Substitution of this value into Eq. [10] yields i_{max}, the highest c.d. at which accurate correction can be made for the *IR* drop in the electrolyte. For 0.1M H_2SO_4 ($\kappa = 0.046$) in the cells used ($d = 0.02$, $r_o = 0.50$), one obtains $i_{max} = 1 \times 10^{-2}$ amp cm^{-2}.

In order to determine *IR* drops within the oxide coating, the total *IR* drop included in the measured overpotential was evaluated directly at 10^{-2} amp cm^{-2} in 1.0M H_2SO_4, with an oxide of typical thickness preformed over the anode. The interrupted-current method was used: the electrode was polarized to the steady-state potential, the applied current was switched off by means of a rapid electronic switch, and the anode vs. SCE voltage-decay curve displayed on an oscilloscope.[4] The "instantaneous" voltage decay agreed with that calculated from Eq. [10] within 1 mv. Thus the *IR* drop within the oxide was negligible at 10^{-2} amp cm^{-2}, or at any lower c.d. Similar measurements were not made in 0.1M H_2SO_4, but the same conclusion was drawn from the absence of appreciable deviations from Tafel's equation as described below.

Table II. Overpotential-current density relationship for oxygen evolution at gold anodes in 0.100M H_2SO_4, 25.0°C

Electrode	Cell	Tafel constants a'	Tafel constants b
Plated	I	0.977	0.0461
Plated	II	0.977	0.0450
Solid	II	0.976	0.0445
Solid	II	0.976	0.0447
Mean Tafel line		0.977	0.0450

Concentration changes at the anode surface.—The increase in acid concentration at the anode surface may be estimated from Eq. [5]. At any current density i, $f = (1 - t_+)i/2\mathbf{F}$, where t_+ is the cation transference number. For 0.1M H_2SO_4, $t_+ = 0.82$ (42), $D = 1.9 \times 10^{-5}$ cm^2 sec^{-1} (43), $l = 0.005$ cm (38), and the calculated concentration change at $i_{max} = 0.010$ amp cm^{-2} is $C_e - C_o = 0.002_4$ mole l^{-1}, a change of only 2.4%. Therefore concentration polarization effects were expected to be negligible in these experiments.

Overpotential-current density relationship.—Over the c.d. range for precise measurements as defined above, 3×10^{-5} to 10^{-2} amp cm^{-2}, Tafel's equation was accurately obeyed. The Tafel constants for various runs are given in Table II, and Fig. 8 shows a typical Tafel line. In each run the points obtained with decreasing and then increasing current densities all fell on the line within ±1 mv. Essentially the same Tafel constants were obtained in all runs; substitu-

[4] Tektronix, Inc., Portland, Oreg., type 545 oscilloscope with type 53/54D amplifier.

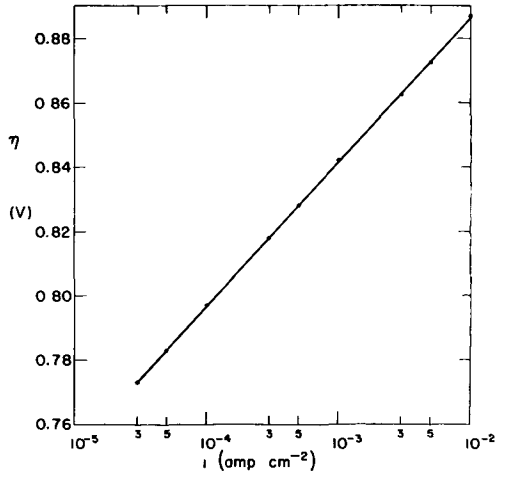

Fig. 8. Typical Tafel plot for oxygen evolution at gold anode in 0.1M H_2SO_4, 25°C.

tion of the slot cell for cell II or of the plated gold electrode for the solid one had no appreciable effect.

The Tafel constants in Table II are based on the apparent surface area; roughness factors were not measured. It was anticipated that the roughness factor for the dull oxide surface on the plated electrode (q_p) would be greater than that (q_s) for the solid electrode (bright oxide surface which reflected clear images). If $q_p = 2q_s$, for example, the effect on the Tafel a constant would be 0.015 v. The fact that no appreciable effect was found indicated that oxide growth on these two surfaces produced the same roughness factor, in spite of the large difference in surface brightness.

The mean value, $b = 0.045$ at 25°C, does not coincide with the predicted value for any mechanism of anodic oxygen evolution given in the compilation of Bockris (1). The exchange current density:

$$i_o = 10^{-(a/b)} = (1/q)\ 10^{-(a'/b)} \qquad [11]$$

has the unusually low value $2 \times 10^{-22}/q$. In addition to the Tafel constants, the measurements required to fix the mechanism of anodic oxygen evolution include the effects of pH and neutral salts on the overpotential. Conclusions concerning the mechanism, therefore, must be deferred to a future paper in which such measurements will be presented.

Manuscript received Oct. 13, 1958. This paper was prepared for delivery before the Ottawa Meeting, Sept. 28-Oct. 2, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Electrokinetic Measurements on Stainless Steel Capillaries

B. Levy and A. R. Fritsch

Radiation & Nucleonics Laboratory, Materials Engineering Departments, Westinghouse Electric Corporation, East Pittsburgh, Pennsylvania

ABSTRACT

Electrokinetic potentials of stainless steel in HCl, H_2SO_4, and $K_2Cr_2O_7$ solutions have been measured by the streaming current technique. Negative zeta potentials are obtained in H_2O and in low acid concentrations. Isoelectric acid concentrations occur between 10^{-4} and $10^{-3}N$. At higher concentrations positive potentials are obtained. $K_2Cr_2O_7$ adsorbs irreversibly at its isoelectric concentration of 10^{-3}M as evidenced by the inability of water washing to return the sample to its original negative zeta potential.

A technique has been developed recently by Hurd and Hackerman (1, 2) making it possible to measure the electrokinetic potentials of bulk metals. Prior to this all quantitative measurements have been made on metal sols (3). The experiments performed by Hurd and Hackerman involved platinum, silver, and gold capillaries and water solutions of KCl and KOH in the concentration range from 10^{-6} to 10^{-2}M. In all cases the electrokinetic potential was found to be negative. The magnitudes of the potentials were explained on the basis of the relative strengths of the metal oxide and the oxide-counter ion bonds, the larger negative potentials being obtained with the metals forming the stronger oxide bonds. In the present study, electrokinetic potentials of types 304 and 347 stainless steel were measured in HCl, H_2SO_4, and $K_2Cr_2O_7$ solutions. The purpose of the work is to determine if changes in the electrical double layer of adsorbed ions, as determined by electrokinetic measurements, can be correlated with such factors as corrosion, corrosion inhibition, and formation of deposits on metal surfaces. This paper is in the nature of a report on the progress that has been made thus far.

Experimental

The technique developed by Hurd and Hackerman was employed in making the measurements. It consists of measuring the streaming current due to liquid flow through a metal capillary. Unless special precautions are taken, part of this streaming current will flow through the walls of the capillary, thus obscuring the results. In order to eliminate this difficulty an external shunting resistor is placed in series with a pair of Pt electrodes located close to, but not touching, the ends of the metal capillary. It has been shown by Hurd and Hackerman that, if the outside walls of the capillary are isolated from the solution, then the "apparent" resistance of the Pt, Au, and Ag capillaries is large compared to an external resistor ranging from 10^4 to 10^5 or 10^6 ohms. This effect has been verified for the stainless steel capillaries in the present study and is probably due to polarization at the ends of the capillary (Table I, sample 4).

A L&N No. 9835 D-C microvolt amplifier and Varian G-10 recorder are used to measure the voltage drop across this resistor, thus making it possible to calculate the streaming current and thereby the zeta potential from the following equation:

$$I = \frac{\Delta P r^2 D \zeta}{4 \eta l}$$

where I is streaming current, statamp; ΔP the pressure drop across the capillary, dynes/cm^2; ζ the zeta potential, statvolts; η the viscosity, poises; D the dielectric constant of the solution; r the radius of the capillary, cm; and l the length of the capillary, cm.

A check on the operation of the equipment is shown in Fig. 1, where the voltage drop across a 40-k external resistor is plotted against the pressure drop (ΔP).

All of the solutions used in the experiments were prepared from reagent grade chemicals using singly distilled water. The steel capillaries were used as received or treated with acetone, boiling NaOH, and HNO_3. The results were similar qualitatively regardless of pretreatment as is seen in Table I, samples 1-4.

Results and Discussion

Table I lists the results, in the order performed, on type 304 stainless steel capillaries as a function of H_2SO_4 concentration. As is seen, the agreement between the samples is not too good except insofar as the isoelectric point is concerned. This occurs at a concentration close to $10^{-4}N$ H_2SO_4. The lack of quantitative agreement is probably not too surprising. Since the zeta potential of the metal is apparently that of an oxide layer, differences in the nature and extent of oxide film buildup will affect the magnitude of the zeta potential but may not affect the isoelectric point.[1] The transformation from a negative to a positive zeta potential may provide a sensitive indication of the first signs of metal corrosion.

If Grahame's model (4) for the electrical double layer is assumed, the situation at the metal-H_2O interface may be pictured schematically as in Fig. 2. The zeta potential is, by definition, the potential at the surface of shear of the double layer as compared to that of the solution. This surface of shear is generally assumed to coincide with the boundary between the outer Helmholtz layer and the diffuse layer. The sign of the zeta potential is determined by the excess charge in the combined inner and outer Helmholtz layer. Experimentally, type 304 stainless steel has a negative zeta potential in H_2O. Therefore, Fig. 1 shows an excess of OH^- ions in the Helmholtz layer located at sites adjacent to metal atoms. The oxygen atoms would appear to be ideal sites for the adsorption of protons. Perhaps the reason that stainless steel does not have a positive

[1] Suggested by one of the reviewers of this paper.

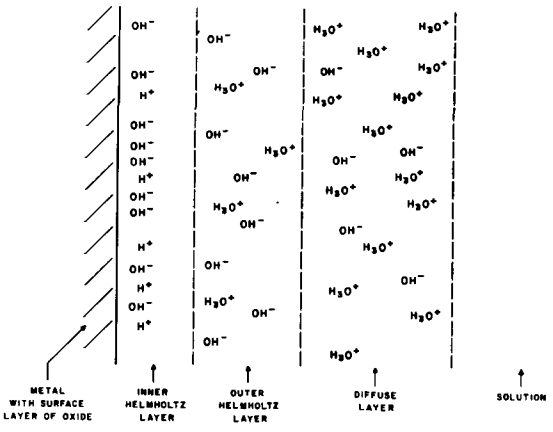

Fig. 2. Structure of the electrical double layer

zeta potential in water is the relatively high dehydration energy that must be supplied in order for the protons to enter the inner Helmholtz layer as compared to the similar process with OH^- ions. As H_2SO_4 is added to the solution there are fewer OH^- ions in the solution and correspondingly more H_3O^+ ions. This leads to a decrease in negative potential due to: (*a*) a decrease in the number of OH^- ions available for adsorption in the inner Helmholtz layer, (*b*) adsorption of protons at oxygen sites, and (c) partial decomposition of the oxide by protons accompanied by the formation and adsorption of positively charged metal ions.

These processes proceed with continued increase in acid concentration until a point is reached where there are an equal number of positive and negative ions in the Helmholtz layer. Further addition of acid causes the zeta potential to become positive.

In Table II the results are given for type 304 stainless steel in HCl solutions. Once again the zeta potential changes from negative to positive with increased HCl concentration. The isoelectric point occurs between 10^{-4} and $10^{-3}N$ HCl. Potentials with HCl were found to be more erratic than with H_2SO_4 solutions, possibly due to the ability of the Cl^- ions to penetrate the surface film which in turn may

give rise to active corrosion. These special properties of Cl^- ions are evidenced by their ability to cause stress corrosion cracking (5).

Tables III and IV give the results for type 347 stainless steel in H_2SO_4 and HCl solutions, respectively. In H_2SO_4 the isoelectric point occurs between 10^{-4} and $10^{-3}N$. In HCl it is probably closer to $10^{-3}N$. For both solutions the results are somewhat more erratic than with the type 304 stainless steel.

The effects of the acid on the metal surface do not appear to be permanent since the shift to positive potentials with high acid concentration can be reversed easily to negative values by flowing H_2O through the capillary in most instances. This offers support to the generally accepted view that an oxide layer is formed quickly on clean metal surfaces (6), if it is assumed that the acid treatment completely dissolved the oxide layer.

Table V gives the results of a series of experiments that have been run with type 304 stainless steel in $K_2Cr_2O_7$ solutions. The zeta potential was found to be negative in concentrations from 10^{-5} to 10^{-4}M. At 10^{-3}M $K_2Cr_2O_7$ and above, the potentials obtained appear to become insensitive to pressure changes and alternate erratically between low positive and low negative values. Powers and Hackerman (7) have demonstrated by tracer techniques that S.A.E. 1020 steel forms distinct anodic and cathodic areas, accompanied by the deposition of a nonadherent film, in 10^{-4}M Na_2CrO_4. They find that at concentrations of 10^{-3}M Na_2CrO_4 the steel is passivated, and chromate is deposited uniformly on the steel surface and cannot be removed by any physically nondestructive means. King, Goldschmidt, and Mayer (8) have demonstrated a significant decrease in the corrosion rate of iron in 10^{-3}M $K_2Cr_2O_7$ as compared to that found at lower concentrations. The results of the zeta potential determinations in $K_2Cr_2O_7$ at concentrations greater than 10^{-4}M may be the result of the masking, by polarization, of anodic and cathodic areas. Measurements were made with a fresh sample of type 304 stainless steel at successively higher concentrations of $K_2Cr_2O_7$. At 10^{-3}M $K_2Cr_2O_7$ the zeta potential becomes zero. The apparatus was then rinsed with distilled water and a determination made using the same capillary in H_2O. The sample remained at the isoelectric point. Previous measurements showed that there was no apparent permanent change in the behavior of the metal when treated with HCl and H_2SO_4 solutions. Evidently there is a very strong irreversible attachment of the Cr_2O_7 equal to the steel surface, in agreement with the data of Powers and Hackerman. To test this point still further, a new sample of type 304 stainless steel was treated first with H_2O, then 10^{-3}M $K_2Cr_2O_7$, and finally with H_2O. Once again the 10^{-3}M solution caused the zeta potential to go to zero and remain there after treatment with H_2O. Still another series of experiments were performed with a new sample of stainless steel. The order of the experiments consisted of runs with H_2O, 10^{-4}M $K_2Cr_2O_7$, and H_2O. The zeta potential remained negative in the 10^{-4}M $K_2Cr_2O_7$ solution.

Gatos (9) has measured the supression of the polarographic maxima by corrosion inhibitors in systems containing either dissolved O_2, Ni^{++}, or Pb^{++}. At cathodic potentials lower than those at which the polarographic maxima occur, the dropping mercury electrode is assumed to be nonpolarized. When the potential of the polarographic maxima is reached and at higher potentials where the diffusion current is the controlling factor, the dropping mercury electrode is generally considered to be polarized. Enhanced corrosion inhibition is often considered to be due to polarization of the metal by the inhibitor. Gatos has shown a distinct correlation between the supression of the polarographic maxima and corrosion inhibition, and thereby has given strong support to the theory of corrosion inhibition by adsorption of polarizing substances. He has pointed out that,". . . capillary active anions and negative colloids in general preferentially suppress (polarographic) maxima appearing on the positive side of the electrocapillary zero (positive maximum)

whereas capillary-active cations and positive colloids are effective with the negative (electrocapillary) maxima."

The electrokinetic data with $K_2Cr_2O_7$ solutions bear a certain similarity with that of Gatos in that both are concerned with the electrical double layer of adsorbed material at the metal-solution interface. When a concentration is reached at which the isoelectric point is observed in the streaming current experiments, the nature of the metal-solution interface must be similar to that which occurs at the electrocapillary maxima with the dropping Hg electrode, since both correspond to a net zero charge of adsorbed ions at the surface. It may therefore be assumed in the electrokinetic studies that the metal is polarized at the isoelectric point and thereby passivated. As Gatos has pointed out, the polarographic technique for screening corrosion inhibitors is nonspecific in that a substance which is effective in suppressing the polarographic maxima may prove to be a good inhibitor for one substance and be a poor one for another. The electrokinetic technique makes it possible to run tests on the material of immediate interest and to correlate the results with corrosion data on systems containing the identical type of metal, corrosion solution and inhibitor.

Summary

1. The zeta potentials of type 304 and type 347 stainless steel were measured in H_2SO_4 and HCl solutions in the concentration range of from 10^{-6} to $10^{-1}N$. Steel samples go through the isoelectric point at concentrations between 10^{-4} and $10^{-3}N$.

2. The irreversible adsorption of 10^{-3}M $K_2Cr_2O_7$ was demonstrated by electrokinetic measurements and found to be in agreement with the data in the literature.

Acknowledgment

The authors wish to express their sincere appreciation to Drs. W. E. Wallace, K. H. Sun, G. R. Taylor, and D. G. Gardner for their many helpful discussions and suggestions, and also to the Pennsylvania Advanced Reactor Project jointly sponsored by Westinghouse Electric Corp. and Pennsylvania Power and Light Co. for supporting the work.

Brief Communications

Electron Diffraction of Zinc Silicate Phosphor

S. Yamaguchi

The Institute of Physical & Chemical Research, 31 Kamifuji (Hongo), Tokyo, Japan

A commercial sample of zinc silicate phosphor (Zn_2SiO_4:Mn), in powder form and of unknown history, was studied by electron diffraction using two different wave lengths (0.029 and 0.0455Å) (1). Electrons accelerated to 150 kv or more can penetrate thick grains to a depth of about 3000Å, whereas soft electrons at about 50 kv can only graze their surfaces. The thickness of the surface layer which can be penetrated by the latter electrons is about 200Å. The diffraction patterns observed at the same spot of the sample with the soft and hard electrons are shown in Fig. 1 and 2, respectively. For convenience in comparing these two figures, the negatives were enlarged 2.3 and 3.7 times, respectively. This is the approximate ratio of ring diameter at the two wave lengths.

Estimation of grain size.—A phosphor of practical use is as a rule granular, and it is of significance to estimate the grain size. A discontinuous diffraction ring [for the interplanar spacing 4.04Å, the (300) diffraction from the hexagonal pseudocell of Zn_2SiO_4 (2)] found in Fig. 2 was utilized for a rough estimation of the grain size. In this ring we can count about 80 spots diffracted from individual crystallites. The cross section of the incident beam used was about 0.05 mm. If we assume that the diffraction spots (4.04Å) correspond to sixfold symmetry of each crystal, we obtain the grain size of the sample

$$S = \frac{50}{80/6} = 4\mu$$

Diffraction intensity.—In comparing the figures we recognize that the intensity of certain diffraction spots found in Fig. 1 is distinctly stronger than that of the corresponding spots in Fig. 2. This implies that on the surfaces of the phosphor grains there

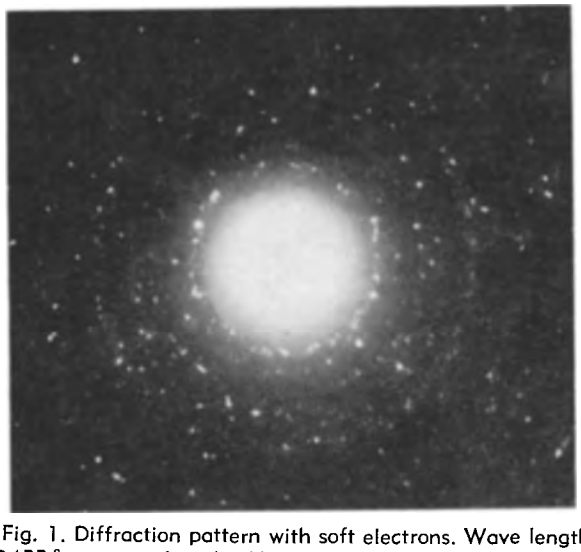

Fig. 1. Diffraction pattern with soft electrons. Wave length, 0.0455Å; camera length, 495 mm; positive enlarged 2.3X.

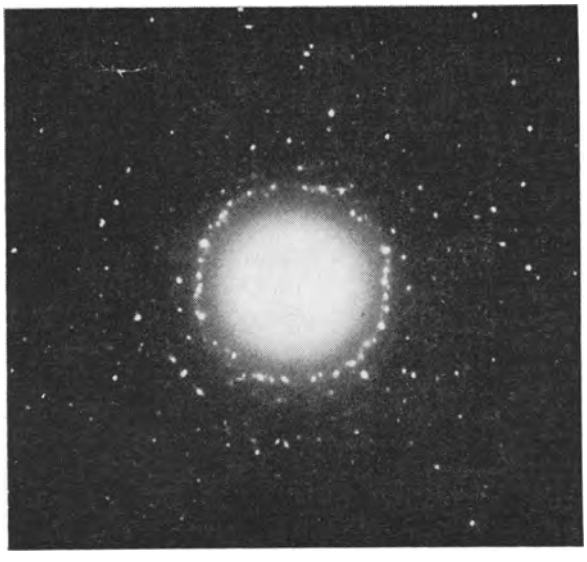

Fig. 2. Diffraction pattern with hard electrons. Wave length, 0.0290Å; positive enlarged 3.7X.

are lattices which are not only distinguishable from those of the substrate, but also are suitable for diffracting soft electrons. The number of diffraction spots found in Fig. 1 is roughly proportional to the number of crystallites able to diffract the soft electrons. Since the electrons used for a television screen are rather slow (about 10 kv), the diffraction phenomenon taking place on this screen is quite similar to that in Fig. 1. An important problem to be studied in the future, is whether electroluminescence depends on the coherent scattering of the incident electrons or not.

Manuscript received March 2, 1959.

Influence of Crystallographic Orientation on the Pitting of Iron in Distilled Water

Jerome Kruger

National Bureau of Standards, Washington, D. C.

A review paper by Greene and Fontana (1) indicates that pitting is random with respect to surface structure. Recent work in our laboratory indicates, however, that this is not true for pit formation on iron in distilled water. Initially this work was carried out with an Armco iron single-crystal sphere ⅜-in. in diameter which had flat surfaces cut parallel to the {111}, {110}, and {100} planes. These surfaces were prepared by mechanical polishing prior to chemical polishing using MirroFe[1] solution. When the crystal thus prepared was immersed for 3 hr in distilled water at room temperature, it was observed that the {110} plane had the greatest number of pits per unit area. The {100} had approximately one-half as many pits as the {110}, and the {111} had only around one-quarter as many as the {110}. The number and location of pits was not always the same for a given time interval of immersion. The order of pitting activity, {110}> {100}>{111}, however, remained the same in every one of the seven runs carried out. Figure 1 illustrates this order of activity on the three different planes cut on the same iron crystal.

In order to see if the use of MirroFe for polishing was responsible for the effect observed, the surfaces after mechanical polishing were etched with a dilute solution of HCl prior to carrying out a run. The results were the same as for the surfaces polished with MirroFe. The effect of orientation of the corroding surface, horizontal or vertical, was also checked, and again the same order of pitting activity was observed for the crystallographic planes studied.

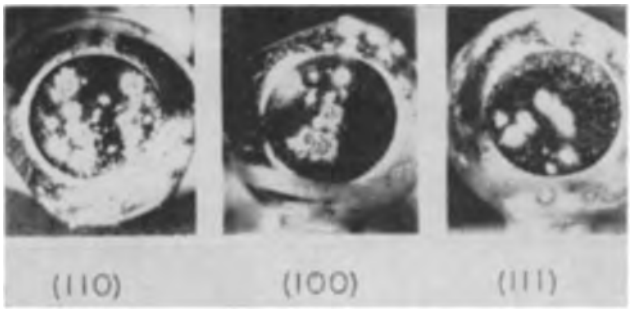

Fig. 1. Three different crystallographic planes of an iron single crystal corroded in distilled water for 3 hr at 25°C. 2.5X.

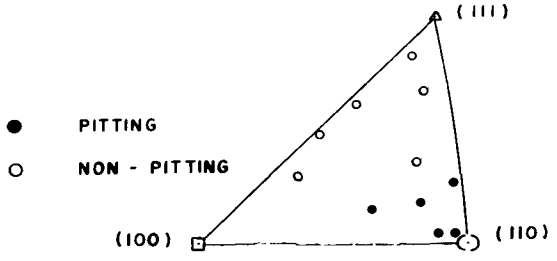

Fig. 2. Stereographic triangle showing pitting on grains of iron having different crystallographic orientations.

Other studies were carried out using a purer iron than Armco (235 ppm of impurities to 2460 ppm for Armco). Here a specimen containing large grains of many different surface orientations were used. As Fig. 2 shows, all those grains whose orientations were near that of the {110} crystallographic plane pitted every time or every time but one, while those which were nearer the {111} or {100} orientations pitted only once or not at all during the course of five runs.

As with the Armco iron, those surfaces having an orientation nearer the {110} exhibited the greatest amount of pitting. Irrespective of crystallographic orientation, the general level of pitting attack was lower for the purer iron.

Titanium and Zirconium As Primary Cell Anodes

Milton A. Thompson, Allen B. Scott, Donald Chittick, and Paul M. Gruzensky

Department of Chemistry, Oregon State College, Corvallis, Oregon

ABSTRACT

Polarization, chemical corrosion rates, and the anodic electrochemical equivalence for titanium and zirconium were measured in several electrolytes, chiefly fluoride solutions. Titanium exhibited satisfactory electrode characteristics in dilute HF, containing added NH_4F, except for somewhat excessive chemical corrosion. Zirconium was corroded severely by fluoride solutions in which its electrode characteristics were otherwise satisfactory and was somewhat less suitable as an electrode in H_2SO_4 solutions in which chemical corrosion was not serious. The Ti-HF, NH_4F-MnO_2 cell operated stably during discharge with good anode utilization but is probably limited to use as a reserve cell chiefly because of the deleterious effects of fluoride upon the MnO_2 electrode.

The experiments described in this paper were undertaken in order to determine the suitability of titanium and zirconium as negative electrodes in primary cells. Both metals are characterized by large negative electrode potential, corrosion resistance in many electrolytes, galvanic corrodibility in some of these solutions, and relatively low equivalent weight and equivalent volume. On the other hand, both may be rendered passive by oxide films when anodized under certain conditions. While the cost of the metals is still high compared to that of zinc, magnesium, and aluminum, it is decreasing rapidly and continually, and even now an amount of Ti electrochemically equivalent to the Zn contained in a flashlight D cell costs only 4.5 cents.

Electrochemical data for Ti and Zr are given in Table I; data for Zn are also given as a comparison.

Considerable information is available concerning the corrodibility of Ti and Zr in the more common electrolytes (3). Both metals are highly resistant to corrosion under a variety of conditions; however, Ti is attacked by H_2SO_4 above 5% concentration, HCl above 5%, H_3PO_4 above 30%, certain organic acids and HF at all concentrations. Zirconium is corroded by H_2SO_4 above 80%, $FeCl_3$ and $CuCl_2$ solutions, and HF at all concentrations. Straumanis and Gill (4) reported that the addition of NH_4F increased the dissolution rate of Ti in HCl and H_2SO_4 up to a concentration of 4M NH_4F, above which the metal was rendered practically passive. In HF, the effect of NH_4F was to reduce the dissolution rate at all NH F concentrations.

Table I. Comparison of Ti, Zr, and Zn as anode materials

Standard oxidation potential,[b] (2) v	1.19	1.53	0.76

[a] Based on oxidation to tetravalent Ti and Zr.
[b] For couples: $Ti\text{-}TiF_6^{--}$, $Zr\text{-}ZrO^{++}$, and $Zn\text{-}Zn^{++}$, respectively.

Schlain and co-workers (5) studied galvanic corrosion of Ti and Zr. When coupled with several other metals in a variety of electrolytes, both were usually cathodic; however, Ti was anodic to stainless steel in H_2SO_4 and to Al after several days in a deaerated H_2SO_4 solution.

Several studies of electrode potentials of Ti and Zr have been reported. Botts and Krauskopf (6) and more recently Sato and Yamane (7) attempted to obtain the standard electrode potential of Ti in $Ti_2(SO_4)_3$ solutions. The values obtained, e.g., −0.355 v in the latter experiment, were far different from the value −1.30 v calculated from thermodynamic data (2), showing that the electrode was not reversible. Other experiments (5, 8) generally support the conclusion that potentials of these electrodes in many electrolytes are variable with time, sensitive to degree of aeration, and that the electrodes are highly irreversible. Straumanis and Chen (8) found that the Ti electrode potential in HF becomes more negative with increasing HF concentration up to 0.20*N*, beyond which it was constant at −0.768 v. Addition of NH_4F resulted in a potential of −0.95 v.

Anodic polarization and oxide film growth during anodization of Ti and Zr have been extensively investigated (9). Passivity is usually attributed to a layer of TiO_2 or ZrO_2.

The only application of either Ti or Zr in a primary cell, to our knowledge, involves a positive electrode of porous Ti coated with depolarizer (10). Schlain (5) obtained a current as high as 11 ma from a Mg-Ti couple in which Ti was cathodic.

In the course of this investigation the following quantities were determined: (*a*) electrode potentials for Ti and Zr as a function of anodic current density in a variety of electrolytes; (*b*) average charge of the ion produced by the anode reaction in several electrolytes and at several current densities; (c) characteristics of more than a hundred primary cells having either a Ti or Zr anode and either a Pb-PbO_2 or C-MnO_2 cathode.

Experimental

Titanium sheet,[1] 0.25 mm thick, was cut to the desired size and polished with emery paper for use as electrodes. Titanium tubing,[2] 3.17 cm O.D., was used for the construction of dry cells. Zirconium sheet, 0.25 mm thick, was either Iodide Process[3] or Kroll Process.[4] No significant differences were observed in the behavior of the two types of Zr. All reagents were C.P. or Analytical Reagent grade.

Single electrode potentials were measured by means of a L&N Type K potentiometer. Cell voltages were measured either potentiometrically or by means of a vacuum-tube voltmeter. Current densities were computed from the measured area of electrodes without application of a roughness factor. The electrode area was regulated by coating the entire electrode with paraffin and cleaning off the desired area on one side of the electrode, finally polishing the exposed area with emery paper.

C-MnO_2 electrodes were of the commercial D-cell type.[5]

In order to select an electrolyte and a usable cathode for detailed tests, the behavior of Ti and Zr coupled to other electrodes in about 40 electrolytes was studied. The open-circuit voltage and the voltage of the couples connected by a 12-ohm resistor were measured. The electrolytes were principally solutions of H_3PO_4, HF, H_2SO_4, $FeCl_3$, NH_4F, and combinations of these. The other electrodes were Cu, Al, Pb, stainless steel, and MnO_2. Most of the couples exhibited either a low open-circuit voltage or severe polarization under load; however, Ti coupled with the MnO_2 electrode in 1*N* HF gave 1.37 v open circuit and 0.600 v under load. A Zr-MnO_2 couple, with 0.1*N* HF, gave 1.60 v open circuit and 0.89 v under load. The highest current drawn was 75 ma, using an anode area of 2 cm^2.

It is evident that acid fluoride solutions are the most effective in reducing polarization under load in the case of both Ti and Zr. The C-MnO_2 electrode, although undoubtedly adversely affected by fluoride, was selected for detailed investigation because of the high voltage observed when coupled with Ti and Zr in many different acid fluoride solutions.

Polarization Measurements

Titanium or zirconium was made the anode in electrolytes composed chiefly of HF, NH_4F, KCl, and in some cases H_2SO_4. The single electrode potential was measured by means of a reference normal calomel electrode, as a function of current density. The single electrode potentials of replications agreed within 1% at current densities less than 1 ma cm^{-2} and within 5% at the highest current densities. Representative curves are presented in Fig. 1 and 2. Potentials are taken with respect to the standard hydrogen electrode.

In the case of Ti (Fig. 1), as the current density was increased, a point was attained at which the electrode potential suddenly became strongly positive. The current density at which this occurred is indicated by the broken vertical portion of the polarization curve, and electrodes which have undergone the sudden positive change in potential will be referred to as passive. In this condition, oxygen is evolved and the electrode is presumably covered by a protective film. The current density for passivation, i_p, was not very reproducible, even though the electrode potentials prior to passivation were quite so. This arose from the fact that i_p depended markedly on the rate at which the current was increased. The curves were selected to show typical passivity behavior.

Zirconium electrodes generally showed less tendency to become passive. However, in solutions containing only HF, or dilute mixed solutions of HF and NH_4F, i_p was lower for Zr than for Ti, as shown in Fig. 2. NH_4F was very effective in eliminating passivation of Zr, even in the absence of HF.

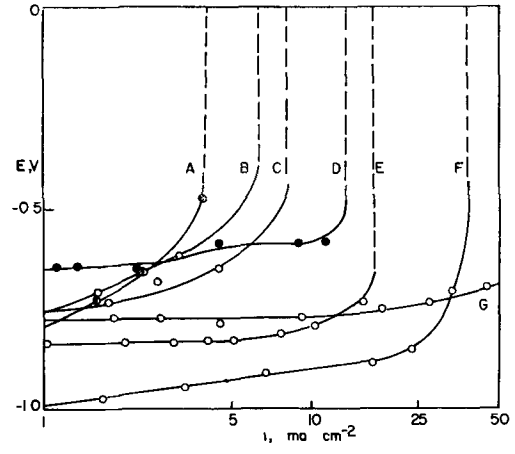

Fig. 1. Polarization and passivation of Ti in fluoride solutions. Curve A, 0.05N HF; B, 0.075N HF; C, 0.1N HF; D, 1N HF, 20% NH_4F; E, 0.2N HF; F, 0.075N HF, 0.1N KCl, 6% NH_4F; G, 1N HF. i_p for 1N HF was 110 ma cm^{-2}.

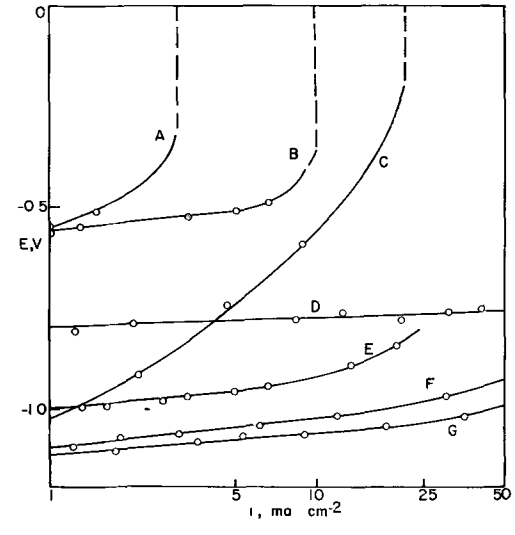

Fig. 2. Polarization and passivation of Zr in fluoride solutions, and Zn in Leclanche electrolyte (curve D). Curve A, 0.1N HF; B, 1N HF; C, 0.1N HF, 1% NH_4F; E, 8% NH_4F; F, 0.075N HF, 4% NH_4F; G, 0.075N HF, 8% NH_4F. Passivity did not occur in E, F, or G, even though in G i was taken as high as 180 ma cm^{-2}.

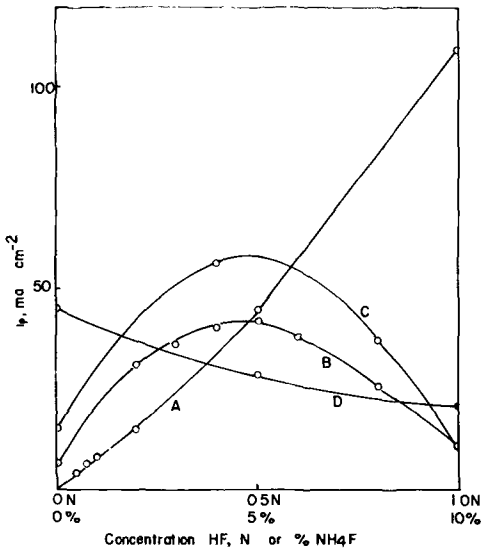

Fig. 3. Dependence of the passivation current density of Ti on HF and NH_4F concentration. A, HF only; B, 0.075N HF, added NH_4F; C, 0.2N HF, added NH_4F; D, 0.5N HF, added NH_4F.

Returning to Fig. 1, we note in particular the effect of HF concentration on the slope of the E vs. i curve for Ti and on the value of i_p. Even more important is the beneficial effect of added NH_4F in dilute HF solutions on the potential, polarization, and passivation current density for Ti, as illustrated by the difference between curves B and F. (KCl had a very minor effect on electrode behavior and was added to several electrolytes for the purpose of increasing conductivity.) Although i_p was somewhat uncertain, enough values were at hand to allow an approximate evaluation to be made of its dependence on electrolyte composition. In Fig. 3, the passivation current density is plotted against the concentration of HF (with no NH_4F), or against % NH_4F at fixed HF concentration. NH_4F exerts a beneficial influence up to about 5% in dilute HF (0.2N) but a deleterious effect at higher HF concentrations. This is also clearly shown by curves D and G of Fig. 1. In 1N HF i_p was reduced from 110 ma cm^{-2} to 8.1 ma cm^{-2} by the addition of 20% NH_4F. In NH_4F solutions with no HF (except that arising from hydrolysis), i_p was very low, e.g., 2.6 ma cm^{-2} in 8% NH_4F.

Considering also the chemical corrosion of Ti which increases rapidly with HF concentration and is inhibited by NH_4F, we conclude that the best electrolyte to be used with Ti is 0.075N HF containing 5-6% NH_4Cl and about 0.1N KCl. For brevity this solution is designated solution A. The potential of Ti in solution A is −1.02 v (about 0.2 v more negative than Zn in the usual dry-cell electrolyte) and remains below −0.8 v up to a current density of 28 ma cm^{-2}.

This current density may be compared with typical values at the Zn electrode in the Leclanché cell. During discharge of a fresh D-cell under 4-ohm load the anodic current density is about 6 ma cm^{-2}, and during operation of an ordinary 2-cell flashlight it is about 20 ma cm^{-2}.

There were too few cases of passivity for Zr to permit the same kind of correlation between i_p and electrolyte composition. Curve G of Fig. 2 shows, however, that the most satisfactory electrolyte for Zr from the standpoint of polarization was 0.075N HF with 8% NH_4F. The addition of KCl caused no significant difference. In this electrolyte the potential of Zr is superior to that of Zn (curve D, Fig. 2) in a solution containing 26% NH_4Cl, 8.8% $ZnCl_2$, and a trace of $HgCl_2$ (a common dry-cell electrolyte) at all current densities up to 200 ma cm^{-2}.

Corrosion

The corrosion rates of Ti and Zr were measured in electrolytes which appeared promising from polarization studies and in several other solutions used in the experimental cells described later. Solutions were in contact with air at room temperature, but not stirred. The favorable effect of added NH_4F on the corrosion of Ti by HF, previously reported (4), was confirmed. The rate for Ti in electrolyte A was 22 mdd, which, while not excessive, sets an upper limit of about six months on the life of a 0.25-mm sheet anode in this electrolyte.

On the other hand, Zr corroded rapidly in all acid fluoride solutions investigated, and the addition of NH_4F was of no benefit. The rate was 6000 mdd in electrolyte A and 800 mdd in 8% NH_4F alone. Small concentrations of Pb, Zr, and chromate ions reduced the corrosion rate in 0.1N HF, but not to a useful level. $Na_2Cr_2O_7$ reduced significantly the corrosiveness of H_2SO_4 on Zr, the rate in the case of 80% H_2SO_4, 1% $Na_2Cr_2O_7$ being only 2.3 mdd.

Anode Reaction

The number of faradays to dissolve a mole of metal, z, when Ti or Zr was made the anode was measured over a series of current densities and with varying electrolyte composition.

Electrolytes used with Ti were all mixtures of NH_4F, KCl, and HF, containing from 4 to 8% NH_4F, 0.1N KCl, and from 0.075 to 0.1N HF. Current densities ranged from 1 to 20 ma cm^{-2}. There was no observable dependence of z on either composition or current density. The average of 16 measurements of z which lay between 3.93 and 4.18 was 4.04.

Electrolytes used with Zr included 0.05 to 0.2N HF, 5 to 10% NH_4F, mixtures of HF and NH_4F, $CuCl_2$, $FeCl_3$, NH_4Cl, and HCl of several concentrations each. Current densities were higher than in the case of Ti in order to reduce the time required and thus the error due to chemical corrosion, ranging from 50 to 140 ma cm^{-2}. At 100 ma cm^{-2}, the anodic corrosion rate is 2 x 10^5 mdd. z did not depend on either composition or current density. The average of 14 measurements of z, which lay between 3.25 and 4.44 was 3.90.

It is clear that the only reaction of significance in these cases is oxidation of the metal to the tetravalent state. Chemical corrosion during the measurements has the effect of reducing z below the actual value; this may account for the somewhat smaller average value for Zr, since in some electrolytes the chemical corrosion rate was in the neigh-

borhood of 3% of the anodic corrosion rate. Oxygen was evidently not produced in a significant quantity.

Primary Cells

Cells were made in open beakers using Ti or Zr anodes and either PbO_2 or MnO_2 cathodes. The principal electrolytes used were solution A (0.075*N* HF, 6% NH_4F, 0.1*N* KCl), mixtures of A with H_2SO_4 and additional NH_4F, H_2SO_4, and H_2SO_4 containing $Cr_2O_7^{--}$. Th PbO_2 electrodes were made with commercial positive grids, pasted and formed in the laboratory according to the method described by Vinal (11). Representative data for four types of cells are shown in Fig. 4. Curves A through D were obtained by measuring the cell voltage during very short periods of discharge through a variable load. The drain is given by i_a, the anodic current density. In all cases the cathode was of much greater area than was the anode.

Curves C and C' represent the behavior of a Ti-MnO_2 cell containing solution A. The open-circuit voltage was 1.75. When discharged at $i_a = 10$ ma cm^{-2} the voltage remained about 1.4 for delivery of 25 amp min, and dropped to 1.0 v at 39 amp min. This corresponded to 81% utilization of the anode. The behavior of these cells was not very reproducible, and the example cited here was representative of several of the best cells studied. Unfortunately, fluoride solutions affect MnO_2 electrodes deleteriously, so that even the open-circuit voltage of such cells would fall to zero after 2 or 3 days.

The use of PbO_2 in place of MnO_2 resulted in a much higher initial open-circuit voltage (2.2 to 2.7 v). The addition of a small concentration of H_2SO_4 to the electrolyte increased the PbO_2 potential. Titanium became more positive with increasing H_2SO_4 concentration, but the polarization characteristics were improved. These effects are illustrated by Fig. 5. However, the polarization of Ti with time during continuous discharge was more severe in solutions containing H_2SO_4. Thus we find that, although the voltage remained high for high drain of short duration (curve A, Fig. 4), the discharge characteristics were disappointing (curve A'). Much of the decrease in voltage during discharge was due to failure of the PbO_2 electrode in fluoride solution. At the end of the discharge, the PbO_2 single electrode potential had fallen from an original value of 1.4 v to 0.6 v.

Zr-MnO_2 cells containing solution A were similar (see curve D, Fig. 4) to the Ti cells except for the much greater chemical corrosion of the anode. Many cells of the type Zr-H_2SO_4-PbO_2 were tested, to several of which chromate was added to reduce corrosion. The performance of the best of these is illustrated by curve B, Fig. 4. Discharge characteristics were generally inferior to the Ti-PbO_2 cells.

"Dry" cells were constructed from Ti tubing or Zr sheet, commercial MnO_2 electrodes, and a starch paste containing solution A. These cells polarized completely at low current density, probably because the polarization product was held mechanically in contact with the electrode, while in the open-beaker cells it was allowed to drop off.

Other electrolytes used in experimental cells were chosen with the purpose of eliminating water or reducing its activity markedly in the hopes of avoiding the formation of oxide layers on the Ti or Zr electrodes. Fused hydrates of NaOAc, $FeCl_3$, $CaCl_2$, and KF, and the nonaqueous solvents glacial acetic acid, fused alkali halides, fused KI_3 methanol, diethyl ether, nitrobenzene, SCl_2, S_2Cl_2, formamide, acetone, acetic anhydride, and dioxane all gave unsatisfactory results. Cells containing H_2SiF_6 in aqueous solution were moderately successful but corrosion was severe.

Polarization Product

The nature of the product responsible for polarization of Ti in solution of HF and NH_4F was not ascertained. Colors commonly observed on polarized electrodes were black, blue, or white and were due to material which could be readily scraped off. X-ray diffraction photographs of four products obtained under different conditions showed that no two were identical, nor were any to be identified with compounds for which data are tabulated by ASTM (12). While TiO_2 is undoubtedly a major

component of the polarization product under many conditions, in no case studied did it appear as a pure product.

Acknowledgments

The work described here was supported by contract with W. J. Kroll, whose generosity and technical advice are gratefully acknowledged. We wish to thank the National Carbon Company, the Carborundum Metals Company, the Titanium Metals Corporation of America, the Foote Mineral Company, and the Burgess Battery Company for gifts of materials used in this study. Thanks are also due N. C. Cahoon and Miss M. P. Korver, with whom valuable discussions were held, Miss Judith Skow and Mrs. Celia Rockholt, who made many of the measurements.

Manuscript received March 2, 1959. This paper was taken, in part, from the Ph.D. Thesis of one of the authors (M.A.T.), Oregon State College (1957).

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Investigation of the Electrochemical Characteristics of Organic Compounds IV. Quinone Compounds

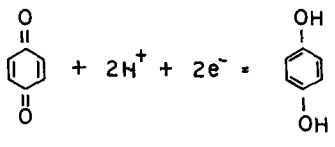
R. Glicksman and C. K. Morehouse

Semiconductor and Materials Division, Radio Corporation of America, Somerville, New Jersey

ABSTRACT

A study of the electrochemical characteristics of various quinone compounds shows that the cathode potential of these compounds during current flow is dependent on the type and position of substituent groups in the molecule, the pH of the electrolyte, and the nature of the quinone itself. Experimental data are presented for dry cells containing 2,5-dichloro-p-quinone and p-quinone-dioxime as cathodes coupled with a magnesium anode.

Most oxidation and reduction reactions in organic chemistry are irreversible. An exception to this is the group of reactions involving quinoid-benzenoid equilibria. One of the best known of these is the quinone-hydroquinone system, whose potential has been reported by Hovorka and Dearing (1) to be



[1]

In this paper the effect of such factors as group substitution, aromaticity, and pH on the operating potential and coulombic capacity of various quinone compounds are presented and their use as cathode materials in primary cells is considered.

Experimental Data and Discussion of Results

Apparatus and Technique

A technique, previously described (2), has been used to measure the operating potential during current flow and the coulombic capacity of the various quinone-type compounds. This technique consists in discharging at a constant current drain of 0.005 amp/g, in a large volume of electrolyte, a 0.5-g sample of the quinone-type cathode material mixed with 0.05 g of Shawinigan acetylene black. The change in cathode potential with time was measured with a L&N type K potentiometer using a saturated calomel reference electrode. The measured potentials were corrected for the *IR* drop associated with the apparatus and electrolyte by means of an oscillographic technique (3).

All half-cell potential data reported in this paper are referred to the normal hydrogen electrode and include a liquid junction potential, which in most cases is small and can be neglected. For most of the measurements an aqueous magnesium bromide electrolyte and a magnesium anode were used, while in studying the effect of pH on potential, a zinc anode was employed with the acidic NH_4Cl-$ZnCl_2$-H_2O and basic NaOH-H_2O electrolytes.

Half-Cell Potential Studies

Effect of aromaticity.—Figure 1 gives half-cell discharge curves for a series of quinones derived from benzene and other polynuclear hydrocarbons. The ortho quinones have higher operating potentials than their corresponding para quinone compounds. In addition, both the ortho- and para quinones show a marked dimunition in cathode potential as one goes to the bicyclic and tricyclic quinone compounds. For example, a comparison of p-quinone with its corresponding naphthoquinone indicates a difference in potential of 200-300 mv, in agreement with standard potential measurements. Fieser and Fieser (4) attribute the markedly diminished energy content of the bicyclic compounds to the fact that the quinoid double bond is incorporated in the aromatic nucleus and hence is relatively inert. In anthraquinone both the otherwise reactive quinoid double bonds participate in benzenoid ring systems and the potential of the quinone is lower yet. Similarly, because of the higher energy content of the orthoquinones as compared to the isomeric paraquinones the standard potentials of the ortho compounds are 85-95 mv higher.

If the standard potentials of a series of quinones are compared, the change in potential will be dependent on the change in free energy in going from the quinone-hydrogen system to the hydroquinone, according to the following equation

$$E^\circ = -\frac{\Delta F^\circ}{nF} = -\frac{\Delta H^\circ}{nF} + \frac{T\Delta S^\circ}{nF} \qquad [2]$$

It has been found that the temperature coefficient of the standard potential is approximately the same for a large number of quinones and is equal to about 0.7 mv/deg. This temperature coefficient, which corresponds to an entropy change of −32 cal/deg for the hydrogenation of a quinone, corresponds roughly to the entropy of the mole of hydrogen lost in the reaction. Thus the change in potential in a series of quinones will represent the change in the relative heat contents of the quinone and hydroquinone through the series (5). The change in bond energies in the reduction represented by Eq. [1] is the same for all quinones and is small compared to the benzene resonance energy gained on the hydroquinone side. Thus it would be expected that resonance effects would be a controlling factor in the magnitude of the potential. Since the largest contribution to the resonance energy is due to the equivalent Kekule forms, the relative numbers of such equivalent forms may be used as a quantitative estimate of the relative energy of the oxidized and reduced forms.

The relationship between the number of contributing resonance forms in the quinone and hydroquinone and the standard potential of the system has been demonstrated by Branch and Calvin (5). They obtained a straight line relationship between the standard potential of para quinones and the ratio of the contributing forms n_q/n_h.[1] A still better relationship was obtained when the expression $(n_h - n_q)/(n_h + n_q)$ was used instead of the simple ratio and when allowance was made for steric and ortho effects in quinones of polynuclear structure. Similarly, Berliner (6) computed the difference in empirical resonance energies of a number of quinones and their respective hydroquinones from known experimental data and found a linear relationship exists between the oxidation-reduction potential and the difference in resonance energies of the quinones and the respective hydroquinones.

To test the above relationship for electrodes undergoing discharge, the cathode potentials of the quinones after 1 amp-min of discharge were plotted vs. $(n_h - n_q)/(n_h + n_q)$, as shown in Fig. 2. In agreement with the results of Branch and Calvin a straight line relationship was found between the potential and the ratio of the number of resonance forms in the quinone and hydroquinone compounds. In addition a similar line is obtained for the orthoquinones but displaced upward about 0.1 v and parallel to the paraquinone line.

[1] n_q and n_h are the number of forms of the quinone and hydroquinone. For p-quinone there is only one such form, while in hydroquinone there are two Kekule forms. In 1, 4-naphthoquinone there are two, while in the corresponding hydroquinone there are three.

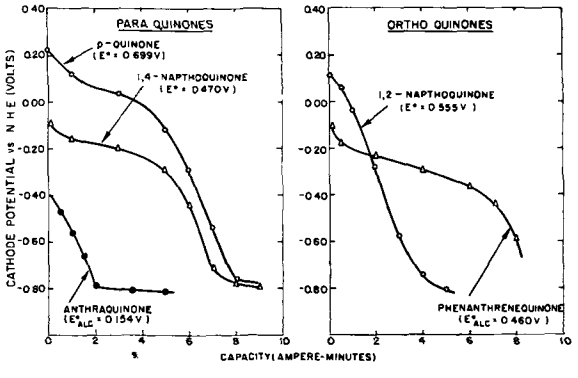


Fig. 1. Half-cell potential studies of various ortho and paraquinone compounds discharged at a rate of 0.005 amp/g in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte.

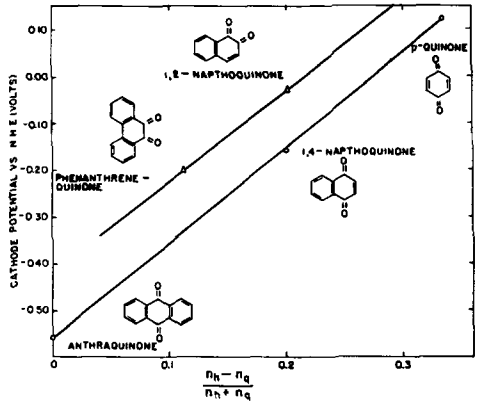

Fig. 2. Relationship between the number of contributing resonance forms in the quinone and hydroquinone and the half-cell potential as measured at a rate of 0.005 amp/g in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte.

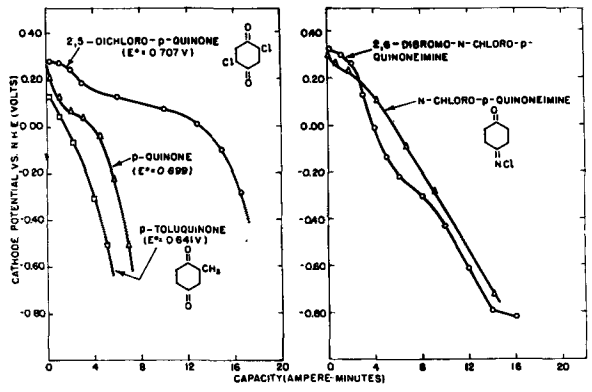

Fig. 3. Effect of group substitution on the cathode potential of p-quinone and N-chloro-p-quinoneimine discharged at a rate of 0.005 amp/g in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte.

Effect of group substitution.—Presented in Fig. 3 are discharge curves for various para quinone and chloroimide compounds illustrating the effect of substituent groups on the operating potential of these compounds. It is seen that an electron-attracting halogen group raises the potential while an electron-repelling methyl group lowers the potential of the parent compound. This type of effect closely parallels the effect of these constituents on the standard potentials of quinones, as well as on the operating potential of aromatic nitro compounds (7).

The effect of substituent groups on the standard potentials of quinone compounds has been studied extensively by Fieser (8, 9). Most of the determinations were carried out in alcoholic solution, but the results would be expected to apply closely to aqueous solutions. In general, it was found that electron-attracting groups, such as $-NO_2$, -CN, -COOH, and halogens, raise the potential of the parent quinone, whereas a potential-lowering effect is exerted by electron-repelling groups such as $-NH_2$, -OH, and $-CH_3$. This is in agreement with the data presented in Fig. 3. These relationships are those expected from the course of aromatic substitutions. Electron-attracting groups tend to decrease the electron density in the vicinity of the oxygen atoms and thus to increase the attractive power of the system for external electrons, rendering the compound a stronger oxidizing agent. Conversely electron-repelling substituents decrease the affinity for electrons and hence lower the potential.

When the substituent is not in the quinoid ring its effect is much smaller and depends to a large extent on its position with respect to the quinoid ring. For example, Fieser (8) has shown that substituents in the 1 or 3 position of phenanthrenequinone have a considerable effect on the potential of phenanthrenequinone while in the 2 or 4 positions they are practically ineffective. The importance of the position of substituent group on the electrode potential of an organic compound has also been shown for both aromatic nitro (7) and nitroalkane compounds (10), and it depends essentially on its effect in altering the electron density in the vicinity of the reducible group.

Effect of electrolyte pH.—For the quinone-hydroquinone system the variation of the oxidation-reduction potential with hydrogen ion concentration is relatively simple in acidic electrolytes, but in alkaline solutions allowance must be made for the ionization of hydroquinone, which can function as a dibasic acid. Thus in acidic electrolyte $dE/d(pH) = 0.059$ for this system, while at pH's higher than about 8 the slope of the potential-pH curve becomes 0.030 to a pH of approximately 11 and is zero in more alkaline solutions (11).

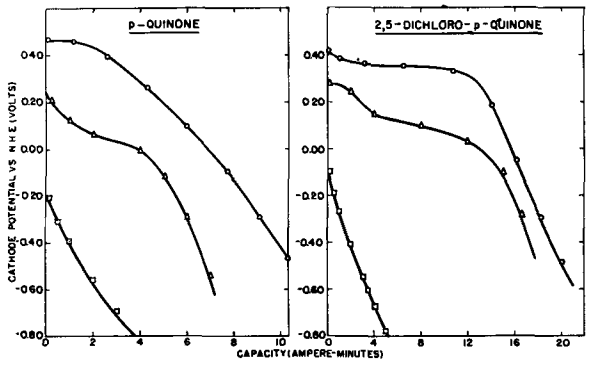

Fig. 4. Effect of pH on the cathode potential of p-quinone and 2, 5-dichloro-p-quinone when discharged at a rate of 0.005 amp/g in various electrolytes. O—25% NH_4Cl, 20% $ZnCl_2$, 55% H_2O; Δ—14% $MgBr_2$, 86% H_2O; □—30% NaOH, 70% H_2O, saturated with ZnO.

Taking into account the effect of pH on potential, it is seen from Fig. 4 that both p-quinone and 2,5-dichloro-p-quinone have initial operating potentials close to their reversible values in the NH_4Cl-$ZnCl_2$ (pH = 4.5) and $MgBr_2$(pH = 8.2) electrolytes. Similarly, the initial operating potentials of the quinone compounds previously presented in Fig. 1 and 3 are also reasonably close to their reversible values in the magnesium bromide electrolyte. However, in the strongly alkaline sodium hydroxide electrolyte, the operating potentials of p-quinone and 2,5-dichloro-p-quinone show a considerable deviation from their reversible values. This is attributed to the decomposition of both the quinone and hydroquinone by atmospheric oxygen in this alkaline electrolyte (12).

Various N-analogues of quinone.—In addition to the various quinone compounds discussed above there are a number of analogous organic compounds containing quinoid structures which are of scientific interest. Many of these compounds are employed as oxidation-reduction indicators in biological applications. Presented in Fig. 5 are discharge curves of

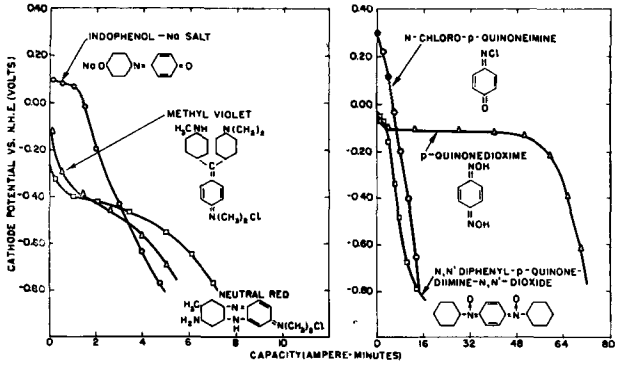

Fig. 5. Half-cell potential studies of various quinone-type compounds discharged at a rate of 0.005 amp/g in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte.

three typical indicators, indophenol-Na salt (indophenol group), neutral red (azine group), and methyl violet (triphenylmethane group). As with the other quinones both indophenol-Na salt and neutral red operate at potentials close to their theoretical values (13) after corrections are made for the *p*H of the solution.

Also shown in Fig. 5 are discharge curves of three other N-analogues of p-quinone, which contain in addition to the quinoid structure additional reducible groups in the molecule. Of the three, N-chloro-p-quinoneimine which contains a positive halogen and p-quinonedioxime with two reducible oxime groups are of the most interest, as the amine oxides in N,N'-diphenyl-p-quinonediimine-N,N'-dioxide are reduced very difficultly (14, 15). Only the N-chloro-p-quinoneimine compound has a higher operating potential than p-quinone and, as evidenced by the data in Fig. 3 for 2,6-dibromo-N-chloro-p-quinoneimine, it would appear that the effect of substituent groups on the operating potential of chloroimides is similar to that of the quinones.

Capacities of Quinone Compounds

Presented in Table I are theoretical capacities and electrode efficiencies of various quinone-type compounds as calculated from the half-cell discharge data in Fig. 1, 3, and 5. It is seen that on the basis of theoretical capacity in ampere-minutes per gram the quinone compounds are superior to manganese dioxide, the cathode material now used in conventional Leclanché dry cells. However, because of the low densities and poor electrode efficiencies of these organic compounds a manganese dioxide cathode would give markedly superior performance when rated on the basis of ampere-minute output per cubic centimeter. As seen from the half-cell potential data in Fig. 4 the use of a more acidic NH_4Cl-$ZnCl_2$ electrolyte has no appreciable effect on the electrode efficiency of the quinones, and no advantage could be gained for the organic compounds in going to this electrolyte.

Table I. Theoretical capacities and electrode efficiencies of various quinone compounds discharged in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte at a rate of 0.005 amp/g

Compound	Capacity, amp-min/g		Efficiency, %
	Theoretical	Actual*

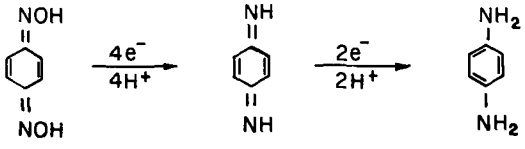
More promising for use as cathodes in primary cell applications are some of the quinones which contain reducible groups in addition to the quinoid structure. These compounds not only have higher theoretical capacities than the quinones but also operate at higher electrode efficiencies. Of particular interest is p-quinonedioxime which has a theoretical capacity of 69.9 amp-min/g and which operates under these conditions of discharge at an electrode efficiency of 93.3%. On the basis of these results and the polarographic data of Elofson and Atkinson (16) it is believed the over-all reduction of p-quinonedioxime takes place with a 6 electron change, the actual reduction probably proceeding through the intermediate diimino stage as shown here:



[3]

Experimental Dry Cell Data

The use of quinone compounds in primary batteries was suggested previously by Arsem (17) who referred to the coupling of a zinc anode with an organic oxidizing agent such as quinone. More recently Tripler and McGraw (18) evaluated tetrachloroquinone as a cathode material in both acid and basic electrolyte using zinc and lead anodes. In the present study the quinones were coupled with a magnesium anode to take advantage of the higher potential of this electrode.

Experimental dry cells containing 2,5-dichloro-p-quinone and p-quinonedioxime cathodes were assembled in the usual manner using an impact extruded magnesium AZ10A alloy AA-size can as anode, and a 500 g/l $MgBr_2 \cdot 6H_2O$ electrolyte. The cathode mix (weighing approximately 4.5 g) consisted of one part by weight of the quinone compound to two parts by weight of Darco carbon black G-60.

Performance characteristics of these cells on a 4- and 50-ohm continuous discharge test are shown in Fig. 6. Included for comparison are performance

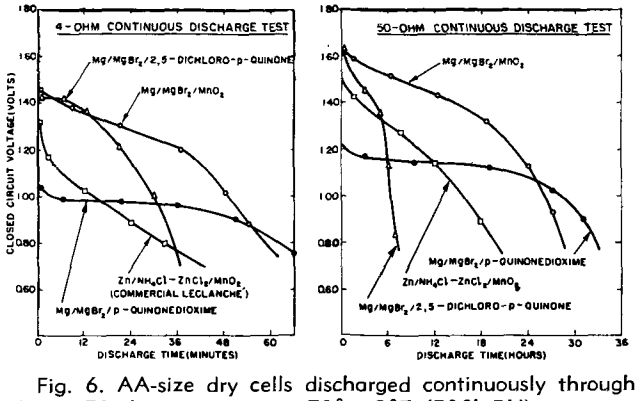


Fig. 6. AA-size dry cells discharged continuously through 4- and 50-ohm resistances at 70° ±2°F. (50% RH).

data for comparable-size commercial Leclanché and magnesium-manganese dioxide dry cells (19) of the type being developed by the Dow Chemical Company. It is seen that the performance of the magnesium-p-quinonedioxime cell is superior to the Leclanché cell on both these tests, while the magnesium-2,5-dichloro-p-quinone cell performs better only on the higher current drain test. Compared to the magnesium-manganese dioxide cell, the quinone cells give inferior performance on these tests. However, the flat voltage discharge curve of the p-quinonedioxime cell is advantageous for some applications.

Summary

An investigation of the electrochemical characteristics of various quinone-type compounds show these compounds to operate close to their reversible values during current flow. The operating potential of these compounds has been found to be dependent on the type and position of the substituent groups in the molecule as well as the pH of the electrolyte, electron-attracting groups and low pH's favoring higher potentials. The operating potential of the quinones is also dependent on the nature of the compound; for example, the ortho quinones operate at potentials approximately 0.1 v higher than their isomeric para quinones, while a decrease in potential is found as one goes to bicyclic and tricyclic members in any given series.

Compared to the conventional inorganic cathode materials the quinone compounds, in general, are not as good. However certain quinone-type compounds containing other reducible groups in the molecule, such as p-quinonedioxime, show some advantages when coupled with a magnesium anode in a magnesium bromide electrolyte.

Manuscript received Feb. 13, 1959. This paper was prepared for delivery before the Ottawa Meeting, Sept. 28-Oct. 2, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

The Cathodic Reduction of Manganese Dioxide in Alkaline Electrolyte

N. C. Cahoon[1] and M. P. Korver

Research Laboratories, National Carbon Company, Division of Union Carbide Corporation, Cleveland, Ohio

ABSTRACT

A study of the mechanism of the reduction of manganese dioxide in strongly alkaline electrolytes has shown that the rather complex process may be considered as occurring in three steps. The first is the simultaneous reduction to form a divalent manganese compound, presumably, $Mn(OH)_2$ and an intermediate oxide tentatively identified as Mn_4O_7; the second step is the electrochemical reduction of Mn_4O_7 to form both Mn_3O_4 and $Mn(OH)_2$; the final step is the electrochemical reduction of Mn_3O_4 to $Mn(OH)_2$. Both chemical and x-ray diffraction analyses of cathodes at various stages of reduction are presented.

The cathodic reduction of manganese dioxide in Leclanché cells (1) has been examined previously and a mechanism proposed to account for the experimental observations. The need of a similar examination of the cathodic reduction of MnO_2 in alkaline electrolytes was recognized some years ago. Accordingly, a study was undertaken to determine the mechanism of the reaction when MnO_2 is used as the cathodic depolarizer in an alkaline cell. The approach to this problem followed the lines of earlier studies in that the products of the cathodic reductions were separated into two fractions by a differ-

ence in solubility. The soluble and insoluble fractions were studied separately by both chemical and physical methods. This paper presents some significant results obtained in the course of the work.

Experimental

A series of experimental cells was prepared from electrolytic grade MnO_2, acetylene black, and an electrolyte containing 7.6*N* KOH. An excess of amalgamated powdered Zn was used in a compressed pellet as the anode, and an adequate supply of electrolyte was provided so that the cathodic depolarizer would be the only service limiting factor. The composition of a representative cell follows: electrolytic MnO_2 0.5128 g, acetylene black 0.1923, KOH (7.6*N*) 0.2949, amalgamated Zn 4.0 (approximately). The parts of the cells were assembled in a bench-type cell of a circular cross section with a cross-sectional area of 2.58 cm^2 (0.40 $in.^2$). A cellulosic separator 0.0208 cm (0.0082 in.) thick was employed. The cell was closed with a close-fitting plunger and throughout the test the unit was maintained under a mechanical pressure equivalent to 4.32 kg/cm^2 (61.5 $lb/in.^2$) of cell area. A continuous load of 30 ohms was placed across the cell, and cell voltage readings were taken periodically with a recording voltmeter.

One cell was removed after each of the following service levels had been reached: 2.20, 4.14, 4.19, 6.12, 8.09, 8.87, and 9.39 amp min. Immediately following the removal from test, the cell was quickly dismantled and the cathode mix was suspended in 500 cc of an aqueous solution of 25% NH_4Cl. The *p*H of this suspension was quickly measured and ½*N* HCl added with adequate stirring to reduce the *p*H to 5.4. The suspension was stirred mechanically for 2 hr at room temperature to permit the solution of any divalent manganese that may have been formed in the cell discharge. Previous studies had shown that MnO_2, $Mn_2O_3 \cdot H_2O$, and Mn_3O_4 are all stable under these conditions and that substantially no complicating reactions would occur at this *p*H. Following the leaching operation, the residue was separated from the filtrate and thoroughly washed. The combined washings and filtrate were made up to one liter and aliquot samples of 100 ml were analyzed for manganese content by the method of Lingane and Karplus.(2)

The residue was dried at 100°-110°C and then subjected to examination by standard x-ray diffraction techniques to identify the solid phases remaining in the cathode. Another portion of the residue was analyzed for available oxygen and total manganese contents by conventional analytical methods.

Discussion

The discharge curve characteristic of this group of cells is shown in Fig. 1. Cells 1 to 5 gave substantially the same discharge curve as shown by the upper line in Fig. 1, while cell 6, which had a somewhat smaller cathode but was otherwise the same as cells 1 to 5, gave a discharge curve shown by the lower line in the same figure. Data obtained from the discharge of the cells and analyses of the soluble portion of the depolarizers are given in Table I. The conditions used for leaching the discharged cathodes were chosen so that any divalent manganese, presumably present as manganous hydroxide, would be dissolved. The amounts of divalent manganese leached from the cathodes in this manner have been calculated to equivalent ampere minutes on the basis of the following reaction:

$$MnO_2 + 2e + 2K^+ + 2H_2O \rightarrow Mn(OH)_2 + 2KOH \quad [1]$$

From this reaction 1 amp min of energy results from the reduction of 0.027 g MnO_2 to form 0.0173 g of

manganese as manganous hydroxide. The proportion of the total output in ampere minutes represented by the manganous hydroxide found and calculated on the above basis is shown in Fig. 2. It is evident from these data that while about half the reaction product is in this form, a sudden decrease in the proportion occurs between 8.09 and 9.39 amp min output. However, the finding that $Mn(OH)_2$ constitutes a large proportion of the cathodic reduction product is not in accord with previously published data (3) which indicate that the product is an orange-red Mn_2O_3.[2]

[2] We are unable to rationalize these earlier data with our findings.

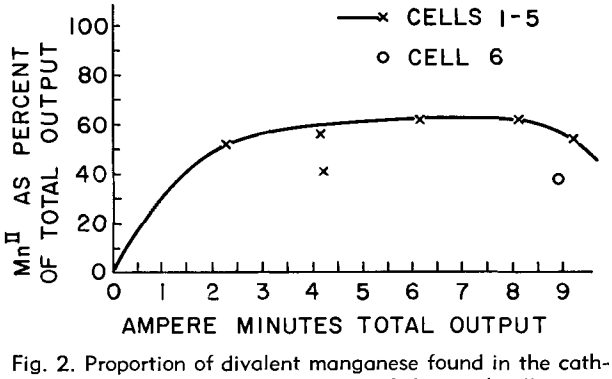

Fig. 2. Proportion of divalent manganese found in the cathodic reaction product as a percentage of the total cell output throughout the test.

Table I shows the depolarizer contents of the five experimental cells in terms of the free MnO_2[3] content and the equivalent theoretical cell output if all this MnO_2 were converted to Mn_3O_4 according to the following cathodic reaction:

$$3MnO_2 + 4K^+ + 4e + 2H_2O \rightarrow Mn_3O_4 + 4KOH \quad [2]$$

In this way 0.0405 g of MnO_2 provides 1 amp min of energy. This basis has been used for general calculation of cell output since work in this laboratory had previously shown that a variety of MnO_2 types was, at least in part, reduced to this compound. Table I also shows the actual electrical output of each cell as well as that portion of the output in equivalent ampere minutes that can be accounted for by the formation of $Mn(OH)_2$. The ampere minute output which must therefore be associated with a change in composition of the insoluble residue is listed. Table II also shows the compositions of these cathode residues. Table III combines the data of Tables I and II and shows the amount of free MnO_2 consumed per ampere minute for that portion of the output associated with the formation of the insoluble cathodic product. The values obtained are calculated on the assumption that only a single insoluble reaction product is formed in each case. By comparison of these values with the amounts of MnO_2 consumed per ampere minute for the reduction to the various lower oxides, some helpful correlations may be found. Thus, in reaction [2] 0.0405 g MnO_2 is required per ampere minute to form Mn_3O_4. Similarly 0.027 g MnO_2 (reaction [1]) and 0.054 g MnO_2 are needed per ampere minute to form $Mn(OH)_2$ and Mn_2O_3, respectively.

Figure 3 shows the ampere minutes per gram of free MnO_2 lost by the residue plotted against the ampere minute output associated with this residue taken from the last two columns in the second part of Table III. The values fall on a smooth curve which approaches the value of 0.0405 characteristic of reaction [2]. However, the three intermediate values for cells 2, 2a, and 3 fall too close to one another to attribute to experimental error. One possible cathodic reaction that gives a value approaching these points is the following:

$$4MnO_2 + 2K + 2e + H_2O \rightarrow Mn_4O_7 + 2KOH \quad [3]$$

This reaction consumes 0.108 g MnO_2/amp min which is not too far from the 0.112 g/amp min obtained from cell 2.

[3] Free MnO_2 is the amount of MnO_2 in the depolarizer available to react electrochemically.

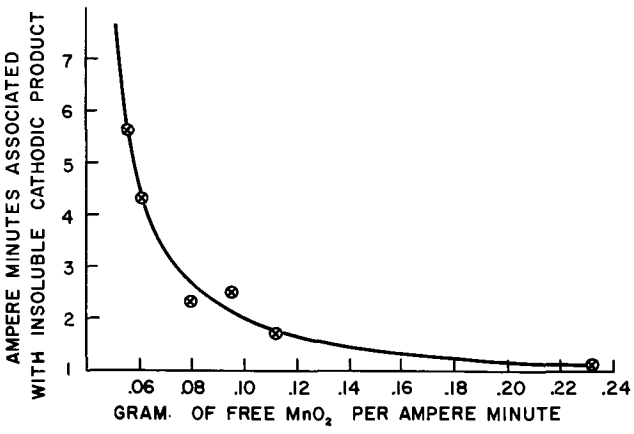

Fig. 3. Relationship between free MnO_2 consumed per ampere minute in the insoluble cathodic product and the extent of discharge.

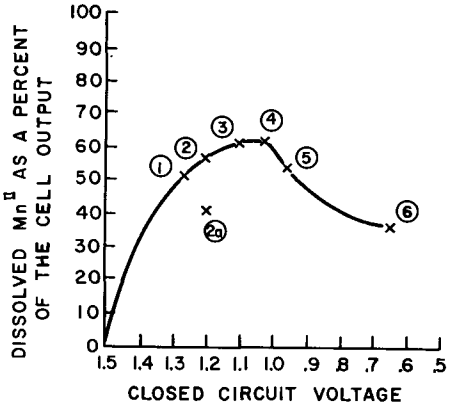

Fig. 4. Relationship between the proportion of divalent manganese found in the cathodic reaction product and the last cell voltage reading.

Data for cell 6, shown in Tables I, II, and III, differ somewhat from that for cells 1 to 5. A lower discharge curve for cell 6 is shown in Fig. 1, and it will be noted that the closed circuit voltage of this unit fell to 0.63 v at the time the test was terminated. The lower voltage of cell 6 probably is the result of the smaller quantity of depolarizer contained in the unit as shown in the tables. When the amount of the cell output represented by the divalent manganese removed from the cathode is plotted on Fig. 3, the point is somewhat lower than the curve given by the data of cells 1 to 5. At this time it appears that the fact that the discharge progressed relatively so much farther in cell 6 than in cells 1 to 5 is probably responsible for this situation. Added evidence to this viewpoint is given by Fig. 4 where there is a sharp break in the curve relating Mn^{II} as a per cent of total output to the last closed circuit voltage reading.

From a consideration of the results of these analyses of the cathode residues, it is concluded that the intermediate oxide is probably Mn_4O_7. However, the evidence we have presented for the existence of this manganese oxide needs further confirmation. The fact that it is cathodically reduced to Mn_3O_4 is not unknown with other manganese oxides. For example, $Mn_2O_3 \cdot H_2O$ when used as the sole depolarizer in experimental cells similar to those used in these tests is electrochemically reduced to $Mn(OH)_2$ and Mn_3O_4 simultaneously. On the other hand, Mn_2O_3 on reduction yields only $Mn(OH)_2$.

The identification of the insoluble cathodic product may also be studied by x-ray diffraction methods since many oxides of manganese possess characteristic patterns. The difficulties inherent in a precise comparison of a possible mixture of manganese oxides are well recognized. However, the results of such a study often yield valuable primary and confirmatory evidence for the existence of a particular solid phase and thereby indicate the reaction by which it may have been formed. A close examination of Fig. 5 showing the actual diffraction patterns of the insoluble residues from the experimental cells shows some rather startling differences. The original electrolytic MnO_2 is a typical gamma structure with the characteristic gamma "hump" and additional characteristic lines. From Fig. 5 it is evident that the shape of the gamma hump changes during the cell discharge from a rounded to a nearer square shape with a wider base and in the last pattern it almost disappears. The charts given in Fig. 5 indicate that each of the so-called gamma humps are topped by a number of small peaks located at specific "d" values. It could be interpreted that the gamma hump itself is only the result of the near coincidence of these specific peaks and many peaks of lesser intensity which are interspersed among them. Attention is drawn to a comparison of the "d" values from 3.0 to 6.0 for the six diffraction patterns. In trying to compare such patterns, considerable care must be taken to avoid misinterpreting random variations in the background counting rate or instrumental hunting as actual but small individual peaks. However, the remarkable regularity shown in the "d" values of the specific lines which occur in several of the gamma hump patterns in Fig. 5 strongly suggest the predominant peaks could represent true diffraction lines.

Note: I indicates the relative intensity of the lines and is a measure of the height of divisions above the background.

It seems clear from Fig. 5 that the relatively simple diffraction pattern of the original electrolytic MnO_2 becomes much more complex as the discharge proceeds. It is quite easy to identify the major new component in cell 6, which was discharged to the lowest voltage, as Mn_3O_4. There is some evidence of the characteristic diffraction pattern lines of this material in the chart for cell 4 also, thus indicating that Mn_3O_4 begins to form after the cell reaches the 0.9-1.0 v level. However, it is in the intermediate range of discharge that the real question arises as to what insoluble cathodic product is present.

In view of the crystallographic difficulties involved in interpreting the significance of the gamma band in the pattern of electrolytic MnO_2, it seems unwise to attempt to assign exact diffraction spacings to the new phase which developed during the cell discharge. More extensive data would be required to establish the presence of such a new phase. Therefore, attention is drawn to the fact that a group of diffraction lines appears in the "d" value region of 3.7 to 3.3 which could be associated with the presence of the intermediate oxide tentatively designated Mn_4O_7. Added emphasis to this general point of view is furnished by the fact that some of these diffraction lines become reduced in intensity as the discharge proceeds and Mn_3O_4 is formed. An alternative explanation of these new diffraction lines would be that they might represent a solid solution of certain reduced manganese compounds in manganese dioxide. No conclusive evidence for solid solutions of manganese oxides in Leclanché dry cells has been published although the concept of a solid solution has been suggested in the absence of definitive data.

Perhaps the most complete analysis of the x-ray diffraction patterns of gamma MnO_2 is that of Cole, Wadsley, and Walkley (4) who postulate gamma, gamma I, and gamma II varieties. Their analysis of the gamma I type, electrolytic MnO_2, gives only the 3.94, 2.57, 2.41, 2.33, 2.11, 1.62, 1.41, and 1.37 lines. The 3.94 line apparently refers to the peak of the gamma band mentioned earlier in this paper. From the data presented in Fig. 5 and Table IV, there seems to be no indication that a change from the electrolytic MnO_2 to either of the other phases described by Cole, Wadsley, and Walkley occurs in the discharge of the experimental cells. The diffraction spacings presented in this paper do not conform with any of the patterns of reduced manganese

Conclusion

A mechanism for the electrochemical reduction of electrolytic manganese dioxide in strongly alkaline electrolytes is proposed which consists of the several steps listed below.

Step 1.—The manganese dioxide is electrochemically reduced according to the two following reactions which occur simultaneously:

$$4MnO_2 + 2K^+ + 2e + H_2O \rightarrow Mn_4O_7 + 2KOH$$

$$MnO_2 + 2K^+ + 2e + 2H_2O \rightarrow Mn(OH)_2 + 2KOH$$

Step 2.—The intermediate insoluble oxide product formed in Step 1 then becomes the depolarizer which is electrochemically reduced by the following two reactions:

$$3Mn_4O_7 + 10K^+ + 10e + 5H_2O \rightarrow 4Mn_3O_4 + 10KOH$$

$$Mn_4O_7 + 6K^+ + 6e + 7H_2O \rightarrow 4Mn(OH)_2 + 6KOH$$

Step 3.—The insoluble product of the second step then becomes the depolarizer and is electrochemically reduced in this manner:

$$Mn_3O_4 + 2K^+ + 2e + 4H_2O \rightarrow 3Mn(OH)_2 + 2KOH$$

Step 1 occurs during the first part of the discharge while the working voltage falls from the initial value of 1.46 to 1.20. Step 2 apparently operates in the working voltage range of from 1.20 to 0.95. Step 3 occurs in the range below 0.95 v to the complete reduction of the oxide to $Mn(OH)_2$. Much of this last part of the discharge often occurs at a working voltage of 0.4-0.5 v or lower.

Manuscript received March 10, 1959. This paper was prepared for delivery before the Ottawa Meeting, Sept. 28-Oct. 2, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

High-Temperature Reaction Rates of Several Metals with Hydrogen Chloride and Water Vapor

Milton Farber

Research Laboratories, Rocket Power Inc., Pasadena, California

ABSTRACT

An experimental study has been made of the high-temperature reaction rates of various metal filaments with HCl and H_2O vapors and mixtures of the two. Measurements were made by an electrical method in which the change in resistance of the metal filament was related to the loss in pure metal due to the vapor-metal reaction. Measurable reaction rates were determined for both nickel and iron in a temperature range from 1000° to 1600°K. Specific reaction rate constants and apparent activation energies are presented. The reaction rates of tungsten with H_2O vapor were measured in a temperature range from 1600° to 2000°K. The reaction rates of chromium, Inconel, stainless steel 18-8, and tungsten did not proceed at a measurable rate in either pure HCl or in mixtures of HCl and H_2O. Nickel, copper, Inconel, and stainless steel 18-8 did not react appreciably with water vapor at temperatures approaching the melting points. The reaction rates for iron in pure HCl varied from 0.03 to 0.04% area loss per second over the temperature range investigated with an apparent activation energy of 10.5 kcal/mole. The reaction rates of iron in mixtures of HCl and H_2O varied from 0.08 to 0.17% area loss per second in the same temperature range with an apparent activation energy of 8.5 kcal/mole. Reaction rates of nickel in pure HCl varied from 0.005 to 0.03% area loss per second in the temperature range of 1000° to 1600°K with an apparent activation energy of 13 kcal/mole. The reaction rates of nickel in the HCl and H_2O mixtures varied from 0.004 to 0.03% area loss per second in the same temperature range with an apparent activation energy of 22 kcal/mole below 1300°K and 13 kcal/mole above this temperature. Reaction rates of iron in H_2O vapor varied from 0.002 to 0.05% area loss per second from 1120° to 1415°K with an activation energy of 28 kcal/mole. Reaction rates of tungsten in H_2O vapor varied from 0.02 to 0.03% area loss per second from 1700° to 2000°K with an activation energy of 14.5 kcal/mole.

In the field of high-temperature reactions of gases and metals, reaction rates are measured in terms of seconds as compared to days and years for reactions between metals and gases at conventional temperatures. This paper is the third in a series of investigations of the reaction rates of several metals with the combustion products of chemical propellants. Previous papers (1, 2) include the study of several metals with H_2S, SO_2, and NO at a temperature range from 1000°-2000°K.

Concerning the reactions of metals with HCl some previous work of a qualitative nature has been reported. A few investigators have studied this reaction by allowing the metal to remain in the HCl atmosphere for a period of time and obtaining the corrosion rate by the loss in weight of the metal (3, 4). Brown, DeLong, and Auld (5) studied the corrosion rates of nickel, platinum, gold, Inconel, stainless steel, Monel, copper, iron, and several nickel and chromium alloys in dry HCl and also in a mixture of HCl containing 0.2% H_2O. They found that nearly all the metals, with the exception of gold and platinum, are corroded quite readily at fairly low temperatures and that the addition of the water vapor increases the corrosion rate only slightly.

When a metal is corroded in an atmosphere of either dry or wet hydrogen chloride, the reaction products are usually the metal chloride and hydrogen as:

$$M + HCl = MCl + \tfrac{1}{2}H_2$$

In the presence of water vapor the reaction can become quite complicated because of the possible formation of other compounds of the metal besides the chloride.

The dissociation of water to H_2 and OH radicals is less than 1% at temperatures below 2000°K, while

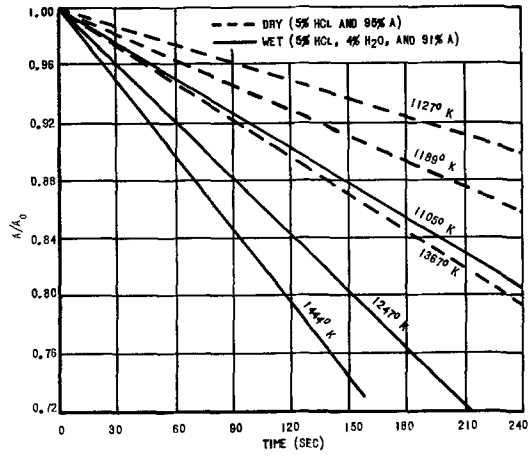

Fig. 1. Corrosion rate of Fe with dry and wet HCl vs. time

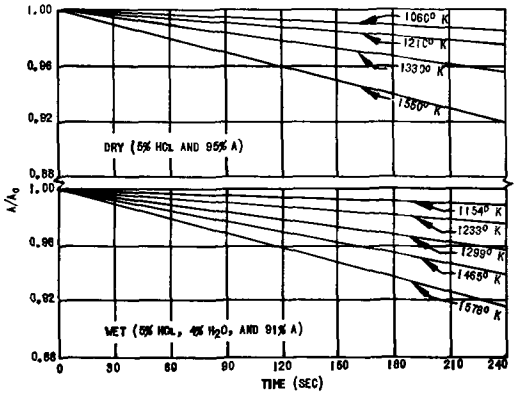

Fig. 3. Corrosion rate of Ni with dry and wet HCl vs. time

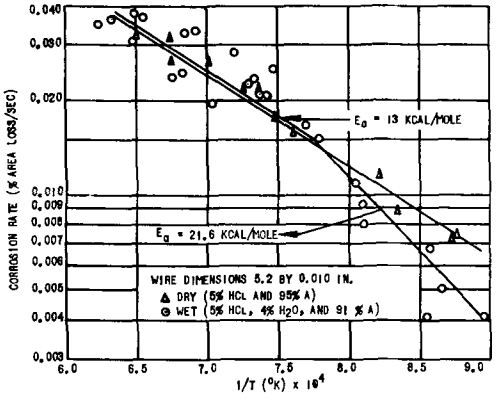

Fig. 4. Corrosion rate of Ni with dry and wet HCl as function of 1/T.

the dissociation of water to O_2 and H_2 does not become appreciable below 3000°K.

Experimental Procedure

The author (1, 2) has previously employed the method presented in this paper for measuring the reaction rates of various metals with H_2S, SO_2, and NO and the apparatus has been described. Garner, Gray, and Stone (6) studied the reaction rate of copper with oxygen by measuring the increase in resistance of a copper film which was plated on the walls of a glass bulb. Wilson (7) and Hudson (8) studied corrosion rates by measuring the change in electrical conductivity of flat metal strips. The method employed here and described in detail earlier (1) is concerned with the measurement of the change in resistance of a metal filament (hot wire) of 0.010 in. diameter in a corrosive medium. Since the corrosion rate is obtained directly from the resistance change, a recording mechanism is necessary to indicate the current and voltage across the filament. The arrangement of the equipment used to conduct rate experiments has been described previously (2).

In order to obtain uniform corrosion of the wire, it is necessary to use filaments which have been accurately machine-drawn. Thus, hot spots can be eliminated and consistent burnout times obtained, justifying the resistance method for measuring corrosion rates.

Theoretical corrosion rate laws have been derived (2) for these cylindrical wires. These resulted in the following rate laws for

parabolic

$$A/A_o = 1 - 2\sqrt{\frac{2\pi kt}{A_o}} + \frac{2\pi kt}{A_o} \qquad [1]$$

rectilinear

$$A/A_o = 1 - 2(\pi/A_o)^{1/2} kt + \pi/A_o k^2 t^2 \qquad [2]$$

logarithmic

$$A/A_o = 1 - 2(\pi/A_o)^{1/2} \ln (1+kt) + \pi/A_o \ln (1+kt)^2 \qquad [3]$$

The results obtained for the metals studied yield an experimental rate law of

$$A/A_o = 1 - k/100\, t$$

where: A is the cross-sectional area of wire remaining at time t, A_o is the initial area of wire, and k is per cent area change per second.

This expression is similar to the logarithmic rate law for thin coatings and also to the rectilinear rate law for initial corrosion, wherein the third term is small compared to the second.

It was shown in the previous papers (1, 2) that the conductivity of oxide coatings was negligible in comparison to that of the pure metal even at high temperatures (9). However, in the case of the chlorides, metal chlorides are usually in the vapor phase at the temperatures in question and the surface remains essentially clean during the course of the experiment.

The effect of the solubility of the gases on the resistance of the metal filaments investigated was negligible since there was no discernible change in their resistance at temperatures just below the point of corrosion. However, it was not possible to study the corrosion rates of metals such as zirconium or titanium because the solubility of oxygen and nitrogen changed their resistivities to such an extent that the change in resistance due to corrosion could not be measured.

Results

Reaction Rates of Metals with HCl

Reaction rates of iron with HCl.—Corrosion rates of iron were investigated in both dry HCl (95% A-5% HCl) and wet HCl (91% A-5% HCl-4% H_2O) over a range of temperature from 1100° to 1450°K. The results of the corrosion rates are shown as a function of time in Fig. 1. As may be seen from this figure, the corrosion rate of iron in the wet HCl is slightly faster than in the dry HCl. This fact would tend to indicate that the presence of water speeds up the reaction. In Fig. 2, the logarithm of the rate is plotted against the reciprocal of the absolute temperature. The activation energies are 8.5 and 10.5 kcal for the wet and the dry HCl, respectively. The rate constants as functions of the temperature are given in Table I.

Reaction rates of nickel with HCl.—The corrosion rate of nickel was also investigated in both dry and wet HCl mixtures over a temperature range from 1050° to 1600°K. The rates are given in Fig. 3. The corrosion of nickel with dry HCl shows a slightly higher rate than with wet HCl, particularly in the lower temperature range, as can be seen from the plot of the logarithm of the corrosion rate as a function of the reciprocal of the absolute temperature shown in Fig. 4.

The activation energy for the wet HCl is of the order of 22 kcal/mole for temperatures below 1300°K and decreases to 13 kcal/mole above this temperature. This latter value is approximately the same as for the dry HCl over the entire temperature range covered. The rate constants for the corrosion rates of nickel in both dry and wet HCl are given in Table I. The rates are of the order of approximately 20% of those for iron in the same gas mixtures.

Reaction Rates of Several Metals with Water Vapor

Several metals including iron, tungsten, nickel, copper, Inconel, and stainless steel 18-8 were tested in a gas mixture containing 95% A and 5% H_2O vapor. Iron and tungsten were the only metals of the group that corroded at a measurable rate at temperatures approaching the melting points.

Reaction rates of iron with water vapor.—Corrosion rates of iron in a mixture of 95% A and 5% H_2O vapor were measured in a temperature range of 1100° to 1400°K. Corrosion rates are plotted against time in Fig. 5. A plot of the logarithm of the corrosion rate against the reciprocal of the absolute temperature gives an activation energy of 28 kcal/mole (Fig. 6). The rate constants k, which are listed in Table II, vary from 0.0020 (% area loss/sec) at 1120°K to 0.047 at 1415°K.

Reaction rates of tungsten with water vapor.—The corrosion of W in H_2O does not become appreciable until temperature of 1600°K is attained. The corrosion rates of tungsten in a gas mixture of 95% A and 5% H_2O vapor were measured in the temperature range from 1685° to 1995°K. At the higher temperatures the dissociation of H_2O to H_2 and OH is in the neighborhood of 0.1%. The curves of corrosion rate vs. time are shown in Fig. 7. The plot of the logarithm of the rate vs. $1/T$ gives an activation energy of 14.5 kcal/mole (Fig. 8). The rate constants listed in Table III vary from 0.0170 (% area loss/sec) at 1685°K to 0.0313 at 1995°K.

Manuscript received Aug. 9, 1957. Some of the laboratory work for this paper was performed at the Jet Propulsion Laboratory, California Institute of Technology under Contract No. DA-04-495-ORD 18, sponsored by the Department of the Army, Ordnance Corps.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

The Electrochemical Behavior and Passivity of Titanium

Milton Stern and Herman Wissenberg

Metals Research Laboratories, Union Carbide Metals Company, Division of Union Carbide Corporation, Niagara Falls, New York

ABSTRACT

In the active condition, corrosion of titanium is controlled by activation polarization. The metal presents a surface with a low exchange current for a variety of electrochemical reactions. Low exchange currents are not conducive to establishment of passivity. However, this is overcome by unusually active critical potentials for passivity. This accounts for the ease with which titanium is passivated by many substances which are only slightly oxidizing. It also explains the ease with which the metal can be protected anodically by galvanic coupling to other metals and alloys. Anodic deposition of thick titanium oxide films is observed under some experimental conditions.

The mechanism of passivating-type inhibitors has been described (1) solely in terms of the kinetics of the various electrochemical processes which occur, without the necessity for reference to the nature of the passive film. The environmental parameters which are pertinent to the achievement of passivity are the exchange current, Tafel slope, and limiting diffusion current for cathodic processes. Passivity is favored by high values of exchange current and limiting diffusion current and by low values for the Tafel slope. The important parameters related to the metal are the critical anodic current and the critical potential for passivity. A low value of critical anodic current and a relatively active critical potential favor passivity.

Titanium shows active-passive behavior similar to stainless steel except that it is not affected adversely by chloride ion and does not exhibit transpassive behavior. This work was done to obtain data which would relate the anodic behavior of Ti to the parameters of temperature and acid concentration. Such information should help in understanding passivity of Ti and permit more efficient use of passivating inhibitors.

Experimental Procedure

Electrodes, glass cells, and methods for measuring potential were generally the same as those reported elsewhere (2) except that anodic polarization measurements were conducted with an Analytical Instruments Company[1] potentiostat, an electromechanical device. It was necessary to use the same material for the test electrode and for a potentiostat reference electrode and to place the two electrodes in the same solution, since the potentiostat does not operate properly if a high impedance exists between these electrodes. Auxiliary electrodes of the same material as the test electrode were placed directly in the cell. All electrodes were aged for about 30 min in the solution before the first measurement. Potentials were measured by means of a Luggin probe to minimize errors caused by *IR* drop. Potentials were measured against a saturated calomel electrode external to the cell at room temperature. No effort was made to correct for liquid junction potentials or temperature effects when the solution was hot.

In systems where hydrogen was used, the gas was purified with Cu at 500°C followed by Pt and Pd catalysts. The solution was further purified by pre-electrolysis for 3 hr on a Ti cathode held at −1.0 v vs. saturated calomel with the potentiostat. The current density during pre-electrolysis was greater than 80 ma/cm^2. In this case, auxiliary electrodes were external to the cell and connected to it by salt bridges.

The Ti metal was of commercial purity containing 0.032% C and 0.13% oxygen.

Behavior of Hydrogen-Saturated H_2SO_4

Figure 1 shows anodic and cathodic polarization curves for Ti in hydrogen-saturated 20% H_2SO_4 at

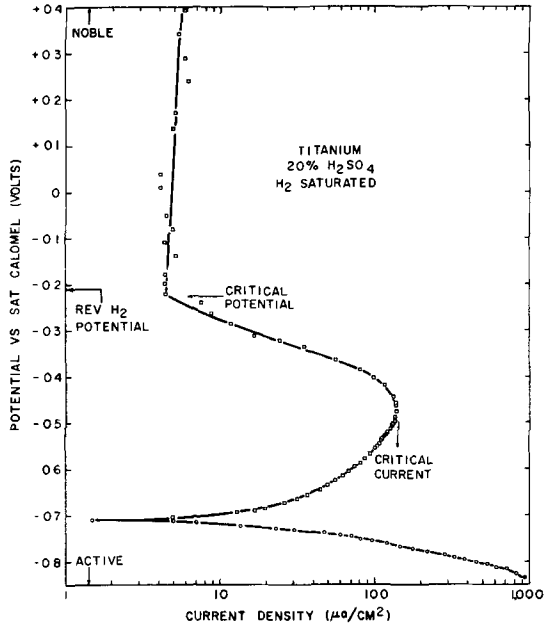

Fig. 1. Anodic and cathodic behavior of Ti in room-temperature, hydrogen-saturated 20% H_2SO_4.

[1] Bristol, Connecticut.

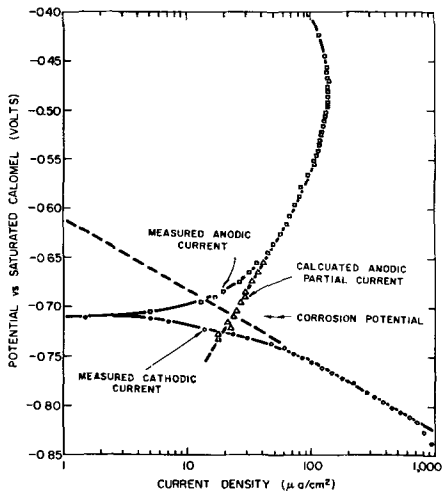

Fig. 2. Expanded view of Fig. 1 showing the calculated anodic polarization curve of Ti.

room temperature. The reversible hydrogen potential of this solution, measured with platinized Pt, is —0.21 v vs. saturated calomel. Polarization data were obtained with the potentiostat by starting at a potential of —0.85 v and gradually increasing the potential in the noble direction. The cathodic curve exhibits a Tafel slope of 0.07 v and an exchange current of only 1.9 (10^{-12}) amp/cm². Relatively small changes in Tafel slope will have a marked effect on exchange current, since extrapolation to the reversible hydrogen potential is made over a potential range of about 0.6 v. Thus, the measured exchange current could be in considerable error. It is evident, however, that the hydrogen ion reduction reaction on Ti is accompanied by a high overvoltage (approaching that of Hg) because of the extremely small exchange current. This agrees with other observations (3, 4).

The anodic data show a critical current for passivity of 140 μa/cm². The critical potential for passivity is about —0.23 v vs. saturated calomel which is 20 mv more active than the potential of Pt in the hydrogen-saturated 20% H_2SO_4 solution. If one defines passivity as the state where the potential of a metal is more noble than the critical potential shown in Fig. 1, then it becomes evident that Ti can show stable passive behavior in solutions which contain a redox system no more oxidizing than the hydrogen ion-hydrogen gas system. Passivity in hydrogen-saturated solutions is an unusual phenomenon which is not observed in Fe- or Ni-base alloy systems. The relatively active critical potential exhibited by Ti explains, in part, the ease with which this metal is passivated by many oxidizing inhibitors.

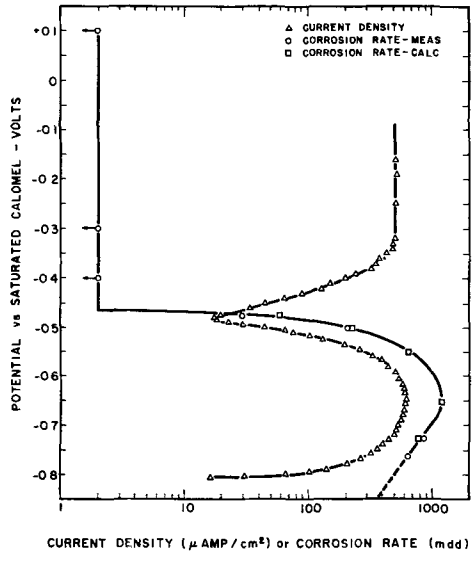

Fig. 3. Current density and corrosion rate at controlled potentials for Ti in boiling 2% H_2SO_4 containing 5% Na_2SO_4.

The data of Fig. 1 permit an examination of the dissolution kinetics of Ti in the active potential region to determine if they are consistent with presently accepted views on electrode kinetics involving activation overvoltage. Figure 2 shows an expanded view of the data close to the corrosion potential. Calculated values of the dissolution rate of Ti as a function of potential are shown as triangles. The methods used for this calculation are similar to those already described (2). The points more noble than the corrosion potential were obtained by summing the extrapolated rate of hydrogen reduction and applied anodic current at any given potential. The points on the active side of the corrosion potential were obtained by subtracting the applied cathodic current from the extrapolated rate of hydrogen reduction at any given potential.

It is evident that in this potential region the dissolution kinetics are controlled by activation polarization with a Tafel slope of 0.22 v. While this value is high, the kinetics near the corrosion potential cannot be considered unusual. Thus, the phenomena associated with passivity are not evident near the corrosion potential but become significant near the potential region associated with the critical current for passivity.

Correlation of Polarization Data with Weight Loss Measurements

An anodic polarization curve, such as that shown in Fig. 1, is expected to represent the dissolution rate of Ti as a function of potential, except in the region close to the corrosion potential where the measured current is significantly less than the dissolution rate as illustrated in Fig. 2. To check this, data were obtained with Ti in boiling 2% H_2SO_4 containing 5% Na_2SO_4, where corrosion rates are higher than at room temperature and more easily measured.

Figure 3 shows the anodic polarization curve obtained. The portion below the critical potential for passivity is as expected. The current rises to some maximum value (the critical current for passivity) and then falls to a low value at the critical potential for passivity. Weight loss measurements in the same environment utilized separate electrodes, each held at a controlled potential for 18-24 hr. Continuous recording during these measurements revealed long-time current variations. These are attributed to changes in the environment caused by accumulating corrosion products from the sample, the auxil-

iary electrodes, and the potentiostat reference electrode. Assuming that Ti corrodes to form trivalent ions, integration of each current-time curve leads to a calculated corrosion weight loss which is also plotted on Fig. 3 (squares) along with the measured weight loss (circles).

It is evident from Fig. 3 that dissolution rate as a function of potential closely parallels the anodic polarization curve in the potential region more active than the critical potential for passivity. Quantitative agreement between the measured corrosion rates and the anodic polarization curve is precluded by differences in experimental procedure. For example, each point on the polarization curve represents only 3 min at that potential contrasted to a minimum of 18 hr for a weight loss measurement.

Unexpected behavior is found in the anodic polarization curve above the critical potential for passivity. Rather than remaining relatively constant with increasing potential as shown in Fig. 1, the current again rises and finally reaches a limiting value. This does not represent the anodic behavior of Ti, but is an artifact resulting from the experimental procedure used. This can be shown in the following manner. Electrodes held at constant potential in this region show a considerable weight gain and develop a thick oxide coating which is not particularly adherent. Scraping the oxide off accounts for all of the weight gain within the error of the technique, and the final sample shows a corrosion rate of less than 2 mdd. Therefore, anodic current measured in this region does not represent oxidation of metal but rather represents a different oxidation process. The most likely process is electrodeposition of oxide in accordance with a reaction of the type $Ti^{+3} + 2H_2O \rightarrow TiO_2 + 4H^+ + e$. It is quite possible that this is not the specific reaction which occurs, since lower oxides could also have been produced. In any event, it is clear that corrosion products are plated onto the anode surface in the form of oxides. The vertical line on the polarization curve probably represents the limiting diffusion current for the process.

The current associated with oxide deposition may obscure the true value of the critical potential for passivity. The critical potential shown in Fig. 3 could be slightly more active than the true value. This error is probably not significant as evidenced by the weight loss data.

Since the corrosion rate of Ti in the potential region of oxide deposition was less than 2 mdd (the experimental error in weight change), the points on Fig. 3 are shown at 2 mdd with arrows indicating the rate is less than this value. Thus, above the critical potential for passivity, the dissolution rate is very slow.

Cotton (5) has measured corrosion rate as a function of potential for Ti in 40% H_2SO_4 at 60°C. His data are similar to those shown here and extend to 2 v more noble than the saturated calomel electrode.

Anodic Polarization by Galvanic Coupling

Anodic passivation of Ti by means of an externally applied potential is described above. Titanium can also be passivated by galvanic coupling (5-7) with some metal or alloy whose potential is more noble than the critical potential for passivity of Ti in the given environment. The mixed potential of the resulting couple must also be more noble than the critical potential. Since the couple mixed potential is dependent on cathodic polarization, large cathode areas should favor passivation of Ti.

Table I. Effect of galvanically coupling titanium to various cathodic materials in boiling H_2SO_4 solutions

Couple	Area ratio A (Ti) / A (Cathode)	Weight loss of titanium (mdd) Boiling* 1% H_2SO_4	Boiling† 3% H_2SO_4 + 5% Na_2SO_4	Boiling‡ 5% H_2SO_4 + 5% Na_2SO_4
Ti		1400	1800	2900
Ti-(18-8)	1	0		
	2	10		
	6.6	6		
Ti-(Hastelloy alloy F)	1	0		
	12	2		
Ti-C	0.2	0	0	3600
	0.5		0	
	1		1200	
Ti-Pt	0.25			21
	1			65
	2			65
	4			108
	35			1700

* Critical potential for passivity of Ti is −0.45 v vs. saturated calomel.
† Critical potential for passivity of Ti is −0.42 v vs. saturated calomel.
‡ Critical potential for passivity of Ti is −0.34 v vs. saturated calomel.

Table I shows the effect of coupling Ti to Pt, C, 18-8 stainless steel, and Hastelloy alloy F in several environments as a function of the ratio of Ti area to cathode area. All the above materials exhibit potentials in these environments which are more noble than the critical potentials for passivity of Ti. In these experiments, no effort was made to estimate surface roughness factors, and all areas are calculated from geometric measurements assuming smooth surfaces. Results show that all of these materials can passivate Ti if sufficient cathode area is present. The more aggressive the environment, the greater the cathode area necessary to passivate. It is important to note that stainless steel and Hastelloy alloy F are both electrochemically active in boiling 1% H_2SO_4. However, their active mixed potentials are still sufficiently more noble than the critical potential for passivity of Ti to produce passivity when galvanically coupled to this metal.

Effect of Temperature on Dissolution Kinetics

Since temperature is known to affect the behavior of passivating inhibitors, it is important to establish how temperature affects those metal dissolution parameters which determine when stable passivity can be achieved.

Figure 4 shows the anodic polarization behavior of Ti in hydrogen-saturated 5% H_2SO_4 containing 5% Na_2SO_4. The critical current for passivity increases considerably as temperature is increased from 50° to 95°C. The critical potential for passivity is not significantly affected. In general, temperature

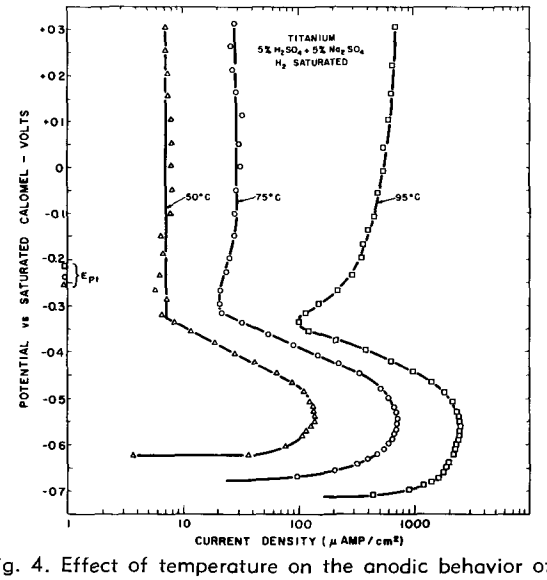

Fig. 4. Effect of temperature on the anodic behavior of Ti in hydrogen-saturated 5% H_2SO_4 containing 5% Na_2SO_4.

serves only to increase reaction rates, shifting the curves to higher current values with an increase in temperature.

At 95°C, where corrosion product build-up is faster, oxide deposition is again observed as evidenced by the shape of the polarization curve in the passive region. At 50° and 75°C, the oxidation rate of corrosion products is probably not significant, and passive currents represent the dissolution rate which also increases with temperature.

The measured potential of platinized Pt as a function of temperature is also shown on Fig. 4. It is important to note for subsequent discussion that the critical potential for passivity of Ti is again more active than the reversible hydrogen potential for this system.

Effect of Acid Concentration on Dissolution Kinetics

Figure 5 shows the anodic polarization behavior of Ti in various concentrations of boiling H_2SO_4

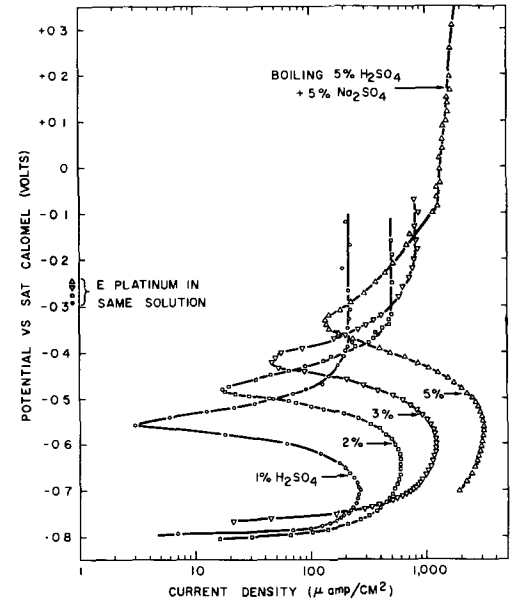

Fig. 5. Anodic behavior of Ti in boiling H_2SO_4 solutions containing 5% Na_2SO_4.

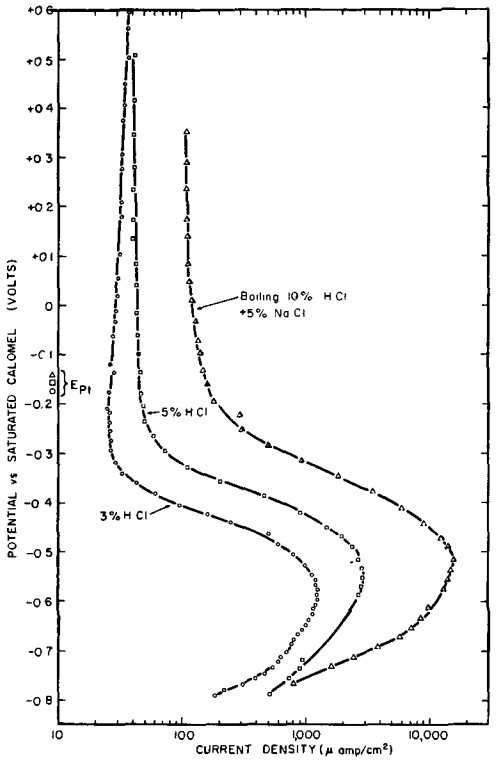

Fig. 6. Anodic behavior of Ti in boiling HCl solutions containing 5% NaCl.

containing 5% Na_2SO_4. Paralleling the effect of temperature, increasing acid concentration markedly increases the critical current for passivity. However, the critical potential for passivity and the potential at the critical current are shifted in the noble direction.

Corrosion product build-up in the solution is sufficiently fast at the boiling point to cause oxide deposition in the passive region. Thus, as described above, anodic current in the passive region does not represent the effect of acid concentration on passive corrosion rate. Rather, the vertical section probably represents the limiting diffusion current for the deposition process which increases with acid concentration because corrosion product build-up increases.

Oxide deposition is not observed in HCl as shown in Fig. 6, where it is evident that the passive corrosion rate increases with acid concentration.

Discussion and Conclusions

In the active condition, corrosion of Ti is controlled by activation polarization. The metal exhibits a particularly high hydrogen overvoltage (low exchange current). In general, it presents a surface with a low exchange current for a variety of electrochemical reactions as evidenced by measurements of rates of ferric ion reduction and oxygen evolution (8). Low exchange currents are not conducive to establishment of passivity. However, this is overcome by unusually active critical potentials for passivity. The critical potential for passivity of Ti is about 0.6 v more active than the corresponding value for Fe and about 0.1-0.2 v more active than the value for stainless steel. The exact differences, of course, are dependent on the environment used

for comparison. This, in large part, accounts for the ease with which Ti is passivated by many substances which are only slightly oxidizing. It also explains the ease with which the metal can be protected anodically by galvanic coupling to other metals and alloys.

Potentiostatic measurements in H_2SO_4 containing corrosion products of Ti show that increasing anodic polarization of Ti in the passive potential region results in an increasing current. This current is caused by anodic deposition of titanium oxide rather than an increasing Ti corrosion rate.

Data presented here show that, as temperature increases, the concentration of inhibitor required to passivate increases. Since the inhibitor concentration must provide a limiting diffusion current greater than the critical current for passivity (1), measurements of the type presented here permit an estimate of the minimum concentration of inhibitor required to attain passivity of a given system as temperature is raised.

The situation is similar for an increase in acid concentration except that, since the critical potential for passivity becomes more noble, the inhibitor must exhibit a greater oxidizing character (more noble reversible potential) for more acid environments.

For anodic protection of Ti by galvanic coupling to a cathodic metal or alloy, data presented here assist in the determination of the couple area ratio required to produce passivity of Ti. The cathodic polarization behavior of the cathode member of the couple also must be known and its area made sufficiently large so that the mixed potential of the couple is more noble than the critical potential of Ti in the environment.

Acknowledgment

The authors acknowledge the skillful assistance of E. J. Bartolomei who obtained much of the data presented here.

The Influence of Noble Metal Alloy Additions on the Electrochemical and Corrosion Behavior of Titanium

Milton Stern and Herman Wissenberg

Metals Research Laboratories, Union Carbide Metals Company, Division of Union Carbide Corporation, Niagara Falls, New York

ABSTRACT

Alloying of titanium with small amounts of noble metals markedly improves its corrosion resistance in reducing-type acids without any impairment of its high resistance to oxidizing media. The mixed potentials of titanium noble metal alloys are more noble than the critical potential for passivity of titanium in the same environment. Passivity is observed in hydrogen-saturated systems without the presence of a redox system more oxidizing than the hydrogen electrode. The mixed potential of titanium noble metal alloys is much more sensitive to traces of oxidizing agents than unalloyed metal.

Previous work (1) proposed that passivating-type inhibitors function primarily by creating a mixed potential more noble than the critical potential for passivity of the metal involved. The establishment of a potential more noble than some critical value is a basic concept which applies not only to inhibitors but also to the phenomenon of anodic protection (2) and prevention of corrosion by galvanic coupling to suitable cathode materials (3-5).

Anodic polarization under a variety of conditions shows that Ti exhibits unusually active values of critical anodic potential (5). Often, this potential is even more active than the reversible hydrogen potential of the solution. This permits establishment of passivity by alloying with elements having low overvoltage characteristics.

The purpose of this work is to describe the corrosion and electrochemical characteristics of these alloys.

Theory of Noble Metal Alloying to Obtain Passivity

According to what has already been described, passivity is obtained by producing a condition which results in a potential more noble than the critical potential for passivity. Without an externally applied potential, a metal in solution can attain a passive mixed potential only if the solution contains a redox system with a reversible potential more

noble than the critical potential for passivity of the metal. This is a necessary, but not sufficient, condition for stable passivity (1).

Alloying can contribute to the passivation of metals by two distinctly different principles:

1. Alloy addition may affect those metal dissolution parameters (the critical anodic current and the critical anodic potential) which, in turn, determine the ease of passivation. This is the effect which Cr has on Fe in the stainless steels. Increasing Cr content decreases the critical anodic current (6) and moves the critical anodic potential in the active direction (7,8).

2. Alloy addition may influence the reduction kinetics of the cathodic process. Mixed potentials in the passive potential region are favored by an increase in exchange current and a decrease in the cathodic Tafel slope (1).

An example of cathodic process influence was described by Tomashov (9). Alloying of 18% Cr-8% Ni stainless steel or 27% Cr stainless steel with Pt or Pd markedly improves corrosion resistance in room-temperature H_2SO_4 by facilitating the cathodic reaction. While it is not clear whether these experiments were done with intentional aeration of the acid, oxygen was most likely present in solution.

Passivation by alteration of cathodic process kinetics is of special interest when the critical anodic potential of the metal is more active than the reversible hydrogen potential of the solution. Under these circumstances, passivity theoretically can be achieved with the presence of a redox system no more oxidizing than the hydrogen electrode. Under conditions where the metal exhibits a relatively high hydrogen overvoltage, a passive mixed potential may not be obtained directly. However, passivity can be accomplished by alloying such a metal with an element which is essentially insoluble in the environment and which exhibits a high exchange current for the hydrogen ion reduction process. A small amount of corrosion should leave the alloy addition essentially in elemental form on the surface. The surface is now a bi-electrode, or galvanic couple, with one of the constitutents presenting a low-hydrogen overvoltage surface. This is shown schematically in Fig. 1 which may be considered typical of the behavior of Ti. The exchange current for the hydrogen reduction reaction of Ti is very small (5) resulting in an active mixed potential. When alloyed with a metal like Pt, regions with very high exchange currents are produced on the surface creating a mixed potential in the passive potential range. This results in a markedly reduced dissolution rate. Evidence for this is presented below.

Procedures

In general, electrochemical techniques and procedures were similar to those reported previously (5). Alloy buttons were prepared in an argon atmosphere by nonconsumable arc melting on a water-cooled Cu hearth. The buttons, weighing approximately 50 g, were melted three times, reduced in thickness about 50% by cold-rolling, and heat-treated at 1000°C in vacuum for 18-24 hr followed by furnace-cooling.

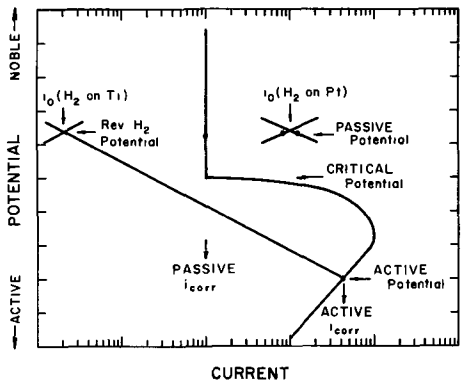

Fig. 1. Schematic diagram showing how alloying with a noble metal produces a passive mixed potential and a marked reduction in corrosion rate.

Corrosion Behavior

Table I shows the effect of ten alloy additions on the corrosion rate of Ti in boiling H_2SO_4 and HCl. Corrosion resistance is markedly improved in many cases. The best results are produced by Pt, Pd, Rh, and Ru; Os, Ir, and Re are intermediate in effect; Au is beneficial only in higher concentrations, while Ag and Cu are detrimental. As expected, the effectiveness of the various additions is roughly in the same order as their hydrogen overvoltage. Generally, Pt and Pd exhibit very low-hydrogen overvoltages, whereas Au, Ag, and Cu may be considered the relatively high-hydrogen overvoltage elements of those evaluated. The approximate exchange current densities (10) in HCl for the various metals are Pt (10^{-3}), Pd(10^{-3}), Rh(10^{-4}), Au(10^{-5} to 10^{-6}), Ag (10^{-7}), Cu(10^{-7}) amp/cm^2.

Table I. Effect of various alloy additions on corrosion resistance of Ti

Composition	Weight loss in 24 hr* (mil/yr)

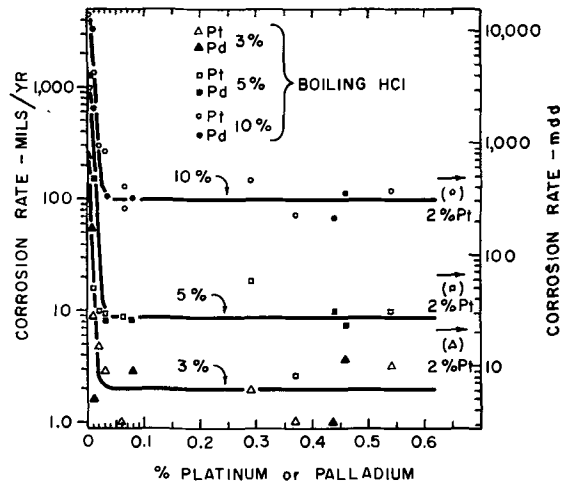

Fig. 2 Effect of Pt and Pd additions on corrosion rate of Ti in boiling HCl solutions.

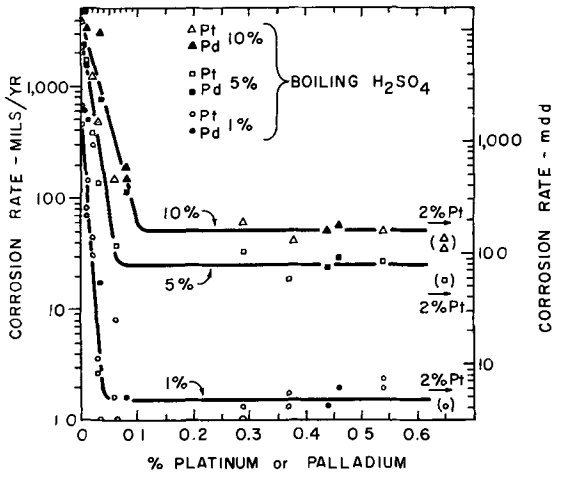

Fig. 3. Effect of Pt and Pd additions on corrosion rate of Ti in boiling H_2SO_4 solutions.

The qualitative theory of noble metal alloy additions described above does not permit an estimate of the alloy concentration required to produce a maximum effect. However, one would predict that, in a given environment, increasing the alloy concentration and noting the effect on corrosion rate should reveal a composition above which no additional benefit is produced. This is the concentration sufficient to produce a mixed potential more noble than the critical potential for passivity. One would also expect that insufficient alloy addition would be detrimental, since the mixed potential would move in the noble direction, yet remain in the active potential region.

Figure 2 shows the effect of Pt and Pd additions to Ti on corrosion rate in boiling HCl solutions. Both of these alloying elements apparently behave in a similar manner, and this observation was used to combine the data on one plot. It is evident that about 0.05% Pt or Pd reduces the corrosion rate by a factor of from 50 to 100. Increased concentrations of noble metals are not additionally beneficial. These data are the results of 24-hr corrosion tests. The sample size was such that a corrosion rate of about 2 mil/yr is within the possible weighing error of the test.

Figure 3 shows similar data in boiling H_2SO_4. In this case, it appears that more noble metal is required to achieve the maximum beneficial effect. Also, in this environment, Pd appears to be not quite as effective as Pt, although only one line is drawn through the points in each H_2SO_4 concentration.

As expected, alloy additions above some critical concentration do not further reduce corrosion rate. However, contrary to expectations, very small alloy additions do not increase the observed corrosion rate. This is because the observed corrosion rate is an average value for a 24-hr test. As will be shown below, these alloys are initially active and probably corrode at an accelerated rate. However, they become passive during the test so that the average corrosion rate is between that of active and passive Ti.

Data not presented here show that such alloying is not detrimental to behavior in highly oxidizing media, such as concentrated HNO_3 or ferric chloride. This is expected since Ti does not exhibit a transpassive potential region where the dissolution rate increases at quite noble potential values. Similar alloying in the case of stainless steels (9) is expected to be detrimental under highly oxidizing conditions because of the transpassive behavior of such alloys.

Electrochemical Behavior

Figure 4 shows potential-time data in boiling 1% H_2SO_4 for Ti and a series of Ti alloys containing various amounts of Pt. The data were recorded continuously using high impedance instrumentation. Note that all Pt-bearing alloys reach the passive potential region during the 24-hr test period. Those alloys containing the higher concentrations of Pt are passive from the very beginning of test, whereas the more dilute alloys remain active for some time prior to becoming passive. It is believed that during this active period the surface concentration of Pt is increasing as a result of corrosion until the area ratio is sufficient to produce a noble mixed potential. Anodic polarization of Ti in this environment, Fig. 5, shows a critical current of about 1000 μamp/cm^2

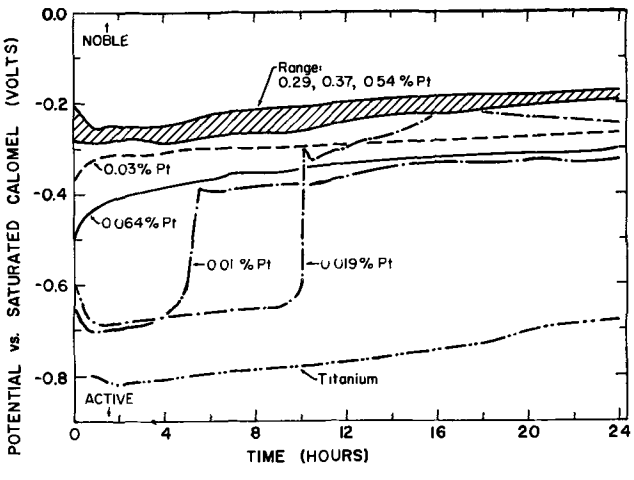

Fig. 4 Potential as a function of time for Ti alloyed with various concentrations of Pt in boiling 1% H_2SO_4.

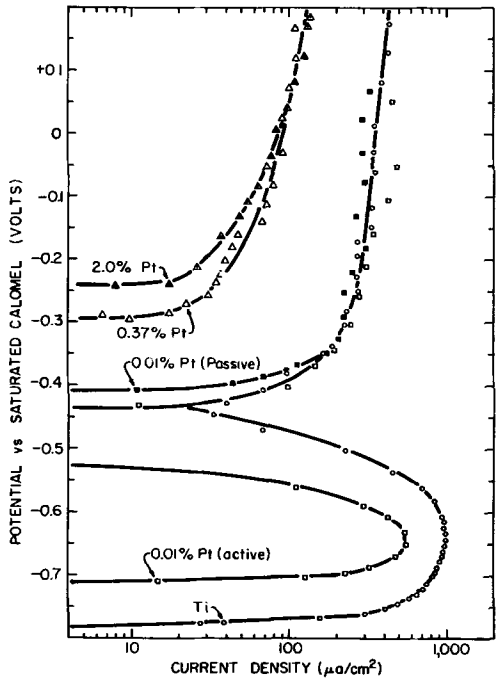

Fig. 5. Anodic polarization of Ti and Ti-Pt alloys in boiling 1% H_2SO_4.

at a potential of —0.64 v vs. saturated calomel. The critical anodic potential is about —0.44 v on the same scale. It is interesting to note in Fig. 4 that the two dilute alloys, 0.01% Pt and 0.019% Pt, which are active for a relatively long period, rapidly pass through the potential region where the polarization curve of Ti has a negative slope. Also, the rapid change in potential occurs when the electrodes have reached values of about —0.64 v. This indicates that this potential region is unstable for these alloys.

Figure 5 shows anodic polarization data for three alloys in boiling 1% H_2SO_4 compared with that of unalloyed Ti. If such measurements are conducted with the 0.01% Pt alloy soon after it is immersed in solution while its potential is still relatively active (see Fig. 4), the polarization curve (open squares) is essentially that of a typical active metal. However, if this alloy is immersed in solution overnight prior to anodic measurements, the data (solid squares) closely parallel the behavior of unalloyed Ti in the passive region. The 0.01% Pt alloy, initially in the active condition, shows negative (cathodic currents) in the potential region between about —0.53 and —0.44 v. This phenomenon has been described adequately by Edeleanu (2), and this observation is consistent with his explanation, since this alloy is expected to exhibit a higher exchange current for the hydrogen ion reduction reaction than unalloyed Ti.

Titanium alloys containing 0.37% or 2% Pt are passive very soon after immersion. Anodic polarization shows only passive behavior as expected. As shown earlier (5) in H_2SO_4 solutions containing appreciable quantities of corrosion products, measured currents in the passive potential region represent the rate of titanium oxide deposition rather than metal oxidation. Thus, currents observed for the 0.37% and 2% Pt alloy are less than that for Ti or the 0.01% Pt alloy because corrosion product build-up in solution (from the sample and the auxiliary electrodes) is slower.

According to the mechanism of protection obtained by noble metal alloying described above, one would expect that cathodic polarization of a Pt-containing alloy would cause a marked increase in corrosion rate. This was found with the 0.37% Pt alloy in boiling 1% H_2SO_4. The potential of this alloy is normally in the passive range between about —0.2 and —0.3 v. It was held at a potential of —0.55 ±0.05 v (see Fig. 5) for 19 hr with a potentiostat. The cathodic current required to accomplish this was very high (0.2-0.3 amp/cm²), presumably because of the high Pt content of the surface. The corrosion rate for this period was 110 mil/yr compared with normal corrosion rate of less than 2 mil/yr in this environment. This supports the mechanism proposed.

Ease of Passivation

Titanium alloyed with noble metals should show another particularly beneficial property. Such alloys should become passive in aggressive environments with concentrations of oxidizing agent insufficient to passivate unalloyed Ti.

A schematic polarization diagram which illustrates this property is shown in Fig. 6. The solid cathodic curve originating from i_{01} represents hydrogen ion reduction on Ti and produces an active mixed potential E_1. The solid cathodic curve originating from i_{02} represents reduction of an oxidizing agent on Ti which produces either a passive potential at E_2' or an active potential E_2. Oxidation and reduction of the oxidizing agent on the alloy surface, where the noble metal content markedly raises the exchange current, are shown at i_{03}. In this case, only one passive mixed potential, E_3, is obtained (1). Evidence for this behavior was obtained in the following experiments.

Corrosion measurements were obtained in H_2SO_4 and HCl at 190°C (374°F). Samples with areas of 2-3 cm² were sealed in heavy wall Pyrex tubes containing 40 ml acid solution. Prior to sealing the tubes, a stream of nitrogen was bubbled through the acid for about 2 hr and continued while the tube

was being necked down. Although the gas inlet tube was removed just prior to sealing, the solutions cannot be considered completely oxygen-free. The tubes then were heated in a pressurized autoclave. The weight loss results for Ti and Ti alloyed with Pt and Pd are shown in Table II. Unalloyed Ti corrodes at very high rates, whereas Pt and Pd additions are quite effective in rather high concentrations of acid. The persistence of the noble metal effect at this high temperature is in itself quite important and can be explained in view of evidence (5) showing that temperature does not markedly affect the critical potential for passivity of Ti. What is most significant about these data is that the corrosion rates observed are considerably less than those obtained at the boiling point of the acids. Small quantities of oxygen present during the test are believed responsible for the lower corrosion rate at the higher temperature.

These data alone are probably not sufficient evidence for the general conclusion that noble metal alloying improves the susceptibility to passivation by oxidizing agents. More direct evidence was obtained by a combination of electrochemical and corrosion data. It was observed that in 20% H_2SO_4 at room temperature, unalloyed Ti shows unstable passivity when the solution is oxygen-saturated. This is shown in Fig. 7A. The potential oscillates in an unpredictable manner from a value only slightly more noble than the critical potential for passivity (shown in Fig. 7B) to an active value. The relatively active value of the passive potential of unalloyed Ti is due primarily to a particularly small

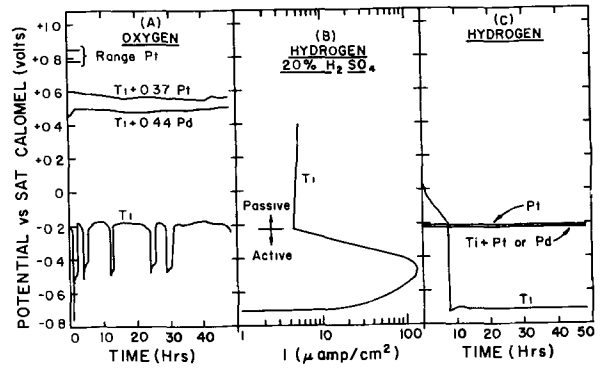

Fig. 7. Anodic behavior of Ti and electrode potential of Ti and Ti alloyed with Pt or Pd in 20% H_2SO_4 at room temperature.

value of exchange current for oxygen reduction on the Ti surface. Alloys containing Pt and Pd are 0.7-0.8 v more noble than unalloyed Ti and only about 0.3 v more active than Pt in the same solution. These data are an ideal illustration of the mechanism shown in Fig. 6.

Figure 7C shows potential-time behavior in hydrogen-saturated solution. Platinum exhibits the reversible hydrogen potential. Potentials of Ti containing Pt and Pd are within 25 mv of this value. The potential of unalloyed Ti, which initially had an air-formed film, is active. This illustrates the basic mechanism of noble metal alloy additions shown in Fig. 1.

Note in Fig. 7 that relatively stable potentials are not observed in the potential region where the anodic polarization curve has a negative slope. When the potential of passive Ti reaches the critical potential, it moves rapidly to active values. When active Ti reaches potentials close to that at the critical current, it moves rapidly to passive values. Also note that the potential of active Ti in oxygen-saturated solution is more noble than active Ti in hydrogen-saturated acid because of the combined cathodic reduction of oxygen and hydrogen ions.

Weight loss data for the electrodes whose behavior is described in Fig. 7A and C are shown in Table III. Alloys containing Pt or Pd are passive and exhibit negligible corrosion rates in either hydrogen- or oxygen-saturated acid. Unalloyed Ti is active in hydrogen-saturated solution and is intermittently active in oxygen-saturated solution. In the latter case, the weight loss is between that observed for the active and passive conditions.

These experiments in 20% H_2SO_4 support the concept that Ti containing noble metal alloy additions is much more sensitive to oxidizing agents than unalloyed metal. Data, which show that this extends to trace concentrations of oxidizing agents, were obtained by measuring the mixed potential of Ti and Ti alloys containing Pt as a function of ferric ion concentration in boiling 1% H_2SO_4. Measurements which were conducted in the manner described previously (1) are shown in Fig. 8. Titanium, which is initially active, requires a ferric ion concentration of about 0.2 mg/ml to passivate. Platinum-containing alloys which are already electrochemically passive in this environment (see Fig. 5) without ferric ion additions respond markedly to concentrations of the oxidizing agent which

are less than one-hundredth of that necessary to passivate Ti.

Conclusions

1. Alloying Ti with small amounts of Pt, Pd, Re, Ru, Ir, Os, Rh, and Au markedly improves corrosion resistance to H_2SO_4, HCl, and other reducing-type media.

2. The mixed potentials of Ti-noble metal alloys which exhibit low corrosion rates are more noble than the critical potential for passivity of Ti in the same environment. Anodic polarization of these alloys shows only passive behavior, whereas cathodic polarization into the active potential region produces an increase in corrosion rate.

3. Electrochemical passivity is observed in hydrogen-saturated systems without the presence of a redox system more oxidizing than the hydrogen electrode.

4. The mixed potential of Ti-noble metal alloys is much more sensitive to traces of oxidizing agents than unalloyed metal.

5. The above observations are consistent with the theory of noble metal alloying proposed. Titanium is particularly susceptible to improvement by alloying because it exhibits unusually active values of critical potential for passivity in a variety of media.

6. Alloying Ti with noble metals is not detrimental to behavior in oxidizing media, such as HNO_3 or ferric chloride. This is expected since Ti does not exhibit a transpassive potential region where the dissolution rate increases at quite noble potential values. Similar alloying in the case of stainless steels is expected to be detrimental under highly oxidizing conditions because of the transpassive behavior of Fe-Cr-Ni-type alloys. Thus, the addition of small amounts of noble metals to Ti produces a material with unusually broad corrosion resistance to both oxidizing and reducing-type media.

High-Temperature Sulfiding of Iron Alloys in Hydrogen Sulfide-Hydrogen Mixtures

E. W. Haycock

Shell Development Company, Emeryville, California

ABSTRACT

Rates of sulfide scale formation on pure iron and a series of chromium steels have been measured over the temperature range 400°-550°C in H_2S-H_2 mixtures at a total pressure of 600 psi with an H_2S partial pressure of 0.6 psi for exposure periods up to 500 hr. A mechanism of scaling, involving the depletion of a barrier scale layer by recrystallization and grain growth processes, is proposed and substantiated by laboratory studies of the structural properties and mode of formation of scales grown on the various materials studied. A single kinetic equation, based on this mechanism, is shown to satisfy the rate curves over the complete range of conditions studied. A solid defect structure, protons trapped at metal ion vacancies, is suggested to explain the effect of hydrogen on the scaling process. The term "E" center is suggested to describe such a lattice irregularity.

Interest in the high-temperature steel-hydrogen sulfide reaction has been stimulated in recent years by scaling problems experienced in high-temperature refining operations of the petroleum industry. Corrosion due to presence of H_2S in hydrorefining processes has been unexpectedly severe, chromium steels containing up to 9% chromium scaling equally as rapid as carbon steel. Several investigations of

this reaction have been reported (1). Of these investigations, those carried out under well-controlled conditions have, for the most part, involved relatively short duration exposures and have been performed at or near atmospheric pressure. The primary objective of the investigation reported here was to study the kinetics and mechanism of scaling under conditions similar to those experienced in refinery operations. This has involved scaling experiments at elevated pressures and with exposure times beyond the range reported by previous investigators. In the present investigation, corrosion rates of pure iron and iron-chromium alloys have been compared with those of commercial steels and scaling rates studied as a function of chromium content.

Dravnieks and Samans (2) recently have suggested a mechanism for the steel-hydrogen sulfide reaction. Mechanistic studies of the iron-H_2S reaction have been reported by Delahay and coworkers (3). The interpretation of kinetic data in these studies is complicated by the thermodynamic possibility that FeS_2 could be formed as well as FeS. In the present work the H_2S/H_2 mole ratio has been maintained at a sufficiently low value to insure that over the entire range of conditions studied FeS was the only stable product phase. As a result of the present kinetic and mechanistic studies a new mechanism of the reaction is proposed. Although the present studies confirm certain hypothetical features of the Dravnieks-Samans mechanism, our kinetics analysis differs significantly from that of the above authors and allows the experimental data to be explained by a single rate equation over the entire range of conditions studied.

Experimental Rate Measurements

The rates of scaling of pure iron, ½% Mo steel, and a series of chromium steels were measured over the temperature range 400°-550°C in H_2S-H_2 mixtures at a total pressure of 600 psi with an H_2S partial pressure of 0.6 psi. On the basis of thermodynamic data published by Rosenqvist (4), FeS is the stable product under these conditions. The compositions of the alloys studied are given in Table I. Two pure irons, Armco and Ferrovac E, were used, and no significant differences were observed in the relatively long exposure scaling rates studied. Commercial ½% Mo steel was used rather than carbon steel to avoid hydrogen attack of the metal.

The experiments were made in the apparatus shown schematically in Fig. 1. Metal specimens were

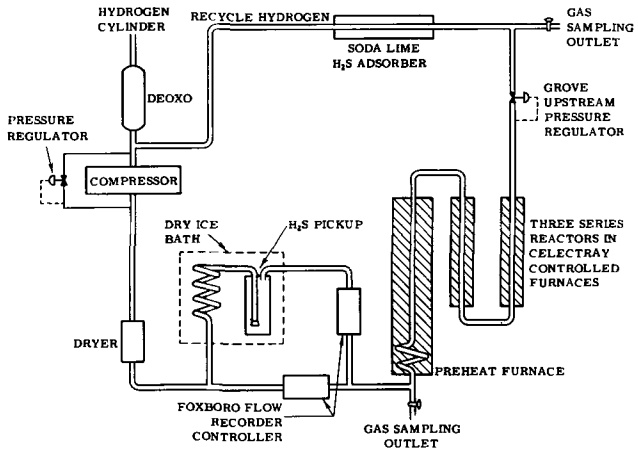

Fig. 1. Schematic diagram of apparatus used to measure metal scaling rate in H_2S/H_2 mixtures at 600 psi.

exposed in three stainless steel reactor tubes heated by electric furnaces which were maintained at chosen temperatures ±2°C by a Celectray indicator-controller. The temperature controller was actuated by iron-constantan thermocouples situated in thermowells close to the metal specimens.

Cylinder hydrogen (99.8% H_2, 0.15% O_2, 0.05% N_2) was led through a Deoxo catalytic cartridge and drying column to remove oxygen. The desired H_2S-H_2 mixture was obtained by dividing the hydrogen stream and passing part of it through liquid H_2S in a dry ice bath. The divided gas stream then was remixed and passed through a preheat column into the reactors. Division of the hydrogen stream to the desired extent was achieved by the use of Foxboro flow recorder-controllers. The total flow of gas over the scaling specimens was maintained at a sufficiently high rate to keep the effluent H_2S concentration to within 10% of the inlet concentration. The gas composition at both the inlet and outlet was checked at frequent intervals, and in many experiments the difference in inlet and outlet composition was considerably less than this amount. For ease in long term continuous operation, H_2S was removed from the effluent gas in soda lime towers and the hydrogen recycled.

The metal specimens studied were in the form of cylindrical rings approximately ½ in. long, ⅝ in. O.D., with 3/32 in. wall thickness. Ring specimens were chosen primarily to insure that scale samples would be obtained *in situ* on the metal surface for subsequent examination by metallurgical microscopic techniques. The scales formed under com-

* Vacuum melted pure iron.

pression on the inside of the rings remained intact, whereas in many cases the scales on the outer surfaces of ring specimens or on flat specimens would spall on cooling from the reactor temperatures. Up to ten specimens could be supported in each reactor tube.

The experimental procedure adopted was as follows. Prior to exposure, specimens were ground smooth and sharp edges removed with 180 grit abrasive followed by soft rubber erasing. Specimens then were washed with acetone, weighed, and loaded into preheated reactor tubes under nitrogen. Final temperature adjustments were made as the nitrogen was swept out with hydrogen and the pressure brought up to 600 psi. The hydrogen sulfide-hydrogen stream then was introduced and scaling allowed to proceed for various exposure times up to 500 hr. Experiments were terminated by stopping flows to the reactors, venting, and purging with nitrogen. To determine the extent of metal consumption after each exposure, the specimens were descaled in an electrolytic cleaner in 5%w sulfuric acid, dried, soft rubber erased, and weighed. Duplication of alloy specimens allowed additional sampes for scale analyses and microscopic examination.

Experimental Results and Discussion

The rate curves obtained were similar in form to those obtained for carbon steel by Dravnieks and Samans (2). For all of the alloys studied, the rate of scaling was observed to be high initially and gradually decrease over the first 20-30 hr to approach an essentially constant value.

The scaling rate curves for pure iron, ½% Mo steel, and 5% Cr, ½% Mo steel are illustrated in Fig. 2, 3, and 4 for exposures up to 500 hr. The shapes of these curves are typical of all of the alloys studied including 18-8 stainless steel. Several ex-

periments with pure iron-chromium alloys, made by vacuum melting "Ferrovac E" pure iron with electrolytic chromium, showed no significant difference in scaling properties between these materials and the corresponding commercial alloys. A large number of scaling experiments, which will not be reported in detail here, have been made under varying partial pressures of H_2S and H_2. These experiments have confirmed previously reported (1) observations that, within the thermodynamic limits of FeS stability, the over-all scaling rate depends on the partial pressure of H_2S and is not affected by changes in the partial pressure of H_2.

Scale structure and composition.—Scales formed on all of the materials investigated consisted of two well-defined layers. The scales resembled those described by Delahay (3) for the pure iron-H_2S product and by Dravnieks (2) for the carbon steel corrosion product. The layer next to the metal consisted of small disorganized crystallites and was coherent and adherent. The second layer adjacent to the gaseous environment consisted of a columnar array of relatively large crystals with pores extending from the gas interface to the surface of the adherent sulfide layer. The scale structure illustrated by the photomicrograph shown in Fig. 5 is typical of that obtained on all of the materials studied.

Chemical analyses of the individual scale layers showed that, for pure iron and the low chromium steels, the main constituent of both layers was metal deficient ferrous sulfide. Similar results for pure iron have been reported by Delahay (3). This was confirmed by power x-ray analyses, the iron sulfide

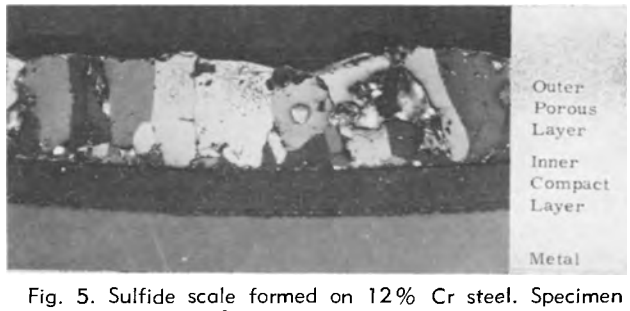

Fig. 5. Sulfide scale formed on 12% Cr steel. Specimen scaled 400 hr at 565°C, partial pressure, H_2S 0.3 psi in 600 psi H_2. Magnification 100X before reduction for publication.

super lattice (α') pattern being obtained in all cases. This structure is associated with the FeS composition range 50-50.74 at. % sulfur. Similar x-ray patterns have been reported by Bruns (5). For the chromium alloys, chemical analyses showed that chromium and molybdenum were retained in the scale layer next to the metal. Other trace metals present such as nickel and manganese were found to be distributed throughout both layers, although some tendency to retain nickel in the inner layer was observed. Silicon and carbon were found to accumulate in the inner layer. For the higher chromium steels and for low chromium steels which had been exposed sufficiently long to allow a significant concentration of chromium to be built up in the inner scale layer, an x-ray pattern corresponding to the spinel structure $FeCr_2S_4$ was observed. Although no thermodynamic data are available for this compound, by comparison with the analogous oxygen compound, it would be expected to have a high negative free energy of formation and its occurrence accounts for the retention of chromium in the inner scale layer.

Mechanism of scale formation.—Microscopic study of scale structure strongly suggests that the outer porous scale layer is formed at the expense of the inner layer by a recrystallization and grain growth mechanism. This is indicated by the sharpness of the interface between the scale layers and the change in crystal size and orientation from one layer to the other. It is also in keeping with the observation that for pure iron both layers are identical within the limits determinable by chemical and x-ray analyses.

To obtain confirmation of this general model, inert marker experiments were performed on 1% Cr, ½% Mo steel, and ½% Mo steel scaled under the conditions previously described for the rate measurements. Three marking materials were used: chromium oxide, aluminum oxide, and platinum metal dust. The positions of the chromium oxide and platinum markers were studied by metallographic techniques and aluminum oxide by chemical analyses of the scale layers. In all cases markers were found distributed throughout the outer scale layers and on the outermost scale surface. Some markers, particularly in the case of chromium oxide, were found at the interface between the scale layers, and the relative number and appearance of these markers suggested that the chromium oxide was not entirely inert and that some inhibition of the processes taking place at the interface between the two scale layers was occurring. The fact that no markers were found in the inner layer or at the metal surface clearly indicates that the inner scale layer was formed by sulfide ion diffusion to the metal surface. The general scattering of markers through the outer layer suggests that continuous rearrangement takes place in this layer, and this is in keeping with the proposed model of its formation by recrystallization and grain growth processes.

The growth of the inner layer by sulfide ion diffusion to the metal surface necessitates that this layer be formed under high compressive stress. The molar volume of ferrous sulfide is considerably greater than that of the parent metal and, except for some relief due to slight plastic deformation, the product sulfide is confined beneath existing scale to the same volume as that initially occupied by the parent metal. It seems probable that the stress in the inner scale layer is the main driving force for nucleation and growth of the outer scale layer. The phenomenon of stress induced recrystallization is well known, particularly in metal systems. A pertinent example of this is the observation that the growth of single crystal tin "whiskers" from polycrystalline tin is greatly enhanced by the application of a compressive stress (6).

The difference in the mechanism of scale formation in hydrogen sulfide environments as compared to sulfide formation in sulfur vapor studied by Birchenall (7) is dealt with later when interaction of hydrogen with metal deficient ferrous sulfide is discussed.

Kinetic analysis of rate data.—Microscopic examination of sulfide scales formed in hydrogen sulfide environments indicates that the porosity of the outer scale layer is sufficiently high to render it ineffective as a solid diffusion barrier between the metal and the gas phase. The main resistance to reaction appears to reside in the inner barrier layer scale. The simplest kinetic model which adequately explains the experimental observations is one to which a combination parabolic-linear law may be applied in which the linear component of the rate is associated with the process occurring at the interface between the compact and the porous scale layers. By comparison with other solid-state interface transformations, the proposed recrystallization process for the formation of the porous layer would be expected to occur at a linear rate and the interfacial area will remain sensibly constant throughout the reaction. The barrier layer scale therefore will grow by the diffusion of sulfide ions to the metal surface and be depleted at a constant rate by the process forming the porous outer scale layer. If it is assumed that diffusion across the inner scale layer determines the rate of metal consumption, then this rate will be inversely proportional to the inner scale thickness. The rate of scaling will start therefore at a high value and decline as the inner scale thickens. When the rate of metal consumption approaches the rate of recrystallization, the inner scale layer will approach a constant thickness and the scaling rate will approach a constant value. This model leads to the expression

$$x = \frac{K_p}{K_l} \ln \frac{K_p}{K_p - K_l(x - K_l t)} \qquad [1]$$

for the metal weight loss as a function of time, where x equals metal weight loss, t, time, K_p is a rate constant associated with the parabolic diffusion process by which the barrier layer is formed, and K_l a rate constant associated with the linear recrystallization rate by which it is depleted.

Equation [1] is a general expression for the rate of scaling of any system in which a diffusion barrier, which would normally be formed parabolically,

is depleted at a constant rate by any secondary process. Its derivation, which is an extension of the work of Loriers (8) and Wagner (9), will be given in more detail in the following paper (10) where it is applied to systems other than sulfiding.

The close correspondence between the present experimental data and the theoretical rate curves obtained from Eq. [1] for the range of conditions studied is shown in Fig. 4 for 5% Cr, ½% Mo steel. Similar agreement has been found for the other alloys studied.

Equation [1] is based on a model of an ideal system. The assumptions made in its derivation are: (*a*) the consumption of metal is controlled solely by diffusion processes in the compact layer, i.e., no surface or interface reaction influences the primary reaction; (*b*) the diffusion coefficient of the rate-determining species is constant throughout the reaction; (c) the secondary interface reaction giving the porous scale layer depletes the diffusion barrier at a uniform rate; and (*d*) both scale layers begin to grow at $t = 0$ and have constant density throughout the reaction. For the early stages of scaling on pure iron and the low chromium steels, these requirements apparently are obeyed reasonably well. However, at long exposure times deviations are to be expected and the results of some of these are apparent in scales formed in long term experiments in both laboratory and refinery plant equipment. The presence of nonmetallic materials (carbon and silicon) in the steels may introduce a changing additional resistance to the consumption of metal at the metal-scale interface. The enrichment of certain alloy constituents in various locations in the scale gradually will effect the diffusion coefficient of other constituents. The outer scale layer, as it thickens, may offer a gradually increasing resistance to gas flow to the interface between the two scale layers. Thus, at the base of pores of the outer scales, the ratio of H_2 to H_2S may increase as the porous scale grows and gaseous diffusion paths to the reaction zone become longer. The compact diffusion barrier may develop stress cracks as the reaction proceeds. The scale interface reaction, which is thought of basically as a recrystallization process, could be affected by changes in concentration of foreign materials at the interface.

Experimental observations of scale layer thicknesses made in the present study indicate that the inner scale layer thickens over the first 24-hr exposure to a value which remains essentially constant for 70-100 hr. A slight but continuous thickening of the inner layer takes place for 100-500 hr exposure and this is accompanied by a slight decrease in the rate of thickening of the outer porous layer. These deviations from the theoretical model do not appear to be of sufficient magnitude to prevent the experimental rate curves being fitted adequately by Eq. [1].

Values of K_p and K_l, plotted as a function of temperature according to the Arrhenius equation, are shown in Fig. 6 and 7. Straight lines were obtained in all cases, which adds support of internal consistency to the proposed mechanism and kinetic

analysis. For the purpose of clarity, the pure iron K_p plot has been omitted from Fig. 6 and the lines for various alloys have been grouped in Fig. 7. Activation energies and pre-exponential factors determined from the data for each individual metal are given in Table II for the diffusion and recrystallization processes. The accuracy with which weight losses could be determined and the deviations of individual points from the theoretical curves obtained from Eq. [1] set a limit of accuracy of ±1 kcal on the reported activation energies for all alloys except 18-8 stainless steel. In this case weight losses were very small and the experimental data more widely scattered. The data given for 18-8

Table II. Activation energies and pre-exponential factors for parabolic and linear processes
$K = Ae^{-E/RT}$

Alloy	Parabolic rate constant, K_p		Linear rate constant, K_l	
	Activation energy, E, kcal/mole	Pre-exp. factor, A, mg^2/cm^4 hr	Activation energy, E, kcal/mole	Pre-exp. factor, A, mg/cm^2 hr

18-8, type 304	17	3.7×10^7	16	7×10^8

stainless steel therefore could be considerably in error and should be taken for comparison in a qualitative rather than quantitative sense. It will be seen that, with the chromium alloys, the activation energy for the diffusion process increases as the chromium content of the steel increases. The activation energy of the recrystallization process, however, stays essentially constant until the 12% chromium alloy is reached and then increases sharply for the 18% Cr, 8% Ni stainless steel.

These activation energy data serve to illustrate several practical features of the scaling process. Since, on the basis of the proposed model, the ultimate rate of scale formation is determined by the recrystallization rather than the diffusion process, the constancy of the activation energies and preexponential factors for the recrystallization process are to be expected since practical experience has shown that chromium additions of less than 12% to steel are not beneficial in lowering the long-term scaling rate (1). The fact that the activation energies for the diffusion process increase with chromium content implies that, if the scaling process involved the diffusion-controlled formation of the barrier scale only, then low percentage chromium additions would be beneficial in reducing scaling. This is in keeping with experience in oxidation of chromium steels where no porous scale layer is produced and low percentage additions of chromium lower the scaling rate. It is anticipated that additions of chromium would be beneficial in the pure sulfur vapor scaling system.

Effect of Hydrogen on Ferrous Sulfide Scale Formation

The effect of hydrogen in high-temperature sulfiding of iron can be appreciated best by comparison of the scaling processes in hydrogen sulfide and in pure sulfur vapor. In hydrogen sulfide environments the rate of scaling is high initially and falls to an essentially constant value. A two-layer scale is formed, the inner layer growing by sulfide ion diffusion to the metal surface. In contrast to this, the iron-sulfur vapor reaction follows a parabolic rate law (7). A single layer scale is formed and has been shown by Birchenall to grow by iron ion diffusion from the metal surface to the scale-gas interface. Since the product in both cases is iron deficient ferrous sulfide, it is evident that hydrogen plays an important role in the mechanism of scale formation in hydrogen sulfide environments.

To obtain a quantitative measure of the interaction of hydrogen with ferrous sulfide, the all glass apparatus shown schematically in Fig. 8 has been used. In a typical experiment a sample of ferrous sulfide in bulb A was equilibrated with a reservoir mixture of approximately 6% hydrogen sulfide in hydrogen at atmospheric pressure for 15 hr at 500°C. This gas composition was suitable to maintain ferrous sulfide thermodynamically stable against bulk reduction at this temperature. The adsorption chamber A was then evacuated to 10^{-6} mm Hg at 500°C for 8 hr. A known amount of H_2S-H_2 mixture was introduced into the system from the reservoir, and the adsorption of gases fol-

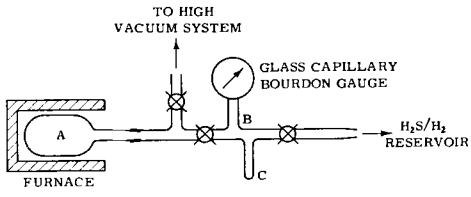

Fig. 8. Schematic diagram of apparatus used to measure absorption of hydrogen by ferrous sulfide.

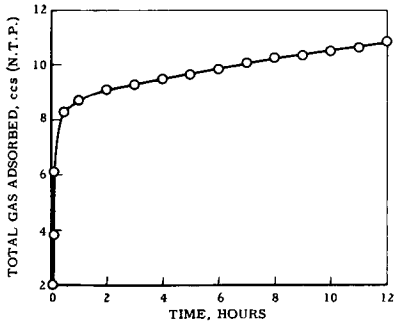

Fig. 9. Adsorption of H_2S/H_2 mixture on ferrous sulfide at 500°C. Weight of ferrous sulfide, 75.6 g; surface area (after experiment), 0.11 m^2/g; gas pressure at zero time, 40.8 cm Hg; gas pressure after 12 hr, 15.8 cm Hg; initial composition of H_2S/H_2 mixture, 6.15% H_2S; gas composition after 12 hr, 10.9% H_2S; hydrogen adsorbed after 12 hr, 10.4 ccs (N.T.P.); hydrogen sulfide adsorbed after 12 hr, 0.34 ccs (N.T.P).

lowed by the reduction in pressure measured with a glass capillary bourdon gauge (11). At any stage of the adsorption a part of the ambient gas could be isolated in section B of the apparatus and the H_2S condensed out in the ampoule C. This allowed a measurement of the H_2S/H_2 volume ratio existing above the adsorbent at any given time. The volumes of the various sections of the apparatus were calibrated with helium. Furnace temperatures were controlled to ±2°C. The surface area of the sulfide was determined after each experiment to allow for any sintering which might occur. Surface areas were measured by the B.E.T. method using nitrogen. A typical adsorption isotherm is shown in Fig. 9 with the pertinent primary and calculated data for the experiment. It will be seen that the system had not reached equilibrium even after 12 hr. Even if it is assumed that the evacuation treatment before adsorption removed all of the hydrogen associated with the ferrous sulfide, the total measured amount of hydrogen adsorbed after 12 hr exceeds the value expected for a monolayer. The slow, essentially linear, adsorption observed after 1 hr is attributed to the solution of hydrogen into the bulk sulfide.

The adsorption of hydrogen by metal deficient oxides, materials known as p-type semiconductors, has been studied extensively and it is known that the adsorption of hydrogen is accompanied by a decrease in electrical conductivity (12). It is anticipated therefore that the adsorption of hydrogen by ferrous sulfide and incorporation into the lattice would be accompanied by a decrease in the concentration of positive holes. From a chemical point of view this is equivalent to adsorbed hydrogen reducing the number of ferric ions in the metal deficient ferrous sulfide lattice. Assuming this to be

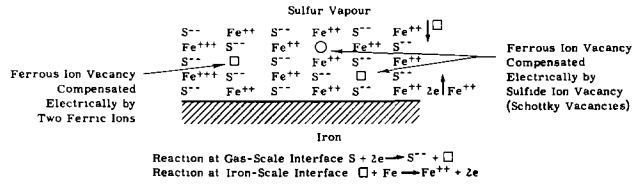

Fig. 10. Growth of iron-deficient ferrous sulfide in the iron-sulfur system.

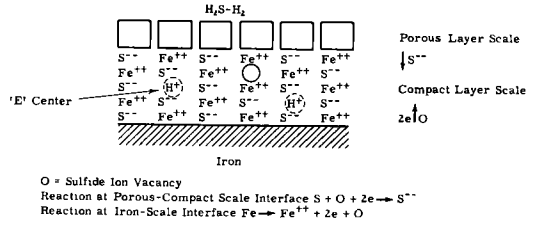

Fig. 11. Growth of iron-deficient ferrous sulfide modified by hydrogen.

the case, and recognizing the difference in scaling mechanism observed in hydrogen sulfide and sulfur vapor, i.e., scale formation by diffusion of sulfide rather than iron ions, it appears that hydrogen is incorporated in the ferrous sulfide lattice as protons associated with metal ion vacancies. As illustrated schematically in Fig. 10, iron deficient ferrous sulfide formed by the reaction of iron with sulfur vapor would be expected to contain metal ion vacancies, of which a part are compensated for electrically by sulfide ion vacancies and a part by the existence of ferric ions. It is suggested that interaction of hydrogen with this system results in a structure shown in the reaction scheme illustrated in Fig. 11. In addition to chemisorbed hydrogen at the surface, protons will be incorporated into the lattice reducing the number of ferric ions. This structure can be regarded as equivalent to a number of HS^- ions incorporated in the lattice, these ions being dissociated to an extent dependent on temperature. Since metal ion vacancies carry an effective negative charge, they would be expected to be efficient traps for protons in the lattice. It is proposed to name the defect structure of a proton trapped at a metal ion vacancy an "E" center. A previous suggestion of such a structure has been made by Caplan and Cohen (13) to explain the inhibiting effect of water in the high temperature oxidation of iron-chromium alloys. An "E" center would be expected to have certain properties similar to those of the well-established "f" center, i.e., an electron trapped at an anionic vacancy. The effective diameter of protons trapped at metal ion vacancies would increase with temperature and, under the scaling conditions studied, an "E" center could be expected to present an effective barrier to the migration of metal ions.

The recrystallization phenomena observed with sulfide scaling in the presence of hydrogen suggest that, in addition to blocking iron ion diffusion, the interaction of hydrogen enhances the mobility of the relatively bulky sulfide ions. This is readily understood on the basis of the above model since the presence of singly charged HS^- ions will tend to loosen the close packed sulfide ion lattice. Surface mobility of sulfide ions would be expected to increase since the energy required to transfer an HS^- ion from the bulk sulfide to a surface adsorbed state would be considerably less than for a S^{--} ion. Such surface mobility is the process considered to be important in recrystallization and grain growth processes.

The enhanced surface ionic mobility in the presence of hydrogen has been demonstrated by sintering experiments. Powdered ferrous sulfide with an initial B.E.T. surface area of 0.5 sq meter/g was maintained in a vacuum of 10^{-6} mm Hg for 5 hr at 500°C. No detectable change in surface area occurred. Heating the powder at the same temperature in a hydrogen-7% H_2S atmosphere for 2 hr reduced the surface area to a half of its initial value, and the powder had visibly sintered to a porous plug.

On the basis of hydrogen interacting with the ferrous sulfide product to (*a*) retard metal ion diffusion, and (*b*) accelerate surface and bulk diffusion of sulfide ions, it is possible to account for the difference in mechanisms observed when steel is scaled in hydrogen sulfide and in sulfur vapor.

The general similarity in oxide and sulfide systems suggests that the effects of hydrogen interaction discussed here for iron sulfide would also apply to metals oxidized in water vapor, although similar effects might be expected to occur over different temperature ranges due to the difference in stability of OH^- and SH^- ions. The study by Gulbransen (14) of the orientation of oxide crystals formed on iron lends support to the suggestion that the interaction of hydrogen with iron oxides will enhance the mobility of oxide ions. It was shown that iron scaled in pure oxygen produced a poorly oriented surface oxide. However, iron scaled in water vapor was found to form a highly oriented film. The bulky anions in the presence of hydrogen apparently possessed sufficient mobility to achieve a desired orientation in the time of oxide formation. The system Fe-H_2O-H_2 has been studied by Chaudron and co-workers (15), and these authors describe a double scale formation similar to that observed in the iron-hydrogen sulfide reaction. Further experimental work will be required, involving measurement of cation and anion diffusion rates in metal deficient oxides and sulfides in the presence of hydrogen, to firmly establish the effects suggested by the present study.

Acknowledgment

The author is indebted to Mr. W. H. Sharp for obtaining the rate data used in this article and to Mr. H. S. MacKinnon for his assistance in the remainder of the experimental work. Helpful discussions by Mr. R. S. Treseder and Dr. A. Wachter are also gratefully acknowledged.

Manuscript received Oct. 13, 1958. This paper was prepared for delivery before the Ottawa Meeting, Sept. 28-Oct. 2, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

Transitions from Parabolic to Linear Kinetics in Scaling of Metals

E. W. Haycock

Shell Development Company, Emeryville, California

ABSTRACT

A general rate equation is derived for a model of a barrier scale layer being formed by a diffusion process and simultaneously being depleted at a constant rate by a secondary process. The equation, derived to satisfy rate curves for sulfide scaling of iron in hydrogen sulfide, is shown to be applicable to the oxidation of aluminum and hafnium over ranges of conditions where two or three rate equations have been used previously to explain the experimental data. The validity of this equation emphasizes the importance of secondary processes, such as scale recrystallization, in determining the over-all rate of high-temperature corrosion reactions.

An important part of fundamental studies of the mechanism of high-temperature corrosion is the fitting of theoretical rate equations, derived from mechanistic models, to experimental scaling data. The basis of nearly all kinetic treatments of scaling processes, beyond the thin film range, is the simple, diffusion-controlled formation of a barrier product layer. The accepted mechanism by which the barrier scale grows according to a parabolic rate equation is attributed mainly to Wagner (1) and has been described exhaustively in recent review texts (2, 3). Many scaling systems, however, do not follow a parabolic equation except over limited ranges of temperature. Other rate equations such as linear, cubic, exponential, or combinations of these have been shown to fit experimental rate data for various systems, and a number of mechanisms have been suggested to account for these deviations from parabolic behavior (2, 3).

For the oxidation of most metals, an intermediate temperature range has been observed over which a parabolic rate law is reasonably well obeyed. At low temperatures a tendency toward logarithmic laws has been noted, while linear kinetics are favored at elevated temperatures. The apparent need for more than one theoretical rate equation to satisfy experimental data over a range of temperatures usually has been ascribed to transitions in the mechansim of scaling.

Systems which have not received an adequate quantitative treatment are those whose rates begin at a high value and then decrease over a certain time period to follow linear kinetics for the remainder of the scaling reaction. In these systems the linear portion of the rate curve may begin close to the origin or may not be apparent until the scaling reaction is well advanced, depending on the temperature of reaction. The purpose of this paper is to develop a quantitative approach which yields an equation capable of satisfying rate curves of this type over a wide range of conditions.

Mechanisms Associated with Linear Kinetics

Linear rate laws generally are associated with one of two mechanistic features. Surface reactions occurring at either the metal-scale or scale-gas interface can be considered in some cases to be slow and therefore rate determining. If the interface has a constant area throughout the reaction, then an overall linear rate law would be expected. The second mechanism giving rise to linear kinetics depends on the formation of an "open" or porous scale structure. This includes systems where volatile products are formed. Early investigators of oxidation systems associated a porous scale with metals, such as the alkaline earth metals, whose oxides have a smaller molar volume than the parent metal. The oxides of these systems were supposed to be formed under tension, and hence crack and shear as the scale thickened to give access of reactant gas to the metal surface at a constant rate. This is the basis of the well-known Pilling-Bedworth (4) rule. An improved understanding of the mechanism of oxide formation, however, has shown that the Pilling-Bedworth rule is without theoretical foundation (5, 6) for scales formed by metal ion diffusion. A more reasonable explanation, discussed by Evans (7), is that cracking, shearing, etc., can occur as a result of stresses

in the product scale but that the rate of metal consumption is determined by diffusion across a thin barrier layer on the metal surface which builds up to and then maintains a constant thickness. Such a mechanism can apply equally well to systems whose oxides have a molar volume greater or less than that of the parent metal.

Following a study of the oxidation of cerium, Loriers (8) suggested that the observed linear kinetics could be explained by the formation of a porous CeO_2 layer on top of a nonporous Ce_2O_3 barrier layer. The outer scale layer was observed to grow at the expense of the barrier layer at a constant rate while the consumption of metal was controlled by a diffusion process in the barrier layer. The barrier layer approached a constant thickness as the rate of its formation became equal to the rate of formation of the outer porous layer. The over-all rate of reaction therefore was high initially and decreased to approach a constant value. Similar reasoning has been applied by Wagner (9) to the oxidation of tungsten, and it appears that the same mechanistic approach can be used for the oxidation of uranium (10) and thorium (11). In all of these cases a two-layer scale is formed. The outer layer is porous and is a higher oxide of the metal than the compact inner barrier scale. In these systems it is reasonable to assume that the porous layer is formed at the expense of the barrier layer by nucleation and growth of a different chemical phase.

There are other scaling systems, such as iron-H_2S (12), and the oxidation of aluminum (13, 14), hafnium (15), calcium (16), and magnesium (17), where linear rate curves are obtained over certain temperature ranges. In these cases, however, where two scale layers have been observed, both layers have been found to be chemically the same material. In these systems it seems logical to extend the kinetics described qualitatively by Loriers (8) and to attribute the formation of the porous second layer to recrystallization and grain growth processes. Such a mechanism is treated in the following section.

Proposed Scaling Mechanism

By extending the qualitative arguments of Evans (7) and Loriers (8), the mechanistic model illustrated in Fig. 1 can be described in a quantitative manner.

A barrier layer scale AB is formed on the metal surface, its rate of formation being governed by ionic diffusion. Simultaneously, a secondary process is superimposed upon this primary process which depletes the barrier layer at a constant rate. In Fig. 1 this secondary process is shown to give the scale layer BC which is assumed to be sufficiently porous so that it offers no significant barrier to the availability of reactive gas at the interface B. The rate of metal consumption will be inversely proportional to the thickness of the compact barrier layer and will be given by the standard parabolic equation (18).

$$dx/dt = ak_p/2\mu \qquad [1]$$

where x is metal weight loss at time t; μ, thickness of compact layer at time t; k_p, parabolic rate constant;

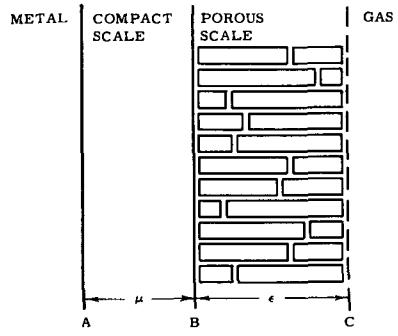

Fig. 1. Schematic model for derivation of rate equation

and a, a conversion factor relating the thickness of metal reacted to the thickness of the compact scale produced. In an unhindered, single scale forming reaction governed entirely by a parabolic kinetic law, a would be defined by $x = a\mu$. In addition to the usual assumptions of constant diffusion coefficient and uniform area at interface A, Eq. [1] assumes that layer AB has a constant uniform density.

Let ϵ be the thickness of the porous layer at time t. As a first approximation we assume the recrystallization process to begin at $t = 0$. Then

$$\epsilon = k_i t \qquad [2]$$

where k_i = linear rate constant of the interface reaction forming BC. We write

$$x = a\mu + b\epsilon \qquad [3]$$

where a and b are the density conversion factors from metal to the two scale types. This introduces the assumption that the porous layer has a constant density throughout the reaction. Substituting in Eq. [3] from Eq. [1] and [2], μ and ϵ in terms of x and t, we obtain

$$\frac{dx}{dt} = \frac{K_p}{x - K_i t} \qquad [4]$$

where

$$K_p = a^2 k_p/2$$

$$K_i = bk_i$$

Integration of Eq. [4] yields the equation giving metal weight loss as a function of time

$$x = \frac{K_p}{K_i} \ln \frac{K_p}{K_p - K_i(x - K_i t)} \qquad [5]$$

In the general case, the process which depletes the barrier layer may be either vaporization of the primary reaction product or, as in the case illustrated, the formation of a solid second scale layer. If a solid second layer is formed, it must either be porous and offer negligible resistance to the availability of reactive gases at the interface between the two-scale layers or it must have a structure such that solid diffusion rates in it are very rapid compared to those in the barrier layer. Mechanical processes such as cracking, spalling, etc., can be considered as possible mechanisms of porous second layer scale formation. However, the general smoothness of linear rate curves and conformance with the Arrhenius

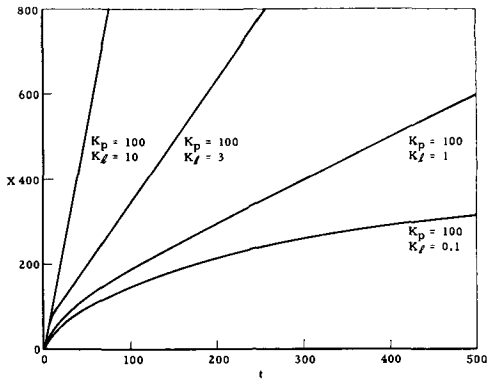

Fig. 2. Theoretical rate curves. $X = \frac{K_p}{K_1} \ln \frac{K_p}{K_p - K_1(X - K_1 t)}$

equation as a function of temperature are considered evidence against such an unpredictable process as mechanical cracking being important in more than a few cases. In instances where the porous and barrier layers are chemically identical, the most reasonable mechanism of porous scale formation appears to be recrystallization and grain growth.

If we eliminate x and ϵ from Eq. [1], [2], and [3] we obtain

$$\frac{d\mu}{dt} = \frac{K_p}{a^2\mu} - \frac{K_l}{a} \qquad [6]$$

The inner scale grows, i.e., $d\mu/dt$ is positive, as long as $K_p/a^2\mu > K_l/a$. As μ approaches a thickness given by $K_p/a^2\mu = k_l/a$, then $d\mu/dt$ approaches zero. The inner layer, therefore, approaches a constant thickness $\mu = K_p/aK_l$. It should be pointed out that mathematically this occurs at infinity. However, for practical purposes, the inner scale layer can be considered to become essentially constant after it has achieved 95% of its ultimate thickness. Equation [6] has been derived by Wagner and co-workers (9) for the oxidation of tungsten.

A plot of Eq. [5] yields a curve which approaches the straight line $K_p - K_l(x - K_l t) = 0$. The general shape characteristics of the curve are determined by the relative values of K_p and K_l. When K_p is large compared with K_l, the parabolic features of the equation are emphasized and the plot is considerably curved for short exposure time. As K_l increases relative to K_p, the linear portion of the plot begins closer to the origin of reaction. These variations are illustrated by the theoretical rate curves shown in Fig. 2.

In the following sections, Equation [5] is applied to systems where scale recrystallization appears to be the mechanism of porous second layer scale formation, and sufficient data are available to test the equation. The K_p and K_l values reported for these systems were obtained from the experimental data in the following way. A trial asymptote was drawn to the final stages of the rate curve. As stated above, this line should follow the equation $K_p - K_l(x - K_l t) = 0$, and hence the gradient was an approximate value of K_l and the intercept on the x axis an approximate value of K_p/K_l. The approximate values of K_p and K_l obtained in this way were then adjusted slightly to give the best coincidence with the experimental data. The number of significant figures to which values of K_p and K_l are reported is an indication of the sensitivity with which the experimental rate curves could be fitted.

Application of Proposed Mechanism and General Rate Equation

Iron-hydrogen sulfide reaction.—In the preceding paper (19), Eq. [5] was shown to satisfy sulfiding rates of iron and a series of chromium steels over a range of environmental conditions. For this system two scale layers are formed. Both layers consist of iron deficient ferrous sulfide. The inner barrier layer is formed by the diffusion of sulfide ions to the metal-scale interface. Since this involves the formation of ferrous sulfide beneath existing scale, it is expected that the barrier layer would be formed under high compressive stresses. The formation of the porous layer is attributed to stress induced recrystallization of the inner scale layer.

Oxidation of aluminum.—An apparent kinetic transition from parabolic to linear oxidation of aluminum has been observed at 475° to 500°C by Gulbransen (13) and Smeltzer (14). Hunter and Fowle (20) have shown that oxide films on aluminum consist of two layers, a barrier layer and a porous outer layer. Vermilyea (6) has suggested that recrystallization qualitatively could account for the formation of the porous layer and explain the transition to linear kinetics.

Equation [5] is fitted to the experimental data of Gulbransen (13) in Fig. 3. The three lower curves in this figure have been fitted with a parabolic equation by Gulbransen, while no attempt was made to satisfy the upper curve. It can be seen that Eq. [5] is capable of fitting all the curves over the apparent transition range. The rate constants K_p and K_l obtained from Fig. 3 have been plotted according to the Arrhenius equation in Fig. 4. Straight lines are obtained, and this is an indication of internal consistency in the application of Eq. [5] to the aluminum system. The experimental activation energy of 23 kcal for K_p is identical to that obtained by Gulbransen from parabolic rate constants of the lower temperature curves and is of the order of magnitude expected for the movement of metal ions in an oxide system. The activation energy of 49 kcal for K_l is similar to the value of 50.5 kcal obtained by Leontis and Rhines (17) for the linear high tem-

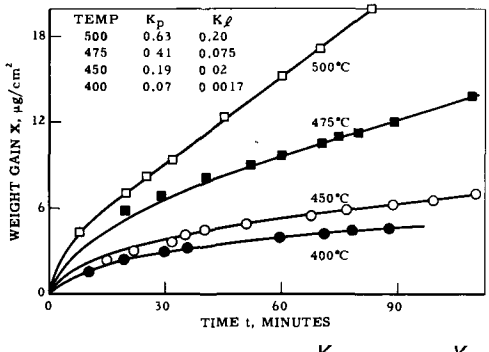

Fig. 3. Application of equation $X = \frac{K_p}{K_1} \ln \frac{K_p}{K_p - K_1(X - K_1 t)}$ to aluminum oxidation rate data. Experimental data taken from Ref. (13).

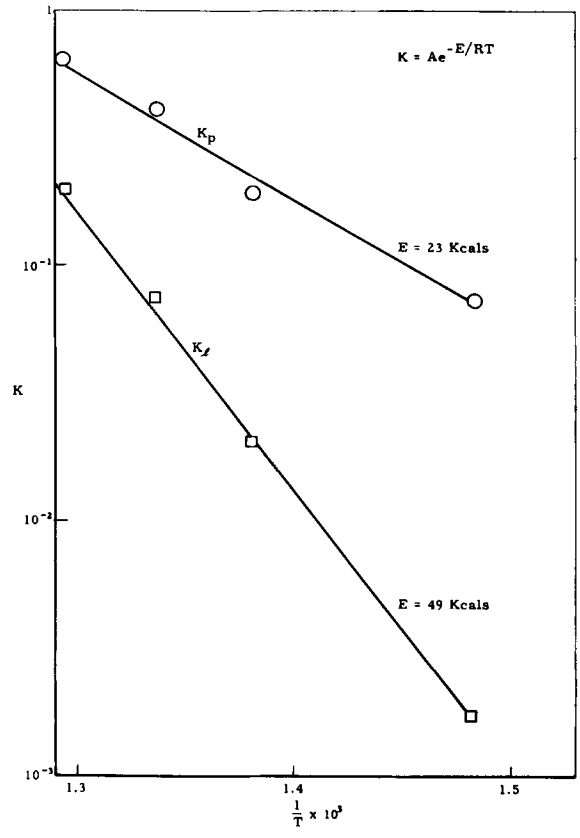

Fig. 4. Arrhenius plots for the oxidation of aluminum

perature oxidation of magnesium. It would be expected that the rate of recrystallization in aluminum oxide would be controlled by the surface mobility of the relatively bulky oxide ions. A high activation energy for this process would be expected for refractory oxides such as alumina and magnesia which are known to be difficult to sinter even at very high temperatures.

On the basis of our previous discussion of the effects of the relative values of K_p and K_l on the shape of the plot of Eq. [5], it would be expected that the apparent transition from parabolic to linear kinetics would occur over a small range of temperature for systems in which K_l has a high temperature coefficient compared with K_p. This effect is well illustrated by the oxidation of aluminum.

The successful application of Eq. [5] to the oxidation curves shown in Fig. 3 emphasizes that short term experiments can be misleading in mechanistic studies. If the mechanism associated with Eq. [5] is correct, then the low temperature curves in Fig. 3 would become straight lines if the experiments were continued for sufficient time. The application of parabolic equations to these curves is misleading, especially if a particular mechanism is associated with the parabolic law. It is important that the correct mechanism and kinetic equations be established if the kinetic data are to be used for theoretical absolute rate calculations such as those attempted by Gulbransen (21).

Oxidation of hafnium.—The oxidation of hafnium from 350° to 1200°C has been studied recently by Smeltzer and Simnad (15). The mechanism appears to be very similar to that of the iron-H_2S system. A two-layer scale is formed. Both layers consist of HfO_2, and the outer layer is very porous. Inert marker experiments indicate that the barrier layer is formed by diffusion of oxygen from the gas-scale interface to the metal surface and hence would be formed under a high compressive stress. The above authors have used an exponential, parabolic, and linear law successively to satisfy empirically the experimental data over the temperature range studied. The scale thickness measurements reported by Smeltzer and Simnad support the mechanism used to derive Eq. [5]. They have shown that the barrier layer approaches a constant thickness which can be expressed in terms of the rate constants K_p and K_l.

The application of Eq. [5] to the experimental results of Smeltzer and Simnad is shown in Fig. 5. It can be seen that the equation explains the data previously fitted by three equations. There is no theoretical evidence therefore of "transitions" occurring over the temperature range studied. As a further test of internal consistency, the straight-line Arrhenius plots, for values of K_p and K_l obtained from Fig. 5, are shown in Fig. 6. The activation energy of 36 kcal obtained for K_p is identical to the value reported by Smeltzer and Simnad from parabolic rate constants obtained by approximating portions of the experiment rate curves to parabolas over the temperature range 470°-1200°C. The activation energy of 18 kcal for K_l is somewhat lower than the value of 26 kcal reported by the above authors from linear rate constants obtained from portions of the experimental rate curves in the temperature range 900°-1200°C. This difference results because, in our analysis of the experimental rate curves, only the 1200°C curve was considered to have reached the final linear stage. The curves presented by Smeltzer and Simnad for 900° and 1000°C were considered not to have reached the final linear rate of reaction in the exposure time studied. Since Smeltzer and Simnad illustrated the growth of the barrier layer oxide by oxide ion diffusion, the activation energy of 36 kcal is associated with the bulk mobility of oxide ions in polycrystalline hafnia. On the basis of a recrystallization process determining the rate of formation of the outer porous scale layer, the activation energy of 18 kcal is associated with the surface mobility of ions. Since, in this case, the temperature coefficient of K_p is greater than that of K_l, apparent transitions in short term exposures are spread over a wide temperature

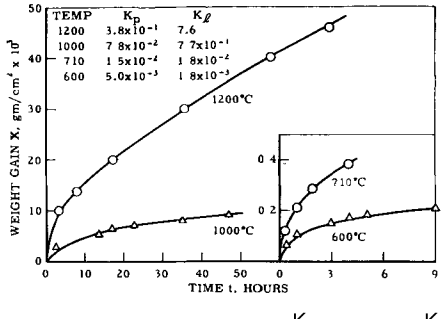

Fig. 5. Application of equation $X = \frac{K_p}{K_l} \ln \frac{K_p}{K_p - K_l(X - K_l t)}$ to hafnium oxidation rate data. Experimental data taken from Ref. (15).

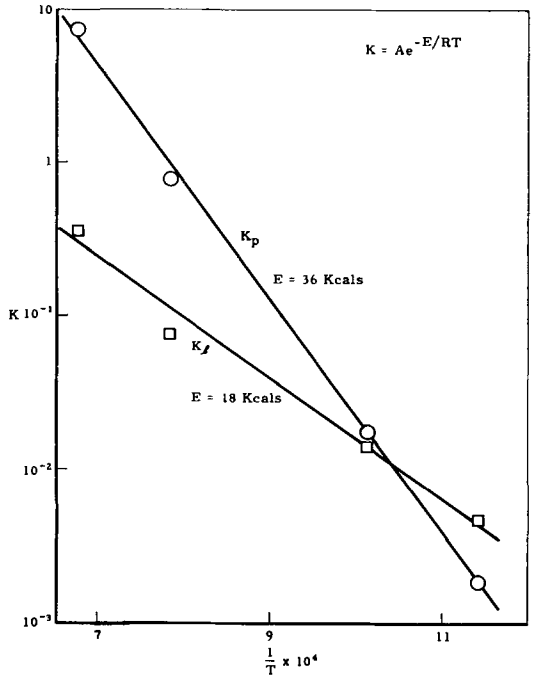

Fig. 6. Arrhenius plots for the oxidation of hafnium

range. The closest approximation of the rate curves to parabolas occurs at the highest temperatures.

A possible extension of the proposed kinetic treatment is that Eq. [5] will be modified in some cases to include the possibility that the secondary process does not begin at $t = 0$. In cases similar to those discussed, this would correspond to the requirement that a minimum stress level be reached before formation of the porous layer begins. This modification yields a rate equation of the form

$$\frac{dx}{dt} = \frac{K_p}{x - K_l(t + t_o)} \qquad [7]$$

where t_o is the time at which the secondary process begins. Such an equation would be expected to apply to systems such as the oxidation of niobium studied recently by Cathcart, Campbell, and Smith (22).

Conclusions

It has been shown that a single rate equation can replace the need for multiple equations in several systems for which sufficient experimental data are available to test its validity. It is probable that, when more data are available, it will be possible to show its general applicability to other scaling reactions. For the systems discussed, the concept of transitions in mechanism occurring over certain temperature ranges has been shown to be an unnecessary complication of previous kinetic treatments. The present analysis emphasizes the fact that short duration experiments can be misleading in studies of scaling mechanisms.

The general validity of Eq. [5] for the systems discussed indicates that secondary processes, such as scale recrystallization, can be of considerable importance in determining the rate of scaling processes. The application of Eq. [5] in future studies, and further development of the mechanistic concept associated with it, should be helpful in improving our understanding of the mechanism of corrosion at high temperature.

Acknowledgment

The author is indebted to Mr. H. S. MacKinnon for valuable assistance in the analysis of the rate data reported and to Mr. R. S. Treseder and Dr. A. Wachter for encouragement and helpful discussions.

Manuscript received Oct. 13, 1958. This paper was prepared for delivery before the Ottawa Meeting, Sept. 28-Oct. 2, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

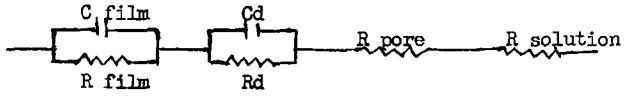
The Effect of Halides on the Capacity and Resistance of the Magnesium Electrode in Aqueous Solutions

G. R. Hoey and M. Cohen

Division of Applied Chemistry, National Research Council, Ottawa, Ontario, Canada

ABSTRACT

A study of potential-time decay curves at anodically and cathodically polarized magnesium by the d-c current interrupter method is presented. Potential-time oscillograms and polarization curves were determined for magnesium electrodes in buffered and unbuffered aqueous solutions containing chloride, bromide, iodide, and fluoride. Film capacity, solution double layer capacity, and resistance data determined from the oscillograms using the electrical analog



is presented where Cd and Rd are the capacity and resistance of the Helmholtz-Gouy double layer. The effect of specific adsorption of anions and the physical nature of the film on the magnesium electrode are discussed.

Local corrosion (1-3) and electrochemical formation of Mg^{+} (4-10), Mg_2^{++} (11), and $Mg \cdot Mg^{++}$ (3) have been suggested to explain the negative difference effect observed for magnesium. The existence of the ions Mg^{+}, Mg_2^{++}, and $Mg \cdot Mg^{++}$ has not been definitely established, and the negative difference effect of Mg may, in fact, be explained solely on the basis of local corrosion. It can be stated with certainty, however, that even if Mg^{+} is formed, local corrosion must also occur. This conclusion follows from the experimental facts: (*a*) values of the apparent Mg valency (determined coulometrically) less than unity as well as greater than unity have been observed; (*b*) a positive difference effect is observed for Mg at low anodic current densities in solutions containing HCl or NH_4Cl (9, 12). Observed Mg valencies greater than unity may be explained by electrochemical formation of Mg^{++}, either directly or via the reaction, $Mg^{+} \rightarrow Mg^{++} + e$ (5).

From the above considerations it may be concluded: (*a*) the potential of Mg is a mixed anodic-cathodic potential, and (*b*) although the mechanism of the local anodic reaction is uncertain it consists, in part, of the electrochemical formation of Mg^{++}, either directly or via monovalent Mg. The local cathodic reaction is generally the hydrogen evolution reaction but may under some experimental conditions consist both of the h.e.r. and the oxygen adsorption reaction (13, 14).

The potential of the Mg electrode may be under anodic, cathodic, or mixed control depending on the experimental conditions. In acid solutions (*p*H's < 3 in unbuffered solutions) the corrosion reaction is probably under cathodic control; the potential becomes more noble with increasing hydrogen ion concentration (15) and the corrosion proceeds under H_3O^{+} diffusion control (16, 17). At high *p*H's (*p*H $>$ 11 in unbuffered solutions), the potential increases sharply in the more noble direction with increasing *p*H and anodization causes passivation (15) which indicates that at high *p*H's the reaction is under anodic control. In the intermediate *p*H range the potential of Mg is practically independent of *p*H and a transition from cathodic to anodic control probably occurs. Film formation at high *p*H's undoubtedly plays a major role in the transition from cathodic to anodic control and there are indications that transport phenomena through surface film may be partly rate controlling even at low *p*H's (18). Although the chemical composition of the surface film is reasonably well established (19-23), little is known concerning such important factors as the conductivity and porosity of the film. The Mg electrode potential is dependent on the nature and concentration of inactive anions in solution (24) which suggests that specific adsorption effects of anions on the electrode might also be important.

This study was undertaken in order to gain further information on the roles of specific adsorption of anions and film formation in the electrochemical behavior of Mg. It was felt that a comparison of the effect of halide ions on the Mg electrode capacity, resistance, and polarization curves would provide information on specific adsorption and film effects. A limited amount of data exists in the literature which might be used for predicting the adsorption behavior of halide ions on Mg. Cl^{-1}, Br^{-1}, and I^{-1} form soluble salts with Mg, whereas MgF_2 is insoluble leading to passive films. The order of increasing adsorption of these ions on mercury are $F^{-1} < Cl^{-1} < Br^{-1} < I^{-1}$ (25). The fluoride ion is not considered to be specifically adsorbed on mercury. On platinum, I^{-1} is probably more strongly adsorbed than Cl^{-1}; the minimum in the Pt electrode capacity vs. potential curve for solutions containing I^{-1} is more cathodic than that for solutions containing Cl^{-1} (26). The same order of

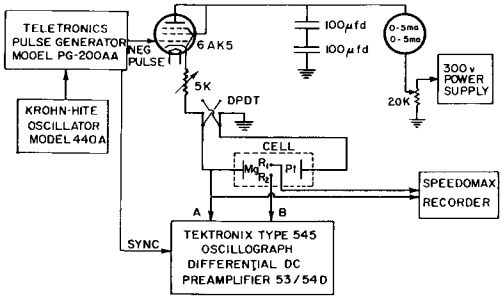


Fig. 1. D-C current interrupter apparatus

adsorbability of Cl^{-1}, Br^{-1}, and I^{-1} might be expected for Mg as for Hg and Pt.

Experimental

Polarization capacity and resistance was determined by the d-c current interrupter method. The current interrupter technique used was similar to that of Shuldiner and White (27). The circuit is given in Fig. 1. The cell was polarized by means of a constant current supplied in the plate circuit of the pentode 6AK5. The pentode was hooked up as a triode. By reversing the DPDT switch the Mg electrode could be made anodic or cathodic. The potential of the Mg electrode was continuously recorded on a Speedomax recorder. Potential-time oscillograms were determined as follows. A negative pulse with a rise time of 0.1 μsec was supplied to the grid of the pentode which shuts off the tube for the pulse interval; the Teletronics pulse generator was used to give interruption times from 1 μsec to 1 msec, and a Tektronix type 161 pulse generator was used for pulse widths from 1 msec to 0.1 sec. The pulse generator could be triggered by the oscillator to give from 0.1 pulses/sec to 5000 pulses/sec; repetition rates less than 0.1 pulses/sec could not be recorded on the oscilloscope. The pulse generator was triggered to a Tektronix type 545 oscilloscope which recorded the potential-time changes occurring at the Mg electrode during the current interruption. The maximum sensitivity of the Tektronix type 53/54D preamplifier was 1 mv/cm. Oscilloscope traces were photographed with a type 299 Dumas oscilloscope recording camera.

Potential-current polarization curves were determined using the constant current method. The Mg electrode was anodically polarized at 0.4 ma/cm² for 12 hr during which time the potential reaches a steady value. The current was then changed in steps lasting about ½ hr from 0.4 ma/cm² anodic to 0.4 ma/cm² cathodic and back again to 0.4 ma/cm² anodic in steps. At each setting of the current the potential was recorded on the Speedomax recorder and potential-time oscillograms were taken. The electrolytic cell was machined from Lucite, cylindrical in shape, with a slit along the top through which the reference electrodes could be immersed in the solution. The distance of the reference electrode from the Mg electrode could be varied along the length of the cell. The working electrode was platinized platinum; the reference electrode (R_1) was a silver-silver halide electrode; and R_2 was a Mg wire reference electrode (Fig. 1).

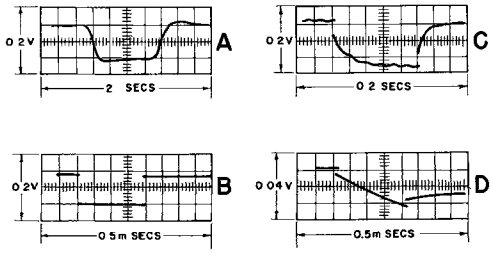

Fig. 2. Potential-time decay curves of anodically polarized Mg; A, B, and C; solutian, 0.05M NaOH, 0.186N H_3BO_3; 0.1M NaCl; pH = 8.9; 0.4 ma/cm². D; solution 0.1M NaF; 0.035 ma/cm².

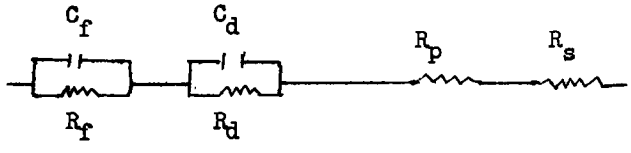
The Mg test electrode (area = 5 cm²) was machined from commercially distilled pure Mg. This material was supplied to have a minimum purity of 99.96% with a total Fe, Ni, and Cu content not greater than 0.005%. The Mg electrode surface was prepared by polishing on silicon carbide papers followed by a 1 min etch in 10% HNO_3 acid solution. The optical and electron microscopes revealed a clean surface preparation. By electron diffraction examination the film remaining on the Mg electrode after the chemical etch was shown to be MgO and $Mg(OH)_2$.

Solutions were prepared from reagent grade salts. During a run fresh solution was continuously supplied to the cell solution by means of an overflow system.

Results

Typical potential-time decay curves are given in Fig. 2, 3, and 4. The potential-time curves are interpreted in terms of the equivalent electrical circuit:



C_f is the capacity of the electrical double layer with the film as dielectric and R_f is the polarization resistance of the film; C_d and R_d are the capacity and polarization resistance of the solution electrical double layer; R_p is that part of the pore resistance of the film which is noncapacitive; and R_s is the resistance of the solution between the reference electrode and the magnesium electrode.

The equivalent electrical circuit is based on the model of the metal electrode given in Fig. 11 which

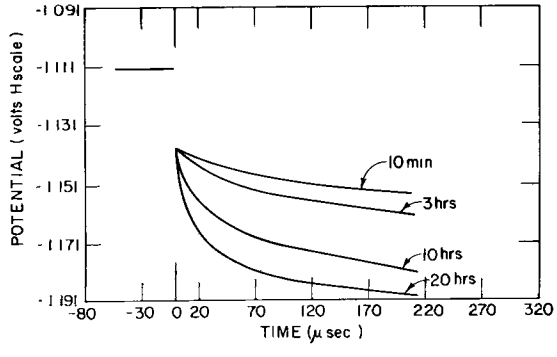


Fig. 3. Potential-time decay curves of anodically polarized Mg after various polarization times in a solution containing 0.1M NaOH; 0.1M H_3BO_3, and 0.1M NaBr; 0.4 ma/cm²; pH = 11.

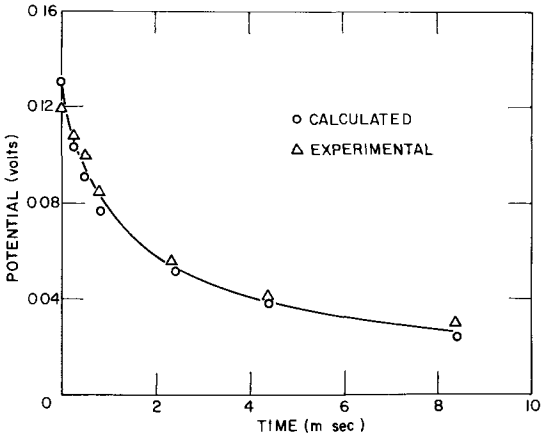

Fig. 4. Calculated and experimental potential-time decay curves of anodically polarized Mg in solution containing 0.05M NaOH, 0.186 H_3BO_3, and 0.1M NaCl; 0.4 ma/cm²; pH = 8.9.

is described in the Discussion. The solution double layer (Fig. 11) is considered to be in a pore of a nonconducting type film. The comparison of the electrical double layer of the electrode with an equivalent circuit is not strictly correct, but it is a simple and convenient manner in which to express the results of this type of experiment.

The components of the equivalent circuit are determined from the potential-time oscillograms. The potential drop which occurs in the first 0.3 μsec of the interruption in Fig. 2A, which will be called the series polarization, is the sum of the potential drops across elements of the equivalent circuit with time constants < 0.3 μsec; the series resistance (R_x) is equal to the series polarization divided by the value of the current before interruption. R_x is equal to the sum of R_p and R_s and will also include R_f and R_d if R_fC_f and C_dR_d is < 0.3 μsec. The residual series resistance exclusive of the solution resistance is obtained by measuring the series polarization at various points from the Mg electrode; R_s is a function of the distance of the reference electrode from the Mg electrode whereas R_f and R_p are not. Typical plots of the series resistance vs. the distance of the reference electrode from the Mg electrode are given in Fig. 5; the residual series resistance for both cases is 25 ohm-cm². For the experimental conditions studied in this work the contribution of the residual series resistance to the overpotential of the Mg electrode is less than 5% in active solutions and less than 1% in passive solutions.

The capacity of the Mg electrode (C) is defined by the expression:

$$C = -i^\circ/(dE/dt)_{t=0} \qquad [1]$$

where i° is the current at the moment of interruption and $(dE/dt)_{t=0}$ is the slope of the potential-time decay curve taken at $t = 0$.

The rate of potential decay across the capacitive part of the equivalent circuit is

$$dE/dt = -(E_f/R_fC_f + E_d/R_dC_d) \qquad [2]$$

where E_f and E_d are the potentials across the film and solution double layer circuits, respectively. At $t = 0$, $E_f/R_f = E_d/R_d = i^\circ$

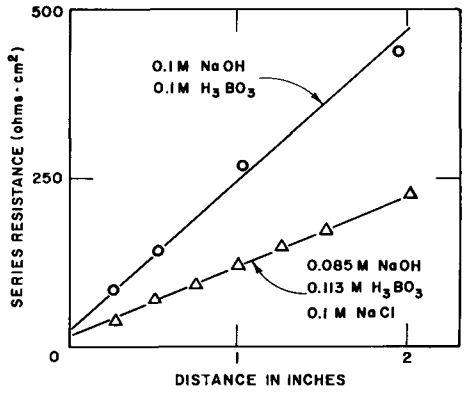

Fig. 5. Series resistance as a function of distance of the reference electrode from the Mg electrode: 0.4 ma/cm².

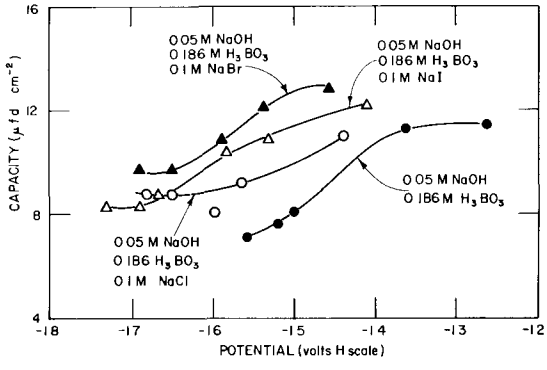

Fig. 6. Magnesium electrode capacity as a function of polarization potential; pH = 8.9.

$$(dE/dt)_{t=0} = -i^\circ(C_f + C_d)/C_fC_d \qquad [3]$$

and

$$C = C_fC_d/(C_f + C_d) \qquad [4]$$

Equation [3] is simplified when the time constants R_fC_f and R_dC_d are quite different, and then

$$(dE/dt)_{t=0} = -i^\circ/C_f \qquad [5a]$$

$$\text{or} \qquad = -i^\circ/C_d \qquad [5b]$$

depending on the time range studied by the oscilloscope. Magnesium electrode capacity data are given in Fig. 6 and Table I. The experimental capacities are correlated with the components of the equivalent electrical circuit in the discussion.

The parallel polarization resistance is obtained from the potential time oscillograms using the equation:

$$R_{f,d} = -\frac{|\Delta E|_{t=0}^{t=t}}{C} \Big/ |dE/dt|_{t=0}^{t=t} \qquad [6]$$

where $R_{f,d}$ is the parallel polarization resistance of either the film or the solution double layer; $|\Delta E|_{t=0}^{t=t}$ is the difference in potential and $|\Delta dE/dt|_{t=0}^{t=t}$ is the difference in rate of potential decay at times $t = t$ and $t = 0$. Equation [6] is valid when the time constants for decay across the film and solution double layers are equal or when one of the two decay rates is small compared to the other. Resistance data for the solutions studied are given in Table I. The reproducibility of $R_{f,d}$ determinations using Eq. [6] is about ±50%.

tions are given in Fig. 7, 8, 9, and 10. The reproducibility of potential measurements for the experimental conditions of Fig. 7, 8, and 9 is 30 mv and for Fig. 10 the reproducibility is 0.2 v. Cathodic polarization measurements of Mg in solutions buffered at pH = 11 containing NaCl, NaBr, or NaI and unbuffered solutions containing NaCl, NaBr, or NaI are nonreproducible and are not presented.

Discusssion

An exact theoretical treatment of the potential time curves observed in this work is not possible; the current density is probably nonuniform over the electrode surface and the electrochemical mechanism is complicated and uncertain. However, a semiquantitative and perhaps fortuitous agreement between the current interrupter theory and experiment was found.

An equation for the potential-time decay curves is derived in the following manner. Assume the rate-controlling reaction is:

$$Mg = Mg^{n+} + ne \qquad [7]$$

The forward current ($\vec{i}$) and the reverse current ($\overleftarrow{i}$) of reaction [7] are given by the equations (28),

$$\vec{i} = i_o \exp(\alpha n\mathbf{F}\,\Delta E_c/RT) \exp(\alpha n\mathbf{F}\,\Delta E/RT) \qquad [8]$$

$$\overleftarrow{i} = i_o \exp(-(1-\alpha)n\mathbf{F}\Delta E_c/RT) \exp(-(1-\alpha)n\mathbf{F}\Delta E/RT) \qquad [9]$$

$$i = \vec{i} - \overleftarrow{i} - i_{corr} \qquad [10]$$

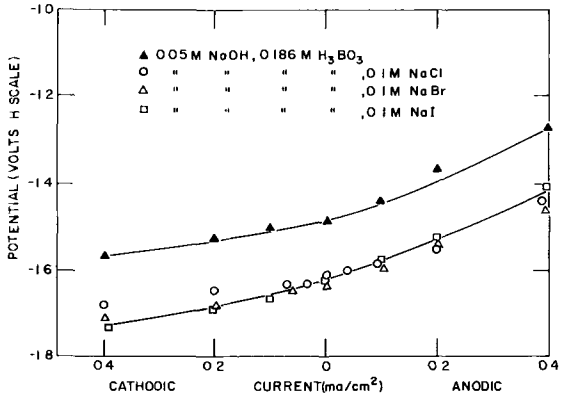

Fig. 7. Anodic and cathodic polarization curves of Mg corrected for series polorization; pH = 8.9.

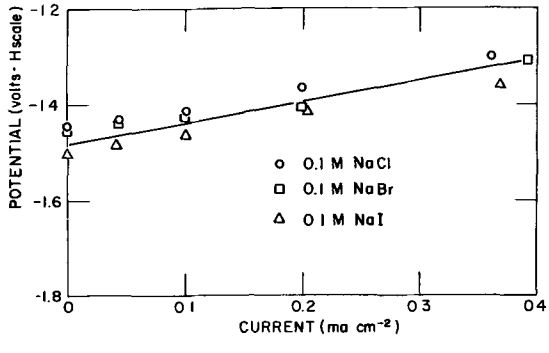

Fig. 8. Anodic polarization curve of Mg corrected for series polarization; pH = 10.5.

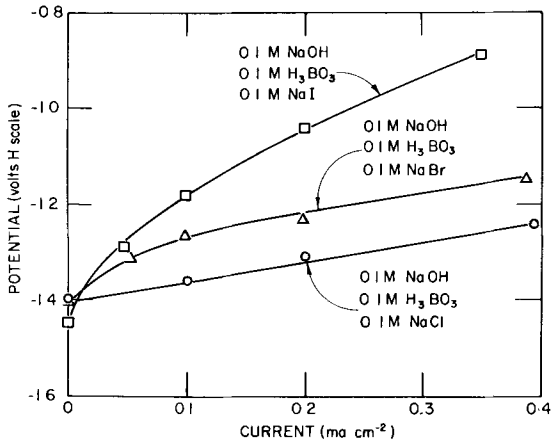

Fig. 9. Anodic polarization curve of Mg corrected for series polarization; pH = 11.

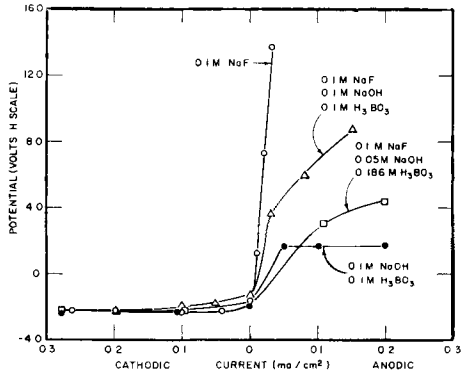

Fig. 10. Anodic and cathodic polarization curves of Mg corrected for series polarization; •, pH = 11; □, pH = 8.9; △, pH = 11; ○, pH = 10.

where $\Delta E = E - E_c$, and $\Delta E_c = E_c - E_o$; i_o is the exchange current and α is the transfer coefficient for reaction [7]; **F** is the Faraday; R is the gas constant; T is the absolute temperature; E is the polarization potential; E_c is the corrosion potential at zero applied current; E_o is the equilibrium potential for reaction [7]; i is the applied current and i_{corr} is the corrosion current. The current efficiency for the anodic dissolution of Mg assuming $n = 2$ (3) is independent of current density at high current densities ($i > 0.05$ ma/cm²) which indicates that the corrosion current is directly proportional to the applied current. Thus, it may be assumed that $i_{corr} = (K - 1)\, i$ where K is a constant ($K > 1$) which is independent of the applied current.

Since

$$dE/dt = -\, i/C \qquad [11]$$

then

$$\int \frac{d\,\Delta E}{\underset{i}{\rightarrow} - \underset{i}{\leftarrow}} = -\int (1/CK)\,dt \qquad [12]$$

where it is assumed that E_c and E_o are independent of applied current. Integration of Eq. [12] by Grahame's method (29) using the assumptions $\alpha = \frac{1}{2}$, $\exp(\alpha n\mathbf{F}\Delta E_c/RT) \approx 1$, and C is independent of ΔE yields the equation

$$\Delta E = \frac{2RT}{n\mathbf{F}} \ln \frac{1 + \exp(-n\mathbf{F}i_o(t + t^1)/RTCK)}{1 - \exp(-n\mathbf{F}i_o(t + t^1)/RTCK)} \qquad [13]$$

t is measured from the moment of interruption and t^1 has the meaning that ΔE would be infinite at $t = -t^1$. The assumption that $\exp(\alpha n\mathbf{F}\Delta E_c/RT) \approx 1$ may set a fictitious value to the equilibrium potential for reaction [7], i.e., $E_o \approx E_c$, when Eq. [13] is applied to a corroding Mg electrode; the simultaneous occurrence of the cathodic and anodic reactions on anodically polarized Mg could have the effect of displacing the experimental potential of the electrode from the potential of the anodic reaction toward the potential of the cathodic reaction if an appreciable ohmic potential drop exists between the reaction paths of the cathodic and anodic reactions.

Equation [13] was derived for an electrode with a uniform current density over the surface. In active solutions at pH = 8.9 a uniform attack occurs on Mg which indicates a uniform current density. The general form of the potential-time decay curves for Mg in this type of solution is represented by Eq. [13]. In Fig. 4 the potential-time decay curve for anodically polarized Mg calculated from Eq. [13] using assumed values of n, t^1, K, and i_o ($n = 2$, $t^1 = 0.1$ msec, $K = 2$, and $i_o = 0.024$ ma/cm²), and $C = 10$ μ f/cm² from initial slope compares well with the experimental potential-time decay curve. The rate of reaction [7] calculated from Eq. [10] is within an order of magnitude of the rate of dissolution of Mg in this particular solution at the same current (10^{-8} moles/cm²/sec).

In view of the many simplifying assumptions necessary for the derivation of Eq. [13] further interpretation of the results in terms of this equation would be unwarranted. The remainder of the discussion will be concerned with qualitative interpretation of the capacity and potential data in terms of the equivalent electrical circuit previously given and the following concept of the structure of the Mg electrode interface.

The structure of the Mg electrode interface will be assumed to be of the form schematically represented in Fig. 11. Positive and negative polarization refers to polarization relative to the potential of the zero point of charge. The anodic and cathodic reactions are assumed to occur at the barrier film-solution interface. In Fig. (11B) the electrode is considered to be sufficiently polarized to completely suppress the anodic reaction. The nature of the film is pH dependent. A thin nonporous barrier film is assumed to be present at all pH's. In active solutions, at pH's $\gtrsim 10.5$, thick white films (10^{-4} cm) are formed on Mg; at pH's < 10.5 thin films ($< 10^{-5}$ cm) are formed. The discontinuity in film formation is due to precipi-

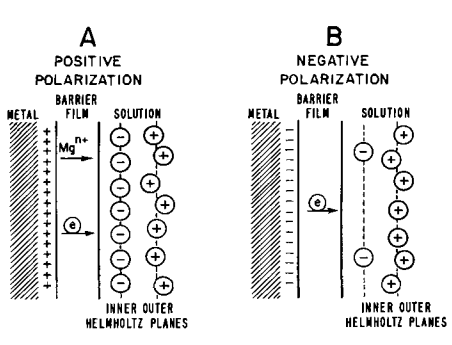

Fig. 11. Schematic diagrams of the electrical double layer of positively and negatively polarized Mg.

tation on the Mg at pH's $\geqq 10.5$ of $Mg(OH)_2$ from solution (3). At the low field strength used in this work transport of ions and electrons through the thick film would not occur for nonpassive films.

The capacity of the barrier film is a decreasing function of pH and polarization current since these factors would tend to increase the barrier film thickness. The polarization resistance of the barrier film is dependent on thickness and chemical and physical structure of the film; the latter factor controls the type of transport (ionic or electronic). The capacity of the solution double layer which includes the fixed double layer and the diffuse double layer is a complex function of potential; several maxima and minima are sometimes observed (25). In the simplest case the capacity of the solution double layer reaches a minimum at the potential of the zero point of charge and increased polarization increases the capacity due to the decrease in effective distance between the outer Helmholtz plane and the barrier film. The electrode capacity per unit of apparent area is directly related to the pore area and the polarization resistance of the electrode is inversely proportional to the pore area.

Specific adsorption of anions on Mg would have the effect of increasing the capacity of the solution double layer and displacing the potential of the zero point of charge to more cathodic potentials. Specific adsorption of anions provides a means of explaining the negative difference effect of Mg. Increased anodic polarization causes increased adsorption on the barrier film which results in an increased positive charge on the diffuse double layer and a closer proximity of the diffuse double layer to the barrier film. Hydrogen ions in the diffuse double layer are therefore more easily discharged at the barrier film by increased anodic polarization.

In the following sections a satisfactory explanation of the experimental results is presented in terms of the pore theory.

Buffered Solutions at pH = 8.9

The halide additions affect the polarization curves of the buffer solutions but no specific effect of the anions Cl^{-1}, Br^{-1}, or I^{-1} are apparent (Fig. 7). The shift in potential observed in solutions without halide additions is probably due to higher Helmholtz-Gouy double layer impedance corresponding to the lower conductivity of the buffer solution. The Mg electrode capacity is probably the solution double layer capacity (C_d) since the capacity increases as the anodic polarization is increased (Fig. 6). Thus, it appears that the time constant for decay across the barrier film at pH = 8.9 is less than 0.3 μsec. Specific effects of each of the halides on the capacity are not evident within the reproducibility of the experiments. The borate ion is apparently preferentially adsorbed on Mg in these solutions.

Cathodic polarization in the range studied does not effect a change in sign of the charge on the metal surface from positive to negative (Fig. 11) since the capacity did not go through a minimum on cathodic polarization. The rate of dissolution of cathodically polarized Mg in these solutions is quite large which serves to maintain the Mg metal surface positively charged or perhaps neutral (there is the possibility that the minimum in the capacity vs. potential curves was reached at the most cathodic potentials studied).

Buffered Solutions at pH = 11

The capacity of the Mg electrode at pH = 11 is considerably lower than the capacity at pH = 8.9 (Table I). A decrease in capacity of both the barrier film and the solution double layer is expected due to the decreased reacting area of the electrode and increased barrier film thickness. The formation of the porous film or barrier film is a slow process; the Mg electrode capacity changes from 2 $\mu f/cm^2$ at 10 min polarization to 0.4 $\mu f/cm^2$ at 20 hr polarization (Fig. 3). Trends of the observed capacity at pH = 11 with specific halide ion or potential may be hidden due to the low reproducibility of capacity measurements in these solutions. Therefore, it is not possible to decide whether the experimental capacity is C_f, C_d, or the series capacity, $C_f C_d/(C_f + C_d)$:

Buffered solutions at pH = 11 without a halide additive exhibit passive potentials on anodic polarization in contrast to solutions buffered at pH = 8.9 (Fig. 10). Halide additions destroy this passivity (Fig. 9). The order of increasing effectiveness of the halide ions as depassivating ions is $I^{-1} < Br^{-1} < Cl^{-1}$. The depassivating effect of halide additions on the passivity of Mg at pH = 11 is explicable in terms of the pore theory if it is assumed that the pore size is large enough for penetration by halide ions and too small for penetration by BO_3^{-3} ions. The relative depassivating effect of the halide ions may be due to the relative mobilities of the halide ions which follow this same order, i.e., $I^{-1} < Br^{-1} < Cl^{-1}$.

Unbuffered Solutions

The film formed on Mg in unbuffered solutions of NaCl, NaBr, and NaI is similar to that at pH = 11 but the pH in the pores is probably lower than the bulk pH of the unbuffered solution. The reacting area of the Mg metal surface is increased over that in buffered solutions at pH = 8.9 by a change in type of attack from general to pitting and film formation in unbuffered solutions tends to decrease the reacting area of the barrier film. Without a knowledge of relative roughness factors of the electrode it is impossible to compare observed capacities in unbuffered solutions with those in buffered solutions. The capacity of the Mg electrode in NaCl solution is significantly greater than for solutions of NaBr and NaI, which indicates that the Cl^{-1} ion is more strongly adsorbed on Mg than either the Br^{-1} ion or I^{-1} ion which is the reverse of what might be expected from data on Pt and Hg (25, 26). If this is true specific adsorption of anions does not produce significant changes in the potential of Mg (Fig. 8). The capacity of the Mg electrode in 0.1M NaCl solution determined by Tomashov, *et al.* (13) using the a-c bridge method (500-5000 cps) is 7-8 $\mu f/cm^2$ which is in good agreement with this work (9 $\mu f/cm^2$).

Sodium Fluoride Solutions

Magnesium in NaF solutions exhibits high anodic polarization (Fig. 10); the rest potential is active yet the corrosion rate is small. These facts may be ex-

plained by a pore theory with the following assumptions: the barrier film is nonporous MgF_2 with inclusions of porous film; the area of the porous film is small compared with the area of the nonporous film; and the nonporous film becomes charged on anodic polarization, but electrochemical reaction both cathodic and anodic occurs only at the porous areas. Thus, at zero applied polarization the corrosion of Mg occurs at a slow rate at the pores which explains the active rest potential observed; anodic polarization would partially fill up the pores with MgF_2 at a rate proportional to the applied polarization current and raise the potential in the pores to passive potentials. The anodic overpotential of Mg is less in buffered solution of NaF than in unbuffered solutions. Evidently the BO_3^{-3} ion has a similar effect on the passivity of Mg in NaF solution as Cl^{-1}, Br^{-1}, and I^{-1} have on the passivity of Mg in the buffer solution at pH = 11 but to a much lesser degree. Partial filling up of the pores with $Mg(OH)_2$ explains the fact that the anodic overpotential is higher for NaF solutions buffered at pH = 11 than at pH = 8.9. The relatively lower overpotential for the cathodic polarization indicates that cathodic polarization does not reduce the pore area.

The capacity in buffered and unbuffered solutions of NaF varied from 0.3 to 0.5 $\mu f/cm^2$ over the entire potential range studied. The invariance of the capacity over the large range of potentials suggest that the capacity is due to the nonporous areas of the film, the effective thickness of which is independent of potential. The double layer with the nonporous areas of the film as dielectric discharges through the pores in the film.

Resistance Measurements

In solutions containing fluoride the parallel polarization resistance ($R_{f,a}$) varied from 600 ohm-cm^2 to 3200 ohm-cm^2; in all other solutions the parallel resistance varied from 25 ohm-cm^2 to 250 ohm-cm^2. Little significance can be given to the values of $R_{f,a}$ due to the poor reproducibility except to state that the relative magnitude of $R_{f,a}$ for Mg in NaF solution indicates that the pore area is smaller than for the other solutions.

The contribution of the ohmic potential drop to the total overpotential of Mg in the passivating solutions studied in this work is less than 1% which is in general agreement with the work of Epelboin, *et al.* (30). By application of a circuit breaking technique Epelboin, *et al.* (30) have shown that the high potentials observed in passivating, anodic oxidation, and electrolytic polishing experiments are not due to diffusion overvoltage or ohmic drop but are probably due to adsorption effects of anions at the metal surface.

Acknowledgment

The authors wish to express their appreciation to Mr. L. T. Bradley for assistance in the design of the d-c current interrupter apparatus, and to Dr. P. B. Sewell and Mr. E. G. Brewer for examination of the magnesium surface preparation used in this work by electron diffraction and the electron microscope.

Use of Nickel-Aluminum Alloy Coatings for the Protection of Molybdenum from Oxidation

W. Beck[1]

American Electrometal Corporation, Yonkers, New York

ABSTRACT

Coatings produced by electrodeposition of aluminum on nickel-plated molybdenum protect this metal effectively against high-temperature oxidation. Information about composition and distribution of the Ni-Al phases formed in the coating was obtained from a metallographic analysis of a layer created by deposition of aluminum from the cryolite bath on a sheet of high-purity nickel.

Effective protection of molybdenum against high-temperature oxidation by a coating consisting of nickel aluminides has been reported recently by Couch, Shapiro, and Brenner (1). The coating was produced in an unorthodox fashion by electrodeposition (1, 2) of aluminum from a fused cryolite bath onto nickel, which had been plated from an aqueous solution onto chromium-plated molybdenum. Some years ago, the author of this report (3) succeeded in imparting to Mo, protection against high-temperature oxidation by converting its surface into a Mo-Al alloy, created during electrodeposition of Al from the cryolite bath.

This paper is concerned with the production of Ni-Al coatings on Mo, removal of bath salts from the coating, testing of the effectiveness of the alloy layer to protect Mo against high-temperature oxidation, and the metallographic studies of a Ni-Al diffusion couple.

These investigations were completed some years ago but were not published until now.

Experimental Procedures and Results

Specimens and pretreatment.—The specimens consisted of rods of Mo of 99.9% purity, ¼ in. in diameter and 6 in. long. The ends were rounded in order to avoid sharp angles, ground with a green wheel, and finally polished on a hard rubber wheel.

Various pretreatments were used to achieve satisfactory adhesion of the Ni plate to the Mo surface, including an anodic treatment in HF-HCl mixture and immersion in aqua regia. The latter method, which gave the best results, consisted of a 1-min dip in the acid mixture, followed by cleaning the specimen with cotton under streaming water. This procedure was repeated several times. Immediately following the last immersion and cleaning, the specimen was Ni plated.

Nickel plating.—Nickel was electrodeposited from a Watts-type bath. The average plating thickness was 0.8 mil.

Aluminum plating.—Aluminum was deposited on the Ni plating from a eutectic mixture of 75% cryolite with 25% NaF at a temperature of 1005° ± 5°C. A uniform coating was obtained only when the total concentration of Al in the bath was kept above a minimum value. The Al used up during plating was replaced when necessary by recharging the crucible containing the bath with Al_2O_3 (saturated concentration of Al_2O_3 in the eutectic mixture at 982°C is 15%).

After keeping the rods in the bath for 1 min, Al was plated at a current density of 0.15 amp/cm^2. The approximate total thickness of the aluminide layer, after a plating time of 15 min, was 1.8 mil.

All coatings were produced in a graphite crucible which served as the anode. Bath components were fused by means of high-frequency heating.

Leaching of excess Al and bath salts and testing for protection against high-temperature oxidation.—To avoid premature breakdown of the coatings in the blast burner test to be described below, it is of the utmost importance to remove from the surface excess Al and cryolite without attacking the coating itself.

Numerous attempts were made to solve this problem; some of the results are reproduced in Table I. Most effective and least damaging is apparently a 20% HCl solution when used at room temperature.

After leaching, the rods were fastened securely in holders and about 1 in., measured from the tip of the rod, was inserted in the oxidizing cone of an air-gas blast burner. The temperature of the specimens in the flame was determined by optical measurements to be approximately 800°C. They were kept in the flame until the coating broke down and the Mo began to oxidize, evidenced by a change in color of the flame from reddish orange to bright yellow, which is caused by the oxidation products of Mo. The times to breakdown recorded on specimens leached in different solutions are listed in Table I.

Microscopic examination of the nickel-aluminide coating, as plated and after breakdown.—Two sections were taken through each rod after breakdown had occurred, section A about ¼ in. from the tip of the rod, section B approximately 1 in. from section A.

The specimens were mounted in a mixture of amber Bakelite and phenolic resin which has been found to be particularly suitable for coated material,

[1] Present address: Aeronautical Materials Laboratory, Naval Air Material Center, Philadelphia 12, Pennsylvania.

Table I. Time to breakdown of coated Mo specimens exposed to blast burner after leaching of excess Al and bath salts

Composition of coating	Average thickness of alloy coating, 1.8 mil Leaching solution	Appearance of solution or coating after leaching	Time to breakdown in hours in blast burner, Temp. of specimens about 800°C
Ni-Aluminide	Specimen quenched without delay in 20% HCl	Solution showed in all cases green color [1]	Max. 435 Min. 208[2]
Ni-Aluminide	Specimen cooled to room temperature and leached in 20% HCl	In some cases, solution showed slight green color	Max. 1100 Min. 100[2]
Ni-Aluminide	Specimen cooled to room temperature and leached in 37% (conc.) HCl	No change in color became visible	Max. 200
Ni-Aluminide	Specimen cooled to room temperature and leached in 20% NaOH[3]	Coating changed color from dark to black	Max. 100
Mo-Aluminide	Dip in alkali melt[4] followed by leaching in 20% HCl	No change in color became visible	Max. 600
Ni plated from aqueous solution	—	—	Max. 24

Notes:
[1] Leaching time in HCl in all cases was 2 hr; leaching solution was frequently renewed.
[2] Total number of leached specimens was in all cases 10; 80% of specimens had maximum lifetime.
[3] Leaching time was at least 4 hr.
[4] Alkali melt consisted of 60% NaOH and 40% Na_2CO_3 and was used at 540°C.

polished in the conventional manner, etched with Kellers (4) reagent, and then repolished. Subsequently, photomicrographs were taken.

Figures 1 to 3 are photomicrographs of section A. Figure 1 pictures a specimen in the as plated condition. Micrographs shown in Fig. 2 and 3 are taken on specimens after 100- and 540-hr exposure to the blast burner. The coatings represent single phase systems and a number of breakdowns can be distinguished. The coating thickness decreases slightly with increasing oxidation time.

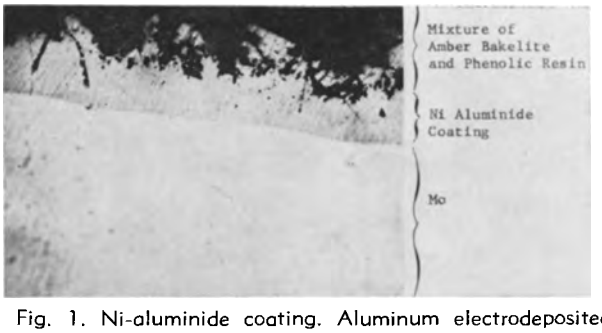

Fig. 1. Ni-aluminide coating. Aluminum electrodeposited from eutectic NaF-cryolite bath on Ni plated on Mo; as plated; leaching in 20% HCl; Keller's etch. Magnification 500X before reduction for publication.

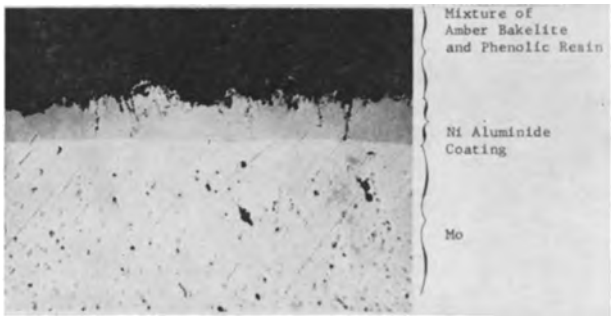

Fig. 2. Ni-aluminide coating. Breakdown after 100-hr exposure to oxidizing flame at approx. 800°C; leaching in 20% HCl; Keller's etch. Magnification 500X before reduction for publication.

Figure 4 exhibits the characteristic "oxidation fingers" which are formed after the coating has broken down and the unprotected Mo is exposed to oxidation. There were no startling differences between the A and B sections.

Phase identification in a Ni-Al *diffusion layer.*— Various attempts to identify the phases formed in the nickel aluminide layer on Mo were not successful, therefore, a different approach was used. Aluminum was electrodeposited from the cryolite bath saturated with Al_2O_3 onto a sheet of A nickel (5),

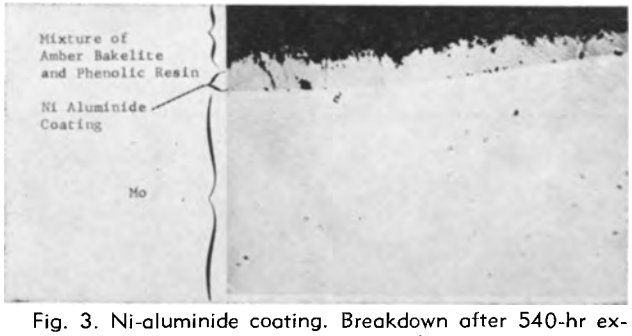

Fig. 3. Ni-aluminide coating. Breakdown after 540-hr exposure to oxidizing flame at approx. 800°C; leaching in 20% HCl; Keller's etch. Magnification 500X before reduction for publication.

Fig. 4. Type of oxidation fingers formed by oxidation of Mo on breakdown points of Ni-aluminide coating at 800°C. Magnification 500X before reduction for publication.

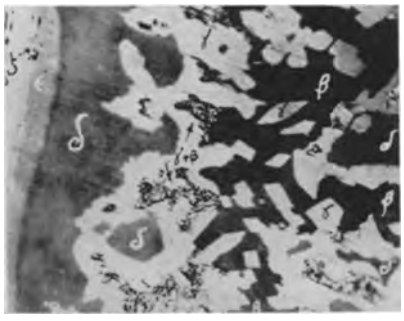

Fig. 5. Phases and phase distribution in Ni-Al diffusion layer produced by electrodeposition of Al from a eutectic NaF-cryolite bath (saturated with Al_2O_3) on a sheet of A Ni. Excess Al was removed in 20% HCl, anodic etch in 1 part conc. HCl with 3-5 parts ethyl alcohol, 1 v, 0.5 amp/in.^{2}, 10 sec. Magnification 1000X before reduction for publication.

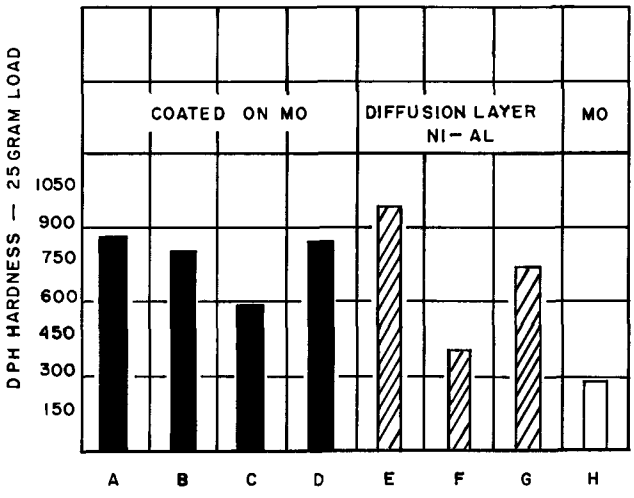

Fig. 6. Hardness measurements made at room temperature: A, Al on Ni, as coated; B, Al on Ni, exposed for 540 hr at 800°C; C, Ni on Al, as plated; D, Ni on Al, exposed for 540 and 1000 hr at 800°C; E, δ phase; F, γ phase; G, β phase; H, Mo.

which was polished to a mirror finish and degreased prior to plating.

The longest time of electrolysis was 5 hr. A number of experiments were made with shorter exposures; however, this did not produce any essential change in the phase distribution shown in Fig. 5. The current density was the same as that used to deposit Al on Ni-plated Mo. After removal from the cryolite bath, the specimen was cooled in ambient air and the coating etched anodically (6).

At the current density and plating time employed, it has to be inferred that the Al diffuses essentially from the liquid phase into the solid Ni after being formed at the cathode, by "direct" electrochemical reduction of an Al donor (7, 8). The Ni is thus in contact with superheated molten Al at a temperature a little above two-thirds of its melting point. By reference to the phase diagram (9), it may be ascertained that Ni may take upwards of about 6 w/o (or 12 a/o) approximately of Al to form the solid solution phase zeta (ζ). This may be assumed to take place by the simple dissolving action of molten Al on Ni, a mutually interpenetrating action between the Al and Ni caused by their comparatively equal atomic sizes, unit cell structure, high temperature, and driving force of the current in the electrolytic cell.

The intermediate phases or secondary solid solutions ε, δ, and γ (10), occur in sequence as the distance from the surface of the Ni is increased. These may be assumed to have been nucleated by a diffusion process dependent on the operation of Fick's law at the environmental conditions obtained in the cryolite cell. The basis of the identification of these various secondary solid solution phases lies in their proximity, or lack of it, to the surface of the Ni cathode, their comparative hardness determined by microhardness tests (to be presented in the next section), and their obviously different etching characteristics.

On removal of the Ni cathode from the cryolite bath, an interface between the γ secondary solid solution and molten Al would be formed. On cooling, as may be seen from the phase diagram (9), the incongruently melting phase β would be formed by the peritectic reaction of the γ and molten Al.

This is believed to be the origin of the mixed black and white areas which appear as islands interspersed in the γ secondary phase. A peritectic reaction would also explain the proximity of the free β phase to these areas. The β phase was also identified by its comparative hardness.

Hardness measurements.—Hardness measurements were made with the Bergsman hardness tester and are presented in Fig. 6. These values are the averages of 3 determinations. Nickel aluminides of three different compositions, Ni_2Al_3, NiAl, and $NiAl_3$, were made by casting (11) and their hardnesses determined. Hardness values of some of the phases formed when Al was deposited on the Ni sheet were determined also. Comparison of these values with those of the cast nickel aluminides was then used as one method of identifying the γ, δ, and β phases in the diffusion coating.

As may be seen from Fig. 6, the hardness values determined on the coatings on Mo did not correspond directly to any Ni-Al system. However, the hardness of the coatings in the as-plated condition and after oxidation periods of 540 and 1000 hr was close to that of the very hard, high melting δ phase.

That the coatings contained ample Ni and Al was proven by chemical analysis of a strong HCl solution in which the coatings had been stripped anodically.

Coatings of Ni on diffused Al.—The adhesion of Ni plated on Mo covered with a molybdenum aluminide coating produced by electrodeposition of Al from the cryolite bath was excellent. The molybdenum aluminides are characterized by good electrical conductivity and, therefore, Ni can be plated on them easily from an aqueous solution. The author has succeeded in identifying by x-ray diffraction (3) the two brittle intermetallic systems, Al_2Mo and Al_5Mo, in the coating and, as could be expected, the oxidation life of specimens covered with a molybdenum aluminide layer, overplated with nickel, was rather limited.

Further work to improve the effectiveness of the protection of Mo against high-temperature oxidation by coatings containing Ni and Al, the latter being

electrodeposited from the cryolite bath, should, therefore, be restricted to the nickel aluminides.

Electroplating Metal Contacts on Germanium and Silicon

Dennis R. Turner

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Various metals have been plated on germanium and silicon. These semiconductors usually have oxide layers on them which could interfere with the intimate contact required between metal and semiconductor for good adhesion and the desired electrical properties. Oxide films and residues from chemical etching on germanium can be removed by cathodic reduction prior to metal deposition in many plating solutions. Sixteen different metals were plated on n- and p-type germanium. Since oxide films on silicon are difficult to reduce cathodically, other methods of removing the oxide film are employed to produce adherent electrodeposits on silicon.

Solid-state electronic devices made from semiconducting materials require some kind of electrical contact to the semiconductor. Electroplating techniques have been used to make ohmic contacts to semiconductors for many years. More recently, good rectifying contacts have been made by electroplating small metal spots ($\sim 10^{-3}$ cm^2) on germanium and silicon (1-4). Much of this work was carried out using a jet plating technique. One of the best types of plating baths, cyanide solutions, was avoided completely. This paper discusses the results of experiments which sought to determine the solutions and conditions that give high quality, large area deposits with maximum adhesion on Ge and Si. Either ohmic or rectifying contacts can be obtained by electroplating the proper metal on Ge and Si.

Germanium

Semiconducting materials usually have oxide layers on them which could interfere with making an intimate contact between plated metal and the semiconductor. Some oxides on metals can be removed by electrochemical reduction. For example, Linford and Feder (5) have shown that copper oxide layers up to about 650Å thick are completely reduced electrochemically prior to nickel deposition. Turner (6) demonstrated that the continuous monolayer of oxide formed on Ge during anodic dissolution is reduced cathodically in acid solutions prior to hydrogen gas evolution. Many residues from chemical etching and oxide films thicker than a monolayer on Ge can also be reduced electrolytically. This is demonstrated in Fig. 1. If a Ge electrode is chemically polished in C.P.-4 solution,[1] rinsed in distilled water and then subjected to a cathodic treatment in 0.1*N* H_2SO_4, a cathodic reduction curve is obtained. The number of coulombs in the potential arrest stage corresponds to about 2 atom layers of oxide.[2] The cathodic reduction curve obtained on a Ge electrode previously anodized in a fused salt bath (34% $LiNO_3$ + 66% KNO_3, mp $\sim$ 155°C) to produce a thicker oxide layer

[1] Composition of C.P.-4 etch: 5 parts by vol. conc. HNO_3, 3 parts by vol. 48% HF, 3 parts by vol. glacial acetic acid, and 10 drops liquid bromine/50 cc of acid mixture.

[2] Acid fluoride solutions may actually leave a fluoride film on the surface.

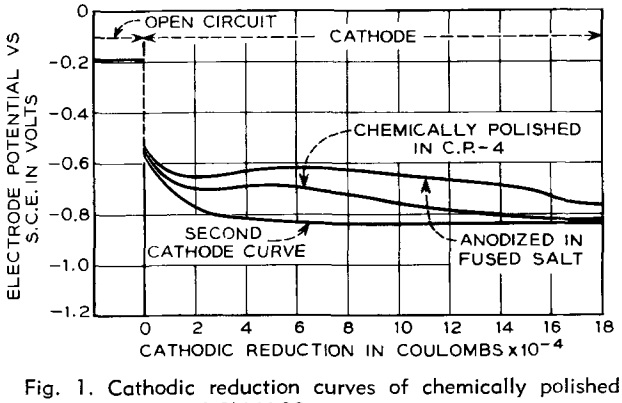

Fig. 1. Cathodic reduction curves of chemically polished and anodized Ge in 0.1N H_2SO_4.

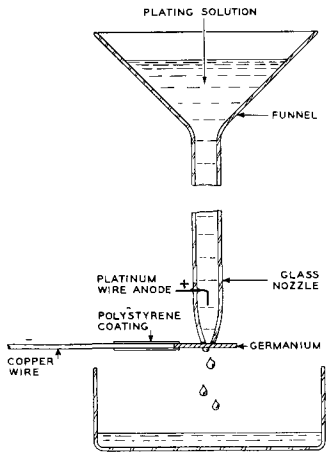

Fig. 2. Experimental arrangement for plating metal spots on Ge.

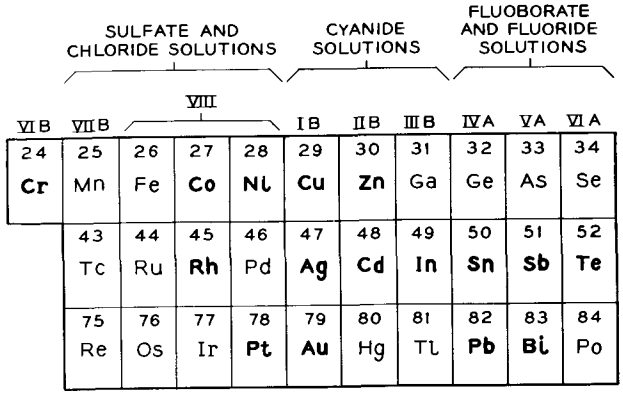

Fig. 3. Metals plateable from aqueous solutions. Bold lettered metals were plated on Ge. Preferred plating solutions are indicated above table.

is also included in Fig. 1. The length of the potential arrest corresponds to about 4 atom layers of oxide. The second cathodic curve obtained in each experiment is included to show that all reducible material is removed in the first cathodic treatment and that the reduced material in the initial curve is not due to some solution impurity. Schmidt (7) has found that thick layers of GeO_2, formed anodically in N-methylacetamide, can be reduced in the same solvent.

These results suggest that the best choice of metals and solutions for electroplating intimate metal contacts on Ge are those which deposit metal only after all oxide films or residues from chemical polishing are removed by cathodic reduction.

Experimental

The experiments were carried out with Ge electrodes about 1 cm square by 1 mm thick. These were cut from two single crystals, one 4-ohm cm n-type Ge and the other 3-ohm cm p-type Ge. An ohmic contact was made to the Ge by abrading one edge and soldering it to a 1.3 mm (0.050 in.) diameter copper wire using a standard lead-tin solder and an acid zinc chloride flux. The solder joint and about 2 cm of the copper wire were coated with polystyrene cement to protect them from the acid etches used later. Prior to plating, the surface of the germanium was chemically polished in the C.P.-4 solution. After a thorough water rinse the Ge was placed against a glass nozzle as shown in Fig. 2. This procedure confined the area of metal plated mainly to the inside diameter of the nozzle tip. A Pt wire sealed into the glass about 2.5 cm above the nozzle tip served as the anode. A glass or polyethylene funnel served as the solution reservoir. Plating solutions that work best above room temperature were preheated prior to filling the funnel. A section of Tygon tubing connected the funnel to the nozzle. Relatively high plating current densities were possible since the solution flowed continuously during plating. About 0.025 mm (0.001 in.) of metal was plated for the contact studies. After plating, the samples were water rinsed and given a brief etch in a suitable acid solution to remove the feather edge around the main spot of metal. This acid etch after plating was often essential for good rectifying contacts.

Sixteen different metals were plated on n- and p-type Ge. They represent practically all of the readily plated metals. The section of the periodic table containing all the elements plateable from aqueous solutions is shown in Fig. 3. The bold lettered metals were plated in this study. The preferred solutions, with a few exceptions, are indicated above the chart. A sulfate solution was used to plate indium instead of the cyanide bath because it was more stable chemically. As a rule the cyanide solutions are to be preferred in this application since metals deposit in them at potentials considerably more negative than that required to reduce oxide films on Ge. Electrodeposits from cyanide baths also are usually of good quality, i.e., smooth and dense. The chromium spots were plated from a standard chromic acid sulfate bath. Bismuth was plated from a perchlorate solution (8) while the tellurium deposits were obtained from a fluoride-sulfate solution (9).

Only technical grade chemicals were available for some of the plating baths. These solutions were purified electrolytically to remove metallic impurities. Overnight electrolysis with a dummy Pt cathode at 2 ma/cm^2 current density was usually sufficient.

Electrical contact to the plated metal spot was made by touching it with a loop of gold wire. Measurements of the electrical properties of the metal-germanium junction consisted first of observing the E-I pattern on an oscilloscope screen using a conventional display circuit and then making a point by point plot of both the forward and reverse E-I characteristic using d. c.

Results of Plated Metal Contacts on Ge

All the plated metals tested except antimony produced rectifying contacts on n-type Ge and ohmic contacts on p-type Ge. Electroplated Sb contacts behaved just the opposite, i.e., they were ohmic on n- and rectifying on p-type Ge. Borneman, *et al.* (3) reported that all plated metals gave rectifying contacts on n- and ohmic contacts on p-type Ge. The reverse voltage-current curves of the sixteen metals plated on n-type Ge are shown in Fig. 4. These results were obtained with circular metal spots about 2 mm in diameter. Most of the curves have the same general shape but are displaced from one another along the current axis. The large differences in the

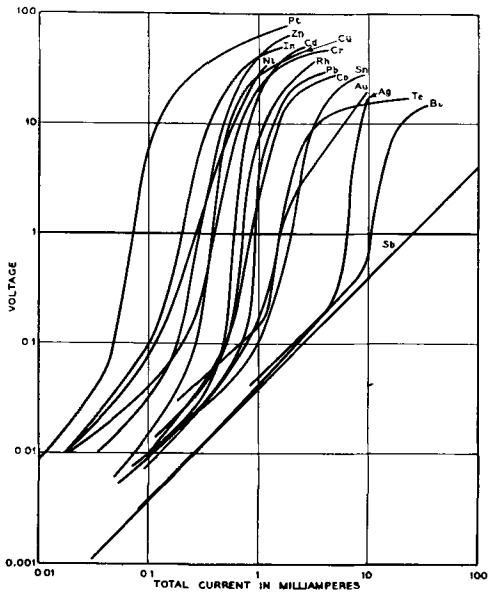

Fig. 4. Reverse curves for 2 mm diameter plated metal contacts on n-type Ge (measured in room air).

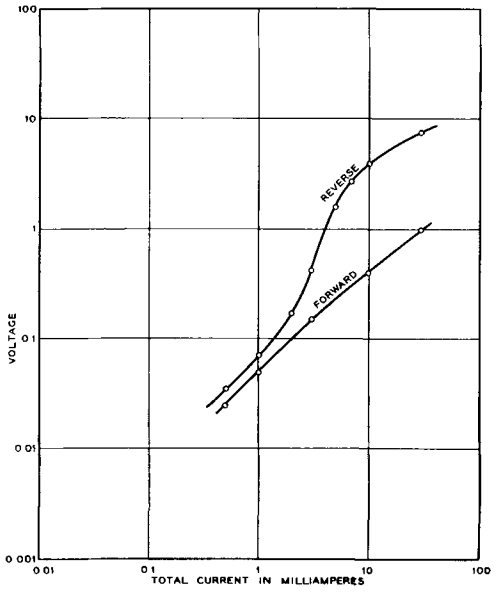

Fig. 5. Forward and reverse curves for a 2 mm diameter plated Sb spot on p-type Ge.

saturation currents are attributed to variations in the state of the surface after etching and also to differences in the adhesion of the various electrodeposits on Ge. In general, the poorer the adhesion the higher the saturation current. The silver deposits on Ge had the poorest adhesion of all and one of the highest saturation currents. Plated 2 mm diameter Sb contacts on n-type Ge were ohmic up to the highest current passed through the contact, 200 ma.

When the results with Sb were obtained, it was thought that perhaps all the metals in groups VA and VIA of the periodic table would behave the same way. Initial tests with Bi and Te in fact did give nearly ohmic contacts to n-type Ge. After the Bi and Te plating solutions were purified by electrolysis, however, both metals produced rectifying contacts on n-type Ge as shown in Fig. 4.

An interesting effect was observed with nickel plating on Ge when the solution was at room temperature. The Ni deposit often curled up at the edges a short time after plating and attached to the Ni were large pieces of Ge. There is a certain amount of hydrogen codeposited with Ni which produces a stress in the deposit. Since the adhesion between electroplated Ni and Ge is good, the stress in the deposited Ni is transmitted to the Ge. The stress apparently is sufficient to crack the Ge under the Ni and the peeling is actually due to this rupture in the Ge. The effect was eliminated when a hot (~60°C) Ni plating solution was used. An increase in the plating solution temperature presumably decreases the amount of codeposited hydrogen in the Ni which reduces the stress transmitted to the Ge under the deposit.

Antimony, the only metal found to give rectifying plated contacts on p-type Ge, was plated from a fluoborate solution. It was prepared by dissolving 6 g of technical grade antimony fluoride in 100 ml of solution containing 10 g of fluoboric acid. As made up, the solution produced Sb-plated spots which were ohmic on both n- and p-type Ge. After electrolytic solution purification, the antimony deposits on n-type Ge remained ohmic but those on p-type Ge became rectifying. Figure 5 shows the forward and reverse voltage-current curves for a 2 mm diameter plated Sb spot on p-type Ge. This represents the first time a rectifying characteristic has been obtained by electroplating a metal contact on p-type Ge. The saturation current in the blocking direction probably could be lowered by the use of plating solutions made from very pure materials. Schmidt (7) reports that a lithium pressure contact on p-type Ge is rectifying. This is attributed to the diffusion of donor lithium atoms into the Ge which converts the surface region to n-type.

Silicon

Metals electroplated on polished Si using ordinary plating techniques have poor adhesion and the deposits usually blister. Wurst and Borneman (4) plated small metal dots on Si using the jet electroplating technique and reported good adhesion. Using their pretreatment procedures and plating solutions, metal electroplated on polished Si specimens with about 2 cm^2 surface area always blistered. The poor adhesion is attributed to a surface oxide layer which cannot be reduced cathodically in aqueous solutions prior to metal deposition as it is on Ge. Archer (10) has estimated the oxide layer thickness on Si after etching to be about 10Å or 2 to 3 atom layers. To improve the adhesion between plated metal and Si, the oxide film must be removed or at least reduced in thickness. Silicon dioxide is soluble in both strong alkaline solutions and HF.

One method which has been found effective in improving the adhesion considerably is to subject the Si to a brief etch in a hot concentrated potassium or sodium hydroxide solution prior to metal plating in a hot cyanide plating bath. Hot, strongly alkaline solutions attack Si vigorously. The Si is transferred quickly from the hot alkaline solution to the plating bath without rinsing and with current on as the Si enters the plating solution. By not rinsing the Si, the corroding effect of the hot alkaline solution continues

until metal deposition begins. By this process, metal plates over at most a monolayer of oxide, and in some places there is direct contact between plated metal and semiconductor.

Another method which gives adherent Ni deposits on Si makes use of a Ni plating bath containing HF. The Si is allowed to soak in the plating solution for about 1 min before the plating current is started. Hydrofluoric acid dissolves silicon dioxide, but the surface may not be clean since there is some evidence that the fluoride simply replaces the oxide on the surface (11). Whatever the mechanism, the adhesion of a subsequent Ni deposit is greatly improved by this procedure. A Ni plating solution developed for plating Ni on Mg (12) was found to be satisfactory: HF (48%) 78 cc/l, citric acid 30 g/l, basic nickel carbonate 130 g/l, wetting agent (sodium lauryl sulfate) 20 drops/l.

Six metals were plated on chemically polished Si using one of the preplating procedures just described. Results are summarized in Table I. The plating solutions used were of standard composition. A "strike" plating technique improved the adhesion of Cu and Zn deposits but not the others. The high initial current density in Cu and Zn plating was reduced after a few seconds to deposit the bulk of the metal. Copper deposits were the most adherent, while Zn gave the poorest results by comparison. The test for adhesion consisted simply of cutting through the deposit by scratching with a sharp object. Even Zn plating, however, did not show signs of the blistering which is common when metals are deposited on Si by ordinary procedures.

The electrical properties of these metal contacts on n- and p-type Si are also given in Table I. These results were obtained with metal spots 1 mm in diameter. Qualitatively they agree with those reported by Wurst and Borneman (4) except for Cu and In on n-type Si, which gave opposite results.

Effect of Semiconductor Electrode

The semiconducting properties of Ge and Si have not been a factor in the electroplating results discussed thus far. Brattain and Garrett (13) have shown that holes are required to carry out anodic processes on semiconductors and electrons are necessary for cathodic reactions. An adequate supply of electrons are present at the surface of n-type semiconductors, under cathodic bias, since they are the majority current carrier. Relatively few electrons are available in p-type Si. If the surface of p-type material is abraded, additional electrons become available at the surface due to a large increase in the generation-recombination rate of hole-electron pairs. A light of high intensity directed at the Si will also raise the minority carrier concentration at the surface. The comparatively few electrons at the surface of chemically polished p-type semiconductors exposed to subdued room light are depleted in a cathodic reaction at very low current densities. This surface depletion of electrons results in a space charge region in the semiconductor. It can be thought of as a concentration polarization of electrons in the semiconductor. Attempts to increase the cathode current by applying more voltage to the cell merely result in increasing the depth of the space charge region in the semiconductor. The current barrier at the surface of the semiconductor eventually breaks down, allowing more current to flow, if the applied voltage is high enough.

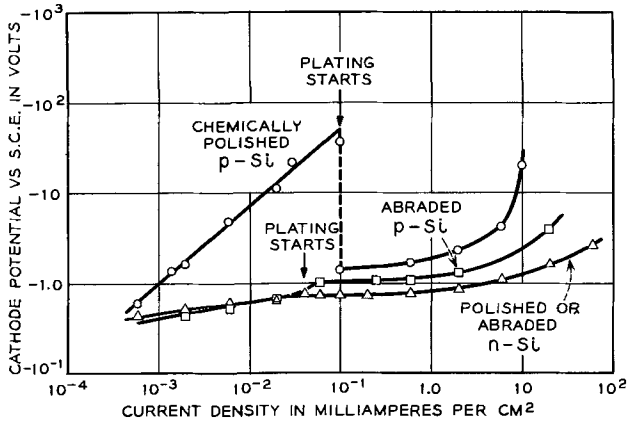

Fig. 6. Cathode potential-current density curves for Ni plating on abraded and polished n- and p-type Si.

An example of what may be encountered in attempting to plate metals on chemically polished p-type semiconductors is illustrated in Fig. 6. It is a log-log plot of the cathode potential vs. current density of 1Ω cm n- and 12Ω cm p-type Si with abraded and polished surfaces in a Ni plating solution. These data were obtained by increasing the current in steps. The current was held constant at each setting and the electrode potential measured when it appeared to reach a steady state. The plating bath was a standard "cold" Ni solution containing nickel chloride, ammonium chloride, and boric acid. Below about 0.1 ma/cm², the cathode reaction is the discharge of hydrogen ions. The E_c-i curves for abraded and polished n-type Si are identical. An abraded

Table I. Metals electroplated on Si with good adhesion and their electrical properties as contacts

Metal	Solution type	Current density, ma/cm²	Relative adhesion	Electrical properties of contact	
				n-Si	p-Si
Cu	Cyanide	200-75	Very good	Ohmic*	Rectifying
Au	Cyanide	15	Good	Rectifying	Ohmic
Ni	Fluoride	40	Good	Rectifying	Rectifying
In	Cyanide	30	Fair	Rectifying*	Rectifying
Sn	Stannate	20	Fair	Ohmic	Rectifying
Zn	Cyanide	100-30	Poor	Ohmic	Rectifying

* Result different from Wurst and Borneman.

p-type Si electrode has about the same E_c-i curve as n-type up to the current density where Ni starts depositing. The potential difference between the two curves is attributed to a small rectifying barrier between plated Ni and the abraded p-type Si.

Polished p-type Si deviates from the other curves even at very low current densities. The experiment was carried out in subdued room light. Most of the voltage applied to the plating cell appears across the space-charge region in the Si. As shown in Fig. 6, the cathode potential can reach as much as 50 v without plating any Ni.[3] At the critical cathode potential (the value is different for each Si electrode), Ni begins to deposit. The start of Ni plating is probably coincident with a local breakdown of the potential barrier at the surface of the Si. The cathode potential drops slowly as Ni covers the Si. The drop in cathode potential at a constant current density is attributed to hole injection by the electroplated Ni contact on the Si. This collapses the space-charge region which reduces the potential drop in the semiconductor.

If the plating solution is capable of corroding the Si, even at a moderate rate, the large polarization effect inside polished p-type Si made cathodic is not observed. This is due to the fact that excess holes and electrons are produced at the surface of Si whenever it is corroded (14). Both strong alkaline and acid fluoride plating solutions will etch Si. The number of electrons produced at the surface in these solutions in the etching process is sufficient to carry out cathode reactions up to current densities where metal deposition begins without surface depletion. Germanium is corroded to some degree in most aerated aqueous solution (15) so that the "internal" polarization effect may not be observed with polished p-type Ge.

Summary and Conclusions

Oxide films and chemical polishing residues on Ge are cathodically reduced in plating solutions prior to metal deposition if the potential at which metal starts depositing is more negative than that required to reduce the surface films. Cyanide plating solutions are usually preferred for this reason. All electroplated metal contacts except Sb gave rectifying contacts on n-type Ge and ohmic contacts on p-type Ge. Antimony behaved just the opposite.

Oxide films on Si are not reduced cathodically in aqueous solutions. When special preplating techniques are used, the adhesion of electrodeposits on Si is improved considerably. Plating solutions that corrode Si serve a double purpose: (*a*) they remove or reduce the oxide layer thickness prior to metal deposition, and (*b*) they prevent the formation of a large polarization effect due to electron depletion inside the Si.

[3] In one experiment, more than 200 v had to be applied to the plating cell before Ni would deposit on polished p-type Si.

Acknowledgments

The author wishes to acknowledge the help received from H. E. Haring and W. A. Sunder in the work on germanium and to G. H. Peranteau for his assistance with the study of contacts on silicon. Thanks are also due to U. B. Thomas for his comments and discussion of the work.

Manuscript received March 30, 1959. This paper was prepared for delivery before the Ottawa Meeting, Sept. 28-Oct. 2, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

On the Research and Development of Electron Emitting Substances for Gas Discharges

D. M. Speros

Lamp Research Laboratory, Lamp Development Department, General Electric Company, Cleveland, Ohio

ABSTRACT

Criteria for the stability and chemical behavior of electron emitting substances in gas discharges are obtained by means of thermodynamics. Theoretical analysis is supplemented by means of experimental methods intended for the study of processes at elevated temperatures, such as thermogravimetry and differential thermal analysis. The application of the above permits some insight into the processes of formation, activation, and detrition of electron emitting compositions, guiding the development of a number of improved cathodes.

The purpose of this work was to develop cathodes meeting the requirements of new gas discharge devices. To effect this, a better understanding of the fundamentals involved was necessary. Therefore, a major portion of this work was devoted to the chemical and thermochemical aspects of electron emitting substances, which are but poorly understood at present.

The concern of the theoretical part is to evaluate a degree of relative stability for these materials (with respect to dissociation, sublimation, chemical interaction, physical state, and sputtering) and to predict the processes expected during their history, (such as formation, activation or reduction, and normal detrition) without extended experimentation of a trial and error nature. This part of the work forms an extension or generalization of the thermochemical calculations of Rittner (1) which were concerned primarily with the reduction reaction of the oxide cathode. From the chemical point of view, thermodynamic considerations are obvious in many of their aspects; however, since they appear to be of general usefulness in cathode research, they are outlined in this paper.

The chemical processes occurring in cathodes belong to the realm of solid-state chemistry. Therefore, experimental methods designed for the study of reacting solids were applied to supplement the theoretical analysis and provide information when thermodynamic and kinetic data were lacking.

Procedure

Theoretical basis.—A cathode system is defined as one consisting of α moles of substance A, β moles of substance B, γ moles of substance C, etc., and is represented as follows:

$$A_\alpha B_\beta C_\gamma \ldots .$$

A binary system $A_\alpha B$, where α is the number of moles of A per one mole of B, is for the purpose at hand a sufficient approximation to a large number of actual cathodes. For example, $A_\alpha B$ could represent a common form of the oxide cathode for A = BaO and B = SrO; for A = La and B = B, the boride cathode; for A = Th and B = W, the thoriated cathode, and so on.

The process of formation in each case is as follows:

$$\alpha A(c) + B(c) \rightarrow A_\alpha B(c) \qquad [1]$$

which involves a free energy change:

$$\Delta F = F_{A_\alpha B(c)} - \alpha F_{A(c)} - F_{B(c)} = \Delta H - T\Delta S \qquad [2]$$

As already implied in the above examples, Eq. [1] may represent a chemical reaction, the formation of a solid solution, a process of adsorption, or a combination of more than one of these processes. Since at a temperature T:

$$\Delta F = \Delta F^\circ + RT \ln \frac{A_\alpha B(c)}{A(c)^\alpha B(c)}$$

and at equilibrium $\Delta F = 0$ and

$$\ln \frac{A_\alpha B(c)}{A(c)^\alpha B(c)} = \ln K = -\frac{\Delta F^\circ}{RT}$$

the standard free energy change for the formation of $A_\alpha B$ from its components αA and B was used as a quantitative criterion for the stability of electron emitting substances $A_\alpha B$ with respect to dissociation.

In nearly all cases of interest the vapor pressure of one of the components, B, and of the compound $A_\alpha B$ is negligible in comparison to that of the component A. Therefore, the process of sublimation proceeds for all practical purposes as follows

$$A_\alpha B(c) \rightarrow \alpha A(g) + B(c) \qquad [3]$$

The accompanying free energy change is

$$\Delta F_2 = \alpha F_{A(g)} + F_{B(c)} - F_{A_\alpha B(c)} \qquad [4]$$

The process of sublimation of pure A and the corresponding free energy change are as follows

$$\alpha A(c) \rightarrow \alpha A(g) \qquad [5]$$

$$\Delta F_1 = \alpha F_{A(g)} - \alpha F_{A(c)} \qquad [6]$$

Since obviously:

$$\Delta F_1 - \Delta F_2 = \Delta F \qquad [7]$$

Table I. The $\Delta F^\circ = f(T)$ relations for a number of processes of interest

Process	$\Delta F^\circ = f(T)$	T range of applicability

$BaO\ (c) + WO_3\ (c) \rightarrow BaWO_4\ (c)$	$-74{,}300 + 0.6T$	298-M.P.

* Available in this form in the literature (2).

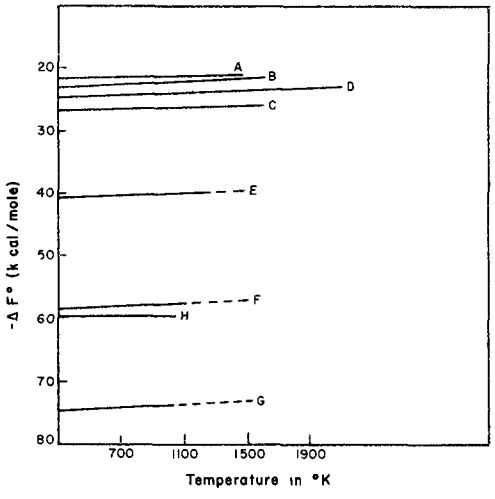

Fig. 1. Standard free energy change as a function of temperature for the formation of some interoxide compounds from the oxides: A, $CaSiO_3$; B, $SrSiO_3$; C, $BaSiO_3$; D, $BaAl_2O_4$; E, $CaWO_4$; F, $SrWO_4$; G, $BaWO_4$; H, $BaMoO_4$.

the free energy change ΔF for the formation of $A_\alpha B$ from its components αA and B is also useful in determining the comparative stability with respect to sublimation of each component A from its combination with a given component B.

The standard free energy change as a function of temperature is shown in Table I for a number of processes of interest which lead to the formation of interoxide compounds.[1] These were evaluated using data in references (2) and (3); since however these calculations involved, in some instances, estimates of entropy and heat capacity values, they are to be considered accurate only in their relative magnitude. These $\Delta F^\circ = f(T)$ functions are plotted in Fig. 1. In accordance with the above, the lower the $\Delta F^\circ = f(T)$ relation for a given compound in this figure, the more stable the compound with respect to dissociation and sublimation.

A third area in which the considerations leading to Fig. 1 are of importance is that of chemical interaction between $A_\alpha B$ and other substances with which it may come in contact. Since all systems tend toward a state of minimum free energy, all substances as shown in Fig. 1 will be thermodynamically unstable in the presence of the free oxides of substances below them in the $\Delta F^\circ = f(T)$ diagram. Further, since in most instances each A may tend to form a number of different combinations with B, an interoxide compound in Fig. 1 will be unstable in the presence of another one if the change of the free energy for their interaction is favorable. Finally, interoxide systems may combine to form a solid solution or compound such as, for example, $Ca_2Al_2SiO_7$.

These considerations also govern the interaction between a component of A or B and a third reagent. In general it can be shown that their combination increases their stability toward chemical attack. For example, it will be seen that $BaO \cdot Al_2O_3$ (or $BaAl_2O_4$) is, for all practical purposes, completely inert in the presence of tungsten, while BaO is not.

If the relative amounts of the components of an emission material are known, the above are useful for the understanding of the nature of cathode coatings and of the interface composition between the coating and the supporting electrode.

Not much is known about the quantitative aspects of sputtering of composite surfaces. However, the process represented by

$$x(\text{solid}) \rightarrow x(\text{gas})$$

will involve the same amount of energy regardless of the path the process follows, the efficiency involved, or the agent causing it. Therefore, from basic considerations alone it can be expected that the separation of an atom or molecule from the surface will involve, as one factor at least, the energy of sublimation regardless of whether this "sublimation" is achieved thermally or by ionic bombardment. Thus it is not surprising that important recent studies on sputtering (4) have succeeded in interrelating, empirically at least, this phenomenon with the heat of sublimation, among other factors. Therefore the criterion ΔF, used for the stability with respect to sublimation, dissociation, and chemical reactivity was used also for the stability with respect to sputtering as the best alternative at the present state of knowledge.

The physical state of $A_\alpha B$ as a function of temperature, the nature of the combination $A_\alpha B$ as a function of α and temperature, and an estimate of the magnitude of the thermodynamic quantities involved were obtained from the study of the appropriate phase diagram.

The application of the above considerations to actual systems involves the well-known limitations of thermodynamics. The experimental work indicated,

[1] The oxides that combine to form these substances do not differ enough in their acidic character to justify the term "oxygen salts" nor do they exist in such a loose combination as to correspond to "mixed oxides." The term "interoxides" is proposed to define this class of materials.

however, that the activation energy and diffusion barriers were of lesser magnitude than should have been expected from solid-state reactions. Therefore, these limitations were of lesser importance than would have otherwise been the case.

Experimental Methods

The awareness of the importance of the thermochemical history of the electron emitting materials led to the application, in this work, of thermal methods of experimental investigation such as thermogravimetric analysis (T.G.A.), and differential thermal analysis (D.T.A.)

The basis for the application of these methods is as follows: It has been shown in the previous section that if A and B will form a combination A_aB such as to increase the stability of A, the sign of ΔF for the process of this combination will be negative.

Since the entropy change for processes in the solid state is small,[2] then

$$\Delta F \cong \Delta H$$

If the change in heat content ΔH is unknown, the next best thing is to determine its sign. By means of D.T.A., the temperature range at which the process takes place, the exothermic or endothermic nature of the process, as well as a very approximate magnitude of ΔH are determined.

This method was also used in order to obtain an indication of the rates at which the thermodynamically predicted processes take place.

Phase diagrams and thermodynamic data for the binary sytems A_aB of interest are few; for the ternary systems resulting from the processes exemplified by Eq. [8], below, are virtually nonexistent. Hence, once the A_aB system was evaluated, D.T.A. provided the means of determining whether the process of Eq. [8] produced a system of increased stability.

The difficulties of interpretation of D.T.A. records can often become formidable when a complex process, such as that of the activation of an emission material, is being studied. Other methods such as x-ray diffraction, mass spectroscopy, microscopy, and T.G.A. were then applied in conjunction with D.T.A.

The maximum temperature attainable by the conventional D.T.A. apparatus used was 1500°C.[3] Therefore, approximate melting point determinations of compounds melting at higher temperatures were performed in inert atmospheres inside a tungsten wound furnace. The temperature was determined by means of a calibrated micropyrometer focused at a "blackbody" cavity formed by a tungsten container into which a small crystal of the compound was placed.

The thermionic behavior of selected materials was examined by means of high vacuum diodes for academic purposes; since it is unknown whether thermionic or secondary processes predominate in a given gas discharge, greater reliance was placed on results obtained by studying the breakdown voltage and the cathode drop in the actual gas discharges for which these cathodes were intended.

[2] This is also true for the evaluation of stability with respect to sublimation, since the difference $\Delta F_1 - \Delta F_2$ cancels out the large increase of entropy on sublimation of αA.

[3] For substances containing excess barium, the D.T.A. apparatus could not be used above 950°-1000°C because of severe chemical attack on the Pt-Pt:13% Rh thermocouples.

Interoxide Systems As Electron Emitting Substances

Interoxide systems $(M_xO_y)_a \cdot (R_zO_w)$, where M_xO_y represents an "emissive" oxide, BaO for instance, and R_zO_w a refractory oxide such as Al_2O_3, if used as such, form poor lamp cathodes even if $\alpha > 1$. Their behavior as cathodes however improves appreciably if an excess of the emissive metal M is introduced. This was done by chemically reducing part of the M_xO_y component as follows:

$$(M_xO_y)_a \cdot (R_zO_w) + \beta R \rightarrow \left(\beta \frac{wx}{zy}\right) M \cdot \left(\alpha - \beta \frac{w}{zy}\right) M_xO_y \cdot \left(\frac{\beta}{z} + 1\right) R_zO_w \quad [8]$$

where the left hand side of the equation represents the emission mixture while the right hand side represents the activated cathode. The reducing agent R used was the same, in each case, as the R of the refractory oxide. This was done in order to obtain, after activation, the simplest possible chemical species hence the easiest to study.

The type of cathode thus produced was controlled by adjusting the following variables: (*a*) selection of the interoxide system; (*b*) selection of the reducing agent; (*c*) amount of the reducing agent; (*d*) state of subdivision of the reducing agent.

In cases where it was desirable that the reduction reaction proceed in a short time, a potent reducing agent (1)[4] in fine powder form was mixed with the powder of the interoxide substance. In the other extreme, the reducing agent was alloyed with the cathode support.

It may be noted that, in all cases, the process of activation, being a chemical reaction in the solid state, does not involve evolution of gases (see below, Process of Activation), nor does it necessitate any particular atmosphere or lack of it for its progress. If the composition of the interoxide system is such that $\alpha \leqq 1$, the emission mixture is stable in the atmosphere for extended periods of time as shown in Fig. 2. Finally, the reduction in volume of the emission mixture upon activation is much less than if, for instance, it had involved the decomposition of carbonates, a helpful fact, as it will be seen when the system is used in conjunction with a refractory metal sponge or compact.

The electron emitting behavior of interoxide systems in lamps parallels that found in this work and by others (5, 6) by means of measurements of the thermionic emission constants of interoxide systems consisting of BaO and a number of refractory oxides. An inspection of these results brings out the possibility that the value of the work function ϕ, or more precisely the slope of the Richardson plots, is approximately the same and in the vicinity of 1.6 e.v. at 750°-850°C regardless of the refractory oxide (Al_2O_3 or ZrO_2, etc.) and, except at the two extremes of

[4] In general, however, it should be remembered that now the ΔF reduction = $\Delta F_R + (\Delta F'' - \Delta F')$ where ΔF_R is the free energy of reduction of M_xO_y to M and R_zO_w, and $\Delta F''$, $\Delta F'$ are the free energies of formation from the oxides of the final and original interoxide substances, respectively.

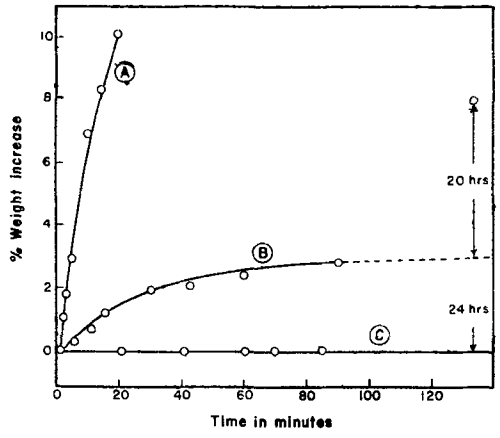

Fig. 2. Weight gain of cathode materials on exposure to air of relative humidity as stated. A, BaO; relative humidity: 70%; B, 0.76 $BaO \cdot BaAl_2O_4$; relative humidity: 80%; C, $BaAl_2O_4$; relative humidity: 80%.

composition, regardless of the BaO content of the interoxide system. In this work the emission coatings were applied on cathodes made of molybdenum, tungsten, and nickel; hence to this extent this value of ϕ is independent of the cathode base. Furthermore, the value of A in the Richardson equation

$$i = AT^2 e^{-e\phi/kT}$$

seems dependent on the amount of Ba present in excess of the stoichiometric formulas for the interoxide system, being very small for the pure substances and increasing with the Ba content.

This evidence points to the hypothesis that the work function in interoxide systems is determined by the nature of the emissive sites involved (BaO-Ba in this case, see also below, Process of Activation) while the saturated current density is determined by the number of these sites per unit area.

If the above is true, then the role of the refractory component is simply to increase the stability of the BaO-Ba emissive sites, as explained, and to increase the amount of Ba that may be combined with the BaO-refractory oxide matrix, as will be explained.

Preparation of Starting Materials

Interoxide substances usually are prepared by heating a mixture of alkaline earth carbonates or oxalates, nitrates, sulfates, etc., with the oxides, hydrates, or other compounds of the refractory component to the point of melting.

In this work the interoxide substances of interest were prepared by the direct combination of the two oxides in the solid state,

$$\alpha M_xO_y + R_zO_w \xrightarrow{\text{heat}} (M_xO_y)_\alpha \cdot (R_zO_w) \qquad [9]$$

In most instances the reactions proceeded at relatively low-temperature ranges and rather short reaction times as shown in the D.T.A. records of Fig. 3. At a heating rate of 15°C/min, it is seen that $BaAl_2O_4$ is formed between 400° and 500°C; $BaZrO_3$ between 200° and 800°C; and $BaThO_3$ between 200° and 900°C. The over-all effect is exothermic. It is interesting to note that in all three cases depicted the reactions proceed in three main stages although these stages may occur at different temperature ranges

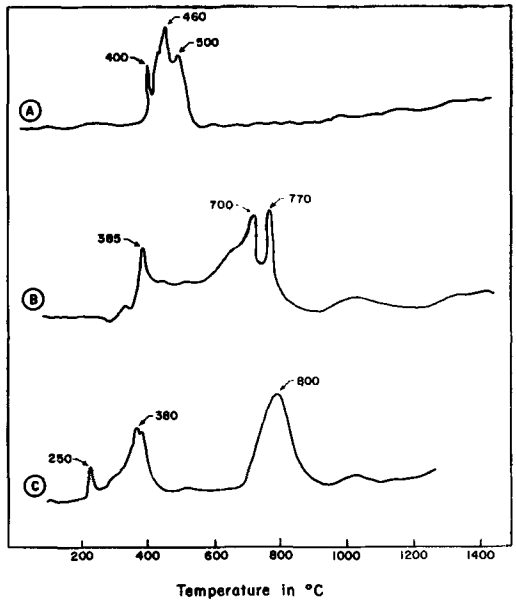

Fig. 3. D.T.A. curves for the formation of some interoxide systems from their component oxides.

(A) $BaO(c) + Al_2O_3(c) \rightarrow BaAl_2O_4(c)$
(B) $BaO(c) + ZrO_2(c) \rightarrow BaZrO_3(c)$
(C) $BaO(c) + ThO_2(c) \rightarrow BaThO_3(c)$

in each case. The reaction leading to the formation of $BaThO_3$ does not proceed to completion in the 50 min of heating as shown, but the other two apparently do proceed to completion: if the aluminate or zirconate samples are taken out of the apparatus after the last stage, reground, replaced in the apparatus, and heated again, no evidence of further reaction is observed. Melting point determinations, chemical analysis, and x-ray diffraction data confirm this to the extent that published data are available. X-ray powder pattern data have been obtained for $BaAl_2O_4$ prepared as described above, which is presented in Table II compared with the data in A.S.T.M. card No. 2-0545. It is seen that the A.S.T.M. intensity values,[5] with the exception of the intensity of the principal line at $d = 3.17$, are approximately twice those determined[6] in this work. As the value assigned to all intensities is relative to that of the principal line (which is assigned the value of 100), we believe, as suggested by Dr. Addamiano, that the values given by the A.S.T.M. card for $BaAl_2O_4$ are higher than the actual ones by a constant factor because of film saturation by the principal line reflection.

Preparation of Cathodes

The interoxide substance is ground and mixed with the powder of the reducing agent. Then, depending on the particular intended application, the mixture is either suspended in a comparatively volatile organic liquid such as butyl acetate, or used as the dry powder. The liquid suspensions may be used for coatings by dipping, spraying, or painting in the usual manner.

The dry powder may be used to provide very thin coatings of the mixture on the electrodes or to form dispersions in refractory metal compacts (or sponges). In connection with the former use it has

[5] Obtained from photographic film recordings.
[6] By means of a Geiger counter detector.

been found that some of these mixtures, for instance, that of $BaAl_2O_4$ and Al, will adhere to clean metals if the mixture contains a slight excess of BaO or $BaCO_3$ (see below, Chemical Processes). For some uses a thin coating, visible to the naked eye only by direct comparison of the coated and uncoated portions of the electrode, is sufficient to provide desirable performance.

In connection with the latter use the interoxide substance and its reducing agent are mixed in powder form with a chemically inert (see below) refractory metal powder, usually tungsten, the latter being in large excess, as for example 9:1 by weight, for one of the applications reported here. The resulting mixture is pressed without benefit of binders, lubricants, or other additives into compacts of the desired shape and dimensions. A pressure of 6000 kg/cm^2 is sufficient for simple shapes such as that of a short cylinder. The compacts then are placed in refractory firing boats and fired at a temperature of

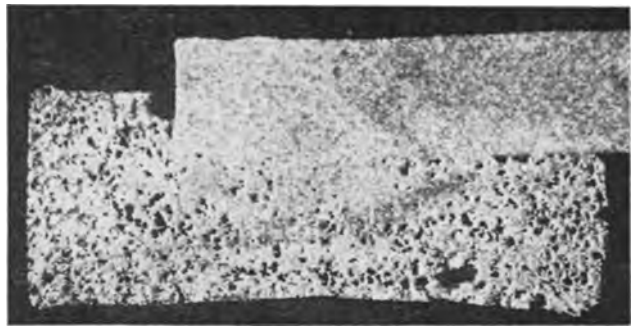

Fig. 4. Photomicrograph of cross section of pellet cathode bottom attached by means of spot welding to the tungsten electrode shown at the top. (Specimen and photomicrograph by K.S.G. Pertwee of Large Lamp Department.)

1050°C in dry hydrogen or an inert atmosphere for at least 20 min. This treatment causes the compacts to sinter into hard, porous pellets of a density range of 8.5 to 9.5 g/cm^3. If the tungsten content is more than approximately 60% by weight, the resistance of the pellets is very low; therefore it may be spot welded directly on a metal lead to form one type of cathode as shown in Fig. 4.

The purpose of the above procedure is primarily to sinter the tungsten particles; for, as will be seen, the activation process involves lower temperatures and shorter times than those mentioned above. The resulting structure is quite similar to cathodes already reported (7), the basic difference being that, due to the choice of $\alpha \leqq 1$ for the interoxide system and to the incorporation of R, the activation is independent of the tungsten sponge which serves simply as a physical support (see below, Chemical Processes).

After activation the coatings obtained from liquid suspensions and the thin dry powder coatings are unstable in the ordinary atmosphere; the sintered tungsten compacts however are stable even if stored for several weeks under saturated humidity conditions (see below, Chemical Processes).

The Process of Activation

The D.T.A. records of Fig. 5 indicate that Eq. [8] describes in reality a complex, multistage process.

From a practical point of view the low temperatures and short times[7] of "activation" are convenient in that the cathodes become activated while lamps are being processed in ovens.

From the theoretical point of view it is interesting to note that the similarities observed in the reactions of formation of the interoxide compounds, Fig. 2, have a parallel in their reactions of reduction. These consist of two main processes: a low-temperature sharp exothermic reaction and a process at higher temperature proceeding at a slower rate and having a hump-like appearance. An increase in β (Eq. [8]) causes an increase in the height and area of the peaks as shown in Fig. 5A. Both processes decrease in intensity and are displaced toward higher temperatures as α is decreased to the extent of necessitating longer time intervals for their completion than indicated by Fig. 5. Finally for $\alpha < 1$ the low-tem-

[7] The D.T.A. experiments were performed in argon at atmospheric pressure at a heating rate of approximately 15°C/min.

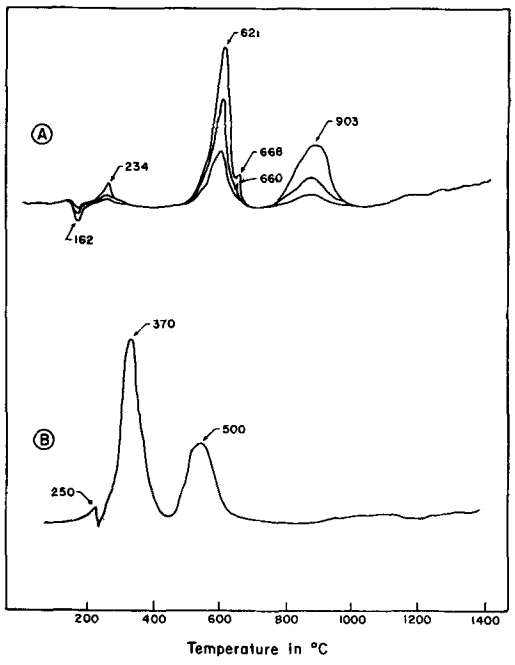

Fig. 5. D.T.A. curves for the reduction (activation) processes

(B) $9BaO \cdot 1ZrO_2 + 2.3Zr \rightarrow 3.3(1.33BaO \cdot 1ZrO_2 \cdot 1.39Ba)$

perature process begins to become endothermic while the higher temperature hump has still an exothermic appearance.

Repetition of the runs using various proportions of reactants, x-ray diffraction studies, mass spectroscopic work, and chemical analyses were of assistance for the interpretation of the records of Fig. 5 as follows.

At approximately 160°C the small amount of water adsorbed by the powders begins to separate causing the endothermic peak at 186°C on the record for the aluminate case. As the water vapor diffuses out of the sample it attacks the reducing metal it encounters causing the formation of refractory oxide and hydrogen. This exothermic process occurs in the aluminate near 280°C. In the zirconate case this reaction begins at a lower temperature to the extent of balancing the endothermic effect of the desorption of water.

The main reduction reactions then follow peaking at 370° and 620°C for the zirconate and aluminate, respectively. In the case of the aluminate, when the temperature attains the value of 660°C, the melting point of aluminum, the remaining quantity of unreacted aluminum melts, impregnates the sample, and reacts causing the small exothermic peak at 668°C. The area corresponding to the peak at 620°C where aluminum is presumed still solid is far larger than that at 668°C. As this is also the case in the zirconate-zirconium reaction, it may be concluded that the reactions are capable of proceeding in the solid state and it is not necessary to assume the formation of (reducing metal)-(barium) eutectic compositions, which are liquid at the reaction temperatures, in order to explain the progress of these reactions in the short reaction times and low temperatures observed.

The reduction reaction is always followed by a slower exothermic process appearing as a hump on the D.T.A. records. Neither this process nor the unexpectedly exothermic behavior[8] of the peaks attributed to the main reduction reaction have been completely understood to date; however, work in progress has permitted interesting glimpses into their nature which may be summarized as follows.

When the reduction reaction begins, the reducing metal, which is present in excess at the particle interface with the interoxide compound, will reduce a larger quantity of barium oxide than that intended by Eq. [8]. Soon a gradient will be established across the reaction front which in the case of $(BaO)_a$ (Al_2O_3)-Al reaction, for instance, involves the series: Al Al_2O_3 $BaO \cdot 6Al_2O_3$ $BaO \cdot Al_2O_3$ $3BaO \cdot Al_2O_3$ with the quantity of barium produced increasing in the same order as that of aluminum oxide. As shown in the reactions of formation in Fig. 3, the interdiffusion rate of these species is appreciable and a series of exothermic reactions are thermodynamically predictable to take place; as for example,

$$5Al_2O_3 + BaO \cdot Al_2O_3 \rightarrow BaO \cdot 6Al_2O_3$$

Since these reactions depend on the diffusion of molecules bulkier than Al or Al_xBa_y, they would manifest themselves on the D.T.A. record as humps rather than as sharper peaks as the reduction reaction does.

It is suspected that the above explains the hump process only in part and that this process, as well as that causing the sharper peak at lower temperatures, also involves the exothermic interaction between the Ba formed by the reduction reaction and the resulting interoxide substance. Thus, for instance, the 0.31 g of Ba that is theoretically produced by 1 g of a mixture of $BaAl_2O_4$ and Al according to

$$BaAl_2O_4 + 0.4Al \rightarrow 1.2(0.34BaO \cdot 1Al_2O_3 \cdot 0.5Ba)^9 \quad [10]$$

is not detected by means of x-ray diffraction techniques; hence it does not exist in the elementary crystalline state. This is confirmed by thermogravimetric experiments using a Chevenard thermobalance. Except for a weight loss of approximately 1.8% between 70° and 300°C, which has previously been shown to be due to the evolution of water and hydrogen, there was no other significant weight change up to 1050°C, the maximum temperature attainable by the apparatus used. The experiments were performed in a flow of purified argon (600 cc/min) at atmospheric pressure, using 1-g samples of powder consisting of the mixture shown by the left hand side of Eq. [10]. On the average, the sample was at a temperature above 710°C, the melting point of Ba, for at least 2 hr.

In order to overcome the limitations imposed by the inability to perform these experiments in vacuum, and also in order to obtain an indication of the

[8] Thermochemical calculations show most of these reactions to be slightly endothermic within the limits of uncertainty of the available data.

[9] In addition to Eq. [10], the following give specific examples involving actual cathodes.

$$BaZrO_3 + 0.25Zr \rightarrow 1.25(0.4BaO \cdot 1ZrO_2 \cdot 0.4Ba) \quad [11]$$

$$BaThO_3 + 0.2Th \rightarrow 1.2(0.5BaO \cdot 1ThO_2 \cdot 0.33Ba) \quad [12]$$

nature of the apparent combination between barium and the interoxide system, the thermogravimetric experiments were repeated in a flow of hydrogen instead of argon. The behavior in the 70°C range was nearly the same as in the case of argon; however, an increase in weight was observed at 650° to 700°C because of the formation of barium hydride. This permitted the estimation of a maximum for the heat of the combination Ba-X as follows:

$$Ba - X(c) \rightarrow Ba(c) + X(c) \quad \Delta H = ? \quad \Delta F = ? \quad [13]$$

where ΔH is the quantity to be estimated. This process is the sum of

$$Ba - X(c) + H_2(g) \rightarrow BaH_2(c) + X(c) \quad \Delta H_1 = ? \quad \Delta F_1 = ? \quad [14]$$

and

$$BaH_2(c) \rightarrow Ba(c) + H_2(g) \quad \Delta H_2 = +40.9 \; \Delta F_2 = ? \quad [15]$$

therefore $\Delta H = \Delta H_1 + 40.9$ and $\Delta F_1 + \Delta F_2 = \Delta F$.

Reaction [14] proceeds spontaneously and to an appreciable extent even if the flow of H_2 is stopped. Hence $\Delta F_1 \leqq 0$ and therefore $\Delta F \leqq \Delta F_2$ or $\Delta H - T\Delta S \leqq 40.9 - T\Delta S_2$. Since ΔS refers to a reaction involving solids only, it will be small; ΔS_2 refers to a reaction resulting in a gaseous product and will therefore have a larger positive value. Hence $\Delta S_2 > \Delta S$ and therefore $\Delta H \leqq 40.9$ kcal/mole, thus establishing an upper limit for Ba — X.

Subject to further verification this evidence indicates that at least a part of the barium formed is not in a "free" state. This contributes to the explanation of Fig. 5 and the stability of the postulated Ba-BaO-refractory oxide electron emitting sites.

Chemical Processes Involving Refractory Sponge Cathodes

It was seen that the reasons for the choice of equimolar proportions for the composition of the starting interoxide materials included stability in air, low temperatures of activation, lack of copious gas evolution during activation, and ease of control of the chemistry involved in their selection, preparation, and activation.

A further reason is their reduced reactivity toward the refractory metal of the cathode support. As the activation of the interoxide substance is controlled by the reducing agent, it is not necessary that further reduction be made to occur; nor is this desirable because this interaction will result in the creation of an interface concentration gradient and its associated problems.

The pairing of the electron emitting materials and metal supports involves the theoretical considerations at the beginning of this paper. Below, these are applied to the pair $BaAl_2O_4$ — W as an example pertinent to this work. This application necessitates the knowledge of the initial and final states of reactants and products. It was shown in the previous section that the exact state of the barium produced by the reduction process, and hence the final state of the products, are in doubt. Therefore, for comparison purposes, the final state of barium will be taken as being gaseous, because this state offers a common basis for the relative evaluation of the pairs of interest.

The vapor pressure of barium produced in a number of processes was evaluated and is given in Table III. Once again, by necessity, estimates of thermo-

(H) $BaAl_2O_4 \rightarrow Ba(g) + \frac{1}{2} O_2(g) + Al_2O_3(c)$

chemical data had to be made. Results are plotted in Fig. 6. It is seen that the vapor pressure of barium produced by the reaction between $BaAl_2O_4$ and W resulting in the formation of $Ba_3WO_6(c)$ is comparable to that produced by the thermal decomposition of BaO(c). As is well known with respect to cathode activation, the latter is negligible. The vapor pressure of barium produced by the reaction resulting in the formation of $BaWO_4(c)$ from $BaAl_2O_4$ and W is even less. When these are compared with the vapor pressure of barium produced by the total[10] reduction of $BaAl_2O_4$ by Al it is concluded that the activation of the $BaAl_2O_4$ + 0.4Al + 13.2 W mixture[11] is independent of the tungsten sponge and that the formation of an interface composition of tungstates is unlikely.

The above was confirmed by means of D.T.A. work: no evidence of a reaction was observed on heating finely powdered mixtures of $BaAl_2O_4$ and W up to 1500°C.

In contrast, the reaction between BaO and W and also that between interoxide systems containing BaO in excess of the equimolar composition is thermodynamically favored to nearly the same extent as that between $BaAl_2O_4$ and Al.[12] However, in these cases the role of the tungstate interface becomes apparent. Thus, although the reaction resulting in the formation of Ba_3WO_6 is more favorable than that resulting in the formation of $BaWO_4$, the former is less favorable kinetically since it and the accompanying production of barium depends on the diffusion of the reactants through the $BaWO_4$ interface. Therefore, a pellet cathode of this kind will depend on concentration gradients and hence, delicately, on the cathode temperature, the control of which for directly heated lamp cathodes is not conveniently effected. This is particularly true, of course, in intermittently pulsed discharges where the bulk of the cathode is only slightly above room temperature.

The stability in air after activation of the pellet cathodes containing interoxide materials is interpreted as follows: Upon exposure to the water and carbon dioxide of the atmosphere barium hydroxide and carbonate form on the surface pores of the pellet, with an accompanying large increase in volume of the emission material that has thus been attacked. As these surface pores were already filled with the interoxide substance inasmuch as the activation did not involve any appreciable reduction in volume, the formation of these impervious "plugs" prevents further penetration of vapors and gases and therefore further attack below the surface. If substances such as the usual carbonates had been used for the formation of the pellets, their activation would have been accompanied by a large decrease in volume making the pellets more susceptible to atmospheric attack. The above constitutes an additional reason for the choice of interoxide systems for the pellet cathodes.

[10] Used here as a limiting case; the vapor pressure of Ba from the actual activating process used (Eq. [9]) is substantially higher, $BaAl_2O_4$ and $BaO \cdot 6Al_2O_3$ being the end products rather than Al_2O_3.

[11] Usually employed to manufacture the compacts.

[12] The theoretical vapor pressure of Ba from the reaction between BaO and W resulting in the formation of Ba_3WO_6 is nearly two orders of magnitude higher than determined experimentally (9), either because the enthalpy estimated in this work for the formation of Ba_3WO_4 from its component oxides is too high or because, as shown in this section, the Ba formed by the reduction reaction becomes at least partly bound into the interoxide lattice.

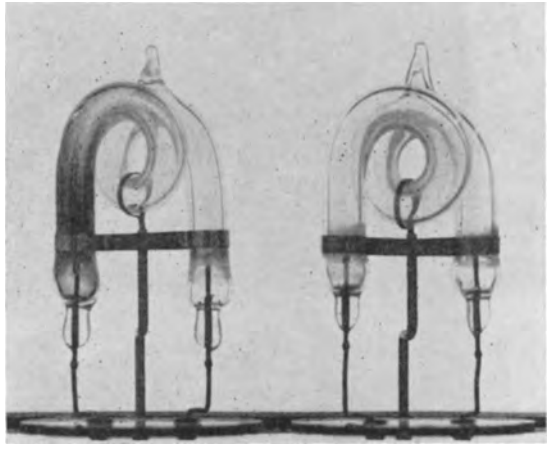

Fig. 7. Left: Standard electronic flashtube after 2500 flashes (near end of life). Minimum average breakdown voltage: 400 v. Right: Lamp identical to that above but using emission materials shown by Eq. [11] (thin film application on tungsten electrode) after 70,000 flashes. Minimum breakdown voltage constant at 285 ±5 v. Both lamps were operated at 125 watt-sec (or Joules) per flash.

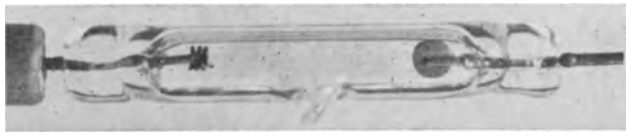

Fig. 8. A new type of repetitive electronic flashtube (used, for instance, for stroboscopic purposes) using pellet cathode of emission materials shown by Eqs. [10] or [11] or [12]. The life of these tubes is several million flashes.

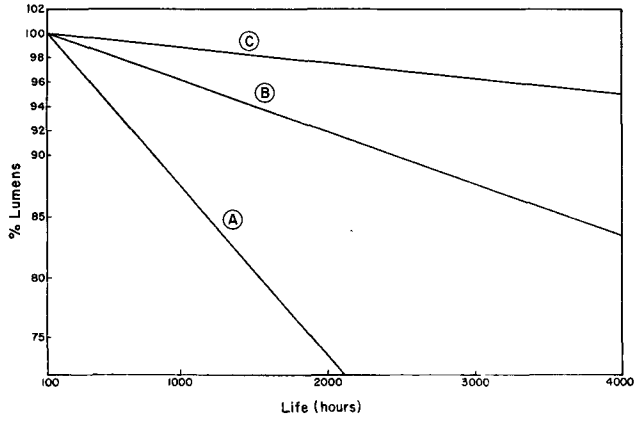

Fig. 9. Maintenance (in per cent of lumen output at 100 hr) vs. life in hours, of: A, standard 400-w high-pressure mercury discharge lamp; B, same as A, but with electron emitting materials as shown by Eqs. [12] or [13] (from liquid suspension); C, same as B, but with modified electrodes.

After manufacture into lamps, the pellet surface is reactivated either thermally or by sputtering. The ease with which this can be accomplished indicates that the attack, even after severe exposure, was very superficial. In the case of thermal reactivation, the formation of tungstates may be expected on the surface. D.T.A. experiments show that barium carbonate and W react at a high rate at 760°C (and slower well below this temperature). T. G. A. work with several interoxide pellets in each experiment failed to detect any weight loss (due to the accompanying evolution of CO) thereby confirming the above results of lamp behavior. This indicates that the formation of tungstates is insignificant. It may become significant, however, when the dry thin coatings mentioned earlier are used on a tungsten base. It will be recalled that these thin coatings adhere tenaciously to the tungsten base and provide good cathode performance if a slight excess of BaO or $BaCO_3$ is introduced. Probably the formation of tungstates to an extent of forming a number of "anchoring" sites but not to the extent of forming an interface could account for this.

Performance Characteristics

In addition to the requirement of ease of manufacture and use already mentioned, lamp cathodes must meet certain standards of performance. These are long life, low breakdown or starting voltage of the lamp, good lamp efficiency (number of lumens output per watt input), and good lamp "maintenance."

Improvements in performance obtained by the use of various forms of interoxide cathodes as described in this paper are shown in the examples of Fig. 7, 8, and 9.

Acknowledgments

The writer is indebted to Drs. J. S. Saby, J. M. Lafferty, V. L. Stout, and Mr. D. E. Elmendorf of this company for their encouragement and discussions. He is also indebted to Mr. R. L. Woodhouse for performing the D.T.A. runs, to Dr. E. G. Zubler for mass spectroscopic work, to Dr. R. P. Taylor for chemical analyses, and for the x-ray diffraction studies to Miss J. R. Cooper and Dr. A. Addamiano, all of this laboratory. For the T.G.A. runs, indebtedness is expressed to Dr. R. C. Griffis of Lamp Metals & Components Department and to Messrs. S. L. Slomski and E. C. Martt of Photo Lamp and Large Lamp Departments, respectively, for tests on lamp performance and general assistance. For discussions on various matters associated with this paper and critical reading of the manuscript, thanks are tendered to Drs. M. D. Gibbons, L. V. McCarty, A. E. Newkirk, H. A. Liebhafsky, T. A. Vanderslice, and J. E. White of this company and E. S. Rittner of Philips Research Laboratories.

Manuscript received March 16, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1960 JOURNAL.

The Calcium Silicate Mn + Pb Phosphor Phase Relationships and Preparation

D. E. Harrison and Mary V. Hoffman

Lamp Wire & Phosphors Department, General Electric Company, Cleveland, Ohio

ABSTRACT

Phase relations were examined in the vicinity of $CaSiO_3$ in the system to pseudowollastonite inversion temperature. Addition of $MnSiO_3$ to (Ca,Pb) $CaSiO_3$-$MnSiO_3$-$PbSiO_3$. Lead solid solutions in $CaSiO_3$ lower the wollastonite SiO_3ss markedly lowers the solubility of lead in (Ca,Mn,Pb)SiO_3ss and causes a change in structure from pseudowollastonite to wollastonite. Application of the phase data is used to demonstrate how the synthesis technique can be varied to produce major differences in particle size of the phosphor.

The properties of the $CaSiO_3$:Mn + Pb phosphor are described by Froelich (1), Merrill and Schulman (2), Schulman, Ginther, and Evans (3) and Fonda and Froelich (4). Various synthesis techniques are described by Steadman (5), Schulman (6), and Froelich (7). Phase data pertinent to the phosphor composition are limited. Glasser (8) recently re-examined the system $CaSiO_3$-$MnSiO_3$ and, in general, he confirmed the earlier results of Voos (9), although differing in many details. No data are reported in either the binary system $PbSiO_3$-$CaSiO_3$ or the ternary system $CaSiO_3$-$PbSiO_3$-$MnSiO_3$.

The object of this study was to examine the pertinent phase relationships in the vicinity of $CaSiO_3$ composition and in particular to determine the extent of the solubility of lead in $CaSiO_3$ and its effect on the inversion temperature. Phase data were used as a basis for the interpretation of the reactions which occur during synthesis of the $CaSiO_3$:Mn + Pb phosphor.

Experimental Procedure

The raw materials used for phosphor synthesis were Mallinckrodt Special Bulky silicic acid, silicic acid prepared from tetraethylorthosilicate, and reagent grade $PbSO_4$ and $MnCO_3$. The $CaCO_3$ was prepared by Chemical Products Plant of the General Electric Company. Compositions in the system $CaSiO_3$-$PbSiO_3$ were made from silicic acid prepared by hydrolysis of tetraethylorthosilicate; all other compositions were made with Mallinckrodt silicic acid.

Preparation of compositions and heat treatments.—The ingredients were ground in either an agate or a glass mortar with reagent grade acetone until dry. Calcines were prepared in either platinum or fused silica crucibles at temperatures ranging from 1000° to 1200°C for 3 hr to one month. Ternary compositions were prepared from preformed $CaSiO_3$, $MnSiO_3$, and $PbSiO_3$. The compositions examined are listed in Table I.

Apparatus and techniques.—(*a*) Phase identification was made with a General Electric recording diffractometer using $Cu_{k\alpha}$ radiation ($\lambda = 1.540$Å) filtered with Ni.

(*b*) Microscopic examinations were made with a petrographic microscope.

(*c*) A quench technique was used to examine the solid solution regions by procedures similar to those described by Shepherd, Rankin, and Wright (10). Thermocouples were calibrated using lithium metasilicate (mp 1201°C) and gold (mp 1063°C).

(*d*) Particle size distribution curves of phosphor powders were calculated from settling rates of particles in water by application of Stokes law using the technique of Rabatin and Gale (11).

Results and Discussion

α(Ca,Mn)SiO_3 fluoresces a weak green and β(Ca,Mn)SiO_3 fluoresces a strong orange with cathode ray excitation. Fonda and Froelich showed that Mn-activated wollastonite, the low-temperature form of $CaSiO_3$ called (β), and not pseudowollastonite, the high-temperature modification called (α), could be sensitized to 2537Å radiation by lead. Therefore, β(Ca,Mn,Pb)SiO_3 is the species implied by the notation $CaSiO_3$:Mn + Pb.

Phase Relationships

Preliminary studies showed that in the vicinity of the $CaSiO_3$ composition, the system CaO-MnO-PbO-

SiO_2 can be regarded as a 3-component system $CaSiO_3$-$MnSiO_3$-$PbSiO_3$. Consequently, examination of the binary systems $CaSiO_3$-$PbSiO_3$ and $CaSiO_3$-$MnSiO_3$ (after Glasser), and the solid solution region β(Ca,Mn,Pb)SiO_3 provided data necessary to understand many of the reactions which occur during synthesis of the $CaSiO_3$:Mn + Pb phosphor.

A discussion of the pertinent phase data follows:

The inversion temperature of calcium metasilicate.—The literature shows conflicting claims on the temperature of the dimorphic inversion in calcium metasilicate. Voos, for example, reports that the inversion occurs at 1210°C whereas Osborn and Schairer (12) give a value of 1125°C. Our attempts to prepare β-$CaSiO_3$ from $CaCO_3$ and $SiO_2 \cdot XH_2O$ always resulted in a mixture of α- + β-$CaSiO_3$ when fired at temperatures below ca. 1170°C; a sample fired at 1000°C for one month consisted of about 50% α- + 50% β-$CaSiO_3$. At 1180°C or above, only α-calcium silicate formed. α-$CaSiO_3$ will begin very slowly to invert to β-$CaSiO_3$ at 1150°C after several weeks. The data are not conclusive but they indicated that the inversion lies between 1150° and 1180°C.

The system $CaSiO_3$-$MnSiO_3$.—Glasser has recently re-examined the system $CaSiO_3$-$MnSiO_3$ and he is in general agreement with the earlier results of Voos except in many details and the disclosure that the solid solution series extends to 90% $MnSiO_3$ rather than to 100% as reported earlier. He shows that $MnSiO_3$ solid solutions in $CaSiO_3$ raise the inversion temperature to a maximum of 1400°C. The $\alpha \rightleftharpoons \beta$-$CaSiO_3$ inversion temperature was not redetermined in the system $CaSiO_3$-$MnSiO_3$. However, Glasser and Osborn (13) found the $\alpha \leftrightharpoons \beta$-$CaSiO_3$ inversion temperature to occur at 1125°C in the system CaO-Cr_2O_3-SiO_2.

The system $CaSiO_3$-$PbSiO_3$.—Nothing has been reported in the binary system $CaSiO_3$-$PbSiO_3$. The high volatility of Pb limited this investigation to the area around the $CaSiO_3$ composition. Solid-state calcines of preformed $CaSiO_3$ and $PbSiO_3$ were used as starting materials for quench studies. The loss of lead after calcining these mixtures for 6 days at 1050°C is shown in Table II. Since 5 to 7 additional days were required for the samples to reach equilibrium in the quench furnace, further lead losses can be expected, but the magnitudes of these losses were not determined.

The quench data are given in Table III and are shown graphically in Fig. 1. The unusual shape of the two phase area, particularly the flat lower limit, probably reflects the fact that the compositions have shifted from the binary join. Consequently, the phase

data can be taken only as an approximation of the true equilibrium relationships.

$PbSiO_3$ is soluble in α calcium metasilicate to at least 6 mole % and it lowers the inversion temperature; the addition of 3 mole % $PbSiO_3$ lowers the inversion below 1125°C. Extrapolation of the two-phase area boundaries to pure calcium silicate indicates that the inversion occurs at 1160° ± 10°C.

The (Ca,Mn,Pb)SiO_3 *ss phase region.*—A portion of the plane $CaSiO_3$-$MnSiO_3$-$PbSiO_3$ in the vicinity of $CaSiO_3$ was examined at 1160°C. This temperature was selected because it is near the inversion temperature and also is a practical temperature for phosphor synthesis. Calcines were prepared by heating mixtures of preformed α(Ca,Pb)SiO_3 and $MnSiO_3$ for periods up to three weeks with a thorough grinding every 12 hr.

Lead is much less soluble in β- than in α-$CaSiO_3$ in the presence of $MnSiO_3$. For example, solution of 3 mole % $MnSiO_3$ in α(Ca,Pb)SiO_3 changes it to β(Ca,Pb,Mn)SiO_3 and lowers the Pb solubility from over 6 mole % to less than 1 mole %.

The loss of Pb after various firing times from a typical phosphor composition is shown in Table IV. These data reveal that 8.3% Pb is lost during the formation α(Ca,Pb)SiO_3ss (prepared from PbO + CaO + SiO_2) whereas 33.3% Pb is lost after 4 hr and 53.7% Pb after 16 hr at 1160°C from the reaction of α(Ca,Pb)SiO_3 + $MnSiO_3$ to yield the quaternary composition $\beta(Ca_{0.94-x}Mn_{0.06}Pb_x)SiO_3$. The greater stability of lead in α(Ca,Pb)SiO_3ss than in β(Ca,Mn,Pb)

SiO_3ss can be demonstrated qualitatively by a spot test with an acidic solution of KI. α(Ca,Pb)SiO_3ss (Sample B) gave no test for Pb, whereas β(Ca,Mn, Pb)SiO_3 (Sample E) gave a strong test for Pb even after most of the surface Pb had been removed by refiring with NH_4Cl.

The area adjacent to the solid solution region is a liquid plus crystal area. The presence of liquid was detected by quench studies and by its effect on the oxidation state of Mn. Compositions in the crystal plus liquid area had a permanganate pink color and they were sintered into dense agglomerates. In contrast, composition within the solid solution region remained nearly white in body color and did not sinter.

Table IV. Loss of Pb from phosphor composition

Composition	Wt % Pb content	% Pb lost
(A) Batch (CaO + PbO + SiO_2)	1.08	—
(B) 1st Fire, 1140°C/4 hr (Ca, Pb) SiO_3 ss	0.99	8.3
(C) 2nd Fire, 1160°C/4 hr (Ca, Mn, Pb) SiO_3 ss	0.72	33.3
(D) 2nd Fire, 1160°C/ 16 hr (Ca, Mn, Pb) SiO_3 ss	0.50	53.7
(E) 3rd Fire, 1160°C/4 hr + NH_4Cl(Ca, Mn, Pb) SiO_3 ss	0.43	60.2

Because of the volatility of Pb, the quaternary solid solution region reported can be regarded only as a rough approximation to equilibrium conditions. For this reason, the diagram of the plane $CaSiO_3$-$MnSiO_3$-$PbSiO_3$, shown in Fig. 2, has curved dashed lines to indicate the approximate Pb contents.

Preparation of the $CaSiO_3$:Mn + Pb *phosphor*

Synthesis techniques in which all of the components, i.e., CaO+MnO+PbO+SiO_2 are initially fired together require an excess of Pb in order to allow for losses by volatilization. A typical initial composition is indicated in Fig. 2 by point "A" which is in the liquid plus crystal area adjacent to the solid solution region. As the firing progresses the composition gradually shifts to point "B" located within the solid solution region. The metastable liquids formed serve as effective mineralizers, but they promote large particle size and higher oxidation states of Mn. A second firing with NH_4Cl is necessary to remove a surface film of "lead-manganese-silica" which coats the phosphor crystallites.

Certain applications require a phosphor with smaller particle size. In this case it is desirable to avoid formation of metastable liquids. According to the phase data it should be possible to prepare either β(Ca,Mn)SiO_3ss or α(Ca,Pb)SiO_3ss and react each material with either PbO or MnO to form β(Ca,Mn, Pb)SiO_3ss. In this way, metastable liquids are

avoided in the system $CaSiO_3$-$MnSiO_3$-$PbSiO_3$. However, the quaternary solid solution is unstable due to the volatility of lead so that the reaction:

$$\beta(Ca,Mn)SiO_3ss + Pb^{2+} \rightarrow \beta(Ca,Mn,Pb)SiO_3ss \quad [1]$$

cannot be expected to be very successful.

The alternative reaction:

$$\alpha(Ca,Pb)SiO_3ss + Mn^{2+} \rightarrow \beta(Ca,Mn,Pb)SiO_3ss \quad [2]$$

should be more successful due to the greater stability of lead in $\alpha(Ca,Pb)SiO_3ss$ than in $\beta(Ca,Mn,Pb)SiO_3ss$. A sufficiently large excess of Pb can be incorporated initially in $\alpha(Ca,Pb)SiO_3ss$ to allow for losses by volatilization.

Although reaction [2] avoids quaternary liquids, it is still necessary to form $\alpha(Ca,Pb)SiO_3ss$, and low-melting liquids in the system CaO-PbO-SiO_2 cannot be avoided. However, advantage can be taken of the polymorphic inversion from $\alpha(Ca,Pb)SiO_2ss$ to $\beta(Ca,Mn,Pb)SiO_3ss$. Although α- and β-$CaSiO_3$ have about the same densities, a volume change sufficiently large to cause disintegration of agglomerates may be expected in going from $\alpha(Ca,Pb)SiO_3ss$ to $\beta(Ca,Mn,Pb)SiO_3ss$ because of the difference in size between Pb^{2+} and Mn^{2+} ions.

Attempts to prepare $\beta(Ca,Mn,Pb)SiO_3ss$ by reaction [1] did not yield high brightness phosphors since it is not possible to incorporate enough Pb in the phosphor to give sufficiently high absorption for 2537Å.

The preparation of $\beta(Ca,Mn,Pb)SiO_3$ by reaction [2] proved successful. Thus, the preparation of the phosphor involves three steps: (*a*) formation of $\alpha(Ca,Pb)SiO_3ss$, (*b*) formation $\beta(Ca,Pb,Mn)SiO_3ss$, and (c) removal of a surface film of "manganese-lead-silica." Each step is discussed in detail.

(*a*) $\alpha(Ca,Pb)SiO_3$ forms metastably below the inversion temperature so that the reaction proceeds rapidly at temperatures between 1100° and 1200°C. The occurrence of metastable liquids accelerates the reaction and it causes the development of large aggregates having diameters between 30 and 100 μ.
