The Flade Potential of Iron Passivated by Various Inorganic Corrosion Inhibitors

Herbert H. Uhlig and Peter F. King[1]

Department of Metallurgy, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

The characteristic potential obtained just before decay of passivity (Flade potential) was measured for iron passivated by ferrates, nitrites, chromates, molybdates, tungstates, conc. HNO_3, and by anodic polarization in H_2SO_4. The Flade potential is linear with *p*H, of slope 0.059 up to approximately *p*H 4.5. Above this value up to *p*H 11.5, the potentials tend to follow an extension of the data in acids in the case of iron passivated by chromates and nitrites, but reach a constant value for iron passivated anodically or by conc. HNO_3. The standard Flade potential (*p*H = 0) for various passivators is increasingly noble in the order: nitrite (—0.50 v); chromate, ferrate, molybdate (—0.54 v); tungstate (—0.61 v); and anodic polarization or conc. HNO_3 (—0.64 v). The average of these values is in reasonable accord with previously reported values and only small observed deviations from the average indicate that the structure and composition of the passive film on iron is largely independent of the passivation process.

This is explained by a primary passive film consisting essentially of a monolayer of chemisorbed oxygen atoms through gaps of which a layer of O_2 molecules is chemisorbed. The calculated free energy of formation of such a film (—30,000 cal/mole ads. O), the chemical equivalents of passive film substance (0.01 coulomb/cm^2), and the oxidizing capacity (12×10^{-8} equivalents/cm^2) are all consistent with independent data obtained by others for oxygen adsorption on iron, coulometry, and reaction of the passive film with CrO_3^- to form CrO_4^{--}.

The mechanism of passivity, accordingly, is proposed to consist of: (*a*) adsorption of the passivator on the metal or metal oxide surface; (*b*) depolarization of cathodic areas by the passivator accompanied by anodic passivation of residual small areas of exposed metal; the adsorbed oxygen film is formed at anodes by discharge and combination of OH^- at current densities above approximately 17 amp/cm^2 in accord with data of Franck; and (c) very slow formation of iron oxides with continual repair of the adsorbed oxygen film by electrochemical action, as described, at pores in the oxide. Oxide formation is accelerated by elevated temperatures and presence of certain anions, e.g., Cl^-.

It is proposed that the greater stability of the passive film formed by some passivators is accounted for by supplementary adsorption of the passivator on the passive film, accompanied by shift of the Flade potential to a less noble value.

In 1911, Flade (1) showed that if iron is passivated in concentrated HNO_3 or by anodic polarization in dilute H_2SO_4, the decay of passivity with time is represented: first, by a steep fall of potential in the active direction; second, by a less steep change lasting for a fraction of a minute to several minutes; and third, by a steep descent to the active value. The value of potential immediately preceding the steep descent was called by Flade the "umschlagspunkt" and by later workers the Flade potential. This critical potential was shown by Flade to be more noble the higher the concentration of acid in which the decay took place, and also that the value at constant *p*H became more active by about 50 mv as the temperature was decreased from 15° to 0°C. Franck (2) showed that the Flade potential E_F for iron in acid media accurately followed the relation (A.C.S. Sign Convention):

$$E_F(\text{volt}) = -0.58 + 0.058\,p\text{H}$$

suggesting, therefore, a reversible thermodynamic relationship to *p*H of the activating acid. Rocha and Lennartz (3) measured the Flade potentials for Fe-Cr alloys and Cr in H_2SO_4, their values for which showed a slope of potential plotted with *p*H of 0.058 for alloys below about 12% Cr and 2 x 0.058 for alloys of higher Cr content. Earlier, Müller and Cupr (4) provided data for potential behavior of Cr which show on plotting vs. *p*H a slope of 0.058 characteristic for spontaneous activation of Cr in various acids, and 2 x 0.058 for Cr activated by cathodic polarization. Recently Cartledge and Sympson (5) demonstrated that iron passivated by sodium molybdate, tungstate, and chromate or by potassium pertechnetate also exhibits Flade potentials that are linear with *p*H, of slope 0.058, the average absolute values for which parallel those by Franck for iron passivated in con-

centrated HNO_3 or anodically in H_2SO_4. The present measurements explore Flade potentials for iron passivated by ferrates and nitrites in addition to chromates, molybdates, tungstates, concentrated HNO_3, and by anodic polarization in H_2SO_4. The experimental procedure differs somewhat from that used by Cartledge and Sympson, and the *p*H range is increased to include the alkaline region.

Experimental Procedure

Electrodes of about 2 cm^2 area were prepared from mild steel. This composition has an advantage over higher purity iron in that passivity is found to be more stable during transfer from the passivating solution to the activating solution. Carbon steels are more readily passivated by concentrated HNO_3 than is pure iron (6), probably because of cementite present as a second phase in the carbon steels which acts as the noble component of a galvanic couple, hastening anodic passivation of the metallic phase (ferrite). For example, coupling of platinum to iron also hastens passivity. Cementite, accordingly, stabilizes passivity probably by allowing galvanic action to continue during transfer of the specimen. Flade showed earlier (1) that carbon steel or electrolytic iron exhibits essentially the same "umschlagspunkt."

The electrode was assembled with a nickel wire silver soldered to a stem machined on the steel specimen, the wire being enclosed by an 8 mm diameter glass tube. A Teflon gasket maintained a water-tight seal between steel and glass tube at one end, with constant contact being effected by means of a screw, nut, and rubber grommet attached to the wire at the other end. The gasket was machined so as to insure against crevices or leakage which if not avoided made it difficult to obtain optimum passivity.

Passivator solutions were made up from reagent grade salts and distilled water in the following concentrations: (*a*) 0.0025*M* and 0.1*M* $NaNO_2$, (*b*) 0.0025*M* K_2CrO_4, (c) 0.0025*M* Na_2WO_4, (*d*) 0.0025*M* Na_2MoO_4. In addition, concentrated CP HNO_3 was used, and 0.1% K_2FeO_4 solution prepared according to the method described by Thompson, Ockerman, and Schreyer (7).

Electrodes were passivated by immersion in one of the above solutions for a period of usually several minutes up to 1 hr, or whatever time was required to achieve a stable noble potential. Electrodes were then washed successively in 3 beakers of distilled water, and finally immersed in water adjusted to a known *p*H by means of HNO_3, H_2SO_4, or NaOH. It made no apparent difference whether HNO_3 or H_2SO_4 was used for adjustment in the lower *p*H range. The decay of potential vs. time was measured with reference to Ag-AgCl, 0.1*N* KCl electrode using a Na_2SO_4 salt bridge and employing an electronic galvanometer and portable potentiometer. Corrections were not made for liquid junction potentials. Typical decay curves are shown in Fig. 1. The potential obtained just before the abrupt drop was recorded as the Flade potential. Cartledge and Sympson used instead the average value of the potential at the plateau preceding breakdown, but this procedure differs from that first described by Flade. It seems to us more likely that the potential corresponding to

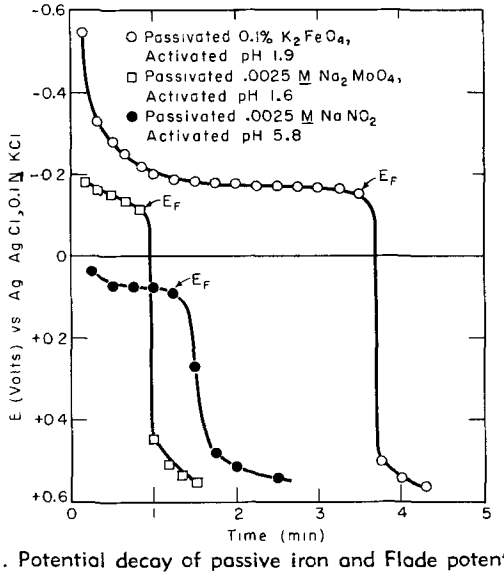

Fig. 1. Potential decay of passive iron and Flade potential E_F

the thinnest passive film, i.e., just before the steep decline, represents the equilibrium state between film and solution, and that it is this potential in which we have most interest. In any case, however, the relatively large experimental error in determining the Flade potential makes the particular procedure in this regard of small consequence. This is evident from the relatively good correspondence of our data with those of Cartledge and Sympson.

The procedure used by the latter authors for activating their electrodes consisted of adding sodium sulfate to the passivator solution until passivity decayed, without removal of the electrode. Our method was to remove the electrode from the passivator solution, wash it, and then place it in an aqueous solution of known *p*H. The latter procedure produced a sharper change from the passive to active state, with apparently less experimental scatter.

Results

Flade potentials determined as described above, where each point represents one or more runs, are plotted vs. *p*H in the acid range up to *p*H 4.5 in Fig. 2 and 3. Although a single line of slope 0.059 and intercept at −0.57 v for *p*H = 0 might have been drawn through all the points with maximum deviation of about ±150 mv, the pattern of data favors individual straight lines through points relating to a

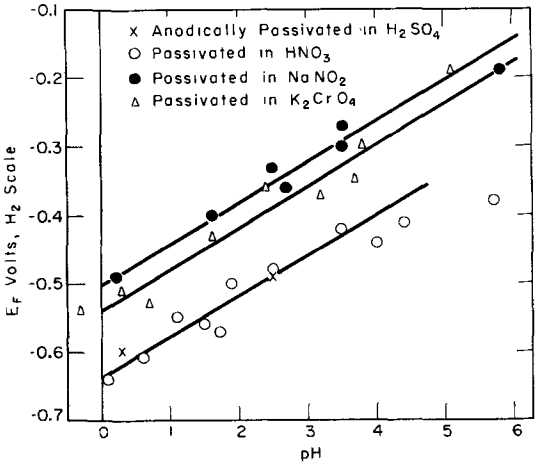

Fig. 2. Flade potentials for iron in acid range

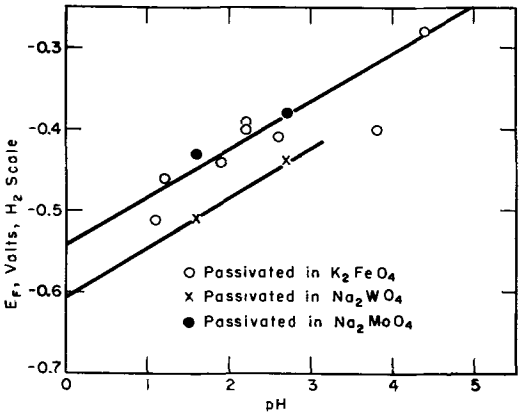

Fig. 3. Flade potentials for iron in acid range

given passivator. All lines so drawn have a slope of approximately 0.059, but the intercepts are increasingly noble in the following order:

	Passivator	Approx. intercept, $pH = 0$ (H_2 scale) v
1.	$NaNO_2$	—0.50
2.	K_2CrO_4, K_2FeO_4, Na_2MoO_4	—0.54
3.	Na_2WO_4	—0.61
4.	Anodic polarization in H_2SO_4; conc. HNO_3	—0.64

Measurements in the near-neutral and alkaline range were not as reproducible, and passivator solutions behaved with greater individual differences in comparison to their behavior in acid environments. Data are plotted in Fig. 4.

Potentials of Fig. 2 and 3 agree in slope with those reported by Franck, and by Cartledge and Sympson. The average intercept at $pH = 0$ of —0.57 v is also close to the average value of their data. However, drawing the best line through individual points for passivation by HNO_3, or anodically in H_2SO_4, produces an intercept of —0.64 v, which is more noble than the average by 0.07 v. This value can be compared with the still more noble standard Flade potential reported by Rocha and Lennartz for iron anodically passivated in H_2SO_4 equal to —0.68 v.

There is a tendency for Flade potentials of iron previously passivated in K_2CrO_4 and then activated in alkaline solutions to follow an extrapolation of data obtained in acid media as indicated by the dotted line of Fig. 4. Two points for $NaNO_2$ fall

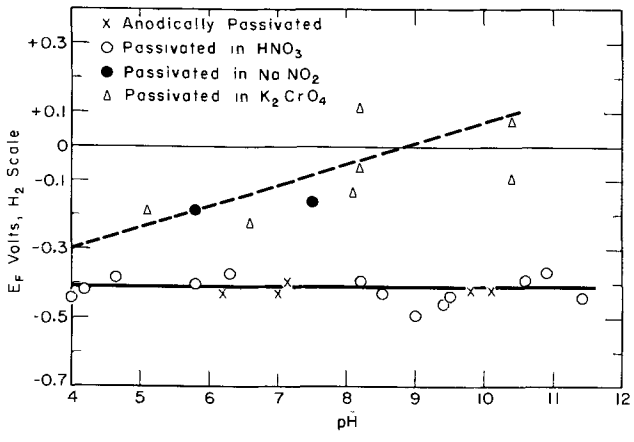

Fig. 4. Flade potentials for iron in near-neutral and alkaline ranges.

within the same region. These data as mentioned earlier are inherently more difficult to reproduce, particularly since breakdown of passivity is sluggish in the alkaline region and sometimes does not occur at all within a reasonable time. More definite conclusions are reached in this region for iron passivated in concentrated HNO_3 or by anodic polarization. Flade potentials lie on a line of zero slope from pH 4 to 11.4, the mean value for which, —0.41 v, is considerably more noble than comparable values for nitrite or chromate.

Discussion

It is significant that all Flade potentials whether in the alkaline or acid region are more noble by several tenths volt than corresponds to potentials for any of the several oxides of iron in equilibrium with metallic iron (8, 9). Hence, the passive film does not appear to be any single known iron oxide. Vetter (9, 10), in order to account for the facts, hypothesized a high potential gradient within a film of Fe_2O_3 overlying a film of Fe_3O_4. Göhr and Lange (11) and Schottky (12) discussed various possible ionic equilibria within the oxide or at the oxide surface.

Göhr and Lange by assuming equilibrium between a layer of γFe_2O_3 overlying a layer of Fe_3O_4, and making certain assumptions regarding the free energy of formation of γFe_2O_3, show that the following reaction may account for the Flade potential:

$$Fe_3O_4 + 1/2\ H_2O \rightarrow 3/2\ \gamma Fe_2O_3 + 2H^+ + 2e$$

Heusler, Weil, and Bonhoeffer (13) concur in a model based on γFe_2O_3 overlying Fe_3O_4. Cartledge (14) suggested an inner oxide, e.g., an abnormal "FeO," in contact with an outer iron oxide in a higher oxidation state to account for the Flade potential.

Some of the assumptions upon which these proposals are made immediately run into difficulty in explaining the Flade potential of Cr (0.2 v) which is also more noble than corresponds to Cr_2O_3 in equilibrium with Cr and for which only one known oxide forms on the metal surface. Furthermore, the total observed thickness of passive film substance, assuming it to be an oxide, is hardly sufficient to accommodate two layers of oxides. For example, the approximate number of chemical equivalents of passive film substance on iron as measured by coulometry (15) or by the oxidizing capacity of the film (16) corresponds to only 0.01 coulomb/cm^2 apparent surface. Assuming that the roughness factor for pickled iron is similar to the measured value of 4 for 18-8 stainless steel pickled in hydrochloric-sulfuric acids (17), the value becomes 0.0025 coulomb/cm^2 absolute surface. This figure becomes larger as iron is polarized to more noble potentials, but becomes smaller as the Flade potential is approached where the passive film reaches minimum thickness consistent with retention of passivity. Hence assuming 0.0025 coulomb/cm^2, the average thickness is 14Å if the passive film is composed of Fe_3O_4, and it can be thinner;[2] if it is γFe_2O_3, the corresponding

[2] Employing for Fe_3O_4 and γFe_2O_3 equivalent weights and densities of 28.9, 26.6, and 5.2, 5.1, respectively. The above thickness of the passive film should not be confused with thicker layers of oxide (25-100Å) residual on iron surfaces after passivity has decayed. This matter is discussed later.

thicknes is 13Å. But the unit cell dimensions of Fe_3O_4 and γFe_2O_3 are 8.3 to 8.4Å (18, 19), the sum of which is 16.7Å. Hence, it does not seem likely that thermodynamic properties of bulk oxides, as employed by Göhr and Lange, for example, can have much significance with respect to properties of the passive film near the Flade potential where the total thickness is less than the sum of the unit cell dimensions. Along the same lines, it is difficult to conceive of a high potential gradient ($>10^6$ v/cm) in a Fe_2O_3 film overlying Fe_3O_4 as hypothesized by Vetter, where the Fe_2O_3 layer has a thickness less than the dimensions of the unit cell. A third difficulty with this duplex oxide film model is that, so far, it has not been able to explain the ability of the passive film to oxidize CrO_2^- to CrO_4^{--} as measured by Uhlig and O'Connor (16).

These difficulties are overcome by the suggestion (20) that the passive film is not an abnormal oxide or double oxide, but is essentially chemisorbed oxygen instead, and that the Flade potential corresponds to the following equilibrium:

$$3H_2O + \text{Fe surface} \leftrightarrows O\cdot O_2 \text{ (adsorbed on Fe)} + 6H^+ + 6e \qquad [1]$$

The standard potential for this reaction (pH = 0) is —0.58 v according to Franck's data or —0.64 v according to Fig. 2. The structure $O\cdot O_2$ (ads. on Fe) signifies a complete monolayer of chemisorbed oxygen atoms through gaps of which a further layer of O_2 molecules is chemisorbed in accord with the suggested structure of chemisorbed oxygen on tungsten (21). This structure is consistent with the observed approximate 0.01 coulomb/cm² apparent surface of passive film substance. At the Flade potential, as mentioned earlier, the film is somewhat thinner than corresponds to $O\cdot O_2$, and may more nearly correspond to a film of atomic oxygen. For passive potentials more noble than the Flade potential, the film probably contains not only chemisorbed oxygen additional to an atomic monolayer, but also adsorbed OH, the amount depending on the extent to which iron is polarized anodically by the passivation process.

On breakdown of passivity in accord with:

$$O\cdot O_2 \text{ (ads. on Fe)} + 2Fe + 3H_2O \rightarrow Fe(OH)_3$$

a residual film of Fe_2O_3, 60Å thick is accounted for, in reasonable agreement with measurements of Schwarz (22) and Gulbransen (23). It is the decomposed passive film which was observed by electron diffraction measurements of Mayne and Pryor (24) which they reported as γFe_2O_3.

A major support for chemisorbed oxygen as the composition of the passive film comes from thermodynamic data. From Tompkin's measurements (25) on the direct chemisorption of gaseous oxygen on iron, ΔH° = —75,000 cal/mole O_2. The standard entropy of adsorption ΔS° is approximately equal to —46.2 e.u. (26) with a standard state of half surface coverage. Hence, since ΔH° is not sensitive to the extent of surface coverage (27) we can use the relation ΔG°, the free energy of adsorption, = $\Delta H^\circ - T\Delta S^\circ$ = —61,300 cal/mole oxygen adsorbed. Accordingly:

$$3/2\ O_2 + \text{Fe surface} \rightarrow O\cdot O_2 \text{ (ads. on Fe)}$$
$$\Delta G^\circ = -3/2 \times 61{,}300 \text{ cal} \qquad [2]$$
$$3H_2O \rightarrow 6H^+ + 3/2\ O_2 + 6e^-$$
$$\Delta G^\circ = 170{,}000 \text{ cal (28)} \qquad [3]$$

Adding [2] and [3]:

$$3H_2O + \text{Fe surface} \rightarrow O\cdot O_2 \text{ (ads. on Fe)} + 6H^+ + 6e^-$$
$$\Delta G^\circ = +78{,}000 \text{ cal} \qquad [4]$$

The corresponding standard potential E° equal to $-\Delta G^\circ/6F$ is —0.56 v. This value agrees within reasonable limits with the measured values of —0.58, —0.64, and —0.68 v quoted previously.

Bonhoeffer (29) and his co-workers showed that passivation of iron in concentrated HNO_3 proceeds by an electrochemical reaction in which nitrous acid, HNO_2, acts as a strong cathodic depolarizer. The major part of the iron surface serves as cathode resulting in very high current densities reaching approximately 17 amp/cm² (2) at small residual anodic surfaces. These high anodic current densities produce the passive film, which in turn becomes the seat of the continuing cathodic reaction, thereby favoring spread of passivity over all the surface.

The nitrous acid resulting from reduction of HNO_3 plays a very important part as depolarizer, therefore, in passivation by nitric acid. It is proposed herewith that the passivators reported in this paper act also by depolarization to produce the passive state, and that the resulting composition and structure of the passive film are basically the same in all cases. The similarity of Flade potentials makes this conclusion plausible. Chromates, for example, first adsorb on the iron surface, and on iron oxides if present, and as such act as cathodic depolarizers. Since adsorption and depolarization occur over the entire surface, current densities at gaps in the adsorbed film easily reach the order of 17 amp/cm². The ultimate passive film, which is essentially chemisorbed oxygen resulting from discharge and combination of OH^-, is formed by anodic polarizaton. It is formed at a rate measurably slower than for nitric acid presumably because of the slower rate of cathodic reduction of chromates as compared with HNO_2.[3] This slower re-

[3] Uhlig and O'Connor (16) proposed that ferrates or similar higher valence iron compounds form when iron reacts with concentrated HNO_3 and that such compounds adsorbed on iron probably constitute the passive film. They calculated the amount of adsorbed ferrate on the iron surface from the ability of the passive film to oxidize CrO_2^- to CrO_4^{--} in NaOH solution.

It now appears from the foregoing data that it is not necessary to assume formation of ferrates as such as source of the observed oxidizing property of the film. Instead, adsorbed oxygen expressed as $O\cdot O_2$ (ads. on Fe) can also account for the facts. This adsorbed oxygen is related to the ferrate structure in that strongly alkaline media convert the adsorbed film continuously to ferrates in accord with the reaction:

$O\cdot O_2$ (ads. on Fe) + Fe + 2NaOH → $Na_2FeO_4 + H_2O$ + Fe surface

as is observed when iron is polarized anodically in concentrated NaOH.

In dilute NaOH, ferrates act as passivators in accord with:

$$2Na_2FeO_4 + 5H_2O + \text{Fe surface} \rightarrow O\cdot O_2 \text{ (ads. on Fe)} + 2Fe(OH)_3 + 4NaOH$$

Iron immersed in K_2FeO_4, therefore, preforms the passive film and no initial reaction occurs on subsequent immersion of iron into conc. HNO_3, a reaction that is necessary otherwise to form a minimum concentration of HNO_2 to serve as depolarizer (16).

The herein-described mechanism of passivation by chromates (and similar passivators) modifies the earlier proposal by one of us that the primary passive film consists of chromate adsorbed directly on the metal. From present data, formation of such a film more likely is the first stage of passivation. This is followed by formation of the anodically produced oxygen film, which is actually the primary passive film. Iron oxides form more slowly as a third stage process, but they contribute relatively less to corrosion resistance compared to the adsorbed oxygen film which continues at the base of pores in such oxide layers so long as chromates are present in solution. Elevated temperatures and certain anions (e.g., Cl^-) accelerate formation of iron oxide and accompanying reduction of chromate.

duction can account for the fact that it requires only seconds for passivation of iron in conc. HNO_3 but about ½ to 1 hr for the passive film to form completely in chromates as indicated by potential measurements (30), and from experiments on the effect of pre-immersion of iron in chromates on the rate of reaction with concentrated HNO_3 (31).[4]

The above described reaction of iron with dichromate can proceed as follows:

$$Cr_2O_7^{--} + 14H^+ + 6e^- \rightarrow 2Cr^{+++} + 7H_2O \qquad E^\circ = 1.33 \text{ v} \qquad [5]$$

$$3H_2O + \text{Fe surface} \rightarrow 6e^- + 6H^+ + O\cdot O_2 \text{ (ads. on Fe)} \qquad E^\circ = -0.54 \text{ v} \qquad [6]$$

Adding [5] and [6]:

$$Cr_2O_7^{--} + 8H^+ + \text{Fe surface} \rightarrow 2Cr^{+++} + 4H_2O + O\cdot O_2 \text{ (ads. on Fe)} \qquad E^\circ = 0.79 \text{ v} \qquad [7]$$

The positive value of emf for reaction [7] indicates that the reaction can go spontaneously; in other words, dichromate can produce the chemisorbed passive film by anodic polarization in the same way as can conc. HNO_3 or direct anodic polarization in H_2SO_4. It is reasonable that a similar reaction should occur in alkaline media forming perhaps basic chromic chromate (32) as end product, but free energy data for this reaction are not available.

According to reaction [7], each mole $Cr_2O_7^{--}$ which is reduced to form the passive film forms two moles Cr^{+++}. If Cr^{+++} so produced is retained on the metal surface, perhaps as hydrated Cr_2O_3 or adsorbed as the ion, the amount so formed is an indication of the number of equivalents of passive film substance per unit surface. Geary (33) found 3×10^{16} Cr atoms/cm² or 5×10^{-8} g-atom/cm² retained on an iron surface after passivation by dichromate using radioactive Cr as tracer. In this experiment, the iron surface was hydrogen-reduced at 1000°C, then exposed to deaerated 0.0005*M* $Cr_2O_7^{--}$ solution of *p*H 1.9 for 2 to 17.5 hr avoiding contact with air. The iron surface was washed in distilled water before counting. The same approximate amount of residual Cr was reported by Brasher and Stove (34), by Powers and Hackerman (35), and by Cohen and Beck (36) for air-exposed iron. This quantity of chromium, calculated in accord with conditions of reaction [7], corresponds to 2.5×10^{-8} mole $O\cdot O_2$ (ads. on Fe)/cm²[5] or 15×10^{-8} equivalents of passive film substance per cm². This value is in good agreement with the maximum amount of passive film substance on iron (2×10^{-8} mole $O\cdot O_2$ ads. on Fe/cm² or 12×10^{-8} equivalents of passive film substance/cm²) found by O'Connor (16) from the oxidizing capacity of the passive film.[6] It is also in accord with Weil's value of about 0.01 coulomb/cm² passive film substance as determined by coulometry ($15 \times 10^{-8} \times 96{,}500 = 0.014$ coulomb).

It is probable that most other passivators operate by a mechanism similar to that outlined above for chromates. This mechanism explains why sulfates or perchlorates are not passivators even though they have the XO_4^{n-} structure. Ions of this kind either do not reduce, or do so too slowly to fulfill the requirements of a cathodic depolarizer. On the other hand, oxidizing substances such as chlorides for which the minimum current density for anodic passivation is very high or infinite, also do not meet the requirements of a passivator. Hypochlorous acid and ferric chloride are in this category. Alkaline inhibitors such as Na_3PO_4, Na_2CO_3, and NaOH act as passivators only in the presence of dissolved oxygen (37, 38) and hence the cathodic reduction of these substances is not required for passivation. Instead, most alkaline substances probably displace adsorbed H, the latter tending to form whenever iron is exposed to an aqueous environment, and favor adsorption of OH^- together with oxygen on the metal surface. Hence for these substances an adsorbed oxygen-hydroxyl ion film can form directly without the necessity of anodic polarization. This same situation applies to Cr and the stainless steels which become spontaneously passive on exposure to air.

Dissolved oxygen is also required for passivation of iron by molybdates and tungstates (38). A possible explanation is that oxygen as well as the passivator adsorbs on the metal thereby increasing cathodic and decreasing anodic areas. This extension of cathodic sites and limitation of anodic sites favors attainment of the critical current density necessary for anodic passivation. Oxygen may be necessary, in other words, because molydates and tungstates are not sufficiently good cathodic depolarizers on a clean iron surface, but they become effective if the galvanic current accompanying their cathodic reduction is restricted to smaller anodic areas as when oxygen is present on the surface.

With chromates, dissolved oxygen is not necessary for passivation, but oxygen does increase the rate of passivation (31) in accord with the mechanism just described.

The passive film formed by pertechnetates may also consist essentially of chemisorbed oxygen. From data by Cartledge and Smith (39) for the reaction:

$$TcO_2(c) + 2H_2O \rightarrow TcO_4^-(aq) + 4H^+ + 3e \qquad E^\circ = -0.738 \text{ v} \qquad [8]$$

it is concluded that the following reaction is spontaneous:

$$2TcO_4^- + 2H^+ + \text{Fe surface} \rightarrow O\cdot O_2 \text{ (ads. on Fe)} + H_2O + 2TcO_2 \qquad E^\circ = +0.20 \text{ v} \qquad [9]$$

Radioactive counts by Cartledge (40) on an iron surface passivated by TcO_4^- corresponding to amounts of Tc much less than 4×10^{-8} g-atom/cm² suggests that reduced TcO_4^-, whatever its composition, enters solution rather than precipitating or adsorbing on the metal surface, in contrast to the situation for

[4] When the passive film is previously formed by immersion of iron in O_2-saturated 0.1% $K_2Cr_2O_7$ for more than but not less than ½ hr, no measurable iron reacts on subsequent immersion in concentrated HNO_3, whereas for air-exposed iron, omitting chromate immersion, about 0.04 mg/cm² (16) reacts before the iron-HNO_3 reaction subsides. In deaerated 0.1% $K_2Cr_2O_7$, the time to reach optimum passivity is longer (approx. 2 hr).

[5] This calculated amount should be reduced by the amount of chromate irreversibly adsorbed on the passive film itself. Since a close-packed monolayer of CrO_4^{--} (diam. = 5.4Å) on a surface of roughness factor = 3 amounts to only 0.2×10^{-8} mole/cm², the correction is small.

[6] The reaction studied by O'Connor is assumed (20) to be the following:

$$O\cdot O_2 \text{ (ads. on Fe)} + Fe + OH^- + CrO_2^- + H_2O \rightarrow Fe(OH)_3 + CrO_4^{--} \qquad \Delta G^\circ = -33{,}000 \text{ cal}$$

He found that a maximum of 2×10^{-8} mole CrO_4^{--} was formed per cm² of passive iron, which was reported as equivalent to 2×10^{-8} mole ferrate/cm² instead of 2×10^{-8} mole $O\cdot O_2$ (ads. on Fe)/cm².

chromates. There is also the possibility that a monolayer or partial monolayer of adsorbed TcO_4^- can in itself satisfy surface affinities, as does CO adsorbed on 18-8 in HCl, without reduction. This seems less likely in view of the fact that Cl^- or SO_4^{--} can and do stimulate reduction of TcO_4^- by metallic iron (41), similar to accelerated reduction of other passivators in presence of these ions.

The slightly more active standard Flade potentials for iron passivated by nitrites and chromates as compared with concentrated HNO_3 or anodic passivation in H_2SO_4 (Fig. 2) is evidence of a slightly greater stability of the passive film formed by the first two substances. This stability is also evident from the usually longer time it requires for passivity to break down using chromates as compared with the less stable passive film formed by HNO_3 or by anodic polarization. The greater stability can be accounted for by adsorption of the passivator substance itself, subsequent to the passivation process, directly on the chemisorbed oxygen film, thereby reducing the over-all free energy of the system. Adsorption of passivator on an underlying oxide layer was proposed by Powers and Hackerman (35, 42) based on contact potential measurements, where, however, an adsorbed oxygen layer would also fit the facts. For example, the following adsorption can occur:

$$O \cdot O_2 \text{ (ads. on Fe)} + H_2CrO_4 \rightarrow$$
$$O \cdot O_2 \cdot H \cdot H \cdot CrO_4 \text{ (ads. on Fe)}$$

the free energy change for which is calculated to be −13,700 cal based on −0.54 v for the standard Flade potential for iron passivated by chromates compared to −0.64 v in concentrated HNO_3. If there is supplementary adsorption of Fe^{+++} or $Fe(NO_3)_3$ on the passive film in HNO_3, as seems likely, the calculated ΔG° is for displacement of such an adsorbate by H_2CrO_4. In other words, the interaction between passivator and passive film on which passivator is adsorbed can account for slight variations in Flade potential and for the observed differences in stability of the passive film. On this basis, nitrites adsorb on the passive film more strongly than do chromates, ferrates, and molybdates (Fig. 2, 3), and the latter in turn more strongly than tungstates.

Reasons for the constant Flade potential in the region of *p*H 4 to 11.5 when iron is passivated anodically or by HNO_3 probably depend on change in mechanism of passive film breakdown for less acid environments. It is known that corrosion of iron in HNO_3 or H_2SO_4 continues even when it is passive, hence, it is not unlikely that the surface *p*H rises and that an insoluble basic ferric salt or ferric hydroxide forms as end product of passive decay in solutions of *p*H as low as 4 to 5.

Since considerable ferric nitrate or ferric sulfate forms at the iron surface just prior to passivity, we can assume with justification that Fe^{+++} or $Fe(NO_3)_3$ adsorbs on the passive film. Accordingly a plausible reaction accounting for breakdown of passivity, which is independent of *p*H, is the following:

$$2Fe^{+++} \cdot O \cdot O_2 \text{ (ads. on Fe)} + 3H_2O \rightarrow 2Fe(OH)_3 - 6e$$
$$\Delta G^\circ = -75{,}440 \text{ cal}$$

The standard free energy change for this reaction is based on standard free energies of formation of $Fe(OH)_3$(s), Fe^{+++}(aq), $O \cdot O_2$ (ads. on Fe) and H_2O(l), equal to −166,000, −2,530, −81,500,[7] and −56,690 cal per mole, respectively, discounting the small free energy of adsorption of Fe^{+++} on the passive film. The standard potential is accordingly 0.54 v, or −0.54 v for the same reaction written as an oxidation step. This is to be compared with the observed potential of −0.41 v (Fig. 4). The difference of 0.13 v is probably due, other than to experimental error, to free energy of adsorption of Fe^{+++} not included in the calculation, and possibly to reaction products differing in composition from $Fe(OH)_3$. The above reaction does not go when iron is passivated by chromates and similar passivators because soluble ferric salts are not formed in high concentration, and hence are not adsorbed on the passive film. Accordingly, for such passivators breakdown of passivity in alkalies follows a course not much different from that in acids, as is observed.

Some Observations on the Mechanism of Inhibition

A. C. Makrides

Metals Research Laboratories, Electro Metallurgical Company, Division of Union Carbide Corporation, Niagara Falls, New York

ABSTRACT

Thiocyanic and citric acids are efficient inhibitors of dissolution of iron in dilute HNO_3 solutions. It is concluded that inhibition does not generally involve "poisoning" the combination step in the hydrogen evolution reaction. Some observations on the kinetics of dissolution of iron in dilute HNO_3 solutions are also presented.

There is little doubt that organic compounds which inhibit dissolution of metals in acids adsorb at the metal-solution interface. There are a number of ways in which the resultant adsorbed film could modify the kinetics of the dissolution process. It has been suggested (1) that adsorbed inhibitor on iron deactivates "active centers" at which the reaction

$$H_{ads} + H_{ads} \rightarrow H_2(g) \qquad [1]$$

between adsorbed hydrogen atoms takes place. According to this view, inhibition of iron dissolution is closely associated with occurrence of reaction [1].

Polarization studies with some organic compounds led Elze and Fischer (2) to the conclusion that inhibition of hydrogen discharge governs the process of dissolution in the presence of inhibitors. The particular inhibitors used by these authors had a negligible effect in the presence of an oxidizing agent (Fe^{+++}). From this result, it was maintained that inhibitors function only if reaction [1] above, which according to Elze and Fischer (2) is sensitive to inhibitors, is included in the over-all dissolution process.

It was pointed out (3, 4) that work of King and Hillner (5) indicates that some organic compounds function as inhibitors in strongly oxidizing solutions where reaction [1] is unimportant. However, the relevance of the work of King and Hillner (5) to the elucidation of the mechanism of inhibitor action was questioned on the ground that the observed decrease in dissolution rate may have been due to pH changes of the bulk solution (6).

Makrides and Hackerman (4, 7) found that butyl thiourea inhibits dissolution of iron in $FeCl_3$-HCl solutions. Any bulk effect of butyl thiourea at the concentrations employed was negligible. It was of interest, therefore, to establish whether other compounds function as inhibitors in oxidizing solutions where reaction [1] may be neglected.

Experimental

The rotating cylinder technique was used (8). Armco iron cylinders (99.92-99.96% iron content), 0.94 cm in diameter and about 8 cm long, were rotated at 250 cm/sec linear speed in 400 ml of solution. The cylinders were polished with 2/0 emery paper and were degreased with CCl_4. Only the lateral surface was exposed to solution, the top and bottom parts as well as the edges being covered with paraffin. The exposed area was measured for each cylinder.

Nitric acid solutions of desired concentration were made from stock by dilution. The HNO_3 concentration was determined by titration. Water was doubly distilled, one distillation being from dilute, alkaline $KMnO_4$.

Stock solutions containing HSCN and citric acid were prepared by dissolving a weighed quantity of the corresponding potassium salt in an equivalent quantity of HNO_3 solution. Desired inhibitor concentrations were obtained by diluting stock with HNO_3 solutions of selected concentration. With this procedure, the hydrogen ion concentration in solutions containing inhibitors was at least equal, and generally greater, than in corresponding solutions without inhibitors.

All solutions were thermostated to within $\pm 0.1°C$.

Results and Discussion

Solutions similar to the ones employed by King and Hillner (6) were used originally. First order rate constants were calculated from

$$k = \frac{2.30\,V_s}{At} \log \frac{X_\infty}{X_\infty - X} \qquad [2]$$

Here, V_s is the volume of solution, A the projected surface area, X the weight loss in time t (300 sec), and X_∞ the calculated weight loss for $t \to \infty$. Table I shows that k varied, with no apparent trend, over the concentration range examined. If the (Cl^-) concentration is varied, while that of (H^+) is constant, k at first is independent of C_{Cl^-}, but shows a maximum at larger (Cl^-) concentrations (Table II). Tables I and II indicate that the rate in solutions containing (Cl^-) depends both on total concentration and on the ratio of KNO_3 to HCl concentration.

These results are in general agreement with the work of Abramson and King (9) who have shown that dissolution of iron in KNO_3-HCl solutions is complex. Since there is no apparent reason for using such mixtures, rather than HNO_3 alone, the procedure of King and Hillner (6) was modified to exclude chloride ion.

Dissolution rates in HNO_3 are given Tables III through VI. The results may be summarized as follows: (*a*) approximately two moles of hydrogen ion are consumed per mole of iron dissolved; (*b*) the rate constant decreases regularly with increasing HNO_3 concentration; (*c*) addition of KNO_3 increases the dissolution rate; with $C_{NO_3^-} \sim 2C_{H^+}$, the rate constant increased by about 15% (Table V); (*d*) addition of (H^+) increases the dissolution rate considerably more than addition of (NO_3^-); with $C_{H^+} \sim 2C_{NO_3^-}$, the rate increased by a factor of about 2 (Table VI).

Observations (*a*), (*c*), and (*d*) suggest that in HNO_3 solutions diffusion of (H^+) largely determines the rate at which dissolution takes place. The (H^+) concentration at the interface, therefore, may be considered negligible. The (NO_3^-) concentration at the interface is also less than in the bulk, but the decrease probably does not exceed 20-25%. While it is not possible to state whether (H^+) is consumed by reaction with reduction products of (NO_3^-) or by reaction with (NO_3^-) after discharge, it may be concluded, in view of the excess of (NO_3^-) over (H^+) at the interface,[1] that the concentration of adsorbed atomic hydrogen is negligible. Under these conditions, the contribution of reaction [1] to the overall rate may be neglected.

The decrease of the specific rate constant with increasing HNO_3 concentration is probably caused, at least in part, by changes of the diffusion coefficient. Since the reaction is under diffusion control,

$$k = D/\delta$$

where δ, the equivalent thickness of the boundary layer, may be assumed independent of concentration (10, 11); D, however, is a function of concentration. Any simple correction for this dependence is not possible here, particularly in view of the unknown

[1] Electrical neutrality is, of course, preserved by an equivalent amount of ferrous ion.

Table I

$T = 30° \pm 0.1°C$; $V = 250$ cm/sec

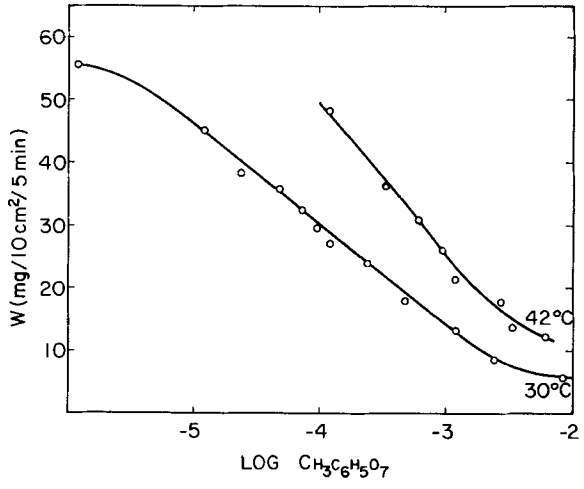

Fig. 2. Rate of dissolution in 0.0231M HNO_3 solutions containing citric acid.

effect of ferrous (or ferric) ions on the activity coefficient of (H^+). There is also the possibility that lack of constancy of k denotes that first order kinetics do not adequately describe the dissolution process in HNO_3 solutions.

Inhibition

Thiocyanic and citric acids were used as inhibitors. HSCN is known to be a good inhibitor in nonoxidizing H_2SO_4 solutions (12), while $H_3C_6H_5O_7$ appeared to be a promising inhibitor according to King and Hillner (6). Runs were made at 30° and 42°C. Results are given in Fig. 1 and 2. In both cases, the solution was 0.0231M HNO_3.

Both compounds proved to be efficient inhibitors. HSCN in particular shows essentially complete inhibition at concentrations above 5×10^{-6} to 1×10^{-5}M. Runs for periods up to 30 min showed that at least half the weight loss observed in this concentration range occurred while the system achieved a steady state. If, as commonly assumed, inhibitors function by adsorption, at small concentrations an appreciable amount of HSCN is removed from solution. At small times, therefore, the solution next to the surface may be depleted and the rate at which adsorption takes place is then limited by the rate of HSCN transport to the interface. From the weight loss-time curve in 5×10^{-6}M HSCN solutions, it was estimated that the time required for adsorption to come to completion was of the order of 1 min.

Of the two compounds used, HSCN is the better inhibitor. It may be inferred that it is adsorbed more firmly. This is borne out by the essentially negligible change in rate observed on raising the temperature to 42°C. The same temperature increase, however, shifts the curve for citric acid toward higher dissolution rates.

It is perhaps worth while to point out again that in neither case can the observed decrease in rate be attributed to a decrease in hydrogen ion concentration of the bulk solution.

Conclusions

Inhibition of iron dissolution under conditions where reaction [1] is negligible by compounds which also inhibit dissolution of iron in nonoxidizing acids suggests that the mechanism of inhibition does not involve, generally, poisoning of the combination reaction between adsorbed hydrogen atoms.

Manuscript received July 17, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Oxidation of Titanium, Zirconium, and Hafnium

G. R. Wallwork and A. E. Jenkins

School of Metallurgy, New South Wales University of Technology, Sydney, Australia

ABSTRACT

A metallographic study of the high-temperature oxidation of titanium, zirconium, and hafnium has shown that alterations in the rate equations relating to such processes may be associated with the establishment of oxygen diffusion gradients in the surface layers of the metal. It has been shown that these diffusion gradients in the metal extend in depth during an initial period in which the total rate of oxidation is given by the familiar parabolic equation. Subsequent changes in oxidation behavior have been related to observed alterations in the form of these gradients.

The high-temperature oxidation of the metals titanium, zirconium, and hafnium has been investigated on many occasions over the last decade. However, there is still much uncertainty concerning the oxidation characteristics of these metals, and the aim of this investigation has been to extend the available experimental results, most of which have been obtained from gravimetric or volumetric oxidation rate measurements.

Earlier work on the oxidation of Ti and Zr (1-3) has shown that, following an initial period, the parabolic rate equations become linear with further passage of time. Smeltzer and Simnad (4) investigated the oxidation of Hf and reported that logarithmic, parabolic, and linear equations describe the oxidation of this metal over the temperature range 350°-1200°C.

The structure of scales formed on Ti in air has been described by Morton and Baldwin (5) and in air and oxygen by Kinna and Knorr (6), and the scales formed on pure Zr in oxygen in the temperature range 500°-700°C have been described by Belle and Mallett (7).

Previous work by one of the authors (1, 2) has indicated the need for a more detailed metallographic examination of the oxidized specimens, and this has now been carried out subsequent to the development of a suitable metallographic technique.

Experimental Procedure

Metal specimens (1.0 x 0.5 x 0.1 cm) prepared as described by Jenkins (1) were oxidized in pure oxygen produced by the thermal decomposition of potassium permanganate. The system was initially evacuated to 15μ Hg, flushed with oxygen, re-evacuated, and then filled to atmospheric pressure. A furnace operating at the required temperature was drawn over a silica tube which contained a specimen hanging from a Pt wire in the oxygen atmosphere. The iodide-refined Ti metal was supplied by the Phillips Laboratories, Eindhoven, and the analysis was reported by Corbett (8). The Hf-free Zr was obtained from the U.S.A.E.C. and the Hf, containing 3-4% Zr, was supplied by the Westinghouse Electric Corporation. The oxidized specimens were mounted on edge in a cold setting polyester resin and abraded on 120, 320, and 400 mesh SiC papers followed by wax laps made from 400, 600, and 850 mesh SiC. Polishing was carried out by first rubbing lightly on a napless cloth impregnated with 1μ diamond paste and then on selvyt cloth carrying an aqueous paste of MgO. The thickness of scale was measured with a filar eyepiece on cross sections of metallographically polished, oxidized specimens. The presence of oxygen in the Ti lattice could be detected by an increase in hardness of the metal, and measurements were therefore made on specimen cross sections utilizing a Leitz microhardness instrument with a standard 124° diamond indenter.

Results

Titanium

Experiments performed in the range 800°-1000°C for long periods indicated that scaling of Ti was influenced greatly by the extent of an oxygen diffusion gradient in the metal phase of the oxidizing specimen. It was noted that the form of this gradient altered during the oxidation at corners and sides of strip specimens, and that ultimately the gradient beneath the main faces of such specimens was affected by the penetration of oxygen to the center of the strip. Further discussion relating to the form of scaling under such conditions is left to a later stage, and the following comments concern the scaling observed on flat surfaces of thick specimens.

The scales.—Two different types of scale were observed. Below 800°C only thin, gray adherent films were obtained, e.g., 0.2 mm thick after 75 hr at 750°C, which on metallographic examination in polarized light proved to be translucent. The gray appearance of the oxidized specimens is considered to be due to reflections from the metal surface beneath the translucent rutile. Above 800°C the scales were pale yellow, and microscopically they exhibited a characteristic form of lamination or banding. On closer examination these layers appeared to alternate in color from translucent yellow to gray, Fig. 1. Platinum marker experiments using wires wrapped around the original specimens showed that the oxide was formed at the metal/oxide interface, and this conclusion was later verified by the use of

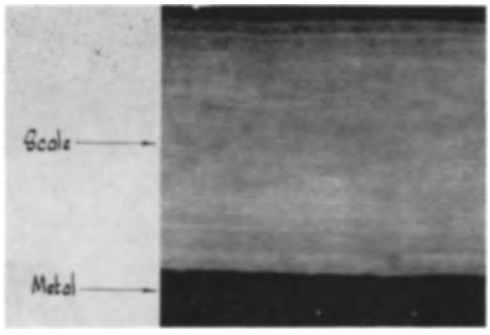

Fig. 1. Scale formed on Ti metal oxidized for 72 hr at 850°C, showing the characteristic form of lamination or banding. (Polarized light, x 250).

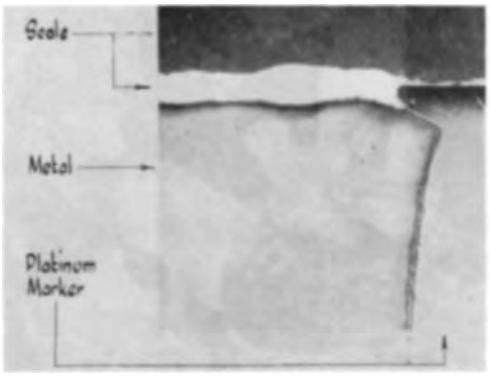

Fig. 2. Scale formed on Ti oxidized for 24 hr at 800°C, showing the inward movement of scale past the Pt marker. (Polarized light, x 125).

Pt plugs inserted through the specimens (Fig. 2). X-ray diffraction studies of the scales and metal cores confirmed that rutile was the only oxide present. The scales, although separated from the metal core on cooling from the oxidation temperature, must have remained in close contact with the oxidizing metal during the tests as they were readily absorbed by the metal when the gaseous supply of oxygen was withdrawn and the tests contained in vacuum for some hours at the same temperature.

The metal core.—Metallographic examination of a cross section of metal cores from oxidized specimens showed that the surface layers contained oxygen in solid solution. In the etched condition these cores taken from specimens oxidized below 800°C showed an oxygen saturated zone outlined by a fine black line just beneath the surface. Above this temperature a much wider band appeared Fig. 3. Previous work (1) had shown that microhardness traverses could be used to follow the form of an oxygen diffusion gradient in Ti. This technique was used to establish the form of the gradients below the saturated surface zone in each section. For each temperature a particular oxygen gradient was established in the core, the extent of penetration being initially time dependent. However, with increasing time the gradient reached a steady state, an example being given in Fig. 4. The time necessary to produce this condition decreased with increasing temperature and coincided with the change from a parabolic to a linear rate equation.

Zirconium and Hafnium

Scales, formed on both metals between 700° and 950°C, were dark gray and adhered to the metal core on cooling. However, the scales were white where they had lifted away from the metal during oxidation. Metallographic examination revealed some cavities penetrating to the metal surface in an otherwise dense, featureless scale structure devoid of layering. Belle and Mallett (7) published a photomicrograph of scale formed on Zr heated in oxygen between 500° and 700°C, and the similarity with the results obtained in the present study indicates that the form of the scale remains unchanged in the range 500°-950°C. Measurements of scale thickness after 24 hr showed a linear increase with respect to both time and temperature. Microhardness traverses revealed that steady oxygen gradients were also established in the cores of these two metals; the periods necessary to accomplish this increased in the order Ti, Zr, and Hf.

"Edge Effect"

Above 800°C, the scales formed on Ti were sufficiently thick to examine in detail, particularly along the edges and corners. At such sites, the yellow translucent scale was invariably thinner than on the main faces and had a crystalline structure distinct from the banded structure obtained elsewhere, Fig. 5. The form of the oxygen gradient in the metal core beneath these edges was traced and its total depth of penetration is shown in Fig. 6 for a specimen oxidized at 850°C for 72 hr.

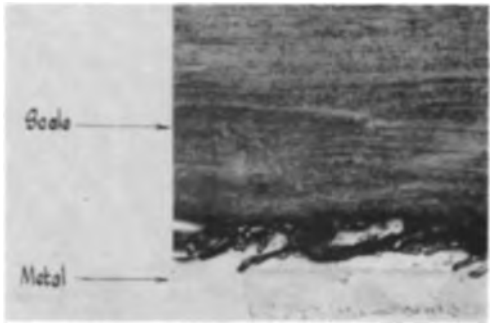

Fig. 3. Same as Fig. 2. The oxygen-saturated zone in the metal core shows as a dark etching band in bright-field illumination. (x 250).

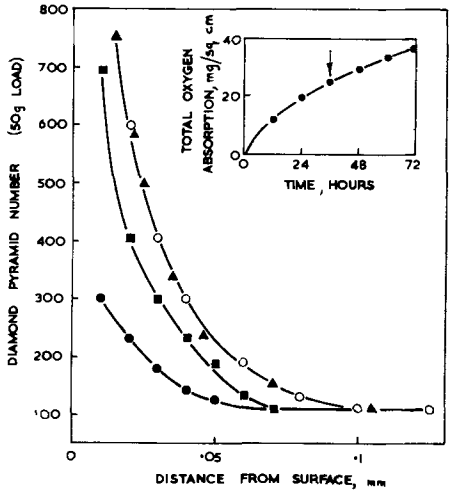

Fig. 4. Penetration hardness curves, showing the development of the gradient and the change from a parabolic to linear rate equation on specimens oxidized at 850°C. ●, 12 hr; ■, 24 hr: ▲, 36 hr; ○, 48 hr.

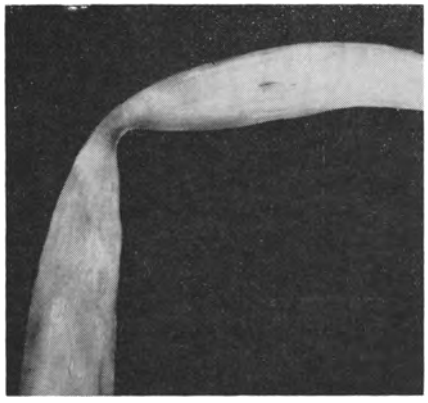

Fig. 5. Section through the center of a specimen of Ti showing the scale formed on a corner ("edge effect"), oxidized at 850°C, for 72 hr. (Polarized light, x 50).

Quite clearly the extent of oxygen penetration into the metal core at the edges was greater than on the flat faces and this affected the form and thickness of the scale at these sites.

Oxidation of Thin Specimens

In the early stages of the investigation, the importance of maintaining oxygen-free metal at the center of reacting specimens was not fully appreciated. Although specimens 1 cm thick were used in later experiments, oxidation at 1000°C for periods in excess of approximately 5 hr produced scaling changes which were attributed to an interruption in the movement of the diffusing oxygen gradient in the metal. This was apparently caused by oxygen penetrating to the center zone of the specimens because the onset of a change in scaling behavior at these high temperatures was noted to vary with the thickness of the specimen. Results of tests carried out under conditions where the diffusion gradient was affected are given in Fig. 7-9. Figure 7 is a cross section of a thin Ti specimen oxidized at 850°C for 72 hr. Initially a normal layered pale yellow scale of considerable thickness was produced (the layers were not reproduced in Fig. 7 so that other features could be high-lighted). However, due to the thinness of the metal specimen, the diffusion

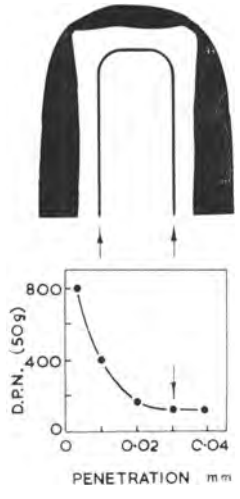

Fig. 6. Shadowgraph of the scale formed on the end of a Ti specimen oxidized for 72 hr at 850°C, showing the position of the extremity of the oxygen gradient and its position in relation to the scale.

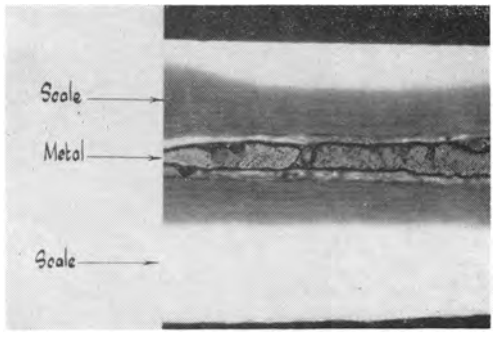

Fig. 7. Scale formed on a thin Ti specimen oxidized for 72 hr at 850°C, showing the effect of through oxidation.

gradients have met in the center, preventing further unhindered progress of the gradients. It is suggested that as a result of a reduced rate of oxygen diffusion into the metal core discoloration of the laminated scale commenced with the onset of cation diffusion outward through the scale toward the gas/scale interface. The metal core eventually received sufficient oxygen to become completely saturated and even produced a film of lower oxide (mainly purple Ti_2O_3) on the large solid particles remaining. As a general rule, the conversion of oxygen-saturated Ti to rutile will by-pass the lower oxides because, as suggested in the following discussion, very thin layers or fragments of oxygen-saturated Ti which have split off from the core are intermittently converted to rutile.

Two additional observations were made on specimens oxidized above 950°C (Fig. 8 and 9). Whenever oxidation conditions permitted the penetration of oxygen to the center zone of each metal specimen, a line of demarcation could be observed in the scale on metallographic examination (Fig. 8). This photomicrograph was prepared from a specimen oxidized at 1000°C for 6 hr, the specimen thickness being such that oxygen penetrated to the center regions. Marker experiments proved that this demarcation line represented the original metal surface. Scale appearing between this line and the metal surface apparently formed during the initial period of oxidation prior to the oxygen penetrating to the center of the metal and possessed the characteristic layered structure (Fig. 1). However, the

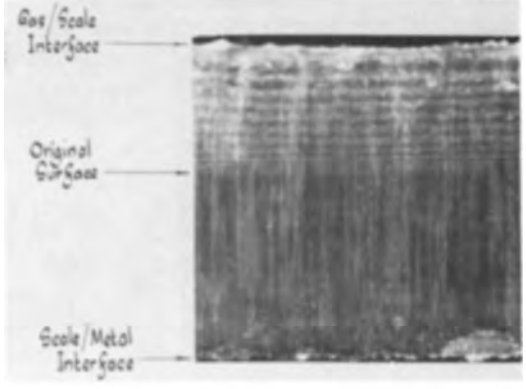

Fig. 8. Scale formed on a Ti specimen oxidized for 6 hr at 1000°C, in which the gradient in the core has been reduced by through oxidation. The columnar structure and the layering in the outer and inner sections of the scale are shown.

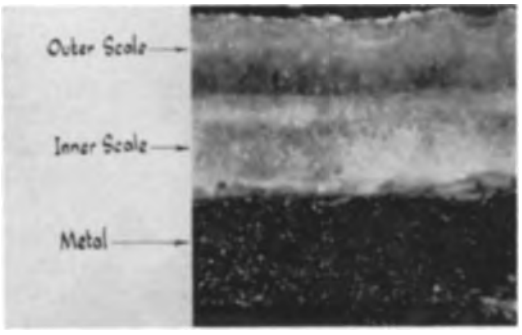

Fig. 9. Scale formed on Ti oxidized for 24 hr at 1000°C, showing the saturated metal core and the two recrystallized layers in the scale.

scale formed between the demarcation line and the gas interface must have been produced as a result of the diffusion of metal cations to the gas interface, and it is evident that the periodicity of the banding has lengthened noticeably toward the end of the oxidation. This portion of the scale forms when the demand for oxygen by the metal phase is reduced for some reason, such as oxygen penetrating to the center of the metal. Microhardness traverses on the remnant metal core beneath the scale shown in Fig. 8 revealed a decrease in oxygen concentration at the surface and a rise at the center, which supports the suggestion concerning reduced oxygen demand by the core. The scale exhibited a gray metallic luster, except at the corners and edges which consisted of large equiaxed crystals. The unusual columnar structure superimposed on the scale structure in Fig. 8 appears to be the result of some cooling phenomenon. The authors believe that a similar observation has been made on rapidly cooled UO_2 crystal aggregates.

Figure 9, taken from a thin specimen oxidized for 24 hr at 1000°C, shows a photomicrograph of the scale produced when the metal core has become completely saturated with oxygen. The two-layer scale is composed of equiaxed translucent yellow crystals of rutile, probably formed at the temperature of test. The core contains a second phase, TiO, which apparently has been rejected during cooling of the saturated solution comprising the core.

Discussion

Earlier work (1, 3) has established that after a brief interval Ti and Zr oxidize according to parabolic rate equations transforming to linear for prolonged periods of time. It is now suggested that the rate equation obeyed by Hf also undergoes a transformation from parabolic to linear upon the establishment of a steady oxygen gradient in the core of the oxidizing specimens. Apart from Loriers' explanation (9) based on a change in scale porosity this transformation has been interpreted in the past as indicating a transition from a diffusion-controlled process (parabolic equation) to a process in which resistance to further diffusion is offered by a barrier of fixed dimensions (linear equation). This barrier was believed to exist in the oxide scale, and the diffusion process was thought to be one in which oxygen penetrated by an anion vacancy mechanism. Metallographic examination has not yet revealed any obvious barrier in any of the scales examined, and density measurements (1) show a 7% porosity at room temperature for rutile scales formed on Ti between 700° and 950°C. However, x-ray diffraction, metallographic, and microhardness techniques have shown that a saturated surface zone together with a steady oxygen gradient is established eventually in the metal core after a period which coincides with the change from parabolic to linear oxidation.

It is now proposed that the scale is not operating as a diffusion barrier in the temperature range considered and that the oxidaiton of Ti, Zr, and Hf is controlled by interstitial diffusion of oxygen in the metal phase. It is considered that the exposure of clean surfaces of these metals to oxygen at high temperatures results first in a rapid gas absorption together with a transient increase in temperature, the gas concentration also rising in the surface layer. Scale formation probably follows the establishment of a saturated surface layer. The conversion of oxygen-saturated metal to rutile is considered to involve an exfoliation of very thin surface layers from the core, conversion to rutile following immediately as the detached metal is exposed to an atmosphere of relatively high oxygen potential. At the high temperature involved, the semiplastic oxide, under stress, would tend to sinter to the previously formed scale, although the junction line may well prove not to be perfect and so lead to the layered scale structure. No layering has been observed in the scales formed on Zr or Hf and this could indicate a difference in the conversion process at the metal/oxide interface.

Scale thickness measurements suggest that the actual scaling rate remains constant during the initial period of parabolic oxidation, whereas the rate of total oxygen absorption decreases with time, the decrease probably reflecting the establishment of the oxygen gradient in the metal core. This would explain the observed parabolic to linear transition in the rate of total oxygen absorption, because a stage must be reached at which the oxygen absorption by the metal core balances the conversion reaction at the metal/oxide interface. Oxygen entering the core then would be used periodically to establish saturated conditions in the core surface and to convert the detached layers to rutile. The following modified parabolic equation should apply during the establishment of the oxygen gradient in the metal,

$$\frac{dn}{dt} = \frac{K_1}{K_2 + n}$$

where n is the number of oxygen molecules absorbed at time t, and K_1 and K_2 are the rate constants for the diffusion and interface reactions. Integrating between the limits (n_0, n), $(0, t)$ we obtain the equation

$$n - n_0 = \Delta n = 2K_1 \left(\frac{t}{\Delta n}\right) - 2(n_0 + K_2)$$

Mathematical substitution in this equation will result in evaluation of the constants K_1 and K_2.

Finally, the influence of the diffusion gradient on the oxidation of Ti is revealed if, for some reason, the gradient of the core is upset. This can occur at corners and edges of specimens where the gradient is extended in depth and also over the main faces of thin specimens in which oxygen has penetrated to the center of the core. When this occurs, the gradient is apparently reduced, the absorption of oxygen by the core is therefore reduced and, if the specimen is scaling in the linear region, the scaling rate must then decrease. The experimental results suggest that the subsequent alteration in scaling behavior then depends on the temperature. Below about 900°C, it appears that a thinner scale remains over such sites, with the possibility of recrystallization at the corners and edges. However, at higher temperatures, it appears that the decrease in the absorption of oxygen at the core surface results in a longer period elapsing between the continuous process of saturation and separation of the core surface layers. Cation diffusion out through the attached scale structure is then observed. Once the usual exfoliation process occurs at the core surface, cation diffusion is halted temporarily until actual contact between scale and core again develops, and this is registered in the widening layered structure (Fig. 8) observed in the outer scale zone of those specimens which have produced a double scale. If this explanation is correct, it would be expected that, as a result of further oxidation of the core and therefore a slower rate of oxygen absorption, an increase in the period elapsing between the detachment of core surface layers would be observed. The result would be that the outermost scale layers formed by cation diffusion, having been the most recent formed, should show the widest banding. It is concluded from the absence of such effects below 850°C (cation diffusion is seen to have commenced in Fig. 4) that the ratio of the diffusivity of Ti cations in rutile to that of interstitial oxygen in the metal may perhaps be increasing with increasing temperature and at a rate such that oxidation at temperatures in the vicinity of 1200°C involves only outward diffusion of the metal cation to the gas-scale interface. Finally, when complete oxygen saturation of the core is approached at high temperatures, it is considered that the scale must eventually recrystallize to form the characteristic pale yellow rutile shown in Fig. 9. Oxygen demand by the core must then be very low, and cation diffusion would operate only as long as contact existed between the scale and the core.

Conclusion

The results of this investigation suggest that the scaling behavior of Ti, Zr, and Hf is controlled by the diffusion of oxygen in the metal phase. The presence of oxygen in the metal core has been used to explain the change in the rate equations during the oxidation of these metals. In the past this has been attributed to a scale barrier of constant thickness, but no such barrier has been detected. However, a diffusion barrier of constant depth is eventually established in the metal core and this is associated with the parabolic to linear transformation. It is considered that the actual isothermal scaling rate for these metals may well prove to be approximately constant, and that the initial parabolic rate of oxygen absorption is associated with the establishment of an oxygen diffusion gradient in the metal core as well as the scaling reaction. Further discussions based on these proposals has produced an explanation for certain effects commonly observed during the high-temperature oxidation of Ti.

Finally, a number of metals other than Ti, Zr, and Hf exhibit a significant oxygen solubility at high temperatures, and therefore their scaling behavior is being examined now along similar lines.

Acknowledgments

The work described in this paper was carried out in the School of Metallurgy at the New South Wales University of Technology, Australia. During the period involved, one of the authors (G.R.W.) held an Australian Atomic Energy Commission Postgraduate Studentship. The authors wish to express their thanks to Professor Rupert Myers for the provision of laboratory facilities and to the Australian Atomic Energy Commission for continued financial support.

Manuscript received March 10, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

The Electrical Resistance of Oxide Films on Zirconium in Relation to Corrosion

R. D. Misch and F. H. Gunzel, Jr.

Argonne National Laboratory, Lemont, Illinois

ABSTRACT

The conductivity of anodic and corrosion films on zirconium was found to increase during heating in vacuum. The conductivity changes at 450°C were studied on anodic films which were 0.6, 0.75, 0.9, and 1.5 μ in thickness. The change in conductivity was attributed to the diffusion of anion vacancies into the oxide with an estimated diffusion coefficient of 4×10^{-13} cm^2 sec^{-1}. Corrosion films produced in water at 350°C appeared to have higher diffusion coefficients. Among the materials zirconium, Zircaloy-1, and Zircaloy-2, specimens of zirconium had the highest corrosion rates and diffusivities (as judged by the conductivity changes). Consequently, an effect of vacuum heating on corrosion was expected and subsequently confirmed. Enhanced oxide growth was observed after corroded specimens were heated at 600°C for 1 min. The increase in weight gain was greater than would be expected from a simple restoration of dissolved oxide.

The corrosion of zirconium in water at high temperature is a sensitive function of metal composition (1). Consideration of this problem has focused attention on changes in the oxide film as a result of additives. An analysis of such effects has been given by Thomas (2). The present study was designed to determine whether the resistance of the oxide plays a role in the corrosion process.

In the case of highly conductive oxides like FeO the effect of small concentrations of impurities is negligible. Zirconium oxide, however, is an insulator at room temperature, and impurities might be expected to decrease its electrical resistivity. Consequently, the resistivity of the corrosion film should reflect the presence of various impurities. The incorporation of such impurities in the oxide has been observed in a 2.5% Sn-Zr alloy where the Sn was found in solid solution in the ZrO_2 layer (3).

Other elements such as Ti, U, Fe, Cr, and Ni have ionic sizes favorable for substitutional replacement of Zr^{4+} in the oxide lattice. Titanium and uranium increase the corrosion rate of Zr in water, while the other elements in small amounts cause a decrease. One may conclude that crystallographic changes are not of primary importance so that emphasis can be directed to changes in the oxide defect structure as determining corrosion behavior. Resistance measurements should be of value in resolving this problem.

A study of the resistance of corrosion films at room temperature was made by Akimov and Clark (4). The film was touched with a mercury droplet. The present technique is similar to that of Savage (5) who examined the resistance of electrical contacts. Contact with the oxide was made with a wire probe, and the underlying Zr formed the other contact.

The oxide on a metal is not a homogeneous, isotropic solid, and the role of inclusions and defects cannot be overlooked. Freshly prepared anodic or corrosion oxide on Zr is an insulator at room temperature, and a low resistance area is an indication of a conducting inclusion. Other factors which influence the data are discussed below.

Experimental

Procedure.—All measurements were made by resting the polished tip of a 10-g Pt probe on the oxidized surface of Zr specimens. The probe made electrical contact through the oxide to another Pt wire spot welded to the Zr. In all measurements the voltage across the oxide was 10 mv, and the current was read on a galvanometer with a sensitivity of 0.005μa/mm of deflection. The circuit and probe are shown in Fig. 1. The magnitude of the current was independent of polarity; usually the probe was maintained positive to the Zr. The Zr specimen rested in the center of a 1-in. diameter Pt tube fur-

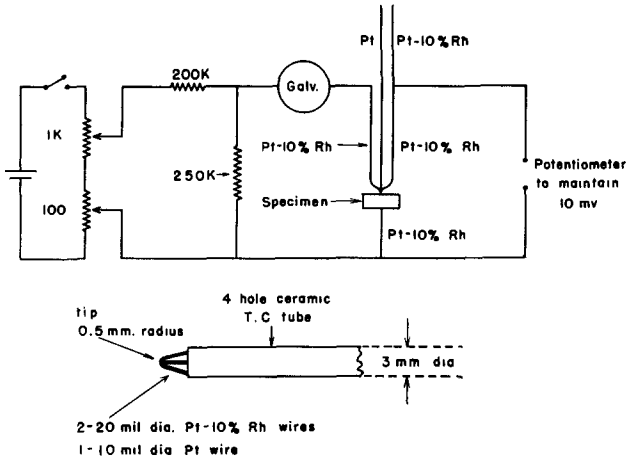

Fig. 1. Schematic drawing of circuit and construction of probe for measuring film conductivity and temperature.

nace, 8 in. long. The furnace was mounted in an 18-in. bell jar which was evacuated to 10^{-6} mm Hg pressure before heating. At 450°C the vacuum was 10^{-5} mm Hg or better.

Materials.—The study was made on reactor grade Zr, Zircaloy-1, and Zircaloy-2. Hafnium was present to approximately 0.02% in all these materials. Specimens were cut from rolled plates having the analyses given below:

Zirconium: (all ppm) 200 O, 70-350 C, 60-150 N, 30-100 Al, 2-10 Cr, 5-20 Cu, 200-700 Fe, 1-20 Mg, 2-7 Mn, 40-80 Ni; each less than 50 ppm: Si, Ti. This material is classified Grade 1 on the basis of corrosion testing in water.

Zircaloy-1: 2.5% Sn, other individual elements below 0.01%.

Zircaloy-2: 1.43% Sn, 0.108% Fe, 0.105% Cr, 0.048% Ni, 0.0032% N, with 30 ppm Al, 50 ppm Ca, 170 ppm Hf, 60 ppm Pb, 50 ppm Si, 15 ppm Ti.

All specimens were prepared by wet grinding to 400 grit paper and etching in a solution of 50 ml 70% HNO_3, 50 ml distilled water, 8 ml 47% HF. Etching time was 1 min at room temperature.

Anodic films.—Anodic films were produced by applying constant voltage to a cell with Zr as the anode and Pt as the cathode. In the present work the electrolyte was purified saturated H_3BO_3 at room temperature. This electrolyte had a high resistance but permitted anodizing up to 500 v. In anodizing of this type the film thickness is proportional to the applied voltage (1). The gain in weight of Zr anodized according to the procedure used in this study was found to be in good agreement with the data of Polling and Charlesby (6), i.e., 0.46 μg cm^{-2} v^{-1}. Charlesby assumed a density of 5.67 g cm^{-3} which gave a thickness-voltage relation of 30Å v^{-1}.

The dependence of film thickness on voltage was also shown by measuring the capacitance of the Zr anode in the electrolyte. The second electrode was Pt gauze. Effectively, the Zr and electrolyte were the plates of the condenser. A General Radio Company Type 650-A bridge was used. It was expedient to substitute acetic acid for boric acid when measuring capacitance in view of the high resistance of the latter soluton. The data are shown in Fig. 2. Zircaloy-2 could not be anodized above 300 v which limited the range in which the film thickness could be varied. This fact was attributed to oxygen evolution at inclusions.

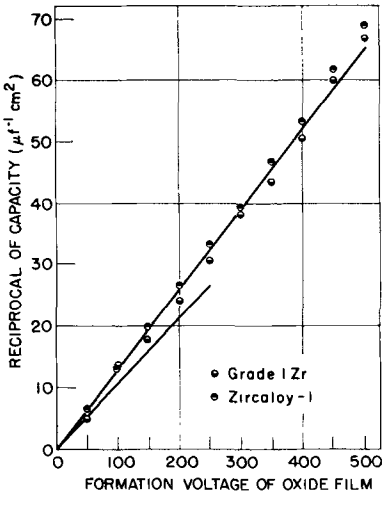

Fig. 2. Reciprocal of capacity of anodic films as a function of the voltage of anodizing of Zr and Zircaloy-1, anodized in boric acid, measured in 1N acetic acid. The short line is from data of Charlesby (14).

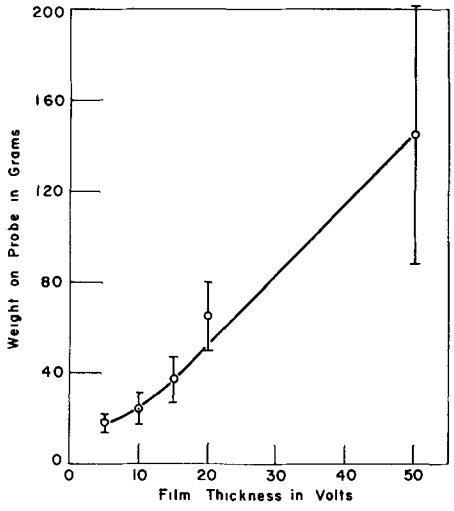

Fig. 3. Region of electrical breakdown of the anodic film on Zr as a function of probe weight and film thickness. The solid line bracketing each point indicates standard deviation.

Autoclave films.—Autoclave films were produced by exposing specimens to degassed, distilled water at 350° ±5°C for periods from 16 hr to 2 weeks. The resultant films were adherent, and weight gains were a measure of film thickness.

Weight on the probe.—The probe rested on the surface with a weight of 10 g. To be certain that the film was not damaged by this weight the maximum tolerable weight at room temperature was determined for different film thicknesses. The data are given in Fig. 3. The film broke down electrically above the line, producing a short circuit. The applied voltage was 10 mv prior to breakdown. An average of 30 points was examined for each anodic film thickness.

Contact area.—The contact area of the probe was very small. To determine this area the 10-g probe was placed on smooth Pt, the resistance was measured, and the area was calculated from the formula of Holm (7). An average of numerous measurements gave a contact area of $1.5 \pm 0.5 \times 10^{-6}$ cm^2. This is the largest error in estimating resistivity.

Results

Effect of Heating in Vacuum

No current was detected when the probe was placed on anodic or autoclave films at room temperature. However, when a specimen was heated in vacuum, current became measurable at 350°C and higher. The conductivity increased with time as well as temperature, and a reversible temperature coefficient could not be obtained. Film history, thickness, and temperature were all found to influence the conductivity changes.

Preliminary work in which specimens were heated and cooled showed that the ZrO_2 films became better conductors and remained so as long as the vacuum

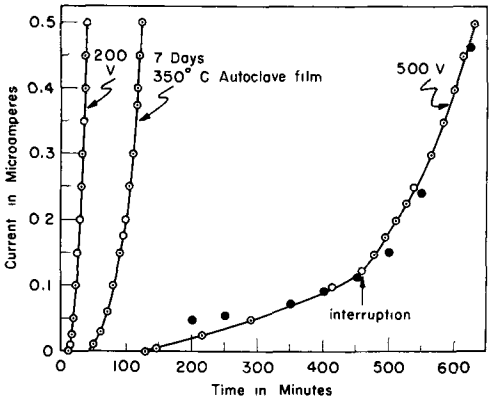

Fig. 4. Typical examples of the change in conduction of the oxide in Zr held at 450°C in vacuum.

was maintained. The conductivity often dropped when air was admitted.

At constant temperature the conductivity increased at a rate dependent on temperature. At 350°C there was no perceptible conductivity up to 16 hr. At 450°C the change in the film was apparent in a matter of minutes. Typical results for heating different specimens are shown in Fig. 4.

Weight gains of these specimens were as follows: 200 v anodized film, 9.1 mg/dm^2; autoclave film, 31.0 mg/dm^2 (somewhat higher than average); 500 v anodized film 22.8 mg/dm^2. These data were for single trials, but the reproducibility may be judged from Fig. 5-7. The "interruption" on the 500 v curve indicates an overnight interval during which the specimen was in vacuum at room temperature. When heating was resumed, the current returned within several minutes to the magnitude recorded just before cooling.

Anodic films of increasing thickness.—To measure the effect of film thickness, a series of anodic films formed at different voltages was studied. The voltages were 200, 250, 300, and 500 and the corresponding weight gains were 9.1, 11.4, 13.7, and 22.8 mg/dm^2. Assuming 5.67 g cm^{-3} as the density (6) the thicknesses of these films were 0.6, 0.75, 0.9, and 1.5μ. The conductivity was measured at 450°C in vacuum,

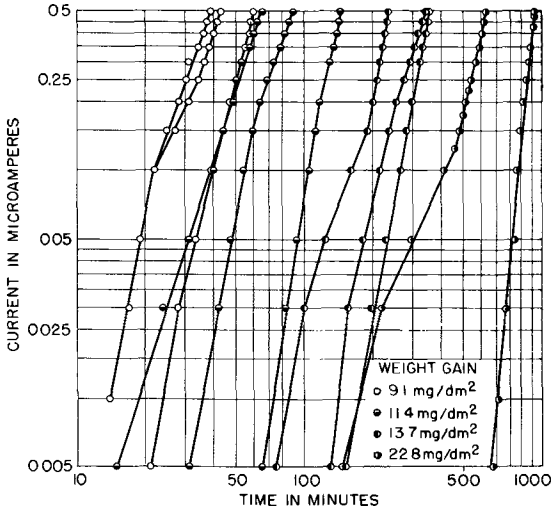

Fig. 5. Current vs. time curves for anodic oxide films on Grade I Zr held at 450°C in vacuum.

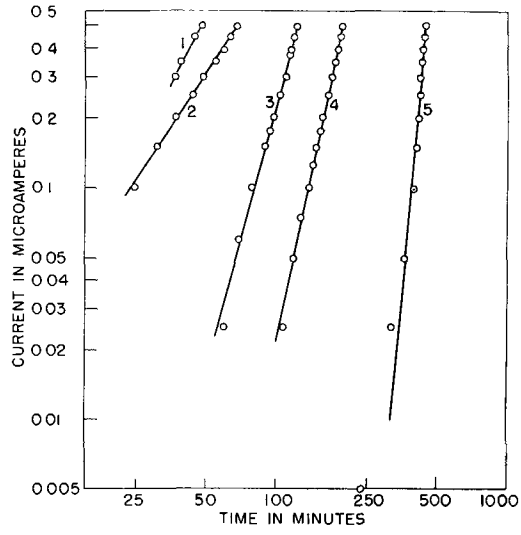

Fig. 6. Current vs. time curves for autoclave films on specimens of arc-melted Zr crystal bar having an average weight gain of 19 mg/dm^2 after 1 week in water at 350°C. Each specimen was held at 450°C in vacuum. Specimens 1, 2, and 3 exhibited patches of gray or white oxide; specimens 4 and 5 were black and uniform.

and the data are plotted as log current (with 10 mv across film) vs. log time in Fig. 5.

Autoclave films.—Here all the specimens had weight gains very close to 21 mg/dm^2. The alloys had uniform black films, while the Zr specimens showed occasional white patches. Measurements were made only on the coherent black film.

The curves for Zr are given in Fig. 6 and the curves for the two alloys in Fig. 7. In the latter case the experimental points are shown only for Zircaloy-2. The experimental data for Zircaloy-1 were in good agreement with the lines as shown, and the points were omitted to avoid overlapping. The slopes of the curves on the autoclave films were similar to those for the anodic films. The experimental spread for Zr was large as compared to the alloys.

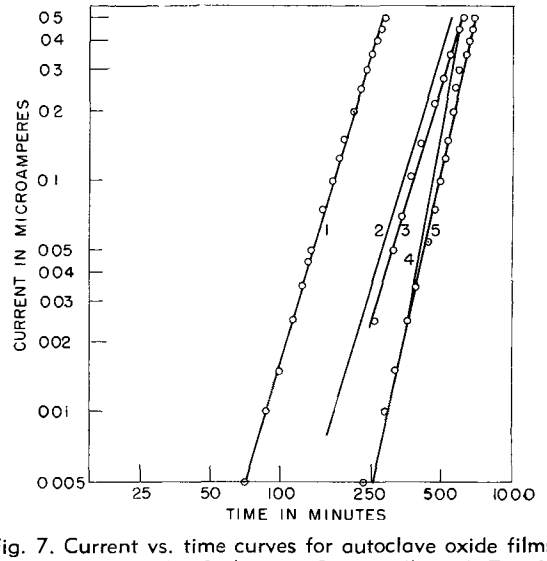

Fig. 7. Current vs. time curves for autoclave oxide films on specimens of Zircaloy-1 (curves 2 and 4) and Zircaloy-2 (curves 1, 3, and 5) having an average weight gain of 24 mg/dm^2 after 1 week in water at 350°C. Specimens were held at 450°C in vacuum.

Vacuum heating and corrosion rate.—The existence of a conductivity effect suggested that the corrosion rates might be increased by vacuum heating. With rapid heating to sufficiently high temperatures the corrosion oxide film became a good conductor at room temperature over its entire surface. The subsequent corrosion behavior should indicate whether film growth is affected. For this purpose the corrosion of Zr specimens was compared before and after a rapid heating to 600°C followed by rapid cooling. The corrosion film was conducting after this treatment. Zirconium specimens were exposed to water at 350°C, periodically removed, and vacuum heated. Comparison with controls revealed no effect of the heating. Consequently, the heating time in vacuum was extended as follows: The specimen was brought to 600°C in 30 sec, kept at 600° for 1 min, and cooled below 400° in 30 sec. The vacuum was 10^{-5} mm Hg or better. This procedure was employed on both Zr and Zircaloy-2 specimens after 16-hr intervals of exposure to degassed water at 350°C. Upon removal from the autoclave the heated films were again insulating.

One set of specimens was used as a control; the other set was vacuum heated before and during the corrosion test. An additional set of specimens was vacuum heated at the same time, but corrosion testing was not carried out until the vacuum heating was discontinued after 320 hr of corrosion exposure.

The corrosion weight gains are shown in Fig. 8 and 9. Initially, the heated specimens had lower weight gains, but they continued to gain weight when the control specimens were leveling off. It was found in a preliminary experiment that these low weight gains did not appear when the vacuum heating preceding the corrosion exposure was omitted. Consequently, the initial low weight gains may be due to a different surface after the vacuum treatment.

The effect of vacuum heating did not last, as shown by the leveling of the curve after 320 hr when this treatment was ended. The four specimens of each material which were vacuum heated and then corrosion tested (data not shown) had essentially the same weight gains as the standards which were

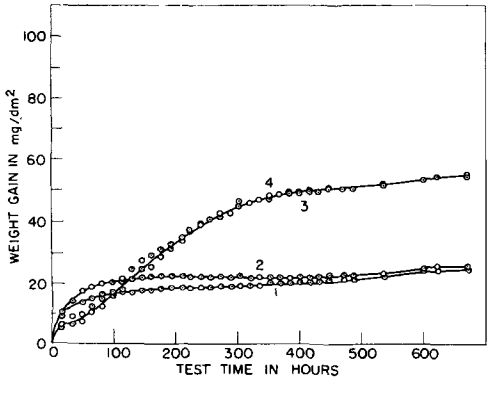

Fig. 8. Weight gains of four specimens of arc-melted Zr, corrosion tested simultaneously in water at 350°C. No. 3 and No. 4 were heated at 600°C for 1 min at the time of each weighing up to and including 320 hr (also prior to testing). Heating was discontinued after this point. Specimen No. 1 and No. 2 were not heated.

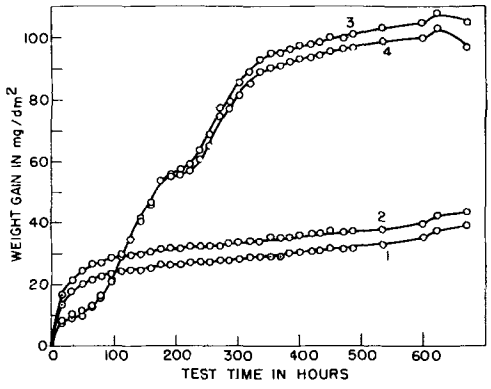

Fig. 9. Weight gains of four Zircaloy-2 specimens, corrosion tested simultaneously in water at 350°C. No. 3 and No. 4 were heated at 600°C for 1 min at the time of each weighing up to and including 320 hr (also prior to testing). Heating was discontinued after this point. Specimen No. 1 and No. 2 were not heated.

not heated. This ruled out any metallurgical effect. Specimen weights were always checked before and after the vacuum heating and did not vary by more than 0.5 mg/dm². This was negligible in comparison to the corrosion weight gains.

At the end of the test the specimens numbered 1 and 2 had a uniform dark lustrous appearance indicative of a protective oxide, for both Zr and Zircaloy-2. Specimens 3 and 4 were light gray. Under a microscope the light gray oxide was seen to vary from gray to white with white predominating. The film on the Zircaloy-2 was breaking away along the lines of inclusions. The Zr surfaces had tiny brown and black spots which were probably deposits from the autoclave.

Discussion

Vacuum heating has been shown to influence both the electrical conductivity of the oxide on Zr and its corrosion rate in water at 350°C. The reasons for electrical changes in the oxide will be considered before discussing the effect of vacuum heating on corrosion.

The nature of the Zr-ZrO_2 system suggests that diffusion is responsible for the conductivity changes. The most likely mechanism to account for the observed changes is the loss of oxygen to the metal which would be accompanied by the formation of anion vacancies in the oxide. The very low dissociation pressure of ZrO_2 (10^{-40} atm at 450°C) is evidence that oxygen will not escape to the vacuum.

The current-time curves can be explained on the basis that the resistance of the oxide drops rapidly with the penetration of anion vacancies. The mean displacement of a diffusing species is $\sqrt{2Dt}$, where D is the diffusion coefficient and t is time (12). If the major part of the observed electrical resistance is provided by the unpenetrated oxide (of unchanged resistivity), one may write

$$i = \frac{k\,V}{\delta - \sqrt{2Dt}} \qquad [1]$$

where i is the current through the film, V is the applied voltage, k is a constant proportional to the area of the contact, and δ is the film thickness. At 450°C

Table I. Diffusion coefficients, D, calculated from the data of Fig. 5 (Anodic oxide on Grade 1 Zr at 450°C)

Anodizing voltage	Film thickness μ	D x 10^{13} (cm^2 sec^{-1}) As calculated	Average for each film thickness
200	0.60	7.6 6.7 4.9	6.4
250	0.75	6.9 5.2 3.2	5.1
300	0.90	2.8 1.9 1.9	2.2
500	1.5	2.9 1.8	2.4

the change in film thickness due to dissolution can be neglected.

This equation provides a reasonable representation of the observed data as indicated in Fig. 4 where the solid points were calculated from Eq. [1] using the values $D = 2.72 \times 10^{-13}$ cm^2 sec^{-1} and $k = 3.1 \times 10^{-5}$ μa^{-1} cm^{-1}. These empirical values were calculated from two points on the experimental curve (0.05 μa, 290 min and 0.4 μa, 600 min); k was an average for these points.

Two points from a curve are sufficient to solve for D from the equation

$$\frac{i_2}{i_1} = \frac{\delta - \sqrt{2Dt_1}}{\delta - \sqrt{2Dt_2}} \qquad [2]$$

Using i_2 as 0.5 μamp and i_1 as 0.025 μamp, the diffusion coefficient was calculated for the curves of Fig. 5. The resulting values are shown in Table I. The average from all the curves was 4.0×10^{-13} cm^2 sec^{-1}.

This result may be compared with 2×10^{-15} cm^2 sec^{-1} which Pemsler (8) obtained for the diffusion of oxygen into Zr metal at 450°C. The difference between 4.0×10^{-13} and 2×10^{-15} is consistent with the observation that conductivity changes can be observed in films where dissolution is almost insignificant. However, in the absence of corroborative information it should not be concluded that the "vacancy diffusivities" presented here are valid diffusion coefficients.

The conductivity changes of the corrosion oxide films on Zr showed a wide variation although the films were of equivalent thickness. The following diffusivities for the corrosion films heated at 450°C were calculated in the same manner as for the anodic films (the designations refer to Fig. 6): Curve 1, 2.5×10^{-12} cm^2 sec^{-1}; curve 2, 2.1×10^{-12} cm^2 sec^{-1}; curve 3, 1.4×10^{-12} cm^2 sec^{-1}; curve 4, 0.86×10^{-12} cm^2 sec^{-1}; curve 5, 0.38×10^{-12} cm^2 sec^{-1}.

As would be expected, curve 5 represents a lower diffusion coefficient than curve 1.

The better reproducibility of the curves for Zircaloy-1 and 2 suggests that the oxide is more homogeneous on these alloys than on Zr. The curves for these alloys are similar to curve 5 for Zr so that a comparable diffusivity can be expected. It is possible that a low diffusivity as estimated from conductivity changes may be related to a low corrosion rate.

The effect of vacuum heating on corrosion cannot be explained readily. The increase of electrical conductivity during heating indicates that changes are taking place within the oxide. In addition, some of the oxide is dissolving as a result of oxygen diffusion into the Zr. The rate of dissolution has been used to determine the diffusivity of oxygen in Zr (8).

Considering the latter process, the effect is to make the oxide film slightly thinner. In previous work (11), using the same equipment as this study, it was shown that about 100Å of oxide was dissolved while heating 1 min at 600°C. This is somewhat smaller than the results of Pemsler (8) where approximately 250Å would be expected to dissolve in the first minute. Using the smaller number the decrease in thickness would be 0.2μ after twenty heatings. This corresponds to 3 mg/dm^2 of oxygen. The final differences in weight gains between heated and unheated specimens were much larger than this, indicating that the weight increases are not simply due to the restoration of dissolved oxide.

As already mentioned the heated film did not remain conducting after exposure in the autoclave but was apparently restored to its original insulating character. This suggests that the defect structure produced by heating is eliminated by re-exposure to water. In such a case a weight gain would be expected, corresponding to a filling of vacancies.

As shown by the data on corrosion weight gains a specimen gained weight each time it was vacuum heated and returned to the autoclave. In the case of Zr which had a weight gain of 40 mg/dm^2 without heating, the additional weight gain after each vacuum heating and re-exposure was approximately 2.5 mg/dm^2. The latter figure represents 6% of the oxygen in the film before re-exposure in the autoclave. Consequently, one may postulate that 6% of the oxygen sites were emptied by diffusion during vacuum heating and refilled upon subsequent exposure in the autoclave.

Under the same circumstances, the 40 mg/dm^2 film on Zircaloy-2 gained about 5 mg/dm^2, representing a 12.5% vacancy concentration. These percentages seem unreasonably high because the oxygen consumed in the dissolution of oxide at 600° (100Å) is only 0.15 mg/dm^2 or 0.4% of 40 mg/dm^2. This suggests that other factors are increasing the corrosion rate.

Perhaps the structure of the oxide is changed by heating, or the diffusion of oxygen into the Zr promotes the subsequent conversion of some of this diffused layer into oxide during corrosion. More evidence concerning these factors is desirable.

This phenomenon may be related to the "memory" effect noted by Thomas (13) where Zr specimens maintained a high corrosion rate after the corrosion temperature was lowered.

The Structure of Electro-Deposited Nickel

B. C. Banerjee and A. Goswami

National Chemical Laboratory, Poona, India

ABSTRACT

An electron diffraction study was made on the crystal structure, orientation, and mode of growth of nickel deposits from sulfate-chloride-boric acid and chloride-boric acid baths under various bath conditions. The effect of *p*H, temperature, concentration, current density, mechanical stirring, etc., and of additions such as hydrogen peroxide, nickel nitrate, and sodium chloride was investigated on polycrystalline substrates. Depending on bath conditions various preferred orientations (one-degree), mixed or otherwise, were developed and their causes have been discussed in detail. These have been correlated also with the mode of cathodic crystal growth process.

It has been shown previously that the crystal structure and orientations of electrodeposited nickel are profoundly affected by the bath conditions (1-5). In what follows an account is given of a comparative survey of the crystal orientations in deposits from nickel chloride and sulfate-chloride baths as commonly used in industrial plating.

Experimental

In order to restrict the substrate influence on crystal size and orientation of electrodeposits, mechanically polished brass disks (70:30) of about 3.0 cm^2 significant area were used as cathodes, the nonsignificant portions being covered with collodion. Compositions of the baths were: (*a*) $NiSO_4 \cdot 7H_2O$ 280 g/l + $NiCl_2 \cdot 6H_2O$ 48 g/l + H_3BO_3 31 g/l; (*b*) $NiCl_2 \cdot 6H_2O$ 150 g/l + H_3BO_3 31 g/l; (c) $NiCl_2 \cdot 6H_2O$ 280 g/l + H_3BO_3 31 g/l; and (*d*) $NiSO_4 \cdot 7H_2O$ 280 g/l + H_3BO_3 31 g/l. The chemicals used were of AR or CP quality. The above solutions were purified and adjusted to desired *p*H values in the manner described previously (3). Unless otherwise stated, the current density employed was 10 ma/cm^2, and the solutions were unstirred. When stirring was resorted to, the sweep of the glass propeller was close to the cathode surface.

After electrodeposition, the specimens were washed thoroughly with distilled water, with alcohol, and then immediately examined in a Finch-type electron diffraction camera (6) working with 45-65 kv electrons, the camera length being about 50 cm. The lattice parameter of the deposit was determined by dusting graphite powder over the specimens and using $11\bar{2}0$ ring of graphite ($d_{11\bar{2}0} = 1.230$Å) as the internal standard. Since the reflection technique was used, the diffraction of electrons was due to the top surface layers only. In order to study the change of surface structure with time of deposition, specimens were examined by electron diffraction at various deposit thicknesses.

The deposition was carried out to well beyond the stage where the polycrystalline deposits had developed preferred orientations (one-degree). By preferred orientation, it is meant that the polycrystalline deposits had a common lattice row normal to the deposit surface, or in other words had a common lattice plane parallel to the deposit or substrate surface. The orientation plane is generally indicated by {hkl}.

Results

The appearance of nickel deposits varied from semibright and dull matte to dark gray or even black, depending on the deposition conditions. Pitting and pinholes were observed in deposits formed under the conditions giving rise to profuse hydrogen evolution. Electron diffraction studies of the cathode surface revealed that the deposits were initially polycrystalline but randomly disposed; with increasing thickness, the deposits developed one degree orientations determined by bath conditions. The lattice constant of the coatings ($a_o = 3.543$Å) was found to be similar to that of f.c.c. nickel (7). Occasionally, however, hexagonal form of nickel

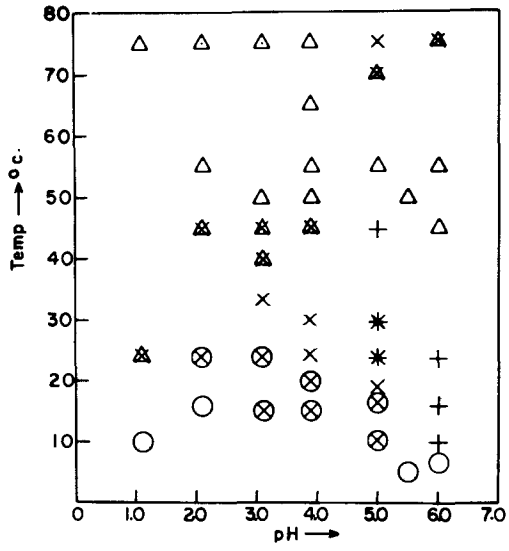

Fig. 1. Change in orientations of nickel deposits with pH and temperature; bath (a). × means {100} orn; △ means {110} orn; + means {211} + {10$\bar{1}$0} orn; O means {210} orn.

(7) also appeared along with the f.c.c. structure. The results are shown in Fig. 1-7.

Influence of Various Factors

pH and temperature.—It will be seen from Fig. 1-3 that, with increasing bath temperature, the orientations changed eventually from {210} (○) to {110} (△) irrespective of *p*H values. At an intermediate range, however, depending on *p*H and bath composition, {100} (×) and a mixed {211} + {10$\bar{1}$0}$_{hex}$ (+) orientations were generally observed.

Metal ion concentration.—The orientations of the deposit crystals were also influenced by metal ion concentrations. Baths (*a*) and (*b*) under different *p*H conditions were diluted in the ratio of 1:1, 1:3, and 1:9 maintaining the *p*H in each case the same as that of the undiluted bath. Thus with gradual dilution, the initial {211} + {10$\bar{1}$0}$_{hex}$ (+) orientations changed to {100} (×) and finally to {110} (△)

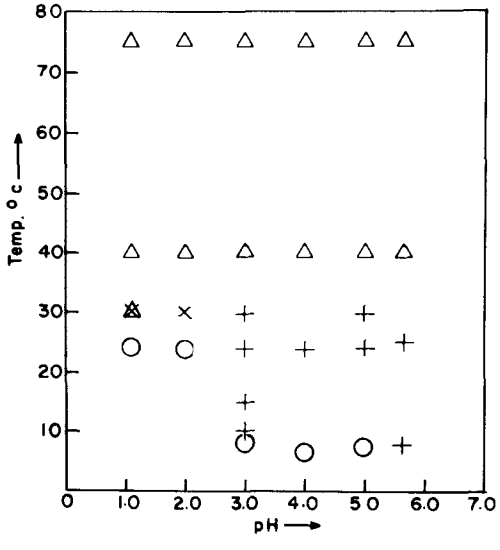

Fig. 2. Change in orientations of nickel deposits with pH and temperature; bath (b). Symbols have same meaning as in Fig. 1.

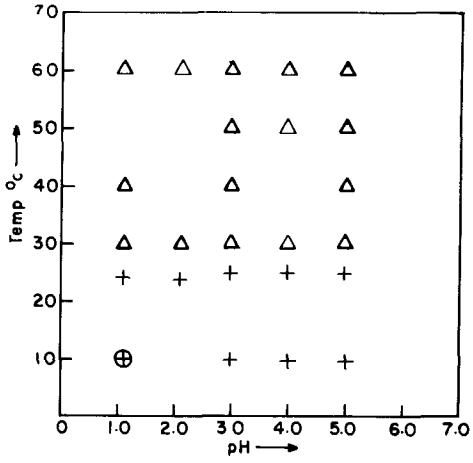

Fig. 3. Change in orientations of nickel deposits with pH and temperature; bath (c). Symbols have same meaning as in Fig. 1.

as can be seen from Fig. 4. Similar results were also obtained even when the concentration of boric acid was maintained to 31 g/l in the diluted baths. This suggests that boric acid content has no significant effect on the orientations of nickel deposits.

Oxidizing agents.—The addition of hydrogen peroxide or nickel nitrate to the baths suppressed pitting of deposits and also affected the crystal orientations (Fig. 5a and 5b). Addition of hydrogen peroxide (≅1 g/l) resulted in the {210} orientation (○) gradually changing to {100} (×) or {211} + {10$\bar{1}$0}$_{hex}$ (+) at all *p*H ranges and at temperatures up to 35°C. At higher temperatures, however, hydrogen peroxide decomposed without oxidizing hydrogen evolved at the cathode, and no further change in orientation was observed. With further increase in hydrogen peroxide concentration, the crystal orientations changed to {110} (△) (Fig. 5a). If the concentration of hydrogen peroxide was still further increased, the deposits became rough and were often covered with basic nickel salts.

Nickel nitrate (about 0.8 g/l), on the other hand, favored {110} (△) orientation of the deposit crystals under conditions which would otherwise have developed {210} (○), {100} (×), or {211} + {10$\bar{1}$0}$_{hex}$ (+) orientations (Fig. 5b).

Mechanical stirring.—Stirring of the solutions affected the crystal orientation by reducing the con-

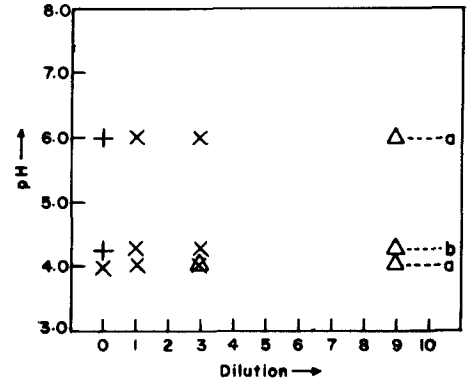

Fig. 4. Change in orientations of nickel deposits with dilution and pH; baths (a) and (b). Symbols have same meaning as in Fig. 1.

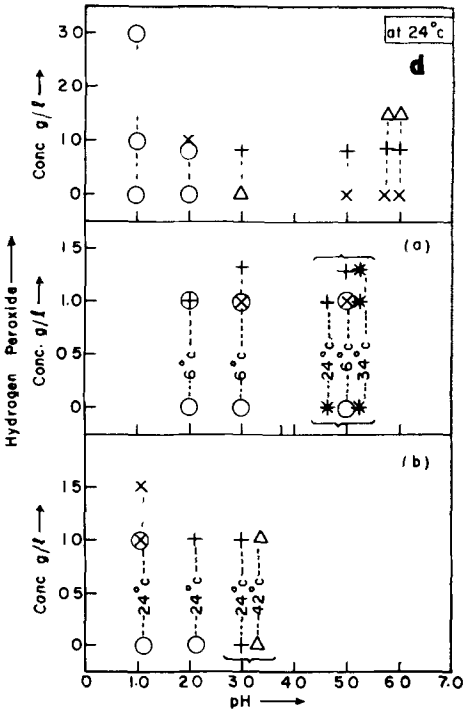

Fig. 5. (a) Change in orientations of nickel deposits with hydrogen peroxide and pH; bath (a), (b), and (d); Fig. 5 (b). With nickel nitrate. Symbols have same meaning as in Fig. 1.

centration gradient in the catholyte layer and possibly also by facilitating the removal of hydrogen from the cathode surface. Thus, instead of the {210} (○) orientation of the deposit-crystals favored at a low temperature in a still bath, a mixture of {210} (○) and {100} (×) orientations occurred at 250 rpm and, finally, {211} + $\{10\bar{1}0\}_{hex}$ (+) orientations at about 1000 rpm (Fig. 6). Similarly, instead of the {110} (△) orientation normally developed at 55°C in an unstirred bath, a {100} (×) orientation appeared at 300 rpm. Mechanical stirring, however, did not affect the continued development of {100} (×) or {211} + $\{10\bar{1}0\}_{hex}$ (+) orientations when the unstirred were favorable to the formation of these orientations.

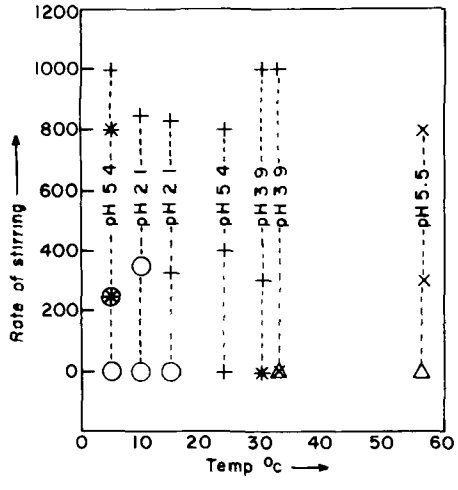

Fig. 6. Change in orientations of nickel deposits with rate of stirring and temperature; bath (a). Symbols have same meaning as in Fig. 1.

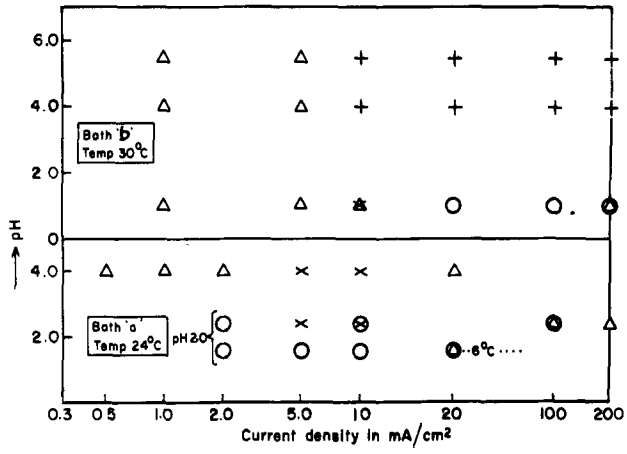

Fig. 7. Change in orientations of nickel deposits with current density and pH; baths (a) and (b)

Current density.—The effect of current density on the deposition of nickel is very interesting. It may be seen (Fig. 7) that except at low temperature, the deposits developed {110} (△) orientation in the lower current density range. At an intermediate range of current density, however, either {100} (×) or {211} + $\{10\bar{1}0\}_{hex}$ (+) orientations were favored. At a still higher current density {110} (△) orientation was developed sometimes accompanied by {210} (○) orientation, especially at low pH ranges. In bath (c), however, lateral {100} (×), {211} + $\{10\bar{1}0\}_{hex}$ (+) types of deposits were always obtained, even at a current density as high as 200 ma/cm^2.

Chloride ion concentration.—An increase in the chloride ion concentration in the bath generally favored {211} + $\{10\bar{1}0\}_{hex}$ (+) orientations in place of {100} (×) and the bath could tolerate a higher current density range than the usual. Figure 8 shows typical {211} + $\{10\bar{1}0\}_{hex}$ orientations of the deposit crystals.

Discussion

The mode of cathodic crystal growth and its influence on the orientation of the resulting deposits have recently been discussed by Finch and coworkers (1, 2) and ourselves (3-5, 8). The orientations developed in electrodeposits are determined primarily by the growth process of the deposits. The chief factors controlling the process are: (*a*) rate of supply of cations through the diffusion layer to

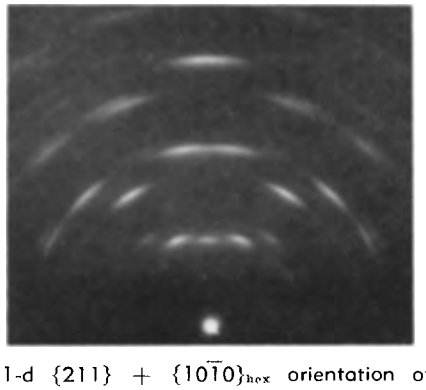

Fig. 8. 1-d {211} + $\{10\bar{1}0\}_{hex}$ orientation of nickel deposits.

the cathode; (*b*) rate of discharge of cations; (*c*) thickness of the diffusion layer; and (*d*) formation of films near the cathode surface region. Any change in the deposition conditions may materially affect one or more of the above factors determining the over-all deposition process and thus modify the orientation of the deposited crystals. When the rate of supply of metal ions to the catholyte is plentiful compared with the rate of their discharge, the deposits grow laterally with a densely packed plane lying parallel to the substrate surface. On the other hand, when the rate of supply of cations at the cathode is inadequate, resulting in an impoverishment of metal ions at the catholyte, the deposit-crystals grow outward in such a way that a densely packed atom row is normal to the cathode surface. In the case of nickel {111}, {100} (×), and also {211} + $\{10\bar{1}0\}_{hex}$ (+) orientations, as recently shown by Goswami (8), are characteristics of lateral growth-deposits whereas {110} (△) indicates an outgrowth mechanism.

Other orientations also may develop due to factors which come into play during deposition. The appearance of {210} (○) orientation, for instance, seems to be associated with the adsorption or otherwise of hydrogen, presumably atomic, by the deposits which are known to be in a highly active condition when freshly deposited (9). This is evident from the change of orientation from {210} (○) to {100} (×) or $\{10\bar{1}0\}_{hex}$ and {211} (+) effected by the addition of hydrogen peroxide to the bath (Fig. 5a). The rate of discharge of hydrogen ions at the cathode will be increased due to the oxidation of atomic hydrogen to water molecules in the presence of hydrogen peroxide. This will, no doubt, facilitate the formation, precipitation, and occlusion on the cathode surface of colloidal nickel hydroxides or basic salts, thus reducing the effective metal ion concentration in the catholyte and favoring an outgrowth mechanism.

Nickel nitrate influences the orientation of the deposits in a different manner. Hydrogen, atomic or molecular, formed at the cathode reduces the nitrate in its immediate vicinity finally to ammonia which in turn forms nickel ammonium complexes. The effective metal ion concentration thus reduced should favor outgrowth.

Mechanical stirring, as has been mentioned before, reduces the thickness of the catholyte layer and maintains metal ion concentration at the cathode surface region; hence orientations of the deposits tend to be characteristic of the lateral growth. By disturbing the adsorption of hydrogen at the cathode, mechanical agitation also reduces and ultimately eliminates pitting pinholes in the deposit surface.

When a bath is much diluted, the effective metal ion concentration is low and hence the deposits are of outgrowth type as has been experimentally observed by us.

The effect of temperature on the crystal is peculiar. A higher temperature should increase the mobility of the ions and at the same time reduce the thickness of the diffusion layer. Normally this should favor lateral growth-deposits. On the other hand, our experimental results show that higher temperatures favor outgrowth-deposits at all *p*H conditions excepting in bath (*a*) at 75°C at *p*H 5.0. This may be due to the increased rate of hydrolysis of the nickel salts with the rise of bath temperature. It is well known that nickel salts hydrolyze to hydroxides or basic salts when the *p*H of the solution is appropriate at room temperature and this is increased still more at higher temperatures. This leads to outgrowth-deposit.

The effect of high current density is generally to increase the rate of discharge of metal ions at the cathode without a corresponding increase in their rate of supply to cathode surface region, thereby causing an impoverishment of cations at the cathode surface and thus favoring outgrowth. The formation of lateral-growth deposits at an intermediate current density range may also be similarly understood. A very peculiar observation, as mentioned before, was the development of {110} (△) orientation at very low current densities. This cannot be explained easily. The effect of current density and temperature will be discussed in a separate paper.

An increase in chloride ion concentration generally induces crystal twinning and ultimately results in a new orientation. This has recently been studied in detail on single-crystal substrates. The development of {211} + $\{10\bar{1}0\}$ (+) orientation in the concentrated chloride bath can thus be easily understood, but it is not yet clear why chloride ions should favor twinned structures. However, it is known that these ions are adsorbed more easily by the cathode surface than the bivalent sulfate ions (12), and hence it may be possible that they influence the potential energy configuration of the substrate surface, thereby inducing a twinned structure on the deposits.

The System ZnO-CdO-B_2O_3, Phase Relationships, and Fluorescence

D. E. Harrison

Luminescent Materials Laboratory, Lamp Wire and Phosphors Department, General Electric Company, Cleveland, Ohio

and

F. A. Hummel

Department of Ceramic Technology, The Pennsylvania State University, University Park, Pennsylvania

ABSTRACT

The subsolidus phase relationships were investigated using x-ray and petrographic methods. Two compounds were isolated: $2ZnO \cdot CdO \cdot B_2O_3$ which fuses at about 860°C and $ZnO \cdot 2CdO \cdot 2B_2O_3$ which melts congruently at 797° ± 3°C. Excitation by either 2537Å or cathode rays produces a maximum orange (6200Å) fluorescence in $2ZnO \cdot CdO \cdot B_2O_3$ with 0.004 wt % Mn and a maximum red (6400Å) fluorescence in $ZnO \cdot 2CdO \cdot 2B_2O_3$ with 0.080 wt % Mn. The fluorescence of $ZnO \cdot 2CdO \cdot 2B_2O_3$ was examined using Ag, Sn, Tl, Pb, and Sb as single activators as well as sensitizers with Mn.

Ohno (1) claimed a region of manganese activated zinc-cadmium borate compositions which when blended with $MgWO_4$ yielded a white fluorescent substance. Interest in the zinc-cadmium borate component and the lack of any phase data in this ternary system stimulated the present investigation.

The study was limited to the determination of compatibility triangles, isolation of compounds, and examination of the fluorescence of certain compositions with various activators.

Experimental Procedure

Mallinckrodt reagent-grade boric acid and cadmium carbonate, and New Jersey Zinc Company U.S.P. zinc oxide were used as starting materials. Reagent-grade $MnSO_4$, $Mn(NO_3)_2$, $AgNO_3$, Tl_2CO_3, $Pb(NO_3)_2$, SnO_2, or Sb_2O_3 were used as activators.

The ingredients were ground in an agate mortar with acetone until dry. Calcines were prepared in platinum crucibles at temperatures ranging from 700° to 900°C for periods from 8 to 48 hr.

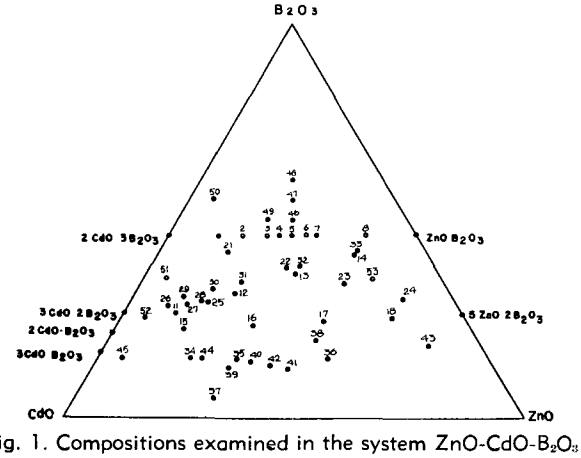

Fig. 1. Compositions examined in the system ZnO-CdO-B_2O_3

X-ray data were obtained from Norelco and General Electric recording spectrometers using $Cu_{K\alpha}$ radiation (λ = 1.537Å) filtered with nickel.

The immersion technique was used to determine the refractive indexes of crystals to an accuracy of ±0.002, using white light and index oils which were calibrated with an Abbe refractometer.

Differential thermal analysis (DTA) data were obtained with automatically recording apparatus described by Gruver (2).

Emission curves were obtained with an automatically recording General Electric spectroradiometer. Visual examinations were made under 2537Å, 3650Å, and cathode-ray excitation.

Compositions.—The compositions examined are listed in Table I and are shown graphically in Fig. 1.

Experimental Results and Discussion

Phase relationships.—The compatibility triangles were determined by comparing the x-ray data of ternary compositions with the data for binary compounds in the systems CdO-B_2O_3 and ZnO-B_2O_3 as reported by Subbarao and Hummel (3) and Harrison and Hummel (4), respectively.

Two new ternary compounds were discovered and individually prepared, and the compatibility triangles were determined as shown in Fig. 2. An unidentified phase is situated in the subtriangle $3CdO \cdot B_2O_3$-$2ZnO \cdot CdO \cdot B_2O_3$-$ZnO$, but its exact composition is not readily discernible because of the extensive solubility of $3CdO \cdot B_2O_3$ and ZnO in $2ZnO \cdot CdO \cdot B_2O_3$.

The compound 2ZnO:CdO:B_2O_3 (2:1:1) is biaxial negative with a very small 2 v angle and R.I. of $n_\alpha = 1.709$, $n_\beta > 1.79$, $n_\gamma > 1.79$. Because of the difficulty in obtaining this composition as a glass, neither the nature of the fusion nor the exact melting temperatures could be determined by the conventional quench technique. However, DTA revealed an endothermic peak at 860°C at which temperature the sample fused. X-ray examination of 2:1:1 after firing at various temperatures supported the DTA data that no polymorphs existed between 100°C and the fusion temperature. A characteristic x-ray pattern is given in Table II.

Crystals of the compound ZnO:2CdO:$2B_2O_3$ (1:2:2) remained too small, even after prolonged heat treatment, to determine their optical properties accurately. However, 1:2:2 exhibited high birefringence with maximum and minimum R.I. of about 1.78 and 1.75, respectively. The 1:2:2 compound melts congruently at 797° ±3°C and it has no polymorphs between 100°C and its fusion temperature. A characteristic x-ray pattern is given in Table II.

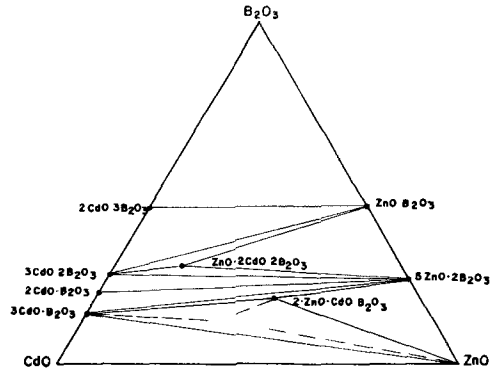

Fig. 2. Compatibility triangles in the system ZnO-CdO-B_2O_3

With the exception of the subtriangle $3CdO\cdot B_2O_3$-$2ZnO\cdot CdO\cdot B_2O_3$-ZnO, petrographic and x-ray data revealed no extensive solid solution in the ternary system. The compound 1:2:2 gave no evidence of solid solubility between it and compatible phases.

Fluorescent studies.—The compounds 2:1:1 and 1:2:2 were prepared with various Mn concentrations. Excitation by either 2537Å or cathode rays, but not 3650Å, gave an orange (6200Å) fluorescence in 2:1:1 and a red (6400Å) fluorescence in 1:2:2. Variation in Mn concentration in either 2:1:1 or 1:2:2 affected the fluorescent intensity, but it did not produce any noticeable shift in the emission

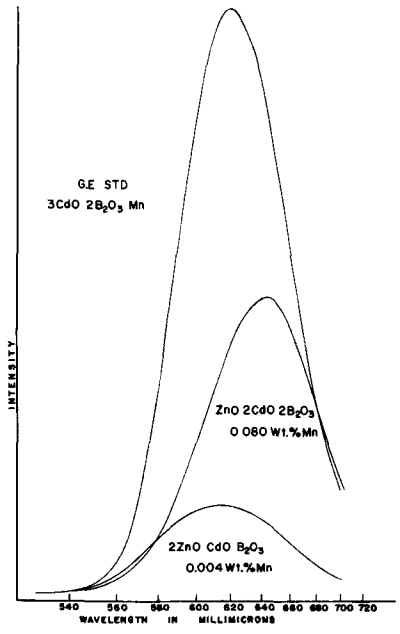

Fig. 3. Spectral distribution and relative intensities excited by 2537Å radiation.

spectrum. Optimum brightness occurred at 0.004 wt % Mn in 2:1:1 and at 0.080 wt % Mn in 1:2:2. Manganese concentrations in the range 1 to 5 ppm were sufficient to activate either 2:1:1 or 1:2:2. However, decreasing fluorescent brightness with decreasing Mn concentration indicates that the pure compounds are not luminescent. The small amounts of Mn necessary to activate the ternary compounds did not appear to introduce new phases.

Spectral distributions of 2:1:1:Mn and 1:2:2:Mn compared to Std. G.E. $3CdO \cdot 2B_2O_3$:Mn using 2537Å excitation are shown in Fig. 3. The intensities are relative to Std. G.E. cadmium borate phosphor and thus give a comparison of absolute intensities obtained. Visual examination of the phosphors under cathode rays gave results comparable to those obtained by 2537Å excitation.

The rarity of red (6400Å) emitting borate phosphors directed attention to 1:2:2 as a possible matrix for other activators. These included Ag, Tl, Pb, Sn, and Sb as single activators, as well as sensitizers with Mn. Only one level of activator concentration at 0.1 wt % was investigated. Since the phosphors were prepared under oxidizing conditions, Sn^{4+} was probably the oxidation state involved.

After firing the singly activated 1:2:2 compositions at 700°-750°C for from 8 to 12 hr, visual examination with excitation by 2537Å, but not 3650Å, gave a weak red fluorescence. The sample prepared without the addition of an activator remained dead after this heat treatment.

When viewed through a Corning No. 2418 red filter, the Tl addition showed the greatest brightness followed in order of decreasing brightness by Sb, Ag, Pb, and Sn additions. Only the Pb-activated phosphor showed a blue band in addition to the weak red band when viewed through a Corning No. 5850 blue filter.

Increasing the firing temperature to values close to the melting temperature of 1:2:2 (797° ±3°C) produced weak red fluorescence in the activated as well as the "nonactivated" phosphors.

Evidently the addition of Tl, Sb, Ag, Pb, or Sn sensitized the residual Mn present in the nonactivated material when the phosphor was prepared at the lower temperature. Also, the additive may have had a mineralizing effect on the phosphor matrix. With the exception of Pb none of these additions introduced emission bands of their own.

When either Tl, Ag, Sn, Pb, or Sb was used as a sensitizer with Mn, all at concentrations of 0.1 wt %, and when the compositions were fired at 700°-750°C for from 8 to 12 hr, excitation by 2537Å or cathode rays, but not 3650Å, produced a bright red fluorescence. Mn + Tl and Mn + Ag additions were brighter and exhibited much shorter afterglows than did Mn additions alone. Thus an Mn + Tl activated 1:2:2 composition fired at 700°-750°C was as bright as a phosphor activated with Mn alone and fired close to the melting point. When viewed through a Corning No. 2418 red filter, Mn + Tl addition showed the greatest brightness followed in order of decreasing brightness by Mn + Ag, Mn alone, Mn + Sn, Mn + Pb, and Mn + Sb additions. None of these phosphors showed a blue component when examined through a Corning No. 5850 blue filter.

The differences in fluorescent brightness between the various additions became smaller as the firing temperature approached the melting point. However, the brightness did not exceed that produced by Mn + Tl at the lower temperature. Both the Mn + Tl and Mn + Ag additions exhibited shorter afterglows at the higher firing temperature than did Mn additions alone.

Manuscript received April 18, 1958. This paper was prepared for delivery before the New York Meeting, April 27-May 1, 1958. It is a part of a thesis submitted by D. E. Harrison in partial fulfillment of the requirements for the Ph.D. degree to The Pennsylvania State University; contribution No. 57-83 from the College of Mineral Industries, The Pennsylvania State University.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Activation of ZnS and (Zn,Cd)S Phosphors by Gold and Other Elements

S. T. Henderson, P. W. Ranby, and Margaret B. Halstead

Thorn Electrical Industries, Ltd., Enfield, Middlesex, England

ABSTRACT

A study has been made of the spectral emission characteristics of zinc and zinc-cadmium sulfide phosphors, activated by gold and excited by long wave ultraviolet at 25° and —120°C. The positions and heights of the Gaussian sub-bands constituting the emission were examined and compared with those derived from the series activated by copper, silver, and chloride ("self-activated"). Copper and gold produce the most similar phosphors, with 3 sub-bands each; silver and chloride give 2 sub-bands, and resemble each other particularly in the effects associated with crystallographic change. Linear relations in the peak locations and an energy diagram are discussed. Other observations concern cathode-excitation, the effects of substituting selenium for sulfur, and a recently reported emission band of higher frequency.

The zinc and zinc cadmium sulfide phosphors have been investigated very extensively, especially with activation by Cu, Au, and Mn. There has been comparatively little interest in Au as the impurity metal, and it is remarkable that these sulfides are the only phosphors, so far as is known, which can be activated by Au. In the following a survey is given of work published hitherto on the subject.

Indications of ZnS:Au as a distinct phosphor began when a blue emission band was observed in a slightly different position from that of "unactivated" ZnS under excitation by ultraviolet (1, 2) or cathode rays (3). Since then a number of observations have been made on the emission peaks of ZnS with trivalent cations and variable Au content (4), and the cathodoluminescent efficiency of this material (5); on the emission shift due to incorporation of ZnO (6); and on the glow curve of ZnS:Au,Cl (7). More recently Arpiarian has used ZnS:Au to study intensification and killing effects produced by Fe, Co, and Ni (8), and Destriau has found that field-enhanced luminescence of (Zn,Cd)S:Mn under x-rays is improved by traces of Au in the phosphor (9).

The well-known (Zn,Cd)S series has received little attention in regard to activation by Au. This activator was mentioned by Leverenz as applicable to the (Zn,Cd)(S,Se) series but no emission data were quoted (10). Byler attempted to explain the effects of changing CdS content by assuming a set of emission bands in fixed positions and independent of the activator (Cu,Ag,Au, Mn, or none) (11). The most extensive investigation on record is concerned with developing a single phosphor of white cathodoluminescence, namely, (Zn,Cd)S:Ag,Au,Al; in this case the emission data for (Zn,Cd)S:Au were presented only as chromaticity plots (12).

There is no doubt that Au is a specific activator, although in the past the blue band it produces in ZnS has sometimes been mistaken for that in ZnS without added metal activator.

The present work is concerned primarily with the effects of activation by Au, but for comparison other better known activators also have been used. The properties of ZnS phosphors with the various activators and different preparative details are first considered, particularly with regard to the effects on emission band positions and intensities of changes of temperature or of crystal form. Next, phosphors in the (Zn,Cd)S series with the same activators are discussed, with special reference to the shift of the bands as the CdS content is changed. A search for regular progressions between different series with Cu, Ag, and Au activators has been unrewarding, although interesting comparisons between Cu and Au have emerged. The individual behavior of activators is in fact much more striking than their similarities.

It has been reported previously that the frequencies of emission band peaks in the (Zn,Cd)S series, under cathode-ray excitation, give closely linear plots against weight proportions of the matrix (3). This inexplicable relation applies reasonably well to most of the data in the present work, but the apparently more rational scale of molecular proportions has been used in the graphical presentation. Other variables have been plotted against peak band wave number; of these only the c_o dimension of the hexagonal lattice gave any approach to linearity.

Measurement and Presentation of Emission Spectra

In the present work long wave-length ultraviolet excitation has been used in the main, with a few observations made under cathode-ray excitation. Samples were generally contained in a brass cell with a quartz window for exposure to 125-w mercury arc lamps in Wood's glass bulbs. This excitation by the group of lines near 3650Å produced a phosphor brightness of the order of 0.25 to 0.5 stilb. For the experiments on cooled samples the powder was used in the apparatus shown in Fig. 1. This

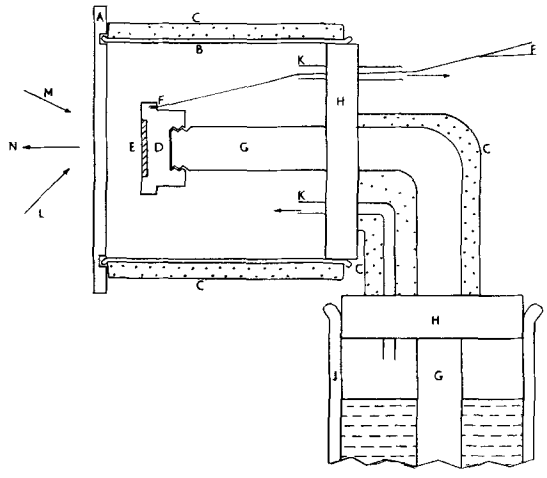

Fig. 1. Apparatus for excitation under ultraviolet at low temperature. produced reasonably low phosphor temperatures without a vacuum enclosure, and condensation on the phosphor was prevented by a stream of evaporated oxygen.

Spectral emission curves were measured on a spectrophotometer previously described (13), with an exit slit width of 5Å at 4000Å and 42Å at 7000Å. Beyond the latter wave length the low sensitivity of the 1P22 photomultiplier and the background radiation from the mercury lamps made the measurements unreliable. Although wave lengths in the visible spectrum are more familiar than wave numbers and are largely used in the literature of phosphor emission bands, in the present work wave numbers have been used to permit analysis of the emission bands into Gaussian sub-bands. Therefore, emission curves are drawn with ordinates representing relative energy emitted per unit wave number interval instead of the usual energy per unit wave length interval. The Gaussian bands isolated from these curves were taken to be the ultimate components of the emission and were considered as the basic experimental data. This agreement of emission curves with a sum of Gaussians is of somewhat uncertain significance, but it provides a convenient method of analysis and presentation. Peak intensities of the bands have been examined in detail; band widths were found to be not very consistent, and therefore band areas (equivalent to energy) were not used.

ZnS with Au and Other Activators

Preparation.—Samples were prepared by mixing pure precipitated ZnS with aqueous solutions to give 5% by weight of chloride ion (added as an equimolecular mixture of sodium and magnesium chlorides) and 0.01% by weight of Au, Ag, or Cu, as chloride, nitrate, or sulfate, respectively. After drying, the finely powdered mixtures were heated in 100-g quantities for 1 hr at 1100°-1150°C in air in plugged silica tubes, then removed from the furnace to cool. The products were washed free from fluxes, dried, and sieved. Other phosphors were prepared in a precisely similar manner but omitting the heavy metal addition. Also, a few samples of cubic structure were made by firing at 800°C, and of partially cubic structure by firing at 1100°C in the presence of excess of S contained in the raw ZnS. Other workers have referred to ZnS with no other foreign ion than chloride as "self-activated," "zinc activated," or "unactivated." In the following the term "chloride activated" is used. The residual chloride in these materials is in fact of the usual order of activator proportions. The metal-activated phosphors also contain small amounts of chloride and are described as ZnS:Au,Cl, etc.

Emission characteristics.—When activated by Au instead of by Cu, Ag, or Cl, ZnS emits two closely overlapping bands with peaks about 600Å apart; these are of the same order of intensity when the excitation is by long wave-length ultraviolet. There is in addition a weaker band in the yellow region. The over-all effect is that the fluorescence is much paler than for the other phosphors examined and is of a light bluish green color, similar in hue to that of 80 mole % ZnS·20% CdS:Ag,Cl, or 85%ZnS·15%CdS:Cl, but less saturated (see Fig 2. and 3 for examples of emission curves).

Table I summarizes the average values for emission peak positions. Wave lengths are given to correspond to the wave numbers: it must be emphasized that such values are not really equivalent owing to the different shapes of the wave number and wave-length curves. Peak values read off directly from the latter curves are included for comparison.

Table II shows changes observed on cooling the samples during excitation. Details are included for preparations of similar composition but different crystal structure.

Table III summarizes changes at 25°C caused by these different structures.

For Table I accuracy is estimated at ±100 cm^{-1} except for the more uncertain bracketed values. The

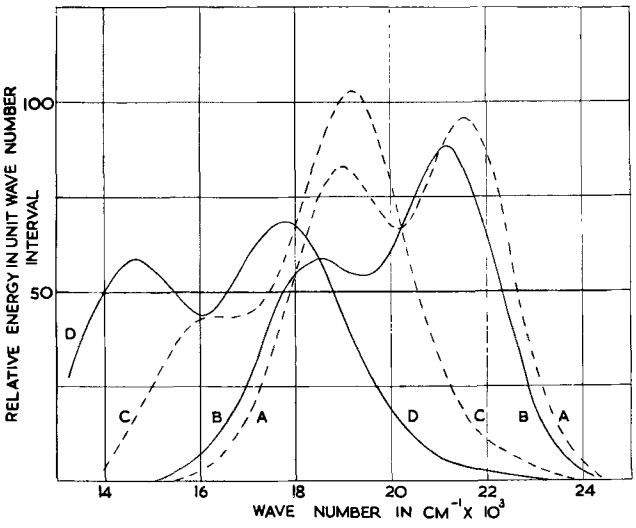

Fig. 3. Spectral emission of Au activated phosphors at —120°C. A, B, C, D: 02.7, 16.5, 30 mole % CdS, respectively.

convention adopted is to number the bands in order from the blue end of the spectrum, as Au I, II, etc. A band appearing only at low temperature is not included in this scheme (see Discussion).

Band peak positions.—The most interesting feature is the similarity between Au and Cu as activators. The well marked shifts to increased wave number on cooling and the contrary effect observed for ZnS:Cl agree with the findings of Tomlinson for his "self-blue" and "Cu-blue" bands (14) and of Shrader and Larach for their blue bands in ZnS:I, ZnS:Cu,I, and ZnS:Ag,halide (15).

For ZnS:Ag,Cl there is a small increase of wave number in Ag I on cooling. This places Ag with Cu and Au, as chemical considerations would suggest. Silver activation however is known to show anomalous behavior compared with Cu and Cl when ultraviolet excitation of cubic samples is changed to cathode-ray excitation (3). Other unusual effects have been described also for Ag in (Zn,Cd)S (16). To summarize present information on this topic:

(*A*) Cu, Ag, and Au at about 0.01% concentration and with Cl also, in cubic or hexagonal ZnS under ultraviolet, produce an increase of wave number on cooling, and Cl alone shows the reverse effect.

(*B*) A change to cathode-ray excitation increases wave number for Cl and Cu,Cl (cubic), and Au,Cl (hexagonal), but the reverse is true for Ag,Cl (cubic).

(*C*) Under cathode-ray excitation, cooling increases wave number for Cu,Cl (cubic), and decreases it for Ag,Cl and for Cl (cubic). It appears that it would be worth-while to pursue such measurements in the hope of correlating some of the variables.

Of the small bands isolated, Ag II and Cl II have not been reported before, while Cu III is probably the yellow band at 5800Å described by Froelich, but not the red band at 6700Å which moves to a lower wave number on cooling (17, 18).

Most of the samples considered in this paper were entirely hexagonal in structure. Table III shows considerable shifts of bands to lower wave numbers for cubic forms of ZnS with metal activators, and for a ZnS:Cl with about 50% cubic structure. Shifts of —400 to —600 cm^{-1} have been reported for this crystallographic change in ZnS:Cl, ZnS:Cu,Cl, and ZnS:Ag,Cl (19). The changes mentioned in this paragraph are all for excitation at room temperature; cooling introduces more complications.

Relations between band peak intensities.—The relative heights of the peaks vary with method of preparation of the phosphor, and with temperature of excitation. In almost every case the ratio of blue Au I to green Au II is increased by cooling to —120°C, that is, the green band is suppressed, as with Cu II. Another similarity to Cu is provided by an increase of the green band with more Au.

Modifications of the phosphor preparation, using several rates of cooling graded from instantaneous quenching in water to 16 hours' cooling in the furnace, made a progressive increase of Au II at the expense of Au I as the cooling became faster, and the more so for higher initial firing temperature.

	(~0.01 Cl)	Hex	−250				
			− 80				
Cl		50:50 Cub-hex	−175				

Quenching also produced unusual results on the positions of Au I and II when the phosphor was excited at −120°C. The hexagonal form showed small or no shifts compared with excitation at room temperature, while the cubic suffered wave number decreases of 200-300 cm^{-1} instead of the "normal" increases given in Table II.

Cathodoluminescence.—A few phosphors were examined when scanned by a defocused spot at 14 kv and 3 μa/cm^2. This produced an approximate doubling of the blue band at the expense of the others. Of the ZnS:Au,Cl samples, those with 0.01% Au showed shifts of all three bands, to wave numbers higher by 100-450 cm^{-1}, compared with ultraviolet excitation (see Fig. 2 for an example).

Selenium replacement in ZnS.—When Se replaces increasing proportions of S in ZnS:Au,Cl, phosphors result which resemble the (Zn,Cd)S:Au,Cl series under ultraviolet. The color changes are produced in part by the suppression of Au I and in part by shifts in the positions of Au I and II which are smaller than those found with equivalent substitution of CdS. For instance, a sample containing 27.6% of ZnSe has an emission curve which is nearly a pure Gaussian of Au II, peak 17875 cm^{-1}, and with a visual color close to that of (Zn,Cd)S:Au,Cl containing 20% CdS. At −120°C the Au I band is largely restored in relation to Au II for those phosphors with smaller ZnSe contents.

Table III. Shifts of component bands of ZnS at 25°C by change from hexagonal to cubic structure

	Band I	Band II	Band III

0.01% Cu,Cl	−700	−500	+200
Cl (50% cubic)	−600	−400	

(Zn,Cd)S Series with Au and Other Activators

Au *activator: preparation, composition, and spectral characteristics.*—Samples were prepared by the general method described above, replacing proportions of ZnS in the initial mixture by an equal weight of precipitated CdS, usually in multiples of a nominal 10% by weight of ZnS up to 80% CdS. The percentages of ZnS and CdS in the phosphors were determined by analysis involving the initial removal of Cd by precipitation with phenyl trimethyl ammonium iodide; the Zn was then precipitated by 8-hydroxyquinoline, followed by the standard volumetric estimation. The precipitated Cd was determined volumetrically by iodate. In the text and figures percentages of CdS given are molecular values unless stated otherwise. The analyzed CdS weight percentages were up to 4% less than the nominal values (increasing with CdS content), this difference arising largely from a small amount of ZnS present in the CdS raw material.

In appearance under ultraviolet the Au,Cl series varies from pale bluish green to very pale yellow to colors resembling those of higher members of the other series. The unsaturated color of phosphors low in CdS is very marked, but at 25% CdS the yellow fluorescence is similar to that of 10% CdS:Cu, Cl, 50% CdS:Ag,Cl, and 35% CdS:Cl. Examples of emission curves at 25° and −120°C appear in Fig. 2 and 3, and of resolution into sub-bands in Fig. 4. The peak wave numbers are plotted against molecular percentage of CdS in Fig. 6, which also includes a weight percentage plot for Au I.

Cathode-ray excitation gave results similar to those for ZnS, namely, a relatively doubled emis-

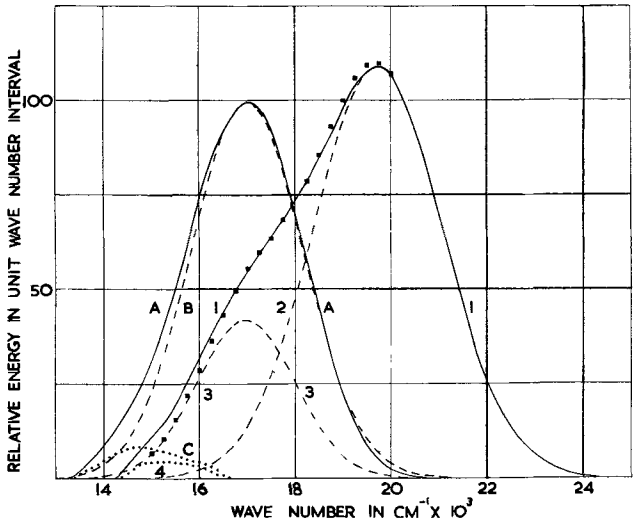

Fig. 4. Resolution of emission curves at 25°C into Gaussian sub-bands. Solid line, measured emission; broken line, Gaussian; dotted line, remainder not resolved into Gaussians; square points, sums of constituent Gaussians. 1-4: 8.5 mole % CdS: Au, Cl; A-C: 48 mole % CdS: Ag, Cl.

sion of band Au I compared with ultraviolet excitation, and band shifts between 100 and 300 cm^{-1} to higher wave numbers.

Other activators.—Samples were made with 0.01% Cu or Ag, or without metal addition, all with chloride. In the last mentioned type, analysis of well-washed samples established the residual chloride content to be 0.007% by weight in a 3.5% CdS phosphor and 0.01% in a 7% CdS phosphor, compared with 0.008% in a ZnS:Cl.

Examples of band resolution are given in Fig. 4 and 5, while peak wave number data from the complete series are presented in Fig. 7-9, where linear relations are evident as in Fig. 6. The Cu II band is also plotted on a weight percentage scale.

It will be observed that qualitatively Cu resembles Au in its band structure: to visual inspection the Cu and Au phosphors are similar in their long phosphorescence which contrasts with the short afterglow in the Ag series. There is a resemblance between the slopes of the Ag and Cl plots, but all the

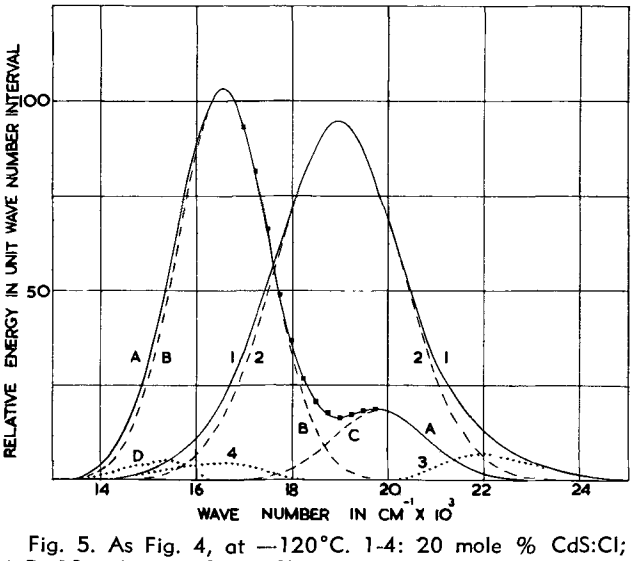

Fig. 5. As Fig. 4, at —120°C. 1-4: 20 mole % CdS:Cl; A-D: 18 mole % CdS: Cu, Cl.

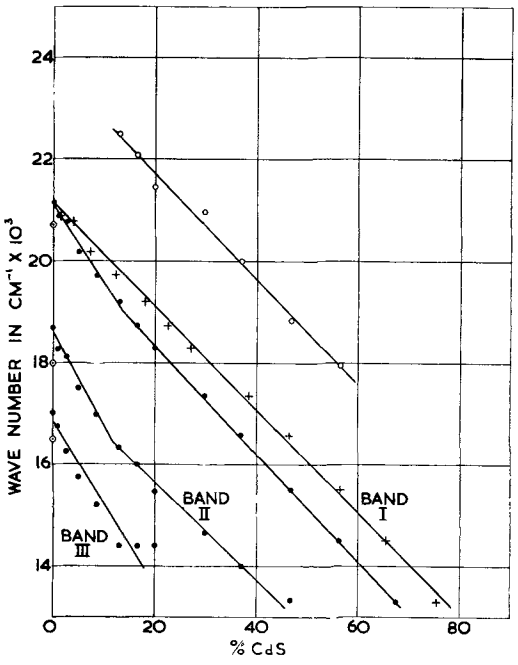

Fig. 6. Location of emission band peaks of (Zn, Cd)S: Au, Cl at 25°C. Circled points, cubic samples; open circles, low temperature peak; crosses, plot with weight percentage obscissae.

series show a break at about 15 mole % CdS. If weight proportions are used for plotting, the data for Cu and Au may be expressed by straight lines from 0 to 80% CdS, while Ag and Cl require broken lines like those in Fig. 8 and 9. These breaks occur near the point at which cubic forms can no longer be made as CdS content increases, owing to the preponderance of the hexagonal CdS structure.

Another series of samples was fired at 1100°C without metallic activator but with ZnS containing much free S, which assists the formation of the cubic structure below about 15 mole % CdS. The emission

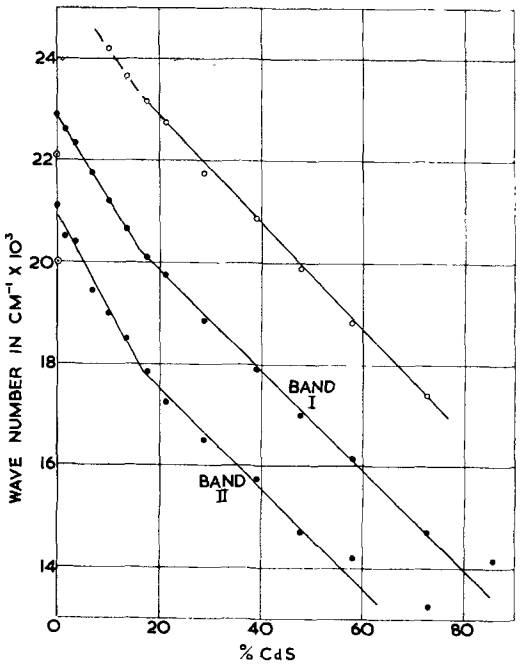

Fig. 8. Location of emission band peaks of (Zn,Cd)S:Ag, Cl at 25°C. Circled points, cubic samples; open circles, low temperature peak.

band peaks of these materials lie on the general plots above 15% CdS, but below this point the wave numbers are lower, as shown in Fig. 9 for band Cl I.

The peak intensities of the bands in the (Zn,Cd)S series with any of the four types of activator decrease as the CdS content rises to 10-15%, the fall of intensity being between 10 and 30%; a rise follows by which the values for 0% CdS may be reached or exceeded (at a CdS content of 15-30%); finally with more CdS a general fall occurs. In Fig. 2 and 3 the ordinates (except for the cathode-ray excitation example) are nearly proportional to the true intensities.

Low temperature effects in the (Zn,Cd)S *series.*— The emission spectra of the series with four different activators have been investigated at −120°C. When plotted in the manner of Fig. 6-9 the component band peaks lie on lines of similar slopes, and with the same breaks, as those of the corresponding bands at 25°C. These plots are not reproduced here. They show closer fit of points to lines owing to the sharper band structure at −120°C. In the case of Cu I at 25°C it is difficult to isolate this small component from the emission, and the plot in Fig. 7 is irregular. At −120°C a more normal pattern reappears; see Table IV, which summarizes all the measurements and indicates some similarity of Cu and Au on the one hand, and of Ag and Cl on the other.

The uppermost lines on Fig. 6, 8, and 9 refer to another band, not hitherto mentioned, found only at the low temperature; this is discussed in the next section.

Discussion

Reference has been made to the representation of emission band peak positions in terms of straight line plots. These varied linear relations are difficult to interpret, although their occurrence is quite striking. The data are probably not sufficiently precise to determine the exact relations which exist, but one interesting possibility is suggested below.

The emission band structure and its behavior on temperature change are important in relation to the theory of activator center structure and of energy levels. For Cu a third long wave-length band has been confirmed, and for Au three bands have been demonstrated. With both activators band II appears to be the typical one due to the metal, possibly as Cu^{+} or Au^{+} substituted for Zn^{++}. If the blue bands Cu I and Au I are assumed due to Cl producing cation vacancies, in the way that Bowers and Melamed have proposed for Cl "blue I," the anomaly arises that these bands differ from Cl I in their response to cooling (20). It is therefore suggested that, contrary to the views of Bowers and Melamed, blue Cu I and Au I are not due to the presence of cation vacancies even though all the phosphors did contain chloride. When, besides the chloride, an activating metal is also present, its effect seems to predominate.

With regard to the emission changes by cooling the main series of hexagonal phosphors, it is reasonable to attribute all the bands in ZnS and (Zn,Cd)S with Au or Cu to associated groups of acceptor levels near the valence band, whereas Cl as sole activator produces donor levels nearer the con-

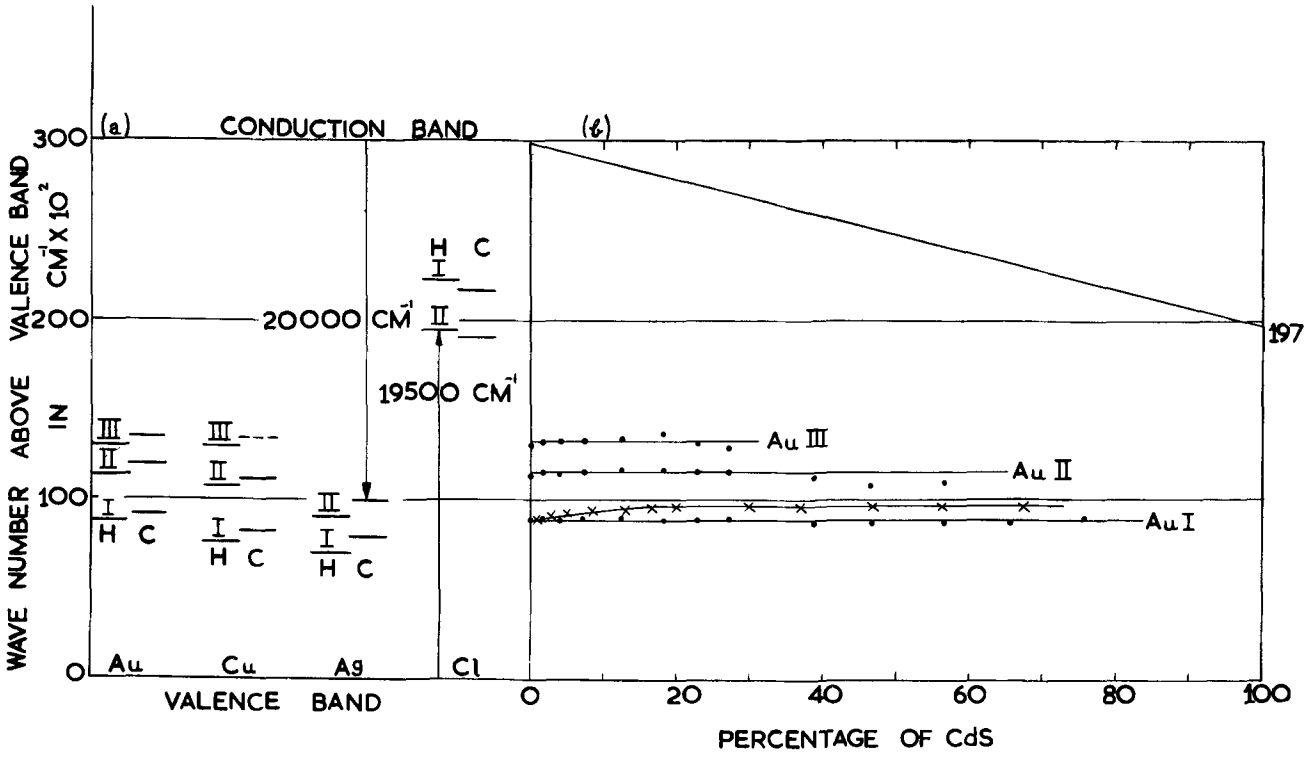

Fig. 10. (a) Energy level diagram for Cu, Ag, Au, Cl bands in ZnS at 25°C. Arrows indicate luminescent transitions; H, levels for hexagonal crystals; C, for cubic. duction band in the sense of the model of Lambe and Klick (21). These different types of radiative transition may account for the differences in temperature effects. Figure 10a gives the simplest energy diagram on these assumptions. Over the temperature range used in the work, the energy gap in the ZnS crystal increases by about 300-500 cm^{-1} according to determinations by Coogan and others (22). The observed emission band shifts on cooling suggest that the Au, Cu, and Ag levels remain nearly in the same position with respect to the valence band as the energy gap increases. In contrast, for Cl alone the levels must approach the valence band appreciably on cooling. All the shifts discussed are very small compared with the energy gap or the radiated quanta, and they are so easily altered by change of phosphor preparation method that the above details cannot be generally applicable. The approximate constancy of the separation between activator and valence band is shown better by assuming a linear variation of the energy gap between ZnS and CdS, the observed emission wave numbers being then plotted from the conduction band downward, as in Fig. 10b for the gold-activated series, where abscissae give weight percentages of CdS. A recent extensive study of (Zn,Cd)S phosphors by Hoogenstraaten develops similar ideas on activator levels (23). He refers to molecular proportions of CdS, but in Fig. 10b this scale is seen to give worse agreement with a linear relation than does the weight proportion scale; in fact the line for Au I could be drawn in two sections, as in Fig. 6, and the part above 15% CdS would be parallel to the x-axis.

A band of shorter wave length than those already discussed, and not included in the band numbering, was found only under excitation at −120°C, and for phosphors with over 10 mole % CdS. Peak locations are shown in Figs. 6, 7, and 9 on the lines which are all of the same slope (-102 ± 2 cm^{-1}/1 mole % CdS), with possibly a steeper part below 15% CdS making extrapolation difficult; however it is likely that the 0% CdS value is that attributed by Melamed (24) to the emission due to anion vacancies in cooled ZnS, namely 3950Å or approximately 25000 cm^{-1}. Similarly van Gool (24, 25) has reported a band in CdS:Ag at 6200Å or approximately 16000 cm^{-1}. The present results extrapolated would give a much higher wave length. This band did not appear with Cu activator except doubtfully in a few samples of low CdS content, and at 25°C.

There is clearly a great deal more to be discovered about the emission spectra of these phosphors and their mutual relations. Correlation with other physical parameters may be difficult or impossible but this is merely a consequence of the most striking characteristic of phosphors as a whole, namely the extreme sensitivity of their emission, both qualitative and quantitative, compared with any other measurable properties.

Particle Size Effects and the Distribution of Barriers in Electroluminescent Zinc Sulfide Phosphors

Paul Goldberg

Central Research Laboratories, Sylvania Electric Products Inc., Bayside, New York

ABSTRACT

The particle size of electroluminescent phosphors is found to be a significant factor in empirical equations describing brightness-voltage relationships. These observations can be understood by considering the following factors: (*a*) number and distribution of barriers in a single particle, (*b*) division among the barriers of the voltage drop per particle, and (*c*) dependence on the particle size of the voltage drop per particle. Equations are derived which permit a comparison of the brightness of different phosphors.

In the recent literature on the electroluminescence of zinc sulfide, the barrier concept finds wide support. According to this mechanism electrons are accelerated in the barrier region and cause excitation through impact ionization of luminescent centers (1-6). Radiation occurs when the ionized centers and free electrons recombine. The barrier picture is appealing for at least two reasons. First, it provides an explanation of how an electric field can raise electrons to several electron volts above their ground states without electrical breakdown of the crystals. Second, the concept of localized barriers correlates well with the observed inhomogeneous distribution of emitted light (2, 7, 8).

Information on the number and distribution of barriers is not obtained easily. This is particularly true of powder layers. Electroluminescent phosphors are reported to possess both "surface" (2) and "volume" (9) electroluminescence, reflecting possible differences in barrier distribution. The present work is one approach for obtaining information on the number and distribution of barriers in polycrystalline phosphors.

If it is assumed that the barriers are located near the surface of the particles, one may ask what happens to the electroluminescent properties as the specific surface, (i.e., particle size) is varied. To study this problem effectively, a series of electroluminescent phosphors is needed in which the members have equal chemical and physical properties but have varying particle sizes. While it is hardly feasible to synthesize separately the individual members of such a series, one promising approach is through fractionation by particle size. Most of the work presented here employed this technique.

Experimental Technique and Results

The starting materials were two phosphors representative of the blue- and green-emitting materials of Homer, *et al.* (10). These were fractionated according to particle size by settling from water or aqueous glycerine solutions. Turbulent stirring of the suspensions with a surface active agent prior to settling reduced flocculation. Also, the green-emitting phosphor was subjected to ultrasonic vibration as an added measure to break up agglomerates. Nevertheless, some aggregation undoubtedly occurred prior to settling as some of the fractions showed a plurality of log-normal distributions. Unfractionated phosphors showed only a single log-normal distribution. Individual particles were mainly globoid. A few particles showed triangular faces with rounded corners.

The measurement of the luminous emittance of the powders was made using a cell similar to that described by Lehmann with castor oil as the suspending dielectric (11). The cell dimensions were 1 x 1 x 0.005 in. A 1P22 photomultiplier was used as the detector. The phosphor concentration was held at a fixed volume fraction of 0.25 for all measurements. The experimental spread in duplicating a given emittance measurement, including factors for making the castor oil slurries, loading the cell, and aging it under an applied field, is about 10%.

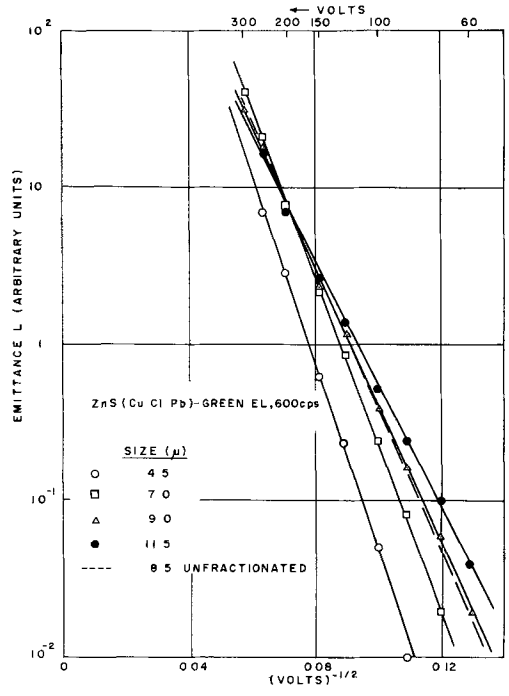

Fig. 1. Brightness-voltage characteristics of a green-emitting electroluminescent powder and some representative fractions.

It has been demonstrated by Zalm (2) and Alfrey and Taylor (3) that brightness data are well represented by straight lines when the log of the luminous emittance L is plotted vs. $V^{-1/2}$, where V is the rms applied voltage. Figure 1 shows the emittance-voltage data of four fractions and of the unfractionated green-emitting electroluminescent powder plotted in this way for a frequency of 600 cps. There is a distinct regularity in the variation of the slopes and the apparent intercepts with particle size. Variations in the emittances of up to an order of magnitude at 60-70 v are evident. Figure 2 shows the data taken at 6000 cps for the blue-emitting phosphor, with a similar result. For both phosphors the effect has been observed at other frequencies in the range 60-6000 cps.

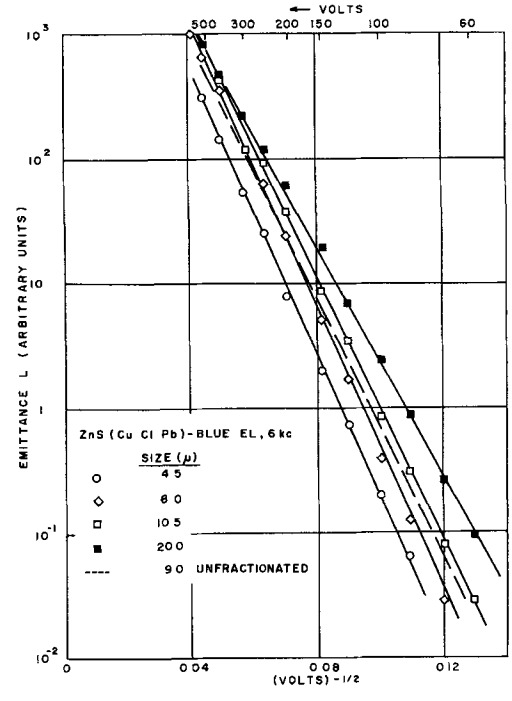

Fig. 2. Brightness-voltage characteristics of a blue-emitting electroluminescent powder and some representative fractions.

Analysis of Results

An attempt will be made to analyze the emittance data in terms of the luminous flux from each particle. This flux itself originates at point sources of emission. We shall assume that a potential barrier exists at each point source and the flux from it is determined by the voltage drop, V_B, across the barrier. V_B will be determined largely by the voltage applied to the cell. However, it may have different values depending on the particle size and the number and distribution of barriers in each particle. The procedure will be to evaluate V_B for a given applied voltage and for different types of distributions. We then may express the dependence of the flux from each point source on the applied voltage and the parameters describing the particular distribution of barriers. The emittance of the cell is obtained by summing the flux from each point source in a particle and then summing the contributions to the total emittance from each particle in the cell. Lehmann discussed this approach but did not attempt a quantitative development (12) .

For the a-c case, V_B will vary with time during a cycle and, therefore, we must visualize it as corresponding to an average value. Zalm (2) and Alfrey and Taylor (3) have discussed this point and also the factors which determine how much of the voltage applied to the crystal appears across the barrier.

The voltage dependence of the luminous flux from the individual point sources will be assumed to be of the same form as the dependence of the emittance of the whole cell.[1] Thus the flux F_B from one point source of those making up a given particle is

$$F_B = F_o \exp\left(-b'/V_B^{1/2}\right) \qquad [1]$$

where F_o and b' are parameters which are independent of voltage.

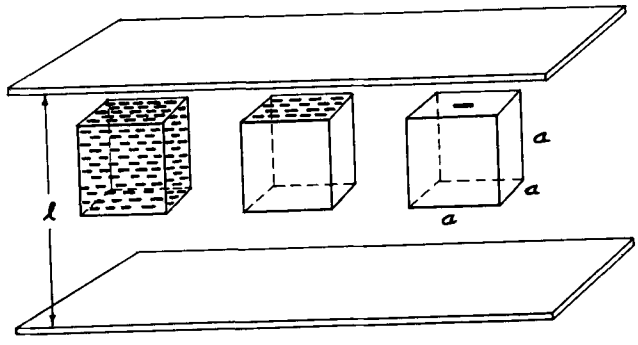
To evaluate V_B in terms of the voltage applied to the crystal we shall assume that the electroluminescent layer is represented by a mixture of two homogeneous dielectrics. The phosphor phase is considered to be a rectangular array of cubic phosphor grains of uniform size dispersed in the insulating medium between plane parallel electrodes in the manner shown in Fig. 3. Following Roberts (12), the electric field in a particle E_p is proportional to the mean applied field E_m through a factor dependent upon the ratio, r, of matrix and phosphor dielectric constants, and the volume fraction v of the phosphor, i.e., $E_p = E_m \cdot f(r, v)$. The voltage drop V_p across one of the cubes in Fig. 3 is thus

$$V_p = (Va/l) \cdot f(r, v) \qquad [2]$$

where V is the applied voltage, l the distance between electrodes, and a the cube edge.

At this point some choice must be made as to the

[1] Zalm (2) measured the flux from single grains of electroluminescent ZnS and showed that the dependence of the emission from single grains follows closely that of the composite cell.



$F_B \sim \exp(-bV_B^{-1/2})$

Fig. 3. Schematic diagram of electroluminescent particles with (a) volume distribution of barriers, (b) surface distribution of barriers, and (c) a constant number of barriers per grain, unity in the case pictured.

distribution of potential barriers in the particle. The choice of the distribution will determine how much of the voltage applied to the crystal as a whole will appear across each barrier and, therefore, governs the magnitude of the luminous flux from the region near each barrier. Three cases will be considered: (*a*) uniform distribution of barriers throughout the volume of the grain; (*b*) uniform distribution of barriers over the surface of the grain; and (c) constant number of barriers per grain regardless of dimensions.

These cases are represented schematically in Fig. 3 and considered in detail below.

(*a*) *Uniform distribution of barriers throughout the crystal volume.*—Let the volume density of a system of identical barriers be n_v/cm^3. Then along a line of force through a crystal with rectangular orientation relative to the electrodes there will be $n_v^{1/3}$ barriers per cm.[2] In a crystal of edge a cm there are $n_v^{1/3}a$ barriers through the crystal in the direction of the applied field. Dividing the V_p by this number of barriers gives for the voltage drop per barrier

$$V_B = V_p/n_v^{1/3}a = (V/ln_v^{1/3}) \cdot f(r, v) \qquad [3]$$

and substitution in Eq. [1] gives for the luminous flux from the region near each barrier

$$F_B = F_o \exp[-b/(V/ln_v^{1/3})^{1/2}];\ b \equiv b'/f^{1/2}(r, v) \qquad [4]$$

There are n_va^3 barriers in the grain and the total flux F_p from the particle is $F_p = n_va^3\ F_B$. For a volume fraction of phosphor v in the suspending dielectric the number of grains N per cm^3 of suspension is v/a^3. The flux per cm^3 of suspension is $F = F_pv/a^3 = vn_vF_B$ or from Eq. [4]:

$$F = vn_vF_o \exp[-b/(V/ln_v^{1/3})^{1/2}] \qquad [5]$$

The luminous emittance L from a layer of the suspension l cm thick is proportional to $F \cdot l$ and therefore

$$L \sim vn_vlF_o \exp[-b/(V/ln_v^{1/3})^{1/2}] \qquad [6]$$

Thus, as the particle size a does not occur in Eq. [6], neither the intercepts nor the slopes of data plotted as in Fig. 1 should depend on particle size for grains with a volume distribution of barriers.

(*b*) *Uniform distribution of barriers on the surface of the grains.*—Let us next consider the barriers to be distributed over the surface of the grains at a concentration of n_s barriers per cm^2. The number of barriers on one cube face is n_sa^2. Also, as there is only one barrier along any line of force perpendicular to the surface, the full voltage applied to the grain will appear across each barrier.[3] Thus, $V_B = V_P = (Va/l)\ f(r, v)$. Therefore from Eq. [1]:

$$F_B = F_o \exp[-b/(Va/l)^{1/2}] \qquad [7]$$

The flux from each particle is $F_P = n_sa^2F_B$. The total flux per cm^3 is $F = vn_sF_B/a$ and the emittance is given by

$$L \sim (vn_slF_o/a) \exp[-b/(Va/l)^{1/2}] \qquad [8]$$

Here both the slope and intercept of log L vs. $V^{-1/2}$ will vary with particle size. It is seen from Eq. [8] that for all particle sizes, plots of log (La) vs. $(Va/l)^{-1/2}$ should be coincident.

(*c*) *Constant number of barriers per grain.*—Next let us visualize a specific number of barriers, n, to exist on the surface of each particle and let n be constant for all particle sizes. The entire voltage drop per crystal is across the barrier as in case (*b*), and again $V_B = V_P = (Va/l)\ f(r, v)$. The total flux per particle is

$$F_P = nF_o \exp[-b/(Va/l)^{1/2}] \qquad [9]$$

and

$$L \sim (vnlF_o/a^3) \exp[-b/(Va/l)^{1/2}] \qquad [10]$$

where again

$$b \equiv b'/f^{1/2}(r, v)$$

Here too, both the intercept and the slope of log L vs. $V^{-1/2}$ vary with particle size. In contrast to the previous section, plots of log (La^3) vs. $(Va/l)^{-1/2}$ for various particle sizes should be coincident. The data in Fig. 1 and 2 eliminate the possibility of a volume concentration of barriers, as prominent particle size effects are evident. The model of a surface density of barriers is also not satisfied by the data, as Fig. 4 shows a test of Eq. [8] for the fractions in Fig. 1. While the slopes of separate fractions show some degree of uniformity in Fig. 4, there is still a wide discrepancy among the intercepts. Good agreement with case (c) is found for the data of Fig. 1. The application of Eq. [10] to these data is shown in Fig. 5. The simple model of a constant number of barriers per grain fits well for this phosphor.

While the blue-emitting phosphor of Fig. 2 shows pronounced particle size effects, the data are not satisfied by Eq. [10]. This is seen in Fig. 6; a dependence of slope on particle size still persists. For this phosphor it can be shown that the slopes in Fig. 2 vary roughly as $a^{-1/4}$.

The development presented above can also be tested with unfractionated phosphors of differing mean particle size. Figure 7 shows a plot of the slope of (log L vs. $V^{-1/2}$) vs. $a^{-1/2}$ for a group of blue-emit-

[2] The number of barriers in the direction of the lines of electrical force will actually be proportional to $n_v^{1/3}$. Setting the number of barriers/cm equal to $n_v^{1/3}$ simply introduces a different arbitrary constant at a later point.

[3] We visualize the barriers on only one side of the crystal to be operative during one half cycle of a.c. and those on the opposite side during the following half cycle.

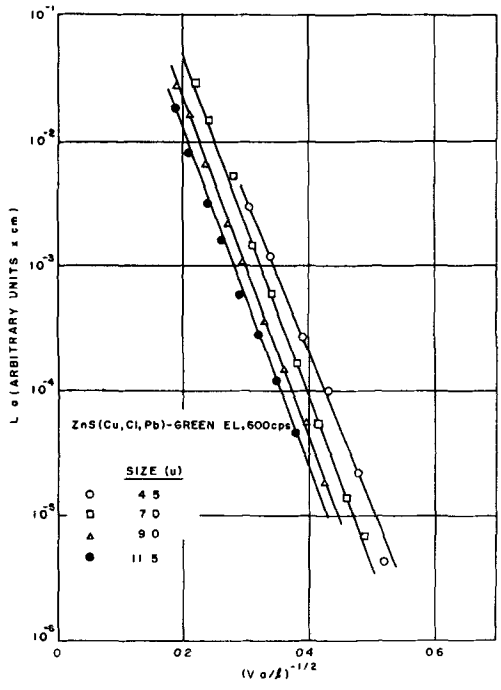


Fig. 4. Test of Eq. [8] corresponding to a surface density of barriers (case b). Data are taken from Fig. 1.

ting phosphors of the ZnS:Cu, Cl, Pb or ZnS:Cu, Cl type. The data fall close to a straight line with a slope greater than zero. This eliminates the possibility that the group is characterized by a volume distribution of barriers. It is not possible, however, to distinguish between cases (b) and (c) for these phosphors.

It should be mentioned that, for a given field strength, Eq. [10] predicts a particle size a_m which gives maximum emittance: $a_m = b^2/36(V/l)$. This condition arises from the fact that as a decreases, the number of emitting particles per cm^3 increases.

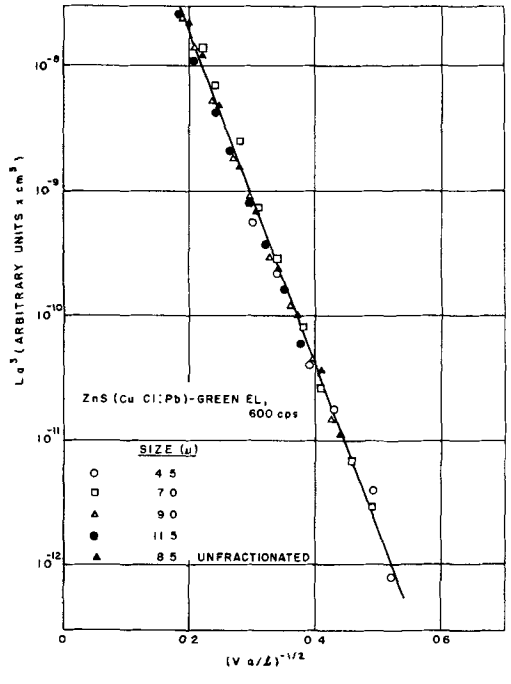

Fig. 5. Test of Eq. [10] corresponding to a constant number of barriers per grain (case c) for the data of Fig. 1.

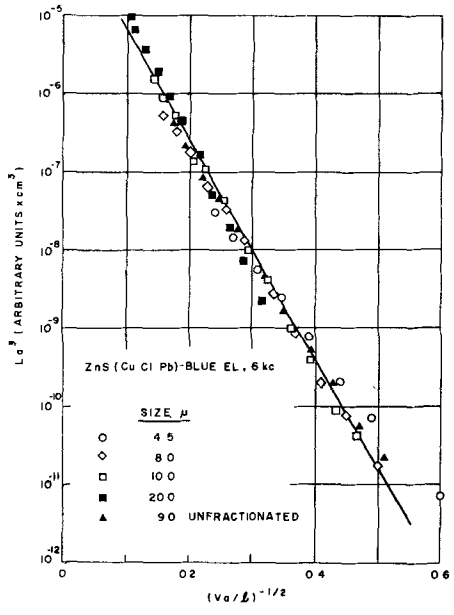

Fig. 6. Test of Eq. [10] corresponding to a constant number of barriers per grain (case c) for the data of Fig. 2.

At the same time however, the luminous flux per particle decreases with decreasing particle size.

Discussion

The data presented above show that the particle size is a significant factor in the brightness-voltage characteristics of electroluminescent phosphors. Limited agreement is obtained between the data and a simple theory based on a specific distribution of barriers in the phosphor particles. For both the fractionated green-emitting phosphor and the unfractionated group of Fig. 7 the slopes of the exp $(V^{-1/2})$ lines vary as $a^{-1/2}$. In particular, the data for this fractionated phosphor support case (c) corresponding to a constant number of barriers per grain. It should be emphasized that this concept, being derived as it is from the emittance data, applies only to the barriers which are active in the excitation processes. Other barriers or similar physicochemical constructs may be present in the particles but are not revealed by the emittance data.

The reasons for the failure of the blue-emitting phosphor of Fig. 2 to show the same detailed behavior as the green-emitting one are not clear. The assumptions regarding the identity of chemical com-

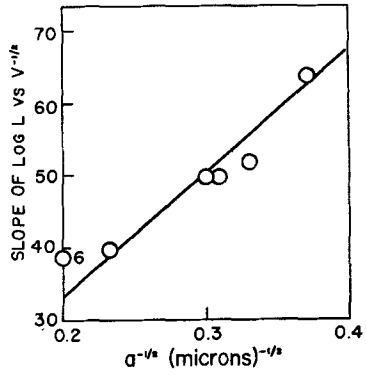

Fig. 7. Slopes (of log L vs $V^{-1/2}$ plots) vs. $a^{-1/2}$ for some unfractionated blue-emitting electroluminescent phosphors with various thermal histories and particle sizes.

position of the fractions and the existence of a simple distribution of barriers possibly need closer examination. Poor separation during fractionation may also be a factor as the blue-emitting phosphor did not have the benefit of ultrasonic dispersion prior to settling.

The development assumes that for barriers distributed as in cases (*b*) and (c), the voltage drop per barrier V_B will be determined largely by the grain size. This concept finds support in the work of Waymouth and Bitter (8), who studied the effects of geometric crystal orientation, relative to the field vector, on the emission from individual particles. They examined particles of elongated shape in which single spots of emission could be observed. These spots were brightest when the field was parallel to the long axis of the particle. One possible interpretation of this from the present work is that the elongated particle exhibits the greatest "effective particle size" when oriented parallel to the field, causing V_B and therefore F_B to be larger than for any other orientation.

We can only speculate at present on the number of barriers per grain for case (c). The choice of one barrier per grain is attractive. Waymouth and Bitter examined a large number of single grains of phosphors also synthesized by the method of Homer, *et al.* (10) and observed brightness waves with only one major emission peak per cycle. If more than one barrier were operative in a crystal, then emission during each of the two half cycles would be expected.

In practical electroluminescent cells the grains are not cubic and perfectly oriented. However, the aim of the development is to produce the correct functionality in equations relating light output to particle size. Absolute values are not of concern. The shape might have been taken to be something other than cubic with the same result; the cube of a characteristic linear dimension would enter into the pre-exponential factor in Eq. [10] and as the negative ½ power in the exponential term, regardless of particle geometry. Neither does the fact that only polydisperse materials can be obtained by fractionation limit the validity of the arguments. It is seen that the unfractionated powder behaves as if it were a fraction with the effective particle size equal to the average.

It is possible to employ the present analysis in several ways. First, it provides a possible approach to distinguishing between classes of phosphors possessing dissimilar distributions of barriers. However, the equations do not provide means for distinguishing between surface and volume barriers. For instance, Eq. [10] can be obtained by choosing a small value for the number of barriers in each grain and distributing them throughout the volume. If the density of such barriers is low, so that a single line of force through the crystal sees only one barrier, then the equation so derived is exactly of the same form as Eq. [10]. For other phosphors, distributions not considered here may be of importance.

Second, if the distribution of barriers can be established, the characteristics of phosphors with different particle sizes can be compared, with allowance for size. Thus if the data for a pair of phosphors are plotted as in Fig. 4, comparison of the ordinates for a specified value of the abscissa gives a measure of the relative light output corrected to the same particle size and applied field.

Third, it may be possible to employ the analysis for a better understanding of the factors which influence the efficiency of the excitation process. Figure 7 shows that a constant slope exists for several electroluminescent phosphors of the ZnS:Cu, Cl type. Theoretical arguments have been advanced which state that the slopes are related to the probability that an electron accelerated in the region of a potential barrier will result in impact ionization (2, 3). Changes in the composition of the phosphor which change the slopes may yield information on the chemical and physical factors which govern the properties of the barriers.

A Method for the Purification of Selenium

S. Nielsen and R. J. Heritage

Royal Radar Establishment, Great Malvern, England

ABSTRACT

A method has been worked out for purifying selenium based on the formation and decomposition of hydrogen selenide. Details of an apparatus capable of producing about 10 g/hr of extremely high purity selenium are given. Several analytical methods used in examining the product are outlined.

Selenium is recovered industrially from two main sources (*a*) flue dust obtained in burning pyrites in the manufacture of H_2SO_4, and (*b*) anode slimes from electrolytic refining, particularly of Cu. Usually the crushed ore is roasted in air and the SeO_2 formed, sublimes, and is collected in water. Selenium is recovered from this solution by reaction with SO_2 according to the equation

$$H_2SeO_3 + 2SO_2 + H_2O = Se + 2H_2SO_4$$

Material prepared in this way is approximately 99.5% pure, the main impurities being S and Te (1).

Further purification has been achieved in several ways. Henkels (2) recommended a 4-stage procedure: (*a*) distillation of the Se at atmospheric pressure, (*b*) conversion to SeO_2, (*c*) purification of the SeO_2 by sublimation, (*d*) recovery of the Se by reaction of the dioxide with gaseous ammonia according to the equation

$$3SeO_2 + 3NH_3 = 3Se + 2N_2 + H_2O$$

High purity Se has also been produced commercially by the ammonia reduction of SeO_2, which has been prepared by the catalytic vapor phase oxidation of Se (3). A recent patent (4) pointed out that selenium could be obtained spectrographically pure by a direct solution method. In this process Se was dissolved in a hot aqueous solution of sodium sulfite and a small quantity of aluminum sulfate solution added. Aluminum hydroxide precipitated, carrying with it impurities present in the solution. After filtration, purified Se was precipitated on cooling. Nijland (5) recommended a sublimation procedure at a pressure of 10^{-3} mm Hg and claimed that sublimation was much better than distillation. Also methods based on the purification of SeO_2 in solution using ion exchange resins have been used (6).

Distillation and sublimation techniques are to be preferred since they are simple and the purification of other chemicals is not required. However our experiments with radiotracers suggested that to achieve a significant reduction in impurities repeated sublimation would be necessary. Our attempts to purify Se by zone melting were also without success.

Selenium doped with 10 ppm of radioactive Cu and Sb was sublimed in a simple tube-type apparatus. The results indicated that the Cu content of the sublimate was reduced to about 0.5 ppm and the Sb content to about 0.2 ppm.

An ingot of Se which had been previously doped with 100 ppm of each of the impurities shown in Table II was zone-melted in a sealed evacuated silica tube. After 30 passes, samples taken from along the ingot were examined spectrographically, but no movement of impurities could be detected. The ingot length was ~30 cm, the zone length ~2 cm, although there was a pronounced tendency for supercooling, and the rate of zone travel was 5 cm/hr.

These experiments suggested that neither sublimation nor zone melting processes were particularly effective, and we report here a new method which we believe to provide very pure Se. The method involves the formation and decomposition of H_2Se. Hydrogen selenide is formed by bubbling purified hydrogen through molten Se at 650°C. The H_2Se is decomposed by passing the gas through a silica tube maintained at 1000°C. With a suitably constructed tube about 70% of the selenide is decomposed. Undecomposed H_2Se is condensed in a liquid air trap and later allowed to recirculate through the decomposition tube. In this way practically all the H_2Se is decomposed. The Se liberated is collected by melting into a silica crucible.

The only other elements likely to form hydrides under these conditions and consequently those likely to be impurities in the final material are F, Cl, Br, I, O, S, Te, P, As, and Sb. The first 6 of these elements form hydrides more readily than Se and the others less readily. Further, the hydrides of the first 6 are less easily decomposed at 1000°C than H_2Se, while the others are more easily decomposed (cf. Table I). The difference in stability is utilized in this process. Further purification of the H_2Se could be obtained by fractional distillation (cf. Table I) or gas chromatographic procedures, but we have not found these necessary.

The advantage of the process lies in the purity which can be obtained in one operation. For instance, it has been shown using radiotracers that, if 1 ppm of the Cu or Sb is added to the starting material, there is an improvement of the order of 10^4. It is clear also that very low grade Se can be purified in this way. A serious disadvantage, however, is that H_2Se is very toxic and consequently care must be

Table I. Physical properties of hydrides

taken to avoid leakages when assembling and handling the apparatus.

Apparatus

The general arrangement of the apparatus, as illustrated in Fig. 1, is described below, followed by details of the individual units. Hydrogen is purified (H_2 purifier) and bubbled through molten Se where a portion is converted into H_2Se (H_2Se generator). The gas stream then passes though trap I at 300°C and through trap II at −20°C. During the first ½ hour's operation the gas is led direct to waste with taps B and D being open and taps C and E closed. After this time, tap D is closed and C and E opened and the gas stream is led into condenser I. This is maintained at −196°C by surrounding it with liquid nitrogen when H_2Se is condensed. When a suitable quantity of H_2Se has been collected, the hydrogen flow is stopped, taps A and B are closed, and the H_2Se is allowed to evaporate into a silica tube maintained at 1000°C (decomposition tower). In this

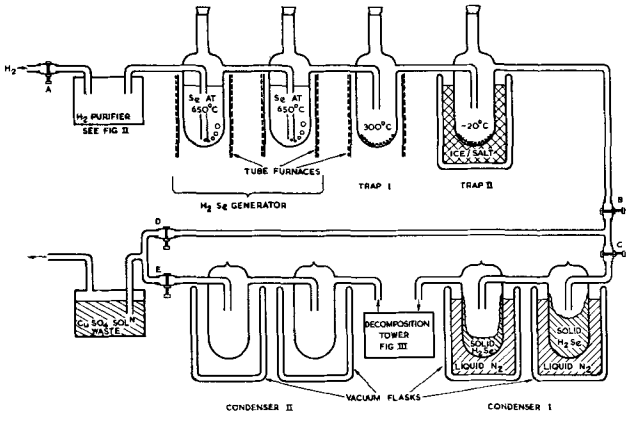

Fig. 1. General arrangement of apparatus

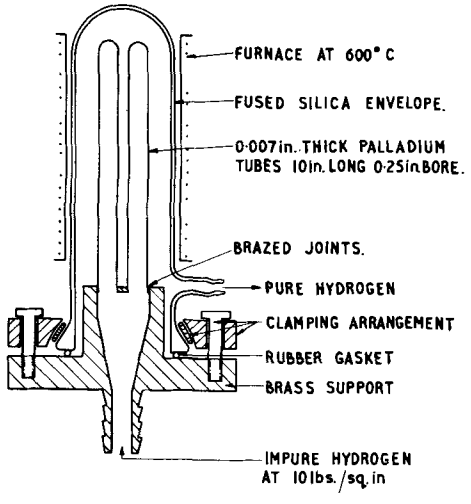

Fig. 2. Hydrogen purifier

tower H_2Se is cracked into its elements and the Se is collected by melting into a silica tube. Most of the undecomposed H_2Se is trapped in condenser II which is surrounded by liquid nitrogen and any which passes through this is converted into copper selenide by bubbling through a solution of copper sulfate (waste). After the H_2Se in condenser I has been passed through the tower, tap E is closed and D opened and the selenide in condenser II is allowed to evaporate through the decomposition tower in the reverse direction. Any undecomposed H_2Se then passes into waste where it is converted into copper selenide.

Periodically, crude Se is added to the generator and the purified Se collected from the tower. Hydrogen selenide can be recovered from waste by reaction of the copper selenide with acid.

Hydrogen Purifier

We have used oxygen-free hydrogen which has been further purified by passing through a palladium diffusion unit (Fig. 2) followed by a liquid air trap. In most of our experiments, a flow rate of 2 l/hr was maintained. When flow rates of 10 l/hr were used the hydrogen was purified by passing through a "Deoxo" catalytic purifier[1] again followed by a liquid air trap.

Generator

The purified hydrogen is passed through molten Se in a simple trap-type apparatus illustrated in Fig. 1. The apparatus is made of fused quartz and contains 150 g of crude Se. The Se is introduced in pellet form via a long arm closed with a rubber bung. For the first ½ hour's operation the Se is maintained at 550°C and after this time at 650°C.

A temperature of 550°C is used initially when volatile materials and elements which react readily with hydrogen are expelled from the Se, these being sent direct to waste. During the remainder of the operation a temperature of 650°C is maintained. At this temperature the reaction $H_2 + Se = H_2Se$ precedes more rapidly than at 575°C, the temperature at which the concentration of H_2Se in the equilibrium mixture is greatest (7). Actually we have used two generators coupled in series to insure that a near equilibrium concentration of H_2Se is attained. The fact that the second generator does not lose weight suggests that this may be so. Under these conditions, we expect those materials such as the halides, oxygen, and sulfur, which form hydrides more readily than selenium, to be removed during the preliminary ½ hr at 550°C. We have found from doping experiments that Te, As, and Sb are not carried over under the normal experimental conditions. The only

[1] Made by Baker Platinum Ltd.

impurities likely to be present in the gas stream leaving the generator are volatile materials such as hydrocarbons, etc., not removed by the preliminary stage and particles which are carried along in the gas stream.

Impurity Traps

Trap I is maintained at 300°C such that any hydrides of As, Sb, and Te which may be present would be decomposed. Trap II is cooled in an ice/salt mixture at −20°C to collect any particles carried over in the gas stream and any vapors which may be condensed at this temperature, e.g., mercury or water. Both the traps are of the same design as the generator and made of fused quartz (cf. Fig. 1).

Condensers

The gas stream is then passed into condenser I which is maintained at −183°C. The condensers are made of quartz, and a very simple design such as illustrated in Fig. 1 is satisfactory. Two condensers of 300-ml capacity, coupled in series could be used with the generator for about 4 hr. After this time, the H_2Se is allowed to evaporate over into the decomposition tower. The condensation and subsequent distillation result in further purification of the H_2Se and also enable the gas to be recirculated through the tower.

Decomposition Tower

From preliminary experiments we found that a decomposition tower of the type illustrated in Fig. 3 was very satisfactory. It appeared that the H_2Se needed to be raised to 1000°C and then the products cooled rapidly, so that they did not reform H_2Se. Selenium condenses at points shown in Fig. 3 and is melted with a bunsen burner into a silica collecting crucible.

Under equilibrium conditions, at 1000°C, about 75% of the H_2Se is decomposed. Table I indicates the extent to which the other hydrides decompose at 1000°C. From this, it is suggested that only sulfur and iodine may appear in the final product, and the concentrations of these will be appreciably reduced.

Any H_2Se which escapes the condensers, passes into waste. This consists of two bubblers. The first bubbler contains 50% H_2SO_4 to prevent water and oxygen diffusing back into the tower. The second contains copper sulfate solution in which the H_2Se decomposes according to the reaction $H_2Se+CuSO_4=CuSe+H_2SO_4$. Periodically the copper sulfate is renewed.

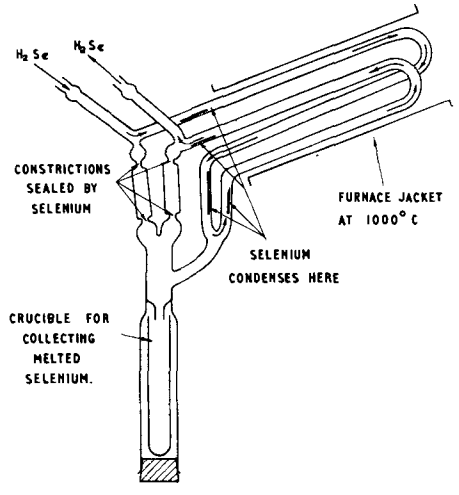

Fig. 3. Decomposition tower

Taps and Assembly

The units of the apparatus have been sealed to each other, but the final assembly is fragile. We have found it more convenient to use polythene, silicone rubber, or rubber tubing to connect the units. The tubing quickly becomes coated with a layer of Se which would tend to reduce any possible exchange reaction. The separate units are cleaned by soaking in a mixture of HNO_3 and HF, washing with metal-free water and finally with distilled acetone. The units are heated to a high temperature in air to remove adhering liquid and then heated by a flame when assembled in the apparatus with a stream of hydrogen passing through.

Results

The efficiency of the process was estimated by weighing the generator before and after an experiment and weighing the amount of purified Se obtained. In a typical experiment the following results were obtained: 28 g of Se was used in the generator and the H_2Se produced was trapped in condenser I. When this was allowed to evaporate through the tower, 20 g (70%) of Se was formed. Undecomposed H_2Se which was trapped in condenser II was recycled through the tower and yielded a further 4 g (14%) Se. The total yield of the process was, therefore, 84%. In an experiment not using condenser I, the gas mixture leaving the generator being passed directly into the decomposition tower, the following typical figures were obtained: 33 g of Se was used in the generator and 21 g (64%) of Se was obtained after passing through the tower. The undecomposed H_2Se trapped in condenser II was recirculated through the tower and a further 8 g (24%) produced, giving a total yield of 88%. The efficiency of the process is seen to be high and yields near 100% are possible if the undecomposed H_2Se is recirculated through the tower after condensing.

Analytical Tests

1. Selenium doped with 100 ppm of each of the elements Cu, Hg, Pb, Sn, Ag, Bi, Fe, Si, and 500 ppm

Table II. Results of analytical test No. 1

Impurity	Initial ppm	Final	Detection limit ppm
Cu	100	Not detected	0.2
Hg	100	Not detected	1
Pb	100	Not detected	1
Sn	100	Not detected	10
Ag	100	Not detected	0.1
Bi	100	Not detected	20
Fe	100	?*	10
Si	100	?*	20
As	500	Not detected	300
Sb	500	Not detected	50
Te	500	Not detected	200

* Traces of these were also visible with blank electrodes.

of As, Cb, and Te was used in the generator and the purified Se examined spectrographically. Ten-mg samples of Se were arced at 6 amp D.C. between graphite electrodes on Hilger Medium Quartz Spectrograph. Results are given in Table II. The limit of detection of the process was obtained by successive dilution of the doped Se.

2. Selenium doped with 1 ppm of radioactive Sb and Cu (separately) was used in the generator. After operation, traps I and II, condensers I and II, and the purified Se were examined for radioactivity. Quantitative estimation of the impurity content was obtained by dissolving the Se in HNO_3 and using a solution counting method.

3. The Li, Na, and K content of the purified Se was examined, using an Evans flame photometer. Samples of Se (10 g) were dissolved in concentrated HNO_3 (30 ml) and the solution evaporated to dryness. Selenium dioxide was then sublimed at 300°C. The residue was taken up in warm metal-free water (10 ml) and examined in the photometer. Calibration, using a series of standards, indicated that the galvanometer reading on the photometer varied linearly with concentration in the ranges 0-1 ppm for Na, 0-3 ppm for Li, and 0-5 ppm for K, with a standard deviation of ±0.05, ±0.1, and ±0.1 ppm, respectively. These tests also indicated that Na, Li, and K, were not lost during the evaporation of SeO_2. Results with purified Se are given in Table III.

4. Copper, silver, mercury, tin, zinc, lead, indium, and bismuth in the purified Se were estimated using the following procedure. Selenium (5 g) was dissolved in warm concentrated HNO_3 (20 ml) and the solution adjusted to pH 9.5 with ammonia. The solution was then extracted with 5 ml of a 0.005% solution of dithizone (diphenylthiocarbazone) in chloroform. The chloroform extract was then allowed to drip on to a sample of ammonium sulfate (5 mg) maintained at 85°C. The chloroform evaporated leaving the solute adsorbed on the ammonium sulfate; this was then arced on the spectrograph as described previously. Checks on the limit of detection were made by introducing impurities as nitrates into the solution of Se in HNO_3. Results are given in Table III. We found that it was necessary to redistill all the reagents in quartz apparatus and to carry out all operations in quartz vessels to avoid pickup of traces of impurity from glass. It was also advantageous to work in clean laboratory with still air.

5. We are also greatly indebted to the Boliden Mining Co., Skelleftehamn, Sweden, for the analytical results presented in Table IV, which, we understand, were obtained by a modified spectrographic technique.

Analytical Results

The results of the analytical experiments are shown in Tables II and III.

Our analytical techniques could detect no difference in the impurity content of the final Se whether the H_2Se was condensed before entering the decomposition tower or allowed directly through.

In the experiments with radioactive Cu no trace of radioactivity could be detected in the final Se or in any part of the apparatus except the generator.

Table III. Results of analytical tests Nos. III and IV

Method	Impurity	ppm in purified selenium	Detection limit ppm
Flame photometer	Li	Not detected	0.07
	Na	0.25	0.02
	K	0.3	0.10
Dithizone Extraction and spectrograph	Zn	Not detected	1
	Cu	0.04	0.04
	Ag	0.04	0.04
	Pb	Not detected	0.4
	Hg	Not detected	0.5
	Bi	Not detected	1
	In	Not detected	2
	Sn	Not detected	1

As 1 ppm of Cu was used, this means less than 2×10^{-3} ppm was present in the purified Se. Using radioactive Sb, however, a trace of activity was found in trap II and the final material appeared to contain about 10^{-5} ppm. Selenium obtained when H_2Se from condenser II was recycled through the decomposition tower showed no trace of activity.

Combined results of the analysis suggest that traces of Na, As, Pb, and Cu may be present in the purified material. Although the total amount of impurity appears to be small, the difficulty of analysis at these concentrations precludes an accurate estimate.

Discussion

If Cu is regarded as typical of cations which do not form hydrides, then the experiment using radioactive Cu indicates that such cations are not carried over during the purification procedure. The presence of Cu shown by direct analysis suggests that it has either been picked up from the silica apparatus or has been introduced during the transfer operation. We have also found it extremely difficult to remove traces of Cu from the reagents. It is probable that the other cations indicated by the analysis are also introduced in these ways. The experiment with radioactive Sb suggests that traces of the hydride of Sb may be formed during the experiment but an improvement of 10^5 may be expected.

It is not certain, at present, whether the As present in the final material has been transferred as the hydride or is due to pickup from the silica apparatus, in which it is known to be present. The absence of detectable S and Te in the product is encouraging

Table IV. Results of the Boliden analysis

Impurity	Impurity content in sample	Detection limit ppm	Impurity	Impurity content in sample	Detection limit ppm
Ag	Not detected	0.03	Ca	Not detected	1
Cu	0.20 ppm	0.1	Cr	Not detected	0.3
Hg	Not detected	0.5	Mg	Not detected	0.3
Fe	0.60 ppm	0.3	Mn	Not detected	0.1
K	Not detected	0.3	Ni	Not detected	0.3
Na	0.40 ppm	0.1	Pb	0.6 ppm	0.3
Te	Not detected	1	Sb	Not detected	1
Al	Not detected	0.3	Si	Not detected	1
As	1.0 ppm	1	Sn	Not detected	0.3
Bi	Not detected	0.1	S	Not detected	5
Zn	Not detected	1	Ce	Not detected	2

and suggests that these are at least substantially reduced by the process.

The amount of Se which could be purified appears to be limited only by the rate of flow of hydrogen through the Se. Flow rates of 10 l/hr result in production of about 10 g of Se/hr. It is important that the flow rate is such that H_2Se attains 1000°C in the decomposition stage. Analytical results (cf. Table II) suggest that quite impure Se may be refined in this way.

It may be mentioned that the purified H_2Se may be decomposed chemically if suitably pure reagents are available and may also be converted directly into a metal selenide should this be required.

Acknowledgment

The authors wish to acknowledge the help and interest shown by the Boliden Mining Company, Skelleftehamn, Sweden. They are also indebted to Miss I. Betteridge and Messrs. A. Fray, D. Maines, and J. Conaboy for help with the apparatus and to Miss P. Butcher for some of the analytical work. Acknowledgment is made to the Controller, Her Majesty's Stationery Office for permission to publish this paper.

Manuscript received July 16, 1957.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Electrodeposition of High-Purity Chromium

F. E. Block, P. C. Good, and G. Asai

Bureau of Mines, Region I, Albany, Oregon

ABSTRACT

Thick chromium deposits were prepared by the electrolysis of aqueous chromic acid baths. Metal containing 0.005% oxygen, less than 0.002% nitrogen, and only traces of metallic impurities was obtained upon electrolysis of purified solutions at elevated temperatures. After consumable electrode arc-melting, this type of chromium could be hot-worked to rod and drawn to wire that was ductile at room temperature.

The electrolysis of chromic acid solutions was selected for study as a method of preparing high-purity chromium because metallic impurities may be excluded easily and gaseous impurities remain at very low levels. Although a low current efficiency is obtained in electrowinning chromium from hexavalent solutions and chromic anhydride is an expensive reagent, this method was adopted because it was found that metal could be prepared sufficiently pure to permit a study of its properties without additional purification steps which, in turn, are costly.

Electrodeposition from chromic acid solutions has been practiced from the time Fink (1) patented his process in 1926; however, its use has been confined mainly to decorative plating. Adcock (2) prepared massive deposits in 1927 as a means of making chromium for physical studies, but it was not until more recently that Greenaway (3) and the Bureau of Mines, United States Department of the Interior (4) employed high-temperature baths operated at high current density to yield thick deposits of low-oxygen chromium.

Brenner, Burkhead, and Jennings (5) investigated the properties of thin chromium electrodeposits plated under widely differing conditions of solution concentration, temperature, and current density. Their work indicated that the level of oxygen contamination in the electrodeposits was governed primarily by the temperature of deposition, with high temperatures favoring lower oxygen contents. Consequently, high-temperature baths were employed exclusively in this work. It has been demonstrated (6-8) that oxygen has little effect on the ductility of chromium metal; however, the object of this investigation was the preparation of the pure metal for direct study and for alloy studies, and since oxygen is generally the major contaminant in chromium, efforts were made to maintain a low oxygen level.

Experimental Work

Description of Apparatus

A number of different cells and procedures were studied during the course of the investigation, but only the more recent apparatus used in preparing metal for fabrication studies is described here.

The bath was maintained in a circular steel tank 18 in. in diameter and 16 in. in height lined on the inside with unplasticized polyvinyl chloride. This

was found to be one of the few corrosion-resistant nonmetallic materials that would withstand the operating temperatures of 90°C. A 6-in. diameter aluminum tube in the center of the cell served as cathode. In earlier runs the anode consisted of a 16-in. diameter coil of ¾-in. lead tubing which served also as a cooling coil. In later runs the cell comprised a lead vessel in a steel container, and the cell was used as an anode, the electrolyte being cooled by circulating water in the annular space between the cell and the steel container. In either type of cell the flow of water was regulated with a Powers regulator[1] activated by a temperature-sensitive, lead-sheathed bulb in the electrolyte. The tubular lead anode was more effective in removing heat and controlling temperature at high current densities, but the lead-pot type suffered less anodic corrosion.

Because the bath was operated at its boiling point and was in a constant state of violent agitation, due to the large amount of hydrogen being produced, a Micarta cover was fitted over the cell to direct the escaping mist and vapors to a glass reflux condenser which returned them to the cell. Losses of uncondensed liquid were made up from a reservoir placed above the cell and connected to a constant-level device to maintain a uniform electrolyte level in the cell.

Cell Operation

The electrolyte was made up by dissolving chromium trioxide in distilled water and adding sulfate ion as H_2SO_4.

Since the electrolyte was used repeatedly, impurities were prevented from building up by contacting the solution with a cation-exchange resin before each run. A 4-in. diameter resin bed 30 in. deep was employed. By analyzing the H_2SO_4 solution used to regenerate the resin, it was determined that Al, Cu, Fe, Ni, Si, and Sn were being removed by this treatment.

Cation-exchange resins of the sulfonated polystyrene type have been recommended (8) for treating strongly oxidizing solutions, such as chromic acid. Although this general type was employed, there was considerable variation with respect to stability among the different resins tested. Amberlite IR-120 was found to be highly resistant to oxidation at room temperature when used with solutions containing up to 250 g/l of chromic acid.

During electrolysis the chromium concentration in the electrolyte was determined twice daily by specific gravity measurements and adjusted by the addition of chromium trioxide to the feed reservoir or directly into the cell. The sulfate ion concentration was adjusted at the beginning of each run.

Direct current was supplied to the electrodes from a 4000-amp selenium rectifier.

To take advantage of the relationship between operating temperature and the oxygen content of the deposit, the electrolyte temperature was maintained near the boiling point. Since early deposition tests at lower operating temperatures had confirmed the temperature-oxygen content relationship as reported by Brenner and co-workers (5), all runs in this investigation were made in the 85°-90°C range.

During electrolysis, the deposit appeared first as a smooth surface having a matte finish, but as deposition continued it changed to a more nodular form. Because the electrolyte had poor throwing power, the nodules grew quickly into long dendrites, which eventually broke from the cathode and dropped to the bottom of the cell. Although the dendrites could be recovered as metal, it was necessary to treat them with nitric acid to remove lead chromate, which sloughed off the anode and mixed with the dendrites. Also, the dendrites consistently contained more oxygen than the adherent deposits.

For these reasons attempts were made to minimize the growth of dendrites. This could be accomplished to some degree by changing cathodes at shorter intervals before the dendrites formed; however, the thinner deposits were very difficult to remove from the cathode by mechanical methods. It was found that a deposition interval of 72 hr generally yielded a deposit between 1/16 and 3/32 in. thick, which was plated in a highly stressed condition. A deposit of this nature could be removed by striking the cathode a sharp blow with a hammer. Scoring the surface of the aluminum cathode into 1-in. squares before electrolysis caused a thinner deposit to be formed at the score marks and facilitated removal of the deposit.

Experimental Results

Table I shows the results of 72- and 96-hr deposition tests at cathode current densities ranging from 340 to 1100 amp/ft^2 and with various electrolyte compositions. Analyses were performed on specimens taken from ingots arc-melted from representative portions of the deposit. Oxygen and hydrogen were determined by vacuum fusion analysis, and nitrogen was determined either by vacuum fusion or Kjeldahl analysis.

Figure 1 is a plot of the data appearing in Table I and shows the relationship between the cathode current density and the proportion of the cathode deposit that appeared as loose dendrites. This plot indicates the advantage of operating at lower cur-

* P = deposit adhering to cathode; D = dendrite deposit fallen from cathode.

rent densities if a greater proportion of low-oxygen, solid deposits are desired. These data are not strictly comparable, because larger amounts of chromium usually were deposited in the tests at higher current densities, and a greater proportion of dendrites might be expected under these circumstances. However, the relationship appears to be independent of either the current efficiency or time of deposition, which might also be expected to influence the results if the relative amount of deposit was a major factor.

Table I indicates that the current efficiency was independent of the current density at constant bath composition. These data also suggest that optimum current efficiencies were obtained when baths were used having CrO_3 to SO_4 ratios of approximately 50, with somewhat lower efficiencies resulting from either higher or lower ratios. In this respect, the present investigation is in general agreement with the work of Greenaway (3).

At constant temperatures the oxygen content of the deposit appeared to be independent of both current density and bath composition. In all instances the dendritic deposits were found to contain a significantly higher amount of oxygen than the corresponding deposits which adhered to the cathode; however, the dendrites also exhibited a significantly greater amount of surface, which might account for the higher oxygen level. Usually the deposit which was removed from the cathode was found to contain between 50 and 250 ppm oxygen and less than 20 ppm nitrogen.

Metallic impurities were not determined quantitatively, but qualitative spectrographic analysis indicated that the deposits usually contained trace amounts of aluminum, iron, or silicon. There was no detectable difference between the dendritic or adherent deposits with respect to metallic impurities.

Figure 2 shows photomicrographs of arc-melted chromium representing both types of deposits. The increased amount of second-phase material in the dendritic deposit illustrates the higher oxygen level in this material.

Physical Testing

For evaluation, the deposits were consolidated by the inert atmosphere, cold mold, arc-melting technique. Homogeneous samples were prepared for analysis by melting a 50-g representative portion of

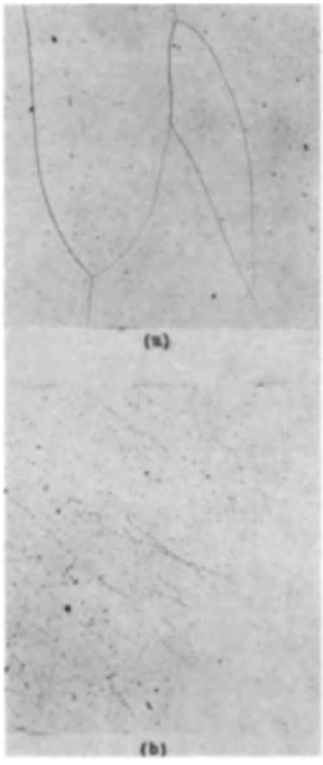

Fig. 2. Photomicrographs of arc-melted, as-cast chromium electrodeposits, chromic acid-electrolytic etch. (a) Adherent deposit 40 ppm oxygen, (b) dendritic deposit 600 ppm oxygen. Magnification 100X before reduction for publication.

each deposit, employing a nonconsumable tungsten electrode for arc melting. Larger ingots were prepared for physical studies by melting the chromium as a consumable electrode into a 2-in. diameter, water-cooled copper crucible. In this case the deposit was crushed to pass minus-8-mesh and compressed into 1-in. by 1-in. electrodes 10 in. long. The electrodes were sintered 8 hr in purified hydrogen at 1200°C to increase their mechanical strength.

Tensile tests were made on wire specimens prepared from the arc-cast ingots. Ingots were scalped, sheathed in stainless steel, and swaged at 1100°C to approximately 1-in. diameter. The 1-in. diameter swaged rods were recrystallized by heating to 1200°C sheathed in mild steel and swaged to approximately 0.25-in. diameter. After recrystallization the rods were reduced to 0.125-in. diameter test wire by drawing through tungsten carbide dies at 350°C. All of the specimens were tested in the 50% worked condition. Tensile specimens were prepared by stopping off the ends and electrolytically

etching the wire surface in the center portion to yield a reduced section along the gauge length. In this work, as in previous investigations (9, 10), the full ductility of the material was not realized until a thin surface layer had been removed from the specimens by etching. Although the wires could not be bent before etching, after removal of the surface layer the wires could be reverse-bent by hand repeatedly without fracture.

Table II shows the results of tensile tests at 25°C representing specimens prepared from two ingot melts. Because of the opportunity for gaseous contamination during the sintering, arc-melting, and annealing steps, the broken tensile specimens were analyzed for nitrogen content as shown. The results indicate that material containing 50 ppm or less nitrogen is ductile, while chromium containing on the order of 200 ppm nitrogen has no ductility. This shows the importance of preparing and maintaining a low nitrogen content in the metal if ductility is desired.

Figure 3 represents the stages employed in preparing chromium wires, showing the electrodeposit, a section of partly melted consumable electrode, an ingot section, swaged rod, and drawn and etched ductile wire.

Conclusions

High-purity chromium can be prepared conveniently by high-temperature electrodeposition from purified chromic acid solutions, yielding deposits containing only trace amounts of metallic impurities, with oxygen the chief impurity. After having been melted and worked into shapes, electrolytic chromium exhibits tensile properties comparable to chromium prepared by refining commercial grade material by hydrogen treatment. The low nitrogen content of electrodeposited metal favors this method as a means of preparing chromium for physical studies.

Some Effects of Pressure on Consumable Electrode Arc Melting

J. W. Suiter[1]

Mines Branch, Department of Mines and Technical Surveys, Ottawa, Ontario, Canada

ABSTRACT

The effect of pressure in a consumable electrode arc furnace on the weight of metal melted per unit of energy dissipated was investigated while melting titanium electrodes of negative and positive polarity and steel electrodes of negative polarity. Provided that the arc length was sufficiently short, the weight of metal melted per unit of energy dissipated increased continuously as the pressure of argon was decreased from 650 to 1×10^{-2} mm Hg.

Many workers (1, 2) have reported the weight of metal melted per unit of energy dissipated in consumable electrode arc melting, but in most cases the experiments were done only at a few widely separated pressures. Beall, *et al.* (3) have reported the effects of varying the pressure in the range 10-760 mm Hg when melting titanium electrodes in an argon atmosphere. However, the present emphasis on vacuum arc melting has made it desirable to extend their investigations to lower pressures.

The paper reports the effects of varying the argon pressure in the range of 1×10^{-2} to 650 mm Hg on the weight of metal melted per unit of energy dissipated when melting titanium and steel in a consumable electrode arc furnace.

Materials and Experimental Procedure

The titanium electrodes were produced by welding, end to end, compacts of sponge titanium (20.4 x 5.1 x 5.1 cm) each weighing 1600 g. The mild steel (0.1% C) electrodes consisted of rolled bar 3.8 x 3.8 cm in cross section. These electrodes were attached to a water-cooled copper electrode stub which passed through a sliding seal in the top of the furnace. The electrodes were melted into a mold 34 cm long and 12 cm in diameter, producing ingots of 4-5 kg weight.

Power for melting was supplied by three motor-generator welding machines connected in parallel. The same generator settings were used in all experiments, and the arc current and voltage were allowed to vary with the pressure.

During melting the feed rate of the electrode was adjusted by the operator while observing the arc voltage pattern on a direct current oscilloscope and also the arc voltage and current as indicated by conventional meters. The desirable arc length was such that the pattern on the oscilloscope indicated the presence of occasional, momentary dead shorts. It was thought that these momentary dead shorts were due to droplets of molten metal shorting between the electrode and the molten pool. It was not possible to measure such an arc length but it appeared to be less than 1 cm. For some melts at pressures of 25 and 10 mm Hg, an arc length of approximately 8 cm was deliberately maintained; these were duplicates of melts made at the same pressures with a normal short arc length. The long arc length was used to determine what effect the presence of positionally unstable arcs would have on the weight of metal melted per unit of energy dissipated. It was possible to observe, through a sight glass, the presence or absence of positionally unstable arcs within the mold.

In the pressure range 10-650 mm Hg a static atmosphere of argon was used, but in the pressure range 10^{-1}-10 mm Hg it was necessary to remove gas from the system while melting to maintain a constant pressure. No argon was used for pressures less than 10^{-1} mm Hg which were obtained by continuously evacuating the furnace so that the steady pressure during melting depended on the speed of the pumps being used and the amount of gas evolved from the electrode. The gas pressure was measured in the body of the furnace, for it has been shown (4) that this pressure is very close to that in the melting region of this type of furnace if there are no volatile materials in the electrode. There were only very small quantities of volatile materials in the steel electrodes used in these experiments, but the titanium electrodes contained such volatiles as magnesium and magnesium chloride. Thus, the pressure measured in the body of the furnace did not indicate accurately the pressure in the melting region when melting titanium electrodes at very low pressures.

The energy dissipated during melting was calculated from the arc voltage, the arc current, and the time of the melting operation.

[1] Present address: Baillieu Laboratory, The University of Melbourne, Victoria, Australia.

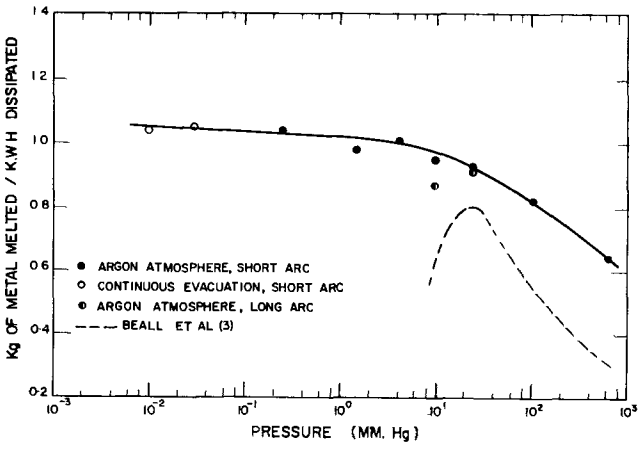

Fig. 1. Effect of pressure on the weight of titanium melted per unit of energy dissipated when melting electrodes of negative polarity.

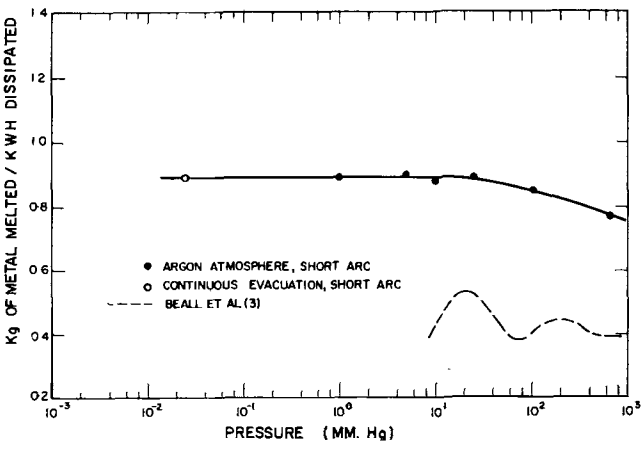

Fig. 2. Effect of pressure on the weight of titanium melted per unit of energy dissipated when melting electrodes of positive polarity.

Results

The effect of pressure on the weight of metal melted per unit of energy dissipated when melting titanium electrodes of negative polarity is shown in Fig. 1. As the pressure was decreased from 650 mm Hg to approximately 10 mm Hg the weight of metal melted per unit of energy dissipated increased, but at lower pressures the increase was less marked. As the pressure was decreased the arc voltage decreased from 36 v at 650 mm Hg pressure to 28 v at pressures less than 5 mm Hg, and in the same pressure range the arc current increased from 1800 to 2200 amp.

In the pressure range 2 x 10^{-1} to 20 mm Hg, positionally unstable arcs were seen occasionally within the mold, but these were eliminated by decreasing the arc length. Two electrodes were melted at 25 and 10 mm Hg pressure while maintaining an arc length of approximately 8 cm. At a pressure of 25 mm Hg, melting with a long arc had little effect on the weight of metal melted per unit of energy dissipated. At 10 mm Hg pressure, the weight of metal melted per unit of energy dissipated was less when melting with a long arc, and there was also a large increase in the amount of positionally unstable arcs within the mold.

Figure 2 shows that the weight of metal melted per unit of energy dissipated increases with decreasing pressure when melting titanium electrodes of positive polarity, but the increase is less than when melting titanium electrodes of negative polarity (compare Fig. 1 and 2). Thus, at low pressures the weight of metal melted per unit of energy dissipated was higher when melting electrodes of negative polarity, but near atmospheric pressure the position was reversed.

The effect of pressure on the weight of metal melted per unit of energy dissipated when melting steel electrodes of negative polarity is shown in Fig. 3. The results are similar to those obtained when melting titanium electrodes of negative polarity. At all pressures the weight of steel melted per unit of energy dissipated was greater than that of titanium, but this result was not unexpected in view of the different heat contents of the two materials at temperatures just above their melting points. As in the case of titanium electrodes of negative polarity, a

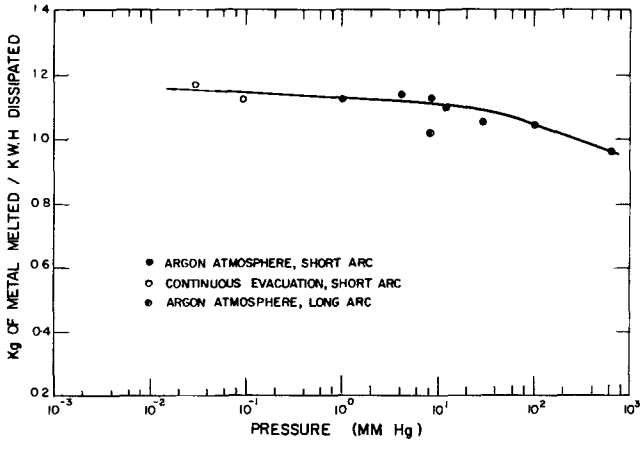

Fig. 3. Effect of pressure on the weight of steel melted per unit of energy dissipated when melting electrodes of negative polarity.

long arc at a pressure of 8 mm Hg led to positionally unstable arcs and a decreased weight of steel melted per unit of energy dissipated.

Discussion

When melting titanium electrodes of negative and positive polarity and steel electrodes of negative polarity in a consumable electrode arc furnace, the weight of metal melted per unit of energy dissipated increased continuously as the pressure was decreased. Beall, *et al.*, (3) have reported the results of melting titanium electrodes in argon atmospheres in the pressure range of 10-760 mm Hg, and they found a sharp decrease in the weight of titanium melted per unit of energy dissipated as the pressure was reduced below 20 mm Hg (see Fig. 1 and 2). Beall, *et al.* suggested that this decrease was due to the formation of positionally unstable arcs. The present work confirmed that the formation of these arcs led to a decreased weight of metal melted per unit of energy dissipated but that by maintaining a sufficiently short arc length these positionally unstable arcs could be avoided. If they were avoided, then the weight of metal melted per unit of energy dissipated increased continuously as the pressure decreased. Beall, *et al.* used two horizontally opposed electrodes in a relatively large furnace in their experiments,

and the different size and arrangement of electrodes used in the two sets of experiments may account for the different values of the weight of titanium melted per unit of energy dissipated that were obtained in the two sets of experiments near atmospheric pressure.

Although most of the melting experiments were done in an argon atmosphere, no argon was used for the melts when the furnace was evacuated continuously, and the pressure during melting was less than 1×10^{-1} mm Hg. Since the results obtained under these conditions followed the same trend as those obtained when melting in an argon atmosphere, it appeared that at very low pressures the atmosphere in which melting occurred had little effect on the weight of metal melted per unit of energy dissipated. The steel electrodes contained very little volatile material, and the composition of the gas in the melting region when melting these electrodes under continuous evacuation differed greatly from the gas composition when melting titanium electrodes. These changes in the composition of the gas in the melting region appeared to affect neither the behavior of the arc nor the weight of metal melted per unit of energy dissipated.

Acknowledgments

The work was done under the general direction of H. V. Kinsey, of the Department of Mines and Technical Surveys, Ottawa, and was made possible by the award of a Fellowship by the National Research Council of Canada. Thanks are due to R. H. Landry, technician, for assistance with the experimental work.

Tungsten Zone Melting by Electron Bombardment

R. G. Carlson

Lamp Wire and Phosphors Department, General Electric Company, Cleveland, Ohio

ABSTRACT

An apparatus for refining tungsten in vacuum by the floating zone method is described. It consists of four components: vacuum system, power supply, anode support, and traversing cathode. Included is a brief résumé on the theory of refining by this technique. Spectrographic analyses along the length of a purified tungsten rod indicate that molybdenum may not be removed by zone refining, but rather by volatilization. Further, x-ray diffraction studies show that tungsten rods purified in this manner are single crystals and these crystals as grown from the melt do not exhibit preferential growth. It is demonstrated, by bending one of the single crystals, that the purified tungsten rods have relatively high ductility.

Zone melting, developed by Pfann (1), has attracted great interest as a process for the purification of metals. In this process a small molten zone traverses the length of a solid rod. Impurities that are more soluble in the liquid phase than in the solid phase migrate with the molten zone, leaving behind a purer metal. In the case of zone melting tungsten purification also occurs because of the outgassing and volatilization of impurities.

It is exceedingly difficult, if not impossible, to retain W in a molten state by conventional techniques without impairing its purity because of the refractory nature of this metal. Tungsten can be zone melted by utilizing the floating zone technique and heating by electron bombardment. The principle of this heating, simply the blasting of a material anode with electrons through a high potential gradient, is not new nor unique since it has long been used in the outgassing of electronic vacuum tubes and occurs in the operation of x-ray tubes. However, because of the characteristics inherent in electron bombardment heating, i.e., ability to operate at low pressures, ability to direct and concentrate the heat, ease of temperature control over a wide range, and relative simplicity of the power supply, this type of heating is employed advantageously in laboratory (2-4) as well as commercial furnaces (5).

This paper covers the design and construction of an Electron Bombardment Zone Melting Apparatus (EBZMA), includes a brief discussion on the theory of purification, and presents data on the removal of Mo and on crystal orientation.

Electron Bombardment Zone Melting Apparatus

The equipment consists of four components: vacuum system, power supply, anode support, and traversing cathode.

Vacuum system.—The anode and cathode are enclosed by a Pyrex bell jar 10½ in. in diameter and 14 in. high mounted on a brass plate (Fig. 1). There

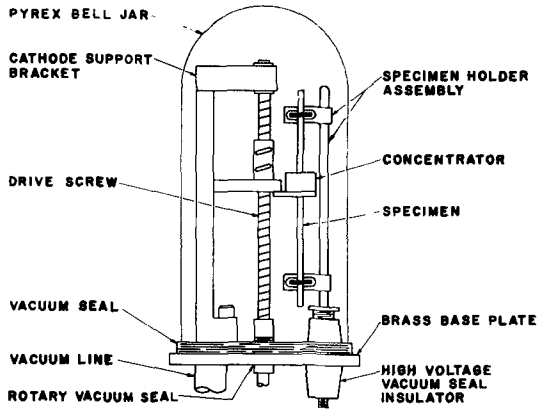

Fig. 1. Schematic drawing of the vacuum system

are five holes in this plate: three ⅝-in. diameter holes for electrical binding posts; one 2-in. diameter hole for the vacuum line; and one rotating "O" ring seal for the cathode traversing helix.

The 2-in. vacuum line is constructed with a vertical pipe extending down to a "T" section. One leg of this section forms a liquid nitrogen trap; the other leg is connected to a MCF-60 CEC oil diffusion pump, which in turn is backed up by a Kinney KC-2 mechanical pump.

Power supply.—A small power unit supplies d.c. at a maximum of 5000 v and 300 ma. It consists of a variac that limits the 110 a-c volt power to the high voltage transformer. This high voltage is then rectified by a pair of 866 A half-wave mercury rectifier tubes. The positive side of this high voltage is fed through the high-voltage-high-vacuum-throughput to the anode support. The cathode is the ground terminal. Figure 2 is a schematic of the power supply.

Anode support.—The support shown in Fig. 1 can accommodate rods up to ¼ in. in diameter. The upper and lower holding blocks are critical parts. They should possess four properties: (*a*) high melting point; (*b*) stable material in order that W is not contaminated, i.e., low vapor pressure; (*c*) high electrical conductivity; (*d*) low thermal conductivity. No one material has all these properties, but because of its superiority in the first three properties and its ability to be easily fabricated, Mo is used. A small groove in each block at the point of specimen contact reduces the heat transfer.

The specimen is held in position in each of the

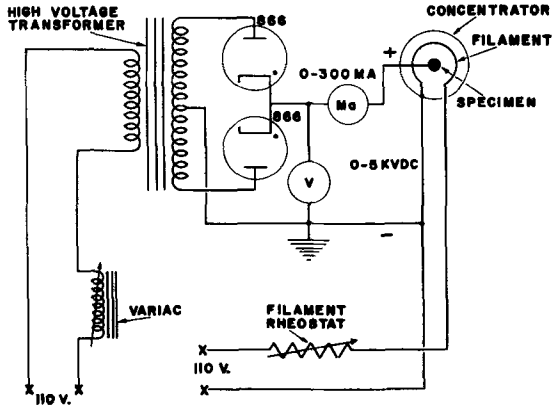

Fig. 2. Schematic drawing of the power supply

holders by flat tungsten strip that acts as a spring contact. This spring serves a dual purpose. One is to support the rod during the movement of the floating zone and the other is to allow the specimen to expand and contract in the heating and cooling operation.

Traversing cathode.—The cathode is the moving terminal; it is composed of a filament that emits the electrons, a concentrator that directs the flow of the electrons, and a mechanism that moves the cathode with respect to the stationary tungsten rod.

Traversal of the specimen occurs by the movement of a screw drive with the torque being transmitted through a rotating "O" ring seal in the brass plate. The torque is supplied through a gear train by a 3 rpm a-c reversible motor. The output of the gear train varies from 0.1 to 12 rpm producing a cathode movement of 0.3-4 cm/min.

The concentration of the electrons to the anode is an important factor. This is achieved by enclosing a W filament with a Mo concentrator of the same potential. To obtain more efficient concentration the sides of the concentrator are parabolic. The top and bottom are changeable disks with different diameter center holes, approximately ⅛ in. diameter larger than the specimen diameter.

The W filament, 15 mils in diameter, is heated by a 110 a-c power supply as shown in Fig. 2. The filament rheostat regulates the current flow to obtain sufficient emission of electrons to melt the sample, i.e., in the order of 200-250 ma.

Theory

In the zone refining process the molten zone is moved repeatedly in the same direction. Solute elements that depress the melting point of the solvent metal concentrate in the terminal end of the rod and have a distribution coefficient, k, less than one. Solute elements that increase the melting point have a k value greater than one and tend to concentrate at the starting end. The distribution coefficient is defined by the equation

$$k = \frac{N^s}{N^l} \qquad [1]$$

where N^s is mole fraction of the solute in the solid phase and N^l is the mole fraction in the liquid phase.

The distribution coefficient can be determined simply by referring to a phase diagram. From the Mo-W equilibrium phase diagram (6), the equilibrium distribution coefficient (k_o) for Mo in W is found to be 0.91.

Another approach in the determination of the distribution coefficient would be to utilize thermodynamics and, if the alloy forms ideal liquid and solid solutions, apply the well-known van't Hoff equation

$$\ln \frac{N_{Mo}{}^{l}}{N_{Mo}{}^{s}} = -\frac{\Delta H_f{}^{Mo}}{R}\left(\frac{1}{T} - \frac{1}{T_M{}^{Mo}}\right) = K_{Mo} \qquad [2]$$

or

$$\frac{N_A{}^{l}}{N_A{}^{s}} = e^{K_{Mo}} \qquad [3]$$

then

$$k_o = \frac{1}{e^{K_{Mo}}} \qquad [4]$$

where T equals the temperature considered, in this case the melting point of W, 3680°K; T_M^{Mo} equals the melting point of Mo, 2900°K; ΔH_f^{Mo} equals the heat of fusion for Mo, 6700 cal/mole; R equals gas constant. From Eq. [4] we determine that k_o equals 0.78.

As originally stated, purification of W also occurs by outgassing and the volatilization of metallic impurities on fusion in vacuum. In this particular case we will consider only the volatilizaton of Mo. The vapor pressure ($p°$Mo) for Mo at a temperature slightly above the melting point of W, 3800°K, equals 3.83 mm Hg, while the vapor pressure for W, at the same temperature, equals 0.046 mm Hg. If the mole fraction of Mo (N_{Mo}) is assumed to be 0.00002, by assuming ideality ($a_{Mo} = N_{Mo}$) and using Raoult's law ($p = a \cdot p°$Mo), the vapor pressure of Mo in the melt is 7.7×10^{-5} mm Hg. This would indicate that, if the pressure of Mo in the environment was less than 7.7×10^{-5} mm Hg, Mo would volatilize from the melt. The rate of evaporation can be calculated from the formula (9)

$$\frac{m}{t \cdot A} = P\sqrt{\frac{M}{2\pi RT}} = G \qquad [7]$$

where P is pressure (microbars); M, molecular weight; A, area (cm²); t, time (sec); R, gas constant (8.31×10^7 erg/°K/mole); T, temperature (°K); m evaporation (gr), or the ratio of the evaporation rates can be determined from the equation

$$\frac{G_{Mo}}{G_W} = \frac{P_{Mo}}{P_W}\sqrt{\frac{M_{Mo}}{M_W}} \qquad [8]$$

From this equation the ratio of evaporation rate of Mo to W is found to be 1.21×10^{-3}, i.e., of the metal evaporated during melting, 0.121% by weight is Mo.

Results

Many rods have been zone melted with this apparatus; two of the zone melted rods after five passes are shown in Fig. 3. It was found on evaluation of the purified rods that they were high in purity, single crystals, and exhibited a comparatively large amount of ductility.

It is difficult to obtain quantitative data on samples containing less than 10 ppm of an impurity. The initial concentration of all elements other than Mo were less than 10 ppm and could not be detected by spectrographic analysis. The initial concentration of Mo was estimated to be of the order of 10 ppm. To determine the amount of Mo present after the bar was traversed five times at a speed of 0.33 cm/min the rod was severed at intervals along its length. Each end of the severed section was arced against its adjacent section. The initial concentration in the rod was arbitrarily assigned the value of 10. In Fig. 4, the relative amounts of Mo, as determined by quantitative optical spectrography, are plotted against the distance along the zone purified rod.

An apparent discrepancy existed at the beginning and the end of the zone melted portion. According to the theory of zone purification, if $k < 1$, a zone of higher purity should be present at the start and a concentration of the impurities at the end. Because this did not occur, it was reasoned that either a distribution coefficient greater than one existed, or possibly the Mo evaporated from the zone melted region.

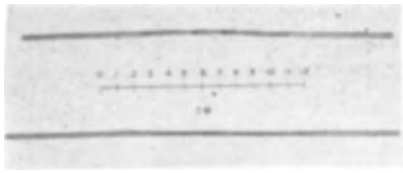

Fig. 3. Zone melted W rods, after five zone passes

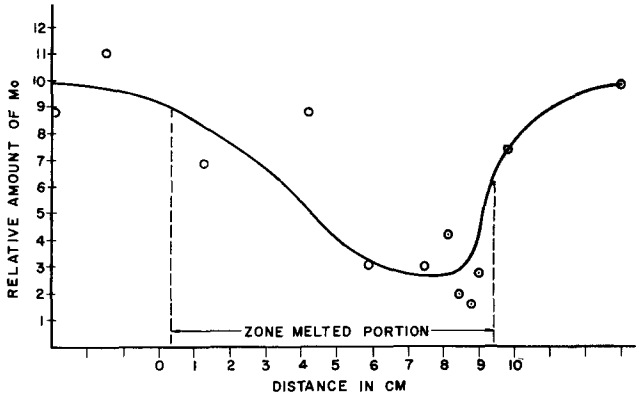

Fig. 4. Relative concentration of Mo vs. distance in zone melted portion.

To substantiate the absence of an increase in Mo concentration at the end of the rod, five separate analyses were obtained in this region. If a zone of higher Mo concentration was present, it must have existed in a length less than 4 mm long, and this is not very probable. On the basis that $k_o = 0.91$, the lowest possible concentration of Mo that could exist after 5 passes was calculated to be 6.24, assuming equilibrium existed and that the original concentration of Mo = 10. Using the same assumption and now $k_o = 0.78$, the lowest concentration was calculated to be 2.89. This latter value, as can be noted in Fig. 4, falls in the range of the lowest concentration. Of course, this lowest concentration of the solute should have occurred at the start. More work is currently being performed to support the validity of these initial results.

To determine the orientations of the rods and to ascertain if the rods after zone melting were single crystals, six were examined by x-ray diffraction utilizing the transmission Laue technique, and two were examined metallographically. Results of x-ray

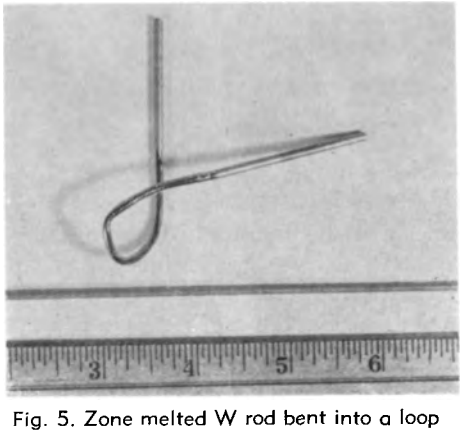

Fig. 5. Zone melted W rod bent into a loop

Table I. Crystal orientation

Plane	Angle between major plane normal and rod axis 1	1A	ZMW-1	ZMW-2	ZMW-3	ZMW-4
(100)	37	33	38	25	6	18
(110)	20	14	7	21	42	32
(111)	22	29	33	32	49	37

orientation determination are recorded in Table I. These suggest that no one preferential direction of growth existed, Rod 1A and ZMW-1 were examined at several points along the length of the crystal, and it was determined that the orientation remained the same, indicating only one crystal of the same orientation existed. Metallographic observation confirmed these results, that the rod was a single crystal along its length.

A qualitative measure of the high ductility at room temperature was obtained; this is shown in Fig. 5. Here the ⅛-in. zone melted tungsten rod was bent approximately 270° into a loop.

Conclusions

Single crystals of tungsten can be grown in the Electron Bombardment Zone Melting Apparatus. These crystals are greatly purified and exhibit a larger amount of ductility than can be obtained in an equivalent sized polycrystalline material.

Vapor Pressure of Niobium

Rudolph Speiser

Department of Metallurgy, The Ohio State University, Columbus, Ohio

P. Blackburn

Research Laboratory, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

H. L. Johnston

H. L. Johnston Associates, Columbus, Ohio

ABSTRACT

The Langmuir method has been used to determine the vapor pressure of niobium. An accommodation coefficient of unity was assumed. Least square treatment of the vapor pressure data yields the equation

$$\log P_{atm} = -\frac{(40{,}169)}{T} + 8.872$$

The heat of sublimation at absolute zero, ΔH°_0, is 171.80 ± 0.49 and $\Delta H^\circ_{298.15}$ is 172.53 kcal/g atom.

Prior to this investigation, the only data (1) available for the computation of vapor pressures of Nb was the rate of sublimation from a Nb wire heated by the passage of an electric current. Since these measurements were made at only three temperatures, and since the temperature measurement depended on an accurate determination of the emissivity of the wire, it was decided to repeat these measurements using the method and apparatus described in previous publications (2). The Langmuir method was employed, and an accommodation coefficient of unity was assumed.

Experimental

The measurements consisted of determining the rate at which a Nb surface sublimed into a high vacuum. The sample was supplied by the Fansteel Corporation and was assayed at a purity of 99.9%. The sample was in a form of an annular ring 0.985 in. OD, 0.374 in. ID, and 0.357 in. thick. The effective internal area (3) of the annular ring was computed from the expression

$$\text{Eff. area} = \pi b(\sqrt{a^2 + b^2} - b) \qquad [1]$$

where a is the inside diameter and b, the thickness.

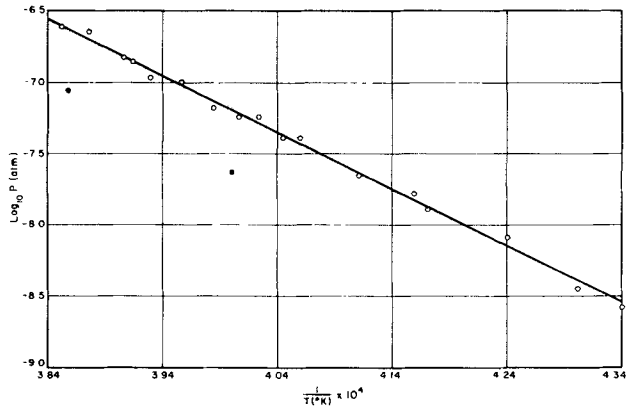

Fig. 1. Plot of the logarithm of the pressure of Nb in atmospheres vs. the reciprocal of the absolute temperature. Solid circles represent the data of Reimann and Grant (1).

The area of the sample was also corrected for the thermal expansions from room temperature to the temperature of the measurement. The sample was placed in a metal cell (2) and after thorough outgassing was then heated by induction under a vacuum of the order of 10^{-6} mm.

The effective time at the temperature of measurement was determined as described previously (2).

Temperatures were measured under black body conditions by sighting into a hole drilled into the sample. A L&N disappearing filament optical pyrometer which had been calibrated by the National Bureau of Standards and frequently checked against a standard lamp furnished by the Bureau was used to measure the temperature. Pyrometer readings were reproduced to ±2°.

Results and Discussion

Experimental results are plotted as log P_{atm} vs. $1/T$ in Fig. 1 and summarized in Table I. Thermodynamic functions are tabulated in Table II; the thermal data for solid and gaseous Nb were taken from the compilation of Stull and Sinke (4). The computed value of $\Delta H°_0$, the heat of sublimation at 0°K, is 171.80 ±0.49 kcal/g atom. This value is to be compared with a $\Delta H°_0$ value of 176.82 kcal/g atom computed from the vapor pressure data of Reimann and Grant at 2600°K. Vapor pressures in this research are higher by a factor of 2.8 than those measured by Reimann and Grant. An error of 70° in the temperature scale could account for this discrepancy, and an error of this magnitude is quite possible when temperature measurements dependent on the emissivity of a surface are made.

Least square treatment of the vapor pressure data for Nb yields the equation

$$\log P_{atm} = -\frac{(40{,}169)}{T} + 8.872 \qquad [2]$$

These data also yield a value of $\Delta H°_{298.15}$ of 172.53 kcal/g atom.

Manuscript received July 14, 1958. This paper was prepared for delivery before the New York Meeting, April 27-May 1, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

The Occurrence of Impurities in Rock Salt, Solar Salt, and Purified Sodium Chloride

Arthur Bloomberg and Kurt Ladenburg

Research Laboratory, International Salt Company, Inc., New York, New York

ABSTRACT

Because of the known interference of certain impurities and the suspected effect of others in the electrolytic cell processes for the production of sodium and chlorine-caustic soda, the presence or absence of thirty-five elements in sodium chloride samples was investigated spectrographically, allowing detection of extremely low concentrations. Results are reported for rock salt from four different locations, for three different solar salts, and for purified salt from two separate plants.

The chlorine caustic industry has reliable information (1-4) regarding the influence of trace impurities on the electrolysis of sodium chloride by the mercury cell process. The presence of certain metals (V, Mo, Cr, and Ti) in concentrations as low as 0.25 mg/liter of brine (equivalent to 0.8 ppm in dry sodium chloride) decreases cathodic current efficiency considerably.

The sodium chloride brines used are derived from different sources and from various locations, viz., rock salt, brought to the surface dry; rock salt, dissolved underground and pumped to the surface through brine wells; natural underground brines; solar salt; vacuum pan salt.

Although rock salt and raw brines are usually purified before use, it is of considerable interest to know to what extent the harmful metals occur in the salt. Since the literature provides practically no information on this subject, a spectrographic investigation of different types of sodium chloride from different locations was undertaken. Rock salt samples were obtained from Louisiana, Michigan, New York, and the Dominican Republic; solar salt from California, The Great Salt Lake, and the Bahamas; purified vacuum pan salt from Louisiana and New York.

Considerable variation exists in quantity, and some variation in kind, of impurities found in natural salt deposits.Unrefined rock salt contains some water-insoluble matter, mostly anhydrite, plus traces of other minerals: dolomite, hematite, quartz, celestite, clay (aluminum silicate), etc. Since trace quantities were to be determined, an effort was made to determine the variance in results between duplicate analyses and between samples taken from the production line at least one week apart. The analyses on rock salt from New York, Michigan, and Louisiana were run in duplicate on two samples taken at different times. A single analysis of the purified salt was made on two samples taken several weeks apart. Kilogram samples were used in all analyses to increase precision and to compensate for the non-uniform distribution of impurities in the rock salt deposits. In no instance, where more than one analysis was made on salt from a given source, was there any wide discrepancy in results between the several samples.

Solar salt may contain traces of many of the constituents of sea water, depending on the control exercised during the evaporation and crystallization process. Most of the natural impurities are water-soluble except for mechanical contaminants such as clay or calcium sulfate from pan bottoms, or windblown dust.

Purified vacuum pan salt was included to indicate, by difference, the extent to which trace elements are removed by chemical purification.

Experimental

A kilogram of salt was dissolved in 3500 ml of distilled water, allowed to stand over night, and then filtered through Whatman No. 41 paper. The residue was washed with several portions of distilled water, the washes being added to the brine. The filter paper and insolubles were dried over night at 110°C. The paper was separated and ashed separately. The residue was added to the ash and the total weighed as "insolubles." This was ground in an agate mortar and analyzed spectrographically. In the case of the purified salt samples there was no insoluble portion.

The trace elements in the soluble fraction were precipitated with H_2S from slightly alkaline brine, using high-purity lead as a carrier.

The filtered brine was made alkaline with 5 ml of C.P. NH_4OH. Fifty mg of 99.99+% lead, as a lead nitrate solution, was added to act as "carrier." The precipitation of the sulfides was carried out under a slight pressure of water-washed H_2S and with stirring. A blank containing 5 ml NH_4OH and 50.0 mg Pb was run along with the brine samples. To avoid colloid formation, the solution was evaporated to 400-500 ml before the H_2S was added.

In the analysis of the sulfides, the following metals were determined quantitatively with the aid of specially prepared standards: Ni, Co, Cr, Cu, Mn, Zn, Fe, and V. All other analyses were made semiquantitatively.

The precipitate was allowed to settle over night and was then separated from the alkaline brine by centrifuging. It was washed several times with slightly alkaline H_2S-saturated distilled water. The washed precipitate was then transferred to a crucible, dried at 110°C, and analyzed spectrographically as was the alkaline "mother liquor." Since no information was available on the efficiency of this method of separation of trace elements, a separate spectrographic analyses was also made on the filtered mother liquor.[1]

To evaluate the contribution of the water impurities to the mother liquor analysis, the alkaline solution, after the removal of the sulfides in the blank analysis, was evaporated to dryness and the residue analyzed spectrographically.

All spectrographs were made using a Bausch and Lomb Littrow instrument. Samples were burned to completion using a d-c arc. Fifty mg of the "insolubles" or 100 mg of the salt obtained by evaporating the mother liquor was used for each analysis. The standards were prepared by adding 0.01 mg of each of the metals to 50.0 mg of high-purity lead and converting to sulfate. In each analysis of the "Sulfide Precipitate," the entire precipitate was converted to sulfates and burned to completion. The standard sulfate sample contained the equivalent of 0.01 ppm of each of the metals based on the original sample weight of 1000 g.

Discussion of Results

Table I gives the minimum concentration of each element detectable by the techniques used and the wave lengths used for detection. The data give the maximum amount of each element found.

Tables II and III give the analyses of the different salt samples. To conserve space the analyses of the sulfides and the mother liquors are combined under the heading of "Brines." The alkali metals and alkaline earth metals were not found in the sulfide precipitate. The only metallic impurities found in the filtered mother liquor were Cu, Fe, and Mn. These were close to the limit of detection and may be due largely to trace impurities in the graphite electrodes. The values listed for these metals in the brine column are based on analysis of the sulfides. Silicon

[1] Vanadium content of Pacific Coast solar salt found spectrographically, 5 ppb; independent analysis by colorimetric method, 7 ppb.

was estimated only in the insoluble portion. Sufficient silicon can be extracted from laboratory glassware to show up in the spectra of the sulfides and mother liquors.

Where semi-quantitative analyses were made, the higher value of the range is listed. The symbol "N" in the tables indicates that the element was not detected, and (-) indicates that the concentration was not estimated. All values are corrected for the concentrations found in the blanks. An element listed in Table I, but not in the other tables, indicates that the element was not detected in either the insoluble or soluble portion.

The Oxygen Electrode

I. Isotopic Investigation of Electrode Mechanisms

Myron O. Davies,[1] Milton Clark,[2] Ernest Yeager, and Frank Hovorka

Department of Chemistry, Western Reserve University, Cleveland, Ohio

ABSTRACT

Isotopic techniques involving O^{18} have been used to study the cathodic and anodic properties of the oxygen-peroxide couple on partially hydrophobic, active carbon electrodes in alkaline solution. The isotopic analyses have been carried out with an analytical mass spectrometer. For the cathodic reaction, tracer and equilibration experiments prove that all of the peroxide oxygen originates from gaseous oxygen and that the O-O bond is not actually broken in the formation of the peroxide. Tracer experiments also indicate that the oxygen gas liberated during the anodic oxidation of the HO_2^- ion contains only peroxide oxygen. These results are interpreted in terms of various possible reaction mechanisms.

Various investigators (1-5) have demonstrated the reversibility of the oxygen-peroxide couple on active carbon electrodes in alkaline solution in the absence of a polarizing current. The over-all electrode reaction in alkaline solution may be represented as follows:

$$O_2 + H_2O + 2e \rightleftharpoons OH^- + HO_2^-$$

[1] Present address: N.A.S.A. Laboratory, Cleveland, Ohio.
[2] Present address: National Carbon Co., Cleveland, Ohio.

Cathodic (5,6) as well as anodic (7) polarization measurements[3] at Western Reserve University have indicated that the activation polarization associated with the oxygen-peroxide couple on active carbon in alkaline solution is generally small even at apparent current densities as high as 500 ma/cm^2. Concentration polarization involving the perhydroxide ion and molecular oxygen transport are the predominant sources of polarization under these conditions. As a result, polarization measurements have yielded only limited information concerning the electrode mechanisms associated with the oxygen-peroxide couple.

The following questions have been raised concerning the cathodic reaction:

(*A*) Does all of the peroxide oxygen originate from molecular oxygen? (*B*) Is the oxygen-oxygen bond actually broken in the formation of the peroxide? Similar questions have been proposed for the reverse anodic reaction. On a theoretical basis, the answer to the first question should be positive and to the second question negative, but no one had ever proved it conclusively.

The present experiments involving isotopic techniques represent an attempt to provide a definite proof. While tracer experiments involving O^{18} can be used to answer the first question, equilibration experiments are necessary to answer the second question. All of the isotopic experiments described in this paper have been carried out under substantially reversible electrochemical conditions.

Experimental Procedures

Isotopic concentrations in non-equilibrated oxygen gas.—In terms of the isotopes 16 and 18, oxygen gas contains the three molecular species O^{16}-O^{16}, O^{18}-O^{16}, and O^{18}-O^{18}. The O^{18}-enriched gas available for these experiments is approximately 1.4% O^{18} on an atomic basis. The concentration of O^{18}-O^{16} is twice the O^{18} concentration because there are two chances for the inclusion of an O^{18} atom in a given molecule (see Table I). The concentration of O^{18}-O^{18}, however, is approximately the square of the O^{18} concentration since the probability of two simultaneous, substantially independent events is involved. The latter is true only if the gas is completely equilibrated. Consider the results of diluting this O^{18}-enriched gas sample with oxygen gas containing no O^{18} in a 1:1 ratio. Table I indicates the concentrations for the case of nonequilibration and equilibration. For the former, the concentration of the species O^{19}-O^{18} is reduced by a factor of two, whereas in the latter case the concentration is reduced fourfold.

In the present research, various experiments have been performed in which nonequilibrated oxygen gas is converted to hydrogen peroxide. The peroxide is then oxidized to yield oxygen gas which is subsequently examined with a mass spectrometer to see if it has been equilibrated. From this information it is possible to establish whether the oxygen bond has been broken during any step.

[3] These polarization studies will be the subject of later papers in this series.

Table I. Effects of dilution on isotopic concentrations

	O^{18} %	O^{18}-O^{16} %	O^{18}-O^{18} %
1. Original sample	1.4	2.8	0.02
2. Diluted sample (1:1)			
a. Equilibrated	0.7	1.4	0.005
b. Nonequilibrated	0.7	1.4	0.01

Preparation of O^{18}-enriched gas.—The oxygen gas used in the isotope experiments was prepared by the electrolysis of O^{18}-enriched water (1.4% H_2O^{18}).[4] Sufficient H_2SO_4 was added to provide an approximately 1M solution. The electrolysis was carried out in an H-cell between smooth platinum electrodes. The oxygen gas was collected by means of an automatic system and stored as a liquid at liquid nitrogen temperatures for subsequent use.

Electrolytic cells.—Two cells of different design were required for the cathodic and anodic experiments. Figure 1 shows the cell used for the cathodic experiments. The cathode consisted of a porous graphite plug with a layer of active carbon approximately 1 mm thick on the surface exposed to the electrolyte. The apparent area of the cathode was approximately 3 cm^2. The oxygen gas was introduced through the rear side through inlet F. The side arm E, which was submerged in the water within a test tube, served as a pressure control by venting excess gas. The anode consisted of a 1-cm^2 piece of smooth platinum, which was enclosed in a separate compartment with a small hole connecting to the main cathode compartment. This arrangement reduced greatly the rate at which the peroxide generated at the cathode diffused to the anode where it would be oxidized. Oxygen liberated at the anode did not diffuse to the cathode in any appreciable amounts.

The active carbon layer on the cathode must serve the dual purpose of providing sites for the electrochemical reduction as well as a means by which molecular oxygen is readily transported to these sites. The effective transport of oxygen in the electrode structure has been shown (5, 6) to require a

[4] Obtained from the Stuart Oxygen Co. of California.

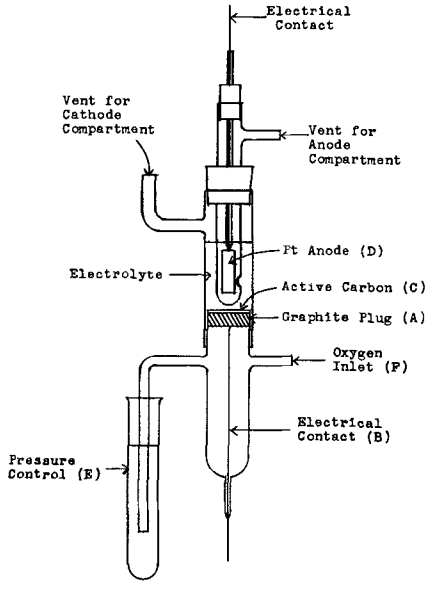

Fig. 1. Cathodic cell for O^{18} experiments

microporous structure containing no solution. For these reasons, the active carbon electrode must be partially hydrophobic to prevent the penetration of the solution into the porous structure. While active carbon itself is somewhat hydrophobic to alkaline solutions, additional waterproofing is obtained through the use of a material such as polyethylene, paraffin, or gum rubber, which also functions as a binder. In the present work, the active carbon layer was applied to the graphite plug by a technique similar to that used by Berl (1). A benzene suspension of active carbon containing gum rubber (5% by weight of carbon) was sprayed with a small atomizer onto the porous graphite plug. The graphite plug was warmed with an infrared lamp both before and after spraying and suction applied on the rear surface of the plug to expedite the rapid and complete removal of the benzene from the active carbon layer. Nuchar C 115[5] was chosen as the active carbon because cathodes prepared from this carbon have low polarization and do not decompose hydrogen peroxide very readily.

The cell used for the anodic experiments is shown in Fig. 2. The anode, A, consisted of a smooth platinum electrode with an area of approximately 3 cm^2. This platinum electrode was corrugated so that it would fit under the hood, B, and then was sprayed on both sides with active carbon by a procedure similar to that used for the preparation of the cathodes in Fig. 1. A small piece of platinum foil, C, located outside of the hood served as the cathode. The oxygen gas resulting from the anodic oxidation of the hydrogen peroxide in the solution was collected in the tube, E.

Cathode measurements.—Two types of cathodic experiments were carried out with the cell in Fig. 1. In one, ordinary oxygen (Linde) was used in conjunction with an enriched 1M KOH solution, prepared by dissolving analytical grade KOH in O^{18}-enriched water. In the second, the electrolytic solution was unenriched, but a 1:1 mixture of enriched oxygen and ordinary oxygen gas was fed to the cathode. No hydrogen peroxide was added to the electrolyte in the cathodic experiments.

[5] Product of West Virginia Pulp and Paper Co.

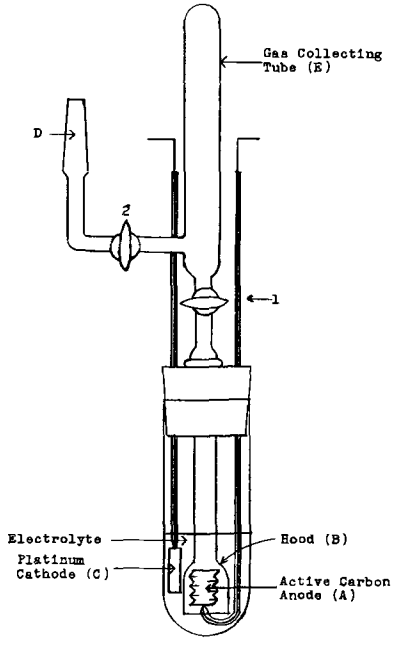

Fig. 2. Anodic cell for O^{18} experiments

In the experiment using the enriched oxygen mixture, the 1:1 mixture of enriched and unenriched oxygen was prepared by condensing an equal volume of Linde tank oxygen (U.S.P.) into the same tube in which the electrolytically produced, O^{18}-enriched oxygen had been collected. The two gases were mixed by distilling them over into another tube which was kept in a Dewar of liquid nitrogen until used in the electrochemical experiment. The outlet of this tube was connected to inlet F of the cathodic cell, the stopcock opened, and the Dewar lowered just enough to allow the oxygen to boil at such a rate that a steady stream of bubbles came from the outlet tube immersed in test tube E. For the majority of the experiments using only unenriched oxygen, the oxygen tank was connected directly to inlet F and the appropriate rate of flow obtained by means of the needle valve of the tank regulator.

After the oxygen flow had been adjusted, approximately 10 ml of electrolyte was added to the cell and the current turned on. Reduction was continued for 15 min after which the sample was quickly transferred to the peroxide decomposing system to be described shortly. Although it is possible for O^{18} to exchange between HO_2^- and H_2O, it has been shown (as will be described later) that no significant exchange occurs within 30 min. In all experiments this was the maximum time allowed to elapse from the beginning of the experiment until the solution was frozen in the peroxide decomposing system.

Anodic measurements.—The electrolyte consisted of 5M KOH prepared with O^{18}-enriched water to which sufficient 90% unstabilized H_2O_2 was added to yield a solution of approximately 0.9M with respect to peroxide. A volume of 25 ml of solution was required to fill the cell in Fig. 2. The solution was sucked up within the cell as far as stopcock 1. This stopcock was then closed and tube E was evacuated through outlet D, after which stopcock 2 was closed. The current was then turned on.

All of the oxygen liberated from the anode, as well as some oxygen resulting from the decomposition of hydrogen peroxide, was collected in the upper part of the tube above the hood below stopcock 1. Hydrogen from the cathode escaped into the atmosphere. From time to time oxygen which had collected in the upper part of the hood tube was admitted to the evacuated collecting tube E by opening stopcock 1. Care was taken to allow as little electrolyte as possible to be sucked into the upper tube. When sufficient oxygen gas had been obtained for the pressure in tube E to be 1 atm, the current was turned off. The total length of time from the introduction of the peroxide to the electrolyte until the end of the electrolysis was not more than 30 min.

After the completion of the electrolysis, the oxygen gas in tube E was passed through a dry ice-methanol trap to remove moisture and transferred to a storage bulb for subsequent mass spectrometer analysis.

Table II. Results of isotopic experiments

Conditions	O^{18}-O^{16} %	O^{18}-O^{18} %
A. Adsorption of enriched, nonequilibrated oxygen on active carbon at liquid nitrogen temperature, followed by desorption.		
1. Experimental	1.54	0.012
Expected if equilibration occurred	1.58	0.0062
Expected if no equilibration occurred	1.58	0.012
2. Experimental	1.50	0.0096
Expected if equilibration occurred	1.48	0.0055
Expected if no equilibration occurred	1.48	0.0086
B. Unenriched hydrogen peroxide in alkaline solution with enriched water for 30 min.		
Experimental	0.41	0.0008
Expected if no exchange	0.40	0.0004
Expected if complete exchange	2.8	0.020
C. Peroxide formed cathodically at an active carbon electrode in basic solution, using enriched, nonequilibrated oxygen and unenriched water.		
1. Experimental	1.27	0.0078
Expected if the oxygen in the peroxide came from the water only	0.40	0.0004
Expected if the oxygen in the peroxide came from the oxygen gas only		
With equilibration	1.24	0.0038
With no equilibration	1.24	0.0067
2. Experimental	1.37	0.0086
Expected if the oxygen in the peroxide came from the water only	0.40	0.0004
Expected if the oxgen in the peroxide came from the oxygen gas only		
With equilibration	1.41	0.0050
With no equilibration	1.41	0.0083
D. Peroxide formed cathodically at an active carbon electrode in basic solution, using tank oxygen and enriched water.		
1. Experimental	0.45	0.0023
Expected if the oxygen in the peroxide came from the water only	2.80	0.020
Expected if the oxygen in the peroxide came from the oxygen gas only	0.43	0.0026

Expected if the oxygen in the peroxide came from the water only	2.80	0.020
Expected if the oxygen in the peroxide came from the oxygen gas only	0.41	0.0021
E. Peroxide formed cathodically at an active carbon electrode in basic solution using enriched water and unenriched oxygen gas prepared by partial evaporation of liquefied tank gas.		
1. Experimental	0.42	0.00088
Expected if the oxygen in the peroxide came from the water only	2.80	0.020
Expected if the oxygen in the peroxide came from the oxygen gas only	0.40	0.00089
2. Experimental	0.43	0.00094
Expected if the oxygen in the peroxide came from the water only	2.80	0.020
Expected if the oxygen in the peroxide came from the oxygen gas only	0.40	0.00089
F. Oxygen gas formed anodically at an active carbon electrode in basic solution containing unenriched hydrogen peroxide.		
1. Experimental (with unenriched water)	0.39	0.00076
2. Experimental (with enriched water)	0.38	0.0014
Expected if the oxygen came from the water	2.80	0.020
Expected if the oxygen came from the peroxide	0.39	0.00076

Analytical procedures.—The hydrogen peroxide samples were decomposed with ceric sulfate as an oxidant in order to recover the peroxide oxygen for mass spectrometer analysis. Cahill and Taube (8) have shown that oxidation with this reagent liberates oxygen exclusively from the peroxide without exchange with oxygen of the water. These workers also believed that the rupture of the oxygen-oxygen bond does not occur in the oxidation of hydrogen peroxide with this reagent. The present experimental work verifies this conclusion.

Prior to the oxidation with ceric sulfate, the hydrogen peroxide solutions as well as the ceric sulfate-sulfuric acid solutions were degassed[6] to remove any dissolved molecular oxygen. The oxygen gas from the oxidation of the hydrogen peroxide was dried by means of a dry ice-methanol trap and then stored in a glass bulb for subsequent isotopic analysis.

A Consolidated Engineering analytical mass spectrometer (modified type 21-101) was used for all the isotopic analyses. This instrument was equipped with a nonmagnetic stainless steel analyzer tube in which the ionization zone was thermostated to 250° ±0.3°C. The surface of the tungsten filament within the analyzer tube was kept well carbided to minimize the attack of the filament by the oxygen gas. The mass spectrum for each sample was scanned from mass number 26 to 42 in order to include the peaks for nitrogen and argon, if present, as well as the various isotopic O_2 peaks. It was necessary to scan this range twice for each sample, once at high amplifier sensitivity and once at low amplifier sensitivity, because the high sensitivities required to give measurable 36 peaks (O^{18}-O^{18}) gave 32 peaks (O^{16}-O^{16}) which were too large to record. Mass 34 peaks (O^{18}-O^{16}) were measurable at both sensitivities.

The calculations of the relative isotopic concentrations are based on the assumption that the isotopic concentrations are directly proportional to the peak heights minus the background peak heights on the records from the mass spectrometer with the same proportionality constant for all three mass numbers: 32, 34, and 36. This assumption is justified only if the accelerating voltages used in the mass spectrometer are approximately the same for the various mass numbers. Such was the case in the present work. Corrections were made for nonlinearity in the recording system. An additional correction was necessary for the 36 peaks corresponding to O^{18}-O^{18}. Argon occurs as an impurity in oxygen gas prepared by liquefaction of air to the extent of about 0.5%. Evidence of this situation is readily apparent from the relatively prominent mass number 40 peaks in the mass spectra. Since argon has an isotope of mass 36, it has been necessary to apply a correction for this isotope. The ratio of the 36 to 40 peaks for argon is 0.31 to 99.68 in argon in the air (10). This ratio was assumed to apply to the argon in the oxygen gas as an approximation, although the actual ratio is probably higher because of the fractional distillation involved in the preparation of oxygen gas from air. The height of the 40 peak multiplied by 0.003 was subtracted from the 36 peak.

[6] For details concerning the procedure used for the recovery of the peroxide oxygen, see Ref. (9).

Experimental Results

Preliminary Experiments

Several preliminary experiments were carried out to become familiar with the techniques as well as to check certain aspects of the electrochemical experiments which might prove troublesome. The first experiment involved the adsorption of nonequilibrated oxygen gas on an active carbon sample (Nuchar C115) from which physically adsorbed gas had been removed previously. After 45 min at liquid nitrogen temperatures, the gas was desorbed by warming the sample of carbon to room temperature. The amount of gas adsorbed at the liquid nitrogen temperatures was just slightly less than that corresponding to a monolayer coverage as determined by earlier surface area measurements. The data in part A of Table II indicate that no equilibration occurred within the limits of reproducibility of the experiment. Since this experiment was for the most part at liquid nitrogen temperatures, the results do not imply that equilibration does not take place at room temperatures to some extent. Reproducibility generally was limited by contaminants in the oxygen gas, and to a lesser extent, background associated with the mass spectrometer.

The second preliminary experiment involved a check to see if appreciable exchange between oxygen in the water and oxygen in the peroxide occurs in alkaline solution during the time periods required for the electrochemical experiments. If such an exchange had occurred to any significant extent, the electrochemical experiments would have been invalidated. Sufficient 90% unenriched, nonstabilized hydrogen peroxide was added to a 1.4M KOH solution containing enriched water (approximately 1.4% O^{18}) to yield approximately 0.4M H_2O_2 solution. After 30 min the H_2O_2 was decomposed by the procedure described previously. The results are given in part B of Table II and indicate no exchange of peroxide oxygen and water oxygen within the limits of reproducibility during a period of 30 min. This was the maximum length of time during which H_2O_2 and H_2O were in contact in alkaline solution in the subsequent electrochemical experiments.

Electrochemical Experiments

In parts C to E of Table II are summarized the results of the cathodic experiments with O^{18}-enriched gas and water. In part F the results for the anodic experiments with O^{18}-enriched water are given.

All of the expected values for the O^{18}-O^{16} percentages in Table II are based on the original concentration of this species in the oxygen gas or the water involved in the experiment, as the case may be. In parts A and C the expected non-equilibration values for O^{18}-O^{18} are the same as for the original nonequilibrated enriched gas, while the expected equilibration values for O^{18}-O^{18} are calculated from the concentration of O^{18}-O^{16} in the original oxygen gas. The expected values for the concentration of O^{18}-O^{18} in parts D, E, and F of the table are based on the original oxygen gas used in the experiment or calculated on the basis of the atomic per cent O^{18} in the water, depending on which prediction is involved. In the predictions based on the O^{18} content of the original water used in preparing the solution, no correction was made for the small dilution effect of the base on the O^{18} content of the resulting solution.

Examination of the data revealed one fact which required further investigation. Unenriched oxgyen should contain only 0.0004% of O^{18}-O^{18}. Experimental values were consistently higher than this, as is evident in part D of Table II. If the unenriched oxygen gas was first liquefied and a fraction distilled off, the results were found to be closer to the expected values. An unenriched oxygen sample thus treated gave results of 0.40% for O^{18}-O^{16} and 0.0009% for O^{18}-O^{18}.

The remaining discrepancy of approximately twofold between the calculated value of 0.0004% for O^{18}-O^{18} and the measured value of 0.0009% for O^{18}-O^{18} is not surprising because these values are near the limit of sensitivity of the mass spectrometer and because relatively large background corrections are involved. The analyses of oxygen obtained from H_2O_2 produced cathodically from unenriched oxygen gas which had been fractionally distilled in the above manner also gave lower results for O^{18}-O^{18}. The data for two such experiments in 1M KOH with enriched water are given in part E of Table II. The agreement is considerably better than in part D. The nature of the impurity in the unenriched Linde U.S.P. oxygen which caused the discrepancies is not known, but apparently it is carried through the entire experimental procedure when the oxygen is not first distilled.

Conclusions

The data in parts C to F of Table II support the following conclusions concerning the oxygen-peroxide couple on active carbon in alkaline solution:

1. In the reduction of oxygen gas to hydrogen peroxide, all of the peroxide oxygen originates from the molecular oxygen. The reverse is also true for the anodic oxidation of peroxide to oxygen gas.

2. In the cathodic formation of hydrogen peroxide, the O-O bond is modified in type but not actually broken. In addition it is evident that the O-O bond is not broken in the oxidation of hydrogen peroxide with ceric sulfate in acid solution.

The following are three possible mechanisms for the oxygen cathode on carbon in alkaline solution:

Mechanism 1

$$H_2O + e \rightarrow H\ (ads) + OH^- \quad [1a]$$
$$O_2\ (gas) \rightarrow O_2\ (ads) \quad [1b]$$
$$O_2\ (ads) + H\ (ads) \rightarrow HO_2\ (ads) \quad [1c]$$
$$HO_2\ (ads) + e \rightarrow HO_2^- \quad [1d]$$

Mechanism 2

$$H_2O + e \rightarrow H\ (ads) + OH^- \quad [2a]$$
$$O_2\ (gas) \rightarrow O_2\ (ads) \quad [2b]$$
$$O_2\ (ads) + H\ (ads) \rightarrow HO_2\ (ads) \quad [2c]$$
$$HO_2\ (ads) + H\ (ads) \rightarrow H_2O_2 \quad [2d]$$
$$OH^- + H_2O_2 \rightarrow H_2O + O_2H^- \quad [2e]$$

Mechanism 3

$$O_2\ (gas) \rightarrow O_2\ (ads) \quad [3a]$$
$$O_2\ (ads) + H_2O + 2e \rightarrow HO_2^- + OH^- \quad [3b]$$

where step [3b] is intended to represent the direct electrochemical reduction of O_2 (ads) to HO_2^- without intermediate reactions involving adsorbed hydrogen. Step [3b] may proceed by several steps: for example,

$$O_2 \text{ (ads)} + H_2O + e^- \rightarrow HO_2 \text{ (ads)} + OH^-$$
$$HO_2 \text{ (ads)} + e^- \rightarrow HO_2^-$$

The authors favor mechanism 3, but the first two mechanisms involving chemi-adsorbed hydrogen cannot be discarded on the basis of information available at present.

It is not possible to distinguish between these mechanisms on the basis of the present isotope experiments. Mechanisms 1 and 2 may be considered as corresponding to hydrogen electrodes with the surface concentration of adsorbed hydrogen depressed by the reactions with adsorbed oxygen.

In later papers in this series, an attempt will be made to elucidate further the electrode mechanism in terms of cathodic and anodic polarization measurements for the oxygen-peroxide couple. In addition, fractionation experiments involving the oxygen-peroxide couple are planned.[7]

Acknowledgments

The authors are pleased to acknowledge the support of this research by the Office of Naval Research under Contract Nonr 58100 and by E. I. du Pont de Nemours and Company through a graduate fellowship to one of the authors (M.O.D.)

Manuscript received April 3, 1958. This paper was prepared for delivery before the Cincinnati Meeting, May 1-5, 1955.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

[7] It is interesting to note that fractionation experiments involving the anodic formation of oxygen on various surfaces have been reported by Anbar and Taube (11).

Technical Notes

Magnesium-Bismuth Oxide Dry Cells

C. K. Morehouse and R. Glicksman

RCA Laboratories, Radio Corporation of America, Princeton, New Jersey

The oxides of mercury, thallium, and lead have been studied extensively as cathode materials for electrochemical cells. Mercuric oxide and lead dioxide are of practical significance, finding use as cathode materials in the zinc-mercuric oxide dry cell (1, 2) and the lead-acid storage cell (3, 4). Thallium(III) oxide (5), despite its desirable electrochemical properties, has not proved of practical value probably because of its high cost and two step voltage-time discharge curve during current flow (6). Bismuth oxide, the next oxide in this series, also has some attractive physical and chemical properties for use as a cathode material in electrochemical cells. For example, it has a low solubility in neutral solutions, is stable over a wide temperature range, and has a flat voltage-time discharge curve during current flow (6). Although bismuth oxide has a considerably lower reversible electrode potential than manganese dioxide and mercuric oxide cathode materials used at present in commercial dry cells, it does have greater theoretical ampere-minute capacity per unit of weight (20.7 amp-min/g) and volume (176 amp-min/cc) than these materials. Using the half-cell technique for evaluating cathode materials (7), it has been found that a bismuth oxide electrode operates at a potential (vs. hydrogen) of −0.30 to −0.40 v over a wide range of current densities and at an electrode efficiency in excess of 90% when discharged at a constant current drain of 0.005 amp/g in an aqueous solution of magnesium bromide (250 g/l $MgBr_2 \cdot 6H_2O$).

Heil (13) describes a cell containing a mixture of bismuth oxide and manganese dioxide coupled with a zinc anode, while Edison (14-17) refers to the use of bismuth oxide in a nickel-iron storage cell, claiming that the addition of bismuth oxide to the electrodes results in improved performance. However, no practical dry cells containing this material have

been reported, probably because of the low resultant voltage obtained when coupling this cathode with a zinc anode.

In this paper the construction and performance characteristics of magnesium-bismuth oxide dry cells are described.

Experimental

Magnesium-bismuth oxide dry cells were assembled, using an impact extruded magnesium AA-size (height 1.82 in., OD 0.521 in., ID 0.441 in.) can, composed of AZ10A Dow Chemical Company alloy. The magnesium cans were lined with a piece of Nibroc salt-free paper (2¼ x 2¼ x 0.002 in. thick), and an extruded slug of cathode mix inserted in the lined can and consolidated. A carbon rod (height 1.787 in., diameter 0.159 in.) containing a brass cap was then inserted in the center of the cathode mix and the cells sealed with a rosin base wax seal in the conventional manner. Each cell contained approximately 10 g of cathode mix of the following formulation:

	% by weight
Bismuth oxide	54.7
Shawinigan acetylene black	6.8
Barium chromate	1.9
Electrolyte (an aqueous solution of 500 g/l $MgBr_2 \cdot 6H_2O$ and 1.0 g/l $Li_2CrO_4 \cdot 2H_2O$)	36.6

The open-circuit voltage of the bismuth oxide dry cells ranges between 1.60 and 1.65 v, the high voltage being due either to adsorbed air in the cathode mix or to the small amount of chromate which is added to inhibit the corrosion of the magnesium anode. When current is withdrawn from the cells, the voltage drops to a low value followed by a gradual increase to its operating voltage level. After the initial voltage drop, the cells have a flat voltage discharge curve operating slightly above 1.00 v for most of their useful discharge life as illustrated in Fig. 1. The initial voltage drop, which is believed to be due to changes which occur at the bismuth oxide electrode, is more noticeable at the high current drains and is different from that experienced with other magnesium dry cells.

Performance data in terms of hours of continuous service to a 0.90 v end voltage vs. load resistance are presented in Fig. 2. Also included are watt-minute capacity per unit of weight and volume data plotted against average continuous power output in milliwatts.

A favorable shelf life for the magnesium-bismuth dry cell is indicated by the fact that AA-size dry cells have given 75-80% of initial capacity as measured on 50- and 150-ohm continuous discharge tests to a 0.90 v end voltage after storage for 18 and 24 months at 70°F, 50% R. H.

The magnesium-bismuth oxide dry cells described in this paper have a flatter voltage-discharge curve and give more hours of service on continuous tests to end voltages of 1.00 v and lower than both the zinc-manganese dioxide Leclanché and magnesium-manganese dioxide (18) dry cells. At the present state of the development the technical difficulties

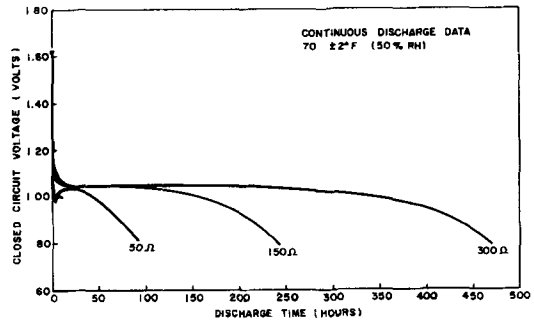

Fig. 1. AA-size magnesium-bismuth oxide dry cells discharged continuously through 50-, 150-, and 300-ohm resistances at 70° ± 2°F (50% R. H.).

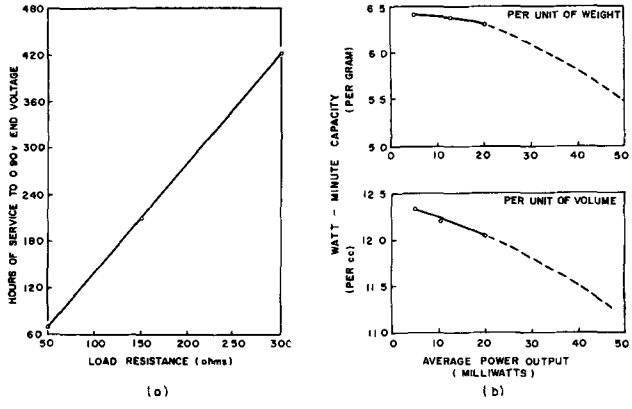

Fig. 2. Capacity data for AA-size magnesium-bismuth oxide cells in (a) hours of service to a 0.90 v end voltage vs. load resistance (b) watt-minutes per unit of volume and weight vs. average power output (capacity and average power computed to 0.90 v end voltages from continuous discharge data).

associated with these new cells are: (*a*) "delayed action," (*b*) high internal impedance, and (*c*) loss in capacity on light intermittent tests. These difficulties are believed to be associated with the magnesium electrode and can be solved with further research and development. It should be recognized, however, that bismuth oxide is inherently more expensive than manganese dioxide and, even if the technical problems can be overcome, these magnesium-bismuth oxide dry cells probably would find only limited application.

Acknowledgment

The authors wish to express their appreciation to Mr. G. R. Ganges for assisting in gathering some of the cell data.

Corrosion Product and Inhibitor Films on Aluminum

H. W. McCune

Miami Valley Laboratories, The Procter & Gamble Company, Cincinnati, Ohio

Effect of Inhibitors on Triphosphate Sorption

When aluminum corrodes in an alkaline sodium triphosphate solution, phosphate is incorporated into the surface oxide film on the metal (1). Corrosion in such sequestering solutions is more rapid than in most other alkaline solutions at the same pH, perhaps because a complex of Al(III) and sequestrant forms in the oxide surface at the solution-solid interface and plays an important role. Sodium silicate, potassium permanganate, and sodium chromate have been suggested as inhibitors for Al exposed to alkaline solutions (2). Sodium silicate has been suggested specifically for sodium pyrophosphate and sodium triphosphate solutions and has found wide application as an inhibitor in household detergent mixtures containing polyphosphates (3, 4). A comparison of the character of the corrosion product film with the inhibitor films was thought to bear on the mechanism of corrosion by sequestering agents and on the inhibition of such corrosion. The effect inhibitors have on the amount of triphosphate appearing on the surface of Al exposed to inhibited solutions of sodium triphosphate was first determined.

In Table I, the entries under "$Na_5P_3O_{10}$ deposited" were calculated from the phosphorus-32 activity sorbed on the Al specimens which were exposed to uninhibited and inhibited radioactive sodium triphosphate solutions. Triphosphate ion is probably the chief phosphate species sorbed. Hydrolysis in the bulk test solution is negligible, so only if a surface-catalyzed hydrolysis takes place would much lower phosphate be sorbed. The sorbed phosphate will be spoken of as "triphosphate," recognizing that its identity has not been proven. The specimens were weighed before and after exposure under stagnant conditions and after a standard dip in concentrated HNO_3 (5). Determination of the weight loss in HNO_3 is usually a rough measure of corrosion products. The "Total weight loss" of Table I is the sum of weight lost during exposure and during the HNO_3 dip. The metal was prepared as was described previously (1). The reported weight loss data were determined using 7.62 x 1.90 cm specimens. In the tracer determination of phosphate deposition, 1.90 x 1.90 cm specimens were used for convenience in counting. The sensitivity of the radiochemical determination was 0.001 mg/cm^2 and the precision was ±0.001 mg/cm^2 (95% confidence level).

Table I. Effect of inhibitors on triphosphate sorption

(0.02% inhibitor, 0.18% $Na_5P_3{}^{32}O_{10}$, 3.0 hr, 60°C, pH 9.5, 6.9 ml solution/cm^2 3003 Al)

Inhibitor	$Na_5P_3O_{10}$ deposited, mg/cm^2	Weight loss in HNO_3, mg/cm^2	Total weight loss, mg/cm^2
None	0.017	0.05	0.59
SiO_2 (sod. silicate)	0.000	0.00	0.01
$KMnO_4$	0.003	0.03	0.06*
K_2CrO_4	0.024	0.07	0.39

* Weight gain.

When sodium silicate was present at inhibitory concentrations, triphosphate was prevented from depositing in the film. Potassium permanganate almost eliminated phosphate deposition and formed a highly effective inhibitory coating. The film was highly colored, indicating that permanganate had been included in it. Potassium chromate increased the amount of phosphate deposited and had a slight inhibitory effect. The concentrated HNO_3 removed all of the radioactive phosphorus in these experiments except in the permanganate experiment, where it removed none. In the permanganate experiment determination of weight loss in HNO_3 obviously does not represent all of the corrosion products. The adsorbed triphosphate was roughly one-third of the total corrosion product in the uninhibited test and in the potassium chromate test. Not enough silica or corrosion product to be weighed was deposited with the silicate inhibitor in these experiments.

The attack of uninhibited alkaline triphosphate solutions on Al might be by way of the complexing of aluminum ions in solution, or by the formation of surface complexes with the oxide film, which is suggested by the incorporation of triphosphate into the film. The fact that the effective corrosion inhibitors, silicate and permanganate, largely prevent the incorporation of phosphate in the film and a poor inhibitor, chromate, does not prevent incorporation of triphosphate adds some support to the suggested role of the surface complex in increasing corrosion.

Sorption of Silicate

It has been reported that the hydrous metal oxide corrosion product plays an essential part by inter-

acting with silicate ions or silica to attach the protective film to the metal; chemical analysis, microscopic examination, and x-ray diffraction indicate that the film is mostly amorphous silica (6). The report that the siliceous film cannot continue to grow on itself (7) is a further indication of the importance of the metal oxide. Examination of the sorption of silicate on Al might indicate whether an inhibitory concentration is sufficient to cover the metal surface.

A sorption isotherm was determined using granular Al, reported to contain 1% or less impurity, which was given a wash with very dilute alkali followed by three washes with distilled water, a rinse in ethanol, and air drying. The 200-270 mesh fraction was taken, and the average particle size with respect to surface was determined microscopically. The specific surface was calculated to be 7.9 x 10^3 cm^2/g. Sodium silicate solutions were made from filtered stock solution and analyzed for silica colorimetrically before and after shaking with the metal for 0.5 and 1.5 hr; there was no difference in the results obtained at these two times. The weight of the sorbate was calculated as SiO_2 from the decrease in solution concentration. The error introduced by loss of solvent to sorbent is estimated to be negligible compared to the variability of the data. If the weight of water sorbed is equal to the weight of the siliceous aluminum oxide film (see below), the volume of the solution would be changed less than 1%. Sodium triphosphate was absent in these experiments, but this appears to be justified by the absence of triphosphate from the inhibitory film formed when both silicate and triphosphate were in the solution.

The results in Fig. 1 show that at 60°C sorption on Al from a sodium silicate solution is essentially complete at about 0.45 mg SiO_2 per g of Al. From the specific surface of the Al granules used, this is 5.7 x 10^{-5} mg/cm^2. If it is assumed that the true area was determined microscopically and that SiO_2 molecules with an area of 12.3 sq Å are sorbed (8), calculation indicates a coverage of 0.7. However, these are not very good assumptions, and whether less than a monolayer, a monolayer, or a few monolayers saturate the surface is unimportant for understanding corrosion inhibition in this case. The equilibrium concentration of SiO_2 corresponding to saturation of the surface is 150-250 mg/100 ml, which is an order of magnitude greater than the concentration of about 10-20 mg/100 ml which inhibits corrosion at the same temperature (4) (Table I). Apparently silicate by itself does not cover the metal but cooperates with the hydrous aluminum oxide to form the protective film.

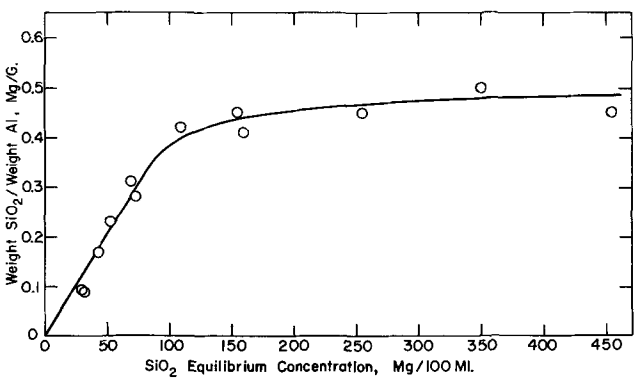

Fig. 1. Sorption isotherm of silica on Al at 60°C

Hypotheses advanced to explain how Si is built into the surface film on protected metals involve interaction of some combination of ions of the metal or the hydrous metal oxide with silicate ions or "silica micelles" (6). It is not possible to progress much further by examining the existence of possible reactants under pertinent conditions. The possibility of reaction of free aluminum ions can be dismissed in favor of aluminum ions bonded with water, hydroxide ions, and oxide ions and forming a continuous hydrous oxide film covering the metal surface. A reasonable picture of the reaction might be hydrous aluminum oxide reacting with monomeric or low molecular weight silicic acid, perhaps slightly ionized, depending on the pH (9), to produce an aluminum silicate. The aluminum ion is small enough to replace Si to some extent, adopting a coordination number of four toward oxygen, as half of the aluminum ions do in sillimanite, Al_2SiO_5, and as is common in other aluminosilicates (10). Aluminum is corroded much more rapidly by uninhibited triphosphate solutions and is protected much more effectively from sodium triphosphate solutions at low concentrations of silicates than is Zn, Ni, Ag, brass (4), Cu, or Pb. The decreased effectiveness of the inhibitor may be because the ions of these metals and alloys are larger than the aluminum ions and are not incorporated easily into metallosilicate structures.

Characterization of Isolated Films

Surface films were collected by exposing 50 to 150 dm^2 of Al foil (1100 purity, 0.0002 in. thick), then dissolving the metal in 5% bromine in methanol. The remaining solid film was filtered off on sintered glass, washed with methanol, and dried at 80°C before weighing. An exposure of 3 hr in 0.18% sodium triphosphate solution at 60°C gave 0.04 mg of corrosion products film per cm^2. This weight agreed fairly well with the weight loss in HNO_3 (Table I). It was found by chemical analysis that a similar film contained phosphorus equivalent to 0.016 mg $Na_5P_3O_{10}$ per cm^2 (1) which agrees well with the value in Table I determined by the use of P-32. Evidently the Al_2O_3 film contains a substantial fraction of phosphate. The triphosphate solution with sodium silicate equivalent to 0.02% silica added and also adjusted to pH 9.5, gave a film weighing 0.0013 mg/cm^2 under the same conditions. A correction of 0.0008 mg/cm^2 for the insoluble material in the clean, untreated foil must be subtracted from the weights collected. Clearly the inhibitory film is very thin, a few tens of angstroms thick. X-ray diffraction indicated that the insoluble material from the foil itself contained crystalline Si and a little Cu; after ignition, a pattern for a crystalline aluminum silicate was obtained, indicating the presence of Al from the air-formed film initially present on the foil.

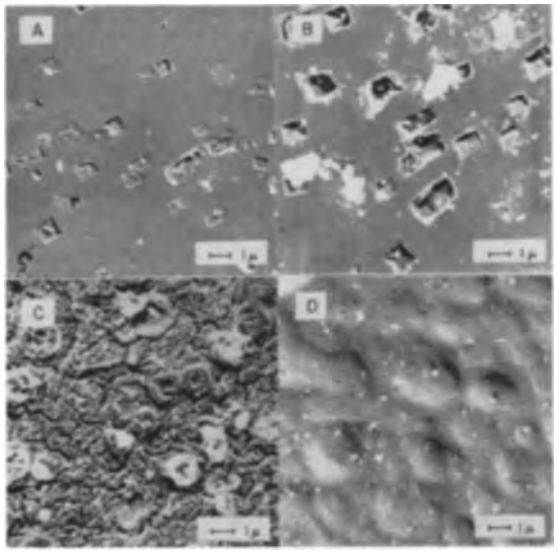

Fig. 2. Electron micrographs of Al surfaces: A, polished and etched; B, after exposure to 0.18% $Na_5P_3O_{10}$, 0.02% SiO_2, 3 hr, 60°C, pH 9.5; C, same as B without the SiO_2; D, same as C after corrosion products were removed in concentrated HNO_3.

Neither sample of film from treated foils gave crystalline x-ray diffraction lines other than those of Si and Cu, with CuK_α radiation.

Electron Microscopy of the Surface

Portions of the 3003 sheet Al were electropolished in an aqueous solution of methanol and perchloric acid. The samples were then lightly etched in a methanol solution of bromine for 15-30 sec, washed, and exposed to the corrosive conditions of interest. After removal of the metal from the test solutions, liquid was blown off with an air jet. Chromium replicas about 150Å thick were prepared by oblique evaporation and freed by dissolving the aluminum in bromine-methanol. To demonstrate that the results were not affected by the method of sample preparation, additional samples were prepared by polishing with an abrasive and etching with a dilute HNO_3-HF-HCl solution. Similar electron micrographs were obtained, but electropolishing followed by bromine-methanol etch gave more nearly reproducible surfaces and more sharply defined etch pits.

Sheet Al is polycrystalline, but the electron micrographs shown include portions of only one or a few crystallites. Electropolishing gave a smooth, abrasive-free surface like the background of Fig. 2A. The samples were all etched in bromine-methanol to remove, by dissolving the metal, any film left by polishing and to give a texture to the surface which might permit observation of surface films. Rectangular etch pits developed and, from their orientation, show that Fig. 2A includes parts of two crystallites. In electron micrographs of samples exposed to triphosphate solutions inhibited with sodium silicate there was no evidence of a continuous film covering the surface and obscuring the edges of the pits (Fig. 2B). Evidently the siliceous film is textureless, and probably it is very thin. The white, irregular unshadowed particles prominent in Fig. 2B and 2D are absent in many other micrographs of similar subjects; hence it is concluded that they are accidental contamination. The set of micrographs shown in Fig. 2 was chosen from the sets available as the most informative over-all despite the contamination. In a majority of micrographs, the rectangular pits appear larger in samples exposed to inhibited triphosphate solution than in the etched blanks, but this does not necessarily represent a real difference. When the inhibitor was omitted, corrosion product was built up, and the metal was attacked within the crystallites (Fig. 2C). A dip in concentrated HNO_3 removed the corrosion products and revealed that corrosion gave rise to shallow circular pits (Fig. 2D).

Acknowledgment

The author wishes to express his thanks to A. P. Murphy, who is responsible for the light and electron microscopy, and to W. E. Cooley for aid in preparing the manuscript.

Additives and Grain Refinement

D. A. Vermilyea

Research Laboratory, General Electric Company, Schenectady, New York

Most commercial plating baths contain some addition agent which is added to produce a desirable structure in the deposits. These addition agents are usually high molecular weight organic compounds or colloids, small ions or molecules being generally not very effective (1). The purpose of this note is to suggest a mechanism by which such addition agents may modify the crystal structure of electrodeposits. Silver will be used as an example.

It has often been observed (2-4) that the deposition of Ag from a $AgNO_3$ solution containing high molecular weight organic compounds may result in the formation of filaments or "whiskers" of Ag. Whiskers of Cu have also been reported (5, 6). A theory to account for such growth has been given by Price, Vermilyea, and Webb (7). According to the theory, organic molecules adsorb on the crystal and interfere with the motion of lattice steps over the surface. When the concentration of molecules adsorbed on the surface is above a critical value depending on the overvoltage, step motion is completely blocked and no further growth of the crystal occurs. On the other hand, molecules adsorbed on a rapidly growing surface are thought to be incorporated into the crystal as lattice steps move around and past them. According to this picture, therefore, molecules adsorbed on the surface interfere with growth; they may be removed from the surface by incorporation into the crystal. If the crystal grows rapidly enough, the surface will be kept clean because adsorbed molecules are buried as fast as they reach the surface by diffusion. At slower growth rates adsorbate reaches the surface faster than it can be buried; the surface becomes severely contaminated, and growth stops.

A major prediction of the theory of Price, Vermilyea, and Webb (7) is that there is a critical current density for the continued growth of a metal crystal in a solution containing large, strongly adsorbed molecules. At the critical current density there is a balance between the rate of diffusion of molecules to the surface and the rate of incorporation into the crystal. The equation for the critical current density for a spherical crystal of a given metal for a given metal ion concentration and temperature is

$$I_c = \text{const}\left(\frac{C_i}{r}\right)^{1/3} \qquad [1]$$

where C_i is the concentration of adsorbate in the solution, and r is the radius of the crystal. Equation [1] is valid for crystals with radii less than about 10 μ. Typical critical current densities observed from whisker growth experiments range from 0.1-10 amp/cm^2; somewhat larger values may be expected with the larger additive concentrations used commercially.

Now consider the electrodeposition of a metal from a solution containing some substance, either organic compound or colloidal material, which is strongly adsorbed on the electrode surface. Before the application of current, the electrode will be completely contaminated. When a current is passed through the cell the electrode potential will rise until deposition begins to occur on the most active sites of the electrode. Crystals would probably start growing at many points on the surface. The overvoltage required to start the deposition would be large because of the initial contamination of the electrode, and the crystals once nucleated would grow very rapidly. Consequently, there would be a rapid and considerable concentration polarization in the vicinity of each growing crystal.

Now consider just one of the many small growing crystals. Around the crystal there will be a hemispherical diffusion field, and if the crystal is small ($< 10\mu$ diam) the gradient at the crystal surface will be proportional to the concentration difference between the bulk of the solution and the surface of the crystal and to the reciprocal of the crystal radius. As the crystal grows a larger concentration difference is required to maintain the same concentration gradient at the surface. When the concentration of metal ions at the surface has become essentially zero it will no longer be possible to maintain the same gradient at the crystal surface, and further growth of the crystal will result in a rapid decrease in the current density.

It is clear, therefore, that eventually it will not be possible to maintain the critical current density of Eq. [1], and that the crystal surfaces will become contaminated and stop growing.

On the electrode as a whole, crystals will continually nucleate, grow, reach a limiting size, become contaminated, and stop growing. It is unlikely that a new crystal will nucleate near or on one which has just stopped growing because the solution in that area is depleted of metal ions. The tendency of new crystals to start as far as possible from ones which just stopped will insure a uniform coverage of the electrode.

It is possible to estimate the size of the crystals which result from such a process. The current density at a growing crystal is given by

$$I = zFD\frac{dC}{dr} \qquad [2]$$

where I is the current density, z the ionic charge, F the Faraday constant, D the diffusion coefficient, and dC/dr the concentration gradient at the crystal surface. For a small hemispherical crystal $dC/dr \sim \Delta C/r$, and hence with $D \sim 10^{-5}$cm^2/sec, $\Delta C_{max} = 10^{-3}$ mole/cc, $I_{max} = 10^{-3}/r$. Hence, if the critical current density is

10 amp/cm^2 the maximum particle size is about 1μ, a reasonable size for a fine-grained deposit.

This simple picture accounts for the very fine grain size produced by additives and for the uniformity of the deposit. It also accounts for the fact that the addition agents which are effective in altering the structure of the deposit are invariably incorporated into the deposit in rather large quantities (of the order of a percent) (8). It also accounts for the absence of specificity reported by Fischer (9); since almost the only requirements for effectiveness are that the units of the additive be large and strongly adsorbed, it is apparent that many substances can accomplish about the same result.

Measurement of Carbon-Metal Contact Resistances

H. L. Foltz and M. R. Hertz

Technical Division, Goodyear Atomic Corporation, Portsmouth, Ohio

The use of large quantities of elemental fluorine in AEC gaseous diffusion plants has led to numerous research projects concerning materials suitable for use in fluorine generators. The cell being used at present to generate fluorine consists basically of a Monel shell and head assembly from which wire mesh diaphrams, steel cathode, and carbon anode subassemblies are suspended.

One of the major causes of low power efficiency and early cell failure has been the electrical deterioration of the carbon anode-metal connection in the anode subassemblies. Since an initially high contact resistance would be conducive to heating of the carbon anode-bus-bar joint with further corrosion of the contact areas, still higher resistance, and so on, work has been completed to determine the relation between contact pressure and contact resistance for various carbon-metal joints. From this work it has been determined that of five metals tested, copper and beryllium copper give the lowest contact resistance, followed by phosphor bronze, magnesium, and steel.

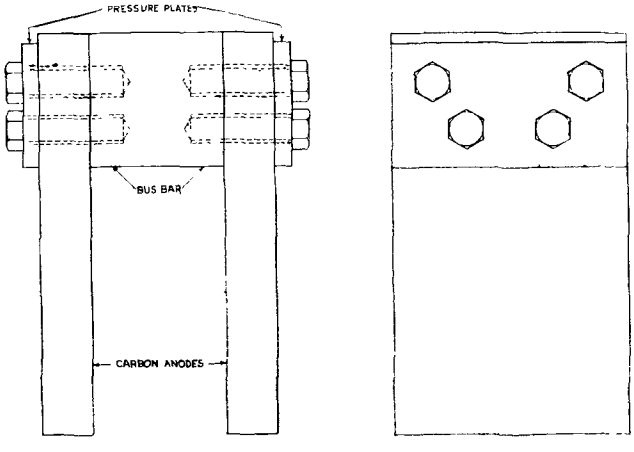

Fig. 1. Anode clamping assembly

Measurements of anode-bar contact resistance as a function of torque did not give consistent results, possibly because of pressure plate warping or a nonlinear increase in thread friction as torque was increased.

As shown in Fig. 1, the carbon anodes are clamped between the bus bar and pressure plates by four ¾-in. steel cap screws per anode. The contact areas of the anodes are specified to be ground smooth and parallel. Original cell assembly specifications called for the cap screws to be torqued to 85 ft lb, which is approximately equivalent to 1400 psi pressure on the anode contact area, the exact pressure being a function of the condition of the threads and their lubrication.

In Fig. 2 the test set-up used is shown. A carbon sample block was compressed between the two metal contact plates by means of a hand operated hydraulic press; the force was applied through a Baldwin SR-4, Type U-1 load cell, which was coupled to a type M strain indicator. Precautions were taken to make sure that the load was applied to the specimen on the vertical axis. The load cell-indicator combination was checked against an Olson testing machine and was found to have an accuracy of ± ¼% of full range (5000 lb). One metal contact plate was insulated from the press so that resistance measurements could be made between the two plates.

For resistance measurement current and potential leads, attached to the contact plates, were connected to a Biddle Model 713 "Ductor" Low Resistance Ohmmeter. This instrument operates on a somewhat similar principle to that of a Kelvin bridge, except that it incorporates a special highly sensitive D'Arsonval-type meter with both a current and a voltage coil to replace the bridge circuit. Thus, increased current tends to decrease the reading, while increased voltage increases the reading. The meter has a basic 0 to 100 micro-ohm range with five

10 amp/cm^2 the maximum particle size is about 1μ, a reasonable size for a fine-grained deposit.

Measurement of Carbon-Metal Contact Resistances

H. L. Foltz and M. R. Hertz

Technical Division, Goodyear Atomic Corporation, Portsmouth, Ohio

The use of large quantities of elemental fluorine in AEC gaseous diffusion plants has led to numerous research projects concerning materials suitable for use in fluorine generators. The cell being used at present to generate fluorine consists basically of a Monel shell and head assembly from which wire mesh diaphrams, steel cathode, and carbon anode subassemblies are suspended.

One of the major causes of low power efficiency and early cell failure has been the electrical deterioration of the carbon anode-metal connection in the anode subassemblies. Since an initially high contact resistance would be conducive to heating of the carbon anode-bus-bar joint with further corrosion of the contact areas, still higher resistance, and so on, work has been completed to determine the relation between contact pressure and contact resistance for various carbon-metal joints. From this work it has been determined that of five metals tested, copper and beryllium copper give the lowest contact resistance, followed by phosphor bronze, magnesium, and steel.

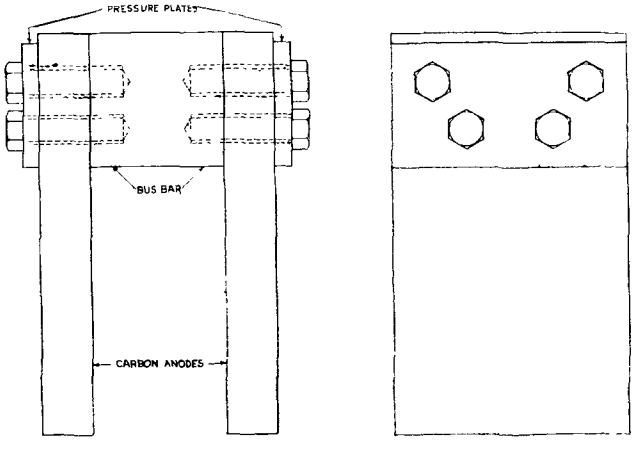

Fig. 1. Anode clamping assembly

Measurements of anode-bar contact resistance as a function of torque did not give consistent results, possibly because of pressure plate warping or a nonlinear increase in thread friction as torque was increased.

As shown in Fig. 1, the carbon anodes are clamped between the bus bar and pressure plates by four ¾-in. steel cap screws per anode. The contact areas of the anodes are specified to be ground smooth and parallel. Original cell assembly specifications called for the cap screws to be torqued to 85 ft lb, which is approximately equivalent to 1400 psi pressure on the anode contact area, the exact pressure being a function of the condition of the threads and their lubrication.

In Fig. 2 the test set-up used is shown. A carbon sample block was compressed between the two metal contact plates by means of a hand operated hydraulic press; the force was applied through a Baldwin SR-4, Type U-1 load cell, which was coupled to a type M strain indicator. Precautions were taken to make sure that the load was applied to the specimen on the vertical axis. The load cell-indicator combination was checked against an Olson testing machine and was found to have an accuracy of ± ¼% of full range (5000 lb). One metal contact plate was insulated from the press so that resistance measurements could be made between the two plates.

For resistance measurement current and potential leads, attached to the contact plates, were connected to a Biddle Model 713 "Ductor" Low Resistance Ohmmeter. This instrument operates on a somewhat similar principle to that of a Kelvin bridge, except that it incorporates a special highly sensitive D'Arsonval-type meter with both a current and a voltage coil to replace the bridge circuit. Thus, increased current tends to decrease the reading, while increased voltage increases the reading. The meter has a basic 0 to 100 micro-ohm range with five

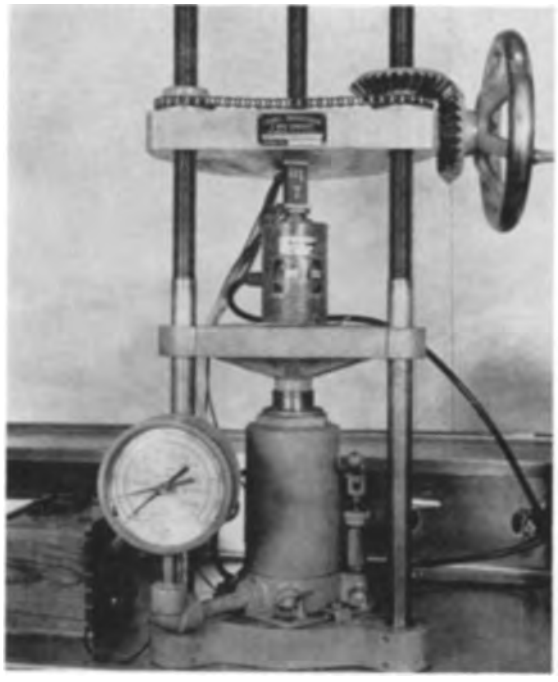

Fig. 2. Compressing carbon block samples between metal contact plates.

decade multiplying ranges giving an over-all range of 0-1 ohm with an accuracy of 1% of full scale for any range. This permits an error approaching 10% at certain readings.

Carbon sample blocks, 1 in.^{2} in cross section and approximately 2 in. high, were cut from the contact area of anodes so that the original surface was retained for the contact pressure vs. resistance measurements. For steel contacts, sections were cut from actual steel pressure plates, while for other metal contacts various metal stock was used, finished with a series of grades of emery paper of increasing fineness.

The actual resistance reading was that for two 1-in.^{2} carbon-metal contact areas and of a 2-in. length of carbon 1 in.^{2} in cross section, all in series. Contact resistance per square inch of area is then:

$$R = (R_t - R_c)/2$$

where R_t is the resistance measured on the meter and R_c is the specific resistance of the carbon in ohms per cubic inch. Since the potential leads were attached directly to the contact plates, the resistance of the metal plates themselves could be disregarded. This was checked by pressing the two plates together while resistance was measured. The resistance was found to be negligible even though an added metal-metal contact was involved.

The specific resistance of National Carbon Company Type YBD carbon, which is not graphite, as given by the manufacturer, is 1550 μ ohms/in.^{3}. This value was obtained by measuring the resistance of a large number of full size anodes lengthwise, using a Kelvin bridge. When this figure was used for the specific resistance of carbon in preliminary tests, the results were somewhat variable from sample to sample. However, when resistance vs. pressure curves were run several times on the same carbon sample block, there was little variation.

Variation could be attributed either to differences in the condition of the carbon contact surfaces from sample to sample, or to differences between the specific resistance of the carbon in the various samples. Since the anodes are formed by extrusion in a lengthwise direction, there should be some difference in carbon density in various locations in the anode, and some pore orientation should occur in the lengthwise direction. This in turn could be expected to result in a lower specific resistance of carbon lengthwise than across the anodes, the latter applying to this experiment. In addition, the National Carbon Company has measured air permeabilities twice as great in the lengthwise as in the transverse direction. Twenty-eight blocks, nominally 1 x 1 x 2 in., were cut from each of two anode blades, half lengthwise, as National Carbon measured resistance, and half transversely, the ends being the normal contact area. They were each placed in the press between pressure plates in the normal manner and resistance measured between two scribe marks, 1 in. apart. Exact dimensions were measured with a micrometer calipers. Values for transverse specific resistance varied from 1600 to 2100 μ ohms/in.^{3} with an average of 1810 μ ohms/in.^{3}. Standard deviation was approximately 100 μ ohms/in.^{3}. With samples cut in the lengthwise direction, variation was similar but the average value of specific resistance was 1190 μ ohms/in.^{3}. This was somewhat lower than that obtained by National Carbon Company. In view of the large variation between samples, the specific resistance was measured for each block and this value used in calculating contact resistance.

Several samples were loaded over a range of pressures from 600 to 5000 psi. Pressure was increased by 400-lb increments up to 5000 lb and then decreased by the same increments back to 600 lb, 5000 psi approaches the compressive strength of carbon and should be avoided for design purposes. The plots of contact resistance vs. pressure were found to approximate straight lines on a log-log graph, although the slopes were slightly smaller for the unloading curves. These plots are shown in Fig. 3.

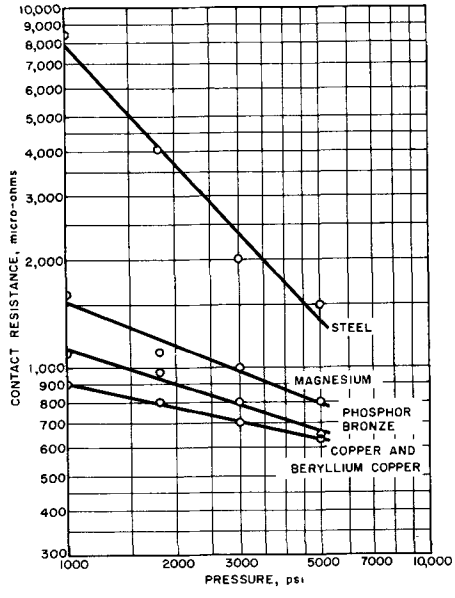

Fig. 3. Contact resistance as a function of pressure

It can be seen that, while the steel-carbon contact resistance decreases rapidly when pressure increases, it never approaches the copper-carbon contact resistance and is greater than the contact resistance of any of the other metals tested.

It has been proposed that the measured contact resistance in newly assembled cells might give some indication of the expected performance of the cell. Since humidity of the anode storage and assembly environment is one factor that is not controlled, a test was made to determine the contact resistance-pressure function of anode material which had been oven dried as compared to that which had been stored for some time in an atmosphere at 100% humidity. Some samples were dried for 165 hr at 210°C, while others were stored for 96 hr in a desiccator containing a wet sponge. When tested with both copper and steel no significant difference in contact resistance was found between dried samples, those which were in equilibrium with the laboratory atmosphere, and those stored at 100% humidity.

In the cell, the carbon metal contact is exposed to a mixture of fluorine and hydrogen fluoride gases, as well as to the liquid electrolyte which may enter the joint through capillary action in the somewhat porous carbon anode.

With the experimental set-up used it was impossible to expose the contact to a fluorine atmosphere while under pressure. The metal plates, however, were fluorinated for 48 hr with 100% fluorine at 100°C. The metal plates were then removed and contact resistance against carbon determined as before. Care was exercised that the fluorinated layer was undisturbed. Results are shown in Table I.

The increase in contact resistance was negligible for beryllium-copper, a factor of approximately three for copper and magnesium, and a factor of five for phosphor-bronze. Contact resistance for steel could not be measured with the normal equipment and was found to be greater than 20 megohms when measured with a conventional ohmmeter. It must be noted that the fluorination was done with dry fluorine which contained no hydrogen fluoride. Fluorination in a cell might not affect the micro-areas of the metal actually in contact with carbon. However, the extreme insulating value of the fluoride layer on steel indicates that this metal is of doubtful value as a contact material in a fluorine cell.

Table I. Contact resistance-pressure values for carbon-fluorinated metal

Pressure psi	Steel megohms	Contact resistance in micro-ohms/in.^{2} Mg	Phosphor-Bronze	Cu	Be-Cu
1000	>20	3560	4830	2330	900
1800	>20	2440	3170	1610	683
3000	>20	1760	2260	1140	575
5000	>20	1230	1600	858	517

The resistance-pressure relationship for any metal has the general equation:

$$R = a P^m$$

where R is contact resistance, a, a constant, P, pressure, and m, slope of log-log plot. Both a and m are different for each metal.

From the results it is apparent that the largest unit pressure possible, applied uniformly over the contact surfaces, results in the lowest contact resistance. The use of copper alloys and magnesium result in lower contact resistance than does the use of steel. Copper contact plates have been used for at least fifteen years and the tests confirm the suitability. Steel appears to be of doubtful value in this application.

Manuscript received May 16, 1958. The work on this paper was performed under Contract AT-(33-2)-1 with the U. S. Atomic Energy Commission.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Technical Review

Electrodeposition of Powders for Powder Metallurgy

C. L. Mantell

Department of Chemical Engineering, Newark College of Engineering, Newark, New Jersey

ABSTRACT

A very large number of articles are made by powder metallurgical methods from electrolytically reduced powders. In powder production, cathode current densities are much higher than those of refining; loosely adherent deposits are produced. These are dried, surface oxides removed, and classified by screening. Important electrolytic powders are those of copper, iron, nickel, zinc, some alloys, as well as duplexes. Operating details are reviewed.

Metal deposited at the cathode varies widely in its characteristics, depending on the electrolyte itself, the ions present, and operating conditions. Silver deposited from a solution of $AgNO_3$ forms large, readily visible crystals. Tin from a solution of $SnCl_2$ will form long needles which may rapidly "bridge" from the anode to the cathode. Lead from a chloride or acetate solution gives crystals different from those from a chlorate or perchlorate electrolyte. Nickel deposits from a sulfate bath are hard and may be polished but not with ease, while nickel from a naphthalene sulfonate gives bright deposits needing little if any polishing.

In plating, efficiency of utilization of electrical energy is secondary to quality. High current and energy efficiencies may be sacrificed without upsetting the economics of the operation. Particularly where thermal or chemical processes compete, power cost in refining is a major item; maximum current and energy efficiencies are vital. In electroforming, of which metal powder production is a form, conditions approach refining to a far greater degree than plating, as the procedures compete with thermal and mechanical disintegration procedures.

The nature of the electrolyte, its pH, metallic ion concentration, anodic and cathodic current density, temperature, the simplicity or complexity of the metallic ion including its primary and secondary ionization, as well as the presence of modifying or "addition" agents, have effects on the character of the deposit.

The crystalline structures of cathode deposits may be classified as follows:

Group I. The initial nuclei or crystals continue to grow throughout the deposit forming (*A*) isolated crystals: which are (*a*) symmetrical or (*b*) acicular; or giving rise to (*B*) contiguous crystals: which may be (*a*) columnar or (*b*) fibrous.

Group II. Part of the initial nuclei or crystals continue to grow. These are (*A*) conical ("normal") or (*B*) twinned.

Group III. The nuclei or crystals do not grow for any extended period. Their shapes are (*A*) broken (compact), or (*B*) arboreal, sometimes called "fernlike" ("treed"), or (*C*) powdery (spongy), and (*D*) slimelike.

If any addition which would increase the cathode polarization be made to the solution, the number of crystal nuclei increases. The current densities may be increased, and the effective metal ion might be decreased in the film or thin layer of solution adjacent to the cathode by (*a*) diluting the solution; (*b*) decreasing the temperature, which in turn reduces diffusion and convection; (c) adding a salt having an ion common with those already present; (*d*) introducing a colloid; (*e*) increasing the viscosity of the solution; and (*f*) causing the formation of complex ions. These factors increase the difference in cathode potential, the number of crystal nuclei, and the production of fine-grained deposits.

Dissociation, ionic migration, diffusion, and convection, particularly at the surface of the cathode, replenish the metal ion concentration. Growth of existing crystals may be favored by acceleration of these factors. The tendency of metals such as silver and lead, when deposited from nitrate solutions, to form isolated crystals is partly the result of the relatively large change in density of the solution produced by the removal of the metal. The effects of various factors upon the structure of deposits are summarized in Table I.

Decreasing the metal ion concentration decreases the size of the crystals. Fine-grained, bright, or hard deposits are produced at low temperatures, while increase of temperature causes coarse or soft deposits. The effects of increases of current density and

Table I. Direction of effects on structure of deposits

Change in operating condition	Change in structure group*
Increase metal salt concentration	III → II → I
Increase metal ion concentration	III → II → I

Elevate temperature	III → II → I
Increase conductivity of solution	III → II → I
Add colloids to solution	I → II → III
Increase viscosity of solution	I → II → III
Increase current density	I → II → III

* Groups as described above in the text.

temperature are in opposite directions. Therefore, it is possible to obtain fine-grained deposits in warm solutions at a high current density. Addition of colloids in more than small amounts, increase of viscosity, and increase in current density tend in the direction of broken crystals, arboreal, or powdery electrolytic precipitates.

Deposited metal powders are represented by the Group III type of crystals. They are "poor" electroplates. Powder production is favored by low metal concentration, low metal ion concentration, unagitated solutions, low temperatures, solutions of low conductivity, addition of colloids, increases in viscosity, and marked increases in current density. The effect of each variable is not of the same order of magnitude; the effects are cumulative and interdependent; changes in concentration may be of greater importance than variation of temperature; vigorous agitation may offset the effect of increase of current density.

Electrolytic powders of commercial importance are of two varieties. Loose crystals may be formed in the cells as nonadherent powders, or the powder may result from grinding relatively hard, brittle, partially coherent deposits. Examples of the first class are Cu, Zn, Ni, Ag, and Pb; of the second Fe and Mn. These will be briefly described from the viewpoint of their production. While electrolytic Zn, Ni, and Pb powders are interesting, they are commercially unimportant in that powders of these metals are the result of other methods; industrially only electrolytic Cu, Fe, and Mn command markets. Silver crystals are the conventional result of electrolytic refining. Disintegration converts them to a powder.

The powders all command "shape" premiums in price over ingot metal or cathode chip of the same purity.

In practice, cathode current densities are higher than those of refining, so that loosely adherent spongy deposits which are periodically removed by scraping or tapping devices or by electrolyte circulation may be produced. In the case of Cu powder, acid electrolytes of lower metal and higher acid concentration than those used for refining or plating are preferred. When operated at high cathode density and with hydrogen evolution, the finely divided metal crystals often have a fernlike appearance under the microscope. It is necessary to remove the cathode frequently; otherwise the effective area of the deposit is increased to such an extent that the current density is lowered and coarse deposits formed.

The fineness of the powder may be varied over a considerable range by changes in the composition, temperature of the electrolyte, and variation of the cathode current density, as well as by the introduction of addition agents, reducing compounds, or substances which are cathodically reduced and anodically oxidized but are not plated out. Cathode current densities are different from those at the anode, usually higher. The deposited powders are washed, dried in inert or reducing atmospheres, and cooled to room temperature.

Copper

French electrolytic copper powders were produced through the addition of colloidal materials, such as H_2SO_4-treated glucose, for example, to the electrolyte (1). The colloid was thought to make possible the production of extremely fine powders with the elimination of hydrogen evolution at the cathode and higher current efficiencies. American production of copper powder made the material in modified refining tanks from selected regular anodes and smooth copper cathodes.

Large quantities of industrial Cu powders are electrolytic. They are made by electrodeposition using a soluble anode and a nonattackable cathode. The electrolytic step transforms solid Cu into discrete, finely divided particles of controlled and reproducible characteristics. Since high purity is essential, the anodes are electrolytically refined Cu. Large-scale attempts to use anodes of lower purity so that refining and powder formation could be combined have been commercial failures because of the wide variations in the characteristics of the end product. Insoluble anodes have been investigated, but have not proved commercially feasible for the production of high-grade Cu powders.

The cathodes are lead alloy sheet. Silicon-iron, briquetted iron oxide, various stainless steels, magnetite, and graphite, have not been satisfactory.

The electrodes are arranged in parallel in lead-lined or rubber-lined tanks, and are frequently inspected as in refinery practice for irregularities to insure uniform current density and elimination of short circuits in the cells.

In contrast to the copper refining practice, electrolysis is carried out at current densities from 5 to 10 times higher, at lower temperatures and low concentrations, and low circulation. By control at various levels, marketable copper powder is produced varying from 1.5 to 3.5 g/cm^3 in apparent density and from 30 to 98% minus 325-mesh in particle size. The widely differing demands of powder metallurgy make this necessary.

Copper deposits as discrete particles at the cathode and is collected at the bottom of the cell, or as a loosely adherent deposit which may be lifted from the cell and washed off the cathodes. Periodically the sludge is removed, filtered, and washed free of electrolyte. The large surface area and activity of wet Cu powder make thorough washing and immediate drying essential to avoid oxidation of the Cu particles.

The powder is dried in controlled-atmosphere, continuous furnaces. Reducing conditions are main-

tained to remove surface oxides. The furnaces are operated at 315°-760°C (600°-1400°F) in atmospheres of 10-30% hydrogen and 5-20% carbon monoxide. Furnace conditions are closely controlled. Excessive fritting or sintering of the powder into a ductile mass must be avoided.

The discharge from the furnaces is fed to high-velocity impact mills to break up clusters without excessive cold working and hardening. Powder which is milled too lightly will contain a high percentage of agglomerated fines. Powder milled too heavily will contain flakes, roughly spherical, or cold-worked particles which will destroy its compacting qualities.

Size fractionation is by screening and air separation. The various fractions are stored in airtight, dessicated containers. Blending of the various fractions produces desired types of powder.

Lead

Mantell described the preparation of Cu-coated Pb powder using an acetate electrolyte with Cu and Pb anodes and Ni cathodes at cathode current densities of 18 amp/ft^2 at a power consumption of 1.5 kwhr/lb of 200-mesh powder containing 60% Cu and 40% Pb (2). These have been used for bearings whose operating temperatures may exceed the melting point of Pb. No lead "bleeding" results.

Zinc

Electrolytic zinc powder is made from flue dust with a caustic leach liquor and an electrolyte of sodium hydroxide and sodium zincate. The product shows a typical fern-leaf appearance of sizes 45-60 μ long. Zinc dust is employed as a reducing agent in the manufacture of hydrosulfites and in the preparation of organic compounds. Commercial operating data of a plant employing hollow magnesium alloy cathodes are given in Table II.

Nickel

Electrolytic Ni has been made by Mantell (3) employing an NH_4Cl electrolyte whose pH was adjusted by means of NaOH, using Ni anodes and cathodes. Operating details are given in Table II.

Lead

The inter-relation of operating conditions in producing lead powder was shown by Crownover (4) who found: "Spongy deposits were formed at lead concentrations between 7.23 and 16.2 oz per gal and free HBF_4 concentrations between 51.5 and 27.6 oz per gal at current densities ranging from 1,325 to 177 amp per sq ft for 2 minute deposition periods. Particle size increased with increasing time of deposit and decreasing current density. Dendritic growths formed on the edge of the cathodes at current densities between 257 and 835 amp per sq ft and electrolyte concentrations of 16.6 to 28.1 oz per gal lead and 27.6 to 12.4 oz per gal free HBF_4 for deposition periods of 4 to 30 minutes. Easily removable powdered lead could not be produced at current densities between 299 and 835 amp per sq ft when the electrolyte contained 28.1 oz per gal lead and 12.4 oz per gal free HBF_4. A firm adhering deposit formed on the cathode at a current density of 1,100 amp per sq ft. No difference was noted in the use of copper, carbon steel or stainless steel for cathodes."

Electrode spacing	1.18 in. (30 mm)	1.5 in.
Final product, % metal	Paste 35-45 Zn, dry dust 85-95	98-99

Iron

Electrodeposition of iron dates back to 1846 when Bottger used a bath of $FeSO_4 \cdot 7H_2O$ and NH_4Cl. Bietz in 1869 produced electrolytic Fe and employed it for making magnetic tests. Siemens (5) in 1889 proposed a general process in which sulfide-iron minerals were leached with ferric chloride or sulfate, the Fe deposited from the leach liquors on a cathode in a diaphragm cell, and the leach regenerated. The first serious attempt to produce electrolytic Fe in quantities was in 1904 (6), when the metal was deposited from a mixture of ferrous and ammonium sulfates at a current density of 6-10 amp/ft^2 (0.65-1 amp/dm^2) at 30°C and an average emf of 1 v. In the plant of the Western Electric Company (7) the anodes were cast steel and the bath carried slightly on the alkaline side so that a considerable amount of oxides would be deposited in the cathode to make the latter brittle and easily ground up in connection with the manufacture of electrical "loading coils." It was not necessary to make a pure grade of Fe. A further modification of the Burgess process was used by the Westinghouse Electric & Manufacturing Company (8) in which a pure grade of Fe was produced for use in the manufacture of alloys for electromagnetic machinery and instruments. Commercially pure Fe anodes were used, but the refining range of the process was very small. Cathodic products would often be produced which were too high in either C or S or both.

In 1914 an electrolytic iron plant was installed at

Grenoble, France (9), in which a hot neutral solution of ferrous chloride was employed as an electrolyte to which iron oxide was added as a depolarizer, with cast-iron anodes and rapidly rotating mandrels for cathodes. Both tubing and plates were produced of electrolytic Fe of good purity, showing Fe 99.967%, C 0.008%, Mn 0.009%, P 0.002%, Si 0.014%, S trace (10). In commercial operation the electrolyte was circulated over Fe turnings, and iron oxide was added; or else air was blown in to keep the H^+ ion concentration of the solution low. Current density was 93-105 amp/ft² (10-11 amp/dm²) at a temperature of 80°C. The small hydrogen content of the metal was removed by annealing at 900°C. Power requirements were of the order of 1.8 kwhr/lb.

A bath used in Germany, originated by Fischer (11), contained 450 g $FeCl_2$, 500 g anhydrous $CaCl_2$, 750 g water, operated at 90°-110°C at 93-185 amp/ft² (10-20 amp/dm²). Owing to the high working temperature, the Fe deposited is relatively free from hydrogen and is therefore not brittle. It has a purity of at least 99.95% and can be deposited in thick, dense layers.

With the development of powder metallurgy, a demand for Fe powder arose. Part of this is met by electrolytic iron made by Plastic Metals of Johnstown, Pa. The operating conditions are tabulated in Table III (12).

Manganese

Manganese powder is the product of grinding electrolytic "cathode chip" metal in ball mills in nitrogen, helium, or argon atmospheres with particular care to keep temperatures low because of the pyrophoric nature of the powder. More recently Mn powder has been made successfully on crushing rolls. Manganese powder finds tonnage applications in welding rods and coatings therefore, as well as magnetic materials.

Manganese is electrowon from reduced ores or equivalent Mn containing materials which are

leached with return electrolyte, which when purified becomes cell feed (13). Operating conditions are given in Table III.

In the preparation of electrolyte from which the metal is deposited, the solution is purified completely of Fe, As, Sb, Sn, Pb, Ni, Co, Mo, SiO_2, Al; Ca and Mg are also removed. Diaphragms are around the cathodes, and the anolyte fills the cell around the diaphragms.

The electrowinning of Mn depends on very pure solutions. In addition, there is dependence on the combination of factors such as concentration, pH, temperature, current density, cathode and anode material, rate of flow to the cells, as well as other variables. Problems of dealing with an alkaline catholyte and an acid anolyte in a two-compartment cell, as well as the impossibility of considering any of the variables separately because of their influence on each other, cause Mn electrowinning to be almost in a class by itself. It demands much more delicate control than does the electrowinning of Zn and Cu, for it carries all their problems and many more.

Brief Communication

On the Hydrogen Evolution Reaction

Ralph J. Brodd

National Bureau of Standards, Washington, D. C.

Theoretical calculations of the rates of electrochemical reactions have been the subject of many publications. Most treatments in recent years involve the assumption of an activated complex and suffer in that the energy terms for the activated complex cannot be evaluated accurately. In the case of electrode reactions it would appear that a promising line of approach to take would involve the assumption that the charge transfer at the electrode occurs by a tunneling process and that this tunneling process is the controlling factor in the rate of the reaction (1).

Kinetic theories of the hydrogen evolution reaction usually assume that the initial reaction step at an elecrode is

$$H^+ \text{ (sol'n)} + e \underset{M}{\rightarrow} H \qquad [1]$$

It can be shown that the rate of this reaction may be approximated from (1) by

$$\text{rate} = \Gamma \exp(-\Delta U/kT) \qquad [2]$$

where

$$\Gamma = \exp\left[-\frac{(2m)^{1/2}}{h}(\phi)^{1/2} R\right] \qquad [3]$$

and

$$\Delta U = \phi - E_a - \frac{e^2}{4R} + (E_{zpc} + \chi) \qquad [4]$$

In these equations e, h, k, m, and T have their usual significance. ϕ is the work function of the metal electrode, E_a is the electron affinity of H^+ in Eq. [1], E_{zpc} is the potential of the hydrogen electrode vs. the zero point of charge, χ is the surface potential for hydrogen adsorption on the metal, and R is the distance of approach of hydrogen ions to the surface of the metal when the charge transfer occurs. R is assumed to be 0.49Å, the average of the Goldschmidt and Bohr radius of the hydrogen atom.

In Table I are found the results of calculations

Table I. Calculated and experimental rates of hydrogen evolution reaction

Metal	Cal'd. rate, amp/cm²	Expt'l. rate (2), amp/cm²
Hg	5.8×10^{-13}	2×10^{-12}
Ni	2.5×10^{-4}	1×10^{-6}
Cu	2.5×10^{-7}	2×10^{-7}
Ta	7.2×10^{-6}	1×10^{-5}

of the rates of the hydrogen evolution reaction at the reversible potential, and H^+ (sol'n) concentration of unity. Experimental rates of the hydrogen evolution reaction at approximately the same conditions are given for comparative purposes.

The table shows that the calculated and experimental values are in fairly good agreement. Since the calculated values are very sensitive functions of R, E_{zpc}, and χ, as seen in Eqs. [3] and [4], the agreement is fortuitous in some cases.

The following model may be associated with the process given in Eq. [1]. The metal electrode is assumed to be a perfect conductor. The electron from the metal electrode moves through an energy barrier at the surface of the electrode described by the Γ function in which the barrier height is ϕ and the barrier width is R. Then, at distance R from the electrode the electron combines with a proton from the hydrogen ion solvation complex in the electrical double layer to form a hydrogen atom. A somewhat similar model in principle has been proposed by Gurney (3).

Manuscript received Aug. 22, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Zinc-Mercuric Dioxysulfate Dry Cell

Samuel Ruben

Ruben Laboratories, New Rochelle, New York

ABSTRACT

A dry cell is described which provides some of the desirable characteristics of the mercuric oxide alkaline cell while allowing the use of inexpensive conventional dry cell construction. The system is $Zn/ZnSO_4/HgSO_4 \cdot 2HgO + C$ and has an over-all reaction of $3Zn + HgSO_4 \cdot 2HgO \rightarrow ZnSO_4 + 2ZnO + 3Hg$. A relatively flat discharge characteristic is obtained within the proper limits of current density. The cell capacity is directly referable to the $HgSO_4 \cdot 2HgO$ or $3HgO \cdot SO_3$ content.

The alkaline mercuric oxide cell (1-3) possesses a number of characteristics, particularly for specialized use such as military applications where compactness, long shelf life, and storage at high ambient temperatures are necessary. It is used in commercial applications requiring cells of high capacity in small dimensions such as in hearing aids and other miniaturized electronic devices. One specific characteristic of this system, the maintenance of a flat discharge voltage and low impedance during discharge, has been of particular advantage in transistor applications.

An electrochemical system has been developed which is suitable for many applications and which combines some of the desirable discharge characteristics of the mercuric oxide cell with the low cost structure of the Leclanché zinc-carbon cell.

In the past, attempts have apparently been made (4) to use mercury compounds in the cathode of a nonalkaline dry cell, but these have failed because of inherent limitations of the materials used.

Zinc-Mercuric Dioxysulfate Cell

In the new cell, which might be termed the Mercury-Zinc Carbon Cell, the cathode reactant is a basic mercurial compound, such as mercuric dioxysulfate, and the electrolyte is a zinc sulfate solution in which the cathode is stable. The anode is zinc. The combination permits conventional zinc carbon cylindrical and flat cell constructions.

The electrochemical system in the presence of an aqueous solution of zinc sulfate can be expressed as

$$Zn/ZnSO_4/HgSO_4 \cdot 2HgO + C$$

with an over-all reaction on the discharge as

$$3Zn + HgSO_4 \cdot 2HgO \rightarrow ZnSO_4 + 2ZnO + 3Hg$$

In addition to the reactive components it is desirable to add a buffer agent to raise and maintain the *p*H of the electrolyte in the desired range to reduce the solubility of the mercuric dioxysulfate to a minimum. Various buffers have been used, such as the addition of calcium carbonate to the cathode mix or the addition of acetate to the electrolyte, to maintain the *p*H in the range of 5 to 6.

An inhibitor such as potassium dichromate is added to the electrolyte to inhibit continued amalgamation of anode by the slight amount of active cathode material in solution. The cathode is spaced from the anode by a paper cellophane laminate processed to provide barrier action and control of electrolyte transfer.

Construction of the Cell

The dry mix is composed of 8 parts mercuric dioxysulfate and 1 part acetylene black.

The electrolyte consists of a 20% solution of $ZnSO_4 \cdot 7H_2O$ to which 1% of $K_2Cr_2O_7$ is added. The electrolyte is added to the dry mix in the proportions of 1 part electrolyte to 2 parts dry mix.

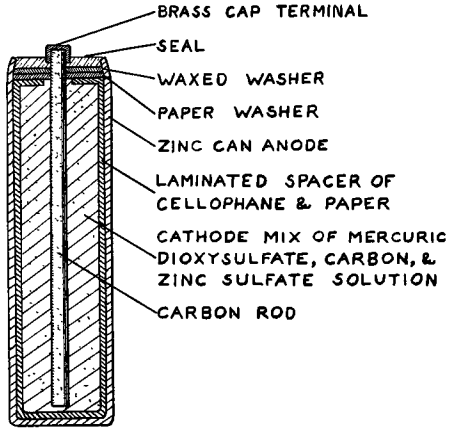

Fig. 1. Construction and components of the zinc-mercuric dioxysulfate cell.

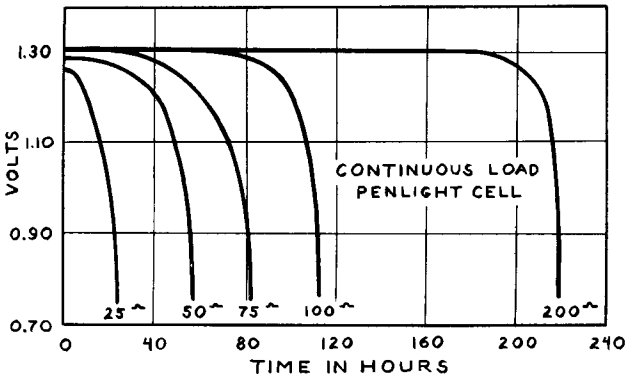

Fig. 2. Discharge characteristics of an AA-size cell discharged continuously at loads of 25, 50, 75, 100, and 200 ohm.

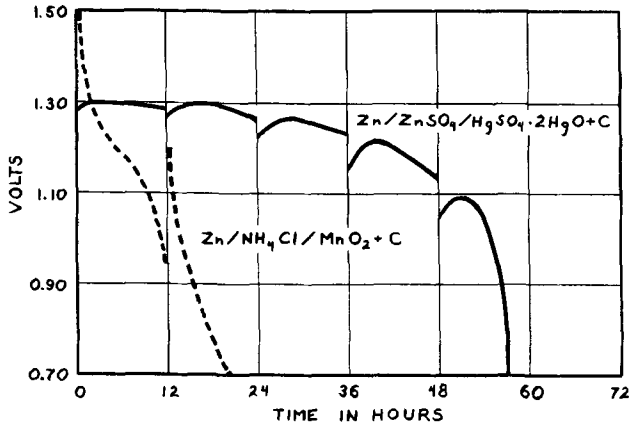

Fig. 3. Discharge characteristics of an AA-size cell discharged at 50 ohms 12 hr/day.

The zinc can is lined with a spacer which consists of a laminate of 0.004 in. paper and 0.0009 in. cellophane cemented together and coated with an aqueous glycerine gum arabic solution. The paper side of the laminate contacts the zinc can.

No free space is incorporated in the cell since there is negligible expansion of the bobbin during use. The top edge of the zinc can is rolled over and the space between the rolled edge and waxed washer on top of the bobbin filled with sealing compound. This gives a secure top seal and holds the bobbin in intimate contact with the lined can. The can thickness is about 0.004 in. greater than used in standard zinc-carbon cells to allow higher capacity without puncture at end of life.

Freshly made cells have an open-circuit voltage of 1.45 v. This stabilizes with initial use or on shelf to 1.36 v. The closed circuit potential has 1.3 v for loads within the rated current density.

Due to the high efficiency of the cathode mix, the capacity per unit volume exceeds that of the conventional zinc-carbon cell and is directly referable to the $HgSO_4 \cdot 2HgO$ content. The theoretical capacity of the $HgSO_4 \cdot 2HgO$ is approximately 0.22 amp-hr/g and the practical capacity, 0.21 amp-hr/g. Cells connected to a gas collecting apparatus and maintained at 45°C (113°F) have shown negligible gas evolution over several months tests.

Electrical Characteristics

Figure 1 illustrates the construction and components of the cell.

Figure 2 illustrates the discharge characteristic of AA (penlight) size cells discharged continuously through resistances of 25, 50, 75, 100, and 200 ohms.

Figure 3 illustrates the discharge characteristics of AA (penlight) size cells discharged intermittently 12 hr per day through a resistance of 50 ohms. Similar discharge of a commercial Leclanché cell of the same size is included for comparison.

Figure 4 illustrates the discharge characteristics of AA cells after 8 months' casual storage.

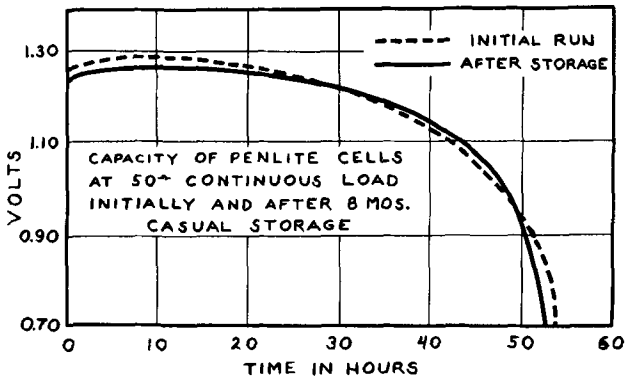

Fig. 4. Discharge characteristics of AA cells after 8 months' casual storage.

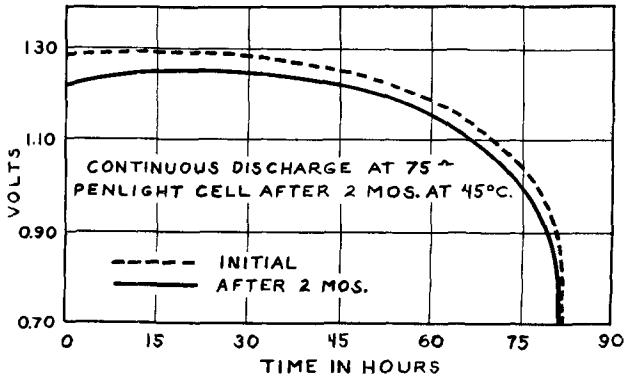

Fig. 5. Discharge characteristics of AA-size cells after 2 months' storage at 45°C (113°F).

Figure 5 illustrates the discharge characteristics of AA-size cells after two months' storage at 45°C (113°F).

The initial impedance of an AA-size cell at 1000 cycles is eight-tenths ohms and the impedance after continuous discharge is one ohm. On intermittent loads the impedance is higher at the start of each cycle and decreases to the normal value.

The weight of an AA-size cell constructed with a capacity of 1360 ma-hr is 20 g.

In summary, the new cell described has some desirable characteristics where a low current discharge is required over long periods of time with a flat voltage output. One such application has been for electronic clocks where D-size cells have been operating for a year with a total capacity of 8.0 amp-hr.

The Potential of the Manganese Dioxide Electrode and the Surface Composition of the Oxide

Akiya Kozawa[1]

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Nagoya, Japan

ABSTRACT

When manganese dioxide is heated, the electrode potential decreases with the heating temperature. This potential decrease cannot be explained as a phase transformation nor as an ordinary decomposition of MnO_2 to Mn_2O_3. A lower oxide film is formed on the surface of MnO_2 when it is heated at temperatures up to 450°C. The potential decrease on heating can be explained as the result of the lower oxide film formation, the potential of manganese dioxide depending on the surface oxidation state. The reaction of Mn^{++} in slightly alkaline electrolyte with MnO_2 gives a similar decrease in potential explainable as a surface effect.

When a MnO_2 electrode is discharged the potential decreases gradually as reduction takes place to a lower oxide such as Mn_2O_3 (or MnOOH) or to Mn^{++} ion. To understand the potential decrease, we must know what factors determine the electrode potential.

The potential of the MnO_2 electrode in neutral or alkaline solution free from manganese(II) ion may be expressed by

$$E = E^\circ - 0.059\ pH - \frac{RT}{2F} \ln \frac{a_{Mn_2O_3}}{(a_{MnO_2})^2} \qquad [1]$$

$$E^\circ_{red} = 1.014$$

corresponding to the reaction

$$2MnO_2 + 2H^+ + 2e = Mn_2O_3 + H_2O \qquad [2]$$

However, the potential seems to be dependent on the composition of the oxide surface rather than on the activities of two separate phases in neutral electrolyte (2). In this paper the effect on the potential of alteration of the surface composition of MnO_2 by heating at moderate temperatures and by the adsorption of Mn(II) ion is considered. Heating at 100°-450°C affects the potential, the discharge capacity, and the water content (2-5) although the decomposition temperature is higher than this, 480°-580°C for different kinds of manganese dioxide. The decrease in potential on heating has been ascribed to a change in crystal form (5).[2] The experiments to be described lead to a different explanation, namely, that the change in potential is the result of loss of oxygen at the surface.

[1] Present address: Department of Chemistry, Western Reserve University, Cleveland, Ohio.

[2] The idea that different phases of manganese dioxide may have different potentials can be tested by calculating the approximate free energy difference between γ-MnO_2 and β-MnO_2 using the decomposition temperature of MnO_2 to Mn_2O_3 at 1 atm pressure. The decomposition temperature is measured as 480°C for γ-MnO_2 and 580°C for β-MnO_2 from the author's thermal balance experiments, which can be seen to be the starting point of the decomposition in Fig. 1. From the Nernst approximation formula $\log P_{O_2} = \Delta H/4.579T + 1.75 \log T + 2.8$, ΔH is calculated for each MnO_2, then the potential difference $\Delta E = (\Delta H_{480} - \Delta H_{580})/4F + T(\Delta S_{480} - \Delta S_{580})/4F$ is obtained, where the second term is neglected. The results shows γ-MnO_2 should be 44 mv higher than β-MnO_2 in potential. The 44 mv is too small to explain the potential decrease (about 250 mv) on heating.

Experimental

Preparation of oxides.—An electrolytic oxide, presumably γ-MnO_2, was prepared by electrodeposition from an acid bath at 97°-98°C with a current density of 1.74 amp/dm². Initially the bath was 0.85 mole/l $MnSO_4$ and 0.03 mole/l H_2SO_4 and at the end 0.48 mole/l $MnSO_4$ and 0.51 mole/l H_2SO_4.

Figure 1 gives the result of a differential thermal analysis of this MnO_2 along with one of natural pyrolusite. The electrolytic oxide was ground to pass through a 100-mesh sieve. The powdered sample was washed with hot 2*N* H_2SO_4 several times, then several times with water, and finally with very dilute ammonia solution. It was dried at 80°C for 10 hr. Samples of this oxide, of the oxide before washing, and of a natural pyrolusite were heated at various temperatures from 160° to 438°C for 1 hr in an electric furnace in air.

Some of the γ-MnO_2 was heated to constant weight at 800°C. The resulting oxide was shown by analysis to be Mn_2O_3.

Potential of heated MnO_2.—The potentials of the heated oxides were measured as follows. A 1.00-g sample of each oxide was placed in 50 ml of 2M NH_4Cl and NH_3, pH 8.35, in an Erlenmeyer flask, shaken occasionally for 3 hr, and then digested overnight at room temperature. The mixture was cen-

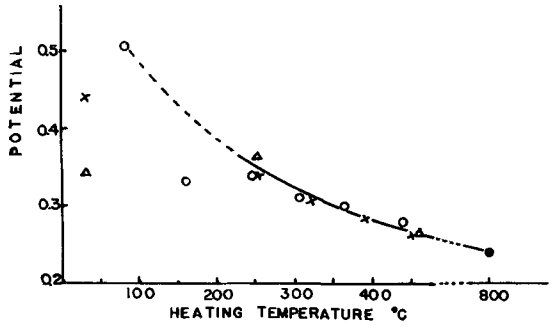

Fig. 2. Potentials, corrected to pH8, vs. saturated calomel electrode of heated manganese dioxides. O, electrolytic MnO_2 washed with H_2SO_4, X, electrolytic MnO_2 not washed; △, natural pyrolusite (β-MnO_2); •, Mn_2O_3 made from the electrolytic MnO_2 by heating at 800°C.

trifuged in a 15-ml centrifuge tube with a narrow bottom. A platinum foil electrode was inserted in the manganese dioxide layer at the bottom of the centrifuge tube. The potential then was measured against a saturated calomel electrode and the *p*H of the solution was measured by a glass electrode *p*H meter.

Results are shown in Fig. 2 for all potentials which were corrected to *p*H 8.0 assuming a change of −60 mv per *p*H unit. It is clear that the potential decreases with heating temperature between 250° and 450°C regardless of the kind of manganese dioxide and of acid washing. Although three different unheated samples gave very different potentials, they came to agreement on heating above 250°C. The potential after heating to 450°C was fairly close to that of Mn_2O_3, although the composition was not much different from that of the original unheated sample, as shown in Fig. 3.

Analysis of the heated MnO_2 was carried out by the $FeSO_4$ method for available oxygen and by the $NaBiO_3$ method for total Mn. The calculated x values in MnO_x, as shown in Fig. 3, decrease with heating temperature from 1.977 to 1.946.

According to Fig. 1 no extensive decomposition takes place below 450°C, and the small change in x-value (in MnO_x) confirms this. Heating at 250°C did not give a continuous change; after 1 hr the x-value (in MnO_x) was 1.965, after 4 hr, 1.963, and after 6 hr, 1.964. Previously (2) heating at 450°C gave a similar result. Maxwell and Thirsk observed

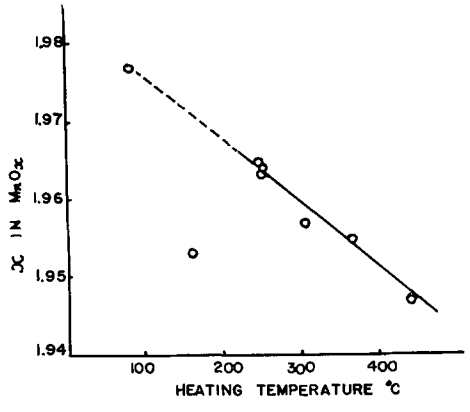

Fig. 3. Results of analysis of electrolytic MnO_2 heated at various temperatures; values of x in MnO_x. Three points around 250°C are for different heating times, 1, 4, and 6 hr.

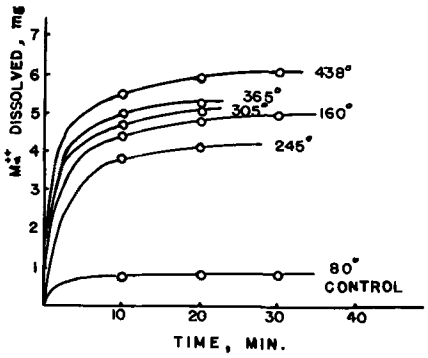

Fig. 4. Manganese (II) ion dissolution from heated manganese dioxide (0.5 g) by 1N H_2SO_4 stirring at room temperature. After 10 min stirring, it was allowed to stand for 5 min which was not counted in the abscissa of this figure. Heating temperatures of MnO_2 are indicated in the figure.

a similar decrease in x value of MnO_2 heated under O_2 atmosphere (6).

The sample of γ-MnO_2 heated at 160° differed in x value, potential, and also in dissolution of Mn^{++} (as shown in Fig. 4) from what would be expected on the basis of the data for the other heated oxides. A similar deviation was observed previously (2). That the deviation is real and not the result of an error is suggested.

Changes on heating can be shown to be the result of the MnO_2 surface. Samples of the heated oxides (of electrolytic origin) of 0.50 g each were mixed with 50 ml of 1*N* H_2SO_4, the mixtures being stirred at room temperature for exactly 10 min. After 5 min, a 5-ml sample of the supernatant solution was taken for Mn^{++} ion determination. The sample was added to 5 ml of 0.01M E.D.T.A. solution and buffer ($NH_4Cl + NH_3$) added to adjust the *p*H at 9 to 9.5. Then the excess E.D.T.A. was titrated with a standard $ZnSO_4$ solution (0.0100M) using Eriochrom Black T as indicator. In this method, small particles of manganese dioxide, if any are present, do not interfere. Then the mixture of MnO_2 and H_2SO_4 solution was stirred again for 10 min and, after 5 minutes' standing, another sample was analyzed, and the whole procedure repeated a third time.

Results are shown in Fig. 4. The unheated original MnO_2 (control in Fig. 4) was washed with 2*N* H_2SO_4 previous to the experiment and gave only a little Mn(II) ion dissolved. Most of the Mn(II) ion dissolves in 10 min.

The larger amount of Mn(II) dissolved from heated MnO_2 may be considered as the result of lower oxide formation on the surface of manganese dioxide by heating. Increase of heating temperature gives an increase in Mn(II) ion dissolved, except that the 160°C curve is out of place, as mentioned above.

The decrease in x-value of the various samples can be compared with the Mn(II) ion dissolved by acid. A decrease in x from 1.977 for the original sample to 1.947 for the sample heated at 438°C corresponds to the reduction of about 3% of the total Mn from Mn(IV) to Mn(II). In the 0.5-g sample treated with acid, 3% of the total Mn, or 8.6 mg, should have been Mn(II) according to the analysis and calculation. The acid treatment extracted 5.9

mg of Mn(II) according to Fig. 4, but this should be corrected by 0.8 mg extracted from the unheated sample, leaving 5.1 mg additional extractable Mn(II) as the result of heating. This is 59% of the total estimated from the analysis.

Another experiment was carried out to confirm the lower oxide formation on the surface of MnO_2 using three kinds of MnO_2: γ-MnO_2 or electrolytic MnO_2, α-MnO_2 or cryptomelane made from the electrolytic MnO_2 by autoclaving with NH_4Cl solution at 170°C (7), and β-MnO_2 or natural pyrolusite. Two grams of each sample heated at various temperatures for 3 hr were shaken with a $MnSO_4$ solution buffered with acetic acid-sodium acetate (*p*H, 5.4), then the supernatant solution was analyzed to determine the adsorption of the divalent manganese ion on the manganese dioxide. Results are shown in Fig. 5. The absolute value of the Mn(II) ion adsorption should be affected by the surface area and the original surface oxidation state of the manganese dioxides. However, the results show that the higher the heating temperature the smaller is the adsorption. This means the more of the lower oxide on the surface the less of a reaction between MnO_2 and Mn(II) ion to form the lower oxide, $MnO_2 + Mn^{++} \rightarrow Mn_2O_3$.

From the above results it seems possible to conclude that the potential decrease of heated manganese dioxide is the result of lower oxide formation on the surface, and also that the potential of manganese dioxide depends mainly on the surface oxidation state.

In an electron diffraction study of manganese dioxide, Butler and Thirsk (8) found a lower oxide on the surface of manganese dioxide, but they pointed out that it may have been formed there by the bombardment with electrons.

Potential change on heating various MnO_2 *samples.*—Samples of four oxides: B, electrolytic MnO_2 or γ-MnO_2; A, sample B treated by Na_2CO_3 solution for dry-cell use; C, natural ore, probably α-MnO_2; D, natural pyrolusite or β-MnO, were heated at various temperatures for 3-4 hr. Then 5.00 g of each sample was digested with 25 ml of 0.5M NH_4Cl solution for 5 days at 25°C with occasional shaking. The potentials and *p*H values of the solutions were measured as described before. Results are shown in Fig. 6. On heating below 250°C no regularity was found between the *p*H and the potential, and those points are omitted from Fig. 6. However, above 250°C a straight line relationship for each temperature was obtained between *p*H and potential irrespective of the kind of manganese dioxide, and the slope was near the theoretical 0.059 v per *p*H unit.

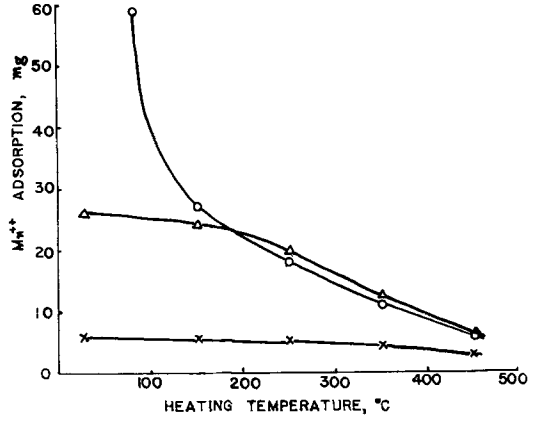

Fig. 5. Adsorption of Mn^{++} on MnO_2 heated. o, γ-MnO_2; △, α-MnO_2; x, β-MnO_2. 2-g sample was shaken with 50 ml of NaAc-HAc buffered solution containing $MnSO_4$ (100 mg as Mn^{++}), pH 5.4.

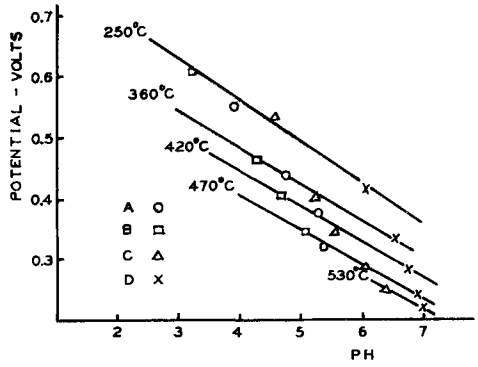

Fig. 6. Potentials of various MnO_2 samples after heating. Potentials were measured against a 0.1N calomel electrode. A, B, γ-MnO_2; C, probably α-MnO_2; D, β-MnO_2.

This result can be interpreted in terms of a surface layer of lower oxide. Originally each of the four samples had its individual surface oxidation state, so there was no consistent relation between the potentials of different samples and the *p*H. However, on heating at 250°C or higher the surface attains the same oxidation state for all, determined only by the temperature and irrespective of the original surface oxidation state, crystal structure, and chemical composition of the interior of the crystals.

Potential of MnO_2 *with a known amount of lower oxide on the surface.*—MnO_2 reacts with Mn(II) ion in a solution of suitable *p*H as follows:

$$MnO_2 + Mn^{++} + H_2O \rightarrow Mn_2O_3 + 2H^+ \qquad [3]$$

and the lower oxide (Mn_2O_3 or MnOOH) will remain on the surface of the MnO_2. When MnO_2 having a known surface area reacts with a known amount of Mn(II) ion, we can calculate the percentage of surface covered by the lower oxide. Therefore, a quantitative relation between the electrode potential and the surface oxidation state can be established. Some experiments were carried out to examine this point of view.

Powdered MnO_2 made by electrodeposition was washed with 2*N* H_2SO_4 several times to remove lower oxide and then washed with water and dried at 80°C. The sample had a surface area of 60 m^2/g as measured by the B.E.T. method by N_2 adsorption at liquid nitrogen temperature. Samples of 1.50 g were treated with 50 ml of 0.5M NH_4Cl containing varying amounts of manganese sulfate (0-180 mg of Mn^{++}). The *p*H of the solution was adjusted to around 8 by addition of NH_3. The mixtures were heated at about 70°C for 1 hr with occasional shaking and allowed to stand overnight at room temperature. Then the potential and *p*H of the solution were measured. Colorimetric tests showed that the

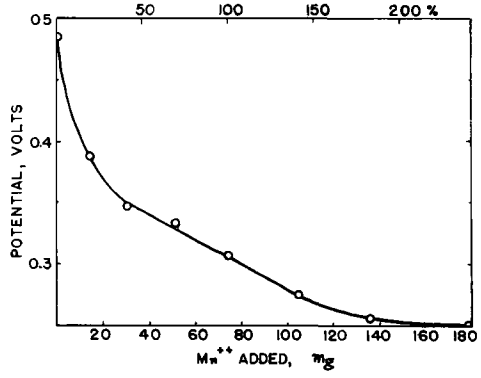

Fig. 7. Potential (vs. saturated calomel electrode) of manganese dioxide with known amount of lower oxide on the surface. The upper obscissa scale represents the percentage of the surface covered by lower oxide.

supernatant solution contained no detectable Mn(II) ion; that is, all Mn^{++} added had reacted with the manganese dioxide. Figure 7 shows the potentials corrected to *p*H 8 using a theoretical coefficient, −60 mv/*p*H. The lower scale of abscissas represents divalent manganese added to 1.50 g of the manganese dioxide. The upper scale represents the percentage of the surface covered by lower oxide assuming that all Mn(II) ion added remains on the surface of MnO_2.

The number of manganese atoms on the MnO_2 surface can be calculated from $n = \left(\frac{d \times N}{MnO_2} \right)^{2/3} \times 100^2 \times S$, in which d is the density of MnO_2 taken as 4.020 found from pycnometer measurements for this sample, N is Avogadro's number, MnO_2 represents the formular weight, and S is the surface area (m^2/g). Let it be assumed that for each atom of Mn(IV) on the surface one Mn^{++} ion from the solution is added to form Mn_2O_3 as indicated in Eq. [3]. Then 75.4 mg of Mn^{++} is necessary to cover the total surface of 1.5 g of this MnO_2 by Mn_2O_3.

The results in Fig. 7 show that one and half layer or two layer coverage of the MnO_2 surface by Mn_2O_3 gives nearly the same potential as that of Mn_2O_3, which is shown in Fig. 2.

From the data in Fig. 7, E° in Eq. [1] can be calculated, if the ratio $a_{Mn_2O_3}/a_{MnO_2}$ is taken to be the ratio in the surface. When 50% of the surface is covered in Mn_2O_3, E is 0.342 v (from Fig. 7). If activity coefficients can be neglected, Eq. [1] becomes:

$$0.342 = E^\circ - (0.059 \times 8) - 0$$

Then, E° is 0.814 v referred to the calomel electrode or 1.056 v referred to the hydrogen electrode. This is near enough to the calculated value 1.014 v from thermal data to support the assumption that the potential is determined by the composition of the surface.

Discussion

When a MnO_2 electrode is discharged the potential decreases and on interruption of the discharge the potential is recovered. As one of the factors to explain the potential recovering process, the following mechanism has been considered (9). On the discharge of MnO_2, lower oxides (Mn_2O_3 or MnOOH) may be formed on the surface of MnO_2, and on interruption the lower oxides may start to diffuse into the interior of the MnO_2, namely, a rearrangement between the surface and the inside may take place in such a way that only electrons and protons are moving (10).

The results given in the present paper have shown that the lower oxide on the surface of MnO_2 is fairly stable (from experiments shown in Fig. 5-7) even for electrolytic MnO_2 containing water (about 8%) which may help to move proton. The potential of the MnO_2 electrode, therefore, is dependent mainly on the surface oxidation state of the dioxide instead of the activity of the whole oxide.

Therefore it seems that the rate of the rearrangement process would be very slow if there is any contribution of it to the potential recovery process.

Acknowledgment

The author wishes to express his appreciation to Professor W. C. Vosburgh, Duke University, who has given much helpful advice in preparation of this paper and particularly under whom the experiments of Fig. 7 have been carried out. The author is indebted to Dr. K. Nagasawa, Nagoya University of Japan, for the differential thermal analysis. This portion of the work was supported in part by the Office of Naval Research.

Thanks are also due Professor E. Yeager and Professor F. Hovorka, Western Reserve University, and Professor K. Sasaki, Nagoya University, Japan, for their encouragement and valuable comments.

Manuscript received July 28, 1958. This paper was presented at the Cleveland Local Section meeting of The Electrochemical Society on April 8, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Anodic Dissolution of Magnesium Alloys in Aqueous Salt Solutions

R. Glicksman

RCA Laboratories, Radio Corporation of America, Princeton, New Jersey

ABSTRACT

The anodic dissolution of a magnesium AZ10A alloy has been studied by measuring corrosion rates and electrode potentials as functions of current density, pH, and electrolyte concentration. Results are interpreted in terms of a rate-controlling proton transfer step through a surface film of magnesium oxide and/or hydroxide.

The effect of different alloy compositions and soluble metal additives to the electrolyte on the anodic corrosion rate and electrode potential also has been measured.

Although the theoretical advantages of magnesium as an anode for primary batteries have been recognized for well over fifty years (1), nothing significant had been reported on a Mg dry cell until the recent work of Kirk, George, and Fry (2, 3). Their cell, which is patterned after the conventional Leclanché cell, contains a magnesium alloy anode, a manganese dioxide cathode, and a magnesium bromide electrolyte. More recently, magnesium dry cells containing a magnesium bromide electrolyte and organic cathode materials have been reported (4, 5).

These developments indicate that magnesium may find extensive use in primary cells. However, some basic problems present themselves. One of these is the poor electrode efficiency of the magnesium alloys. Information on the mechanism of anodic dissolution should help to explain these low electrode efficiencies and could indicate new approaches that might be taken to improve anode performance. In the present investigation the anodic dissolution of an AZ10A magnesium alloy has been studied by measuring corrosion rates and electrode potentials as functions of current density, pH, and electrolyte concentration. The effect of different alloy compositions and soluble metal additives to the electrolyte on the anodic corrosion rate and electrode potential also has been measured.

Experimental

Corrosion rates were obtained by measuring the amount of hydrogen liberated at a magnesium anode while it was undergoing anodic dissolution. The apparatus used in making these measurements is shown in Fig. 1. A carbon rod was used as the cathode, while the anode consisted of cylinders of magnesium approximately 2.5 cm in diameter and 2.5 cm long. These were mounted on a steel shaft with ends protected by plastic washers. The remainder of the shaft was protected by a close fitting Bakelite sleeve, which is set tightly on a ground glass male joint.

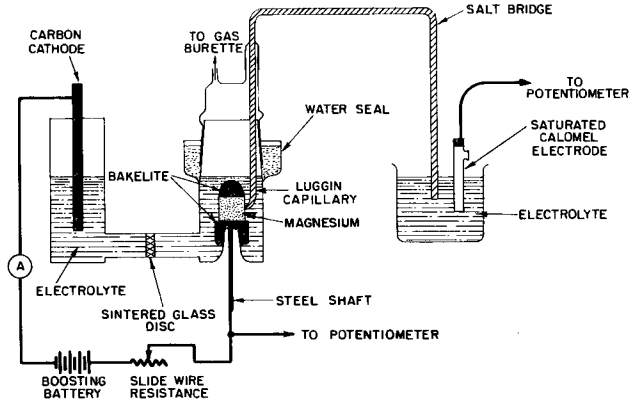

Fig. 1. Apparatus used to investigate magnesium corrosion rates and anode potentials.

The current flow in the circuit was maintained constant by means of a variable resistance and booster battery, and the hydrogen was collected in a gas buret in the usual manner. The procedure and apparatus were checked by measuring the volume of hydrogen liberated at a platinum electrode in 2*N* HCl solution, which corresponded to within 1% of the theoretical amount of hydrogen expected, based on calculations using Faraday's law.

The magnesium specimens, compositions of which are shown in Table I, were prepared by etching them in dilute acetic acid for 1-2 min and washing them in distilled water. Solutions were prepared with Fisher purified magnesium bromide and certified sodium bromide reagents using doubly distilled water. All solutions were saturated with Fisher N. F. magnesium hydroxide reagent.

The duration of each run was 3 hr except in the more corrosive solutions where quantities of hydrogen in excess of 100 cc were evolved in shorter time intervals. With but few exceptions all reported measurements represent the average of two or three runs, and each result was obtained with fresh electrolyte and a newly prepared magnesium cylinder. Duplicate runs varied from 1 to 3% for most of the

measurements, while a variation of 5-6% was obtained with the more corrosive solutions. Average values in terms of mg/dm²/day (mdd) are reported for the dissolution rates.

All runs were made at room temperature which varied from 24°-30°C during the course of this investigation. The effect of temperature on the corrosion rate over this temperature range has been shown to be negligible (6), and duplicate runs made at varying temperatures indicate no correction for this factor was necessary. Measurements of the effect of dissolved oxygen on the corrosion of magnesium in magnesium bromide solution (7) showed it has little or no effect on the corrosion rate, a result in agreement with previously reported data (8). Therefore, this factor was not controlled either.

The magnesium potentials were measured with a L&N type K potentiometer at the completion of each run using a Luggin capillary and a saturated calomel reference electrode as shown in Fig. 1. The reported potentials are all steady-state values and represent the average of two or three measurements. The individual measurements had a reproducibility of ±0.001 v for the majority of the runs.

Effect of Current Density

The effect of a polarizing current on the dissolution rate of a magnesium AZ10A alloy[1] in 2*N* $MgBr_2$ solution is shown in Fig. 2. When the specimen is made anodic, the observed dissolution rate is the sum of the rate due to the external current as defined by

$$Mg \rightarrow Mg^{++} + 2e^- \qquad [1]$$

and the rate due to local action as defined by

$$Mg + 2H_2O \rightarrow Mg(OH)_2 + H_2 \qquad [2]$$

It is seen that the local corrosion rate increases with increasing anodic current density. This is known in the theory of corrosion as the negative difference effect. For magnesium, the magnitude of this effect has been found by Robinson (9) to be dependent on

[1] This alloy, which was furnished by the Dow Chemical Co., consists principally of magnesium, but contains in addition 1% aluminum and 0.5% zinc.

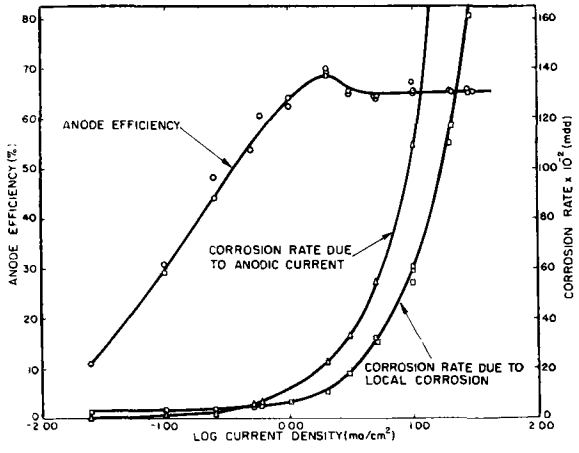

Fig. 2. Effect of current density on the local corrosion rate and anode efficiency of a magnesium AZ10A alloy dissolving in 2N $MgBr_2$ electrolyte [st'd with $Mg(OH)_2$].

both the electrolyte and anode composition including alloy ingredients and level of impurities.

For such an anode, the electrode efficiency is given by the following relationship:

Electrode efficiency =

$$\frac{\text{number of Faradays passed through the circuit}}{\text{number of equivalents of magnesium dissolved}} \times 100 \qquad [3]$$

i.e., by the rate of useful corrosion over the total dissolution rate. For many anodes the electrode efficiencies would approach 100% as a limit. However, if the rate of local corrosion were to increase with the rate of useful corrosion, efficiencies would tend to approach a limiting value of less than 100%. This is indicated by the anode efficiency curve for the magnesium AZ10A alloy which reaches a limiting efficiency of 65% at current densities above 1 ma/cm² in the 2*N* $MgBr_2$ electrolyte, although efficiency values as high as 68-69% are attained at a current density of 2 ma/cm².

Figure 3 is a plot of the negative difference effect obtained on a magnesium AZ10A alloy in 2*N* $MgBr_2$ vs. the anodic current density. It is seen that the

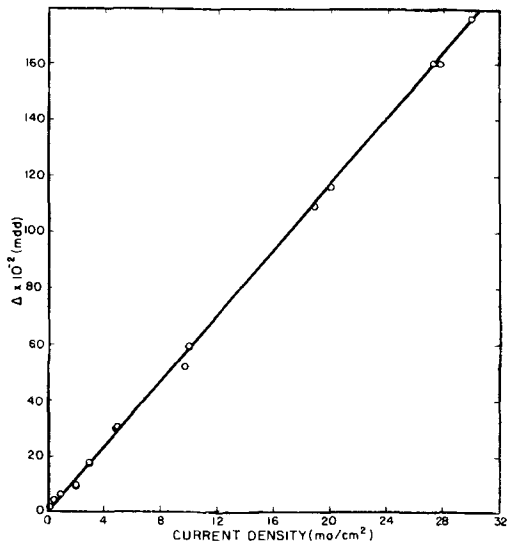

Fig. 3. Effect of current density on the negative difference effect obtained from a magnesium AZ10A alloy in 2N $MgBr_2$ electrolyte [st'd with $Mg(OH)_2$].

difference effect is directly proportional to the galvanic current up to 30 ma/cm². This type of effect has also been observed on magnesium corroding in a 3% NaCl solution (10) and is usually found with very active anodic metals covered by a protective layer. The positive effect is found in the absence of a protective layer as in the case of magnesium dissolving in HCl (11). Similarly, aluminum anodes show positive difference effects in certain corrosive electrolytes such as NaOH (12) and HF (13) which can dissolve the protective film, while the negative effect shows up in HCl (13) because of the presence of a film on the metal. The work of Kroenig and Uspenskaja (10) indicates that the magnitude of the negative difference effect increases with the thickness of the oxide layer.

There are two hypotheses which explain the negative difference effect. The first of these attributes the increased corrosion of magnesium to the destruction of the anodic films with increased current density, resulting in continuous exposure of impurity particles which serve as sites for cathode reactions (13, 14). The second hypothesis explains the experimental results by assuming that unipositive magnesium is formed as an unstable intermediate. Oxidation of this species to the common dispositive state by water

$$2Mg^{+} + H_2O \rightarrow MgO + Mg^{++} + H_2 \qquad [4]$$

was held responsible for hydrogen evolution (15, 16). All efforts to isolate and identify a compound containing unipositive magnesium thus far have been unsuccessful. Although the various experimental observations on the magnesium anode can be explained by either of these hypotheses, the experimental evidence available at the present time cannot serve as a convincing demonstration of the correctness of one or the other of these hypotheses.

It is proposed that a more appropriate model with which to consider the anodic corrosion of magnesium is one in which the over-all rate is controlled by the rate of either proton or magnesium ion transport through a surface film of magnesium oxide and/or hydroxide. (Control by proton transfer appears more likely because of the apparent ease with which magnesium ions penetrate the film during anodic dissolution.) This model, suggested by Casey and Bergeron (17) to explain the dissolution rates of magnesium in acidic salt solutions, is used to explain the experimental data in the present study. Thus, the negative difference effect could be attributed to the action of the polarizing current in breaking down the protective film. This would manifest itself as an increased rate of local corrosion, since changes in the structure of the film due to the anodic current would be reflected by changes in the rate of passage of any particle through the film.

Effect of Soluble Metal Additives to the Electrolyte

In the corrosion of metals, where the cathode process is hydrogen evolution, the nature of the cathode material, specifically its hydrogen overvoltage, plays an important role in the corrosion reaction (18). Thus the galvanic currents observed when magnesium anodes were coupled with various other metals in a 3% NaCl solution bore no relationship to the reversible electrode potentials of these metals, but were governed by their hydrogen overvoltages, the metals of lowest overvoltage permitting the greatest galvanic currents. In regard to promoting corrosion, the elements arranged in an increasing order of effect, were found by Kroenig and Kostylev (19) to be Hg, Zn, Mn, Pb, Cu, Ni, Fe, Al, and Pt.

In order to study the effect of impurities on the anodic dissolution rate of the magnesium AZ10A alloy, corrosion rates and electrode potentials were measured in a 2*N* $MgBr_2$ electrolyte containing various soluble metal additives in the form of their bromide salts. Solutions were made up by adding 1 g of the metallic bromide to a liter of 2*N* $MgBr_2$ electrolyte and saturating the resultant solution with magnesium hydroxide to maintain the *p*H constant. Experimental measurements were made with solutions containing the following salts: $ZnBr_2$, $PbBr_2$, TlBr, $AlBr_3$, $MnBr_2$, Hg_2Br_2, $CdBr_2$, $CuBr_2$, AgBr, and $PtBr_4$.

In Fig. 4, the local corrosion rates are plotted against the logarithm of the exchange current for the hydrogen evolution reaction on the corresponding metal. The exchange currents, which provide a standard state at which the velocities of the reaction $2H^{+} + 2e^{-} \rightarrow H_2$ on various metals can be com-

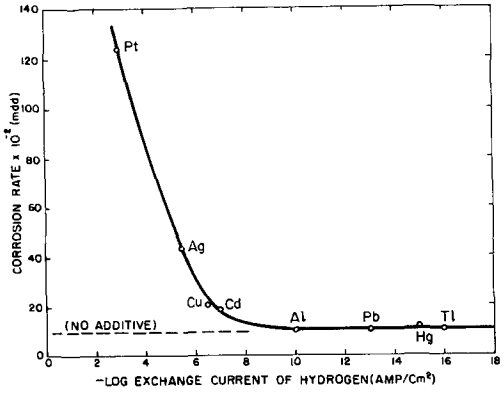

Fig. 4. Effect of various soluble metal bromide additives on the corrosion rate of a magnesium AZ10A alloy dissolving anodically in a 2N $MgBr_2$ electrolyte [st'd with $Mg(OH)_2$] at a current density of 2.0 ma/cm².

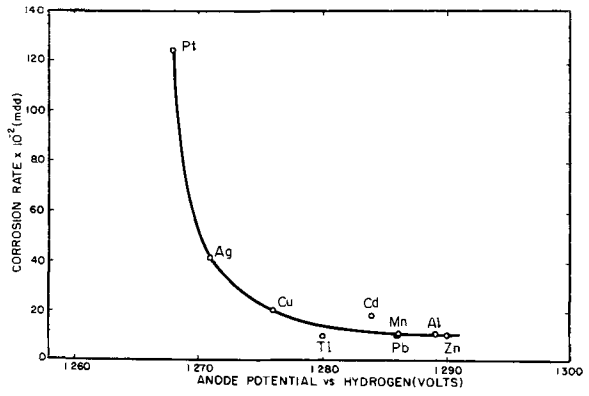

Fig. 5. Relationship between the corrosion rate and anode potential of a magnesium AZ10A alloy dissolving anodically in a 2N $MgBr_2$ electrolyte [st'd with $Mg(OH)_2$] containing various soluble metal bromide additives at a current density of 2.0 ma/cm².

pared, were estimated from the data available in the literature (20-22). For the corrosion of magnesium in a neutral or slightly alkaline aqueous salt solution, it is seen that a small quantity of low overpotential metal in the solution greatly accelerates the corrosion reaction. Apparently these metals are deposited on or in the oxide film and form centers on which hydrogen can come off more easily. Metals having hydrogen exchange currents of 10^{-9} or less appear to have little effect on the local corrosion rate as measured under these experimental conditions.[2]

The effect of the various additives on the anode potential is illustrated in Fig. 5, where the corrosion rate is plotted vs. magnesium potential. It is seen that, with the metal additives which cause little or no change in the corrosion rate, the anode potentials range from 1.280 to 1.290 v as compared to a potential of 1.287 v in solutions containing no additives. The low overpotential metal additives, such as Cu, Ag, and Pt, which cause a marked increase in the corrosion rates, lower the magnesium potential by 0.01-0.02 v, the greatest effect occurring with the Pt additive.

Assuming the anodic polarization curve of magnesium is the same for all these solutions, any differences in the corrosion currents and potentials would be dependent on the cathodic polarization curve. If the cathodic areas possess a low overpotential, the cathodic polarization curve slopes down less than if the overpotential is high. Thus the current is greater, and the potential more noble, in agreement with the experimental data.

The effect of the Hg additive on the potential was quite marked, resulting in an anode potential of 1.376 v, a value too high to be shown in Fig. 5. The high potential encountered with this additive is believed due to the partial removal of the magnesium oxide film by amalgamation. This type of behavior is similar to that found for amalgamated aluminum anodes. The effectiveness of the Hg additive in maintaining a low corrosion rate, despite the absence of a controlling oxide film, is attributed to the difficulty of proton discharge on this high overvoltage metal.

[2] The corrosion rates of the magnesium AZ10A alloy in solutions containing $ZnBr_2$ and $MnBr_2$ were 10.0 and 10.8 x 10^2 mdd, respectively. These results were not included in Fig. 4 because their hydrogen exchange currents were not known.

Effect of Electrolyte

The effect of electrolyte concentration and pH on the local corrosion rate and electrode potential of a magnesium AZ10A alloy dissolving anodically in various magnesium and sodium bromide solutions is shown in Fig. 6.

It is seen that the corrosion rate of magnesium in the magnesium bromide solutions increases approximately linearly with decreasing electrolyte pH over the range of 6.3-8.1 pH units. At pH values greater than 8.1, the corrosion rate approaches a constant value of 12.7 x 10^2 mdd, which corresponds to an anode efficiency of 63%. The minimum in the corrosion rate occurs at a pH of 8.1, corresponding to an anode efficiency of 68%.

In contrast to the marked change in electrolyte pH with magnesium bromide concentration, which is a consequence of the common ion effect, the sodium bromide electrolyte shows only a 0.7 variation in pH over a concentration range of 1.0-6.0 *N*. Over this small range of pH 9-10 the corrosion rate is essentially constant at a value of 11.5-12.1 x 10^2 mdd. This result is comparable to those obtained in magnesium bromide electrolytes having pH values of 8 or higher.

The effect of electrolyte pH on the anode potential of the magnesium AZ10A alloy also is illustrated in Fig. 6. For the magnesium bromide electrolyte it is seen that the anode potential falls rapidly with increasing pH in the basic pH range. For the weakly acidic solutions the potential varies only slightly with pH, approaching a constant value of 1.36 v. In contrast to the marked drop in potential observed in the weakly basic magnesium bromide solutions, the anode potential in the sodium bromide electrolytes decreases only 0.04 v in the pH range 9.3-10.0.

The data in Fig. 6 can be explained in terms of the effect of these electrolytes on the structure of a surface film which must be magnesium oxide and/or magnesium hydroxide. This film is more easily penetrable at low pH values because the OH^- ion concentration is too low to maintain an effective magnesium hydroxide film. Thus at low pH values,

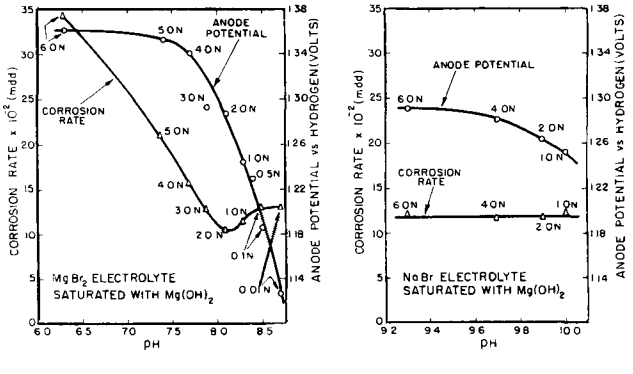

Fig. 6. Effect of pH on the corrosion rate and anode potential of a magnesium AZ10A alloy dissolving anodically in various $MgBr_2$ and NaBr electrolytes [st'd with $Mg(OH)_2$] at a current density of 2.0 ma/cm².

high corrosion rates and high anode potentials are observed.

At high *p*H values the OH^- ion concentration of the electrolyte controls the precipitation of the Mg^{++} ions produced at the anode, which, according to Robinson (9), are precipitated so close to the anode as to stifle the anodic reaction. This results in more cathodic potentials, a decrease in local corrosion, and excessive polarization of the anode.

In an intermediate *p*H range, precipitation of magnesium hydroxide occurs at a sufficient distance from the active anodic areas to permit the anodes to function normally. It is in this *p*H range that other properties of the electrolyte exert a greater influence over such factors as local corrosion and anode potential. Since the magnesium bromide and sodium bromide electrolytes appear to operate in this intermediate *p*H range, the similar corrosion rates in the 1.0-6.0*N* NaBr and 0.01-3.0*N* $MgBr_2$ electrolytes are to be expected, despite the differences in electrolyte *p*H. At the higher magnesium bromide electrolyte concentrations, *p*H becomes the dominant factor, and the corrosion rates in the magnesium bromide solutions are much greater than in the sodium bromide electrolyte.

The slightly lower corrosion rates found in the 1.0-3.0*N* $MgBr_2$ electrolytes as compared to the more basic sodium bromide electrolytes are similar to the type of results obtained by Casey and Bergeron (17), who found that the dissolution rates of magnesium in acidified potassium chloride solutions are greater than those in comparable magnesium chloride solutions of the same *p*H. Their results were explained on the basis of a thicker or less porous oxide film on magnesium in the magnesium chloride electrolyte, formed as a result of the lower solubility of magnesium hydroxide in the magnesium chloride solutions. The lower solubility in this electrolyte is a consequence of the common ion effect. Thus, if the rate of dissolution of magnesium in aqueous salt solution depends on the solubility of the magnesium hydroxide film, as was first suggested by Whitby (23, 24), it follows that corrosion rates would be greatest in those electrolytes where a thinner or more porous oxide film on magnesium is obtained.

The electrode potential data in Fig. 6 can be explained in the following way. Because of the higher *p*H of the sodium bromide solutions, the potential of magnesium, when measured at a current density of 2.0 ma/cm^2, is more anodic for the concentrated (3.0-6.0*N*) $MgBr_2$ solutions. However, for the more dilute magnesium bromide solutions the anode potential decreases rapidly with increasing *p*H, becoming more cathodic than the potentials measured in the sodium bromide electrolytes. These lower potentials are attributed in part to the effect of the Mg^{++} ions in stifling the anode reaction with increasing *p*H. In addition a significant portion of the potential ennoblement at the low magnesium bromide concentrations is due to the decreased bromide ion concentration of the electrolyte.

Effect of Anode Composition

It has been shown by Hannawalt, Nelson, and Peloubet (25) that the presence of certain impurities and alloying metals has a marked effect on the corrosion characteristics of magnesium alloys in an aqueous salt solution. They determined tolerance limits of impurities such as Fe and Ni, for magnesium and some of its alloys. When the amount of the element present exceeds this tolerance limit, there results a large increase in corrosion rate. These findings point to the importance of knowing the concentration of deleterious impurities and their tolerance limits when investigating alloy effects. In addition, it must be realized that the corrosion behavior of magnesium alloys in other electrolytes will be different from that in the 3% NaCl solution of Hanawalt, *et al.* and care should be exercised in extending their results to other electrolyte systems.

In Table I are presented corrosion rates and anode efficiencies of six different commercial magnesium alloys along with their compositions and significant metal impurities. It is seen that magnesium alloys containing aluminum and manganese operate at higher anode efficiencies than commercially pure magnesium, as well as the ZK60A and M1A magnesium alloys. Alloying the magnesium with aluminum permits removing most of the major cathodic impurity, iron, by precipitation with manganese. The corrosion resistance of such high-purity alloys is very good and, as anodes, they perform more efficiently than any of the magnesium compositions tested to date (9).

Also presented in Table I are anode potentials of these alloys, when measured in a 2*N* $MgBr_2$ electrolyte at a current density of 2.0 ma/cm^2. It is seen that the alloys containing Al or Zn are 0.04-0.10 v more cathodic than commercially pure magnesium. The pure magnesium has a potential of 1.33 v on the normal hydrogen scale, as compared to values of 1.23-1.29 v for the Mg-Al alloys, whose potential is more anodic with decreasing amounts of Al. This type of behavior has been found by other investigators with other electrolytes (9, 26).

Conclusions

It is proposed that the most appropriate model with which to consider the anodic corrosion of magnesium in aqueous salt solutions is one in which the over-all rate is controlled by the rate of proton transport through a surface film of magnesium oxide and/or hydroxide. The anodic corrosion rates and potentials of a magnesium AZ10A alloy in various magnesium bromide and sodium bromide electrolytes can be explained in terms of the effect of these electrolytes on the structure of this film.

It has also been shown that the presence of certain low overvoltage metal impurities, such as Cu, Ag, and Pt, with hydrogen exchange currents greater than 10^{-9} amp/cm^2, have a deleterious effect on the corrosion characteristics of magnesium alloys in an aqueous salt solution.

Acknowledgments

The author wishes to express his appreciation to G. S. Lozier and C. K. Morehouse for their many helpful suggestions during the course of this investigation.

Electrolytic Transition of Ag_2O to AgO in Alkaline Solutions

Thedford P. Dirkse and George J. Werkema

Department of Chemistry, Calvin College, Grand Rapids, Michigan

ABSTRACT

An interrupted current technique was used to study the electrolytic oxidation of silver in alkaline solutions. The short voltage peak just preceding the stage corresponding to the production of AgO in the voltage-time curves is interpreted as being due to the high electrical resistance to the Ag_2O layer.

During the anodic treatment of silver in alkaline solutions a two level curve is obtained when voltage is plotted against time. Such a curve, obtained by a constant current oxidation, is shown on Fig. 1. Part a corresponds to the formation of Ag_2O, part c to the formation of AgO, and d to the evolution of oxygen. The work reported here deals with the peak represented by b. Such a peak may or may not be present also at the beginning of stage a, but is usually present during the transition from stage a to stage c. It is found whether a constant current or a constant potential process is used. It is also found in the charging curves for commercial silver-zinc batteries.

Although very little has been written about this peak, two different explanations for it appear in the literature. The first was given by Hickling and Taylor (1) who suggested that the peak corresponds to the change

$$Ag_2O + 4OH^- \rightarrow Ag_2O_3 + 2H_2O + 4e \qquad [1]$$

and the Ag_2O_3, being unstable, quickly decomposes as follows:

$$Ag_2O + Ag_2O_3 \rightarrow 4AgO \qquad [2]$$

As soon as this latter reaction begins the voltage begins to decline from the peak. This mechanism, whereby the oxidation of Ag^+ to Ag^{++} proceeds through the formation of Ag^{+++}, has been proposed also for acid solutions by others.

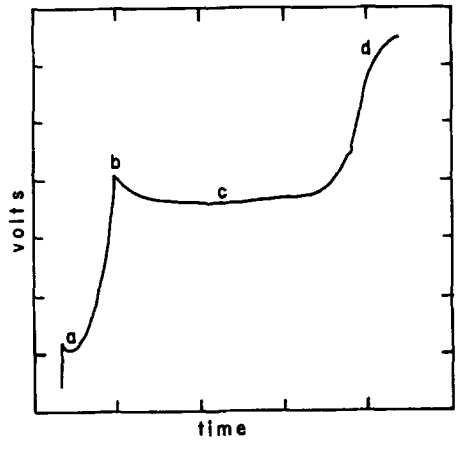

Fig. 1. Typical voltage-time curve for constant current oxidation of silver in KOH solution.

Yost (2) studied the catalytic effect of Ag^+ on the oxidation of Cr^{+++} by persulfuric acid. He suggested a mechanism for this action in which the persulfate first oxidized the Ag^+ to Ag^{+++} and the latter, in turn, oxidized the Cr^{+++} to dichromate. This mechanism is consistent with the kinetic data obtained for this process. Later Noyes, *et al.* (3) studied the rate of oxidation of $AgNO_3$ by ozone in acid solution and interpreted their kinetic data in a way similar to that of Yost. A study of the rate of reduction of Ag^{++} by water in acid solution showed this process to be fairly complex, but it was suggested that Ag^{+++} was an intermediate in this reaction also (4). Gordon and Wahl (5) used a similar mechanism to explain their data on the rate of the exchange reaction between Ag^+ and Ag^{++}.

This interpretation has, however, not gone unchallenged. Bawn and Margerison (6) studied the oxidation of a hydrazyl using Ag^+ and persulfuric acid. They suggest that their results can be interpreted in a manner similar to that proposed by Yost (2). However, they contend also that such results can be interpreted just as well without assuming the formation of Ag^{+++} as an intermediate. They prefer a mechanism involving the formation of free radicals and Ag^{++}.

Aside from the fact of the existence or nonexistence of tripositive silver, it is doubtful whether peak b in Fig. 1 is due to its formation. This peak is obtained even when the potential of the silver electrode is kept 100-150 mv above the reversible potential of the Ag_2O-AgO couple in alkaline solution, and such a potential is not of sufficient magnitude to result in the formation of Ag^{+++} from Ag^+ or Ag^{++}. This value is lower than that generally accepted as the potential of Ag^{+++}-Ag^{++} in alkaline solutions (7).

Another explanation of this peak has been given by Jones, *et al.* (8). They suggest that the transition from Ag_2O to AgO proceeds with difficulty and the peak represents the difficulty of forming centers of AgO in the lattice of Ag_2O. They also suggest that some Ag_2O_3 may be formed, but at the end rather than at the beginning of stage c.

Because of this divergence of opinions, and because of the possibility that a proper understanding of the meaning of this peak may afford a clue to the unravelling of the kinetics of these particular electrode reactions, a special effort was made to study this phenomenon further.

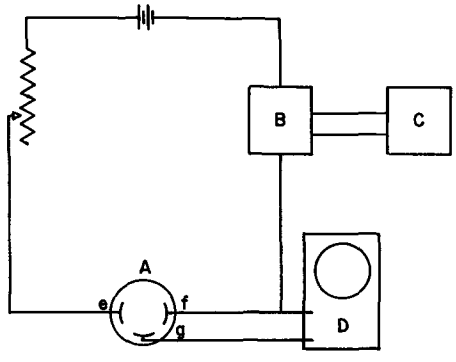

Fig. 2. Schematic diagram of interrupter apparatus. A, cell; B, Western Electric 275 Relay; C, sine wave generator; D, oscilloscope; e, auxiliory silver electrode; f, working electrode; g, reference electrode.

Experimental

The method used in this study involved the passage of interrupted current through the electrode. The voltage changes were observed on an oscilloscope both during passage of the current and during decay (open-circuit condition). A schematic diagram of the apparatus is shown on Fig. 2. The Western Electric 275 relay served as a current interrupter, and frequency of interruption was governed by the frequency delivered by the sine wave generator. The working electrode was a silver wire with about 0.5 cm^2 surface area. Constant current processes were used in all this work. The auxiliary and reference electrodes were relatively large pieces of silver screen. The traces on the oscilloscope were recorded photographically. All runs were made at room temperature. The variables studied were: concentration of KOH, current density, and effect of oxygen. The last of these was studied by bubbling air through the solution and then making an identical run except for the fact that purified nitrogen was bubbled through the solution during the run.

Results

The nature and shape of the traces obtained were the same whether air or nitrogen was bubbled through the electrolyte during the run. Consequently, the phenomena observed were not due to the presence or absence of oxygen in the electrolyte.

In all cases the electrolyte was a solution of KOH. A change in the concentration of the electrolyte did not give rise to any changes in the traces that were obtained. When the more concentrated KOH solutions were used the electrolyte gradually became discolored due to the presence of finely divided particles of silver oxides. Furthermore, since the silver oxides are slightly soluble in KOH solutions, it was possible that the nature of the decay curve could be affected by the solubility of the oxides produced during passage of current. For these reasons, the results used here are those obtained when 1*N* KOH was the electrolyte.

Types of the traces that were obtained are shown on Fig. 3. These were all traced from photographs taken during the runs. Similar traces were obtained

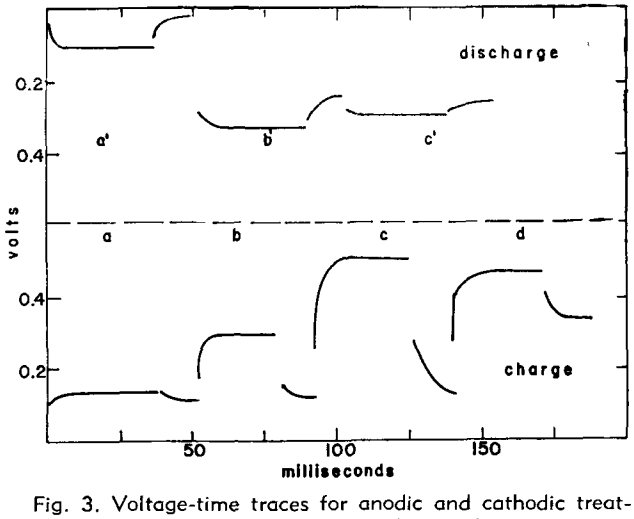

Fig. 3. Voltage-time traces for anodic and cathodic treatment of silver electrode in N KOH solution. Current density, 7 ma/cm^2.

over an apparent current density range of 1-10 ma/cm^2. The voltages are expressed as the difference between that of the working electrode and of the reference electrode. A base line was recorded before beginning each charge or discharge. The charge curves on Fig. 3 are given in the order in which they appear. At the beginning of the charge the traces are of the type shown in panel a. As the treatment continues the amplitude of this curve increases slightly. This is followed by a rapid transition from type a to type c. Panel b represents an intermediate in this transition. In each case the decay curve shows that Ag_2O is the oxide still on the surface. The curve in panel c represents the peak referred to in Fig. 1. Curve d is of the type that follows the transition from a to c. It should be noted that the decay curve now shows the presence of AgO on the electrode, and at the same time the charging voltage is lower than that in panel c. Traces of the type shown in panel d continue for a while, and then the voltage levels become higher as gassing begins.

During discharge a similar sequence takes place, see the upper set of curves in Fig. 3. Here the top border of the graph represents the base line obtained before the discharge was begun. Panel a' represents the kind of trace obtained at the beginning of discharge. The decay curve shows the presence of AgO. Then there follows a rapid transition to traces such as shown in panel c'. Panel b' shows an intermediate trace. Here again the voltage during passage of current (discharge) is lower in panel b' than in panel c'. This is similar to the peak obtained on charge.

Discussion

It is suggested here that these phenomena can be interpreted in terms of the resistance of the Ag_2O layer that is formed on the electrode. It has been pointed out (9) that the electrical resistance of Ag_2O is considerably greater than that of AgO. According to this interpretation, then, as the oxidation of silver proceeds, a film of Ag_2O is formed on the surface of the electrode. As this film builds up, the electrical resistance at the electrode-electrolyte interface increases. When this film completely covers the surface, the resistance, and consequently the *IR* drop also, increases giving rise to the peak represented by b in Fig. 1. The traces on Fig. 3 also show a relatively large *IR* drop at this point (panel c). As soon as some of this Ag_2O is changed to AgO, the resistance of the surface film decreases, the *IR* drop decreases, and the open-circuit voltage (on decay) rises to that of AgO. As more AgO is formed the resistance of the surface film and the voltage decrease slightly.

This explanation also accounts for the phenomena observed on discharge. As the discharge progresses, AgO is changed to Ag_2O and the resistance of the surface layer increases. When all the surface AgO has been changed to Ag_2O this resistance is at its maximum and there is the greatest voltage loss on discharge. The open-circuit voltage is that of Ag_2O, Fig. 3 b'. This trace also shows a large *IR* drop. On further discharge the Ag_2O changes to Ag and the resistance of the surface layer decreases. Consequently, the discharge voltage is a little higher, Fig. 3 c'.

It is believed that this interpretation is more consistent with the data obtained than are the other interpretations that have been offered. The existence of Ag_2O_3 is doubtful, particularly in alkaline solutions. Moreover, if Ag_2O_3 were an intermediate in the formation of AgO from Ag_2O, this might account for peak b in Fig. 1 but would not account for a corresponding dip in the discharge curve when the AgO is gone.

Similar reasoning tends to eliminate the idea that the peak on charge is due to the difficulty of forming AgO nuclei in an Ag_2O lattice. Again, this suggestion can be used to account for the charge phenomenon, but it does not account for a similar event on discharge.

Strain Electrometry and Corrosion, IV

Film Properties and Strain Potential

J. Calvin Giddings, Albert G. Funk, Carl J. Christensen, and Henry Eyring

University of Utah, Salt Lake City, Utah

ABSTRACT

Measurements of the strain transients have been recorded here for several metal electrodes including copper, aluminum, zinc, nickel, silver, and iron. The magnitude of the transients as a function of the percentage strain are treated by an extension of previous theoretical results. It is found that the transients depend on the position of an electrode in the emf series and on the protective nature of the film as predicted by the theoretical considerations. In addition, several experiments have been reported concerning the effect of corrosion inhibitors and organic coatings on strain transients. Some possible theoretical interpretations are made on these preliminary results.

It has been shown that the magnitude of the strain transient for a metallic wire is related to the chemical and physical nature of the protective film along with the chemical nature of the surrounding solution (1-3). In order to extend this study of rapid interface reactions we have measured and compared strain transients for a group of metals possessing films of greatly differing nature. It has been found possible to correlate approximately the relative values of these transients with the position of the metal in the electromotive series, for the same per cent strain, of the metals used (Cu, Al, Zn, Ni, Ag, and Fe). This is done using the concept that a stationary electrode potential is fixed when the rates of competing anodic and cathodic reactions are equal. A sudden strain causes film rupture, and temporary changes of the interface rates occur. The change is in such a direction as to account for the clean metal surface exposed when the film is broken. Metals such as aluminum show transients as high as a volt since, when the highly protective film is removed, the surface of the aluminum, which is very electropositive, reacts to yield aluminum ion. Metals such as iron, however, show much smaller transients, in the range of 100-200 mv. This results since the protective film on iron is sufficiently porous that the straining of the metal causes a relatively small increase in anodic area compared to that obtained by straining aluminum.

According to the same picture metals only slightly electropositive would be expected also to show small transients. The transient of silver is about 50 mv in confirmation of this general picture. The above picture can be written in a quantitative form that approximately describes these voltage transients under various conditions. In particular, an equation has been derived that relates the maximum voltage change, $-\Delta V_m$, to the fractional elongation of the wire electrode. Strain electrometry is another tool that can be used for the elucidation of the complex reactions of corrosion inhibitors. Preliminary results have been obtained in this important field.

The experimental methods used in strain electrometry have been described elsewhere (2, 3). The potentials recorded here are measured and recorded against the saturated calomel electrode.

Strain Transients of Metals

It is convenient to study the potential transients of strain electrometry in relation to Fig. 1. This schematic diagram is similar to one presented in an earlier publication (1), but here it is extended to include an approximate description of several metals.

Each electrode reaction has a reverse reaction acting to charge the electrode in the opposite direction. If only one reaction and its reverse were operative, an equilibrium electrode potential would be realized. These are denoted by the solid lines in Fig. 1. If more than one reaction is operative, the final, steady-state potential will differ from all of the equilibrium potentials. It will, however, lie nearest the equilibrium potential established by the fastest reactions. The steady-state potentials are shown as dotted lines. Potentials shown in Fig. 1 conform to the European sign convention.

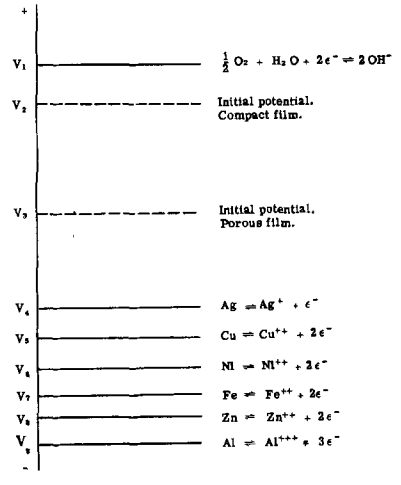

Fig. 1. Schematic diagram of equilibrium potentials and steady-state potentials for electrode reactions.

In most aerated solutions there are two reactions of paramount importance in establishing the steady-state potential. These are the oxygen reaction, tending to establish the potential at V_1, and the metal, metal-ion reaction tending to establish the potential, in the typical case of Ni, at V_6. If the metal possesses a highly protective film, the metal, metal-ion reaction is slowed considerably, since it has the equivalent of a small anodic area and the initial (before strain) steady-state potential is near the oxygen equilibrium potential, V_1. Such metals are Ag, Cu, Ni, and Al with a steady-state potential shown at V_2. These potentials are not all equal, but schematically they may be considered to be the same.

In the case of metals with a porous film, metal ions can escape easily into solution, and the initial steady-state potential is established nearer the metal, metal-ion pair. Probable examples are Fe and Zn with an initial, steady-state potential, V_3.

When the metal electrode is suddenly strained, the brittle oxide film is ruptured, thus increasing the anodic area. This greatly facilitates the metal, metal-ion reaction and establishes a new potential nearer the metal, metal-ion pair. This potential is of short duration since various factors, such as regrowth of the oxide film and concentration polarization (caused by corrosion of the metal), tend to reestablish it at the original value.

It is clear from this discussion that the transient potential is dependent on the amount of strain. A larger strain causes the new potential to establish itself nearer the metal, metal-ion pair. Thus the potential difference that is recorded at the point of maximum change, ΔV_m, becomes more negative as strain increases. We return to this point later.

The strain transient recorded for a given metal, ΔV_m, is the difference between the initial steady-state potential and a potential that is close to that particular metal, metal-ion pair. This increases in magnitude (the values of ΔV_m are negative) as (*a*) the metal becomes more electropositive (higher in the emf series), thus establishing a larger negative potential with strain, and (*b*) the metal has a more compact film, for which the initial potential is more positive. Silver has the smallest transient, since it is not electropositive. It is likely in this case that hydrogen and metallic impurities in the silver cause the strain transient since, unless Ag^+ is extremely dilute, the Ag, Ag^+ equilibrium is higher than that for oxygen. (The reason, of course, that Fig. 1 is schematic is that every equilibrium potential depends on the concentration of some ionic species. Since these are greatly changed from one metal to another, due to polarization, etc., a completely accurate diagram cannot be made.) The value of $(-\Delta V_m)$ for silver at 7% strain is 39 mv, as shown in Table I.

Beyond silver, the value of $-\Delta V_m$ at 7% strain increases in the order of Cu, Fe, Ni, Zn, and Al; whereas, in order of increasing emf, they are Ag, Cu, Ni, Fe, Zn, and Al. The order of Fe and Ni has been reversed since the emf, by itself, does not account for the magnitude of the transient. This is better illustrated in Fig. 2 where $(-\Delta V_m)$ is plotted against emf. A smooth curve is obtained with the exceptions of Fe and Zn. These lie below the curve in accord with the picture that a porous film will reduce the observed magnitude of the transient.

Table I. Transient potentials in distilled water at 7% strain; temperature, 25°C

Metal	Strain transient (approximate), mv
Aluminum	—800
Zinc	—224
Nickel	—194
Iron	—148
Copper	—95
Silver	—39

Dependence of Voltage on Relative Strain

It is useful to derive an approximate equation showing the dependence of $(-\Delta V_m)$ on the applied strain on the electrode. An equation derived in an earlier paper (1) reads

$$-\Delta V_m = \frac{kT}{ze} \ln \left(\frac{\epsilon u_{i0}\, \epsilon v^1_{i0}}{\epsilon u^1_{i0}\, \epsilon v_{i0}} \right)$$

where the terms, u_{i0}, u^1_{i0}, v_{i0}, v^1_{i0} are various reaction velocities (cm^{-2} sec^{-1}) of processes that transfer charge across the metal-solution interface: v_{i0}, *i*th anodic velocity, before strain; v^1_{i0}, *i*th cathodic velocity, before strain; u_{i0}, *i*th anodic velocity, after strain; u^1_{i0}, *i*th cathodic velocity, after strain. The reaction velocity "after strain" is the reaction velocity where the transient acquires a maximum value. The zero subscript simply means that these reaction velocities are all measured at some standard voltage. This voltage can be arbitrarily picked without changing the ratio of terms in Eq. [1]. The other terms are Boltzmann's constant, *k*; the electron charge unit, *e*; the temperature, *T*; and the average charge, in electron charge units, transferred across the interface in a single process, *z*.

Approximations made in the derivations of Eq. [1] include, (*a*) the charge transferred in the *i*th

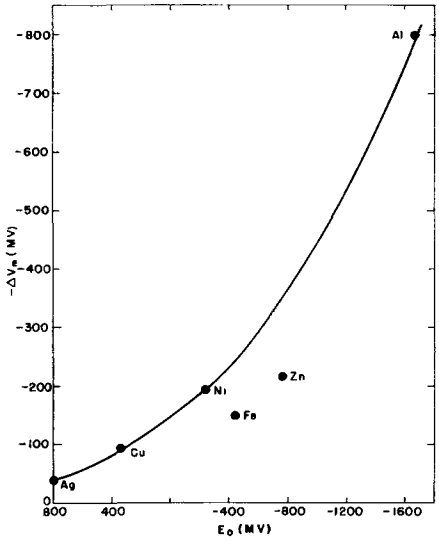

Fig. 2. Strain transients vs. the emf of metal electrodes. Distilled water at 25°C.

process, z_i, can be replaced by some average charge for all processes, z, and, (b) the potential energy barriers for these charge-transfer processes are symmetrical. In view of these approximations, and those to be introduced, only a rough agreement with experiment is expected.

The simplest assumption that can be made with respect to Eq. [1] is that the cathodic reaction velocity (at the fixed reference potential) is not changed as the electrode is strained.

$$\epsilon v^1_{io} = \epsilon u^1_{io} \qquad [2]$$

The anodic reaction velocities at this potential, however, are increased since deformation of the metal increases the anodic area. We can assume that this increase in the anodic rate is proportional to the relative elongation of the electrode, s.

$$\epsilon u_{io} = \epsilon v_{io} + gs \qquad [3]$$

where g is the relative anodic rate of a clean metal surface.

As s approaches zero, the anodic velocity after strain, u_{io}, must approach the anodic velocity before strain, v_{io}, as in Eq. [3].

When Eqs. [2] and [3] are substituted into Eq. [1], we obtain

$$-\Delta V_m = \frac{kT}{ze} \ln (1 + \alpha s) \qquad [4]$$

where $\alpha = g/\epsilon v_{io}$. This equation follows the approximate form of the experimental data, as shown in Fig. 3 for Cu. Best fit is obtained when $z = 0.92$ and $\alpha = 407$. For most of the metals used, αs is considerably larger than unity in the higher range of s. When this assumption can be made, Eq. [4] has only the term (αs) remaining in the logarithm. Although this assumption results in a considerable error, particularly for Ag, Zn, and Fe, it is justified considering the approximate nature of the other assumptions introduced. With this assumption, then, we can write Eq. [4] as

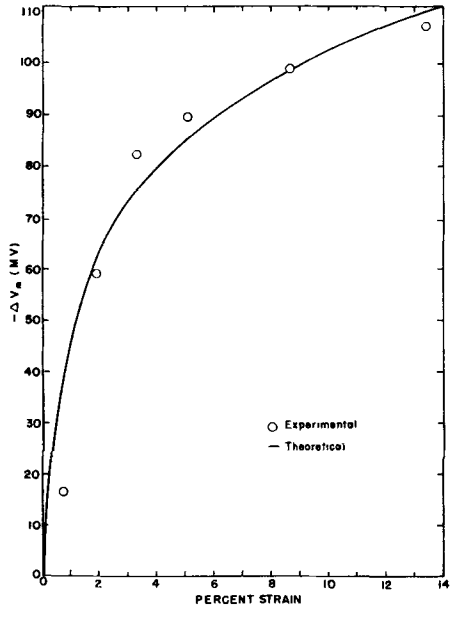

Fig. 3. Strain transient vs. per cent strain of copper

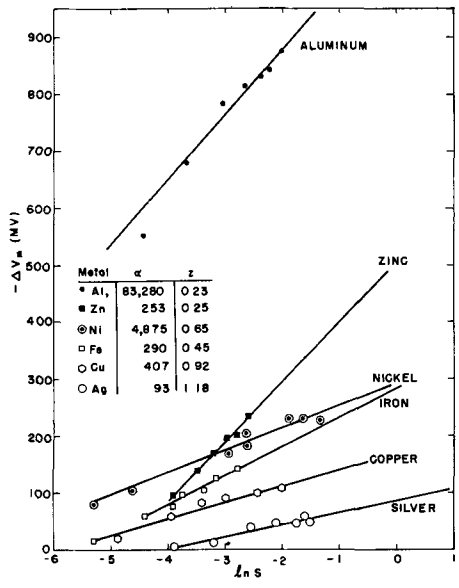

Fig. 4. Strain transients vs. ln (strain). Distilled water at 25°C.

$$-\Delta V_m = \frac{kT}{ze} \ln \alpha + \frac{kT}{ze} \ln s \qquad [5]$$

A plot of $-\Delta V_m$ vs. ln s is shown in Fig. 4. The slope of the line, kT/ze, determines z. The intercept at ln $s = 0$ is kT ln α/ze. The values of z are of the right order except for Zn and Al. Whether this discrepancy is due to the back reaction of metal ions (thus violating Eq. [2]), or to some other effect, has not been ascertained.

The quantity α, as determined from experimental data, is interesting in its dependence on the nature of the metal and the oxide film. Since $\alpha = g/\epsilon v_{io}$, it is determined by g, the relative anodic rate of a clean metal surface, and ϵv_{io} which is the anodic reaction rate of a metal surrounded by an oxide film. The latter quantity is proportional to the rate of dissolution of the metal ion through the oxide film, or the corrosion rate. The former quantity, g, should be an increasing function of the emf of the metal since the emf is a measure of the anodic rate of the clean metal surface. The values of α increase in the order, Ag, Zn, Fe, Cu, Ni, Al, which is the order in the emf series if Zn and Fe are excluded. Zinc and iron have unusually small values of α since the corrosion rate of these metals, appearing in the term ϵv_{io}, is large.

Corrosion Inhibitors

The reactions due to corrosion inhibitors and promoters are expected to reflect themselves in the measured strain transients. The nature of the change in these transients depends on the type of reactions occurring. Thus, with most metals, a pH decrease leads to film dissolution, and a resultant decrease in the transient voltage. At the same time corrosion rates have been increased due to decreased film protection. In practice, many other reactions occur simultaneously and complicate the over-all picture, thus a sufficient pH decrease inhibits some corrosion processes (4). It is still valuable, however, to suggest the effects of single contributing reactions. These reactions may be important in the following ways.

Corrosion inhibitors and promoters are responsible for changing the rates of various electrode reactions. The changed reaction rates are reflected both in corrosion measurements and in strain-electrometry measurements. The latter shows promise of providing a rapid and sensitive measurement of reactions involved in corrosion. A good deal of additional knowledge is needed before this method can be employed generally. Preliminary results are reported here.

An acid is a common example of a corrosion promoter. The corrosion rate is greater and the strain-transient is smaller upon the addition of an acid. Both effects are due to the dissolution of the protective film. As indicated earlier, the strain-transient is a measure of the protective nature of the film, and if this is changed by added substances it is indicated immediately in an altered strain transient.

Inhibitors and promoters are involved in a large number of reactions in addition to those that dissolve the protective film. Although these cannot be enumerated fully at present, a number of reasonable postulates can be made. We may assume, for instance, that some added substances alter the structure of the film—something short of dissolution. Depending on the structure change, corrosion may be promoted or inhibited. Another reaction that has been discussed extensively is ion and molecular adsorption; such adsorption is effective in inhibiting the anodic dissolution of the metal (5-8).

It is well known that the corrosion rate of any given metal depends on the potential of the metal with respect to its environment (9). This potential can be altered by electrical means or by chemical reactions. Thus the addition of oxygen to a metal surface leads to a more positive potential in an aqueous environment; this in turn speeds the reaction of metal ions, $M \rightarrow M^{n+} + ne^-$, and thus the corrosion rate is increased. In some cases however, the adsorption of oxygen inhibits corrosion due to its effect on the oxide film. Thus oxygen can work simultaneously in opposite ways in its effect on corrosion rates. Similar effects might be expected for many additives.

One class of corrosion inhibitors are strong oxidizing agents such as $KMnO_4$ and $K_2Cr_2O_7$. These substances usually act in such a way as to make the potential more positive. This effect by itself would promote corrosion, so apparently there are additional effects (6-8, 10). Another effect such as the surface adsorption (7, 8) of MnO^-_4 or $Cr_2O^=$ must be responsible for the inhibiting effect.

Table II shows the effect of these inhibitors on aluminum, brass, zinc, iron, and copper in different solutions. The value of the potential is given before strain, V_o, and at the maximum of the transient. V_m, the difference, is the maximum value of the strain transient (the potential amplitude) $V_m - V_o = \Delta V_m$.

Several interesting features are shown in Table II. First, it may be seen that the V_o of Al is not shifted in the positive direction by $KMnO_4$. It is expected that in this strongly basic solution other reactions are rapid enough to overshadow the oxidation of the metal by $KMnO_4$. This reaction, of course, would shift the potential in the positive direction. When the electrode is strained, V_m is more positive in the presence than in the absence of inhibitor. It is possible that the reduction of $KMnO_4$ has been catalyzed by some newly exposed surface sites.

Table II. Effect of oxidizing inhibitors on strain transients and electrode potentials. Saturated calomel reference is used, 4% strain.

Electrode and solution	Inhibitors		Without inhibitors, mv	With inhibitors, mv
Copper in HOH	0.2% $K_2Cr_2O_7$	V_o	4	35
		V_m	−81	59
		ΔV_m	−85	24
Copper in $CaCl_2$ (one half saturated)	0.07% Na_2CrO_4	V_o	−350	−250
		V_m	−373	−270
		ΔV_m	−23	−20

		V_m	−382	−179
		ΔV_m	−132	−107

Several of the strain transients involve two peaks instead of one. Only the larger peak is shown in Table II. Copper in distilled water with inhibitor shows a negative transient with $\Delta V_m = -15$ mv and a positive transient with $\Delta V_m = +24$ mv. In calcium chloride solution with inhibitor the two amplitudes are −20 mv and +16 mv. The time elapse between the two peaks is approximately 0.25 sec in the first case and 1.5 sec in the second. Only a single peak is observed in the absence of inhibitor. Aluminum shows a similar behavior, but the first peak, a negative one, occurs with an amplitude of only about 1 mv.

In the cases mentioned above, it appears that the reactions occurring in the first 0.01 sec or so after strain are the same as when the inhibitor is not present. After this very rapid negative surge, supposedly due to anodic dissolution of the metal, a cathodic process becomes predominant. Either the effect of cathodic reactions has increased, or anodic reaction rates have decreased. It is possible that new surface sites are exposed with strain, and the anodic reaction proceeds briefly before the inhibitor becomes effective in this newly exposed region. Or it is possible that the inhibitor must diffuse to the new surface, after which it becomes reduced in a cathode reaction. In either case, this effect is an interesting reflection of inhibitor reactions.

A great number of substances are used to decrease corrosion other than those already discussed. A few examples are shown in Table III. Especially prominent in protecting metals against corrosion are those substances that form a distinct physical coating in addition to any that might exist by virtue of

Table III. Effects of inhibitors and organic coatings on strain transients and electrode potentials. Saturated calomel reference is used; strain, 4%

the metal oxide on the surface. Films formed by organic substances fall into the general classes (11): paints, varnishes, enamels, lacquers, plastic films, and bitumens. The results of strain-electrometry measurements with a paint and a varnish are reported here as examples of organic coatings. Results were obtained with both Ni and Fe, and are reported in Table III. The initial potentials become negative when the coating is applied (with excessively thick coatings the electrode is insulated to such an extent that the potential cannot be measured). The strain transients are smaller than without the coating. The potential at the maximum of the transient, V_m, is not strongly altered when the coating is used. Apparently the new film is partially ruptured just as oxide films are. Since V_m is about the same in either case, similar regions of anodic (metallic) surface must be exposed.

These results give an indication of the brittleness and the protective nature of the artificial coatings as well as showing their role in altering the potential in comparison to inhibitors.

Acknowledgment

The authors would like to acknowledge grants from the Atomic Energy Commission, Contract No. At (11-1)-82, Project No. 1, and Army Ordnance Research Contract No. DA-94-495-ORD-959, in support of this work.

Manuscript received May 5, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Oriented Dioxide Films on Uranium

J. T. Waber, J. A. O'Rourke, and R. Kleinberg

University of California, Los Alamos Scientific Laboratory, Los Alamos, New Mexico

ABSTRACT

The growth habit of UO_2 on uranium during the oxidation by water vapor has been analyzed with the aid of detailed x-ray diffraction work and pole figures. The dioxide grows with a (110) planar texture which bears no epitaxial relation to the underlying metal crystallites. Although the polycrystalline alpha uranium has a strong and anisotropic preferred orientation as a result of fabrication, the oxide forms without azimuthal directionality in the plane of contact. The lack of alignment in the plane of contact also was confirmed in an experiment with a single crystal of uranium.

The texture of UO_2 formed during annealing in vacuum also was found to be planar without significant directionality. In such cases, the (100) planes were parallel to the surface of the metal substrate, and large amounts of uranium monoxide always were present in such films. Subsequent oxidation of specimens covered with the (100) texture yielded the characteristic (110) dioxide texture.

In incidental experimental work on the vapor deposition of UO_2 the octahedral or (111) texture was observed on glass and tantalum substrates, and the cubic or (100) texture was developed on several ionic substrates.

In a preliminary investigation, the rate law for the formation of uranium dioxide under conditions which produce such oriented films was found to be logarithmic.

Oriented layers of uranium dioxide form without any evident relationship to the orientation of parent metal during high-temperature exposure to moderate vacuum and water vapor. This occurrence appears to be unusual since it is commonly thought that the first layers of oxide are oriented epitaxially with the parent metal. For example, Gulbransen and Ruka (1), employing electron diffraction, showed that strongly oriented films are obtained on iron in $H_2 + H_2O$ mixtures and that these bear a rational epitaxial relationship to underlying metal. Mehl and McCandless (2) oxidized single crystals of iron in wet hydrogen and obtained the same epitaxial relations by x-ray diffraction on films thick enough to show interference colors.

Mehl, McCandless, and Rhines (3) were probably the first investigators to discuss the orientation of Cu_2O on copper. The results of eleven subsequent studies were reviewed by Lawless and Gwathmey (4). These authors made a very careful investigation of the degree of orientation of Cu_2O as a function of temperature, oxide thickness, and crystal face of the copper crystal. The degree of orientation increased with reaction temperature but decreased with oxide thickness. These studies were all conducted on relatively thick films.

Recently Harris, Ball, and Gwathmey (5) published the results of a very thorough electron microscope and electron diffraction study of the first few Angstroms of Cu_2O formed on copper single crystals. They found that the degree as well as the symmetry of orientation increased with oxide thickness. This confirmed the earlier observation of Pinsker and Tatrinova (6). More specifically, Harris, Ball, and Gwathmey observed that the thin films were composed of small oxide crystals having ". . . particular planes parallel to particular planes of the copper and random orientation about the plane normal. This orientation is designated type II. The oriented oxide of the thicker films was made up of oxide crystals with particular planes parallel to particular planes of the copper but with a common zone axis in the plane. This orientation is designated as type III. The common planes were: $(110)Cu_2O//(311)Cu$, $(111)Cu_2O//(111)Cu$, and $(111)Cu_2O//(100)Cu$. The common zone axis was [110]." That is, in thicker films, the degree of orientation increased so that the [110] direction in the oxide became parallel to [110] direction on the underlying copper. This parallelism was discussed also by Lawless and Gwathmey (4).

Oxide films with only one degree of orientation (type II cited by Harris, *et al.*) generally have not been recognized as they are evidenced only by unusual differences in line intensities on the diffraction pattern. Kerr and Wilman (7), in a recent electron diffraction study, reported that BeO forms on randomly oriented beryllium (either abraded or electropolished) with a (001) planar orientation at temperatures from 400° to 500°C and with a mean (100) orientation above 700°C.

Although unusual differences in line intensities on a diffraction pattern imply preferred orientation of the material under study it is difficult to identify the texture with certainty from these alone. Usually a pole figure technique is the only satisfactory method of studying texture. Very thin films are not readily studied by x-ray diffraction techniques, however, and the more complicated methods entailed in the study of texture by electron diffraction methods must be utilized. As far as the authors are

aware, only Harris, Ball, and Gwathmey have been able to verify in this way the suspected orientation of initially formed films.

Fortunately, for studies of UO_2 films, x-ray diffraction methods are adequate. Films of UO_2, thin enough to exhibit interference colors (200-300Å), can be studied satisfactorily by x-ray techniques.

It was possible in the present research to form, in a moderate vacuum, one planar orientation of UO_2 without azimuthal alignment in the surface plane and subsequently to convert it to a second planar orientation when the specimens were heated and oxidized in water vapor. To a large extent, the experiments described here deal with oxide films formed on polycrystalline uranium sheet. Both abraded and electropolished samples were studied. An experiment with a single crystal of uranium metal confirmed the conclusion that the growth habit of UO_2 films does not bear a unique relationship to the orientation of the underlying metal.

Pertinent Crystal Structures

An excellent summary of the physical and chemical properties of uranium metal has been published (8). With increasing temperature, at 668°C the orthorhombic alpha phase changes to a complex tetragonal beta phase. Above 774°C, the latter changes to the body-centered cubic phase which is then stable to the melting point at 1132°C.

Uranium dioxide is the principal compound formed during oxidation of uranium. It has the CaF_2 structure, and the stoichiometric compound has a lattice parameter of $a_o = 5.470$Å. Belle and Lustman (9) have reviewed the extensive information on the physical properties and chemical reactivity of UO_2. An oxide, referred to in this paper as the monoxide, having an x-ray structure compatible with the composition UO (an NaCl type structure with $a_o = 4.93$Å) has been observed by many investigators to form during the vacuum annealing of uranium. There is doubt that it is an equilibrium phase in the U-O system.

Experiment

The texture of the cold-rolled metal was first studied prior to oxidation. The reader is referred to a standard text (11) for details of constructing pole figures and interpreting orientation textures from them. Using a modified Schulz camera mounted on a Norelco wide range goniometer (10), pole figures were prepared from samples of sheet which had received varying amounts of cold reduction, both with and without subsequent annealing. Since only the center 60° of each pole figure could be obtained from the flat sheet as such, longitudinal and transverse sections through the sheet were necessary to complete each pole figure. These were prepared by sectioning the sheet in the appropriate directions, as indicated in Fig. 1, and then rotating the segments 90° about their long axis and bolting them together again. In the following discussions the bolted compacts which had been prepared from longitudinally sectioned segments, i.e., those which had been rotated 90° about the rolling direction RD as axis, are designated by the letter L following the sample number, while those prepared from transverse sections are designated by the letter T.

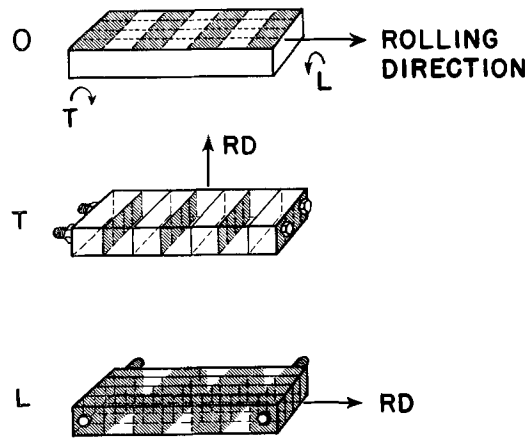

Fig. 1. Surfaces of uranium presented for oxidation by the rolled metol as well as the bolted compacts.

Since the oxide did not deposit epitaxially, details of the various metal textures developed during rolling are omitted here. It is sufficient to show that highly oriented textures were developed. This fact is demonstrated in Fig. 2, which shows the pole figure of an 86% cold-rolled uranium sheet. The same major texture developed here with a spread between (102)[010] to (203)[010] was evidenced by all the unrecrystallized samples used in this work. Different crystallographic planes, then, are predominantly parallel to the surface in the normal, transverse, and longitudinal samples. For example, if the (102) planes are parallel to the surface of the rolled sheet, (010) and (203) planes are parallel to the surface in the transverse and longitudinal sections, respectively.

The pole figure study of the dioxide presented a somewhat different problem. Here the (110) or (100) textures were developed on all of the sections, and were developed independently of the orientation of the underlying metal. Only the inner 60° of the pole figure could be plotted from an examination of the oxidized surfaces as such, and any study of the outer periphery would involve oxidizing the flat segments nearly to completion and then rotating

Fig. 2. The (111) pole figure of cold rolled alpha uranium

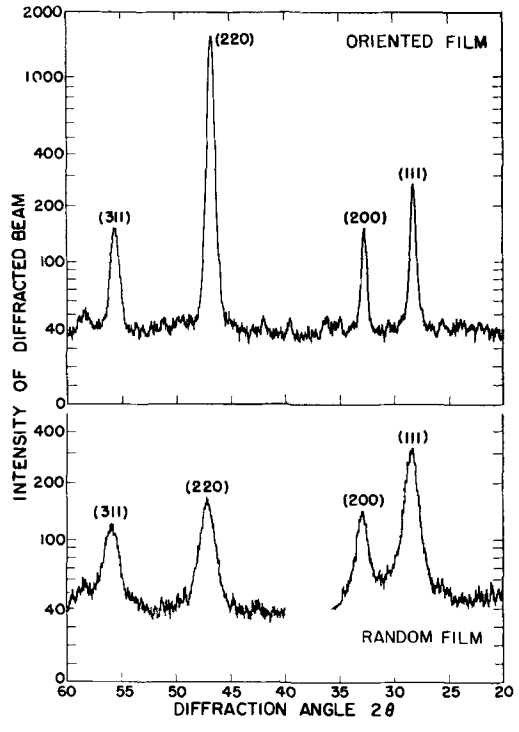

Fig. 3. Powder patterns token of UO_2 films on uranium. Intensities ore plotted on a logarithmic scale. The randomly oriented film occurred on a uranium sample after 10-hr immersion in boiling water. Ratio of the intensity of (220) to (111) is equal to the ideal value of 0.46. The oriented film occurred on the uranium after 40-min exposure to 22 mm water vapor at 400°C. The intensity ratio $I_{(220)}/I_{(111)}$ was 6.6. The triplet of alpha uranium lines which lie near the Debye 2θ angle of 36° has been omitted in the random pattern to simplify the pattern and reduce confusion.

them 90° about the long axis and bolting them together, as illustrated in Fig. 1. The necessity for resorting to this lengthy procedure was overcome by preparing pole traces of several different planes and using known crystallographic relationships for completing the analysis.

Once the nature of the orientation texture has been established, a semiquantitative estimate of the degree of orientation could be obtained from the relative intensities of lines on a diffractometer tracing. The ratios $I_{(220)}/I_{(111)}$ and $I_{(200)}/I_{(111)}$ were utilized in much of the oxidation study to evaluate the development of the (110) and (100) textures. An example of such a tracing is given in Fig. 3, together with a tracing illustrating a nearly random texture. The oriented film pattern is from a sheet sample oxidized in water vapor and exhibiting a fairly strong (110) texture. Here, the ratio of $I_{(220)}/I_{(111)}$ is 6.6, and values as high as 35 were observed in the course of the experiments. The intensity ratios for a random sample using various planes are given in Table I.

1802	1000	19	10^{-5}	210	32	1.56	0.6

Results

Several pole figures were constructed for mechanically polished specimens heated in a vacuum of 10^{-5} mm Hg or better. This metal was oxidized by the residual gas in the vacuum system. Both uranium dioxide and uranium monoxide were present in the film. Analysis of the pole figures for these vacuum treated specimens established that the (100) planes of the dioxide were formed parallel to the metal substrate during vacuum oxidation.

Oxidation experiments were conducted at 400°, 600°, and 1000°C. Results are summarized in Table II. At each of these temperatures, the dioxide is oriented principally with its (100) planes parallel to the specimen surface. Uranium monoxide was formed simultaneously in all such films, and the restraint it imposed on the texture of the dioxide is not known.

The relative amounts of monoxide in the films are indicated somewhat semiquantitatively by the relative intensities of the (111) lines of the UO and UO_2, since the scattering factor for this plane of the monoxide is approximately 91% of that for the dioxide. More quantitative estimates would require that both oxides have a similar or random orientation.

Oxidation in water vapor appears to favor the formation of the (110) or dodecahedral orientation. Several (110) and (100) pole figures were prepared from samples oxidized in water vapor. One such pole figure is presented in Fig. 4 to illustrate the relatively small spread in the angle of inclination between the pole of plane investigated and the [110] pole of the oxide. The weak directionality indicated by the broken "ring" in Fig. 4 is believed to result from the physical dimensions of the sample (the x-ray beam covered an area slightly larger than the sample in one of its orientations) rather than from any real directionality. A strong (100) texture having little or no directionality was always developed during vacuum annealing.

Starting with the oxidized sheet having the (100) or cubic texture it was possible to oxidize the metal further in water vapor and develop the (110) orientation. Admittedly, the texture was less highly oriented when preformed layers were present. One metal sample was oxidized in vacuum at 600°C and examined by x-ray diffraction to establish the nature of the film. This sample and another mechanically polished piece of the same rolled stock were placed in the furnace and oxidized at 600°C and at a water vapor pressure of 0.3 mm Hg. After x-ray determination, the two samples were replaced in the furnace and oxidized for 1 hr at 6.2 mm pressure. As indicated in Table III a significant increase in the

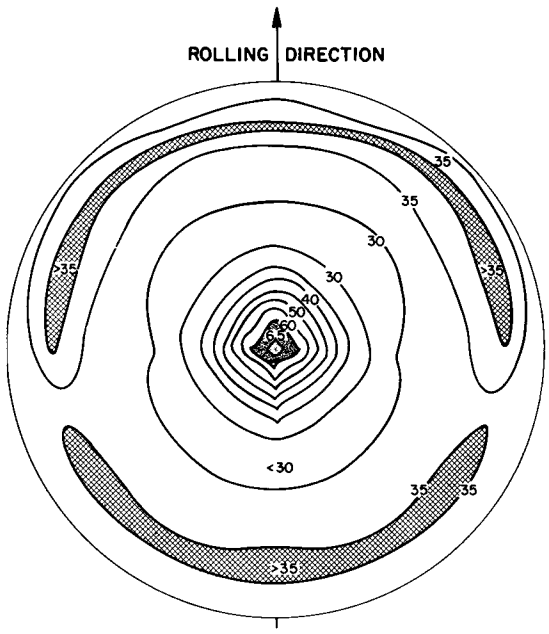

Fig. 4. Typical (110) pole figure of uranium dioxide which was formed on rolled alpha uranium sheet by oxidation in water vapor. Only the inner 60° of the stereographic projection is drawn here. The central peak and the incomplete ring illustrate the lack of significant azimuthol directionality. The intensity ratio $I_{(220)}/I_{(111)}$ was 5.6.

(110) component was observed. Specimen 1954 (Table II) was subsequently oxidized in water vapor at 600°C. Pole figures constructed using the (200) and (220) planes of UO_2 confirmed that the UO_2 was forming with the (110) planes predominantly parallel to the specimen surface.

Bolted metal compacts were oxidized for 40 min at 400°C and at 17-28.4 mm Hg water pressures. Pertinent test data are presented in Table IV. The electropolished specimen, 2130L, was heated in vacuum (10^{-5} mm Hg) at 400°C for 90 min. The predominant orientation appeared to be that of the (100) UO_2 planes parallel to the surface. This sample was oxidized to form sample 2131 which then exhibited a pronounced (110) or dodecahedral texture. The preformed (100) orientation, then, did not deter the (110) formation on subsequent oxidation.

Pole figure studies of samples, oxidized as indicated in Table III and IV, established that the uranium dioxide formed with a planar orientation on

Table III. Comparison of the degree of orientation resulting from the oxidation of preformed films at 600°C

Specimen No.	Treatment given	Orientation ratio* $I_{(220)}/I_{(200)}$†	$I_{(200)}/I_{(111)}$
1952	Vacuum, ½ hr	0.25, 0.09	1.6, 3.8
1952	Vacuum, 1 hr	0.25, 0.20	1.7, 3.3
1952a	Vacuum + 0.3 mm Hg	0.23, 0.30	2.0, 1.5
1952b	Vacuum + 0.3 mm + 6.2 mm	0.45, 0.48	0.79, 0.83
1966	0.3 mm	0.74, 0.89	5.4, 4.0
1966a	0.3 mm + 6.2 mm	1.29, 1.86	4.0, 4.0

* Duplicate values are for observations made, respectively, parallel and transverse to the rolling direction.
† Intensity ratio for random samples is 1.21.

Table IV. Orientation ratios and test conditions

Specimen No.	Preliminary treatment	Water pressure	Ratio of intensities $I_{(220)}/I_{(111)}$	$I_{(200)}/I_{(111)}$
2130L	Electropolished	Vacuum	1.0	6.4
2131L	Vac. anneal	28.4 mm Hg	1.0	0.30
2132L	Electropolished	28.4	1.80	0.59
2133T	Electropolished	17.0	18.2	1.47
2134T	Electropolished	17.0	35.0	2.70
2135L	Front, electropolished	22.1	2.4	0.26
2135L	Back, after mech. polish	22.1	2.7	0.27
2136L	Electropolished	22.1	6.4	0.5

the sheet surface, and that there was definitely no epitaxial relationship between this oxide and the underlying metal. Longitudinal, transverse, and normal samples of the same rolled sheet all exhibited identical textures when oxidized under like conditions.

A second texture develops, during this recrystallization of uranium, with the [140] pole parallel to the original rolling direction and with the poles of the planes parallel to the sheet surface having a small spread about [112]. By using bolted compacts, two other metal planes were examined to ascertain whether they influenced the oxide orientation markedly. Six such compacts were oxidized simultaneously in 20 mm Hg water pressure for 3 hr at 450°C. Data are summarized in Table V.

It is reasonable to conclude that the same dodecahedral texture devoid of azimuthal directionality developed on the recrystallized metal as well.

Single-Crystal Experiment

It was possible to confirm these conclusions with a "single crystal" of uranium obtained from Argonne National Laboratory. It was a cylinder approximately ⅛ in. in diameter and ⅜ in. long, and contained five grains. The largest of these grains filled the central cross section of the cylinder and extended along the axis in both directions.

Following oxidation in water vapor at 450°C and a pressure of 15 mm Hg for 17 min, it was examined by Olsen,[1] using a cylindrical x-ray camera. Six photographs were taken at different angles normal to the cylindrical axis; three of these photographs were overlapping oscillation patterns covering an angular range of 44°. Fairly uniform diffraction

Table V. Orientation ratios for the oxidation of rolled and recrystallized uranium sheet

Specimen No.	Ratio of intensities $I_{(220)}/I_{(111)}$	$I_{(200)}/I_{(111)}$
	Rolled Sheet	
2918 as rolled	4.82	1.38
2919 longitudinal	2.46	0.34
2920 transverse	3.20	0.38
	Recrystallized Sheet	
4123 as rolled	5.21	1.37
4124 longitudinal	1.89	0.43
4125 transverse	1.44	0.57

"rings" were obtained and there was no evidence of preferred alignment between the metal and oxide. The (110) planar orientation was concluded to have formed on the cylindrical metal surface.

Other Observations of Oxide Orientation

Numerous additional examples of the preferred growth habits of UO_2 can be gained from a study of the literature. Uranite and other minerals involving partial replacement of the uranium atoms, such as thorianite, occur mainly as cubes and octahedrons (12). Occasionally, dodecahedrons are found.

The octahedral or (111) growth habit was observed during an electron diffraction (13) study of a vapor deposit of UO_2 formed on a smooth glass substrate. When it was deposited under similar conditions on tantalum, the [111] pole was not perpendicular to the substrate as on glass but was inclined to it, which suggests that the higher thermal conductivity of tantalum reduced the substrate surface temperature and thus reduced the surface mobility.

Wilman and co-workers (7, 14-16) have discussed numerous examples of oriented overgrowths. In particular, they evaporated various metals and ionic salts onto substrates in such a way that the line of flight taken by the evaporating substance was oblique to the surface of the substrate. Low melting materials were observed to be arranged with some rational and densely packed plane parallel to the substrate surface. However, with refractory materials, the orientation axis of the deposit was inclined to the surface presented by the substrate, and the direction of preferred growth was approximately parallel to the line of flight. When the substrate has good thermal conductivity the kinetic energy of the depositing material is reduced and the molecules lose a portion of their surface mobility. If the substrate does not conduct heat well, high surface temperatures, high surface mobilities, and thus more perfectly oriented deposits are to be expected.

The cubic or (100) growth habit was observed for heated substrates (17). Uranium dioxide was distilled from a tungsten boat at approximately 2800°C in an evacuated system containing a few millimeters of hydrogen and was deposited onto a polished single crystal of either CaF_2 or KBr which was held at approximately 600°C. The deposit showed preferred orientation with the (200) line being very prominent.

Thus vapor deposition favors the same two growth habits that are found in naturally occurring crystals. The dodecahedral habit, however, is associated with the oxidation of uranium. Mogard (18) reported that, during the corrosion of uranium in molten sodium, uranium dioxide forms by combining with the small amounts of oxygen dissolved and entrained as Na_2O in the molten sodium. The films formed at 475°C exhibited the (110) planar orientation. At higher temperatures, a porous and relatively nonoriented layer occurred on top of the coherent hard oxide layer adjacent to the base metal. During the cathodic vacuum etching of uranium in tank argon, thin UO_2 films form. These films are formed with the (110) planes parallel to the metal substrate.

These observations suggest that the formation of this dodecahedral orientation results from growth of the oxide film in a preferred direction. The interfacial temperature of the uranium is probably high enough during oxidation to permit surface migration and preferred growth of those oxide crystallites which are favorably oriented.

Rate Law Involved

Rate data were obtained in connection with the orientation of the oxide. It is surprising that a logarithmic law is followed. Doubtless this can only occur at such a high temperature because of the low pressure of the oxidant, water.

The change in weight of the specimen was determined from the extension of a fused silica spiral spring. By using three springs, which were each able to support 3-g loads safely, and by arranging them in tandem, a spring constant of 10.84 cm/g was obtained at room temperature. A 1-mg change in weight corresponded to a 0.108-mm extension, which could be read easily with a cathetometer. The spring constant was determined with the furnace in place and with the specimen, bucket, and a portion of the spring at 400°C. For example, it was found that the helix, with the bucket containing a piece of gold, changed in length from 40.950 cm at room temperature to 41.150 cm at 400°C mainly as a result of the change in the spring constant.

The system was evacuated and the specimen brought to temperature and equilibrated for approximately 1 hr. The water was admitted to the system by breaking a sealed ampoule in that portion of the system at room temperature. The initial cathetometer reading was taken approximately ½ min after the reaction commenced.

The high-purity uranium metal used for this test was rolled to approximately 0.002 in. thick sheet and annealed. This annealed sheet was cut and polished through 4/0 metallographic paper. An extension of 0.1 mm corresponded to a weight increase of 30.67 $\mu g/cm^2$ of the specimen.

Typical weight changes with time are illustrated in Fig. 5 for two separate runs conducted at 400°C

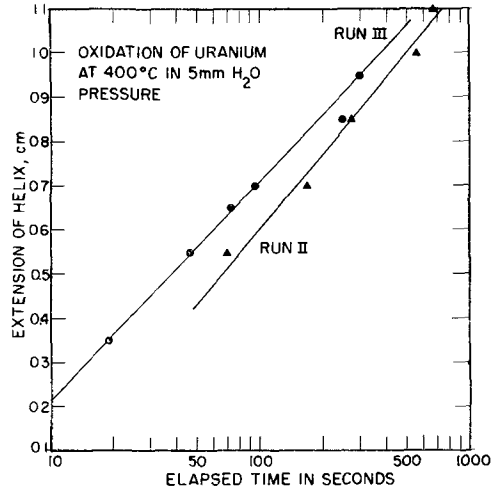

Fig. 5. Semi-logarithmic plot of the length of the silica helical spring vs. the duration of oxidation. Data are for two separate runs at 400°C.

and 5 mm water pressure. A logarithmic growth law was obtained with a fair degree of reproducibility.

The orientation of the oxide was examined after removal of the samples from the furnace. The ratios $I_{(220)}/I_{(111)}$ were found to be 1.1 for Run II and 2.15 for Run III.

Discussion

Several hypotheses could be advanced which would afford an explanation for the formation of the planar texture of the overgrowth. One of the most logical explanations would involve the use of dislocation theory. A thin layer of oxide next to the metal is disorganized and is not aligned epitaxially with the metal. A few oxide grains will contain, or form, one dislocation emerging essentially perpendicular to the specimen surface. Diffusion of ions along this dislocation will be relatively rapid, as has been indicated by the experiments of Turnbull and Hoffman (19, 20) on the self-diffusion of silver along grain boundaries. Inward diffusion of oxygen along such dislocation "pipes" will increase the rate of oxidation. Thus oxide grains with favorably oriented dislocations will penetrate faster. The favored grains need have no azimuthal relation to the substrate. At a later stage, when such a grain has penetrated more deeply than most, the diffusion resistance along this dislocation pipe will increase until it is equal to that along most paths. The tip of the favorably oriented grain will then advance inwardly at almost the same rate as does the bulk of the oxide. However, an alternative path lying partly along the dislocation and partly perpendicular to it has lower resistance. Thus the penetrating grain will spread laterally near the interface and will become roughly pyramidal. The high temperature in the oxide film from the heat of reaction will facilitate the recrystallization of the disorganized oxide thus enlarging the large favorable grains. Experiments to establish the essential features of this explanation are in progress.

Two important studies have been reported recently. Miller and Lawless (22) have obtained electron-photomicrographs of spiral growth terraces such as are associated with screw dislocations on Cu_2O polyhedra formed on copper single crystals. An experiment by Harris, Ball, and Gwathmey (5) strongly indicated that the nucleation and formation of Cu_2O polyhedra was related to dislocations in the copper itself. These polyhedra are oriented with a common [110] zone axis in the interface as cited above for the thick oxide films (4, 5). Webb and Foreng (23) have observed the formation of α-Al_2O_3 whiskers and platelets during the oxidation of aluminum or of Al_3Ti in wet hydrogen at 1300°-1500°K. Invariably the whiskers were single crystals with the [001] direction parallel to the principal growth direction. Dragsdorf and Webb (24) have shown that these whiskers contain screw dislocations. Terraced growth steps have been observed optically on α-Al_2O_3 platelets.

The formation of a smooth oxide film of uniform thickness can no longer be envisaged as the proper description. The growth and nucleation of discrete oxide grains are the dominant processes initially. Similar phenomena have been observed for the formation of AgBr on silver by Newman and Pashley (25). More work is needed to elucidate the role of dislocations in the metal substrate and in the compound formed.

Belle and Lustman (9) have reviewed the evidence which leads to the conclusion that ionic migration in UO_2 occurs by the diffusion of anions. The formation of anti-Frenkel defects (interchange between an anion in its sublattice with a vacant interstitial site) contributes to the higher mobility of anions in the fluorite lattice as Ure (21) has shown for doped CaF_2. Because of this anion diffusion, the dioxide grows inward during the oxidation of uranium leaving superficial markers unaffected on the original surface. Thus external growth patterns are not anticipated in the UO_2.

Conclusion

It has been shown that uranium dioxide formed by the reaction of uranium with water vapor at moderate temperatures occurs with a distinctive growth habit. The (110) planes of the dioxide lie parallel to the surface of the polycrystalline uranium substrate. No evidence was found for an epitaxial relation between the metal and the oxide. Although preformed dioxide films having a (100) planar texture were developed, subsequent oxidation yielded the (110) texture.

The formation of the dodecahedral texture is uncommon in naturally occurring crystals or in vapor deposition. The planar texture is explained on the basis of recrystallization of the oxide and preferential growth of oxide grains containing favorably oriented dislocations.

Acknowledgment

The authors are deeply indebted to Professor Robert Brick for his interest in the problem and for his valuable suggestions during the course of the work. The single crystal of uranium was generously given by Dr. Frank G. Foote of Argonne National Laboratory. The assistance of many members of the laboratory in connection with the experimental work and the preparation of this report is gratefully acknowledged. Particularly we should like to mention Donald Prys and Marguerite Coleman. Dr. R. B. Roof, Jr., calculated the intensity of the lines in the UO_2 x-ray diffraction pattern. Edward S. Wright, Dawn D. Whyte, and William R. Hickey contributed to the experimental work.

Manuscript received Nov. 26, 1956. A portion of this paper was prepared for delivery before the Cleveland Meeting, Sept. 30-Oct. 4, 1956 and a portion was reported at the Gordon Research Conference on Oxidation Processes, New London, N. H., July 1954. The work was done under the auspices of the Atomic Energy Commission.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Kinetics of the Uranium-Steam Reaction

B. E. Hopkinson[1]

Atomic Energy Research Establishment, Harwell, England

ABSTRACT

Reaction rates of unalloyed uranium with super heated steam at 160°-1400°C and 1 atm pressure have been determined by a thermogravimetric method. Up to 880°C the reaction follows a linear rate law with maximum rates at approximately 300° and 750°C. Above 880°C a parabolic rate law applies for the first 60-120 min, after which corrosion is linear; the oxide formed in the initial period gives protection to the underlying metal, and the subsequent linear rate is as low as that at about 200°C. X-ray diffraction of the reaction product indicated that uranium dioxide was formed over almost the whole temperature range.

Previous quantitative work on this reaction has been confined to temperatures below 600°C. The earliest investigations (1) reported uranium to be attacked rapidly by steam from 150° to 400°C, with a reaction product of uranium dioxide at the lower temperatures; this changed to U_3O_8 on rise of temperature until at 400°C U_3O_8 constituted about 92% of the total oxide produced. Other workers (2) found that steam reacted rapidly with uranium turnings at 250°C to give a mixture of uranium dioxide and uranium hydride, but at 600° and 1000°C only uranium dioxide and hydrogen were formed; no U_3O_8 was reported at any temperature.

Huddle (3) gave some experimental data up to 600°C and also assessed the kinetic possibilities at higher temperatures, concluding that the uranium dioxide formed would be sufficiently protective to give a low reaction rate. The reaction rates obtained here indicate that the uranium oxide does in fact tend to be protective at high temperatures.

Experimental

Materials

Uranium.—Two different sizes of uranium specimens were used. The first, of rectangular shape, was satisfactory at low temperatures but oxidized completely in a few minutes at 750°C. It was therefore replaced by a larger cylindrical sample for experiments above 600°C.

The rectangular specimens weighed about 6.5 g and were approximately 1.3 x 1.9 x 0.15 cm (surface area 5.7 cm^2). They were fabricated by rolling as-cast Springfields uranium into a sheet at 450°C and punching out to size. The cylinders weighed 30 g and were approximately 1.26 cm in diameter and 1.27 cm in height. They were cut from a bar of cast uranium and machined to the approximate dimensions. Before the experiment each specimen was polished to 00 emery paper under oil, degreased in acetone, and stood for 12 hr in a desiccator over calcium chloride.

Steam.—Steam was obtained from a main supply, the line pressure being reduced by a valve which maintained the pressure inside the reaction chamber slightly above one atmosphere.

Argon.—Argon was used to provide an inert atmosphere when preheating the specimen to reaction temperature. It was purified from oxygen and nitrogen by passing over calcium turnings at 600°C followed by bubbling through Na/K alloy at room temperature.

[1] Present address: Research Laboratory, The International Nickel Company, Inc., Bayonne, N. J.

Procedure

The reaction rate was followed by continuous weighing of the specimen on a modified thermobalance. The apparatus was as described by Kubaschewski and Hopkins (4) except for the provision of a heater to prevent condensation of steam on the platinum suspension wire where it emerged from the reaction chamber.

A platinum or nichrome wound furnace maintained the specimen temperature, which was measured by a chromel/alumel or platinum/platinum rhodium thermocouple placed adjacent to the specimen in a silica "pocket." The thermocouple measured the temperature of the gas stream, which may be lower than that of the specimen by an amount depending on the degree of self-heating. This self-heating, due to the exothermic nature of the reaction, is unavoidable. At 350°C it can be as large as 150°C (3) but above 880°C, when the protective oxide scale has formed, the heat of reaction is not likely to contribute materially to the specimen temperature when compared with the external heat input. The actual temperature fluctuations recorded were between 10° and 40°C for each experimental run.

When carrying out the experiment, the furnace, argon purifier, and heating tapes were brought up to the appropriate temperature, the specimen placed in the fused silica reaction chamber, and argon flushed through. After elevating the furnace to a position around the specimen and preheating in a flow of argon to the required temperature for about 30 min, steam was admitted at roughly 2 l/min. Weight increases were recorded at appropriate time intervals. After the required period, the steam flow was stopped and the specimen cooled in argon before removal. In nearly all experiments the specimen showed a small weight increase when being preheated, and this was attributed to impurities still remaining in the argon after purification.

The specimens were always enclosed in a basket of platinum gauze (52 mesh) to retain oxide that fell away from the metal; the basket in turn was suspended from the balance.

Table I. Rates of reaction over the temperature range 160°-1400°C

Results

The rates of corrosion, i.e., the slope of the curves, are detailed in Table I. Usually several values of the reaction rate were determined at each temperature by independent experiments.

The scatter of rates shown in this table may be due partly to lack of control of temperature because of self-heating and partly to other variations in the experimental conditions, e. g., traces of oxygen in the steam supply.

The behavior of solid uranium in steam from 160° to 880°C is represented by a linear relationship between weight increase and time; an exception is at 230°C. Figures 1(a) and 1(b) show typical curves for this part of the temperature range

From 880° to 1060°C the curves [Fig. 1(c)] are initially parabolic changing to linear after times ranging from 60 to 120 min. The linear rates are detailed in Table I. The parabolic or near-parabolic nature of the initial part of the curve was shown by the slope of a log-log plot of weight increase per unit area (y) against time (t). This slope should ideally be 0.50. Actual values are reported in Table I, column 3.

Two experiments were carried out with molten uranium. Figure 2 shows that at about 1200° and 1400°C the rate fell initially with time to a steady value of 4-5 mg/cm²/min. Some difference in the form of the two oxidation curves was evident.

Figure 3 shows the linear reaction rate of each specimen plotted against the temperature of the experiment.

Other observations.—The physical nature of the reaction product varied with the temperature of oxidation. Below 500°C the oxide was a voluminous fine powder, but above this temperature larger particles began to appear. Above 880°C the oxide formed a complete shell, which adhered to the uranium and remained intact on cooling the specimen to room temperature. When cold, this shell could be stripped off easily. Figure 4 shows typical changes in the reaction product with temperature. The bulk densities of the oxide produced at higher temperatures were measured by weighing in air and water and are given in Table II.

The reaction products over the temperature range 200°-1400°C were examined by x-ray diffraction. All the samples gave a uranium dioxide type pattern except one at 300°C which appeared to be U_3O_8; this does not imply a stoichiometric composition of $UO_{2.0}$

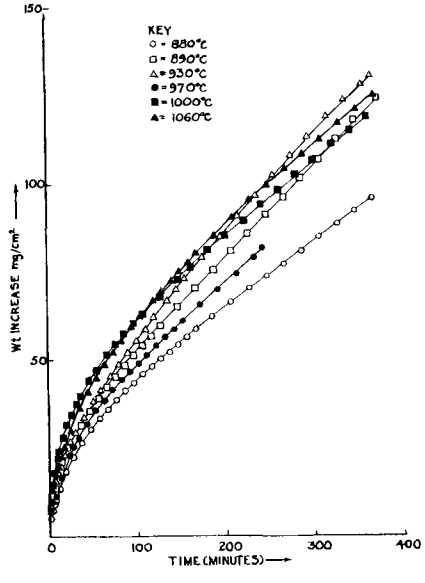

Fig. 1 (c). Uranium in steam 880°-1060°C. Plot of weight increase (mg/cm²) V time (min).

but is typical of compositions between $UO_{2.0}$ (α-UO_2) and $UO_{2.24}$ (β-UO_2).

Three specimens which had been exposed to steam at 200°, 930°, and 1060°C were examined metallographically. The 930° and 1060°C specimens showed similar characteristics and are considered together. The outer layer of oxide, about 1 mm thick, had flaked off, but an adherent coating approximately 5μ thick remained. No evidence of preferential grain boundary attack was observed, and inclusions originally in the uranium appeared unchanged in the oxide. These inclusions were thought to be uranium monocarbide since they etched black in a mixture of equal parts of nitric acid and water. After corrosion, inclusions of a new type were present in addition to the carbide. These consisted of light brown areas (Fig. 5) generally serpent-like in shape at grain boundaries and almost invariably containing a spine of small, dark, fairly equiaxed inclusions. The brown inclusions occupied about 0.25 vol % of the material and were more numerous in the center than the periphery. Mogard and Cabane (5) indicate that this type of inclusion is uranium hydride. The solubility of hydrogen in γ-uranium is 15-17 ppm but is less than 2 ppm in α-uranium (6). Since 0.25 vol % of uranium hydride corresponds to 18 ppm of hydrogen, it appears that during corrosion with steam the uranium becomes saturated with hydrogen which precipitates on cooling.

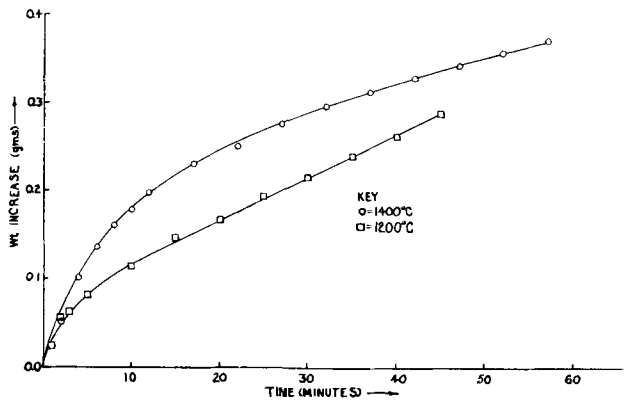

Fig. 2. Molten uranium in steam. Approximate surface area of molten uranium exposed to steam = 0.9 cm².

Examination of the specimen corroded at 200°C showed no such hydride. Except for a few large fissures, attack was fairly uniform, and no trace of preferential attack along the grain boundaries was found. The fissures ran parallel to strings of uranium carbide inclusions, but the carbide content in the region of the fissures did not appear above average. Uranium hydride was found near the tips of the fissures, either along the stringers of carbide inclusions or as needles at an angle to the fissure (Fig. 6).

Discussion

From the results obtained on solid specimens two oxidation maxima are observed at approximately 300° and 750°C, with two minimum at about 550° and from 800°-1050°C.

It is possible to explain the first maximum at 300°C by considering the rate of variation of uranium hydride formation with temperature. Uranium hydride is unstable above 433°C under 1 atm partial pressure of hydrogen, and the rate of reaction be-

Table II. Bulk densities of the oxide scales formed above 880°C

Photograph of uranium specimens before and after corrosion in steam: (a) rectangular specimen before corrosion; (b) cylindrical specimen before corrosion; (c) specimen after exposure to steam at 200°C for 6¾ hr; (d) specimen after exposure to steam at 300°C for ¾ hr; (e) specimen after exposure to steam at 500°C for 1 hr, 40 min; (f) specimen after exposure to steam at 700°C for 20 min; (g) specimen after exposure to steam at 840°C for 1 hr, 20 min; (h) specimen after exposure to steam at 1000°C for 6 hr.

tween uranium and gaseous hydrogen reaches a maximum at 225°-250°C. It has been reported (7) that below 450°C uranium reacts with steam to give a mixture of hydride and oxide according to the equation

$$U + H_2O \rightarrow UH_3 + UO_2$$

and that the uranium hydride reacts slowly (8) with more steam to give uranium dioxide. Therefore, reaction below 450°C should yield a mixture of uranium hydride and uranium dioxide,[2] the latter predominating, as confirmed by metallographic examination of a specimen corroded at 200°C. It is probably justified to infer therefore that the maximum oxidation rate of uranium by steam at 300°C is determined by the variation of the rate of uranium hydride formation with temperature.

Above 500°C, hydride formation is improbable and the reaction may be written

$$U + H_2O \rightarrow UO_2 + H_2$$

the hydrogen being evolved as a gas or dissolving in the metallic uranium. In the temperature region above 500°C the cohesive properties of the oxide become important as a rate-determining factor. Up to 500°C the reaction product is in the form of a fine

[2] It is not clear whether the U_3O_8 found at 300°C is a definite reaction product (1) or results from air oxidation of uranium dioxide or uranium hydride after removal from the apparatus.

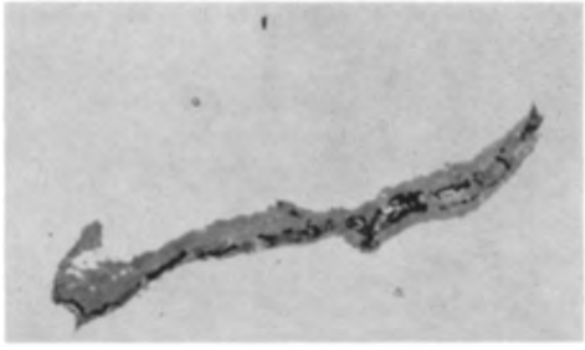

Fig. 5. Hydride precipitate in specimen after exposure to steam at 1060°C and cooled to room temperature. Magnification 1200X.

powder, but above 500°C granular particles are formed. Normal sintering of uranium dioxide occurs at about 1300°C (0.6 Tm), but it has been suggested that the presence of steam enhances the sintering characteristics of uranium dioxide (9). Also, an oxide film growing on the metal may behave differently from discrete oxide particles. The high reaction rates observed in part of this temperature range, i.e., 700°-880°C, may result from the increased surface area caused by the specimen splaying out at the top and bottom during oxidation. Why this occurs only between 700° to 880°C is not clear, but it may be that at these temperatures the oxide does not sinter sufficiently to protect the uranium completely, and that the stresses developed as the scale grows prove too much for continued cohesion, resulting in breakdown and high oxidation rate. It was noted that an induction period of up to 20 min occurred in experiments betwen 650° and 840°C before the reaction rate increased to a high value. This may indicate a change in mechanism but, since the size of the specimen had to be increased to work in this region, this also may have influenced the appearance of an induction period.

It is above 880°C that the most significant change in the rate of the reaction occurs. Above this temperature a hard compact scale forms, the density lying between 10.95 and 11.00 g/cc which compares well with theoretical values from lattice parameters given by Grönvold (10) viz., 10.954 g/cc for $UO_{2.00}$ and 11.297 g/cc for $UO_{2.25}$.

The results from 880° to 1060°C show large initial weight gains increasing roughly according to a parabolic law. After 60-120 min however, a change occurs and the weight increase becomes linear with time and continues linear for the rest of the experiment.

The rate in the linear range is between 0.2 and 0.3 mg/cm²/min over the temperature range 880°-1060°C. Therefore once an oxide film has been formed, the reaction rate between uranium and

steam is smaller above 880°C than at any lower temperature down to about 200°C.

To explain this, the two rate laws which characterize the reaction may be discussed briefly.

(*A*) The parabolic rate law can be expressed as $y = kt^{1/2}$ and traditionally is derived from the diffusion of reactants through the oxide as the rate-determining step.

(*B*) The linear law $y = kt$ can be ascribed to oxidation of metal by the following two mechansims: (i) when the rate-controlling step is a surface reaction at one of the interfaces; (ii) if the rate is controlled by diffusion through an oxide layer of constant thickness.

The change from parabolic to linear oxidation with time at constant temperature has been reported for a number of reactions (11-16).

To explain the change from a parabolic to linear oxidation rate three mechansims may be considered. First, the heat of oxidation could result in self-heating of the specimen, thereby increasing the temperature and rate of oxidation. Second, if the surface area changes as oxidation proceeds (i.e., a decrease in roughness) this may cause a change in the oxidation rate. Davies and Birchenall (13) explained the initial parabolic oxidation of titanium in oxygen as being due to a change of surface area as oxidation proceeded, the over-all rate-controlling stage being the interface reaction of oxygen and titanium oxide. Third, there is the idea of a "barrier film" of constant thickness controlling the rate of oxidation. This mechanism has been used to explain the majority of transitions from parabolic to linear-type rate laws.

A mechanism involving control by an oxide layer of constant thickness appears to serve the facts of the uranium-steam reaction above 880°C and is put forward to explain these results.

The actual diffusing species through the oxide layer is probably anionic. The presence of uranium hydride in the metal after corrosion at high temperatures in steam indicates that hydrogen either as molecular hydrogen, protons, or hydroxyl ions is able to penetrate to the uranium in some way. One suggestion (3) is that water vapor is first chemisorbed on the uranium dioxide at the oxide/steam interface. The chemisorbed complex then produces hydroxyl ions, which are further reduced at the metal/oxide interface, the hydrogen dissolving in the metal. The hydrogen is precipitated as hydride in the grain boundaries when the specimen is cooled within the hydride formation range.

Conclusions

The rate of attack of uranium by steam varies with temperature over the range 160°-1060°C, and two maxima are obtained at about 300° and 750°C. Above 880°C however, a protective scale is formed, due to coalescence of the oxide. Once this scale has been produced the rates of oxidation above 880°C are smaller than those found between 200° and 880°C.

From the results given the trend of the reaction has been indicated, but further work will be needed to confirm the true rate-controlling mechanisms over the whole temperature range.

Acknowledgments

Thanks are due to K. A. Peakall for some of the early experimental work, to Dr. D. K. Thomas for the x-ray diffraction studies, and to P. E. Madsen for the metallographic examination. For helpful discussion and constructive criticism the author is indebted to Mr. R. A. U. Huddle, Dr. H. M. Finniston, Mr. J. N. Wanklyn, and Dr. P. Murray.

Manuscript received Dec. 23, 1957. This paper was prepared for delivery before the Ottawa Meeting, Sept. 28-Oct. 2, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Tarnishing Reactions of Silver in Iodine Atmospheres

Donald M. Smyth and Marjorie Cutler

Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

The tarnishing of silver in halogen vapors, particularly iodine vapor, has been studied as a function of reaction temperature, halogen pressure, silver purity, and concentration of foreign vapors in the halogen atmosphere for reaction times up to several hours. The reaction temperature range studied was 25°-150°C for reactions in iodine and up to 200° in bromine and chlorine. In pure halogen vapor the reactions follow the familiar parabolic rate expression and are proportional to the square root of the halogen pressure. In the presence of small partial pressures of water or carbon tetrachloride vapor, however, the tarnishing rate is suppressed and is independent of the tarnish film thickness.

The tarnishing of silver in halogen atmospheres has been described by several investigators using various techniques (1-4). Since the publishing of Wagner's theory of the mechanism of these reactions (1, 5), however, very little work has been done on the tarnishing of undoped silver in halogen vapor, and, in particular, there has been no evaluation of the role played by foreign gases in the halogen atmosphere. Neither has there been any extensive study of these tarnishing reactions in the temperature range 25°-150°C. This range of reaction temperature has been examined in this laboratory for the silver-iodine system for silver samples of differing purity and for pure iodine atmospheres and iodine atmospheres containing water vapor or carbon tetrachloride vapor. Exploratory experiments have also been made on the effect of water vapor and carbon tetrachloride vapor on the tarnishing rate of silver in bromine and chlorine atmospheres.

Previous publications in this field are in agreement that the high-temperature tarnishing of silver in halogen vapor follows a parabolic rate expression

$$x^2 = kt \qquad [1]$$

where x is the tarnish film thickness, t the reaction time, and k the rate constant. The reaction rate has been found to be proportional to the square root of the halogen pressure, $P_{X_2}^{1/2}$, and inversely proportional to the concentration of cation vacancies, $[Ag^+]$, in the silver halide. The cation vacancy content can be controlled by the addition of polyvalent metallic impurities to the silver (2, 3). Our experiments in the reaction temperature range 25°-200°C indicate that the factors determining the tarnishing rate are essentially the same in the case of tarnishing reactions in pure halogen vapors. In the presence of even small partial pressures of water or carbon tetrachloride vapors, however, the nature of the reaction is altered completely. Reaction rates become independent of tarnish film thickness and follow a linear expression,

$$x = at \qquad [2]$$

where a is a new rate constant. Reaction rates are relatively insensitive to reaction temperature and halogen pressure under these conditions.

Experimental

The reactions were followed by measuring the weight increase of silver foil in a halogen atmosphere by the extension of a quartz fiber spring balance (McBain balance). The silver samples were cut from 0.001-in. foil and had a geometrical surface area of 19.4 cm^2. The samples were cleaned just prior to use by a dip in concentrated cyanide solution to remove atmospheric tarnish and by a light etch in dilute nitric acid. After being rinsed and air dried, the specimens were weighed and hung in the reaction chamber on the end of the quartz fiber spring. The iodine pressure was determined by thermostatting iodine crystals. In order to avoid condensation of iodine, the atmosphere surrounding the experimental system was heated slightly above the temperature of the iodine crystals.

When all parts of the apparatus had reached temperature equilibrium and the system had been evacuated to less than 30 μ pressure, the iodine container was opened to the reaction chamber. As the spring oscillations caused by the flow of iodine vapor into the reaction chamber ceased, an initial spring level reading was taken and the timer started. The spring depression then was measured every 1-5 min for a total time of ½-6 hr depending on the reaction rate. To terminate the reaction, the system was evacuated and flushed with air; then the sample was removed and weighed. The difference between the actual total weight increase and the weight increase which occurred during the measured reaction time as calculated from the total spring depression gave the amount of reaction which occurred before the first reading was taken. This initial amount of reaction was transformed into an equivalent spring depression which was added to each measured spring depression. These corrected values thus correspond to the total weight increase of the sample normalized to the clean, unreacted silver foil. This procedure was necessary because of the possible shift of the equilibrium spring position during the large, initial oscillations. The

square of the corrected spring depression was plotted against the reaction time, and the slope of this line when transformed into appropriate units gives the reaction rate constant k. (Microscopic examination of cross-sectioned samples showed that the bulk density of the silver halides can be used to calculate the film thickness.)

The technique was slightly more involved when the reaction rate was measured in the presence of a foreign vapor. In this case, a second isolated and thermostatted container was added to the apparatus to hold the thoroughly outgassed water or carbon tetrachloride. The two vapor sources generally were held at different temperatures and thus could not be opened to the system at the same time. An initial film of tarnish product was formed on the silver by exposure to halogen and foreign vapor. Then the reaction was halted and this initial film was exposed to the foreign vapor for 15 min after which the reaction rate with iodine was measured. No subsequent readmission of foreign vapor was necessary since additional exposures at the same pressure did not change the reaction rate.

Materials.—The silver[1] was of the following types:

1. Commercial silver, nominally 99.9+% pure. Spectrographic analysis showed copper to be the major impurity with a concentration of the order of 0.05% with lead, iron, and calcium being present in slightly lesser concentration.[2]

2. Laboratory refined silver, initially prepared as a powder 99.995+% pure. Some surface contamination may occur during rolling but this is probably removed by the etch treatment.

3. Cadmium doped silver prepared from laboratory refined silver. This alloy contained 0.046% cadmium according to the suppliers assay. The copper content was 0.003% and no other impurity was present in concentration greater than 0.001%.

Matheson, Coleman, and Bell Reagent iodine crystals (resublimed) were used without further purification. Baker Reagent Grade bromine was dried by several passes through a tube of anhydrous calcium sulfate. Baker and Adamson Reagent carbon tetrachloride was used without further purification. The source of water vapor was demineralized water of greater than 1 megohm cm resistivity.

Several quartz springs were used during this investigation, all having spring constants of about 0.05 g/cm. The spring constants were determined by measuring the extension caused by known loads over the pertinent load range and were found to be constant within ±5% over the entire experimental temperature range. The spring depression could be read to ±5μ through a 10X telescope mounted on a micrometer head.

Results

The experimental results may be summarized as follows: the reaction of silver with pure halogen atmospheres followed parabolic rate expressions, Eq. [1], except for some deviations observed during the first few minutes of reaction; in halogen atmospheres containing water or carbon tetrachloride vapor above some minimum pressure the reaction rates were linear with time and followed Eq. [2]. The reaction rates behaved reversibly to changes in halogen pressure and foreign gas pressure but not to changes in reaction temperature since a decrease in reaction temperature does not change the reaction rate to the rate obtained when the reaction is started at the lower temperature. All of these factors will be discussed in detail.

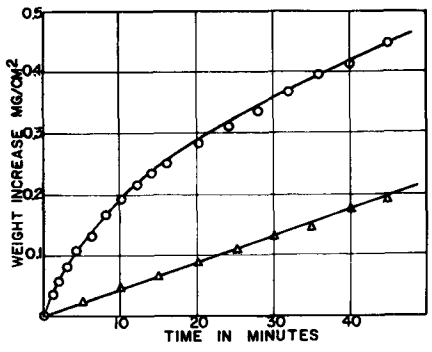

Fig. 1. Tarnishing of silver in 0.2 mm iodine vapor at 39°C. ○ Pure iodine vapor; △ iodine vapor plus 0.37 mm H_2O vapor.

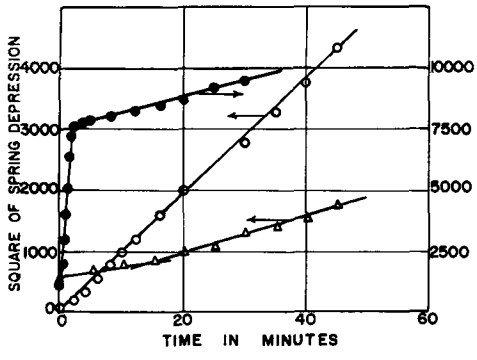

Fig. 2. Tarnishing of laboratory refined silver (99.99+%) in 0.2 mm pure iodine vapor. Typical experimental data. ○ Parabolic throughout, reaction at 69°C; △ slow initial reaction at 68°C; • fast initial reaction at 137°C; the arrows indicate the ordinate scale to be used with each set of data.

Typical tarnishing data are shown in Fig. 1 for the silver-iodine system. Similar results were obtained for the silver-bromine and silver-chlorine systems. The figure shows data obtained from two reactions performed under identical conditions except for the presence of a small partial pressure of water vapor in one case (laboratory refined silver was used in each experiment). Figure 2 shows the types of initial deviation from parabolic reaction rates observed for the reaction of silver with pure iodine vapor. Almost all of the reactions of fine silver and some of those of laboratory refined silver followed a simple parabolic expression throughout the measured time. A large number of the reactions with laboratory refined silver had an initial, slow reaction rate which changed into a final rate after 2-15 min. For each batch of laboratory refined silver, there was a temperature between 100° and 130°C above which the reaction initially proceeded very rapidly for several minutes before abruptly slowing down to a rate comparable to that observed at lower temperatures. Above 145°

(the transition temperature for the phase change $\alpha AgI \rightarrow \beta AgI$) the fast reaction rate continued without change. This initial fast reaction also was observed for some lots of fine silver at temperatures just below the transition temperature.

In Fig. 3 and 4 are shown the results of a large number of tarnishing experiments carried out under a variety of conditions. The reaction rates of commercial purity silver (99.9+%) with pure iodine vapor as a function of reaction temperature with iodine pressure as a parameter are shown in Fig. 3. Each point represents an individual tarnishing experiment at constant temperature and iodine pressure, and smooth curves have been drawn through points obtained at the same iodine pressure. The tarnishing rates are expressed in terms of the parabolic tarnishing constant k in Eq. [1] in units of (cm of film thickness)^2/sec. The line in Fig. 3 which is labeled $T_{Ag} = T_{I_2}$ connects points at which the iodine pressure is in equilibrium with the reaction temperature.

In Fig. 4 are shown the results of a large number of tarnishing experiments on high-purity and cadmium doped high-purity silver. The rate of the brief, initial reaction is not shown in this figure except for the very fast initial reaction observed in the higher temperature range, and this is designated by the symbol •. The variation in reaction rate for separate lots of silver (represented by different symbols) is apparent in this figure as is the scatter of reaction rates within the same batch. The effect of divalent metallic impurities is shown by the cadmium doped samples. All of the experiments in Fig. 4 were carried out in 0.2-mm iodine pressure and the dashed line represents the averaged tarnishing data for the commercial grade silver in iodine vapor of this pressure.

The tarnishing rates of the commercial grade silver and of silver heavily doped with cadmium are not reversible with temperature as shown by the following experiment. If a piece of commercial grade silver foil is tarnished at 30° and the reaction temperature is then raised to 100°, the reaction rates correspond to the values for these temperatures shown in Fig. 3. If, however, the reaction temperature is reduced to 30° again, the reaction rate increases only a fraction of the amount required to restore the original rate found at this temperature. The same effect is obtained when a tarnish film is heated a few minutes at the higher temperature without exposure to iodine vapor. A similar but more striking behavior is noted when fine silver containing 0.09% cadmium is tarnished. The initial tarnishing rate is similar to that of undoped silver but, after "annealing" an initial tarnish film, the subsequent reaction rate may be lowered by as much as a factor of 50. Thus, the exposure of a tarnish film to a higher temperature tends to lower the rates of subsequent reactions carried out at lower temperatures, and the effect is more pronounced in less pure silver. These phenomena will be discussed further with respect to the mechanism of these reactions.

Laboratory refined silver was employed for the tarnishing experiments carried out in iodine in the presence of water or carbon tetrachloride vapor. The reaction rates in 0.20 mm of iodine vapor as a function of water vapor pressure at three different reaction temperatures and as a function of carbon tetrachloride vapor pressure at one reaction temperature are shown in Fig. 5. In this case, the reaction rate constant represents the constant, a, in the rate expression of Eq. [2], indicating that the reaction rate is independent of film thickness. For water vapor pressures below 0.1 mm, the reaction follows the same parabolic rate equation found for the anhydrous reaction. There is a narrow, intermediate range of water vapor pressure in which the reaction rate is erratic and is sometimes linear and sometimes parabolic. For higher water vapor pressures, the reaction rate is always linear and gradually decreases with

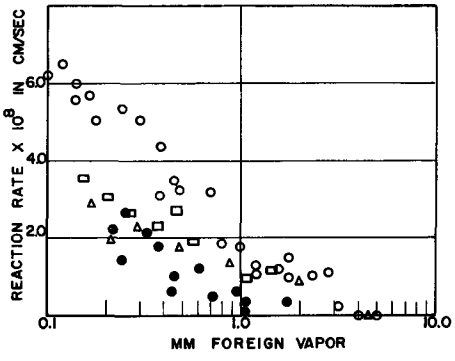

Fig. 5. Tarnishing of laboratory refined silver in 0.2 mm iodine vapor plus H_2O or CCl_4 vapor. □ H_2O vapor, reaction at 40°; ○ H_2O vapor, reaction at 69°; △ H_2O vapor, reaction at 101°; • CCl_4 vapor, reaction at 33°.

increasing water vapor pressure until at a water vapor pressure of 4 mm the reaction becomes too slow to observe. It is not clear whether the reaction actually stops in the presence of larger concentrations of water vapor or whether it decreases steadily but remains finite. The situation is similar for carbon tetrachloride except that this vapor is apparently somewhat more effective in suppressing the tarnishing rate than is water vapor.

Figure 6 shows the reaction rate of silver with moist iodine vapor as a function of reaction temperature with iodine vapor pressure as the parameter. Although the results are scattered, it is clear that the reaction temperature has very little effect on the reaction rate and that the reaction rate increases with iodine vapor pressure.

A few tarnishing experiments were also carried out in bromine atmospheres and the results were similar to those found for iodine. The reaction of silver with anhydrous bromine follows parabolic rate expressions, while the wet bromine atmospheres give linear reaction rates. One major difference from the iodine reactions was that the linear reaction rate did not change with the water vapor pressure. Thus at a reaction temperature of 105° and a bromine pressure of 43 mm, the linear reaction rate constant, a, was $6 \pm 2 \times 10^{-8}$ cm/sec in nine experiments over the water vapor pressure range 0.06-1.5 mm. The reaction temperature was also found to have little effect on the reaction rate since at a water vapor pressure of 1.0 mm and a bromine pressure of 43 mm, the reaction rate less than doubled between 105° and 190°C. Over the same temperature range the anhydrous parabolic rate constant increased by a factor of about 700.

In 600 mm of chlorine vapor and 0.045 mm of water vapor the laboratory refined silver tarnished at a linear rate of 0.5×10^{-8} cm/sec at 172° and 2.0×10^{-8} cm/sec at 194°.

Discussion

Tarnishing in Pure Halogen Vapor

It is assumed that the anhydrous tarnishing reactions proceed according to the theory of Wagner (1, 5). This states that the parabolic reaction rate is determined by the diffusion of an ionic or electronic species across the bulk of the tarnish film and proposes the following equilibrium reaction at the halide-halogen interface

$$\tfrac{1}{2}\,X_2\,(\text{gas}) = AgX + \boxed{Ag^+} + \textcircled{e^-} \qquad [3]$$

where X is a halogen, $\boxed{Ag^+}$ is a silver ion vacancy, and $\textcircled{e^-}$ is an electron hole in the electronic structure of the silver halide. If we consider the silver halides as predominantly ionic conductors, the migration of electron holes across the silver halide must be the rate-determining step. Assuming that the ionic disorder of the lattice is large compared with the cation vacancies injected according to Eq. [3], the theory predicts the following dependence of the parabolic rate constant, k, on the halogen pressure, P_{X_2}, the cation vacancy concentration, $\boxed{Ag^+}$, and the mass action constant, K, for Eq. [3]

$$k \propto \frac{K\,P_{X_2}^{1/2}}{\boxed{Ag^+}} \qquad [4]$$

The proportionality of the tarnishing rate with $\sqrt{P_{I_2}}$ is shown in Fig. 7 in which reaction rate constants taken from the smooth curves in Fig. 3 are plotted against $\sqrt{P_{I_2}}$ for several different reaction temperatures. This proportionality apparently does not hold for very low iodine pressures. The inverse proportionality to the cation vacancy concentration has been demonstrated by other workers for other silver halides at higher reaction temperatures by adding a sufficient amount of impurity to determine the cation vacancy concentration (2, 3).

All of the rate-determining factors in Eq. [4] should behave reversibly to changes in temperature except perhaps the cation vacancy concentration. The irreversible "annealing" effect observed for reactions of the low-purity silver and the more striking effect observed with cadmium doped silver points to the vacancy content as an important factor in determining the rate. The cation vacancy concentration depends on the purity of the halide since the substitution of a polyvalent cation M^{a+}, for a monovalent silver ion in the lattice requires the formation of n-1 cation vacancies to maintain electrical neutrality. Teltow (6) determined the solubility limits of $CdBr_2$, $PbBr_2$, and $ZnBr_2$ in AgBr over a considerable temperature range, and by extrapolation of his results it is clear that the solubilities will be only a small fraction of a per cent at tempera-

tures below 150°. The behavior of the iodides may be assumed to be quite similar. It is not unreasonable to expect that for a silver sample of low purity there will be sufficient polyvalent metal ions to saturate the halide lattice up to an appreciable temperature. Thus as the reaction temperature increases, the concentration of dissolved impurities in the AgI also increases due to the increase in solubility. As a result, the quantity $[Ag^+]$ increases and from Eq. [4], the reaction rate decreases with increasing temperature. At these low concentrations the concentration of dissolved impurities would probably not decrease reversibly with decreasing temperature but would remain in a state of supersaturation. This would account for the irreversibility of the reaction rate with temperature as observed for the lower purity silver. In addition to this factor, there may be a temperature dependence arising from K, but this should behave reversibly to temperature changes.

If the ionic conductivity of the silver halide is playing any part in controlling the reaction rate, the polycrystalline nature of the tarnish film may be important since there is evidence that ionic conduction takes place very readily along grain boundaries (7). In this case, the annealing effect could be enhanced by a decreased concentration of grain boundaries due to a growth in crystal size in heated tarnish films.

The nature of the temperature coefficient of reaction rate found here supports some of the earlier work on the Ag-I_2 system. Tammann (4) found no change in reaction rate in the temperature range 15°-100°C. Dubrisay (8) observed a slight decrease in tarnishing rate as the reaction temperature was raised from 24° to 60°. Balarew (9) found a very slight increase in reaction rate between 50° and 70°, followed by a slight decrease again at 100° and a sharp dip in reaction rate at 120°. This pronounced minimum in tarnishing rate has not been reported elsewhere. All of these works employed the interference color technique to measure the tarnish film thickness and thus deal with thinner films than discussed in this paper. It is of interest to note that the behavior is similar over such a wide range of film thickness. Evans and Bannister (10) made an extensive study of the rate of reaction of silver with organic solutions of iodine and found that the reaction rate at 35° is about twice that at 0° for carbon tetrachloride solutions of iodine. The use of organic solvents may invalidate a direct comparison to reactions in pure iodine vapor however.

The brief, rapid reaction rates noted for pure silver reacting with iodine vapor at reaction temperatures just below the α-β phase transition temperature of AgI (145°C) are of the same magnitude as the continuous reaction rates observed above the transition temperature. Thus it appears that the initial film may have the α phase structure for 1-3 min after which it abruptly changes back to the phase in equilibrium at the reaction temperature. It was considered that the samples might be heating themselves above the transition temperature by their own heat of reaction. This possibility was investigated numerically by Miss Alma Marcus of these laboratories, who computed the temperature rise of a sample considering the heat evolved by the reaction and the heat loss through radiation and conduction. It was found that for typical reaction conditions the rise in sample temperature would reach a maximum of 1.4°C after 1.7 sec and this is insufficient to explain the experimental results. It is possible that the crystalline structure of the silver substrate may influence that of the initial silver iodide film and that close to the transition temperature the high temperature structure is favored. This would conflict with the observation of Tammann and Köster (11) that the phase transition takes place at 145°C even for layers of silver iodide on silver which show optical interference colors.

The initial, slow reaction rate observed in some reactions of high-purity silver at temperatures below 100° does not fit in with the general behavior outlined above and is not understood at present.

Tarnishing in the Presence of Foreign Vapors

The linear rate expression, Eq. [2], followed by the tarnishing reactions carried out in the presence of foreign vapors implies that the rate-determining factor is an interface phenomenon and hence independent of the tarnish film thickness. This factor has not been identified experimentally but it is suspected that adsorption of the impurity gas on the halide surface results in modification in the space charge layer at the AgI surface adjacent to the iodine atmosphere. Speculations along this line will be the subject of a future publication from this laboratory. The diffusion rate of the halogen through the adsorbed film of foreign vapor may also be of importance.

The experimental results from the Ag-I_2 system (see Fig. 4 and 5) indicate that the amount of foreign vapor is the main rate-determining factor since the reaction temperature has no significant effect and the influence of iodine pressure is small. The two gaseous atmospheres extensively investigated in this work, iodine with water vapor and iodine with carbon tetrachloride vapor, show that the effect is not dependent on the polarity of the foreign molecule since the nonpolar carbon tetrachloride is even slightly more effective in suppressing the reaction rate than is water. This fact implies that a wide variety of vapors would act similarly to the two investigated here. The results also show that a foreign vapor is not consumed by the tarnishing reaction. Once the tarnish film has been exposed thoroughly to the foreign vapor, the reaction rate continues unchanged for hours without further addition of water or CCl_4 vapor, and neither do subsequent additions at the same vapor pressure alter the reaction rate. The effect is perfectly reversible and the tarnishing rate can be changed immediately in either direction by suitable adjustment of the pressure of the foreign vapor.

Since the character of the tarnish film does not seem to be altered by the presence of the foreign vapor, the reaction rate for any particular experiment will be parabolic or linear depending on whether the bulk diffusion process or the interface process is the slower. Thus for very low foreign vapor pressures,

the interface process will not be slower than hole diffusion and the reaction will be parabolic. The rate of diffusion will decrease as the tarnish film thickens and it will eventually become the rate-determining step regardless of the experimental conditions unless the foreign vapor completely stops the reaction. The ideal situation can be described by the following simplified considerations. The reaction rate will follow the linear rate equation (Eq. [2]) unless the diffusion process is rate determining, in which case the reaction follows the parabolic rate expression (Eq. [1]). A change from the linear to the parabolic reaction will occur at the film thickness, x_1, at which the reaction rate dx/dt is the same for both equations

$$x_1 = \frac{k}{2a} \qquad [5]$$

This thickness will be reached after a reaction time t_1,

$$t_1 = \frac{k}{2a^2} \qquad [6]$$

Subsequent to the time t_1 the reaction will follow the expression

$$x^2 = k\left(t - \frac{k}{4a^2}\right) \text{ for } x > x_1 \qquad [7]$$

where $k/4a^2$ is the difference in times that the parabolic and linear reactions would require to build up a tarnish film x_1 cm thick starting from bare silver. This behavior is illustrated in Fig. 8 which compares the tarnishing rate in dry iodine with two reactions carried out in the presence of water vapor. In the presence of 0.94 mm of water vapor the reaction follows a linear rate throughout (Eq. [6] indicates that the transition to a parabola should occur after 295 min of reaction). The data shown for reaction in the presence of 0.26 mm of water vapor have been found to follow Eq. [2] and [7] with $a = 3.3 \times 10^{-8}$ cm/sec, $k = 8.7 \times 10^{-12}$ cm^2/sec, and a transition time of 52 min. (The fact that the initial linear reaction does not extrapolate to the origin of coordinates has been taken into account.) These rate values are in satisfactory agreement with the average anhydrous tarnishing rate, $k = 9.5 \times 10^{-12}$ cm^2/sec, and moist tarnishing rate, $a = 3 \times 10^{-8}$ cm/sec, observed under similar conditions for the same batch of silver foil.

The effect of moisture on the tarnishing rate explains some of the previously published results of

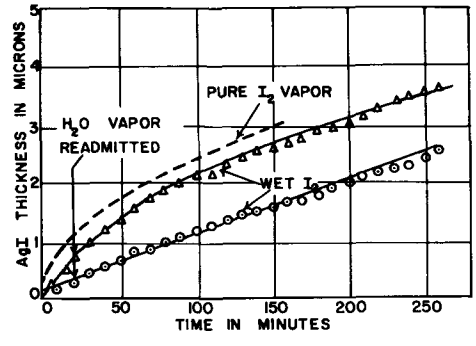

Fig. 8. Influence of moisture content of atmosphere on tarnishing rate of laboratory refined silver at 35°C in 0.2 mm iodine vapor. — — — Averaged data from reactions in pure iodine vapor; △ 0.26 mm H_2O vapor; ○ 0.94 mm H_2O vapor.

tarnishing reactions of silver with halogens. In many instances the reactions did not follow a parabolic rate expression and this can almost invariably be explained by the presence of moisture in the halogen vapor. For example, Hartung measured the tarnishing rate of silver with iodine and bromine at 25° (12, 13). The iodine atmosphere was obtained from an aqueous KI-I_2 solution and thus was saturated with water vapor. The tarnishing rates followed linear rate equations for the range of iodine concentrations studied. Hartung does not describe any purification or drying of his bromine and it was undoubtedly moist since the reaction rates were found to be linear after an initial fast reaction lasting about 100 sec.

Kohlschütter and Krähenbühl investigated the reaction of silver with iodine and found some variation in reaction rate depending on the dryness of the halogen atmosphere (14). Their results do not follow either parabolic or linear rate expressions but some intermediate rate equation. It is possible that their data follow the linear expression for the initial reaction period and then transform into a parabolic reaction rate as described above, but since the authors give no quantitative data, it is not possible to investigate this possibility thoroughly. Using Cl_2 and Br_2, Kohlschütter and Krähenbühl found faster reactions with silver in the presence of moisture than in the dry halogen. The use of streams of N_2 or CO_2 to carry the halogen over the silver may have had some influence on the reaction rate.

Several publications report observations which conflict with those described here (15-19). In general, these papers contain very little quantitative data and are therefore difficult to evaluate.

Other tarnishing reaction systems have been observed to be affected by the presence of water vapor. Solovjev (20) has found that there is apparently an optimum water vapor pressure for maximum reaction rate of copper with iodine. He also noted a decrease in reaction rate of iron with iodine with decreasing water vapor pressure. Bircumshaw and Everdell found a linear reaction rate for copper reacting with aqueous solutions of KI and I_2 (21) whereas the reaction rate depended on the tarnish film thickness in organic iodine solutions (22). The authors attribute this behavior to a wetting and penetration of the tarnish film by the aqueous solutions while the organic solutions do not wet the film and the reaction can proceed only by bulk diffusion through the iodide. Campbell and Thomas (23) investigated the oxidation of copper in dry and moist oxygen. In dry oxygen the reaction was parabolic while in moist oxygen the results had a smaller dependence on the film thickness. In general, these experiments show the care necessary in controlling all of the experimental conditions in order to obtain meaningful results. Even the presence of what might be usually considered "inert" gases may drastically alter the nature of the reaction.

Acknowledgments

The work reported herein was carried out under United States Army Signal Laboratories Contracts DA-26-039-sc-63151 and DA-36-039-sc-72349. The

authors wish to express their appreciation to Dr. Kurt Lehovec of these laboratories for much stimulating discussion and advice.

Potential Studies on Passivity to Corrosion Induced by Pretreatment Processes for Metals

I. Aluminum

K. S. Rajagopalan

Central Electrochemical Research Institute, Karaikudi, India

ABSTRACT

Potential and polarization characteristics of aluminum which has been subjected to various chemical oxidation processes are reported. It is shown that a more negative initial electrode potential is recorded by the treated metal as compared to the untreated metal. The cathodic polarization curve of the treated metal is also much steeper. These results are satisfactorily explained by the application of the Glasstone, Laidler, and Eyring theory of electrode processes to the potential of a corroding metal.

Electrode potential measurements have been widely used in studying corrosion and corrosion inhibition (1-6). Such measurements have thrown valuable light on the intrinsic corrodibility of metals and alloys, the manner in which corrosion-inhibitive constituents added to the corrosive medium affect the corrosion process, and have also helped in understanding the role played by various types of pigments. Similarly, anodic and cathodic polarization curves of corroding metals have given valuable information on the mechanism of inhibition by corrosion inhibitors (7, 8). Numerous chemical processes have been developed in recent years which improve the resistance of metals to corrosion in different corrosive environments by the formation of thin, protective oxide, chromate, or phosphate films (9-14). The resistance to corrosion conferred by these treatments have been studied mainly by means of accelerated corrosion and field tests. Potential and polarization studies with the object of obtaining an insight into the mechanism by which chemical surface treatments confer passivity to the metal surface have, however, not yet been carried out. This paper is the first of a series describing such studies and concerns aluminum for which a number of simple processes involving only a dip treatment are known.

Experimental

Metal.—Indal 2 S to B.S. 1470 (commercially pure aluminum of 99% purity) from Indian Aluminum Co., Belur, Calcutta, cut into 1 x 1 in. specimens was used.

Scratch-free material was cut into the size required and given a high degree of polish with cloth buff soaked with wet pumice (15). This was followed by solvent cleaning in hot benzene and acetone, cleaning with alkaline cleaner (16), rinsing with cold water, and treatment in one of the following processes:

1. *MBV process* (17): 5-min treatment at 90°-100°C in solution containing 5% sodium carbonate and 1.5% sodium chromate.

2. *E.W. process* (18): 10-min treatment at 90°-100°C in MBV solution to which 0.1% sodium silicate has also been added.

3. *Pylumin process* (19): 5-min treatment at 95°-100°C in solution containing 6% sodium carbonate, 2% sodium chromate, and 0.2% disodium phosphate.

4. *Alrok process* (20): 20-min treatment at boiling point in solution containing 2% sodium chromate and 0.5% potassium dichromate.

5. *Chrome pickle* (21): Dipping for 2 min at 60°-70°C in solution containing 17.5% (w/v) chromic acid and 3.5% (w/v) H_2SO_4.

6. *Phosphoric acid pre-treatment* (22): 5-min treatment in cold solution containing 10% (v/v) of orthophosphoric acid (85%), 70% (v/v) butyl alcohol, and 20% water.

7. *Acid cleaning* (23): 5-min immersion in cold solution of 5.6% of phosphoric acid (v/v) and 1.7% chromic acid.

8. *Chemical polishing* (24): 5-min treatment at 90°C in solution 80% (v/v) of phosphoric acid (85%), 3.5% (v/v) nitric acid, and 16% water. After treatment, the specimens were given a thorough rinse in cold water and dried with a hot air blower.

Procedure

The procedure followed was similar to that described by Brasher (25) with the difference that the sealing of the junction between metal and the external lead and glass tube was done in three stages using different mixtures of beeswax-rosin, beeswax-ceresin, and ceresin. This seal remained unaffected up to 60 days. The corroding medium, 3% NaCl in water, was contained in a 600 ml beaker and the specimen was fitted by means of rubber cork to the perspex cover of the beaker and lowered into the solution to a depth of 1 in. below the solution level. The test solution was aerated for 15 min before test to saturate it with oxygen.

Potentials were measured against a saturated calomel electrode using a Beckman *p*H meter as the null instrument. Only 10^{-11} amp passed on off balance. Polarization studies were carried out by external application of current with a duplicate specimen as the auxiliary electrode and the potentials measured as before. All measurements were made at 35° ± 0.1°C.

Results

Potentials given by a replicate number of untreated specimens and specimens treated by the MBV process immediately after immersion in sodium chromate solution are given in Table I. The instantaneous potentials of untreated aluminum are found to be reproducible with ±10 mv while more variation is observed in the case of the treated specimens.

Potentials of treated and untreated metal were recorded frequently up to a period of 4 hr and then at the end of 1 and 2 days. Results are given in Table II.

The potential of untreated aluminum is found to be fairly steady for several hours at −0.745 v and then falls to more negative values, indicating failure of the protective oxide film in the corroding medium containing chloride ion in solution. The potential of the treated metal, which is highly negative to start with, rises quickly to the potential of untreated aluminum and falls again.

Reproducibility of potential-time curves with untreated and treated metal.—Potential-time curves given by replicate specimens of treated and untreated metal up to a period of 60 days are plotted in Fig. 1. It is seen from the figure that the potential-time curves of the untreated metal are generally characterized by a gradual drift in the course of 4 days to a constant potential which is 200 mv more negative; that of treated metal is, on the other hand, characterized by a rapid rise in the course of a day to the initial potential of untreated aluminum followed by a much slower fall. The extent of drift with

time of immersion is, however, not so reproducible in the case of treated metal.

Potential-time curves of aluminum treated by different pretreatment processes. — Potential-time curves of aluminum treated by three more processes are given in Fig. 2 along with those of untreated metal and metal treated by MBV process.

It is seen from Fig. 1 and 2 that the rise in potential of untreated metal is not significant beyond 7 days. The initial potential of metal treated by the EW process is the same as that of untreated metal, and this potential falls at a much slower rate than that of untreated metal. The metal treated by the Alrok process gives a highly negative initial potential to start with, and there is not much change in this potential with time. Metal treated by the Pylumin process behaves similarly.

Initial potentials and changes in potential of aluminum treated by etching and polishing solutions.— An understanding of the data obtained with various passivating solutions may be facilitated if the effects of chemical treatments which involve etching, cleaning, or polishing of the surface on the potential are known. Therefore, the metal was treated by four solutions, one of which just etched the surface, the other cleaned it free of oxide film, the third one primed the surface for painting, and the last one gave a chemical polish. Results obtained are given in Table III.

It is seen from Table III that the behavior of the metal treated by any of the above methods is generally similar to that of untreated metal. The initial potential is the same as that of untreated metal, and this potential increases fairly rapidly to a more negative potential similar to untreated metal.

Polarization curves of untreated aluminum and aluminum treated by MBV process.—It is known that increased cathodic polarization of aluminum takes place when dc currents of the order of 100 μa are passed from an external source through the metal as cathode, and hardly any polarization is observed with the metal as the anode (26-28). The effect of MBV treatment on the anodic and cathodic polarization curves of aluminum is, therefore, of interest. Anodic and cathodic polarization curves of treated and untreated aluminum are compared in Fig. 3.

It is seen that the cathodic polarization curve is made much steeper by treatment, and comparatively little change is observed at the anode.

Discussion

The fall in potential of untreated aluminum with time in the chloride medium is readily understood in terms of classical ideas on the meaning of electrode potential. It is associated with the breakdown of the protective oxide film and the final potential of —0.9 v signifies the equilibrium state between the breakdown of the oxide film by the corrosive action of chloride ions and repair of this film by oxygen present in the liquid. It is more difficult to understand the highly negative initial potential observed with metal treated by MBV, Pylumin, and Alrok processes. Passivation of a metal surface is usually accompanied by the potential becoming ennobled. Here, however, there are a number of systems where this is not the case. Mears (29) has shown, however, that, if the over-all electrode potential of a corroding metal is given by the convergence point of the polarization curve of the local anodes and cathodes (30), then instances can occur where passivity of the metal surface is accompanied by shifting of the electrode potential in the negative direction.

The greater corrosion resistance of more electronegative aluminum as compared to steel in salt solutions is believed to arise from such a mechanism. This shift of potential in the negative direction, according to Mears, arises from increased polarization of the local cathodes. When the MBV treated metal is polarized cathodically by the application of external emf (see Fig. 3), the treated metal is polarized to a much greater extent than the untreated metal at equal current densities. The extent to which the two metals are polarized anodically does not differ to a significant extent. The more negative initial potential of MBV-treated aluminum and the polarization data are, therefore, explained satisfactorily in terms of this mechanism. But, as Mears pointed out, this approach has substantial limitations. First, it may not be correct to assume that anodic and cathodic polarization curves obtained by the application of an external current reproduce the polarization behavior of the local anodes and cathodes in the absence of an applied emf. Second, the indirect methods (7, 31) that have been suggested for measuring the polarization curves of the local anodes and cathodes stipulate a number of conditions which cannot be met in the case of the present systems. Further, the changes in potential with time, e.g., rapid rise in potential of MBV treated metal to that of untreated aluminum, do not lend themselves easily to explanation on the basis of the above mechanism.

It was considered worth while, therefore, to see if the Glasstone, Laidler, and Eyring theory of rate processes (32) threw more light on the significance of such potential changes. According to this theory, the rate of the forward and reverse processes taking place at an electrode and the magnitudes of the currents flowing in the two directions as a result can be expressed in the form of an equation involving the concentration terms controlling each reaction, the specific velocity of the reaction, energy transfer coefficient, number of electrons involved in the electrode reaction, and the potential of the electrode, each of which can be measured under well-defined circumstances. The reactions taking place at each of the two electrodes constituting any one of the innumerable local cells present on a corroding metal also can be expressed in terms of such an equation. At each electrode, there is a forward and reverse reaction and there is a net flow of current. The local cells of a corroding metal are, however, short circuited through the metal and the total net current at all the local anodes equals the total net current at all the local cathodes. The two currents can, therefore, be balanced as follows:[1]

Net cathodic current from all the local cells:

$$i_1 = Z \cdot f \cdot A_c \left\{ \prod_1^{\nu i} (a_i^{\nu_i}) \cdot K_1 \cdot e^{-\alpha' Z f v/RT} - \underbrace{\prod_1^{\nu i} (a_i \nu_i) \cdot K'_1 \cdot e^{(1-\alpha')Z f v/RT}}_{\text{negligible}} \right. \quad [1]$$

where A_c = total cathodic area in cm^2, $\prod_1^{\nu i} (a_i \nu_i)$ = product of concentration terms controlling the cathodic reaction, K_1 = specific velocity of the reduction reaction in cathodic areas, α' = symmetry factor or energy transfer coefficient, Z = No. of electrons involved in the electrode reaction f = 96,500 (coulombs/mole, v = potential, R = gas constant, and T = temp °K

Net anodic current from all the local cells:

$$i_2 = A_a \cdot Zf\{(\underset{\text{negligible}}{\quad}) - \prod_1^{\nu_2^1} (a_i \cdot \nu_i) \cdot K_2^1 \cdot e^{(1-\alpha'')Z f v/RT} \quad [2]$$

where A_a = total anode area in cm^2, K_2 is the specific velocity of the oxidation reaction in anodic areas and α'' is the symmetry factor.

In the present case, potentials of the treated and untreated metal in 3% NaCl solution are all in the range of −0.7 to −1.2 v in which the anodic reaction terms of Eq. [1] and the cathodic reaction term of Eq. [2] would be negligible. Therefore, $i_1 = i_2$, where positive value denotes a cathodic current and negative value denotes anodic current, and

$$e^{-Z.v.f(\alpha'+1-\alpha'')/RT} = \frac{A_a \prod_1^{\nu_2^1} (a_i \cdot \nu_i) \cdot K_2^1}{A_c \cdot \prod_1^{\nu_1} (a_i \cdot \nu_i) K_1} \quad [3]$$

and

$$-v = \frac{RT}{Z \cdot f \cdot (\alpha' + 1 - \alpha'')} \cdot \ln \frac{A_a \prod_1^{\nu_2^1} (a_i \cdot \nu_i) \cdot K_2^1}{A_c \prod_1^{\nu_1} (a_i \cdot \nu_i) K_1} \quad [4]$$

$$-v = \frac{RT}{Z \cdot f \cdot (\alpha' + 1 - \alpha'')} \cdot \ln \frac{A_a \cdot X_2}{A_c \cdot X_1} \quad [5]$$

where

$$X_2^1 = \prod_1^{\nu_2^1} (a_i \cdot \nu_i) K_2^1 \text{ and } X_1 = \prod_1^{\nu_1} (a_i \cdot \nu_i) K_1$$

Application of Eq. [5] to the behavior of untreated and treated aluminum in chloride solutions is of interest. From the tendency of aluminum to suffer localized corrosion or pitting, it may be concluded that A_a must be small compared to A_c. From the fact that the corroding metal registers a high negative potential, it also may be concluded with the help of the above equation that $A_a \cdot X_2$ must be greater than $A_c \cdot X_1$ and X_2 must be much greater than X_1. The observed steep polarization of the metal when it is made cathodic by an external emf is in agreement with the idea of $A_c \cdot X_1$ being small. Similarly, the sluggishness with which the metal polarizes, when it is made the anode, is in agreement with the idea of $A_c \cdot X_2$ being large. The steeper cathodic polarization curve for the treated metal means that $A_c \cdot X_1$ is smaller than it was before treatment. This change is more likely to have taken place in respect to the effective area of the cathode A_c rather than in respect to the velocity factor. The effective cathodic area must, therefore, be considered to have diminished as a result of treatment. It also is seen from the above equation that when $A_c \cdot X_1$ becomes smaller the potential of the metal also falls. This is exactly what is observed in the case of the passivation treatments under study.

According to this interpretation the shift of potential of treated aluminum in the negative direction after immersion in the corroding solution arises from an increase in the anodic area, which is in conformity with the idea of breakdown of the film. The rise in potential of treated metal immediately after immersion should, according to this view, indicate an increase in the effective cathodic area, and this apparently comes to a stop when the solution has permeated all the pores of the treated metal. This approach also explains why treatments such as the EW process, which form extremely thin films similar to the naturally formed oxide films and which are practically free from pores, do not show such a tendency. In this case, the fall in potential with time is slower than that of untreated aluminum, thereby indicating that the production of anodic points is much less favored by the film formed under the conditions of this process than in the case of the natural oxide film. Observations made with specimens treated in solutions which have essentially a cleaning or smoothing effect on the metal surface are also explained. The initial potentials as well as the main trend of the potential time-curves of these specimens are parallel to the untreated metal. This shows that no film formation or conversion of the surface has taken place which is different from that which

[1] After this paper was completed, the author came across an interesting paper by M. Takahashi [*J. Electrochem. Soc. Japan*, 25, (4) E 36 1957] giving the derivation of the equations for the potential of the corroding metal on the basis of the Glasstone, Laidler, and Eyring theory of rate processes as well as the experimental verification of the same.

happened to the untreated metal during exposure to air. The final potentials of untreated aluminum and aluminum treated by the different passivation processes do not differ considerably. This nearness of these electrode potentials despite the fact that the corrosion rate of treated aluminum is much lower than that of untreated aluminum can only be understood if the factor dominating the observed potential is the ratio between the anodic and cathodic areas. As long as this ratio remains the same, the potential will not differ considerably, but the corrosion rate may be markedly minimized if both anodic and cathodic areas are diminished. This leads to the important conclusion that the factor responsible for passivation by these treatments is the diminution in the cathodic area. The tendency of aluminum to be subjected to localized corrosion or pitting may, therefore, be expected to be minimized by the chemical oxidation processes investigated, unlike anodic inhibitors, e.g., chromates and phosphates.

Mechanism of Electrodeposition of Nickel from Liquid Ammonia Solutions of Spin-Free Nickel(II) Complexes

George W. Watt and David A. Hazlehurst

Department of Chemistry, The University of Texas, Austin, Texas

ABSTRACT

Data on cathode current efficiencies for the electrolysis of solutions of $[Ni(NH_3)_6]^{2+}$, $[Ni(en)_3]^{2+}$, and $[Ni(dn)_2]^{2+}$ in the presence of Br^-, I^-, and SCN^- are interpreted on the basis of an S_N2 mechanism in which the rate-controlling step is most probably dependent on the translabilizing effect of the entering ligand that is involved in the formation of an initial transition state complex.

Continued interest in the electrodeposition of metals from nonaqueous media (1-5) from both theoretical and practical viewpoints has prompted us to re-examine certain data that were obtained several years ago. It was observed that deposition from ammonia solutions of hexamminenickel(II) bromide, trisethylenediaminenickel(II) bromide, and bisdiethylenetriaminenickel(II) bromide occurred at negligibly low rates; upon addition of the potassium salts of Br^-, I^-, and SCN^-, however, deposition occurred at markedly increased rates that were dependent on the identity of the added anionic ligands. It is of interest to consider these data in the light of generalizations and mechanisms proposed by Lyons

(6-8) with reference to deposition from aqueous solutions, and to propose an alternative mechanism for the genesis of a transition state complex.

Experimental

Materials.—Hexamminenickel(II) bromide (calculated: Br^-, 49.9; found: Br^-, 50.0) was prepared as described elsewhere (9). Trisethylenediaminenickel(II) bromide 1-hydrate was prepared as described by Werner and Megerle (10); the anhydrous salt (calculated: Br^-, 39.9; found: Br^-, 40.1) resulted upon heating the 1-hydrate for several hours at 100°-105°. Similarly, bisdiethylenetriaminenickel (II) bromide (calculated: Br^-, 37.6; found: Br^-, 37.6) was formed from the corresponding 1-hydrate (11).

Equipment and procedures.—The equipment employed was essentially the same as that described by Booth and Merlub-Sobel (12) except that the design of the electrode holders was such that the electrodes could be removed readily for direct weighing before and after electrolysis. Nickel anodes (Ni, 99.5) and bright platinum cathodes were used in all of the experiments reported here. The electrical circuit included a silver coulometer and otherwise was conventional in all respects.

The electrolysis cell was predried, thoroughly, and strictly anhydrous conditions were maintained in all experiments. The solvent ammonia was dried over sodium amide and, just prior to use, was bubbled through a solution of potassium in ammonia. The ammonia was condensed at −45°, after which the temperature was raised to and maintained at a temperature just slightly below the normal boiling point of the solvent (−33.5°). Following electrolysis, the ammonia solution was siphoned from the cell and the electrodes were washed, dried, and weighed. After evaporation of the solvent from the combined electrolytic solution and washings, Ni^{2+} could be determined gravimetrically by the dimethylglyoxime method.

Experimental data.—In a series of experiments involving the cationic nickel(II) complexes indicated above, the total solution volume was 75 ml, the concentration of the nickel(II) salt was 0.02*M*, the concentration of the added potassium salts was 0.1*M*, and the current density was 0.54 ± 0.05 ma/cm^2. Other pertinent data are included in Table I.

Table I. Electrolysis of liquid ammonia solutions of nickel(II) salts

	Added salt	Potential, v	Time, hr	Cathode current efficiency, %
$[Ni(NH_3)_6]Br_2$	KBr	2.85	3.0	3
	KI	1.57	3.0	80
	KSCN	1.50	3.0	108
$[Ni(en)_3]Br_2$	KBr	3.00	2.0	9
	KI	1.72	2.1	75
	KSCN	1.48	3.0	105
$[Ni(dn)_2]Br_2$	KBr	2.80	1.0	12
	KI	1.88	1.5	67
	KSCN	1.55	3.0	109

Although bright adherent deposits of nickel were obtained in the electrolysis of ammonia solutions of tetramminenickel(II) thiocyanate (13), the deposits in the experiments reported here were less satisfactory but nevertheless sufficiently adherent not to introduce appreciable errors in determining the total nickel deposited by direct weighing of the cathodes. Neither microscopic examination nor electron photomicrographs served to reveal any consistent characteristics of the deposits as a function of the ligands employed.

Discussion

With reference to the electrodeposition of metals from cationic complexes, Vlcek (14) has proposed that the essential step involves the formation of a zerovalent species, after which metal-ligand bond breaking leaves the free metal as a deposit on the cathode. If such a mechanism were operative, it is not immediately apparent in the present case why cathode current efficiencies should be influenced so profoundly by specific anionic ligands.

Lyons (7) suggested a primary heterolytic dissociation, or S_N1 mechanism[1] in which metal-ligand bond breaking provides an available bonding orbital for the establishment of a partially metallic bond with the cathode lattice.

We wish to propose, largely on the basis of the results reported above, that there is an alternative and more probable mechanism. The nickel(II) complexes used in the present studies are all of the octahedral sp^3d^2 or spin-free type. If the observed trends in cathode current efficiencies may be assumed to have even qualitative kinetic significance, it seems reasonable to assume that the primary reaction involves an initial nucleophilic attack by the added anions, e.g., Br^-, I^-, and SCN^-. Thus, it is assumed that an S_N2 mechanism is operative, that the coordination number of nickel in the transition state complex is seven, and that rupture of one of the original metal-ligand bonds occurs trans to the incoming anionic ligand. Accordingly, a bonding orbital is made available and the subsequent events may well occur as pictured by Lyons (7). Irrespective of the stereochemical configuration of the transition state complex and regardless of whether cis or trans attack is involved, the proposed S_N2 mechanism suggests two possible rate-limiting steps both of which must take into account the fact that the neutral solvent molecules as incoming ligands are potentially competitive with the added anionic ligands. In view of the data in Table I, however, it seems apparent that the solvent molecule is not thus competitive.

First, the formation of a transition state complex may be rate limiting and dependent on the relative nucleophilic character of the incoming ligands. From Table I it may be seen that the increasing order of cathode current efficiencies for the three added anionic ligands is $Br^- < I^- < SCN^-$. Although still of questionable status (15) and in any event probably not quantitatively applicable to ammonia solutions, the order of nucleophilic constants (16, 17) for these

[1] The nomenclature employed herein is that recommended by Basolo and Pearson (15).

ions is $Br^- < SCN^- < I^-$. A second and more attractive alternative would assume that bond breaking is the rate-limiting step; in this case the observed rates should correspond to the relative translabilizing effects of the entering ligands. If we may assume the same order for octahedral as for square planar complexes (18), i.e., $NH_3 < Br^- < I^- < SCN^-$ (where only the relative position of the latter is in doubt, but nevertheless reasonable) then the correlation with the data of Table I is self-evident.

It is our intention to provide further experimental data bearing on this question.

Acknowledgments

This work was supported in part by the U. S. Atomic Energy Commission, Contract AT-(40-1)-1639. The nickel anodes used in these studies were supplied by the International Nickel Co.

Manuscript received Sept. 3, 1958.

Electrodeposition of Molybdenum

T. T. Campbell

U. S. Bureau of Mines, Albany, Oregon

ABSTRACT

Electrodeposition studies performed at the Northwest Electrodevelopment Laboratory of the U. S. Bureau of Mines, Albany, Oregon, are described. Research was directed toward the electrodeposition of molybdenum from nonaqueous media such as liquid ammonia, formamide, acetamide, hydrazine, and other organic solvents and the preparation of pure anhydrous molybdenum halides. While thin plates of molybdenum were obtained, the growth of massive deposits was not realized.

The requirements of modern technology for materials possessing high temperature strength and corrosion resistance properties has, in recent years, stimulated an intensified ilnterest in molybdenum.

Molybdenum is produced commercially by hydrogen reduction of molybdenum oxides. The metal powder resulting from this treatment is not of uniform quality and purity although it can be converted into usable forms by powder metallurgy techniques.

While the literature reports many claims for the successful electrodeposition of Mo (1), thorough analyses of and attempts by later investigators to duplicate these claims lead to the conclusion that the only practicable method of electrodepositing molybdenum is from the fused salt bath recently developed by Brenner and Senderoff of the U. S. Bureau of Standards (2). The prevailing opinion is that electrodeposition of pure Mo from aqueous solutions is unlikely. On the other hand, the use of organic solvents, fused salt baths, and other nonaqueous solvents such as hydrazine or liquid ammonia as media for the electrodeposition of Mo has had only limited attention. Efforts to electrodeposit Mo at the Albany station of the U. S. Bureau of Mines were restricted mainly to studies in nonaqueous solvents since a preliminary period spent in duplicating other published methods proved fruitless.

Discussion

It is doubtful whether simple ions as such are present in solutions containing Mo compounds, either because of reactions occurring between the solutes and solvents or because of the tendency of Mo ions to form polyions by polymerisation and condensation reactions. In addition, Mo compounds may disproportionate to give complex compounds in which the metal ion may exist in any of its oxidation states. It is probable that only complex systems result during efforts to electrodeposit Mo, regardless of the media used.

Studies of electrode potentials in fused salt baths carried out by Brenner and Senderoff (2) indicate that the reduction of Mo to trivalent oxides proceeds at a more noble potential than does reduction to

metal. The same situation apparently holds true either in aqueous or organic solutions, and on this basis it would seem that oxygen or oxygen containing compounds must be absent from the electrolytic system in order to obtain the metal. Reduction of Mo ions *in situ* by hydrogen, postulated as a mechanism in chromium deposition, does not occur; this fact, and the low hydrogen overvoltage of Mo (3) are major factors preventing deposition of Mo from aqueous systems.

While the metal can be deposited from the fused salt baths developed by Brenner and Senderoff, the utility of their techniques from an economic standpoint does not appear promising. The procedures outlined offer formidable difficulties such as operation of corrosive fused salt baths at temperatures ranging from 600° to 900°C with the necessity of complete exclusion of air or moisture from the cell. While these baths presumably could be useful for specialized electroplating or electroforming operations, it is doubtful if they could be adapted to widespread general usage.

On the basis of the foregoing discussion, it appears obvious that a practicable solution to the problem of Mo deposition is needed. The application of nonaqueous solvents other than fused salt baths to the problem of Mo deposition offers many interesting possibilities: (*a*) studies can be made on systems from which oxygen or oxygen containing compounds can be completely excluded; (*b*) exploration in a comparatively new and untried field of research is possible; and (c) if successful, research of this type may provide a new approach for the electrodeposition of other rare and refractory metals.

Experimental Procedures and Apparatus

For reasons previously expressed, it was considered desirable to conduct tests in systems which completely excluded oxygen either in the solutes or the solvents. This program necessitated careful examination of methods for preparing Mo compounds. Much of the work was restricted to molybdenum chlorides and bromides since these compounds proved reasonably soluble in many of the solvents studied. Most of the solvents had relatively high dielectric constants although solvents were not excluded from study even when the dielectric constant was of a rather low order.

Since the majority of the work carried out in this study was exploratory in nature, the equipment and procedures utilized were varied in nature. In general, Pyrex beakers of 250-500 ml capacity were used as cells, although small rectangular glass cells (800 ml capacity), U tube cells, and 3-necked Pyrex flasks were utilized during various phases of the investigation. Those tests carried out under an inert atmosphere usually were carried out in 3-necked flasks or in Pyrex tubes sealed with rubber stoppers. Argon or helium atmospheres were maintained above those systems which were sensitive to carbon dioxide, oxygen, or moisture. The liquid ammonia study was carried out in equipment similar to that described by Merlub-Sobel (4). Liquid ammonia cells were operated at either low temperatures (below −33°C) and atmospheric pressure, or at room temperature when a high pressure (above 145 psig) cell was used. After initial study in the field of aqueous electrolysis proved unsuccessful, the solubility of various Mo compounds in organic and other nonaqueous solvents was determined. Quantitative solubility tests were carried out in a temperature controlled (±1°C) water bath in the 25°-100°C range and in an ondina oil bath (a USP grade mineral oil) for temperatures up to 200°C. The Mo compounds were added in 100-mg quantities to 50 ml of the solvent until insoluble material remained for at least 1 hr. The temperature was increased by 20°C increments with periodic additions of solute until the highest practicable operating temperature for the particular solvent was reached. The maximum solubility of the solutes over a wide temperature range was obtained by this procedure. Qualitative data on solubilities were also obtained on many of the systems studied. Since solubility data of Mo compounds in nonaqueous solvents are not generally available in the literature, the results of this work are presented in Table I.

Conductivity tests were made on all of the solvents in which Mo compounds were reasonably soluble. Column 5 of Table I indicates those solvents which were conducting or nonconducting, along with other pertinent remarks. Anodes and cathodes of graphite, copper, iron, platinum, molybdenum, stainless steel, lead, etc., were used, the particular electrode material used depending on the type of solvent employed. A Beckman (Model H-2) *p*H meter was used to determine *p*H values during the course of the study. A 50 amp-24 v capacity selenium rectifier was used as a source of d-c current.

Electrolytic tests generally covered a wide range of current densities and temperatures over varying periods of time. The course of electrolyses was followed by observation of current, voltage, and *p*H readings. The effectiveness of any particular system for Mo deposition was determined by visual inspection of the cathode. Whenever metallic deposits were obtained they were subjected to x-ray diffraction study and to spectrographic analyses. While no massive deposits of Mo were obtained from any of the systems studied, thin deposits of Mo and alloys of Mo with Fe, Pb, or Pt were readily obtained. The usual cathode products were lower oxides, hydroxides, or other reduced compounds of Mo.

Because of the great number of systems covered during this study and the negative character of some of the results, it is impracticable to show all the data obtained. For this reason, Table II shows only the data for those experiments which either gave thin deposits of pure Mo or alloys of Mo with other metals.

Preparation and Handling of Mo Halides

Since much of the work described utilized either the chlorides or bromides of Mo as solutes, the preparation of these compounds required detailed attention. The preparation of the dichloride and dibromide of Mo posed no particular problem as disproportionation of molybdenum tribromide in a 2-in. Vycor tube was found to proceed smoothly at 600°C to give molybdenum dibromide and disproportiona-

tion of molybdenum trichloride at 600°-650°C gave good yields of molybdenum dichloride.

Direct chlorination of Mo powder at 350°-400°C was found to give a product whose major constituent was the pentachloride. The product almost always contained some unreacted metal powder and small amounts of lower valent chlorides. Direct chlorination of molybdenum disulfide in a Ni-lined vertical shaft type chlorinator at 500°C was attempted. Pure molybdenum pentachloride could not be isolated by this method. The product was contaminated with molybdenum compounds that contained sulfur (Mo_2S_3) which tended either to sublime along with the molybdenum pentachloride or were carried over by entrainment. Efforts to free the molybdenum pentachloride of sulfur compounds by sublimation at 280°C were unsuccessful.

Molybdenum trichloride was prepared by the reaction of molybdenum pentachloride with powdered molybdenum at 350°C as shown in the equation below:

$$3MoCl_5 + 2Mo \xrightarrow{350°C} 5MoCl_3$$

Direct bromination of Mo powder at 300°-350°C produced a mixture of molybdenum tribromide and molybdenum tetrabromide; however, analyses indicated the product to be primarily tribromide.

With the exception of the dibromides, tribromides, and the dichlorides, the halides of molybdenum are all hygroscopic, sensitive to oxygen and moisture in the air, and form oxycompounds readily.

The preparation of definite compounds was not successful except in the case of the divalent halides; in all other cases the products were contaminated to some extent with unreacted metal powder or were a mixture of tri, tetra, and pentavalent halides.

In order to prevent the formation of oxy compounds, it was necessary to exercise extreme precautions while transferring the halides from the reaction tubes to storage vessels and finally to the electrolytic cells. Large rubber transfer tubes, filled with argon gas, were used at all times to prevent air contamination of the halides. The prepared halides were stored in bottles under an argon atmosphere and sealed with polyethylene tape which was in turn paraffin covered. Avoidance of these procedures inevitably led to rapid contamination of the halides and the formation of oxy compounds.

Conclusions

The inability to obtain pure massive Mo deposits from either aqueous or nonaqueous systems containing oxygen compounds probably is caused in part by the low overvoltage of hydrogen on Mo and by the fact that deposition of oxides occurs at a more noble potential than does reduction to metal. While many thin plates of Mo were obtained during this study, once the cathode was covered with a thin film of Mo, the following situations developed: (*a*) passivation set in, (*b*) hydrogen, nitrogen, or ammonia evolved at the cathode, (c) lower oxides, hydroxides, or other reduced compounds continued to deposit at the cathode.

In several instances, alloys of Mo with Fe, Pt, or Pb were obtained; the source of the alloying agent in most instances originated from the anode.

Reduction of molybdenum ions to metal *in situ* by hydrogen, postulated as a possible mechanism for Cr deposition, does not seem to occur. Recovery and examination of the Mo salts, after evaporation of the solvents, indicated that Mo halides readily form a wide variety of complex compounds with nonaqueous solvents. It is doubtful if simple molybdenum ions were present in any of the systems studied.

Both qualitative and quantitative solubility data for a number of Mo compounds in a variety of organic solvents are shown.

While massive deposits of Mo were not obtained, the results obtained in this study are encouraging. The application of much higher current densities than those reported in this study, coupled with more stringent atmosphere control, may well provide a means toward the electrodeposition of massive Mo.

The use of nonaqueous solvents in conjunction with anhydrous Mo compounds, while faced with serious difficulties, offers an interesting and challenging approach to a very difficult problem.

Manuscript received April 13, 1956. This paper was prepared for delivery before the San Francisco Meeting, April 29-May 3, 1956.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Microfurnace for Thermal Microscopy and Studies at High Temperatures

W. A. Lambertson and G. Lewis

Research and Development Division, The Carborundum Company, Niagara Falls, New York

ABSTRACT

A small laboratory furnace is described for use in high-temperature microscopy and for determining chemical compatibility, wetting, sintering, and temperatures of apparent melting up to 3000°C (5433°F). The furnace shell is a water-cooled, 5-in. copper tee and is of such construction as to afford a controlled atmosphere. Water-cooled electrodes are designed to hold refractory metal strip heaters (either plain or with a wedge for better black body conditions) or special-machined graphite heaters. Stepless power input is provided by variac-controlled, saturable core reactor.

Furnace Description

Figure 1 shows the furnace diagram. The furnace shell was fabricated from 12.7 cm (5 in.) ID copper tubing which was cut and welded to form a "T". Cooling was provided by 6.25 mm (¼ in.) copper tubing tracing welded to the outside of the shell. The ends of the furnace through which pass the terminal connections were isolated electrically from the furnace shell by Teflon rings, and an atmospheric seal is provided by "O" ring seals. Water-cooled terminal connections, fabricated from 1.9 cm (¾ in.) diameter copper rod, were led into the furnace through rubber gasketed CGB cable connector seals in the end plates. The seals provide both an electrical and atmospheric seal, and, when loosened, permit the terminals to be rotated easily or moved in and out. Each terminal had interchangeable threaded end pieces which served as adapters so that several types of heater configurations may be used.

The furnace is loaded through an "O" ring sealed cover, about 5 in. in diameter, on the center leg of the "T." This cover has a 1-in. diameter sight port for visual observation and temperature determination of the sample. There are two additional sight ports, one directly opposite the sight port in the cover and one displaced 30° from the center line passing through the two former ones. Three ports are needed for high-temperature microscopy work, one for the microscope, one for an arc light which provides additional illumination when necessary, and one for an optical pyrometer.

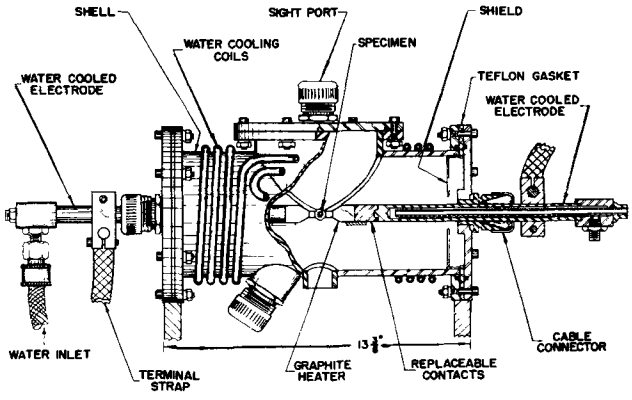

Fig. 1. High-temperature microscopy furnace

Heaters.—Three types of resistors have been used. The furnace was originally designed to use two refractory metal strip heaters 7.6 x 1.27 x 0.00127 cm (3 x 0.5 x 0.005 in.) (top Fig. 2) for wetting angle studies. The metal strips are clamped in copper holders; the sample rests on the lower heater while the upper strip functions as a radiation guard heater. For oxidizing atmospheres, a platinum-40% rhodium metal strip (mp 1900°C) is used. With inert atmospheres, a tantalum, tungsten, or molybdenum strip is used for still higher temperatures.

Reaction of some samples with metal heaters is sometimes a problem, and crucibles of boron nitride or thoria are placed on the lower heater to hold the sample. Boron nitride is satisfactory as a crucible up to 2000°C, but at higher temperatures it reacts with the heater. A guard ring of tungsten is placed around the crucible to reduce radiation loss from the side and to make the temperature more uniform.

In melting point studies it was found that reactions between the materials under study and the heater strip were sometimes severe, so a heater was constructed from a graphite block 7.6 cm (3 in.) long by 1.9 cm (¾ in.) square at the terminals. The central section was made considerably smaller in area and contains a thin-walled cylindrical furnace chamber (Fig. 2). This cylinder provides a hot zone with a 6.25 mm (¼ in.) inner diameter by 1.59 cm (⅝ in.) high. The sample is generally formed into 3.2 mm (⅛ in.) diameter rod about 2.54 cm (1 in.) long and is supported on a graphite pedestal. Several refractory metal shields are placed around the heater to reduce radiation losses.

At temperatures above 2500°C, even with a flowing argon atmosphere, there is sufficient vaporization of graphite to cause problems of contamination of the sample. A small amount of work has been done on the possibility of using heaters made from the high melting tantalum carbide-zirconium carbide solid solution. These heaters are difficult to fabricate and very susceptible to thermal shock. A few have

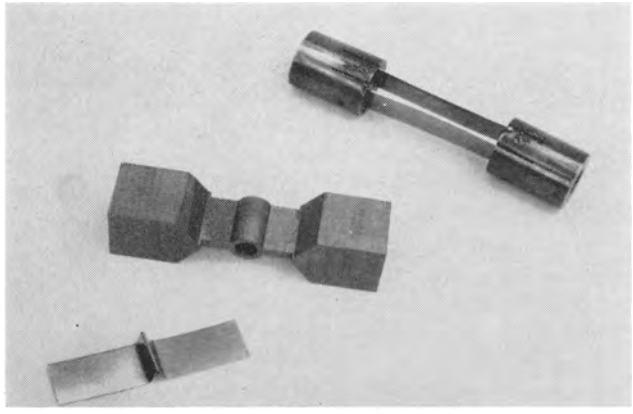

Fig. 2. Furnace heaters, double wedge, graphite block, and "V" types.

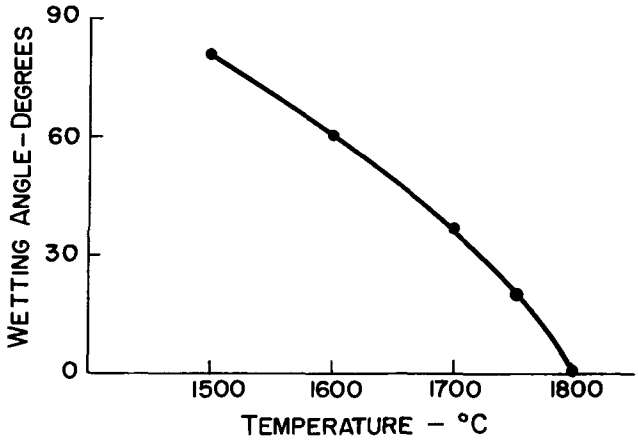

Fig. 4. Wetting of SiC by $FeSi_2$

been used satisfactorily, but further development work is needed to reduce thermal shock problems. A second technique which has proved helpful is to line the inside of the graphite heater with tantalum or tungsten foil.

Power supply.—The saturable core reactor d-c bias is controlled by a manually operated powerstat on a 110-v line, through a small transformer which reduces the voltage, and then through a rectifier to provide d-c control. This manual control is entirely satisfactory for most applications of the furnace, because the firing times are usually short. Four 5 kva step-down transformers are used with the primaries in parallel and the secondaries in series. Figure 3 shows the power consumption for various types of heaters. Maximum secondary current drawn is slightly in excess of 500 amp.

Temperature measurement.—In addition there are two other sources of uncertainty in knowing the temperature of the sample.

The optical pyrometer is accurate to ±13.9°C and this was checked regularly by comparison with a standard. Temperature is read through a Vycor sight glass which adsorbs a certain, though small, amount of energy at the wave length used for measurement, 0.65μ. The sight glass was calibrated using an optical standardization apparatus, and the correction factor corresponded with the simplified Wein equation, $1/T_t - 1/T_a = C$, where T_t is equal to the true absolute temperature, T_a is the apparent absolute temperature, and C is the calibration constant. The value of this constant was found to be -6.7×10^{-6} and resulted in the addition of 35°C at 2040°C, the melting point of aluminum oxide.

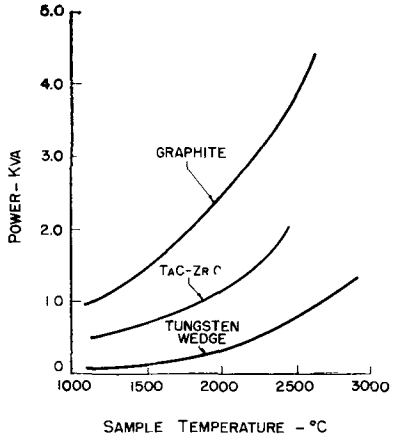

Fig. 3. Micro furnace-power-temperature relationship.

The variation from black body conditions in the furnace constitutes a source of error. Because the sample can be seen when it is melted in this furnace, true black body conditions are not obtained. The effective emissivity falls between one and the true emissivity of the material under test. Using a material of high purity for which the melting point is well established, it is possible to calculate the apparent emissivity if the correction constants are known for the optical pyrometer and the sight glass. The apparent melting temperature of aluminum oxide and the literature value for aluminum oxide, 2040°C was used to calculate the emissivity as 0.9594. Assuming that the apparent emissivity does not change at higher temperatures, and for other oxides the emissivity correction for the zirconia melting point, 2656°C, is 16°C, and for the urania melting point 2740°C, 17°C.

Experimental Results with Furnace

Melting Points

Table I shows some of the melting points which have been obtained compared with values from the literature. Aluminum oxide is readily available in high-purity form and its melting point is well established. This material was used as a standard for checking the sight glass calibration and for calculating the effect of emissivity on the experimental conditions. High-purity zirconia is available in quantity, and represents an excellent high-temperature standard material. Zirconia with 2% hafnia was chosen as a standard because of some previous work (3). High-purity urania is available, but may not be a good standard because of the possible variations in the uranium to oxygen ratios.

The reason the melting point of alumina checked satisfactorily and those for zirconia and urania by two different methods did not is not understood. Lambertson and Mueller (3) used a tungsten crucible ¼ in. in diameter by 2 in. long heated in a tungsten heater ¾ in. in diameter by 6 in. long. They obtained black body conditions. Melting was determined by observing the sample before and after

heating. The crucible bottom may have been at a lower temperature than that indicated through radiant heat loss. In the present work only the part that melts is seen but deviation from black body conditions presents a source of error.

Wetting Angles

Wetting angles of $FeSi_2$ on SiC vs. temperature are plotted in Fig. 4. In this work the sample is placed on a pin or in a crucible on strips and heated to the test temperature. It is then held for a few seconds, the furnace turned off, and the sample quenched by the rapid cooling of the furnace. The sample is removed from the furnace and ground so that the angle between the melt and the crystal can be seen easily. This is then projected on a screen and the angle measured.

Acknowledgments

The authors would like to express their appreciation to Mr. Henry N. Baumann for his suggestions, to Dr. F. K. Davey for his work on the power supply and the development of the graphite heater, and to many others of the Carborundum Company who contributed their ideas, suggestions, and help in obtaining the data presented in this report.

Zirconium Coating of Uranium by the Iodide Process

W. L. Robb[1]

Knolls Atomic Power Laboratory
(Operated for Atomic Energy Commission by General Electric Company), Schenectady, N. Y.

ABSTRACT

A method for coating uranium metal with a bonded layer of crystalline zirconium metal has been developed. It consists of thermally decomposing zirconium iodide vapors on the surface of uranium metal heated to about 1100°C in vacuum. Prior to coating, the uranium metal surface is cleaned by iodizing it and then vaporizing the uranium iodide. Greatly increased diffusion between the uranium and deposited zirconium can be obtained if the uranium is alloyed previously with as little as 0.5% zirconium. This increased diffusion improves the corrosion resistance of the coatings.

The desirability of coating uranium or uranium alloy fuel elements with zirconium arises from the excellent corrosion resistance of zirconium, plus its low thermal neutron cross section. Of particular interest are 1-10 mil thick zirconium "sweater" coatings, for use as secondary corrosion resistant barriers. This paper describes one of the more successful methods for achieving such a coating.

The coating process examined in this study was based on the van-Arkel-de-Boer (1) process for producing pure zirconium metal. It consisted of first forming volatile zirconium iodides, and second, decomposing or disproportionating these iodides on the hot surface of a uranium specimen (2). The process is carried out most successfully in an evacuated system, although coatings of less desirable nature can be obtained in the presence of an inert gas or a reducing gas such as H_2.

[1] Present address: Research Laboratory, General Electric Company, Schenectady, N. Y.

Experimental

The apparatus used to coat 1 x ¾ in. uranium disks is shown in Fig. 1. The uranium disk was heated inductively by a 5 kw Ajax converter, the disk's temperature being measured by an optical

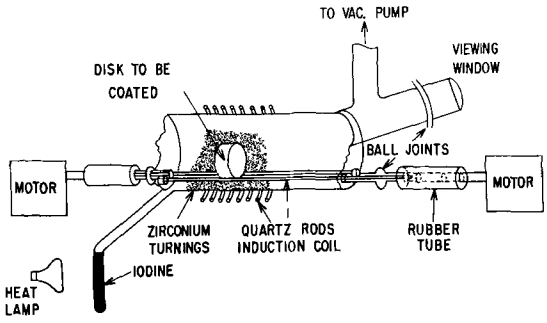

Fig. 1. Cut-away viewing of vapor coating apparatus with disk rotator.

pyrometer through a glass window. Uranium temperatures of 1050°-1100°C could be maintained to ±5°C. The zirconium was in the form of 10-mil turnings twisted into cigar shaped bundles which were then placed in the tube around the uranium. It was necessary that the ends of the bundles did not complete a circle within the induction field. Thus the zirconium was heated mainly by radiation from the uranium disk. This was sufficient to heat the zirconium to 200°-400°C. The iodine pressure was controlled by regulating the temperature of the iodine supply tube generally between 20°-50°C.

The coating cell was evacuated continuously, using a fore pump and diffusion pump, although once a thin coating of zirconium had been deposited and the uranium and zirconium had been completely degassed, the coating cell could be operated without continuous evacuation.

A somewhat thicker coating was obtained near the edge of the sample as compared to the middle due to (*a*) the nearness to the zirconium supply, and (*b*) the higher temperature of the edge of the disk as compared to the middle.

In order to coat a disk completely in one operation, the uranium disk was supported on rods which could be rotated continuously. Quartz rods were found suitable for the rollers as long as the rate of rotation was sufficiently rapid and the weight of the disk not too high. Otherwise the uranium was oxidized by the quartz, and nonbonded coatings resulted. Required rates of rotation for the rods were 1-3 rpm. The rod diameters for 1-in. diameter uranium disks were about 3/16 in. Thin metal foils of tantalum and molybdenum were tried as covers for the quartz rods but were not useful since the foil stuck to the hot uranium.

Prior to coating a specimen, the uranium was cleaned by an acid dip or by electrocleaning. The simplest method of cleaning consisted of dipping the uranium sample in concentrated nitric acid, followed by a water rinse and an acetone rinse. The sample was placed in the coating cell, which then was evacuated as quickly as possible. After the cell had been evacuated to better than 0.01μ Hg (with leak rates of less than 8μ ft^3/hr) the liquid nitrogen was removed from the iodine supply and the induction furnace turned on. As the uranium disk became hot it was iodized, forming UI_4 which vaporized from the surface as the disk reached red heat. This served to clean the surface just prior to coating and was a most important step in obtaining bonded coatings. As the temperature of the uranium approached 1080°C the equilibrium of the reaction:

$$U + \frac{X}{2} I_2 \rightleftharpoons UI_x$$

shifted more and more to the left. Thus, at coating temperature, the iodization rate of U could be reduced greatly by maintaining the iodine pressure below 60μ Hg (3).

By the time the uranium had reached 1050°C (2-4 min), ZrI_4 was already being formed and could be seen condensed on the cold outlet of the deposition cell. Coating of the uranium had to begin immediately in order to prevent the formation of a diffusion blocking layer of uranium oxide. Coating times of ½-6 hr were tried, with rates as high as 2-3 mils/hr being obtained. Runs usually were 2-3 hr long, at 1 to 2 mils/hr coating rate.

Coated samples were removed from the apparatus under a purge of N_2, A, or He gas to prevent oxidation of the condensed ZrI_4. This eliminated the need to clean the apparatus after every coating test.

Results and Discussion

By means of the equipment and procedures described above, zirconium coatings have been applied on uranium disks and cylinders of various shapes and sizes. A photograph of a typical coating, shown in Fig. 2, illustrates the very crystalline nature of the deposited zirconium. The nature of the diffusion bond of the zirconium to the uranium can be seen in Fig. 3. The diffusion was considerably less than expected from measured diffusion rates of uranium and zirconium (4). Furthermore, the annealing of coated uranium disks did not increase the diffusion layer thickness noticeably.

Fig. 2. Zirconium coated uranium disk, actual size

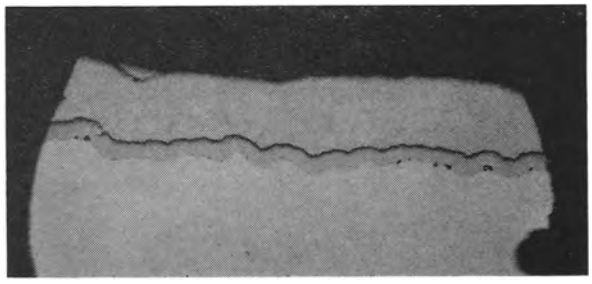

Fig. 3. Zirconium coating on uranium. Magnification 250X B.F.

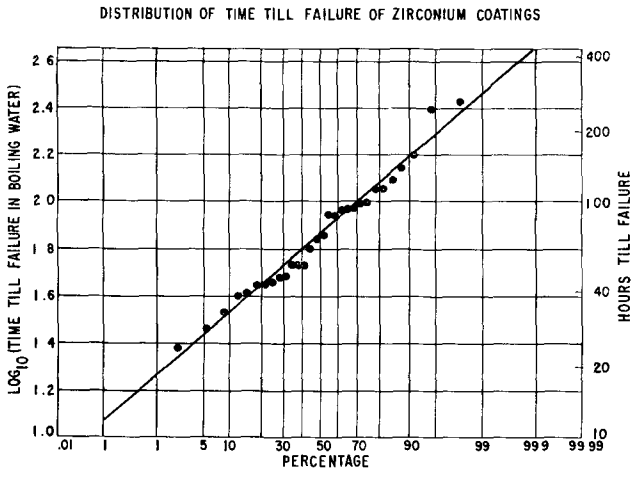

Fig. 4. Distribution of time until failure of zirconium coatings.

The corrosion resistance of these coatings was determined by noting the time required for their rupture or penetration in boiling water. More specifically, failure was indicated by UO_2 powder in the water, by a blister on the surface of the coated specimen, or by the enlarging of a pore hole on the surface. The times required until failure of coatings on pure uranium are shown on a probability graph, Fig. 4, and it is seen that the log mean time till failure for 30 samples was 73 hr.

Except for the cases where failure of the coatings was due to a poor diffusion bond (caused by poor cleaning or by uranium oxidation on heating), the most common cause of failure was porosity of the crystalline coatings. As a result, several methods for reducing this porosity were tried. These methods and their results are listed in Table I.

As is seen from the table, no major improvement in corrosion resistance was observed for any of the additional treatments. It was observed, however, that coatings on the sides of disks which were rolled on the quartz rods while the zirconium was being deposited were not nearly as porous, nor as brightly crystalline, as were the unpressed faces of the disks. If a practical way could be found to deform or to press the zirconium deposit continually over the entire disk while the deposit was being laid down, less porous coatings could be obtained.

Table I. Corrosion times in boiling water of zirconium coatings on pure uranium disks

	Hours until failure in boiling water
Coatings deposited in 1-2 hr	115, 115, 161, 87, 44, 49, 29
Coatings deposited in 2-3 hr	94, 73, 126, 54, 88, 72, 54, 54, 94, 91, 64, 41, 98, 45, 48
Coatings deposited in 3-5 hr	250, 24, 100, 34, 46, 40
Coatings deposited in 5-6 hr	142, 271

Coatings shot blasted	74, 74
Coatings hot pressed	116, 114, 73, 71
Coatings with Ni and Zr co-deposited	49, 88, 21, 38, 24, 117, 134, 157, 67, 67, 116, 70, 41, 17, 72, 73, 22, 77
Coatings deposited in reverse plating runs	190, 60

The codeposition of Ni from $Ni(CO)_4$ and Zr from ZrI_4 results in a lower melting Ni-Zr and Ni-U alloy being formed. This causes increased diffusion between the U and Zr, and when carefully controlled could result in improved coatings. Figure 5 shows this increased diffusion. The presence of Ni in the coating was verified by x-ray fluorescence measurements, but the occlusions in the Zr coating were not identified and could be either nickel, zirconium oxide, or zirconium carbide. The scattered appearance of these occlusions is due to the intermittent introduction of nickel-carbonyl into the coating chamber.

Depositing the zirconium coating on a uranium alloy disk previously alloyed with a small amount of zirconium resulted in markedly improved corrosion resistance of the zirconium coatings. This had been noticed by Campbell and Powell (5) on a cementation process for depositing zirconium on uranium. Figures 6 and 7 show zirconium deposited on a 99% U —1% Zr alloy and illustrate the type of diffusion obtained when zirconium is deposited on the uranium alloy. As would be expected from previously measured diffusion rates of U in Zr (4), the uranium is completely diffused through the zirconium coating and 1 mil layers machined off the outer surface of coatings have analyzed as high as 43% uranium. X-ray diffraction measurements on successive 1 mil layers indicate a concentration profile going from alpha zirconium through epsilon phase uranium-zirconium alloy to alpha uranium. Uranium metal alloys containing from 0.5 to 4% zirconium were coated and over this range the results were very similar. Figure 8 shows several coated alloy disks. The

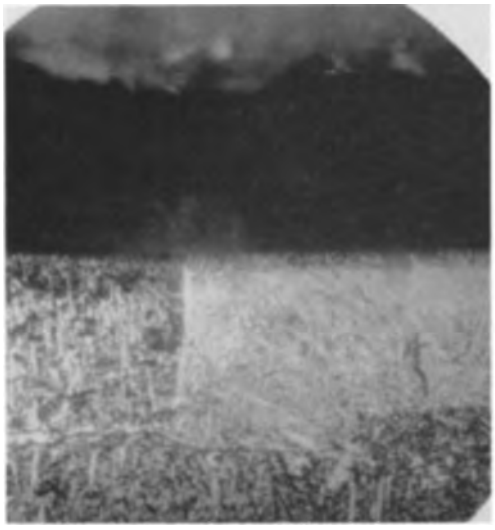

Fig. 7. Zirconium coating deposited on 99.5% U—0.5% Zr alloy. Magnification 250X Pol.

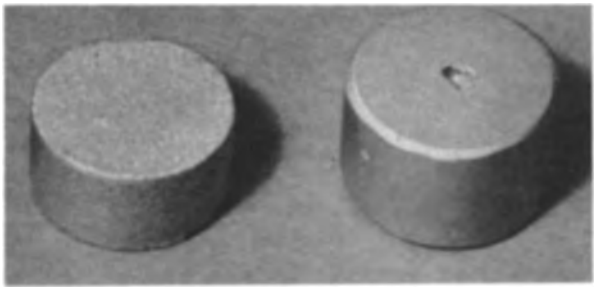

Fig. 8. Photographs of Zr deposited on U-Zr alloy. Magnification 1X.

coatings on these alloy disks are very smooth compared to the macro crystalline coating deposited on uranium and shown in Fig. 2. Corrosion tests on the coated alloy samples showed greatly increased protection (Table II). For example, a coating deposited in 1 hr and annealed for 1 hr lasted 447 hr and was still intact at the end of the test. Some failures occurred in less than 100 hr but they could be accounted for largely by pits or holes in the uranium alloy metal used. Although the inside of the holes were coated to some extent, the holes still presented weak spots in the coatings.

The zirconium apparently fixes the carbon usually found in uranium, thus preventing its migration to the uranium-zirconium coating interface. Since ZrC is more stable than UC, it would be expected that the carbon in the uranium would diffuse to the zirconium, and in this way cause a ZrC diffusion blocking layer to be formed at the U-Zr interface. This explains why the expected amount of codiffusion between U and Zr was not observed in the initial coating experiments.

Conclusions

It is possible, but difficult, to obtain pore-free zirconium coatings on present grade uranium metal. Under carefully controlled conditions the coatings probably can be made to resist boiling water consistently for over 100 hr. On low zirconium alloy specimens (or possibly on uranium containing very little carbon) pore free coatings can be obtained easily, and coatings to resist 100°C boiling water for over 200 hr or 170°C water for 80 hr should be produced easily.

Table II. Corrosion times of zirconium coatings on uranium-zirconium alloy disks

* Quenched from the beta phase for grain refinement.

So far only coatings on uranium or uranium-zirconium alloys have been described. However, the method also has been used at KAPL to coat thorium and graphite. Other reactor materials including beryllium metal, beryllium carbide, beryllium oxide, boron, and boron carbide, may also be coated in the same manner.

Although this method of coating is limited in use by the high temperature required for the decomposition of zirconium tetraiodide, it does represent a possible method for producing coatings of zirconium metal. The cost for this type of coating probably will be higher than that for electroplated coatings. But, for specialized cases where diffusion bonded and corrosion resistant coatings of low neutron cross section are required, it alone affords a method of producing thin bonded zirconium coatings.

Transport Numbers and Ionic Mobilities in the System Potassium Chloride-Lead Chloride

Frederick R. Duke and Richard A. Fleming

Institute for Atomic Research and Department of Chemistry, Iowa State College, Ames, Iowa

ABSTRACT

Values of ionic transport numbers and ionic mobilities were determined for the fused system potassium chloride-lead chloride. Cation transport numbers were found: 0.24 for $PbCl_2$ at 525°C, 0.62 for KCl at 850°C. In each mixture, t_- deviated positively and t_+ and t_{++} deviated negatively from linearity when plotted against equivalent fraction. The initial, very rapid depression of total equivalent conductance from that of pure KCl, caused by addition of small amounts of $PbCl_2$, was found to be due to the depression of the ionic conductance of K^+ rather than complexing between Pb^{++} and Cl^- as had been supposed previously. The relative mobilities of K^+ and Pb^{++} were compared with those of Li^+ and Pb^{++} in the system LiCl-$PbCl_2$, calculated from available literature data.

The transport numbers and mobilities of the ions in a mixture of $AgNO_3$ and $NaNO_3$ have been determined (1). This system proved to be ideal in the sense that the ionic mobilities were independent of composition. The system $PbCl_2$-KCl is of interest because of the possibility of complex ion formation involving Pb^{++} and Cl^-; furthermore, it might be expected that a mixture of a biunivalent salt with a uniunivalent one would show a different behavior from the $AgNO_3$-$NaNO_3$ system.

Complex ions of Pb^{++} and Cl^- in the molten system $PbCl_2$-KCl have been reported on the basis of phase diagram (2), electrical conductance (3), surface tension (4), and molar volume measurements (5). In addition, previous studies on transport numbers in this system have indicated that complex ions might play a large role in the mobility of the ions. Lorenz and Ruckstuhl (6) observed that the lead ions are apparently anionic ($PbCl_3^-$ or $PbCl_4^=$) in mixtures containing more than about 25 mole % KCl. Wirths (7), using radioactive Pb^{++} as tracer, obtained some evidence that lead ion migrated toward the anode in mixtures of $PbCl_2$ and KCl. These transport studies were lacking in precision, however. With more precise experimental techniques available, the present work on the $PbCl_2$-KCl system was done.

Experimental

Two experimental quantities must be determined in order to calculate the transport numbers of the three ions. One of these, designated ϕ by Aziz and Wetmore (8) (where $\phi = 1 - t_{++} - E_1 t_-$), is related to experimental values by $\phi = (E_2 N_1 - E_1 N_2)/Z$, where t_{++}, t_+, and t_- are the transport numbers of Pb^{++}, K^+, and Cl^- ions, respectively, E_1 and E_2 are the original equivalent fractions of $PbCl_2$ and KCl, respectively, N_1 and N_2 are the total number of equivalents of $PbCl_2$ and KCl in the anode compartment after electrolysis between Pb electrodes, and Z is the charge transferred in faradays. The other experimental quantity is t_- measured directly by radio tracer methods.

Apparatus.—The cell used in the determination of ϕ and t_- is shown in Fig. 1. The low temperature runs were done in Pyrex with the membrane consisting of an ultrafine Pyrex disk. For high temperature, the cell was made of quartz; the membrane was specially prepared for each cell from commercial fine porosity quartz disks. To reduce the porosity of the fine quartz disks, ethyl silicate and concentrated HCl were allowed to react in the disk, with a heating period (850°C) after each treatment, until sufficiently fine porosity was obtained. The porosity was calibrated by measuring the time required for 1 ml of water to pass through the disk under 1 atm pressure. Disks having "water times" above 600 sec were found to be satisfactory. Contact to the electrodes was made through loosely fitting caps, with tungsten wires passing through the center tube in the cap.

The furnace used was a Marshall tube furnace with external compensating taps on the heating coil. The temperature was controlled by a chromel-alumel thermocouple which operated a Brown indicating controller. In addition, the furnace contained an indicating chromel-alumel thermocouple connected to a L&N No. 8662 potentiometer with reference junction compensator. The center zone of the furnace

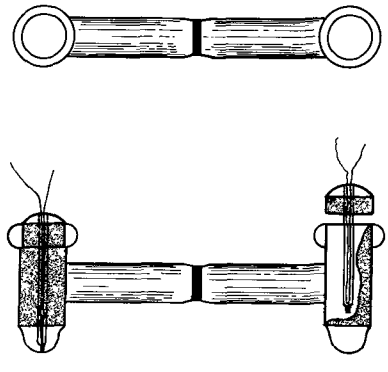

Fig. 1. Transport cell

had a temperature gradient of less than 5° and could be controlled to ±1°C of any desired temperature at a given point. Direct current up to 300 ma was available through a bank of selenium rectifiers in a smoothing capacitance-inductance circuit. A Model 100 Berkeley Decimal Scalar was used in making all radioactivity counts.

Determination of ϕ.—The cell shown in Fig. 1 was loaded with an intimate mixture of reagent grade solid KCl and $PbCl_2$. Pure lead metal was used for the electrodes. In general, the amount of molten salt filled the horizontal tube of the cell only partially, allowing a large surface area and minimizing differences in head across the membrane as the experiment proceeded. After a suitable quantity of electricity had been passed, the cell was broken at the membrane and the catholyte and anolyte collected separately and analyzed as follows. The weighed samples were pulverized, heated in boiling water, cooled, and filtered. This procedure was repeated three times, thus removing all of the KCl and part of the $PbCl_2$. The remaining $PbCl_2$ was dried and weighed. The filtrate was titrated with the sodium salt of cyclohexanediaminetetraacetic acid (9) to determine the dissolved lead, and K^+ was precipitated and weighed as the tetraphenylborate (10).

Determination of t_-.—Radioactive Cl^{36} with a half-life of 3.08×10^5 years, was used as tracer. If all the radioactive chloride is placed initially in the cathode compartment of the cell shown in Fig. 1, it can be shown that

$$t_- = K_a C_a E_c / K_c C_c Z \qquad [1]$$

where C_a is the counting rate of the anolyte, corrected for diffusion, after passage of Z faradays, C_c is the counting rate of the catholyte before the run, and E_c is the total number of equivalents of Cl^- in the catholyte initially. K_a and K_c take into account the aliquation and the geometry of the counted sample so that, for example, $K_a C_a$ gives the amount of Cl^* in the anode compartment. For K_a to equal K_c, the counting efficiencies and the aliquation and other similar variables must be the same when counting catholyte and anolyte.

After the current was run, the cell was broken at the membrane and the anolyte and catholyte samples were collected carefully and weighed. For analysis, a $NaCl^*$-$PbCl_2^*$ sample was homogenized by completely dissolving it in boiling water. This was followed by concentrating portions of the solution by evaporation and then cooling to precipitate $PbCl_2^*$, the form in which Cl^{36} was counted. The original portion size and the extent of concentration by evaporation were adjusted so that a final $PbCl_2^*$ weight of about 0.1 g was obtained, after water and acetone rinses to remove KCl^*. From the observed counting rates of five or six samples, the counting rate of a 0.1000-g sample of $PbCl_2$ was determined. This weight represents 0.000719 equivalents of Cl^-. By knowing the total number of equivalents of Cl^- in the sample, the radioactive Cl^- aliquot of 0.1000 g $PbCl_2$ was determined, and the total counting rate of the sample was found by multiplication.

The final weight of the anolyte sample was known. The final concentration of the anolyte was calculated from the results of ϕ runs made on samples of the same composition. Thus, total Cl^- and then the anolyte's uncorrected counting rate were calculated. To determine C_a, one need only correct the observed counting rate for leakage and diffusion of Cl^* into the anolyte.

Values of C_c were obtained in two ways. Proceeding exactly as in the case of the anolyte sample, one can determine an observed final counting rate for the catholyte. Then one need only add the uncorrected anolyte counting rate to this term to determine the initial counting rate of the catholyte. Alternately, one may proceed so that in every run exactly the same number of equivalents of Cl^- are present initially in the catholyte. Also, one may introduce Cl^* from an active KCl^* (or $PbCl_2^*$) stock and use the same weight of stock for each run. Then C_c will be the same for each run and, if the same number of faradays are passed in each run, Eq. [1] simplifies to

$$t_- = AC_a \qquad [2]$$

This method demands care in weighing out a homogeneous radiochlorine source, but it is time saving. The value of A is known once $K_c C_c$ has been determined, and each catholyte need not be collected individually and counted.

Diffusion leakage corrections were made by reference to a calibration plot of "water times" vs. diffusion leakage determined on a number of membranes. The calibration plot is a straight line, and corrections amounted to 5% or less of the total radioactivity transferred across the membrane in all experiments.

Results

Experimental results are summarized in Table I. The equivalent and mole fractions of KCl in the KCl-$PbCl_2$ mixtures are listed in the first two columns, for seven compositions studied (a to g) at the temperatures listed in the third column. The experimentally determined values of ϕ and t_- are listed in the fourth and fifth columns, respectively. The definition $\phi = 1 - t_{++} - E_1 t_-$ involves the equivalent

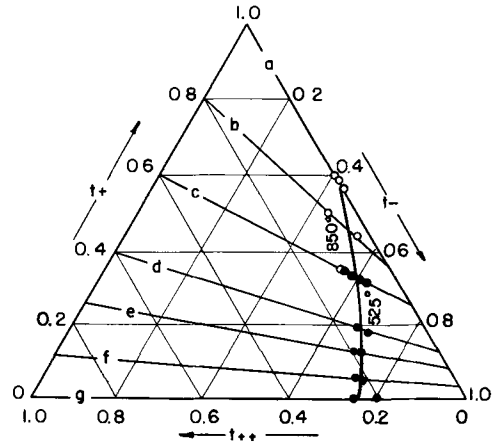

Fig. 2. Triangular diagram of the three transport numbers t_-, t_+, and t_{++} in fused KCl-$PbCl_2$ systems at several compositions: (a) pure KCl; (b) 19.0 mole % $PbCl_2$; (c) 36.9 mole % $PbCl_2$; (d) 54.2 mole % $PbCl_2$; (e) 68.8 mole % $PbCl_2$; (f) 84.0 mole % $PbCl_2$; (g) pure $PbCl_2$; and at 525° (•) and 850°C (O). The straight lines (a to g) correspond to the experimental values of the parameter ϕ (Table I). Experimental points correspond to the measured values to t_- (Table I), plotted for each composition (a to g) on the appropriate ϕ line. The smooth curve drawn through the points defines the transport numbers t_-, t_+, and t_{++} as a function of composition (a to g).

fraction E_1 of $PbCl_2$ which is simply equal to $1 - E_2 = 1 - E(\text{KCl})$. The corresponding mole fractions are $X_1 = E_1/(2 - E_1)$ and $X_2 = 2E_2/(1 + E_2)$ for $PbCl_2$ and KCl, respectively.

Since t_- was determined independently by the use of a radiochlorine tracer, as described, the definition of ϕ above and the relation $1 = t_- + t_+ + t_{++}$ provide a system of two equations which can be solved for the two unknowns t_+ and t_{++}, once the value of ϕ has been determined experimentally, as described.

Since the three transport numbers add up to unity, the equilateral triangular diagram (Fig. 2) lends itself particularly well to this solution for two unknowns. The defining equation for the parameter ϕ corresponds to a straight line in this diagram, whose intercept on the $t_- = 0$ axis (left side of Fig. 2) is $t_{++} = 1 - \phi$, and whose intercept on the $t_{++} = 0$ axis (right side of Fig. 2) is $t_- = (1 - \phi)/E_1$.

Seven straight lines (marked a to g) have been drawn in Fig. 2, corresponding to the seven compositions studied and to their experimentally determined values of ϕ (Table I). For line c, the values of ϕ at 525° and 850°C coincided within experimental error. Once the ϕ lines were drawn in Fig. 2, the experimentally determined t_- points (Table I) could be plotted, each set of points being plotted on the ϕ line corresponding to the same composition. The locus of these t_- points defines the three transport numbers for each one of the seven compositions studied. The smooth curve drawn through the points shows how the transport numbers t_-, t_+, and t_{++} vary as the composition goes from line a (KCl) to g ($PbCl_2$). The lack of a break in the curve in line c suggests that the transport numbers are insensitive to temperature changes between 525° and 850°C. The values of t_+ and t_{++} given in the sixth and seventh columns of Table I were read off the intersections of the smooth curve with the ϕ lines in Fig. 2.

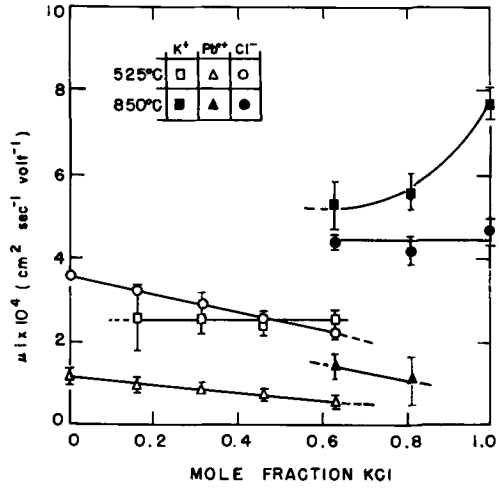

Fig. 3. Mobility of the ions vs. mole fraction in the fused KCl-$PbCl_2$ system.

Equivalent conductance data for the $PbCl_2$-KCl system are available from density data of Boardman, Dorman, and Heymann (11) and specific conductance data of Bloom and Heymann (3). The conductance data of Yaffe and Van Artsdalen (12) were used for pure KCl. The total equivalent conductances λ of the mixtures are given in the last column of Table I. The ionic equivalent conductances λ_i may be calculated from the equation $\lambda_i = t_i\lambda/E_i$, where t_i is the transport number and E_i the equivalent fraction of the i^{th} ion. The ionic mobilities, $u_i = \lambda_i/F$, are shown in Fig. 3, as a function of composition. It is noteworthy that the transport numbers for pure $PbCl_2$ determined here with radiotracers agree very well with those determined using the bubble cell (13, 14).

Discussion

The most striking observation provided by the data is the rapid decrease in mobility of K^+ ion upon addition of $PbCl_2$ to KCl. This observation is understandable if Pb^{++} ion is present in $PbCl_2$ and if Pb^{++} ion combines with negative holes, the holes into which K^+ ion would normally move. The lowering of the K^+ ion mobility cannot be due to the formation of complex ions; the chemical nature of K^+ ion is not that of complex former. On the other hand, the fairly high mobility of Pb^{++} ion is greater than one would expect on the assumption that Pb^{++} ion moves into doubly charged negative holes; such doubly charged holes should be difficult to create energetically and, in the presence of the singly charged Cl^- anion, should split readily into two singly charged holes. To accommodate both facts, the mobility of Pb^{++} ions and the combining of Pb^{++} ion with negative holes, it is necessary to postulate an equilibrium between Pb^{++} and $PbCl^+$, the latter accounting for the mobility of the Pb^{++} ions. The general change in mobility of Cl^- and Pb^{++} ions with composition change is gradual enough to be accommodated by general changes in the properties of the medium in which the ions move.

The disagreement between the present data and those of Lorenz and Ruckstuhl (6) is explained easily on the basis of leakage of salt through the membrane of the cell. Values of ϕ are very insensitive to such leakage. As mentioned previously, there is no effect on ϕ if the composition of the melt flow-

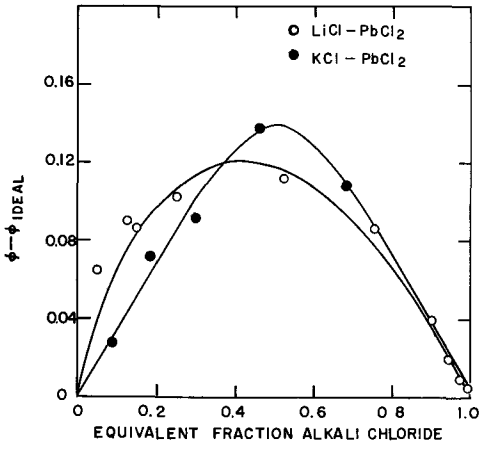

Fig. 4. Comparison of the ϕ parameter for fused $LiCl-PbCl_2$ systems at 650°C [O, cf. Ref. (15)] and for fused $KCl-PbCl_2$ systems at 525° and 850°C (•, cf. Table I); ϕ_{ideal} is here taken equal to the equivalent fraction of alkali chloride in both mixtures (see text).

ing through the disk is that of the original sample. Values of t_+ determined by a change of weight method, such as that used by Lorenz and Ruckstuhl, are extremely sensitive to leakage, while values of t_+ determined radiochemically in an experiment such as is outlined here are much less sensitive. This is because of the immediate dilution of Cl^{36} by the anolyte. The effect of temperature on the transport number is small. In changing from 525° to 850°C, the transport numbers for all of the ions remain constant within experimental error. The temperature change here is sufficiently large that if there were significant differences in the activation energies for mobility of the ions, there would be a sensible change in the transport numbers. Note that the mobilities of the ions change very appreciably in this temperature interval.

An interesting experiment was performed recently by Klemm and Monse (15). With an ingeniously devised moving boundary, they determined relative mobilities of cations in the system $LiCl-PbCl_2$. In essence, they determined ϕ for this system. It can be shown that $\phi = b_{13}E_1/(b_{13}E_1 + b_{23}E_2)$, where b_{13} and b_{23} are Klemm and Monse's notation for the mobility of $1(Li^+)$ and $2(Pb^{++})$ with respect to $3(Cl^-)$, and E_1 and E_2 are (here only) the equivalent fractions of uni- and divalent salts. The similarities and dissimilarities of the two alkali chloride-lead chloride systems are such as to make their data of obvious interest. Values of ϕ in this system were computed together with values of $\phi - \phi_{ideal}$; ϕ_{ideal} becomes numerically equal to the equivalent fraction of the alkali chloride, if the simplifying assumption can be made that uni- and divalent cations have the same mobility.

With this simplifying assumption, ϕ_{ideal} is the same for corresponding equivalent concentrations in the two systems; values of ϕ are compared most easily by looking at the sensitive function, $\phi - \phi_{ideal}$. These values are presented in Fig. 4. It is interesting to note the close similarity in the behavior of the two systems. Nothing can be said regarding absolute values of t_+ and λ_+ in the $LiCl-PbCl_2$ system, however, until an independent set of determinations relating them to measurable quantities is available.

Galvanic Behavior in Fused Electrolytes

I. The Nominal System Mg/LiCl-KCl/Ni

Sidney M. Selis,[1] Guy R. B. Elliott,[2] and Laurence P. McGinnis

Diamond Ordnance Fuze Laboratories, Washington, D. C.

ABSTRACT

The galvanic function of cells containing hygroscopic molten electrolytes involves hydroxide ion as an active material if no stronger oxidizing agent is present. For the system without additional components two sets of reactions are postulated; the operative set would depend on the temperature range. At lower temperatures (390°-440°C), hydroxide ion is cathodically reduced to hydrogen gas plus oxide ion; at higher temperatures (445°-535°C), nickel(II) oxide, formed by the action of hydroxide ion on nickel metal, is the cathodically reduced species. In both temperature ranges magnesium oxide is formed at the anode. At higher temperatures, the magnesium and nickel electrodes obey Nernst's law with respect to the additions of magnesium, nickel, and oxide ions in the concentration range of interest. The electrodes are reversible and of the second kind.

The galvanic system of interest here nominally includes a magnesium anode, an electrolyte which is a molten mixture of potassium chloride and lithium chloride, and a nickel cathode. In the course of the work, the effects of additional components were noted but only to assist in the postulation of electrode reactions. The system is related to some which have been discussed before (1), but it contains no strong oxidant and therefore is not capable of supplying appreciable currents.

On the basis of the present work, half-cell reactions are postulated and, at least under certain conditions, electrode reversibility is demonstrated.

Experimental

Materials.—The nickel(II) oxide, potassium chloride, lithium chloride, lithium carbonate, nickel(II) chloride hexahydrate, and silver chloride were of the usual reagent grade and were not purified further. The nickel content in the nickel(II) chloride hexahydrate was determined gravimetrically by the dimethylglyoxime method. Reagent grade magnesium chloride hexahydrate was dehydrated by a method similar to that of Kelley and Moore (2). All solid chemicals were handled, as far as possible, in a "dry room" (relative humidity 6% under usual room temperature and pressure).

The hydrogen and helium gases were dried by bubbling through concentrated sulfuric acid followed by passage over potassium hydroxide pellets.

The sheet magnesium, generally 0.13 mm thick, was of the commercial electrolytic grade (over 99.5% pure). The impurities included small amounts of silver, aluminum, copper, and calcium as determined by spectrographic analysis. Just prior to use, the dark film on the metal was removed by immersion in 1% hydrochloric acid solution followed by thorough rinsing in distilled water. The metal was wiped dry with a soft lint-free paper.

The sheet nickel was also 0.13 mm thick and was of a good commercial grade (over 99.5% pure). A spectrographic analysis revealed small amounts of zinc, iron, and cobalt. It was found that, other than a thorough washing with a mild soap and water, no treatment of the metal surface was needed.

Another type of electrode material was sintered nickel plate. The preparation and properties of this material have been described by Fleischer (3). This porous material was thoroughly rubbed with nickel (II) oxide to provide a nickel, nickel oxide electrode. (The original sintered plate was not impregnated with nickel hydroxide as described by Fleischer.)

Procedure.—The electrodes were prepared from 3.8-mm strips of the magnesium and nickel. One end of each strip was joined to tungsten wire leads by spot welding. These strips were inserted into lengths of 7-mm Pyrex tubing which were sealed at one end to the tungsten so that copper wire could be joined to the latter. At the other end of the glass tubes, 10 mm of electrode strip protruded. The total length of the electrode assemblies was about 25 cm, of which 3-4 cm was to be submerged in the electrolyte.

Except for minor differences, the cell arrangement was similar to that pictured by Jennings (4). A magnesium and a nickel electrode assembly, a Pyrex thermocouple protection tube, and a Pyrex gas inlet tube were inserted through a cap and sealed in place. The faces of the electrodes were oriented directly opposite to each other and the thermocouple occupied a central position. The electrode tubes were placed approximately 3 cm apart.

For individual electrode polarization measurements, a large cylindrical working electrode of sheet nickel was used. The reference electrodes were contained in 7-mm Pyrex tubing closed at one end. The

[1] Present address: Catalyst Research Corporation, Baltimore, Md.
[2] Present address: University of California, Los Alamos Scientific Laboratory, Los Alamos, N. Mex.

reference system was either Ag(c), AgCl (1, unit mole fraction), or Ni(c), KCl-LiCl-NiCl (1, mole fraction 1.00×10^{-3}) in glass. The silver or nickel electrode leads were 2-3 mm in diameter.

To start a run, a 38 x 200 mm Pyrex test tube was charged with the initial electrolyte salts. This was then placed in a noninductively wound electric furnace, and the cell temperature was adjusted to approximately 320°C by the use of a variable autotransformer. This temperature was maintained until most of the adsorbed water was removed. The temperature then was increased and when the electrolyte was molten, the electrodes, thermocouple tube, and gas inlet tube were positioned.

When a hydrogen or helium atmosphere was used, the gas was slowly bubbled through the melt for 30-60 min. (The loose fit between cap and test tube permitted the escape of gas.) The gas flow was stopped some minutes before emf readings were made.

Electromotive forces of cells and of chromel-p-alumel thermocouples were measured with a null-balancing potentiometer (cell emf's to the nearest centivolt). Temperature values are correct to about ±1°C. The current through the polarized electrodes was measured with a d-c milliameter. The current source was a storage battery with a voltage divider.

The x-ray analysis of the matter insoluble in the molten electrolyte, which was observed on the electrodes and at the bottom of the cell, was accomplished with powder samples mounted in a Debye-Scherer camera. A copper target was used in providing the 30 kv x-radiation. Sixteen-hour exposures were made, and d/n values as determined were checked against known tabulated values.

Results

Electrolyte composition.—Nominally the electrolyte composition was the eutectic mixture of potassium and lithium chlorides and the stated amounts of added components. This eutectic composition is 58 mole % of lithium chloride and 42 mole % of potassium chloride. The eutectic temperature as 354°C [cf. Solomons, *et al.* (5)]. Actually, water and hydroxide ion were also included as demonstrated by Laitinen, *et al.* in terms of polarographic residual current measurements and cold trap collection of water (6). The presence of these species also was shown clearly by the present authors. Quantities of water were collected in a cold trap on evacuation of tubes containing electrolyte; pieces of calcium reacted with the electrolyte to release hydrogen gas. Of course, the presence of hydroxide ion at elevated temperatures implies the additional presence of oxide ion.

Measurements of hydrogen-ion concentration were made on water solutions of frozen electrolyte containing only the eutectic chloride mixture. The pH values were such as to indicate concentrations of hydroxide and oxide ions in the electrolyte ($[OH^-] + 2[O^=]$) to be of the order of 10^{-3} moles/liter.

Behavior at lower temperatures (390°-440°C).—To assist in the postulation of reactions, the effects of internal atmosphere were determined for cells Mg/KCl-LiCl/Ni at 420°C. Unit pressures of air, hydrogen, and helium were used; cells under reduced pressure were measured also. Steady cell potentials were reproducible to within ±0.01 v.

The results of measurements with different atmospheres at 420°C can be summarized as follows: (*a*) with ordinary air atmosphere, the emf was 1.67 v; (*b*) with dry hydrogen atmosphere, 1.58 v; (c) with dry helium atmosphere, 1.67 v; and (*d*) under reduced pressure (10μ Hg), 1.61 v.

It is apparent that, while the use of dry hydrogen gave a lower potential than that of an air-atmosphere cell, the use of dry helium had no such measurable effect. Moreover, evacuation of a cell also depressed the potential, but not as much as the hydrogen atmosphere did.

When an external resistive load was placed across the electrodes, such that electrode current densities were about 10 ma/cm^2, gas was evolved from the nickel cathode. This evolution ceased when the load was removed.

In order to obtain some qualitative information as to the reversibility of the magnesium and nickel electrodes at 420°C, anodic and cathodic polarization measurements were made on both electrodes. For current densities of 3 ma/cm^2, there were no overpotentials within experimental error (±0.01 v). Apparently because of the low ohmic resistance of the electrolyte and the small amounts of current used, measured polarizations were independent of the placement of the reference electrodes.

Starting with a temperature of about 390°C, cells of the type Mg/KCl-LiCl/Ni were heated slowly to 440°C, and the emf was studied as a function of temperature. The portion of the curve in Fig. 1, which has a steep slope, is fairly well established. The points were derived from three separate cells. For a given temperature in this region, the potential remains stable for at least 1 hr. On reversing the direction of temperature change, the emf eventually stabilizes at the value associated with a given temperature.

From the observed dE/dT in the 390°-440°C region, a cell reaction entropy of 55 cal/°C/mole was calculated for a two-electron transfer.

X-ray examinations of the scrapings from electrodes used in the lower temperature range revealed magnesium oxide. No oxide of nickel was detected.

Behavior at higher temperatures (445°-535°C).—

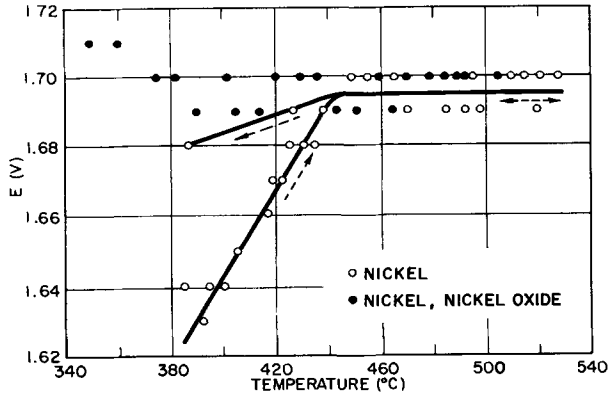

Fig. 1. Electromotive force vs. temperature for the nominal system Mg/KCl-LiCl/Ni.

Upon increasing the temperature of the system Mg/KCl-LiCl/Ni to 445°C, a leveling-off occurs, and on lowering the temperature, a higher potential persists as shown in Fig. 1. The higher potential of 1.70 v also was observed at all temperatures, on heating and cooling, by using a sintered nickel positive electrode into which had been rubbed nickel(II) oxide (NiO).

Examination of cells in the higher temperature region with magnesium and bright nickel electrodes (NiO not deliberately added) revealed the presence of insoluble matter on the electrodes and at the bottom of the cell. X-ray analysis of this material indicated MgO and NiO.

The potentials of magnesium and nickel electrodes at 480°C were studied as a function of concentrations of magnesium (Fig. 2), nickel (Fig. 3), and oxide (Fig. 4) ions in the electrolyte. The ions were introduced by adding to the electrolyte magnesium chloride, nickel chloride hexahydrate, and lithium carbonate, respectively. Often as much as 2 hr was required for stabilization of the potential. However, a stable potential would usually remain so for several hours, and emf values could be confirmed by repetitive measurements with duplicate cells.

Values given in Fig. 2-4 are electrode potentials with respect to the Ag, AgCl (1), glass electrode. At the beginning of a run, the composition of the electrolyte would nominally include both magnesium and nickel chlorides at mole fractions of 3.16×10^{-4} (log N = −3.50). In any one run, only one type of ion was added.

It will be noted that the addition of magnesium or nickel ions causes the electrode potentials of both magnesium and nickel electrodes to rise (become more noble) linearly with the logarithm of the mole fraction of the added ion (Fig. 2 and 3); on the other hand, the addition of oxide ion causes the potentials of both electrodes to fall (become less noble, Fig. 4).

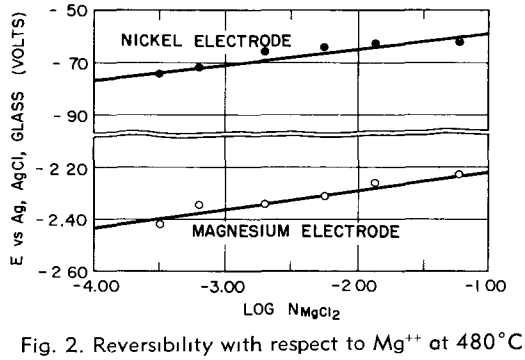

Fig. 2. Reversibility with respect to Mg^{++} at 480°C

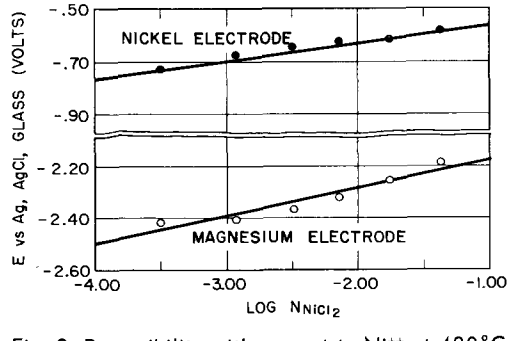

Fig. 3. Reversibility with respect to Ni^{++} at 480°C

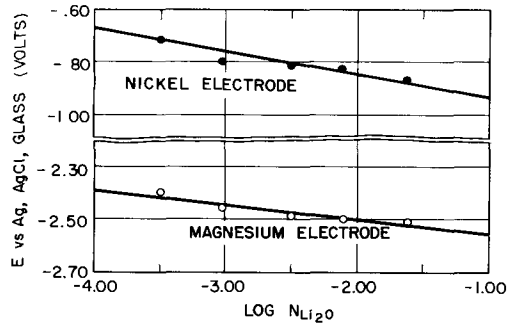

Fig. 4. Reversibility with respect to $O^{=}$ at 480°C

The slopes of the potential-log N curves are given in Table I. The theoretical slopes of ±0.075 are equal to 2.303 *RT*/2F.

Discussion

Cells at Lower Temperatures

On the basis of experimental observations reviewed above, the authors suggest reactions [1a, b, and c] below for the system at 390°-440°C. At the anode,

$$Mg(c) + O^{=}(l) \rightarrow MgO(c) + 2e^{-} \qquad [1a]$$

At the cathode,

$$2OH^{-}(l) + 2e^{-} \rightarrow H_2(g) + 2O^{=}(l) \qquad [1b]$$

Net reaction,

$$Mg(c) + 2OH^{-}(l) \rightarrow MgO(c) + H_2(g) + O^{=}(l) \qquad [1c]$$

Supporting evidence may be summarized as follows: (*a*) The emf was responsive to changes in the internal atmosphere. As compared with an air atmosphere, the use of hydrogen resulted in a depressed emf; vacuum partially restored the cell potential; a helium atmosphere had no particular effect. (*b*) There is definite evidence for the presence of hydroxide ion and/or water. (c) With fairly low current densities, gassing at the cathode was observed upon application of load. Attendant cell polarization was not excessive. (*d*) The cell reaction has a high apparent entropy, which is consistent with the formation of gas. (*e*) X-ray analysis of the anode surface revealed magnesium oxide. A study of the cathode showed no oxide of nickel for cells used in the lower temperature range.

Cells at Higher Temperatures

On heating above 445°C, the emf was relatively unresponsive to temperature change. The observed (and reproducible) discontinuity in the emf-temperature curve suggests a change in mechanism, and indeed, nickel(II) oxide is to be found on the cathode surface if the latter is heated above 450°C in the electrolyte. The negligible entropy of reaction at the

Table I. Slopes of electrode potential vs. log N curves at 480°C

Added ion	Electrodes: Observed Mg v	Observed Ni v	Theoretical Mg v	Theoretical Ni v
Mg^{++}	+0.070	+0.060	+0.075	+0.075
Ni^{++}	+0.110	+0.070	+0.075	+0.075
$O^{=}$	−0.057	−0.090	−0.075	−0.075

higher temperatures indicates disappearance of the gas phase reaction.

Reactions postulated for the system at higher temperatures are as follows. At the anode, [1a] as above, and at the cathode,

$$NiO(c) + 2e^- \rightarrow Ni(c) + O^= (l) \qquad [2a]$$

Net reaction,

$$Mg(c) + NiO(c) \rightarrow MgO(c) + Ni(c) \qquad [2b]$$

It is suggested that the nickel oxide is formed by reaction [3]

$$Ni(c) + 2OH^-(l) \rightarrow NiO(c) + H_2(g) + O^= \qquad [3]$$

This reaction becomes thermodynamically possible in the temperature region of interest. The presence of water and hydroxide ion, which react with both magnesium and nickel to form metal, metal oxide electrodes, has been discussed above.

Lack of information on the free energy of oxide ion in solution does not permit calculation of emf's in the lower temperature region. However, reaction [2b] is amenable to an approximate calculation of potential. Coughlin (7) gives the following standard free energies at 450°C

$$Mg(c) + \tfrac{1}{2}O_2(g) \rightarrow MgO(c),$$

$$\Delta F^\circ_{450^\circ C} = -125.1 \pm 0.2 \text{ kcal} \qquad [4]$$

$$NiO(c) \rightarrow Ni(c) + \tfrac{1}{2}O_2(g),$$

$$\Delta F^\circ_{450^\circ C} = +41.2 \pm 0.1 \text{ kcal} \qquad [5]$$

The sum of reactions [4] and [5] gives, for reaction [2b] $\Delta F^\circ_{450^\circ C}$ -83.9 ± 0.3 kcal. This is equivalent to a standard emf of 1.82 ± 0.01 v. The observed value is 1.70 ± 0.01 v.

The difference between the calculated E° and the observed emf is about a tenth of a volt. However, it should not be inferred that the nickel oxide in the actual cell is at unit activity. Verwey (8) and Tichenor (9) discuss the presence of lithium ion in the nickel oxide lattice. The former induces the presence of nickel(III) oxide which can combine with Li_2O (10). Nickel(II) oxide itself forms a solid solution with lithium oxide, at least on the surface (11).

In any case, the half-reactions [1a] and [2a] are electrodes of the second kind as evidenced by the data in Fig. 2, 3, and 4. That is to say, the magnesium and nickel electrodes are constituted by a metal, a partially soluble metal oxide, and oxide ion in solution. As metal ion is added, it reacts with oxide ion in the electrolyte, and since the oxides are only partially soluble, relationships [A] and [B] will hold:[3]

[3] E′ and K′ imply the use of concentrations instead of activities. Activity coefficients are not known but it is assumed that they are constant throughout the concentration ranges of interest.

$$[Mg^{++}][O^=] = K'_1 \qquad [A]$$

$$[Ni^{++}][O^=] = K'_2 \qquad [B]$$

The Nernst equations for the electrode potentials of the magnesium and nickel electrodes are given by the relationships,

$$E(Mg,Mg^{++}) = E^{\circ\prime}(Mg,Mg^{++}) + (RT/2F) \ln [Mg^{++}]$$
$$= E^{\circ\prime}(Mg,Mg^{++}) + (RT/2F) \ln K'_1/[O^=], \qquad [C]$$

$$E(Ni,Ni^{++}) = E^{\circ\prime}(Ni,Ni^{++}) + (RT/2F) \ln [Ni^{++}]$$
$$= E^{\circ\prime}(Ni,Ni^{++}) + (RT/2F) \ln K'_2/[O^=] \qquad [D]$$

The slopes of E vs. log N_{MgCl_2} or log N_{NiCl_2} curves are calculated to be $+0.075$ v; the slope of the E vs. log N_{Li_2O} curve is calculated to be -0.075 v. These are to be compared with the experimental values in Table I. The authors consider the agreement to be good considering the various experimental difficulties.

Relationships [C] and [D] may be combined to give relationship [E] which expresses the emf of the nominal system:

$$E \text{ (system)} = E^{\circ\prime}(Ni,Ni^{++}) - E^{\circ\prime}(Mg,Mg^{++}) + (RT/2F) \ln K'_2/K'_1 \qquad [E]$$

It can be seen that this latter emf should be independent of the concentrations of magnesium, nickel, or oxide ions for a given temperature.

Manuscript received June 14, 1954. This paper was prepared for delivery at the Cincinnati Meeting, May 1-5, 1955.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Enhanced Surface Reactions

III. Adsorption of Gases on Prepared Ruthenium Surfaces

Manfred J. D. Low and H. Austin Taylor

Nichols Laboratory, New York University, New York, New York

ABSTRACT

Rates of adsorption of H_2, CO, and O_2 on $Ru \cdot Al_2O_3$ catalyst surfaces prepared by pre-adsorption of gases were studied. Pre-adsorption of CO increases the rate and extent of H_2 adsorption. Adsorption of CO and of O_2 irreversibly poisons the surface. The Elovich equation is applicable to the data. The results are discussed in terms of a site-creation mechanism. It is found that the pre-adsorption of a gas may influence both the initial and the ambient rates of adsorption to various and at times opposite extents, resulting in several types of "poisoning."

In the study of chemisorption, catalysis, and similar surface processes it is of interest to examine the effects of one gas on the reaction of another with a solid surface. Whereas numerous examples of the "poisoning" of chemisorption and heterogeneous, catalytic processes exist, relatively few data on the opposite effect are to be found in the literature. A study of the effects of one pre-adsorbed gas on the adsorption kinetics of another has been undertaken, and is presented here.

Experimental

A commercial catalyst of 0.5% Ru on alumina was used as adsorbent. A 28-g sample of the solid was placed in a Vycor tube which was subsequently sealed to a conventional constant volume adsorption system. The adsorbent was heated to 500°C and evacuated for about 10 hr to a pressure of 10^{-6} mm Hg or less. Appreciable amounts of gas and water were evolved during the first hour of pumping. The catalyst retained its original black color.

Palladium-filtered H_2 was admitted to the catalyst at 500°C and 1 atm pressure. After a few minutes the catalyst turned gray and retained that color until exposure to oxygen occurred. Subsequent reduction with hydrogen restored the gray color. After being in contact with H_2 for 10 min the system was pumped on for 2 hr at 500° to 10^{-6} mm Hg or less. Experiments on H_2 adsorption were then made. All experiments were done with the adsorbent at 100°C and were numbered consecutively in the order of execution. Volumes are reported in ml. N.T.P. At the completion of each experiment the system was evacuated, the adsorbent heated to 500°C and pumped on at that temperature for 10 hr, with the exception of several "pretreatments" described later. All H_2 was purified by passage through Pd. Carbon monoxide was prepared by dehydration of formic acid with H_2SO_4. Oxygen was purified by passage through a train of ascarite and drierite traps.

Surface preparation.—To prepare the catalyst by pre-adsorption, the following general procedure was adopted. After the 10-hr pumping period, the catalyst was isolated from the system, cooled, and then thermostatted to 100° ± 0.1°C in a steam bath. A predetermined amount of pre-adsorbate was placed in the system of known volume, and the pressure was measured. The stopcock isolating the adsorbent was then opened, admitting the gas to the catalyst chamber. Within 1 min or less the pressure in the system, measured on a manometer containing dibutyl phthalate (DBP), fell to less than 0.1 mm. After about 30 min the adsorbent was isolated and the system evacuated. Gas to be adsorbed "on top of" the first gas was placed in the system at a predetermined pressure. This gas was then admitted to the prepared adsorbent, and the rate of gas-uptake was measured.

Results

Adsorption of hydrogen.—The rate of adsorption of H_2 was measured on the catalyst immediately after the initial H_2 treatment described above. The kinetics of H_2 adsorption on this adsorbent have been studied previously (1). It was found then, as now (Table I), that the kinetics obeyed the Elovich equation (2)

$$\frac{dq}{dt} = a\, e^{-\alpha q}$$

q being the amount of gas adsorbed at time t, a and α constants depending on temperature and initial gas pressure (1-3, 7). The data were internally con-

sistent and well represented by the integrated Elovich equation,

$$q = \frac{2.3}{\alpha} \log_{10} (1 + a\alpha t)$$

Because $a\alpha t > 1$, this is tantamount to representation of data by $q - \log_{10} t$ plots. Whereas in the previous study linear $q - \log_{10} t$, or Elovich, plots were obtained, isothermal anomalies (2) were found in plots of the data of present experiments. Figure 1 shows a plot of the data of Run No. 1 and also that of a comparable run of the previous investigation.

At the end of the previous investigation (1) the catalyst was removed. Fresh adsorbent from the same batch of catalyst used previously was added to the sample to bring its weight to 28 g. It seems plausible, in view of the results to be discussed later, that the break in plot I of Fig. 1 and in other Elovich plots was caused by contamination, possibly

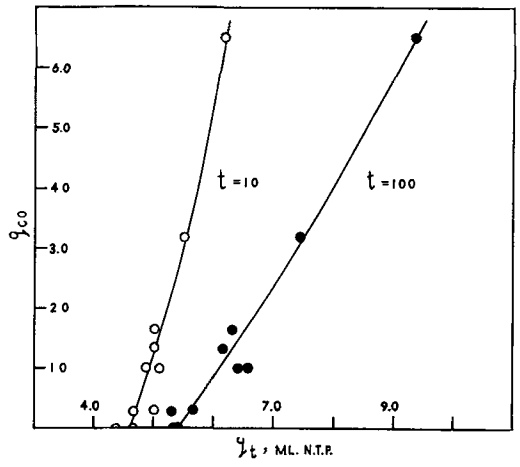

Fig. 3. Adsorption of H_2 on top of CO. The variations of the amount of H_2 adsorbed at time t, qt, with variation in q_{CO}.

by atmospheric oxygen not removed by the initial H_2 treatment of the present investigation.

Adsorption of hydrogen on surfaces containing CO.—Data for eight such experiments are given in Table I. The rate of H_2 adsorption on surfaces containing varying amounts of CO was measured. In each case, the $q - \log_{10} t$ plot of the data resulted in a straight line which, after a certain time, abruptly changed in slope in a fashion similar to that of plot I, Fig. 1. The constants a and α for the initial and final part of each plot were designated by subscripts 1 and 2, respectively. All runs were made at approximately the same initial hydrogen pressure. Inspection of the data reveals some scatter of parameter values, but nevertheless interesting results.

Figure 2 to 4 show the type of relation obtained on plotting several parameters against the amount of pre-adsorbed CO, q_{CO}. In general, it appears that the ambient rates and extents of H_2 adsorption are enhanced, but that the initial rates are decreased, by the pre-adsorption of CO.

Adsorption of CO.—At the end of run 13 the system was evacuated and the temperature of the adsorbent raised to 500° in 20 min. The hot adsorbent was exposed to CO at 80 cm DBP for 2 min, and then pumped on at 500° for 5 min. This CO pretreat-

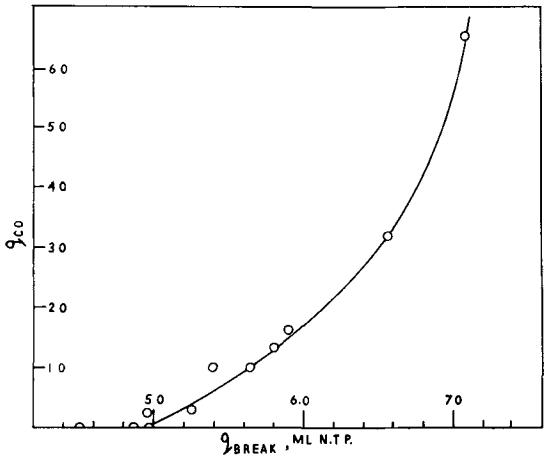

Fig. 2. Adsorption of H_2 on top of CO. The variation of the q-coordinate of the isothermol anomaly, q_{break}, with variation in q_{CO}.

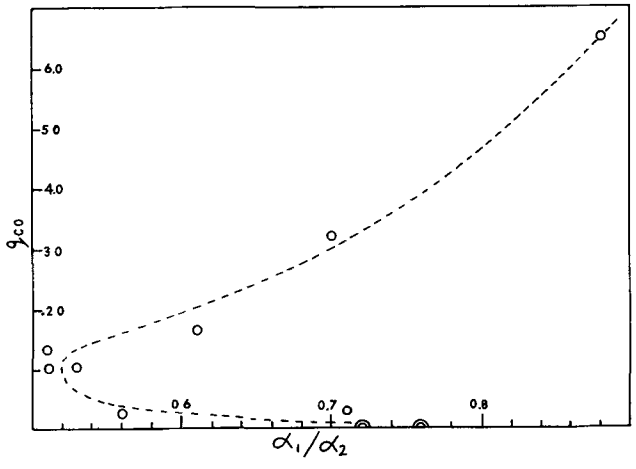

Fig. 4. Adsorption of H_2 on top of CO. The variation of the ratio α_1/α_2, the ratio of ambient rates, with q_{CO}.

ment was repeated twice. The adsorbent was then pumped down to 10^{-6} mm Hg or less for about 12 hr at 500°. Various runs using CO were then made, the parameters of four being given in Table II.

It was found that the experiments were not reproducible and that extreme scatter of parameter values was obtained: there was no gradual change in parameter values with change in the amount of pre-adsorbed H_2. Also, the total amounts of CO adsorbed at 100 min show a steady decrease, dropping from 16.28 ml (run 16) to 13.70 ml (run 29), suggesting that progressive poisoning of the surface occurred.

It is interesting to note that in the first runs using CO on the unprepared surface, Elovich plots wihout breaks were obtained, whereas the data of experiments on surfaces prepared with H_2 (with the exception of the terminal run 29 with 0.08 ml pre-adsorbed H_2) gave discontinuous Elovich plots.

Repetition of hydrogen adsorption.—In order to determine whether the adsorbent had been damaged by the CO pre-adsorption experiments, the H_2 adsorption on an unprepared surface was repeated. After the usual pump-off at the end of run 29, H_2 was admitted to the catalyst at 500° for 5 min at 42 cm DBP. The catalyst was then pumped on for 5 min at that temperature. This treatment was repeated three times, after which the catalyst was pumped on overnight at 500°. Run 30 was then made. The magnitude of the parameters of that run, in comparison to those of runs, 1, 2, and 4, suggests that the surface had been permanently damaged. In view of this it seems possible and perhaps probable that CO poisoning was responsible for the failure of H_2 on O_2 and of O_2 on H_2 experiments, since all may be on top of CO.

Adsorption of oxygen.—An attempt was made to determine the influence of pre-adsorbed H_2 on the adsorption of O_2, and the influence of pre-adsorbed O_2 on the adsorption of H_2. The experiments were not reproducible. It seems probable that, as in the case of CO, an accumulation of irremovable gas occurred on the surface.

Some qualitative information was obtained from ten experiments. (*A*) Each experiment showed internal consistency in obeyance of the Elovich equation. (*B*) Pre-adsorption of O_2 enhances the rate and extent of adsorption of H_2 (Fig. 5).

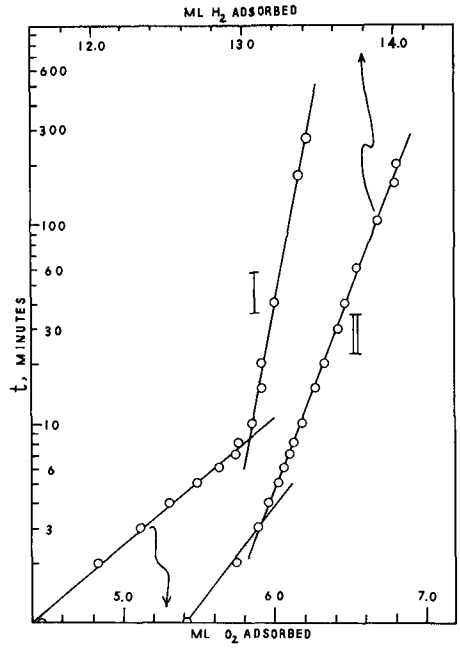

Fig. 5. Adsorption of O_2 and of H_2: I. Adsorption of O_2 on unprepared Ru, Run 33; II, H_2 on top of 0.78 ml O_2, Run 35.

Discussion

The adsorption of H_2 on top of CO is faster and more extensive than that on untreated surfaces. An explanation, in classical terms, comes readily to mind. After 100 min, 5.40 ml of H_2 (run 1) but 16.28 ml CO (run 16) are adsorbed on untreated surfaces. Pretreatment of a surface with CO might therefore cause a part of the surface, originally inert, to take up H_2, or H_2 may form surface H-CO complexes, or H_2 may literally be adsorbing on top of adsorbed CO molecules.

Such effects and mechanisms have been found previously, mainly in equilibrium studies such as the following. The work of Griffin (4) on the effect of pre-adsorbed CO on the adsorption of H_2, and that of White and Benton (5) on the effect of H_2 on Ni "poisoned" with CO are examples. A more recent work is that of Sastri and Wiswanathan (6). The adsorption of CO and H_2 was studied on a Fischer-Tropsch Co-ThO_2-kieselguhr catalyst on which H_2 and CO, respectively, had been pre-adsorbed. It was found that at any temperature the H_2 adsorption was enhanced the higher the amount of pre-adsorbed CO, that for a particular amount of CO the enhancement was larger the higher the temperature, and that the enhancement caused was relatively larger the smaller the volume of gas pre-adsorbed. These effects were explained in terms of surface complexes, since the amounts of pre-adsorbed gas were too small to account for the enhancement by a mechanism whereby one gas became adsorbed on top of the other. A similar postulate was made by White and Benton who, finding that CO enhanced H_2 adsorption, argued that ". . . either the CO can increase the activity of the already active areas, or it can stimulate those areas which do not function until higher pressures, or it can create entirely new areas . . ." (5). Because only small amounts of CO gave the effect, it was suggested that increased adsorption was due to an enlargement of active areas, which are produced by having very small amounts of CO adsorbed on them.

Examination of the present data and reference to "poisoning" effects discussed previously (2, 7, 8) suggest that a more generally applicable approach is desirable. A more general mechanism may be deduced from the theories of Taylor and Thon. It has been shown (2, 7-10) that surface site creation can occur by a branching chain mechanism initiated by the reaction of an active particle, G, with a surface atom, S, causing a "dissociation" of the atom into two adsorption sites, V. The over-all reaction for the branched chain may be written,

$$G + nS \rightarrow GV + (2n-1)\ V$$

Table II. Adsorption of CO, O_2, H_2

Run No.	Pi, cm DBP	α_1 ml^{-1}	α_2 ml^{-1}	ln $a_1\alpha_1$	ln $a_2\alpha_2$	
16	73.8	1.90	—	11.45	—	(a)
17	74.2	2.00	—	11.88	—	(a)
24	73.7	0.98	2.4	5.00	13.08	(b)
28	74.2	0.65	2.4	3.2	12.01	(c)
33	60.2	1.48	15.3	2.83	2.89	(d)
35	75.6	2.3	4.5	12.61	25.17	(e)

(a) CO on untreated surface.
(b) CO on top of 2.58 ml pre-adsorbed H_2.
(c) CO on top of 0.65 ml pre-adsorbed H_2.
(d) O_2 on untreated surface.
(e) H_2 on top of 0.78 ml pre-adsorbed O_2.

The excess (2n-1) sites can be active for adsorption or, alternatively, may suffer bimolecular decay. Enhancement or retardation of chemisorption rates or of the extent of chemisorption by pre-adsorbed gases may be explained in terms of that general mechanism. The effect of an impurity may be expected to be either one, or a combination of, two general effects: (*A*) the initial site creation process may be affected, i.e., the parameter n (chain length) may be greater or smaller than usual; (*B*) the bimolecular decay process may be affected, poisons permitting easier recombination of sites, promoters hindering the decay and thus permitting a longer "site-life." Several combinations of *A* and *B* are thus possible.

In the present case of H_2 adsorbed on top of CO, the initial rate, a_1, is seen to decrease with increasing q_{CO} (Table I), a_1 falling from about 10^6 on the pure surface to about 10^1 on a surface having 6.5 ml of pre-adsorbed CO. Simultaneously, the total amounts adsorbed at $t = 100$ min increase (Fig. 3) and the parameters α, reflecting the reciprocal ambient rates, decrease. It appears that the initial site creation process was hindered, and that fewer sites were available initially for the adsorption of H_2. Thus the increase in the adsorption process seems to be wholly due to a reduced site decay rate.

Conversely, the parameters of run 35 (Table II) suggest that the site creation process was affected mainly. In this case, on adsorbing H_2 on top of 0.78 ml O_2, a_1 was changed from 10^6 to 10^{12}, while α_1 declined slightly: it appears that many more sites were created initially than in the case of H_2 adsorption on the untreated surface. The over-all effect is thus one of "promotion."

Further over-all effects may be predicted. An outright "poisoning" may occur, where both the initial and ambient rates of adsorption are decreased. The lack of reproducibility of CO adsorption rates and the diminution in the extent of adsorption of that gas, noted above, may be ascribed to such an effect: the rate of site recombination is greatly increased and the initial site creation process hindered, resulting in outright, true poisoning. Such true poisoning is also shown by Iijima's data (11, 12): the pre-adsorption of mercury or of CN by a Ni catalyst decreases both the initial and ambient rates of adsorption of H_2.

Also, a "pseudo-poisoning" may occur, in which case the ambient rate is decreased, but the initial rate is increased. The pre-adsorption of a gas thus may cause increased total adsorption, but at greatly reduced rates, the bulk of the gas adsorbing in a very short time.

It appears that the reverse of the last example may exist: there may be decreased total adsorption, but at a higher rate. Agliardi and Morelli (13) thus found that when cobalt catalyst is poisoned with CO, less H_2 is adsorbed, but also that the rate of adsorption is greater, than by cobalt not poisoned by CO. This case may be ascribed to the dual action of a decreased initial site creation and a hindered rate of site decay. A further example of pseudo-poisoning is given by Iijima's data (12) on the adsorption of H_2 on top of CO on a Ni catalyst. The total adsorption after 19 hr decreases, the parameters α_1 increase, and the initial rates a_1 increase, with increasing amount of pre-adsorbed CO.

These considerations suggest that the determination of rates of adsorption may be more fruitful in pre-adsorption studies than the usual static isotherm or isobar measurements.

It has been postulated previously (2) that the isothermal anomalies sometimes found are due to a change-over of the adsorption process from one type of adsorption site to another. Recently this postulate has been supported by Meller (14), who derived the Elovich equation by assuming the chemisorption process to consist of two independent but simultaneous processes.

Such a mechanism also is implied to be operative at the present time. Thus the appearance of a break in the Elovich plots of data of CO adsorption on H_2-treated surfaces, while no such breaks were found to occur with CO adsorptions on untreated surfaces, may be said to be due to the influence of H_2 on the site creation of decay mechanism. Similarly, the displacement of amount adsorbed, q_{BREAK}, at the discontinuity in Elovich plots with increasing amounts of pre-adsorbed gas—a behavior also apparent in the data of Iijima—may be bound up with such a mechanism (Fig. 2).

Not enough data exist at present for a quantitative treatment of these effects, but qualitatively the above mechanism may be applied to the various relations shown by Fig. 2-4. However, because the presence or absence of isothermal anomalies seems to depend on the past history of the surface, there may be no real significance, from a general quantitative point of view, between the relations of parameters vs. q_{poison} for several different poisons. Further work is in progress.

Technical Notes

Electrolytic Preparation of Titanium from Fused Salts

II. Design of Laboratory Cells

Marshall B. Alpert, James A. Hamilton, Frank J. Schultz, and William F. Sullivan

Titanium Division, Research Department, National Lead Company, Sayreville, New Jersey

Previously a process was described for the preparation of Ti metal by the electrolysis of an alkali or an alkaline earth metal chloride melt containing the reduced chlorides of Ti (1). The reduced chlorides were prepared *in situ* by electrolytically reducing $TiCl_4$ introduced through a hollow cathode. Variables important in obtaining a good yield of coarsely crystallized, ductile Ti metal adhering to the cathode included careful sealing of the cell, maintenance of the soluble Ti largely in the divalent state, and avoidance of melt agitation during metal deposition. Provision of an adequate diaphragm and gas barrier arrangement to avoid oxidation of soluble reduced Ti at the anode was also considered.

The relation between design and function of externally heated laboratory cells is an important factor. Modifications were made in the single diaphragm cell leading, on the one hand, to diaphragm cells operating continuously rather than on a charge-strip basis and, on the other hand, to alternative deposition procedures. These include both one-step diaphragmless and electrorefining procedures.

Single Diaphragmed Cell

The usual laboratory single diaphragm cell used, of approximately 10-liter capacity and externally heated by a Globar furnace, is similar to the cell illustrated in Fig. 1, except that no diaphragm surrounded the introduction cathode. The porous, fused alumina diaphragm rests on a pedestal, since it has been found that, as long as the diaphragm is not under tension by support from above, no difficulty is experienced with breakage in the fused salt system. The gas barrier is fitted inside the diaphragm so that the Cl_2 atmosphere does not contact the catholyte containing reduced Ti; spacing is sufficiently close to insure that practically no rising Cl_2 bubbles slip between the diaphragm and the gas barrier. Current efficiencies for Cl_2 gas were about 90% with this arrangement. The cell may be pressure tested for air leakage even while hot by use of an attached manometer. It is essential that the cell be sealed carefully from atmospheric contamination. Laboratory equipment of this type has been operated for periods of over three months without breakdown.

Certain limitations are inherent in this cell. The current for extended periods of operation is limited to about 60-100 amp to avoid obstructing the relatively small cross section (7.5 cm diameter) of the diaphragm and gas barrier with salt spray. The relatively small size of the anode and cathodes resulted in a rather high cell resistance, for example, 0.06 ohm with $SrCl_2$-NaCl supporting electrolyte at 700°C. This situation was improved by a concentric design with the graphite anode as a ring external to the diaphragm. Such a cell with a resistance of only 0.01 ohm was studied. The small amount of catholyte (2.8 l) resulted in an inconveniently short charging

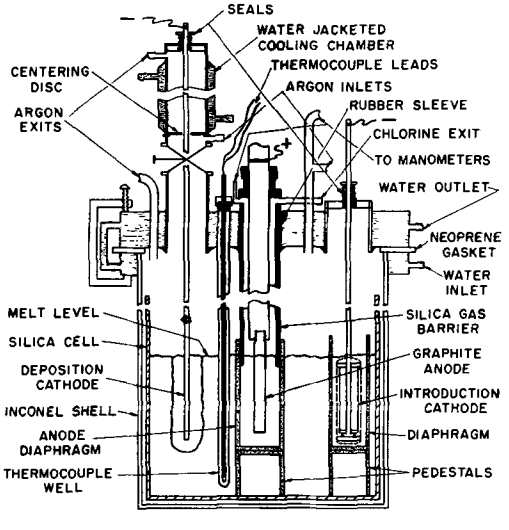

Fig. 1. Schematic drawing of double diaphragm cell

and stripping cycle, and the placing of the necessary accessory parts was difficult because of the small space available.

A major disadvantage of the single diaphragm cell is that the $TiCl_4$ must first be charged to the cell and then the reduced titanium chlorides electrolyzed to yield Ti metal in cyclic rather than continuous operation. Two factors imposed this requirement. Operation of the hollow cathode caused agitation of the melt in the vicinity of the deposition cathode and thereby reduced the crystal size and quality of the metal produced. In the second place, polarization of the hollow cathode at current densities above about 0.1 amp cm^{-2} resulted in the deposition of significant amounts of Ti metal at this electrode. Therefore, introduction of $TiCl_4$ at a rate of one mole per two faradays gave less than optimum degree of reduction for the melt, unless low hollow cathode current densities were employed or the melt was further reduced at low current densities prior to the metal deposition stage.

Some of the difficulties with cyclic operation may be eliminated by avoiding the use of a diaphragm entirely. If the current through the introduction cathode is increased to a value of approximately $4/f$ faradays per mole of $TiCl_4$, where f is the current efficiency of the cell, the reduced titanium chlorides formed exist only transiently and do not escape in significant amounts from the vicinity of the introduction cathode. The melt therefore is substantially free of reduced Ti salts and no diaphragm is required (6,7).

Double Diaphragm Cell

Figure 1 shows a cell in which the introduction cathode is also surrounded with a porous fused alumina diaphragm similar to the anode diaphragm (2). This cell permitted continuous reduction of $TiCl_4$ to Ti metal. When a high soluble Ti concentration was built up within the introduction diaphragm, the amount of Ti introduced as $TiCl_4$ and the amount leaving the introduction catholyte for the deposition catholyte were balanced by hydrostatic flow. The hydrostatic head resulting in this flow stems from the weight of $TiCl_4$ being added and from ionic migration effects (1). The deposition of coarsely crystallized, ductile metal was obtained while $TiCl_4$ was continuously introduced, since agitation of the melt about the hollow cathode no longer disturbed the electrolyte about the deposition cathode. In addition, polarization of the hollow cathode did not prevent maintenance of the degree of reduction of the melt desired, a level of at least 70% Ti^{++}. In this case polarization of the hollow cathode occurred at a higher current density because of the higher concentration of total Ti and hence of Ti^{+++} in the introduction catholyte melt. Also, metal produced by polarization was ultimately dissolved in the introduction catholyte by reaction with either $TiCl_4$ or $TiCl_3$.

During continuous operation of the cell illustrated in Fig. 1 approximately 50 amp was passed through the introduction cathode while 45 amp was the deposition current. Typically, using the $SrCl_2$-NaCl eutectic melt as supporting electrolyte, the concentration of reduced titanium chloride was about 6M in the introduction catholyte and about 0.6M in the deposition catholyte; approximately 80% was Ti^{++}. Current efficiencies averaged 90% and recoveries were about 80% ductile Ti metal. The anode gas was 98.6% Cl_2 and 1.4% $TiCl_4$

Titanium Bed Introduction Cell

An alternative cell design which also allows continuity of operation and, in addition, can be used to produce secondary as well as primary metal, is shown in Fig. 2. In this design, $TiCl_4$ was reacted with a bed of Ti metal to produce the reduced titanium chlorides required for the deposition of Ti metal. The bed of Ti metal may be replenished either by adding a portion of the deposited metal or by adding Ti metal scrap. In the cell illustrated in Fig. 2 alternate deposits were dropped to the bed. The net reactions are given by the equations

$$\left(\frac{4}{N} - 1\right) \text{Ti (scrap or dropped deposit)} + TiCl_4 \rightarrow \frac{4}{N} TiCl_N \text{ (chemical)}$$

$$\frac{4}{N} TiCl_N \xrightarrow{4/f \text{ faradays}} \frac{4}{N} Ti + 2Cl_2 \text{ (electrochemical)}$$

$$\left(\frac{4}{N} - 1\right) \text{Ti (scrap or dropped deposit)} + TiCl_4 \xrightarrow{4/f \text{ faradays}} \frac{4}{N} Ti + 2Cl_2 \text{ (over-all)}$$

where N is the apparent valence of the Ti dissolved in the melt and f is the current efficiency of the cell. Note that when scrap Ti is employed instead of dropped deposits and the Ti dissolved in the melt is maintained largely in the divalent state, each $4/f$ faradays produced 1 mole of primary metal and also almost 1 mole of secondary metal. In a simple primary cell the same amount of current would produce only 1 mole of Ti metal. In the cell illustrated the electrolyte selected was a mixture of 8% $SrCl_2$ and 92% NaCl, requiring an operating temperature of about 830°C. The current was 65 amp with the $TiCl_4$ feed rate at 1.6 g/min. The concentration of reduced titanium chloride, approximately 80% divalent Ti, was maintained about 0.25M in the catholyte.

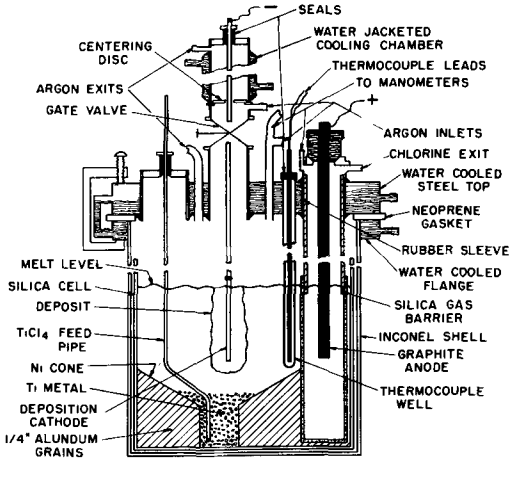

Fig. 2. Schematic drawing of titanium bed cell

Recovery averaged about 83% of ductile Ti metal. A further improvement in design which completely avoids any disturbance of the catholyte during $TiCl_4$ introduction may be realized in the case of scrap metal by using a design similar to the double diaphragm cell. The scrap metal is added to the introduction catholyte.

Refining of scrap Ti metal may also be accomplished separately by using a cell with a scrap Ti anode. Such cells are particularly simple to construct, since neither a gas barrier nor a diaphragm is used, and no protection against corrosive Cl_2 is required. At low current densities the anode dissolves to yield reduced titanium chlorides substantially at concentrations set by the equilibrium

$$Ti + 2TiCl_3 \rightleftharpoons 3TiCl_2$$

and, since Ti is deposited from the same melt at close to reversible conditions, the cell emf is small, less than 0.1 v at 700°C, $SrCl_2$-NaCl melt, anode current density 0.25 amp cm^{-2}. At higher anode current densities increasing amounts of Ti^{3+} are produced because of anodic polarization and the cell emf is increased. Most contaminating metals are left effectively at the anode and oxygen remains as a reduced titanium oxide anode sludge (3-5).

Process for Electrolytic Extraction of Titanium Metal from Titanium Carbide Anodes

Guy Ervin, Jr., Herbert F. G. Ueltz, and Malcolm E. Washburn

Research and Development Department, Norton Company, Worcester, Massachusetts

Extractive metallurgy of titanium has been discussed in several review articles (1-8). Increasing interest has been shown in molten salt electrolysis using soluble anodes, but confined chiefly to electrorefining, in which high-purity metal is recovered from scrap or other sources of impure metal. However, one article (9) and several patents (10-14) deal with production of Ti by electrolysis of soluble anodes containing TiC.

The key to the process is the fact that, although TiC is a metal carbide with a limiting composition of 1:1, it behaves during electrolysis as though it were metal with high carbon content. Since the other refractory carbides probably have the same property, the method is potentially applicable to production of Zr and other refractory metals.

The work reported here was started in this laboratory several years ago. It shows that better than 90% of the Ti in TiC can be extracted electrolytically in fused halide baths and deposited as dendritic Ti metal. The dendritic deposit contains entrapped electrolyte which must be removed by leaching with dilute acid. Current efficiency and product quality are variable and depend on several factors including electrode configuration, physical and chemical characteristics of the TiC anode, chemical composition of the electrolyte, and to a lesser extent on current densities and temperature of the bath.

Experimental

The cell used for most of the experiments consisted of a graphite crucible lined with carbon-bonded TiC and containing the molten electrolyte, with a metal cathode mounted centrally in the bath, and with an external container of nickel or steel, closures being made with rubber O-rings clamped between water-cooled flanges. Operation was in a purified argon atmosphere, and precautions were taken to remove traces of air and moisture from all raw materials and cell parts. Several sizes of cell were used, varying in metal product capacity from 20 g to 12 lb.

Carbon-bonding of TiC in the anode was achieved either by sintering at about 2300°C or more commonly by forming a mixture of the carbide with pitch, molding to shape, and baking at 1000°-1200°C in inert atmosphere to drive off pitch volatiles. Anodes formed in this way from pitch were strong and porous, with good electrical conductivity, and their use permitted rather complete electrolytic extraction of the Ti in the TiC.

Some typical results are shown in the following Tables I and II.

Table I. Electrolytic titanium from titanium carbide

Anode composition,‡ %			Electrolyte composition*	Cathode C.D., amp/cm²	Voltage	Current efficiency Ti^{+4} basis	Metal Composition, %			Hardness† BHN
Ti	C	Fe					Fe	C	O**	
69	24	0.15	LiCl-KCl	2	3.8	45%	0.2	0.4	0.3	310
66	31	0.15	NaCl-$TiCl_3$	2	3.6	65	0.5	0.5	0.5	380
70	27	0.6	NaCl-K_2TiF_6	2	4.5	49	0.6	0.02	0.14	174
67	31	0.1	NaCl-K_2TiF_6	2	4.5	47	0.1	0.3	0.3	250
79	20	0.03	NaCl-K_2TiF_6	2.5	4.1	51	0.1	0.05	0.12	157

Table II. Electrolytic refining of titanium

99.4	0.15	0.1	NaCl-$TiCl_2$	1.5	0.7	130	0.03	0.02	0.12	120
99.1	0.02	0.7	NaCl-K_2TiF_6	1	0.5	105	0.01	0.00	0.11	104

* When $TiCl_3$ or $TiCl_2$ was present the concentration was 5% Ti, K_2TiF_6 in the bath corresponded to 3% Ti. Temperature approximated 850°C in all cases.
** Oxygen was calculated from hardness plus Fe and C analyses.
† Measured as Rockwell C or B and converted to BHN.
‡ Exclusive of the carbon bond. Note that in all cases but one, substantial quantities of free carbon were present, above the stoichiometric value of 20%.

Metal could be produced with electrolytes containing no Ti initially, or with $TiCl_3$ present, but coarser crystals were produced with electrolytes containing K_2TiF_6. Figure 1 shows metal dendrites typical of the cathode deposits described in the last row of Table I, made from relatively pure TiC.

Table II shows data on electrorefining of primary metal made electrolytically from TiC. This produced much coarser crystals, of the type shown in Fig. 2, and purity was improved.

Discussion

Dissolved Ti in the bath is trivalent, when the anode is TiC. If a bath containing $TiCl_2$ is used, it rapidly converts to $TiCl_3$, contrary to the behavior with Ti metal anodes. The theoretical basis for this is that the electrode potential at the anode due to decomposition of TiC is lower for formation of Ti^{+3} (0.59 v) than for Ti^{+2} (0.89 v). Furthermore this potential probably exceeds that for oxidation of Ti^{+2} to Ti^{+3} so that, before any Ti ion is produced anodically from the TiC, all of the $TiCl_2$ in the vicinity of the anode is oxidized to $TiCl_3$. This makes it impossible to use iron cells and iron anodes as has been done elsewhere (15) because $TiCl_3$ attacks iron. For the same reason little refining with respect to iron can be expected when the anode is TiC.

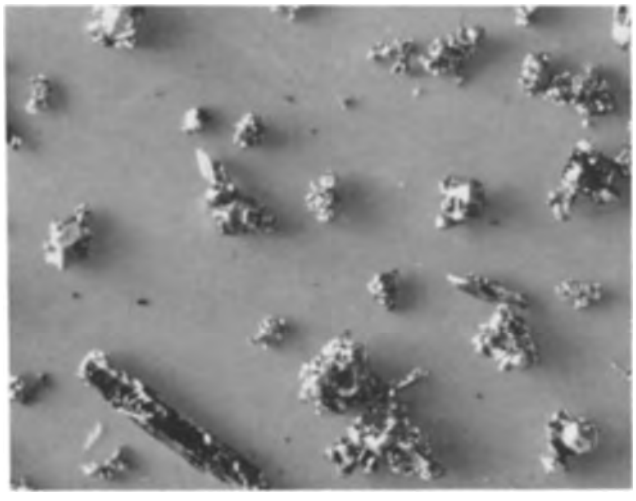

Fig. 1. Titanium metal dendrites 99.6% Ti, BHN 157, made from TiC anode. Magnification, X25.

Fig. 2. Titanium crystals 99.8% Ti, BHN 110, made by two-stage electrolysis from TiC. Magnification X8.

Important impurities other than iron to be considered are carbon and oxygen. Carbon contamination was caused by loosening of particles from the anode, but could be kept below about 0.05% C by proper bonding of the anode. Oxygen contamination kept decreasing during the course of the project as techniques were improved. There was no evidence of any transfer of oxygen from the carbide anode to the product, and it seems probable that metal of suitably low oxygen content could be produced in larger equipment. However, direct oxygen analyses of TiC and the metal produced from it were not made so that direct evidence for refinement with respect to oxygen is lacking. Estimating oxygen by difference indicated that metal with 0.1 to 0.2% oxygen was produced from arc-furnace TiC containing 0.5% or more oxygen.

Conclusion

Titanium metal powder can be produced in fused salt electrolyte from titanium carbide anodes. Purity of the metal is adequate for many uses including

powder metallurgy and for feed material to an electrorefining process making maximum purity metal. There is a reasonable expectation that commercial development would lead to higher product purity direct from TiC.

One of the cheapest ways to get metal from its oxide is to reduce the oxide with carbon, if possible. Reduction of titanium oxide with carbon does not yield metal but does yield metal-like carbide from which metal can be produced electrolytically. Viewed in these simple terms the method has strong commercial potential for titanium metal production.

Comparison of the Life of Linings in Rotating and Stationary Phosphorus Furnaces

M. M. Striplin, Jr., J. M. Potts, and E. C. Marks

Tennessee Valley Authority, Wilson Dam, Alabama

The first commercial-size rotating phosphorus furnace, a TVA development (2), was placed in operation in October 1950. The furnace is similar to the rotating alloy and carbide furnaces described by Ellefsen (1). It is of about 10,000-kw capacity and has been operated with conventional stationary furnaces as an integral part of the TVA plant. Except for information on the life of the furnace lining, which is a factor of major importance, fairly complete operating results on the rotating furnace have been published (3). Now, further information is presented which compares the life of the lining in this furnace with those of the TVA stationary furnaces.

TVA operates five rectangular stationary furnaces of conventional design and one round rotating furnace. Unless hot spots show up to indicate the need for repairs, the furnaces are normally operated at least 2 years between lining inspections. At the time of inspection, superficial damage to the lining is repaired by ramming in hot carbon paste, although such repairs to the surface of the hearth are of doubtful value. Major repairs involve replacement of a substantial number of carbon blocks used in the lining, or the entire lining.

Data on the performance of the linings in the TVA furnaces during the 8 years since the rotating furnace was started show a big advantage in favor of the rotating furnace (see Table I). For the stationary furnaces, the record shows that during the 8-year period, there were 12 times when holes developed in the furnaces unexpectedly spilling the molten contents (tapouts). Only minor repairs that could be made from the outside of the furnaces were sufficient in some cases, while others involved major repairs. Hot spots developed frequently, causing a need for decreased power input and special precautions to avoid further damage. Operation on low power usually was continued until such time as the hot spots disappeared or it was decided to shut down for major repairs to the lining. Twelve major repairs were made to the stationary furnaces during this period; this averaged a major repair to each furnace once every 3 years.

In comparison, during the same period, the rotating furnace had no hot spots, no tapouts, and no major repairs. The only patching has been after each of the four inspections, when carbon paste was used to cover eroded surfaces caused by normal wear and by the tools used to dig out the charge. The last inspection showed the original floor of this furnace to be in excellent condition. Erosion of the carbon amounted to about 2.54 cm/year (the thickness of the carbon floor is 104 cm).

Even at the slag line, there has been little or no wear of the carbon blocks in the rotating furnace. In the stationary furnaces, this is an area of high normal wear. This contrast was experienced even though the outer surfaces of the electrodes in the rotating furnace are 27% closer to the side walls than in any of the other furnaces. Maintenance costs have been considerably less on the rotating furnace than on the stationary furnaces.

For the same hearth area, the rotating furnace has a higher kilowatt capacity than the stationary furnaces. As an example, this factor expressed as kilowatts per square meter of hearth area (power density) shows the rotating furnace to have been oper-

ated at a value of 503 as compared with 310 to 426 for the other furnaces. Localized overheating or overexposure of the lining to corrosive conditions occurs in stationary furnaces because the furnace lining remains in the same relative position with respect to the tips of the electrodes, which are the focal points of energy input to the furnaces. In the rotating furnace no area of the lining remains near the tips of the electrodes very long. Localized overexposure is thereby avoided and more energy can be concentrated into the same space. Also, whatever normal wear is encountered is more uniformly distributed.

One of the few features of the original design of the rotating furnace that failed to give completely satisfactory service was the molten lead seal, which was provided at the juncture between the stationary roof and rotating crucible to prevent the escape of gas. This seal required considerable attention and maintenance. After 5½ years of operation, the seal was replaced with a 51-cm water seal. Fresh water is fed continuously to the seal and is allowed to overflow down the furnace shell as supplemental cooling water. The new seal has required no maintenance and has given good service.

The TVA rotating furnace, although relatively small in comparison with the furnaces constructed recently by industry, has demonstrated adequately that rotating furnaces have important advantages over stationary furnaces. The feasibility of rotating larger phosphorus and other types of furnaces has been demonstrated by industry.

The trend in the phosphorus industry seems to be away from furnaces with the electrodes arranged in line and toward furnaces with a triangular arrangement of the electrodes. The electrical load is more equally distributed to each electrode in these furnaces than in furnaces with the electrodes arranged in line. Even distribution of the electrical load may contribute to longer life of the furnace lining and is beneficial in other respects. Inasmuch as it is possible to operate a round furnace at a slightly higher power input when the furnace is rotated, the cost of a rotating furnace per unit of capacity is essentially the same as that of a stationary round furnace. Additional rotating phosphorus furnaces may be expected as soon as the benefits to be derived from this type furnace are fully appreciated.

Manuscript received June 16, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

June 1959 Discussion Section

A Discussion Section, covering papers published in the July–December 1958 JOURNALS, is scheduled for publication in the June 1959 issue. Any discussion which did not reach the Editor in time for inclusion in the December 1958 Discussion Section will be included in the June 1959 issue.

Those who plan to contribute remarks for this Discussion Section should submit their comments or questions in triplicate to the Managing Editor of the JOURNAL, 1860 Broadway, New York 23, N. Y., *not later than March 2, 1959*. All discussion will be forwarded to the author, or authors, for reply before being printed in the JOURNAL.

Technical Feature

Electrolysis of Organic Solvents with Reference to the Electrodeposition of Metals[1]

Abner Brenner

National Bureau of Standards, Washington, D. C.

This lecture was instituted to honor the memory of one of the founders of our society, J. W. Richards. Since it is now many years since he died, and since few of us had a personal acquaintance with him, it is fitting that I say a few words about him. He was not only one of the organizers of the Society, but also its first president, holding office in 1903. He served as Secretary-Treasurer for 17 years until his death in 1921. He was very active in both the administrative and scientific affairs of the Society and commented on most of the papers that were presented at the annual meetings. He was known the world over as an eminent metallurgist and served on numerous technical committees. He made one of his greatest contributions to science in his capacity as Professor of Metallurgy at Lehigh University where he taught until the time of his death. He was the author of two textbooks on metallurgical subjects.

In appraising the list of previous Richards Lectures, I note that 12 lectures have been given previously at an average interval of 2.5 years. Since there is an interval of five years between this lecture and the previous one, I assume that the Society intentionally passed the thirteenth, and that this one should be considered as the fourteenth. Can it be that the directors of the Society are superstitious?

I have also noted with interest that the previous lectures have covered such subjects as history, metallurgy, and electronics. Only one lecture, the last one, dealt with an electrochemical subject—overvoltage. I believe that the lecture that I am giving this afternoon is also an innovation, because it is the first one concerned with electrodeposition. No doubt some members of the audience are glad to see that electrochemistry is finally winning public recognition.

The subject of this lecture is the "Electrolysis of Organic Solvents with Reference to the Electrodeposition of Metals." Since this is a rather specialized subject and since electrodeposition is not usually presented at the Spring Meeting, I was pleased to see so many members assembling for the lecture. I mentioned this to Dr. Steinberg just before starting, and he replied that, inasmuch as it was raining outside, the members had no where else to go.

Research on the electrolysis of organic solutions has been sadly neglected in favor of a slavish devotion to aqueous systems. I did not understand this attitude until I happened to see a cartoon pinned on a laboratory bulletin board that made clear the reason for this. It depicted a students' laboratory. A voluptuous young woman was working at the bench blissfully unaware that she was the cynosure of two pairs of male eyes, focused from across the room. One male student was saying to the other, "and just think, she is over 90% water!" The great practical importance of water in our daily living has induced scientists to study aqueous systems far beyond their scientific importance. There are many more new phenomena to be discovered in the study of nonaqueous[2] systems.

The subject matter of this lecture is divided into two parts. Beginning with the more complex subject, attempts to electrodeposit metals from nonaqueous media are discussed and next, the more fundamental subject, the electrolysis of nonaqueous solvents themselves.

Deposition from Nonaqueous Media

The first interest in electrodeposition of metals from nonaqueous media developed in connection with the measurement of the conductivity of solutions. It was natural that the investigator should seek to determine whether conducting solutions would yield electrodeposits as do aqueous solutions. The first record is the work of Laszczynski (1) in 1895, who was measuring the conductivity of solutions of salts in acetone. He electrolyzed several of the solutions and observed that the deposits on the cathode gassed or sparked if placed in water. He concluded that lithium and potassium had been deposited. He also deposited silver. Within the next five years both he (2) and Kahlenberg (3) electrodeposited several metals from pyridine solutions. Kahlenberg showed that, under the best conditions, the theoretical quantity of metal deposited.

During the next 25 years the deposition of metals from a small number of solvents was studied in a qualitative fashion. This early work has been re-

[1] This paper was presented as the J. W. Richards Memorial Lecture, April 28, 1958, at the New York Meeting.

[2] In this paper nonaqueous systems do not include fused salts.

viewed by Audrieth (4). Among the solvents used were acetone, pyridine, ethylenediamine, ammonia, formamide, and acetamide. Apparently nitrogen-containing solvents commanded the most attention. Grignard reagents were electrolyzed and yielded mossy deposits of magnesium (5).

The amount of early work was rather small and attracted little interest. Within the last decade there has been a revived interest in the study of nonaqueous media because of the possibility of depositing some of the less common metals which cannot be deposited from aqueous solution.

About 30 metals can be deposited from aqueous solution. These metals will be referred to as the aqueous group and the other metals as the nonaqueous group. The early studies of nonaqueous solvents dealt mainly with the aqueous group of metals. Since these metals can be deposited more readily and in a purer condition from water solution, these studies were of little practical interest. Few of the nonaqueous group of metals were deposited. Lithium and some other alkali metals were purported to have been deposited. However, the purity was not substantiated by analysis and certainly many of the deposits were far from pure, as Pospekhov (6) has shown. Furthermore, since the metals could be obtained more readily by deposition from fused electrolytes, there was no incentive to further study.

The nonaqueous group of metals which has been of more recent interest contains the light metals, beryllium, aluminum, and magnesium; the semiconductor, germanium; and the refractory metals, titanium, zirconium, tungsten, and molybdenum. Of these by far the most attention has been given to the deposition of aluminum. Furthermore, aluminum is the only nonaqueous metal that can be considered to have been successfully deposited. By this is meant that the metal can be obtained at high cathode current efficiency in high purity and with good physical properties.

Studies at the National Bureau of Standards

This lecture is largely, although not exclusively, concerned with the work done by the Electrodeposition Section of the National Bureau of Standards. Our work in this field started rather suddenly. About 1950 we became interested in the electrodeposition of aluminum and were repeating some of the recently published work. About this time lithium aluminum hydride became commercially available and we studied the electrolysis of ether solutions of this compound. These experiments led to the development of a new type of nonaqueous plating bath (7). The Navy Bureau of Aeronautics sponsored further investigations of the process because of the possibility of electroforming aluminum wave guides. This interest seemed to have kindled a spark. Other Government agencies became interested in depositing some one of the less common metals for various purposes. The AEC sponsored a project on the deposition of beryllium (8); the Wright Air Development Center, on the deposition of titanium and zirconium (9); and Springfield Armory, on the deposition of molybdenum. An investigation of the deposition of magnesium (10) was also carried out. Although some interesting developments resulted, they were not the practical objectives desired by the sponsors, and after a period of three or four years the program ceased about as suddenly as it had started.

I wish to mention briefly some of the equipment used in our work with nonaqueous solvents. Since many of the experiments involved the preparation and use of compounds, such as metal alkyls and borohydrides, which were sensitive to air or moisture or even spontaneously inflammable, the techniques and equipment used were somewhat different from those used in ordinary plating experiments. Indispensable to our work were inert atmosphere chambers (11) of which two were constructed. A dry atmosphere of helium was circulated continuously through the chambers and deoxygenated. For running electrolytic experiments in the laboratory some special cells were designed (12) which excluded the air and yet allowed the cathodes to be removed and examined, and fresh ones put in if necessary.

Since aluminum is the nonaqueous metal which has received most study and also is the one most successfully deposited, it is discussed in some detail as a typical example. Space does not permit the mention of all of the early attempts to deposit this metal from organic solvents. A partially successful deposition was done by Blue and Mathers (13) from organic solutions similar to the Friedel-Craft reagents and from aluminum alkyl halide solutions. The deposits were not of good quality. The first successful deposition of aluminum from a nonaqueous solution at room temperature was accomplished by Hurley and Wier (14) using a solution of aluminum chloride in ethyl pyridinium bromide. This bath had more the characteristics of a molten salt bath than a typical bath made from an organic solvent. Menzel (15) deposited aluminum from solutions of aluminum ethyl or aluminum phenyl and aluminum chloride in toluene.

At the National Bureau of Standards a hydride plating bath was developed which yielded a pure, ductile deposit of aluminum (7). The bath consisted of aluminum chloride dissolved in ether with the addition of lithium aluminum hydride. Evans and Kennedy (16) by conductometric studies have shown that the ionizing complex in this type of solution is probably $Al_2Cl_5^+ \cdot AlH_4^-$. Deposits several hundredths of an inch thick were readily obtained from the bath. To prevent formation of nodules, methyl borate was used as an addition agent.

The bath had some interesting characteristics. It had a limited life and could tolerate the presence of oxygen but not moisture. Baths were used up to periods of a year or more by occasionally rejuvenating them with lithium aluminum hydride. Decomposition of the bath occurred mainly during electrolysis, not as a result of atmospheric attack. During operation hydrogen was given off at both the cathode and anode, but the quantity was greater at the anode than at the cathode. Apparently the decomposition of the bath occurred anodically, although aluminum went into solution with 100% anode current efficiency. Another peculiarity of the

bath was that the amount of aluminum deposited from it was about equivalent to the amount of aluminum that had been added to the bath as aluminum chloride. The aluminum that went into solution anodically did not appear to enter into the same kind of chemical combination as the aluminum initially introduced, and apparently metal did not deposit readily from this anodically dissolved aluminum. Thus, additional aluminum chloride had to be added to the bath at intervals. Eventually, the bath became so viscous that it could not be used any longer. Up to this point about 250 g Al had been deposited from about 1 l of bath.

Some experiments were made to determine whether the hydrogen that was liberated at the anode in the electrolysis of the aluminum plating bath would cause embrittlement of steel. We used steel rings to test this and found that the rings were embrittled more severely than in a water solution. The decrease in breaking load was 30-50%. Cathodic discharge of hydrogen from several other organic solvents did not cause appreciable hydrogen embrittlement.

More recently another bath for depositing aluminum has been developed by Ziegler (17) in Germany, the man of polyethylene fame. This bath is unique because it involves the formation of a complex between triethyl or methyl aluminum and sodium fluoride. The aluminum alkyl by itself does not conduct the current, but the complex does and yields very pure aluminum on electrolysis. We have prepared the bath and confirmed that it does operate satisfactorily. Also the complex can be prepared in ether solution and then is much less inflammable.

Most recently, Murphy and Doumas (18) reported the deposition of aluminum from aluminum chloride dissolved in an ethereal solution of butyl amine. We have not had much success with this bath. A private communication to me indicates that the deposit may be an aluminum compound.

I shall briefly touch on our work with some of the other elements (8-10) of the nonaqueous group and then attempt to summarize the state of our knowledge. I believe that the work will be easier to follow if it is organized with respect to the type of compound involved rather than to take each metal separately.

The success of the hydride bath for depositing aluminum led us to attempt the deposition of other metals from similar types of baths, but the hydride bath appears to be specific for aluminum. Soluble hydrides of titanium and zirconium could not be prepared as lithium aluminum hydride precipitated the elements or a compound from ether solution. Ethereal solutions containing beryllium aluminum hydride and magnesium aluminum hydride were prepared and yielded alloys containing aluminum and the other metal, but the quality of the deposits was rather poor.

The metal alkyls were investigated as electrolytes because Grignard reagents had yielded magnesium on electrolysis. Our experience with the magnesium deposits was unsatisfactory as they were not dense and coherent. Beryllium was deposited from an ethereal solution of beryllium dimethyl, the best results being obtained from a solution that contained both beryllium dimethyl and beryllium chloride. The beryllium was about 95% pure under the best conditions. We made a number of attempts to prepare alkyl derivatives of titanium and zirconium but all of these ended in failure, although a number of interesting compounds were encountered which we did not have time to investigate. Solutions of the cyclopentadienyl derivatives of titanium and zirconium conducted poorly and did not yield metal on electrolysis.

The most interesting phase of the work was the preparation and electrolysis of metallic borohydrides. The metallic borohydrides had only recently been prepared when we started our work. The pure borohydrides of aluminum and zirconium are liquids but they do not conduct. In ether solution, the borohydrides of aluminum, magnesium, and beryllium conduct, and alloys are obtained containing the metal and boron. The most interesting deposit was one containing about 30% boron, the remainder beryllium. The ether solutions of titanium and zirconium borohydrides did not yield the metals on electrolysis. However, by mixing the aluminum hydride plating bath with borohydride solutions of titanium or zirconium, deposits were obtained which contained aluminum, boron, and titanium or zirconium. The refractory metals were not present in large percentages. The titanium content was about 7% and zirconium between 15 and 40%.

We also attempted to prepare a molybdenum borohydride, by the dry reaction of molybdenum pentachloride, or molybdenum hexafluoride, with $LiBH_4$, but after the apparatus blew up twice we gave up. However, a molybdenum compound containing borohydride radical and chloride was obtained by a reaction in solution. In the course of our program on nonaqueous plating we made a considerable number of attempts to deposit molybdenum, but all these were negative and it is not likely that we shall publish the results of that investigation.

To complete the picture of the deposition of the less common metals from organic solutions, germanium was deposited from a solution of germanium tetrachloride in propylene glycol by Szekely (19). Because the cathode current efficiency was less than 1%, the process is not practicable. The claim of Müller and associates (20) to having deposited some of the alkaline earth metals from pyridine solution is open to question since they did not actually isolate the metals but only examined the current density potential relations during the electrolysis. Several investigators have made unsuccessful attempts to deposit the rare earths from basic solvents (21). Jonassen (22) has been unsuccessful in depositing tungsten or molybdenum from a wide variety of compounds and complexes dissolved in various organic and inorganic solvents.

Discussion of Nonaqueous Plating

Now I wish to evaluate the work that has been done in the field of nonaqueous deposition with respect to its practicability, its achievements, and its theoretical interest. Certainly there is no practical

interest in the deposition from nonaqueous media of those metals which can be deposited from water solution. The success which has attended the efforts to obtain the nonaqueous group of metals has not been very great. As already mentioned, aluminum is the only nonaqueous metal that can be deposited conveniently in a satisfactory physical condition and with a good cathode current efficiency. Some commercial interest has been manifested in the deposition of aluminum, but no actual uses have developed. At one time there was some interest in depositing aluminum on copper wire. The aluminum was to be anodized and thus form a high temperature insulation for the wire, but it is not known whether this process was actually tried. The deposition of other nonaqueous metals has not been sufficiently successful even to consider practical applications.

In general the metals which separate from nonaqueous media are less pure than those obtained from water solution. This may be caused partly by incomplete reduction and partly by adsorption of the organic material on the nascent surface of the metal. Adsorption also occurs to some extent in deposition of metals from aqueous solutions, but since the solvent molecules are much smaller the adsorption is much less. As examples of the contamination of metals deposited from nonaqueous solution, Pospekhov (6) showed that the alkali metals deposited from nitrobenzene solution in some instances contained only 25% of the metal. In our own work we were unsuccessful in obtaining satisfactory nickel or cobalt deposits from organic solvents. They were stressed and exfoliated. The nickel deposits were only 85% metallic. Some of the beryllium deposits obtained from the alkyl baths contained so many inclusions that if scratched they spontaneously ignited.

The last topic to be considered concerns the generalizations that are helpful in investigating nonaqueous deposition. Before taking these up, it is necessary to dispose of some ideas that have been suggested but which are not applicable. The magnitude of the dielectric constant of a solvent has been considered an index of its ability to form conducting solutions and, by inference, good plating baths. However, this criterion is not valid because ether is a good nonaqueous solvent for depositing several metals and yet its dielectric constant is only about 4.5. On the other hand, anhydrous HCN, which has a high dielectric constant, is not a particularly good electrolytic solvent. Incidentally, even if one could predict solutions that would be conductive, it would be of little help to nonaqueous plating, because the difficulty is not in finding conductive solutions but in finding conductive solutions that yield metals on electrolysis.

Water and a number of other polar solvents such as acetone, alcohol, and dimethylformamide, which readily form conducting solutions, have themselves in the pure state an appreciable electrical conductivity of about 10^{-7} ohm^{-1} cm^{-1}. This conductivity might seem to be an index of a good electrolytic solvent. However, this generalization is vitiated by the fact that ether has a conductivity of about 4×10^{-13} ohm^{-1} cm^{-1}. Toluene has a conductivity of 10^{-14} ohm^{-1} cm^{-1}, and yet aluminum can be deposited from certain toluene solutions.

The crystal structure of a compound is regarded as an index of its ability to ionize and form a conducting solution when dissolved. This idea is expressed tacitly when a salt is said to have an ionic structure. However, the solute is not the only factor, inasmuch as the solvent plays an equally important role. An "ionic" compound which forms a conducting solution in water does not necessarily form a conducting solution in nonaqueous solvents.

In considering those few generalizations which are helpful in nonaqueous plating, it is necessary to discuss the aqueous and nonaqueous groups of metals separately. The aqueous group can be deposited readily from polar solvents using common salts in many instances. This subject is not of interest in the present discussion and need not be considered further.

The nonaqueous group of metals may be divided into two subgroups: (*A*) active metals like the alkali and alkaline earth metals, which are too active to be deposited from aqueous solution, and (*B*) less active metals such as tungsten, germanium, etc., which are thermodynamically capable of depositing from aqueous solution (12, 23) but do not because of the nonreactivity of their ions. The alkali metals, as already mentioned, have been deposited from a few organic solvents. Presumably this is possible because in these solvents the hydrogen is more strongly bound than in water and the deposition potential of these metals can be attained.

However, little success has attended the deposition of the (*B*) subgroup of nonaqueous metals. The nonreactivity of their ions seems to be as much of a stumbling block in nonaqueous as in aqueous media. In fact, alloys of tungsten and molybdenum are more readily deposited from aqueous than from nonaqueous solutions. The fact that lithium and sodium can be deposited from the very solution containing one of the subgroup (*B*) metals further confirms the fact that the difficulty is not one of thermodynamics.

The metals magnesium, aluminum, titanium, zirconium, and beryllium, because of the difficulty of depositing them, seem to belong more to subgroup (*B*) than (*A*). The following generalizations apply to them. The best plating solutions appear to be made from solvents and solutes that can coordinate mutually. The solvents and solutes are probably similar to the classes of compounds that have been designated as Lewis bases and acids. The only useful solvents are those containing a weak coordinating center, for example, the oxygen atom of an ether or the double bond of an aromatic hydrocarbon. Other solvents with a more unsaturated coordinating center, for example, nitrogen or carbonyl groups, form too stable a complex. On the other hand, solvents which have virtually no coordinating ability, such as aliphatic hydrocarbons, do not even form conducting solutions.

The solutes found useful for depositing metals are very specific: certain halides, metal alkyls, hydrides, and borohydrides. The conventional solutes—ordinary salts—which are useful for aqueous solutions are of no value in nonaqueous plating. In no case

has the salt of an oxyacid been useful for depositing the metals considered here.

To summarize, the electrodeposition of the nonaqueous group of metals is intensely interesting from an academic and theoretical point of view, but it does not have a bright future for practical purposes. It is unlikely that baths for depositing the subgroup (*B*) metals can be developed by systematically and empirically trying all available compounds of the elements in all available solvents. The further developments will probably depend on the general development of the chemistry of complexes; that is, new types of complexes will have to be produced. It is likely that the type of complex that will solve the problem of depositing some of the nonaqueous metals has not yet been prepared.

Electrolysis of Organic Solvents

Background and Literature

Our attempts to electrodeposit some of the metals of the nonaqueous group, although lacking in practical success, have made us cognizant of the vast, unexplored field of nonaqueous electrochemistry. In our researches many nonaqueous conducting solutions were prepared and electrolyzed without obtaining a metal at the cathode, indeed, in many instances without any visible signs of reaction. Thus we became interested in the nature of the electrode reactions, not only as a matter of curiosity, but also because basic information might eventually lead to a better approach to the electrodeposition of metals.

After some deliberation and exploratory work we decided on a research dealing with the electrolysis of pure nonaqueous solvents, mainly organic solvents, as being the most basic study in electrolysis that could be undertaken. We were interested in the mechanism of the electrode reactions, the products formed, and the dynamic potentials involved. The electrolyses to be studied were analogous to the electrolytic decomposition of water. Electrolyses in which a compound was added to the solvent to impart conductivity were not excluded from the investigation, but it would be necessary to show, eventually, that the electrolytic decomposition of the solvent, as in the case of water, was independent of the nature of the conducting additive.

In the introduction to the previous section, the statement was made that the electrochemistry of nonaqueous systems has been largely neglected. To this can be added the observation that, in the study of the electrochemistry of the nonaqueous systems, dynamic electrode processes have been slighted in favor of the measurement of static potentials and conductivities. Measurements of potentials without an identification of the electrode reactions do not possess much meaning. The lack of interest in electrolyses of nonaqueous systems becomes evident from a perusal of several monographs. The books by Jander (24) and Audrieth (25) which deal with nonaqueous solvents contain little information on electrolyses. Brockman's book (26) deals almost exclusively with the electrolysis of organic compounds in aqueous solutions. The "Electrochemie Nichtwässeriger Lösungen" of Walden (27) is mainly concerned with the conductivity of solutions. Measurements of conductivity have little direct relation to electrolysis. This is evident, since conductivities can be measured by methods that do not involve electrolysis, for example, by the use of induced currents.

Studies of the electrolysis of inorganic solvents other than water are few. In most instances the interest centered on the electrolysis of a dissolved substance rather than of the solvent. Cady and Taft (28, 29) attempted to study electrolytic oxidation and reduction in liquid sulfur dioxide and in phosphorus oxychloride but were not very successful. The electrolysis of sulfur dioxide and of solutions of salts in sulfur dioxide was studied by several investigators (30), but the results were inconclusive. Stefan and Nagel (31) noted that electrolysis of solutions of various organic compounds in ammonia yielded only nitrogen and hydrogen on electrolysis, and the organic compound was frequently recovered unchanged.

Although a number of investigations have involved the electrolysis of organic solutions, in most of these the interest also was centered on the electrolytic decomposition of a substance dissolved in the solvent, the latter playing a minor role. The attempts to deposit metals from organic solutions form the largest group of investigations and these already have been discussed adequately. The remainder of the literature deals with organic solutions that undergo complicated reactions on electrolysis. The electrolysis of ether solutions of Grignard reagents (5) has been studied thoroughly. The electrolysis of organic solvents containing dissolved hydrogen fluoride (32) has become of commercial importance. Another 15 or 20 references (33) cover most of the subject of electrolysis of organic solutions, but as already noted these dealt with the dissolved substances rather than with the solvent.

Work at the National Bureau of Standards

The study of the electrolysis of nonaqueous solvents at the NBS is at an early stage. Preliminary investigation showed that various difficulties attended the electrolysis of some organic solvents, for example, the formation of tarry materials. One class of compounds that seemed amenable to study was the amides. Thus far we have electrolytically decomposed several simple amides. Most of the work has been done with formamide and dimethylformamide in a simple cell having both electrodes in the same compartment. The main products of the electrolysis of formamide are hydrogen and cyanuric acid. This had previously been shown by Schaum and Schneider (33c). The products formed in the electrolysis of dimethylformamide have not yet been identified.

Since eventually the anode and cathode reactions must be studied separately, a divided cell must be used. Conventional equipment, such as U-tubes or H-tubes of the types used for transference experiments, is not suitable, because a considerable electrical migration of material occurs when an appreciable fraction of a faraday is passed during electrolysis to provide sufficient reaction products for examination. The use of a porous diaphragm between the cathode and anode compartment, which is a common practice, is not successful in dealing with

nonaqueous solvents because electro-osmosis is considerable. To prevent it the diaphragm must be very porous.

Several different types of divided cells have been constructed. The most promising type consists of three compartments, one each for the anode and cathode and a chamber between these two. By allowing fresh solvent continually to flow through the middle compartment to a discard, products from either the anolyte or catholyte that migrate into the center chamber are removed before they can migrate into the opposite electrode chamber. Some further modifications of the flowing junction type of cell are contemplated.

The performance of a given electrolytic cell in keeping the anolyte and catholyte from mixing was determined qualitatively by electrolyzing boron trifluoride etherate with copper electrodes. Copper which dissolved at the anode was precipitated as metal by reaction products that formed in the catholyte. Thus the presence of copper on the walls of the vessel was evidence that mixing or electrical transport of the contents of the compartments had occurred. The apparatus with the flowing junction had only a slight deposit of copper.

Future Program

The study of the variables involved in electrolysis will be directed toward answering the following questions:

1. Are the products of electrolysis of the pure solvent the same as those obtained in the presence of a conducting additive or obtained in the electrolysis of an aqueous solution of the solvent?

2. Do the solvents have a definite decomposition potential?

3. Can the solvents be arranged in a series, either on the basis of the decomposition potential or of the enthalpy change of the electrolysis, such that in a mixture the solvent lower in the series is preferentially decomposed electrolytically?

More specifically, by electrolyzing various substituted amides we hope to arrive at an understanding of the mechanism of the electrolysis.

In conclusion, a systematic study of the electrolysis of nonaqueous media will greatly advance the science of electrochemistry and contribute to the chemistry of nonaqueous solvents. The electrolysis of nonaqueous media is probably the most neglected field of inquiry in both electrochemistry and the chemistry of nonaqueous solutions. At the present time most of the knowledge of electrolysis has been obtained from aqueous solutions, and many of the phenomena observed for water may be specific for that solvent. The study of the electrolysis of a large number of other solvents will lead to generalizations that cannot be obtained from a study of a single solvent.

Manuscript received Sept. 8, 1958. This paper is the Richards Memorial Lecture presented at the New York Meeting, April 27-May 1, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Brief Communication

Composition and Properties of Saturated Solutions of ZnO in KOH

Thedford P. Dirkse

Calvin College, Grand Rapids, Michigan

In many alkaline batteries a soluble zinc anode is used. This produces, on discharge, a solution of ZnO or zincate in the electrolyte. To deal with such solutions theoretically, it is often necessary to know the values for certain physical properties of such solutions. For that reason saturated solutions of ZnO in KOH were prepared and studied at different temperatures.

All KOH solutions were made by addition of water to a saturated stock solution. C.P. ZnO was added to these KOH solutions. Because of the possibility of phase changes, the solutions were allowed to stand at least several months before analysis. Pyrex glass and polyethylene containers were used. Several different series of solutions were prepared at 25°C and run independently of each other. Some of the solutions were saturated at a higher temperature before being cooled and allowed to equilibrate at the desired temperature; some solutions were saturated at the temperature indicated; some were saturated by allowing water to evaporate at a consider-

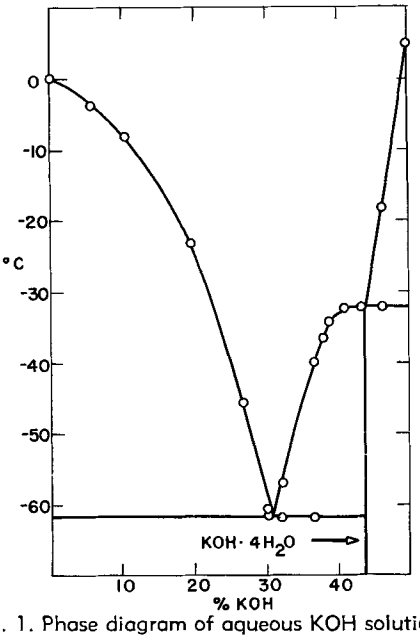

Fig. 1. Phase diagram of aqueous KOH solutions

ably reduced pressure; and some were prepared by dilution of more concentrated solutions.

Each solution was analyzed for potassium and zinc. All the potassium analyses were made spectrophotometrically (1, 2). Zinc was determined most often by titration with standardized potassium ferrocyanide solution, but also spectrophotometrically using dithizone (3). All solutions were filtered through glass filtering crucibles before analysis. Precautions were taken to avoid contact with CO_2. The melting points of aqueous KOH solutions were determined from cooling and warming curves. Duplicates and checks were run constantly and the results agreed to within 0.1°C.

Results are given in the accompanying Tables I and II and Fig. 1. The solid phases were ZnO and various hydrates of KOH. In operating batteries the zinc content, and hence density and viscosity, may rise temporarily considerably above the values given here (4).

and L. J. Minnick and W. F. Meyers
G. and W. H. Corson, Inc., Plymouth Meeting, Pennsylvania

ABSTRACT

A new type of reserve battery is described. In storage, the solvent for the electrolyte, liquid ammonia, is kept separate from the dry, deliquescent solute. On activation, ammonia vapor is released to condense rapidly in the cells and energize the battery. A large number of practical cells can be built using this principle. Characteristics of several are presented. Some properties of electrolytes in liquid ammonia are also discussed.

For more than a century the solvent properties of liquid ammonia have intrigued chemists. A large body of literature has derived from the research of Franklin and of Kraus and their students. Franklin (1), Audrieth and Kleinberg (2), and Sneed, *et al.* (3) have surveyed liquid ammonia chemistry.

Many substances dissolve in liquid ammonia to form conducting solutions. Most investigators have been concerned with dilute solutions, particularly their behavior with respect to relationships such as those of Debye and Hückel, Onsager, and Walden. The solutions used in the batteries under discussion are highly concentrated, and, as in the case of concentrated aqueous solutions, adequate theoretical relationships between various properties and concentration have not been derived. The literature on concentrated solutions deals largely with the solubility of salts at various temperatures. This information is well summarized by both Audrieth and Kleinberg (2) and Sneed, *et al.* (3). Data are also given by Seidell (4).

Vapor pressure studies on the systems NH_4SCN-NH_4NO_3-NH_3 and NH_4SCN-NH_3-H_2O were made by Foote, Brinkley, and Hunter (5-7) and on solutions of NH_4Cl, NH_4Br, NH_4I, and NH_4NO_3 in NH_3 by Hunt and Larsen (8).

The conductance at −40°C of solutions of eighteen salts was measured by Pleskov (9), whose data extend only to regions of moderate concentration. Specific conductances at 0°C for the system NH_4SCN-NH_3 are given by Foote and Hunter (7).

Standard oxidation potentials in liquid ammonia are discussed by Jolly (10) whose table includes most of the previously published data. A series of papers on potentiometric titrations in liquid ammonia has been published by Watt and his students (11).

The development of ammonia vapor activated batteries derives from research into the recovery of calcium from lime deposits carried out by Minnick and Presgrave (12), who developed a process for electrowinning this metal from solutions of its salts in liquid ammonia at −50°C. The process was later enlarged to include other materials such as alkali metals. In the course of investigating these cells, a rechargeable current-producing cell system capable of delivering about 4.5 v was discovered. It was possible to operate lamps and other devices for a considerable period with the cell at −50°C. The physical chemistry of electrolyte solutions potentially desirable for use in batteries was extensively studied by Minnick, Presgrave, and Meyers, and the behavior of elementary cells incorporating various electrodes was investigated with the particular objective of high-rate, short-duration discharge. Many cells suitable for such applications were found to self-discharge rapidly and were deemed unsatisfactory for batteries in general.

An interesting discovery during these studies was that a cell could be built in which one constituent of the electrolyte was placed in a dry condition between the electrodes. Activation of the cell was accomplished merely by exposure to a vapor, in this case ammonia. Among the advantages of gas or vapor activation is the fact that there is no liquid to be moved as in the conventional types of reserve batteries. The geometry of the stack is therefore less critical and internal short circuits arising from electrolytic paths across edges are virtually eliminated.

Electrolytes

The ammonium salts, which are the acids in liquid ammonia chemistry, and salts with nitrogen-containing anions are useful as solutes for AVA (ammonia vapor activated) batteries. NH_4SCN solutions, for example, have been found particularly effective. On exposure of the dry salt to ammonia vapor, condensation occurs rapidly, forming a colorless solution. The vapor pressure of saturated solutions is less than 4% of that of pure ammonia at temperatures between −55° and +75°C and never exceeds 1 atm in this range. For some solutions formed in AVA batteries, pressures may be well above atmospheric under extreme environmental conditions.

The conductance of NH_4SCN solutions is high over a wide temperature range and has a smaller temperature coefficient than is characteristic of

aqueous solutions. Foote and Hunter (5) list specific conductances at 0°C ranging from 0.20 to 0.11 ohm^{-1} cm^{-1} for solutions ranging from 25 to 43 mole % NH_4SCN. This high conductivity is related in part to the low viscosity of the solvent.

Other solutes and mixtures of solutes have been used successfully in AVA cells, although in most instances the rate of condensation is appreciably slower than when NH_4SCN is used.

Electrodes

The principal metals used for anodes have been magnesium, zinc, and lead. The magnesium has usually been an alloy of the AZ31 series, but pure vapor-deposited magnesium has also been tried. Both rolled zinc, either pure or containing a small percentage of lead and cadmium, and electroplated zinc have been used. The lead anodes have generally been electrodeposits, but some tests were made using lead foil. In no case has there been any appreciable difference in performance between the "pure" coatings and the alloys. Experiments have also been performed using cadmium, lithium, lithium-aluminum alloys, calcium, and other anodes.

Much of the work has included the use of manganese dioxide and lead dioxide cathodes. The former has been electro ore mixed with carbon black for the most part, but some tests have also been run with MnO_2 electrodeposited on carbon rods. The lead dioxide has usually been electrodeposited on a stainless steel base. An extensive test program using silver chloride and silver oxide cathodes was fairly successful. However, the high solubility of silver compounds in ammonia limits their usefulness for many applications. Numerous other materials can be used as cathodes.

Structures

Most of the development studies on AVA cells have been carried out using cells of laminar construction. Thin electrodes were blanked from strip stock, between which one or more dry electrolyte pads were placed. The basic experimental cells have been annular in shape, with NH_3 admitted from the center. Electrolyte pads have comprised a porous vehicle, of which filter paper is a typical example, impregnated from an aqueous solution of the desired salt and dried. It has been found that for a given vehicle, the weight of salt impregnated per unit area from a solution of given concentration is reproducible within 10%, even with rudimentary controls, and that the uniformity of impregnation of the vehicle in sheet form is acceptable. Inclusion of more than one electrolyte pad in a cell permits the use of differing amounts of salt in the catholyte and the anolyte pads. Some 20 cellulose papers ranging in free volume from 35 to 82% and two glass fiber papers of 29 and 95% free volume have been used.

In the cells using MnO_2-C as the depolarizer mix, a somewhat similar construction has generally been employed. The basic cells have been sandwiches of circular disks, with NH_3 admitted from the outer perimeter. The anode has been the same type of material used in the annular cells. The pads, however, have been blanked and then impregnated by addition of a definite volume of solution from a buret. The MnO_2-C has been pelletized by compression, and a carbon cathode has been used. Corson has also done some work with cylindrical cells using variations of the typical Leclanché cell structure.

Cells are connected as required by the application and are placed in a suitable container, which to date has been either steel or aluminum, although magnesium is also practical. The ammonia source may be either external, in which case a suitable fitting is provided, or internal, using a releaser within the battery actuated by a mechanical or electrical impulse. Depending on the rapidity of activation required, a source of heat may be included in the releaser to achieve rapid evaporation of NH_3.

The container is hermetically sealed after evacuation to a "soft" vacuum of 1 mm Hg or slightly less, primarily to remove all but the last traces of water or NH_3 and to avoid back pressure in the cells. The battery is provided with an exhaust hole over which a cap is soldered under vacuum. The cap may be unsoldered in an ammonia atmosphere and the battery checked electrically. The NH_3 is then exhausted, the battery re-evacuated, and the cap resoldered returning the battery to an inert condition. This feature is unique among reserve batteries insofar as the authors are aware, and should enhance the reliability of the product.

Cell Characteristics

The program to evaluate design parameters has comprised thousands of cell discharges. Each particular construction of cell has been tested at room temperature by discharge at constant current immediately after activation from a source of NH_3 at about 10 atm to depletion of the cell by exhaustion of depolarizer or electrolyte. The evaluation has included tests at several current densities. Variations in construction have involved (*a*) the anode metal, (*b*) the amount of depolarizer on the cathode, and (*c*) the type of electrolyte vehicle and the effect of varying the salt content thereof. The more promising constructions are then evaluated at several temperatures and also by testing after various periods of activated stand.

The nature of the electrolyte solutions has dictated that even the most elementary tests be conducted in special test vessels; working in open vessels or in glass is impractical. For repeated use in test equipment, parts coming in contact with cell components are best made of Teflon or polyethylene, although nylon is adequate unless the stand time or discharge is prolonged. Insulation of wires requires also that Teflon, nylon, polyethylene, or similar materials be used.

As expected, there is no one combination of components that gives the best performance under all conditions. Figures 1, 2, and 3 present discharge voltages as a function of delivered capacity for the $Mg/NH_4SCN/PbO_2$, $Zn/NH_4SCN/PbO_2$, and $Pb/NH_4SCN/PbO_2$ systems, using for each the construction

that has thus far given the most energy per unit volume of cell. The most efficient Mg and Zn cells, on this basis, are electrolyte limited. Their capacity depends on the amount of NH_4SCN initially in the cell and not on the total amount of PbO_2 present. On the other hand, Pb cells with the same amounts of NH_4SCN and PbO_2 are limited in capacity by the depletion of PbO_2. This results from the relatively rapid reaction of Mg and Zn with the acid solution, which removes NH_4^+ ion that would have been available for the cathode reaction. Lead, however, is cathodic to hydrogen in acid solutions in ammonia. This makes it possible to operate lead cells for long periods at very light loads or after extended activated stand, whereas Mg or Zn cells are subject to rapid self-discharge. Figures 4, 5, and 6 show capacity to depletion of Mg, Zn, and Pb cells, respectively, as a function of current density. Current densities are cited in terms of the equal apparent areas of the electrodes. The effect of self-discharge in the Mg and Zn cells may be perceived by comparing the ordinates with the theoretical capacities of 10 and 12 coulombs/cm², respectively. At current densities below 31 ma/cm² (200 ma/in.²), the Pb cells operate essentially at 100% cathode efficiency. If the proportion of NH_4SCN in Mg or Zn cells is made large with respect to the amount of PbO_2 on the cathode, the PbO_2 can be made limiting so that efficiency of Mg or Zn cells approaches 100% based on PbO_2. The energy density suffers considerably in doing this.

Figure 7 shows the effect of temperature on cell capacity for the $Zn/NH_4SCN/PbO_2$ system. The results are attributed to more rapid corrosion of the Zn as the temperature is increased.

Tests of the $Mg/NH_4SCN/MnO_2$-C cell have been concerned with modifications of the electrolyte to reduce or eliminate the self-discharge at the anode. Self-discharge in this system can be reduced significantly by using additives that buffer the electrolyte, neutral salts such as $Mg(SCN)_2$, or substances that limit the diffusion of NH_4^+ ion toward the anode to a rate less than that of transport toward the cathode.

The ability to evacuate AVA cells rapidly has been used to obtain information on chemical changes as a function of stand time and discharge. Such tests show qualitatively that on activation there is a reaction between MnO_2 and SCN^- ion, resulting in an appreciable decrease in the available oxygen of the depolarizer mix. However, a product of this reaction is presumably thiocyanogen, which is available as a depolarizer in the cell, but which is leached from the MnO_2 prior to analysis for available oxygen. The increase in Mg^{++} ion in the cell was found to be the sum of the amounts formed by self-discharge, as determined from stand tests without discharge and the amount electrochemically equivalent to the capacity delivered.

A unique apparatus for analyzing the characteristics of the components of operating cells has been developed by Meyers. It involves a Haring cell operated with breaker techniques. It is intended to describe this test method in a future paper. Tests

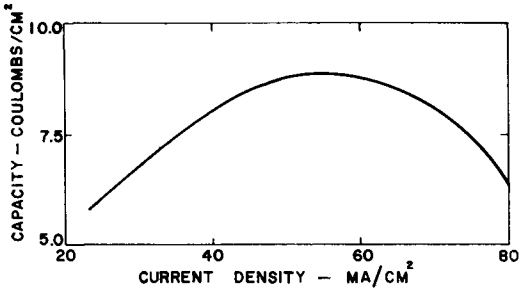

Fig. 5. Capacity to NH_4SCN depletion for Zn/NH_4SCN/PbO_2 AVA cells at 25°C (77°F). Theoretical capacity — 12 coulombs/cm².

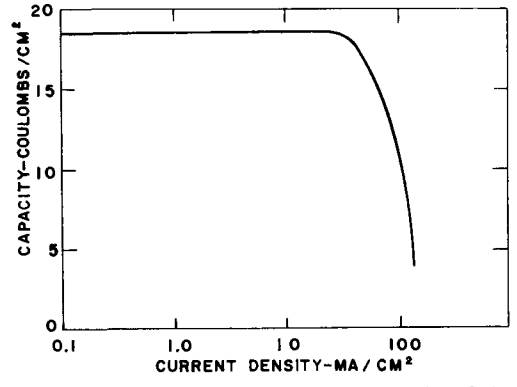

Fig. 6. Capacity to PbO_2 depletion for Pb/NH_4SCN/PbO_2 AVA cells at 25°C (77°F). Theoretical capacity — 18.6 coulombs/cm².

of the Mg/NH_4SCN/MnO_2-C cell showed that anode polarization increases at a small constant rate during discharge. The anode, electrolyte, and over-all cell resistances also increase linearly during discharge. The resistivity of the cells was initially 55 ohm-cm and increased to 100 ohm-cm during complete discharge (to 0 v), the major part of the increase being in the anode film. Similar evaluation of cells with PbO_2 cathodes is now in process. Surge discharges of Pb/PbO_2 cells of 0.3 amp/cm² (2.0 amp/in.²) for 10 msec result in over 80% instantaneous recovery of voltage on removal of the load, and complete recovery within 2 msec. Surges of 0.15 amp/cm² (1.0 amp/in.²) for 100 msec result in better than 90% recovery in 10 msec.

Although few tests have been conducted at temperatures below —25°C, liquid system reserve batteries have operated as well at —55°C as at room temperature. Small vapor activated batteries have also been successfully activated and operated at —55°C. On the basis of work to date, the capabilities of AVA batteries appear to lie in the range

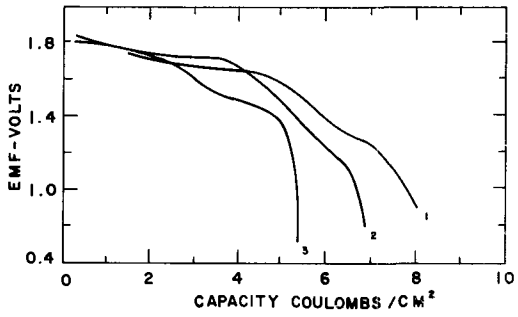

Fig. 7. Effect of temperature on discharge of Zn/NH_4SCN/PbO_2 AVA cells at 35.3 ma/cm² (228 ma/in.²). Curve 1 at 25°C, curve 2 at 50°C, curve 3 at 70°C.

of 1.0 wmin/cm³ (0.3 whr/in.³) for high rate discharges (over 25 ma/cm²) to more than 3.6 wmin/cm³ (1 whr/in.³) for low rate applications (under 3 ma/cm²). These are equivalent to a range of 0.6 to 2.5 wmin/g (5 to 20 whr/lb).

General and Intergranular Corrosion of Austenitic Stainless Steels in Acids

Effect of Cations in the Acids and the Influence of Heat Treatment and Grain Size of the Steel

Michael A. Streicher

Engineering Research Laboratory, Engineering Department, E. I. du Pont de Nemours & Co., Inc., Wilmington, Delaware

ABSTRACT

Corrosion of stainless steels by nitric acid is determined largely by the crystallography of grain boundaries. There is preferential attack even on annealed steels. Increasing the rate of dissolution, either by an anodic current or by oxidizing cations, intensifies intergranular penetration. The same crystallographic factors which determine preferential corrosion also determine the precipitation of chromium carbides. Their presence leads to a very great intensification of intergranular attack, as does sigma phase, even as an invisible, pre-precipitation constituent.

Oxidizing cations, such as Cr^{+6}, Ce^{+4}, and Fe^{+3}, increase the corrosion of stainless steels in nitric acid by cathodic depolarization, by shifting the open-circuit potential of cathodic areas toward more noble values and, probably, by depolarization of anodic areas.

The effect of surface finish on corrosion rate is largely a function of the true (absolute) area produced by various finishes.

Ferric ions in ferric sulfate-sulfuric acid solution greatly inhibit general, or grain-face, corrosion by anodic polarization. In place of the reduction of hydrogen ions and the evolution of hydrogen gas at cathodic areas, ferric ions are reduced. The consumption of ferric ions is electrochemically equivalent to the weight of steel dissolved. On steels containing intergranularly precipitated chromium carbides, intergranular attack leads to dislodgment of grains and a readily detectable weight loss.

Data obtained in sulfuric acid solutions containing ferric nitrate in place of ferric sulfate suggest that it may be possible to develop a 24-hr evaluation test with this solution.

The action of cupric sulfate in copper sulfate-sulfuric acid solution is similar to that of ferric ions. However, intergranular attack on susceptible steels does not dislodge grains readily, and, therefore, weight loss cannot be used for routine evaluation of the results.

Intergranular attack in this solution is greatly accelerated by metallic copper immersed simultaneously with the stainless steel specimen or in contact with it. This acceleration is a result of the formation of cuprous ions and of galvanic action by copper, which is the anode of this couple. The resulting galvanic current and the cuprous ions reduce anodic polarization most readily at grain boundaries containing chromium carbide precipitate and thereby greatly increase the rate of intergranular penetration. Sigma phase does not lead to accelerated intergranular attack in this solution.

The influence of grain size on intergranular corrosion depends on the method used for measurement, change in electrical resistance or weight-loss, and composition of the corroding acid solution.

Dissolution of stainless steels in all three acid solutions is predominantly under anodic control. The difference in grain surface corrosion and in intergranular penetration at susceptible boundaries is attributed primarily to a lower anodic polarizability of the metal in such grain boundary zones rather than to any difference which may exist in the open-circuit potentials of grain surfaces and grain boundaries.

The intensity of intergranular attack on stainless steels exposed to certain acid solutions may range from light etching of grain boundaries, which merely outlines the granular structure, to intense penetration, which may lead to complete loss of mechanical strength or even disintegration of the metal. Whether corrosion is predominantly by intergranular or by general attack depends on the difference in the rate of corrosion of the grain-boundary zones and of the grain faces. This difference in rates is determined by

the structure and composition of the grain boundaries and by the composition of the corroding solution.

In the present investigation a detailed study has been made of the type of intergranular attack produced by three acid solutions which are used, or have been proposed for use, in evaluation tests. These are nitric acid, ferric sulfate-sulfuric acid, and copper sulfate-sulfuric acid solutions. Special attention has been given to the electrochemical action of the cations encountered in these solutions, either as inhibitors of general corrosion or as corrosion products, which may accelerate or retard intergranular attack. Among the pertinent factors in the stainless steels, chromium carbides, sigma phase, and grain size have been investigated in their effect on intergranular attack.

It was essential to know whether or not a given specimen had been made susceptible previously to intergranular attack by heat treatments which formed intergranular precipitates of chromium carbides and/or sigma phase. The presence or absence of chromium carbide precipitate was determined by electrolytic etching in oxalic acid. This etch, originally described by Ellinger (1), has been developed into a standard testing method (2, 3). A 10% solution of oxalic acid is used for anodic etching at a current density of 1 amp/cm^2 for 1.5 min. In the absence of chromium carbides a "step structure" is formed, Figure 1A. Evidence of chromium carbide precipitate is shown by ditches at the grain boundaries. If the ditches do not envelope any one grain completely, the etch is classified as "dual structure," and if one or more grains are completely surrounded, as "ditch structure," Figure 1B. To detect susceptibility to intergranular attack associated with sigma phase, the steels were tested in nitric acid, since it was found that this is the only method which will detect the presence of certain kinds of sigma phase.

Corrosion in Nitric Acid

The investigations in nitric acid were made in boiling, 65% acid solution. This is the temperature and concentration of acid used in the standard nitric acid test (2) first proposed by Huey (4). In the standard test the weight loss of a specimen of known surface area (20-40 cm^2) is determined after each of five 48-hr exposure periods. New acid is used for each of these periods. Tests are made in 1-liter wide-mouth Erlenmeyer flasks, containing 600 ml of acid. Evaporation is prevented by a "cold-finger" type of condenser and the specimens are held in glass cradles. (This apparatus was also used for tests with the other acids.) On a steel (Table I) which is resistant to accelerated intergranular attack, the corrosion rate (slope of annealed line, Fig. 2) is low and constant throughout the entire exposure period. The surface structure produced on this type of

specimen during exposure to nitric acid is shown in Fig. 3A. It is apparent that even on a steel which is resistant to accelerated intergranular attack there is some etching at the grain boundaries which is so slow that it does not lead to undermining of these grains. In contrast, on susceptible specimens the attack at the grain boundaries leads to undermining and dislodgment of grains (Fig. 3B) and, consequently, to progressively increasing corrosion rates (slopes of tangents of curves in Fig. 2). The factors determining the rate of increase in slopes of these curves, such as composition of the steel, its heat treatment, and grain size, are dealt with throughout this discussion.

Influence of Surface Finish

The curves of Fig. 2 do not pass through the origin when extrapolated to zero exposure time, i.e., the corrosion rate at the beginning is high compared to the subsequent rate of attack. Specimens used for the tests of Fig. 2 were ground to an 80-grit finish. To determine whether this finish is responsible for the high initial corrosion rate, a number of specimens having other finishes, sand blasted, polished, and pickled, were exposed to nitric acid. Results have been plotted in Fig. 4 and show that both the high initial corrosion rate and the constant rate reached after 48-96 hr are a function of the type of surface finish.

On specimens having a smooth finish, produced by polishing or bright pickling, the corrosion rate is constant throughout the exposure period. Only when

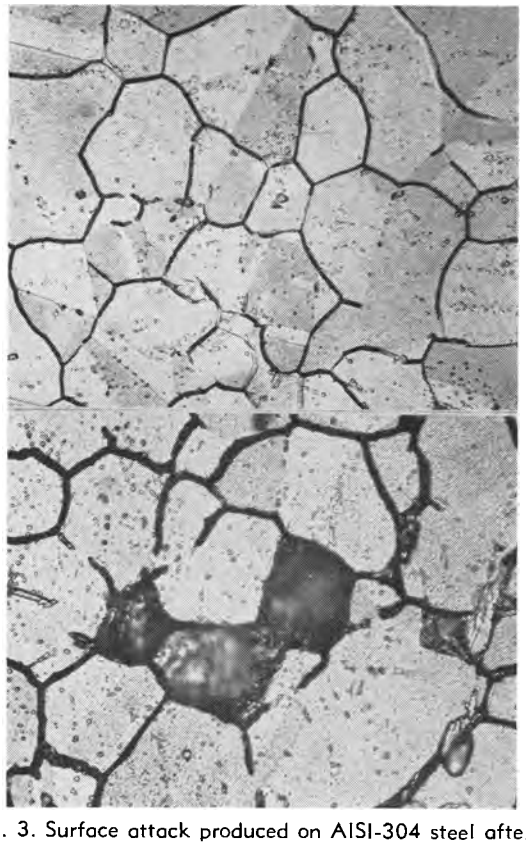

Fig. 3. Surface attack produced on AISI-304 steel after 80 hr of exposure to boiling 65% nitric acid. A (top), annealed; B (bottom), heated 3 hr at 1250°F. Steel: FK-2, 0.031% C. Magnification 500X before reduction for publication.

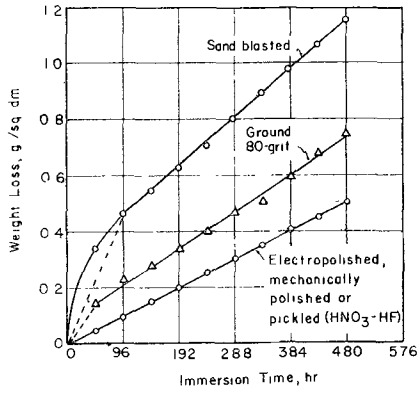

Fig. 4. Influence of surface finish on corrosion of AISI-304 steel in boiling 65% nitric acid. Annealed steel, heated 1 hr at 1950°F, W.Q.

the finishing operation produces sharp edges, as in grinding (abrading) or sand blasting, is there a high initial corrosion rate, which gradually decreases until it reaches a constant value.

Examination of the surface of the ground specimen at 750X shows that many edges and scratches on the ridges and valleys of the main grinding contours are eliminated during the first 50 hr of exposure. The main ridges remain, even after 500 hr of immersion, and suggest that the differences in corrosion rates during the period of changing rates and of constant slope (Fig. 4) are related to absolute areas. Thus, the slopes increase with the roughness of the surface finish. These observations are supported by some surface-area measurements made by O'Connor and Uhlig (5) on austenitic stainless steels. They found roughness factors (ratios of absolute to geometric areas) of 1.1 for electropolished, 1.4 for HNO_3-HF pickled, and 3.1 for (2/0) abraded finishes.

Unless otherwise noted, all specimens used in this investigation were given an 80-grit finish.

Stresses and metal deformation produced by surface treatments do not appear to have an appreciable effect on corrosion rates. The rate of the mechanically polished specimen is the same as that of the electropolished specimen. Also, it is of interest that the various surface finishes do not change the electrode potential of the steel when exposed to boiling 65% nitric acid. Measurements were made with the apparatus shown in Fig. 5.

Method of Measuring Electrode Potentials

The arrangement shown in Fig. 5 was used throughout this investigation to measure electrode potentials on stainless steels in boiling, concentrated acids. A 1-liter wide-mouth Erlenmeyer flask with a cold finger condenser was modified for this purpose. To make contact with the calomel cell a glass tube with a fritted glass filter at its end was sealed into the flask. This filter retarded movement of the acid electrolyte in and out of the flask. A glass tube was sealed into the condenser for the stainless steel wire used to make electrical contact with the specimen. This wire was welded to the specimen, covered with a plastic coating, and bent, as shown, to prevent condensate from running onto the specimen. At the top of the condenser, rubber tubing and a clamp were

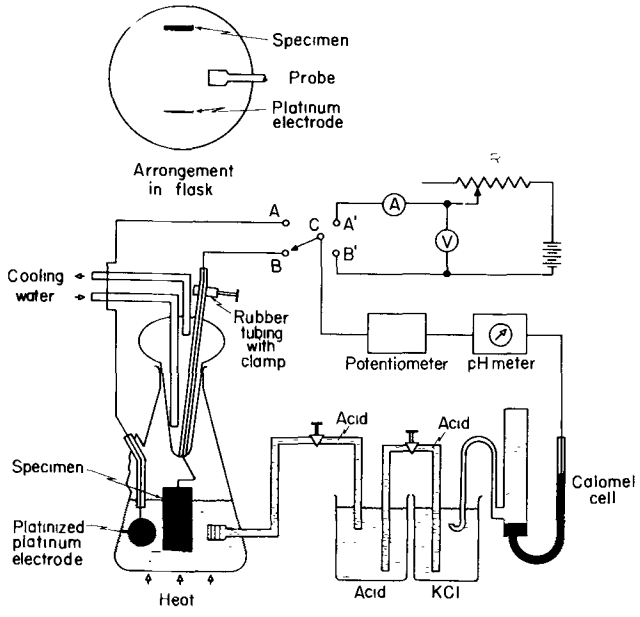

Fig. 5. Apparatus used for electrode potential measurements in boiling acids. As the reference cell, a saturated potassium chloride calomel cell was used.

used to prevent the loss of vapor from this glass tube. For anodic and cathodic polarization by an external current and for potential measurements, a platinized platinum electrode was inserted in the flask via a ground glass joint.

To prevent mutual contamination of acid electrolyte and the calomel cell, bridges were used. Only the flask was heated. The temperature of the calomel cell was 40°C. No temperature or junction potential corrections have been applied to the measurements reported.

Potential measurements on the stainless steel specimen or the platinum electrode were made by using a *p*H meter, with an impedance of 10^{10} to 10^{12} ohms, as a nil current indicator connected in series with a potentiometer (6). For polarization measurements, the circuit shown in Fig. 5 was used.

Effect of Corrosion Products

As the stainless steels dissolve, iron, chromium, and nickel corrosion products accumulate in the nitric acid solution. DeLong (7) has shown that, of

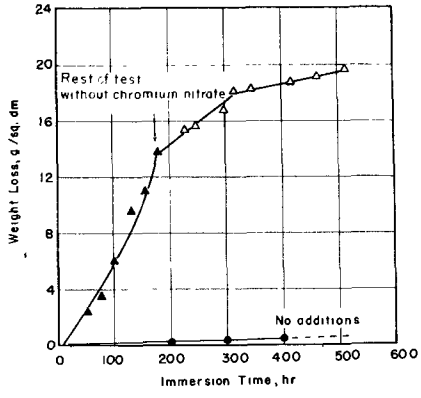

Fig. 6. Effect of chromium nitrate additions on the corrosion of AISI-304 in 65% boiling nitric acid. Steel: annealed condition, heated 1 hr at 1950°F, W.Q., HM-3. Addition: 1.26 g $Cr(NO_3)_3 \cdot 9H_2O$ in 600 ml acid for a solution containing 0.02% Cr (0.005 mole/liter). Solution changed every 24 hr.

these, only dissolved chromium affects corrosion in the concentrations likely to be encountered during evaluation tests. He found that concentrations greater than about 0.004% chromium (0.033 g Cr in 600 ml 65% nitric acid) greatly increase the rate of corrosion. Tests were made to determine the form and the mechanism of corrosion responsible for this great increase caused by dissolved chromium.

Previous investigators (8-11) have shown that acceleration is due to the action of chromium in the hexavalent state. When chromium dissolves in acids, it enters the solution as divalent ions, blue, which are rapidly converted to the trivalent state, green. These ions are then oxidized more gradually in nitric acid to the hexavalent state, orange. A green solution of 0.005 mole/l trivalent chromium in 65%, boiling nitric acid turns orange in 24 hr. For some of the tests described below, trivalent chromium was added to simulate as closely as possible the action of chromium dissolving from stainless steel.

A 1-cm^2 area was electropolished on the AISI-304 specimens for metallographic observation of the form of corrosion. New solutions were used every 24 hr. The weight-loss measurements have been plotted in Fig. 6, and microstructures are given in Fig. 7. Results on AISI-321 steel (not shown) were similar.

From these figures it is apparent that dissolved

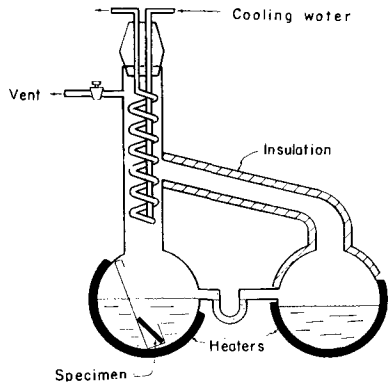

Fig. 8. Apparatus for continuous removal of soluble corrosion products from boiling solutions. Both 1-liter flasks are heated electrically. Corrosion products accumulate in specimen-free flask.

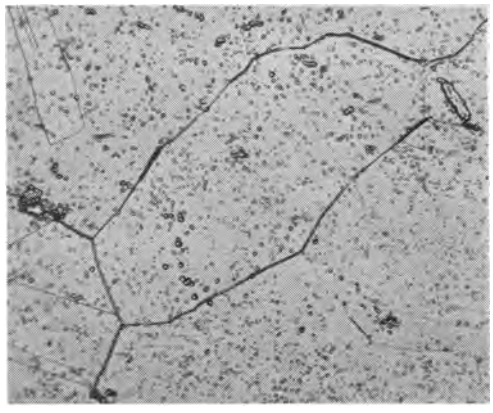

Fig. 9. Corrosion of annealed AISI-304 steel in pure nitric acid. Specimen exposed 254 hr to boiling 65% nitric acid in apparatus of Fig. 8. Magnification 500X before reduction for publication.

chromium greatly increases the weight loss of annealed stainless steels, largely as a result of accelerated intergranular attack. Grains are dislodged, even though both steels tested are in the annealed condition and do not contain any intergranularly precipitated chromium carbides or sigma phase. There is also some increase in general, or grain-face, corrosion, but most of the weight loss is due to grain dropping.

When a specimen which has been exposed to nitric acid containing chromium is immersed in pure nitric acid, the higher weight losses persist until these loosened layers have been removed completely. There is a gradual decrease in rate until the rate of the annealed steel is approached (Fig. 6).[1] Another factor which prolongs higher weight losses is the dissolution of the dislodged grains in the fresh nitric acid. Accumulation of hexavalent chromium is accelerated in this way.

Further tests on the effect of dissolved chromium were made to establish whether accelerated corrosion is by intergranular attack on other grades of stainless steels. Annealed specimens of AISI-304, 347, and 430 (17% Cr, no Ni) were immersed in boiling, 65% nitric acid containing direct additions of hexavalent chromium, 0.10 mole/l CrO_3. Within 2 hr very rapid intergranular attack produced dislodgment of appreciable numbers of grains on all three steels.

Continuous removal of corrosion products.—This intense intergranular attack on annealed steels produced by small amounts of added hexavalent chromium suggests that the chromium corrosion product which inevitably accumulates even during the 48-hr standard exposure periods used between renewal of acid may be the cause of grooving on annealed steel (Fig. 3A). The apparatus of Fig. 8 was used to determine whether there is intergranular grooving even when corrosion products are removed continuously. Its design is based on the principle of the multisample tester of DeLong (7). Each 1-liter flask contains about 500 ml of 65% nitric acid at the beginning of the test. The vapors from the solution containing the specimen (tester) are condensed and returned to this flask. Pure vapors from the other flask (boiler) are carried over to the cooling coil and condensed into the tester, causing a continuous overflow of solution containing corrosion products into the boiler, where they accumulate. This solution turns yellow during the test, while the solution with the specimen remains clear, even during a 500-hr test.

A metallographically polished specimen of annealed AISI-304 steel was exposed to 65% nitric acid for 516 hr in this apparatus without change of acid. The weight loss was 0.18 g. Analysis of the acid in the tester gave 1.1 ppm Fe, 0.12 ppm Ni, and less than 0.1 ppm Cr. Figure 9 shows the grooving at grain boundaries which took place even with continual removal of corrosion products.

In standard 48-hr flask tests the grain boundary grooves formed in this way accumulate chromium ion corrosion products, which then intensify the grooving action. The high corrosion rates observed on very small grained, annealed stainless steels are due to this type of action. Such steels have more grain boundaries per unit area of surface than large-grained steel. The grooving of very small grains may even lead to undermining and dislodgment of grains on annealed steels exposed to nitric acid solutions which are renewed every 48 hr.

Grain boundary grooves on annealed stainless steels may also be formed by making the steel anodic with an external current and an auxiliary electrode in 65% nitric acid (Fig. 10).[2] Longer etching or higher current densities make these grooves deeper and wider and lead to some grain dropping (Fig. 10B). Note the absence of grooves at the sides of twin boundaries (Fig. 10A). Preferential attack at grain boundaries of single-phase metals has also been found in other systems to be a function of the orientation of the two grains making up the boundary and its direction (12). Grooving in Fig. 3A and 9 shows evidence of this effect.

Mechanism of acceleration by oxidizing cations.—Hexavalent chromium is readily reduced at cathodic areas on steels exposed to acid solutions.

[1] Accelerated intergranular corrosion caused by precipitation of chromium carbides also is increased greatly by dissolved chromium in nitric acid. A concentration of 0.02% dissolved chromium increased the rate of a sensitized specimen by a factor of 10.

[2] These grooves are in contrast to the step structure produced on this same specimen by anodic etching in oxalic, sulfuric, and other acids.

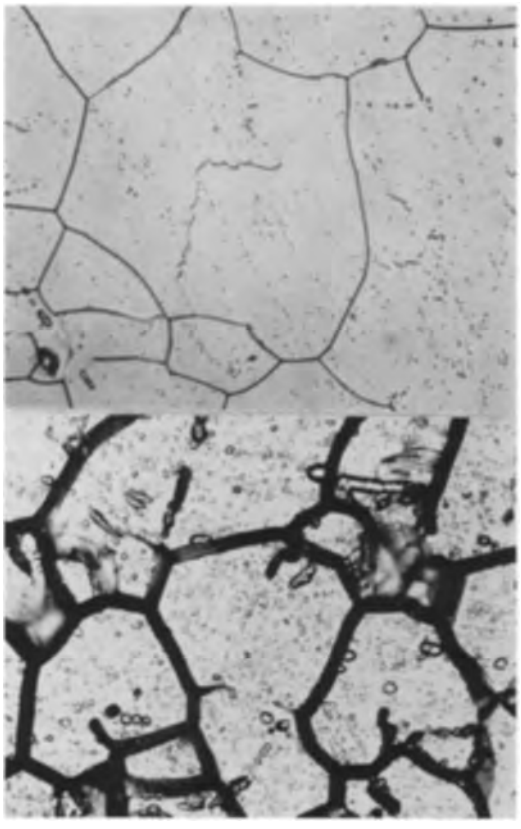

Fig. 10. Microstructure produced by anodic dissolution of annealed AISI-304 steel in 65% nitric acid. Etched at 0.02 amp/cm², temperature 25°C. A (top), 15 min; B (bottom) 60 min. Magnification 500X before reduction for publication.

$$Cr_2O_7^{-2} + 14H^+ + 6e = 2Cr^{+3} + 7H_2O$$

This reaction takes place more readily at cathodic points on the metal surface than does the reduction of hydrogen ions or of nitric acid. As a result, there is acceleration (depolarization) of the cathodic reaction. This makes possible a corresponding increase in the anodic, metal dissolution reaction. In this sense, the effect of oxidizing cations and of an anodic, external current is the same, i.e., the removal of electrons from the metal is accelerated. The result of this acceleration of dissolution, preferential grain boundary attack, is also the same in both cases (Fig. 7 and 10). The process is self-accelerating because hexavalent chromium ions accumulate more rapidly in the grooves, which tend to retard their diffusion into the solution.[3]

The effect of two other oxidizing cations, Fe^{+3} and Ce^{+4}, was also investigated. Weight-loss data obtained with ferric nitrate additions are plotted in Fig. 11A. Relatively large amounts are required before there is an appreciable increase in corrosion rate. As in the case of hexavalent chromium, the increase is largely a result of intergranular attack. Because of the high concentration of ferric ions required and the much greater effectiveness of dissolved chromium, their influence is not observed in nitric acid testing solutions containing only those ferric ions formed from dissolving stainless steels.

[3] Concentration of chromium-ion corrosion products in cavities is also responsible for accelerated attack at cross-sectional surfaces of bar stock, end-face corrosion. Hexavalent chromium collects in the small pits frequently formed when inclusions are removed by acid corrosion. These pits are then greatly enlarged by the rapid intergranular attack produced by the chromium ions.

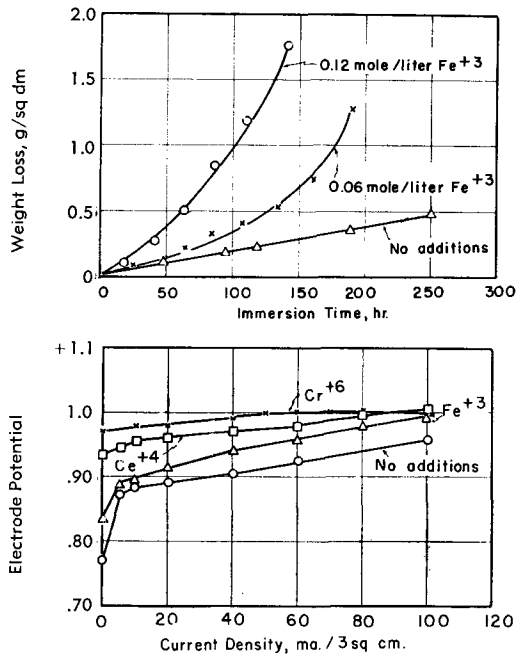

Fig. 11. Effect of cations in nitric acid on corrosion of stainless steel. A (top), acceleration of intergranular attack by ferric nitrate; Addition: $Fe(NO_3)_3 \cdot 9H_2O$, solution changed every 48 hr. B (bottom), anodic polarization of stainless steel. Concentration of cations: 0.10M. Additions: $Fe(NO_3)_3 \cdot 9H_2O$, CrO_3, and $Ce(HSO_4)_4$. Potential: against saturated KCl, calomel electrode, apparatus, Fig. 5.

What property of these ions determines the amount of acceleration, the oxidation potential, the valence change, or their influence on anodic and cathodic polarization? In another system in which oxidizing cations accelerate corrosion, iron dissolving in sulfuric acid, Gatos (6) found that the increase in corrosion was proportional to the concentration of the cation and its valence change in the reduction reaction. The rate of corrosion in this system depended on the rate of diffusion of the cations to the cathodic points on the surface of the metal rather than on a partially protective film on anodic areas. Since the diffusion rate was nearly the same for most cations investigated, it followed that the amount of acceleration was a function of the valence change of each ion. For the case of stainless steels in nitric acid, McIntosh (9) has suggested that the oxidation potential of the cations is the determining factor.

Polarization and corrosion rate tests were made to obtain data on this problem. The corrosion of annealed AISI-304 steel was determined in boiling, 65% nitric acid solutions, each of which contained 0.10 mole/l of a different oxidizing cation, hexavalent chromium, trivalent iron, and tetravalent cerium. Weight-loss measurements, together with other pertinent data, are given in Table II. These data show that the valence change involved in the cathodic reaction does not determine the corrosion rate, i.e., cathodic depolarization, while accelerating the rate of dissolution, is not the rate-controlling process. This indicates that the rate-controlling process is a combination of changes in the open-circuit potential of cathodic areas and, probably, in anodic polarization. The potentials of cathodic areas are changed in the cathodic direction to various de-

Table II. Effect of oxidizing cations on corrosion of AISI-304 steel in boiling 65% nitric acid

Cation*	(Concentration 0.10 mole/l) Electrode potential, Measured, Pt‡	Electrode potential, Measured, Stainless steel	Valence change	Weight loss, g/dm² 2 hr	Weight loss, g/dm² 8 hr**
HNO_3	+1.07 (1.20) +	+0.75 (0.95) +			
Fe^{+3}	+1.05	+0.79	1	0.0†	0.1
Cr^{+6}	+1.13	+0.97	3	1.4	10.3
Ce^{+4}	+1.22	+0.94	1	1.7	6.0

* Added as $Fe(NO_3)_3 \cdot 9H_2O$, CrO_3, and $Ce(HSO_4)_4$.
** After 8 hr the effect of Cr^{+6} is greater than that of Ce^{+4} because there is profuse grain dropping in the Cr^{+6} solution, while in Ce^{+4} solution there is less intergranular penetration, more widening of grain boundaries, and, therefore, almost no grain dropping.
† As is shown in Fig. 11A, there is acceleration of corrosion by ferric ions, but this is not sufficient to be detectable in a 2-hr exposure.
‡ Potential of platinized platinum electrode vs. saturated KCl calomel electrode.
+ Potential increases gradually with time at boiling temperature, 122°C.

grees by different cations; these changes increase the difference in the open-circuit potentials and, therefore, the corrosion rate (Table II).

A possible effect of the cations on the anodic polarization (formation, dissolution, and permeability of the protective film) is indicated by the data of Fig. 11B. As stainless steel is made anodic in nitric acid by an external current, its potential increases in the cathodic direction. However, the change in potential per milliampere of current depends greatly on the cations in the solution. The change in potential produced by a 100 ma current is 0.20 v for nitric acid without additions, 0.05 v for Cr^{+6}, 0.07 v for Ce^{+4}, and 0.16 v for Fe^{+3}. Thus, the ions which have the greatest effect on the corrosion rate also are most effective in reducing anodic polarization. These anodic polarization measurements suggest, but do not prove, the effect of cations on the anodic process, because the local cell current to which the external anodic currents of Fig. 11B are added also vary with the type of cation in the solution.[4]

These factors have been summarized in the schematic diagram of Fig. 12. Oxidizing cations increase the corrosion of stainless steel in nitric acid by cathodic depolarization (increase in rate of cathodic reaction), by shifting the open-circuit potential of cathodic areas toward more noble values and thereby increasing the open-circuit potential of the local cell,

[4] In ferric sulfate-sulfuric acid solution (see below) Cartledge (24) has found by radiotracer techniques that dissolved cations became part of the anodic film.

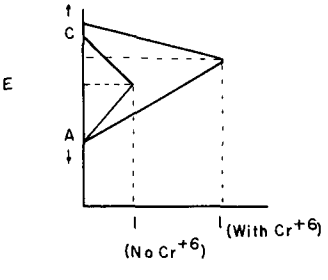

Fig. 12. Schematic potential-current diagram of local-cell action on stainless steel in nitric acid. Effect of dissolved chromium. "C" and "A" are open-circuit potentials of the local cathodic and anodic areas, and "I" is the corrosion current.

and, probably, by anodic depolarization (decreasing the protective properties of the anodic films).

Effect of Heat Treatment

Exposure of austenitic stainless steels to temperatures in the range of 1000°-1600°F may produce either or both of two types (chromium carbide and sigma phase) of susceptibility to intergranular attack, depending on the composition of the steel. The degree of susceptibility to intergranular attack increases with increasing temperature of heat treatment to a maximum at about 1250°F and then decreases with further increases in temperature. Heat treatments above 1700°F, with water quenching, do not result in appreciable susceptibility to intergranular attack in these steels (13).

The sigma phase responsible for susceptibility to intergranular attack may or may not be detectable in the microstructure. It can be revealed with certainty only by exposure of the steel to the nitric acid test. An example of this phenomenon is given by the steel whose microstructure is shown in Fig. 13. Because of the low carbon content there is no precipitation of chromium carbides after heating 1 hr at 1250°F, nor is there any visible formation of sigma phase. Yet the nitric acid corrosion rate is 35 times as great as that of an annealed specimen of the same heat of steel. While such examples are not common, similar behavior has been described by other investigators (14, 15).

In steels containing more than about 0.007-0.009% carbon, chromium carbides may be formed by heat treatments in the range of 1050°-1300°F. This lower limit of solubility was determined (14, 16) by heat treatments lasting from one day to three weeks.

The formation and growth of chromium carbides at grain boundaries can be shown by very gradual cooling of a large-grained specimen. Electrolytic etching reveals the dendritic impression in the steel left when the carbide is removed (Fig. 14A). An actual dendritic carbide, isolated from this steel, is shown in Fig. 14B. The carbide was isolated by the method of Mahla and Nielsen (17) who have made an extensive investigation of isolated carbides. A solution of bromine in anhydrous methanol was used to dissolve the stainless steel. The carbides were left

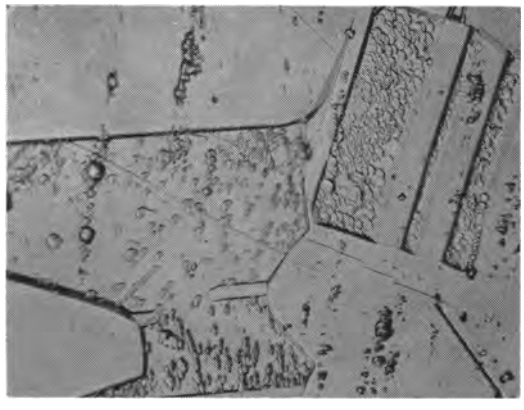

Fig. 13. Electrolytic etch of AISI-316L steel in 10% oxalic acid. Steel: FI-4 (0.020% C, 16.2% Cr) heated 1 hr at 1250°F. Etch: 1 amp/cm² for 1.5 min. Step structure: nitric acid corrosion rate 0.04 in./mo. Magnification 500X before reduction for publication.

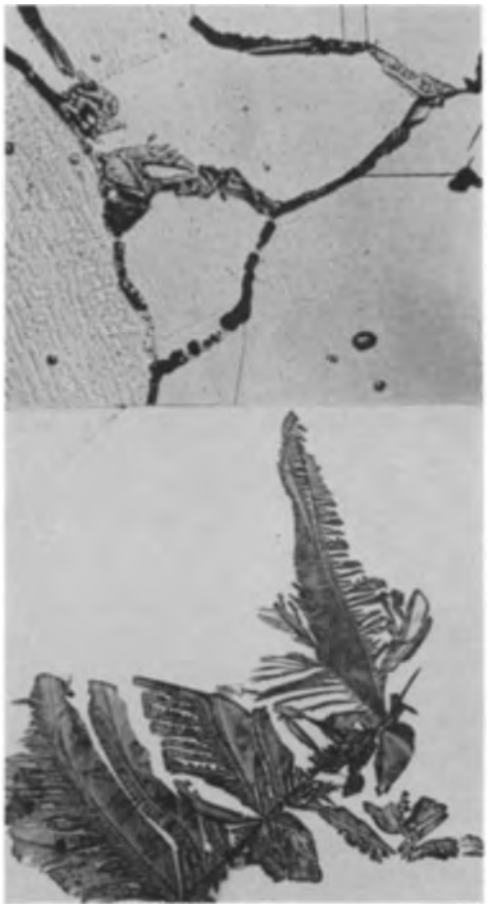

Fig. 14. Carbide precipitation in AISI-304 steel. A (top), etched electrolytically in oxalic acid. Traces of dendritic carbides (magnification 1000X before reduction for publication); B (bottom) electron photomicrograph of dendritic carbide isolated in bromine-methanol solution (magnification 5000X before reduction for publication). Steel: 0.05% C heated to 2000°F (1080°C) in evacuated, sealed quartz tube and furnace cooled.

behind in a residue layer, from which they were collected, washed, dried, and caught on a screen for examination in an electron microscope. As in the case of grain-boundary grooving of annealed steel, intergranular precipitation of chromium carbides depends on the structure of the grain boundaries. Thus, brief exposure at 1250°F produces carbides at certain preferred sites, and longer heating results in precipitation in most grain boundaries except twin boundaries. Prolonged heating (100 hr) precipitates carbides even at twin boundaries (18). This dependence of intergranular precipitation on the orientation of the grains has been observed in other alloys (19, 20).[5]

As the length of time of heat treatment at 1250°F is increased, more and more grains are completely enveloped by carbide precipitate. Upon subsequent exposure to boiling nitric acid, these grains are readily dislodged and the corrosion rate of the steel is increased (Fig. 2). It is apparent that a 1- or 2-hr sensitizing treatment of this steel at 1250°F does not produce the maximum possible amount of susceptibility to intergranular corrosion.

[5] During the formation and growth of chromium carbides the metal adjacent to the carbide is depleted in chromium. Since the carbides grow away from the boundary in very thin plates, the zone of metal depleted in chromium is parallel to the carbide and not to the grain boundary.

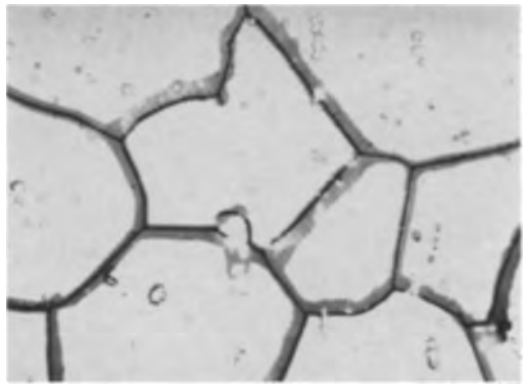

Fig. 15. Intergranular attack on AISI-316L steel in boiling 65% nitric acid. Print made from two superimposed negatives taken of the same surface area after 30 and 124 hr of exposure to acid. Narrow, dark lines show original location of grain boundaries. Steel: FH-5 (0.026% C) heated 1 hr at 1300°F. Magnification 500X before reduction for publication.

A further indication of the influence of grain orientation on intergranular precipitation and attack is given in metallographic studies of progressive corrosion. By photographing the same area of a corroding specimen after various periods of exposure to nitric acid, a series of negatives is obtained which shows the widening of grain boundary grooves. A print, made by superimposing a negative taken near the beginning of the test on one taken after considerable intergranular attack has taken place, shows the relative contributions to the grooves made by each grain (Fig. 15). In agreement with observations on intergranular precipitation, the amount of metal dissolved from various grains to make the grooves varies greatly. The grain in the center is oriented in such a way in relation to those adjacent that it contributes practically no metal to the grooves made in the exposed surface. Thus, the same crystallographic factors which determine preferential attack on annealed steel also determine the location of precipitates whose presence leads to a very great intensification of intergranular attack.

Susceptibility to intergranular attack on sensitized steel could not be detected by electrode potential measurements. Annealed and sensitized AISI-304 specimens had the same electrode potentials in boiling 65% nitric acid. This suggests that dissolution is under anodic control, i.e., the greater rate of intergranular attack on sensitized steel is a result of a lower polarizability as compared with that of the grain boundaries of annealed specimens.

Corrosion in Ferric Sulfate-Sulfuric Acid Solutions

Recent work (21) on the inhibition of corrosion of stainless steels in various acids by ferric salts has led to the development of a new test for evaluating the susceptibility of austenitic stainless steels to intergranular attack. This ferric sulfate-50% sulfuric acid test (22) is specific for revealing only the chromium carbide type of susceptibility to intergranular attack in unstabilized steels and requires only 120-hr testing time.

Mechanism of Ferric-Ion Inhibition

The minimum amount of ferric ions required for inhibition was determined for 50 and 60% solutions

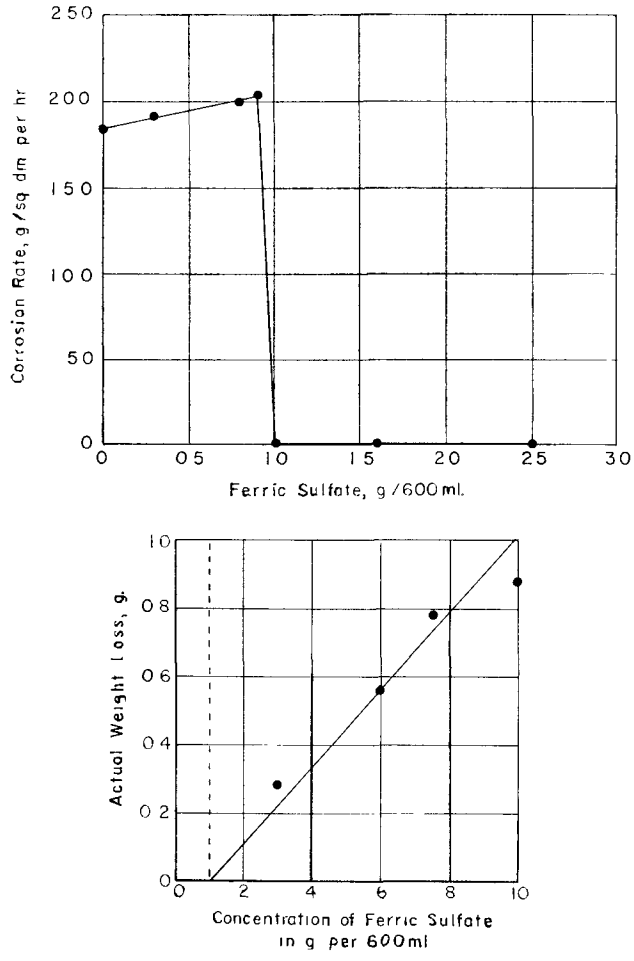

Fig. 16. Effect of ferric sulfate on corrosion of annealed AISI-304 steel in boiling 60% sulfuric acid. Ferric sulfate: 75% $Fe_2(SO_4)_3$. A (top), minimum amount of ferric sulfate required for inhibition; B (bottom), consumption of ferric sulfate. Weight loss of stainless steel at time of exhaustion of ferric sulfate as a function of amount of ferric sulfate added initially.

of boiling sulfuric acid by exposing specimens of AISI-304 stainless steel to a series of flasks to which various amounts of ferric sulfate had been added. At low concentrations of ferric ions there was no appreciable change in the very high, uninhibited corrosion rate (Fig. 16A). At a certain concentration (1 g ferric sulfate per 600 ml of 60% and 0.8 g in 50% acid) there was a sudden decrease in rate to a very low value. Corrosion was reduced from 200 to 0.037 g/dm²/hr in 60% acid.[6]

Clues to the mechanism of this process of inhibition are the absence of any hydrogen gas bubbles on the stainless steel, even though there is readily detectable corrosion, and the gradual dissolution of excess ferric sulfate in boiling acid solutions containing rapidly corroding (sensitized) stainless steel specimens. These observations suggest that ferric ions are consumed during inhibition.

When 18 Cr-8 Ni steel dissolves, divalent iron, chromium, and nickel are formed (reaction [1]). In acid solutions this anodic process is electrochemically equivalent to the discharge of hydrogen ions at cathodic areas (reaction [2]). However, in the presence of ferric ions, reaction [2] may be completely replaced by the reduction of ferric ions (reaction [3]) which results in consumption of inhibitor.

$$\left.\begin{matrix}Fe\\Cr\\Ni\end{matrix}\right\} \xrightarrow{-e} Fe^{+2} + Cr^{+2} + Ni^{+2} \qquad [1]$$

$$2H^{+} + 2e \rightarrow 2H \rightarrow H_2 \qquad [2]$$

$$Fe^{+3} + e \rightarrow Fe^{+2} \qquad [3]$$

The consumption of ferric ions to an amount just below the minimum required for inhibition is clearly indicated by the sudden onset of profuse evolution of hydrogen (change from reaction [3] to [2]).

To obtain data on the relationship of dissolution of stainless steel and the consumption of ferric ions, tests were made on coils of annealed stainless steel foil in a series of flasks containing 60% boiling sulfuric acid with various amounts of ferric sulfate in excess of the minimum amount (1 g/600 ml) needed for inhibition. This system was selected to obtain accurate weight loss-time data, which could be extrapolated 1 or 2 hr. Total testing time had to be restricted to about 7 hr because it was observed that there is gradual conversion of ferrous to ferric ions in boiling sulfuric acid solution.[7]

To expose large surface areas of steel which would provide readily detectable weight losses in periods of 0.5-7 hr the foil was made into cylindrical coils of about 600 cm² total surface area. From one to three coils were immersed in the flasks containing various amounts of ferric sulfate. The weight-loss-time data resulted in a straight line for all coils. At the instant of sudden activation (profuse hydrogen evolution) the total length of time of immersion was noted and used to determine the weight of metal dissolved by a small extrapolation of the weight loss-time line. In Fig. 16B these weight losses have been plotted against the total amount of ferric sulfate added at the beginning of the test.

The origin of the line in Fig. 16B is at 1 g ferric sulfate because the amount consumed is only that in excess of the minimum amount required for inhibition. Dissolution of 1 g of stainless steel is accompanied by the consumption of 9 g of ferric sulfate. This is in good agreement with the theoretical value of 9.7 g, derived[8] on the assumption that reactions [1] and [3] describe the process. This agreement between observed and theoretical amounts of ferric ion consumption, together with the fact that no hydrogen gas bubbles were observed in any of the solutions, some of which contained as much as 1500 cm²

[6] Sixty per cent acid was used for these tests to provide measurable corrosion rates in 7 hr or less. In the ferric sulfate-sulfuric acid test for detecting susceptibility to intergranular attack 50% acid is used (22). The minimum concentration of ferric ions required for inhibition depends on the alloy content of the steel and, therefore, may vary somewhat for different heats of 18-8 stainless steel (21). Larger concentrations of ferric ions are required to suppress corrosion of an active specimen than to prevent the onset of corrosion of an uncorroded specimen.

[7] Conversion of ferrous to ferric ions was detected by periodically exposing a stainless steel specimen to a boiling 50% solution of sulfuric acid containing 15 g per 600 ml of ferrous sulfate (colorless). This solution gradually turned yellow. When the specimen was immersed after 31 hr of boiling, it remained passive; i.e., at least 0.17 g per 600 ml of ferric ions (the minimum amount required for inhibition) had been formed.

[8] The stainless steel used was 18.9% Cr, 9.27% Ni, and, by difference, 71.8% Fe. One gram of this steel contains 0.018 moles of metal. Each mole of metal dissolving to divalent ions consumes two moles of ferric ions. The ferric sulfate used contained 20.8% iron by analysis, or one mole of ferric ions in 269 g of ferric sulfate. Therefore, the amount of ferric sulfate consumed during the dissolution of 1 g of steel is $2 \times 0.018 \times 269 = 9.7$ g.

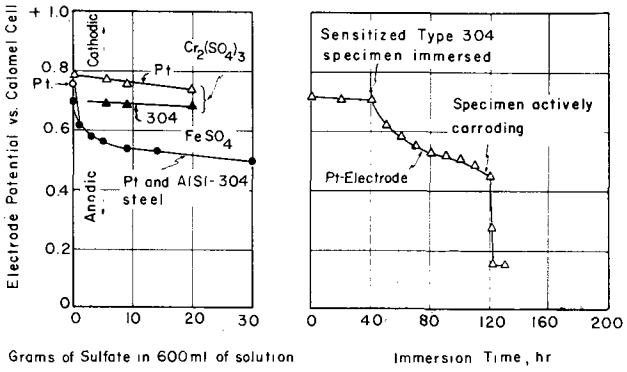

Fig. 17. Electrode potentials in boiling solutions of 50% sulfuric acid containing 15 g/600 ml of ferric sulfate. (For apparatus used see Fig. 5; all potentials measured against saturated potassium chloride calomel electrode.) A (left), effect of synthetic corrosion products on electrode potential; B (right), effect of corroding stainless steel specimen on potential of platinum electrode.

of corroding surface, shows that the reduction of ferric ions is electrochemically equivalent to the amount of metal dissolved. The corrosion current involved in reactions [1] and [3] in boiling 60% acid was derived from the weight loss, exposure time, and area of the specimen, and found to be 0.026 ma/cm^2.

Electrode potential measurements.—In 50% boiling sulfuric acid, 18 Cr-8 Ni steel has a potential of −0.34 v. With ferric ions the potential changes about 1 v in the noble direction to +0.70 v. When additions of small amounts of ferrous ions are made to the ferric sulfate-sulfuric acid solution, either as corrosion product from dissolving stainless steel or as an addition in the form of ferrous sulfate, the potential of stainless steel is the same as that of the platinum electrode, Fig. 17. Thus, the anodic areas on the steel are polarized to the potential of the cathodic areas on which the reduction of ferric ions takes place. The potential is the same for annealed and for sensitized steel and is independent of acid concentration (Table IV).

Neither ferrous ions nor other corrosion products affect corrosion in ferric sulfate-sulfuric acid solution (22). The effect of nickel and chromium sulfate additions on electrode potentials is shown in Fig. 17A. Divalent chromium (light blue) is rapidly changed to the trivalent (dark green) state in these solutions. Hexavalent chromium (orange-red), which accelerates corrosion of stainless steel, does not form in sulfuric acid during the dissolution process. This is in contrast to the behavior in nitric acid in which trivalent chromium is oxidized to the hexavalent state.

When ferrous ions accumulate from dissolving steel and reduction of ferric ions, the potential gradually changes in the anodic direction. As soon as the ferric ion concentration has been reduced to a value below that required for inhibition, the stainless steel becomes active and there is a further, rapid change to more negative potentials (Fig. 17B).

Rapid cathodic reduction of ferric ions in turn accelerates the anodic reaction, i.e., the dissolution of metal in pores of the protective film. The surge of metal (Fe, Cr, Ni) ions produced then makes possible the rapid formation of more film which heals the pores. [In the case of *iron* dissolving in sulfuric acid

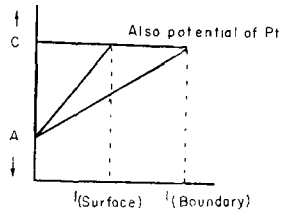

Fig. 18. Schematic potential-current diagram of local-cell action on stainless steel in ferric sulfate-sulfuric acid solution containing some ferrous ions. "C" and "A" are the open-circuit potentials of the local cathodic and anodic areas, and "I" is the corrosion current.

containing ferric ions the anodic corrosion product, ferrous ions, cannot form a protective film, and the result is an increase in the corrosion rate (6).] The passive state is dynamic. There is continual breakdown and repair of the surface. Ferric ions in solution and the ferrous ions formed by their reduction probably aid in the formation of this film (24).[9] There is also a possibility that film formation is promoted by oxygen evolved in the thermal reaction of water with ferric ions (25). The rate of dissolution of this film in the acid and/or the rate of diffusion of ions through the film determine the corrosion rate of the steel.[10]

The fact that the potential of annealed and of sensitized (chromium carbide type) steel is the same indicates that dissolution is under anodic control. The difference in grain face corrosion and intergranular penetration is primarily a result of the lower polarizability of the metal in grain boundary zones containing chromium carbide precipitate, rather than of any difference which may exist in open circuit potentials of grain centers and grain boundaries. This is also the case in nitric and in copper sulfate-sulfuric acid solution.[11]

A schematic diagram of local cell polarization is given in Fig. 18. The intersection of the polarization lines is the measured potential. Since the potential of stainless steel is the same as that of the platinized platinum electrode, the corrosion current "I" depends on the slope of the line representing anodic polarization. At grain boundaries containing chromium carbides and, therefore, a zone depleted in chromium, polarizability is less than at grain surfaces.

Intergranular Corrosion

Ferric ions greatly retard general, or grain face, corrosion (23). However, intergranular attack cannot be suppressed. As the concentration of sulfuric

[9] As a result, anodic polarization may be affected by cations in the solution. This may be different from polarization produced on stainless steel in pure sulfuric acid solutions by an anodic external current. Local cell polarization has, therefore, been described in terms of the simplified, schematic diagrams of the type of Fig. 18, rather than in reference to a specific polarization curve determined in pure acid solutions by means of an external current.

[10] In sulfuric acid solutions, without ferric ions, anodic polarization and consequent suppression of corrosion of stainless steel may be produced by means of an external electrical current or by aeration (26-29, 50, 55). Alloying additions of about 0.1% platinum and palladium to stainless steel have also been used to provide areas in the surface on which the rates of cathodic reactions are increased to permit more rapid formation of protective films on anodic areas (51).

Metal dissolution in aqueous media by diffusion of cations through protective films has been proposed by Petrocelli (48), Hoar and Evans (49), and Vetter (57).

[11] Support for this mechanism is given by electrode potential measurements made on grain surfaces and grain boundaries of large grained sensitized specimens using the technique described by Dix (53). There was no difference in these potentials in a solution of nitric-hydrofluoric acid. Similar measurements have been made by Standifer (54), who also found that the potentials of susceptible boundaries are the same as those of grain surfaces in several acids.

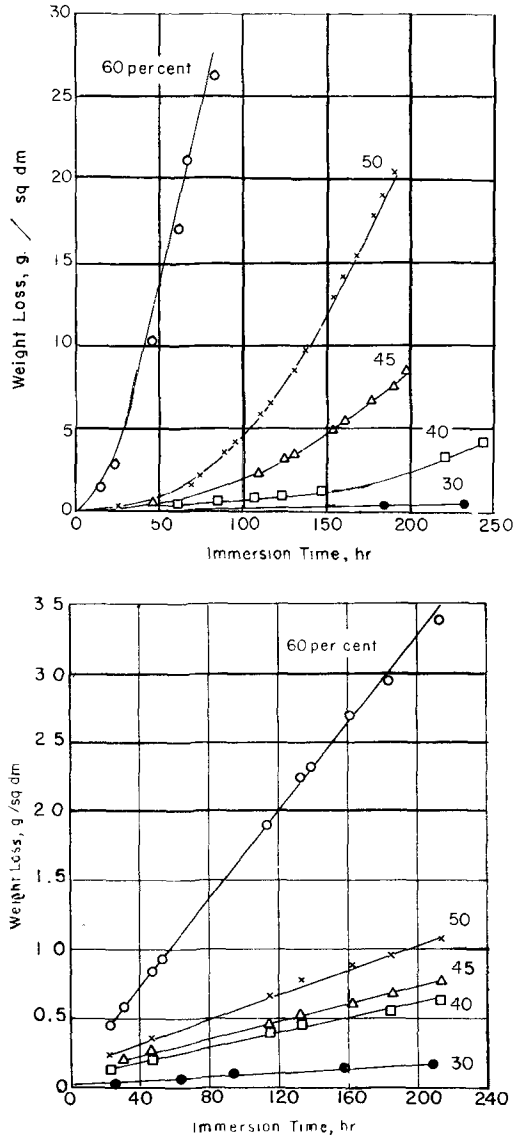

Fig. 19. Effect of concentration of sulfuric acid on corrosion of AISI-304 steel in boiling ferric sulfate-sulfuric acid solution (22). Solution: 600 ml with 15 g ferric sulfate (acid concentrations in weight per cent). Specimens: A (top), AISI-304 (M304, Table I) heated 1 hr at 1250°F; B (bottom), (M304, Table I) annealed.

acid is increased from 30 to 60% there is a large increase in intergranular corrosion of a steel containing chromium carbides (Fig. 19A). The morphology of intergranular penetration remains unchanged in this range of acid concentration (data in section on "Comparison of Types of Intergranular Attack"). General corrosion also increases as the acid concentration is increased (Fig. 19B). At a given length of exposure time, the ratio of intergranular to general corrosion is a measure of the resolving power or sensitivity of the solution to detect susceptibility to intergranular attack. Increases in acid concentration and testing time increase the ratio (22).

Intergranular corrosion in this solution leads to undermining and dislodgment of grains (Fig. 20) at a rate about twice that in the nitric acid test. This is shown by a comparison of ratios as given in Table III. On the AISI-304 steels the ratios obtained in 120 hr of exposure in the ferric sulfate-sulfuric acid solution are the same as those found after 240 hr of

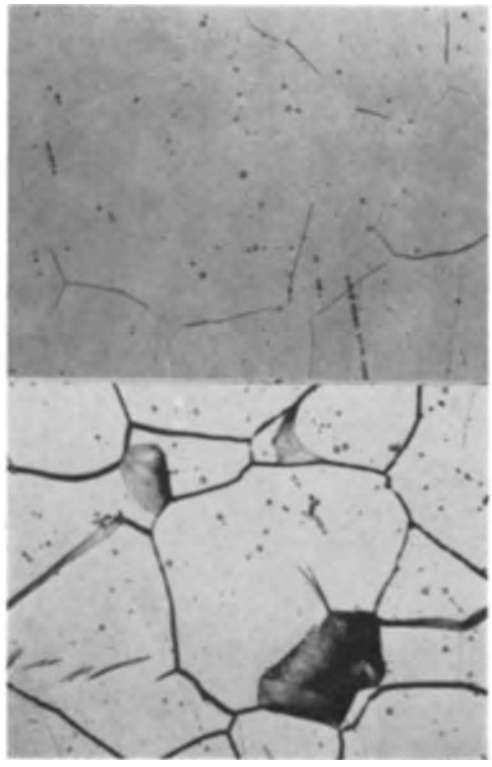

Fig. 20. Corrosion of AISI-316 steel in boiling ferric sulfate-sulfuric acid solution. Solution: 50% sulfuric acid containing 15 g/600 ml ferric sulfate. Steel: M316, analysis Table I. testing in the nitric acid test. The conditions of acid concentration and testing time of the new evaluation test were selected on the basis of this type of data.

Table III also shows that on AISI-316 and 316L steels the ferric sulfate-sulfuric acid test does not reveal the type of susceptibility associated with sigma phase. Most of these steels have very high ratios in nitric acid but have a ratio of unity in the 120-hr ferric sulfate-sulfuric acid test. For example, steel FI-4, which does not contain any carbides after

heating 1 hr at 1250°F (Fig. 13), has a ratio of 35.6 in the nitric acid test as a result of severe intergranular corrosion of the sensitized specimen. In the ferric sulfate-sulfuric acid test there is essentially no intergranular attack on this steel even though there is some grain boundary grooving. This is a more severe form of the grooving shown on annealed AISI-316 steel in Fig. 20A.

Use of other ferric salts and other acids.—Corrosion and inhibition may be influenced greatly by the anion of the ferric compounds used for inhibition. Thus, ferric chloride and bromide readily break down passive films and lead to severe pitting (21, 30). The oxalate is decomposed in sulfuric acid solution, and the products of decomposition reduce ferric to ferrous ions.

Also, the anion of the ferric salt may affect the rate of intergranular attack. For example, ferric nitrate increases the rate of intergranular attack as compared with the rate obtained with ferric sulfate. The comparison of ratios in Table III suggests that a 24-hr test with the ferric nitrate inhibitor is equivalent in resolving power to a 120-hr ferric sulfate-sulfuric acid or a 240-hr nitric acid test. Thus, it may be possible to develop a 24-hr ferric nitrate-sulfuric acid test.

A further development of accelerated evaluation tests for susceptibility to intergranular attack may be possible by the combined use in these tests of ferric compounds and the very acid to which the steel is to be exposed in plant service. Ferric ions inhibit general corrosion in a number of acids, e.g., acetic, formic, oxalic, sulfamic, and sodium bisulfate (21). The use of ferric compounds in these acids makes it possible to use boiling solutions at acid concentrations selected to give the most rapid intergranular attack on susceptible steels. Thus, if a certain steel is to be used in acetic acid service, its susceptibility to intergranular attack might be determined by exposing it in boiling, ferric-ion inhibited, 20% acetic acid.

Corrosion in Copper Sulfate-Sulfuric Acid Solution

This combination of reagents, originally developed by Hatfield (31), has been widely used to determine the susceptibility of austenitic stainless steels to intergranular corrosion. Exposure to this solution at boiling temperatures produces intergranular attack only on steels containing intergranularly precipitated chromium carbides (13, 32, 33). The attacked zone at grain boundaries is such that the large majority of grains remain in place. Also, general corrosion on grain faces is very low. As a result, the change in weight, even on steels susceptible to intergranular attack, is very small and has not been used as a routine means of measuring the extent of intergranular corrosion.[12]

The most commonly used method for routine evaluation of this test consists of bending a 2-cm wide by 5- or 8-cm long specimen through 180° and examining the surface for cracks, which indicate intergranular attack. This qualitative evaluation method has actually been found to be a more sensitive indication of intergranular corrosion than measurement of changes in electrical resistance (33) or of weight loss. For resistance measurements, first used by Rutherford and Aborn (35), a modified Kelvin bridge, thin specimens, 4- to 10-cm long, and exposure periods of hundreds of hours are required.

A method of greatly accelerating intergranular attack in the copper sulfate-sulfuric acid solutions has recently been developed by Rocha (36). This consists of placing the stainless steel specimen in contact with copper metal chips during exposure in the test solution. As a result, the exposure time is reduced from 200 to 24 or 48 hr before evaluation by the bend test.

Intergranular Corrosion

A boiling solution of 15.7% sulfuric acid and 5.7% $CuSO_4$ (by weight) was used for all tests. This was prepared by adding 100 g $CuSO_4 \cdot 5H_2O$ and 100 ml H_2SO_4 (sp gr 1.84) to 840 ml of water (37). Apparatus was the same as that used for the nitric acid and the ferric sulfate-sulfuric acid solutions, i.e., a 1-liter Erlenmeyer flask, containing 600 ml of solution, with a cold finger condenser. To avoid accumulation of corrosion products frequent changes of solutions were made. For electrical resistance measurements the stainless steel specimens were machined and ground to a cross section of 0.6 x 0.15 cm and a length of 3 to 6 cm. Any heat treatments required were made on the specimens before machining.

Changes in electrical resistance of these specimens were measured with a precision Kelvin bridge. These resistances varied from 0.001 ohm on specimens before testing to about 0.06 ohm on specimens whose grain boundaries were extensively corroded. All resistance measurements were converted to per cent change in resistance. By determining this change for segments of various lengths of one specimen, it was found that the per cent change in resistance was independent of the length of specimens used in this investigation.

Before resistance measurements are made the specimens must be immersed in acetone to remove residual liquids and soluble solids from corroded grain boundaries

Dislodgment of grains in the cupric sulfate-sulfuric acid solution is very slow, especially from AISI-316 steels. Even though the grain boundaries may be penetrated enough to make a 6-cm long specimen bend under its own weight the surface may be almost unchanged in appearance. In the case of AISI-304 steels, grains are dislodged more readily and the specimens sometimes break in handling.

Effect of metallic copper.—Quantitative data were obtained on the acceleration of intergranular attack produced by immersion of metallic copper in the testing solution. Three types of tests were made: (*a*) simple immersion of stainless steel in cupric sulfate-sulfuric acid solution, (*b*) simultaneous immersion with metallic copper, but not in contact, and (c) immersion of steel in contact with copper. Contact with metallic copper was provided by partially filling the glass cradles, used to hold the steel specimen, with copper turnings. A weighed and measured cop-

[12] An intergranularly corroded specimen gives off a dull sound when dropped on a hard surface. This effect has been investigated by oscillographic analysis (34).

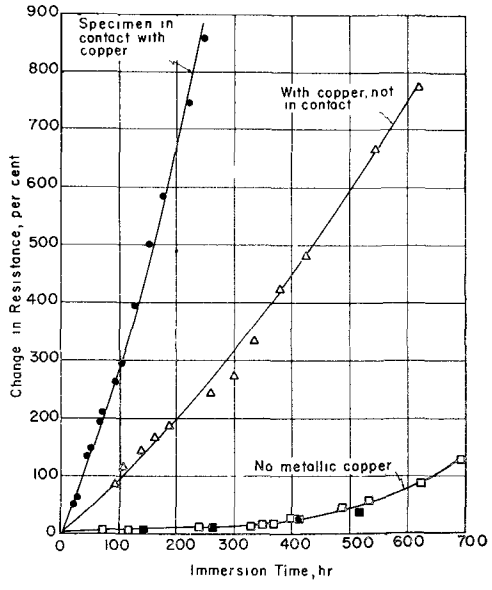

Fig. 21. Change in electrical resistance of sensitized AISI-316 steel in boiling copper sulfate-sulfuric acid solution. Effect of metallic copper. Solution: 15.7% H_2SO_4 and 5.7% $CuSO_4$. Steel: AISI-316 (EW-6) heated 1 hr at 1250°F.

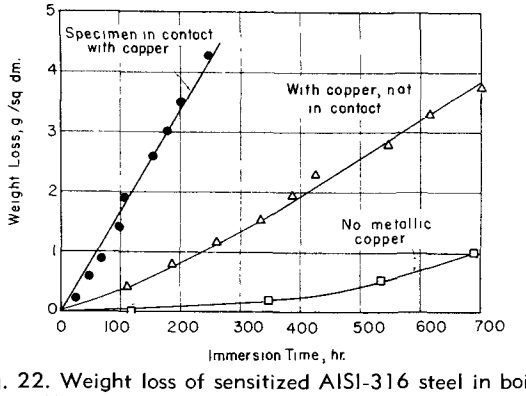

Fig. 22. Weight loss of sensitized AISI-316 steel in boiling copper sulfate-sulfuric acid solution. Same tests as Fig. 21.

per specimen was used for the simultaneous immersion tests.

The results of electrical resistance and weight-loss measurements are given in Fig. 21-23. It is apparent that without the use of metallic copper the rate of intergranular attack is very slow. After 240 hr the change in resistance is only 10% and the weight loss only 0.1 g/dm² (in a 120-hr exposure in 65% nitric acid the weight loss of this steel was 31.5 g/dm²). Simultaneous immersion of the copper, about 20 cm² in area, increases the rate of intergranular attack by a factor of 24 (at 240 hr of immersion) as determined by change in resistance (Fig. 21). Contact with the copper specimen produces a further increase in the rate of attack—by a factor of 85 over the copper-free test. These differences in rates of intergranular attack also are reflected in the weight losses (Fig. 22).

To determine whether this increase of corrosion by copper is a result of simple acceleration of the type of intergranular attack observed without immersion of copper, or the result of a change in the geometry of grain-boundary attack the per cent changes in resistance have been plotted against the weight losses (Fig. 23). In this graph the time factor has been eliminated. The resulting relationship of resistance change to weight loss is the same for all three tests. Thus, metallic copper increases corrosion by accelerating the type of intergranular attack produced in the absence of copper, rather than by changing the character of grain boundary attack.

A photomicrograph of intergranular attack produced in copper sulfate-sulfuric acid solution with the stainless steel in contact with copper is shown in Fig. 24. Even though the attacked grain-boundary zone is very narrow in comparison with that produced in nitric acid and ferric sulfate-sulfuric acid solutions (Fig. 3 and 20), there has been enough penetration to undermine and dislodge grains.

Effect of sensitizing time.—Increasing the heat treatment at 1250°F from 1 hr to 2 hr increases the amount of intergranularly precipitated chromium carbides and probably also the size of the carbides. Figure 25 indicates that the character of intergranular attack on specimens of the same heat of steel is changed by varying the length of time of sensitizing. Each specimen has its own resistance change vs. weight relationship. Greater amounts of carbide precipitate produce a more rapid increase in resistance than in weight loss in the cupric sulfate-sulfuric acid solution (without metallic copper). The rate of intergranular penetration increases more rapidly than does grain dropping.

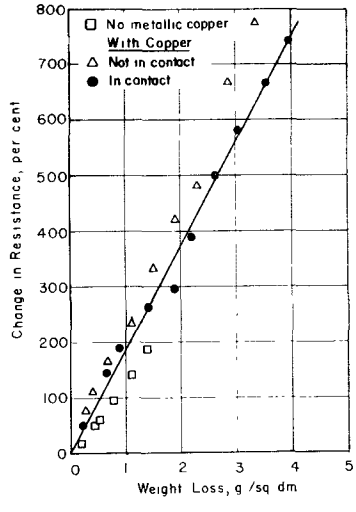

Fig. 23. Relationship of change in electrical resistance and weight loss of sensitized AISI-316 steel in boiling copper sulfate-sulfuric acid solution. Same tests as Fig. 21.

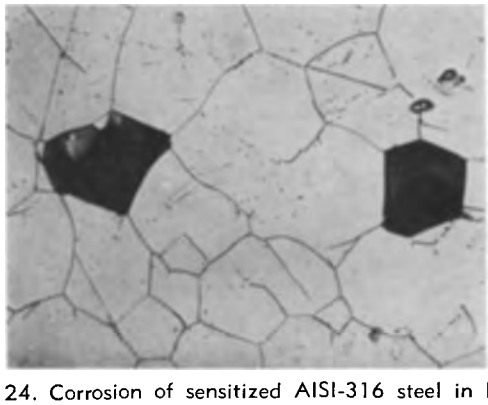

Fig. 24. Corrosion of sensitized AISI-316 steel in boiling copper sulfate-sulfuric acid solution. Specimen in contact with copper. Steel: AISI-316 (EW-6) heated 1 hr at 1250°F. Exposure: 23 hr. Magnification 500X before reduction for publication.

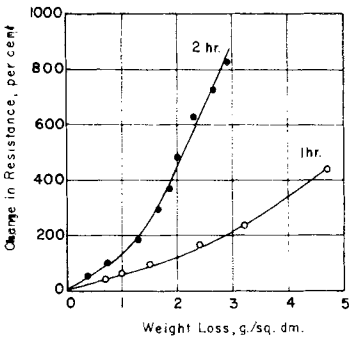

Fig. 25. Effect of length of time of heat treatment on intergranular penetration in boiling copper sulfate-sulfuric acid solution. AISI-316 (M 316) heated at 1250°F. As shown. Tests made without metallic copper.

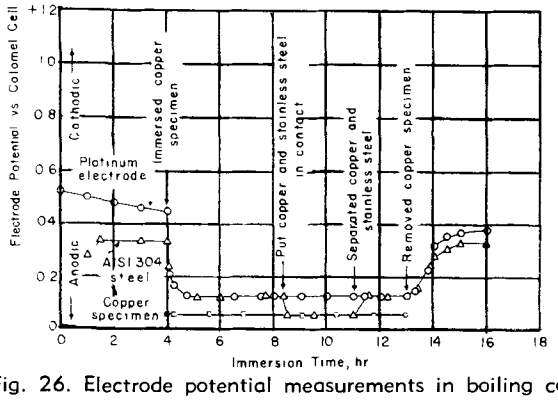

Fig. 26. Electrode potential measurements in boiling copper sulfate-sulfuric acid solutions. Effect of metallic copper. Solution: 15.7% sulfuric acid and 5.7% $CuSO_4$. (For apparatus used see Fig. 5; all potentials measured against saturated potassium chloride calomel electrode).

Tests have also been made in cupric sulfate-sulfuric acid solution on steels containing the sigma type of intergranular susceptibility. The results, discussed below, are in agreement with those of previous investigators (13, 32, 33) and show that the sigma type of susceptibility does not lead to accelerated intergranular attack in this solution.

Effect of dissolved iron.—Ferrous sulfate was added to copper sulfate solutions to give a concentration of 1.3 to 2.6 g/l of ferrous ions. Dissolved iron in this range of concentration was without effect on the weight loss of annealed or of sensitized steel, with or without metallic copper in the solution. However, in some tests dissolved iron reduced the change in resistance of sensitized specimens, which is in agreement with results of Brauns and Pier (39), who reported a decrease in intergranular attack (no metallic copper) as determined by the bend test, which indicates total penetration, as does the change in resistance.

Electrode Potential Measurements

Potential measurements in boiling solutions of copper sulfate-sulfuric acid of the same concentration as described above were made to provide data for an interpretation of the action of metallic copper and the mechanism of dissolution in this solution. Some results have been plotted in Fig. 26.

Initially, the potential of the platinized platinum electrode is about +0.53 v and that of a stainless steel specimen, +0.34 v. Immersion of a piece of copper (40 cm^2 surface area) in this solution, but not in contact with either the stainless or platinum electrode, very rapidly changes the potential of both electrodes in the anodic (active) direction to +0.13 v. Both electrodes now have the same potential, which is constant. The potential of the copper is constant at 0.06 v. When the copper is put in contact with the stainless electrode there is a further change in potential of the steel in the active direction to that of copper, which remains unchanged (large surface area). The potential of the solution (Pt electrode) remains unchanged. Breaking contact between the stainless steel electrode and the copper specimen reestablishes the potential of the stainless steel at the same value as that of the platinum electrode. Upon removal of the copper specimen the potentials of both platinum and stainless steel electrodes increase in the cathodic direction. As in the beginning, the platinum electrode assumes the more cathodic potential. These measurements are readily reproducible and are the same on annealed and on sensitized steel.

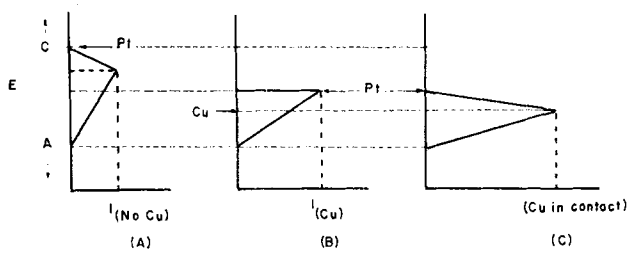

Fig. 27. Schematic potential-current diagrams of local-cell action on stainless steel in copper sulfate-sulfuric acid solution. Effect of metallic copper. "C" and "A" are the open-circuit potentials of the local cathodic and anodic areas, and "I" is the corrosion current. The electrode potentials of a platinized platinum electrode and the metallic copper, immersed together with the stainless steel, are indicated by arrows.

The action of metallic copper in this solution is shown by a comparison of weight-loss measurements obtained on copper in boiling sulfuric acid, with and without cupric sulfate. Without cupric sulfate the weight loss was about 0.3 g/dm^2 in 20 hr. Addition of cupric sulfate to make a 5.7% $CuSO_4$ solution increased this weight loss 40-fold by cupric-ion corrosion.

$$Cu + Cu^{+2} \rightarrow 2Cu^{+1}$$

Accumulation of cuprous ions in the cupric sulfate-sulfuric acid solution changes the potential in the anodic direction to the same value on both the platinum and stainless steel electrodes, which indicates that the local anodes are polarized to the potential of the cathodic areas. Thus, in copper sulfate-sulfuric acid solution, as well as in the other two acid solutions investigated, corrosion of stainless steel is controlled by the polarizability of anodic areas. These changes in potential are shown schematically in terms of local cell action in Fig. 27A and B.

When the copper specimen is put in contact with the stainless steel there is a further change in the potential of the steel, in the anodic direction, to that of the copper. (The potential of the platinum electrode remains constant.) This change indicates cathodic polarization of the steel.[13] Therefore, stainless

[13] Making an electrode a cathode by means of an external current either has no effect on its potential or changes it in the anodic direction. In turn, anodic polarization changes the potential in the cathodic direction.

steel is the cathode of the steel-copper galvanic couple.[14] There is a simultaneous reduction in anodic polarization, primarily at susceptible grain boundaries, and, consequently, an increase in corrosion rate, or corrosion current, in terms of the diagram in Fig. 27C. In this system cathodic polarization increases corrosion.[15] As suggested by Rocha (36) the copper contact produces dissolution of the stainless steel at a constant potential, i.e., the copper provides a very simple equivalent of a constant-potential instrument, a potentiostat.

Since copper is the anode of the galvanic couple with stainless steel, it might be expected that its rate of corrosion is increased. However, no increase was observed because of the very great difference in the corrosion rates of the stainless steel and the copper. The galvanic current produced by the couple doubles the corrosion rate of the stainless steel (Fig. 22). Only a small fraction of this is actually due to metal dissolution; most is a result of grain-dropping. The galvanic current passing to the stainless steel from the rapidly corroding copper (0.65 g/dm²/hr) produced such a small increment in this rate that it could not be detected.

Dissolution of stainless steel in cupric sulfate-sulfuric acid solution without metallic copper gradually changes the oxidation reduction potential of the solution in the anodic direction as cuprous ions are formed by reduction of cupric ions on the surface of the steel. However, in the presence of relatively large concentrations of dissolved ferrous ions this shift is suppressed. In agreement with Brauns and Pier (39) it was found that 1-3 g/l of ferrous ions retards or prevents the change of potential in the anodic direction. Ferrous ions were oxidized to the ferric state. A blue solution containing 1.3 g/l ferrous ions becomes blue-green in 12 hr at boiling temperature. When metallic copper was added, dissolved iron remained in the ferrous state and the potentials of copper and of stainless steel in contact with it were the same as in solutions without iron.

Comparison of Types of Intergranular Attack

In this concluding section the techniques described in the previous parts are used for a comparison and interpretation of the types of intergranular attack produced by various solutions. The data have been summarized in terms of criteria which can be used to compare the applicability of these corroding acids for routine evaluation tests. A description of experimental work undertaken to reveal the effect of grain size on intergranular corrosion concludes the discussion.

Effect of Acids

Some results obtained on AISI-304 and 316 steels in the three acid solutions discussed above are shown in Fig. 28. In these two graphs the effect of length of testing time has again been eliminated by plotting change in resistance against the weight loss of a given (sensitized) steel. Elimination of the testing time facilitates the comparison of types of intergranular attack, because the factors in the acids which determine the rate of intergranular penetration do not affect its character. Thus, it was shown (Fig. 23) that the very great acceleration of intergranular attack caused by the use of metallic copper in the copper sulfate-sulfuric acid test does not alter the characteristics of this attack. This is also the case for increasing acid concentration which greatly affects the rate of corrosion in the ferric sulfate-sulfuric acid solution (Fig. 19). The data on AISI-304 and 316 steels in Fig. 28, obtained in 15.7 and 50% acid, provide the evidence for this observation. Even though corrosion on the AISI-316 steel is increased 300-fold in 77 hr by this increase, the points for both concentrations fall on one line. A discussion of "characteristics of intergranular penetration" is given below.

The relationship of change in resistance and weight loss on intergranularly corroding specimens may be described with reference to an imaginary specimen suffering uniform general corrosion. Cal-

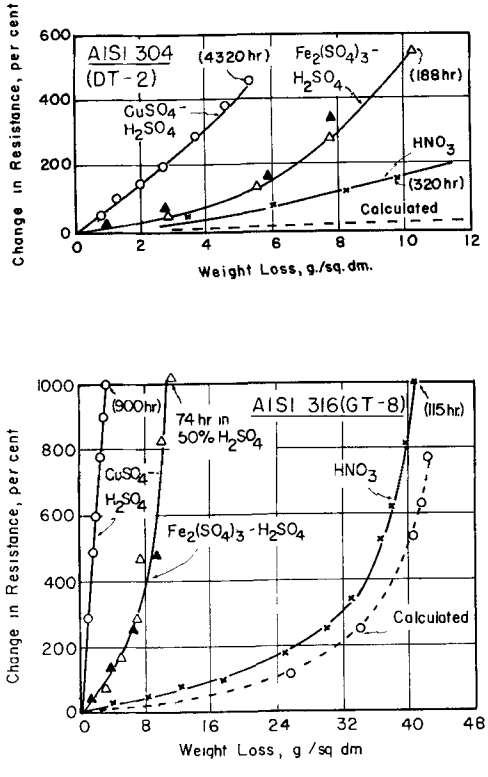

Fig. 28. Comparison of intergranular penetration and weight loss in three boiling acid solutions. Steels: A (top), AISI-304 (DT-2) heated 1 hr at 1250°F; B (bottom), AISI-316 (GT-8) heated 1 hr at 1950°F, then 1 hr at 1250°F. Solutions: O, 15.7% H_2SO_4 — 5.7% $CuSO_4$ (no metallic copper); △, 50% H_2SO_4 — $Fe_2(SO_4)_3$; ▲, 15.7% H_2SO_4 — $Fe_2(SO_4)_3$; x, 65% HNO_3.

[14] Confirmation of this relationship in the copper-stainless steel couple was obtained in a test in which the current and its direction in this couple were measured. Specimens of copper and stainless steel, connected through a microammeter, were partially immersed in boiling sulfuric acid without cupric sulfate. The stainless steel dissolved with vigorous evolution of hydrogen and was the anode of the couple. When the couple was immersed in a second solution of sulfuric acid of the same concentration containing cupric sulfate, evolution of hydrogen on the stainless steel was suppressed. There was a reversal and a large decrease of the current between the specimens. The stainless steel became the cathode and the copper became the anode of the galvanic couple.

[15] This is in contrast to the behavior of some metals in nearly neutral solutions. Cathodic polarization frequently reduces corrosion in such systems (cathodic protection). On metals exposed to solutions in which they evolve hydrogen [steels in acids, aluminum in sodium hydroxide (38)] cathodic polarization usually does not affect the corrosion rate.

culations[16] were made of the per cent change in resistance as a function of the weight loss of such a stainless steel specimen (of similar cross-sectional area as those used in the laboratory tests) and have been plotted in Fig. 28. At a given weight loss the difference in per cent change in resistance between the calculated curve and one of the experimental curves is an indication of the extent of intergranular penetration beyond the metal surface produced by grain dropping. This difference in per cent resistance change is a measure of the grain boundary attack which has taken place, but which did not contribute to the weight loss. (The assumption is that the weight loss is very largely due to dislodged grains rather than to dissolved grain boundary material.)

Examination of the curves in Fig. 28 shows that intergranular penetration in addition to that indicated by weight loss measurements is greatest in copper sulfate-sulfuric acid solution and least in nitric acid. Also, this type of penetration is less for AISI-304 than for 316 steel in the two sulfuric acid solutions. These conclusions are in agreement with the qualitative observations made on corroded specimens. In the copper sulfate solution there is relatively little dislodgment of grains as compared with that produced in the other tests. Also, in copper sulfate-sulfuric acid solution grain dropping on AISI-304 steel is greater than on the 316 steel. On both steels there is more intergranular penetration beyond the surface in the ferric sulfate-sulfuric acid than in the nitric acid solution.

The slopes of the curves in Fig. 28 are determined by the ratio of intergranular penetration along susceptible grain boundaries to the rate of grain surface corrosion. If the rate of grain surface corrosion is low, there is little widening of grain boundary grooves following dissolution of the zone which contains chromium carbide or sigma phase constituent, and, therefore, the grains tend to remain in place (large slope). High rates of grain surface corrosion lead to widening of the attacked zone and to profuse grain dropping (low slope). In the narrow space formed by dissolution of the grain boundary zone the ratio of surface area to volume of solution is much greater than in the bulk solution. As a result, corrosion products may have a great effect on subsequent dissolution in these confined spaces.

Data on specimens corroding in ferric sulfate-sulfuric acid solution of various concentrations of acid support this view of the importance of the ratio of intergranular to grain surface corrosion. The resistance change-weight loss relationship in this solution is the same for 15.7 and 50% acid (Fig. 28). Thus, the ratio of intergranular penetration to grain surface corrosion should be independent of acid concentration. Evidence for this can be derived from the data plotted in Fig. 19, which shows the effect of acid concentration on the corrosion of annealed and of sensitized steel in ferric sulfate-sulfuric acid solutions. For this comparison the weight loss on sensitized specimens (Fig. 19A) may be used as a measure of intergranular penetration. From Fig. 28, it is apparent that the penetration measured by weight loss does not represent the total depth of penetration. Also, there is a relatively small amount of general corrosion reflected in this weight loss. However, these factors are eliminated by determining the ratio of intergranular to grain surface corrosion in solutions of various acid concentrations at the same stage of intergranular disintegration, i.e., at the same weight loss of the sensitized specimens, rather than at a certain time of immersion.

At a weight loss of 8.0 g/dm^2 the specimen (Fig. 19A) in 45% acid has corroded 192 hr. The weight loss of an annealed specimen in 45% acid after 192 hr is 0.70 g/dm^2, and the ratio of intergranular to grain surface corrosion is 8.0/0.70 = 11.4. Identical ratios are obtained in 50 and 60% acid. At a weight loss of 4.0 g/dm^2 the ratios are 5.7(40%), 7.25(45%), 7.25(50%), 7.25(60%). Thus, the ratio of intergranular to grain surface corrosion is independent of acid concentration.

The data of Fig. 23 show that the ratio of intergranular to grain-face corrosion in the copper sulfate-sulfuric acid solution is unaffected by the action of metallic copper.

In nitric acid, corrosion products, especially hexavalent chromium, greatly accelerate corrosion and cause widening of the spaces between the grains. Consequently, the depth of the layer of grains removed is almost equal to the depth of intergranular penetration (Fig. 28).

To compare corrosion currents and the corresponding electrode potentials in the three acid solutions, corrosion rates of annealed specimens have been converted to milliamperes per square centimeter, Table IV. Even though the corrosion current in ferric sulfate-sulfuric acid solutions varies by a factor of 88 in the range of 10-60% acid, the potential is essentially the same at all concentrations.

Effect of Chromium Carbide and Sigma Phase

The effect of length of time of sensitization on intergranular penetration and grain dropping de-

* Calculated from corrosion rates, which are constant with immersion time on annealed chromium carbide- and sigma phase-free) steel.

† Also the potential of platenized platinum electrode in these solutions.

[16] The per cent change in resistance was derived from

$$\% \Delta R = \frac{R_t - R_o}{R_o}(100) = \frac{A_o - A_t}{A_t}(100)$$

where R_t, R_o, A_t, and A_o are the resistances and areas of cross sections of the specimens, at the beginning of the test and after exposure, t. To relate change in resistance to weight loss a specimen of 100 cm^2 surface area (neglecting the ends) 0.15 × 0.60 cm in cross section (66.6 cm long) was assumed. Using 8.04 g/cm^3 as the density for 18 Cr-8 Ni stainless steel, the changes in weight for various changes in cross-sectional areas of the specimen was calculated. These same cross-sectional areas were used in the formula above to determine the accompanying change in resistance.

pends on the solution to which the steel is exposed. Results obtained in copper sulfate-sulfuric acid solution have been plotted in Fig. 25. Intergranular penetration (per cent change in resistance) per gram of weight loss is greater on the specimen heated for 2 hr at 1250°F than for that heated 1 hr. Comparable tests have been made in ferric sulfate-sulfuric acid and in nitric acid solutions.

In ferric sulfate-sulfuric acid the difference in change in resistance between specimens heated 1 and 2 hr at 1250°F was only 35% at a weight loss of 8 g. This is much less than in the copper sulfate-sulfuric acid solution. Also, penetration per gram of weight loss was greater for the specimen heated 1 hr than for the 2-hr specimen. In nitric acid intergranular penetration and grain dropping were identical on both specimens. The data for the 1- and the 2-hr specimens, when plotted as in Fig. 25, fell on one curve. As expected, the rate of change in resistance and the rate of weight loss for a given length of exposure time was greatest in all three solutions for the specimen sensitized 2 hr.

These observations may also be interpreted in terms of the ratio of intergranular to grain face corrosion and the role of corrosion products. Increasing the length of sensitizing time from 1 to 2 hr increases the amount of chromium carbides formed and, to some extent, their size, i.e., the distance which they grow into the grains. There is some increase in widening of grooves and, therefore, an increase in grain dropping, and a consequent decrease of the slope of the resistance change-weight loss curve. In the ferric sulfate-sulfuric acid solution, in which corrosion products do not affect corrosion, there is such a decrease. In the copper sulfate-sulfuric acid solution increasing the length of sensitizing time increases intergranular penetration without a corresponding increase in grain dropping. In nitric acid, the accelerating effect of corrosion products obscures the influence of length of time of sensitizing. Again, grain boundaries are widened and lead to such rapid dislodgment that there is little penetration ahead of the surface produced by grain dropping.

For a comparison of the action of the acid solutions on various types of steels, the ratio of the corrosion rate (at a given exposure time) of a sensitized specimen to that of an annealed specimen of the same heat of steel has been applied. This ratio, which has already been used in connection with Table III, is a sensitive measure of the power of a solution to detect susceptibility to intergranular attack. In addition, it eliminates any changes in corrosion rates caused by small variations in alloy composition of the steels.

When these solutions are used for routine evaluation by means of weight-loss determinations, it usually is not necessary to test an annealed specimen along with the one being evaluated. The corrosion rate of the latter is compared with the maximum permissible rate established for the given solution and type of stainless steel. Selection of this maximum permissible rate is based, in part, on the known general or grain face corrosion.

There is one exception to this practice. In nitric-hydrofluoric acid solutions general corrosion is very sensitive to variations in alloy content (chromium) of the stainless steels. In the range of 16-19% Cr the corrosion rate of a group of AISI-316 steels varied from 2.7 to 0.8 in./mo; i.e., by a factor of 3. This solution has been employed occasionally as a qualitative method for detecting weld decay (32, 40, 41) and has been used in this investigation for comparison with the other three solutions. Because of the relatively large influence of small variations in chromium content on grain-face corrosion the ratio must be determined even for routine evaluation purposes.

A summary of results obtained on five different heats of steel is given in Table V. The susceptibility to intergranular attack in these steels varies from the pure chromium carbide type (AISI-304) to the pure sigma phase type (AISI-316L, FI-4). A combination of both types is illustrated by the two AISI-316 heats (M316, GT-8).

First, all specimens, except FI-4, show some completely encircled grains in the oxalic acid etch structure after heating 1 hr at 1250° (and 2 hr in the case of M316) and are, therefore, classed as "ditch" struc-

tures. The number of grains completely encircled varies from only a few grains on FK-2 to complete encirclement of almost all grains on I-9, GT-8, and M316. Only the FI-4 (0.020% C) steel is entirely free of chromium carbides after the sensitizing treatment (Fig. 13).

A comparison of the ratios obtained in nitric-hydrofluoric acid, ferric sulfate-sulfuric acid, and the 1000-hr cupric sulfate-sulfuric acid test shows that all these solutions give similar results. They reflect the chromium carbide type of intergranular susceptibility. The ratios of the FK-2 steel are smaller than those of the higher carbon, I-9 steel. Among the 316 steels the GT-8 heat is consistently higher than the M316 steel, which has been sensitized 1 hr. Extending the sensitizing treatment of M316 to 2 hr increases the ratio in all of these solutions. Also, the FI-4 steel, which is free of carbides, has a ratio of unity. In the copper sulfate test resistance measurement is a more sensitive indicator of intergranular attack than the ratio based on weight loss. The discrepancy between the ratio and the per cent change in resistance increases rapidly at the higher ratios.

In the *nitric acid* test the ratios on I-9 and FK-2 follow the trend of the other tests. However, on FI-4 there is a large increase in intergranular corrosion due to sigma phase, which is not detectable in the microstructure.[17] The relatively large ratios in nitric acid of the AISI-316 heats, especially GT-8,[18] are also caused by sigma phase in combination with chromium carbides.

All five tests reveal the presence of the chromium carbide type of susceptibility to intergranular attack. The sigma type is detected only in nitric acid.[19] Since the sigma type in 316 steel is known to cause intergranular attack only in nitric acid (42), one of the other quantitative evaluation tests could be used for routine evaluation of all stainless steels, except those AISI-316 and 316L steels which are intended for use in nitric acid. In determining which of these is the most promising, the following factors are of importance.

The most sensitive quantitative measure of intergranular attack in the copper sulfate-sulfuric acid test is the change in electrical resistance. Specialized apparatus is required for such measurements, and the test specimen must be relatively long and thin. Weight losses in this solution are relatively small and not nearly so sensitive as in the other solutions.[20] The nitric-hydrofluoric acid test is rapid (4 hr or less) (56), but requires testing of two specimens because evaluation is by ratio. Special equipment and care are required for handling hydrofluoric acid and holding the solution at a temperature considerably below the boiling point. For these, and other reasons, the 120-hr ferric sulfate-sulfuric acid test has been proposed to meet the need for a quantitative method of evaluating austenitic stainless steels for the chromium carbide type of susceptibility to intergranular attack in unstabilized stainless steels (22).

[17] An attempt was made to detect this phase by electrolytic etching in 15 other reagents, which included sulfuric, chromic, phosphoric, citric, and formic acid. In every case, a step structure similar to that obtained in the oxalic acid etch was the result. Intergranular attack in this steel in nitric acid is, therefore, associated with a preprecipitation form of the sigma constituent.

[18] Note that the ratio given in Table V is only for a 120-hr exposure in nitric acid. After the regular 240-hr test this ratio would be much greater.

[19] In terms of the polarization concepts developed above, this indicates that the presence of chromium carbides leads to a decrease in polarizability at grain boundaries in all five solutions. However, sigma phase, which is also a chromium-rich phase, occurring in 18 Cr-8 Ni-Mo steel, decreases polarizability of grain boundary zones only in nitric acid.

[20] For example, it was not possible to detect by weight loss or resistance change the relatively small variations in intergranular attack produced by various lengths of sensitizing heat treatments on FK-2 steel. In nitric acid these changes were readily found, as shown in Fig. 2.

Effect of Grain Size

Discussions of grain dropping and intergranular penetration, as given above, lead to the problem of the influence of grain geometry on these processes. Does the grain size of the steel affect the rate of intergranular corrosion? On the basis of corrosion tests in sulfuric acid, with and without copper sulfate, Newell (43) has concluded that susceptibility to intergranular attack increases with grain size. Rutherford and Aborn (35) and Ferri (44) have made resistance measurements on specimens exposed to copper sulfate-sulfuric acid solution, which also showed more rapid intergranular penetration on large than on small grained steel. On the basis of these observations some investigators (35, 43, 45, 46) have concluded that intergranular carbide precipitation per unit surface of grain boundary is a function of grain size. However, on steels corroding in nitric and other acids it has frequently been observed in the present investigation that small-grained steels drop grains after shorter exposure periods than large-grained specimens. Also, on specimens having grains of various sizes the smallest are the first ones to be dislodged. Furthermore, they are the most likely to be surrounded completely by ditching in the oxalic acid etch structures.

In order to obtain quantitative data on this problem, specimens having appreciably different grain sizes were required. Various combinations of mechanical deformation and heat treatments were tried to induce grain growth. These were unsuccessful. The only method found to produce exaggerated growth was a cyclic heat treatment. A group of AISI-304 specimens was welded into a stainless steel vessel and heated to 2200°F for 7 hr and then furnace cooled. This procedure was repeated three times. The over-all diameter of the grains was thus increased from 0.04 mm to 3 mm.

It was evident that there had been some decarburization of the specimens during these heat treatments. They were bright as a result of oxide removal by reaction with carbon in the steel. Examination of carbides isolated from these specimens, after sensitizing heat treatments, showed that these were entirely different in size and shape from those found in this steel before the high-temperature heat treatments. Thus, besides grain growth, there had been other changes which were known to affect intergranular penetration. (Figure 25 shows that a 2-hr sensitizing treatment results in a different type of intergranular attack than 1-hr treatment.) For these reasons, the data obtained on these specimens are not presented in detail but are used for qualitative comparison with those of another heat of steel in which a

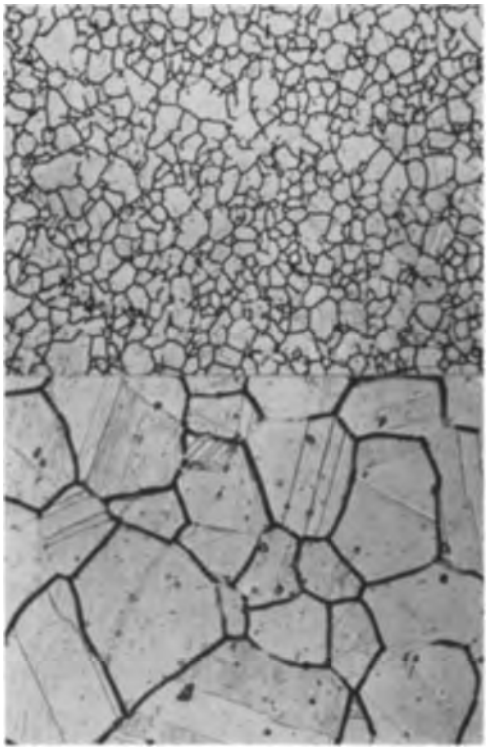

Fig. 29. Microstructure of AISI-316 steel used for grain size study. Steel: AISI-316 (GT-8, Table I). Etched electrolytically in oxalic acid. A (top), steel as received and heated 1 hr at 1250°F (unusually small grain size); B (bottom), heated first for 1 hr at 1950°F, W.Q., and then 1 hr at 1250°F. Magnification 500X before reduction for publication.

Fig. 30. Electron photomicrographs of carbides isolated from sensitized AISI-316 steel. Steel: GT-8, specimens same as Fig. 29. A (top), from small-grained specimen; B (bottom), from large-grained specimen. Magnification 20,000X before reduction for publication.

variation in grain size was induced without extensive heat treatments.

A heat of AISI-316 (GT-8) steel was found which had an unusually small, uniform grain size (Fig. 29A). This was readily changed to a normal grain size by a 1-hr heat treatment at 1950°F. The ratio of internal boundary area of the small-grained to the large-grained steel as determined by the method of random sectioning (47) was 5.7. Carbides were isolated from both types of specimens and examined in the electron microscope. The shapes and sizes of the carbides appear unchanged by this grain growth (Fig. 30A and B). As might be expected, the quantity of carbides remaining after some metal had been dissolved was much greater on the small-grained than on the large-grained specimen. Results obtained on sensitized large and small-grained specimens of this steel in three acid solutions have been plotted in Fig. 31.

The relatively high carbon content (0.074% C) of this steel leads to very high corrosion rates in all tests. An appreciable amount of the sigma type of susceptibility has also been formed during sensitization (Table V). The rates in nitric acid were so high that it was not possible to complete the standard 240-hr test because the ⅛-in. thick specimens became too thin.

In all three tests, Fig. 31, the small-grained specimens had a greater weight loss (corrosion rate) than the large-grained specimens, especially in the copper sulfate-sulfuric acid solution.[21] (This was also the case on the normal and large-grained AISI-304 steel.) However, changes in resistance are greater on the large-grained specimen in nitric acid and in ferric sulfate-sulfuric acid solution. In copper sulfate-sulfuric acid the small-grained specimen shows the greatest increase. This reversal may be due to an unusual amount of grain dropping, which is implied in the high weight loss in this solution. The grains are so small that there is profuse dropping even on an

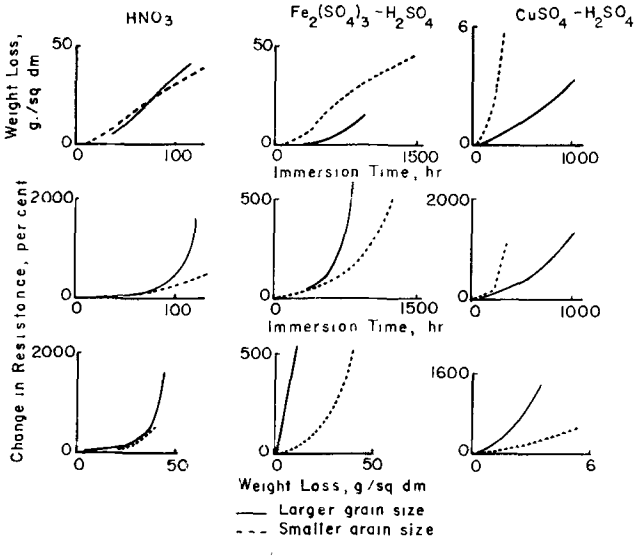

Fig. 31. Effect of grain size on intergranular corrosion of sensitized AISI-316 steel in three boiling acids. Steel: AISI-316 (GT-8) in two grain sizes as shown in Fig. 29. Specimens heated 1 hr at 1250°F. Solutions: 65% nitric acid; ferric sulfate, 15.7% sulfuric acid; 5.7% cupric sulfate, 15.7% sulfuric acid (no metallic copper).

[21] There is less difference between the two specimens in nitric acid than in the other solutions, and after about 80 hr the curves cross. Rapid accumulation of corrosion products and consequent acceleration by hexavalent chromium may have obscured the effect of grain size.

AISI-316 steel. Normal or large grains are not readily dislodged by this solution.

Despite these differences in behavior, the resistance change accompanying a given weight loss is greater on the large-grained specimen in all three solutions (bottom row, Fig. 31). Because small grains drop more readily, the results on the smaller steel are closer to the calculated curve.

In conclusion, the effect of grain size on corrosion depends on the method of measurement (weight loss or resistance change) and on the testing solution. While the total amount of intergranularly precipitated chromium carbides is greater in the small-grained than in the large-grained steel, the amount of carbide per unit area of internal grain surface is probably the same in both. Only when the diameter of the small grains approaches the width of the grain boundary zone containing chromium carbides will the grain size affect the amount of precipitate per unit area. The width of this zone depends, among other factors, on the length of time of the sensitizing treatment, i.e., the size of the carbides (cf. Fig. 14B and 30).

The Diffusion of Oxygen in Alpha and Beta Zircaloy 2 and Zircaloy 3 at High Temperatures

M. W. Mallett, W. M. Albrecht, and P. R. Wilson[1]

Battelle Memorial Institute, Columbus, Ohio

ABSTRACT

The diffusion rates of oxygen in alpha and beta Zircaloy 2 and Zircaloy 3 were determined in the range 1000°-1500°C. For alpha Zircaloy 2, the variation of the diffusion coefficient, D, in cm²/sec, with temperature is given by the equation

$$D_\alpha = 0.196 \exp(-41{,}000 \pm 1500/RT)$$

For beta Zircaloy 2,

$$D_\beta = 0.0453 \exp(-28{,}200 \pm 2400/RT)$$

Spot checks of the diffusion of oxygen in alpha and beta Zircaloy 3 to 1100° and 1400°C show that the rates are in close agreement with those for oxygen in Zircaloy 2.

The diffusion coefficients for oxygen in beta Zircaloy 2 and Zircaloy 3 are about 10 times greater than those for nitrogen in high-purity beta zirconium.

The water and steam corrosion of Zircaloy 2 has been investigated up to 400°C (1, 2). The corrosion reaction proceeds principally by formation of a surface film of ZrO_2. One of the processes that occurs during the reaction is the diffusion of oxygen in the metal. At the temperatures that have been investigated, the diffusion rates are very slow and do not contribute to the over-all corrosion process. However, at high temperatures above 1000°C or so, the rate of diffusion becomes appreciable and may play a large part in the over-all reaction. Therefore, as part of a study of the high-temperature corrosion of Zircaloy 2 and Zircaloy 3, the diffusion coefficients of oxygen in the alpha and beta phases of the materials were determined at 1000°-1500°C. Rather complete data were obtained for Zircaloy 2. The diffusion in Zircaloy 3 was spot checked to obtain a few rates for comparison with those for oxygen in Zircaloy 2.

Experimental

Materials

The Zircaloy 2 and Zircaloy 3 for this work were fabricated into 5/8-in.-diameter rods. Specimens for the experiments were machined from these rods. Analyses of both alloys were obtained by spectrographic, chemical, and vacuum-fusion techniques. Results are given in Table I.

Oxygen was prepared by the thermal decomposition of degassed potassium permanganate as described by Hoge (3). It was dried with a dry ice-acetone cold trap.

Zirconium-Oxygen Phase Diagram

Knowledge of the phase diagrams of the Zircaloy 2 and Zircaloy 3 oxygen systems should be known in preparing suitable diffusion specimens to determine diffusion coefficients, but no information is available on either system. However, it is believed that the zirconium-oxygen system (4) is very similar to the Zircaloy-oxygen systems since the basic structure of the alloys is not changed from that of zirconium, that is, alpha and beta Zircaloy alloys have the same structures as alpha and beta zirconium. Therefore, the zirconium-oxygen system was used as a source of oxygen-concentration data needed for diffusion studies of the Zircaloy materials. A partial phase diagram of the zirconium-oxygen system is reproduced in Fig. 1. The portion of the diagram of interest for this study is that from 1000° to 1500°C. In this range, the beta-alpha plus beta boundary represents the maximum solubility of oxygen in beta (solid solution) zirconium. The alpha plus beta-alpha boundary represents the lowest oxygen concentration required to maintain a single phase of alpha (solid solution) zirconium. The alpha-alpha plus ZrO_2 boundary represents the maximum solubility of oxygen in alpha zirconium.

Table I. Analyses of Zircaloy 2 and Zircaloy 3

Element	Amount present, wt %	
	Zircaloy 2	Zircaloy 3
Sn	1.5	0.22
Fe	0.20	0.34
Cr	0.05	0.03
Ni	0.03	0.005
Si	0.007	0.05
Al	0.006	0.005
Mn	0.002	0.01
Mg	0.002	0.001
Pb	0.002	—
O_2	0.089	0.14

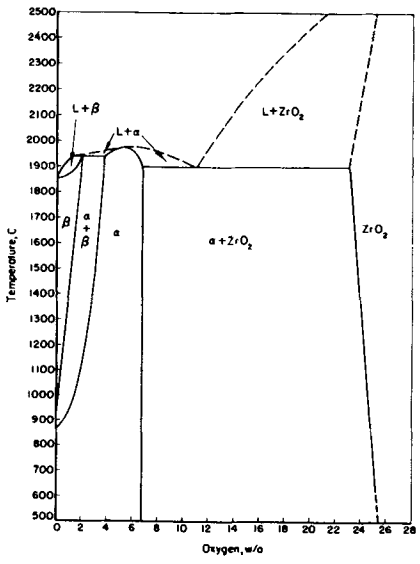

Fig. 1. Partial phase diagram of the zirconium-oxygen system.

Concentration-Gradient Technique

The concentration-gradient technique (5) was used to determine the diffusion coefficients for oxygen in beta-phase Zircaloy 2 and Zircaloy 3. Essentially, the method consists of analyzing the concentration gradient in a cylindrical specimen resulting from reaction with oxygen at a given temperature for a predetermined length of time. The diffusion coefficient was determined from the concentration gradient by a graphical method.

Specimens having gradients were prepared as follows. A Zircaloy 2 (or Zircaloy 3) cylinder about 1 cm in diameter and 4 cm long was dry abraded with 240-grit silicon carbide paper. After the dimensions of the cylinder were measured, the specimen was placed in the Vycor furnace tube of a modified Sieverts apparatus (2). The sample then was induction heated in a vacuum for 1 hr at the temperature of the run. Temperatures were measured under black-body conditions with an optical pyrometer. With the sample at the desired temperature, an amount of oxygen (based on the maximum solubility in beta phase at desired temperature) calculated to maintain a thin oxide film on the sample was added to the reaction chamber. The sample was heated for a length of time sufficient to prepare a suitable gradient; that is, enough oxygen was diffused to just begin to affect the core. At the end of this time, the sample was quenched as rapidly as possible. Temperatures below 500°C were attained in less than 30 sec. At 500°C and below, diffusion is extremely slow so that very little movement of oxygen occurred below this temperature. The film on the sample contained the phases shown in the phase diagram, Fig. 1. Proceeding from right to left on the diagram at the temperature of the run, the outer layer is ZrO_2; beneath this is a very thin layer of alpha solid solution. Beneath this is the beta core which contains the oxygen gradient being measured. It should be noted that two-phase regions are not produced by diffusion in a heterogeneous binary system (6).

Since diffusion occurs from the ends of the cylinder as well as the sides, lengths equal to the radius were cut from each end of the specimen and discarded. This insured that the remaining sample would have a concentration gradient as uniform as possible from end to end. The remainder of the sample was machined radially into layers of equal weight and each layer analyzed for oxygen by the vacuum-fusion method. Diffusion coefficients then were determined by the graphical method, using the average oxygen concentrations of the layers, the average radii, and the time. The thin surface layer, which contains alpha and oxide phases, was not used in the calculations.

Moving-Boundary Technique

The diffusion coefficients of oxygen in the alpha phase of Zircaloy 2 (and Zircaloy 3) were determined by the moving-boundary technique described by Jost (5).[2] This method was developed by Wagner for the case of diffusion into a heterogeneous system of given over-all concentration. The mathematical treatment of this case is based on the fact that a displacement, ξ, of the phase boundary produced by the diffusion of a single species is proportional to the square root of the time of diffusion, i.e.,

$$\xi = 2\gamma\sqrt{Dt} \qquad [1]$$

where ξ is the displacement of the phase boundary, cm; γ, a dimensionless parameter characteristic of the system; D, diffusion coefficient, cm²/sec; and t, time, sec. The parameter, γ, is defined as follows:

$$\frac{C_s - C_{II,I}}{C_{II,I} - C_0} = \sqrt{\pi}\,\gamma \exp\gamma^2 \operatorname{erf}\gamma \qquad [2]$$

where C_s, $C_{II,I}$, and C_0 are concentrations of the diffusing species at various phase boundaries. In the present case, for a given temperature, C_s is the maximum solubility of oxygen in the alpha phase, $C_{II,I}$ is the oxygen concentration at the alpha plus beta-alpha boundary, and C_0 is the oxygen concentration at the beta-alpha plus beta boundary. The term erf γ is the "gaussian error function." Values of erf γ may be found in Jost (7) and Carslaw and Jaeger (8). The value for γ was determined from Eq. [2] by a graphical method.

To determine the value of the diffusion coefficient, it is necessary to have values of ξ, t, and γ at a given temperature. The slope of the plot of ξ vs. $t^{1/2}$ is equal to $2\gamma\sqrt{D}$ from which D may be evaluated.

Experimental techniques used to obtain the moving-boundary measurements are as follows. A cylindrical specimen about 1 cm in diameter by 4 cm long was prepared as described above for the gradient method. A calculated quantity of oxygen, C_0, was then added in slight excess to saturate completely the beta phase at the experimental temperature. This sample was heated at temperature for 6 to 8 hr. The specimen then was quenched to room temperature. To check the homogeneity of the

[2] Jost presents the solution of Fick's law for movement of a boundary in a plate. Brief calculations showed that for small displacements of the boundary in a cylinder, the equations for plates could be used in calculating diffusion coefficients without introducing significant errors.

specimen, metallographic examination was made of a cross section. A uniform distribution of a few alpha grains in a beta zirconium matrix was observed. This would be expected since even slight lowering of the temperature would supersaturate the beta phase in respect to oxygen. The alpha grains must have formed during the 30-sec cooling required to reach a temperature below which diffusion was negligible. This cooling time introduces an error of not more than 10% in measuring the minimum diffusion time of 5 min. At maximum diffusion times (120 min) the error was less than 0.4%.

The surface oxide (excess oxygen) was abraded from the surface of the sample which was then cut into three cylinders. The cylinders were heated in an oxygen atmosphere at temperature for various periods of time. A calculated quantity of oxygen was reacted to maintain an oxide film at all times but to keep its thickness at a minimum. The thickness of the oxide was always less than 5% of the alpha layer and was ignored in all calculations. At the end of the heating period, the sample was quenched as rapidly as possible and cut in half diametrically. The cross section was examined metallographically to determine the movement of the alpha-beta boundary. The diameter of the beta core was measured and subtracted from the original diameter of the cylinder. From this, the displacement of the boundary was determined. Then, the diffusion coefficient was determined from the slope of a plot of the displacement, ξ, against $t^{1/2}$.

Results and Discussion

The diffusion coefficients for oxygen in alpha and beta Zircaloy 2 were determined in the range 1000°-1500°C at 100°C intervals. Experimental diffusion times ranged from 5 to 120 min. Attempts were made to obtain coefficients at 1600°C; however, no suitable gradients or moving boundaries could be prepared. The experimental times (less than 5 min) at 1600°C necessary to prepare optimum diffusion samples were so short that errors in the measurement of the time required to quench to room temperature would introduce large errors in the estimation of actual diffusion times. The data obtained on a gradient prepared in beta Zircaloy 2 at 1100°C for 35 min are shown in Fig. 2 The thicknesses of the machined layers and the average oxygen concentration of each layer are shown. The solid line is the theoretical curve derived from diffusion theory (5) for this gradient. It is seen that there is good agreement between the experimentally determined concentrations and the theoretical curve. Also, it was found that the terminal solubilities of oxygen in beta Zircaloy 2 (obtained from concentration gradients) agreed with those for oxygen in pure zirconium. It is seen from Table II that with the exception of the 1400°C value these solubilities show an average difference of only 0.03 wt %. This supports the earlier assumption that the Zircaloy(s)- and zirconium-oxygen phase relationships are closely similar. The 1100°C terminal oxygen solubility for beta Zircaloy 3 also agrees with zirconium data, but again the

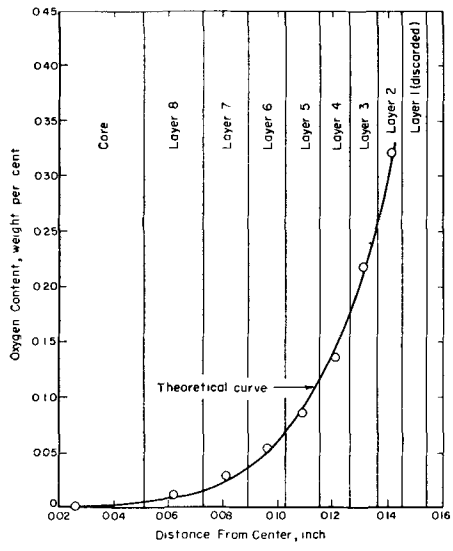

Fig. 2. Oxygen concentration gradient prepared in beta Zircaloy 2 at 1100°C for 35 min.

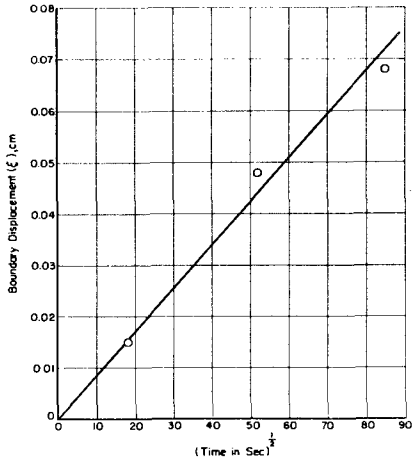

Fig. 3. Variation of displacement of alpha-beta boundary with time for oxygen in alpha Zircaloy 2 at 1200°C.

1400°C value shows a large discrepancy. The fact that the greatest differences were noted at 1400°C is believed to be coincidental rather than systemic. In Fig. 3 is shown a typical plot of the alpha-beta boundary displacement, ξ, against $t^{1/2}$ for alpha Zircaloy 2 at 1200°C. The slope of the line is equal to $2\gamma\sqrt{D}$. At 1200°C, the value of γ is 0.895. From

Table III. Diffusion coefficients for oxygen in alpha and beta Zircaloy 2 and Zircaloy 3

Material	Diffusion coefficient, cm²/sec, at temperature indicated, °C					
	1000	1100	1200	1300	1400	1500
Zircaloy 2, alpha	1.8×10^{-8}	4.8×10^{-8}	2.3×10^{-7}	3.6×10^{-7}	7.9×10^{-7}	1.7×10^{-6}
Zircaloy 2, beta	8.2×10^{-7}	1.4×10^{-6}	2.4×10^{-6}	3.8×10^{-6}	8.1×10^{-6}	2.4×10^{-5}
Zircaloy 3, alpha	—	5.8×10^{-8}	—	—	1.4×10^{-6}	—
Zircaloy 3, beta	—	1.4×10^{-6}	—	—	6.5×10^{-6}	—

these values the diffusion coefficient was calculated. All the data are given in Table III. The diffusion coefficients for oxygen in alpha Zircaloy 2 range from 1.8×10^{-8} cm²/sec at 1000°C to 1.7×10^{-6} cm²/sec at 1500°C. Those for oxygen in beta Zircaloy 2 range from 8.2×10^{-7} cm²/sec at 1000°C to 2.4×10^{-5} cm²/sec at 1500°C.

In Fig. 4 and 5 are shown the variations of the diffusion coefficients with temperature for alpha Zircaloy 2 and beta Zircaloy 2, respectively. The logarithms of the diffusion coefficients are plotted against the reciprocal of temperature (Arrhenius-type plot). Equations for the best straight lines through the points were determined by the method of least squares. The equation for the diffusion coefficient, D, in cm²/sec, for oxygen in alpha Zircaloy 2 is

$$D = 0.196 \exp [(-41{,}000 \pm 1500)/RT] \quad [3]$$

For oxygen in beta Zircaloy 2,

$$D = 0.0453 \exp [(-28{,}200 \pm 2400)/RT] \quad [4]$$

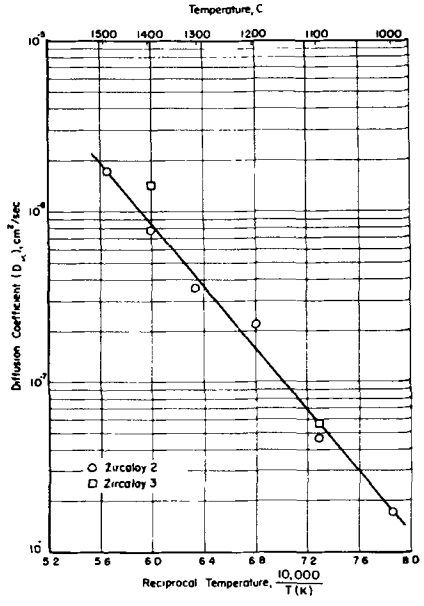

Fig. 4. Temperature variation of the diffusion coefficient for oxygen in alpha Zircaloy 2 and Zircaloy 3.

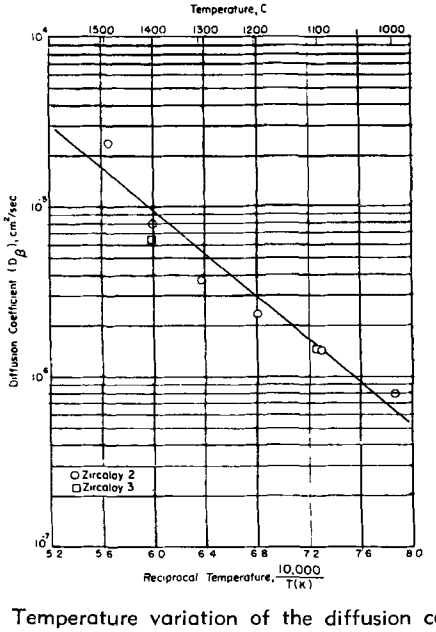

Fig. 5. Temperature variation of the diffusion coefficient for oxygen in beta Zircaloy 2 and Zircaloy 3.

The diffusion coefficients for oxygen in alpha and beta Zircaloy 3 were determined at 1100° and 1400°C. The values also are given in Table III and plotted in Fig. 4 and 5. It is seen that they are in good agreement with those for Zircaloy 2. Apparently, the alloying constituents in the range studied have very little effect on the diffusion of oxygen.

The diffusion coefficients for oxygen in beta Zircaloy 2 and Zircaloy 3 are greater (about 10 times) than those for nitrogen in high-purity beta zirconium (9). This difference probably arises from the differences in the size of the diffusing species, oxygen and nitrogen, and not from differences in the alloying constituents. The atomic radius of oxygen is 0.60Å and that of nitrogen is 0.71Å. Since oxygen is the smaller atom, it would be expected to diffuse faster.

Manuscript received Sept. 3, 1957. Work performed under subcontract to the Bettis Laboratory of the Atomic Energy Commission, operated by Westinghouse Electric Corporation. This paper was prepared for delivery before the Ottawa Meeting, Sept. 28-Oct. 2, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Reaction of Aluminum and Carbon Tetrachloride, I

J. D. Minford, M. H. Brown, and R. H. Brown

Alcoa Research Laboratories, Aluminum Company of America, New Kensington, Pennsylvania

ABSTRACT

Many aluminum alloys are corroded severely by boiling CCl_4. Two of the products of the reaction are aluminum chloride and hexachloroethane. The presence of anhydrous aluminum chloride accelerates the reaction. A number of chemical agents can retard this reaction apparently by combining with aluminum chloride as it is produced. The reaction of aluminum alloys drops off rapidly as the magnesium content increases.

Aluminum reacts rapidly with boiling carbon tetrachloride to form aluminum chloride and hexachloroethane (1) as follows:

$$2Al + 6CCl_4 \rightarrow 2AlCl_3 + 3C_2Cl_6 \qquad [1]$$

Previous investigations have been concerned with the effect of impurities in the carbon tetrachloride and the relative rate of attack on different alloys. However, there has been little evidence to establish a suitable reaction mechanism. Since the use of aluminum with halogenated hydrocarbons has important commercial applications, a need exists for better understanding of the mechanism of the reaction.

Stern and Uhlig (2) investigated certain phases of the reaction between aluminum and boiling carbon tetrachloride and concluded that an induction period of about 70 min exists during which no reaction takes place. It was found that the length of the induction time could be increased in the presence of either water or carbon disulfide and decreased in the presence of the corrosion products (Eq. [1]). They also found no consistent difference in corrosion rates between cathode and anode from either galvanic coupling or an applied potential of 1.5 v. When they applied a potential of 1000 v, the anode corroded about 1 hr before the cathode, but this was described as being the result of a premature breakdown of the protective coating on the aluminum surface. These authors interpreted these results as excluding an electrochemical mechanism and concluded that the reaction proceeds by a "typical direct chemical reaction."

In a subsequent paper Stern and Uhlig (3) proposed that the reaction proceeded by a free radical mechanism. This conclusion was based on the fact that the reacting solution is colored and that water and oxygen, which increase the induction period, also are known to combine with free radicals. Also, substances such as quinone, 1, 4-napthoquinone, and nitrobenzene, which have been listed as free radical suppressors, act as inhibitors for this reaction. Additional experiments to supplement this data and determine the feasibility of this free radical mechanism will be presented in a subsequent paper (3a).

The importance of the practical application of aluminum with halogenated hydrocarbons has led to considerable investigation during the last seven years. As a result, significant data pertinent to the mechanism, not available in the literature, have been obtained.

Characteristics of the Reaction (99.99% Al)

Visible effects.—Most of the experiments were carried out in a 500-ml round-bottomed glass flask connected to a reflux condenser by a ground glass joint. Two hundred and fifty milliliters of carbon tetrachloride were placed in the flask and heated on an electric hot plate. The aluminum specimens (0.064 x ½ x 3 in.) were placed in the carbon tetrachloride after the boiling point was reached.

As previously reported (2) it was observed that the first sign of corrosion usually appeared as a small black spot of corrosion product on the surface of the specimen after about 30 min. These spots increased in number until the entire surface was covered. The solution turned a faint pink after several hours and gradually darkened, finally becoming black with the formation of a large amount of insoluble black corrosion product. When the solution was filtered to remove the black insoluble product and then evaporated, a yellow residue was left indicating that a soluble reaction product had been formed.

Weight loss vs. time relationships.—The weight loss data given in Table I show that very little corrosion occurred in the first hour, but following that it proceeded rapidly. This apparent induction period had been observed previously (2). As will be shown in the second paper (3a) the reaction proceeds from time zero.

Effect of temperature on reaction.—Zappi (4) has

* Aluminum alloys formed into storage containers with a weld midway up the side wall were half filled with carbon tetrachloride. The containers were stored in a tilted position so that only half of the weld bead was immersed.
† The weight losses represent averages from duplicate storage tests. The initial weights of the containers were about 270 g.
Note: The exposed area was 45 in.^{2}.

reported that no reaction occurred between aluminum and carbon tetrachloride at room temperature in a four-month test period. When aluminum was sealed in a tube with carbon tetrachloride and heated to 110°C, however, rapid reaction ensued.

Observations of the present authors indicate a rather critical temperature dependence for this reaction. The reaction proceeded rapidly at the boiling point of carbon tetrachloride (77°C), but very little reaction occurred at 50°C over a 60-day test period and none occurred in 18 months at room temperature (see Table II).

Yields of reaction products—Although Rhodes and Carty (1) stated that aluminum and carbon tetrachloride react to form aluminum chloride and hexachloroethane, two additional experiments were carried out to determine the yields based on the above reaction and to see if any additional reactions were involved.

The yield of the soluble fraction (assumed to be entirely hexachloroethane) in duplicate runs was 41.2 and 48.7% of the theoretical and the yield of insoluble fraction (assumed to be entirely aluminum chloride) was 83.8 and 100.6% of the theoretical. The theoretical yields were calculated from the weight loss of aluminum assuming that hexachloroethane and aluminum chloride were the only products formed according to the following reaction:

$$2Al + 6CCl_4 \rightarrow 3C_2Cl_6 + 2AlCl_3$$

Examination of fraction originally insoluble in carbon tetrachloride.—An x-ray diffraction analysis of the carbon tetrachloride insoluble fraction showed that aluminum chloride was the only identifiable component. Chemical analyses for aluminum and inorganic chlorides are shown in Table III.

The insoluble fraction does not appear to be pure aluminum chloride because the ratio of chlorine atoms to aluminum atoms was 2.74 instead of 3 as in pure aluminum chloride. In this case Stern (5) reported the Cl/Al ratio to be 2.8. These results indicate that some of the aluminum valence bonds were linked to some element other than chlorine. Since carbon and chlorine were the only elements present in addition to aluminum, it seems apparent that about 8.7% of the aluminum valence bonds were linked directly with carbon.

Table III. Chemical analysis of fraction originally insoluble

Sample No.	Al, %	Inorganic Cl, %	Ratio Cl atoms / Al atoms
1	18.6	67.3	2.74
2	18.9	68.1	2.74

The black carbon tetrachloride insoluble fraction almost completely dissolved in water with evolution of heat. A small quantity of the black material is insoluble in water. If this water insoluble material is dried and placed in carbon tetrachloride, it dissolves readily forming a dark brown colored solution. Upon evaporation of the carbon tetrachloride, a black resinous material is left behind. The carbon tetrachloride insoluble fraction contained 3.18% of this resinous material. Chemical analysis of the black resinous material revealed that its carbon content was 42.2%. These data are in accord with previously reported information (2).

The fact that this black resinous material is insoluble in carbon tetrachloride until it is treated with water suggests that an aluminum-carbon-chlorine complex is formed which is broken up by reaction with water. The formation of a resinous solid indicates that the complex must have a high molecular weight.

Examination of the fraction originally soluble in carbon tetrachloride—The carbon tetrachloride soluble fraction was a yellow solid. Chemical analysis showed that the aluminum content was less than 0.005%. An x-ray diffraction analysis of the soluble fraction revealed that it was mainly hexachloroethane. The soluble fraction also was analyzed by index of refraction measurements. In this method of structural determination, an equation developed by one of the authors was used (6).

$$n-1 = \frac{5.07}{\frac{m-1}{dA}}$$

Where n is the refractive index; m, the molecular weight; d, the density; and A, the sum of constants based on actual atomic volumes (A) of the atoms in the molecule ($A = 0.821$ for carbon, 1.800 for chlorine, and 0.436 for a double bond). For hexachloroethane, $A = (2)\ (0.821) + (6)\ (1.800) = 12.442$.

In using this method, the index of refraction for the structural formula in question is calculated using the measured density for the unknown. If the structural formula is correct, the calculated value of refractive index should agree with the observed value.

Since hexachloroethane is a solid it was necessary to dissolve the soluble fraction in a solvent to make the refractive index measurements. The solvent used was 1, 2, 4 trichlorobenzene. The value of m/A for the trichlorobenzene was determined experimentally as 14.19 by determining d and n in the equation $m/A = \frac{5.07d + (d-1)\ d}{n-1}$. When using a mix-

ture of two compounds the values of m and A should be average values based on the molecular percentages of the two components. The composition of the solution used was 22.3 mole % soluble fraction and 77.7 mole % trichlorobenzene.

If the soluble fraction was 100% hexachloroethane, the m/A value for the solution would be 15.25, whereas, the measured value was 15.17 ± 0.01. These results indicate that the soluble fraction was not pure hexachloroethane. It seems logical to assume that some of the hexachloroethane could have reacted with aluminum to form high molecular weight carbon-chlorine compounds. Several possible formulations of this type are given below along with the calculated m/A values if they replaced hexachloroethane completely in the trichlorobenzene solution.

Type of compound	Structure	m/A (calc.)
Straight chain polymer	$\begin{bmatrix} Cl\ Cl\ Cl\ Cl \\ -C\ -C\ -C\ -C- \\ Cl\ Cl\ Cl\ Cl \end{bmatrix}_n$	15.20
Branched chain polymer	$\begin{bmatrix} Cl \\ -C- \\ \prime \end{bmatrix}_n$	15.10
Unsaturated straight chain polymer	$\begin{bmatrix} Cl & Cl \\ -C = & C- \end{bmatrix}_n$	15.08
Unsaturated branched chain polymer	$\begin{bmatrix} & Cl \\ -C = & C- \\ \prime & \end{bmatrix}_n$	14.37

The evidence indicates that the small amount of impurity in the soluble fraction is not a straight chain polymer. The presence of branched chain, unsaturated straight chain, or unsaturated branched chain polymers could lower the m/A value from 15.25 for pure hexochloroethane to the 15.17 value actually measured.

Indications are that the impurities in the soluble fraction are intermediate compounds in the formation of the black resinous material since their carbon contents are between those of hexachloroethane and the black resinous material.

Table IV. Effect of reaction products on the corrosion of 99.99% aluminum in boiling carbon tetrachloride

Specimen No.	Conditions	Time, hr	Weight loss, g
1	Corrosion products from 1.6701 g spec.	1.00	0.3251
2	Corrosion products from 1.7359 g spec.	1.00	0.3774

9	Saturated with $AlCl_3$	4.50	2.7282
10	0.5% (by wt) hexachloroethane	4.00	0.9222
11	0.5% (by wt) hexachloroethane	4.50	1.1880
12	0.5% (by wt) hexachloroethane	5.50	1.5364
13	0.5% (by wt) hexachloroethane	6.50	1.8670

Effects of Reaction Product on Reaction

Tests were run exposing 99.99% aluminum specimens in solutions containing reaction products from previous exposures. The results given in Table IV show that the presence of reaction products increased the initial corrosion rate. Since aluminum chloride and hexachloroethane are the main reaction products, tests were run with additions of these two compounds to fresh carbon tetrachloride to determine their influence on the reaction. Since aluminum chloride is only slightly soluble in carbon tetrachloride, a saturated solution was used. An excess of anhydrous aluminum chloride was added to carbon tetrachloride and refluxed for 1 hr. The carbon tetrachloride then was decanted into another flask for the corrosion tests. It was observed that a faint pink color, which gradually darkened, developed in the boiling carbon tetrachloride saturated with aluminum chloride. No color developed when hexachloroethane was dissolved in boiling carbon tetrachloride.

The results of these tests are given in Table IV. This information in graphical form along with data from Table I is shown in Fig. 1. The presence of hexachloroethane had no detectable effect on the reaction, but the addition of aluminum chloride had a marked accelerating effect. This indicates that aluminum chloride acts as a reaction accelerator, probably through the formation of complexes with carbon tetrachloride.

Effective Retarding Agents

On the basis of the preceding discussion of factors that markedly affect the reaction of aluminum with carbon tetrachloride, it is obvious that aluminum chloride is one of the most potent promoters accelerating the reaction. The possibility was considered that chemical agents could retard this reaction by combining with the aluminum chloride to retard its effect on the reaction. In this manner, the stimulating effect normally produced on the carbon tetrachloride-aluminum reaction would be retarded.

Since benzoyl chloride has been reported in the literature to form a molecular complex with aluminum chloride (7), it should have a retarding effect

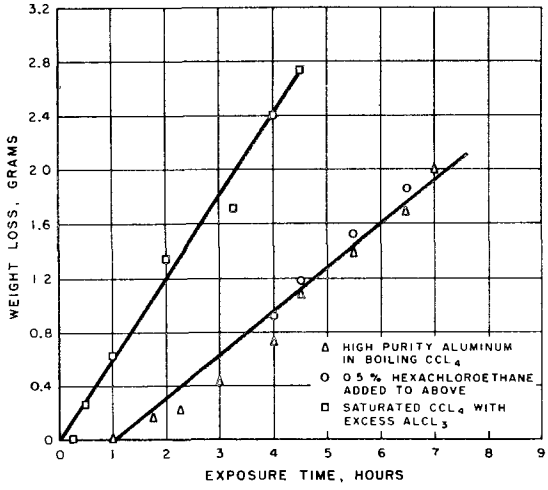

Fig. 1. Effect of anhydrous aluminum chloride and hexachloroethane additions.

on the reaction between aluminum and carbon tetrachloride by complexing the aluminum chloride and rendering the aluminum chloride unavailable for accelerating the reaction. Since significant retardation was obtained when 1% of freshly distilled benzoyl chloride was added to the carbon tetrachloride, the theory of an inhibitor operating by complexing the aluminum chloride was demonstrated.

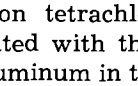
It was also shown that the corrosiveness of carbon tetrachloride for aluminum was decidedly greater in the presence of a given added quantity of aluminum chloride than in the presence of the same quantity of aluminum chloride combined with benzoyl chloride in a molecular complex. The fact that aluminum reacted with somewhat greater rapidity in the presence of this complex than in the absence of any added aluminum chloride was attributed to the effect of some small amount of aluminum chloride that did not complex with the benzoyl chloride. This was further confirmed by the fact that the solution of carbon tetrachloride containing the complex became colored in a short time as if a relatively small amount of the total aluminum chloride had been separately added to the carbon tetrachloride (i.e., was not combined in the complex).

Additional support for the theory that retarding agents operate by complexing aluminum chloride was obtained by converting a corrosive carbon tetrachloride solution containing added aluminum chloride into a noncorrosive solution by removing the colored aluminum chloride-carbon tetrachloride complex that forms when aluminum chloride is heated with carbon tetrachloride. This was accomplished by the addition of any one of three different retarders (2, 5 hexanedione, ethyl acetoacetate, aluminum nitrate $.9H_2O$) in the following manner. Sufficient anhydrous aluminum chloride was added to refluxing carbon tetrachloride to produce the deep color associated with the beginning stages of the corrosion of aluminum in the halogenated hydrocarbon. If 1% by weight of either of three different retarding agents (i.e., an excess with respect to the amount of added aluminum chloride) was added, the characteristic color was rapidly removed and the carbon tetrachloride became noncorrosive to aluminum. Subsequent analysis disclosed that all the detectable aluminum chloride was now in the precipitate which formed simultaneously as the color of the solution disappeared. All compounds that were known to be effective retarding agents precipitated aluminum chloride in this manner. The explanation of the results of this type of experiment can be explained most satisfactorily in terms of the previously projected theory of complexing the aluminum chloride. It now appeared to be a logical step to search for new retarding agents among chemical compounds that offered the possibility of known or projected reactivity with aluminum chloride.

The possibility that acid anhydrides might have retardation properties was predicted on the basis of the use of anhydrides in organic syntheses with aluminum chloride acting as a catalyst through a complex intermediate. Both acetic anhydride and phthalic anhydride acted as effective retarding agents, although the possibility of conversion to the corresponding acid made their practical use questionable. Phthalic anhydride, however, proved to be equally effective as a retarder in the presence or absence of water in refluxing carbon tetrachloride. Phthalic acid, on the other hand, was ineffective as a retarding agent unless water was present in the carbon tetrachloride. The equilibrium established between the anhydride or the acid and water in carbon tetrachloride that affords such excellent retardation is not known at this time. Phthalic anhydride, itself, has proved to be the best retarder at the lowest levels (0.1-0.2% by weight) of all the retarding agents investigated.

One successful class of retarders for this reaction is the carbonyl compounds. Acetone is the simplest member of this series and its complexing with $AlCl_3$ has been reported (8). Acetone serves as an effective retarder at a concentration of 0.2% by weight. The difficulty of maintaining an adequate concentration of acetone is increased, however, because of its relatively low boiling point. A more effective carbonyl agent is 2,5-hexanedione. Although the ratio of C=O/C is the same as in acetone, some advantage is obtained through the lower volatility as well as in the possibility of chelation. Other effective carbonyl-type retarding agents that react with aluminum chloride are acetophenone (9, 10) and benzophenone (10). They offer the advantage of a lower volatility than acetone but require a larger addition of retarder because of the increased molecular weight. On the other hand, they are not so effective on a weight basis as 2,5-hexanedione but are considerably cheaper.

Other retarding agents related to the carbonyl compounds are the esters that contain the group



—C—O—R. A number of different esters have been reported to form complexes with aluminum chloride (11, 12). Ethyl acetate and ethyl acetoacetate both proved to be good retarders for this reaction. Ethyl acetate has the advantage of having about the same boiling point as carbon tetrachloride which might be desirable in certain industrial applications. Ethyl acetoacetate is the better retarder of the two as might be expected because of the combination of a carbonyl and an ester group as well as offering the possibility of chelation.

Some heterocyclic ring system compounds such as thiophene, pyrrole, and quinoline act as effective retarding agents. These compounds were selected for several reasons. For example, all of them enter into condensation reactions in the presence of aluminum chloride in which it is often necessary for the aluminum chloride to be present in a mole-for-mole ratio or greater. They might also work since onium-type compounds could be produced in such situations where a Lewis type acid, such as aluminum chloride, comes in contact with a Lewis type base such as the heterocyclic atom in these ring systems.

Several olefin-type compounds (cyclohexene and isoprene) in which no heterocyclic atom is present also were effective although to a lesser extent than the other retarders previously mentioned. There is a basis for selecting olefins since olefins formed by pyrolysis of paraffins in the presence of aluminum chloride polymerize and remain bound fast with the aluminum chloride according to Nenitzescu (13-15). The specificity of the olefinic linkage was demonstrated by showing that cyclohexane has no retardation effect. On the other hand, benzene does have some retardation effect although, as might be expected, it is not so good as cyclohexene; this is because the compound is aromatic and hence none of the bonds have 100% double bond character.

It has been shown that another halogenated hydrocarbon that could complex $AlCl_3$ was capable of retarding the reaction with carbon tetrachloride. Benzyl chloride, for example, will complex with aluminum chloride and will retard the reaction when present at a concentration of 1%. Benzyl chloride, itself, is reactive toward aluminum at its boiling point.

Two amines which retard the reaction (triethylamine, 2-methyl-2-amino-1 propanol) have the ability to remove almost quantitatively aluminum chloride from a carbon tetrachloride solution saturated with aluminum chloride. The response to the addition of the amine is immediate and can be followed by noting the loss of pink color in the solution as well as by analysis for the aluminum in filtered carbon tetrachloride solution. Other amine retarding agents are methylamine, diethylamine, trimethylamine, n-butylamine, 3-methoxypropylamine, and cyclohexylamine. One of the disadvantages of the amines as practical retarders is their separate reactivity with carbon tetrachloride to form voluminous precipitates; however, under some conditions amines may be practical.

The ability of 21 hydrated inorganic salts to retard this reaction has been noted. The salts tested were generally in four classifications: nitrates, sulfates, chlorides, and sulfides. Only the hydrated nitrate and sulfide salts were retarding agents. Unlike the anhydrous salt, the hydrated aluminum chloride did not accelerate the reaction rate. The attempt to relate this phenomena to the coordination number of the metal ion of the salt was unsuccessful. Likewise, when the equivalent of the total water of crystallization was added as water to the carbon tetrachloride, its retarding influence was not nearly as effective as the hydrated inorganic salt.

On the assumption that an agent that might chelate $AlCl_3$ would be an effective retarder, 8-hydroxyquinoline was added at levels of 1% or less. Comparison on a weight basis shows that 8-hydroxyquinoline is one of the two best retarders (the other is phthalic anhydride).

Table V. Effect of retarding agents on reactivity in carbon tetrachloride in contact with aluminum

Additive (1% by wt of each)	Reactivity (first visible attack) In CCl_4	In CCl_4 saturated with $AlCl_3$
None	1 hr	<5 min

Tests for Evaluating Effectiveness of Retarding Agents

Since some retarders seemed capable of protecting aluminum for almost indefinite periods of time, some means of accelerating the test was needed to determine the relative effectiveness of the retarders. Exposure of aluminum specimens to refluxing carbon tetrachloride saturated with aluminum chloride is a much more stringent test than exposing them to refluxing pure carbon tetrachloride. To establish the relative effectiveness of the best known retarders, the same concentration by weight of each retarder was added to carbon tetrachloride saturated with aluminum chloride at room temperature. In order to insure that uniform conditions were maintained, the carbon tetrachloride was degassed in a dry box with nitrogen flushing through both the solution and the box. The total volume of carbon tetrachloride to be employed was saturated with $AlCl_3$ inside the box. The carbon tetrachloride was transferred to reflux flasks inside the box and the retarder and specimens added before the flask was stoppered. The time necessary for corrosion to appear on the aluminum specimen exposed in the boiling solution was a measure of the relative efficiency of the retarder. For example, some of the retarders classified in order of decreasing effectiveness were as follows: phthalic anhydride, 8-hydroxyquinoline, 2,5-hexanedione, ethyl acetoacetate, ethyl acetate, aluminum nitrate·$9H_2O$, and cyclohexene. The first two retarders completely prevented reaction under this condition for the five day test period. The actual periods of retardation are given in Table V.

Reaction of Carbon Tetrachloride with Magnesium and Aluminum Alloys

Tests were run with magnesium and ten aluminum alloys. The results given in Table VI and Fig. 2 show that magnesium in aluminum alloys has a pronounced effect on the corrosion rate. The corrosion

Table VII. Effect of $AlCl_3$ and $MgCl_2$ on the corrosion of magnesium and aluminum alloys in CCl_4

Alloy	Exposure time, hr	Specimen size, in.	Additive	Weight loss, g	Calc. vol. metal loss, in.³/in.²/yr.

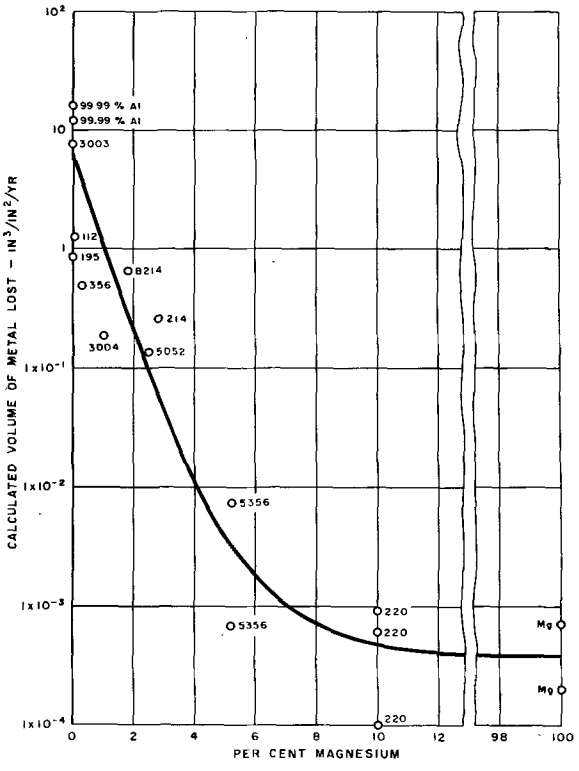

Fig. 2. Effect of magnesium content of aluminum alloys on corrosion rate in boiling CCl_4.

rate drops off rapidly as the magnesium content increases, becoming negligible for 220 cast aluminum alloy and magnesium. It should be pointed out that in Table VI and Fig. 2 varying exposure times were used to calculate the values of $in.^3/in.^2/yr$ and, hence, these values may not represent the true rates.

Tests also were run exposing magnesium and aluminum alloys 5356 and 220 to carbon tetrachloride saturated with aluminum chloride. The results given in Table VII show that the presence of aluminum chloride increased the corrosion rates of magnesium as well as the aluminum alloys. It was shown also that the presence of magnesium chloride or magnesium turnings had no significant effect on the corrosion of 99.99% aluminum in refluxing carbon tetrachloride. These results indicate that magnesium must be present as an alloying constituent in order to retard the reaction.

Conclusions

1. As reported by several others (1,2,5), many aluminum alloys are corroded severely by boiling carbon tetrachloride.

2. The reaction decreases rapidly when the temperature is dropped from the boiling point (77°C) to 50°C and is insignificant at room temperature. Some alloys show great resistance to carbon tetrachloride, even at the boiling point.

3. The addition of reaction products to carbon tetrachloride increases the initial reaction rate. Hexachloroethane had no effect on the reaction. Aluminum chloride, however, promotes the reaction and, when initially present, the reaction attains within a few minutes the same rate that is reached after several hours when starting with fresh carbon tetrachloride. This indicates that aluminum chloride acts as a reaction accelerator, probably through the formation of complexes with the carbon tetrachloride.

4. Chemical agents which can retard this reaction probably operate by combining with the aluminum chloride as it is produced. In this manner, the accelerating effect normally produced by the aluminum chloride is absent. Only anhydrous aluminum chloride accelerates corrosion.

5. Certain chemical agents that act as retarders for this reaction have shown the ability to decolorize a boiling solution of carbon tetrachloride containing aluminum chloride and to precipitate simultaneously and quantitatively in complexed form the aluminum chloride from the solution. Such a solution is noncorrosive if the retarder has been added in excess of that amount necessary to precipitate all the aluminum chloride.

6. Classes of retarding agent have been selected on the basis of known or projected reactivity with aluminum chloride. Some of the successful classes of retarders are acid anhydrides, amines, esters, heterocyclic compounds, halogenated hydrocarbons (which can complex aluminum chloride), ketones, olefins, and chelating agents in general. Certain hydrated nitrate and sulfide inorganic salts also were effective although the mechanism of their retardative ability is not clearly understood.

7. Reaction of aluminum alloys in boiling carbon tetrachloride drops off rapidly as the magnesium content increases. Addition of magnesium chloride or the presence of magnesium metal in carbon tetrachloride has no significant effect on the corrosion of high purity aluminum.

Manuscript received Nov. 13, 1957. This paper was prepared for delivery before the Buffalo Meeting, Oct. 6-10, 1957.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Reaction of Aluminum and Carbon Tetrachloride, II

R. H. Brown, E. H. Cook, M. H. Brown, and J. D. Minford

Alcoa Research Laboratories, Aluminum Company of America, New Kensington, Pennsylvania

ABSTRACT

The mechanism of the reaction between aluminum and boiling carbon tetrachloride appears to be electrochemical. Conductivity measurements indicate that the reaction starts as soon as the aluminum is exposed to the boiling solution. The increase in the conductivity with time is caused by the presence of $AlCl_3$ and parallels the increase in weight of aluminum reacted as the reaction proceeds. The application of a cathodic current prevents attack of an aluminum specimen, indicating that the initial attack is caused by the presence of an ionic species. Trace amounts of the reaction product hexachloroethane were produced electrochemically in the absence of any aluminum.

Substances that retard the reaction apparently function by forming inactive complexes with the $AlCl_3$. The rate-determining step in the reaction does not appear to involve free radicals since the majority of the effective inhibitors failed to react with known free radicals.

It has been shown (1) that two of the products of the reaction between aluminum and carbon tetrachloride, are aluminum chloride and hexachloroethane. Evidence was also obtained for the presence of high molecular weight carbon-chlorine compounds soluble in carbon tetrachloride and high molecular weight carbon, chlorine, and aluminum compounds which were insoluble in carbon tetrachloride.

A rather critical temperature dependence can be shown for this reaction, ranging from rapid reaction at the boiling point to negligible reaction in eighteen months at room temperature.

The presence of the reaction products accelerates the reaction because of the presence of aluminum chloride. Hexachloroethane has no effect on the reaction. The aluminum chloride acts as a reaction accelerator probably through the formation of complexes with the carbon tetrachloride.

Chemical agents that act as retarders do so by reaction with the aluminum chloride as it is produced. This was demonstrated by quantitatively removing the aluminum chloride from a corrosive boiling carbon tetrachloride solution and rendering it noncorrosive in the process.

A number of classes of retarding agents were discovered on the basis of known or projected reactivity with aluminum chloride. Some of these were acid anhydrides, amines, esters, heterocyclic compounds, halogenated hydrocarbons (which can complex aluminum chloride), ketones, olefins, and chelating agents in general. Retardation was also secured with a number of hydrated inorganic nitrates and sulfides for less definitive reasons.

Reaction of aluminum alloys in boiling carbon tetrachloride drops off rapidly with increasing magnesium content. Magnesium metal or magnesium chloride has no significant effect on this reaction.

Studies of Conductivity

High-purity (99.99%) aluminum is attacked severely in boiling carbon tetrachloride but is resistant to carbon tetrachloride at room temperature. Since the conductivity of carbon tetrachloride is much higher at the boiling point than at room temperature, it was thought that a relationship might exist beween conductivity and corrosion.

The apparatus shown in Fig. 1 was used to measure conductivity. As shown in Fig. 2, the conductivity increased steadily for about 5 hr after aluminum specimens were immersed in boiling carbon tetrachloride, indicating that the conductivity increased as the corrosion products increased. On the basis of weight loss measurements, there would appear to be an induction period of about 1 hr; however, the more sensitive conductivity measurements show that the reaction starts soon after the aluminum is placed in the boiling carbon tetrachloride (see also Fig. 11). Since aluminum chloride and hexachloroethane were identified as two of

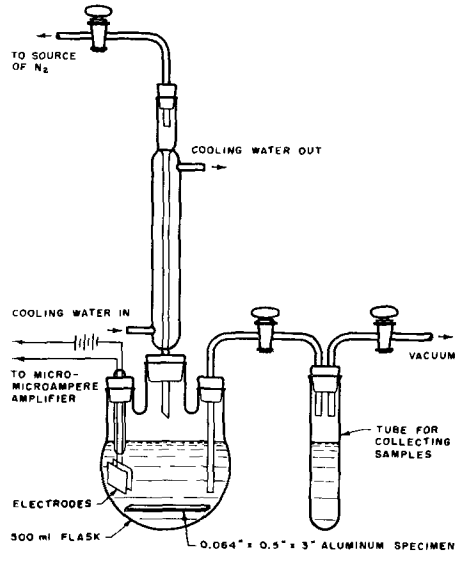

Fig. 1. Apparatus used for measuring conductivity and removing samples simultaneously.

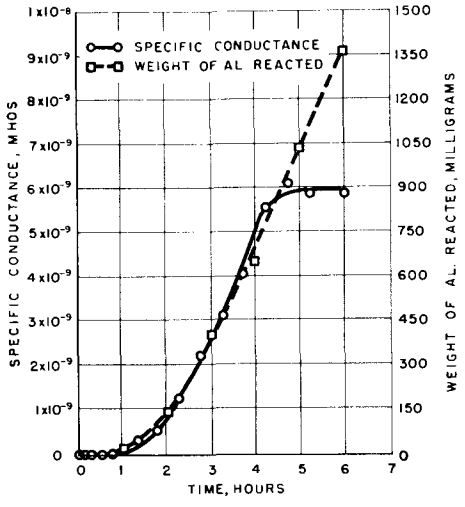

Fig. 2. Plot of specific conductance and weight of aluminum reacted vs. time.

the corrosion products, these compounds were added singly to determine the effect of each compound on conductivity. As shown in Fig. 3, aluminum chloride had a marked effect. The conductivity increased rapidly during the first 20 min and then leveled off. The reaction resulting when an aluminum specimen was added after the conductivity leveled off, caused the conductivity to rise to a value about ten times that of carbon tetrachloride saturated with aluminum chloride, indicating that additional ionized complexes are formed. No significant change in conductivity occurred when hexachloroethane was added to boiling carbon tetrachloride.

In another experiment, samples of solutions were withdrawn periodically and analyzed for aluminum at the same time as conductivity measurements were being made on the solution remaining in the flask. The results are shown in Table I and Fig. 2. The data show that the increase of conductivity and weight of aluminum reacted in the carbon tetrachloride roughly parallel each other in the first 4.5 hr. In Fig. 4,[1] a comparison of the curves of conductivity and total aluminum reacted shows that the aluminum reacted increases linearly with specific conductivity up to 5×10^{-9} mhos. The specific conductivity reaches a limiting value of about 6×10^{-9} mhos while the total aluminum reacted continues to increase. It can be seen in Fig. 5[2] that the reaction rate increases with increasing specific conductivity and levels off as the specific conductivity approaches 6×10^{-9} mhos. As shown in Fig. 6, the reaction rate increases with time up to 4 hr, where it reaches a constant value. As can be seen in Fig. 2, the specific conductance also reaches a limiting value after about 4 hr. These results which indicate a relationship between the reaction rate and specific conductivity suggest that ions may be involved in the reaction.

The conductance of a solution is proportional to the mobility and number of ions in the solution. The

[1] Figure 4 was plotted by taking points from the two curves on Fig. 2 for the same time, and plotting the points against each other.

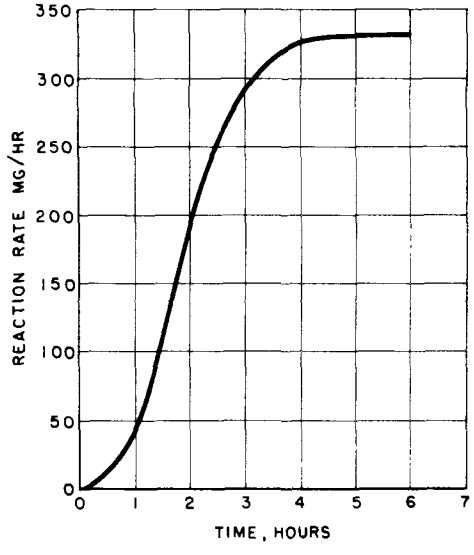

Fig. 6. Plot of reaction rate vs. time

slope of the line from a plot of log specific conductance vs. $1/T$ is the temperature coefficient. The smaller the temperature coefficient the greater the number of ions in a given solution. The relationship can be demonstrated by comparing the temperature coefficients for distilled water and the more highly ionized 0.01M KCl solution. The temperature coefficients are —0.208 for distilled water and —0.084 for 0.01M aqueous potassium chloride solution (2).

Figure 7 shows the effect on the temperature coefficient of carbon tetrachloride due to addition of aluminum chloride or corrosion products from the aluminum-carbon tetrachloride reaction. These results show that the addition of aluminum chloride to carbon tetrachloride decreases the temperature coefficient, indicating that the addition of aluminum chloride increases the number of ions. The presence of aluminum corrosion products further decreases the temperature coefficient indicating an additional increase in the number of ions. These results also suggest that an ionic mechanism may be involved.

The increase in conductivity with time that accompanies the reaction between aluminum and carbon tetrachloride is observed in other corrosion reactions occurring in aqueous solutions. Since conductance in solution depends on the presence of ions, this indicates that this reaction may proceed by

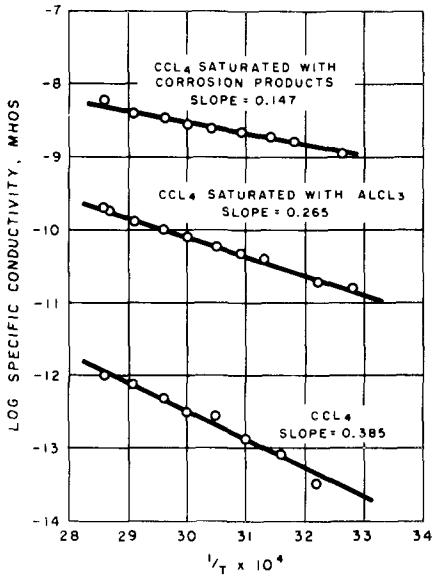

Fig. 7. Temperature coefficients for CCl_4 and CCl_4 saturated with $AlCl_3$ and corrosion products.

an electrochemical mechanism involving oxidation and reduction (3). For these reasons, electrochemical relationships that might be involved were further investigated. For example, if it could be shown that the reaction with carbon tetrachloride could be prevented by cathodically protecting the aluminum, this would support an electrochemical mechanism. However, it should be pointed out that the inability to protect the aluminum cathodically would not be sufficient to disprove such a mechanism. A reduction or an increase in the corrosion rate caused by the coupling to dissimilar metals or by an applied current would lend support to an ionic mechanism.

Effect of Galvanic Corrosion

A sample of high-purity sheet aluminum (99.99% Al) was coupled to a mild steel sheet specimen in boiling carbon tetrachloride. The electrodes were 1 in. apart. The exposed area of each specimen was approximately 3 in.^{2} and the initial galvanic current between the specimens was 2×10^{-11} amp. When the boiling carbon tetrachloride was saturated with aluminum chloride, in order to increase the conductance, the galvanic current increased over a 15-min period and leveled off at a value of 10×10^{-9} amp. During this time, the solution darkened, and the aluminum specimen became coated with corrosion product, while the steel specimen remained clean. The evidence of a current flow as a result of bimetallic coupling further indicated the analogy with similar reactions occurring in aqueous solutions. The fact that Stern and Uhlig (4) were unable to notice an increased weight loss effect from bimetallic coupling based on a 6-hr test in carbon tetrachloride is understandable in view of the very high solution resistance encountered between electrodes. The corrosion of aluminum in carbon tetrachloride could proceed by an electrochemical mechanism to give high corrosion rates if the local anodes and cathodes on the surface of the aluminum are only a few angstroms apart. This proximity of anode and cathode would enable the reaction to proceed at relatively

rapid rates even though the resistance of the solution were high.

Observations with an Applied Potential

Based on results with galvanic couples one would expect an externally applied current to protect an aluminum specimen cathodically in boiling carbon tetrachloride. To study the effects of an applied cathodic and anodic current on an aluminum specimen in carbon tetrachloride, a rather high emf source is required to overcome the resistance of the carbon tetrachloride. For the following experiment a potential source of 200 v d.c. was used.

To prevent attack on the portions of the electrodes in the vapor phase, the possibility of a coating resistant to boiling carbon tetrachloride and its vapors was investigated. It was found that an anodic coating (Alumilite[3] 204) prevented attack except at the edges of an aluminum sheet. By using round rods with rounded ends it was found that these anodic coatings almost completely retarded the attack. Round rods 99.99% Al, ¼ in. in diameter with rounded ends, were given Alumilite 204 treatment except for a band ½ in. long located ¼ in. from the end of the rod.

When an external potential was applied across two round aluminum rods (⅜ in. apart) of 99.99% Al in 400 cc of boiling carbon tetrachloride saturated with aluminum chloride, the corrosion of the cathode was slightly retarded, whereas the corrosion of the anode began almost immediately. A blank placed in the same solution clearly shows that the corrosion of the anode was accelerated and that of the cathode was slightly retarded (Fig. 8). Initially the current passing between the two electrodes was 10 x 10^{-8} amp. After about 200 min the rate of attack of the cathode increased and approached that of the anode. The current at this point increased to 110 x 10^{-8} amp. This increase in current was caused by an increase in solution conductivity because of the presence of aluminum corrosion products. At this point the solution was rather dark and the attack of both specimens was caused largely by local action rather than by the applied current. At the time the experiment was discontinued the current through the solution was 200 x 10^{-8} amp. This increase in current with a constant applied potential parallels the increase in conductivity which accompanies the corrosion of aluminum in boiling carbon tetrachloride.

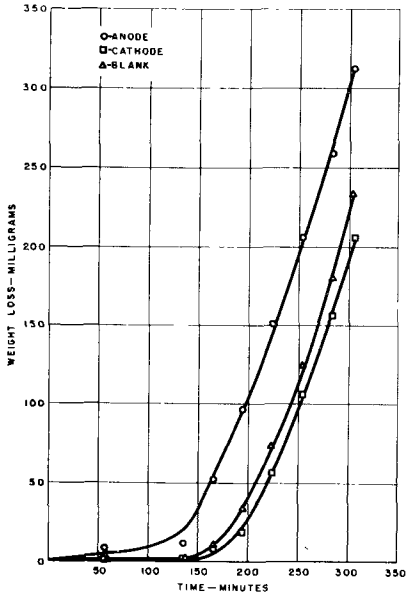

Fig. 8. Effect of an applied potential on aluminum rods in boiling carbon tetrachloride saturated with aluminum chloride.

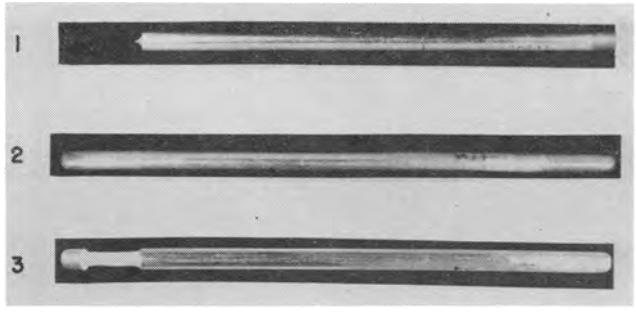

Fig. 9. Cathodic protection of aluminum in carbon tetrachloride: 1, An aluminum rod suspended in boiling carbon tetrachloride for four days (no cathodic current applied); 2, an aluminum rod suspended in boiling carbon tetrachloride for 28 days, with an applied cathodic current of 5 x 10^{-9} amperes. This specimen was completely protected; 3, The cathodically protected specimen 48 hr after the applied cathodic current had been removed.

In view of the above results, an experiment was devised to determine whether a specimen could be protected cathodically in boiling carbon tetrachloride. When an aluminum rod was suspended in boiling carbon tetrachloride, the unanodized portion completely reacted within four days, although the attack did not begin until about the third day (Fig. 9). This increase in induction time indicated the significance of eliminating corners and rough edges from the specimens.

When a potential of 220 v was applied across the aluminum rod and a cylindrical platinum gauze (the aluminum being the cathode), no attack of the aluminum specimens by boiling carbon tetrachloride was observed after 28 days (Fig. 9). The average current between the electrodes was 5 x 10^{-9} amp. This current was relatively constant over the 28-day time interval.

When the applied potential was removed, the corrosion of the aluminum began within 30 hr; in 48 hr the attack was severe (Fig. 9). This experiment was then repeated with lower currents and shorter periods of observation. The results indicate that cathodic protection was complete for the period of observation (Table II).

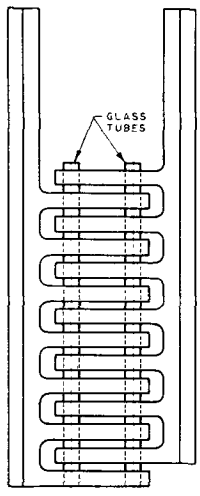

Fig. 10. Schematic diagram of corbon electrodes used for electrochemical production of hexachloroethane from carbon tetrachloride.

In the case of (*b*) and (*e*) (Table II), when the current was removed after the time of observation, corrosion began within 24 and 30 hr, respectively. All these results are indicative of an electrochemical mechanism for the attack of aluminum by carbon tetrachloride.

It was not possible to protect cathodically an aluminum rod in carbon tetrachloride saturated with aluminum chloride at the reflux temperature. It was estimated from the rate of attack of an aluminum specimen in this solution that a current density of at least 50 ma/cm^2 would be required to prevent attack of the aluminum. With the high resistance of the solution, such a current could be obtained only with excessively high applied potentials.

Thus, the reaction in carbon tetrachloride can be prevented for an indefinite period by cathodically protecting the aluminum with an applied potential. Therefore, it is concluded that the initial attack of the aluminum is caused by the presence of an ionic species.

During the corrosion of an aluminum specimen in boiling carbon tetrachloride, the energy supplied by the oxidation of the aluminum produces hexachloroethane as a reduction product. If reduction of the carbon tetrachloride to hexachloroethane can be produced in the absence of metallic aluminum by means of an applied potential, this fact would lend support to an electrochemical mechanism.

Graphite electrodes were constructed (Fig. 10) to give a large surface area and a small distance between anode and cathode. Each electrode consisted of seven plates (3 x 1¾ x ¼ in.) placed ½ in. apart. The electrodes were then placed so that the distance between each plate was about ⅛ in. Platinum was used to connect the electrode to the potential source.

Approximately 1 liter of carbon tetrachloride was added to the cell using aluminum chloride as the electrolyte. At a potential of 850 v the average current in the cell was 200 μa for a period of twelve days. At the end of the twelve-day period, the solution was filtered and the carbon tetrachloride evaporated on a water bath to a volume of about 50 cc. Because of the ease of sublimation of hexachloroethane, the remainder of the solution was evaporated at room temperature. The concentrated solution was yellow. When the solution was evaporated to dryness, an odor resembling hexachloroethane was detected in the residue (which also contained some aluminum chloride).

By means of infrared spectroscopy, hexachloroethane was detected, but special techniques were necessary. The hexachloroethane has two detectable absorption bands; one is rather weak while the stronger band is masked by carbon tetrachloride absorption. Because of the volatility of the product and its low yield, it was impossible to obtain a large enough sample to identify the weaker band of hexachloroethane. Consequently, the residue from the carbon tetrachloride evaporation was dissolved in spectral pure cyclohexane and submitted for analyses. Hexachloroethane was detected in this solution at the stronger wave length (12.77 μ). In an identical experiment in which there was no applied current, no hexachloroethane could be detected by the above procedure.

Relationship of Conductivity to Retarding Agents

Since the conductivity is markedly affected by the concentration of aluminum chloride in carbon tetrachloride solution, any factors that affect the aluminum chloride would also result in conductivity changes. Hence, the addition of retarding agents to colored carbon tetrachloride solutions containing anhydrous aluminum chloride should result in a subsequent drop of the conductivity to essentially the level of pure carbon tetrachloride (Fig. 11).

The results shown in Table III indicate that a good retarding agent can be generally predicted based on its ability to lower the conductivity of the corrosive carbon tetrachloride solution. Of all the retarding agents tested, only the addition of cyclohexene to the carbon tetrachloride-aluminum chloride solution failed to lower the conductivity by ap-

proximately a factor of ten or more. It should be pointed out that this particular agent was also considered least effective as a retarding agent when evaluated with a test specimen in a carbon tetrachloride solution initially saturated with anhydrous aluminum chloride. It can also be seen in Table III that the various retarding agents at 1% concentration have negligible effect on the conductivity of pure carbon tetrachloride. Accordingly, it is presumed that the conductivity changes are the result primarily of interaction of the colored ionized complex (between carbon tetrachloride and anhydrous aluminum chloride) and the retarding agent. It does not appear, however, that a direct proportional relationship exists between the ability of an agent to lower the conductivity a specific amount and its effectiveness as a retarding agent. For example, 8-hydroxyquinoline, 2,5 hexanedione, and phthalic anhydride are all highly effective retarding agents by actual test and do lower the conductivity of carbon tetrachloride-aluminum chloride solution but not to the same degree. For example these compounds lower the conductivity by factors of 20, 100, and 250, respectively.

One practical application of this relationship might be to follow the conductivity of a closed aluminum system containing inhibited carbon tetrachloride. A warning that the concentration of the retarding agent was inadequate would be indicated by a rise in conductivity. Addition of more retarding agent followed by a drop in the conductivity would mean the carbon tetrachloride was again adequately inhibited. Conceivably, this type of control could be exercised with other halogenated hydrocarbons where similar relationships between conductivity, aluminum chloride, and retarding agents might be established.

Discussion of Possible Alternate Free Radical Theory

As pointed out by Stern and Uhlig (5) several theoretical reasons indicate that the reaction may proceed by means of a free radical mechanism. It was concluded, therefore, that the reaction was initiated by free radicals whose formation accelerated with time until the rate of generation equaled the rate of destruction. This could be one of several possible explanations for the constant corrosion rate found for high-purity aluminum in carbon tetrachloride. However, an ionic mechanism would also be consistent with the observed data. In the following equilibrium,

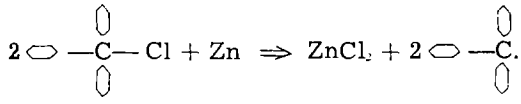
$$AlCl_3 + CCl_4 \rightleftharpoons (CCl_3)^+ + (AlCl_4)^-$$

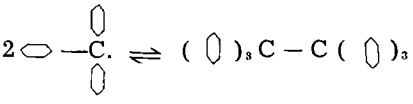
the concentration of the ionic species is so small that a steady-state condition would soon be obtained. In view of the complexity of the reaction, it would not be unreasonable to assume that some of the steps may involve free radicals. However, our data indicates that the rate-determining step is one involving an electrochemical mechanism.

Stern and Uhlig (5) have shown that certain free radical supressors are capable of retarding the aluminum-carbon tetrachloride reaction. If effective retarders do combine with free radicals, this would be another indication that the rate-controlling step is free radical in nature.

Tests for Free Radicals

The following experiments were carried out to determine whether or not free radicals are present in measurable quantities in boiling carbon tetrachloride. A solution of triphenylmethyl free radicals was prepared by dissolving 0.25 g triphenylchloromethane in 50 ml of benzene and adding 3 g of zinc filings and allowing the mixture to stand at room temperature for 6 hr in a sealed bottle. The presence of free triphenylmethyl radicals was indicated by the appearance of a yellowish-orange color. The free radicals form according to the reaction shown below:





The solution of free radicals in benzene was decanted and added to 50 ml of carbon tetrachloride and the mixture refluxed under nitrogen for 10 min. The color did not fade during this period. The solution was then divided into two portions. One portion was placed in a bottle and sealed to exclude air. The color of this solution did not fade. The other portion was poured into an open beaker. The color of this solution faded completely within a few minutes indicating that the color was caused by the presence of free radicals and that the free radicals were destroyed by reaction with oxygen when the solution was exposed to air. One of the properties of triarylmethyl free radicals is the rapid absorption of atmospheric oxygen to form colorless triarylmethyl peroxides (6). If appreciable amounts of free radicals were present in the boiling carbon tetrachloride, it would be expected that the free radicals would be removed by the following reactions causing the color of the solution to fade in a short time:

Another experiment was run in which 1 g of zinc filings, 50 ml of benzene and 50 ml of carbon tetrachloride were placed in a reflux flask and brought to the boiling point, 0.25 g of triphenylchloromethane was then added and the flask flushed with nitrogen. A dark yellow-orange color appeared in a short time. After refluxing for 10 min the solution was decanted and divided in two portions. One portion was sealed in a glass bottle and remained colored; the other portion was poured into an open beaker and became colorless within a few minutes. A blank was run in which 1 g of zinc filings, 50 ml of benzene, and 50 ml of carbon tetrachloride were refluxed for 30 min. This solution did not develop any color. The above results indicate that the rate of formation of free radicals from carbon tetrachloride was too low to prevent the formation of triphenylmethyl free radicals.

A number of the retarder materials investigated in this laboratory (1) as well as some mentioned by Stern and Uhlig (5) were tested for their ability to react with triphenylmethyl free radicals.

Some amines have already been mentioned as being reactive with aluminum chloride as well as carbon tetrachloride. The amine, 3-methoxypropylamine, does, in addition, react with triphenylmethyl free radicals almost as rapidly as the free radical reacts with air with the resultant solution becoming water clear. On the other hand, retarders containing carbonyl groups such as ethyl acetate, ethyl acetoacetate, 2,5-hexanedione, and phthalic anhydride which range from good to excellent as retarding agents do not react with solutions of this free radical species, and it is necessary to expose these solutions to air in order to decolorize them. Acetone was an exception to this rule.

Heterocyclic ring-type compound retarders such as thiophene did not react with the triphenylmethyl free radical. The olefin, cyclohexene, which is only a fair retarder for the carbon tetrachloride reaction, readily reacts with the colored free radical. The inorganic salt Al $(NO_3)_3 \cdot 9H_2O$, an effective retarder, can also decolorize the colored free radical solution.

Two of the free radical supressors mentioned by Stern and Uhlig (5), quinone and napthaquinone, could not be evaluated by this method since both materials give yellow colored solutions in benzene. However, nitrobenzene, another retarder mentioned by Stern and Uhlig, did react to the extent that small amounts of nitrobenzene lightened the deep yellow color of the free radical solution and air did not further lighten the color.

On the basis of the above results, it was concluded that the ability of a substance to react or not react with triphenylmethyl free radicals bears no relationship to its ability to retard the carbon tetrachloride-aluminum reaction. Therefore, the evidence indicates that the rate-determining step for this latter reaction is controlled largely by an electrochemical mechanism (7).

Results with Other Halogenated Hydrocarbons

This proposed electrochemical mechanism applies only to carbon tetrachloride and was not established for other halogenated hydrocarbons. High-purity aluminum specimens could not be cathodically protected in the case of the eight other halogenated hydrocarbons tested. From the initial high rates of attack, relatively high current densities would be required to achieve cathodic protection if the mechanism were electrochemical. These high current densities were not possible with the available equipment. The halogenated hydrocarbons were 2- chloro -2- methylbutane, 2-chloro -2- methylpropene, (1, 4-dichlorobutane), (1, 1, 2, 2- tetrachloroethane), α-chlorotoluene, methlychloroform, (1, 1, 2- trichloroethane), and 3- chloro -2- methylpropene. The inability to achieve cathodic protection in these cases

could be explained by (*a*) inability to achieve the minimum cathodic current required because of high solution resistance and limited emf source, or (*b*) the rate-controlling step being other than electrochemical.

Summary

1. Conductivity of a boiling carbon tetrachloride solution with high-purity aluminum present increases steadily as the reaction proceeds and after about 4-5 hr reaches a constant value.

2. Addition of hexachloroethane to boiling carbon tetrachloride has no effect on conductivity, but addition of aluminum chloride produces an immediate elevation of the conductivity. An additional elevation of the conductivity can be secured by reacting an aluminum specimen in this solution, suggesting that additional ionized complexes are formed.

3. Increase of conductivity in a corroding solution parallels the increase in weight per cent aluminum in solution which occurs as the reaction proceeds. However, the more sensitive conductivity measurements show that the reaction starts soon after the aluminum is placed in the boiling carbon tetrachloride; hence the induction period referred to in previous literature reports is only an "apparent induction time."

4. The fact that the reaction rate increases with increasing conductivity suggests an electrochemical mechanism. Changes in the temperature coefficient of the conductivity in the presence and absence of corrosion products also suggests this type of mechanism.

5. Cathodic protection successfully prevented the corrosion of high-purity aluminum in boiling carbon tetrachloride. This also supports an electrochemical mechanism since it must be concluded that the initial attack of the aluminum is caused by the presence of an ionic species.

6. Additional evidence for an electrochemical mechanism was obtained by producing an identifiable amount of hexachloroethane (a primary reaction product) by electrolysis of a carbon tetrachloride solution saturated with aluminum chloride.

7. The addition of retarding agents resulted in an alteration of the ionized aluminum chloride-carbon tetrachloride complex so that the conductivity dropped essentially to that of pure boiling carbon tetrachloride. There is no direct proportional relationship between the ability of an agent to lower the conductivity a specific amount and its effectiveness as a retarding agent. Following the pattern of conductivity in the carbon tetrachloride solution should, however, be indicative of the level of protection of a retarder agent added to the solution.

8. There was no apparent reaction between triphenylmethyl free radicals in benzene and boiling carbon tetrachloride, although a portion of the same solution reacted with the oxygen of the air. Similarly, triphenylmethyl free radicals could be made in the presence of boiling carbon tetrachloride, indicating that the rate of formation of free radicals in carbon tetrachloride, if present, was too low to prevent the formation of the triphenylmethyl free radicals by reaction.

9. Several of the retarder materials listed in previous publications were tested for their ability to react with triphenylmethyl free radicals. There was no relationship between the ability of a substance to retard this carbon tetrachloride-aluminum reaction and to react with triphenylmethyl free radicals.

Manuscript received Nov. 13, 1957. This paper was prepared for delivery before the Buffalo Meeting, Oct. 6-10, 1957.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Copper-Activated Calcium Orthophosphate and Related Phosphors

Yasuo Uehara, Yoshimasa Kobuke, and Isoo Masuda

Matsuda Research Laboratory, Tokyo Shibaura Electric Co., Ltd., Kawasaki, Japan

ABSTRACT

The preparation and properties of copper-activated calcium orthophosphate and related phosphors are described. Copper-activated β-calcium orthophosphate phosphor fired in a reducing atmosphere produces a strong blue fluorescence peaked at 4800Å under excitation by 2537Å and cathode rays. With partial substitution of Ca by bivalent metals such as Be, Cd, and Sr the emission remains unchanged, while introduction of Mg and Zn gives a strong violet fluorescence peaked at about 4400Å and 4500Å, respectively. Phosphors containing boron produce a blue to greenish yellow fluorescence depending on the content of boron. All of these phosphors give a strong thermoluminescence. Only the blue fluorescent phosphor gives also a weak red emission stimulated by 3650Å radiation. Introduction of Mn or Sn as secondary activators into Cu-activated β-calcium orthophosphate or into the Cu-activated substituted phosphors gives rise to a red band due to Mn or Sn in addition to the original blue or violet band. The luminescent properties of zinc or cadmium orthophosphate are similar in some respects to those of zinc or cadmium sulfide phosphors.

Calcium metaphosphate and halophosphate activated with Cu have been reported to produce a weak blue fluorescence (1). According to the present investigation, calcium orthophosphate with added Cu and fired in air shows practically no fluorescence at room temperature under excitation by 2537Å, 3650Å, and cathode rays. However, calcium orthophosphate containing Cu which was fired in a reducing atmosphere was found to give a strong blue fluorescence under excitation by 2537Å and cathode rays. This phosphor also shows a strong blue thermoluminescence and a weak red emission stimulated by 3650Å. The present paper describes the preparation and properties of Cu-activated calcium orthophosphate fired in a reducing atmosphere and related phosphors.

Preparation and Structure of Phosphors

Calcium orthophosphate phosphors were prepared from dibasic calcium phosphate ($CaHPO_4$) and calcium carbonate. These materials were prepared from purified solutions of dibasic ammonium phosphate, calcium chloride, and ammonium carbonate. A solution of purified copper sulfate was added to a mixture of 2 mole dibasic calcium phosphate and 0.9 mole calcium carbonate. The blend was dried at about 200°C, then milled to assure intimate mixture. It was fired in a silica tube in an electrically heated furnace for about 30 min at 1100°C in air. The air-cooled powder was reground and fired in a reducing atmosphere for about 30 min at 1100°C, then cooled in the same atmosphere. As the reducing gas, a mixture of 75% nitrogen and 25% hydrogen was used for the most part. If pure hydrogen was used as a reducing gas, the resulting powder showed a grayish color and low fluorescent efficiency due to excessive reduction.

Optimal concentration of the activator was about 5×10^{-3} g-atom Cu for 1 mole calcium orthophosphate. Any departure of the activator concentration from its optimal value leads to a rapid decrease of the fluorescent intensity under excitation by 2537Å at room temperature, as shown in Fig. 1.

In order to obtain the brightest phosphor, it is preferable to use an amount of calcium carbonate about 10 mole % less than that required for the stoichiometric composition, as shown above. Even in this case, it was verified by x-ray analysis that the resulting phosphor has the calcium orthophosphate structure. Copper-activated calcium orthophosphate fired above about 1200°C in the same atmosphere shows only a weak blue fluorescence under excitation by 2537Å and cathode rays at room temperature, in contrast with the phosphor fired below about 1200°C. It was also verified by x-ray analysis that the former had α-form structure and the latter had β-form structure.

With partial substitution of bivalent metals such as Be, Mg, Zn, Cd, and Sr for Ca in the Cu-activated β-calcium orthophosphate, similarly efficient phosphors can be obtained. However, substitution of about 7 mole % Ca by Ba results in a weakly purple fluorescent phosphor. Phosphors containing Mn or Sn as secondary activators were prepared by

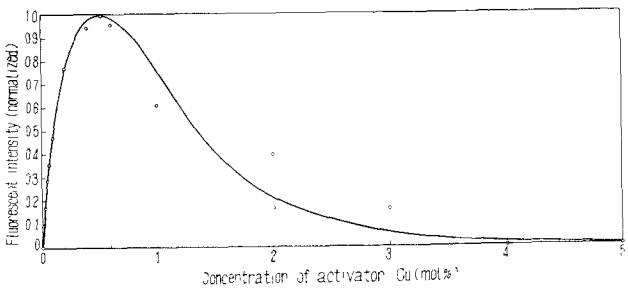

Fig. 1. Relative fluorescent intensity vs. activator concentration of Cu-activated β-calcium orthophosphate phosphors fired in a reducing atmosphere. Excitation with 2537Å at room temperature.

the same method as Cu-activated β-calcium orthophosphate.

Measurement Techniques

The spectral energy distribution of the phosphor excited by 2537Å was measured with a Zeiss three glass prism spectrograph which was equipped with an exit slit and a photomultiplier. This allowed its use as a constant deviation type monochrometer whose resolving power corresponded to a single 60° prism having 21-cm base length. The spectral sensitivity of this optical system was calibrated by use of a standard lamp.

In order to investigate the absorption characteristics of the phosphor, the spectral reflectance of a phosphor layer of about 2-mm thickness was measured relative to that of a plaque of smoked magnesium oxide whose spectral reflectance was measured previously. The spectral range from about 2300Å to the visible part of the spectrum was covered. This measurement was carried out with a Beckmann-type monochrometer combined with a photomultiplier. As a light source a low pressure hydrogen lamp was used. The arrangement of the optical system was similar to that reported by Botden and Kröger (2). In the measurement of the spectral reflectance, various cut-off filters were used to eliminate the fluorescent radiation from the reflected light. Using this apparatus, the quantum efficiency of fluorescence also was measured. The detailed method of the measurement and measured results for various phosphors, except some typical phosphors which are described below, will be published elsewhere.

Decay characteristics of Cu-activated β-calcium orthophosphate excited by cathode rays at room temperature were measured with a demountable cathode ray tube. The phosphor was placed as a uniform layer of powder in a shallow, nickel plated brass cup. A square wave of voltage from a Hewlett Packard 212A pulse generator was fed to the grid of the electron gun of the cathode-ray tube. The pulse width and frequency of excitation were variable. The emitted light was received by a RCA 1P21 photomultiplier through a glass window of the cathode-ray tube. Its output was fed to the vertical amplifier of a Tektronix 545 oscilloscope.

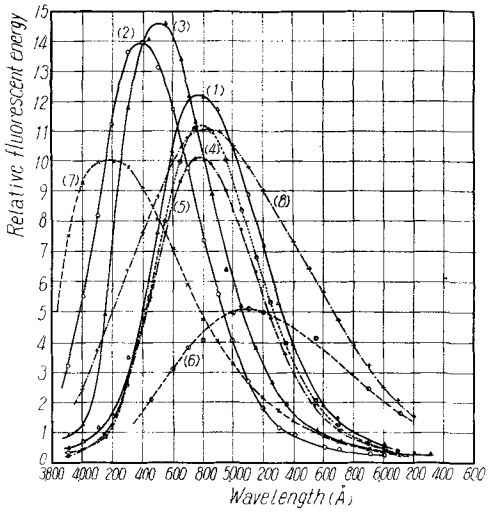

Fig. 2. Spectral energy distribution of Cu-activated calcium orthophosphate and substituted orthophosphates fired in reducing atmospheres, in comparison with tungstate phosphors. All phosphors excited with the same intensity of 2537Å at room temperature. Curve 1, 2.9 CaO · P_2O_5: 5 x 10^{-3} Cu; curve 2, 2.5 CaO · 0.4 MgO · P_2O_5 x 10^{-3} Cu; curve 3, 2.7 CaO · 0.2 ZnO · P_2O_5:5 x 10^{-3} Cu; curve 4, 2.7 CaO · 0.2 CdO · P_2O_5 x 10^{-3} Cu; curve 5, 2.7 CaO · 0.2 SrO · P_2O_5 x 10^{-3} Cu; curve 6, 2.9 CaO · 0.15 B_2O_3 · P_2O_5 x 10^{-3} Cu; curve 7, $CaWO_4$; curve 8, $MgWO_4$.

The decay characteristics of the persistent phosphorescence with 2537Å excitation at 297°-298°K were measured with a Brown Electronik Recording Electrometer in combination with a photomultiplier. Periods of constant excitation by 2537Å varied from 10 sec to 6 hr. Curves of the decay characteristics were recorded with the recording electrometer for periods of time from 1 to 100 min after the end of excitation.

The buildup and decay characteristics of thermoluminescence with a thin layer of the phosphor which was excited by 2537Å at about 280°K and then heated at about 465°K were measured by using the recording electrometer combined with a photomultiplier. However, the rate of buildup of thermoluminescence was too fast to be measured accurately by this method, and only the rate of decay could be determined.

Phosphor Characteristics

Emission under excitation by 2537Å, 3650Å, and cathode rays.—Cu-activated β-calcium orthophosphate fired in a reducing atmosphere shows a strong blue fluorescence peaked at 4800Å under excitation by 2537Å and cathode rays, while with 3650Å excitation it produces only an extremely weak blue fluorescence at room temperature. The spectral energy distribution of this phosphor excited by 2537Å at room temperature is shown by curve 1 in Fig. 2, compared with that of calcium tungstate (curve 7) and magnesium tungstate (curve 8). All the curves shown in Fig. 2 were obtained under conditions of constant 2537Å intensity and identical geometry of the optical system.

Cu-activated β-calcium orthophosphate fired in air shows practically no fluorescence at room or low temperature under excitation by 2537Å, 3650Å, and cathode rays, as mentioned before, but it produces a very weak blue fluorescence at temperatures higher than about 500°K with 2537Å excitation. Cu-activated α-calcium orthophosphate fired in a reducing atmosphere shows only a weak blue fluorescence under excitation by 2537Å and cathode rays at room temperature, as mentioned before. Therefore, only Cu-activated β-calcium orthophosphate fired in a reducing atmosphere can give an efficient fluorescence.

Partial substitution of Be, Cd, and Sr for Ca in Cu-activated β-calcium orthophosphate fired in a reducing atmosphere has very little effect on the intensity and color of fluorescence. The substituted orthophosphate phosphors containing 0.2 g-atoms of the bivalent metals mentioned above still produce a fairly strong fluorescence, but as the amount of bivalent metals is further increased, the intensity of the fluorescence gradually decreases. The spectral energy distribution curves of the substituted

phosphors containing 0.2 g-atoms of Cd and Sr are shown by curves 4 and 5 in Fig. 2.

Partial substitution of Mg and Zn for Ca in Cu-activated β-calcium orthophosphate shifts the peak of emission toward shorter wave lengths and increases the efficiency of fluorescence. The peak position of the substituted phosphors containing 0.4 g-atoms of Mg and 0.2 g-atoms of Zn are 4400Å and 4500Å, respectively, as shown by curves 2 and 3 in Fig. 2. The band widths of the phosphors mentioned above are very narrow compared with that of calcium or magnesium tungstate. Fluorescent lamps made with these phosphors show a very saturated blue or violet color and the average output in 20-w fluorescent lamps made with Cu-activated β-calcium orthophosphate was 370 lumens at 100 hr.

If boron compounds such as ammonium borate or boric oxide are introduced into Cu-activated β-calcium orthophosphate in amounts of 0.1 mole, the color of fluorescence is practically identical with that of the original phosphor, but as the amount of boric oxide is further increased, the color of the fluorescence shifts gradually from blue to green and finally to greenish yellow with about 0.4 mole of boric oxide. Besides, the intensity of the fluorescence is lowered as the amount of boric oxide is increased. The phosphor containing about 0.15 mole of boric oxide gives a very broad band peaked at 5100Å, as shown by curve 6 in Fig. 2.

Copper-activated orthophosphates of Be, Mg, Sr, and Ba which were prepared by firing at 850°-950°C in air for 30 min and then in a reducing gas for 30 min show essentially no fluorescence under excitation by 2537Å, 3650Å, and cathode rays at any temperature ranging from room to liquid air temperature. However, Cu-activated zinc orthophosphate fired in a reducing atmosphere at 850°C gives a green fluorescence of moderate intensity at room temperature with 3650Å excitation and a very weak green fluorescence with 2537Å excitation, but not with cathode ray excitation. At liquid air temperature, the fluorescence increases in intensity without change of color. Pure zinc orthophosphate without added activator and fired in a reducing atmosphere at 800°C, also produces a weak green emission peaked at 5000Å at room temperature but only with 3650Å excitation. At liquid air temperature, it shows a green fluorescence of moderate intensity under excitation by both 3650Å and 2537Å.

Copper-activated cadmium orthophosphate fired in a reducing atmosphere at 850°-900°C gives a weak orange fluorescence at liquid air temperature only with 2537Å excitation, but it does not fluoresce at room temperature under excitation by either 2537Å, 3650Å, or cathode rays. However, pure cadmium orthophosphate without added impurities and fired at 900°C in a reducing atmosphere or in nitrogen gives a weak whitish yellow fluorescence at room temperature with 2537Å excitation. At liquid air temperature, the fluorescence increases in intensity. Pure cadmium orthophosphate fired in air at 850°C for 30 min shows a weak whitish yellow fluorescence at liquid air temperature under excitation by 2537Å and 3650Å. At room temperature, it shows no fluorescence under excitation by 2537Å, 3650Å, and cathode rays.

Introduction of Mn, in addition to Cu, into β-calcium orthophosphate fired in a reducing atmosphere produces a whitish purple fluorescence which consists of a blue band and a sensitized red band. Calcium orthophosphate doubly activated with Cu and Sn and fired in a reducing atmosphere produces a blue to whitish red fluorescence depending on the Sn concentration. With partial substitution of Mg and Zn for Ca in β-calcium orthophosphate containing Mn or Sn, in addition to Cu, the peaks of the red band due to Mn or Sn, as well as that of the blue or violet band due to Cu, are shifted toward shorter wave lengths. As a typical example, the spectral energy distribution of β-calcium orthophosphate doubly activated with Cu and Sn, calcium magnesium orthophosphate containing 0.2 g-atoms of Mg and 2.7 g-atoms of Ca and doubly activated with Cu and Sn, and calcium orthophosphate doubly activated with Cu and Mn are shown by curves 1, 2, and 3 in Fig. 3. These curves were obtained under the same conditions as those for Fig. 2 and the ordinate scale is the same as that of Fig. 2.

The peak positions of the red bands of β-calcium orthophosphate doubly activated with Cu and Sn, and with Cu and Mn are about 6300Å and 6600Å, respectively, as seen in Fig. 3, and they are in good agreement with those of the corresponding bands of β-calcium orthophosphate activated with Sn alone and with Sn and Mn which have already been reported by Butler (3).

As clearly seen in Fig. 2, the peak intensity of calcium orthophosphate, calcium·magnesium orthophosphate, and calcium·zinc orthophosphate activated with Cu is larger than that of calcium or magnesium tungstate. The measured quantum efficiency of fluorescence of Cu-activated calcium·magnesium orthophosphate and calcium orthophosphate was about 0.9 and 0.8, respectively, with 2537Å excitation at room temperature. Considering a rather large absorption of the phosphors in the visible part of the spectrum, a correction for absorption loss must be made in order to evaluate the intrinsic quantum efficiency of fluorescence. Ac-

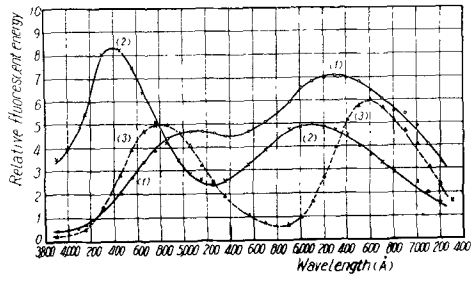

Fig. 3. Spectral energy distribution of orthophosphates doubly activated with Cu and Sn or Mn and fired in reducing atmospheres. All phosphors excited with the same intensity of 2537Å at room temperature. Curve 1, 2.9 CaO · P_2O_5:5 × 10^{-3} Cu + 5 × 10^{-3} Sn; curve 2, 2.7 CaO · 0.2 MgO · P_2O_5 × 10^{-3} Cu + 5 × 10^{-3} Sn; curve 3, 2.9 CaO · P_2O_5:5 × 10^{-3} Cu + 3 × 10^{-2} Mn.

cording to Bril and Klasens (4), the intrinsic quantum efficiency of fluorescence, νi, is given by

$$\nu i = \frac{2}{1 + R\infty}\,\nu m,$$

where νm is the measured quantum efficiency of fluorescence and $R\infty$ is the reflectance of the phosphor layer having practically infinite thickness. Since the value of $R\infty$ for both Cu-activated calcium·magnesium orthophosphate and calcium·orthophosphate was about 0.8 over the wide range of the visible part of the spectrum, a value close to unity was obtained for the intrinsic quantum efficiency of Cu-activated calcium·magnesium orthophosphate with 2537Å excitation at room temperature. The intrinsic quantum efficiency of Cu-activated β-calcium orthophosphate evaluated by the same method was about 0.9 with 2537Å excitation at room temperature, and a value of about 0.1 with 3650Å excitation at about 600°K was estimated.

Temperature dependence of fluorescent intensity.—The temperature dependence of fluorescent intensity of a typical β-calcium orthophosphate activated with 0.5 mole % Cu and fired in a reducing atmosphere is shown in Fig. 4. Curves 1 and 2 were obtained under excitation by 2537Å and 3650Å, respectively, and show a remarkable difference in behavior.

Although the emission peak of Cu-activated calcium orthophosphate shifts slightly toward shorter wave lengths at temperatures higher than room temperature, the effect of variation of the peak position on the measured intensity of fluorescence at higher temperatures will be small. Since the intensity of exciting radiation used in this measurement is rather weak, the intensity of fluorescence at various temperatures will be proportional to the quantum efficiency of fluorescence at the corresponding temperatures. The units of the ordinate in Fig. 4 are given so that the curves shown in this diagram express the temperature dependence of the intrinsic quantum efficiency of fluorescence.

The temperature dependence curves of fluorescent intensity of the Cu-activated phosphors substituted with Be, Mg, Zn, Cd, and Sr were similar to that of Cu-activated β-calcium orthophosphate.

Absorption.—The reflection spectra of typical phosphors measured at room temperature are

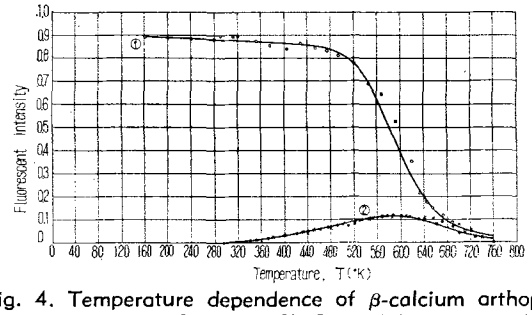

Fig. 4. Temperature dependence of β-calcium orthophosphate activated with 0.5 mole % Cu and fired in a reducing atmosphere. (Ordinate is equivalent to the intrinsic quantum efficiency of fluorescence). Curve 1, 2537Å excitation; curve 2, 3650Å excitation.

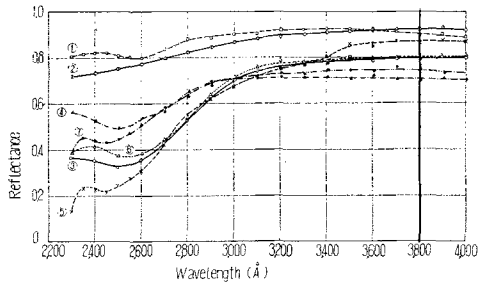

Fig. 5. Reflection spectra of pure and Cu-activated calcium orthophosphates and related phosphors at room temperature. Curve 1, β—2.9 CaO · P_2O_5 fired in a reducing atmosphere; curve 2, β—2.9 CaO · P_2O_5 fired in air; curve 3, β—2.9 CaO · P_2O_5:5 x 10^{-3} Cu fired in a reducing atmosphere; curve 4, α—2.9 CaO · P_2O_5:5 x 10^{-3} Cu fired in a reducing atmosphere; curve 5, β—2.9 CaO · P_2O_5:5 x 10^{-3} Cu fired in air; curve 6, β—2.5 CaO · 0.4 MgO · P_2O_5:5 x 10^{-3} Cu fired in a reducing atmosphere; curve 7, β—2.9 CaO · 0.15 B_2O_3 · P_2O_5:5 x 10^{-3} Cu fired in a reducing atmosphere.

illustrated in Fig. 5. Pure calcium orthophosphates fired in air or in a reducing atmosphere give rather flat reflection curves throughout the measured range of the spectrum, as shown by curves 1 and 2 in Fig. 5.

Copper-activated β-calcium orthophosphate fired in a reducing atmosphere gives a pronounced absorption band ranging from about 3100Å down to the short wave-length region of the spectrum and peaking at about 2550Å, as shown by curve 3 in Fig. 5. The reflection spectra of this phosphor measured at higher temperatures were practically identical with curve 3 in Fig. 5. Therefore, the temperature dependence of fluorescent intensity shown in Fig. 4 will be essentially independent of the absorption transition probability in the activator center.

The absorption of Cu-activated α-calcium orthophosphate shown by curve 4 in Fig. 5 is shallower than that of Cu-activated β-calcium orthophosphate in the shorter wave-length region below about 3000Å, but in the long wave-length region the situation is reverse. The shallowness of the absorption in the α-form, as well as the difference in structure, may be responsible for the low efficiency of its fluorescence. It is interesting that the absorption of Cu-activated β-calcium orthophosphate fired in air is stronger than that of the phosphor fired in a reducing atmosphere, at least in the shorter wave-length region below about 2700Å, as shown by curve 5 in Fig. 5. This fact, together with the temperature dependence of fluorescent intensity mentioned before, suggests that the trapping or quenching effect of this phosphor is much stronger than that of the phosphor fired in a reducing atmosphere.

The effect of the introduction of Mg or boron in Cu-activated calcium orthophosphate is shown by curves 6 and 7 in Fig. 5.

The measured reflection spectra of pure zinc orthophosphate and cadmium orthophosphate, which were prepared by firing in air or nitrogen, showed a flat and strong absorption with absorption edges at about 3900Å and 3200Å, respectively. The interesting fact was found that the characteristic ab-

sorption of these phosphors was decreased by the introduction of Cu or by firing in a reducing atmosphere. Detailed quantitative results will be published elsewhere.

The properties of zinc and cadmium orthophosphate phosphors, for example, absorption and emission characteristics, thus resemble those of zinc sulfide phosphors.

Although the detailed results of the reflection spectra of bivalent metal phosphates (except for a series of calcium orthophosphates) will be published elsewhere, it will be noted here that all curves of the reflection spectra of magnesium, strontium, and barium orthophosphate with added copper and fired in a reducing atmosphere were similar in shape to those of pure calcium orthophosphate (curves 1 and 2 in Fig. 5), but they were deeper in absorption. The average reflectance of these phosphors in the spectral region from 2300Å to 4000Å was about 0.7, 0.65, and 0.55, respectively. The detailed hue of color of these powders depends on the nature of the matrix. The natural color of the magnesium, strontium, and barium orthophosphates is reddish, grayish, and reddish, respectively.

Decay characteristics of phosphorescence.—The measured decay characteristics of the phosphorescence of Cu-activated β-calcium orthophosphate were of a monomolecular type under excitation by both 2537Å and cathode rays. The measured decay constants of this phosphor were 0.13 μsec for a fast component of afterglow and 1.6 μsec for a slow component under excitation by cathode rays of about 5 kv and 0.07 μsec pulse width at room temperature.

The measured decay constants for the components of the persistent phosphorescence with 2537Å excitation were 3.87 hr, 24.6 min, 4.13 min, and 0.931 min at 297°-298°K and their relative light sums were 100, 19.7, 6.9, and 3.9, respectively. The intensity of the persistent phosphorescence is extremely weak and the initial intensity of the most persistent component of the phosphorescence was of the order of 10^{-4} compared with the fluorescent intensity at about 300°K. The color of the phosphorescent light was identical with that of the fluorescent light.

Thermoluminescence.—Copper-activated β-calcium orthophosphate fired in a reducing atmosphere shows a strong blue thermoluminescence when it is heated after a previous exposure to 2537Å radiation for more than 10 min, and even after storage in the dark for times longer than about 10 hr at about 280°K. The intensity of thermoluminescence is dependent on the intensity of 2537Å, time of exposure to 2537Å, and temperature during excitation as well as the heating temperature. When the excitation by 2537Å is made at low temperature such as liquid air temperature or at higher temperatures than about 500°K, the phosphor shows no thermoluminescence. The brightest thermoluminescence was obtained after excitation by 2537Å at about 280°K. The phosphor excited with 3650Å showed no thermoluminescence.

The decay characteristics of thermoluminescence at a constant heating temperature were exponential. The decay constant of thermoluminescence measured at 465°K was about 10 sec. The rise time was very fast compared with the decay time. The characteristics of thermoluminescence of Cu-activated orthophosphate phosphors containing Be, Mg, Zn, Cd, Sr, and boron are similar to those of Cu-activated β-calcium orthophosphate, and only detailed behaviors are dependent on the amount of the added elements.

Stimulation by 3650Å radiation.—When Cu-activated β-calcium orthophosphate fired in a reducing atmosphere was first excited to saturation with 2537Å and then irradiated with 3650Å, it produced a weak red emission. The peak of the red emission was judged to be in the spectral range from 6000Å to 6500Å, according to visual inspection. The intensity of the red emission depended on the duration and intensity of the 2537Å excitation and on the intensity of the 3650Å radiation, but it was insensitive to the time of storage after exposure to 2537Å radiation as well as thermoluminescence. Indeed, we could observe the red emission after more than 10 hr following the excitation at about 280°K. This duration time for the stimulated red emission together with the thermoluminescence is of the same order as that of the most persistent component of the phosphorescence, whose decay constant is 3.87 hr at about 298°K. The red emission showed a very fast rise time, but its decay time was as long as minutes under stimulation by 3650Å of moderate intensity at room temperature. The brightest red emission was observed under excitation by 2537Å at about 280°K.

The blue fluorescent orthophosphate phosphors containing Be, Cd, Sr, or boron also gave the stimulated red emission, but the violet fluorescent orthophosphate phosphors containing Mg or Zn did not produce the red emission at all over a wide range of temperatures at which excitation was made with 2537Å.

In order to investigate the effect of impurities on the stimulation, a number of compounds of elements were added in the preparation of Cu-activated β-calcium orthophosphate. Introduction of about 0.01 mole of compounds of Ce, Zr, Mo, Ni, Se, V, Cr, Au, U, Co, Sn, and Mn per mole of Cu-activated β-calcium orthophosphate suppressed the red emission. On the other hand, introduction of K, Na, As, and boron compounds enhanced the red emission. However, if the amount of these added impurities except boron exceeded about 0.1 mole per mole of the matrix, the red emission was also suppressed completely.

Discussion

Although the properties of the phosphors here described are more complicated than those of the usual oxide-type phosphors, it does not seem to be difficult to give a straightforward theoretical interpretation, at least qualitatively. Quantitative explantations have already been formulated by one (6) of the present authors, and detailed results will be published in the near future. Therefore, only a qualitative discussion for the observed results is given here.

It is reasonable to suppose that the activator of Cu-activated β-calcium orthophosphate fired in a reducing atmosphere is different from that of the phosphor fired in air, because their respective characteristics of emission and absorption are quite different. Considering the firing process, it is natural to assume that the activator center of the phosphor fired in air may be formed by a Cu^{++}ion, while that of the phosphor fired in a reducing atmosphere may be ascribed to a Cu^{+}ion. Indeed no paramagnetic resonance absorption was detected in Cu-activated β-calcium orthophosphate fired in a reducing atmosphere.[1] The grayish color of the phosphor prepared by firing in pure hydrogen may be attributed to colloidal copper formed through a process of reduction from Cu^{+} ion to Cu atom as may be understood from the following consideration. Referring to the color of the magnesium, strontium, and barium orthophosphates mentioned before, we assume that the copper added to these phosphates is dispersed uniformly in the matrix in the form of neutral atoms, and we can then expect a pronounced characteristic absorption due to the Cu atoms in the near u.v. or visible region of the spectrum which, however, is contrary to the observed results. Therefore, the natural color of these phosphates may be attributed to the colloidal copper dispersed in the matrix. For the same reason, the grayish color of Cu-activated calcium orthophosphate fired in pure hydrogen may be ascribed to the same origin, as mentioned before.

Referring to the position of the activator in Cu-activated calcium orthophosphate, and assuming that the activators occupy interstitial sites in the lattice, we cannot find any convincing reason why copper cannot be introduced into the matrix of magnesium, strontium, or barium phosphate as an effective activator. However, the experimental results mentioned above will be explained by assuming that the activator in Cu-activated calcium orthophosphate can replace Ca^{++}ions at lattice sites in the form of Cu^{++} or Cu^{+}ions, as suggested above. If we consider the Cu^{+}ion to be the activator in Cu-activated β-calcium orthophosphate fired in a reducing atmosphere, we must assume that a vacancy of a single O^{--}ion may be generated by the replacement of two Ca^{++}ions by Cu^{+}ions in order to satisfy the condition of charge neutrality in the phosphor.

According to the above consideration concerning the activator center in Cu-activated β-calcium orthophosphate fired in a reducing atmosphere, the allowed transition of $^1S_0 \rightarrow {}^3P_1^0$ may be responsible for the absorption band peaking at about 2550Å, and also the transition $^1S_0 \rightarrow {}^3D_{1,2,3}$ or $^1D_2$ for the weak absorption in the spectral range above about 3100Å. Although the latter transition is originally forbidden in a free Cu^{+}ion, we can expect that it will be allowed by the interactions between the activator center and lattice ions. If the trapping state for the most persistent component of phosphorescence, thermoluminescence, and stimulation is attributed to the $^3P_2^0$ or $^3P_0^0$ states because of their similar decay constants, the stimulation by 3650Å may be caused by the absorption transition $^3P_2^0$ or $^3P_0^0 \rightarrow {}^1P_1^0$ and the red emission by the transition $^1P_1^0 \rightarrow {}^1S_0$ which is allowed. This absorption transition in a free Cu^{+}ion is originally forbidden because of the same odd parity of the spectrum terms. However, if we assume that it will be allowed by the interactions between the activator center and Ca^{++}ions in the lattice, we can explain the experimental result that no stimulated red emission could be observed in the phosphors containing Mg or Zn in the following way. The transition $^3P_2^0,0 \rightarrow {}^1P_0^0$ may become completely forbidden in the phosphor containing Mg or Zn because of the small interactions between the activator center and Mg^{++} or Zn^{++} ions which have smaller ionic radii than Ca^{++} ions; thus it results in complete suppression of the red emission. Incidentally, the effect of the introduction of boron on the stimulated red emission will be explained satisfactorily in a similar way. The observed peak position of the emission band peaking at a longer wave length and the large width of the emission band of the phosphor containing boron in contrast with those of the phosphor containing Mg or Zn suggests large interactions in the activator center. Thus we can expect an enhanced red emission of the phosphor containing boron in accordance with the observed result.

The experimental result that neither thermoluminescence nor stimulation could be observed under excitation by 2537Å at lower or higher temperatures, as mentioned before, suggests that some activation energy will be necessary for the transition $^3P_1^0 \rightarrow {}^3P_2^0,0$ in the activator center.

The effect of boron introduced in the phosphor on the fluorescence and stimulated red emission is quite different compared with that of the other elements, as mentioned before. We are inclined to believe that boron may replace phosphorus in the matrix.

Crystal Growth of Electrodeposited Zinc

An Electron Diffraction and Electron Microscopic Study

Ryoitiro Sato

Mitsubishi Metal Mining and Metallurgical Laboratory, Omiya City, Saitama Prefecture, Japan

ABSTRACT

Crystallographic aspects of zinc electrodeposited on to polycrystalline cathode from $ZnSO_4 + H_2SO_4 + H_2O$ baths with or without organic colloids have been investigated by electron diffraction (reflection method) and electron microscopy (replica method). At the initial stage of deposition, the zinc layer always consists of fine-grained crystallites oriented at random. As the zinc layer becomes thicker, some of these crystallites grow larger to yield a fiber orientation depending on the depositing condition. For such relatively thick zinc layers deposited under various degrees of influence of hydrogen and/or organic colloids, the orientation and texture are interpreted from standpoint of crystal growth.

Electron diffraction investigations of crystal growth of a variety of metals at the cathode during electrodeposition have so far been carried out by many authors (1-10). Although a comprehensive interpretation of their results is given by Finch, *et al.* (7), crystal growth of metals of lower symmetry has not yet been sufficiently explained, contrary to that of cubic metals. For this reason, zinc, a hexagonal metal, was chosen for this investigation, and it has been approached first in a study of crystal growth on a polycrystalline cathode.

Although addition of organic colloids to the electrolytic bath is of great technical importance, the crystallographic aspects of their effects have been studied little by means of electron diffraction. Again, zinc, which has moderate inhibitor sensitivity (11, 12), is suitable for such a study.

Thus, this paper reports electron diffraction (reflection method) and electron microscopic (replica method) investigations of zinc films electrodeposited under the following conditions: insoluble anode, polycrystalline cathode, and $ZnSO_4 + H_2SO_4 + H_2O$ baths (with or without addition of various organic colloids).

Experimental

The aqueous solution of $ZnSO_4 \cdot 7H_2O$ was purified by zinc dust. The organic colloids used were proteins (glue, gelatin, and albumin), a gum (gum arabic), and carbohydrates (dextrin, soluble starch, and saponin).

Electrodeposition was carried out in a 300-ml beaker, using a platinum plate as anode (1 cm x 1 cm x 0.2 mm) and a mechanically polished plate of α-brass as cathode (1 cm x 1 cm x 1 mm). These were separated by 4 cm. Depositing time varied from several seconds to 20 min. Immediately after taking out the cathode, it was washed successively with running water, distilled water, and acetone. To avoid chemical change of the cathode after the deposition, the procedure was carried out rapidly.

The accelerating voltage of the electron beams for diffraction work was 35-50 kv. The sample to plate distance was 30 cm. To obtain the electron micrographs of the surface of the deposited layer, a two-stage replica method (acetylcellulose-carbon, followed by shadowing with Ge) was adopted. Usually the cathode which had served as the sample for the electron diffraction was itself subsequently observed by the electron microscope.

Results and Discussion

Experiments Using Baths Containing No Organic Colloids

(I) In some cases a diffraction pattern due to a substance other than zinc was obtained (Fig. 1a). In the corresponding electron micrograph (Fig. 1b) the substance covering the zinc layer is observed. Since the pattern is more marked with the baths containing comparatively low concentrations of the free acid, the substance is probably soluble in sulfuric acid. The analysis of the pattern is given in Table I. The data of hydrated basic zinc sulfate ($4ZnO \cdot SO_3 \cdot 7H_2O$) (13) agree fairly well with the analysis of Table I. The pattern appears invariably

1.18	m
1.02	m
0.90	m

as Debye-Scherrer rings, showing no particular orientation relationship of the substance to the underlying zinc layer.

(II) In the zinc patterns obtained, almost always two blurred halos are observed, the one at the inside of the innermost ring of zinc and the other between the (10.2)-ring and the (11.0)-ring (e.g., Fig. 2a, 4a, and 5a). The same pair of halos appeared also in the pattern from the zinc layer deposited from a cyanide bath. The halos can be ascribed neither to minute crystallites of hydrated basic zinc sulfate nor to those of zinc oxide, which might be formed by oxidation of the deposited zinc.

(III) In the zinc patterns the (00.2)-ring is usually imperceptible. This anomaly in intensity of the diffraction patterns shows that the crystallites of the deposit are flat plates parallel to the basal plane (14). This is supported by the corresponding electron micrographs (e.g., Fig. 3b, 4b, and 5b).

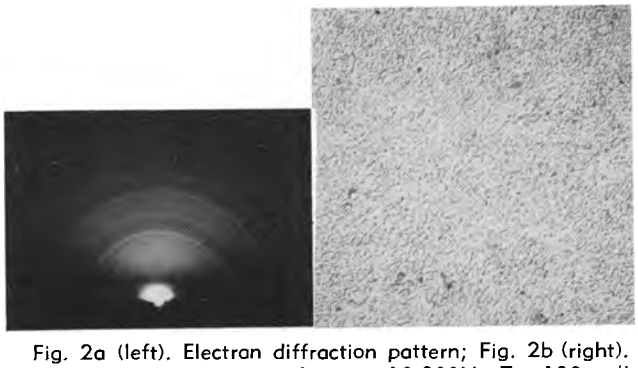

Fig. 2a (left). Electron diffraction pattern; Fig. 2b (right). Electron micrograph, magnification 10,000X. Zn 100 g/l + H_2SO_4 100 g/l; room temperature; D_k = 4 amp/dm²; θ = 700 Å. Random orientation.

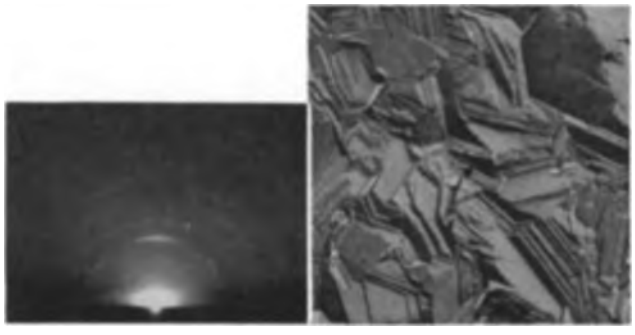

Fig. 5a (left). Electron diffraction pattern; Fig. 5b (right) electron micrograph, magnification 5,000X. Zn 10 g/l + H_2SO_4 100 g/l; room temperature; D_k = 3 amp/dm²; C_{eff} = 58%; θ = 50 x 10^3 Å. Plane of orientation : (10.l), l ≈ 1.

(IV) All of the zinc patterns show that the zinc crystallites take a fiber orientation (including random orientation), whose axis stands upright to the cathode surface. To denote such a fiber orientation, its "plane of orientation," i.e., the crystallographic plane of zinc which tends to lie parallel to the surface, is used in the following descriptions.

(V) With various bath compositions and depositing conditions, the zinc layer deposited in initial stages (up to several thousand angstroms in thickness) consists invariably of fine-grained crystallites (approximate dimension : 300Å in Fig. 2b, and 5000Å in Fig. 3b), and the tendency for a fiber orientation is very weak (Fig. 2a and 3a). This is in harmony with the results of Finch, *et al.* (7).

(VI) With continued deposition, the crystallites grow larger and a fiber orientation characteristic of the bath composition appears (Fig 4a, 4b, 5a, and 5b). According to Bauer (15), this kind of orientation should be called orientation due to crystal growth (vide infra). Table II gives a summary of the orientations. Variations in the temperature and in the current density within the ranges of the experimental conditions of plating had no noticeable effects on the plane of orientation.

(VII) According to Table II, except for deposits from baths having relatively high ratios of H_2SO_4/Zn, (11.*l*)-orientation (Fig. 4a and 4b) is invariably obtained. The occurrence of this orientation may be explained as follows. Since the surface of the growing layer is not atomically flat parallel to the cathode surface (as evidenced by the electron

micrographs, as well as by the spotty nature of the diffraction patterns), the zinc ions are carried to the surface from any direction in the bath. Under such a condition, among the many crystallites which were oriented randomly in the initial stage of the deposition, only those having by chance an orientation favorable to growth do grow and become predominant over those having unfavorable orientations. This favorable orientation is most likely determined by the relation of the growth velocities (or the surface energies) of various crystallographic planes. Thus, it is supposed that every crystallite near the surface of the relatively thick zinc layer has a tendency to be bounded by three crystallographic planes, i.e., the plane of the lowest outward velocity (basal plane) and a pair of planes of the second lowest outward velocity. If for the latter planes two prismatic planes of the first order, (10.0), [or two pyramidal planes of the first order, (10.1)] are assumed, the occurrence of the (11.l)-orientation is readily understood (Fig. 6). Although the value of l (not necessarily an integer) should be determined by the competition in the growth of the basal plane and the above prismatic (or pyramidal) plane, the quantitative data on their outward velocities of growth are not available. In this connection, the reversed order of the outward velocities of growth due to Stranski, *et al.* (16-19), together with the order of the reticular densities, are listed in Table III for various crystallographic planes of close-packed hexagonal metal. The morphology observed in the electron micrographs of Fig. 4b seems to support the point of view of this paragraph. Finch, *et al.* (7) postponed the explanation for their observation of (11.2)-orientation of electrodeposited cadmium. This may also be accounted for along the above line (15).

(VIII) As seen from Table II, when the ratio H_2SO_4/Zn of the bath is relatively high, the (11.l)-orientation is replaced by the (10.l)-orientation (Fig. 5a and 5b). This change may be related to the increased hydrogen evolution which occurs with these baths. Straumanis made observations on

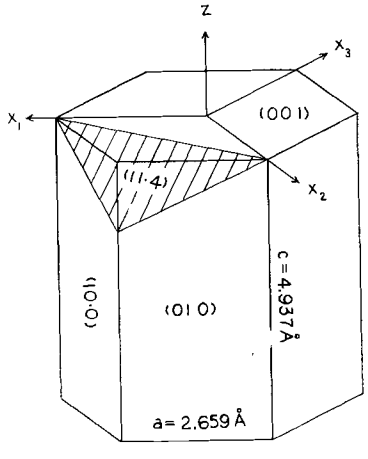

Fig. 6. Explanation of the occurrence of the (11.l)-orientation. Only (00.1) and (10.0) are depicted as the permanent faces determining the plane of orientation. l is assumed to be 4.

Table II. Plane of orientation characteristic of the bath composition

the crystal growth of zinc, which was formed by evaporation in hydrogen atmospheres (21). According to him, under hydrogen pressures lower than ~4 mm Hg the permanent crystallographic faces of zinc are: (00.1) (basal planes), (10.0) (prismatic planes of the first order), (10.1) (pyramidal planes of the first order), and (11.0) (prismatic planes of the second order). When his results are compared with the theory of Stranski, *et al.* (16-19), it seems that differences in growth velocities of the planes of lower indices of zinc (except for the basal plane) are slight, and that even a reversal of the velocities can be effected by the presence of hydrogen. Such a reversal of growth velocities of planes resulting from adsorption of impurity is discussed by Smekal (19). In (VII) the occurrence of the (11.l)-orientation was explained by assuming that the permanent faces of zinc are the basal plane and a pair of prismatic (or pyramidal) planes of the first order. Now, taking into account the consideration regarding the reversal of the growth velocities of the planes, if a pair of prismatic planes of the second order is substituted for the pair of the first order, the (10.l)-orientation is reasonably reached in the same manner as in (VII).

Results and Discussion

Experiments Using Baths Containing Organic Colloids

The effects on the zinc plating by minor quantities of addition agents, which eventually lead to structural modifications of the deposited layer, are caused by complex factors such as a change in viscosity of the bath, cathode polarization, hydrogen overvoltage, current efficiency, etc. However, the

most essential function of an addition agent on the deposited layer seems to lie in its adsorption on the surface of the layer. A simple measure of adsorbability of an organic colloid is the well-known "gold number," which refers to the protective action of the colloid on red gold sol. Note that a lower value of gold number means a higher adsorbability (or protective action) of the colloid. The gold numbers of the organic colloids used in the present experiments are listed in Table IV (22). Their values were estimated roughly by using the red gold sol prepared by utilizing the reducing flame of coal gas (23). The obtained values fell in the ranges shown in Table IV.

As mentioned earlier, the (11.*l*)-orientation is characteristic of the zinc layer electrodeposited from the baths of $ZnSO_4 + H_2SO_4 + H_2O$ system, except for the baths of relatively higher values of the ratio H_2SO_4/Zn. Consequently, in most of the following experiments to clarify the effects of organic colloids on the structure of deposited zinc, the concentrations of zinc and sulfuric acid were chosen both as 100 g/l, since, with no addition agents, this is a bath which leads invariably to the (11.*l*)-orientation (Table II). The temperature of the bath, the current density for the deposition, and the mean thickness of the deposited layer were room temperature, ~4 amp/dm², and $20 - 60 \times 10^3$ Å, respectively. The results of the electron diffraction investigations are summarized in Fig. 7, and some of the electron micrographs are reproduced in Fig. 8b and 9-12.

(I) It is generally accepted that the flatness of the surface of the electrodeposited layer becomes improved by adding an organic colloid to the bath, as the result of its ability to increase cathode polarization and, therefore, throwing power of the bath. Although such a tendency is actually observed with the naked eye with baths of relatively low concentrations of an organic colloid which is a protein or carbohydrate (roughly up to 50 mg/l), the surface is liable to become inhomogeneous with higher concentrations of the colloid. This seems due to the adherence of hydrogen bubbles to the surface, resulting from the increased viscosity of the bath. Gum arabic shows a somewhat different behavior; it makes the surface inhomogeneous at a concentration as low as 10 mg/l and yields a fine-grained surface of blackish appearance at 500 mg/l (Fig. 8b). Unfortunately, it is impossible to obtain

Table IV. Gold numbers of biocolloids used (22)

	Starch	50-250
	Saponin	230

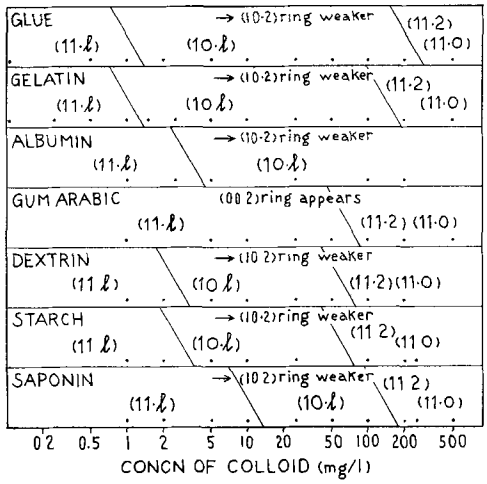

Fig. 7. Effects of organic colloids on plane of orientation. Each fiber orientation involves angular tolerance of about ±15°. Bath : Zn 100 g/l + H_2SO_4 100 g/l + organic colloid; room temperature; D_k : ~ 4 amp/dm²; θ : 20-60 x 10^3 Å. The zinc layers deposited from the baths containing the addition agent concentrations marked by the dots were investigated by electron diffraction and microscopy.

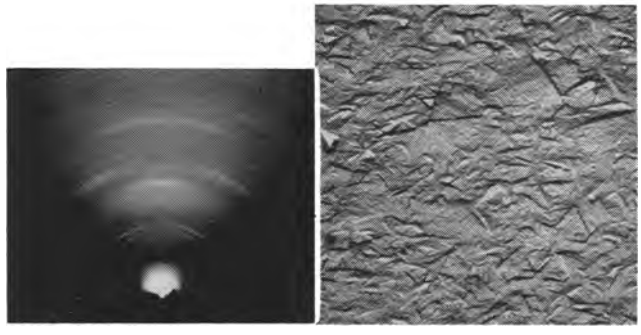

Fig. 8a (left). Electron diffraction pattern; Fig. 8b (right). Electron micrograph, magnification 5,000X. Zn 100 g/l + H_2SO_4 100 g/l + gum arabic 500 mg/l; room temperature; D_k = 4 amp/dm²; C_{eff} = 45%; θ = 24 x 10^3 Å. Plane of orientation : (11.0).

precise values of current efficiency, since the weight increase of the cathode on deposition is usually only several milligrams. It is roughly 92% in the case of no colloids and decreases with the concentration of a colloid down to 65-80% with 200 mg/l addition.

(II) As before, the (00.2)-ring is generally barely perceptible, showing the flatness of the crystallites parallel to the basal plane (layer structure). With the addition of a protein or carbohydrate, besides the low intensity of the (00.2)-ring, the (10.2)-ring shows a tendency to decrease in intensity with increasing concentration. Since among the planes of lower indices, which yield strong reflections, the (10.2)-plane makes a relatively low angle with the basal plane, this is accounted for by the further predominance of the layer structure and agrees with the discussion by Smekal (19) on crystal growth under the presence of impurity. This change of the degree of layer structure with the concentration of addition agent is also morphologically observed in a series of electron micrographs in the case of dextrin (Fig. 4b and 9-12). With gum arabic such a change of the layer structure is not observed. Moreover, it is

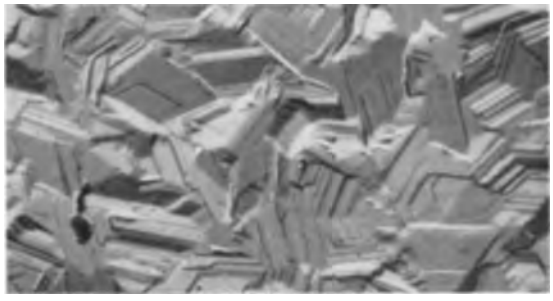

Fig. 9

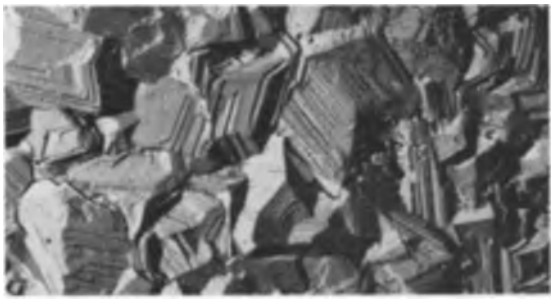

Fig. 10

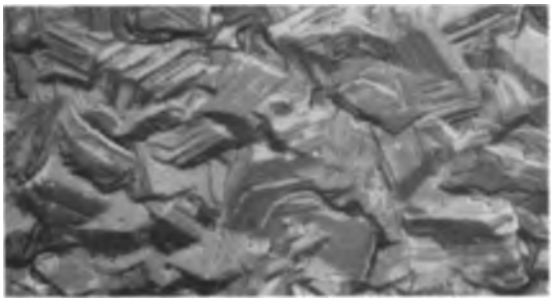

Fig. 11

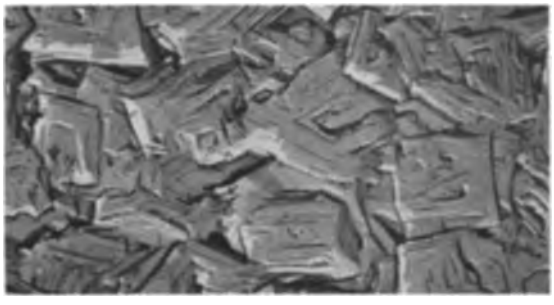

Fig. 12

Fig. 9-12. Electron micrographs, each magnification 5,000X. Zn 100 g/l + H_2SO_4 100 g/l + dextrin (2 mg/l, 10 mg/l, 25 mg/l, and 200 mg/l, respectively); room temperature; $D_k = \sim 4$ amp/dm^2; $C_{eff} = 88$, 86, 82, and 70%, respectively; $\theta = \sim 40 \times 10^3$ Å. Plane of orientation : (11.l), (10.l), (10.l), and (11.0), respectively.

remarkable that the (00.2)-ring appears with 10-50 mg/l of gum arabic (Fig. 7). This seems to have some relation to the inhomogeneity of the zinc layer, which has been touched on just above.

(III) Figure 7 shows changes of plane of orientation with concentration of the seven addition agents. Apart from the case of gum arabic, the following sequence of changes is general:

$$(11.l), l \approx 4 \rightarrow (10.l), l \approx 1 \rightarrow (11.2) \rightarrow (11.0)$$

each fiber orientation involving a considerable angular tolerance of about ± 15°. To the first, (11.l) → (10.l), the discussion made in (VIII) above applies, if it is assumed that the role of hydrogen is now played by organic colloid. This line of consideration is also preferable for elucidation of the predominance of the layer structure with increasing addition agent, which was touched on in (II). The final (11.0)-orientation (Fig. 8a) is an orientation, where the most densely packed atom rows in the most densely packed lattice plane (basal plane) stand upright to the cathode surface. When the concentration of addition agent is sufficiently high, resulting in high viscosity of the bath and low current efficiency for the deposition, the supply of zinc ions to the hollows of the surface and the mobility of zinc ions at the surface are both supposed to be insufficient. It should be understood that the (11.0)-orientation derives from such a situation. The (11.2)-orientation is most likely a transient stage before reaching the final (11.0)-orientation. With gum arabic it is remarkable that the plane of orientation changes from (11.l) directly to (11.2) → (11.0).

(IV) In Fig. 12 a square structure is noticeable. This structure is also observed with high concentrations of others carbohydrates, starch, and saponin. In these cases the plane of orientation is (11.0), and flat plates thin in the direction of c-axis, which lies parallel to the cathode surface, are supposed to be piled up to form a block. If such a block is oriented to an adjacent block of the same nature so as to form twinning on (10.2)-plane, the square structure should appear. It is well known that the twinning plane of close-packed hexagonal metals, such as zinc, is (10.2) (24). For zinc, (10.2) makes 47° 0′ with (00.1), the doubled value of which is near 90°. With proteins this square structure is less noticeable and with gum arabic is never encountered.

(V) In comparing Fig. 7 with Table IV, a reasonable correlation between the gold number of a colloid and its ability to change the orientation of deposited zinc is found in three proteins and in three carbohydrates. However, in spite of the much higher values of the gold number of carbohydrates as compared with those of proteins, they are not so ineffective in changing the orientation. This might be accounted for by the difference of their states of hydration and electric charge in the bath. Elucidation in detail must be postponed. An exceptionally weak ability of gum arabic to change the orientation is remarkable, together with its peculiarity in many aspects mentioned in the foregoing paragraphs.

Conclusion

It has been shown that many experimental results concerning the orientation and texture of electrodeposited zinc layer can be reasonably interpreted from the standpoint of development of crystallographic planes under various degrees of influence of hydrogen and/or organic colloids. However, the interpretation is considerably simplified. The fiber orientations observed in the present study invariably involve some tolerance. This implies that the crystallographic planes other

than those which determine the orientation are not necessarily excluded, presumably owing to slight differences among the surface energies of many crystallographic planes. This situation is reflected in the fine structure of the diffraction spots, which is to reveal the external crystallographic planes. Close examination of the fine structure of the spots shows that it is too complex to permit a simple interpretation, although generally the nature of the fine structure does not contradict the line of consideration described so far.

Changes in Trapping Levels of Zinc Sulfide Phosphors Resulting from Positive Ion Bombardment

William T. Allen[1] and C. H. Bachman

Department of Physics, Syracuse University, Syracuse, New York

ABSTRACT

Utilizing a decay method which consisted of measuring the amount of visible light emitted by the ZnS:Ag phosphor 5.0 msec after excitation by weak ultraviolet, studies were made of the changes in trap distribution on the surface of phosphor crystals which previously had been bombarded by Ar^+, H_2^+, and O_2^+ ions. Interpretation of results was limited to first order kinetics.

The results showed that bombardment by ions caused an increase in the number of traps at the lowest trapping level, 0.28 ev deep, as well as the creation of new traps at depths slightly greater and slightly less than 0.28 ev. This effect was independent of the ion used for bombardment.

In addition, ion bombardment caused new traps to appear at deeper trapping levels: 0.37 ev for Ar^+ ion bombardment, 0.38 ev for H_2^+ ion bombardment, and 0.39 ev for O_2^+ ion bombardment. For the latter, the peak in the difference curve is quite sharp and clearly located at 345°K, locating its depth at 0.39 ev. This corresponds to the next trapping level with increasing depth reported in the literature and thus may indicate that this trapping level is caused by the presence of oxygen in ZnS phosphors.

Ion bombardment, as a cause of deterioration in zinc sulfide phosphors, has been studied by many authors (1-8). In recent years, all research has been done with the working hypothesis that the reduced luminescence is caused by the creation of electronic levels between the valence band and the conduction band, such states making possible direct transition from the conduction band to the valence band.

It was considered desirable to investigate the dis-

[1] Present address: Franklin and Marshall College, Lancaster, Pa.

tribution of states between the valence band and the conduction band and the distribution of the states as a result of ion bombardment on the surface of the crystals.

The Lambe-Klick model (9) for luminescence in zinc sulfide was assumed valid. The depth of a state was designated as the energy difference between the state and the top of the valence band. States with depths less than 1 electron volt (ev) can influence the decay of a phosphor and customarily are called traps.

The usual method for investigating trap distributions is by the use of glow curves, a technique developed by Randall and Wilkins (10). In measuring a glow curve, the phosphor is first cooled to a very low temperature, so that electrons in the traps are stabilized, that is to say, their half-life is much longer than the time required to perform the experiment. Then the phosphor is excited at this low temperature by irradiation with ultraviolet (u.v.) light in order to fill the traps. If, now, the phosphor is warmed at a slow rate, traps filled with holes will be emptied. These holes, thermally excited to the valence band, will be attracted to the luminescent centers. The electron and hole are now in a position to recombine, giving up one photon of visible light, and the phosphor will glow as a result of a great number of these recombinations.

The temperature at which a particular trapping level becomes unstable depends on its depth, the deeper traps becoming unstable as the temperature gets higher. A curve of light output vs. temperature is called a glow curve and can be assumed to represent a trap depth distribution. For example, if a phosphor contains traps at two different depths, then the glow curve will have two different peaks, each representing one of the trapping levels.

Using glow curve techniques, Bube (11) has found that traps are present in ZnS at five distinct trapping levels. These are revealed by five distinct glow peaks at −120°C, −60°C, −25°C, −15°C, and 90°C. Any change in the methods of preparation or in the activator used will not alter the temperature at which these peaks exist but will change the relative heights of the peaks, and hence, the relative numbers of traps represented by each peak.

In the past few years, studies have been made to improve the interpretation of glow curves by considering the second order kinetics or retrapping. Such analyses not only involve consideration of holes thermally excited to the valence band finding their way to luminescent centers, but also holes thermally excited to the valence band and then retrapped and excited again to the valence band one or more times before finding their way to luminescent centers. Satisfactory interpretation of glow curves where more than one level of trap is present and where second order kinetics are considered is very difficult to achieve. It is customary in the literature to present glow curves showing light ouput as a function of temperature at a particular heating rate and leave it for the reader to interpret.

Very roughly, it can be said that if T is the temperature of a glow peak (10), then $E = 20\ kT$, where E is the trap depth and k is Boltzmann's constant. This could mean that a peak occurring at room temperature will represent a trap depth of approximately 0.5 ev.

A decay measurement consists of exciting the phosphor with u.v., cutting off this excitation, and measuring the phosphorescent light output of the phosphor as a function of time, the temperature remaining constant.

In the present investigation a problem arose in that impinging ions with energies of the order of 10 kev do not penetrate the crystal sufficiently so that changes can be observed by the use of glow curves. This is because in the excitation which precedes the warming in a glow curve measurement, the phosphor is maintained for at least several minutes under u.v. radiation, and traps are filled as deeply into the crystal as the u.v. can penetrate. Glow curve measurements are then essentially the determination of trap distributions throughout the volume of the crystal. Any change, therefore, in the distribution of traps in the surface will be largely masked by the response of the remainder of the crystal which has not been damaged.

Young (4) has shown that the deterioration of the phosphor lies in a very thin surface layer, its thickness being of the order of 0.1μ for bombardment by ions of energies in the order of 10 kev. Since the phosphor crystals ordinarily used in television screens have diameters of about 10μ, the volume of the layer is the order of 1% of the volume of the crystals, and for this reason ion bombardment by ions, the energies of which are in the order of 10 kev, does not affect glow curves of the phosphors appreciably.

However, it was observed that a phosphor damaged by ion bombardment exhibits increased phosphorescence when irradiated by low intensity u.v. for times in the order of hundredths of a second. This is because the excitation is only sufficient to fill traps on the surface of the phosphor crystal, and such surface traps are filled preferentially. This observation led to a technique in which observations of the decay characteristics yield information concerning the trap distribution.

Theory for Decay Measurements

Let P be the probability that a hole in a single trapping level of depth E will escape, then,

$$P = \frac{1}{t_d} = G\left[\exp\left(-\frac{E}{kT}\right)\right] \qquad [1]$$

where t_d is the decay time, i.e., the time for the number of holes in a trapping level to reduce to $1/e$ of its value at cutoff, E is the trap depth, k is Boltzmann's constant, T is the temperature in degrees Kelvin, and G is a constant of the order of 10^8 given by Randall and Wilkins (10) and represents the vibration frequency of an atom in the lattice (10^{12} vib./sec) multiplied by the probability that a hole in a trapping state having received enough energy from the lattice to undergo a transition to the valence band will do so.

Figure 1 shows a plot of p_T/p_{T_0} vs. time, where p_T is the density of holes in traps at any time, and p_{T_0} is the density of holes in this trapping level at cutoff. The observed visible light, I, is proportional to the

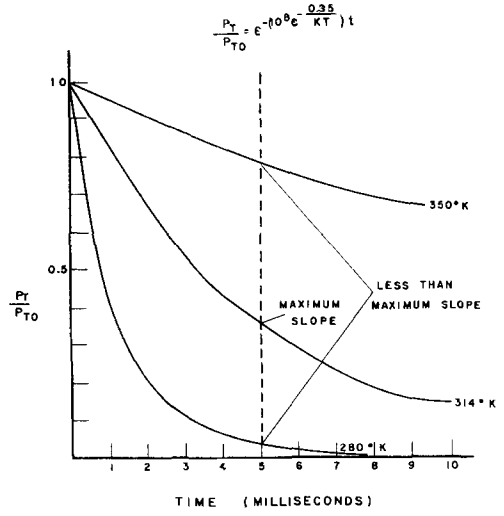

Fig. 1. P_T/P_{To} vs. time for various temperatures

rate of change of p_T with respect to time, or is proportional to the slope of the p_T/p_{To} vs. time curve. If measurements are made at a particular time, say 5 msec after cutoff, it can be seen that the maximum slope occurs at neither a high nor a low temperature, but somewhere between. Location of the temperature at which a peak occurs can be done in the following way:

If we consider a single trapping level of depth E, then from Eq. [1]

$$p_T = p_{To} \exp\left\{-G\left[exp\left(-\frac{E}{kT}\right)\right]t\right\} \qquad [2]$$

The light output I due to this single trapping level as a function of time after cutoff is equal to

$$I = V\frac{\partial p_T}{\partial t} = S\,p_{To} \exp\left\{-\left[\frac{E}{kT} + Gt\exp\left(-\frac{E}{kT}\right)\right]\right\} \qquad [3]$$

where V and S are proportionality constants.

I will be a maximum value when

$$\frac{\partial I}{\partial T} = 0 = Up_{To} \exp\left\{-\left[\frac{E}{kT} + Gt\exp\left(-\frac{E}{kT}\right)\right]\right\} \left\{\frac{E}{kT^2} - Gt\left[\exp\left(-\frac{E}{kT}\right)\right]\frac{E}{kT^2}\right\} \qquad [4]$$

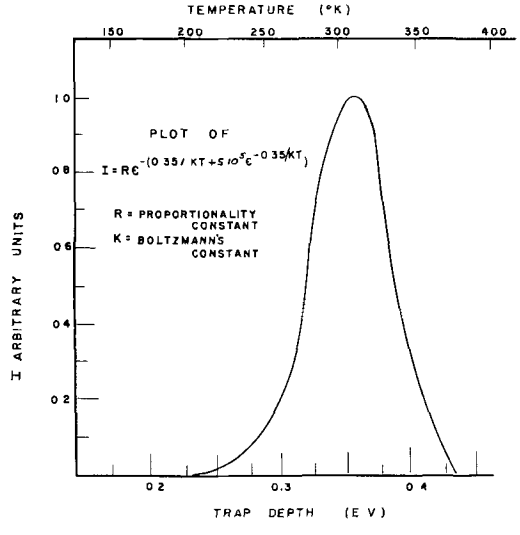

Fig. 2. I vs. temperature at 5.0 msec

where U is a proportionality constant.

$$\exp\left(-\frac{E}{kT}\right) = \frac{1}{Gt}$$

Hence a peak occurs at

$$E = (\log Gt)\,kT = 2.3\,(\log_{10} Gt)\,kT \qquad [5]$$

Thus if measurements are made 5 msec after cutoff, I will be a maximum, or a peak should occur at

$$E = 13.1\,kT \qquad [6]$$

Figure 2 is a plot of I vs. T as a result of holes trapped at a single trapping level of depth arbitrarily chosen to be 0.35 ev. It should be noted that the curve peaks rather sharply at its maximum point and also that it is not completely symmetrical in that it approaches zero much faster at high temperatures than at low temperatures.

It is interesting to compare Eq. [5] with the results obtained by Randall and Wilkins (10). If, in performing a glow curve experiment, the rising in temperature is suddenly stopped at a glow curve peak, then the visible light, according to Randall and Wilkins, will be emitted, but will decay to $1/e$ of its value in a certain amount of time in the order of 10 sec. Substituting $t = 10$ sec in Eq. [5], we have

$$E = (2.3\,\log_{10} 10^8)\,(10\,kT)$$

$$E = (2.3)\,(9\,kT) = 20.7\,kT \qquad [7]$$

or almost exactly the formula given by Randall and Wilkins.

If, during excitation, u.v. light irradiates the phosphor for an amount of time sufficient to allow the emitted light to reach a constant value, an equilibrium exists between the holes in the traps and the holes in the valence band, that is to say, the number of holes entering the traps must equal the number of holes which are thermally ejected from the traps. This can be expressed by the following equation, which should be valid if we consider only one trapping level at cutoff.

$$pb\,(\tau - p_{To}) = p_{To}\,G\left[\exp\left(-\frac{E}{kT}\right)\right] \qquad [8]$$

where p is the density of holes in the valence band, τ is the density of traps, p_{To} is the density of holes in the traps at cutoff, $(\tau - p_{To})$ is the density of empty traps, and b is a constant representing the product of the capture cross section of a trap and the velocity of a hole in the valence band.

Solving for p_{To}

$$p_{To} = \frac{\tau}{1 - \frac{G}{pb}\left[\exp\left(-\frac{E}{kT}\right)\right]} \qquad [9]$$

showing that at cutoff p_{To} is proportional to the number of traps. Since according to Eq. [3], I is proportional to p_{To} then it also, by Eq. [9] is proportional to τ, the density of traps.

It is obvious that by plotting I vs. temperature, where measurements are made 5 msec after cutoff, a curve possessing peaks should be obtained from Eq. [6]. The height of a peak should give a qualitative indication of the density of traps at a particular trapping level, according to Eq. [9]. Since the

heights of the peaks can at best only be compared qualitatively and since the efficiency of the phosphor decreases markedly at higher temperatures, it was decided to measure I/I_0 instead of I, where I_0 is the visible light output of the phosphor at cutoff. The I/I_0 vs. temperature curves therefore should be similar to glow curves except that there should be a shift in the position of the peaks. The amount of such shift can be obtained by dividing Eq. [6] by Eq. [8]

$$\frac{T_{I/I_0}}{T_0} = 1.58 \qquad [10]$$

Thus peaks determined by the decay method should be at temperatures about 60% higher than those from glow curves.

Since ion damage occurs very near the surface of phosphor crystals, it is of importance that a method be utilized which measures only surface effects. In the method of glow curves, every effort must be made to saturate all of the traps as deeply into the crystals as possible in order that the glow will consist of a measurable amount of light. If, however, I/I_0 measurements are made, weak u.v. can be used, and allowed to fall onto the phosphor for a small amount of time, so that only surface traps are preferentially filled during irradiation and can be detected during decay.

The above derivation assumed only first order kinetics, i.e., retrapping is not considered. The reason for this is that there is no way of determining the ratio of the number of filled traps to the total number of traps for any trap depth at cutoff (p_0/τ), since the phosphor is flashed with ultraviolet for a brief period of time and the traps are not saturated. Also (p_0/τ) is not constant at all distances from the surface of the crystal, and an average value of (p_0/τ) would require information not available at the present writing.

Procedure

Description of Phosphor Used

The ZnS phosphor was provided by the General Electric Company and was the blue component of phosphor used for the luminescent screens in earlier television tubes. This phosphor contained 0.015% chlorine by weight, 0.015% sodium by weight, and 0.04% ZnO by weight. The average particle size was 9μ. The phosphor contained 0.05% silver by weight as activator, which was introduced into the crystal with a sodium chloride flux (amounts of retained sodium and chlorine listed above) by heating to about 1000°C for about a half hour. The phosphor was examined by standard x-ray diffraction methods and found to be completely hexagonal.

The phosphor was water settled to a thickness of 0.01 g/cm^2 on aluminum slides 20 mils thick, measuring 15 x 30 mm. Previous to settling, the slides and the beakers used were carefully boiled in detergent and rinsed several times in doubly distilled water. The water used for settling was also doubly distilled.

Description of Equipment Used for Ion Bombardment

The ion bombardment equipment is shown in Fig. 3. The main part of the bell jar can be maintained at a relatively high vacuum (10^{-4} mm or better), and the small discharge chamber can be maintained at about 20μ.

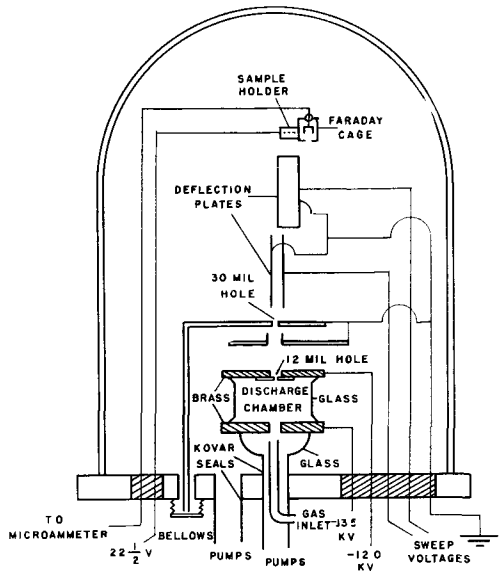

Fig. 3. Apparatus for bombarding phosphors with ions

The center support of the system is a length of heavy cane glass, and all electrical connections are fastened to the cane by means of ring stand clamps.

The output of a 30-kv power supply is applied across a string of 30, 1-megohm resistors. The positive end of the string is grounded and the negative end of the string is connected to the bottom plate of the discharge chamber. A center tap is connected through a 10 megohm resistor to the top plate of the discharge chamber.

With the pressure at 20μ and a voltage applied to the top and bottom plates of the discharge chamber, a discharge results causing positive ions to be produced. The electric field between the plates causes the ions to be accelerated upwards. A ½-in. hole, drilled in the top plate of the chamber is covered by a piece of 5-mil thick tantalum in which a 12-mil hole is drilled. Ions, produced in the chamber, pass through the hole and are accelerated by the electric field in the space between the top plate of the chamber and the next plate, which is at ground potential. Immediately above this plate is a thin sheet of aluminum, 10-mils thick, in the middle of which is drilled an aperture 1½ mm in diameter for the purpose of controlling the diameter of the beam. As an aid to lining up the apparatus, the position of this aperture can be controlled from outside of the bell jar by means of a metal bellows.

The ions proceed upward through two sets of parallel plates, arranged so that one set of plates is perpendicular to the other, but with one pair displaced laterally to allow removal of neutral particles. The electric field between these plates controls the lateral position of the beam at all times, as voltages of from 0 to 10,000 v can be applied to one plate of each set, the other remaining at ground potential. Sweep voltages of 3 and 1/10 cps are used. The sample is mounted with the phosphor facing downward or toward the beam. The sample holder and sample are operated at −22.5 v when the beam, aimed into the hole of the Faraday cage, is being measured in

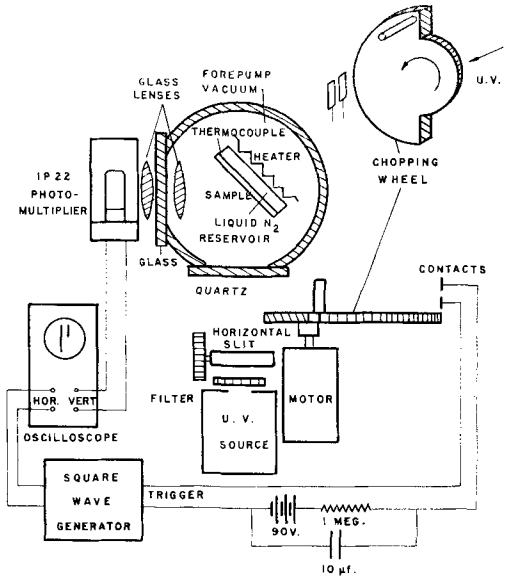

Fig. 4. Apparatus for measuring I/I_0 vs. temperature

order to retard the emission of secondary electrons from the inside of the Faraday cage, but are operated at ground potential when the beam is bombarding the sample.

Apparatus for measuring amount of fluorescent light emitted by the phosphor after a given amount of time.—This apparatus is shown in Fig. 4. The u.v. radiation is produced by the standard Beckman u.v. accessory kit which is intended for use with the Beckman DU spectrophotometer. This source is a hydrogen arc which is rich in u.v. at all wave lengths from 2000 to 4000Å.

First the light is passed through a Corning 9863 filter which passes most of the u.v. emitted by the hydrogen arc, but cuts out the visible light. The light then is passed through a narrow slit, which can be varied in width. Next, the beam is chopped by a wheel rotating at about 25 rps, so that u.v. light passes for 20 msec and is cut off for an equal amount of time. The time required for the intensity of the u.v. to reduce to a negligible value is measured by using a photomultiplier tube and an oscilloscope. This time is less than 50 μsec, which is 1% of the time during which the measurements were made. The chopped beam passes through a quartz window into a chamber maintained at forepump vacuum and onto the phosphor sample which is placed at a 45° angle to the beam.

The sample is so arranged that its temperature can be varied from −150° to +200°C and is in a vacuum in order to avoid the formation of frost on the sample when at low temperatures. All temperatures are measured using a copper-constantan thermocouple and a L&N thermocouple potentiometer. Melting ice is used as a temperature reference junction. The emitted visible light from the phosphor is collected by a lens within the vacuum chamber, transmitted through the glass window, and converged by a second lens onto an RCA 1P22 photomultiplier tube. The electrical signal from the photomultiplier tube is applied with amplification to the vertical plates of an oscilloscope.

The chopping wheel carried a small metal protrusion so arranged that at the time of u.v. light cutoff an electrical contact is made with two wires, thus triggering a Tektronix #162 wave form generator. The wave form generator gives a square pulse 5 msec in duration every time it is triggered. This pulse is then applied to the horizontal plates of the oscilloscope.

The pattern on the screen of the oscilloscope consists of two vertical lines. The vertical deflection is dependent on the light output of the phosphor. The first vertical line indicates the light output under u.v. irradiation. The second, displaced to the right, gives the light output during the 5 msec pulse. By setting the vertical amplifier of the oscilloscope so that top termination of the first vertical line is at 100 on the screen scale and so that the beam is a zero when no u.v. light shines on the phosphor, the termination of the second line immediately gives the percentage of light emitted from the phosphor 5 msec after cutoff.

It was necessary to insure that the u.v. light falling on the phosphor was constant and equal for all samples measured. Before and after each run, a phototube was placed in the vacuum chamber at the exact point where the phosphor was placed during a run, and it was found that, if a half-hour warmup was allowed, the light output never varied more than 1%.

Ion-burning of samples.—With the sample in place and the system evacuated, potentials are applied to create the ion beam. This is deflected into the Faraday cage for current measurement, after which the sweep voltages are applied to the deflection plates, so that the beam now traces a square raster on the phosphor sample. Bombardment is allowed to continue for a length of time dependent on the number of particles per square centimeter desired.

The beam is redirected into the Faraday cage for a check on intensity. The beam current is assumed to be constant throughout the bombardment if the measurements made before and after bombardment are equal.

The sample is then examined under u.v. light and the unaffected portion, which fluoresces brighter than the affected part, is scraped off. The bare aluminum is painted with aquadag to reduce reflected u.v. light. The area of the affected portion is measured so that with measurements of beam current and time of bombardment, the density of particles per square centimeter can be computed.

Measurements.—With the samples in place the chamber is evacuated and the sample is cooled to −150°C by pouring liquid nitrogen into the reservoir The chopping wheel is then rotated at about 25 rps, and the triggered pulse generator is activated.

The heater coils are activated then so that the temperature of the sample increases at no more than 4°C/min. This is sufficiently slow so that glow curve effects can be neglected. The temperature is measured at all times with the thermocouple potentiometer and measurements of I/I_0 are made every 0.25 mv. This amounts to taking a measurement every 10°C at low temperatures and every 4°C at high temperatures.

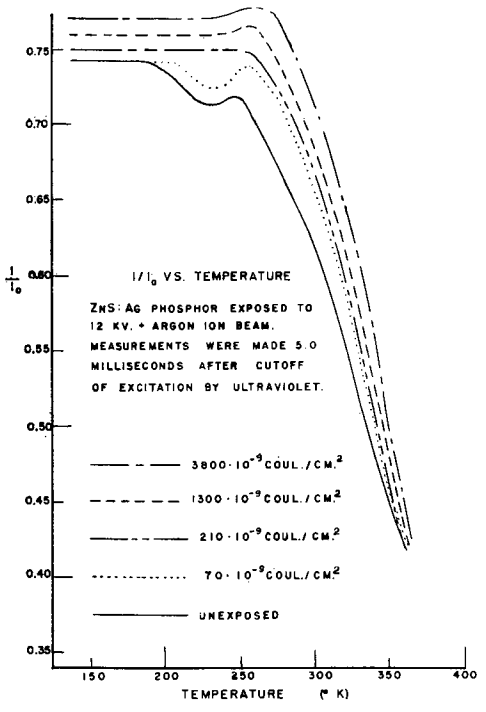

Fig. 5. I/I_0 vs. temperature for argon bombardment

Experimental Results

The curves shown in Fig. 5 represent I/I_0 measurements made on ZnS:Ag phosphor which had been previously bombarded by 12 kv ions of Ar^+.

There are significant differences in the I/I_0 vs. temperature curves for varying degrees of ion bombardment. Whereas the difference in I/I_0 is as much as 12% for some temperatures, it does not always appear to be significant, due to the large negative slope of these curves. For this reason the I/I_0 vs. temperature curve for the unbombarded phosphor was subtracted from the I/I_0 curve for the bombarded phosphor. In this way, it was possible to emphasize the difference in the decay as a result of bombardment. The difference curves are shown in Fig. 6 for argon bombardment; Fig. 7 and 8 show similar difference curves for samples which had been bombarded with H_2^+ and O_2^+ ions.

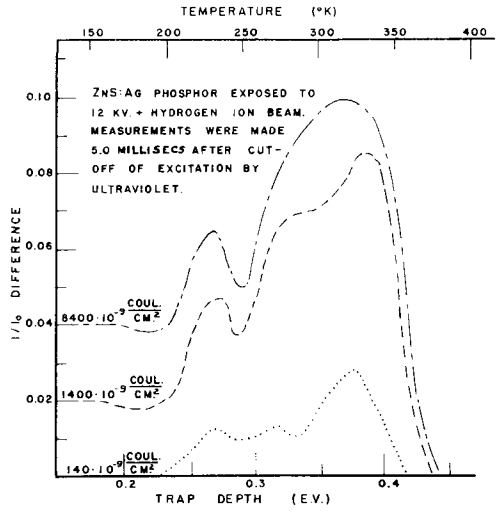

Fig. 7. I/I_0 vs. temperature (difference curve) for hydrogen

In the I/I_0 vs. temperature curve for the standard unbombarded phosphor, it is observed that a peak exists at 250°K. Since this is the lowest observable peak, it is assumed to be due to the trapping level represented by the glow curve peak at −120°C or 153°K. This means that experimentally the ratio

$$\frac{T_{I/I_0}}{T_G} = \frac{250^\circ}{153^\circ} = 1.63 \qquad [11]$$

which agrees very closely with Eq. [10], where the ratio is 1.58. This discrepancy of about 3% is perhaps explained by retrapping or second order kinetics. Since the saturation of traps in this decay method is not attempted, one would expect the percentage of unfilled traps to be higher than that encountered in glow curve measurements. Therefore, the probability of trapping would be somewhat larger since holes excited to the valence band would encounter a greater number of empty traps in which to be trapped. In general the retrapping effect shifts the peak to higher temperatures, as holes which are retrapped on the low temperature side of the peak predicted by first order theory do not recombine with electrons at centers to emit visible light. Also on the high temperature side of the peak predicted

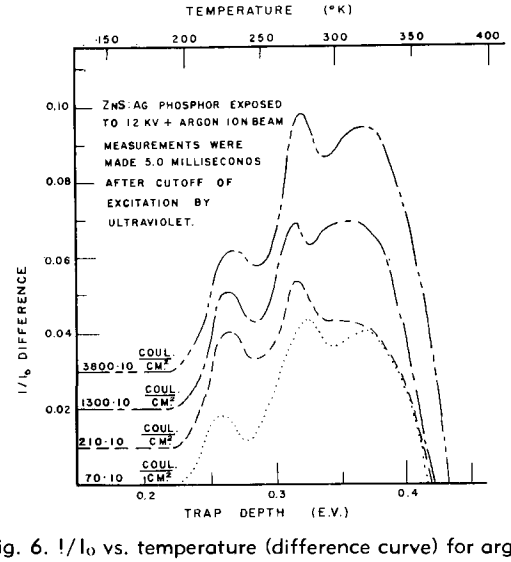

Fig. 6. I/I_0 vs. temperature (difference curve) for argon

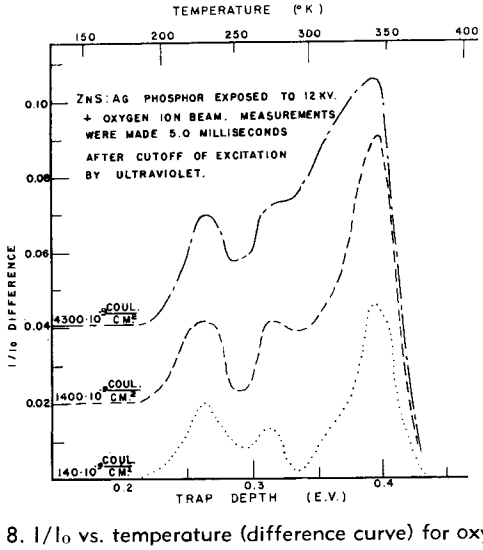

Fig. 8. I/I_0 vs. temperature (difference curve) for oxygen

by first order theory, the probability of holes being thermally ejected from traps becomes very large since it is an exponential function of temperature, whereas the probability of recombination with empty traps is only proportional to the number of empty traps. Accordingly the value of I/I_0 at temperatures below the peak predicted by first order theory should be reduced and at temperatures above the peak predicted by first order theory, I/I_0 should remain about the same. In this way retrapping will tend to cause a peak to shift slightly to the higher temperature.

From the I/I_0 difference vs. temperature curves, Fig. 6-8, one can conclude the following:

1. In general, the heights of the I/I_0 difference vs. temperature curves are dependent on the degrees of bombardment. It appears that small ion exposures are very efficient in creating traps, whereas increased ion exposures yield diminishing changes in the I/I_0 difference vs. temperature curves. There is an apparent saturation of traps at this depth.

2. All I/I_0 difference vs. temperature curves show two peaks, located at 230° and 290°K, that are equally distant from the 250°K peak in the I/I_0 vs. temperature curve. The closeness of these two peaks to the 250°K peak indicates that possibly the new traps at these two levels are related to the 250°K peak. If bombardment by ions had only increased the population in the trapping level represented by the 250°K peak, then the I/I_0 difference vs. temperature curve would have shown a single peak at 250°K. However, if the bombardment had produced new trapping levels not only at the discrete trap depth represented by the 250°K peak but also at levels slightly greater and smaller in depth, then the difference curve would show two peaks on either side of 250°K. This was observed.

It is evident that traps at a depth of 0.28 ev which are represented in the I/I_0 vs. temperature curve by a peak at 250°K are not only increased in number, since the height of the I/I_0 vs. temperature curve was shown in Eq. [9] to be proportional to the number of traps at a particular level, but also, following bombardment, traps exist at depths slightly greater and slightly less than 0.28 ev.

This is not in agreement with work by Martin (8) who found that this trapping level in ZnS:Ag was decreased rather than increased by ion bombardment. He used 45 kev hydrogen ions and measured trap distribution by use of glow curves.

3. In all of the I/I_0 difference vs. temperature curves, another large peak appeared at a somewhat higher temperature. As can be seen in Fig. 6-8, this was dependent on the ion used for bombardment, as the peak in the argon curves was at 315°K, in the hydrogen curves at 330°K, and in the oxygen curves at 345°K, corresponding to trap depths of 0.37, 0.38, and 0.39 ev, respectively.

It is interesting to note that the distinct oxygen peak a 345°K corresponded almost exactly to the predicted second peak at 344°K. Although this certainly is not conclusive evidence, it is clearly indicative that this trap depth of 0.39 ev might be caused by oxygen in the ZnS:Ag crystal replacing sulfur in the lattice either substitutionally or interstitially.

4. Values of I/I_0 were increased at low temperatures as a result of ion bombardment. This might indicate trapping levels of depths below 0.28 ev, but such have not been reported previously in the literature. Such values of I/I_0, which at low temperatures are constant with respect to temperature, but which increase as a result of ion bombardment, may be explained in two different ways.

First, it is possible to assume that, since surfaces are being studied, other trapping levels can exist and these can have a depth distribution which is constant. This assumption appears unlikely as traps are associated with particular kinds of imperfections in the lattice and would be preferentially located at particular levels.

Second, it should be noted that the theoretical curve of I vs. T in Fig. 2 is not symmetrical, but has a tail which is significantly large at low temperatures. It is possible that the tails of many of these curves added together give what appears to be a higher value of I/I_0 constant with respect to temperature.

If the destruction of luminescence is simply a matter of producing levels between the valence band and the conduction band so that radiationless or infrared emitting transitions can take place, then the number of paths for the recombination of electrons and holes will be increased, and the time t_a for the density of holes in the valence band to drop to $1/e$ of its initial value will be decreased. In all of the measurements made, t_a was always observed to increase as a result of ion bombardment. The data gathered at low temperatures indicate that: (*a*) these levels were not produced; (*b*) these levels may be produced, but their effect is overcompensated by the destruction of centers; and (c) these levels may be produced but their effect is overcompensated by the low temperature tail of the curve I vs. T, shown in Eq. [2].

Manuscript received June 11, 1958. This paper has been scheduled for presentation at the Philadelphia Meeting, May 3-7, 1959. The work on this paper was sponsored by the office of Ordnance Research, Department of the Army.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Influence of Firing Conditions, Composition, and Screening Media on the Zeta Potentials of ZnS Phosphors as Related to Adherence to Glass Surfaces

Boris Levy[1]

Electron Tube Division, Radio Corporation of America, Lancaster, Pennsylvania

ABSTRACT

Zeta potentials were determined by the streaming potential method as a function of firing conditions, flux, activator, phosphor coating, and type and concentration of screening media. The effect of these factors on adherence was determined by the jet impingement method. Positive zeta potentials were obtained in $Ba(Ac)_2$ solutions and in H_2O during all stages of phosphor preparation prior to the coating operation. Either positive or negative potentials are obtained with the finished phosphor depending on the type of coating used. Firing conditions also have been found to be important in determining the sign of the zeta potential. A general trend toward enhanced wet adherence with decreasing negative zeta potential and increasing positive zeta potential has been noted.

The influence of electrolyte concentration on the zeta potentials of ZnS powders was measured with solutions of the following materials: $Ba(Ac)_2$, K_2SiO_3, $Ba(Ac)_2$-K_2SiO_3 mixtures, $(NH_4)_2Cr_2O_7$, polyvinyl alcohol, and mixtures of $(NH_4)_2Cr_2O_7$ and polyvinyl alcohol.

Adherence of a phosphor to a glass faceplate is one of the important factors involved in the manufacture of television tubes. The phosphor is commonly applied to the glass by either a settling (1) or slurry technique (2). Both methods involve the preparation of a phosphor suspension containing water, an electrolyte, and a bonding agent, but the nature of the electrolyte and bonding agent differs for the two methods. Different phosphors, or even the same phosphor handled in slightly different manners often have wide variations in screening properties. The concentrations of electrolyte and bonding agent also have marked effects on screen characteristics.

Hazel and co-workers have demonstrated a correlation between zeta or electrokinetic potential and adherence in settled screens (3-5). They found a decrease in the magnitude of the zeta potential with increasing concentration of either $Ba(Ac)_2$ or K_2SiO_3-$Ba(Ac)_2$ mixtures. Similar results were obtained with powdered glass. In the systems in which the potential of the phosphor and glass were negative, measurements of the adherence of the phosphor to glass surfaces indicated enhanced adherence with a decrease in the magnitude of the zeta potential. The explanation offered by Hazel was that the repulsive forces between the two similarly charged surfaces were reduced, thereby giving the silicate a chance to bind the phosphor to the glass in a more compact network.

The present study is an outgrowth of Hazel's work in that it attempts to discover the factors of importance in a phosphor preparation and handling that influence the electrical properties of its surface. To this end streaming potential experiments were performed at various stages of phosphor preparation and under a variety of conditions that might occur in screen application. Attempts were made to correlate the results with adherence measurements.

Experimental

Materials.—Measurements are made on either commercial RCA phosphor powders or on specially prepared samples as described in Table I. Demineralized water is used in the preparation of all solutions used in the measurements. Reagent-grade $Ba(Ac)_2$, KCl, and $(NH_4)_2Cr_2O_7$ are used. The potassium silicate solutions are prepared from Sylvania PS5 (0.96M K_2O-3.05M SiO_2), and the polyvinyl alcohol (PVA) solutions are prepared from du Pont Elvanol #52-22.

Apparatus.—The streaming-potential apparatus used in these experiments combines several of the features used by Gaudin and Fuerstenau (10) and by Hazel and his co-workers (3-5). Calomel electrodes, as used by Hazel, are employed for most of the potential measurements when a L&N Type K potentiometer and galvanometer are used in the measuring circuit. Perforated platinum electrodes, sealed to the ends of specially ground 24/40 standard taper joints, are used for the conductivity measurements. The joints are ground in such a way that a piece of filter paper can be placed over the ends of the electrodes without interfering with the fit of the joints. The filter paper helps to confine the powdered sample in the streaming potential cell between the platinum electrodes. When preparing the streaming potential cell one of the 24/40 joints is sealed with Apiezon W wax and a suspension of powder

poured into the open end of the cell. Suction is applied in order to achieve a tight packing. The other electrode then is sealed into place. Occasionally, when a *p*H meter or an electrometer is used, the platinum electrodes are employed for the potential measurements.

Experimental procedure.—In the streaming-potential experiments, care is taken to rinse out all sections of the apparatus with the liquid being used in the experiments. Measurements are made at several pressures (10-50 cm Hg) and with the liquid flowing in both directions. Potential and conductance measurements are made at each pressure, and sufficient time is allowed for the system to come to equilibrium before each measurement is made. The system is then disassembled, rinsed with 0.010M KCl, and reassembled in order to determine the cell constant of the streaming potential cell under flow conditions analogous to those used in streaming potential determinations.

The formula used to calculate zeta potentials from the experimental data is:

$$\zeta = \frac{4\pi\eta K}{D} \cdot \frac{E}{P}$$

where ζ is zeta potential (mv); η, viscosity of the solution, (poise); D, dielectric constant of the solution; K, specific conductance of the solution within the plug ($ohms^{-1}$); E, streaming potential (mv); and P, driving pressure (dynes/cm).[2]

Assuming that the viscosity (η) and the dielectric (D) of the solution do not differ appreciably from pure water, the following formula is used for the calculation at 25°C:

$$\zeta = 9.69 \times 10^4 \frac{KE}{P}$$

Experimental Results

Effect of firing conditions.—The first experiments performed in this investigation were made with precipitated ZnS (Table I). Because the surface condition of the powder is of paramount importance in streaming potential measurements, some way of removing adsorbed ions on the ZnS was thought desirable. The ZnS used in these experiments was prepared by bubbling H_2S into a solution of $ZnSO_4$. Under these conditions one may reasonably expect that adsorbed Zn^{++} and $SO_4^{=}$ ions will be present on the ZnS surface. If an excess of Zn^{++} ions are on the surface, there will also be a possibility of ZnO formation. The method of obtaining ZnS free of $SO_4^{=}$, Zn^{++}, and ZnO recommended by Larach and Thomsen (11) was used in this study. It consists of firing precipitated ZnS in H_2S at ~1000°C.

Streaming potential measurements on the ZnS powder prepared in this manner initially gave negative zeta potentials in 5.8×10^{-4}M $Ba(Ac)_2$ (Table I, Test No. 4 and 5). Changes in sign, of this nature, indicate rather radical changes in the condition of the surface. Further investigation of firing conditions showed that it is possible to obtain either positive or negative zeta potentials with a given sample of ZnS. For negative zeta potentials, the method used should be:

Method A

1. Fire ZnS in H_2S at 975°C for 1 hr.
2. With the sample at 975°C, flow N_2 through the furnace for ½ hr.
3. Allow the sample to cool in a N_2 atmosphere.

For positive zeta potential the ZnS sample is:

Method B

1. Fired in H_2S at 975°C for 1½ hr, and
2. Allowed to come to room temperature in an H_2S atmosphere.

These results were found to be reproducible as may be seen in Table I. When the H_2S used in the firing was taken from an almost empty cylinder, Method A yielded phosphors having a positive zeta potential (Test 16). Negative phosphors were always obtained when fresh cylinders of H_2S were used on the samples fired according to Method A. Impurities in the H_2S cylinder (definite infrared spectrum evidence for CH_2Cl_2 was found) which become more pronounced as the cylinder is almost empty may be the cause of the positive zeta potentials obtained when samples were fired by Method A (Test 16). Since O_2 is a usual contaminent in nitrogen cylinders, it is possible that ZnO or chemisorbed O_2 may be formed on the surface of the powder when Method A is used. Method B will probably result in adsorbed H_2S.

The ZnS transition temperature for the transformation from cubic to hexagonal form occurs at 1020°C. Tests 16, 17, and 18 were fired at 1100°C. The other firings were below this temperature. There is some indication that crystal habit affects the zeta potential, but it is felt that not enough experiments were performed above the transition temperature to come to any definite conclusions concerning this point.

Several attempts were made to treat a sample that had been fired by Method A with H_2S in order to cause the streaming potential to become positive. Hydrogen sulfide was allowed to come in contact with dry phosphor and with phosphor-water suspensions. The sign of the potential remained unaltered in all cases. Samples fired by Method B were vacuum heated to 160°C in an unsuccessful attempt to remove adsorbed H_2S and cause the samples to revert to negative potentials (Test 19).

Samples of ZnS that were prepared by Method A and had negative zeta potentials were rinsed with a dilute NH_4OH solution (Test 20). This treatment caused the streaming potential to become positive. X-ray analysis of the ZnS samples before and after treatment with the NH_4OH solution revealed several unidentified lines in the sample treated with the NH_4OH that were not present in the untreated sample. NH_4OH treatment commonly is used commercially to neutralize any excess H_2SO_4, formed during the precipitation of the ZnS, that has not been removed by water rinsing.

Streaming potential measurements at various stages of phosphor preparation.—Streaming potential experiments were performed next on a ZnS phosphor during various stages of preparation. Experiments on several lots of precipitated ZnS all resulted in positive zeta potentials in $Ba(Ac)_2$ (5.84×10^{-4}M) (Tests 1, 2, and 3). When various fluxes such as NH_4Cl, NaCl, and $CaCl_2$ were used to incorporate the Ag activator into the ZnS, the zeta potential still remained positive (Tests 21 through 25). It was not until the phosphor was coated with silicate that the zeta potential became negative in the $Ba(Ac)_2$ solution (Test 32). A phosphor that had been fluxed with the NaCl and activated with 0.015% Ag was coated with ZnS. The coating was applied by bubbling H_2S into a suspension of the uncoated phosphor resulting in the formation of an amorphous layer of ZnS on the surface. This phosphor was found to have a positive zeta potential in H_2O (Test 33). CaCdZn hydroxyapatite coatings give negative potentials (Tests 34, 36, and 39). Several experiments were performed using various amounts of silicate coating, and the results indicate that the magnitude of the negative potential increases with increased amounts of silicate (Tests 30, 31, and 32). Tests 37 and 38 show that $Mg(Bo_2)_2$ coatings give negative zeta potentials with the RCA 33-Z-285 phosphor.

Streaming potential experiments on a ZnS:0.015% Ag, *uncoated phosphor* (33-Z-265 *uncoated*).—(*a*)

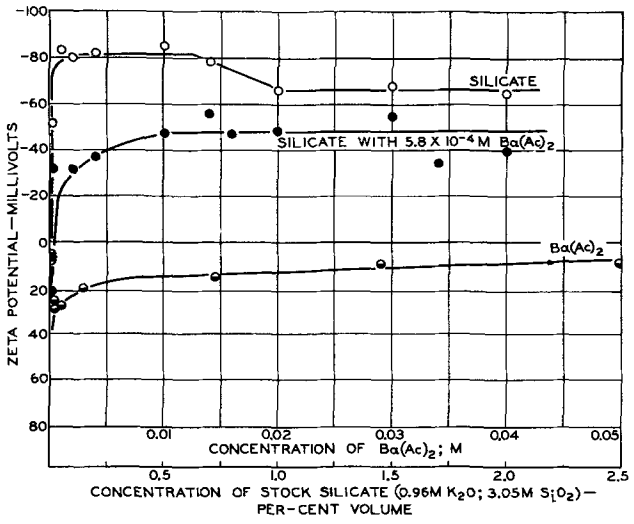

Fig. 1. Zeta potential of RCA phosphor 33-Z-265, uncoated (ZnS:0.015% Ag) as a function of (a) $Ba(Ac)_2$ concentration, (b) silicate concentration, (c) silicate concentration with 5.8×10^{-4}M $Ba(Ac)_2$.

$Ba(Ac)_2$ solution: The results of these experiments are shown in Fig. 1 where the calculated zeta potentials are plotted as a function of the molar concentration of $Ba(Ac)_2$. It is seen that the zeta potential starts at a value of +30 mv at the lowest concentration and falls to a plateau value of about +10 mv at higher concentrations.

(*b*) Silicate: In Fig. 1 the zeta potential is plotted as a function of silicate concentration. The zeta potential starts out with positive values at low silicate concentrations, goes through zero, and continues to increase in magnitude until it reaches a value of about −80 mv. It remains fairly steady at this value and then proceeds to decrease in magnitude in the conventional manner to a plateau value of about −65 mv.

(c) $Ba(Ac)_2$-silicate system, $Ba(Ac)_2$ conc. held constant at 5.8×10^{-4}M: These results are also given in Fig. 1. A comparison of the curves in Fig. 1 shows that the added $Ba(Ac)_2$ has the effect of lowering the magnitude of the zeta potential over those obtained with silicate dose.

Several experiments were performed using 9.93×10^{-4}M $Ba(Ac)_2$ plus 0.05% silicate and 0.2% silicate. The zeta potentials were −6.32 and −23.6 mv, respectively, indicating that additional $Ba(Ac)_2$ further suppresses the magnitude of the potentials as compared to that obtained with silicate.

(*d*) Polyvinyl alcohol-ammonium dichromate system: Streaming potential experiments with PVA have been performed on the regular product 33-Z-265 phosphor (ZnS:0.015% Ag, silicate coated) and on uncoated 33-Z-265 phosphor. The results, given in Table II, show that the PVA does not change the sign of the zeta potential of these phosphors from that in pure water. As will be remembered, potassium silicate solutions caused a reversal from positive to negative in the sign of the zeta potential of the uncoated phosphor.

With $(NH_4)_2Cr_2O_7$ as the streaming electrolyte, the same phosphors gave unusual results. Particular difficulty was encountered with the uncoated phosphor. The streaming potential was found to start out positive and to drop rapidly in magnitude. In some cases when the direction of liquid flow was reversed, the measured potential did not reverse sign in the normal manner. The coated 33-Z-265 also showed some tendency toward a decrease in magnitude of the zeta potential with time, but to a much smaller degree than the uncoated material. The zeta potential of the coated phosphor was negative in all cases and ranged from about −25 to −13 mv with time. The concentrations of $(NH_4)_2Cr_2O_7$ used were 0.001 and 0.0005 wt %.

Table II

RCA Phosphor No.	Per cent of PVA	Zeta potential, mv
33-Z-265 uncoated	0.149	+9.77
33-Z-265	0.149	−12.21
33-Z-265 uncoated	0.0149	+13.89

Experiments using PVA (0.0149 wt %) plus $(NH_4)_2Cr_2O_7$ (0.0005 wt %) were performed on the coated and uncoated phosphor. The coated 33-Z-265 had zeta potentials that ranged with time from −8 to −3.5 mv. The potential of uncoated 33-Z-265 ranged from +31 to +6.5 mv. These changes in zeta potential with time are probably due to chemical interaction of the $(NH_4)_2Cr_2O_7$ with the phosphor and could possibly be used as a means of estimating how well a phosphor has been coated.

Adherence measurements.—Table I and Fig. 2 give zeta potential and adherence data on a number of samples prepared by various firing conditions and with different fluxes and coatings. A water jet impingement method (12) for evaluating wet adherence was used. It consists of first dispersing the sample to be tested in a solution containing 9.25×10^{-5}M $Ba(Ac)_2$ and 0.22% stock potassium silicate and then allowing the sample to settle to the bottom of the vessel. After the prescribed time (20 min) has elapsed, a glass capillary tube with an inner diameter of 1.2 mm is immersed into the vessel and a jet of water allowed to impinge through a given height of liquid (1 in.) onto the settled powder. The geometry and hydrostatic pressure applied to the capillary

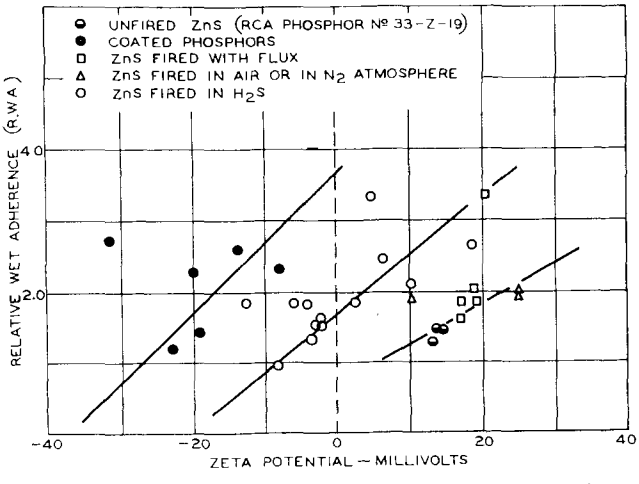

Fig. 2. Correlation between zeta potential and relative wet adherence.

Table III

Conc. $Ba(Ac)_2$, M	Hole diameter*, mm Standard phosphor	Uncoated phosphor
1.06×10^{-3}	8.2	17.2
8.57×10^{-4}	9.3	22.3
8.57×10^{-5}	28.7	38.5
8.57×10^{-6}		39.3

* Large hole diameter indicates poor adherence.

are kept constant (jet-flow rate equals 153 cc/min). The data in Table I for relative wet adherence (RWA) are the reciprocal of the eroded area produced by the water jet on the sample being studied, divided by the reciprocal of the area obtained with a standard sample, and multiplied by 4.05 (the RWA of the standard phosphor).

Wet-adherence measurements using the jet-impingement technique, but with the data reported in terms of eroded hole diameter, were performed on the uncoated 33-Z-265 phosphor as a function of $Ba(Ac)_2$ concentration. The concentration of the silicate was 0.81% of the stock solution. Results are given in Table III.

It is apparent that the uncoated 33-Z-265 phosphor has comparatively poor wet adherence. The fact that the jet impingement test with the uncoated phosphor results in hole diameters that increase with decreasing concentration indicates that it has a negative zeta potential when suspended in the silicate for the wet adherence test. The streaming potential experiments confirm this assumption.

Discussion

The results of the experiments on the effect of firing conditions on the sign of the zeta potential indicate the importance of surface conditions. The difference in sign between ZnS samples that have been fired in H_2S and flushed with N_2 (negative zeta potential) and those fired in H_2S and allowed to cool in H_2S (positive zeta potential) may possibly be due to adsorbed H_2S, in the latter case, and O_2 adsorption or ZnO formation, due to impurities in the N_2, in the former case.

Samples allowed to cool in H_2S may be expected to behave quite differently from those cooled in N_2. Undoubtedly, H_2S will be adsorbed which, when placed in H_2O, will have the opportunity of dissociating into H^+ and HS^- ions. If the H^+ ions remain adsorbed, the diffuse part of the double layer must have an excess of negative charge. This negative charge will result in the observed positive values for the streaming potential and zeta potential. It was not possible to detect any differences in *p*H of water suspensions of ZnS samples prepared by the methods mentioned above, probably because the concentration of HS^- ions discharged from the surface of the powder cooled in H_2S was too small to be effective.

It is difficult to establish from the experiments that have been performed thus far whether the impurities in the N_2 contribute measurably to the resulting zeta potentials. The negative zeta potentials obtained by firing in H_2S and flushing with N_2 may be due to ZnO or O_2 on a ZnS substrate, or simply to ZnS.

The NH_4OH treatment of the sample that had been treated by Method A caused the potential to become positive. Because zinc complexes with NH_3, an adsorbed zinc-ammonia complex may be the cause of the sign reversal. The x-ray data indicate the possible formation of a new species in the NH_4OH treated sample, but the intensity is too low to allow for positive identification.

The streaming potential experiments performed at various stages of phosphor preparation also indicate the importance of surface conditions as compared to bulk modification of a ZnS powder. Thus, the streaming potential was found to remain positive during all stages of phosphor preparation until the coating operation. Additions of various fluxes, as well as Ag activator, resulted in powders with positive potentials. All of the streaming-potential experiments performed by various workers on phosphors have been with finished products (3-5). In all cases but one, negative potentials were obtained. Hazel and Schnabel (4) found that du Pont #1630 (ZnS; ZnCdS) had a positive potential in the absence of K_2SiO_3. They suggest that the positive potential was due to the flux or other impurities. The present findings indicate that the positive potentials are not due to the flux, because the original ZnS starting material has a positive potential. A ZnS coated ZnS:0.015% Ag phosphor was found to have a positive potential. Silicate coatings result in negative potentials with the magnitude of the potential increasing with heavier coatings. The ZnS coated phosphors have all of the free-flowing characteristics that have been found desirable in phosphor coatings that have negative potentials. This information permits the selection of a coating with either a positive or negative potential should a particular screen-application technique indicate one or the other to be most desirable.

Streaming-potential experiments on the ZnS: 0.015% Ag uncoated phosphor (33-Z-265) as a function of $Ba(Ac)_2$ concentration, silicate concentration, and $Ba(Ac)_2$-silicate mixtures are shown in Fig. 1. The curve for zeta potential vs. $Ba(Ac)_2$ concentration shows the usual reduction of the zeta potential with increased concentration of electrolyte as a result of condensation of the diffuse part of the electrical double layer. As may be seen from the curve for zeta potential vs. silicate concentration there is a reversal in the sign of the zeta potential from positive to negative with increasing silicate concentration. The region of rapid increase in negative values of the zeta potential with increasing silicate concentration may indicate only partial coating of the phosphor with silicate. From 0.05 to 0.7% silicate, the phosphor may be completely coated with silicate. It is only at concentrations higher than 0.7% stock silicate that compression of the electrical double layer, caused by additional adsorption of ions into the inner Helmholtz plane and, consequently, reduction in magnitude of the zeta potential, becomes predominant. With an ordinary electrolyte, the zeta potential falls to values considcrably lower than the −64.5 mv at 2.0% stock silicate found in the present system. This reduction may be due to the tendency

of the silicate ions to associate into micells which will result in only a relatively small increase in the concentration of free ions with an increase in silicate concentration.

Comparison of the curve for zeta potential vs. silicate concentration with the curve for zeta potential vs. silicate concentration plus 5.8×10^{-4}M $Ba(Ac)_2$ shows that the added $Ba(Ac)_2$ (5.8×10^{-4}M) has the effect of lowering the magnitude of the zeta potential and of shifting the curve toward the higher concentration range. A possible explanation is that the silicate is forced to compete with the Ba^{++} ions for adsorption sites, despite the fact that different charge types are involved. For example, an adsorbed silicate ion at a positively charged site may prevent adsorption of a Ba^{++} ion at an adjacent negatively charged site by steric hindrance. The silicate ions overbalance the Ba^{++} ions because they cause a phosphor that has positive zeta potentials in H_2O or in $Ba(Ac)_2$ solutions to become negative. The lowered magnitude of the negative zeta potential in $Ba(Ac)_2$ as compared to that found with silicate alone indicates partial adsorption of the Ba^{++} ions in the inner Helmholtz plane in the region of low silicate concentration. Another mechanism that would contribute to the lowered potentials would be strongly adsorbed Ba^{++} ions on top of the adsorbed silicate ions. The drop in the zeta potential, after the maximum value of the negative potential has been obtained, is less pronounced than for the silicate system. This difference is to be expected because the $Ba(Ac)_2$ will tend to gel the silicate system at these higher concentrations, in effect reducing the number of ions available to cause compression of the electrical double layer and, therefore, reduction of the zeta potential.

The experiments with PVA and ammonium dichromate indicate that the PVA does not change the sign of the potential of the uncoated phosphor as compared to that found with water, and also that some reaction occurs between the phosphor and the ammonium dichromate. Perhaps the ZnS is oxidized to the sulfate. The silicate coated phosphor is more resistant to attack by the dichromate, as is evident from the smaller zeta potential change with time as compared to that observed for the uncoated material. Streaming potential measurements on systems of this type may be useful in studying chemical reactions which would otherwise remain undetectable.

Attempts to correlate wet-adherence measurements, performed in 9.25×10^{-5}M $Ba(Ac)_2$ and 0.22% stock silicate, with zeta potential data have not been completely successful. This variance may be due largely to the tendency of the silicate, used in making the RWA measurements, to coat the sample and at least partially mask the electrical properties of the original material. Thus, while there is a trend toward increasing RWA with decreasing zeta potential, the results are not conclusive as there is considerable scatter in the experimental data (Table I and Fig. 2). The best correlation is found with the coated phosphors that have negative zeta potentials in 5.8×10^{-4}M $Ba(Ac)_2$. Thus far, no attempt has been made to study the effect of shape and size distribution on the relative wet adherence and the zeta potential. Because the samples studied were prepared under different conditions of firing, fluxing, activation, and coating, the lack of correlation is not surprising. If the samples are grouped according to treatment when the data are plotted, as has been done in Fig. 2, fair correlation is obtained. It should be re-emphasized, however, that the best correlation between zeta potential and wet adherence is found if the same sample is used and its zeta potential is altered by changing the concentration of the electrolyte.

Conclusions

1. The zeta potential of ZnS may be altered in sign depending on firing technique. Apparently, adsorbed H_2S plays an important role.
2. NH_4OH washing can change the zeta potential of a ZnS sample that has been fired in H_2S and flushed with N_2 from negative to positive. The change is due possibly to an adsorbed zinc ammonia complex.
3. ZnS phosphors have positive zeta potentials during all stages of preparation prior to the coating operation. Silicate coatings yield negative potentials, while ZnS coatings yield positive potentials. These experiments illustrate the importance of surface conditions as compared to bulk properties in determining the zeta potential.
4. The influence of electrolyte concentration on the zeta potential of a ZnS:0.015% Ag, uncoated phosphor has been determined with $Ba(Ac)_2$, potassium silicate, and $Ba(Ac)_2$-potassium silicate mixtures. Similar experiments were performed in the PVA-ammonium dichromate system for the coated as well as the uncoated phosphor. The dichromate interacts chemically with the phosphor, causing rapid changes in the zeta potential.
5. Zeta potential data have been correlated with adhesion measurements.

Acknowledgment

The author is happy to acknowledge the assistance of L. E. Whitmer and Dr. S. A. Harper, who prepared many of the samples used in these experiments. Mrs. K. Maisane performed a major share of the streaming potential experiments concerned with the effect of electrolyte concentration, and her help is gratefully appreciated. Dr. D. J. Donahue and Dr. R. N. Summergrad assisted in many instances with helpful discussion and suggestions.

Manuscript received May 19, 1958. This paper was prepared for delivery before the New York Meeting, April 27-May 1, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Associated Donor-Acceptor Luminescent Centers in Zinc Sulfide Phosphors

E. F. Apple and F. E. Williams

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

Zinc sulfide activated with copper or silver and coactivated with gallium or indium shows two emission bands. The shorter wave-length band does not involve the ground state of the coactivator or donor, whereas the longer wave-length band does. Both bands involve the ground state of the activator or acceptor. The factors contributing to the emission intensities from the various associated donor-acceptor pairs are discussed theoretically. The dependences on temperature and on concentrations of activator and coactivator are in accord with the longer wave-length band involving a highly associated donor-acceptor pair. In addition, the energy levels of the donors, as obtained from thermoluminescent data, are correlated on the basis of the model with the differences in the transition energies of the two emission bands of these phosphors.

Zinc sulfide phosphors coactivated with Group III elements of the Periodic Table have been reported to have a long wave-length emission band in addition to the short wave-length emission band associated with activation by Group I elements and with self-activation. Kröger and Dikhoff (1), for example, reported long wave-length emission in phosphors coactivated with Sc, Ga, or In. The emission bands peaked at 5250Å with Sc, 5700Å with Ga, and 6800Å with In and were relatively independent of the identity of the activator. They also observed that the substitution of ZnS in part by CdS had less effect on the long wave-length emission spectra than on the short wave-length emission spectra. Klasens (2) attributed these long wave-length bands to the radiative recombination of a free hole with an electron trapped at the coactivator. Froelich (3) reported long wave-length emission for Cu and self-activated ZnS phosphors which were coactivated with quite high concentrations of Al. Emission peaks are at 5880 and 5000Å, respectively. Apple (4) has reported that the crystalline structure influences the relative intensities of the two emission bands observed with ZnS: x(Cu, Ag, Au), y(Ga, In) phosphors in which $x < y$. The long wave-length emission was found to be enhanced in hexagonal ZnS. He has suggested that this effect may be related to a change in association of activator and coactivator.

In this investigation a comprehensive study of ZnS:x(Cu or Ag), y(Ga or In) was made. The spectra of the long wave-length emission are found to depend on the identities of both activator and coactivator. The relative intensities of the long and short wave-length emission depend on concentrations of activator and coactivator and on temperature of excitation. These experimental results are explained by means of a model for the long wave-length emission center consisting of a highly associated activator-coactivator center. This center is similar to the associated donor-acceptor system proposed by Prener and Williams (5) to explain the short wave-length emission by radiative transitions from excited states of the donor to the ground state of the acceptor but is different in that the donor and acceptor responsible for the long wave-length emission are more closely associated so that radiative transitions occur from the ground state of the donor to the ground state of the acceptor.

Experimental Results

The phosphor mixes usually were made by adding aqueous solutions of activator and coactivator to a water slurry of ZnS (G.E. luminescent grade); in a few cases the activator and coactivator were added as the solid ternary sulfides, i.e., $CuGaS_2$, $CuInS_2$, or $AgGaS_2$ in the absence of water. The mixes were fired in an H_2S stream either at 950°C to give a cubic material or at 1150°C to give a hexagonal phosphor. The H_2S used was bubbled through $Ba(OH)_2$ solution, then through drying columns containing silica gel and P_2O_5 and a cold trap held at −50°C before coming in contact with the sample.

Emission spectra of the phosphors under 3650Å excitation[1] are shown in Fig. 1-4. Concentrations are given in gram-atoms added per mole ZnS, but the amounts of activator and Ga present after firing were equivalent to the amounts added, whereas the

[1] Essentially 3650Å radiation was obtained from a G.E. mercury lamp, #H100-FL4, in conjunction with Corning #5840 and Kopp #41 uv filters. The spectra were recorded on an automatic spectroradiometer which plots radiant energy flux vs. wave length.

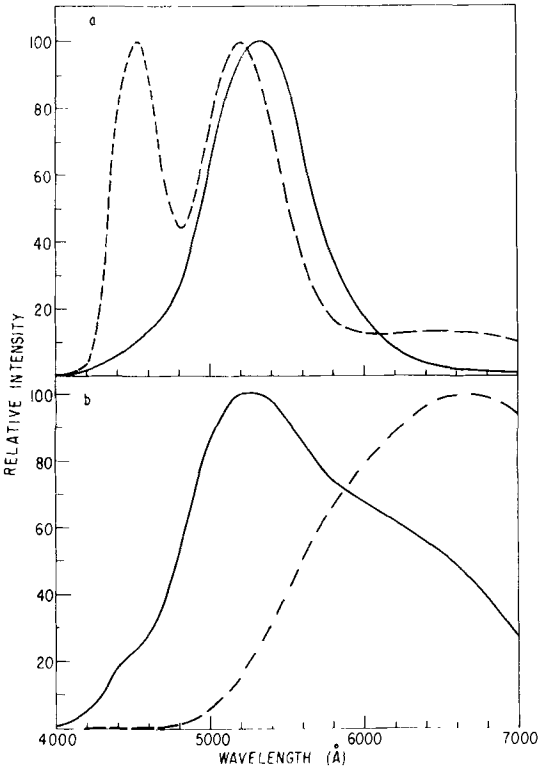

Fig. 1. Emission spectra of ZnS:10^{-4} Cu, 10^{-4} Ga; a, cubic structure; b, hexagonal structure; 3650Å excitation; ——— room temperature - - - - - —196°C.

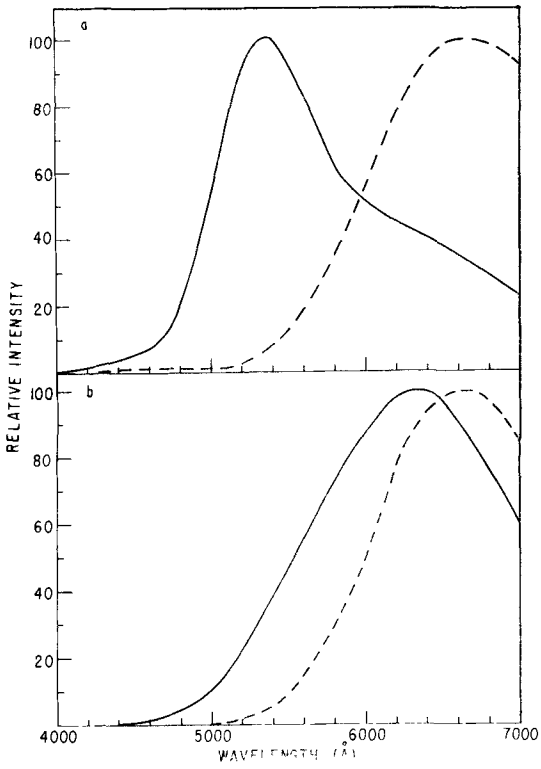

Fig. 2. Emission spectra of ZnS:10^{-4} Cu, 2×10^{-4} In; captions as in Fig. 1.

final In concentration, because of volatization, was approximately equal to the concentration of activator present. Although most of the phosphors were prepared in purified H_2S, they could be made equally well in sealed, evacuated quartz tubes, S_2(p = 30 atm), N_2, or H_2, provided that water and oxygen were excluded in the phosphor preparation.

This class of phosphors clearly shows two emission bands.[2] The shorter wave-length emission, which is in the blue with Ag and in the green with Cu, is dependent on the identity of the activator only, while the longer wave-length emission, which is in the yellow with Ag and orange with Cu, depends on the identity of both activator and coactivator. For example, the longer wave-length emission peaks at 5900Å in ZnS:Ag,Ga and at 6150Å in ZnS:Ag,In.

The relative intensities of the two bands are determined by such parameters as concentration of activator and coactivator, temperature during excitation, identity of coactivator, crystal structure, and firing temperature.

An increase in concentration of activator and coactivator causes an increase in the long to short wave-length emission ratio. For example, consider the emission in cubic ZnS:Cu,In. Below 10^{-5} Cu and In, virtually no contribution from the orange band is observed under excitation at room temperature. Increase in concentration of Cu and In from 10^{-5} causes an increase in the orange emission until at 3 x 10^{-4} Cu and In the intensity of the orange band is about equal to that of the green band and above this concentration, the orange band predominates. In Ga-coactivated phosphors, the shorter wave-length band predominates in samples containing up to about 10^{-2} Cu and Ga. Related to the concentration effect is the dependence of the longer to shorter wave-length emission ratio on firing temperature. In cubic ZnS: 10^{-4} Cu, 2 x 10^{-4} In, this ratio at room temperature is 0.31, 0.27, 0.26 for samples fired at and air-cooled from 600°, 700°, and 900°C, respectively.

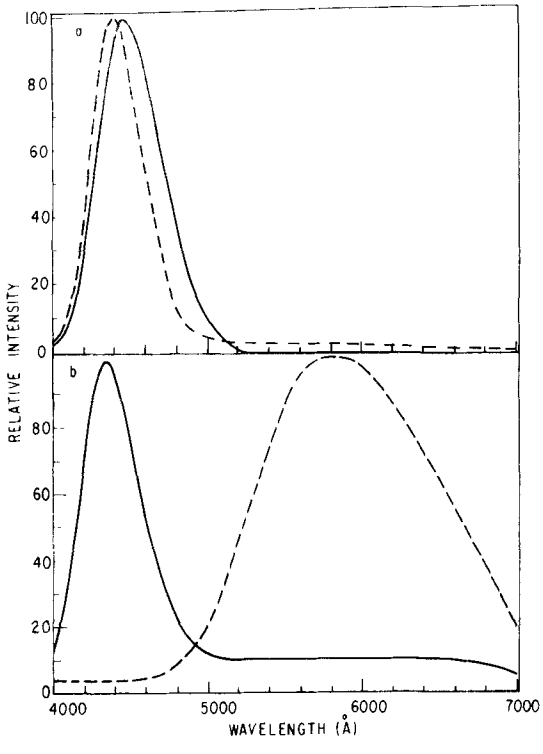

Fig. 3. Emission spectra of ZnS:10^{-4} Ag, 10^{-4} Ga; captions as in Fig. 1.

[2] The additional band at 4500Å observed only in cubic ZnS:Cu, Ga is not discussed in this paper.

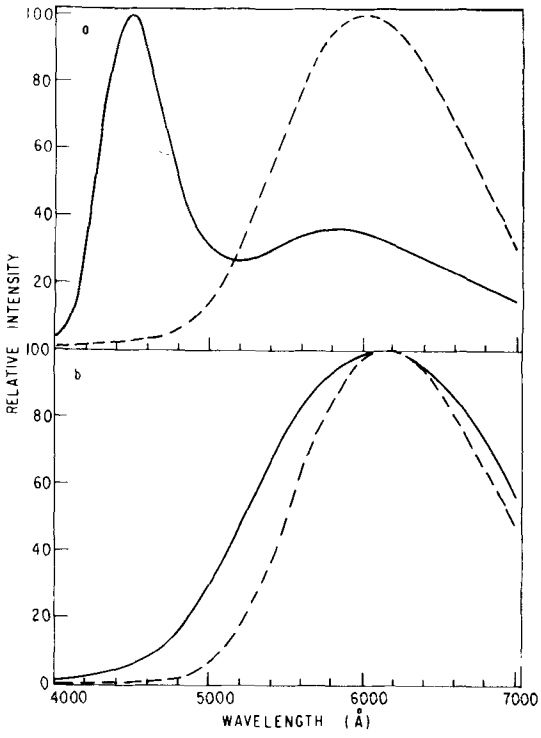

Fig. 4. Emission spectra of ZnS:10^{-4} Ag, 2 × 10^{-4} In; captions as in Fig. 1.

As is evident from Fig. 1-4 the longer wave-length emission is favored under excitation at lower temperatures. The temperature dependence of emission of the phosphors was determined by recording the spectra as the sample contained on a large Cu block in vacuum was cooled slowly from about 275°C to room temperature. Below room temperature, the block was cooled by the addition of small quantities of liquid nitrogen. The temperature change during measurement of the spectrum was in no case greater than 5°C. Figure 5 shows some of the spectra obtained on hexagonal ZnS:10^{-4} Cu, 2 x 10^{-4} In at the temperatures indicated. Even at 255°C, where temperature quenching has begun, the contribution of the orange band is considerable. The slight shift in the spectra at lower temperatures is due in part to the disappearance of the green band below —140°C. Cubic ZnS:10^{-4} Cu, 2 x 10^{-4} In shows the same general temperature dependence, but above 100°C the orange contribution to the spectra is small and the change from predominantly orange to green emission occurs at —35° to 0°C. The green-orange change in emission occurs at lower temperatures as the concentration of Cu and In is decreased. This is observed for both cubic and hexagonal phosphors. Figure 6 shows the temperature dependence of emission for hexagonal ZnS:10^{-4} Cu, 10^{-4} Ga. Above 100°C, the contribution from the orange band is again very small. These data indicate that the temperature dependence of emission at a given concentration of activator and coactivator is determined by the identity of the coactivator. In ZnS:Ag,Ga or In, the data were limited to below about 80°C where temperature quenching of luminescence begins. Consequently, the yellow to blue emission shift was not observed in hexagonal ZnS:Ag,In.

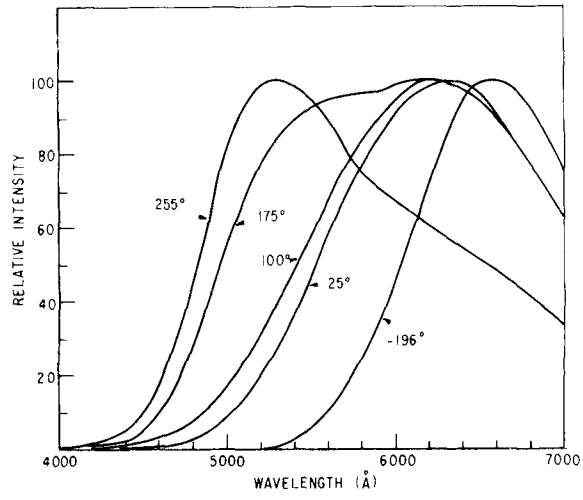

Fig. 5. Emission spectra of hexagonal ZnS:10^{-4} Cu, 2 × 10^{-4} In at indicated temperature using 3650Å excitation.

The effect of structure of the ZnS in luminescence has been mentioned heretofore in connection with the concentration- and temperature-dependent properties of the phosphors. At a given concentration of activator and coactivator, the longer wave-length emission is enhanced in the hexagonal phase of ZnS as, again, is shown in Fig. 1-4. On annealing a hexagonal phosphor for an extended time at 800°-900°C, the shorter wave-length emission typical of cubic phosphors increases concurrently with increase in the amount of cubic phase present. The effect is reversible with change in structure. Also, phosphors with emission spectra characteristic of those prepared at 1150°C can be made at temperatures as low as 600°C provided hexagonal ZnS is used in preparation of the phosphor mixes. The structure of these phosphors remains hexagonal during the 1-hr firing period at 600°C.

Glow curves were obtained on samples previously excited by a BH-4 lamp at —195°C for a 5-min period, and then heated at a rate of 10°C/min. The glow intensity was measured with an RCA 5819 PM tube with S-4 response. Glow peaks apparently resulting from In occur at —140° and —60°C. The thermoluminescence changes from the longer to the shorter wave-length emission during these glow experiments. The high-temperature glow peak at 100°-

140°C observed with Cu-activated materials changes position with change in concentration.

Theoretical Analysis

As a consequence of the association of activator and coactivator impurities into donor-acceptor pairs, a unique impurity system is not expected in these phosphors, but rather a distribution of diatomic centers each characterized by a different interimpurity distance is expected. These pairs will each have a different energy level structure and transition probabilities for excitation and emission.

Prener and Williams (5) have proposed a model for the luminescent center defined in this paper as the short wave-length luminescent center. In this model, the transitions responsible for the short wave-length emission occur between excited states of the donor and the ground state of the acceptor in an associated, but not nearest neighbor, coactivator-activator pair. Because excited states of the donor are involved, the emission is independent of the chemical identity of the coactivator. Recently, Williams (6) extended the original concept of associated pairs at second, third, and fourth nearest-neighbor sites to more widely separated pairs of nonrandomly distributed donors and acceptors contributing to short wave-length emission. The present analysis is consistent with the short wave-length emission involving pairs with sufficiently great interimpurity spacing such that only radiative transitions from excited donor states to the ground state of the acceptor can occur with appreciable probability. The ground state of the donor for these pairs will function as an electron trap. These pairs will be designated s-type and are shown on the left of the band model in Fig. 7. The emission process also is indicated with the transition probability A_s.

We propose that the long wave-length emission arises from coactivator-activator pairs sufficiently closely associated so that radiative transitions may occur directly from the ground state of the donor to the ground state of the acceptor. The probability of this transition depends, of course, on overlap of the ground state donor and acceptor wave functions. Because the energies of the ground states are dependent on the identities of donor and acceptor, respectively, the transition energy for the long wave-length emission will be dependent on the chemical identities of both the coactivator and the activator. These pairs will be designated as l-type and are shown on the right in Fig. 7 along with the emission process indicated by the transition probability A_l.

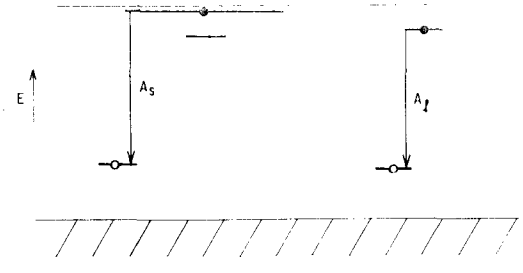

Fig. 7. Band theory model for the short and long wave-length luminescent centers.

The relative intensities of the short and long wave-length emission bands can be analyzed theoretically most readily for temperatures sufficiently great so that thermal equilibrium applies among the electron states and separately among the hole states. The ratio of intensities from s- and from l-type centers will then be of the following form:

$$\frac{I_s}{I_l} = \frac{\rho_s}{\rho_l} \cdot \frac{P(\epsilon_s)}{P(\epsilon_l)} \cdot \frac{A_s}{A_l} \cdot \frac{\alpha_s}{\alpha_l} \qquad [1]$$

where the ρ's, P's, A's, and α's are, respectively, the densities of states, occupational probabilities for each state, transition probabilities for emission, and fractions of pairs responsible for the s- and l-type emission.

Because the s-centers are believed to comprise all the coactivator-activator pairs in which any excited donor state has a finite matrix element for a radiative transition with the ground state of the acceptor and since there are many excited donor states characterized by different spatial extensions of their wave functions, a distribution of pairs with different interimpurity spacings is expected to contribute to α_s. On the other hand, the l-centers probably comprise a unique pair, or at most a narrow distribution of pairs, because the interimpurity spacing must be such that a finite matrix element for a radiation transition exists between the ground states of the donor and acceptor. Only a small fraction α_l of the pairs are consistent with this requirement. In the following analysis the ratio α_s/α_l will be determined theoretically in an approximation consistent with being large compared to unity. From the formula of Prener (7), we obtain:

$$\frac{\alpha_s}{\alpha_l} = \frac{\sum_{l+1}^{\infty}\alpha_m}{\alpha_l} = \frac{\sum_{l+1}^{\infty} Ac\, Z_m e^{e^2/KrmkT_D}\, e^{-c\sum_1^m Z_j}}{Ac\, Z_l\, e^{e^2/KrlkT_D}\, e^{-c\sum_1^l Z_j}} \qquad [2]$$

where Z_j is the number of sites of the jth type and T_D is the temperature during preparation below which diffusion over interimpurity distances cannot occur. We then make a continuum approximation (8) for the pairs of the s-type and replace the sums by integrals. In this approximation $(Z_{l+1} - Z_l) \rightarrow dZ = 4\pi r^2 dr$, and

$$\frac{\alpha_s}{\alpha_l} = 4\pi Z_l^{-1} e^{c\sum_1^l Z_j} \int_{r_l}^{\infty} r^2 e^{\frac{e^2}{KkT_D}\left(\frac{1}{r}-\frac{1}{r_l}\right)} e^{-\frac{4}{3}\pi r^3 c}\, dr \qquad [3]$$

For $T_D \approx 10^8$ °K and $l \geqq 3 (r_l \geqq 7\text{Å})$, the factor $e^{\frac{e^2}{KkT_D}\left(\frac{1}{r}-\frac{1}{r_l}\right)}$ is a sufficiently slowly varying function of r from r_l to ∞ so that a weighted average value can be removed from the integrand. The result is integrated and the relation $\frac{4}{3}\pi r_l^3 = \sum_1^l Z$, between the continuum approximation and the lattice is utilized to yield the following approximate relation:

$$\frac{\alpha_s}{\alpha_l} \approx c^{-1} Z_l^{-1} \left[e^{\frac{e^2}{KkT_D}\left(\frac{1}{r_s}-\frac{1}{r_l}\right)} \right] \qquad [4]$$

in which r_s can be interpreted as a weighted average interimpurity distance for the s-type centers. The factor α_s/α_l will favor s-type emission and is clearly

dependent on the concentration c of activators and coactivators.

On the other hand, the factor in Eq. [1] which takes account of the occupational probabilities of emitting states of the s- and l-type centers favors l-type emission and is strongly temperature-dependent. This is evident from Fig. 7 and also from the equilibrium approximation. For ordinary excitation intensities the fraction of centers excited simultaneously will be sufficiently small so that Boltzmann statistics may be used. The difference in emission spectra of the two bands is a measure of the difference in energies of the states of the two types of centers. We may write, therefore

$$\frac{P(\epsilon_s)}{P(\epsilon_l)} \approx e^{-\frac{hc}{kT}\left(\frac{1}{\lambda_s}-\frac{1}{\lambda_l}\right)} \qquad [5]$$

This formula will be in error by the difference in polarization energy of the two types of centers following emission. This error may be as great as the difference between the thermal depth and the optical depth of the donor. At low temperatures the occupational probabilities will not be determined by equilibrium considerations but rather by detailed balance between excitation and emission within each coactivator-activator pair. Under these conditions Eq. [5] will not apply, and an appreciable fraction of s-type pairs will no longer contribute to emission at low temperatures in the steady state because of electron trapping in the ground state of the donor of these pairs.

The ratio of densities of states ρ_s/ρ_l and transition probabilities for emission A_s/A_l are both expected to be of the order of unity and not appreciably dependent on temperature or concentration of luminescent centers. In the l-type center, emission is exclusively from the ground state of the donor so that ρ_l is obviously unity. The excited states in the highly associated l-type pair have been perturbed back to the conduction band edge (5). In an s-type center the lower excited states which give a finite matrix element for radiative recombination with the positive hole in the associated acceptor contribute to ρ_s, the higher excited states having been perturbed back into the conduction band (5). Since the s-type centers comprise a distribution of pairs with different interimpurity spacings $r_m > r_l$, the identities of the excited states contributing to ρ_s will vary with r_m; however, their number is expected to be a constant small integer. The magnitudes of the matrix elements A for radiative recombination with the positive hole in the associated acceptor should be comparable for s- and l-type emission.

In addition, the ratio I_s/I_l has been investigated with the assumption that the transitions between the unperturbed conduction band states and the ground state of the acceptor are responsible for s-type emission. With this assumption, the same dependence on temperature and impurity concentration is obtained as in the foregoing analysis. However, a pronounced dependence of I_s/I_l on excitation intensity is obtained because I_s is proportional to both the concentration of the electrons in the conduction band and the concentration of empty acceptors, whereas I_l is proportional only to the concentration of empty acceptors. This is not the case with the analysis based on s-type emission involving excited donor or perturbed conduction band states since, for this analysis, both I_s and I_l are proportional only to the concentration of empty acceptors.

The model illustrated in Fig. 7, in addition to providing the basis for the preceding analysis of the relative intensities of the short and long wave-length emission bands, provides a basis for relating the transition energies for emission to other luminescent properties. For example, the ground state of the donor in the s-type center is an electron trap, and therefore, the depth of the trap should be approximately equal to the difference in transition energies for the two emission bands.

$$E_T \approx hc\left(\frac{1}{\lambda_s}-\frac{1}{\lambda_l}\right) \qquad [6]$$

This relation is more nearly correct for the optical, rather than the thermal, trap depth. In addition, this relation is based on the assumption that the energies of the ground states of the donor and acceptor are independent of whether the association is into s-type or l-type pairs.

Since the energies of the states of the donor and acceptor do depend on association, the accuracy with which Eq. [6] is in accord with experiment permits placing an approximate limit on the degree of association of the l-type pairs. Williams (9) recently has examined theoretically the donor-acceptor pair system, which is a two-particle system consisting of an electron and a positive hole bound in the field of a finite dipole. The analysis is similar to the Heitler-London treatment of the hydrogen molecule and takes account of the overlap of the donor and acceptor wave functions. This overlap was neglected in the analysis of Hoogenstraaten (10). The transition energy for emission E_e for pairs characterized by the interimpurity spacing r_i and by radial wave functions for the separated donor and acceptor of the form $a^{-3/2}e^{-r/a}$ is:

$$E_e = -\frac{e^2}{Ka}e^{-2r_i/a}\left[\frac{a}{r_i}+\frac{5}{8}-\frac{3}{4}\frac{r_i}{a}-\frac{1}{6}\frac{r_i^2}{a^2}\right] - \frac{e^2}{12a}\left(\frac{1}{K_o}-\frac{1}{K}\right)e^{-2r_i/a}\left[4\frac{r_i^2}{a^2}+18\frac{r_i}{a}+9\right] + \frac{e^2}{K_o r_i} - E_D - E_A + E_G \qquad [7]$$

where E_D and E_A are the ionization energies for the separated donor and acceptor, K and K_o are the static and optical dielectric constants, and E_G is the band gap. For pairs consisting of donors and acceptors both located at sites of the same sign and with $E_D \geqq 0.5$ ev and $E_A \geqq 0.5$ ev, the perturbation of the ground states and consequent increase in E_e will be quite accurately e^2/Kr_i. The error involved in using Eq. [6] to calculate thermal trap depths tends to cancel the error involved in assuming the energies of the donor and acceptor states to be independent of degree of association.

Interpretation of Experimental Results

The longer wave-length emission is attributed to radiative transitions involving the ground states of highly associated donor-acceptor pairs and consequently should depend on the chemical identity of

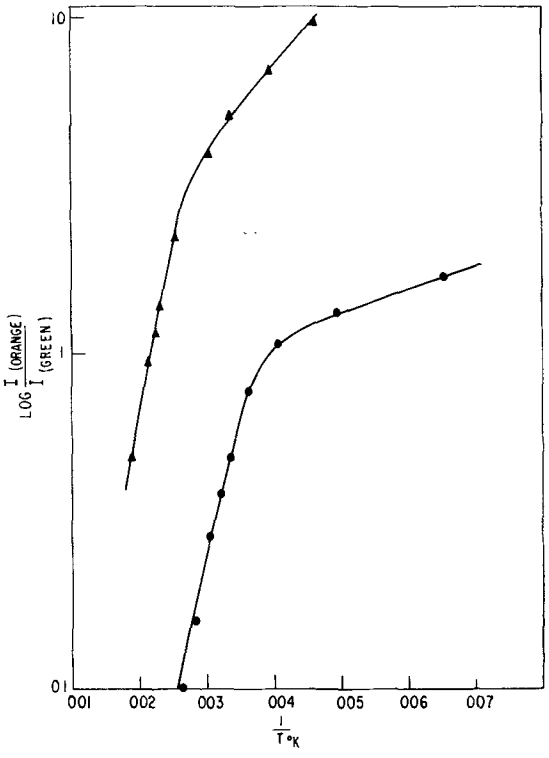

Fig. 8. log I orange/I green vs. 1/T ——— 3650Å excitation; ▲, hexagonal ZnS:10^{-4} Cu, 2 × 10^{-4} In; ●, hexagonal ZnS:10^{-4} Cu, 10^{-4} Ga.

both donor and acceptor. This has been observed experimentally as has already been pointed out with ZnS:Ag,Ga and ZnS:Ag,In. In ZnS:Cu,Ga and ZnS:Cu,In, the difference in spectral distributions of the long wave-length emissions is less marked but present.

In addition, the model for the long wave-length center is in agreement with the fact that the temperature dependent properties are determined primarily by the identity of the coactivator, since the energy level of the activator for both the short and long wave emission is nearly identical, whereas different energies are associated with the Ga and In levels. The latter was pointed out by Hoogenstraaten (10) for the trap depths for Ga and In. This was confirmed in the glow curve measurements of the present study. In Fig. 8 the log of the ratio of orange to green intensities is plotted against the reciprocal of the absolute temperature for hexagonal ZnS:10^{-4} Cu, Ga and hexagonal ZnS:10^{-4} Cu, 2 x 10^{-4} In. The slopes of these plots are the differences in energies of the *s*- and *l*-type centers in their emitting states and are approximately the difference in energies of the donor levels responsible for the short and long wave-length emissions. The total quantum efficiency does not decrease in this temperature interval, and the effects of competing nonradiative processes can therefore be neglected. The nonlinear portions of the plots observed at lower temperatures indicate the absence of thermal equilibrium. The slope is 0.12 ev for ZnS:Cu,Ga and 0.20 ev for ZnS:Cu,In. Although these energies are lower than the values of the trap depths, i.e., 0.50 ev for In and 0.42 ev for Ga, the energy differences are in the right direction and the 0.08 ev difference between Ga and In is the same as the difference in energies reported for the trap depths (10). With decrease in concentration of activator and coactivator, the energies become larger as is shown in Fig. 9. This effect of concentration is qualitatively in accord with the changes in energy level structures of the two types of centers predicted by Eq. [7] since the contribution from each pair changes with concentration.

Using Eq. [6], the trap depths for In and Ga as calculated from emission spectra of Cu-activated materials are 0.47 ev for In and 0.44 for Ga which compare favorably with the thermal trap depths described above. In the case of Ag-activated phosphors, however, the values obtained are 0.80 for In and 0.72 for Ga. The difference in calculated trap depths is 0.08 ev, however.

Equation [4] predicts a slope of minus one between log I_s/I_l and log C, and Fig. 10 shows such a dependence in the cubic ZnS:Cu,In system.

The ratio I_s/I_l was found to be approximately independent of excitation intensity. This experimental result is consistent with the prediction of the theoretical analysis in the Theoretical Analysis Section based on *s*-emission involving excited donor states of donor-acceptor pairs, and is contrary to the results of the analysis based on *s*-emission involving conduction electrons.

In the section on Experimental Results it was pointed out that a higher concentration of Ga than of In is necessary to make the long wave-length emission predominate. Superficially, this might seem in conflict with the model since Ga has the shallower trap depth and consequent greater spatial extension of its wave functions so that sufficient overlap for radiative transitions to a less closely associated ac-

ceptor at a lower concentration would be expected. However, as is evident from Eq. [5] the ratio of occupational probabilities $P(\epsilon_s)/P(\epsilon_l)$ not only strongly favors the long wave-length emission but also is strongly dependent on the energy of the ground state of the donor. The Ga, compared to In, is less favored by this factor to emit in the long wave-length band so that an increased concentration of Ga over In is necessary to attain comparable values of I_s/I_l in these two materials.

In Table I, the energy at the long wave-length emission peak is compared to that calculated from thermal and optical data involving the trap depth of the coactivator and the emission peak of the short wave-length process, respectively. The difference in these two values should give approximately the energy of the long wave-length emission in accordance with Eq. [6]. In the Cu-activated materials, this relation is satisfied but with Ag-activated phosphors the calculated and observed values differ by 0.26 ev in both cases.[3] Because of this approximate agreement of Eq. [6] with experiment a lower limit on the value of l is suggested. From Eq. [7] an increase in the transition energy E_e for nearest-neighbor pairs ($l = 1$) of 3/4 ev is predicted for these phosphors; an increase of 1/2 ev for second-nearest neighbors pairs ($l = 2$); and an increase of 2/5 ev for third-nearest neighbors pairs ($l = 3$). Only $l \geqq 4$ is consistent with the success of Eq. [6]. In addition, the interimpurity distance r_l is different for the cubic and hexagonal structures if $l \geqq 3$, and this may account in part for the dependence on crystal structure of the relative intensities of the short and long wave-length bands.

An interesting sequel to the work reported here is a preliminary study of the effect of Cd substitution on ZnS phosphors showing the long wave-length emission. In hexagonal ZnS: 10^{-4}Cu,In, substitution of up to 15 mole % CdS causes an increase in the ratio of intensities of the short wave-length to long wave-length emission at room temperature. These data are consistent with the analysis of the occupational probabilities of electrons in the emitting states of the s- and l-type centers as discussed in this paper. Up to 15% CdS substitution essentially decreases the depth of the ground state of the donor and thus increases the competition of the short wave-length process with the long wave-length process. A more detailed account of this work will appear in a future communication.

In summary, the long wave-length emission bands observed in ZnS: (Cu or Ag), (Ga or In) phosphors are attributed to transitions between the ground state of the donor and the ground state of the acceptor in highly associated coactivator-activator pairs. The short wave-length emission apparently involves transitions between excited donor states and the ground state of the acceptor in less highly associated pairs characterized by a distribution of interimpurity distances. The spectra and the dependence on temperature and on pair concentration of the intensities of the short and long wave-length bands are in accord with this model.

It is predicted that at low temperatures the centers responsible for the long wave-length emission should be capable of excitation at longer wave lengths than the short wave-length centers, and excitation of single crystals under these conditions with polarized light should yield polarized long wave-length emission since the highly associated pairs have a strong anisotropy.

[3] It should be pointed out that observed and calculated values of the long wave-length emission in ZnS: Au, In agree very well.

Acknowledgment

We wish to acknowledge the contributions from the following people: Mrs. D. J. Weil for sample preparation; Dr. J. S. Prener for suggestions and critical review; Dr. P. D. Johnson for glow-curve measurements; Dr. F. J. Studer for measurement of emission spectra.

Manuscript received Aug. 4, 1958. This paper was prepared for delivery before the New York Meeting, April 27-May 1, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Effect of Various Etches on Recombination Centers at Germanium Surfaces

George Wallis[1] and Shyh Wang[2]

Sylvania Electric Products, Inc., Woburn, Massachusetts

ABSTRACT

Germanium samples were etched with CP-4, hydrogen peroxide, iodine A, electrolytic, and silver etch. The density, energy levels, and capture probabilities of the recombination centers were measured before and after the etched samples were baked. It was found that iodine A and electrolytic etches produce recombination centers of one type, and the remaining etches, centers of another type. Baking converted the centers found on iodine A etched surfaces into the type of centers that are characteristic of surfaces etched with CP-4, hydrogen peroxide, and silver etches. When surfaces were prepared with an etch other than iodine A, baking increased the density but did not affect the types of the centers. The different etches did not produce significant differences in maximum surface recombination velocity either before or after baking.

During recent years, it has become evident that the recombination process on germanium surfaces is described fully by the Shockley-Read theory (1). Good theoretical fits to experimental results can be obtained if it is assumed that the recombination centers are at discrete energy levels, and it has been our experience that within experimental error the same type of recombination centers is found on CP-4 etched surfaces irrespective of conductivity type. The present work was undertaken in order to find out what effect different etches have on the recombination centers. The etches under investigation were CP-4, hydrogen peroxide etch, iodine A etch, electrolytic etch, and silver etch (see appendix). Our results indicate that under favorable conditions all of the above etches produce comparable densities of recombination centers. However, iodine A and the electrolytic etch produce recombination centers of one type while the remaining etches produce centers of a different type. As far as maximum surface recombination velocity is concerned, a range of values between 100 and 200 cm/sec was found for all etches. Baking of the etched samples under atmospheric conditions at 100°C for periods in excess of 16 hr increased the density of recombination centers by varying amounts. In addition, baking converted the type of recombination center found on iodine A etched surfaces into the type characteristic of CP-4, hydrogen peroxide, and silver etch. Baking did not change the type of recombination center when the surfaces were treated previously with any etch other than iodine A.

Theory and Procedure

Previous investigation of the fast states at a CP-4 etched germanium surface has indicated that the following simple model is adequate (2). The fast states are located at four discrete energy levels within the forbidden gap, as shown in Fig. 1. Each of the levels is associated with four parameters, i.e., energy, density, capture probability for holes, and capture probability for electrons. The levels near the two band edges have a larger density than the levels near the center of the gap; however, the levels near the band edges have much smaller capture probabilities for electrons and/or holes. When the surface potential (energy difference between Fermi-level and intrinsic Fermi-level at surface) is in a range $-6\ kT$ to $+2\ kT$, the field effect is controlled by all four levels, but the surface recombination process is controlled primarily by the two levels near the center of the gap. The latter therefore will be referred to as surface recombination centers. It turns out that within experimental error the parameters in the theoretical expression for surface recombination velocity are the same for either recombination level. Hence, the two levels are regarded as constituting one type of recombination centers, having the same capture probabilities for holes and electrons. In view of these simplifications, we are concerned with ten rather than sixteen parameters, i.e., the densities and energies of the four levels, and the capture probabilities for holes and electrons of the pair of recombination centers.

When a freshly etched sample is exposed to various ambient atmospheres, some of these parameters

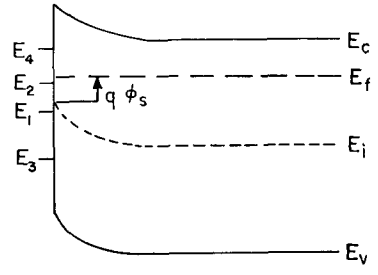

Fig. 1. Band structure of Ge near surface. E_1, E_2, E_3, and E_4 are the energy levels of the four groups of fast states at the germanium-oxide interface.

[2] Present address: Department of Electrical Engineering, University of California, Berkeley, Calif.

evidently change. A consistent interpretation is possible if it is assumed that only the densities of the pair of recombination centers change, and that they change in such a way that the ratio of the densities remains constant.

In the presence of a single type of recombination center with energy level E_t and capture probabilities for electrons c_n and for holes c_p, the photoconductance G_L of a thin sample[3] is given by

$$G_L = k\tau_{eff} = k\{1/\tau + N_t\,(c_p c_n)^{1/2}\,(n_o + p_o)/an_i[C + \cosh q\,(\phi_s - \phi_o)/kT]\}^{-1} \quad [1]$$

where k is a proportionality constant; τ_{eff} and τ are the effective and the bulk lifetime, respectively; N_t is the density of the centers; n_o and p_o are the equilibrium electron and hole concentrations; n_i is the intrinsic carrier concentration; a is the thickness of a sample; ϕ_s is the surface potential; $2q\phi_o/kT = \ln (c_p/c_n)$; $C = \cosh (E_t - E_i - q\phi_o)/kT$; and E_i is the intrinsic Fermi level. The effective lifetime is related to the surface recombination velocity v_s by the equation $\tau_{eff} = [1/\tau + 2v_s/a]^{-1}$.

A range of ϕ_s values can be obtained by exposing a sample to a Brattain-Bardeen cycle (3) of dry oxygen, sparked oxygen, and wet nitrogen. During the cycle, a series of simultaneous measurements of G_L and ϕ_s can be made. The determination of C and ϕ_o from the experimental curves of G_L vs. ϕ_s is straightforward provided N_t, C, and ϕ_o remain constant during a cycle. We believe that C and ϕ_o satisfy this condition. However, N_t did not remain constant on the freshly etched surfaces under discussion. Hence, C and ϕ_o had to be determined by a less direct method (4) which is independent of N_t.

When a small a-c field is applied normal to the surface of a sample, the change in photoconductance ΔG_L may be expressed as

$$\frac{\Delta G_L}{G_L} = (\tau_{eff}/\tau - 1)\,\frac{\sinh q\,(\phi_s - \phi_o)/kT}{C + \cosh q\,(\phi_s - \phi_o)/kT}\,\frac{q\Delta\phi_s}{2kT} \quad [2]$$

This equation contains the same parameters C and ϕ_o as Eq. [1], but it does not contain N_t explicitly. The change in surface potential with field, $\Delta\phi_s$, can be calculated from the field effect conductance, ΔG_s, for a given value of ϕ_s by use of the expression

$$\Delta G_s = \frac{\partial G_s}{\partial \phi_s}\,\Delta\phi_s \quad [3]$$

where $\partial G_s/\partial\phi_s$ is a known function of ϕ_s.

Experimentally, a series of simultaneous measurements of the following four quantities is made during a Brattain-Bardeen cycle: (*a*) surface potential ϕ_s, calculated from the d-c surface conductance; (*b*) field effect conductance, ΔG_s, for a small a-c field applied normal to the surface; (*c*) the a-c photoconductance G_L which results when a region of the sample is illuminated with chopped light from a water filtered light source;[4] (*d*) the change in conductance ΔG with an a-c field of the same strength as in (*b*), measured in the presence of d-c light of the same intensity as the chopped light in (c). ΔG (4) is found to be the sum of the change in photoconductance ΔG_L and the dark field-effect conductance ΔG_s.

From these four quantities, a plot of $\Delta G_L/G_L$ vs. ϕ_s may be constructed which can be fitted by Eq. [2] by means of the adjustable parameters C and ϕ_o. Relative changes in the density of the recombination centers can be deduced by comparing the experimental plot of G_L vs. ϕ_s with Eq. [1] into which the previously derived values of C and ϕ_o have been substituted.

Finally, the densities of the recombination centers and the other two surface states are deduced as follows. In the field-effect experiment, the total charge, induced by the a-c field, is the sum of the charge in the space charge region, ΔQ_{sc}, and the charge in the surface states, ΔQ_{ss}. The total induced charge is known, and ΔQ_{sc} can be computed for each experimental point from the equation

$$\Delta Q_{sc} = \frac{\partial Q_{sc}}{\partial \phi_s}\,\Delta\phi_s \quad [4]$$

where $\partial Q_{sc}/\partial\phi_s$ is a known function of ϕ_s, and $\Delta\phi_s$ is obtained from the field effect by use of Eq. [3]. Hence, one can construct a curve of ΔQ_{ss} vs. ϕ_s. From the latter, the density of each of the surface states can be deduced by curve fitting to the equation

$$\Delta Q_{ss} = q\sum_{n=1}^{4} N_{tn}\,\frac{\exp y_n}{(1 + \exp y_n)^2}\,\frac{q\Delta\phi_s}{kT} \quad [5]$$

where $y_n = (E_{tn} - E_i - q\phi_s)/kT$, and the summation is over the four states.

All samples used in this work were cut from a single crystal of n-type Ge. The resistivity of the samples was 18 ohm-cm and the bulk lifetime about 1000 μsec. All samples were oriented along the same plane (321) in order to exclude possible structural effects. The thickness of the samples was between 7 and 25 mil. Samples were hand polished, and their ends plated with Rh. Ohmic contacts were soldered to the plated ends, and two further contacts which served as voltage probes were soldered to one side of the samples. During an etch, the plated and soldered areas were masked by Apiezon W wax. After etching, the samples were rinsed in distilled water, the wax was dissolved in Triad,[5] and the Triad in turn was rinsed off with acetone, alcohol, and distilled water, in this order. After the last rinse was dried off, the sample was mounted in a glass holder and placed in a double-walled glass tube. Water from a thermostatically controlled tank was pumped through the region between the two walls. Thus, the temperature of the sample during a cycle was kept at 29° ± 0.05°C. Furthermore, the water served to filter out penetrating light.

The d-c conductance was measured to five significant figures. From the conductance, the surface potential was calculated without taking Schrieffer's correction (5) into consideration. The field-effect measurements were made with a 32 cps sinusoidal voltage, using essentially Low's circuit (6). The peak field strength was 4000 v/cm. The photoconductance

[3] The thickness a of the sample must be less than a diffusion length.

[4] The theoretical expressions hold only if injection is limited to the surface. Hence, nonpenetrating light must be used.

Summary of results: $(N_{to})_1$ refers to the density of recombination centers below the intrinsic Fermi level and was measured at $\phi_s = \phi_o$. The density of the recombination centers above the intrinsic Fermi level was found to be $(N_{to})_2 = \frac{1}{2}(N_{to})_1$. $(N_t)_3$ refers to the density of the levels near the valence band which are seen in the field effect but are found to have a negligible effect on surface recombination. The values of $(N_t)_3$ were computed on the assumption that the level is located at $E_t - E_i = -6.8$ kT. The contribution of $(N_t)_3$ to the field effect was negligible on the silver-etched baked surface. The capture cross sections σ_p and σ_n for holes and electrons, respectively, refer to the recombination centers. They are related to the corresponding capture probabilities c_p and c_n by the equations $c_p = v_t\sigma_p$, $c_n = v_t\sigma_n$, where v_t is the thermal velocity 10^7cm/sec at room temperature.

was measured with light from a tungsten lamp chopped at 60 cps. The injection never exceeded 10% of the equilibrium bulk majority carrier concentration. Usually the photoconductance measurement was checked by a direct measurement of effective lifetime by means of the photoconductive decay method. The surface potential was changed by exposing the sample to Brattain-Bardeen cycles of sparked oxygen, dry oxygen or nitrogen, and nitrogen bubbled slowly through distilled water. The oxygen was sparked with a Tesla coil for short periods of time (usually less than a second). The gases were preheated to the temperature of the sample. Measurements were made before and after the samples were baked in a dry room atmosphere at 100°C for a period of 16 hr or more.

Results and Discussion

A summary of the results is presented in Table I. In Fig. 2, we show experimental points of $\Delta G_L/G_L$ and theoretical fits (solid lines) plotted as a function of ϕ_s for surfaces freshly etched with silver etch, electrolytic etch, iodine A etch, and H_2O_2 etch. Corresponding plots for CP-4 have been shown in a previous paper (2). It will be noticed that the theoretical plots (based on Eq. [2]) fit the experimental points quite closely throughout the experimental range of ϕ_s. Notice, also, that there appear to exist two distinct values of ϕ_o, i.e., 1.1 kT and 1.9 kT. The significance of these two values is discussed below. With ϕ_o given by the value of ϕ_s at which $\Delta G_L/G_L$ vanishes, C was the only parameter in each fit. From ϕ_o and C, the energy levels of the recombination centers were deduced for each curve.

Figure 3 presents curves of surface recombination velocity v_s vs. ϕ_s for the same surfaces as the curves in Fig. 2. For comparison's sake, we have added a theoretical curve (dashed line) based on Eq. [1], with the parameters C and ϕ_o, appropriate for the H_2O_2-etched surface and with $(N_t)_1$ and $(N_t)_2$ assumed constant. The experimental curve (triangles) is much flatter and rises beyond the maximum of the theoretical curve. The discrepancies between the experimental and theoretical curves are due entirely to changes in $(N_t)_1$ and $(N_t)_2$ during the cycle. If we had failed to take these changes into consideration,

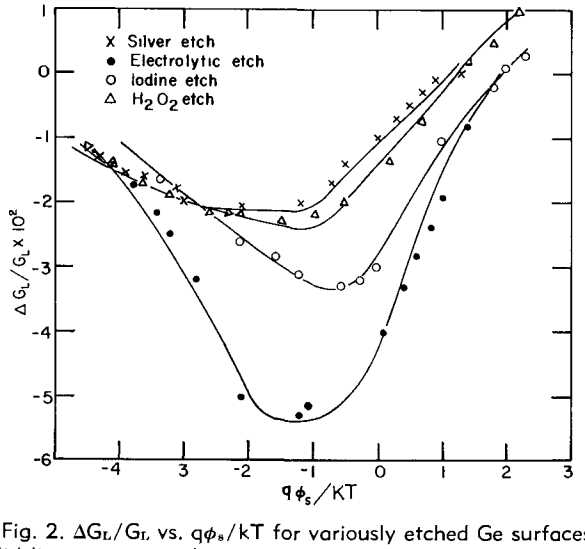

Fig. 2. $\Delta G_L/G_L$ vs. $q\phi_s/kT$ for variously etched Ge surfaces. Solid lines represent theoretical fits to the experimental data.

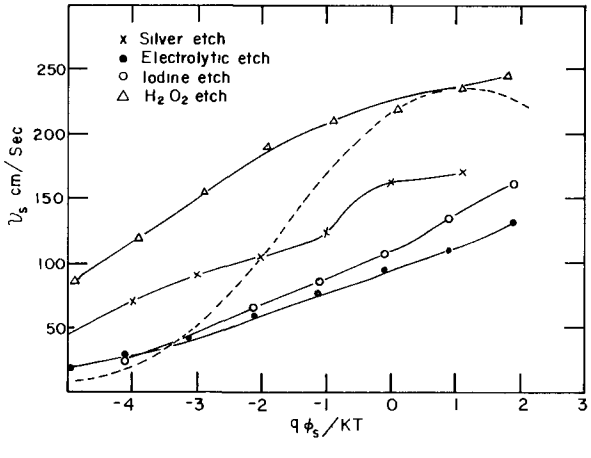

Fig. 3. Surface recombination velocity, v_s, vs. surface potential $q\phi_s/kT$ for the same surfaces as in Fig. 2. Solid lines represent the experimental data. Dashed curve was computed from Eq. [1] for the hydrogen peroxide-etched surface, with the parameters C and ϕ_o as deduced from the corresponding plot in Fig. 2, and with $(N_t)_1$ and $(N_t)_2$ assumed constant.

and if we had attempted to analyze the v_s vs. ϕ_s curves on the basis of Eq. [1], we would have obtained much larger values of C and ϕ_o. These values would have been inconsistent with the experimental $\Delta G_L/G_L$ curves.

By comparison of experimental and theoretical curves of v_s vs. ϕ_s, one can deduce whether relative changes in the density of the two recombination centers have taken place during a Brattain-Bardeen cycle. Typical relative changes for an H_2O_2 etched surface several days after etching (solid line) and after baking (dashed curve) are shown in Fig. 4. N_{to} is the density at the time ϕ_o was measured. N_t is not a function of ϕ_s but has been plotted against ϕ_s merely for convenience. For each curve, the extreme point at the left represents the density of centers immediately after oxygen was sparked. The extreme points at the right were in both cases taken in an ambient of wet nitrogen. Evidently, the baked surface was far more stable than the unbaked surface. Comparable amounts of sparking increased the density of centers on the unbaked surface by a factor of ten, as compared to an increase of less than two for the baked surface. Upon sparking, the unbaked surface became more p-type than the baked surface. On the other hand, in wet nitrogen, the unbaked surface became somewhat less n-type than the baked surface. Therefore, baking appears to make the surface more n-type. Moreover, the same Brattain-Bardeen cycle swung the surface potential of the unbaked surface through a larger range than that of the baked surface. Although these results were not strictly reproducible, these tendencies usually have been observed.

Figure 5 shows plots of $kT\Delta Q_{ss}/q\Delta\phi_s$ vs. ϕ_s for the same surfaces as in Fig. 2. The points were computed from the experimental plots of ΔG_s vs. ϕ_s, as described above. The theoretical fits are based on Eq. [7] which contains eight parameters, i.e., the densities and energies of the four levels. The energy levels near the band edges were far enough removed

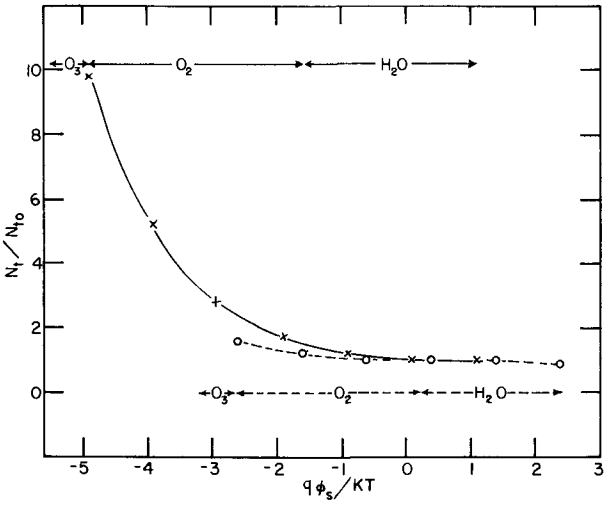

Fig. 4. Normalized density of the recombination centers, N_t/N_{to} vs. surface potential, $q\phi_s/kT$, for the hydrogen peroxide-etched surface during a Brattain-Bardeen cycle. Normalization was arbitrarily carried out at the point $\phi_s = \phi_o$. The solid curve refers to the freshly etched sample, and the dashed curve refers to the same sample after baking.

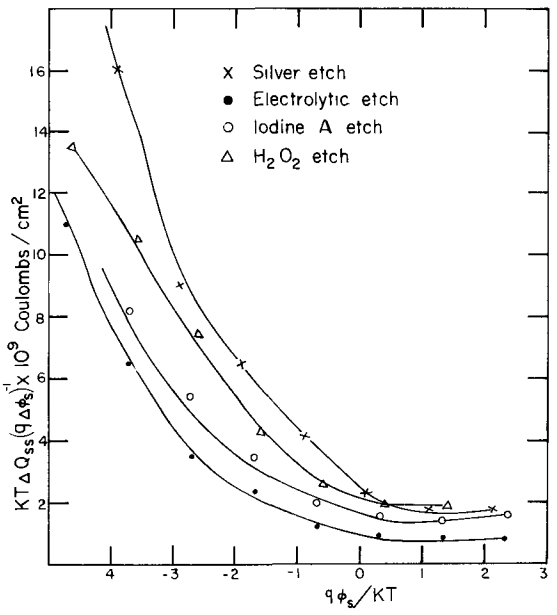

Fig. 5. Change of charge in the fast states per unit change in surface potential, $kT\Delta Q_{ss}/q\Delta\phi_s$, vs. surface potential, $q\phi_s/kT$, for the surfaces shown in Fig. 2 and 3. Solid curves represent theoretical fits to the experimental data.

from our range of ϕ_s values so that the two respective terms $N_{tn} \exp y_n (1 + \exp y_n)^{-2}$, $n = 3,4$, could be replaced by $(N_t)_3 \exp y_3 = A_3 \exp(-q\phi_s/kT)$, where $A_3 = (N_t)_3 \exp(E_{t3} - E_i)/kT$ for the level near the valence band $(E_{t3} - E_i < 0)$, and by $(N_t)_4 \exp(-y_4) = A_4 \exp q\phi_s/kT$, where $A_4 = (N_t)_4 \exp -(E_{t4} - E_i)/kT$ for the level near the conduction band $(E_{t4} - E_i > 0)$. For the energy levels of the states near the center of the forbidden gap (recombination centers), we used the values deduced from Fig. 2. As previously stated, it was assumed that the ratio of the densities of the two recombination centers remained constant during a Brattain-Bardeen cycle. The relative changes in the density of either recombination center were read off from plots such as Fig. 4. Thus, the solid lines in Fig. 5 represent four parameter fits, the parameters being the densities $(N_{to})_1$ and $(N_{to})_2$ of the recombination centers and A_3 and A_4 of the centers near the band edges. The density $(N_{to})_1$ of the recombination center below the center of the gap, $E_{t1} - E_i < 0$, has been found generally to be larger than the density $(N_{to})_2$ of the other recombination center. Almost invariably, the best fits were obtained by setting $(N_{to})_1 = 2\ (N_{to})_2$. The values for the density N_{t3} of the fast states near the valence band were calculated from A_3 on the assumption (2) that the states were located at the level $E_t - E_i = -6.8\ kT$. This level could not be determined with great accuracy. The level near the conduction band contributed relatively little to the field effect. Hence, there is considerable uncertainty about the values of A_4, and since, in addition, there is some doubt about the location of the level, we did not calculate the corresponding densities.

Before the data can be discussed, one must make an estimate of the errors involved in the measurements. No over-all estimates can be given because the accuracy of the different measurements is not the same throughout the experimental range of ϕ_s.

For instance, near the minimum in surface conductance, a large change in ϕ_s corresponds to a small change in surface conductance so that accurate determination of ϕ_s is very difficult. However, when $\phi_s - \phi_{min}$[6] becomes larger than kT, the situation is reversed: a small change in ϕ_s corresponds to a larger change in surface conductance so that fairly accurate determination of ϕ_s becomes possible. On the other hand, the determination of ΔG_L is less accurate near $\phi_s = \phi_o$ than it is for other regions of ϕ_s since it represents the difference between two large quantities, i.e., ΔG and ΔG_s.

We estimate that our values of ϕ_o are reliable to $\pm 0.3\ kT$, the uncertainty being due to inaccuracy in the measurement of ϕ_s and ΔG_L. Values of C were obtained from fits to the $\Delta G_L/G_L$ vs. ϕ_s curves and are estimated to be accurate to 20%. The energy levels were calculated from the values of C and ϕ_o and are reliable to about $\pm 0.5\ kT$. The densities of the recombination centers were obtained from a comparison of three curves, i.e., $\Delta G_L/G_L$ vs. ϕ_s, ΔG_s vs. ϕ_s, and G_L vs. ϕ_s. Moreover, the values are quite sensitive to the exact values for the energy levels. Therefore, they are probably only reliable to about 50%. Finally, the error in the values of $\sqrt{c_p c_n}$ involving C and N_t is also of the order of 50%.

We can summarize the results as follows:

(i) The values of ϕ_o in Table I fall into two groups: one around 1.1 kT and the other around 1.9 kT. With an estimated error of $\pm 0.3\ kT$, one might at first sight hesitate as to whether this difference in ϕ_o should be interpreted as a single level or several levels. However, repeated experiments with electrolytically etched surfaces consistently gave larger values of ϕ_o than were obtained on CP-4 etched surfaces. Hence, we conclude that recombination centers exist at two types of discrete levels, a pair of "CP-4 levels" with a ϕ_o of about 1.1 kT and a pair of "electrolytic levels" with a ϕ_o of about 1.9 kT. It is seen from the table that the pair of "electrolytic levels" are separated by about the same energy interval as the pair of "CP-4 levels" but are displaced from the latter by about 0.8 kT. The capture probabilities for electrons, c_n, have approximately the same value for the two types of levels. However, the capture probabilities for holes, c_p, of the "electrolytic levels" are larger than those of the "CP-4 levels" by a factor of about three.

(ii) After samples etched with iodine A were baked, the initial "electrolytic levels" were found to have been replaced by CP-4 levels. On surfaces prepared with any of the other etches, the same type of centers were observed before and after baking. In all cases, the density of the recombination centers was larger after baking than before baking. The increase in the density of recombination centers during baking appears to take place in a few hours. Further baking at the same temperature has little effect on the density of the centers. This seems to argue for the existence of an equilibrium concentration of recombination centers.

If the baked samples are allowed to stand in a dry atmosphere at room temperature for several days, the density of the centers usually decreases somewhat from the high value immediately after baking. However, the density of centers never recovers to the initial value before baking.

(iii) When a sample is exposed to sparked oxygen, the changes in the density of recombination centers depend on three factors, (a) intensity of the spark, (b) duration of the sparking, (c) history of the sample. The changes are largest for freshly etched samples, and they are small for aged and baked samples. On freshly etched samples, the density of recombination centers often is increased by an order of magnitude when the ambient oxygen is sparked for a fraction of a second. No comparable increases in density have ever been observed after baking. Whereas recovery after baking is very slow and the decrease in density is small, after sparking the recovery is almost complete after about half an hour.

(iv) Exposure of a freshly etched sample to water vapor increases the density of recombination centers by amounts depending on (a) humidity, (b) length of exposure, and (c) history of the sample. The changes are quite gradual, but they can get as large as a factor of twenty if the sample is kept in a humid atmosphere for several hours.

When the humid atmosphere is replaced by a dry ambient, a slow recovery in the density of recombination centers usually is observed. Frequently, the density recovers to a value somewhat smaller than the value before exposure to water vapor. Sometimes, however, no change in density is apparent for an hour or more. A detailed study of these effects has not been made yet.

(v) Irrespective of which of the etches was used, the surface potential of a newly etched sample in a dry oxygen atmosphere was usually near the intrinsic Fermi level, but its exact value depended on the washing procedure after etching. After baking, the surface potential was invariably such as to make the surface more n-type. This is in agreement with the observation of other workers (7) according to which oxidation of a sample tends to make the surface n-type. We have also observed in agreement with other authors (7) that comparable Brattain-Bardeen cycles produce large changes in surface potential on some surfaces and small changes on others. There is an indication that baking and aging of the surface tends to cut down the range over which the surface potential can be changed. When a baked surface is rinsed in distilled water, the range over which the surface potential can be changed is increased and the density in recombination centers is decreased.

Baking, exposure to sparked oxygen, and exposure to water vapor all tend to increase the density of recombination centers and to decrease the range of surface potential. Baking and exposure to sparked oxygen clearly promote oxidation of the Ge surface. The effect of water vapor is more complicated. In part, water vapor may be expected to dissolve small amounts of soluble oxide. In part, water vapor appears to promote the oxidation of insoluble GeO to soluble GeO_2. Thus, our results strongly suggest that

[6] ϕ_{min} is the value of ϕ_s for minimum conductance and is given by $kT/q \ln(bn_o/p_o)$ where b is the ratio of electron to hole mobility.

the density of the recombination centers depends on the condition of the oxide films.

The recombination levels probably arise wherever there is a mismatch between the bulk Ge and the oxide film, at the edges and corners and at imperfections of any kind. Since the oxide films appear to be largely amorphous (8), epitaxical growth probably is confined to small regions where the films nucleate, and regions of mismatch abound. A further important source for imperfections may be the lack of stoichiometry in the film. For instance, surplus oxygen atoms at the interface could provide recombination levels. Another source of recombination centers may be fluorine which is believed to be present in the films (8). In general, it can be said that the density of the recombination centers is probably a measure of the amount of disorder at the germanium-oxide interface. We conclude, therefore, that such oxidation processes as baking, exposure to water vapor, and exposure to sparked oxygen all increase the degree of disorder at the interface. During subsequent exposure to a dry ambient, some degree of order is gradually restored. This throws an interesting light on the details of the oxidation process.

The results in (ii) suggest that not only the density but also the type of recombination centers depend on the oxide film. Any correlation between the type of recombination center and some property of the oxide film is extremely difficult as the following remarks show. Since the centers are probably at the germanium-oxide interface, one would expect that they would be affected only by a few monolayers of film nearest the interface. It is possible that these first monolayers are not representative of the rest of the film. In addition, the oxide films are probably inhomogeneous; both monoxide and dioxide as well as impurity atoms from the etching solution may be present in varying amounts (8). It should also be emphasized that the condition of the first few monolayers at the time of an experimental run may be different from their condition immediately after the etch. A time interval of at least several hours between etch and first run was required to mount the sample and allow it to get into thermal equilibrium with the tube. During most of this time, the sample was kept in a dry atmosphere, but it is nevertheless possible that changes occurred in the oxide film. Further changes undoubtedly occurred during the Brattain-Bardeen cycle. Whether, and to what extent, the few monolayers nearest the germanium-oxide interface were affected presumably depended on the thickness and porosity of the remainder of the film.

It is possible that both types of centers are present simultaneously on an etched surface. Usually, one type of center will be dominant, but in some cases, both may contribute to the recombination process in appreciable amounts. In such cases, our interpretation in terms of a single type of recombination center would be an oversimplification, and the parameters derived on the basis of such an interpretation would, in fact, represent averages over both types of centers. If this is the correct interpretation, it must, however, be assumed that the relative contributions of the two types of centers remained approximately constant during a Brattain-Bardeen cycle. Otherwise, the $\Delta G_L/G_L$ curves could not have been fitted with single values of C and ϕ_o throughout a cycle.

So far, the discussion has been limited to the centers near the intrinsic Fermi level which largely control the recombination process. The existence of another pair of levels near the band edges is indicated clearly by the field effect. The density of these levels is usually an order of magnitude larger than the density of levels near the center of the gap. However, their capture probabilities for electrons and/or holes are so small that their net effect on the recombination process is negligible in the range of surface potential which was used in this work. Likewise, the range of surface potential was too small to ascertain the energy of the levels with any accuracy. On relatively freshly etched surfaces the density of the levels near the band edges was increased by baking. It is possible that some changes in density also occurred during exposure to a Brattain-Bardeen cycle. However, in the analysis, we assumed that the density of the states near the band edges remained constant during a cycle so as not to introduce further parameters. From the quality of the fits in Fig. 4, it appears that, if changes in density did occur, they were relatively small.

Extensive work on the recombination centers on CP-4 etched surfaces has been reported by Brattain and Garrett (9) and by Many and Gerlich (10). The same levels were seen also in field effect measurements by Montgomery and Brown (11) and by Bardeen, *et al.* (12). All of these authors agree that there exists a discrete level near the conduction band and a discrete level near the valence band. There is, however, some disagreement as to whether the levels near the center of the gap are continuously distributed or discrete. Continuous distributions are assumed by Brattain and Garrett, Montgomery and Brown, and by Bardeen, *et al.* Two discrete levels are assumed by Many and Gerlich and by the authors. It is agreed generally that the field effect data at room temperature can be interpreted equally well on either assumption. The low temperature field-effect data of Montgomery and Brown also could be interpreted in terms of discrete levels provided the assumption is made that the density of the levels was smaller at low temperatures than it was at high temperatures. This assumption would explain the small slope of their low-temperature curve of change of charge in surface states vs. surface potential. Surface recombination velocity data have been fitted most closely when discrete levels were assumed.

A comparison of our results and those of Many and Gerlich will be made after a brief description of their procedures and underlying assumptions. Whereas we obtained variations in ϕ_s by exposing the sample to the Brattain-Bardeen cycle, Many and Gerlich varied ϕ_s by the application of high a-c fields normal to the two surfaces of a sample. Measurements of surface conductivity and effective lifetime were made at peak field, peaks of different ampli-

tudes corresponding to different values of ϕ_s. During a run, a sample was kept in a constant atmosphere. In analyzing their data, Many and Gerlich used essentially Eq. [1] and assumed that N_t as well as C and ϕ_o remained constant during a run. By contrast, our analysis was based on Eqs. [2] and [3] and the assumption that C and ϕ_o, but not N_t, remained constant during a run.

Both procedures are open to criticism. Many and Gerlich's assumption that N_t remains constant during a run may not be entirely correct in view of the observations by Statz, *et al.* (13) according to which large applied fields appear to produce changes in the density of surface states. It is frequently difficult to tell from an analysis of the v_s vs. ϕ_s curves whether changes in the density of recombination centers have, in fact, occurred during a run. On the other hand, our assumption that C and ϕ_o remain constant during a Brattain-Bardeen cycle also may be questioned. Indeed, Many and Gerlich conclude that the C and ϕ_o values on a CP-4 etched surface vary through a range larger than the experimental error, and that the values depend both on the history of the sample and on the ambient atmosphere. This would mean that several types of recombination centers can exist on CP-4 etched surfaces, with one type being dominant under one set of ambient conditions, and another type dominant under different ambient conditions. Such a view would present two difficulties:

1. According to Many and Gerlich, $C = 6$ in nitrogen and $C = 12$ in oxygen and sparked oxygen. In the part of the ambient cycle in which we changed from oxygen to nitrogen, the fit to the $\Delta G_L/G_L$ curve is quite sensitive to C, and a change in the value of C by 50% should have been easily detectable. No such changes have been found.

2. During repeated cycles, ϕ_o was found sometimes immediately after the oxygen was sparked, and sometimes, at a considerable time after sparking, during which time the sample stood in a dry oxygen or nitrogen atmosphere. Occasionally, ϕ_o was found in a cycle from which the sparking of oxygen was omitted. Since, according to Many and Gerlich, $\phi_o = 0.35\ kT$ in oxygen and nitrogen and $\phi_o = 0.97\ kT$ in sparked oxygen, one would expect to measure different ϕ_o values depending on the details of the cycle. Within experimental error, we have found no such dependence. Thus, we conclude that we observed during a Brattain-Bardeen cycle either a single type of recombination center or, conceivably, two types of centers whose relative contributions to the recombination process remained approximately constant during the cycle.

Possible explanations for the discrepancies between our results and those of Many and Gerlich are the following. The dependence of C and ϕ_o on an ambient gas may show up only after extended exposure of a sample to the gas. Alternatively, it is possible that once a surface has acquired the recombination centers characteristic of sparked oxygen, it becomes immune to the growth of other types of centers upon subsequent exposure to different ambients.

Another difference between the work of Many and Gerlich and ours is concerned with the interpretation of the parameter $C = \cosh\ (E_t - E_i - q\phi_o)/kT$. The v_s vs. ϕ_s curve has the same shape irrespective of whether recombination centers are located at the level $E_t - E_i = q\phi_o + kT$ arcosh C or at the level $E_t - E_i = q\phi_o - kT$ arcosh C or at both levels. Since ϕ_o/kT is assumed to be temperature independent, the correct level could be deduced in principle from the measurement of C at two different temperatures. Temperature measurements were made by Many and Gerlich, and the results suggest that the recombination center lies at the level $E_t - E_i = q\phi_o + kT$ arcosh C. However, the results are not sufficiently accurate to make this conclusion altogether convincing. We rather incline to the view that recombination centers are located at both levels because the field effect measurements indicate that there exist fast states at both these levels. As far as the principal conclusions of this work are concerned, it does not matter whether one or both of the levels act as recombination centers.

A numerical comparison of results for CP-4 etched surfaces follows. Many and Gerlich find ϕ_o to have a range of values between 0.35 and 1.70 kT under the ambient conditions: vacuum, oxygen, nitrogen, hydrogen, and sparked oxygen. This is to be compared to our value of $1.1 \pm 0.3\ kT$. Many and Gerlich's values for C under the above ambient conditions range from 6.1 to 29.0, while the values found by us for all etches before and after baking are in the range 8 ± 2. From their values of C and ϕ_o, Many and Gerlich calculate that the recombination centers are located at a range of $E_t - E_i$ between 2.9 and 6 kT compared to our corresponding range $3.9 \pm 0.5\ kT$. From their field-effect measurements, Many and Gerlich find another state at about $-1\ kT$. Our corresponding value is $-1.7 \pm 0.5\ kT$. If Montgomery and Brown (11) interpret their field-effect data on the basis of discrete levels, they also find these levels at 3.9 kT and $-1\ kT$. In the calculation of ϕ_s, Many and Gerlich used the Schrieffer correction whereas Montgomery and Brown and the authors did not. Within the range of ϕ_s under discussion, the Schrieffer correction is not important.

The effect of various etches on surface recombination velocity has also been investigated by McKelvey and Longini (14). Their results indicate that progressively larger surface recombination velocities are obtained on n-type germanium with silver, hydrogen peroxide, CP-4, and electrolytic etches. However, large spreads in surface recombination velocity were produced in repeated treatments with a particular etch, and the spreads for different etches were found to overlap. These results cannot be strictly compared with ours because simultaneous measurements of surface potential were not made. However, if McKelvey and Longini made their measurements on thoroughly dried samples and in a dry atmosphere, it is probable that their results represent only 50% or less of the respective maximum surface recombination velocities, corresponding to $\phi_o - \phi_s > 3\ kT$. If this assumption is made, our values of surface recombination velocity (see Table I) are consistent with their range of values. Unlike McKelvey and Longini, we did not observe that some etches produce consistently smaller surface recombination velocities than others.

Acknowledgments

The authors are grateful to P. Wang and J. Flynn for assistance with the chemical aspects of this work and for valuable discussions.

Manuscript received May 15, 1958. This paper was prepared for delivery before the New York Meeting, April 27-May 1, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

APPENDIX

The composition of the five etches used in this work are given below. The reagents are: 70% HNO_3, 48% HF, 30% H_2O_2, 100% HAc.

CP-4: 50 cc HNO_3, 30 cc HAc, 30 cc HF, 0.6 cc bromine.

Hydrogen peroxide: 10 cc HF, 20 cc H_2O_2, 20 cc H_2O.

Iodine A: 30 cc HNO_3, 33 cc HAc, 15 cc HF, 90 mg iodine.

Electrolytic: 2M KOH, 3 v.

Silver: 20 cc HNO_3, 40 cc H_2O, 40 cc. HF, 2 g $AgNO_3$.

Principles and Applications of the Iodide Process

A. C. Loonam

Consulting Engineer, 70 East 45th Street, New York, New York

ABSTRACT

The thermodynamic factors favoring deposition of elements from vapors of their iodides are the low heats of formation of those iodides and the ease with which diatomic iodine dissociates at moderately high temperatures. The vapor pressure of the element and the stability of its lower iodides determine the temperature and pressure range in which deposition can occur. The lower pressure limit for deposition at a given temperature is set by the vapor pressure of the deposited element and the upper limit by the stabilities of the lower iodides. At very low pressures, deposition is a first order heterogeneous reaction, every iodide molecule which strikes the surface adding to the deposit. As the pressure is increased, the deposition rate falls off and eventually becomes zero order, the rate being governed by that at which I atoms evaporate from the saturated surface. At higher pressures the deposition reaction is diffusion-controlled. Factors influencing the character of the deposits, the removal of impurities, and the deposition of alloys are discussed.

The iodide process was introduced by van Arkel and de Boer in 1925 (1). Shapiro (2) gave an excellent account of the development of the process through about 1954. Much of the information in the Government reports to which he referred has since appeared in the technical literature or in patents.

The elements which have been deposited by the iodide process and convenient temperatures for their deposition are listed in Table I.

Some Fundamentals of the Process

To be capable of being refined by the van Arkel-de Boer process, an element must fulfill two requirements:

1. It must be capable of existing in a solid or liquid state at some condition of temperature and pressure in equilibrium with gas containing a high atomic ratio of iodine to element. Thus, both Ti and Zr are in equilibrium with gases containing ratios of I to metal of 80 and higher at temperatures of 1100°C and above at low pressures. It is desirable that the element have a high melting point and a low vapor pressure to permit deposition as the more convenient solid at pressures where high efficiency can be obtained; but neither is essential as shown by the deposition of molten U and the fact that the relatively volatile Si can be deposited from the vapor of its tetraiodide just as well as the much less volatile Zr.

Table I. Elements prepared by thermal dissociation of their iodides

Element	Deposition temperature, °C	Element	Deposition temperature, °C
Be	700-900	Si	1000
Cr	1100	Th	1700
Cu	900	Ti	1400
Fe	1100	U	1100
Hf	1600	V	1200
Ni	1030	Zr	1400
Pa	—		

2. The element must be capable of reacting readily with the gaseous products of the deposition reaction at the same pressure and another temperature to yield a gaseous product with a low atomic ratio of I to element. For example, crude Ti and Zr react readily with I at temperatures in the neighborhood of 200°C to produce gaseous TiI_4 and ZrI_4.

These two statements are perfectly general. It is not essential that the deposition temperature be higher than that of the crude. In an excellent recent paper, Schäfer and Morcher (3) showed that Si can be made to travel either up or down a temperature gradient via the vapors of its iodides by varying the pressure, high pressures favoring transport down the gradient owing to the reversible reaction

$$SiI_4 + Si = 2SiI_2 \qquad [1]$$

and low pressures favoring transport up the gradient via dissociation of SiI_2 and SiI_4

$$SiI_2 = Si + 2I \qquad [2]$$

$$SiI_4 = Si + 4I \qquad [3]$$

In both cases the Si is transported from the region where a gas with a low atomic ratio of I to Si is in equilibrium with the element to the region in which this ratio is higher.

Theoretically, at least, a pressure gradient should have the same general effect as a temperature gradient. Thus, at a suitable temperature, a relatively low pressure should cause reaction [1] to proceed as written, while increasing the pressure should cause it to reverse, thus making Si travel up the pressure gradient. Conversely, reactions [2] and [3] take place at low pressures, but are reversed at higher pressures with the result that Si travels down the pressure gradient.

However, all applications of the iodide process to date have been based on formation or supply of iodide vapors at low temperatures and pressures and their dissociation at high temperatures at essentially the same pressure, i.e., transport up a temperature gradient. Accordingly, this discussion is confined to that phase of the subject.

Thermodynamics of the Process

The most important thermodynamic factors in the iodide process are the low heats of formation of the iodides and the ease with which diatomic iodine dissociates. The latter, data for which are given in Table II, is perhaps the more important of the two factors because, especially with the higher valence elements, it produces a large increase in the number of moles of gas when the iodides dissociate. Accordingly, the dissociation reactions have large positive entropies and, even though the heats of formation of the iodides are moderately high, the free energies of dissociation decrease rapidly with increasing temperature. Thus, $\Delta S°$ at 25°C for the reaction

$$ZrI_{4(g)} = Zr_{(c)} + 4I_{(g)}$$

is about +75 e.u. Furthermore, the expression for the equilibrium constant for this reaction contains the pressure of atomic I to the 4th power, so that even if the value of this constant is rather small, it can still mean that a respectable pressure of I vapor exists in equilibrium with the metal.

Table II. Dissociation of diatomic iodine

Temp, °C	K*	Percent dissociated at 1 atm	100 mm	10 mm	1 mm	0.1 mm
600	2.10×10^{-4}	0.72	2.00	6.31	19.6	53.4
800	1.09×10^{-2}	5.2	14.2	41.4	82.1	97.7
1000	0.166	19.9	48.9	87.1	98.4	
1100	0.482	32.8	69.1	95.0		
1200	1.22	48.3	83.5	97.9		
1300	2.73	63.7	91.6			

* Equilibrium constant, $(pI)^2/pI_2$; p in atmospheres.

It follows from the foregoing that the process should become less well adapted in going from tetraiodides to tri-, di-, and monoiodides. Although, as will be seen later, other factors are also important, this is generally true. It is the author's opinion that monomeric monoiodides which have respectable stabilities in the vapor state cannot be decomposed by dissociation to give solid or liquid metal. Since there is only one mole of gas on each side of the reaction equation, there is no pronounced increase in entropy and therefore no marked reduction in free energy upon heating. The fact that deposition of Ag from AgI vapor has not been reported is to be expected on this basis. It also follows that an element forming a stable gaseous monomeric monoiodide cannot be deposited by dissociation. Indeed, it can readily be shown that deposition of a metal by dissociation of a gaseous iodide, MI_n, requires that the equilibrium constant at the deposition temperature for the reaction,

$$MI_{(g)} = M_{(c,\,l)} + I_{(g)}$$

be greater than $(n\text{-}1)$, i.e., MI must be definitely unstable and to a greater extent the greater the value of n.

The author believes that the monoiodides of Al and perhaps those of the rare earth metals are sufficiently stable to prevent deposition by dissociation. Like Al, such metals probably could be transported down a temperature gradient by disproportionation. In this connection it is to be expected that a high heat of vaporization of the element to be deposited would favor instability of a monoiodide, causing it to break down to the condensed element and gaseous atomic I.

However, if the monoiodide is polymeric in the vapor state, conditions would be quite different. Thus, Brewer and Lofgren's (4) results indicate that the cuprous halides exist as trimers in the vapor state. The condition is now

$$Cu_3I_{3(g)} = 3Cu_{(c)} + 3I_{(g)}$$

indicating a considerable entropy increase. The fact that deposition of Cu from its iodide has been reported therefore is excellent independent evidence of the soundness of these workers' views.

The fact that many of the transition metals are deposited readily from the vapors of their diiodides

may be attributed to the low heats of formation of these vapors resulting from their relatively high heats of vaporization. A comparatively small entropy increase therefore is sufficient to promote instability on heating. There is also good evidence that they are dimeric so that the entropy situation becomes similar to that of the tetraiodides with the advantage that two atoms of metal are deposited for every iodide molecule decomposing.

It is readily apparent that there must be, at any given temperature, a lower pressure limit below which deposition cannot take place. This is at the point where the rate of deposition just equals the rate of evaporation of the deposited element due to its own vapor pressure. At lower pressures the rate of evaporation will exceed that of deposition and there will be a net loss or "chewing" of the deposit.

It is not so readily apparent that an upper pressure limit can also exist. This happens with tri- and higher iodides if subiodides above the mono compound have appreciable stabilities in the gaseous state. Under such conditions there must be a pressure at which the atomic ratio of I to element in the gases in equilibrium with the deposit just equals that in the iodide used for transport. There is therefore no deposition at this point. Reduction of the pressure below this value results in deposition, while an increase produces attack or chewing. The author discovered this situation in the deposition of Ti from TiI_4 many years ago (5), a fact later confirmed by Runnalls and Pidgeon (6) who located this point at a TiI_4 pressure of 38 mm Hg at 1500°C. Schäfer and Morcher (3) located it at several temperatures in the Si-SiI_4 system, e.g., 15 mm of SiI_4 at 1160°, calling it "the critical decomposition pressure"; while Emelyanov, Bystrov, and Evstyukhin (7) found it in the Zr-ZrI_4 system.

Plotting of the percentage iodide decomposition at equilibrium against the pressure in such a system yields a curve which starts at zero at the pressure corresponding to the lower deposition limit, rises to a maximum, falls off to zero again at the upper deposition limit, and then passes into the region of negative decomposition or attack. Such a curve for deposition of Sn from SnI_4 at 1300°C is shown in Fig. 1.

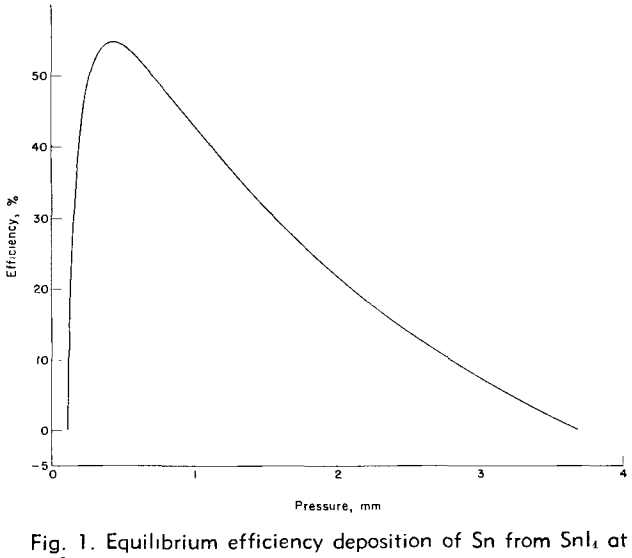

Fig. 1. Equilibrium efficiency deposition of Sn from SnI_4 at 1300°C.

In general, the value of the upper critical pressure increases with temperature. It can also be raised by reducing the ratio of I to element in the gas contacting the deposition surface and indeed may disappear altogether, but the fact remains that there will be no net decomposition of the highest iodide at pressures above its upper deposition limit. In this connection, it is important to note that, given a fixed temperature and pressure in the presence of deposit and I gases alone, the equilibrium composition of the gases will be the same regardless of the starting material.

In systems where lower iodides do not exist, the decomposition efficiency-pressure curve starts at zero and rises to a maximum as before, but then falls more slowly, approaching the zero axis asymptotically.

Given sufficient reliable thermodynamic data, it is relatively easy to calculate whether a given element can be deposited from the vapors of its iodides and, if so, the pressures and temperatures at which it can occur and the equilibrium efficiencies obtainable. At present, however, although the situation is slowly improving, no such fund of data is available for any element. It is therefore necessary to resort to estimates and even educated guesses. On the basis of these and also by analogy with other cases the author believes that B, C, Co, Ge, Mo, Nb, Ta, Sn, and perhaps Re, can be deposited from the vapors of their iodides. This statement does not mean that all of these elements can be refined by the van Arkel-de Boer process. In some cases, e.g., carbon, it would be necessary to prepare the iodide by an external process.

Kinetics of the Deposition Reaction

The writer believes that in the region represented by the lefthand leg of the curve in Fig. 1 and at low pressure, i.e., in the free molecule region where the Knudsen number (the ratio of the mean free path to the diameter of the deposition surface) is greater than about 10, the deposition reaction is a heterogeneous one, the rate being given by the Knudsen equation with an accommodation efficiency of unity, i.e., every iodide molecule which strikes the surface adds to the deposit. The reaction is therefore first order modified perhaps by the rate of evaporation of the metal itself, the activation energy is zero, and the deposition rate is proportional to the exposed surface area. This high efficiency is in accord with the findings of Holden and Kopelman (8) and Döring and Molière (9) with Zr. The author calculated the vapor pressure of TiI_4 from Fast's deposition rate at a bulb temperature of 50°C on this basis, and obtained a value which, when combined with that at the melting point derived from the data of Blocher and Campbell, yielded a figure for the heat of fusion of TiI_4 only 1.3% lower than that determined calorimetrically. Furthermore, calculation of the vapor pressure of ZrI_4 from Fast's rate of deposition of Zr at 150°C gave a value equal to 72% of that given by Rahlfs and Fischer's simple log $P - 1/T$ equation (10) and

120% of that obtained from the free energy equation using what is believed to be an accurate expression for the specific heat difference. Finally, rates of deposition of chromium from CrI_2 vapor were very close to 1.4 times those to be expected on the basis of measurements of the vapor pressure of the iodide if it were a monomer in the gaseous state and almost exactly that to be expected if it were a dimer, thus providing evidence that the latter is the case. Indeed, measurement of the rate of deposition of a metal is recommended as a method for determining the vapor pressure of its iodides at low pressures (11).

Since the primary deposition reaction is so highly efficient, it follows that it must be at least nonendothermic and more probably strongly exothermic. In the author's opinion the only one which can fulfill this requirement is the direct reaction of the incident molecule with the deposition surface to produce an atom of deposit and a chemisorbed monolayer of I atoms, i.e.

$$MI_n(g) = M_{(c)} + nI_{(ads)}$$

Such a mechanism would require heats of adsorption of I atoms on Ti and Zr of at least 42 and 50 kcal, respectively. They could be considerably higher than these values and still be consistent with that of 53.7 kcal found by Van Praagh and Rideal (12) for I atoms on Pt. The author believes that the chemisorbed I is mobile at deposition temperatures and that it evaporates at a rate consistent with its heat of adsorption.

On the basis of this mechanism, the deposition reaction should be first order with 100% efficiency so long as a large part of the deposition surface is free of adsorbed I, the rate of evaporation of I atoms just equalling that of deposition. On continued increase in pressure, however, the chemisorbed I layer covers a larger and larger fraction of the surface until ultimately it forms a complete monolayer. At this point the deposition reaction should become zero order, the deposition rate being governed solely by the rate of evaporation of the I. There is meager evidence that the point of complete surface coverage is identical with the maximum in the equilibrium efficiency curve of Fig. 1.

It is to be expected that any free I striking the deposition surface will also deposit with 100% efficiency. If its pressure and therefore its deposition rate is high enough to cause formation of the monolayer, it should reduce the rate of metal deposition, but it should have little or no effect at lower pressures.

It is believed that the foregoing mechanism applies to cases, such as the deposition of Cr from Cr_2I_4, in which lower iodides do not play any part. If, on the other hand, lower iodides can be formed, the reaction also approaches zero order, but attack of the metal begins via the I monolayer. This is in accord with the results of Langmuir on the reaction of oxygen with tungsten. He found (13) that at low pressure, oxygen formed a chemisorbed monolayer of atoms on the tungsten surface which evaporated as atoms at high temperature and was not readily reduced by hydrogen or other reducing agents. Furthermore, it showed no tendency to form WO_3. On raising the pressure of oxygen above that required to form the monolayer, however, formation of WO_3 set in.

The foregoing picture applies only to the free molecule region. As the pressure is increased with suitable adjustment of the temperature to maintain deposition, a point is ultimately reached where diffusion becomes an important, and ultimately, the controlling factor, the deposition rate being governed by that at which the iodide molecules diffuse to the deposition surface through the adjacent stationary gas film and the I atoms diffuse away.

Schäfer, Jacob, and Etzel have recently published two important papers on this phase of the subject (14, 15), in the first of which they discuss the theory of the transport of condensed phases through a temperature gradient via reversible gaseous reactions, and in the second of which they give experimental data for the transport of Fe and Ni via the vapors of their iodides and present calculations showing that the results can be accounted for by assuming equilibrium at both ends of the gradient with transport by diffusion. They secured good agreement between experimental and calculated results on the basis of diffusion coefficients derived from kinetic theory. They bring out that their treatment holds only within a definite pressure range. Presumably at lower pressures the foregoing free molecule form of transport applies, while at higher pressures transport is promoted by convection. Schäfer and Morcher (3) also discuss this subject.

One consequence of diffusion control is that the rate of deposition on a cylindrical surface, such as a filament coaxial with a cylinder of crude, becomes constant per unit length and independent of filament diameter. Shapiro and others (2) analyzed this situation and showed that the rate should be not quite independent of filament diameter, but inversely proportional to the log of the ratio of the inside diameter of the cylinder of crude to the diameter of the filament, similar to the conduction of heat radially through a cylindrical wall. In the corresponding heat transfer case, Kyte, Madden, and Piret found (16) that the ratio of the effective diameter of the stationary gas film to that of the filament was an inverse function of the Grashof and Prandtl numbers and the ratio of diameter to the length of the filament. They also took the mean free paths of the gas molecules into account at low pressures and small filament diameters.

Some of the foregoing statements regarding conditions in the range where diffusion is controlling must be accepted with qualifications. The one that the deposition rate on a filament is nearly independent of diameter is true only for relatively large diameters. That this must be so follows from the simple fact that, given any reasonable rate of deposition per unit length of, say a ½-in. filament and indefinitely reducing the diameter, a point must be reached where the original deposition rate cannot possibly be maintained because an insufficient number of iodide molecules strike the surface.

The surface reaction then becomes controlling and the rate proportional to the square of the diameter. A relation beween the deposition rate as a function of diameter and the Knudsen number probably exists for any given temperature, although the change in the diffusion gradient would also have to be taken into account.

The assumption of equilibrium at both ends of a temperature gradient is probably valid for systems in which both temperatures are high and also at the high temperature ends of other systems, but it certainly is not valid in the refining of Ti, Zr, and probably Hf with crude temperatures of 100°-200°C. These processes depend on the dynamic formation of the volatile tetraiodides instead of the much less volatile di- and triiodides which are in thermodynamic equilibrium with the metals. Under equilibrium conditions it is necessary to go to temperatures above 400°C to secure adequate vapor and dissociation pressures of the lower iodides.

These metals therefore have two distinct ranges of crude temperatures in which the process can be operated and which, as will be seen later, can yield deposits of quite different properties. As Fast has shown with Ti (17) and Döring and Molière with Zr (9), a temperature range of zero or low deposition rate can be found between them under suitable conditions, the lower limit of this gap being determined by the upper pressure deposition limit of the tetraiodides and the rate at which they are reduced, and the upper limit by the vapor and dissociation pressures of the lower iodides. Incidentally, the author believes that the tetraiodides are the primary products of the reaction of I with these metals at low temperatures and that formation of lower iodides is a secondary reaction.

Finally, the assumption of a simple diffusion gradient in the cases of Ti and Zr may be an oversimplification. In the range between 200° and 1400°C, two potentially important processes can take place in the gas phase, namely combination of I atoms at temperatures below about 900° and tetraiodide dissociation above 1000°C. There is reason to believe that both processes should be active even at the low pressure ordinarily prevailing. It is known that such reversible reactions markedly increase the thermal conductivity of a gas and they could have similar effects on other transport properties. It is possible that relatively few tetraiodide molecules reach the deposition surface at high surface temperatures and pressures where diffusion is controlling.

As Shapiro showed when he compared the rate of deposition of Zr from cut up crystal bar with that from Kroll process sponge (2), the reactivity of the crude can also be rate-controlling.

Removal of Impurities

In general, the purpose of an iodide process is to secure a high purity product. The elimination of impurities is therefore of the utmost importance. Both equilibrium and dynamic considerations are important in this connection.

If the iodide to be dissociated is prepared in a separate operation, it can be purified by any of the usual methods, filtration, fractional condensation, crystallization from a solvent, sublimation, fractional distillation, and even zone refining (18-20). Furthermore, these unit operations can be modified to meet special requirements. Thus KI has been added to a mixture of TiI_4 and AlI_3, which have very similar boiling points, to form $KAlI_4$ which is not volatile at a low red heat and from which the TiI_4 can be readily boiled away (21). Again, Zr and Hf have been separated by taking advantage of the difference in reducibility of their tetraiodides to less volatile lower iodides (22). Finally, U and Zr have been separated in a mixture of iodides produced by iodination of reactor fuel by fractionally condensing the less volatile U iodide and allowing the ZrI_4 to pass on (23).

One is somewhat more restricted when the operation is confined to a single unit as in the de Boer-van Arkel process, but even here advantage can be taken of a number of equilibrium and dynamic effects. In this connection, it is worth noting that I does not react with C or the oxides of any of the heavy polyvalent metals except perhaps those of Cd and Hg at any reasonable temperature. Indeed, the reverse is the case. The iodides of these metals can readily be roasted to oxide and iodine vapor in air or oxygen.

Probably the elements most readily refined by the de Boer-van Arkel process are Ti, Zr, and Hf. At the low crude temperatures possible when transfer takes place via the volatile tetraiodides, nitrides, carbonitrides, silicides, and perhaps other intermetallic compounds, as well as oxides and carbides, are unattacked, while the iodides of divalent metals have negligible vapor pressures if they are formed.

To secure the maximum benefit of these advantages, it is necessary to maintain a low temperature of the crude metal. This material can have considerable resistance to heat flow and, if reasonably thick, the surface facing that on which deposition is taking place can have a temperature at which the divalent iodides have large vapor pressures, carbonitrides and silicon are attacked by iodine, and even carbon monoxide can be formed by reaction of liberated carbon with oxides with consequent transfer of both components. Carbon monoxide can exist in equilibrium with iodine and iodide vapors at high temperatures.

Close control of the temperature of the crude may permit some interesting separations. Thus, Fast (24) secured no appreciable deposit from ZrI_4 at a bulb temperature of 100°C because of the low vapor pressure of the iodide, but he secured a considerable deposit of Ti from TiI_4 at a bulb temperature of 50° (17). Possibly Zr and Hf might be separated similarly.

One apparently neglected field has been the introduction of foreign substances into the units to aid in separations. This would seem to have definite possibilities. Thus, following Blumenthal and Smith (21), KI might be introduced into a Ti unit to prevent transfer of Al and other metals. Similar separations might be made among the fourth group

metals. Thus, KI does not form a complex with TiI_4 but it may with ZrI_4 or HfI_4. It is worth noting in this connection that there is less tendency to complex formation in the tetraiodide-alkali iodide systems than in the corresponding chloride systems, but that the tendency increases with the atomic weight of the alkali metal. Thus, K_2SnCl_6 is well known, but only Rb_2SnI_6 and Cs_2SnI_6 are known in the anhydrous state.

Another possibility is the introduction of an oxide. Chaigneau recently published two papers on the preparation of a large number of iodides by reaction of the corresponding oxides with AlI_3 at moderate temperatures (25, 26). Of the 29 oxides tried, 26, including TiO_2 and ZrO_2, yielded pure iodides; only one, Cb_2O_5, yielded an appreciable quantity of oxyiodide; and two, Cr_2O_3 and B_2O_3, did not react. There was no report on SiO_2.

Presumably, then, the presence of TiO_2 in a Ti bulb could prevent transfer of Al if the reaction rate were fast enough. Indeed, it should be possible to make up a list of elements in order of ease of conversion of their oxides to iodides with the alkali metals at the top and B and Al near the bottom.

Formation of stable "intermetallic" compounds does not appear promising from a thermodynamic standpoint because of the presence of free I in the system. However, empirical research could disclose compounds of value because of the slowness with which they react. Thus, addition of C might reduce the rate of transfer of strong carbide formers, while Ti might prevent transfer of N.

Application of the de Boer-van Arkel process to the divalent transition metals as well as U, and, to some extent, Th, presents greater difficulties because the high crude temperatures necessary to secure useful iodide pressures promote attack on nitrides and other relatively inert compounds as well as formation of CO by reaction of C with the generally less stable oxides. Furthermore, all iodides have appreciable vapor pressures at these temperatures, making separations more difficult.

Another factor of importance in the case of Cr, V, Fe, Co, and Ni is that their diiodides have appreciable dissociation pressures in the temperature range where their vapor pressures are appreciable (15, 27-29). Accordingly, the I pressure gradient is from that at the deposition surface to a finite value and not to zero at the crude. This could mean that, if there were any considerable temperature gradient in the crude metal, the vapor pressure of the iodide would tend to be fixed by the cold end of that gradient and the minimum I pressure by the hot end. This would reduce diffusion of both components with a consequent reduction in deposition rate.

However, the situation is by no means entirely unfavorable, as shown by the appearance of iodide chromium on the market. Because of the instability of the iodide vapors, deposition surface temperatures can be considerably lower than for the Ti group metals (cf Table I).

When operated under optimum conditions, the process can yield products of extraordinarily high purity. On the basis of his experiments with spent uranium reactor fuel, Robb (23) concluded that the process is capable of producing better decontamination than any of the known pyrometallurgical processes under study and that theoretical considerations and study of the vapor pressures of the pertinent iodides indicate that separation from every fission product should be possible. Additional evidence to this effect is the recent production of ultra pure Si (19, 20, 30).

Finally, one curious fact is that a sample of iodide Cr, analyzed by the radioactivation method at Oak Ridge, was found to contain less I than one of chromate electrolytic metal analyzed at the same time (31).

Character of the Deposits

One generalization which has appeared in the study of the iodide process is that diiodides, such as FeI_2 and CrI_2, tend to yield spiny, noncompact, noncoherent deposits. Compact deposits can be secured by proper choice of conditions, but even then the coherence is low because of low adhesion between the individual grains. On the other hand, the tetraiodides of Ti, Zr, and Hf, readily give compact, coherent deposits which can be mechanically worked directly.

Factors responsible for this situation are:

1. The high-temperature gradient in the deposition of Ti, Zr, and Hf from their tetraiodides and the fact that, for Ti and Zr at least, there is a temperature at which deposition changes to attack. Accordingly, a "sprout" or protuberance cannot grow very far, and the growing deposit maintains a reasonably smooth surface. With the divalent metals on the other hand, there are no lower iodides to produce a deposition limit, and the low volatility of their diiodides requires a high crude temperature, thereby reducing the temperature gradient. Furthermore, because of the high temperature of the crude, the gases leaving are nearly in thermodynamic equilibrium with it, thereby reducing the concentration gradient. Hence, a sprout can grow quite a distance without being attacked.

In support of this viewpoint are the facts that Ti deposited at high crude temperatures, where the temperature gradient is less and lower iodides participate in the transport, is much less compact than that deposited at low crude temperatures, and that Th, which requires relatively high crude temperatures because of the low volatility of its tetraiodide (bp 839°C) also gives noncoherent deposits according to Veigel, Sherwood, and Campbell (32).

2. The greater volatility of the divalent transition metals. At 1300°C, the vapor pressure of Cr is 417 times and that of Fe 90 times that of Ti, the most volatile of the fourth group transition metals. Accordingly, these metals have a much greater tendency to sublime from the high temperatures of crevices in the deposits to the ends of sprouts. The monoiodides of the divalent metals could enhance the rate of this transport down the temperature gradient. As pointed out they can be more stable than those of the tetravalent metals without preventing deposition.

Deposition of Alloys

Alloys can be deposited by the iodide process. De Boer and Fast (33-35) prepared alloys of Zr with Sn and Al, as well as Ti-Zr and Zr-Hf alloys over their entire composition ranges, while Shapiro (2) prepared alloys of Zr with Cr, Fe, Ni, and Sn. Very recently, Robb (23) reported deposition of U-Zr alloys ranging in Zr content from 16 to 97% from a 40% Zr-60% U alloy by changing conditions.

Factors of importance in the preparation of alloys are: (*a*) relative stability of the iodides; (*b*) relative volatility of the iodides; (*c*) relative volatility of the metals. By employing a high filament temperature, de Boer and Fast (33) prepared Fe-free Zr from a contaminated feed, the volatilized Fe collecting on the cooler electrode. High transfer efficiencies of Fe have, however, been obtained under other conditions (2); (*d*) thermodynamic activity of the second metal in the alloy. If extensive solid solutions or stable compounds are formed, even metals which cannot be deposited in the pure state from their iodides can be codeposited as alloys as shown by the foregoing preparation of Zr-Al alloys.

This whole subject may be summed up in the statement that, if alloys are desired, conditions for obtaining high purity should be avoided. Of course, the converse is also true.

Acknowledgment

The author wishes to thank the Chilean Iodine Educational Bureau, Inc., for permission to present this paper and for its sponsorship of studies of the iodide process at Battelle Memorial Institute, as well as Drs. Ivor E. Campbell and John M. Blocher, Jr., and others of the Battelle staff for many pleasant and illuminating discussions of the process.

Manuscript received July 2, 1958. This paper was prepared for delivery before the New York Meeting, April 27-May 1, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Techniques and Results of Zone Refining Some Metals

J. H. Wernick, D. Dorsi, and J. J. Byrnes

Bell Telephone Laboratories, Inc., Murray Hill, New Jersey

ABSTRACT

Techniques and results are given for the floating zone refining of Ni, Ti, V, and for boat zone refining of Al and Au. These elements have been purified by zone melting. A considerable amount of purification was obtained by volatilization during floating zone melting.

The need for purer metals for basic research and development purposes is great. Because of these needs, we have zone refined a number of metals by floating zone and boat techniques. Some of the results are discussed here.

Floating Zone Refining Equipment

The floating zone refining was done in vacuum in a vapor plating unit[1] adapted for this work. It is similar to the unit used by Buehler (1). Figure 1 shows a schematic drawing of the equipment. The liquid nitrogen trap, diffusion, and mechanical pumps are not shown. The ends of the rod to be zone refined are placed in quartz holders which in turn are held in the yoke by chucks made of stainless steel. The upper chuck (Fig. 2) is so designed that, as the chuck body moves upward, the steel balls prevent the chuck body from returning to its original position.[2] This prevents squeezing out of the molten zone after melting. The yoke is attached to a water-cooled push-rod which passes through an O-ring vacuum seal (Fig. 3) on the base plate. The high-frequency power leads pass through a coaxial vacuum seal, the details of which are shown in Fig. 4. The pressure attained prior to heating is 10^{-6} mm Hg and rises to 10^{-5} mm Hg during refining.

Radio frequency power is obtained from an Ecco 10-kw output generator at a frequency of either 5 mc or 450 kc. The tank circuit for the 450-kc frequency is located within the unit, whereas the tank circuit for 5 mc is located under the base plate of the vacuum system to minimize power loss (Fig. 1). A frequency of about 5 mc was used exclusively for

[1] Consolidated Electrodynamics Corporation LCI-18 Vacuum Coater.

[2] This chuck, as well as the mechanical feed mechanism, was designed by J. J. Gillich.

the floating zone refining of metals, although a frequency of 450 kc could also be used.

The work coils are made of 3/16 in. D copper tubing, and those used for Ni, Ti, and V (a, b, and c, respectively) are illustrated in Fig. 5. Some trial and error effort is involved in determining the proper coil, because one needs a sufficient concentration of power and yet obtain a stable zone. The zone travel rate was 0.07 in./min for these elements, and the zone lengths varied from ¼ to ⅜ in. For the case of Ni, the zone melted bar was more uniform in cross section when the zone traveled from top to bottom.

Floating Zone Melting Results

Figures 6, 7, and 8 are photographs of zone melted Ni, Ti, and V rods. The starting high purity Ni was obtained from K. M. Olsen and was made by a crucible melting technique(2). The analytical data for this Ni are shown in Table I (2). Examination of the phase diagrams of Ni with the metal impurities indicates that the equilibrium distribution coefficients for these impurities in Ni are not too different from unity.

The zone refined Ni (2¼ in./hr travel rate) was evaluated by measuring the residual resistances, at liquid He temperature, of sections of the zone refined ingot, as described by Kunzler and Wernick (3). A decrease in the residual resistance indicates purification. Figure 9 shows the resistance ratio $R_{4.2°K}/R_{273°K}$ (residual resistance) as a function of position along the bar. The control data are for the unmelted sections at the ends. Note that crucibleless zone melting, after four passes, resulted in purification, mainly by volatilization of volatile impurities, as indicated by the absence of appreciable pile up of impurities at either end.

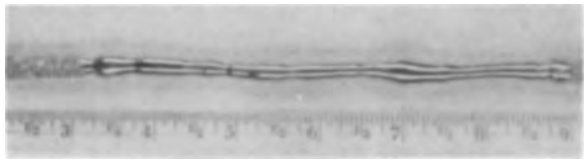

Fig. 7. Zone melted ¼ in. D Ti rod

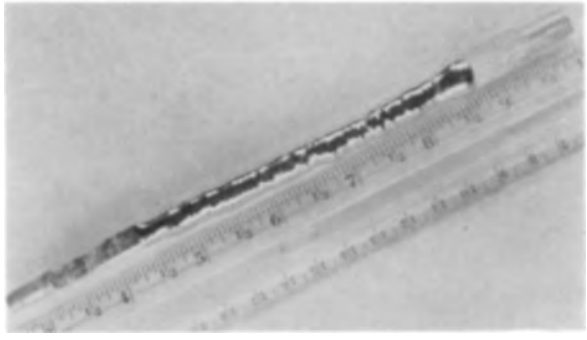

Fig. 8. Zone melted ⅜ in. D V rod

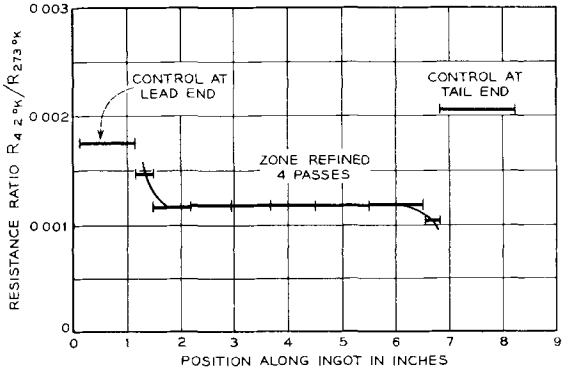

Fig. 9. Low-temperature resistivity of floating zone refined Ni

The zone melted Ti bar (6 passes, 1¼ in./hr travel rate) was analyzed spectroscopically. Titanium is not cubic, and residual resistance measurements for determining purity would be difficult to interpret unless one has a single crystal. Quantitative analytical data are shown in Table II. It appears that purification was mainly due to volatilization, as indicated by the absence of appreciable pile up of impurities at either end. No carbon and oxygen analyses were obtained.

The qualitative spectroscopic data for zone melted V (6 passes, 2¼ in./hr travel rate) are shown in Table III. Purification was obtained both by movement of impurities and by volatilization.

Boat Zone Melting Results for Al and Au

The zone refining of aluminum in Al_2O_3 boats has been discussed by Albert, *et al.* (4), Caron (5),

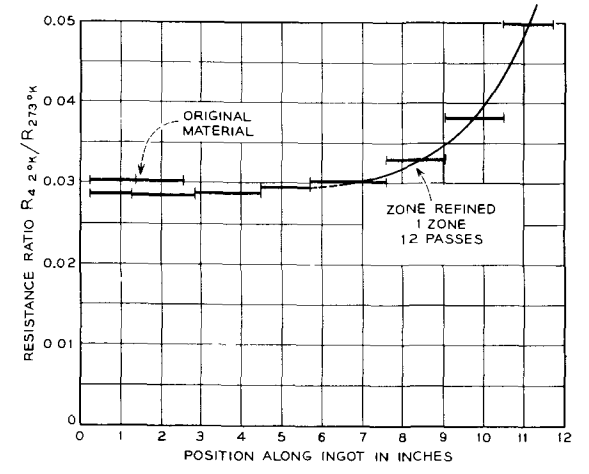

Fig. 11. Low-temperature resistivity of zone refined Au

Montariol (6), and in graphite boats by Demmler (7). We have zone refined Al in graphite boats[3] in a flowing purified argon atmosphere (4.9 in./hr travel rate). The graphite boat is first degassed *in vacuo* at a temperature estimated to be 1200°C. The argon is cleaned by passing it through a bed of drying agent, Linde Molecular sieve, and then through a bed of steel wool held at 600°C. Induction heating (450 kc) was used for zone refining. Mass transfer during zone refining is excessive, and it is prevented by tilting the refiner. This also aids in maintaining a zone of given size during refining. Figure 10 shows a plot of resistance ratio vs. distance along the length of a zone refined bar.[4] Also shown are the resistance ratio data for an annealed section of the original ½ in. D rod (marked control). It is apparent that zone refining was effective in increasing the purity of the 99.999+% Al. Table IV compares the reciprocal resistance ratios of zone refined Alcoa 99.99+% and AIAG 99.999+% Al ingots. The impure ends were not removed at any time during refining.

Gold was also zone refined by induction heating in a degassed graphite boat in a flowing argon atmosphere (3.6 in./hr travel rate). The residual resistance data for an ingot are shown in Fig. 11. Note that some zone refining was accomplished, but that there was also some impurity pickup from the surroundings, as indicated by the rather large pile-up of impurities at the impure end. The nature and source of the external impurities are not known at present.

[3] A limited discussion of this work appears in Ref. 3.

[4] The starting 99.999% Al used for this zone refining work was kindly furnished by Aluminium-Industrie-Aktien-Gesselschaft, Neuhausen am Rheinfall, Switzerland. The American supplier for this material is United Mineral and Chemical Corp., New York, N. Y.

Effects of Electrolytes and of Gelatin on the Half-Wave Potentials of Carbon Tetrachloride, Dibromoacetate, and p-Dinitrobenzene

Leif E. I. Hummelstedt and L. B. Rogers

Department of Chemistry and Laboratory for Nuclear Science, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

Polarograms were obtained in media in which reductions of each compound occurred on both sides of the electrocapillary maximum. Capillary-active anions retarded the less cathodic reduction steps and capillary-active tetramethylammonium ion facilitated the second reduction steps of carbon tetrachloride and the dibromoacetate ion. Capillary-inactive calcium ion had little effect on the halogenated compounds, but it greatly facilitated the second reduction of p-dinitrobenzene thereby suggesting ion-pair formation with the known divalent intermediate

Gelatin, for the first time, was found to shift a reduction to less cathodic values. This occurred only in acidic media when the reduction took place on the negative branch of the electrocapillary curve. The shift was attributed to the presence of protonated gelatin in the double layer.

In an earlier study of the effect of added electrolyte on the half-wave potentials of carbon tetrachloride (1), the possibility existed that the observed changes, which had been attributed to changes in the double layer at the electrode surface, might have been due to changes in junction potential. In the present study, the effects of electrolytes were re-examined using a large concentration of a relatively inert electrolyte in order to minimize changes in junction potential. By examining two different waves of the same compound, each on a different side of the electrocapillary maximum, it was possible to isolate selective influences. By using a single medium for studying carbon tetrachloride, dibromoacetic acid, and p-dinitrobenzene, it was possible to distinguish further between different types of electrolyte effects.

Experimental Details

Apparatus.—Polarograms were obtained using a Sargent Model XXI recording polarograph. The initial and final potentials of each polarogram were measured with a Rubicon or a Sargent potentiometer. All measurements were made against an external saturated calomel electrode (S.C.E) which was connected to the polarographic cell by means of a salt bridge which contained 1*M* potassium chloride. The end of the salt bridge which dipped into the sample was closed by a Vycor plug, the other, by an agar plug. The capillary used throughout the experiments had a value for $m^{2/3}t^{1/6}$ of 1.32 $mg^{2/3}$ $sec^{-1/2}$ at -0.800 v vs. S.C.E. in 0.9*M* potassium chloride. The resistance of the polarographic cell circuit was measured using an Industrial Instruments Company conductivity bridge, Model RC-1B. The *p*H measurements were made using a glass electrode in conjunction with a Beckman H or G *p*H meter.

Reagents and solutions.—Most of the chemicals were analytical reagent grade. However, the dibromoacetic acid was a research sample kindly furnished by Dr. Vernon Stenger of the Dow Chemical Company. The tetramethylammonium chloride was the polarographic grade of Southwestern Analytical Chemicals. The p-dinitrobenzene, after recrystallization from ethanol, had a melting point of 173.2°-173.7°C.

Carbon tetrachloride and dibromoacetic acid were added in the form of methanol solutions to solutions of background electrolyte. The p-dinitrobenzene was added as either a methanol or ethanol solution. Most of the experiments were performed using a high concentration of lithium chloride (2.0*M*) as supporting electrolyte in 41% methanol. Other electrolytes were added to such a solution as solids. To make the background alkaline, the *p*H was adjusted by adding sodium hydroxide; to make it acidic, a phthalate buffer was prepared in the manner described by Pearson (2). In adjusting the apparent *p*H of some of these buffers in different concentrations of alcohol, hydrochloric acid was added. Gelatin was added as an aqueous 0.50% solution.

Procedures.—The polarographic solutions, which were generally 50 ml, were deaerated with prepurified nitrogen that had been passed through a portion of the supporting electrolyte before entering the polarographic cell. Usually 15 min of deaeration was sufficient to remove the oxygen. In working with carbon tetrachloride, the supporting electrolyte was first deaerated for 15 min, whereupon 1.00 ml of the stock solution containing carbon tetrachloride was added and the solution deaerated for an additional period of 1.5 min.

All data were corrected for residual current and *IR* drop. All experiments were performed using a mercury height of 102 cm and a thermostatic bath held at 24.0°C. Electrocapillary curves were determined from recordings for at least 100 drops at each potential.

Results

Effect of Monovalent Ions

Figure 1a shows the effect of potassium thiocyanate and tetramethylammonium chloride, respectively, on the half-wave potentials of carbon tetrachloride solutions in alkaline 2.0*M* lithium chloride containing 41% by volume of methanol. It is apparent that the addition of relatively small amounts of potassium thiocyanate shifted the first wave of carbon tetrachloride in a more cathodic direction, while the second was shifted slightly in the opposite direction. Addition of tetramethylammonium chloride, on the other hand, had no effect on the first wave, while the second was shifted to markedly less cathodic potentials. Addition of an equimolar mixture of potassium thiocyanate and tetramethylammonium chloride simultaneously shifted the first wave toward more cathodic potentials and the second wave toward less cathodic. The shifts observed for the mixture were about half those for the separate components (−0.066 v vs. −0.116 v and +0.181 v vs +0.274 v).

The results of a similar experiment using dibromoacetic acid, a compound extensively studied by Elving, *et al.* (3) are shown in Fig. 1b. The shift in half-wave potential for the second wave was smaller than that for the corresponding wave for carbon tetrachloride, probably because the former is closer to the electrocapillary maximum. The importance of such a factor is qualitatively illustrated by the data of Elving, *et al.* (4) on α-bromo-n-butyric acid. Comparison of Fig. 2 with Fig. 1a and 1b shows that the electrocapillary maximum lay as expected between the two polarographic waves of both carbon tetrachloride and the dibromoacetate ion. Electrocapillary curves for separate additions of either potassium thiocyanate or tetramethylammonium chloride had maxima which fell in the same region of potential as those in Fig. 2.

In an earlier study of carbon tetrachloride by Lothe and Rogers (1) similar shifts in polarographic waves were demonstrated, but contributions from changes in junction potential were present because a high concentration of background electrolyte had not been used. In order to check the constancy of the liquid junction potential in the present study polarograms of 2 x 10^{-3}*M* thallium (I) were run in the same background medium. On addition of a mixture giving 0.05*M* potassium thiocyanate and 0.05*M* tetramethylammonium chloride, the half-wave potential remained constant at −0.447 v; an increase in concentration to 0.20*M* caused only a slight shift to −0.454 v (further complexing of thallium?). The largest effect of the "active" salts on the half-wave potentials of carbon tetrachloride occurred for additions of 0.05*M* or less for which the 2*M* lithium chloride did indeed hold the liquid junction potential constant.

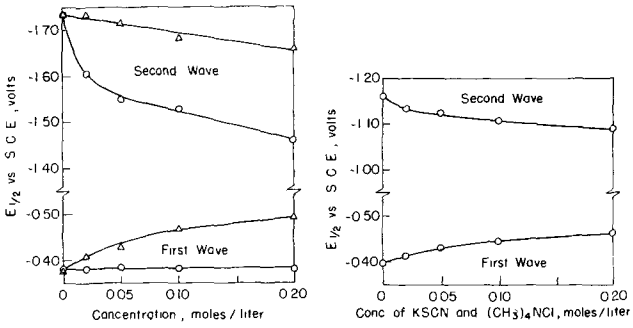

Fig. 1. Effect of electrolytes on the half-wave potentials of carbon tetrachloride and dibromoacetate in solutions of 2.0M lithium chloride and 41% methanol having an apparent pH of 10.9: (a) (left), addition of KSCN (Δ) and $(CH_3)_4NCl$ (O) to 10^{-3}M carbon tetrachloride; (b) (right), addition of an equimolar mixture of KSCN and $(CH_3)_4NCl$ to 1.7 × 10^{-3}M dibromoacetate.

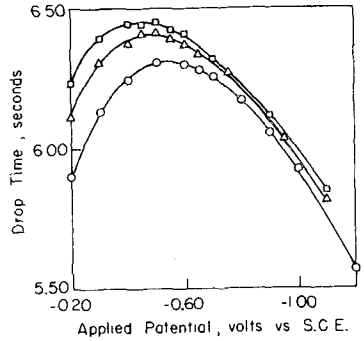

Fig. 2. Drop time as function of applied potential in 2.0M lithium chloride and 41% methanol with different additions of an equimolar mixture of KSCN and $(CH_3)_4NCl$ (□—no addition; Δ—0.05M; O—0.20M). Apparent pH, 10.9.

To evaluate the effect of competition of lithium and chloride ions for positions at the interface, additions of an equimolar mixture of potassium thiocyanate and tetramethylammonium chloride were made to solutions of carbon tetrachloride containing lower initial concentrations of background electrolytes. A change from 2.0*M* to 1.0*M* lithium chloride resulted in a slightly greater shift in each half-wave potential in the range up to 0.05*M* of each electrolyte but, for larger additions, virtually the same shifts were found as those shown for the more concentrated lithium chloride. When 0.60*M* potassium nitrate was substituted for lithium chloride as a supporting electrolyte, the second wave could not be measured because of decomposition of the background. However, the shift of the first wave was practically identical with that observed for 1.0*M* lithium chloride.

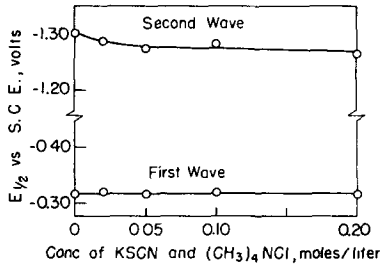

Fig. 3. Effect of an equimolar mixture of KSCN and $(CH_3)_4NCl$ on the half-wave potentials of $10^{-4}M$ p-dinitrobenzene in solutions of 2.0M lithium chloride and 41% methanols having an apparent pH of 10.9.

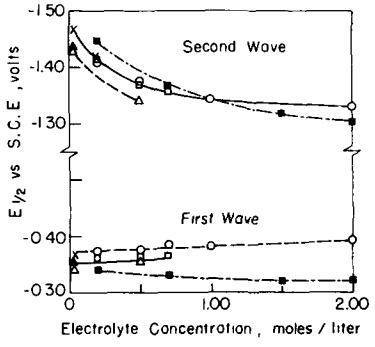

Fig. 4. Effect of electrolytes on the half-wave potentials of $10^{-4}M$ p-dinitrobenzene in 41% methanol. □—KCl, ○—KSCN, △—$(CH_3)_4NCl$, ×—KI, ▲—$(CH_3)_4NI$, ■—LiCl. The apparent pH is approximately 11.9 except for solutions containing LiCl which caused a decrease to 10.9. ——— "Inactive" ions; - - - "Active" ions; - . - . - LiCl curves.

After the similarities of carbon tetrachloride and dibromoacetic acid had been established, p-dinitrobenzene was studied because it represented a different type of reducible group. In the case of an organic halide the transfer of one electron (possibly two) is followed by rapid elimination of a halide ion. The first wave of p-dinitrobenzene in alkaline solution corresponds to a two-electron change with formation of a relatively stable divalent ion; the second wave to formation of p-hydroxylaminoaniline (5). Hence, the organic halides involve electron-transfer to neutral (or monovalent) species whereas the second alkaline reduction step of p-dinitrobenzene goes through a stable divalent intermediate.

Figure 3 indicates that the first wave of p-dinitrobenzene in 2*M* lithium chloride was unaffected by an equimolar mixture of potassium thiocyanate and tetramethylammonium chloride whereas the second wave was shifted, but only slightly, toward less cathodic potentials.

In the absence of 2*M* lithium chloride (Fig. 4) the second wave was shifted considerably by an increase in ionic strength. Potassium chloride, potassium thiocyanate, and potassium iodide behaved the same. Points for tetramethylammonium chloride and tetramethylammonium iodide fell at less cathodic potentials, indicating that the tetramethylammonium ion had a greater effect than potassium. In going from 0.2 to 2.0*M* lithium chloride, the apparent *p*H decreased from 11.55 to 10.90, a change that was confirmed using a hydrogen electrode (6). Correction for the change in *p*H would make the lithium curve essentially parallel to, but more cathodic than, the potassium curve, indicating that lithium by itself was less effective than potassium.

Lithium chloride also caused a small amount of shift in the first wave which, according to Holleck and Exner (5), should be practically independent of the *p*H in the alkaline range. It is possible that a shift of this magnitude (0.02 v) could be caused by a change in liquid junction potential. Although all the electrolytes had only a small effect, values for the first half-wave potential in the presence of thiocyanate or iodide are consistently more negative than the corresponding values for chloride, in accord with known differences in capillary activity of those anions (7).

Agreement between the present study and the earlier one by Holleck and Exner (5) was good for the first wave. However, their values for the second wave were more cathodic (nearly −1.6 v vs. −1.3 v) in spite of the fact that their lower concentration of methanol (20%) would normally be expected to result in a less cathodic wave. Figure 4 shows that a difference in ionic strength is the chief source of the discrepancy since they did not use as highly concentrated background electrolyte.

Though the above discussion refers only to two waves of p-dinitrobenzene, Holleck and Exner (5) showed that this compound has three polarographic waves at intermediate values of *p*H. At high values of *p*H the middle wave is not present but, under the conditions of the present experiment, a small wave was still visible at about −0.88 v. Unfortunately this wave was too small to permit accurate half-wave measurements, so changes in its position were not included in the study. As a further complication, a new wave was observed to grow in at slightly more positive potentials when the solution was allowed to stand a few hours before a polarogram was run. It was established that p-nitroanisole was the compound produced in alkaline methanol.

Effects of Divalent Ions

Prior studies on the reduction of ketones (8) and nitrate ion (9) have indicated that di- and trivalent cations resulted in a less cathodic half-wave potential than monovalent ions of comparable concentration. It was surprising, therefore, to find that the addition of calcium chloride in an amount sufficient to produce a 0.05*M* solution had little effect on the first and second waves of carbon tetrachloride and dibromoacetic acid. In contrast, the second wave for p-dinitrobenzene shifted +56 mv although the first wave remained constant. Barium chloride was also tried and gave a shift of +23 mv for the second wave, but unfortunately a precipitate formed which decreased the concentration of barium by an unknown amount. The fact that calcium exerted little effect on the second waves of the halides (compared to tetra alkylammonium ion) is probably due to its lack of electrocapillary activity (10).

The greater effect of calcium ion on the second wave of p-dinitrobenzene appears to be due to ion-

pair formation with the stable divalent intermediate. Ion-pair formation would decrease the effective negative field around the nitro body and would facilitate further reduction. The acidic reduction of p-dinitrobenzene as well as the acidic and alkaline reductions of o-dinitrobenzene, none of which involve a stable charged intermediate (5), show little effect of calcium (6). The fact that changes in the concentrations of lithium and potassium ions had nearly the same effect as changes in tetramethylammonium ion, plus the fact that doubly charged calcium had a much greater effect than any monovalent cation, suggests that the shift is associated with charge rather than electrocapillary activity.

Effect of Gelatin

In early exploratory runs with p-dinitrobenzene in acidic solutions, gelatin exhibited unusual effects which made further investigation seem worthwhile. In acidic media, p-dinitrobenzene is reduced in two steps, the first corresponding to formation of p-hydroxylaminonitrobenzene and the second to p-hydroxylaminoaniline (5).

Two series of runs were made in different concentrations of ethanol. In one the apparent pH of the buffer was adjusted to 4.1 by the addition of hydrochloric acid, while in the second the electrolyte concentration was held constant and the apparent pH allowed to increase with alcohol concentration. At the lowest ethanol concentration (8%) a maximum was formed on the second wave of p-dinitrobenzene unless 0.002% gelating was present. Hence, the half-wave potential of the second wave in the absence of gelatin was somewhat uncertain in 8% ethanol. At higher ethanol concentrations no maxima were observed even in the absence of gelatin.

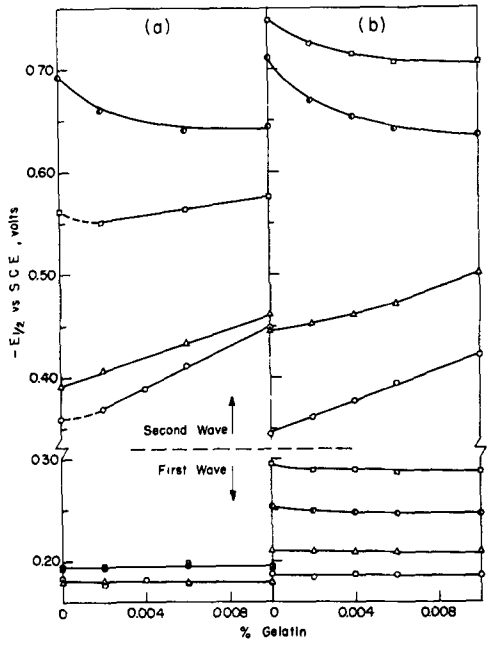

Fig. 5. Effect of gelatin on the half-wave potentials of 10^{-4}M p-dinitrobenzene in 0.07M phthalate buffers of varying ethanol concentration (O—8%; △—29%; ∅—49%; □—73%). (a) Apparent pH maintained constant at 4.1 by adding HCl when increasing the ethanol concentration. (b) Apparent pH allowed to increase with ethanol concentration.

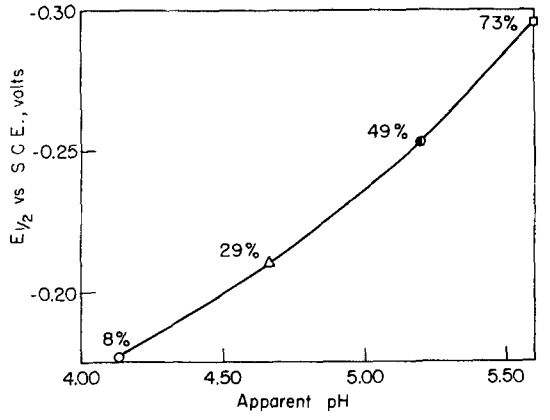

Fig. 6. Changes in the half-wave potential of the first wave of 10^{-4}M p-dinitrobenzene as function of the apparent pH of solutions of different ethanol content with 0.07M potassium acid phthalate as supporting electrolyte.

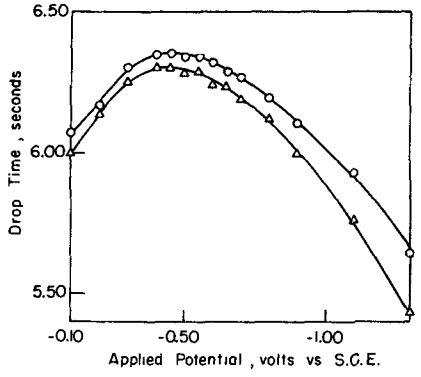

Fig. 7. Effect of gelatin on the electrocapillary curve in 0.07M potassium acid phthalate and 29% ethanol (O—no gelatin added; △—0.01% gelatin present).

As shown in Fig. 5a and 5b gelatin had no effect on the first wave. This probably indicates that this wave is more nearly reversible in character than the second. The shift observed for the half-wave potential as a function of alcohol in Fig. 5b is largely due to a change in pH, though Fig. 6 shows the change to be somewhat greater than expected, i.e., 85 mv per unit of apparent pH. This undoubtedly reflects a change in the composition of the solvent and in the resulting junction potential. This solvent effect is also indicated by the slight cathodic shift of the first wave with increasing ethanol concentration, at constant apparent pH, shown in Fig. 5a.

The behavior of the second wave with a change in concentration of gelatin was complex. At the 8 and 29% levels of alcohol, the difficulty of reduction increased almost linearly with concentration. At the 49% level, reduction was facilitated, an effect not previously reported for gelatin. This must have been due to superposition of a second factor which counteracted the generally observed retardation. Electrocapillary data of the type shown in Fig. 7 showed that these reductions were taking place on the negative branch of the electrocapillary curve. Hence, the acceleration is probably due to protonated gelatin in the double layer.

At the 73% level, the effect of gelatin differed in the two series. In Fig. 5a where the reduction fell

only slightly on the negative side of the electrocapillary maximum (due to a large increase in ionic strength when a large amount of hydrochloric acid had to be added to attain an apparent pH of 4.1), the retarding effect was predominant. In Fig. 5b, the positive-ion effect was still predominant, but smaller, even though the reduction took place at a more cathodic potential than in 49% alcohol. This probably reflects less extensive protonation of the gelatin in the lower dielectric medium, as well as a possible denaturization.

Confirmation of the protonation hypothesis may be found by noting in Table I that, at pH 10.9 where protonation was very slight, the retarding effect was always observed regardless of position of the reduction relative to the electrocapillary maximum. This indicates that the positive-ion effect was indeed the cause of the reversal observed in acidic medium. The only reservations that must be made are: (*a*) the fact that the reduction mechanism for p-dinitrobenzene differs in acidic and alkaline media, and (*b*) a small positive shift was observed for the second wave of carbon tetrachloride. However, the latter data are very uncertain due to superposition of the carbon tetrachloride reduction on that of the background electrolyte.

Discussion

The present study confirms the importance of the position of a polarographic wave relative to the electrocapillary maximum in determining whether one can expect anion or cation effects on the half-wave potential of an electron-transfer controlled reaction (1). Although Ashworth (8) was one of the first to report the influence of cations on irreversible organic reductions (benzophenone and fluorenone) and the fact that similar compounds may react differently to the same ion, the conditions under which the two ketones were examined were not strictly comparable. Thus, his results are difficult to analyze. The present study indicates that one may be able to differentiate between different roles played by the electrolytes. In one case the effect may be a general one and probably depends only on the presence of excess anions or cations sufficiently close to the electrode surface to change the potential at the point where reduction takes place. [There is evidence that tetraalkylammonium ions are not appreciably solvated and are electrocapillary active (11).] Therefore, calcium ion, in spite of its greater charge, may have had less effect on the halide reductions because its solvated ion is not appreciably concentrated by adsorption at the interface. The comparatively small effects in 2*M* lithium chloride of capillary-active monovalent ions on p-dinitrobenzene may be the result of the more nearly reversible character of the waves (especially the first).

The large effect of calcium on the alkaline reduction of p-dinitrobenzene was discussed earlier. Although this may be a specific effect of calcium ion, it appears more probable that the specificity is associated with the divalent intermediate formed in this particular mechanism. However, electrocapillary-inactive ions may exert an additional characteristic influence. Unfortunately, the alkaline reduction of p-dinitrobenzene did not lend itself to such a study because most difficultly reducible multivalent cations form hydroxide complexes or precipitates. However, good examples of specific cation effects have been reported for the electrochemical reduction of nitrate which is affected by a number of multivalent cations in addition to calcium. Collat and Lingane (12) found the products to be quite different if obtained in the presence of uranyl ion instead of lanthanum (III). In fact, somewhat different yields of products resulted in shifting from lanthanum (III) to cerium (III).

The half-wave potentials for irreversible reactions are usually affected by changes in concentration of the reducible substance so the concentration was held constant. However, the volatility of carbon tetrachloride made difficult the maintenance of a constant concentration throughout a series of experiments, so the effect of a change in concentration on the half-wave potential was briefly investigated. A change from 4.1×10^{-4} to 4.1×10^{-3} *M* caused a shift in half-wave potential of about +10 mv, an insignificant amount compared to most of the shifts that were observed.

It was recognized that the results obtained with solutions at apparent pH 10.9 would be open to some question because of the absence of a buffer. Unfortunately, higher concentrations of sodium hydroxide, which would have been better buffers, would also have prevented the study of the calcium effect by precipitating the hydroxide. As a compromise, the concentration of sodium hydroxide used was 0.007*M* which would serve rather well as a buffer for the pH-sensitive reduction of 1×10^{-4} *M* p-dinitrobenzene. The calculated pH of 11.85 was actually observed in the absence of a large concentration of background electrolyte, but the presence of 2.0*M* lithium chloride caused a decrease in apparent pH to 10.9. This decrease was checked and substantially confirmed using a hydrogen electrode although there was a small sodium and lithium error (6).

Table I. Effect of gelatin on the half-wave potentials of carbon tetrachloride, dibromoacetate, and p-dinitrobenzene in 2.0M lithium chloride and 41% methanol of apparent pH 10.9

	Carbon tetrachloride		Dibromoacetate		p-Dinitrobenzene	
Gelatin, %	First wave	Second wave	First wave	Second wave	First wave	Second wave
0	−0.39	−1.71*	−0.414	−1.179	−0.315	−1.284
0.01	−0.42	−1.68*	−0.443	−1.194	−0.318	−1.316

* Values for the second wave of carbon tetrachloride are uncertain due to superposition of the reduction on that of the background electrolyte.

Kinetics of the Cathodic Reduction of Anions: Germanium Oxides

Mino Green[1] and P. H. Robinson

Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts

ABSTRACT

The electrochemical cell Hg(Na)|GeO_2, NaOH(aq)|Pt, gives GeH_4, Ge, and H_2 as end products at the cathode. GeH_4 yields have been obtained with a current efficiency of >40% and a mass conversion efficiency of >80%. The partial currents of GeH_4, Ge, and H_2 have been measured as a function of electrolyte composition, cathode potential, and cathode diffusion boundary layer thickness. A highly reducing reactive intermediate has been detected in solution with a mean life of ~4 min. The value of the Tafel slope for GeH_4 evolution was found to be -56 ± 2 mv per decade. The mechanism for the over-all reaction $GeO_3^= + 7\ H_2O + 8\ e^- \rightarrow GeH_4 + 10\ OH^-$ is discussed and the most likely mechanisms up to the rate-determining step are narrowed down to three possible cases. Further experiments for the final determination of the rate-determining step are suggested.

The work reported here had two main objects: (*a*) the determination of the optimum conditions for the electrochemical preparation of germane, GeH_4; and (*b*) an investigation of the kinetics and mechanism of the cathodic reduction of anions in the light of recent advances in the theory of electrode processes, e.g., Ref. (1). It has been found that the system Na(Hg)|NaOH, GeO_2(aq)|Pt, anode, gives high yields of GeH_4 and therefore it is this system which is discussed here.

Experimental

Materials.—Unless otherwise specified reagent grade chemicals were used. The GeO_2 used contained less than 1 ppm w/w total metallic impurities. The Hg used was triply distilled and all other metallic electrodes used were designated "spectroscopically pure."

Estimation of GeH_4-H_2 ratios.—The gaseous product from the cathode was a mixture of GeH_4 and H_2; no other gaseous species were detected, nor were there any other volatile hydrides of Ge. The GeH_4-H_2 ratio was determined using a Rayleigh-Zeiss interferometer. The essentials of the analytical method, which depended on measuring the differences between the refractive indexes of hydrogen and a GeH_4-H_2 mixture, have been reported elsewhere (2). The procedure has been modified somewhat to extend the range to 100% GeH_4: the accuracy of the method was ± 0.004 mole fraction GeH_4.

Kinetics of the Cathodic Reduction of Anions: Germanium Oxides

Mino Green[1] and P. H. Robinson

Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts

ABSTRACT

The electrochemical cell Hg(Na)|GeO_2, NaOH(aq)|Pt, gives GeH_4, Ge, and H_2 as end products at the cathode. GeH_4 yields have been obtained with a current efficiency of >40% and a mass conversion efficiency of >80%. The partial currents of GeH_4, Ge, and H_2 have been measured as a function of electrolyte composition, cathode potential, and cathode diffusion boundary layer thickness. A highly reducing reactive intermediate has been detected in solution with a mean life of ~4 min. The value of the Tafel slope for GeH_4 evolution was found to be -56 ± 2 mv per decade. The mechanism for the over-all reaction $GeO_3^= + 7\ H_2O + 8\ e^- \rightarrow GeH_4 + 10\ OH^-$ is discussed and the most likely mechanisms up to the rate-determining step are narrowed down to three possible cases. Further experiments for the final determination of the rate-determining step are suggested.

The work reported here had two main objects: (*a*) the determination of the optimum conditions for the electrochemical preparation of germane, GeH_4; and (*b*) an investigation of the kinetics and mechanism of the cathodic reduction of anions in the light of recent advances in the theory of electrode processes, e.g., Ref. (1). It has been found that the system Na(Hg)|NaOH, GeO_2(aq)|Pt, anode, gives high yields of GeH_4 and therefore it is this system which is discussed here.

Experimental

Materials.—Unless otherwise specified reagent grade chemicals were used. The GeO_2 used contained less than 1 ppm w/w total metallic impurities. The Hg used was triply distilled and all other metallic electrodes used were designated "spectroscopically pure."

Estimation of GeH_4-H_2 ratios.—The gaseous product from the cathode was a mixture of GeH_4 and H_2; no other gaseous species were detected, nor were there any other volatile hydrides of Ge. The GeH_4-H_2 ratio was determined using a Rayleigh-Zeiss interferometer. The essentials of the analytical method, which depended on measuring the differences between the refractive indexes of hydrogen and a GeH_4-H_2 mixture, have been reported elsewhere (2). The procedure has been modified somewhat to extend the range to 100% GeH_4: the accuracy of the method was ± 0.004 mole fraction GeH_4.

[1] Present address: Zenith Radio Corporation, Chicago, Ill.

Cell assembly.—The assembly of Fig. 1 was used where quantitative gas collection was required. The system was cooled by flowing water. Current was obtained from a 110 ± 1 v d-c generator and the other circuitry was conventional. The anode con-

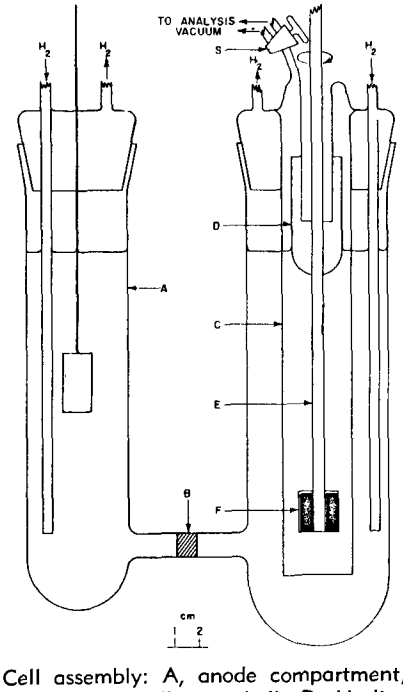

Fig. 1. Cell assembly: A, anode compartment; B, porous disk (medium); C, gas collecting bell; D, Hg-liquid seal; E, "Teflon" shaft; F, Hg cathode.

sisted of Pt(A = 4 cm^2) and the cathode was contained in a cup attached to a Teflon rod. Electrical contact was made to the mercury in the cup by means of a platinum wire which passed down the center of the stirring rod. The exposed area of mercury was about 0.8 cm^2, and the volume of mercury was about 0.5 cc. The cathode could be spun to speeds up to 800 rpm. Gas produced at the cathode was collected in the bell. No corrosion of the glass cup containing the cathode was observed.

A typical run was performed as follows: Current corresponding to the desired current density at the cathode was passed through the cell. The cathode was "run-in" for a suitable time after which liquid was drawn up in the bell to the stopcock, S. At this point the current was recorded continuously on a strip-chart recorder. One determination was completed when the liquid in the bell was displaced by gas down to the level of the cathode surface. Then the gas was transferred to the evacuated collecting bulb via a mixed calcium chloride-barium oxide drying column. The run-in of the cathode was necessary since the sodium first formed at the cathode dissolved in the mercury (fresh Hg used for each run), and only after the cathode reached a certain Na-Hg composition did gas evolution occur. After a further period of electrolysis a determination of composition, etc., was made and this was repeated. The second determination usually gave the same results as the first, indicating that the cathode had reached a limiting Na concentration for both cases. If the second determination did not give the same values as the first, a further determination was carried out and this invariably gave, within experimental error, the same values as the preceding run. Since reproducible yield results were obtained in the manner just outlined, it is reasonable to assume that no error arises out of the possible solubility of GeH_4 in the electrolyte. The temperature near the cathode was 25° ± 3°C for all current densities up to ~ 2 amp-cm^{-2}; for higher current densities (not used in kinetic analysis) the cathode rose to somewhat higher temperatures.

The information available from each run was: the amount and composition of the evolved gas, the rpm of the cathode, and the total coulombs passed. The volume of the bell (about 80 cc) was determined by weighing the amount of Hg required to fill it to the point where cathode/electrolyte contact was broken. The number of moles of GeH_4 produced was calculated taking into account the temperature, atmospheric pressure, and water vapor pressure above the particular electrolyte being used. The coulombs passed were measured by graphical integration of the current-time recording. The rotary speed of the cathode was measured by a stroboscopic illumination method.

Determination of cathode potential.—The potential of the cathode with current passing was determined in an H-shaped cell, using the cathode and Luggin arrangement of Fig. 2. The object of this Luggin capillary arrangement, used by Piontelli and Polli (3), was to avoid measuring any resistive potential drop in the solution. The geometrical surface

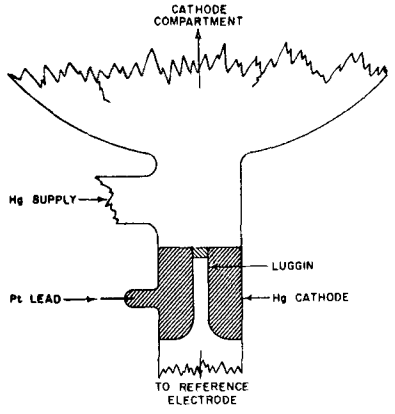

Fig. 2. Backside Luggin capillary arrangement

area of the cathode was 0.31 cm^2 and the outside diameter of the Luggin was 0.02 cm with a wall thickness of about 0.004 cm. In a measurement of cathode potential the Hg was always kept filled to the tip of the Luggin; any excess Hg passed out through the Luggin. Measurements of potential were made at the lowest current density first. The cathode potential measured was in each case the steady-state value, i.e., a run-in period was necessary to allow the Na concentration of the cathode to reach its limiting value (cf. above).

Cathode potential measurements were made in NaOH and also in solutions of GeO_2 and NaOH. Yield values also were determined in the case of GeO_2/NaOH solutions in a cell similar to that shown in Fig. 1 but with the cathode at the bottom of the cathode compartment and identical in construction with that shown in Fig. 2 but without a Luggin. The aim of making the two arrangements identical was to obtain the same hydrodynamical conditions at the cathode. Note that there was no rotation of the cathode in either case; in fact, nearly all the electrolysis data reported here refer to a stationary cathode. It was shown that the cathode potential depended only on the partial current of hydrogen; this enabled an evaluation of the cathode potential if the hydrogen current was known.

Measurement of the lifetime of an intermediate product.—Some of the results reported below pointed to the possible production of an intermediate product which was sufficiently long lived so that there could be substantial diffusion of this material from the cathode into solution. If such an intermediate product were present in solution, it would be a stronger reducing agent than Ge. ($GeO_2 + 4H^+ + 4e_o^- = Ge + 2H_2O$: $e = -[0.15 + 0.059\,pH + 0.015\,pG]$, where pG is the negative of the logarithm of the GeO_2 concentration.) Thus, if Ge/GeO_2 is added to an acid solution containing vanadium (III) and vanadium (II) ions ($V^{3+} + e^- = V^{2+}$: $e^o = -0.255$) no reduction of vanadium (III) will take place, if the conditions of the experiment are such that $e_{GeO_2/Ge}$ and $e_{V^{3+}/V^{2+}}$ are more positive than −0.15 v and more negative than about −0.2 v, respectively. But if this supposedly highly reducing intermediate product were added, a reduction of vanadium(III) might well occur.

A solution of known concentration of vanadyl sulphate in 8*N* HCl was reduced to the V^{2+} state with

(S) Electrode rotated at ~250 rpm. Electrode stationary in all other cases.

Sn. This solution then was placed in a small beaker, and with nitrogen bubbling through the solution the oxidation-reduction potential of the V^{2+}/V^{3+} couple at a platinum electrode was measured against a calomel reference electrode. Then oxygen was bubbled through the solution until most, but not all, of the V^{2+} had been oxidized, as shown by the potential of the platinum electrode (from which the V^{2+}/V^{3+} ratio could be determined). All of the solution (about 10 ml) from the cathode compartment of a small electrolysis cell which had been in operation for about 20 min was drained off, filtered, and equal aliquots of the filtrate added to the $V^{2+} - V^{3+}$ containing solution at regular time intervals. The change in potential of the $V^{2+} - V^{3+}$ solution was measured each time; these changes occurred in a few seconds, and each time the potential remained constant at the new value. From these measurements it was possible to calculate (see later) the reducing power of the solution at each addition and thus to obtain a measure of the lifetime of the strongly reducing substance in the GeO_2/NaOH solution. The same experiments were repeated but without GeO_2 in the NaOH solution; this time material from the cathode compartment did not affect the V^{2+}/V^{3+} couple. Finally powdered Ge was added to the $V^{2+} - V^{3+}$ solution to determine its effect on the redox potential; it was undetectable.

Diffusion layer thickness.—A small quantity (~10^{-5} M) of tagged $Hg(CN)_2$ was added to the electrolyte in the cathode compartment of a cell similar to that shown in Fig. 1 but containing no bell and no stirring arrangement. $Hg(CN)_2$ is reduced readily at a Hg cathode and, since the concentration of the tracer is small, its partial current density can confidently be expected to be its limiting current. Hence a determination of the rate of removal of $Hg(CN)_2$ from

solution can be used to calculate the effective thickness of the diffusion layer, δ. Thus,

$$\frac{1}{\delta} = \frac{S}{DtA} \ln (n_o/n)$$

where S is the volume of solution in the cathode compartment; D is the diffusion coefficient for Hg $(CN)_2$; t is time of electrolysis; A is the surface area of the electrode; and n_o and n are the initial and final radioactivity of the solution, respectively.

Results

Partial currents.—The partial currents for the products of electrolysis, GeH_4, Ge, and H_2 are given in Table I and Fig. 3 and 4. The variation of ϕ, mole fraction of GeH_4 in the gas, with the nature of the cathode material was examined; results are shown in Table II. There is no simple relation apparent between yield and the hydrogen overpotential.

Cathode potential.—Hydrogen overpotential measurements on the cathode as a function of current density, 10^{-2} to 1 amp-cm^{-2}, in solutions of 2 and 10N NaOH are shown in Fig. 5. The Tafel b-function obtained is in agreement with the over-all results of Bockris and Watson (4) obtained at lower current densities and for more dilute NaOH solutions. Cathode potential measurements also were made with a solution of 2N NaOH containing 2 g GeO_2/100 ml; a plot of the cathode potential against the current density for hydrogen evolution gave a curve identical with curve 1 in Fig. 5. Thus the cathode potential in the presence of GeO_2 can be defined as long as the hydrogen current is known.

ϕ = mole fraction GeH_4 in GeH_4 – H_2 mixtures.

A plot of i_{GeH_4} vs. cathode potential (Fig. 8) yields a Tafel slope of -56 ± 2 mv per decade. It is quite possible, however, that the appropriate current to use is not i_{GeH_4}, since, as has been noted above, an intermediate product (abb. I.P.) diffuses away from the cathode. If the I.P. occurs before the rate-determining step, then η vs. i_{GeH_4} is the correct way to obtain the overpotential for the GeH_4 production process. If, on the other hand, the I.P. occurs after the rate-determining step, then the current of material going through the rate-determining transition state will be

$$I = i_{GeH_4} + (8/m) i_{Ge}$$

where m is the number of stages of reduction (from $GeO_3^=$) that the I.P. has gone through. This presupposes that i_{Ge} is due to the I. P., and this interpretation of the facts is suggested by the result that, as stirring at the cathode is increased, i_{GeH_4} decreases and i_{Ge} increases. Furthermore, if Ge were produced at the cathode, the comparative yield of GeH_4 would be very much lower since Ge electrodes give very low GeH_4 yields (whence the reaction Ge → GeH_4 would appear to go with difficulty). Since no plot of η vs. ln I for values of m from 1 to 4 yields a single Tafel slope, it is suggested that the I.P. occurs before the rate-determining transition state.

Intermediate product.—The reducing power of solution drawn from the cathode compartment is shown as a function of time in Fig. 6. The initial concentration of V^{2+}, $(a_{V^{2+}})_{t=0}$, was known and $(a_{V^{2+}})_{t=0} << (a_{V^{3+}})_{t=0}$, i.e., 10^{-4} N: 1N; since the over-all change in $a_{V^{2+}}$ was from 10^{-4} N to 1.8×10^{-4} N the concentration of the V^{3+} can be taken as constant. Thus the change in potential, ΔE, due to reduction of

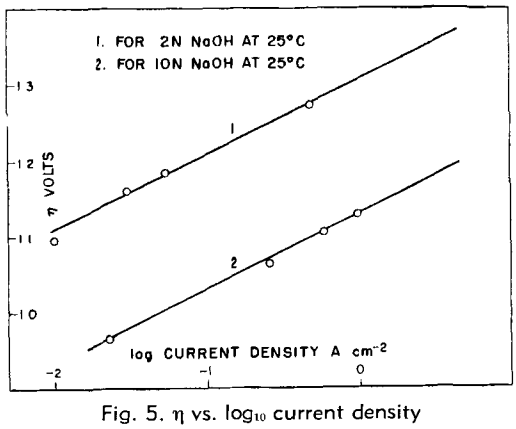

Fig. 5. η vs. $\log_{10}$ current density

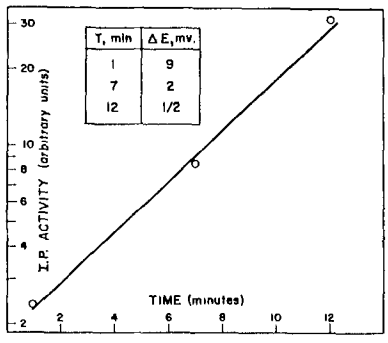

Fig. 6. Decay of intermediate product

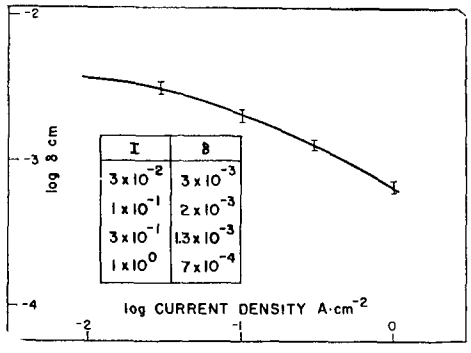

Fig. 7. Change of diffusion layer thickness with current density.

V^{3+}, by reactive intermediate at a time t' after removal from the cathode compartment is,

$$\Delta E = RT/F \ln [(a_{V^{2+}})_{t=t'}/(a_{V^{2+}})_{t=0}]$$

The concentration of the intermediate product is proportional to the amount of V^{3+} reduced, i.e., $\propto [(a_{V^{2+}})_{t=t'} - (a_{V^{2+}})_{t=0}]$. Upon a further addition of reactive intermediate, the new V^{2+} concentration can be determined from the potential change and so the concentration of reactive intermediate at time t'' was

$$\propto [(a_{V^{2+}})_{t=t''} - (a_{V^{2+}})_{t=t'}], \text{ etc.}$$

The slope of the line of $\log_{10} [(\Delta a_{V^{2+}})_{\Delta t}]$ vs. t (Fig. 6) gave a mean life for the intermediate product of 4.3 min: this presupposes a monomolecular decay process.

The nature of the intermediate product has not been established by direct chemical means. However, it has been shown that the intermediate product does not give rise to H_2 in solution. An electrolysis cell with a U-shaped cathode compartment was used; the cathode was in one limb and the other limb was filled completely with electrolyte. Convective mixing was relatively unhampered as shown by the Ge particles first formed near the cathode appearing in the opposite limb in ~ 1 min. There was no accumulation of H_2 gas in the sealed limb after prolonged electrolysis.

Diffusion layer.—The measurement of diffusion layer thickness for various current densities in 2*N* NaOH solution, using tagged $Hg(CN)_2$, is shown in Fig. 7. The presence of GeO_2 in solution could not be tolerated since the Ge metal produced might well adsorb some of the $Hg(CN)_2$. That $Hg(CN)_2$ is the only diffusing mercury species has been established by Tomes (5). Its diffusion coefficient in 10^{-2} *N* NaOH is (6) 1.56×10^{-5} cm^2 sec^{-1} at 28°C. The diffusion coefficient for $Hg(CN)_2$ in more concentrated solutions of NaOH has been calculated from this value assuming Stokes law applies, values for the viscosity of aqueous solutions of NaOH being available (7). The applicability of Stokes law for the diffusion of zinc sulfate and zinc acetate in various concentrations of NaOH solution has been tested by Brasher and Jones (8) and has been found to be valid: it is therefore reasonable to assume that $Hg(CN)_2$ in NaOH solutions also obeys Stokes law.

Discussion

The experiments of Pugh (9) and Carpéni (10) have shown that, when GeO_2 is dissolved in NaOH solutions of $pH \geqq 13$, the Ge will be present as $GeO_3^=$; all the solutions used in this study were of $pH > 14$.

Transport to the cathode.—The variation of ϕ with current density and cathode stirring rate suggests that the over-all electrochemical process is not entirely activation controlled; thus it is necessary to consider the diffusion of various ions toward and away from the cathode. The primary species moving to the cathode are Na^+ and $GeO_3^=$. Na^+ ions move to the cathode under a favorable potential gradient and $GeO_3^=$ ions approach the cathode by diffusion and convection in an adverse potential gradient. Wagner (11) has treated these cases in a theoretical study of the electroreduction of anions in solutions of high electrolyte concentration. The solution of the diffusion equation for the discharge of Na^+ shows that the Na^+ concentration at the cathode does not rise above 1.1 times the bulk Na^+ concentration for the highest current densities employed in this study. The Na^+ concentration is enhanced at the cathode since discharged Na^+ ions react with water; the change in water concentration at the cathode is insignificant. The transport rate per unit time per unit area along the x-coordinate (which is normal to the surface of the electrode and is measured from the cathode) of ions of type i to the cathode under steady-state conditions, is given by (11)

$$\frac{1}{A}\frac{dn_i}{dt} = -c_i D_i \left(\frac{\partial \ln c_i}{\partial x} + \frac{z_i F}{RT}\frac{\partial \Psi}{\partial x} \right) \quad [1]$$

where the symbols are: dn_i/dt, number of moles of i passing cross section, A, per unit time; D_i, diffusion coefficient of ions of type i; c_i, their concentration; z_i, their valence; F, the Faraday; Ψ, electrical potential; R, gas constant; and T, absolute temperature. It is reasonable to make the simplifying assumption that the cathode is covered by a static diffusion layer, thickness δ, beyond which concentration differences are negligible owing to convective mixing: concentration changes will occur only between $x = 0$ and $x = \delta$. In Eq. [1] the first term on the right hand side accounts for transport due to a concentration gradient, and the second term accounts for electrolyte migration. As Wagner points out, if the potential difference across the diffusion layer is $< RT/F$ (0.025 v at room temperature) then the potential gradient will have little effect on anion migration. The value of $(\partial\Psi/\partial x)\delta$ was always <0.025 v in the systems studied. This argument assumes an

essentially linear potential gradient across δ. The validity of this assumption is not in question except at short distances from the electrode, $<10^{-6}$ cm (δ is typically 10^{-3} cm) when deviations from local charge neutrality can occur, i.e., the region of the Stern double layer. Since all the solutions used were concentrated electrolytes it is known that (12) a diffuse layer (i.e., Gouy layer) was not present, so Eq. [1] will be applicable up to the outer Helmholtz plane of the cathode.

The transport of ions from the bulk of the electrolyte to the outer Helmholtz plane has been considered thus far. An outline of the derivation of the equation for electron transfer to an anion follows. Consider the electrochemical reaction

$$A^{z-} + e^- \rightarrow A^{(z+1)-} \qquad [2]$$

For zero applied p.d. the initial state for this reaction is A^{z-} ions in the outer Helmholtz plane and electrons in the cathode. The final state is $A^{(z+1)-}$ anions partially adsorbed on the cathode. When a p.d. η is applied across the Helmholtz double layer the change in Galvani p.d. is η and if the dipole distribution in the Helmholtz double layer is taken to be unchanged, and the fractional surface coverage due to $A^{(z+1)-}$ is far from unity or close to unity (i.e, 0.9) then η may be equated to the Volta p.d. across the Helmholtz double layer. That is, η is due to the building up of excess, equal and opposite charge, on either side of the Helmholtz double layer. This is the usual assumption made in current theories of hydrogen overpotential and seems to be in accord with the facts. If the potential in the outer Helmholtz plane is arbitrarily taken as zero, then an applied (negative) potential η will increase the potential energy of the electrons in the cathode by an amount $F\eta$ per mole. That is, the potential energy of the initial state is increased by amount $F\eta$ per mole. The potential energy of the final state is raised by $(d_o - d/d)F\eta$ per mole, where d_o is the thickness of the Helmholtz double layer and d is the distance from the metal side of the Helmholtz double layer to the species $A^{(z+1)-}$. Thus the applied p.d. will have reduced the activation energy for the forward path of reaction [2] by

$$\beta F\eta(d/d_o) \qquad [3]$$

where β is the Tafel symmetry factor [discussed fully by Bockris (1)]. Since d_o is taken to be 5 to 10 times greater than $(d_o - d)$, the term (d/d_o) in Eq. [3] can be neglected. Whence, in the form usual for electron transfer reactions from the cathode, the forward velocity of reaction [2] is given by

$$i = i_o \exp(-\beta F\eta/RT) \qquad [4]$$

The limiting current, i_l, for $GeO_3^=$ calculated from Eq. [1], using a typical set of values, shows for all but the highest current densities that $i << i_l$: this gives rise to two limiting cases for GeH_4 evolution,

$$i_{GeH_4} = i_o[\exp(-\alpha\eta F/RT)] \qquad [5]$$

and

$$i_{GeH_4} = i_l[1 - \exp(\eta 8F/RT)] \qquad [6]$$

where, for the GeH_4 formation reaction, i_o is the exchange current and α is the Tafel transfer coefficient. Eqs. [5] and [6] are for activation and diffusion controlled processes, respectively. A plot of log i_{GeH_4} vs. cathode potential (Fig. 8) obeys the form of Eq. [5] over a range of >0.2 v and four decades of current density. Thus it is concluded that the GeH_4 formation reaction is largely activation controlled.

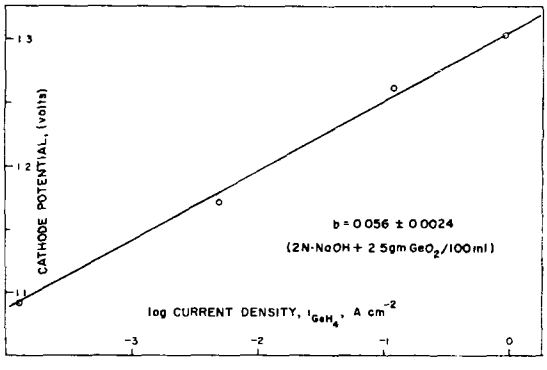

Fig. 8. Tafel curve for GeH_4 evolution reaction

Consecutive electrode processes.—The $GeO_3^=$ reduction process is taken to be a sequence of consecutive reactions. The method of handling such reactions is outlined below. Christiansen (13) has shown how the steady-state reaction rate for an open sequence of reactions can be represented in terms of the rate constants of the elementary reactions and the concentration of the stable components. In a sequence of reactions such as

$$A_1 \underset{s_{-1}}{\overset{s_1}{\rightleftharpoons}} X_1 + B_1\,,\; X_1 + A_2 \underset{s_{-2}}{\overset{s_2}{\rightleftharpoons}} X_2 + B_2 \ldots \text{ etc.} \qquad [7]$$

where the A's and B's are stable components and the X's are reactive intermediates and s and s_- are the forward and reverse reaction rates, respectively. A set of quantities ω are defined such that:

$$\omega_1 = s_1 = k_1 c_{A_1}$$

$$\omega_{-1} = \frac{s_{-1}}{c_{X_1}} = k_{-1} c_{B_1}$$

$$\omega_{-n} = s_{-n} = k_{-n} c_{B_n}$$

The principle of detailed balance is assumed, whence the over-all reaction rate, S, is given by:

$$S = s_1 - s_{-1} = s_2 - s_{-2} \ldots = \omega_1 - \omega_{-1} c_{X_1} = \omega_2 c_{X_1} - \omega_{-2} c_{X_2} \ldots$$

This gives rise to an expression for S which can be written generally as:

$$S = \frac{\prod_{k=1}^{k=n} \omega_k}{\sum_{m=2}^{m=n+1} \prod_{k=m}^{n} \omega_k \prod_{l=1}^{l=m-2} \omega_{-l}} \qquad [8]$$

where m goes from 2 to $n+1$ and $\prod_a^b = 1$ if $b < a$.

Bockris (14) first applied this method to the calculation of the over-all rate of electrochemical reac-

tions for oxygen evolution. The essential change to be made from the application to chemical kinetics is that the rate constants in reactions involving charge transfers are potential dependent. Thus, for a cathodic reaction, the rate constant for a partial cathodic reaction becomes

$$\vec{k} = k \exp [-\beta \Delta \xi nF/RT] \qquad [9]$$

where $\vec{k}$ and $\vec{k}$ are the electrochemical and chemical rate constants, respectively; $\Delta\xi$ is the Galvani p.d. between the electrode and the solution; and n is the number of electrons transferred. Correspondingly for the partial anodic reaction

$$\overleftarrow{k} = k \exp [(1-\beta) \Delta \xi nF/RT] \qquad [10]$$

These rate constants, utilized in partial reactions which involve charge transfer, give rise to potential terms in the final expression for the over-all reaction, and hence allow the evaluation of $\partial\Delta\xi/\partial \ln n_i$, i.e., the Tafel slope, b, characteristic of a given reaction mechanism. Thus a typical reaction sequence is examined for each partial reaction, in turn, being the rate-determining step (r.d.s.). In each case it can be taken that the reactions preceding the r.d.s. are fast, so that $k_+/k_- = K$, an "equilibrium" constant. Further, if $k_{+\text{r.d.s.}} \to k_{-\text{r.d.s.}} \to 0$, and $k_{+\text{r.d.s.}} \geqq 10\, k_{-\text{r.d.s.}}$, then all terms involving $k_{-\text{r.d.s.}}$ in the denominator of Eq. [8] can be neglected. This gives rise to a simple expression for the over-all rate which involves only one rate constant, i.e., $k_{+\text{r.d.s.}}$, and Eq. [8] can be written for the ith rate-determining step:

$$S = \prod_{k=1}^{k=i} \omega_k \Big/ \prod_{k=1}^{k=(i-1)} \omega_{-k} \qquad [11]$$

This expression is used here in the evolution of various reaction paths.

Mechanism of $GeO_3^= \to GeH_4$ *reaction.*—The final chemical products occurring at the cathode are H_2, Ge, and GeH_4. The reduction of $GeO_3^=$ to give GeH_4 can be represented by the over-all stoichiometric equation,

$$GeO_3^= + 7H_2O + 8\, e_0^- \to GeH_4 + 10\, OH^-$$

The over-all reduction reaction is taken to occur in a set of simple consecutive reactions, i.e., it is taken to be an open sequence of reactions. Since it is unlikely that the first step in the reduction of the $GeO_3^=$ ion can occur in two different, and approximately equally probable ways, the production of Ge must be taken to be due to a branch reaction in the $GeO_3^= \to GeH_4$ reaction sequence. If absorbed hydrogen atoms are used at any stage in the reduction of $GeO_3^=$ ions, then the $GeO_3^= \to GeH_4$ reaction sequence is complex, and H_2 evolution can be considered to be a branch reaction. But, if $GeO_3^= \to GeH_4$ does not involve the use of absorbed hydrogen atoms, then H_2 evolution is a process which occurs in parallel with the $GeO_3^=$ reduction process.

If atomic hydrogen is used in the reduction process it must be treated as one of the "stable" products, A, in the reaction sequence, Eq. [7]. Since the reaction which produces atomic hydrogen cannot be treated as in equilibrium as compared with the r.d.s. of the $GeO_3^= \to GeH_4$ reaction an expression for the steady-state concentration of atomic hydrogen is required. Bockris and Watson (4) have shown that the reaction of sodium atoms with water is the rate-determining step in the hydrogen evolution reaction on mercury cathodes in aqueous NaOH solutions. Whence, assuming the reaction

$$Na + H_2O \to Na^+ + OH^- + H$$

The surface concentration of atomic hydrogen will be directly proportional to the surface sodium atom concentration (the activity of water is taken to be large and invariant). Furthermore, these workers found that the surface activity of sodium atoms is proportional to $\exp(-F\eta/2RT)$; thus,

$$c_H = C \exp(-F\eta/2RT) \qquad [12]$$

where C is a constant at constant electrolyte composition.

Unfortunately the work of Bockris and Watson (4) is not completely convincing, e.g., these workers accept the experimental fact that the reaction rate of sodium atoms with water depends on the square root of the sodium concentration but do not show in their proposed reaction mechanism how this comes about. Also, they assume that barium amalgams behave in a similar way, but Kaplsan and Jofa (15) have shown that for Ba the reaction rate with water is proportional to $[Ba]^{1/4}$. Bockris and Watson, however, present cogent reasons for rejecting all other simple reaction paths for the hydrogen evolution reaction of sodium amalgam electrodes in NaOH solution other than the mechanism mentioned above. Thus in the absence of evidence to the contrary the mechanism of Bockris and Watson must be accepted, bearing in mind that the analysis given below would have to be re-examined in the light of any new and contrary development arising out of this point.

Table III. Potential dependent factors introduced into Eq. [11] by an elementary reaction. $x \equiv \eta F/RT$ (when $\beta = \frac{1}{2}$)

Reaction	Factor r.d.s.	Factor Equil.
1. $A^{z-} + e^- \to A^{(z+1)-}$	$e^{-x/2}$	e^{-x}
2. $A^{z-} + H \to HA^{z-}$	$e^{-x/2}$	$e^{-x/2}$
3. $A^{z-} + H + e^- \to HA^{(z+1)-}$	e^{-x}	$e^{-3x/2}$

By means of Eqs. [11] and [12] Table III lists the factor that an elementary reaction will introduce into the final expression for S, depending on whether the reaction is rate determining or precedes the r.d.s. whence it is treated as being in equilibrium. The Tafel slope for the $GeO_3^= \to GeH_4$ reaction is $-RT/F$, from experiment. Use of Eq. [11] shows that each successive stage of reduction leads to a smaller Tafel slope. Thus the possible reaction paths up to the rate-determining step which give a Tafel slope of $-RT/F$ can be written, viz:

(i) $$GeO_3^= + e^- \xrightarrow{\text{fast}} GeO_3^{\equiv}$$
$$GeO_3^{\equiv} + H_2O \xrightarrow{\text{slow}} H\,GeO_3^= + OH^-$$

(ii) $$GeO_3^{=} + H \xrightarrow{fast} H\,GeO_3^{=}$$

$$H\,GeO_3^{=} + H_2O \xrightarrow{slow} H_2GeO_2^{-} + OH^{-}$$

or,

$$(H\,GeO_3^{=} \xrightarrow{slow} GeO_2^{-} + OH^{-})$$

(iii) $$GeO_3^{=} + H \xrightarrow{fast} GeO_2^{-} + OH^{-}$$

$$GeO_2^{-} + H_2O \xrightarrow{slow} H\,GeO_2 + OH^{-}$$

(iv) $$GeO_3^{=} + H + e \xrightarrow{slow} H\,GeO_3^{=}$$

(v) $$GeO_3^{=} + H + e \xrightarrow{slow} GeO_2^{=} + OH^{-}$$

Since an intermediate product of high reducing power appears to diffuse away from the electrode before the r.d.s., from (i) to (v), this must be GeO_3^{3-}, $HGeO_3^{2-}$, or GeO_2^{-}. Thus the reactions (iv) and (v) are excluded as possible reaction paths since $GeO_3^{=}$ is the only Ge species before the rate-determining transition state. It is not possible to say on the basis of the work done here which of the remaining possibilities, (i), (ii), or (iii) is the actual mechanism. However, it should be possible to distinguish between reduction by electron transfer and reduction by atomic hydrogen on the basis of two further experiments, viz., (*a*) reduction in divalent alkali metal solutions, rather than NaOH, where $c_H \propto \exp(-\eta F/RT)$ should give different Tafel slopes if atomic hydrogen is involved in the reduction; (*b*) reduction at high current densities where the surface concentration of atomic hydrogen reaches a limiting value (4) should give $\partial\eta/\partial \ln i \rightarrow 0$ if atomic hydrogen is used in the r.d.s.; otherwise there should be no variation in the Tafel slope with current density.

Acknowledgment

The authors are pleased to acknowledge their thanks to Professor Carl Wagner and Professor J. O'M. Bockris for their interest and helpful suggestions. The method for determining the diffusion layer thickness was based on a suggestion of Professor Wagner's.

Manuscript received March 14, 1958. The research reported in this document was supported jointly by the Army, Navy, and Air Force under contract with M.I.T.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

The Electrical Conductivity of Sweat

II. The Interionic Attraction Factor and the Conductivity of Undiluted Sweat in the Study of Cystic Fibrosis

Andre J. deBethune and Truman S. Licht

ABSTRACT

The electrical conductivity of sweat is a useful criterion for the study and diagnosis of *cystic fibrosis*. The sweat conductivity usually is determined from measurements on diluted sweat solutions. A method of calculation is presented to account for the interionic attraction effects due to the greater ionic strength in the undiluted parent sweat sample. This introduces a correction of the order of 10% in the conductivity based on the dependence of equivalent conductance on ionic strength. Experimental verification of the correction is given for synthetic mixtures of sodium and potassium chlorides and for a natural sweat sample. Sweat conductivity data obtained from a study of 77 control subjects and 47 cystic fibrosis patients are summarized, after application of this correction.

In a study of the electrolyte content of thermally induced eccrine sweat, Licht, Stern, and Shwachman (1) described a technique for the measurement of the electrical conductivity of sweat. They reported values of sweat conductivity for subjects with and without the disease *cystic fibrosis* and showed that for cystic fibrosis patients a threefold elevation of sweat conductivity was obtained which was significant enough to be used as a diagnostic criterion.

The method of obtaining sweat samples by collection on a weighed gauze pad and elution of electrolytes with distilled water necessitates that chemical and physical tests be performed on diluted solutions. As pointed out in (1) calculation of sweat conductivity from data obtained in diluted sweat solutions, without taking into account the interionic attraction effects due to greater ionic strength in the parent sample, results in conductivities approximately 10% too high. While this error is of no significance when sweat conductivity is used as a diagnostic criterion for cystic fibrosis, it does become important when sweat conductivities are correlated with ionic composition, a study which is currently in progress and will be reported elsewhere. The present paper attempts to develop a method of calculation which introduces a correction for the dependence of equivalent conductance on ionic strength. Conductivity data are presented for sodium and potassium chloride mixtures and for pure sweat and diluted sweat solutions which show that sweat conductivities calculated by this corrected method are reliable within 2 to 3%. Sweat conductivities presented in (1) from a study of 77 control subjects and 47 cystic fibrosis patients are recalculated. Availability of these more accurate values will permit correlation with analytical information and aid in the further elucidation of the electrolyte constitution of sweat.

Experimental

The thermal induction of sweat by placing the subject in a plastic bag, the collection of sweat on a weighed gauze pad, and the subsequent measurement of the diluted sweat sample in a special 3-ml conductivity cell with the Serfass conductance bridge has been described in (1). To establish the validity of the interionic attraction factor (described below), it was necessary to collect pure sweat not exposed to air long enough for evaporation to occur. Using a 1-ml pipette as a capillary tube, drops of pure sweat were collected. The volumes of such samples ranged from 0.2 to 1 ml and their conductivity could be measured directly in a Sunderman conductivity pipette[1] with a cell constant of 12.7 cm^{-1}. This pipette, which has a nominal capacity of 0.5 ml, could be used for measuring as little as 0.2 ml by floating the sample on top of mercury (mercury in the stem only). Five to fiftyfold dilutions were prepared with conductivity water and the conductivity again measured. The specific conductance of mixtures of sodium and potassium chloride in the range of pure and diluted sweat samples were measured also.

Theoretical

In (1), the sweat conductivity (i.e., the specific conductance of sweat in micromhos per centimeter),

[1] Available from Arthur H. Thomas Co., Philadelphia, Pa.

to be here denoted by L_s', was calculated from experimental observables by the relation

$$L_s' = (J_o - J_b)KF \qquad [1]$$

where J_o and J_b are the observed conductances in micromhos at 25°C of the diluted sweat solutions and blank solutions, respectively; K is the cell constant in cm^{-1}; F, the dilution factor, is the volume ratio of diluted to undiluted sweat. The grouping $(J_o - J_b)K = L_d$ is the observed conductivity of the diluted sweat solution. Multiplication by the dilution factor F is based on the tacit assumption that conductivity is a linear function of concentration.

This assumption is approximately valid for strong electrolytes over narrow concentration ranges and corresponds to the hypothesis that ionic mobilities and equivalent ionic conductances are constants independent of ionic strength. In point of fact, interionic attraction effects lead to a decrease of ionic mobilities and ionic conductances with increasing ionic strength (2-4).

Over the range of dilution factors F (5-fold to 58-fold) utilized in (1), the equivalent conductances of sodium, potassium, and chloride ions drop by about 5 to 15% in going from the diluted to the parent sweat sample, and the sweat conductivities calculated by Eq. [1] are too high by the same amount.

It is therefore desirable to correct the sweat conductivities L_s'. This can be done by the equation

$$L_s = L_dFS = L_s'S \qquad [2]$$

where L_s is the "corrected" sweat conductivity, and the interionic attraction factor S accounts for the drop-off of the equivalent conductances with increasing ionic strength.

The conductivity L of any electrolyte (in micromhos per centimeter) is equal to the summation of terms of the form $c_j\Lambda_j$ where c_j is the number of milliequivalents per liter and Λ_j is the equivalent conductance of the j^{th} electrolyte. By taking the ratio of L_s to L_dF, it can be shown that the factor S is given by

$$S = \Sigma(x_j\Lambda_j)_s/\Sigma(x_j\Lambda_j)_d \qquad [3]$$

where x_j is the equivalent fraction of the j^{th} electrolyte in the total electrolyte content (normality of j/ total normality of all electrolytes). In both cases, the Λ_j's are determined by the total ionic environment (5, 6), i.e., by the total ionic strength, of the liquid: either the parent sweat sample s or the diluted sweat sample d.

Table I. Conductivity of NaCl—KCl mixtures (25°C)

c (KCl), mEq/l	c (NaCl), mEq/l	L (observed), μmho/cm	L (calculated, Eq. [4]), μmho/cm
100	0	(12,896)	12,896
0	100	10,590	10,674
50	50	11,790	11,785
25	75	11,200	11,230
10	0	1414	1413
0	10	1178	1185
5	5	1288	1299
2.5	7.5	1266	1242
1	1	268	268.5

The composition of sweat (1, 7-10) is such that 60-90% of the conductivity may be attributed to sodium and potassium chlorides, the remainder being due chiefly to calcium, sulfate, and lactate. The pH ranges from 4 to 7. Sodium chloride constitutes 50-90% of the sum of the sodium and potassium chloride normality. It was therefore decided, as an approximation, to restrict the summations in [3] to the two salts j = NaCl, and KCl. Since Λ values for the mixtures of these salts were not readily available, the Λ's of the pure salts were used (4a, 11). It was postulated that *the Λ of a salt in a mixture is equal to the Λ of the same pure salt at the same total ionic strength.* This postulate was verified experimentally by us for synthetic mixtures of sodium and potassium chlorides in the total chloride concentration range of 2 to 100 mEq/l, and shown to be valid within the experimental error of the measured conductivity (1%) (Table I). The calculated values in Table I were computed from

$$L(\mu\text{mho/cm}) = (c\Lambda)_{KCl} + (c\Lambda)_{NaCl} \qquad [4]$$

where the c's are in milliequivalents per liter, and the Λ's are chosen in accordance with the *ionic strength postulate* stated above.

In 1911, Bray and Hunt (12) determined the conductivities of mixtures of sodium chloride and hydrochloric acid. Their observed conductivities agreed with values calculated from the ionic strength postulate within about 1% up to ionic strengths of about 0.1M. Deviations due to the "mixture effect" (5,6) of cations of widely different mobilities with a common anion are to be expected and tend to make the conductivity calculated from the ionic strength postulate slightly high. Bray and Hunt consistently observed a small but systematic deviation in this direction. In their work, this deviation reached a maximum in equimolar mixtures of the two electrolytes, dropping off as the mixtures approached either one or the other pure electrolyte. These maximum mixture effect deviations attained the values: 2.0% in a mixture of 100 mEq/l of HCl and NaCl; 1.1%, in 20 mEq/l of each; 0.68%, in 5 mEq/l of each. Since the mobilities of potassium and sodium ions are much closer than those of hydrogen and sodium ions, the mixture effect should be smaller in sweat and in the synthetic mixtures akin to sweat investigated in the present study than it was in Bray and Hunt's studies. It was felt by us that the mixture effect could be neglected safely, and that the ionic strength postulate should be reliable within 1% or better in the present instance.

The calculation of the interionic attraction factor S is best illustrated by an example. Consider a "parent sweat sample" initially 0.100N in chloride ion. By a 50-fold dilution, this is reduced to 0.002N in the "diluted sweat solution." The Λ's of pure KCl and NaCl at 25°C are, respectively, 128.96 and 106.74 mho cm^2 Eq^{-1} at 0.1N, and 145.80 and 122.70

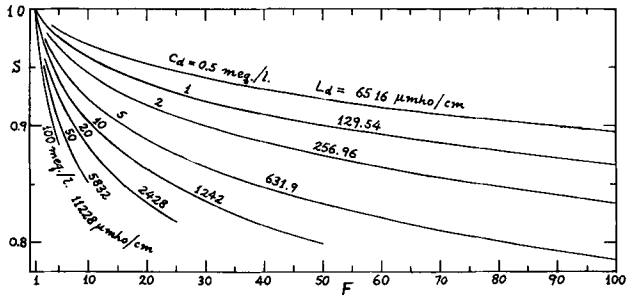

Fig. 1. Interionic attraction factor S for a 25 eq. % KCl : 75 eq. % NaCl mixture as a function of dilution factor F, diluted sweat sample electrolyte concentration c_d (in milliequivalents per liter), and diluted sample conductivity L_d (in micromhos per centimeter at 25°C).

at 0.002*N* (4, 11). The *S* factor calculated from Eq. [3] then takes on the value 0.884, 0.881, 0.878, 0.874, and 0.870, as the equivalent ratio of KCl:NaCl goes from 100:0 to 75:25, 50:50, 25:75, and 0:100, respectively. At less than 50-fold dilution, the spread in *S* values is even less. Thus the *S* factor is an insensitive function of the actual KCl to NaCl ratio. The 25KCl : 75NaCl equivalent ratio was arbitrarily selected as representative of the bulk of sweat samples, and was used in the construction of the family of *S* curves plotted in Fig. 1. Here, the *S* factor is given as a function of two variables, the total chloride concentration c_d of the diluted sample (in mEq/l), and the dilution factor *F*. In addition, each curve (of constant c_d) is identified by the appropriate value of L_d, the diluted sample conductivity (in micromhos per centimeter at 25°C) calculated from Eq. [4].

In practice, the interionic attraction factor *S* is determined as follows. The available empirical data on any actual sweat sample are, as already noted, the diluted sweat conductivity $L_d = (J_o - J_b)K$ and the dilution factor *F*. The value of *S* is then read off the curves of Fig. 1, at the proper value of *F*, by visual interpolation between the several L_d values. The final "corrected" sweat conductivity L_s is then calculated as $(J_o - J_b)KFS$.

Sweat Conductivity

To establish the validity of the interionic attraction factor *S*, pure sweat samples were collected from three subjects as described above and the conductivity of undiluted and diluted portions measured. Table II shows the data obtained for one of these samples from a cystic fibrosis patient whose undiluted sweat conductivity was measured directly

Table II. Comparison of observed and calculated sweat conductivities for a pure and diluted sweat sample (25.0°C, cell constant K = 12.7 cm^{-1}) (CF Subject No. 1693)

L_d (observed), μmho/cm	*F*	*S*	L_s' (uncorrected), μmho/cm	L_s (corrected), μmho/cm

Table III. Typical sweat conductivity data for subjects with and without cystic fibrosis (25°C)

Subject No.	L_d (observed), μmho/cm	Dilution factor, *F*	Interionic attraction factor, *S*	Sweat conductivity: L_s' (uncorrected), μmho/cm	Sweat conductivity: L_s (corrected), μmho/cm
A. For Children with Cystic Fibrosis					
474	229	47.43	0.879	10,860	9540
505	1274	10.60	0.897	13,510	12,110
532	550	21.31	0.896	11,720	10,500
646	2655	5.36	0.920	14,240	13,090
654	481	35.49	0.871	17,060	14,860
B. Healthy Children and those with Miscellaneous Diseases (Control Group)					
513	215	20.55	0.927	4420	4100
520	477	11.48	0.941	5480	5150
526	286	12.95	0.933	3710	3460
650	103	57.69	0.912	5940	5420
651	733	4.68	0.955	3430	3270

C. Summary of Sweat Conductivity Data

Group	No. in group	Sweat conductivity: Mean, μmho/cm	Group standard deviation, μmho/cm	Range, μmho/cm
Cystic fibrosis	47	(uncorrected) L_s' = 16,150	3500	9000-24,640
		(corrected) L_s = 14,380	3130	8030-21,260
Control group	77	(uncorrected) L_s' = 5560	2360	2080-14,380
		(corrected) L_s = 5080	2160	1970-13,340

as 15,500 μmho/cm. The sample was diluted five to fifty-fold, and the conductivity measured again. The uncorrected "sweat conductivities" L_s' calculated by Eq. [1] ranged from 17,150 to 18,320, about 11 to 18% high. Application of the *S* factor (Fig. 1) yielded "corrected sweat conductivities" L_s ranging from 15,300 to 16,030, i.e., from 1.3% low to 3.4% high, the average error being 2.2% for the dilutions of this one sample. On all three subjects, uncorrected conductivities L_s' ranged from 7 to 23% high; values corrected by use of the *S* factor ranged from 2.7% low to 5.7% high, the average error being 3.3%.

In Table III, typical sweat conductivity data, originally presented in (1), are recalculated from Eq. [2] employing the interionic attraction factor. The mean, group standard deviation, and range of sweat conductivities for 77 subjects in a control group and 47 patients with cystic fibrosis are presented in summary. It is noted that a significant change in conductivity values occurs as a result of the application of the *S* factor. The corrected values can be used as a basis for a further correlation between conductivity and electrolyte content currently in progress.

The System LiF-LiCl, LiF-NaCl, LiF-KCl

H. M. Haendler, P. S. Sennett, and C. M. Wheeler, Jr.

Department of Chemistry, University of New Hampshire, Durham, New Hampshire

ABSTRACT

Liquid-solid equilibrium data for the systems LiF-LiCl, LiF-NaCl, LiF-KCl were obtained through the concentration range 0-100 mole % LiF. These data were used to test the formula

$$T_{calc} = T_m \left(\frac{1 + x^2 \Delta F^\circ / L}{1 - \frac{2RT_m \ln (1 - X)}{L}} \right)$$

for the prediction of liquidus temperatures. Activities were calculated from experimental data by

$$a_{M_1A_1} = (1 - X)_{M_1} \cdot (1 - X)_{A_1} e^{X_{M_2} \cdot X_{A_2} \cdot \Delta F^\circ / RT}$$

It was shown that the activities of salt components can be calculated by this formula, if the difference in the sum of lattice energies of the reactants and products of mixing is not too large.

Although phase relationships in fused salt systems have been studied for many years, it is only recently that the practical applications of these relationships have become apparent. One promising new application is in the purification and separation of metals by extraction with fused salt media (1). Of particular interest are systems containing fused LiF as one of the components. Botschwar (2) and Bergman (3) have published data for the system LiF-LiCl. However these phase diagrams are not in agreement, exhibiting a difference in liquidus temperatures over a wide concentration range and a substantial difference in the eutectic temperature and composition. Flood (4) has reported data for the system LiF-KCl over a limited concentration range. The work reported in this paper defines more accurately the system LiF-LiCl and extends the reported data for the system LiF-KCl through the entire concentration range, 0-100 mole % LiF. This paper also presents new data for the system LiF-NaCl.

In addition to determining phase diagrams for binary systems of fused salt systems, it is also of interest to use these data where possible to determine the activities of the salt components in the binary systems. An important contribution to this problem has been made by Flood (4, 5). His equations have been tested with the data reported in this work. For systems with components of similar lattice energies, Flood's equations for the determination of activities and prediction of liquidus temperatures are much better than the Clausius-Clapeyron equation for ideal solutions, when the Temkin model for ideal solutions is used.

Experimental

All chemicals were reagent grade and were used after drying without further purification. Mixtures were prepared by accurate weighing of components and melting in a nickel sample holder. A gas stirring device, described by Campbell and Prodan (6), was used for the LiF-LiCl system and the NaCl-rich portion of the LiF-NaCl system. A nickel stirring paddle connected to a variable speed motor was used for the LiF-rich portion of the LiF-NaCl system and the entire LiF-KCl system.

Temperatures were measured using chromel-alumel thermocouples, calibrated at the melting point of Bureau of Standards samples of aluminum and zinc. The emf of the thermocouple was measured by a L&N Type G two point recording potentiometer and a Rubicon Type B potentiometer.

The samples were heated for ½ to 1 hr at 100° above the expected freezing point. When supercooling was not a problem, the current through the furnace was completely turned off and the sample was

allowed to cool at the rate of about 20°C/min. When supercooling was encountered, the cooling rate was adjusted to 5°C/min.

There was no evidence that the nickel sample holder reacted appreciably with the melt. The pure salts apparently attacked the cell to a lesser extent than did mixtures of intermediate composition. As an example of the extent of corrosion, electrolytic determination of nickel present in the LiF-LiCl system at 10 mole % LiF, gave 0.08, 0.07, and 0.08% nickel in three determinations. X-ray powder pattern data also substantiated these results.

Results

The system LiF-LiCl.—Temperature-composition data were obtained for the LiF-LiCl system over the concentration range 0 to 100 mole % LiF. An eutectic composition of 30.5 mole % LiF was observed, melting at 501°C. Botschwar (2) reported 20 mole % LiF at a eutectic temperature 485°C, Bergman (3) reported 30.5 mole % LiF, 484°C. There was no evidence of compound formation or of solid solutions. The experimental data are recorded in Table I. Figure 1 is a plot of these data. Also plotted are the theoretical liquidus curves for solutions of this system, as calculated from the Clausius-Clapeyron equation.

The System LiF-NaCl.—Temperature-composition data were obtained for the LiF-NaCl system over the concentration range 0 to 100 mole % LiF. The eutectic for this system occurs at 41.5 mole % LiF and 680°C. The phase diagram for this system is similar to that for the LiF-LiCl system, exhibiting a single eutectic, with no evidence of compound formation or solid solutions.

The 50-90 mole % LiF region of this system presented considerable experimental difficulties because of supercooling. Supercooling apparently did not occur in any other composition range. Thermal analysis of mixtures in this range were performed initially using a cell with an air stirring device. Data using this equipment were not reproducible and varied consistently by 10°C from the data reported here. When a more vigorous mechanical stirring device was used, supercooling became small enough so that reproducible results were obtained. The results obtained while using the mechanical stirrer are included in Table II since their reproducibility is considerably better. The values included in Table II and plotted in Fig. 2 for 50-90 mole % LiF are averages of three determinations with a maximum difference of ±2°C.

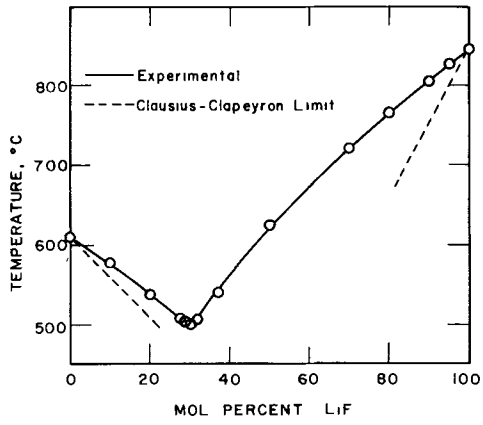

Fig. 1. The system LiF-LiCl

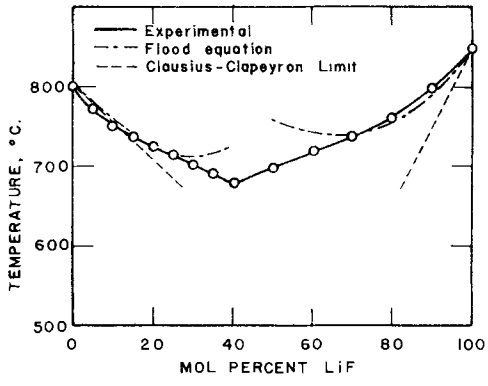

Fig. 2. The system LiF-NaCl

Table II records the experimental data for the system LiF-NaCl. Figure 2 includes a plot of these experimental data and the theoretical liquidus curves for ideal solutions of this system as calculated from the Clausius-Clapeyron equation and Flood's equation.

The System LiF-KCl.—The temperature-composition data obtained for this system in the concentration range 0-100 mole % LiF are listed in Table III.

A plot of these data is shown in Fig. 3, with the theoretical liquidus curves for this system as pre-

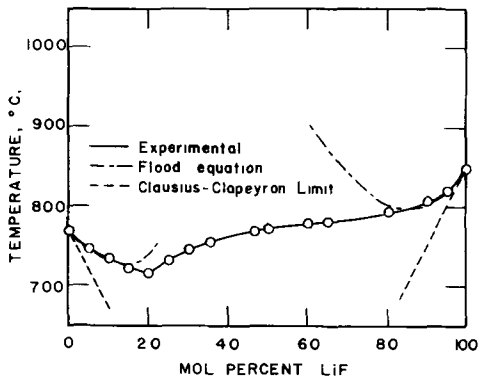

Fig. 3. The system LiF-KCl

dicted by the equations of Clausius-Clapeyron and Flood. This system forms a eutectic at 20 mole % LiF and 715°C. Flood (4) does not list specific eutectic data for this system, but his phase diagram shows eutectic behavior consistent with that which was observed in this work. As will be noted in Fig. 3, the liquidus curve for the potassium chloride side of the eutectic is fairly regular with a slight curvature. On the lithium fluoride side of the eutectic, however, the liquidus curve exhibits a point of inflection. The shape of this curve and its deviation from the general shape of the corresponding curve in the previous two systems can be accounted for in two ways.

The first possible explanation of this curve is that the two components tend toward the formation of an equimolar binary compound. This would account for the abrupt change in the freezing point near the eutectic and the slow change of freezing point with composition in the 40-80 mole % LiF region.

A second explanation for the shape of this type of phase diagram is given by Sidgwick and Ewbank (7). Curves of this shape are due to a submerged miscibility gap. This miscibility gap is unstable with respect to the liquidus curve, that is, it occurs at a lower temperature than the liquidus curve. Presumably if the melt could be supercooled below the liquidus temperature, two liquid phases in metastable equilibrium would appear. This can actually be accomplished in systems where the miscibility gap is not far below the liquidus temperature. It is assumed that solid solubility in these systems is negligible since none of the experimental data indicated any solid solution formation.

Discussion

From a comparison of Fig. 1, 2, and 3 it can be seen that the deviations from ideality on the lithium fluoride side of the eutectic increases in the order LiCl-NaCl-KCl. The most pronounced deviation occurs in the LiF-KCl system on the lithium fluoride side of the eutectic. Of the three systems studied, it is to be expected, based on the influence of ionic sizes and radius ratios, that the maximum deviation from ideality would appear in this system. The apparent tendency toward the formation of two immiscible liquid solutions is consistent with the higher lattice energy of lithium fluoride and the consequent higher attractive forces operative in the fused salt media.

An improvement over the Clausius-Clapeyron equation for calculating the liquidus temperature is given by Flood's equation (4).

$$T_{calc} = T_m \left[\frac{1 + X^2 \Delta F^\circ / L}{1 - \frac{2RT_m \ln (1 - X)}{L}} \right] \qquad [1]$$

Using the solution reaction of KCl in LiF as an example, the terms of this equation have the following meaning: where ΔF° is standard free energy change of the reaction

$$KCl + LiF \rightarrow LiCl + KF$$

L is molar heat of fusion of major component (LiF); T_{calc}, liquidus temperature of melt of mole fraction X; T_m, melting temperature (degrees Absolute) of major component; X, mole fraction of minor component (KCl), M_2A_2; 1 — X, mole fraction of major component, M_1A_1.

It is of interest to determine the activities of the salt components of the two binary systems LiF-NaCl and LiF-KCl. The major component of the binary salt mixtures may be considered the solvent. The activity of the solvent is related to the depression in freezing point of the solvent by the equation (negligible solid solubility assumed)

$$\ln a_{M_1A_1} = \frac{L}{R}\left(\frac{1}{T_m} - \frac{1}{T}\right) \qquad [2]$$

where $a_{M_1A_1}$ is the activity of the major component M_1A_1; L is the heat of fusion of the major component, considered to be constant; T_m is the melting point of the major component in the pure state; and T°K is the experimentally observed temperature for a solution of mole fraction 1 — X.

The activity coefficient $\gamma_{M_1A_1} = \dfrac{a_{M_1A_1}}{(1 - X)_{M_1}(1 - X)_{A_1}}$.

The value of $a_{M_1A_1}$ is calculated from Eq. [2]. The activity coefficients calculated in this fashion will be called γ exp in this paper.

These equations permit the calculation of activities and activity coefficients from liquidus curve temperatures. The equations developed by Flood are intended to provide a means of theoretically calculating the activities and liquidus temperatures for a

binary system, using free energy, heat of fusion, and concentration data.

For the mixing $M_1A_1 + M_2A_2 = M_2A_1 + M_1A_2$, the activity of M_1A_1 may be calculated using Flood's simplified formula

$$a_{M_1A_1} = (1 - X)_{M_1} \cdot (1 - X)_{A_1} \cdot e^{X_{M_2} \cdot X_{A_2} \cdot \Delta F^\circ / RT}$$

where ΔF° is the standard free energy change for the reaction as written.

The activity coefficient may be calculated using

$$\ln \gamma M_1A_1 = X_{M_2} \cdot X_{A_2} \cdot \Delta F^\circ / RT$$

The quantitative comparison between calculated and experimentally determined activity, activity coefficient, and liquidus temperature values is given in Table IV-VII.

Free energies of formation and heats of fusion were taken from National Bureau of Standards Circular 500.

The development of Flood's equation assumes that the entropy condition of the fused salt melt is that of an ideal ion mixture; each cation is surrounded by anions and vice versa; the cations as well as the anions are statistically distributed at random. In addition it is assumed that the heat of mixing is equal to zero. Thus the calculated liquidus temperature and activities of the components are related through the free energy change of mixing to the entropy condition of the mixture.

In a system such as LiF + NaCl = LiCl + Na F the difference in lattice energies of the reactants and products of mixing is much less than for the system Li F + K Cl = LiCl + KF. One may suppose, then, that the entropy condition required by Flood's treatment would more nearly be approximated by the LiF-NaCl system. Consequently liquidus temperature calculated by his equation should more closely correspond to the experimental temperatures for this system than for the LiF-KCl system, in which a greater difference in lattice energies is observed. This is the case and is evident from the plots in Fig. 2 and 3. The theoretically calculated liquidus curve for the LiF-NaCl system is in fair agreement with the experimental curve over a wide concentration range. However, in the LiF-KCl system large positive deviations are observed at concentrations greater than 25 mole % LiF. Apparently due to the strong interionic forces between the Li^+ and F^- ions, the random distribution of cations and anions of the Li^+, F^-, K^+, Cl^- mixture is not realized in these more concentrated solutions. In the LiF-NaCl system the bond energies of the products of mixing more nearly equal those of the reactants. This should provide for a more random distribution of the Li^+, F^-, Na^+, Cl^- ions and consequently for better agreement between theoretical and experimental activities and liquidus temperatures.

Flood (4) has shown that the activities of salt components with lower lattice energies can be calculated accurately with his simplified theoretical formula. The data and calculations reported here for the LiF-NaCl system indicate that the formula can also be used with fair results for a system in which the lattice energies of the components are large, providing the difference in the sum of lattice energies of reactants and products of mixing is not too great. For systems in which the difference in lattice energies of the components is large, the formula fails for solutions of even moderate concentrations.

Technical Notes

Study of Magnetic Oxides by Cathode Rays

S. Yamaguchi

Scientific Research Institute, Tokyo, Japan

The path of cathode rays is deflected by a magnetic field (Lorentz effect). This effect is observable in the electron diffraction pattern obtained from a ferromagnetic substance. In the present study, the magnetic states of two ferromagnetic oxides were investigated by means of electron diffraction.

The two specimens employed were ferromagnetic pure nickel oxide (NiO) and an oxide permanent magnet of practical use (Fe_2O_3:NiO:ZnO = 50:15:35 by weight). The weight of the specimen used for the experiment was about 1 mg.

In Fig. 1, the diffraction rings from a powder of the nickel oxide and those from a nonferromagnetic gold foil are photographed on the same dry plate by means of double exposure. In this procedure, the wave length of the electron beam applied and the position of the photographic plate were kept fixed. It is noticeable in Fig. 1 that the diffraction rings from these two substances are not co-centric. This implies that the paths of the electrons are magnetically perturbed by the ferromagnetic specimen.

In Fig. 2, the diffraction rings from a nonferromagnetic aluminum oxide (böhmite) (1) and those from the gold foil are photographed by the same process as for Fig. 1. In this photograph all the diffraction rings are co-centric, i.e., there is no magnetic effect on the electrons. Figure 2 corresponds to the result of a blank test for magnetic analysis.

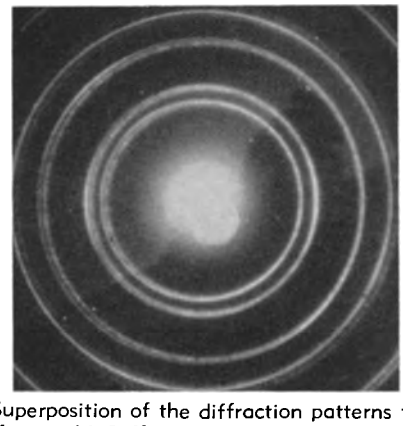

Fig. 1. Superposition of the diffraction patterns from nickel oxide and from gold. Diffraction rings of the former and those of the latter are excentric as the result of Lorentz effect. Wave length, 0.0292Å. Camera length, 495 mm. Positive enlarged 2.1 times.

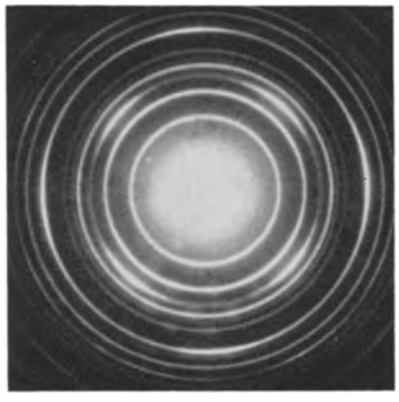

Fig. 2. Superposition of the diffraction patterns from bohmite and from gold. All the rings are co-centric. No Lorentz effect.

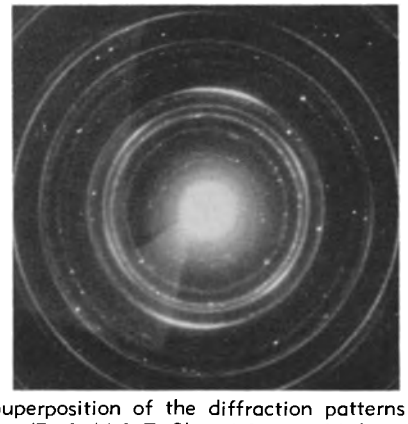

Fig. 3. Superposition of the diffraction patterns from the oxide magnet (Fe_2O_3-NiO-ZnO) and from gold. Lorentz effect. Wave length, 0.0302Å.

The diffraction pattern of Fig. 3 was observed from a powder of the oxide permanent magnet and from the gold foil in the same way as for Fig. 1 and 2. In Fig. 3, the diffraction rings of the oxide and those of gold are not co-centric.

From the diffraction figures thus prepared, it is possible to estimate the strength H of the magnetic field given by the ferromagnetic oxide.

$$H = \frac{m}{e}\frac{v}{lL} \cdot \Delta x$$

or

$$H = \frac{h}{e\lambda lL} \cdot \Delta x \qquad [1]$$

where e is electron charge (1.6×10^{-20} CGSEMU); m, electron mass; v, velocity of electrons; L, camera length (495 mm); h, Planck's constant (6.6×10^{-27} erg sec); l, width of the magnetic field (about 0.5 mm); λ, wave length of the electron wave; and Δx, observed deflection of the electron beam.

In Fig. 1 and Fig. 3,

$$\Delta x = 0.2 \text{ mm } (\lambda = 0.0292\text{Å})$$

and

$$\Delta x = 0.1 \text{ mm } (\lambda = 0.0302\text{Å}),$$

respectively.

According to Eq. [1], therefore,

$$H = 11.4 \text{ and } 5.53 \text{ gauss, respectively.}$$

It is thus possible to investigate ferromagnetic oxides magnetochemically as well as crystallographically by means of electron diffraction.

The Mechanism of Blackening of Nickel Anodes

Thomas C. Franklin and Jack Goodwyn

Chemistry Department, Baylor University, Waco, Texas

In the process of depositing black nickel using a nickel wire anode and cathode and a modification of the bath used by Moline (1) it was noted that the anode as well as the cathode became black. Meyer (2) gave the composition of solutions in which nickel may be blackened without passing current, but no mention was made of the composition of the black coating nor of the mechanism of its formation. Since the solutions used by Meyer and Moline were similar, the coatings were assumed to be the same. This paper describes an investigation on the composition of the black deposit and the mechanism by which it was formed.

Experimental Methods and Results

Composition of the anode coating.—The bath used contained $NiSO_4 \cdot 6H_2O$, 70 g/l; $(NH_4)_2SO_4$, 37 g/l; $ZnSO_4 \cdot 7H_2O$, 34.3 g/l; and KSCN, 17.9 g/l, and was operated at a pH of 5.0, a temperature of 30°C, and a current density of 11 amp/m^2. All chemicals were reagent grade. To determine which component of this bath caused the blackening of the anode, an aqueous solution of each component was prepared, adjusted to a pH of 5.0 with HCl, and a small piece of nickel wire was placed in each solution. The nickel wire in the solution containing potassium thiocyanate darkened in two days. When the pH was lowered to 2.0, the solution darkened the wire in 7 hr. With current passing, both solutions darkened the anode within 6 min. None of the solutions containing the other components blackened the nickel wire. The odor of H_2S was noticed above those test tubes containing potassium thiocyanate.

To identify the reaction which liberated the H_2S, a series of test tubes was prepared with moistened lead acetate paper fastened over the mouth of each test tube. Each tube contained 20 ml of water, 1 g of potassium thiocyanate, and 2 ml of concentrated HCl. To these test tubes 1 g portions of different substances were added and the results were noted. These results are summarized in Table I.

The yellow solid which settled out of the blank solution (No. 1) was a polymerization product of thiocyanic acid (3). Metal ions evidently retard this polymerization as evidenced by the fact that 12 days were required for the formation of crystals in the solutions containing the cobalt and nickel ions and that 15 days were required with zinc ions present. The blackening of the lead acetate paper above test tubes 1, 4, 6, and 7 was due to H_2S from the hydrolysis of thiocyanic acid. The fact that H_2S was generated more rapidly in the solutions con-

Table I. Effect of various materials on acidified potassium thiocyanate solutions

	Material added	Results observed
1.	None	Lead acetate paper blackened in 5 days. Yellow crystals precipitated in 12 hr
2.	Nickel wire	Lead acetate paper blackened in 3 hr
3.	Tin (II) chloride	Lead acetate paper blackened in 3 hr. Brown precipitate formed in solution
4.	Zinc chloride	Only slight darkening of lead acetate paper in 3 days. Crystals formed in solution in 15 days
5.	Copper (II) chloride	Black precipitate [copper(II) thiocyanate] formed in the solution immediately
6.	Cobalt (II) chloride	Slight darkening of lead acetate paper in 3 days. Crystals formed in solution in 12 days
7.	Nickel (II) chloride	Slight darkening of lead acetate paper in 3 days. Crystals formed in solution in 12 days

taining the metal ions than in the blank was due to the inhibition of the polymerization by the metal ions thus making the hydrolysis the major reaction. In the presence of the reducing agents, tin (II) chloride and nickel wire, the evolution of H_2S was much more rapid and proceeded by a reduction similar to the following:

$$2CNS^- + 2Sn^{++} \rightarrow SnS_2 + 2CN^- + Sn^{++++}$$

Both chemical tests and x-ray diffraction showed the presence of nickel sulfide in the anode coating.

Mechanism of formation of the anode coatings.— An examination of the data shows that the reduction of the thiocyanic acid by nickel wire produced a coating in 7 hr while the anodic reaction produced a coating in 6 min. It seems unreasonable that the nickel anode was the reducing agent. Therefore it was postulated that the nickel anode was oxidized to nickel (I) and these ions then acted as the reducing agent on the thiocyanate ion. Kleinberg (4) has postulated a similar mechanism for the anodic dissolution of magnesium in the presence of oxidizing agents.

Because of the formation of nickel (II) sulfide on the anode, it was impossible to check coulometrically the valence of nickel as it went into solution in the presence of the thiocyanate ion. To avoid this difficulty, the nickel was anodically oxidized in solutions containing potassium bromate in place of the thiocyanate. Thus the valence could be checked and any bromine produced by the reduction of the bromate could be detected by odor and by its ability to bleach methyl red indicator. The electrolysis was carried out in a 400 ml beaker containing a 100 ml porous porcelain cup as the anode compartment. Sulfuric acid was used rather than HCl in order to prevent reaction between the chloride and bromate ions. An oxy-hydrogen coulometer, modeled after that of Lingane (5), was used. The potassium bromate was added in the form of a 0.1177M solution. A nickel wire of the same diameter and length as the anode was placed in a solution identical in composition to the anode solution and was left there for the duration of each electrolysis. The small change in weight of this blank was subtracted from the change in weight of the anode to give the exact loss of weight due to electrolytic oxidation. Results are given in Table II.

As can be seen, the valence of nickel anodically dissolved in H_2SO_4 averaged 2.02 ± 0.03. However, in the presence of potassium bromate, the valence of the nickel going into solution dropped below two (runs 3-7 and 15-23). It will be noticed that on repeated use of the bromate solution the valence rose toward two as the bromate concentration was lowered. The introduction of a fresh solution or the addition of more bromate always caused the valence to drop. At the completion of each electrolysis, it was found that the anolyte had a distinct odor of bromine and that it would bleach methyl-red readily. It was not possible to make an extended study since slight changes in current density or in pH caused oxygen to be evolved at the anode.

In order to establish further the existence of nickel (I) as an intermediate in the anodic dissolution of nickel, the nickel was oxidized anodically at low current densities (0.13 amp/m^2) in acetonitrile containing tetramethylammonium chloride as a supporting electrolyte. In this solvent corrosion was not possible. The apparatus was an H-tube with the compartments separated by means of a fine porosity sintered glass disk. The temperature was maintained at 7°C in order to minimize electro-osmosis. Results are summarized in Table III. In all cases it can be seen that part of the nickel dissolves as nickel (I).

Table III. Anodic dissolution of nickel in acetonitrile containing tetramethyl ammonium chloride

Total weight loss, g	N-number of Faradays per mole
0.0213	1.85
0.0230	1.67
0.0285	1.35

From these experiments it was concluded that the black coating formed on nickel anodes in baths containing thiocyanate was nickel sulfide formed by the following series of reactions:

$$Ni \rightarrow Ni^{+} + e$$

$$2Ni^{+} + CNS^{-} \rightarrow NiS + CN^{-} + Ni^{++}$$

These reactions might also be expected to occur to some extent at the cathode in black nickel plating baths. It is known that these black cathodic plates contain nickel sulfide. Sanborn and Orlemann (6) have shown the formation of an intermediate Ni (I) ion during the electrolytic reduction of Ni (II) in concentrated salt solutions. Therefore it is reasonable to expect that part of the nickel sulfide arises from the above reactions.

ZnS Phosphors with P, As, Sb Coactivators

E. F. Apple

Research Laboratory, General Electric Company, Schenectady, New York

In ZnS:P,Cl and ZnS:As,Cl phosphors (1, 2) it is thought that both the Group V element and chlorine occupy S sites in the ZnS lattice. This configuration gives rise to an acceptor-donor luminescent system in which P and As are acceptors or activators and chlorine is a donor or coactivator (3). Emission spectra under 3650Å excitation show a broad band in the yellow with P and a broad band in the yellow-orange with As.

If P or As or Sb is incorporated in ZnS along with Cu, only the blue and green emissions typical of Cu-activated ZnS are observed. These phosphors, which contain (before firing) from 5×10^{-6} to 5×10^{-4} g-atoms Cu/mole ZnS with equal to five times as much Group V element, are prepared in an H_2S stream or in a sealed, evacuated quartz tube at 950°C. Figure 1 shows the emission spectra of ZnS: 10^{-4} Cu, 5×10^{-4} As both under 3650Å and cathode-ray excitation. The spectra of corresponding ZnS: Cu,P and ZnS:Cu,Sb phosphors are almost identical with those shown. Note that under cathode-ray excitation the blue band disappears almost completely. This blue emission, which peaks at about 4450Å, is probably the "Cu-blue" emission previously described in the literature (4, 5). The self-activated blue emission in cubic ZnS peaks at 4600°-4700Å and has a much broader half-width than the blue emission band in ZnS:Cu,As. Increasing the temperature of preparation of ZnS:Cu,As causes an increase in the blue emission and decrease in the green emission intensity. It should be mentioned that ZnS:Cu, ZnS:P, ZnS:As, or ZnS:Sb are all practically nonluminescent when prepared in H_2S at 950°C.

The absence of the P-yellow and As-orange emissions in ZnS:Cu, P and ZnS:Cu, As, respectively, indicates that in the presence of Cu the Group V element assumes a different role than when in the presence of halogens. Because of the similarity in emission to ZnS:Cu,Al, in which Al is a donor, it is concluded that the Group V elements are donors (coactivators) when incorporated in ZnS along with Cu, the acceptor or activator. It is probable that the Group V element occupies a Zn

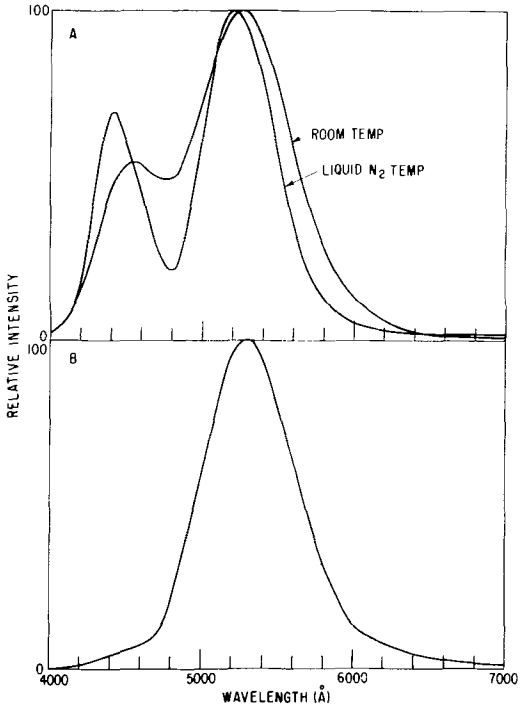

Fig. 1. ZnS: 10^{-4} Cu, 5×10^{-4} g-atoms As/mole ZnS; fired in H_2S at 950°C. A, 3650Å excitation; B, CR excitation (15 kv, 3μa/cm^2).

site when incorporated as a donor, a situation not unexpected; As and Sb occupy metal lattice sites in several ternary sulfides whose structures are related to the zinc blende or wurtzite modifications of ZnS. Phosphors with Group V coactivators have slightly weaker emissions and shorter afterglows than those with Group III coactivators such as Al. Also, Group V elements do not give rise to the self-activated blue center in ZnS.

In covalent compounds, Sb (or As) usually forms only three strong bonds and usually has only three nearest neighbors. For instance, Cu_3SbS_3 has the zinc blende structure in which the Cu and Sb atoms occupy metal sites and one quarter of the S sites are vacant. $CuSbS_2$ has a more complicated structure, related to the wurtzite structure, in which each Sb atom forms three strong pyramidal bonds and Cu four tetrahedral bonds to S atoms. Sb_2S_3 itself has a chain structure in which each Sb atom has three nearest-neighbor S atoms. Arsenic forms similar compounds with correspondingly complex structures (6). In contrast, $CuAlS_2$ and Al_2S_3 both have structures in which the metal atoms are tetrahedrally bonded to four equidistant S atoms (7). In addition to effects on luminescent processes, the differences in bonding between ternary sulfides of Al and As or Sb may be responsible for the more limited solubilities of added impurities in the phosphors containing Cu along with the Group V element. ZnS phosphors containing more than 10^{-3} g-atoms Cu/mole ZnS and equal to five times as much P, As, or Sb, have a very gray body color, and are only weakly luminescent. Presumably, a multiphase system exists. However, ZnS:Cu,Al or $ZnS:CuGaS_2$ phosphors containing 10^{-3} Cu have a light body color, exhibit a fairly bright green luminescence, and are single phase systems (8, 9).

In summary, it has been shown that P, As, and Sb may, under special conditions, function as coactivators in ZnS phosphors. Whether the Group V element acts as an activator and substitutes on S sites or a coactivator and substitutes on Zn sites depends on which type of compensating impurity is incorporated simultaneously. In the presence of halogen, the substitution occurs at S sites, whereas with Cu it occurs at Zn sites.

Preliminary experiments indicate that P, As, and Sb are also coactivators in ZnS phosphors containing Ag or Au activators.

Manuscript received Sept. 25, 1958.

Brief Communication

Titanium Coatings on Molybdenum Wire

Robert L. Bronnes

Philips Laboratories, Irvington-on-Hudson, New York

In an electron tube, the level of primary grid emission is dependent on many factors, including grid and cathode temperatures, rate of supply of evaporation products from emitter material in the cathode, and evolution of gases. Espersen and Rogers of these Laboratories have shown that the emission level may be lowered by controlling grid temperatures and by choosing grid materials which are not readily activated by contamination with evaporation products from the cathode (1). Titanium, in comparison to molybdenum and other commonly used grid materials, is remarkably insensitive to such activation, but does not have sufficient high-temperature rigidity to maintain the anode-grid-cathode spacings. In order to combine the low-level emission characteristics of titanium with the rigidity of molybdenum, a method was developed for depositing a layer of titanium on molybdenum by the evaporation of metallic titanium.

Apparatus and Method

The materials required are 0.010-in. molybdenum wire, 0.010-in. titanium wire, and a 0.020-in. helical tungsten wire heater coil having a diameter of 0.5-in. and 8 complete turns, 1-in. long. The steps required are:

1. Degrease the molybdenum, tungsten, and titanium wires in acetone.

2. Hydrogen-fire the molybdenum and tungsten wires at 1100°C for 30 min to remove surface contamination and reduce surface oxides.

3. Mount the molybdenum wire vertically on a bulb stem inside the tungsten coil. Approximately 50 mg of titanium wire are wrapped uniformly around the tungsten coil.

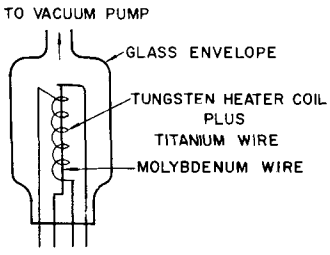

Fig. 1. Evaporation assembly

Fig. 2. Titanium coated molybdenum wire. Original magnification 900X.

4. Thoroughly degrease the assembly in trichlorethylene vapor.

5. Seal the assembly in a glass envelope (Fig. 1), mount on a vacuum pump, evacuate, and bake-out at 450°C for 1 hr. A vacuum of ca 2 x 10^{-7} mm Hg should be obtained.

6. Raise the temperature of the molybdenum wire to 1600°C[1] for degassing, while maintaining a vacuum of at least 6 x 10^{-5} mm Hg. Degas until a vacuum of ca 2 x 10^{-6} mm Hg is obtained. Note power requirements.

7. Lower the temperature of the molybdenum wire to 900°C. A vacuum of ca 6 x 10^{-7} mm Hg should be obtained. Note power requirements.

8. While the temperature of the molybdenum wire is held at 900°C, slowly raise the temperature of the tungsten heater coil to a few degrees above the melting point of titanium. Maintain a vacuum of ca 6 x 10^{-5} mm Hg, and hold at this temperature for 5 min. After the heater coil has cooled down, a vacuum of ca 6 x 10^{-7} mm Hg should be obtained. Since the glass envelope will become opaque during the evaporation of titanium, the temperature of the molybdenum wire can be maintained only by reference to the power requirements noted in Step No. 7.

9. Raise the temperature of the molybdenum wire to 1600°C by using the power requirements noted in Step No. 6. Hold for 1 min.

10. Allow the assembly to cool down and remove from the vacuum pump.

[1] All temperatures are uncorrected, as measured with a L&N optical pyrometer.

Results and Discussion

Smooth, uniform coatings have been obtained by this method with good reproducibility of results. Bonding occurs during deposition and during final heating by the formation of a molybdenum-titanium alloy. The titanium coating and alloyed region are clearly visible in Fig. 2.

If the parts have been carefully processed and a good vacuum maintained, the coatings will be of good physical integrity, firmly bonded and adherent to the molybdenum, and sufficiently ductile so that rupturing will not occur on moderate flexing.

While this process has been described as a laboratory procedure, it is possible to modify the apparatus to permit continuous processing of wire in any desired lengths.

Batteries with Solid Ion Exchange Electrolytes

I. Secondary Cells Employing Metal Electrodes

W. T. Grubb

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

Highly conducting ion exchange polymers can be employed as solid electrolytes in batteries. Their resistivities are intermediate between aqueous electrolytes and the usual inorganic solid electrolytes. Cells containing pairs of metal electrodes behave reversibly. Their emf's form an additive series for the examples tested and are only slightly less than those of their aqueous analogs.

In this paper the phrase ion-exchange battery is used to denote a galvanic cell in which the electrolyte is a solid (although somewhat hydrated) ionically conducting ionizing polymer of the type commonly called ion exchange resins. In these materials the self-diffusion rates and ionic conductances are simply interrelated as has been demonstrated by Coryell and Spregler (1).

Ion exchangers have been used as separating membranes in cells containing two or more electrolyte compartments such as the Daniell cell disclosed by Juda, *et al.* (2) and the concentration battery proposed by Meyer (3). They have been employed to depolarize cells by removing a reaction product (4, 5). They have been employed to supply a reacting ion to the cell reaction. For example, Robinson (6) has disclosed the use of a permanganate anion exchange resin as a cathode depolarizer in an analog of the Leclanché cell.

The present investigation has been concerned with the ion exchange polymers acting as electrolytes wherein the current is entirely conducted by the ionizing polymer itself. At the same time it maintains the physical structure of the cell. The role of the ion exchanger is analogous to that of a silver halide in the more conventional type of solid-electrolyte cells (7) except that the conductance is several orders of magnitude higher. Also, there are more possibilities for the ion-exchange battery since the mobile ion may be selected at will simply by exchanging the electrolyte into a suitable ionic state.

Materials and Methods

Ion exchange membranes.—Synthetic polymers containing strongly ionized sulfonate groups were used. A review (8) of the typical ion-exchange properties and structures may be found helpful. Particular use was made of ion-exchange membranes which consist of sheets of ion-exchange polymer very resistant to direct flow of liquids but highly permeable to ions. Two commercial membranes were employed: Amberplex C-1,[1] a sulfonated polystyrene resin finely comminuted and held in a matrix of an inert polymer; and Nepton CR-51,[2] a homogeneous sheet of sulfonated phenol formaldehyde polymer. These two membranes possess somewhat different electrical and mechanical properties. Hereafter they are referred to as Amberplex and Nepton membranes, respectively.

Conditioning of membranes.—The ion-exchange membranes were converted into a desired ionic form by successive equilibration in several portions of a solution of the cation in question as described by Juda, *et al.* (9). In all cases, the "free" electrolyte was removed by extensive washing with distilled water. In several cases the membrane was equilibrated with water in ethylene glycol, using a large excess of solution and equilibrating for 24 hr or more. The solution contained 12.0% by weight of water or a mole fraction of 0.32. The water-ethylene glycol system obeys Raoult's law (10) approximately.

Solvating liquids.—Laboratory distilled (ρ = 500,000 ohm-cm) water was employed as the aqueous solvate to saturate the membranes. Ethylene glycol, U.S.P. grade, was redistilled at reduced pressure under dry N_2 atmosphere.

Cell construction.—Two cell construction methods have been employed in this work. For high-area cells (A = 10 cm^2) the metal foils have been backed up by ½-in. plexiglas blocks, and the electrolyte has been sealed from evaporation by surrounding it with a silicone rubber gasket. In these cells, the electrolyte overlaps the electrodes to prevent any possibility of edge shorting. Low-area cells (A = 0.3 cm^2) were constructed in trubore tubing (½ in. ID). In this case the electrode and the electrolyte do not overlap but are of the same size, being cut with the same punch and die. Data obtained on the two sizes of cells were mutually consistent.

The metals were of commercial purity, except for copper which was oxygen-free.

Electrical measurements.—Potential measurements were usually made with a Rubicon potentiometer to the nearest millivolt. Currents were obtained to about ½% using a Sensitive Instrument Co. polyranger. These measurements are adequate to the purpose at hand.

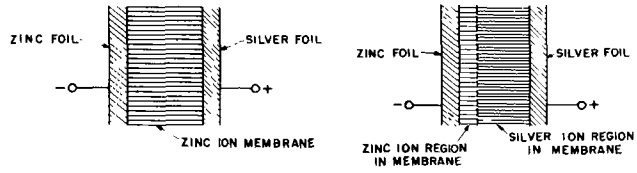

Fig. 1. Schematic diagram of silver-zinc cell. Left, uncharged cell, emf 0.8-1.2 v, right, charged cell, emf 1.4-1.5 v.

Results

Among the possible combinations of electrode and ion-exchanger electrolyte, those in which a metal is in contact with an electrolyte containing ions of the same metal coordinated with the fixed sites on the polymer are probably the simplest. While these might be constructed as primary cells by the use of two metals and two ion-exchange membranes in appropriate ionic state, a simpler method is to form such a cell by charging a single-electrolyte cell. The process is shown diagrammatically in Fig. 1. The cell initially contains an electrolyte in the zinc state between zinc and silver foils. The charging current produces a silver ion region next to the silver electrode.

In order to prove the nature of the charging process, the cell was set up as in Fig. 1 and charged with a known current for a measured time interval. It was then disassembled, the electrolyte washed, and analyzed. The total charge input was 2.00 ma for 4.08 hr, corresponding to 32.8 mg Ag. The analysis for total silver in the membrane was 32.0 mg Ag, indicating quantitative agreement within the error of measuring the total charge.

Both phenolic (Nepton type) and polystyrene (Amberplex type) electrolytes were employed in silver-zinc cells. Measurements of cell voltage as a function of both charging and of discharging current reveal that the emf is a linear function of the current, with the line passing smoothly through the zero current axis, as seen from representative plots in Fig. 2 and 3. Table I identifies the compositions and dimensions of the various cells, and the first column refers to the appropriate curve of Fig. 2 and 3. Data were obtained at 25° ± 0.05°C.

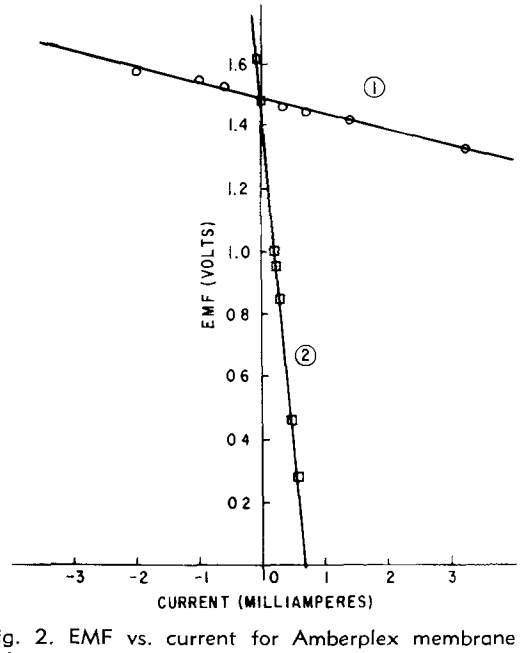

Fig. 2. EMF vs. current for Amberplex membrane cells. Numbers on curves refer to experiment numbers in Table I.

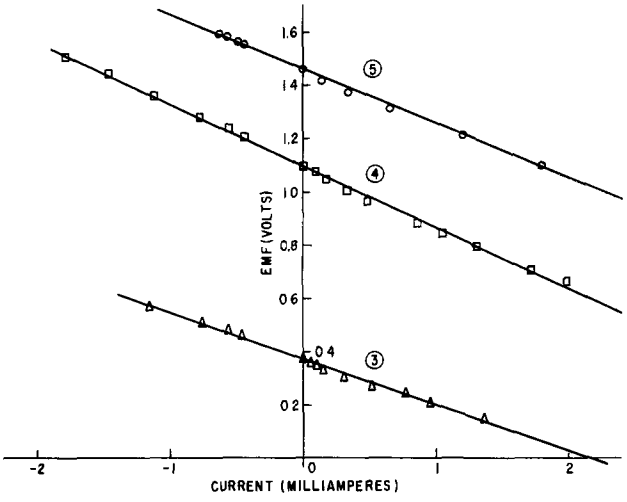

Fig. 3. EMF vs. current for Nepton membrane cells. Numbers on curves refer to experiment numbers in Table I.

In every case the cell was charged at 2.0 ma for 30 min. From the measured capacity data for the H^+ form of the ion exchange membranes, this amount of charge supplies the more noble metal ion to about 4% of the sites in the electrolyte (the membrane capacities per unit volume are similar for Amberplex and Nepton membranes). The data of Fig. 2 and 3 are the emf values after about 10 sec on the given load (or charge).

It might be supposed that concentration polarization is prevented by the nature of the ion exchanger electrolyte since the distribution of ions and their concentrations are held nearly constant by the immobile polymer network. However, concentration polarization actually does occur in the present cells when they are placed on heavier loads for short time intervals. This may be caused by solvate moving with the ions as hydration shells (11).

The present cells are analogous to cells with liquid junctions in conventional electrochemistry. It is likely that liquid junctions are absent in the present cells; first, because of the nature of the electrolyte which requires that the transference number is unity for cations, and second, because of the fixed sites in the network polymer, cross diffusion at the bound-

Table I

Expt. No.	Metal pair	Type of electrolyte	Solvate	Area of cell, cm²	Thickness of cell, cm
1.	Ag-Zn	Amberplex	H_2O	10.0	0.088
2.	Ag-Zn	Amberplex	H_2O + ethylene glycol[a]	10.0	0.088
4.	Cu-Zn	Nepton	H_2O + ethylene glycol[a]	10.0	0.081
5.	Ag-Zn	Nepton	H_2O + ethylene glycol[a]	10.0	0.081
3.	Ag-Cu	Nepton	H_2O + ethylene glycol[a]	10.0	0.081

[a] Concentration = 12.0% by weight of water.

ary of the regions of different ionic form occurs in the manner of an ion exchange reaction and is therefore equal in each direction.

The lines in Fig. 2 and 3 were determined by the method of least squares. In Table II are tabulated the constants for the equations of these lines, which all are of the form, $E = A - bi$ with E in practical volts and i in milliamperes.

The correlation coefficient (12), r, is a measure of the degree to which the least squares line represents the experimental points. It may be concluded that the experimental points are quite well represented by straight lines of constant slope, and therefore within errors of measurement the half-cells of the type metal/ion-exchange polymer, metal salt are reversible when metals such as silver, copper, or zinc are employed. Further evidence of the reversibility of the metal-ion exchanger half-cells is the additivity of potentials using the same electrolyte. From the data of experiments 3, 4, and 5 it is observed that A (3) + A (4) = 1.46_4 and A (5) = 1.46_0.

The internal resistances of the cells are equal to $b \times 10^3$ and represent a composite of two ionic forms of the ion exchanger.

Experiments 1 and 2 illustrate the fact that solvation of the electrolyte has little effect on the emf of a typical cell but has a large effect on the internal resistance. The very slight variation of emf observed when the water activity in the ion exchanger is reduced by a factor of about 3 indicates that the activity ratio of the two ions in the electrolyte is virtually unaffected by the partial removal of the water of solvation and its replacement by ethylene glycol. This effect could be interpreted as being due to the change of dielectric constant which influences the activity of ions in ion exchangers in a manner unspecific as to the nature of the ion. The very marked effect on conductivity is probably caused by a variation in the amount of association between the fixed sites and the mobile ions. This would also be expected from variation of the dielectric constant of the solvating liquid.

A number of cells were put through charge and discharge cycles. In a typical case, a cell of the type of experiment 1, Table I, was charged for 5 hr at 1.0 ma and then placed on a fixed load resistance. The discharge current as a function of time is plotted in Fig. 4. After 5 hr, there had been recovered approximately 80% of the charge input. When cells of the type of experiment 5, Table I, were tested in a similar manner, the charge recovery was only about 40%. Little charge could be recovered from cells

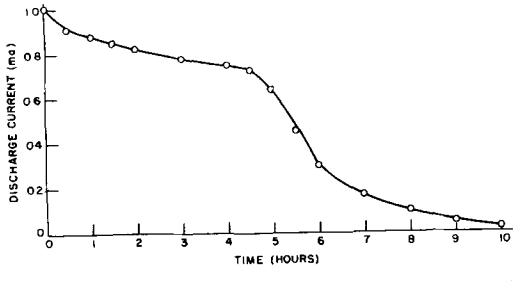

Fig. 4. Discharge current vs. time for Amberplex electrolyte cell. Dimensions: d= 0.088 cm, A = 35 cm²; local resistance = 420 ohms; charge = 1 ma for 5 hr.

Table II.

Expt. No.	A	b	r
1	1.48_5	0.0492	0.993
2	1.48_1	2.20	0.999
3	0.368	0.171	0.996
4	1.09_6	0.232_2	0.999
5	1.46_0	0.205	0.996

which were charged and then allowed to stand for 24 hr before discharging.

Figure 1 represents an idealized situation. The boundary between ionic forms is not sharp as shown but becomes "smeared out" by cross diffusion, and this happens rather quickly in highly conducting systems. Moderate stability is produced by use of partial aqueous solvation, using solutions of water in another polar liquid (e.g., ethylene glycol). Even in this case, silver ions eventually reach the zinc electrode and deposit because of cross diffusion. Such processes destroy the cell for practical purposes.

To prevent silver ion from reaching the zinc foil a barrier layer is needed. One way of achieving this is by use of a highly selective ion exchange resin, and some progress toward this has already been made (13). A more versatile solution perhaps lies in the use of complex ions. If one ion of the cell pair forms a stable complex anion, then an anion exchange resin membrane would effectively protect the less noble metal foil. This modification of the basic cell has not been tried yet experimentally.

The present paper discussed the application of ion exchange resins as solid electrolytes in a secondary cell system employing two metal electrodes and demonstrated that these cells are electrochemically reversible. A study of several types of primary cells employing ion exchange resin solid-state electrolytes has been made and will be reported in a subsequent publication.

Controlled Potential Reactions of Cadmium and Silver in Alkaline Solution

George T. Croft

Edison Laboratory, Thomas A. Edison Industries, McGraw-Edison Company, West Orange, New Jersey

ABSTRACT

Data are reported on the electrochemical oxidation and reduction of both cadmium and silver in potassium hydroxide electrolyte obtained using techniques in which the overpotential was the independent and the current the dependent variable. The rate of oxidation of cadmium is maximum at overpotentials of 18.0 and approximately 40.0 mv. The rate of reduction of cadmium and the rate of oxidation of silver are both monotonically increasing functions of the overpotential.

Very few electrochemical reactions are investigated by methods which use the overpotential as the independent and the current as the dependent variable. However, the application of such methods to investigations of electrochemical reactions which produce insoluble oxide films on the electrode yields information on the kinetics of the reaction not realizable by the conventional procedures which utilize the current as the independent variable (1). Methods utilizing control of the overpotential have here been applied to the study of reactions of cadmium and silver in potassium hydroxide electrolyte with new and important results.

It is well known that the rate of most electrochemical reactions depends exponentially on the overpotential, therefore a measurement of rate as a function of overpotential is inherently a more sensitive indicator of the kinetics of the reaction than a measurement of the overvoltage as a function of the current. Furthermore, given the overpotential as an independent variable we can choose from a number of possibilities a particular reaction for investigation. If the current is the independent variable, the electrode system may seek the kinetically most favorable reaction, especially if the electrode tends toward passivity, rather than the reaction under investigation. By controlling the overpotential we can determine the influence on the reaction rate of thickening of the oxide layer with time. For example, if the rate-limiting step in the oxide growth is transport of ions through the oxide already formed on the electrode and if the driving force is a gradient in the electrostatic potential, the current density is given by

$$I = \left(\frac{\sigma\phi}{2\Omega}\right)^{1/2} t^{-1/2} \qquad [1]$$

If the driving force is a gradient in ion concentration, the current is given by

$$I = \left(\frac{kT}{e}\frac{\sigma}{2\Omega}\right)^{1/2} \left(1 - \exp - \frac{e\phi}{eT}\right)^{1/2} t^{-1/2} \qquad [2]$$

The quantity ϕ is the overpotential, σ the ionic conductivity, T the temperature, t the time, Ω the volume of oxide formed per coulomb of electricity, and k and e are the Boltzmann constant and the charge on the electron, respectively.

Equations [1] and [2] indicate that, if experimental conditions are such that a simple growth law is observed (in this case a parabolic growth law), we might tentatively assume that the reaction rate is given by an equation of the form

$$I = F(\phi)t^{-1/2} \qquad [3]$$

where $F(\phi)$ is some function of the overpotential.

Two methods based on this approach were used to investigate the oxidation and reduction of cadmium and silver in potassium hydroxide electrolyte. Using the first method, the fixed potential method, we measure as a function of time the current required to maintain oxidation at a constant overpotential. We find that after sufficient time has elapsed the current and time are related by an equation of the form of Eq. [3]. Thus once it is established that the oxide grows according to a parabolic growth law, we interpret $F(\phi)$ as a function relating the rate of the reaction to the overpotential.

In employing the second method, an electrode is first oxidized at a fixed rate (constant current) until it becomes passive. This state of the electrode corresponds to the onset of the $t^{-1/2}$ current dependence observed using the fixed potential technique. The electrode is then oxidized or reduced at a rate such that ϕ follows the form of a triangular wave. Simultaneously the current necessary to make the electrode potential follow this wave shape is recorded. Thus if the change in thickness of the oxide layer is negligible during the anodic or cathodic swing of ϕ, measurements of I as a function of ϕ yield $F(\phi)$ vs. ϕ directly. Both methods of measurement yield the result that for anodic values of ϕ, $F(\phi)$ for cadmium electrodes has at least one maximum and often two. Furthermore, the overpotential

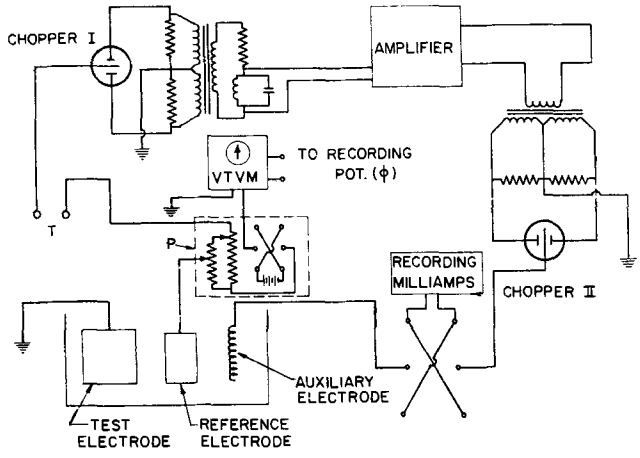

Fig. 1. Block diagram of control circuit used to maintain a given electrode overpotential.

observed during constant current oxidation (before passivity occurs) is equal to the potential corresponding to one of the maxima in the $F(\phi)$ vs. ϕ curve. Similar results were obtained for silver electrodes except that $F(\phi)$ has only one maximum and this for cathodic potentials. The overpotential observed during constant current reduction of the silver electrode is equal to the potential corresponding to the maximum in $F(\phi)$.

Apparatus and Sample Preparation

A block diagram of the instrumentation developed to oxidize or reduce a test electrode at any desired overpotential is shown in Fig. 1. The circuit is designed so that any difference between the desired potential fed in at terminals T and the test electrode potential produces a flow of current through the test electrode via the auxiliary electrode. This current, either cathodic or anodic, causes a change in the test electrode potential which reduces to zero the difference in potential between the test and input potential.

Control of the electrode potential is achieved by converting the difference potential by means of a chopper (Chopper I) to a 400 cps signal which is amplified and used to drive a power amplifier. The output of the power amplifier is fed into the output chopper (Chopper II) which is synchronized with the input chopper. Such synchronization leads to a direct current output which is fed back through the test electrode via the auxiliary electrode in such a direction that the difference potential is reduced to zero.

The potentiometer P is used to buck out the test electrode-reference potential. The reference used was a partially discharged nickel electrode from an Edison nickel-iron-alkaline storage battery. The current and potential were measured on a recording milliammeter and a self-balancing recording potentiometer. Using this circuit one can force the electrode to oxidize at a fixed potential and record the current as a function of time, or make the potential follow some predetermined function of time and record the current necessary to produce this potential variation. If the current through the test electrode does not exceed 25 ma, the circuit maintains the desired potential (either anodic or cathodic) to within ± 0.2 mv.

The cells used in both the fixed and sweeping potential measurements were of conventional design. Nitrogen was bubbled through the electrolyte in the fixed potential cell to reduce the dissolved oxygen concentration and to provide stirring of the electrolyte.

The cadmium electrodes used in the fixed potential experiments were prepared by electroplating cadmium onto nickel plates whose dimensions were 3.7 x 5.2 cm. The cadmium overlay was 0.005-0.01 cm thick and completely covered the underlying metal. The electrodes were cleaned by washing and scouring, followed by an overnight reduction at a cathodic potential of 37.5 mv.

The electrodes used in the sweeping potential experiments on cadmium were made from spectrographically pure Johnson-Matthey cadmium rods which were rolled into sheets, from which were cut electrodes of dimensions 2.86 x 3.00 cm. The electrodes were mounted in an epoxy resin with only one side exposed to the electrolyte.

The following procedure was used prior to recording the sweeping potential data. First the electrode was electrolytically polished in phosphoric acid and washed in distilled water. It was then placed in the cell and reduced at a high current density (approximately 1 amp/cm^2). Hydrogen was evolved over the surface until the electrolyte in the cell was thoroughly flushed with hydrogen. The cathodic current was turned off and the electrode was then oxidized at a fixed anodic current (1 ma/cm^2). When ϕ rose to 30 mv anodic, the current was turned off and the electrode was left to return to thermodynamic equilibrium. The electrode was then alternately oxidized and reduced so that ϕ followed the form of a triangular wave. Simultaneously the current necessary to produce this potential variation was recorded.

Fixed Potential Data—Cadmium

The electrochemical reaction studied was

$$Cd + 2OH^- \rightarrow Cd(OH)_2 + 2e$$

This was established by analysis of the x-ray diffraction lines of the reaction product. No evidence of CdO was observed.

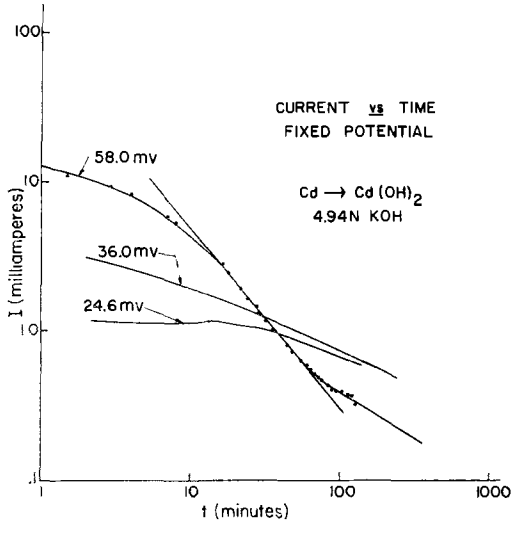

Fig. 2. Log I vs. log t curves for cadmium electrodes oxidized at fixed potential.

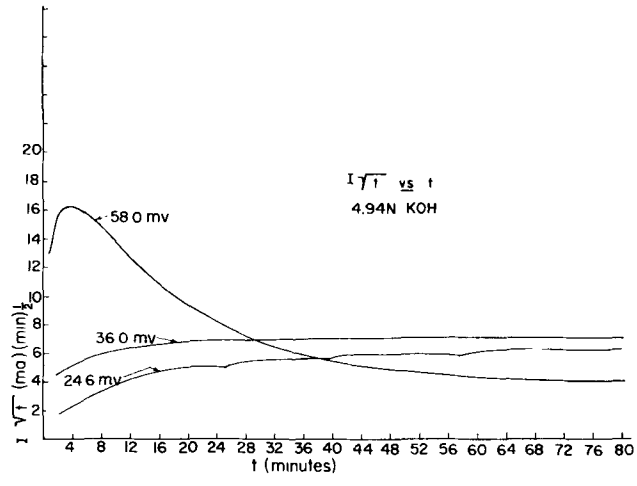

Fig. 3. The quantity $It^{1/2}$ vs. t for cadmium electrodes oxidized at fixed potential. No oxide present initially.

A typical series of log current vs. log time curves are shown in Fig. 2. Each of these curves was obtained by starting with an oxide-free surface previously maintained overnight at a cathodic potential (37.5 mv) and then instantaneously switched to a predetermined anodic potential.

After an initial slow decay, the current for the $\phi = 24.6$ and 36.0 mv runs begins to follow an equation of the form of Eq. [3]. At higher potentials (58 mv) the I vs. t curve has three portions. In the first portion the current decays slowly with time, in the second the current is proportional to t^{-1}, and in the third portion the current is proportional to $t^{-1/2}$.

The quantity $It^{1/2}$ obtained from the data shown in Fig. 2 is plotted vs. t in Fig. 3. For each potential the product $It^{1/2}$ tends toward a constant final value independent of time. This behavior follows directly from the $t^{-1/2}$ decay of current which starts after sufficient time has elapsed. The quantity $It^{1/2}$ for the $\phi = 24.6$ mv run exhibits a number of steps. This is probably caused by cracking or shearing off of the oxide film which exposes unoxidized cadmium to the electrolyte, which then oxidizes anew, etc.

Data similar to those in Fig. 3 are shown in Fig. 4. These results were obtained by suddenly advancing the electrode potential to 36.0 mv after the electrode had oxidized at 24.6 mv until the current was proportional to $t^{-1/2}$. More oxide was grown at this potential until the current decay was again proportional to $t^{-1/2}$. The potential was then suddenly made more anodic and more oxide was grown, etc. These data show that when sufficient time has elapsed after the sudden rise in anodic potential the product $It^{1/2}$ approaches a constant even if an initial oxide is present on the cadmium electrode. In this particular example $It^{1/2}$ tends toward the same value obtained if no oxide was present initially.

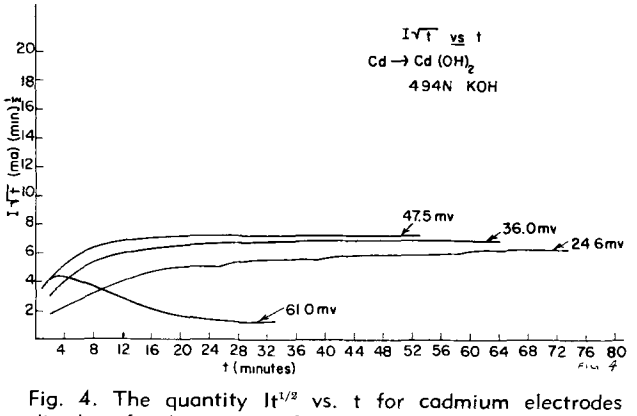

Fig. 4. The quantity $It^{1/2}$ vs. t for cadmium electrodes oxidized at fixed potential. Oxide present initially.

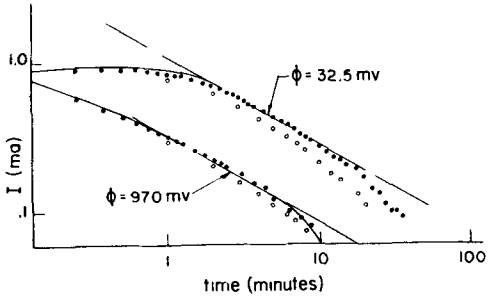

Fig. 5. Log I vs. log t for a cadmium electrode initially in the passive state. The electrode was 2.8 x 3.0 cm with one side exposed to electrolyte.

The characteristic shape of the curves shown in Fig. 2 to 4 is a reproducible function of ϕ, but the currents at equivalent times after application of anodic potentials were not generally reproducible. The curves shown represent some of the more reproducible runs.

Figure 5 is a plot of log I vs. log t obtained by the fixed potential method using electrodes which were first oxidized at constant current until the overpotential rose to 30 mv. (As the constant current overpotential rises to a value greater than 30 mv, the electrode rapidly approaches the passive state. Thus these electrodes for all practical purposes were in the passive state.) The current necessary to force the electrode to oxidize at a fixed potential is greater at 30 mv than at 97 mv. This is consistent with the fixed potential observations on electrodes not previously oxidized.

By fitting the I vs. t data in the $t^{-1/2}$ portion of the curve to Eq. [3] a number of determinations of $F(\phi)$ were made. Values of $F(\phi)$ determined by this procedure are shown plotted vs. ϕ in Fig. 6. Points obtained from additional I vs. t data not shown in this report are also plotted in this figure. The scatter of the points indicates the difficulty of achieving reproducibility from sample to sample, but qualita-

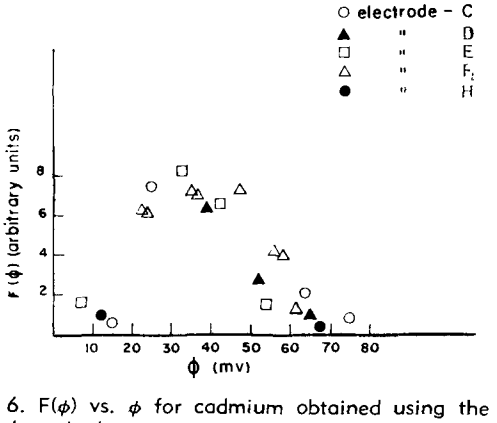

Fig. 6. F(ϕ) vs. ϕ for cadmium obtained using the fixed potential method.

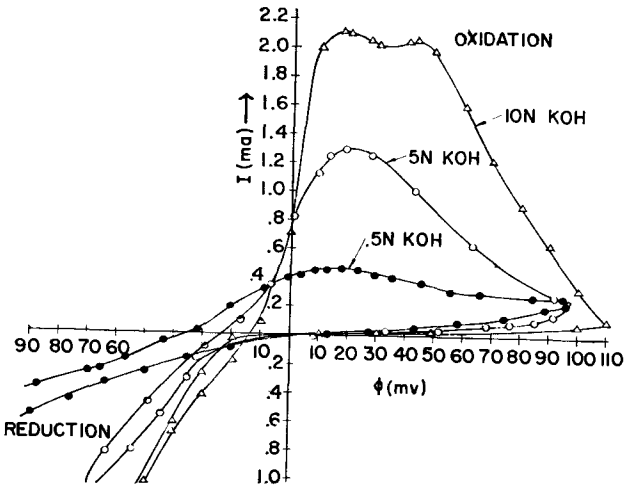

Fig. 7. Rate of oxidation and reduction of a cadmium electrode vs. overpotential obtained by the sweeping potential method.

tively the points show that $F(\phi)$ increases with ϕ to a maximum which lies between 18 and 40 mv. As ϕ is increased to potentials beyond the maximum, $F(\phi)$ decreases rapidly.

Thus fixed potential measurements on electrodes oxidized in a number of ways all indicate that in the final portion of the I vs. t curve the current is proportional to $t^{-1/2}$. This dependence of current on time corresponds to a *parabolic growth law*. Furthermore, besides being a function of time, the rate of growth is a peculiar function of potential which has a maximum for values of ϕ between 18 and 40 mv. Because of the difficulty of forming reproducible electrode surfaces, the potential at which the rate is maximum cannot be determined with great precision by the fixed potential method. However, the data indicate that there is a potential at which the parabolic growth rate is maximum. This result is confirmed by data presented below.

Sweeping Potential Data—Cadmium and Silver

The problem of forming reproducible electrode areas is partially eliminated if one uses the sweeping potential method. This method yields $F(\phi)$ vs. ϕ directly, and all the data are recorded using only one area, i.e., that associated with a single electrode.

Figure 7 is a plot of I vs. ϕ obtained using the sweeping potential method and is typical of the behavior of pure cadmium electrodes. There is at least one potential at which the rate of oxidation is maximum ($\phi = 18$ mv), and often the rate has a peak at $\phi \cong 40$ mv. The rate of reduction is a monotonically increasing function of the overpotential. The data also show a trend toward an increased current density at equivalent potentials as the (OH^-) concentration in the electrolyte increases. It is difficult to make a quantitative statement about effects of (OH^-) concentration changes because of the problem of maintaining reproducible surfaces from electrode to electrode.

Additional data were obtained on cadmium electrodes by simply increasing ϕ linearly with time with no subsequent reversal of potential. The data shown in Fig. 8 with $F(\phi)$ normalized also show peaks at $\phi = 18$ and $\phi = 40$ mv. These curves, when compared with the data plotted in Fig. 6, indicate that both methods, i.e., either fixed or sweeping potential, lead to the result that the rate of oxidation of cadmium in alkaline electrolyte is a function of potential and this function has at least one maximum in the range of potential between $\phi = 18$ and 40 mv. Comparison of Fig. 7 and 8 shows that when the electrode is forced to follow a cyclic variation of ϕ the details of the I vs. ϕ curves near the origin are altered, but the position of the maxima in $F(\phi)$ are unaltered.

These are very important new results. They show clearly that the rate of oxidation of the cadmium electrode is a function of the overpotential, that there is a potential at which the rate is maximum, and that the rate is a multivalued function of the overpotential.

Figure 9 shows I vs. ϕ data obtained using the sweeping potential method and electrodes containing 1 atomic % of indium alloyed with cadmium. These electrodes were 1 x 1 cm in dimension and were also mounted in resin with one side exposed to the electrolyte.

The addition of indium to cadmium electrodes causes supression of the 20 mv peak and the appearance of an additional peak between 60 and 70 mv. The 40 mv peak in the anodic quadrant remains, but a peak in the rate of reduction, i.e., in the cathodic quadrant, is introduced. Thus an indium impurity can introduce new peaks in both the rate of oxidation and reduction and can eliminate peaks associated with the pure electrode.

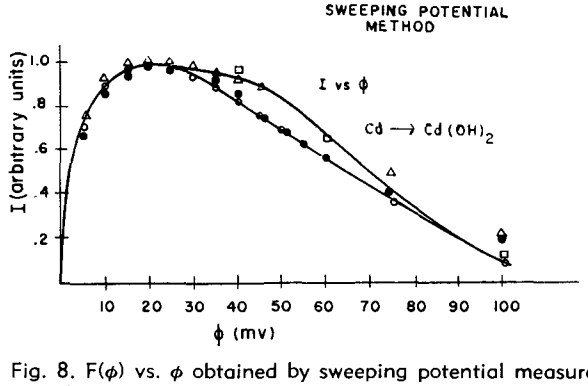

Fig. 8. $F(\phi)$ vs. ϕ obtained by sweeping potential measurements. $F(\phi)$ is normalized to its maximum value. The points represent values obtained in a number of different runs using sweep rates ranging from 4.7 to 22.8 mv/sec.

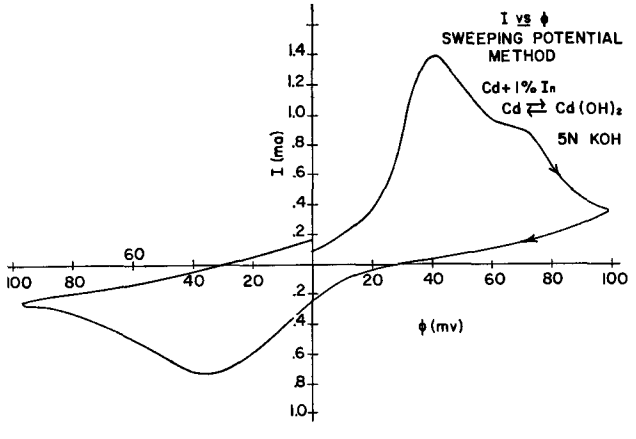

Fig. 9. Rate of oxidation and reduction vs. overpotential for a cadmium electrode containing 1 atomic % indium.

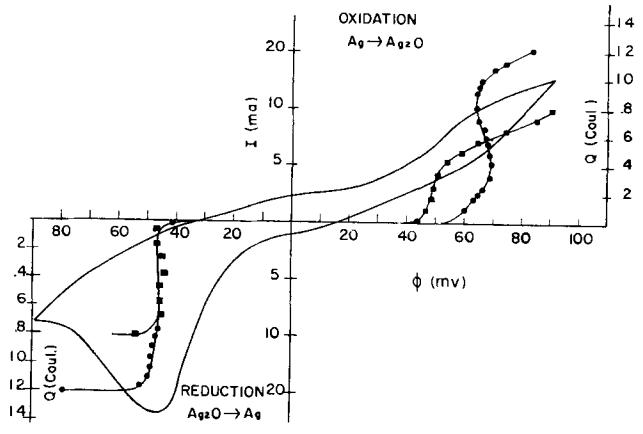

Fig. 10. Comparison of data for silver electrodes using either the overpotentiol, ϕ, or the capacity, Q, os the independent variable. Q in coulombs vs. ϕ is superimposed on the rate vs. ϕ data by plotting both the rate of oxidation and capacity data on the ordinate. —●—● reduced at 2 ma/cm²; —■—■ reduced at 10 ma/cm².

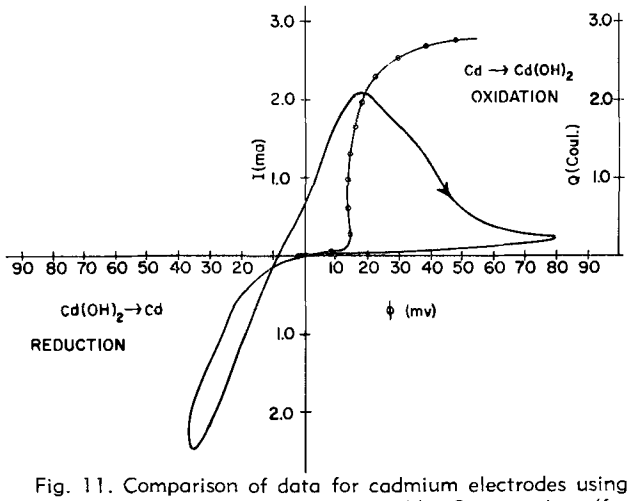

Fig. 11. Comparison of data for cadmium electrodes using either ϕ or Q as the independent variable. Q vs. ϕ data (for oxidation only) is superimposed on the normal I vs. ϕ plot by plotting both I and Q on the ordinate. Constant current oxidation was at 5 ma/cm².

The rate of oxidation and reduction of silver electrodes in KOH electrolyte vs. overpotential was also measured using the sweeping potential technique. The electrodes were plates 1 x 1 cm cast from 99.98% pure silver and mounted in epoxy resin with one polished side exposed to the electrolyte. The studies were made on the reaction,

$$2\,Ag + 2\,OH^- \rightleftarrows Ag_2O + H_2O + 2\,e$$

Figure 10 is a plot of I vs. ϕ data obtained using a silver electrode. (Constant current oxidation data discussed later are superimposed on this plot.) The rate of oxidation is a monotonically increasing function of overpotential, but a strong peak in the rate appears at 46 mv in the reduction quadrant.

Comparison of Overpotential vs. Charge and Current vs. Overpotential Data

The results of constant current oxidation and reduction of a silver electrode are shown in Fig. 10. The overpotential is plotted as a function of the charge Q where $Q = It$. Q is now the independent variable. Superimposed on this plot is the I vs. ϕ curve, where ϕ is the independent variable, which shows that when reduced at constant current the silver electrode overpotential drops to the value corresponding to the maximum in the I vs. ϕ reduction curve. The overpotential remains constant until all of the Ag_2O is reduced to Ag.

A similar plot using cadmium as the electrode is shown in Fig. 11. The constant current anodic overpotential rises to a value which corresponds closely to the potential at the first peak in the I vs. ϕ plots for pure cadmium. The constant current overpotential remains approximately constant at this value over a wide range of Q, but as ϕ exceeds 20 mv, $d\phi/dQ$ increases rapidly with ϕ until the oxidation reaction ceases, and the electrode becomes passive. Thus it appears that there is some fundamental connection between the rate of oxidation as a function of overpotential and the constant current oxidation and reduction characteristics of the electrodes.

The results of the measurements are best summarized in Fig. 10 and 11. It is evident that the rate of oxidation or reduction of Cd and Ag electrodes is a function of ϕ and that it is maximum at particular values of ϕ. There is a connection between the values of ϕ at which the rate of oxidation or reduction is maximum and the overpotential that the electrode seeks under constant current oxidation or reduction conditions. For example, the maximum rate of reduction of Ag_2O to Ag occurs at $\phi = 46.0$ mv and, if this electrode is reduced at constant current, the overpotential drops to 46.0 mv and remains constant until all of the Ag_2O is reduced. Similarly one of the peaks in the rate of oxidation of cadmium occurs around 18 mv which corresponds approximately to the constant current overpotential. As the potential rises above this value the electrode goes rapidly over into the passive state.

The constant current cathodic overpotential of the silver electrode agrees favorably with the value (0.04 v) obtained by Glicksman and Morehouse (2). Comparison of these data is probably legitimate because measurements of overpotential vs. current density on the Ag_2O to Ag system (see Fig. 10) indicate that the overpotential is relatively insensitive to the current density. The value of the constant current overpotential observed by Rozentsveig, *et al.* (3) agrees favorably with our value as does the general shape of the ϕ vs. Q curves.

Discussion of Results and Conclusions

The dependence of rate of oxidation on potential has been measured by two methods and both agree qualitatively. The fixed potential studies of cadmium indicate that if the current is proportional to $t^{-1/2}$ the rate of oxidation is maximum for potentials between $\phi = 18$ and 40 mv. The sweeping potential results show that the rate of oxidation of cadmium is maximum at two values of ϕ, one at approximately 18 mv and the other at 40 mv, and that an impurity in the metal such as indium can influence the potential at which the rate is maximum. Thus the results from each method are in good agreement.

The fixed potential experiments show that after sufficient time has elapsed the rate of oxidation follows a parabolic growth law. A parabolic growth

law is consistent with at least two hypotheses. One is that the necessary electron transfer process in the growth of $Cd(OH)_2$ occurs at the metal-electrolyte interface and that metal ion goes into solution and later precipitates on the metal as $Cd(OH)_2$. The parabolic growth characteristic sets in when the precipitated oxide completely covers the metal except for small pores. The rate is then limited by transport of the Cd^{+2} ion or an equivalent through the pores. As the oxide grows, the Cd^{+2} ion path increases, thus causing a current proportional to $t^{-1/2}$. Muller (4) has advanced a theory of passivity based on this mechanism.

The other hypothesis is that the cadmium ion, or OH^- ion, moves through the oxide and that the electron transfer process occurs at the oxide-electrolyte interface. Using this hypothesis, the parabolic growth law sets in when the exchange currents associated with the metal-oxide and oxide electrolyte boundaries are large compared with the rate of growth so that the rate is limited only by transport through the oxide. As the oxide thickens, the resistance increases and the current required to maintain the imposed potential decreases, thus yielding a parabolic growth law.

The following experimental facts support the latter hypothesis, namely, that the oxide grows by transport of mass and electricity through the oxide and that the solution process is not relevant.

The observations of steps in the $It^{1/2}$ vs. t curve (Fig. 5) are difficult to explain by any other mechanism than local cracking of an adherent solid oxide film which exposes a clean metal surface to the electrolyte for further oxidation. If the solution-precipitation process were relevant, there would be no way of developing strains necessary to cause cracking. Furthermore, if the solution-precipitation process were relevant, the overpotential would be a result of either a gradient in electrostatic potential or gradient in concentration of dissolving species in the pores connecting the metal to the electrolyte. Thus $F(\phi)$ vs. ϕ as determined by the fixed potential method would fit either the expression in Eq. [1] or Eq. [2]. Clearly it fits neither expression, indicating that the solution-precipitation process is not the relevant process in oxidation of cadmium.

We have also noticed that $Cd(OH)_2$ formed by a precipitation process differs in color from that formed by electrochemical oxidation of cadmium. Electrochemically prepared $Cd(OH)_2$ is yellow and we have observed that it is bleached white when exposed to x-rays. Precipitated $Cd(OH)_2$ is white. Again it is difficult to explain (*a*) the difference in color of the two compounds formed (according to the solution precipitation process) the same way, and (*b*) presence of traps in a presumably precipitated compound which are bleached out by x-rays.

One additional fact supporting the solid-state hypothesis is related to the $F(\phi)$ vs. ϕ data. The effects observed using the sweeping potential technique are similar to those observed in oscillographic polarography (6). One then might conclude that the sweeping potential effects are purely polarographic in character. However, it is difficult to reconcile this view with the fact of agreement in the rate of oxidation vs. overpotential data as determined by both the sweeping and fixed potential techniques. If one were observing only a polarographic effect, one would not observe a peak in $F(\phi)$ vs. ϕ using the fixed potential technique. The quantity $F(\phi)$ would be a monotonically increasing function of ϕ with no peaks. Thus the solution hypothesis is not consistent with the facts, and one is forced to the alternate, that of growth controlled by some solid-state mechanism.

Accepting the solid-state hypothesis the data so far not discussed are given the following tentative interpretation.

The 58-mv curve in Fig. 2 shows a continuous transition of the rate of oxidation from a t^{-1} to a $t^{-1/2}$ dependence on the time. The t^{-1} dependence of the rate of electrochemical oxidation corresponds to the logarithmic growth law often observed in air oxidation processes. A logarithmic growth rate is a result of transport of ions through a compound or across an interface, either metal-metal oxide or metal oxide-electrolyte, caused by a large local electric field intensity such that there is no local thermodynamic equilibrium. Thus the 58-mv curve suggests that, for values of ϕ in excess of the overpotential for maximum parabolic growth rate, ions are initially transported either through the hydroxide film or across an interface under nonequilibrium conditions and that, as the film thickens, the internal field is reduced until the ions come to local thermodynamic equilibrium at the interfaces and in the interior of the hydroxide thus yielding a parabolic growth law.

It is of interest to note that the rate-limiting step in the t^{-1} part of the curve could be transferred across either interface. If this is true, additional measurements of rate vs. time in the high overpotential region could lead to a determination of the exchange current at the relevant interface.

Again taking the solid-state view, the new $F(\phi)$ vs. ϕ curve (see Fig. 9) obtained by addition of indium to the cadmium electrode is also given the following tentative interpretation.

It is very probable that some indium becomes incorporated in the cadmium hydroxide lattice causing changes in the type and number of imperfections in the hydroxide. If this is true, the effects caused by indium suggest that the peaks are related to the type of imperfections in the cadmium hydroxide crystal.

If the growth of the hydroxide is via transport of mass and electricity through the hydroxide (as the evidence indicates), the dependence of rate on overpotential must then be related to the transport properties of the hydroxide subject to the boundary conditions imposed by the metal-hydroxide and hydroxide-electrolyte interfaces. Our results indicate that the boundary conditions are related to the electrode overpotential. A more detailed discussion of the implications of this result and an interpretation of the $F(\phi)$ vs. ϕ curves is in preparation and will be published later.

The Stability and Solubility of AgO in Alkaline Solutions

Thedford P. Dirkse and Brandon Wiers

Department of Chemistry, Calvin College, Grand Rapids, Michigan

ABSTRACT

Silver oxide is stable in boiling water and decomposes but very little at room temperature in strongly alkaline solutions. The presence of Ag_2O does not affect this stability, but the presence of unoxidized silver does increase the rate of decomposition. When AgO dissolves in strongly alkaline solutions the dissolved form is primarily AgO and $Ag(OH)_3^-$. The standard free energy of formation of the latter is —85,380 cal/mole.

Silver(II) oxide, AgO, has been known for some time and is now available commercially. Various methods for its preparation have been reported as well as several studies of its properties. Yet, in spite of all this, there is still confusion as to the nature and characteristics of this substance. There is conflicting information on its crystal structure as well as its stability.

The work reported here is the result of a study that has been made of AgO to eliminate some of this confusion and to determine some physical chemical constants.

In general there are two methods for preparing AgO. One of these is the electrolytic oxidation of silver in alkaline solution, or of silver ion in acid solution. However, it is difficult to get a pure product by this method. Our studies of the electrolytic oxidation of silver in alkaline solutions have shown that it is very difficult to oxidize silver completely to AgO. Denison (1) indicates that unoxidized silver is always present. In the preparation of the oxide by oxidation in acid solutions it is difficult to remove the last traces of anion.

The other method of preparation uses chemical oxidizing agents on silver ions. Various oxidizing agents have been suggested, e.g., MnO_4^-, $S_2O_8^{--}$, and ozone, but potassium persulfate in strongly alkaline solutions apparently gives the purest product (2, 3). In our work we used either a product prepared by this method or a commercially available material.

Experimental

Three types of analyses were performed on each batch of material to determine its purity. Samples of AgO were analyzed for oxygen content by heating to drive off oxygen; for silver by the Volhard method; and for oxidizing power by treating with KI and titrating the liberated I_2 with thiosulfate (4). These analyses indicated that the material was always better than 97%, and usually closer to 99% AgO.

In the solubility measurements, the mixtures were quickly filtered through sintered glass filtering crucibles and acidified with HNO_3 to reduce Ag^{++} to Ag^+ (4, 5). The sample was then titrated potentiometrically using a KI reagent and a silver electrode. The reference electrode was a saturated calomel electrode. The same precautions and techniques were used as are described in reference (6).

The KOH solutions were prepared by dilution of a stock solution to which some $Ba(OH)_2$ had been added to remove carbonate.

X-ray diffraction patterns were obtained from a plane surface of the material made by pasting the sample on a platinum screen. A Norelco x-ray unit was used. The radiation was produced by a copper cathode, and a nickel foil served as a filter.

Results

X-ray diffraction patterns.—Schwab and Hartmann (7) prepared AgO by several different methods and, in general, obtained the same x-ray diffraction pattern for each preparation. However, a somewhat different pattern was obtained from a sample prepared by extensive oxidation of silver with ozone, and from an oxide prepared by anodizing silver nitrate between platinum electrodes and then boiling the product in water. These latter patterns were also obtained by others (8) from similarly prepared oxides. This difference in x-ray patterns indicates a

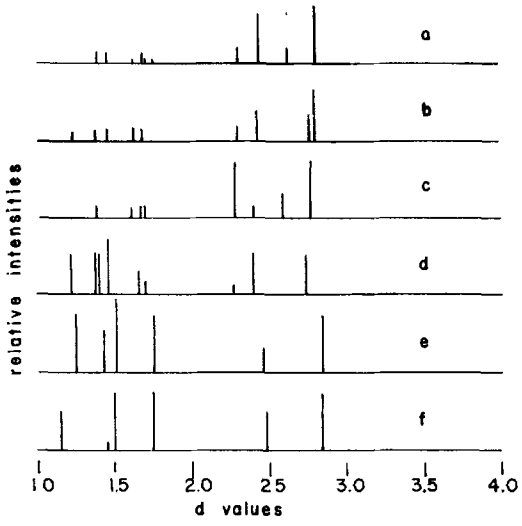

Fig. 1. X-ray diffraction patterns for AgO: (a) commercially available AgO; (b) AgO formed by anodizing Ag in KOH solutions; (c) AgO formed as in (b) but containing excess oxygen, $AgO_{1.17}$; (d) most AgO specimens prepared by Schwab and Hartmann (7); (e) AgO prepared by extensive ozonization of Ag (7); (f) AgO prepared from product obtained by anodizing $AgNO_3$ (7, 8).

difference in structure. Samples prepared by these latter two methods have often been suspected of containing Ag_2O_3 (9). It is possible that some such substance is formed and, being unstable, readily loses oxygen giving, in effect, AgO with somewhat larger lattice parameters.

Much of the work that has been reported on AgO has been based on a study of samples prepared by anodizing silver nitrate. Since such a sample has a different x-ray pattern than the AgO prepared by other methods, it is possible that its properties are also different. The oxides used in our work gave x-ray patterns similar to those of most of the preparations studied by Schwab and Hartmann. This pattern is also obtained from the AgO prepared by the electrolytic oxidation of silver in KOH solutions, Fig. 1. The relative intensities of these lines are not necessarily comparable since some of these patterns were obtained from powders and others from a plane surface.

Stability in aqueous solutions.—Since AgO is a strong oxidizing agent, it is possible that it may be unstable in water. However, reaction [1] is not

$$4AgO + 2H_2O \rightarrow 4Ag^+ + 4OH^- + O_2 \qquad [1]$$

thermodynamically spontaneous. Jirsa, *et al.* (4) studied this by placing AgO in boiling water and observed that the extent of decomposition of AgO increased with the amount of water used. Their explanation was that the decomposition continued until the water was saturated with AgOH. However, it is possible that the AgOH could precipitate as Ag_2O, and thus the decomposition of AgO by water would continue. The extent of decomposition would then depend on the time of boiling rather than the amount of water used.

In our attempt to test this, samples of AgO were placed for 1.5 hr in varying amounts of boiling water. The purity of the samples was determined iodometrically (4). There was no decomposition of AgO with such treatment (see Table I). In fact, the boiling water appears to purify the samples somewhat. It should be noted here that the oxide used by Jirsa and co-workers was prepared from the material produced by the anodization of a $AgNO_3$ solution.

In another test, samples of AgO were placed for 1.5 hr in boiling solutions of $AgNO_3$. Here there was a marked effect on the AgO, Table II. This likely was due to the hydronium ion. The *p*H of the 2.0*N* $AgNO_3$ was 3.5. AgO does decompose in acid solutions (4, 5). The ΔF°_{298} for reaction [2] is

$$4AgO + 4H^+ \rightarrow 4Ag^+ + O_2 + 2H_2O \qquad [2]$$

about −54 kcal.

It is of interest to note whether this stability of AgO changes at still higher *p*H values. Portions of AgO were allowed to stand in KOH solutions at room temperature. Samples were taken at various time intervals to determine the extent of decomposition. Results are given in Table III. It is obvious that a very slight, but definite, deterioration takes place.

To test this stability further, samples of AgO were prepared by treating silver anodically in KOH solutions. After treatment these specimens were soaked in distilled water to remove KOH, dried in a stream of purified nitrogen, and then placed in a desiccator for at least a day. The weight gained in this process was assumed to be due to oxygen. One of these specimens was anodized for several weeks in order to get complete conversion to AgO. This was verified by x-ray diffraction pattern and by analysis. The other sample was anodized for a few days and, while the surface was converted to AgO, not all the Ag was

oxidized to AgO. The total composition could be represented by $AgO_{0.38}$. Both samples were kept in the dark in 30% KOH solutions for 4 months at room temperature. At the end of this time the pure sample had lost 2% of its weight. The amount that could have dissolved would have been only about 0.06% of the original weight. The x-ray diffraction pattern of the surface showed only lines of AgO. Hence any appreciable amount of Ag_2O that formed did not remain on the surface of the electrode. Some may have been shed by the electrode. There was a small amount of dark colored material at the bottom of the test tube when the sample was finally examined.

At the end of the 4 months the $AgO_{0.38}$ had lost only about 0.3% by weight, but this represented all the AgO there was on that electrode since the x-ray diffraction patterns showed that the surface had been completely converted to Ag_2O. Measurement of the potential of this electrode vs. a zinc electrode showed the presence of AgO at the end of 2 months.

These results indicate that pure AgO does decompose slightly even in the more concentrated KOH solutions. This decomposition may be due to the presence of local cell action, with a potential of about 200 mv.

$$2\,OH^- \rightarrow H_2O + \tfrac{1}{2}\,O_2 + 2e \qquad E^\circ = -0.4 \text{ v}$$

$$2AgO + H_2O + 2e \rightarrow Ag_2O + 2\,OH^- \qquad E^\circ = +0.6 \text{ v}$$

This decomposition of AgO would be hastened by the presence of impurities such as Ag. However, at room temperature even this process takes place slowly, as indicated by the very slight decomposition of the $AgO_{0.38}$ preparation over a period of time.

It is possible that Ag_2O may decompose AgO catalytically, but there was no evidence for this even in boiling solutions of KOH, Fig. 2.

Solubility in KOH solutions.—The solubility of AgO in KOH solutions was measured at 25°C. The samples were allowed to equilibrate for at least 2 days although later work showed that equilibrium was reached in a few hours. Some of the results are given on Fig. 3. The solubility is a function of the OH^- ion concentration. This indicates that the AgO dissolves by reacting with the OH^- ions. So far as

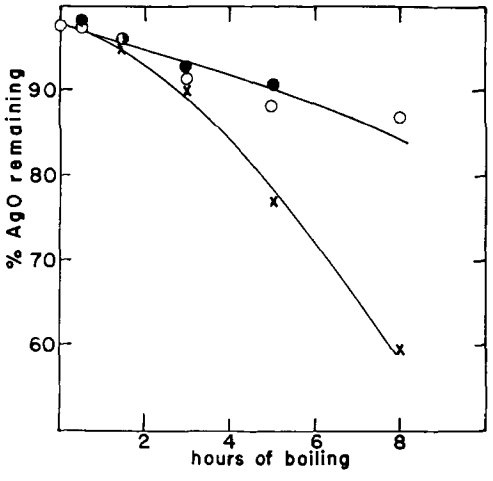

Fig. 2. Effect of boiling solutions of KOH on AgO: O, 7.5% KOH; •, 7.3% KOH saturated with Ag_2O; x, 14.1% KOH.

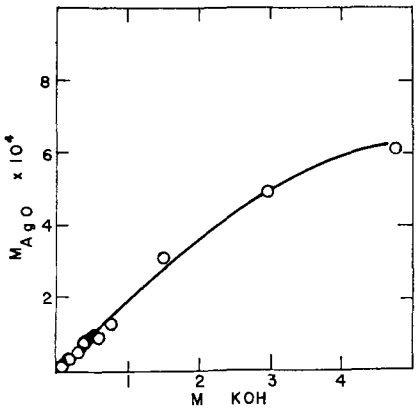

Fig. 3. Solubility of AgO in KOH solutions at 25°C

comparison can be made, these values are the same as those for Ag_2O (6). This is striking because ordinarily the higher valence oxide is more acidic.

Results obtained in more dilute solutions were treated to determine equilibrium constants for the formation of certain ions (10). Assume the following equilibria in solution.

$$AgO + H_2O \rightleftharpoons Ag(OH)_2 \qquad [3]$$

$$AgO + OH^- + H_2O \rightleftharpoons Ag(OH)_3^- \qquad [4]$$

$$AgO + 2\,OH^- + H_2O \rightleftharpoons Ag(OH)_4^{--} \qquad [5]$$

The total solubility, S, then can be expressed as

$$S = M_{AgO} + M_{Ag(OH)_3^-} + M_{Ag(OH)_4^{--}} \qquad [6]$$

or

$$S = M_{AgO} + K_2 M_{OH^-} + K_3 (M_{OH^-})^2/[y \pm (1-1)]^2 \qquad [7]$$

where K_2 is the equilibrium constant for reaction [4] and K_3 for reaction [5], the activities of AgO and H_2O being taken as unity. If now a plot of S vs. M_{OH^-} is made, it is evident from equation [7] that the extrapolated value is M_{AgO} or $M_{Ag(OH)_2}$. Such a plot is shown on Fig. 4. The extrapolated value is 0.27 x 10^{-5}M.

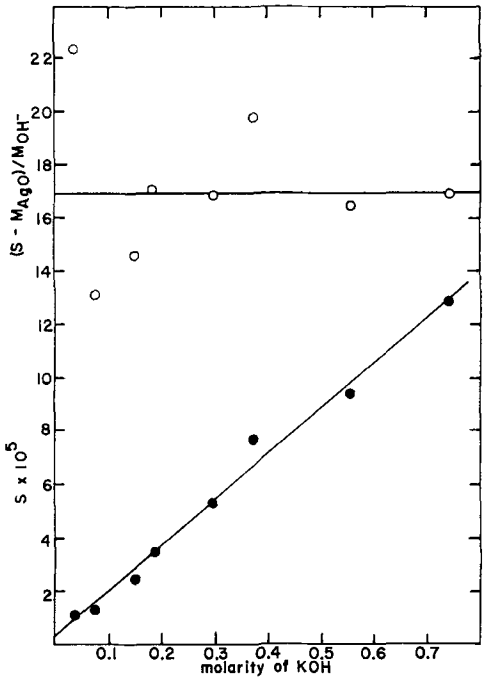

Fig. 4. Plot to determine value of M_{AgO} and K_2

Rearranging equation [7]

$$(S - M_{AgO})/M_{OH^-} = K_2 + K_3 M_{OH^-}/[y \pm (1-1)]^2 \quad [8]$$

Plotting the left hand member vs. M_{OH^-} and extrapolating now gives the value of K_2. This is shown on the upper portion of Fig. 4. The value for K_2 is 17 x 10^{-5}. Since this plot is parallel to the base line, the value of K_3 is zero. Consequently, the dissolved form consists of AgO or $Ag(OH)_2$ and $Ag(OH)_3^-$. Using the same technique the concentration of $AgOH^+$ is shown to be negligible.

$$AgO + H_2O \rightleftarrows AgOH^+ + OH^- \quad [9]$$

A similar treatment of the data of Johnston, *et al.* (6) shows the dissolved form of Ag_2O in alkaline solutions to be Ag_2O or AgOH and $Ag(OH)_2^-$. The value of the equilibrium constant for the formation of the latter is 3.6 x 10^{-3}. Thus, although the total solubility of Ag_2O and AgO in alkaline solutions is practically the same, the concentration of $Ag(OH)_3^-$ is greater than that of $Ag(OH)_2^-$.

Since K_{298} for reaction [4] is 1.7 x 10^{-4} the value of ΔF°_{298} for this reaction is +5150 cal. Using accepted values for the free energy of formation of H_2O and OH^-, and +3615 cal/mole for AgO (11), ΔF°_{298} for $Ag(OH)_3^-$ is −85,380 cal/mole. Likewise, ΔF°_{298} for $Ag(OH)_2^-$ is −57,065 cal/mole.

The rate of solution of AgO in KOH solutions was also studied. This was done by stirring the KOH solutions with solid AgO and analyzing samples of the solution for dissolved AgO. This solubility passes through a rather sharp peak, Fig. 5. This has been observed by others also (12). A similar phenomenon has been noted in perchloric acid (13). It was suggested that this could be due to a solid phase transition. This is a possibility, although x-ray diffraction measurements gave no difference in patterns. Nor is this phenomenon due to a decomposition of AgO. The residue left after allowing AgO to stand in contact with the KOH solutions for several days was analyzed iodometrically, and there was no evidence of decomposition. The residue showed as much oxidizing ability after standing as before. If this peak were due to a reaction such as [10] then the

$$4Ag(OH)_3^- \rightarrow 2Ag_2O + O_2 + 4OH^- + 4H_2O \quad [10]$$

residue would gradually change from AgO to Ag_2O. This reaction is thermodynamically possible, but neither weight measurements, analysis, nor x-ray diffraction patterns indicate that this or similar reactions take place unless, e.g., metallic silver is present. If this peak is due to a phase transition, e.g.,

$$AgO\ (A) + H_2O + OH^- \rightarrow Ag(OH)_3^- \quad [11]$$

$$Ag(OH)_3^- \rightarrow AgO(B) + H_2O + OH^- \quad [12]$$

it is a rapid transition and one not detected by our x-ray diffraction measurements. Furthermore, this peak was observed with samples of AgO obtained by treating $AgNO_3$ with $K_2S_2O_8$ in a strongly alkaline solution, so it is unlikely that further contact with alkaline solutions would cause such a phase change.

It is possible that this peak in the solubility curve is due merely to a time lag necessary for a reaction such as [12] to take place and thus some time is necessary before solubility equilibrium is truly established.

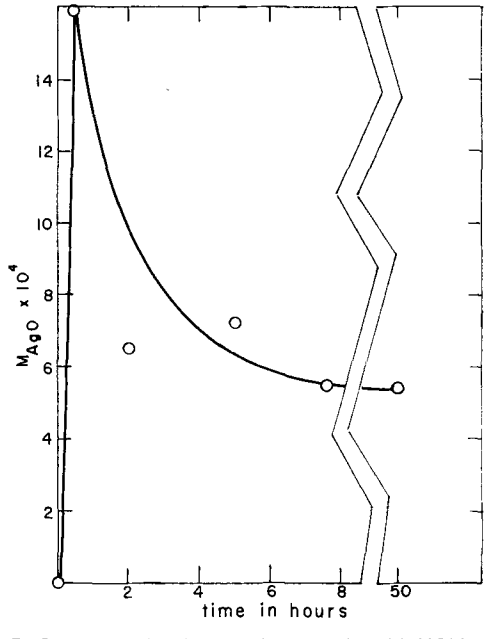

Fig. 5. Rate of solubility of AgO in 4.75M KOH at room temperature.

Acknowledgment

The authors wish to express thanks to the Office of Naval Research for a grant under which this work was undertaken, and to Merck and Company for supplying samples of AgO.

Manuscript received Oct. 8, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Investigation of the Electrochemical Characteristics of Organic Compounds

III. Nitroalkanes

R. Glicksman and C. K. Morehouse

RCA Laboratories, Radio Corporation of America, Princeton, New Jersey

ABSTRACT

A theory based on the electron density in the vicinity of a reducible nitro group which had been used to explain the effect of substituent groups and their position on the operating potential of aromatic nitro compounds has been extended to the nitroalkane compounds. The high theoretical ampere-minute capacity of the nitroalkane compounds, along with their high operating potentials, show these compounds to have considerable promise for use as cathode materials in primary cells.

Previous studies (1-3) of the electrochemical characteristics of organic N-halogen, aromatic C-nitroso, and aromatic nitro compounds have suggested the use of these materials as cathodes in primary cells because of their high theoretical ampere-minute capacities and practical operating potentials.

The performance characteristics of dry cells containing aromatic nitro and C-nitroso compounds as cathodes coupled with a magnesium anode and a magnesium bromide electrolyte have been described in previous papers (4, 5). These cells have many performance characteristics superior to those of existing commercial dry cells.

On the basis of these studies, the most promising class of organic cathode materials appears to be the aromatic nitro compounds because of their high theoretical ampere-minute capacity, both on a weight and volume basis. Since the aromatic nitro compounds represent only one class of a large number of organic compounds, extensive studies were made of the electrochemical characteristics of other organic nitro compounds. This paper deals with the work on the nitroalkanes.

Apparatus and Technique

Because of the irreversible nature of the electrode reaction and polarization effects encountered during current flow, the electrochemical characteristics of many inorganic and organic compounds often cannot be predicted by thermodynamic calculations and a knowledge of their physical and chemical properties. A technique, previously described by the authors (6), has been used to measure the operating potential during current flow and the coulombic capacity of various nitroalkane compounds. This technique consists in discharging at a constant current, in a large volume of electrolyte, a 0.5-g [1] sample of the nitroalkane cathode material mixed with 0.05 g of Shawinigan acetylene black. The change in cathode potential with time was measured with a L&N Type K potentiometer using a saturated calomel reference electrode. The measured potentials were corrected for the *IR* drop associated with the apparatus and electrolyte by means of an oscillographic technique (7).

All half-cell potential data reported in this paper are referred to the normal hydrogen scale and include a liquid junction potential, which in most cases is small and can be neglected.

For most of the measurements an aqueous magnesium bromide electrolyte and a magnesium anode were used, while, in studying the effect of pH on potential, a zinc anode was employed with the acidic NH_4Cl-$ZnCl_2$-H_2O and basic NaOH-H_2O electrolytes.

Effect of Substituted Groups on the Electrode Potential of Nitroalkanes

Experimental Results

Presented in Fig. 1 are half-cell discharge curves for nitrobenzene and some low-molecular-weight nitroalkane compounds, discharged at a rate of 0.030 amp/ml of cathode material in a 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte. It is seen that these simple primary nitroalkane compounds operate at lower potentials than nitrobenzene under these conditions of discharge. The latter finding is in general agreement

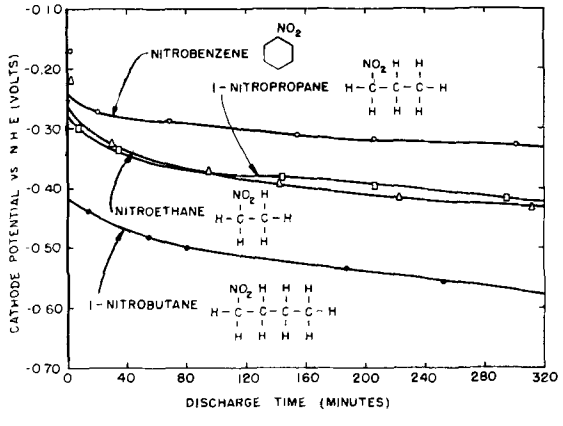

Fig. 1. Cathode potential of various nitroalkane compounds discharged in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte at a rate of 0.030 amp/ml.

[1] Liquid compounds were tested by mixing 0.5 ml of the compound with Shawinigan acetylene black, discharging the resultant mix at the required rate, and making half-cell potential measurements in the usual manner.

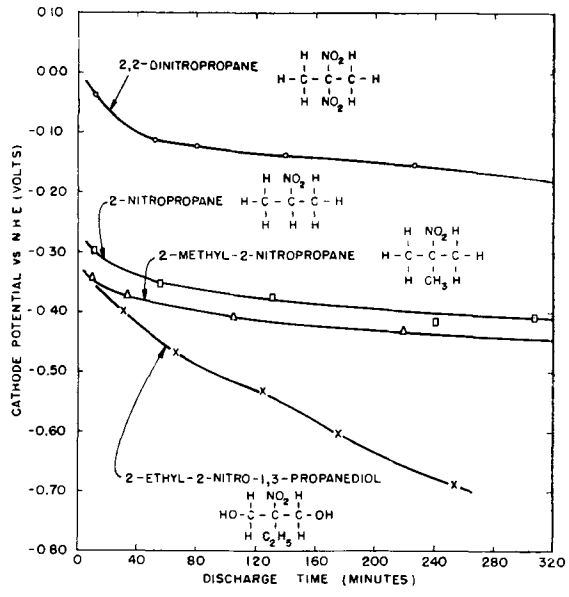

Fig. 2. Effect of substituted groups on the cathode potential of 2-nitropropane discharged in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte at a rate of 0.030 amp/ml and 0.030 amp/g.

with polarographic data (8) obtained from these compounds over a wide range of *p*H values.

To test the effect of substituted groups on the electrode potential of the nitroalkane compounds, some 2-substituted 2-nitropropane derivatives were discharged in the $MgBr_2$ electrolyte. From the data presented in Fig. 2, it is seen that those compounds having electron-repelling groups such as $-CH_3$, and $-C_2H_5$, substituted in the 2-position of 2-nitropropane operate at lower potentials than the parent compound, while a compound such as 2, 2-dinitropropane, with a strongly electron attracting $-NO_2$ group in the 2-position, operates at a potential 0.25 v higher than 2-nitropropane.

In Fig. 3 are presented discharge data for a series of chloronitropropane isomers discharged at a rate of 0.030 amp/ml in the 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte. As with the nitroaromatic compounds (2), the position as well as the type of substituted group

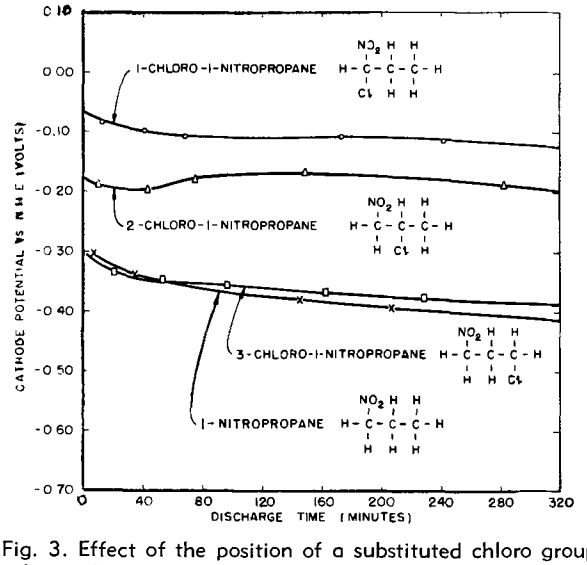

Fig. 3. Effect of the position of a substituted chloro group on the cathode potential of 1-nitropropane discharged in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte at a rate of 0.030 amp/ml.

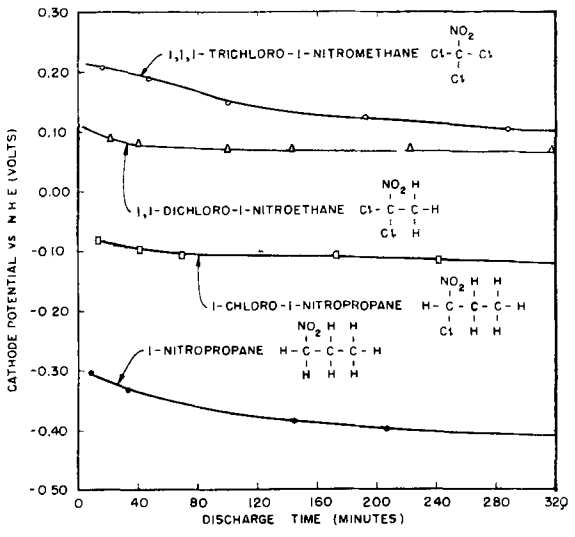

Fig. 4. Effect of the oddition of successive chloro groups to a nitro-carbon atom of a nitroalkane compound discharged in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte at a rate of 0.030 amp/ml.

appears to have a pronounced effect on the operating potential of nitroalkane compounds as evidenced by the progressively higher potentials obtained when the electron attracting —Cl group is successively substituted in the 3-, 2-, and 1-position of 1-nitropropane. The effect of the —Cl group in raising the potential of 1-nitropropane is seen to be appreciable only for the 1- and 2-positions, having very little effect when substituted in the 3-position.

The addition of a second and third —Cl group to a primary nitro carbon atom raises the operating potential of a nitroalkane compound still higher, as evidenced by the discharge curves in Fig. 4 for the various mono-, di-, and tri-chloronitroalkane compounds. It is interesting to note that, although the potential increases with each succeeding chloro addition, the potential increases at a decreasing rate, the increase being approximately 0.25-0.30 v for the

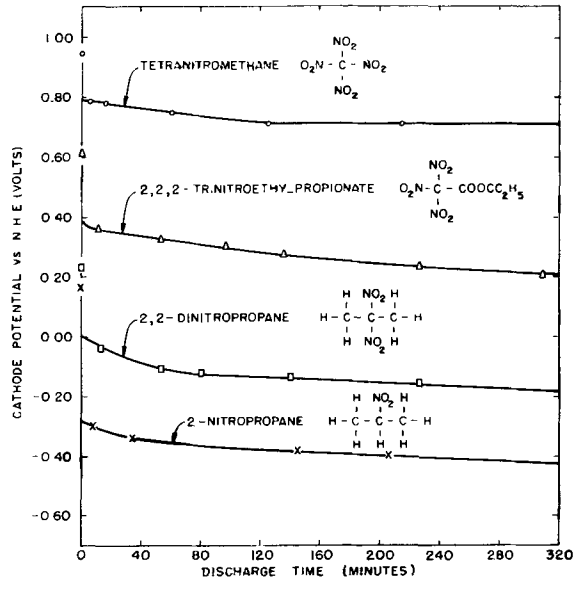

Fig. 5. Effect of the addition of successive nitro groups to a nitro-carbon atom of a nitroalkane compound discharged in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte at a rate of 0.030 amp/ml.

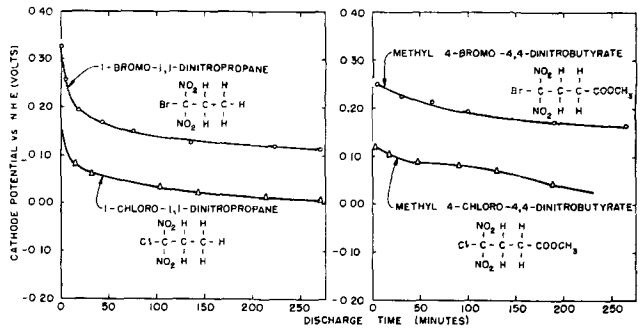

Fig. 6. Cathode potential of various bromo and chlorodinitroalkane compounds dischorged in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte at a rate of 0.030 amp/ml.

addition of the first —Cl group, 0.18-0.20 v for the second, and 0.03-0.12 v for the addition of a third chloro group to a dichloronitro compound.[2]

The effect on potential of adding successive $-NO_2$ groups to a nitro carbon atom is shown in Fig. 5 where it is seen that the potential of the various nitroalkane compounds increases with each succeeding addition of a $-NO_2$ group. The increase in potential due to this strongly electron attracting group is greater than that found for the —Cl group, as evidenced by the considerably higher cathode potential of tetranitromethane compared to that of trichloronitromethane.

In Fig. 6 are presented discharge data for two pairs of bromo- and chlorodinitroalkane compounds, discharged at a rate of 0.030 amp/ml in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte. Under these conditions of discharge the bromodinitroalkane compounds operate at potentials 0.1 v higher than those of the corresponding chlorodinitroalkane compounds.

Discussion

The cathode potential of aromatic nitro compounds has been shown to be dependent on the type and position of the substituent group or groups on the ring (2). This has been explained on the basis of the electron distribution in the molecule. For example, in substituted nitrobenzenes, the introduction on the ring of electron-attracting groups, such as —CHO, —CN, and —Cl, decreases the electron density in the vicinity of the nitro group, thus increasing its affinity for electrons and facilitating its reduction. Conversely, electron-repelling groups such as $-CH_3$, —OH, and $-NH_2$ increase the electron density around the nitro group, thus decreasing its affinity for electrons, resulting in compounds which are more difficultly reduced, i.e., with compounds having a lower cathodic discharge potential than the parent nitrobenzene.

The data presented in Figs. 2-5 also can be explained on the basis of the same theory. For example, it is seen from Fig. 2 that the effect of substituted electron attracting and electron-repelling groups on the potential of a nitroalkane compound during current flow is similar to that found for the nitrobenzene compounds. Further, the increase in potential due to the addition of a $-NO_2$ group to the nitro-carbon atom of a nitroalkane is greater than that found for the addition of a $-NO_2$ group to the para, meta, or ortho position of nitrobenzene. This is attributed to the fact that, for the nitroalkane compound, the substituted $-NO_2$ group is directly on the carbon atom containing the reducible nitro group, while for nitrobenzene such a grouping is impossible, and the effect of a nitro group must be transmitted through the ring carbon atoms.

By the same reasoning, one would expect the effect of an electron-attracting chloro group on the potential of a nitroalkane compound to diminish rapidly as saturated hydrocarbon groups are interposed between it and the $-NO_2$ group. The discharge curves in Fig. 3 for a series of chloro-nitropropane isomers bear out this reasoning. This same effect is operative for a wide variety of other organic reactions (9, 10).

Similarly, the cathode potential of a nitroalkane compound can be increased by the addition of successive electron-attracting groups to the nitro-carbon atom. The effect of each substituted group is to lower the electron density in the vicinity of the reducible nitro group, thus increasing its affinity for electrons and facilitating its reduction. This type of behavior is illustrated by the discharge curves presented in Fig. 4 and 5 for the various mono-, di-, and tri-chloronitro, and the mono-, di-, tri-, and tetranitroalkane compounds.

It has been shown previously that substituted chloro groups raise the cathode potential of nitroalkane compounds. This is in accord with theory. However, contrary to theory, the data in Fig. 6 show that bromo substituted compounds operate at higher potentials under current drain than their corresponding chloro compounds. The reason for this is not known.

As with the aromatic nitro compounds, it is recognized that the reduction of nitroalkane compounds involves the acceptance of hydrogen ions as well as electrons, and either or both might be involved in the rate-determining step. However, the data presented in Fig. 2-5, can be explained readily on the basis of a rate-determining electron transfer step.

Coulombic Capacities and Operating Potentials of Solid Nitroalkane Compounds

Tabulated in Table I are theoretical capacity and electrode efficiency data for some nitroalkane compounds compared with a few aromatic nitro compounds and two of the cathode materials now used in commercial dry cells. The theoretical capacities of the nitro compounds were computed by means of Faraday's Law, with the assumption that each nitro group is reduced to the amino stage, with a corresponding 6-electron change.

It is seen that the listed nitroalkane compounds have theoretical ampere-minute capacities per unit of weight approximately 2 to 10 times those of manganese dioxide and mercuric oxide. The capacities of some of these nitroalkane compounds are comparable to those of the aromatic nitro compounds. As with the aromatic nitro compounds, the low densities of the nitroalkane compounds result in a greatly reduced theoretical capacity advantage over the in-

[2] In making this comparison, it is assumed that the operating potentials of comparable chloronitroalkane derivatives, such as 1, 1-dichloro-1-nitroethane and 1, 1-dichloro-1-nitropropane, are approximately the same.

† Efficiency calculation based on an 85% MnO_2 content.

organic compounds, when these cathode materials are rated on a volume basis (2).

The most attractive of these cathode materials is tetranitromethane, which has a theoretical ampere-minute per gram capacity comparable to that of oxygen, and which, when coupled with a magnesium anode in a magnesium bromide electrolyte, results in a galvanic cell which operates at 2.0-2.1 v for the first reduction step.

Despite the attractive electrochemical properties of tetranitromethane and other nitroalkane compounds, many of these compounds are liquids or are unstable, and for that reason their use in primary cells would be limited. However, these liquid oxidizing agents have potential use as cathodes in continuous-feed cell systems and deserve serious consideration for this application.

There are, however, a number of solid nitroalkane compounds available which, because of their high theoretical ampere-minute capacities and operating potentials, show considerable promise for use as cathodes in primary cells. Coulometric studies of some of these compounds in a magnesium bromide electrolyte are presented in Fig. 7-10, while the electrode efficiencies[3] of a few of these are given in Table I. The results were obtained by discharging a 0.5-g sample of the compounds at a constant current drain of 0.005 amp/g, and measuring the change in half-cell potential with time by the same technique as previously described.

[3] Electrode efficiencies calculated on the basis of a −0.40 v end voltage.

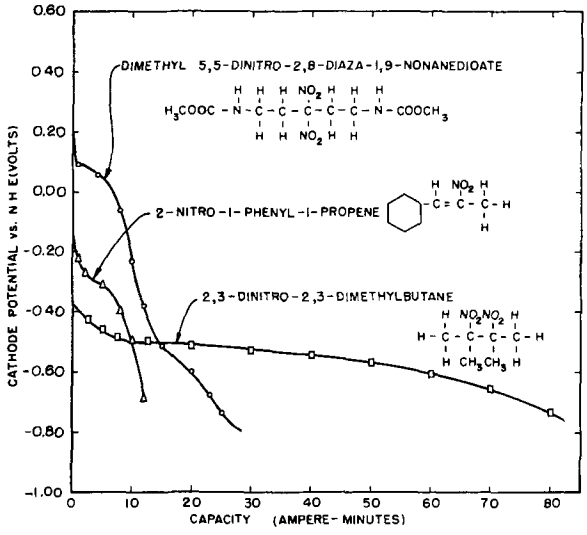

Fig. 7. Half-cell potential studies of various nitro and dinitroalkane compounds discharged in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte at a rate of 0.005 amp/g.

Nitro and Dinitroalkane Compounds

The data presented in Fig. 7 illustrate the fact that an electron-attracting group must be attached to the carbon atom containing the reducible nitro group in order to get useful potentials from nitroalkane compounds. For the compound dimethyl 5,5-dinitro -2,8-diaza -1,9-nonanedioate such a grouping is available, and the reduction of the nitro group takes place at a half-cell potential of 0.00 to +0.10 v.

The low operating potential of the "vic"-2,3-dinitro-2,3-dimethylbutane compound as compared to that of the "gem"[4]-dinitro compound is attributed to the diminished effect of the $-NO_2$ groups on each other as saturated carbon groups are interposed between them, while the higher operating potential of 2-nitro-1-phenyl-1-propene as compared to other mononitroalkane compounds is believed to be due to the effect of the unsaturated double bond in lowering the electron density in the vicinity of the reducible $-NO_2$ group.

Despite their practical operating potentials, the gem-dinitro and 2-nitro-1-phenyl-1-propene compounds have poor electrode efficiencies, as measured under these conditions of evaluation.

[4] The prefix "gem" denotes attachment of both nitro groups to the same carbon atom, while "vic" denotes attachment to adjoining carbon atoms.

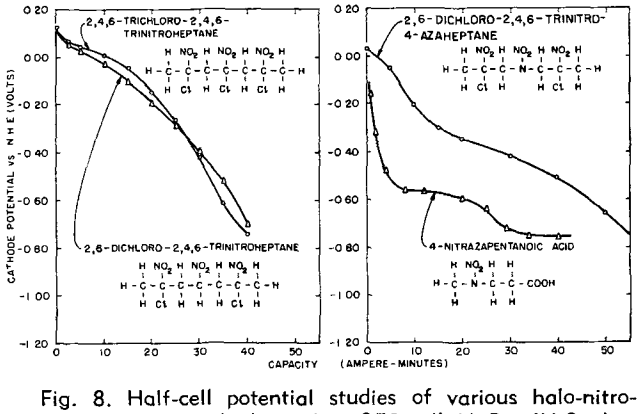

Fig. 8. Half-cell potential studies of various halo-nitroalkane compounds discharged in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte at a rate of 0.005 amp/g.

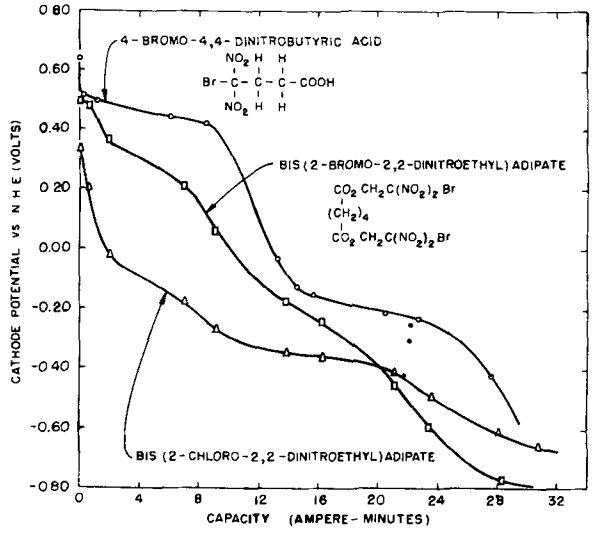

Fig. 9. Half-cell potential studies of various halo-dinitroalkane compounds discharged in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte at a rate of 0.005 amp/g.

Halo-Nitroalkane Compounds

The high operating potential of 1-chloro-1-nitropropane (Fig. 3) prompted a search for structurally similar solid chloronitroalkane compounds, which in addition contain a high percentage by weight of the $-NO_2$ group. Presented in Fig. 8, are data obtained on a number of such compounds, which were discharged at a rate of 0.005 amp/g in a $MgBr_2$ electrolyte. It is seen that both 2,6-dichloro-, and 2,4,6-trichloro-2,4,6-trinitroheptane operate at potentials close to that of 1-chloro-1-nitropropane and give capacities of 30 amp-min/g to a −0.40 v cut off, these capacities being approximately twice the theoretical limit of the inorganic cathode materials. Although these compounds operate at slightly higher potentials than aromatic dinitro compounds such as m-dinitrobenzene, the high electrode efficiency of the latter compound (77%) makes it a more attractive cathode material than a compound such as 2,4,6-trichloro-2,4,6-trinitroheptane which operates at an efficiency of 32% and gives one-third the capacity of the aromatic dinitro compound in a $MgBr_2$ electrolyte.

Also included in Fig. 8 are discharge data for two compounds containing a N-NO_2 grouping. From a comparison of the discharge curves of 2,6-dichloro-2,4,6-trinitroheptane with 2,6-dichloro-2,4,6-trinitro-4-azaheptane, and 4-nitrazapentanoic acid with those of the primary nitroalkane compounds (Fig. 1), it would appear that those compounds containing a N-NO_2 grouping operate at lower potentials than comparable compounds containing a C-NO_2 grouping. A similar type of relationship has been found for the operating potential of C-nitroso and N-nitroso compounds (3).

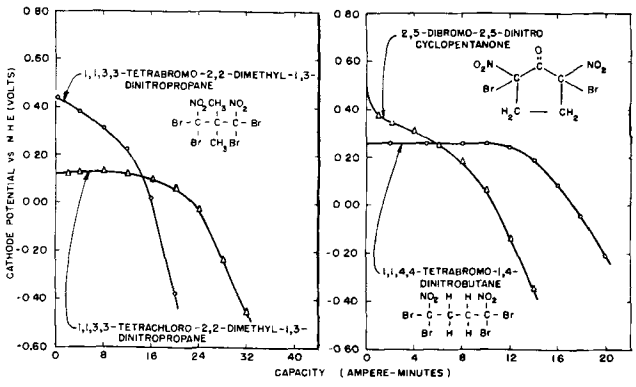

Fig. 10. Half-cell potential studies of various dihalonitroalkane compounds discharged in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte at a rate of 0.005 amp/g.

Halo-Dinitro and Dihalo-Nitroalkane Compounds

It has been shown previously that liquid nitroalkane compounds containing halo-dinitro and dihalonitro groups would operate at higher potentials than the halo-nitroalkane compounds which have just been considered. A number of solid nitroalkane compounds containing these groupings were evaluated as cathodes in a $MgBr_2$ electrolyte, and the results are presented in Fig. 9 and 10.

The halo-dinitroalkane compounds exhibit a two-step discharge curve, probably due to the reduction of one nitro group at a time. The most attractive of these compounds, 4-bromo-4,4-dinitrobutyric acid, operates at a half-cell potential of +0.4 to +0.5 v for the first reduction step and between −0.1 and −0.2 v for the second step. The large difference in potential between the two stages of discharge is undesirable for many primary cell applications, and this together with their poor electrode efficiencies (36% for 4-bromo-4,4-dinitrobutyric acid) would limit the use of these halo-dinitroalkane materials as cathodes in primary cells at the present state of development.

The dihalo-nitroalkane derivatives, whose discharge curves are shown in Fig. 10, comprise another promising class of solid nitroalkane compounds. These compounds, which exhibit relatively flat voltage discharge curves, also operate at higher potentials than their corresponding halo-nitroalkane compounds.

The discharge curves of 1,1,3,3-tetrabromo- and 1,1,3,3-tetrachloro-2,2-dimethyl-1,3-dinitropropane further emphasize the fact that bromo-nitro compounds operate at higher potentials than their corresponding chloro-nitro compounds. Another interesting discharge curve is that of 2,5-dibromo-2,5-dinitrocylopentanone, because of the relatively high operating potential of this monobromo-nitro compound as compared to the dibromo-nitro compounds. The high potential of this compound is believed due to the effect of the electron attracting keto group in raising the potential of the adjacent Br-C-NO_2 groups.

Although the electrode efficiencies of the dihalonitro compounds are low (48-52%) compared to those of the aromatic nitro compounds (70-90%), they represent the best efficiencies which have been attained from any of the solid nitroalkane compounds. The poor electrode efficiencies of the nitroalkanes can be attributed either to the relative difficulty in completely reducing a nitroalkane to its corresponding amine, or to the fact that, under present conditions of discharge, the electrolytic reduction of the nitroalkane compound does not take place to the amine but to some intermediate stage. On the

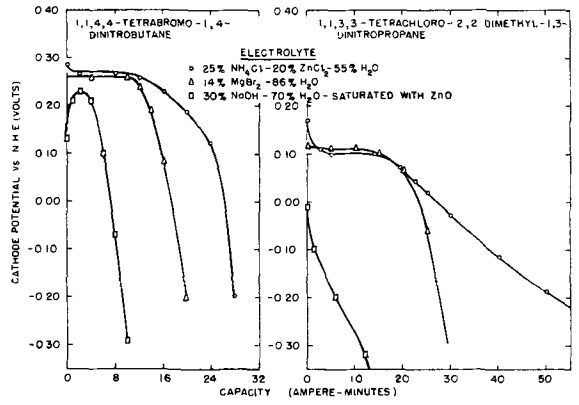

Fig. 11. Half-cell potential studies of 1,1,4,4-tetrabromo-1,4-dinitrobutane and 1,1,3,3-tetrachloro-2,2-dimethyl-1,3-dinitropropane discharged in various electrolytes at a rate of 0.005 amp/g.

basis of the above study, no satisfactory statement can be made about either possibility, and additional study of the reaction mechanism is needed in order to resolve this problem.

A review of the literature revealed that the reduction of mononitroalkanes to primary amines may be effected with a wide variety of reducing agents under various conditions (11-13). Strong reducing conditions yield amines. Hydrogen and a catalyst (Pt, Pd) are most frequently used, but good yields of amine have been reported from reductions by metals and acids, as well as by electrolytic methods. Mild reduction of primary and secondary nitroalkanes with zinc and acetic acid yields aldoximes and ketoximes, respectively, while still milder reducing conditions such as zinc in water or aqueous NH_4Cl yields the N-alkylhydroxylamine.

Additional coulometric studies of 1,1,4,4-tetrabromo-1,4-dinitrobutane and 1,1,3,3-tetrachloro-2,2-dimethyl-1,3-dinitropropane in electrolytes of different *p*H are presented in Fig. 11. It is seen that the cathode capacities of these compounds increase with decreasing *p*H of the electrolyte, especially when taken to a low end potential. However, the capacities obtained in the acidic NH_4Cl-$ZnCl_2$ electrolyte are still considerably less than the theoretical capacities of these compounds when calculated on the basis of a 6-electron change per $-NO_2$ group.

The poor capacities obtained from the nitroalkane compounds in the strongly basic NaOH electrolyte is

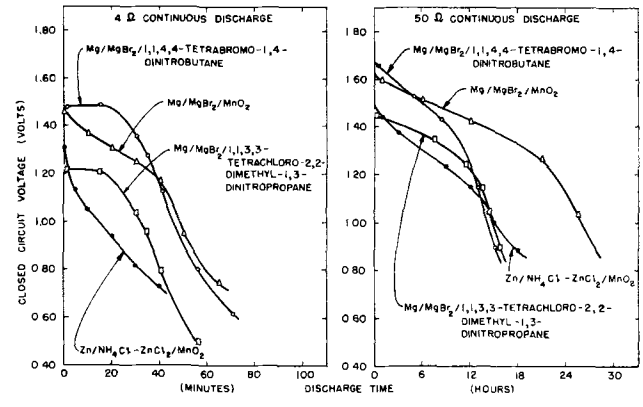

Fig. 12. AA-size dry cells discharged continuously through 4 and 50-ohm resistances at 70° ± 2°F (50% RH).

similar to that encountered for the aromatic dinitro compounds and could be attributed to the presence of side products which are formed by the condensation of the primary reduction products. In addition, nitroalkanes in the presence of alkaline reagents may undergo oxidation-reduction and extensive decomposition reactions, with a concommitant loss in cathode capacity.

It is interesting to note that the effect of *p*H on the operating potential of these nitroalkane compounds is very small, a relationship quite different than that found for the aromatic dinitro compounds (2). This type of behavior agrees with that found from polarographic studies, which show that the half-wave potentials of the nitroalkanes change only slightly with *p*H, while those of the nitroaromatics show a considerable variation with *p*H (8).

Experimental Dry Cell Data

Experimental dry cells containing 1,1,3,3-tetrachloro-2,2-dimethyl-1,3-dinitropropane and 1,1,4,4-tetrabromo-1,4-dinitrobutane cathodes were assembled in the usual manner (4) using an impact extruded Mg AA-size can be composed of an AZIOA Dow Chemical Co. alloy, and a 500 g/l $MgBr_2 \cdot 6H_2O$ electrolyte. The cathode mix (weighing approximately 5 g) consisted of two parts by weight of the nitroalkane compound to one part by weight of Cabot experimental battery black.

The performance characteristics of these magnesium-nitroalkane AA-size dry cells on a 4- and 50-ohm continuous discharge test are shown in Fig. 12. Included for comparison are performance data for comparable size commercial Leclanché, and Mg/$MgBr_2$/MnO_2 dry cells (14) of the type being developed by the Dow Chemical Company.

On the 4-ohm continuous discharge test, it is seen that the magnesium-nitroalkane cells are superior to the Leclanché cell both on the basis of minutes of service to specified end voltages, and operating voltage. Compared to the Mg-MnO_2 cell, the magnesium-1,1,4,4-tetrabromo-1,4-dinitrobutane cell operates at a higher voltage and gives comparable minutes of service to the inorganic cell.

On the lighter drain 50-ohm continuous discharge test, both organic cells give comparable hours of service to the Leclanché cell to a 0.90 v end point but are inferior to the Mg-MnO_2 cell in this respect. The organic cells, however, operate at higher voltages than the Leclanché cell on this test, while the magnesium-1,1,4,4-tetrabromo-1,4-dinitrobutane cell has a voltage comparable to that of the Mg-MnO_2 cell.

These results, while only representing the data obtained on two nitroalkane cathode materials, demonstrate the possible practical application of these materials in primary cells.

Summary

1. A theory based on the electron density in the vicinity of a reducible nitro group is presented which explains the effect of substituent groups and their position on the operating potential of nitroalkanes. For example, the effect of an electron-attracting chloro group on the potential of a nitroalkane diminishes rapidly as saturated hydrocarbon groups

are interposed between it and the nitro group. It is also seen that the addition of successive chloro or nitro groups to a primary nitro carbon atom increases the potential of the parent nitroalkane compound with each succeeding addition of the electron attracting group.

2. Coulometric studies in a $MgBr_2$ electrolyte indicate electrode efficiencies of 36-52% can be obtained from a number of solid nitroalkane compounds, assuming a 6-electron change per nitro group. The latter assumption is in doubt, however, since the reduction mechanism is not known.

3. Magnesium-nitroalkane dry cells have been assembled, and the performance characteristics of these cells indicate that nitroalkane compounds show promise for use as cathodes in primary cells.

Acknowledgment

The authors wish to express their appreciation to Mr. A. M. Cooke and Dr. R. S. Egly of Commercial Solvents Corporation and Dr. M. H. Gold of Aerojet-General Corporation for supplying many of the chemicals used in this investigation. Thanks are due also to Mr. G. R. Ganges of this laboratory for assembling and testing the dry cells.

Manuscript received July 7, 1958. This paper was presented before the Ottawa Meeting, Sept. 28-Oct. 2, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Oxidation Studies on the Iron-Chromium-Aluminum Heater Alloys

Earl A. Gulbransen and Kenneth F. Andrew

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

The oxidation behavior of three iron-chromium-aluminum alloys was studied using sensitive weight gain techniques. In addition, x-ray diffraction methods were used to determine the crystal structure and composition of the oxide films. The adhesion characteristics of the oxide film to the metal were tested by introducing strains into the metal oxide system during oxidation.

Rate studies show a change in rate for the three alloys near 900°C. Between 900° to 1050°C the rate of oxidation remained nearly constant; above 1050°C it increased again. X-ray diffraction studies suggest that a crystal structure transformation was occurring in the oxide. At 1050°C, α-Al_2O_3 was the main oxide in the scale.

The parabolic rate law was used to interpret the rate data. Deviations occurred during the initial reaction period as a result of crystal structure transformations in the film. Heats of activation of 76 to 77 kcal/mole were calculated for the range 700°-900°C.

Strain oxidation studies showed the oxide scale on the high aluminum alloy to be less susceptible to damage than the lower aluminum content alloys. These studies were correlated directly with practical performance tests.

Thermodynamic analyses of the several types of solid-solid and solid-gas reactions were used to interpret the rate and structure studies. Preliminary design principles were proposed for heat resistant alloys.

Heater alloys have been characterized by three important properties: (*a*) high melting point, (*b*) high resistance to oxidation, and (c) good mechanical properties. For extreme service conditions, two types of alloys have been used: (*a*) Ni-Cr alloys of nominal composition 80% Ni and 20% Cr, and (*b*) Fe-Cr-Al alloys of nominal composition 20-25% Cr, 4-6% Al, balance Fe. Both alloy systems consist of a single phase with the Ni-Cr alloys having the austenitic structure and the Fe-Cr-Al alloys the ferritic structure.

The maximum operating temperature in the final analysis is limited by the alloy's solidus point. This is about 1440°C for the Fe-Cr-Al alloys and 1380°C

for the Ni-Cr alloys. Neither series of alloys can be used at temperatures near their solidus point as the rate of oxidation and scaling becomes excessively high and the mechanical properties become poor. At extreme temperatures the oxidation resistance of the alloy determines, in part, the usefulness of the alloy as a high-temperature material.

The oxidation resistance of metals has been related to the formation of lattice defects and the diffusion of cations, anions, and electrons through these defects (1,2). This picture, based on a uniform oxide film, is probably too simple as has been shown by the formation of oxide needles, whiskers, and platelets (3, 4) on the scale. These suggest that certain areas of the metal are much more reactive than the rest of the surface.

If the metal is oxidized under periodic temperature cycles or when subjected to stresses or to a strain, the oxide-metal interface may be damaged (5). As a result, the rate of oxidation increases. The oxidation resistance of the alloy for these conditions is governed not only by diffusion processes but also by the chemical and physical properties of the oxide, alloy, and oxide-alloy interface.

The objectives of this study are: (*a*) to determine the kinetics of the oxidation of three Fe-Cr-Al alloys as a function of time, temperature, and alloy composition, (*b*) to determine the effect of strain on the oxidation process, (*c*) to determine the crystal structure of the oxide scales, and (*d*) to interpret from the experimental observations and thermodynamic analysis the high heat resistance of the Fe-Cr-Al alloys.

Literature.—von Kantzow (6) first observed that the heat resistance of steels was improved by alloying with aluminum. A series of alloys of Fe-Cr and Al were developed and patented. Since 1932 these alloys have been manufactured under the name of Kanthal[1] alloys.

The heat resistance of Fe-Al and Fe-Cr alloys has been studied by several groups (7-12). Hauttman (7) showed the strong effect of increasing the Al content between 4 and 9% at 1000°C. Al_2O_3 was found in the oxide layer on a 9.44% Al alloy. Scheil and Schulz (8) in a study of Cr-Al steels at 1200°C showed that the most oxidation resistant alloys were covered with a white aluminum oxide scale. At temperatures above 1000°C an Al content of greater than 4% was necessary to get a high degree of oxidation resistance. The high oxidation resistance properties and high electrical resistance suggested the use of Al-Cr steels for heater alloys. Ziegler (9) and Portevin, Pretet, and Jolivet (10) also noted the beneficial affect of adding Al to improve the oxidation resistance of steels.

The nature of the scaling process in the oxidation of steels containing Ni, Cr, and Al has been discussed by Krainer, Wetternik, and Carius (11). The loss by scaling was lowest for steel containing 24% Cr and 5% Al and having a scale of Al_2O_3. However, the resistance of the layer to scaling with temperature fluctuations was best for a Cr_2O_3 scale and poorest for an Al_2O_3 scale.

[1] Kanthal is a proprietory name for a series of heater alloys manufactured by Kanthal Corp., Stamford, Conn.

The segregation of aluminum atoms in Al-Cr-Fe alloys toward the periphery is discussed by Sektova (12). Sektova also noted the strong effect of Al to improve the oxidation resistance of these alloys.

Experimental

The vacuum microbalance method has been described (13-15). In this study a microbalance of low sensitivity, 4.39μg/0.001 cm deflection, was used. A total weight change of about 7 mg could be measured with a sensitivity of 1.10×10^{-6} g. This low sensitivity microbalance together with the use of smaller specimens increased the range of the measuring system by a factor of 25.

A vacuum grade mullite furnace tube contained the sample. It was sealed directly to the Pyrex glass system. With the specimen in the furnace tube at 1100°C, a McLeod gauge pressure of 3×10^{-6} mm Hg was readily obtained in the system. The vacuum system and gas preparation system have been described (15).

The furnace temperature was controlled to about ±1.5°C. There was no evidence of a temperature gradient along the 2.25-cm specimen during oxidation.

Weight changes occurring during the reaction were followed in a semicontinuous manner by observing a pointer on a balance beam using a micrometer microscope. Readings of the balance were taken *in vacuo* before reaction at temperature, during the reaction in oxygen, and after reaction *in vacuo*. Weight changes due to reaction of carbon in the metal with the surface oxide and to vaporization of metallic elements from the alloy were small.

Specimens used in this study were three types of commercial heater alloys obtained from the Kanthal Corporation. Table I shows the approximate and spectroscopic analysis of the alloys and their ratings as heater alloys. The 0.025-cm thick specimens were prepared from 0.63 cm wide strips and had surface areas of about 2.25 cm^2. Sample weight was about 0.1886 g. Sections of the strip were abraded starting with No. 1 polishing paper and finishing through 4/0 paper. To avoid oxidation, the last stage was carried out under purified kerosene. After abrading, the samples were cleaned with soap and water, distilled water, petroleum ether, and absolute alcohol, and stored in a desiccator.

Strain oxidation.—Earlier studies of the Ni-Cr series of alloys (5) and the studies of Krainer. Wetternik, and Carius (11) have shown that constant temperature studies cannot be used alone to evaluate the protective characteristics of a particular alloy if the alloy is subjected to stress or to a strain in its use. To give a more complete picture of the physical and chemical factors involved in high-temperature oxidation, a new test method called strain oxidation was developed. In this method the metal is oxidized to a given weight gain, removed from the balance system and strained 1-4% in a tensile machine. After cutting a smaller section of the sample free from grip marks, the specimen was placed in the balance system and re-oxidized. Rate calculations before and after strain were made on a 1 cm^2 basis. To achieve

a strain of 1% a stress corresponding to the yield point or greater was imposed on the sample.

X-ray diffraction method.—Filtered Cr K_α radiation was used with a fine focus x-ray diffraction tube. The diffraction patterns were made at room temperature using a 9 cm Unicam camera.

Oxide samples were removed from the alloy by electrochemical stripping (16). After washing several times in distilled water, the oxide films were rolled on to small glass capillary tubes for mounting in the x-ray camera.

Results

The three alloys were oxidized at 600°-1100°C using an oxygen pressure of 7.6 cm Hg for a reaction time of 2 hr. Weight gain during reaction was calculated in units of micrograms per square centimeter.

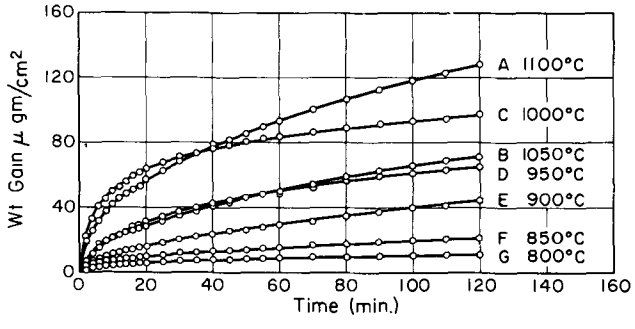

Fig. 1. Effect of temperature on oxidation Fe-Cr-Al alloy 1, 7.6 cm Hg of O_2, abraded through 4/0.

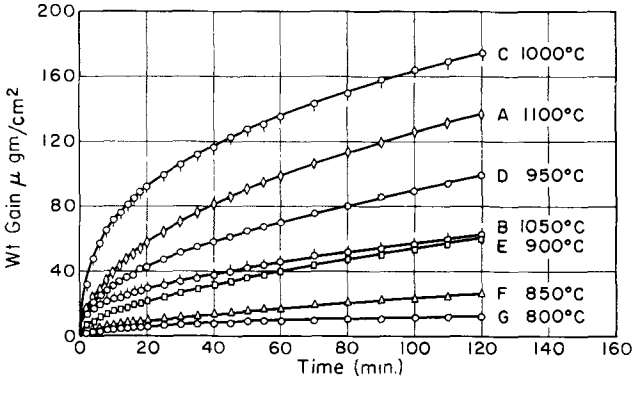

Fig. 2. Effect of temperature on oxidation of Fe-Cr-Al alloy 2, 7.6 cm Hg of O_2, abraded through 4/0.

X-ray diffraction analysis suggested that the oxides were largely α-Al_2O_3 and Cr_2O_3. Assuming α-Al_2O_3 and a surface roughness ratio of unity, a value of 54 was calculated for the relation between the oxide thickness in angstroms and the weight gain in micrograms per square centimeter.

Time and temperature.—Figures 1-3 show oxidation curves for the three alloys in the range 800°-1100°C. There was a rapid initial reaction rate in all curves, with the rate decreasing as the oxide film grows. No evidence was found for a linear rate law for the times studied. All of the oxides were grayish-black and were adherent to the alloy when cooled to room temperature.

Below 900°C the oxidation curves show a strong dependence on the temperature. However, between 900° and 1050°C, the rate was nearly constant for each of the alloys. Above 1050°C it increased again with temperature.

This nearly constant rate of reaction between 950° and 1050°C is of great interest and suggests that major structural changes were occurring in the alloy or in the oxide scale.

A comparison of the rate of oxidation of the three alloys at 1100°C shows only minor differences in the amount of oxidation or in the final rate of oxidation. Practical performance tests of alloys in Table I show alloy 1 to be superior to 2 and 3.

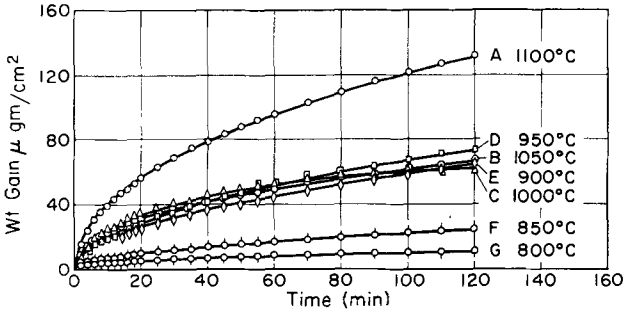

Fig. 3. Effect of temperature on oxidation of Fe-Cr-Al alloy 3, 7.6 cm Hg of O_2, abraded through 4/0.

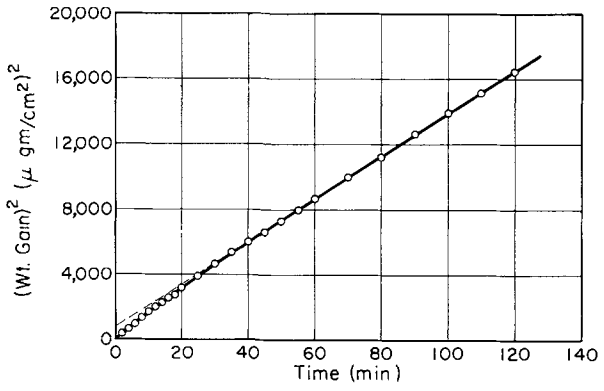

Fig. 4. Oxidation Fe-Cr-Al alloy 2, 1100°C, 7.6 cm Hg of O_2, abraded through 4/0, parabolic plot, A = 2.16 x 10^{-12} $(g/cm^2)^2$ sec^{-1}.

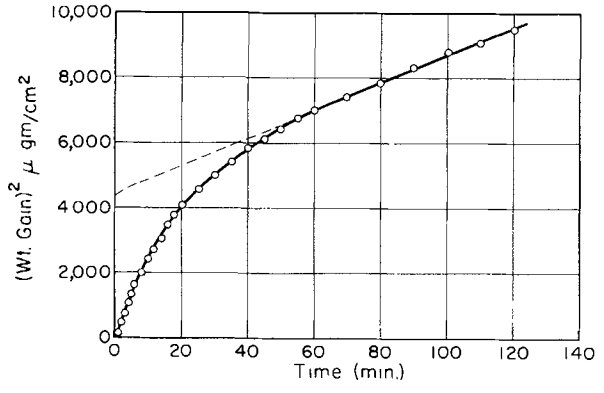

Fig. 5. Oxidation Fe-Cr-Al alloy 2, 1000°C, 7.6 cm Hg of O_2, abraded through 4/0, parabolic plot, A = 0.695 x 10^{-12} $(g/cm^2)^2$ sec^{-1}.

Parabolic rate law.—The parabolic rate law is useful in evaluating the nature of oxidation reactions even though deviations may occur, since the law is based on fundamental physical principles (1, 2). Physical and chemical changes occurring in the oxide film are noted as deviations from the rate law.

The equation states that $W^2 = At + C$. Here W is the weight gain, t is the time, and A and C are constants. Figure 4 shows a parabolic rate law plot at 1100°C for alloy 2. Agreement with the theoretical law was good except for the initial part of the reaction.

From 750° to 900°C the parabolic rate law constant increases during the first several hours of reaction over the initial value, while above and below this temperature range the parabolic rate law constant decreases with time. These effects also may be related to minor changes in the composition or physical structure of the oxide film. In the temperature range 900°-1050°C a major change occurred in the alloy or oxide film, since the temperature coefficient of the reaction was near zero. A change also occurs in the oxide film or alloy as a function of time for this temperature range. This was seen in the 1000°C parabolic rate law plot shown in Fig. 5. The parabolic rate law constant decreased rapidly during the first 60 min of reaction after which a nearly constant value was found.

Temperature dependence.—Figures 6 to 8 show plots of the logarithm of the parabolic rate law constant A vs. $1/T$ for the three alloys. Below 900°C a

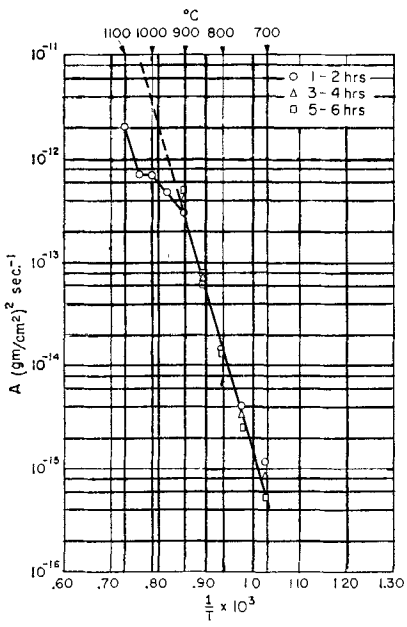

Fig. 6. Oxidation Fe-Cr-Al alloy 1, log A vs. 1/TΔH = 76,900 cal/mole.

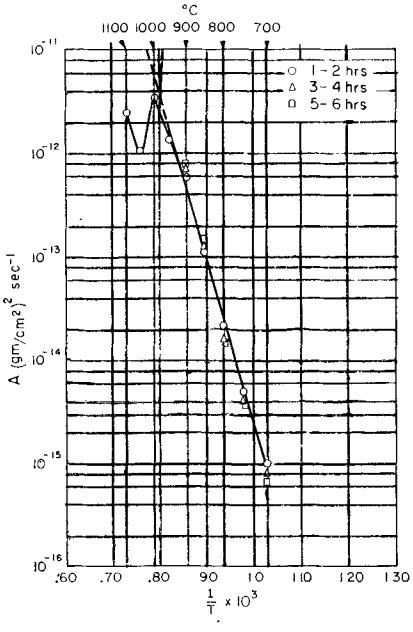

Fig. 7. Oxidation Fe-Cr-Al alloy 2, log A vs. 1/TΔH = 76,900 cal/mole.

straight line relationship was observed. Between 900° and 1050°C the plots show the transition phenomenon already noted. The slopes of the log A vs. $1/T$ plot and the absolute values of A for the three alloys were similar. Analysis of the slopes of Fig. 6-8 for alloys 1 and 2 shows heats of activation of 76,900 cal/mole and for alloy 3, 76,500 cal/mole. These are very high for oxidation processes.

Strain Oxidation

The several alloy specimens were oxidized at 900°C to form an oxide film of about 44.7μg/cm^2 or an estimated oxide thickness of 2410Å. After straining 2-4%, the specimens were re-oxidized at 900°C.

Figure 9 shows the results for a 2% strain for alloy 1. The oxidation curve after 2% strain was nearly continuous with the curve for the initial oxidation.

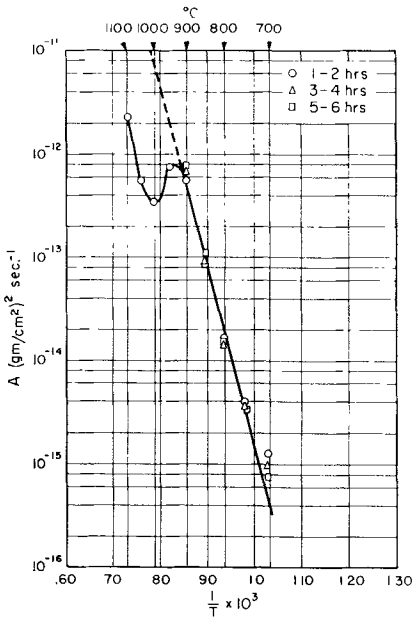

Fig. 8. Oxidation Fe-Cr-Al alloy 3, log A vs. 1/T $-\Delta H = 76{,}500$ cal/mole.

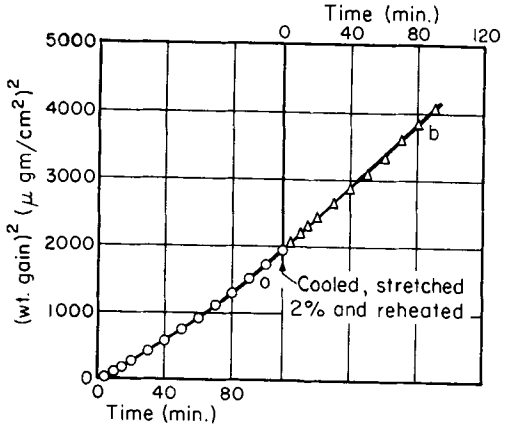

Fig. 9. Strain oxidation of Fe-Cr-Al alloy 1, 2% strain: a, 900°C, 7.6 cm Hg of O_2, A= 3.55×10^{-13} $(g/cm^2)^2/sec$; b, 900°C, 7.6 cm Hg of O_2, after cooling, stretching 2% and reheating, A = 4.0×10^{-13} $(g/cm^2)^2/sec$.

Figure 10 shows the strain-oxidation curve for alloy 1 for a 4% strain. A marked change in the course of oxidation was noted as a result of the 4% strain.

The usual effect of strain between the several oxide layers and the metal is flaking of the oxide with loss of protection of the metal (5). For heat resistant alloys 1-4% strain may not visually destroy the bonding between the oxide and metal but localized damage on a microscopic or submicroscopic level may occur which affects the rate of oxidation.

Some damage in the oxide or at the interface between metal and oxide has occurred as a result of 4% strain of alloy 1 as shown in Fig. 10. This damage was smaller than that observed on other alloys for the same amount of strain (5). Two types of damage are postulated to occur as a result of straining of the alloy. The first is a short-term damage which is rapidly repaired by further oxidation. The second is long-term damage. This damage involves an increase in the rate of reaction which continues over long periods of time. A comparison of the parabolic rate law constants before and after strain shows some

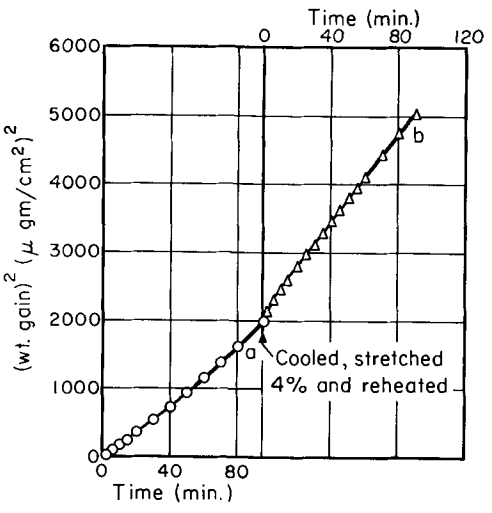

Fig. 10. Strain oxidation of Fe-Cr-Al alloy 1, 4% strain: a, 900°C, 7.6 cm Hg of O_2, A = 4.09×10^{-13} $(g/cm^2)^2/sec$; b, 900°C, 7.6 cm Hg of O_2, after cooling, stretching 4% and reheating, A = 5.12×10^{-13} $(g/cm^2)^2/sec$.

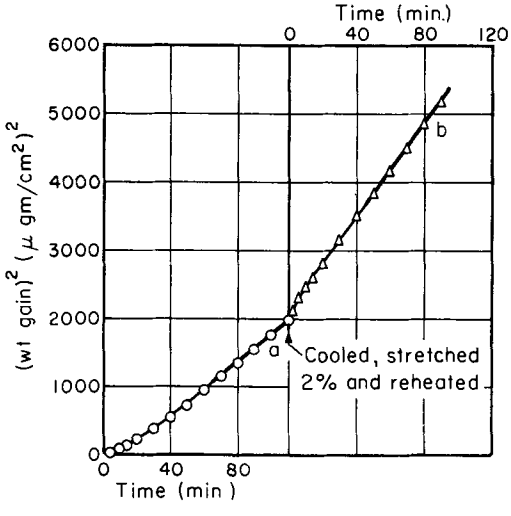

Fig. 11. Strain oxidation of Fe-Cr-Al alloy 2, 2% strain: a, 900°C, 7.6 cm Hg of O_2, A = 3.40×10^{-13} $(g/cm^2)^2/sec$; b, 900°C, 7.6 cm Hg of O_2, after cooling, stretching 2% and reheating, A = 6.41×10^{-13} $(g/cm^2)^2/sec$.

long-period damage for both 2 and 4% strains for alloy 1.

Figures 11 and 12 show the results of strain oxidation studies of alloys 2 and 3. Both alloys show short- and long-period damage resulting from a 2% strain. A comparison of the strain oxidation tests for alloys 1, 2, and 3 show alloy 1 to be superior. These results are in agreement with the useful life tests given in Table I. The useful life tests are temperature cycling tests and are used to evaluate heater alloys.

Crystal Structure Studies

Table II shows the results of crystal structure studies on 2-hr oxidation experiments for the three alloys and for the several temperatures. Crystal structure studies were made above and below the transition temperature region of 1000°C. The x-ray diffraction patterns showed sharp lines for all of the oxide scales studied.

Complete identification of all of the diffraction lines was not possible since the stripping process re-

† tr. = trace.

moves carbides, nitrides, etc. from the surface layer of the alloy. As a result a number of extra reflections occur. Identification of the major oxide components was readily made. Oxides present in trace amounts were identified with less reliability by two or three characteristic reflections.

Alpha-Al_2O_3 was the principle oxide found in all of the oxide scales shown in Table II. Cr_2O_3 and MnO appear in the oxide scale at temperatures of 900°C and lower. The identification of MnO is open to some question since its diffraction pattern is nearly identical to those for NbC, NbN, and TaC (17). These compounds could conceivably be present in trace amounts in high-temperature alloys. Spectroscopic analyses of the alloys in Table I showed no evidence for Nb or Ta in the metal.

In the transition temperature zone the Cr_2O_3 content of the oxide scale decreases. In addition, a spinel, probably $FeO \cdot Al_2O_3$, appears in the oxide having a parameter of 8.12Å (17). These changes in oxide composition occur for all of the alloys.

Alloy 3 containing the lowest amounts of Al, Cr, and Mn shows the largest amount of MnO structure in the oxide scale. Alloy 3 also shows the largest amount of damage in the oxide in strain oxidation tests.

We conclude that crystal structure differences exist in the oxide scales of the three alloys as a result of minor differences in alloy composition. These crystal structural differences affect the adhesion properties of the oxide as shown by the strain oxidation studies or by practical performance tests. These differences do not appreciably affect the rate of oxidation at constant temperatures above and below the transition temperature zone.

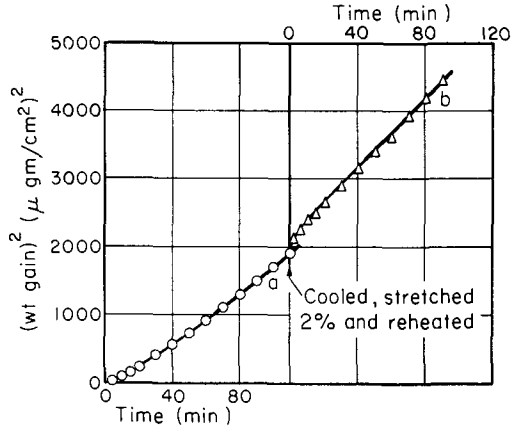

Fig. 12. Strain oxidation of Fe-Cr-Al alloy 3, 2% strain: a, 900°C, 7.6 cm Hg of O_2, $A = 3.29 \times 10^{-13}$ $(g/cm^2)^2/sec$; b, 900°C, 7.6 cm Hg of O_2, after cooling, stretching 2% and reheating, $A = 4.34 \times 10^{-13}$ $(g/cm^2)^2/sec$.

Thermodynamic Interpretation

Table III shows the principal types of reactions which may occur in the oxidation of Fe-Cr-Al alloys. These determine in part the constitution of the oxide scale formed at high temperatures. Precise calculations of the thermodynamic properties of the oxidation products necessitate consideration of the relative rates of attack of the several metals and interdiffusion processes in the alloy, as pointed out by Wagner (18) for a number of binary systems.

The thermodynamic evidence given below for most of these reactions assumes a standard state of unit activity for the component metals. For many of the calculations, the activity correction is small compared to the free energy change in the reaction itself.

Table IV shows logarithms of the dissociation

pressures of the oxides from 25° to 1200°C as calculated from equations given by Kubaschewski and Evans (19). All of the oxides are stable in the atmospheres and temperatures used in the oxidation experiments.

The equilibrium constants for the several solid phase reactions are given in Table V. All are thermodynamically possible over the temperature range. Although ferric oxide may form initially, both Cr and Al can react to form chromium and aluminum oxide as shown by the positive values of $\log_{10}K$. Eventually aluminum oxide should constitute the bulk of the oxide film.

X-ray crystal structure studies (Table II) confirm the thermodynamic predictions that Al_2O_3 should be the chief oxide in the scale. Solid phase reactions may account for the decreases in chromium oxide content of the scale at temperatures above 900°C. The presence of MnO may be due to the high mobility of manganese and to its high thermodynamic stability.

The formation of spinels or other mixed oxide systems may be expected but thermodynamic data for spinels other than Fe_3O_4 are not available. However, the stability of the several spinels of interest can be deduced from structural information. Table VI shows the lattice parameters of some of the known aluminates (17) having the spinel structure as a function of the ionic radii of the bivalent ions. Table VI shows that Co, Fe, and Mn can form spinels with aluminum

oxide. Even though Mn and Co are present in minor amounts in the alloy, they can substitute in the spinel structure and thus appear in the oxide film.

The formation of silicates may be expected from phase diagram studies of the oxides (20). These compounds can exert a major influence on the oxidation process since they may concentrate at the oxide-alloy interface.

The role of the decarburization reaction is not understood. Calculations using data from Kubaschewski and Evans (19) show that, if a carbon content of 0.05% is assumed for the reaction of carbon with ferric oxide, the equilibrium carbon monoxide pressure is 1 atm at 1000°C. Similar calculations for chromic oxide, aluminum oxide, and silicon dioxide show the reaction to occur under vacuum conditions at 1000°C. As the carbon content is depleted, the importance of this reaction diminishes.

Table VII shows the vapor pressures of the metals of interest in this study from 25° to 1200°C. Except for iron the data are calculated from a recent survey by Stull and Sinke (21). The data for iron are taken from a recent study by the authors (22) using the vacuum microbalance method. The measured values for the vapor pressure of iron were lower than the extrapolated values given by Stull and Sinke (21).

Weight loss calculations based on Table VII for oxide free Fe-Cr-Al alloys show rapid evaporation of Al, Cr, and Mn above 1000°C in high vacuum. However, rapid evaporation of these metals has not been observed in our studies or in other studies (6) on these alloys.

In another study (22) the weight loss curves for oxide free surfaces of pure iron, a 5 Al-Fe alloy and a 5 Al-23 Cr-Fe alloy, were determined. The alloys were prepared from pure metals. The 5 Al-Fe alloy gave a weight loss curve somewhat lower than that for pure iron while the 5 Al-23 Cr-Fe alloy gave a weight loss curve a little higher than that for iron. Chemical analyses of the vaporized deposits showed the vapor from the 5 Al-Fe alloy consisted essentially of iron, while the vapor from the 5 Al-23 Cr-Fe alloy consisted largely of Cr and Fe. We conclude that Al does not vaporize effectively from a 5 Al-Fe alloy. However, Cr and Fe do vaporize from an oxide free surface of a 5 Al-23 Cr-Fe alloy. Other studies (6, 22) show that oxidation of an Fe-Cr-Al alloy reduces the evaporation losses at 1050°C. Since Cr_2O_3 is not an important component in the oxide scale at 1050°C, one must conclude that α-Al_2O_3 acts as a barrier to the diffusion of chromium.

Table VII shows manganese to have a high vapor pressure. In these alloys manganese is probably com-

bined with sulfur or with oxygen thus lowering its activity, and little manganese would vaporize.

Effect of Vapor Pressure in Oxidation

With the exception of oxidation resistant metals and alloy at high temperatures, the vapor pressure of the metal has no direct effect on the mechanism of oxidation. This is because breakdown of normal oxidation processes occurs by other mechanisms, such as loss of adhesion at the oxide-metal interface. The first evidence for a vapor pressure effect was found in the oxidation of chromium (23). The rapid increase in the rate of oxidation of chromium was explained as short circuiting by vaporization of normal ion transfer and diffusion processes. This occurs when the transfer of metal ions into the oxide by evaporation approaches the rate of reaction. Vapor transfer of metal can occur at surfaces other than the metal-oxide interface. In this sense the normal diffusion processes are short circuited. The present study shows a rapid increase in the rate of oxidation at 1050°C for the Fe-Cr-Al alloys. The vapor pressure of the metallic components may be important in the high-temperature oxidation of these alloys, as in the case of chromium.

The vapor pressure effect can be studied in two ways. Compare the rate of evaporation of metal atoms from a free surface with the reaction rate expressed in terms of metal atoms leaving the oxide-metal interface. Since the rate of evaporation has a higher temperature coefficient than the rate of oxidation, a sharp break in the rate of oxidation should occur at the temperature where the two rates intersect. Crystal structure studies also can be used to show the vapor pressure effect. If the volatility of a certain metal becomes important, the oxide of this metal could appear in the oxide film even though other metals form more stable oxides.

Alloy 1 having the lowest rate of oxidation in the 1-2 hr period is the best alloy for checking the vapor pressure effect. Figure 13 shows a plot of the rate of oxidation in terms of both iron and aluminum reacting and the experimental weight loss data for the 5 Al-23 Cr-Fe alloy. The rate of oxidation shows a sharp break at the temperature where the metal transfer by evaporation equals the rate of reaction.

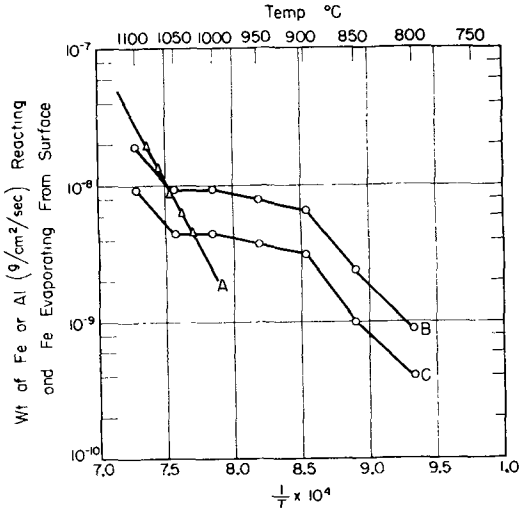

Fig. 13. Comparison weight loss 5Al-23Cr-Fe alloy (curve A) with rate of oxidation in terms of Fe (curve B) or Al (curve C), log rate vs. 1/T, alloy 1.

Table II shows the oxide scale at 1050°C to be α-Fe_2O_3, α-Al_2O_3, and a low parameter spinel (probably $FeO \cdot Al_2O_3$). Below 1050°C iron oxides were not observed. Both the rate studies and crystal structure studies show that the high-temperature rate of oxidation and crystal structure of the scale are related closely to the vapor pressure of the metals in the alloy. The α-Al_2O_3 scale limits in some manner the vapor pressure effect of chromium.

Table II shows for alloy 3, which has the lowest useful life value, the formation of MnO and a trace of Cr_2O_3. This suggests that the lower aluminum content of the alloy 3 is not limiting the formation of MnO and Cr_2O_3 in the oxide scale.

General Principles

The selection of metals for high heat resistant alloys based on iron should be made on the following principles: (*a*) alloying elements should lower the rate of oxidation; (*b*) solid phase reaction should be considered so as to give an oxide having a good crystal structure match with the metal; this property should maximize adherence of the oxide to the metal and minimize the effects of stress or strain; and (c) alloying elements should be chosen to lower the alloy vapor pressure and to limit the vapor pressure of the more volatile but still desirable elements.

Those studies show that increasing the chromium and aluminum contents in alloys 1 to 3 improves the physical properties of the oxide-metal interface as determined by the strain oxidation experiments. A smaller improvement is noted on the constant temperature oxidation rate.

Summary

Three Fe-Cr-Al alloys were studied systematically in regard to their oxidation behavior from 700° to 1100°C. Kinetic studies were made using the vacuum microbalance method. Crystal structure studies were made on the oxide film electrochemically removed from the oxidized alloy. Strain-oxidation studies were made to determine the adherence characteristics of the oxide film. The experimental results were interpreted by thermodynamic and rate analyses of the oxide-metal systems.

Kinetic studies show a unique change in rate of oxidation at 900°C. Over the range of 900°-1050°C the rate of oxidation was nearly constant. Above 1050°C the rate of oxidation again increased. The parabolic rate law could be applied with initial deviations over the complete temperature range. For the temperature range 700°-900°C a logarithmic plot of the parabolic rate law constants vs. $1/T$ gave a straight line and calculated heats of activation of 76-77 kcal/mole for the three alloys.

Crystal structure studies showed α-Al_2O_3 to be the main oxide over the temperature range. Below 950°C some Cr_2O_3 and MnO were observed. These oxides decreased in the oxide scale on passing through the transition temperature region. At 1050°C the oxide was largely α-Al_2O_3.

The crystal studies confirmed thermodynamic predictions as to the composition of the scale. Solid phase reactions of aluminum with chromium oxide were proposed to explain the shift in oxide composition at 950°C.

Strain oxidation studies showed the oxide scale on alloy 1 to be less susceptible to damage than the scale on alloys 2 and 3. These studies can be correlated with practical performance tests.

Comparison of the rate of oxidation with available vapor pressure data showed that metal transfer by vaporization was the rate-controlling factor in the oxidation of Fe-Cr-Al alloys at 1050°C and above. Design principles were proposed for high heat resistant alloys.

The Fe-Cr-Al alloys are good examples of well designed high heat resistant alloys.

Diamond Alkali Company, Cleveland, Ohio

ABSTRACT

A new bath composition and its operating conditions are described for electrodeposition of hard, bright, chromium-iron alloy plate having banded microstructure. A precipitation mechanism is proposed to account for the microstructure of the plate. The process produces plate having almost the same physical properties as conventional hard chromium from a bath composition not based on chromic acid. The plating rate and cathode current efficiency for the alloy are higher than for plating chromium from a conventional bath.

A high-speed chromium-iron-alloy plating process was developed in these laboratories (1). The bath is essentially a chromic- and ferric-alum solution with additions of ammonium sulfate and other salts. In the course of the development program, it was observed that bright chromium-iron-alloy plate having banded microstructure was obtained when hypophosphite was used as a bath additive.

The opportunity to study this particular alloy plate arose when a program for the Navy Department (2) had as its objective the development of hard, wear-resistant plate from a high-efficiency bath. Since plates of laminar (banded) structure resemble conventional hard chromium, they were developed with the ultimate objective of improved abrasion resistance.

Preliminary experiments.—Preliminary efforts were successful in depositing bright chromium-iron alloy having banded microstructure onto 2.5-cm (1-in.)-diameter circular areas of steel cathodes

shielded by a 0.8-cm (5/16-in)-deep plastic frame under the following conditions:

Bath composition (3)

700 g/l chrome alum [$Cr(NH_4)(SO_4)_2 \cdot 12H_2O$] (76 g/l chromium)
13.6 g/l ferrous ammonium sulfate [$Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$]
25 g/l magnesium sulfate ($MgSO_4 \cdot 7H_2O$)
100 g/l ammonium sulfate [$(NH_4)_2SO_4$]
0.2 g/l sodium dihydrogen phosphate ($NaH_2PO_4 \cdot H_2O$)

Operating conditions

Temperature	60°C (140°F)
*p*H	1.5
Cathode current density	54 amp/dm² (500 amp/ft²)

Lead or chromium-iron alloy anodes were satisfactory for oxidizing and maintaining iron in the ferric state, a condition necessary for the best plating results. The initial oxidation of the iron to the ferric state could also be carried out by the addition of chromic acid to the bath. Apparently phosphate, an oxidation product of hypophosphite, could have been responsible for similar bright, banded plate obtained in earlier work.

Mechanism for the Deposition of Chromium-Iron Alloy Having Banded Structure

The apparent mechanism responsible for laminar structure of deposits taken from a chromic-ferric sulfate bath containing small amounts of phosphate is that grain refinement and banding result from precipitation of ferric phosphate in the cathode film during electrodeposition. Since confirmation of this mechanism would make development of the bath an easier problem, experiments were designed for this purpose. If the mechanism were correct, silicate, arsenate, and vanadate additions to the bath should have an effect similar to phosphate additions. All these anions form insoluble compounds with ferric iron. Using the conditions for plating with the phosphate additive, the new anions were substituted for phosphate in amounts varying from 0.1 to 1.2 g/l. The results showed the new anions to have the same effect as phosphate with the exception that larger amounts were required (1.2 g/l as opposed to 0.2 g/l).

Actually, the new anions were an improvement over the phosphate additive, because the concentrations required for producing deposits with banded microstructure were not so critical. Slight excess amounts of phosphate caused burning, but this was not true with the other anions. High current density [43-65 amp/dm² (400-600 amp/ft²)] was required to obtain the desired effects with phosphate and the other anion additives mentioned. The mechanism was supported further by the knowledge that ferric salts of phosphoric, silicic, arsenic, and vanadic acids are insoluble in solutions having *p*H near 2.7, and that cathode film *p*H values are higher than bath *p*H which varied from 0.8 to 2.0 in the tests.

Development of Bath for Deposition of Plate Having Banded Structure

The precipitation mechanism developed in the preceding section suggested the changes necessary to develop a practical bath composition. A buffer was required to equalize the *p*H over the entire face of the cathode so that masking of the cathodes with thick frames would not be necessary.

Many amino acids, such as aminoacetic acid (glycine), have isoelectric points in the *p*H range 2.0 to 2.2 and good buffering capacity in the *p*H range 1 to 3. They should permit deposition of laminar plate uniformly over broad flat cathodes by maintaining uniformly high *p*H in the cathode film. Glycine additions, ranging in concentration from 0.5 to 3.0 g/l, were made to the following bath:

450 g/l basic chromic sulfate (76 g/l chromium)[1]
13.5 g/l ferrous ammonium sulfate [$Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$] (or 16.6 g/l ferric ammonium sulfate [$NH_4Fe(SO_4)_2 \cdot 12H_2O$])
20 g/l magnesium sulfate ($MgSO_4 \cdot 7H_2O$)
100 g/l ammonium sulfate [$(NH_4)_2SO_4$]
1 g/l silicon dioxide (added as water glass, 29.5% SiO_2)

with the result that uniform deposition of laminar chromium-iron-alloy plate could be achieved on flat rectangular steel panels without any form of shielding under the following conditions:

Temperature	54°C (130°F)
*p*H	0.8-1.3
Cathode current density	21-28 amp/dm² (200-260 amp/ft²)
Agitation (work bar)	None to 50 cpm with 3.8-cm (1.5-in.) stroke
Cathodes	Steel-5 x 15 cm (2 x 6 in.) or 3.8 x 10 cm (1.5 x 4 in.)
Glycine concentration (g/l)	0.5 to 3.0
Oxidation state	Iron all ferric with little or no Cr^{+6}.

[1] Technical grade purchased from Mutual Chemical Company of America.

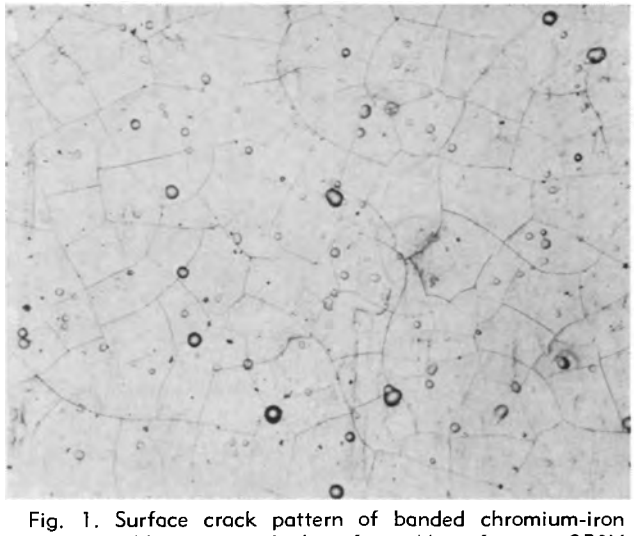

Fig. 1. Surface crack pattern of banded chromium-iron alloy plate. Note: untouched surface. Magnification 250X before reduction for publication.

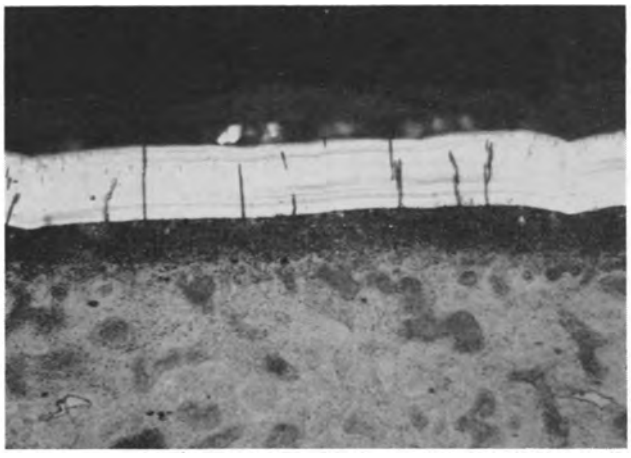

Fig. 2 Polished and etched cross section of banded chromium-iron alloy plate. Note: electrolytically etched in dilute oxalic acid. Magnification 500X before reduction for publication.

Data derived from the operation of this bath include the metallographical examination of fourteen deposits to verify the relation between brightness of the deposits and banded microstructure. Uniformly bright plate and complete lack of columnar structure were observed for operating conditions and bath composition cited above. The function of bath constituents was indicated by the following observations:

1. Only mat columnar plate could be obtained if the *p*H was so low as to solubilize ferric silicate or if the concentration of ferric iron was too low to cause precipitation of ferric silicate at *p*H 3.
2. Without a buffer (glycine) to equalize pH over the cathode surface, plastic shielding frames and current densities on the order of 53 to 63 amp/dm^2 (500 to 600 amp/ft^2) were required for production of uniformly bright and banded plate.

Bath composition was fixed to obtain plate of desired physical characteristics described below. Hence there could be little variation in plate composition from the neighborhood of 85Cr-15Fe. Bath composition was followed by chemical analysis. Iron was maintained by addition of ferrous sulfate or by occasional shifting between soluble Cr-Fe alloy anodes and platinum anodes. The oxidation state of iron was maintained with chromic acid. A few grams per liter of excess chromic acid had no observable effect on the characteristics of the plate. It is noteworthy that no hexavalent chromium had to be present to obtain the alloy plate which resembles hard chromium so long as most of the iron was in the ferric condition.

Bath life and glycine stability were not studied. However, baths were operated 3-4 hr daily for several weeks without any apparent deterioration or need for addition of more glycine.

The procedure according to which the bath was prepared was critical. Solutions of all chromic salts hydrolyze slowly when the temperature is raised. An equilibrium is attained more rapidly when they are cooled from an elevated temperature (over 80°C) to the desired temperature. For this reason a detailed description for bath formulation is given.

Bath formulation.—Basic chromic sulfate is added gradually (with constant stirring) to water at 82°C (180°F). The initial volume of water is about 60% of the final volume of the bath. When all but a small residue of insoluble matter is dissolved, the ammonium sulfate, ferrous ammonium sulfate, and magnesium sulfate are added with continued stirring. Next, the water glass solution diluted with twice its weight of water is added with vigorous stirring to avoid precipitation of silicic acid.[2]

The solution, still at 82°C, is treated with 0.3 g/l activated carbon,[3] usually added as a 4% suspension in water to facilitate wetting. The bath is then aged 4 hr at 82°C and 16 hr or longer at near plating temperature. Next, it is filtered at plating temperature, and the *p*H is adjusted to 1.3 (measured at 55°C)[4] with sulfuric acid. The glycine is then added (preferably 1 g/l), and enough chromic acid is added to give a positive external test for hexavalent chromium using S-diphenyl-carbazide indicator.

Typical plate containing 85Cr-15Fe is obtained immediately at 55°C, 21 amp/dm^2 (200 amp/ft^2) cathode and anode current density, using soluble chromium-iron alloy anodes (85Cr-15Fe). The cathode current efficiency is about 35% based on trivalent chromium. Compared with a conventional hexavalent bath with a cathode current efficiency of about 15% (basis Cr^{+6}) the trivalent bath with a cathode current efficiency of 35% (basis Cr^{+3}) yields about 4.6 times more deposit per unit of electrical current. Such an improvement in electrical efficiency has long been sought in chromium plating. The plating rate is 0.0076 cm/hr (0.003 in./hr) at 230 amp/ft^2 cathode current density.

Properties of the Plate

The plate, containing about 85% chromium and 15% iron, has a banded microstructure with a crack pattern (Fig. 1 and 2) similar to that of conventional chromium plate. The as-plated hardness of the plate is 1000 to 1025 Knoop (0.5 kg load) which is about the same as for conventional hard chromium plate. Thin plates up to at least 0.0025 cm (0.001 in.) have the appearance of decorative chromium plate. Thick deposits are still bright, but hazy, because of micronodules (see photomicrograph of untouched surface, Fig. 1.) Plates as thick as 0.025 cm (0.010 in.) were mat.

The rate of wear on the Taber Abraser,[5] after a short period of initial wear at 0.65 mg per thousand cycles, is 0.00 to 0.03 mg per thousand cycles. The wear for conventional hard chromium by the same method was 0.00 to 0.01 mg per thousand cycles. The as-plated stress[6] in the deposit is tensile and amounts to 5,000 kg/cm^2 (28,000 psi). This might be termed

[2] The solubility of silica as $Si(OH)_4$ is *p*H independent and is about 0.01% at 25°C and 0.02% at 57°C (4).

[3] Activated carbon, Grade S-51, Darco Department, Atlas Powder Company, New York, New York, was used throughout this work.

[4] The *p*H was always measured with a glass electrode standardized at room temperature.

[5] Research Model E-4010, Taber Instrument Corporation, North Tonawanda, New York.

[6] The stress measurements were made with a Brenner-Senderoff Contractometer, Champion Manufacturing Co., New York, N. Y.

residual stress, since stress had been relieved somewhat by cracking.

The frequency of the cracks in the channel-type crack pattern does not appear to vary significantly with bath pH between 1.0 and 1.3, nor with glycine content between 0.5 and 1.5 g/l. Crack counts indicate 250-340 cracks per linear cm (640 to 870 cracks per linear inch) or an average plateau diameter of about 0.0038 cm (0.0015 in.).

Conclusions

The results of this research show that a new chromium alloy electroplate containing a minor amount of iron and otherwise having physical properties close to those of conventional hard chromium (*a*) can be obtained from a bath composition involving little or no chromic acid; (*b*) derives its characteristic banded microstructure from a precipitation mechanism; (*c*) can be deposited at a rate of 0.0076 cm/hr (0.003 in./hr) at a cathode current efficiency of near 35% based on trivalent chromium; and (*d*) can be used as a hard, bright decorative plate. Further study of this interesting bath is required to obtain practical information relative to bath life and to establish a system of soluble and insoluble anodes to maintain bath composition.

ABSTRACT

It has been found that transition metals of groups IV, V, and VI can be plated adherently in the as-plated condition by being subjected first to a cathodic treatment which probably covers the surface with a hydride. By this technique, it is possible to eliminate etching prior to plating, permitting better control of dimensional tolerances. If the part is to be heated after plating, the procedure is to deposit a thin film of nickel or iron after the cathodic treatment, vacuum fire, then plate as desired. The method was used to produce adherent coatings of Ni and Cu on Ti, Zr, Nb, Ta, Mo, and W.

A further study was made of Nb and Nb-Ti alloys, in which an anodizing procedure was developed which permits subsequent electroplating of Fe or Ni without requiring etching (thereby permitting close control of dimensions) or annealing treatments (useful where delicate assemblies are involved).

In the past decade, the transition metals of groups IV to VI have become of increasing commercial importance. Accordingly, there has arisen a demand for electrodeposition on these metals. The main reasons for such electrodeposition are: (*a*) to improve corrosion or high-temperature resistance, and (*b*) to permit ready joining by soldering, brazing, or welding.

Conventional methods.—The usual method of plating other metals on these elements has involved the following steps: "activation" by etching in a suitable acid, deposition of a thin film of nickel or iron; removal of adsorbed gases; and finally heat treating to improve adhesion of the electrodeposited coating to the substrate. Table I gives recent literature references on the subject; in all cases, a heat treatment is applied after subsequent electrodeposition.

The effect of the etch commonly employed in the methods in Table I is to remove scale, oxide films, and the like, remove skins formed by fabricating techniques, and present a fresh, clean surface for plating. In the case of immersion treatments, the oxidizing agent is hydrogen ion, so that the surfaces also tend to become coated with metal hydride or occluded hydrogen during etching. This is especially true of the group V metals, which are especially prone to hydride formation. For this reason, it is worthy of note that such preplating treatments as cathodic cleaning, commonly employed in preparing many conventional metals for electroplating, have

* These references are not directly concerned with plating, but the etches used should be satisfactory prior to plating.

not been mentioned in connection with the substrates of interest in this paper. An exception noted in the tabulation above is the use of strike solutions, which are in effect combined cathodic cleaning and plating solutions.

The principal emphasis found in the literature when electrolytic preplating treatments are employed, is upon anodic treatments, which presumably minimize hydrogen occlusion, or hydride formation. Such treatments, however, are not desirable where accurate dimensional tolerances are involved.

In the course of commercially plating on some of these substrates, a very brief laboratory review was made of typical procedures contained in the table above. In general, it was found that both immersion etch and anodic etch procedures gave reasonably satisfactory results. However, during the course of this limited investigation, intermittent troubles were encountered, usually due to peeling of the as-deposited coating, and also blistering of the coating during the baking step. It was at first thought that these occasional difficulties were due to excessive occlusion of gases, such as hydrogen, on the surface of the substrate prior to plating. Therefore, a preliminary vacuum bake was employed prior to plating. Plating adhesion was found to deteriorate markedly as a result of this operation. This then suggested the possibility that good adhesion was favored by occluded gases, and that perhaps an important function of the preplating etch was to provide such a surface. If true, then it should be possible to substitute for the conventional etch a cathodic treatment in an electrolyte which does not chemically attack the substrate.

It is recognized that impurities often greatly affect the type of results obtained in studies of this type. The substrate used (except for Nb and Nb-Ti alloys) were obtained from A. D. Mackay, and analyzed better than 99.9%; however, no further analyses were made of the impurity contents. The nickel plating solution employed contained the following impurities: Mn, 0.48 g/l; Co, 0.46 g/l; Mg, 0.19 g/l; Fe, 0.028 g/l; Al, 0.018 g/l; Zn, 0.014 g/l; Cu, 0.007 g/l; others, 0.005 g/l. No analysis was made of the nickel

electrodeposits on the substrates discussed in this paper. However, nickel deposits on steel made from the same bath as above indicated an impurity analysis consistent with the above figures.

The reagents used for cathodic treatment were A.C.S. reagent grade.

"Hydride" Plating Procedure

It was indeed found that deliberate evolution of hydrogen on the substrate surface prior to plating markedly improved adhesion of the electrodeposit in the as-plated condition. The essential step in the preplating treatment is cathodic treatment of the metal so as to cause adsorption of hydrogen (with probable formation of surface "hydrides"). This cathodic treatment may be carried out in any electrolyte which does not contain ions of platable metals. Conveniently, dilute mineral acid or alkali metal hydroxide solutions may be used. In this method, the acid etching step may be eliminated, so that no dimensional changes in the substrate occur. However, if the original surface of the substrate is unsound (scale, metallurgically unsound surface skins, etc.) an etch is needed for cleaning purposes.

An example of the procedure is:

1. Soak in alkaline cleaning solution at 180°-200°F.
2. Rinse.
3. Etch in 10% (wt) HF (see Note 1). Immersion—Ti, Zr, Hf. Anodic at 50 asf—V, Nb, Ta, Mo, W.
4. Rinse.
5. Cathodic for 5-15 sec at 10-100 asf at room temperature in a suitable electrolyte (see Note 2).
6. Rinse.
7. Nickel plate for 30 sec to 2 min: $NiSO_4 \cdot 6H_2O$, 300 g/l; $NiCl_2 \cdot 6H_2O$, 37.5 g/l; H_3BO_3, 37.5 g/l; 65°C; 5-100 asf; pH = 4.
8. Rinse.
9. Plate as desired.

Note 1. This step is optional, and is needed only if it is desired to remove the surface and prepare a new, clean one.

Note 2. Suitable electrolytes are 2% (wt) HCl, H_2SO_4, HNO_3, HF, KOH, NaOH. The anode should be inert; platinum was used in the laboratory study.

If the part which has been plated is to be subjected to high temperatures during use the hydrogen present under the deposit (in any form) will cause blistering, and lifting of the deposit may result. For such applications, the following procedure is used:

1-8. As above.
9. Dry.
10. Vacuum fire at 450°-750°C until gas ceases to be evolved.
11. Nickel strike (Wood's nickel), then plate as desired.

In either of the above procedures, iron plating may be substituted for nickel plating in step 7.

The above procedures were used to obtain adherent deposits (0.2-0.3 mils thick) of Ni and Cu on Ti, Zr, Nb, Ta, Mo, and W. It is concluded that the procedure would be satisfactory for plating any group IV, V, or transition metal. Adhesion was determined qualitatively only. In the case of wire substrates, conventional bend tests were employed. For rigid substrates, knife or chisel tests were employed. Details of such tests have been given by Ferguson (33). Adhesion was determined on 0.2-0.3 mil deposits only. Undoubtedly, lower adhesion values would be obtained with thicker coatings. However, within the range of coating thicknesses which was explored, the above method gave results equal to or better than those obtained using conventional etching treatments.

Hydrides on the Surface

The above procedure has been referred to as a "hydride" plating process. The reason for this was to distinguish this procedure from use of conventional cathodic cleaning, as for example, in the preparation of zinc base die castings for electrodeposition, or in the activation of stainless steels prior to plating. In these cases, the saturation of the surface with hydrogen, *per se*, is not the object of the treatment. For the transition metals under discussion, such cathodic treatments have apparently been largely avoided in the past, because of the known ease with which these metals form hydrides. By contrast, this method employed here deliberately saturates the surface with hydrogen.

The word hydride was put in quotation marks in the preceding section because, unfortunately, the very limited scope of the work did not permit proper examination of the cathodically treated surfaces to verify the manner in which the hydrogen was present. However, general reviews on metal hydrides (34, 35) suggest that the hydrides of interest in this paper are so-called "metallic" hydrides. Such materials possess a metallic structure and have metal alloy-like characteristics, lacking stoichiometric formulas characteristic of true electron bonding [for example, Moeller (35) cites $ZrH_{1.92}$, $TaH_{0.76}$, $VH_{0.56}$]. X-ray determinations show the lattice of the substrate metals to be distorted, suggesting that the diffusion of hydrogen is interstitial in nature, resembling formation of a metallic solid solution. The hydrogen probably is present in the atomic state, in view of the strong reducing properties of such hydrides. There is evidence that transition metals of group IV, and to a lesser extent, those of group V, form semimetallic hydrides, i.e., hydrides in which evidence of chemical bonding is stronger, and stoichiometric formulas can be obtained. A hypothesis concerning the role of such semimetallic hydrides in plating is presented below.

In any event, all the transition metals are characterized by a tendency to absorb, occlude, or chemically bond with enormous amounts of hydrogen (palladium, for example, taking up 1000 of its volume of hydrogen when treated cathodically). With reference to the procedures discussed in this paper, Hüttig (36) found that Ta takes up about 0.8 H/Ta at room temperature, this figure falling to a very low value above 700°C, indicating that a true chemical bonding is not present, at least at elevated temperatures. Transition metals of group VIII (Fe,

Co, Ni) have high permeabilities at elevated temperatures, but absorb little hydrogen reversibly at elevated temperatures. Thus, Hüttig (36) cites an absorption of 0.0004 H/Ni, Fe, or less at 700°C. Thus, in the procedures outlined in this paper, the heat treatment after plating would serve to remove hydrogen from the substrate without adversely effecting the plated deposit. When hydrides of the metals discussed above are removed by heating in a vacuum, decomposition is virtually complete at 800°C (27, 32).

No investigation was made of why it is desirable to have a surface covered with hydride prior to plating (if, indeed, such is the case). Possibly, lattice structure is of importance in this connection. Transition metals of groups V and VI are body-centered cubic. Metals of group IV may be hexagonal close packed, but hydrogen tends to stabilize the body-centered cubic form (the β-form) (26). Niobium and tantalum hydrides, at lower hydrogen levels, show a definite body-centered cubic lattice (27, 28). With higher hydrogen contents, transition metal hydrides of groups IV and V tend to form face-centered cubic or face-centered tetragonal structures (29-31). Since nickel is usually deposited in a face-centered cubic lattice, it can be seen why the presence of a hydride of similar structure would augment adhesion since electrodeposits adhere best when deposited in the same lattice form as that of the substrate.

Electroplating on Niobium and Niobium-Titanium Alloys

In the course of the laboratory investigation cited above, particular attention was paid to the problem of plating on niobium and a 75% Nb-25% Ti alloy. The procedure given above was found satisfactory. Equally satisfactory is an etch method suggested by Faust and Beach (7):

1. Etch in HF (49% wt) with a.c. at 200 asf.
2. Rinse.
3. Dip in 50% (vol) HNO_3 (s.g. 1.43) and 2% (vol) HF (49% wt) to desmut.
4. Rinse.
5. Plate with Ni or Fe.
6. Bake at 400°F for 22 hr.
7. Heat treat at 1300°F for 1 hr to insure good diffusion bonding.

However, this method is not ideal when close dimensional tolerances are to be maintained. The "hydride" plating procedure would get around this problem, but involves heat treatments just as does the method of Faust and Beach. Accordingly, further work was done to determine whether a method could be developed which would avoid both etching and annealing treatments, for cases where close dimensional tolerances must be maintained and where the nature of the assembly does not permit annealing. Following the type of procedure used successfully with metals such as aluminum, a brief investigation was made of the feasibility of anodizing the substrate as a basis for electrodeposits. Such a procedure would remove no readily detectable amount of metal, require no activation step, eliminate smutting, and obviate the need for subsequent annealing operations to remove occluded hydrogen and/or hydride.

The procedure when using the anodizing method is:

1. Soak in alkaline cleaning solution at 90°C for 2 min. Any strong ferrous electrocleaner may be employed satisfactorily.
2. Rinse.
3. Anodic in 10% (wt) NaOH solution at about 5 v at room temperature to produce yellow (straw) colored film on the substrate. (Any metal not attacked by NaOH may be used as cathode.)
4. Rinse.
5. Coat with nickel or iron: $NiCl_2 \cdot 6H_2O$, 220 g/l; HCl (sp. gr. 1.18), 125 ml/l; 25°C; 30 asf.

When visibly covered with nickel, rinse and plate: $NiSO_4 \cdot 6H_2O$, 300 g/l; $NiCl_2 \cdot 6H_2O$, 37.5 g/l; H_3BO_3, 37.5 g/l; 65°C; 5-10 asf; pH = 4.

Or, if iron is desired: $FeSO_4 \cdot 7H_2O$, 300 g/l; $FeCl_2 \cdot 4H_2O$, 40 g/l; $(NH_4)_2SO_4$, 15 g/l; 60°C; 10-20 asf; pH = 4.

6. Rinse.
7. Dry.
8. Heat to red heat in air, or in vacuum for about 2 min.

In the anodizing treatment, the color of the anodized film is critical, the other conditions are not. For example, the NaOH may be as dilute as desired, consistent with rendering the solution conductive. It may be as concentrated as desired, up to the limit of solubility. Temperature of the solution may lie anywhere between freezing and boiling. Formation of an improper film may be detected readily by visual means, by observing the color, as follows: (a) colorless—too thin, (b) yellowish-brown—slightly too thick, and (c) blue or purple—much too thick.

In general, increased film thickness is favored by lower temperatures, higher solute concentration, and higher voltage. Therefore, based on the color of film obtained, suitable adjustment of temperature, concentration, and voltage may be made. The NaOH may be replaced by other alkali metal hydroxides, alkaline salts such as alkali metal phosphates, carbonates, and silicates, and by proprietary alkaline cleaning solutions, particularly those designed for cleaning ferrous parts.

It is possible to combine the cleaning and anodizing steps by utilizing PR in the cleaning step:

1. PR treatment in a strong alkaline electrocleaning solution at 90°C at about 5 v, with a cycle of 8 sec anodic and 4 sec cathodic, with treatment time of 2 min.
2. As in steps 4-8 above.

No metallographic cross sections were prepared, but careful stripping indicated that the anodized coating remains on the Nb or Nb-Ti after electroplating. This anodizing procedure has been used to electrodeposit Ni and Fe on Nb and on an alloy of 75% Nb and 25% Ti. Heating the deposit to red heat did not cause blistering or peeling of the deposit, and adhesion remained good, (as determined qualitatively) in spite of the absence of a baking step. Thus, the anodizing method has the advantage over the acid etching and cathodic treatment methods of not requiring an annealing step, and has the advantage over the acid etching method of not attacking the substrate appreciably.

Manuscript received June 16, 1958. This paper was prepared for delivery before the Ottawa Meeting, Sept. 28-Oct. 2, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

A Radioisotopic Study of Leveling in Bright Nickel Electroplating Baths

Seward E. Beacom and Bernard J. Riley

Research Laboratories, General Motors Corporation, Detroit, Michigan

ABSTRACT

A radioisotope-containing addition agent has been synthesized and used as a component in a bright and leveling nickel bath. Investigation by autoradiography and counting techniques shows that this agent is deposited preferentially at the high points of an irregular surface, thereby substantiating a part of leveling theory. The radioactive addition agent also is used in an attempt to understand better the mechanism of formation of laminations in this type of nickel deposit.

In the sequence of events which leads to the production of brilliant, chromium plated parts, the chromium must be deposited on a bright and smooth nickel surface. Such a surface may be produced by buffing a matte or a semi-bright nickel deposit. As an alternative, it is possible to deposit directly, from baths containing organic addition agents, a nickel plate which is bright and which also tends to fill in the micro-irregularities of a surface to make it smooth. Any process which eliminates buffing operations is desirable.

The recognition that certain plating solutions can deposit more than the expected amount of metal in the small recesses or scratches in the basis metal to produce a smoother surface was reported by Meyer (1) in 1940 and also recognized in the patent literature, prior to the noteworthy contribution of Gardam (1a) in 1947. Although this phenomenon subsequently has been known by a variety of terms, such as "smoothing action" and "hiding power," here it is called "leveling." Leveling has been defined by Thomas (2) as the ability of an electroplating solution to produce deposits relatively thicker in small recesses and relatively thinner on small protrusions with an ultimate decrease in the depth or height of the small surface irregularities. If an irregular surface is considered to be a series of peaks and recesses, then any such action which deposits

more metal in a recess than on a peak contradicts normal plating expectancy. In normal plating, more metal would be deposited on the high current density areas which are the high points, or peaks, of an irregular surface. Thus, in addition to its practical significance, the phenomenon of leveling poses a problem which has enlisted the attention of many investigators, and which has led directly to the study reported here. For a comprehensive review of the whole problem of leveling, the report of Leffler and Leidheiser (3) is most informative.

There has been much speculation concerning the mechanism by which the phenomenon of leveling may occur in the electrodeposition of bright nickel. The situation is complicated by lack of agreement among investigators as to the effect on leveling of various plating conditions, including current density, temperature, agitation, and addition agent concentration (2, 4-7). There is, however, general agreement that an increase in polarization accompanies leveling action (4, 6-12). Some theories of the phenomenon assume that an organic addition agent which promotes leveling is adsorbed or codeposited onto the high points, or peaks, of an irregular surface (2, 4, 7-15). This adsorbed material presumably leads to localized polarization which partially inhibits the deposition of metal at the peaks and diverts current flow to recessed areas. Recent work of Watson and Edwards (7) supports this view. They show conclusively that there is increased polarization in solutions possessing leveling ability. Further, they apparently have identified the presence of addition agents in nickel deposits by a staining technique which, for example, caused a darkening on the peak areas of a deposit obtained from a bath containing thiourea. In his study of laminations, Vanderkooi (15) considered that the dark bands present in deposits contain either included addition agents or their reduction products. These observations point up the need for a technique which will show unambiguously the location of addition agents in leveling nickel deposits.

With the particular solutions used in this study, the deposits formed are laminated in structure. While it is known that leveling can be achieved in unlaminated deposits, a theory which can account at least in part for leveling must be compatible with lamination formation.

The purpose of this study is twofold: to determine if an organic agent known to promote leveling is adsorbed preferentially or codeposited on the high points of an irregular surface, and to develop radiotracer techniques suitable for determining the location, within electrodeposits, of a radioactive organic addition agent.

The work of Vanderkooi (15) has shown that the brightener system sodium allyl sulfonate (16) and N-allyl quinaldinium bromide (17) produces bright, leveling, and laminated nickel deposits. These organic addition agents were used in a Watts type nickel bath to produce the electrodeposits examined in this study. The sodium allyl sulfonate was radioactive due to the use of S-35 in its synthesis.

Experimental

Synthesis of radioactive sodium allyl sulfonate.—The microsynthesis of sodium allyl sulfonate containing the radioactive isotope S-35 is one reported by Hoekstra (18). The metathesis reaction is carried out between allyl bromide and sodium sulfite containing S-35 as the labeled atom. One-millimole amounts of each of the reactants are heated together in a closed system at 60°C for 35 hr. Excess allyl bromide is extracted by ether using a Soxhlet extractor. The product was dissolved in water to yield a solution concentration such that 1 ml contained approximately 0.003 g of radioactive sodium allyl sulfonate. A radiochemical analysis of the final product showed a recovery of about 95% of the original activity present in the sodium sulfite.

Plating procedure.—The stock nickel solution was a Watts type bath containing nickel sulfate, 300 g/l; nickel chloride, 30 g/l; boric acid, 30 g/l; and a proprietary wetting agent, 5 ml/l. The *p*H was adjusted to 3.0. Plating was carried out in a small Lucite cell, 2 in. long by 1 in. wide by 3 in. deep. A temperature of 56°-58°C was maintained by immersing the plating cell in a constant temperature water bath. The anode was electrolytic nickel, and agitation was provided by a Hull Cell agitator operating a Lucite paddle which made 110 oscillations per minute. The current density range was from 10 to 55.5 amp/ft^2, and the plating times varied from 20 to 100 min depending upon the thickness of deposit desired. Due to rapid changes in *p*H of the small volume of solution used, frequent additions of dilute sulfuric acid were made to maintain a *p*H range from 2.6 to 3.5.

Inasmuch as a surface consisting of peaks and recesses was desired, grooved cathodes were prepared from brass blocks 1.75 in. by 1 in. by 0.125 in. Grooves 0.030 in. deep, with an included angle of 90°, were cut into one face of the blocks parallel to the long edge. The cathodes had 13 peaks and 12 recesses. To obtain foils of the plated metal, it was necessary to provide a passivated surface. Therefore, the brass cathodes were plated first with a thin deposit of nickel from a sulfamate bath and then passivated by immersion for 1 min in a 0.05% potassium dichromate solution.

The organic addition agent was added to the nickel stock solution in the form of radioactive sodium allyl sulfonate (1 ml equals approximately 0.003 g). Additional nonradioactive sodium allyl sulfonate was added to bring the total concentration up to a range of from 1.5 to 2 g/l. In some of the experiments, a second organic addition agent, N-allyl quinaldinium bromide,[1] was added in sufficient amounts to produce concentrations from 2 to 6 mg/l. All of the additions and plating procedures were carried out under radiochemically safe conditions.

At the conclusion of plating, the cathode was withdrawn from the cell, rinsed with distilled water, and then a scalpel was used to remove the foil from the cathode block. The foil was scrubbed on both top and bottom to remove any adhering material, rinsed with water and with alcohol, and then dried under an infrared lamp preparatory to counting and

autoradiography. The data pertinent to the plating conditions and foils produced are presented in Table I. These results are representative of the 65 plating experiments carried out and the 55 nickel foils produced. The foils varied in thickness from 0.0005 to 0.0025 in.

To check whether or not these solutions and conditions produced leveling, portions of cathodes with two different degrees of surface irregularities were plated under conditions identical with those reported above. Duplicate specimens were plated, one in a solution containing only sodium allyl sulfonate, the other in a solution containing both sodium allyl sulfonate and N-allyl quinaldinium bromide. The plated specimens were cross-sectioned, mounted, polished, and etched in 1-1 nitric acid-acetic acid. Fig. 1 shows photomicrographs of a precision reference specimen of surface roughness (2), with a

peak-to-valley height of 0.002 in., plated from a solution containing sodium allyl sulfonate. The original and final roughness measurements made with a topographic microscope showed that leveling did occur. The solution containing both addition agents produced similar leveling.

Counting procedures and autoradiography.—The counting of the plated cathodes and the foils removed from these cathodes was carried out in a proportional flow counter. This procedure provided a gross count of the activity on the top and bottom of the foils but gave no information relative to the distribution of the radioactivity across the surface of the sample. It did, however, give data which were useful in computing autoradiographic exposure times. Several innovations were tried to give more quantitatively useful data which might augment the results of autoradiography. A 0.005-in. thick piece of lead foil was corrugated to duplicate the surface of the nickel foils by pressing the lead into the grooves of one of the cathodes. A single slit, 0.002 in. wide by 1 in. long, was cut in the center of one peak. This piece was then overlayed on a radioactive foil so as to expose only one peak at a time. In this manner, all of the peaks on a foil were counted individually. By turning the lead foil over, it was possible to fit the slit into a valley and count each valley individually. Continuing in this way, a profile of the peak and valley counts was made for both sides of a foil. The results of this method are shown in Table II.

The primary source of information on the distribution of the radioactivity over the surface of a foil has been autoradiography. Since the S-35 gives off a very weak beta ray, it was considered necessary to have the foil in direct contact with the film. Therefore, most of the foils were flattened mechanically, placed between two pieces of film, and then weighted to insure good contact. Past experience has shown that both chemical and pressure effects on the film can result from this method of exposure. In order to insure that everything which appeared on the final autoradiogram was due to radioactivity and not to side effects, foils containing no radioactivity were exposed under identical conditions to check possible chemical interaction and the effects of pressure. These tests showed no influence of side effects. Although several types of film were used,

the autoradiograms shown in this report were made on Eastman Kodak Type AA film.

Composite data on the counting and autoradiographic exposures are given in Table III, and representative autoradiograms of the top and bottom surfaces are shown in Fig. 2.

The reproductions of the autoradiograms shown in Fig. 2 are positives which are identical with the original autoradiograms. The dark areas indicate the regions of the foils which contain radioactivity. Since it was necessary to make an intermediate negative to achieve this reproduction, some detail has been sacrificed. All of the notches or holes cut into the foils and visible in the autoradiograms were cut so as to identify a peak area. This system of notching not only allowed identification of the individual foils by the number and position of such notches, but also precisely located the peaks and recesses on a given foil.

In addition to visual inspection, densitometric readings on a recording densitometer have been made and are recorded below each autoradiogram in Fig. 2. The apparatus employed was a L&N Linear Recording Densitometer with a General Motors Research Laboratories light source and scanning device. A slit width of 0.005 in. (0.127 mm) was used since narrower ones did not contribute to detail and led to larger instrument fluctuations.

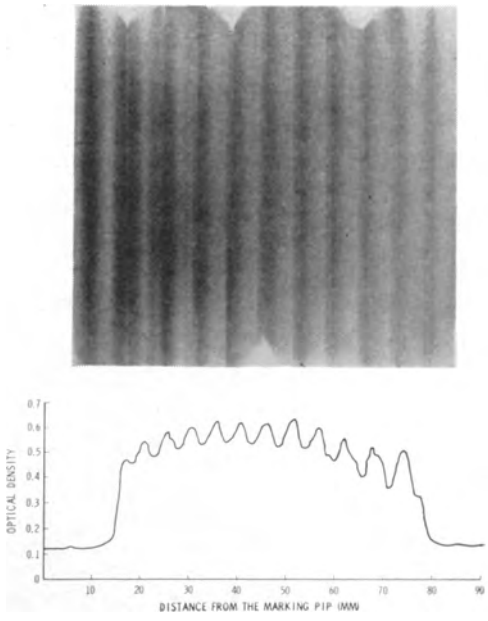

Fig. 2a. Autoradiogram and densitometer trace for the "top" of a foil containing only sodium allyl sulfonate.

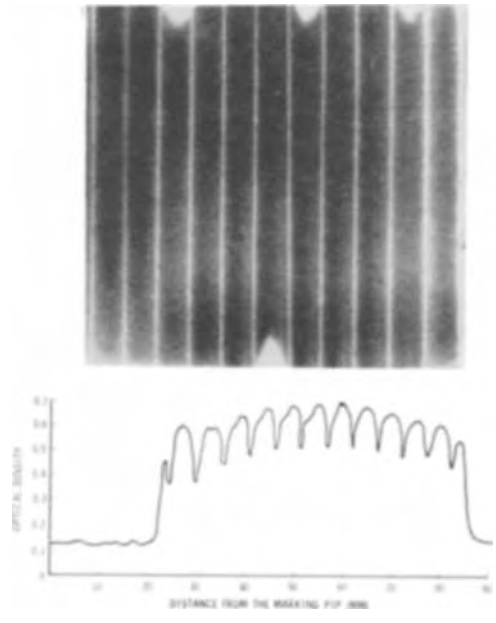

Fig. 2b. Autoradiogram and densitometer trace for the "bottom" of a foil containing only sodium allyl sulfonate.

Because this system recorded a marking pip each 0.5 mm, it was possible, by placing a mark near the edge of the autoradiogram, to measure distances from the edge accurately. The instrument was calibrated with a standard step wedge prior to use. Thus, the densities recorded are the actual densities from the exposure to radioactivity when all possible variables in the film processing are kept constant.

As was indicated previously, most of the foils were flattened mechanically to obviate the differences in distance between the peaks and recesses, and the film, during autoradiography. Some of the foils were quite brittle, thereby making this flattening process very difficult. A check was made, therefore, with a representative foil, to determine if the mechanical flattening gave any advantage,

either for the autoradiogram or for the subsequent densitometer trace. The foil was formed and then exposed for a given length of time to produce its characteristic autoradiogram. The foil was flattened then and another autoradiogram obtained on the same type of film which was exposed for the same length of time and processed under the same conditions. Visually there were no significant differences noted on the autoradiogram, and the densitometer traces, shown in Fig. 3, indicated that there was no advantage in mechanically flattening these foils.

Results and Discussion

An examination of the autoradiograms shown in Fig. 2 reveals a greater darkening on those portions of the film which were irradiated by the peaks of the foils. In those autoradiograms labeled "top," the difference in density of the lines produced by peaks and recesses is evident, but there is also greater smearing of radioactivity than is apparent on the corresponding "bottom" autoradiograms. The concentration of activity in both instances, however, is much higher on the peaks than in the recesses. This is especially true with the "bottom" autoradiograms which show that the activity is concentrated on the obverse of the "top" peaks. This differential darkening of the films means that there is greater radioactivity emanating from the peaks than from the recesses.

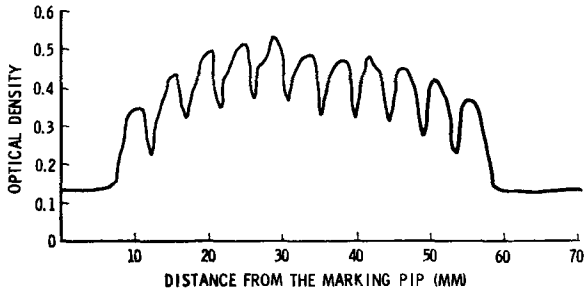

Fig. 3a. Densitometer trace of an autoradiogram made from a foil as it was removed from the brass cathode.

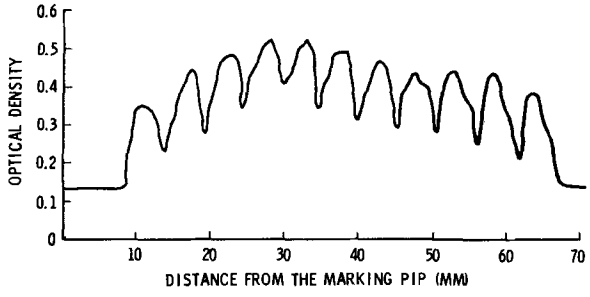

Fig. 3b. Densitometer trace of an autoradiogram made from the same foil after it was mechanically flattened.

The slit-counting data for radioactivity on the peaks and in the recesses, recorded in Table II, serve as quantitative confirmation of the results shown visually by the autoradiograms. Likewise, the densitometer traces made from the autoradiograms show quantitatively the results of distribution of radioactivity over the entire surface. The concentration of activity is highest on the peaks of the "top" autoradiograms and on the obverse of the peaks on the "bottom" autoradiograms. These traces also indicate the manner in which radioactivity increases from a minimum at the bottom of a recess to the maximum at a peak.

In explanation of these results, it is apparent that the ratio of radioactive material (sodium allyl sulfonate or a reduction product containing the S-35) to deposited metal is greater on the peaks than in the recesses. Consequently, there is less self-absorption of the radioactivity by the thinner nickel metal on the peaks and, therefore, a greater darkening of the film occurs. This explanation is consistent with the fact that in leveling less metal is deposited on the peaks and more metal is deposited in the recesses of an irregular surface. In order to initiate the leveling process, the addition agent first must be concentrated preferentially on the peaks. The autoradiograms and the slit-counting data appear to confirm the assumption of a preferential adsorption or codeposition of the addition agent on the peaks. Actually these results, as well as those recorded in the literature, show only that the agent is concentrated at the peak area. The mechanism of this concentrating action has not yet been demonstrated satisfactorily. While some investigators (7, 14) have shown that certain addition agents apparently are deposited with the metal in an unchanged or unreduced state, the work of Hoekstra (18) and Vanderkooi (15) strongly indicates, in the case of sodium allyl sulfonate, that its reduction

product, sulfide ion, is present in the electrodeposited nickel metal. The present work, with this same addition agent, shows only that the labeled S-35 atom is located in the deposit as no attempt was made to distinguish between the possible presence of the sulfonate or the sulfide.

With the type of bath employed in this study, the leveling process is accompanied by the formation of laminations (2, 4, 6, 9, 11, 15, 18, 19). Several investigators (6, 15, 18) have speculated that the "dark" bands contain sulfur, probably in the form of sulfide. It has been proposed by Vanderkooi (15) that the "dark" bands are formed by the reaction between nickel and the reduction product of the sodium allyl sulfonate, while the "light" bands are nickel metal. In order to account for the formation of these laminations, as they accompany the leveling process, it is convenient to assume that both phenomena start with a preferential adsorption of the addition agent on the peaks. It would appear, from an inspection of Fig. 1, that the formation of the laminations is some type of cyclic process wherein alternate layers of metal, and the addition agent or its reduction product, are deposited. The start of this cyclic process and the inhibition of metal deposition on the peaks can be explained by an assumption of preferential adsorption of addition agent.

Summary

A radioactive organic addition agent, sodium allyl sulfonate, containing the beta-emitting S-35 atom, has been synthesized. This addition agent has been used as a component in a bright nickel plating bath to produce leveling nickel deposits. A radiochemical technique has been developed to locate radioactivity in the deposited metal. Autoradiograms and counting data from the nickel foils produced show that the radioactive addition agent, or its reduction products, is preferentially adsorbed or codeposited on the high points of an irregular surface. On the basis of this evidence, confirmation is obtained for a theory which accounts partially for leveling action in the type of bright and leveling nickel solutions considered in this study.

Determination of Crystal Orientation by High Intensity Reflectograms

G. H. Schwuttke

Research Laboratories, Sylvania Electric Products, Inc., Bayside, New York

ABSTRACT

An instrument based on the light figure technique for optical orientation of Ge and Si is described which fulfills all requirements for a fast precision orientation of single crystals. The dependence of high intensity reflectograms on etching conditions is shown and standard etching specifications are given.

Reflectograms are light figures obtained by the reflection of light from an etched crystal surface. This method has been developed by mineralogists to obtain information on the location of crystallographic planes and zones in crystals. Many investigators (1) contributed to the light figure method. The method was first applied to germanium and silicon by Wynne and Goldberg (2) and Faust (3). More recently Wolff, Clark, and Wilbur (4) showed that reflectograms of Ge and Si turned out to be very clear and distinct in accordance with the low coordination number and the strong directional bonding forces of these materials.

If reflectograms are used for the orientation of monocrystals, they give excellent accuracy, competing with that achieved by the use of Laue's back reflection technique. Crystals can be oriented accurately by means of reflectograms as already shown for Ge and Si by Wolff and co-workers (4) who oriented Ge and Si single crystals using the (111) reflection within 1.5 min of arc.

The purpose of this paper is to report on a practical instrument for routine orientation work. By use of this instrument it is possible to orient a crystal in any direction and then cut along this predetermined direction without removing the crystal from its original mount. The reflectograms produced are very bright, so the instrument can be operated in a well-illuminated room. The accuracy of orientation is limited by the goniometer error to 12 min of arc for the (111), (110), and (100) reflections in Ge and Si.

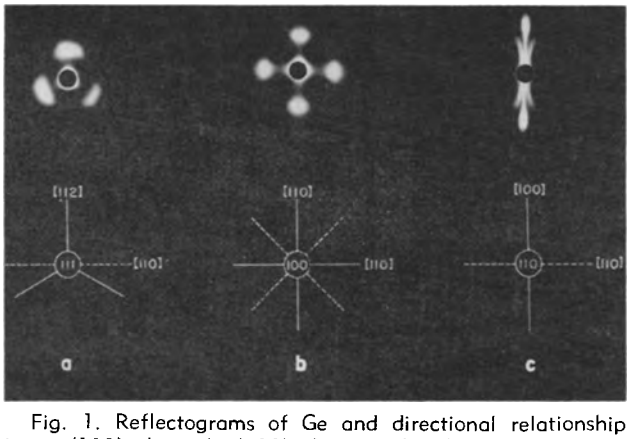

Fig. 1. Reflectograms of Ge and directional relationship in: a, (111) plane; b, (100) plane; c, (110) plane.

Instrument and Method

For optical orientation the crystal surface first is ground and then etched in a specified way. A large number of pits of microscopic size thus are created at the surface of the crystal. These pits are bounded by minute facets which are more or less perfect planes. If a beam of light is directed to such a surface, it splits into a number of components after reflection. If the reflected beam is intercepted by a screen, a light pattern or reflectogram is seen. These patterns show the symmetry of the crystal in the direction of the incident light beam. The pattern for the [111] direction thus shows threefold symmetry (Fig. 1a), the pattern for the [100] direction fourfold symmetry (Fig. 1b), and the pattern for the [110] direction twofold symmetry (Fig. 1c).

The instrument (Fig. 2) consists of an optical system A and a goniometer B for mounting the specimen. The sample can be rotated in both the vertical and horizontal plane without changing the crystal surface to screen distance. A third circle attachment C allows a complete rotation about the horizontal axis of the mounted crystal. The optical system A consists of a 30 watt concentrated arc lamp and a f/1.9 Cintar lens of 50 mm focal length. The screen is a steel plate covered with white paper. A convergent beam of light is focused on the screen, thus achieving very bright reflectograms (5). To orient an ingot, it is cemented onto attachment D as shown in Fig. 2 and D is placed in grooves on goniometer B after removing slice attachment C. The goniometer is built strongly enough to be placed on a cutting machine.

Crystal orientation with a precision of $\pm$ 0.5° of arc is easy to achieve without too much concern for the etching technique. For greater accuracy, however, the etching process is critical. The perfection and shape of the pits developed is strongly dependent on composition of etchant, temperature of etchant, and etching time. For instance, the action of the etching medium might be such that only cubic planes are exposed, thus producing in the (111) plane the well known triangular pit, formed by a three sided pyramid; in the (110) plane an indentation which is saddle shaped; and in the (100) plane a square hole with an uneven bottom. Since the surface in the lower part of these pits is uneven, the resulting reflection is diffused. If these diffused

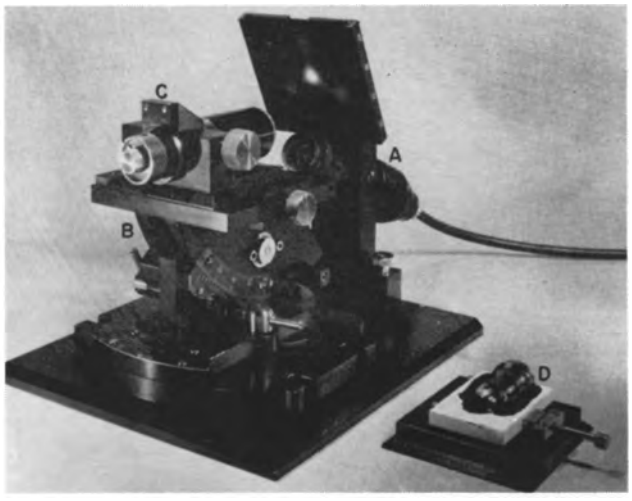

Fig. 2. Instrument for optical orientation: A, optical system; B, goniometer, transferable to cutting mochine; C, third circle attachment; D, ingot mounted for orientation and cutting.

reflections are used for orienting crystals, the accuracy will be less than that obtainable with distinct light figures which correspond to etch pits with flat bottom sections parallel to the plane to be oriented.

The following experimental procedure was adopted: the crystal surface to be checked was hand polished on a glass plate using a water slurry of 500 mesh silica and then etched. The etching solutions, the etching time, and etching temperature as used for Ge and Si are given in Table I. It should be noted that these data apply only to fresh etching solutions. Different etching solutions can be used, but of the ones tried, those listed in Table I gave the most intense reflectograms.

The side walls of the pits in all three planes show a terraced arrangement, corresponding to high index or vicinal planes. These side walls are responsible for the reflections adjacent to the distinct (111), (110), and (100) reflections and aid in identifying different reflections, but their degree of perfection is strongly dependent on etching variables (see Fig. 4 in Ref. 4).

Reflectograms can be used for orientation of single crystals and bicrystals, for tilt angle determination in bicrystals, and many other applications. Once the crystal is etched, measurements can be made in approximately 2 min, a great improvement over the Laue back reflection method.

Table I

	Reflection	Composition of etchant	Time, min	Temp, °C
Ge	(100)	1½ P. HF 2 P. H_2O_2	12	24
	(110)	4 P. H_2O	12	30
	(111)	1 P. HF 2 P. H_2O_2 4 P. H_2O	6	24
Si	(100)	50% NaOH solution	12	65
	(110)	or	12	65
	(111)	50% KOH solution	6	65

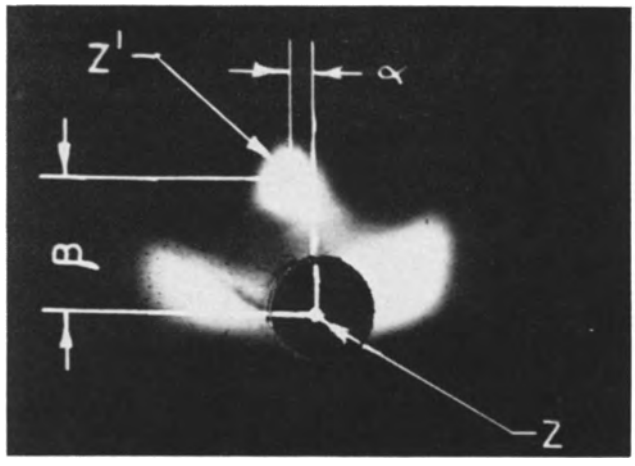

Fig. 3. Ge-(111) reflectogram of 10° misorientation

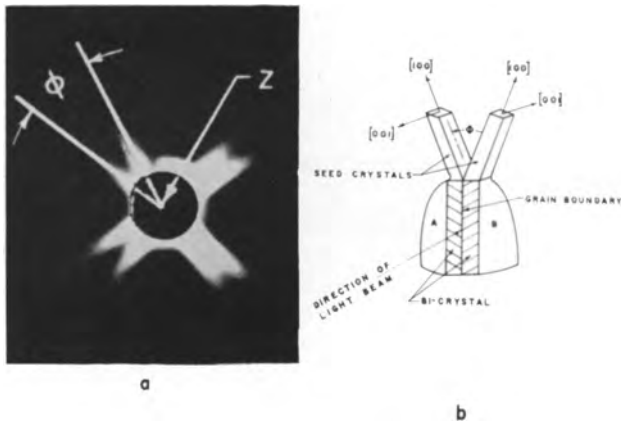

Fig. 4. (a) Tilt angle ϕ determination in a bicrystal by means of reflectograms. (b) Sketch of a bicrystal showing tilt angle ϕ between the two crystals.

Figure 3 shows a (111) reflectogram of a Ge crystal which is approximately 10° off orientation. The angle of deviation is given by α and β and is measured by turning the goniometer circles until the center reflection coincides with a predetermined point on the screen obtained for zero settings of the goniometer from a mounted mirror. The horizontal and vertical scale readings of the goniometer then give the amount of misorientation.

An example of tilt angle determination in a bicrystal is represented in Fig. 4a. This picture shows a reflectogram of a bicrystal taken in such a way that the light beam was straddling the grain boundary. The bicrystal is tilted around the [001] direction as shown schematically in Fig. 4b, therefore the reflectogram is taken in the (001) plane which is common to both crystals. Two superimposed (001) patterns show up. The tilt angle is the rotation angle ϕ which can be measured easily.

Water-Stabilized Arc Tests on Nonmetallic Materials

M. Dank, R. A. Nelson, W. R. Sheridan,[1] and W. H. Sutton

Missiles and Space Vehicles Department, General Electric Company, Philadelphia, Pennsylvania

ABSTRACT

Evaluation of erosion rates on possible high-temperature resistant materials have been carried out in a water-stabilized arc. General classes of materials tested include: graphites and impregnated graphites; ceramics, principally oxides; plastic-ceramic composites; and reinforced ceramics. Results on erosion rates as a function of power dissipated in the arc and time are given, and a general ranking of these materials for high-temperature use is discussed.

Components to function at ultra-high temperatures for short periods range from liners for uncooled rocket engines, where the heat is generated internally, to leading surfaces of high-speed airplanes and missiles which are subject to large heat fluxes as the result of aerodynamic heating, to the experimental machines used in thermo-nuclear research. Temperatures may range up to thousands of degrees; the time of exposure ranges from fractions of a second to minutes.

In order to select or develop materials from which such components can be made, samples of the materials must be tested in an environment comparable to that to which they will be exposed in service. It is desirable that the test duplicate not only the high temperature, but also structural loading, thermal shock, and attack by the gaseous environment to be imposed on the component. One device which has been found useful for the rapid and economical evaluation of materials for resistance to high-temperature gas flow is the fluid-stabilized electric arc.

An arc operating in the vortex formed by a rapidly swirling body of water has developed extremely high temperatures (1). This is due to the increased current density arising from the restricted cross-sectional area of the vortex and the cooling of the outer arc regions, which forces most of the current to flow in the center. Peters (2) described an arc in which the cathode consisted of a plate with a hole from which a stream of "plasma" is issued.

The arc used in the present work is struck in a vortex of water between a ½-in. diameter graphite rod as anode, and a graphite cathode which is in the form of a disk with a 3/16-in. hole in the center. The cathode is mounted in a water-cooled horizontal metal plate, which is at ground potential, while the anode is held by a collet in a vertical position directly below the hole in the cathode. Figure 1 is a schematic diagram of the water-stabilized arc. A Lucite "swirl chamber" surrounds the anode. During operation, water is introduced tangentially into this chamber at 36 psi and forms the vortex in which the arc burns.

The power supply consists of four welding generators connected in series. It has been found desirable for stable operation to dissipate about one half the power in a ballast resistor connected in series with the arc, since when the arc is first struck the voltage and current tend to fluctuate. The sample is

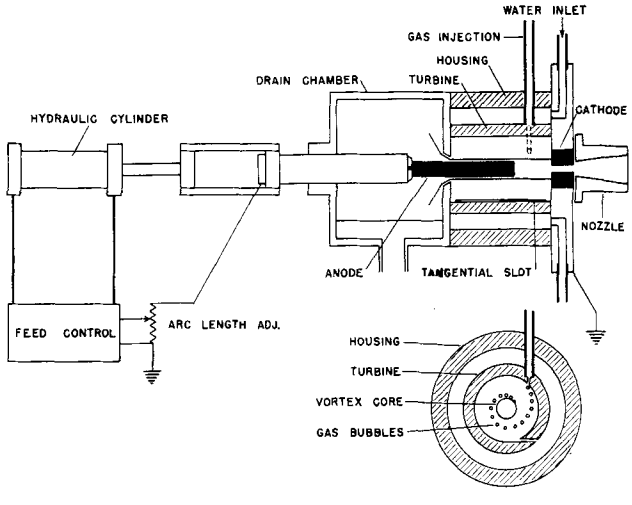

Fig. 1. Schematic diagram of water-stabilized arc

[1] Present address: Sylvania Electric Products, Inc., Buffalo, N. Y.

not introduced into the testing position until stable operation has been obtained. Arc voltage is maintained at 180 v by means of a voltage-sensing device connected across the arc and controlling a hydraulic mechanism which feeds the lower electrode at the proper rate to maintain this voltage. The current under these conditions is 350 amp, giving a power dissipation at the arc of 63 kw.

The samples are ½-in. diameter rods 3 or 4 in. long. Usually flat ended samples are used, but in some cases hemispherical ends have been provided: the hemispherical shape is generally lost rapidly. The sample is introduced so that its axis is aligned with the axis of the arc and its end is one inch above the hole in the cathode. An exposure time of ten seconds is usual and an automatic timer records the exact duration of exposure.

With such a facility it is possible to compare various materials for resistance to high temperature. Samples are weighed and their length measured before and after test. Results may be expressed as rate of loss in milligrams per kilowatt second and as loss of length. Such comparisons appear to be valid as long as exposure conditions are held constant.

It would of course be very desirable to define exactly the conditions to which the samples are exposed, but to date such exact definition has not been possible. Temperature, velocity, and composition of the plasma jet should be different at different locations within the jet.

Work has begun to measure conditions within the jet and some preliminary estimates are available. Temperatures have been estimated from 7,000° to 12,000°K, and velocities from 100 to 1000 m/sec. The composition at the center of the jet has been estimated to be as follows: 10% vaporized carbon; 5% carbon particles from the electrodes; 25% water vapor; 50% dissociated water vapor; 10% ionized atoms and molecules.

In spite of this uncertainty, the arc, used with constant operating conditions, is an excellent tool for preliminary screening and comparison of various materials. However, one useful parameter which may be measured with some accuracy is the rate of heat transfer to a body placed in the jet some distance from the cathode opening. By the use of both solid metal and water-cooled metal calorimeters, it has been possible to establish heat transfer rates averaged radially at various distances from the cathode. Typical results, using a graphite nozzle as a cathode to expand the jet, are shown in Fig. 2.

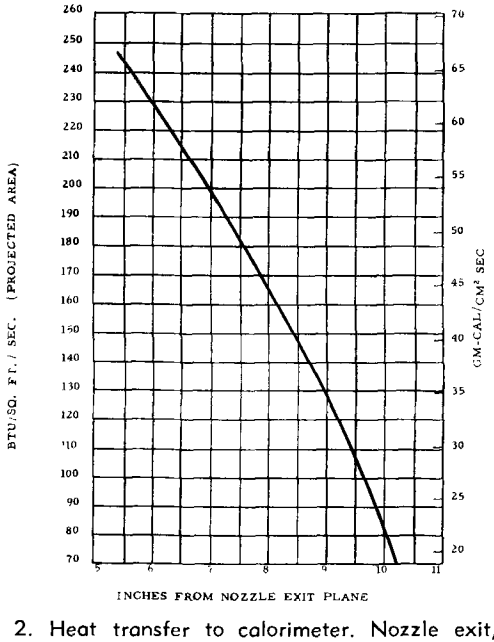

Fig. 2. Heat transfer to calorimeter. Nozzle exit, 1-in. diameter.

Not only is it important to determine which materials are most suitable for component fabrication, but also why. A high decomposition temperature and high specific heat are undoubtedly an advantage. An endothermic decomposition would also be favorable. Samples with low thermal conductivity appear to have an advantage; this is doubly useful since the interior of a component made of such material would remain at a relatively low temperature and better retain its mechanical properties during the service life of the component. An additional advantage of materials with low thermal conductivity is that the surface reaches an extremely high temperature, and heat flux due to radiation from the adjacent hot gases is minimized.

Various classes of nonmetallic inorganic materials have been fabricated and tested in the water-stabilized arc. These include: (*a*) graphites and impregnated graphites, (*b*) ceramics and reinforced ceramics, (c) ceramic-and-plastic composites.

It should be borne in mind that the ranking given these materials is based simply on erosion rates exhibited in the arc and with a high heat influx-short time application in mind. The ranking for a different environment (lower temperatures, longer times) may be very different.

Graphite and Impregnated Graphites

Graphite has many desirable high-temperature properties which makes it a likely structural material: its refractoriness, low density, low thermal expansion, high-temperature strength, availability of the raw material, machinability, etc. Unfortunately, the oxidation resistance, erosion resistance, and mechanical strength at intermediate temperatures may be too low to permit immediate utilization of any present graphite as a high-temperature structural material particularly in large pieces.

According to current theories, the permeable macrostructure which permits oxygen to penetrate the interior of the material and its microstructure, which is highly reactive to oxygen-containing gases at high temperatures, explains the low oxidation resistance of graphite. The use of pitch binders which partially volatilize during baking and graphitization results in a highly permeable macrostructure, while crystallization into a lamellar structure with weak binding between planes explains the ability of oxygen to break the interplanar bonds which results in low erosion resistance.

Attempts to overcome the undesirable effects of oxidation and erosion include experiments on densification, metal oxide and carbide coatings, and impregnation, chiefly liquid metal and liquid glass im-

pregnation of porous graphite. This last approach seems to be the most promising and the most likely to improve the high temperature oxidation and erosion resistance of graphite.

Above 1500°C, graphite becomes stronger mechanically in contrast to most nongraphitic materials; below this temperature, its mechanical strength is about 1/10 that of metals. Its thermal shock resistance is excellent compared to most ceramics but poor compared to metals. It shows practically no ductility below 2200°C, which means there is no relief of localized or unequal stress internally. However, recent work at the Jet Propulsion Laboratory has shown some ductility above 2200°C.

Graphite Materials System

Graphite materials systems can be divided into at least three types: (*a*) graphite structures filled with impregnant: the pores in the massive graphite being filled with an impregnant; (*b*) inorganic or organic structures filled with graphite powder; for example, a cast block of concrete having some of the same replaced by graphite powder; (c) an all-refractory system: a system in which all the ingredients are as equally refractory as graphite. An example would be titanium carbide; here the ingredients could all be added before the mass is graphitized.

Results of water-stabilized arc testing of graphites from many commercial sources showed a very small spread in erosion rates, the average value of which was 1.1 mg/kw sec. The average length loss was 0.25 cm, somewhat higher for more porous graphites.

The best impregnated graphites were found to be a series of composition consisting of silicon carbide and graphite, or silicon metal and graphite which converts to SiC on firing. These show a weight erosion of about 0.6 mg/kw sec and a length loss equivalent to the pure graphite. Since no other impregnant gave better results than pure graphite, the superiority of the carbide-bonded graphite systems seems established, although nitride and boride bonded systems are still to be tested. Other impregnants tested include: oxalic acid, epoxy resin, aluminum sulfate, sulfur, iodine, boric acid, and many others.

Typical test results for graphites and impregnated graphites are given in Tables I and II.

Ceramics and Reinforced Ceramics

Ceramic materials, in general, have poor thermal shock resistance because of their relatively high coefficients of thermal expansion and brittle characteristics. For this reason, most ceramic bodies are not suitable for applications where severe temperature gradients exist. However, successful attempts have been made to increase thermal shock resistance greatly by reducing considerably the thermal expansion coefficients. Unfortunately, the low-expansion ceramic materials are not very refractory. Another approach for improving thermal shock resistance has been to use refractory bodies which are relatively soft and similar to plaster of paris in texture. These materials, when exposed to sudden temperature changes, fail locally at the exposed surfaces while still retaining their strength.

The results of the arc tests on simple ceramics, mostly oxides, are given in Table III.

All samples were obtained from commercial suppliers and were given no further treatment. The fused MgO samples were in the form of 2 x 2-in. plates varying from ¼ to 1 in. in thickness. Since the plasma jet covered only a ½ in. circle in the center of the MgO plates, this undoubtedly contributed to the severe thermal shock observed.

A series of ceramic aggregates (listed in Table IV) reinforced by a cementing agent were tested; these unfired cemented bodies had previously exhibited excellent thermal shock resistance when subjected to the exhaust of a rocket motor. Several samples were made from castable mixes containing water, calcium-aluminate cement, or phosphoric acid, and aggregates of bubble alumina and zirconia, magnesia, several grades of commercial alumina grain, and silicon carbide. These samples were tested in the water arc, and the results are shown along with those of other materials in Table IV.

† F, fine; M, medium; C, coarse.
* Surface temperature by optical pyrometer 2450°C.

The various samples made of Al_2O_3 and MgO eroded quite rapidly compared to the SiC aggregates. Therefore, it appears that the aggregate-type rather than bond-type is more important with regard to erosion resistance. The results indicate that there are no significant differences between samples having different aggregate-size distributions, water content, density, and methods of preparation (casting, troweling, or tamping).

Ceramic-and-Plastic Composites

Although compositions containing organic plastics are not ordinarily considered as refractory materials, certain ceramic-plastic compositions show a surprisingly low erosion rate in the water-stabilized arc tests.

At 3000°C, the organic plastic decomposes into gas and residual carbon as coke on the surface. When glass is present, it fuses and forms a thin viscous layer on the surface which reduces the heat transfer to the model and protects it from the chemical action of the hot gases.

In the 8000°C plasma, even the glass is volatilized, so no liquid protective layer is formed. Here the erosion rate depends on the heat absorbed in converting plastic and glass to vapor at some high temperature and, in the case of supersonic flow, the reduction in heat transfer associated with the addition of the gas to the boundary layer. Since the atoms of the organic part are lighter than those of the glass, the volume of gas generated from a gram of the all-organic material is substantially higher than that from the glass-reinforced material.

Results of arc testing are given in Table V and relative erosion rates for ceramic plastic composites at different temperatures are given in Table VI.

Conclusions

1. A small water-stabilized arc, as described herein, is a suitable device for screening materials considered for short time service at extremely high temperatures. A large number of samples may be tested rapidly and at relatively low cost.

2. The results listed below have been obtained under the conditions described. Only the better plastics and ceramics are included; for example, some ceramics spalled badly and are omitted from consideration.

Materials	Loss of length (When exposed for 10 sec in the plasma 1 in. from the cathode)
Graphite	0.04 to 0.16
Graphite (impregnated)	0.04 to 0.13
Reinforced plastics	0.12 to 0.47
Ceramics	0.13 to 0.40
Copper*	1.0

* Copper is shown here for comparison only.

3. Extrapolation of these results to other thermal and chemical environments or longer periods of time should not be attempted.

Manuscript received July 25, 1958. This paper was presented at the New York Meeting, April 27-May 1, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

An Investigation of the Compound Silicon Boride (SiB_6)

Carl F. Cline

Research and Development Division, The Carborundum Company, Niagara Falls, New York

ABSTRACT

Single crystals of the compound silicon hexaboride have been prepared. Laue, rotation, and Weissenberg photographs indicate an orthorhombic cell with lattice parameters a = 14.39 ± 0.01, b = 18.27 ± 0.01, and c = 9.88 ± 0.01Å. The pycnometer density is 2.43 g/cm³. The average electrical resistivity of single crystals, based on a probe technique, is 0.2 ohm-cm. The melting point is 1950°C. SiB_6 has a Knoop hardness, with a 100-g load, of 1910 kg/mm².

The interest in hard and refractory materials has been prevalent from times dating back to Moissan at the turn of the century. Among the most elusive of these refractory compounds have been the borides of silicon.

Moissan and Stock (1) reported in their original work that they had prepared, by fusion of the elements, two borides, SiB_3 and SiB_6. The SiB_3 was obtained as black rhombic plates with a density of 2.52 g/cm³, and the SiB_6 as black irregular crystals with a density of 2.47 g/cm³. The borides were reported to be hard, to have high melting points, and to conduct electricity.

These properties interested other researchers (2-5) who were unsuccessful in their attempts to duplicate the original work. Recently, Samsonov and Latysheva (6) have reported the properties of a tetragonal SiB_3 phase prepared by hot-pressing the elements. Their results and interpretations were questioned by Ormont (7) who found discrepancies in their x-ray data. Samsonov and Latysheva also prepared a compound, SiB_6, which was studied by Zhuravlev (8) who reported a structure isomorphous with CaB_6.

Concurrent with the Russian research, a study of the silicon-boron system was underway in our laboratories. A preliminary report (9) has been issued on the formation of the compound SiB_6.

Experimental

Preparation.—A review of the methods of preparation of refractory borides and silicides indicated that the synthesis by a combination of the elements was the most logical place to start. The initial experiments were carried out by hot-pressing boron and silicon in a 1 to 3 weight ratio to a temperature of 1700°C. The hot-pressing was performed by induction heating of a graphite mold, which had a boron nitride liner and plungers, using a pressure of 2000 psi and an argon atmosphere. This technique permitted a minimum amount of carbon contamination. Spectrographic analyses of the boron and silicon are given in Table I. The x-ray identification of material obtained by the hot-pressing was difficult due to the presence in the system of unreacted boron which has a complex powder pattern.

To overcome this problem, synthesis experiments were carried out by fusion of the elements at a temperature of approximately 2250°C in an atmosphere of argon. The hold time at 2250°C was usually 1 hr. Fusion was carried out in a boron nitride crucible with a boron nitride lid. The crucible was placed in a graphite susceptor and heated by induction. Fusion experiments were carried out using weight ratios of silicon to boron ranging from 2:1 to 3:1. This was done so that sufficient silicon would be available to react with all of the boron, since a chemical separation of the boron from silicon boride would be extremely difficult. The fused mass was removed from the boron nitride crucible and acid-treated with a mixture of HF and HNO_3 to remove the last traces of free silicon. The crystals were then fused with KOH to remove boron nitride which had formed on the surface. A photomicrograph of a typical melt is shown in Fig. 1. A picture of the crystals after treatment is shown in Fig. 2. After treatment of the melt, the SiB_6 crystals are black and opaque, even when crushed to a fine particle size.

Structure.—A single crystal obtained by the fusion technique shown in Fig. 3 was examined using Laue, rotation, and Weissenberg techniques. The results indicated that the system was orthorhombic with unit cell dimensions of $a = 14.39$, $b = 18.27$, and $c = 9.88$Å. The sample was crushed and a powder pattern was run using a Geiger counter diffractometer. The measured interplanar spacings, as well as the relative intensities, are listed in Table II. CuK α radiation was used in all cases.

The number of molecules per unit cell, Z, was calculated from the pycnometer density of the compound. Using the observed density of 2.43 g/cc, a value of $Z = 40.9$ was obtained.

Chemical analysis.—The wet chemical analysis of silicon boride was carried out by first crushing the treated crystals down to −97 mesh particle size in a hardened steel mortar. A 0.2-g sample was analyzed for boron by the method of Blumenthal (10). The silicon analysis required a 0.5-g sample and was carried out using the conventional sodium carbonate fusion. The boron was removed by dissolving out the oxide, after the fusion, by acidifying and treating with methyl alcohol. The alcohol-treated mass was then evaporated to remove methyl borate. Percentages of boron and silicon in crystals prepared by the fusion technique average 69.7 and 29.3, respectively. Values are shown in Table III.

The chemical analysis of SiB_6 is quite close to theoretical values of 69.8% boron and 30.2% silicon. In all cases the boron analyses were run in duplicate. Nitrogen analyses indicated less than 0.2% N_2 present in the crystals. The SiB_6 is not appreciably affected by solutions of the common acids.

Physical properties.—The apparent melting point of SiB_6 was measured in a small graphite resistance furnace and a value of 1950°C obtained. The melting point of Pacific Coast Borax "fused" boron was 2130°C, as observed in the same furnace.

A schematic drawing of the internal construction of the melting point furnace is shown in Fig. 4. The behavior of the sample is followed visually through a special close-range optical pyrometer equipped with additional filters designed to extend its operating range to 4200°C. Samples were placed inside a hole drilled in a boron nitride rod. The rod was mounted vertically in a graphite pedestal and the graphite heater placed around the sample. Radiation shields were used around the heater to reduce power loss by radiation. Stepless control of power input to the heater was afforded by a Variac-controlled saturable core reactor. Before a run the furnace was evacuated and then filled with argon. The argon was allowed to flow during the run.

The furnace was calibrated by measuring the melting points of Al_2O_3, ZrO_2, and HfO_2. The melting

points agreed with published values within experimental error which was assumed to be ± 20°. Correction for the glass window in the furnace was made using Wien's law. A more complete description of the apparatus is given by Lambertson and Lewis (11).

The electrical resistivity of crystals of SiB_6 was determined by a "probe" method (12, 13). The resistivity was of the order of 0.2 ohm-cm as compared with 6×10^3 ohm-cm for the resistivity of the boron used. It is not possible from these measurements to conclude a reason for this low resistivity for SiB_6; however it is consistent with the low resistivity reported for B_4C (14).

The hardness of SiB_6 was measured on single crystals which were mounted in black bakelite. Samples of silicon carbide, boron, and boron carbide were mounted in the same mount so that a direct comparison could be made. The mount was first rough-polished on a 100-grit diamond wheel. The final polishing was done with a 400-grit diamond wheel followed by 500-grit SiC waterproof paper with a final finish using diamond dust on a polishing cloth.

The samples were indented using a Leitz Mini-load Durimet Tester. The indenter was the Knoop diamond point and the load 100 g in all cases. The hardness values are listed in Table IV.

* Hot pressed slug (had free boron).
† Single crystals by fusion of elements.
Note: Percentages were obtained after treatment of the melt with HF + HNO_3 to remove free silicon followed by fusion with KOH to removed boron nitride. Nitrogen was analyzed to be less than 0.2%.

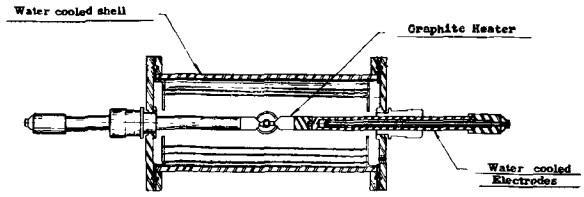

Fig. 4. Schematic drawing of melting point furnace

Discussion of Results

The difficulties experienced by previous investigators in preparing single crystals of SiB_6, as evidenced by the literature survey, appear to have been the result of several factors, of which the most pertinent are:

1. In most instances the reaction was carried out at too low a temperature. It appears that it is necessary to be above the melting point of boron, which is approximately 2130°C.
2. Reactions generally were carried out in the presence of carbon, which appears detrimental to the reaction since silicon and boron tend to form their respective carbides. The fact that a crucible material such as boron nitride was available was indeed fortunate, since silicon carbide and graphite had proven unsatisfactory.
3. A slow cooling rate is essential particularly since indirect evidence indicates that a peritectic reaction is involved.
4. A sufficient amount of silicon is necessary to react with all of the boron, as the final separation of SiB_6 from boron or other compounds is extremely difficult. With this in mind it appears that a two to one weight ratio of silicon to boron is satisfactory.

Structure—Cell dimensions were determined from rotation and Weissenberg photographs.

The orthorhombic structure reported here for SiB_6 is not in agreement with the CaB_6 structure reported by Zhuravlev. X-ray data reported by Zhuravlev matches that for CaB_6, but since no chemical analysis is reported it is not possible to conclude that the pattern applies to SiB_6. The solution to the complete structure should prove interesting since a similarity to B_4C (15, 16) is indicated.

Table IV. Knoop hardness measurements

	L*	Range HK_{100}	Avg. HK_{100}
Boron	24.3	1940-2630	2410
B_4C	21.6	2910-3160	3050
SiC	23.6	2510-2580	2560
SiB_6	27.3	1740-2050	1910

$$HK_{100} = \text{Knoop hardness} = \frac{14230.\,P}{L^2}$$

where P = load grams, L = length of indentation in microns.

* Values for L are an average of 10 indentations.

The chemistry of the borides indicates that one might well expect various other borides of silicon, but as yet no evidence for the SiB_3 phase reported by Moissan has been found.

Physical properties.—The density as determined by the pycnometer method is quite reproducible. The value of 2.43 g/cm³ is slightly less than the 2.47 g/cm³ quoted by Moissan. The density for SiB_3 (2.43 — 2.49 g/cm³) as determined by Samsonov indicates a compound similar to SiB_6 The density of the SiB_6 prepared by Samsonov was reported by Zhuravlev to be 2.16 g/cm³.

The observed melting point for SiB_6 is approximately 1950°C, which is about 200°C below that of elemental boron.

The breakdown of SiB_6 upon melting as observed by x-ray studies suggests a peritectic reaction, but further work will be necessary before the various phases of the binary diagram are established.

The measured hardness of SiB_6 is lower than anticipated from the reported hardness of silicon borides. In view of the hardness values reported by Samsonov it is felt that there may be other silicon borides that will give the expected hardness. SiB_6 is not as prone to cracking under loading as boron or boron carbide.

Summary

1. Single crystals of silicon boride (SiB_6) have been prepared and identified by wet chemical and x-ray analyses.

2. SiB_6 has an orthorhombic structure with unit cell dimensions of a = 14.39, b = 18.27, and c = 9.88Å.

3. SiB_6 has a density of 2.43 g/cm³ based on pycnometer measurements.

4. The number of molecules per unit cell based on a density of 2.43 g/cm³ is 40.9.

5. The melting point of SiB_6 is approximately 1950°C.

6. The electrical resistivity is approximately 0.2 ohm-cm based on probe measurements of single crystals.

7. The Knoop hardness of SiB_6 is approximately 1910 kg/mm² using a 100-g load.

Manuscript received Aug. 7, 1958. This research was carried out in partial fulfillment for the M.Sc. degree at Niagara University.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

The Electrolytic Preparation of *p*-Methoxyphenylacetonitrile

S. Wawzonek and J. D. Fredrickson

Department of Chemistry, State University of Iowa, Iowa City, Iowa

ABSTRACT

Conditions necessary for the electrolytic preparation of *p*-methoxyphenylacetonitrile from α-hydroxy-*p*-methoxyphenylacetonitrile and its esters were determined polarographically. Polarographic reduction waves were obtained in dioxane and water only in the presence of tetrabutylammonium iodide and tetramethylammonium iodide. Alpha-benzoxy-*p*-methoxyphenylacetonitrile which was reduced at the most positive potential gave no reduction wave in the presence of either ammonium chloride or lithium chloride.

On the basis of the ease of reduction and ease of preparation α-benzoxy-*p*-methoxyphenylacetonitrile was used as the starting material in the large scale reduction at a mercury cathode and gave *p*-methoxyphenylacetonitrile in yields averaging 65%.

The preparation of *p*-methoxyphenylacetonitrile is of interest since this compound is an intermediate in the synthesis of numerous alkaloids and synthetic drugs (1, 2). The chemical methods reported are numerous and have involved the metathetical reaction of anisyl chloride with alkali cyanides, the nitration of phenylacetonitrile followed by reduction, diazotization, hydrolysis, and methylation, the catalytic reduction of α-benzoxy-*p*-methoxyphenylacetonitrile, and the reaction of acetic anhydride with the oxime of *p*-methoxyphenylpyruvic acid (3).

The present study describes the electrolytic preparation of *p*-methoxyphenylacetonitrile from α-benzoxy-*p*-methoxyphenylacetonitrile. Polarographic

data were used to determine the conditions necessary for the electrolysis and the derivative of α-hydroxy-p-methoxyphenylacetonitrile most suitable for this preparation.

Experimental

The esters of α-hydroxy-p-methoxyphenylacetonitrile and α-hydroxyphenylacetonitrile (mandelonitrile) were studied polarographically in solutions having the following compositions: (*A*) 0.175*M* tetrabutylammonium iodide and 0.0048% methyl red in 75% dioxane; (*B*) 0.175*M* tetrabutylammonium iodide in 75% dioxane; (*C*) 0.0972*M* tetramethylammonium iodide in 47% dioxane; and (*D*) 0.1312*M* tetramethylammonium iodide in 50% dioxane.

The current voltage curves were obtained with a Fisher Elecdropode having a current scale calibration of 0.0196μa/unit on the galvanometer scale at a sensitivity of one and a Sargent Model XII polarograph having a current scale calibration of 0.00497 μa/mm at a sensitivity of one.

All measurements were made in a water thermostat at 25° ± 0.1° using both a cell with a mercury pool as an anode and a H-type cell fitted with a saturated calomel electrode. The potential of the mercury pool was measured in the various solutions against a saturated calomel electrode (S.C.E.) using a sintered glass salt bridge of the type described by Laitinen (4).

The dropping mercury electrode had the following characteristics. At a pressure of 70 cm of mercury the drop time in 0.1N KCl was 4.3 sec. (open circuit). The value of m was 1.58 mg sec^{-1} with a calculated value of $m^{2/3}t^{1/6}$ of 1.73 $mg^{2/3}$ $sec^{-1/2}$.

Materials.—The dioxane was purified by refluxing with metallic sodium until the molten sodium remained shiny. This process usually required about a week. The ammonium chloride, lithium chloride, and tetramethylammonium iodide used were of a reagent grade. Tetrabutylammonium iodide (5), α-benzoxyphenylacetonitrile (6), α-ethoxycarbonyloxyphenylacetonitrile (6), α-hydroxy-p-methoxyphenylacetonitrile (6), α-ethoxycarbonyloxy-p-methoxyphenylacetonitrile (7), α-benzoxy-p-methoxyphenylacetonitrile (6), and α-acetoxy-p-methoxyphenylacetonitrile (8) were made according to the directions given in the literature.

Electrolysis.—The reduction was carried out in a circular battery jar, 15.7 cm in diameter and surrounded by an ice bath. A 5 x 13 cm porous cup, which was 4-mm thick, was used as the anode compartment and was supported by a small Lucite stand 3 cm above the surface of the mercury pool used as the cathode. The cathode had an area of 193.8 cm^2 and was connected to the external circuit by a glass tube filled with mercury and with a small platinum wire sealed in one end. The anode was a large platinum gauze electrode. An efficient mechanical stirrer was mounted in the cathode compartment close to the surface of the mercury pool.

The anode and cathode compartments were filled with 1700 ml of 0.1*M* tetramethylammonium iodide in 50% dioxane. To the cathode solution α-benzoxy-p-methoxyphenylacetonitrile (20.0 g) was added. The line potential was 80 v. The initial current of 1.7 amp increased to 3.9 amp in the first 20 min as the temperature increased from 21.5° to 50.0°. This current, which corresponded to a current density of 0.020 amp/cm^2, and the temperature were maintained at this point for an additional hour. Gas evolution occurred after 1 hr of electrolysis. To insure complete reduction the electrolysis was continued for a total of 6 hr during which time the current density dropped to 0.010 amp and the temperature to 30°. During the entire period the cathode solution was kept neutral by the dropwise addition of glacial acetic acid (10.65 ml). The resulting catholyte was treated with 800 ml of water, and the dioxane was removed under reduced pressure as an azeotrope. The resulting solution which contained an oil was then extracted with ether. The ether extract after washing with 5% hydrochloric acid and 5% sodium hydroxide gave 13.75 g of an oil which gave two fractions when distilled under reduced pressure. The first (2.5 g) of these, bp 100°-120° (20 mm) corresponded in boiling point to benzyl alcohol; it was not, however, investigated any further. The second fraction (6.3 g, 57% yield), bp 163.5°-164° (22 mm) consisted of p-methoxyphenylacetonitrile, $n_D^{17.0} = 1.5392$. Further proof for the structure was obtained by condensing the product with anisaldehyde in the presence of alkali (9). The product α-(p-methoxyphenyl)-p-methoxycinnamonitrile melted at 107°-109° and did not depress the melting point of an authentic sample (10).

In a smaller run using 10 g of α-benzoxy-p-methoxyphenylacetonitrile 4 g of p-methoxyphenylacetonitrile was obtained (72.5% yield).

Results

The polarographic data obtained for the various substituted phenylacetonitriles are given in Table I.

All the the compounds except α-hydroxy-p-methoxyphenylacetonitrile gave well-defined waves. The latter gave a drawn out wave.

Alpha - benzoxy - p - methoxyphenylacetonitrile failed to give a polarographic wave in either 0.1*M* ammonium chloride or 0.1*M* lithium chloride in 75% dioxane.

The large-scale electrolytic reduction of α-benzoxy-p-methoxyphenylacetonitrile in 50% dioxane containing 0.1*M* tetramethylammonium iodide gave

† $I_d = i_d/Cm^{2/3}t^{1/6}$.

in two runs p-methoxyphenylacetonitrile in yields amounting to 57 and 72.5%, respectively.

Discussion of Results

An examination of the results in Table I indicates that the α-benzoxy derivatives of the two phenylacetonitriles are reduced more easily than the other esters. This behavior points to a greater tendency for the phenyl group in comparison with the ethoxy and methyl groups to withdraw electrons from the ester linkage and thus make this bond more susceptible to reduction. A similar effect is found in the corresponding analogous acids; benzoic acid is more acidic than acetic acid. No value is reported for the dissociation of ethyl bicarbonate, but this acid would be expected to have approximately the same acidity as carbonic acid since the inductive effect of the ethoxy group approximates that of the hydroxyl grouping.

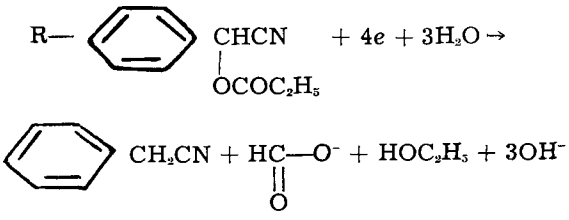
The diffusion current constant obtained for these benzoates pointed to the following electrode reaction.

$$p\text{-}CH_3OC_6H_4\underset{\displaystyle OCOC_6H_5}{\underset{|}{C}}HCN + 2e + H_2O \rightarrow$$
$$p\text{-}CH_3OC_6H_4CH_2CN + C_6H_5COO^- + OH^-$$

This process was confirmed by the formation of p-methoxyphenylacetonitrile in a large-scale reduction. No benzoic acid was isolated in this reduction since the potential was not controlled. A fraction boiling at approximately the same point as benzyl alcohol was obtained, however, and may be formed from the benzoate ion since this is reducible at more negative potentials.

Alpha-hydroxy-p-methoxyphenylacetonitrile and α-acetoxy-p-methoxyphenylacetonitrile from their diffusion current constants undergo a similar reduction to p-methoxyphenylacetonitrile and hydroxide and acetate ions, respectively. The lower values obtained for the currents may be caused by decomposition of these compounds in solution.

The higher diffusion coefficient constants obtained for the α-ethoxycarbonyloxy derivatives suggests that possibly four electrons are involved in the reduction of these compounds. The reduction of these esters to the phenylacetonitrile would involve two electrons and produce the ethyl carbonate ion. This ion can hydrolyze at the dropping mercury electrode to carbon dioxide and ethanol. Carbon dioxide has been shown to undergo reduction at the dropping mercury electrode to formic acid (11) and would be the basis for the higher current observed. The overall electrode reaction for the reduction of the α-ethoxycarbonyloxy derivatives would be the following:



On the basis of the ease of reduction and the ease of preparation α-benzoxy-p-methoxyphenylacetonitrile was used as the starting material for the large-scale electrolytic preparation of p-methoxyphenylacetonitrile. Tetramethylammonium iodide was used as the supporting electrolyte because it was less expensive than the tetrabutylammonium iodide. The average yield of 65% obtained indicated that the electrolytic method offered a suitable way for the preparation of p-methoxyphenylacetonitrile.

Manuscript received Sept. 19, 1958. This paper was abstracted in part from the M.S. Thesis of one of the authors (J.D.F.).

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

The Electrochemistry of Nickel

I. Codeposition of Nickel and Hydrogen from Simple Aqueous Solutions

John Yeager,[1] J. P. Cels,[2] Ernest Yeager, and Frank Hovorka

Department of Chemistry, Western Reserve University, Cleveland, Ohio

ABSTRACT

The simultaneous electrodeposition of nickel and hydrogen has been studied in chloride and sulfate solutions and the individual polarization curves determined from efficiency measurements. Nickel polarization has a Tafel slope of 0.10 and is independent of *p*H and type of anion at constant nickel ion activity. The nickel polarization data can be explained readily in terms of the transfer of a nickel ion from the solution across an unsymmetrical potential energy barrier to the metal phase. The hydrogen overvoltage evaluated during codeposition at constant *p*H is substantially the same for both chloride and sulfate solutions with a Tafel slope of 0.12. Hydrogen and nickel deposition appear to occur without any appreciable interdependence over the range of conditions involved in the present work.

The electrodeposition of nickel has been studied by various workers in the terms of polarization measurements (1-8), structural studies (9-13), and efficiency measurements (7, 14). With only a few exceptions, these measurements have been made in nickel solutions containing two or more anions in appreciable concentrations and often various addition agents. Experimental results obtained with such relatively complicated systems are not conducive to fundamental interpretation.

The present investigation has been directed to the determination of the various parameters associated with the electrodeposition of nickel from relatively simple aqueous solutions containing only one type of anion at a time in any appreciable concentration, i.e., sulfate or chloride. The cathodic polarization and current efficiency with respect to nickel deposition have been measured in sulfate and in chloride solutions as a function of nickel ion concentration, *p*H, and temperature. From these data, the activation polarization for both nickel deposition and hydrogen deposition has been calculated (15) as a function of current density for each process.

Reiser and Fischer (7) have reported on the simultaneous deposition of hydrogen and nickel from a nickel chloride-hydrochloric acid solution and have calculated the individual polarization curves according to the procedure mentioned above. These authors then compared the nickel polarization curve from the simultaneous discharge with the corresponding curve for the deposition of nickel from a boric acid buffered, nickel chloride solution for which the efficiency was close to 100%. Hydrogen polarization for the simultaneous discharge was compared with that for a nickel surface in a pure hydrochloric acid solution. The polarization curves for nickel electrodeposited from the two different solutions were found to be reasonably close in view of the differences in the nickel ion activities and the possibility of nickel hydroxide formation near the cathode at a *p*H as high as 4.4. Major differences were found for the hydrogen overvoltage curves. On the basis of the latter comparison, Reiser and Fischer concluded that the hydrogen and nickel deposition processes are dependent on each other during codeposition on a nickel surface.

Such comparisons are not without question. For example, in the hydrogen overvoltage comparison, no consideration appears to have been given to the differences in the hydrogen ion activities or salt effects. A specific objective of the present research has been to examine further the interdependence of the polarization curves for nickel and hydrogen during simultaneous discharge in terms of the dependence of these processes on nickel and hydrogen ion activities in both chloride and sulfate solutions.

Apparatus

Such factors as mass transport, current distribution, electrochemical purity, and temperature must be controlled carefully in polarization measurements. The polarization cell shown in Fig. 1 has been designed with these factors in mind. The Pyrex cell consists of two U-tubes at right angles to each other with the two U-tubes joined by a T-connection at the cathode compartment. Several small sidearms (not shown) have been incorporated to facilitate the introduction of auxiliary electrodes and a solution bridge to an external reference electrode for *p*H measurements as well as for the filling and subsequent withdrawal of the solution from the cell. The cathode assembly was introduced through a ground joint at the top of the cell while the anode was introduced through a second ground joint (not shown) in the other end of the U-section containing the cathode. The centrifugal glass stirrer and associated drive system, represented diagrammatically

[2] Present address: The Kemet Company, Cleveland, Ohio.

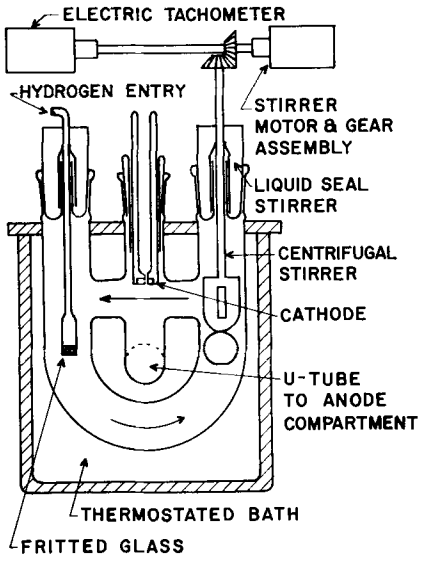

Fig. 1. Polarization cell

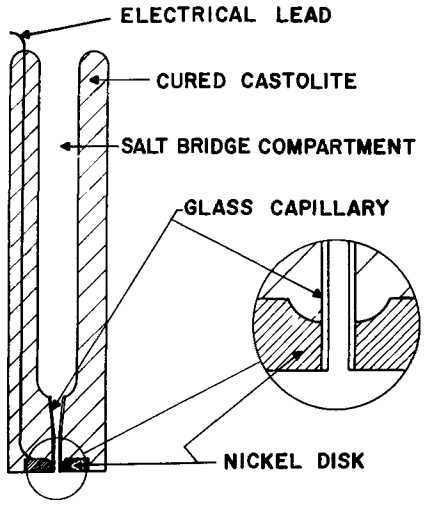

Fig. 2. Plastic cathode assembly with rear-type Luggin capillary.

in Fig. 1, were used to circulate the electrolyte past the cathode surface at a controlled rate with the direction of flow as shown by the arrows. The solution within the cell was saturated with purified hydrogen gas, usually by means of a fritted glass disk. Temperature was controlled to ±0.05°C by means of a thermostatic control mounted within the outer bath in Fig. 1.

The majority of the polarization measurements have been made by the direct method. The Luggin capillary was introduced through the rear of the cathode since this arrangement did not interfere with the flow of the solution past the cathode surface. This advantage more than offsets the possible disadvantage associated with slightly nonuniform current density distribution at the electrode surface. Any *IR* drop effects associated with the use of the rear Luggin capillary arrangement were shown to be negligible on the basis of a check made by the interrupter method.

The cathode design is shown in Fig. 2. A metal disk with an area of approximately 1 cm^2 and a thickness of 1/8 in. was mounted in the cured plastic Castolite.[3] A glass capillary tube with an internal diameter of 1/16 in. extended from the inside of the cathode assembly to the outside. The outside end of the glass capillary tube was ground so as to be flush with the surface of the nickel disk. Electrolytic leakage between the inside of the cathode assembly and the nickel through a path around the outside of the glass capillary tube was not a problem since the capillary tube was cast in the plastic.

The reference electrode for the cathodic polarization measurements was a mercury-mercurous chloride, saturated potassium chloride, reference electrode (S.C.E.). Reagent grade chemicals and triply distilled mercury were used in the preparation of the reference electrode. For all measurements, the reference electrode was maintained at the same temperature as the polarization cell. In order to minimize contamination of the solution within the cathode compartment, an intermediate solution bridge filled with the same solution as in the cell was used between the solution in the rear of the cathode assembly and the reference electrode. Two asbestos-filled capillaries were placed in this solution bridge to prevent any appreciable convection.

The anode for the polarization measurements in nickel sulfate solutions consisted of a platinum foil in the form of a cylinder. This cylinder was welded to a platinum wire which, in turn, was sealed into a soft glass tube. For the chloride solutions, the platinum anode was not used because of possible difficulties associated with liberation of chlorine within the cell. For the chloride solutions, the anode consisted of a cylinder of nickel with a thick plate of nickel electrodeposited from a Watts bath which had been prepared from reagent grade chemicals. The anode was inserted into the cell through a ring-sealed joint. A separate gas vent was incorporated in the anode compartment in order that any gaseous products liberated at the anode would be swept out with the hydrogen, and hence, would not reach the cathode compartment. The anodic efficiency in the chloride solutions with the electroplated nickel anode was close to 100%.

Polarization was measured with a L&N K-1 potentiometer in conjunction with an Eppley unsaturated Weston standard cell. A conventional regulated, filtered powder supply capable of delivering 350 v at 200 ma with a large series resistance was used as a source of polarizing current. The current through the cell was determined by measuring the *IR* drop developed across a standard 10.00-ohm resistance in series with the cell.

The velocity of the electrolytic solution was determined as a function of the voltage output of the electrical tachometer by means of a Pitot tube with an entrance of 1 mm ID. By varying the position of the tip of the Pitot tube in the cathode compartment, it was established that the velocity of the solution was at a maximum at a level corresponding to approximately the top of the intersection in Fig. 1. For this reason, the cathode assembly was placed in the cell in such a way that the cathode surface was

[3] Castolite Company, Woodstock, Ill. This plastic is an unsaturated polyester resin and is insoluble in all common solvents when properly cured.

just a slight distance below the top of this intersection. The final velocity vs. tachometer measurements were made with the cathode assembly in the cell.

Experimental Procedure

The solutions were prepared from recrystallized reagent grade nickel sulfate and chloride. The effect of pre-electrolysis of the electrolytic solutions with platinum electrodes was examined during the preliminary polarization measurements and found to be negligible at potentials for which appreciable nickel electrodeposition occurred. This finding concerning pre-electrolysis is somewhat surprising in view of the general need for pre-electrolysis in polarization studies. The effects of impurities on the polarization, however, are probably considerably less in the case of the deposition of a metal wherein a new surface is constantly being created. At higher *p*H, the pre-electrolysis caused considerable changes in the *p*H. As a result, pre-electrolysis was not used for the majority of the measurements reported in this paper.

The exact concentration of nickel in the various solutions was determined by the cyanide method (16). The *p*H of each solution was determined by measuring the potential of a hydrogen electrode in the particular electrolyte vs. an S.C.E. While the precision of these measurements was of the order of 0.01 *p*H unit, the accuracy was less because of liquid junction potentials. The *p*H of each solution was adjusted to specific values through the addition of either hydrochloric or sulfuric acid to the electrolyte.

The preparation of the cathode surface was as follows. The nickel cathode was first abraded to yield a fresh surface with medium grade (320 A) silicon carbide, waterproof emery paper, wetted with water, and then polished further with fine waterproof emery paper (400 A) until the surface of the nickel disk appeared uniformly smooth. The electrode surface was subsequently etched for 45 sec in a 5*N* nitric acid solution. After the surface was thoroughly rinsed with distilled water, the cathode was quickly inserted into the polarization cell and the solution velocity adjusted to approximately 45 cm/sec in the bulk of the solution adjacent to the cathode. The polarizing current was then adjusted to 15 ma/cm^2, and the electrodeposition of nickel continued at this current density for 10 min. This period of time has been found sufficient for the cathode to attain an essentially steady-state condition with respect to potential.

After 10 min of preplating, the polarization was carefully measured at a current density of exactly 15 ma/cm^2. The current density was then increased to 55 ma/cm^2 and the potential recorded again as soon as a stable value was attained. This usually required less than 30 sec. Polarization measurements were made subsequently at current densities of 45, 35, 25, 10, 6, 4, 2, 1, 4, and 15 ma/cm^2. In each case, a second repeat run was made under similar circumstances with a 10-min preplate period. In the second run, polarization measurements were made at the current densities of 15, 50, 40, 30, 20, 15, 12, 8, 5, 3, 1.5, 3, 5, and 15 ma/cm^2. Area increments under these conditions were negligible. After the completion of the run, the *p*H of the electrolyte was again checked with the hydrogen electrode. The *p*H change during any one run usually was less than 0.02 *p*H unit.

The cathode efficiencies for the electrodeposition of nickel were determined at the potentials associated with current densities of 55, 40, 25, 15, 8, and 5 ma/cm^2 for each solution composition and temperature involved in the polarization studies. In some cases, the amount of nickel that could be deposited in any reasonable time was so small that conventional weighing operations were not suited to the determination of the amount of nickel electrodeposited. Consequently, the procedure adopted for this purpose involved the anodic dissolution of the deposited nickel in hydrochloric acid solution followed by the analysis of the solution for nickel by the cyanide method (16). The electrolytic cell used for the anodic dissolution is described elsewhere in detail (17). The cathode assemblies used in the efficiency studies were similar in design to those shown in Fig. 2 with the exception that the disk of nickel was replaced with a similar disk of silver. The silver surface was preplated with nickel at a current density of 15 ma/cm^2 for 10 min in much the same fashion as in the case of the polarization measurements. The amount of nickel electrodeposited during the preplate time was carefully determined and subtracted from the total amount of nickel deposited on the cathode in the subsequent measurements.

The structural properties of the electrodeposited nickel were examined by means of x-ray diffraction techniques. A modified Wyllie (18) camera, specifically constructed for the examination of electrodeposits, was used for this work. A North American Phillips x-ray diffraction tube with a cobalt target provided an incident x-ray beam at an angle of approximately 15° relative to the surface of the electrodeposit. A cylindrical projection of the diffracted x-rays was obtained. The depth in the deposit to which the x-ray pattern was sensitive was checked by depositing a known amount of nickel on a silver surface and then examining the diffraction pattern for lines corresponding to silver. In the final x-ray examination, the deposit thickness was adjusted so as to prevent the preplated nickel from registering directly in the x-ray diffraction patterns. Because of the relatively small angle of incidence of the x-ray beam, deposits of only a few ten-thousandths of an inch thickness were generally sufficient.

Experimental Results

Flow rate.—At 45°C for all of the solutions involved in the present work, the cathodic polarization was found to approach a limiting value with increasing flow rate even at current densities as high as 55 ma/cm^2. This was not the case at 25°C in the more dilute solutions. Even at the highest available solution velocities (50 cm/sec) in the 0.12M nickel sulfate, the polarization attained a limiting value only at current densities less than 25 ma/cm^2. For this reason, the majority of the polarization measurements have been made at 45°C. Although the

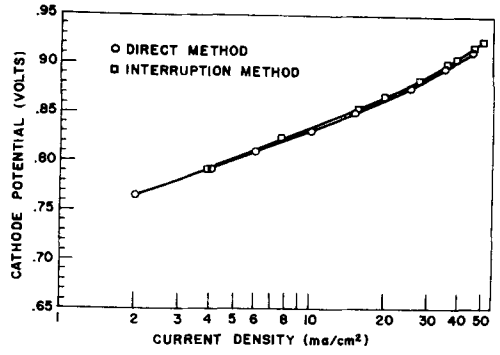

Fig. 3. Comparison of polarization measurements by the direct and interrupter methods. Potentials are negative to the saturated KCl calomel electrode (S.C.E.) at the same temperature. Solution: 0.5M $NiCl_2$ with a pH of 2.0 at 25°C, adjusted by addition of HCl.

polarization attained a limiting value as the solution velocity was increased, it cannot be assumed that the concentration polarization was negligible. The increase of the velocity of flow in the bulk of the solution beyond a certain value probably has relatively little effect on the effective thickness of the diffusion layer at the cathode solution interface. The attainment of a limiting value for the polarization at high flow rates, however, is important because reproducible concentration gradients are then established at the electrode surface. In no case was a limiting current density found with respect to the discharge of either nickel or hydrogen. Unless otherwise indicated, all of the polarization measurements reported in this paper were made with a maximum flow rate in the bulk of the electrolyte adjacent to the cathode surface of 45 cm/sec.

Reproducibility.—In Fig. 3, cathode potentials (negative to an S.C.E. reference) are plotted against total current density for a 0.5M nickel chloride solution with a pH of 2.0 at 25°C. The data noted by the circles were obtained by the procedures described above, whereas the data indicated by the squares were obtained in subsequent measurements by Griffis (19) in a glass polarization cell of somewhat different design. The interrupter method was used for the latter measurements with cathodes of 0.25 cm^2 area with purified hydrogen gas bubbled through the solution. The electronic equipment has been described previously (20). In both cases, the

flow rates in the solution adjacent to the cathode were in excess of 40 cm/sec. The agreement between the two independent sets of measurements is within ±2 mv.

Further evidence of the reproducibility in the present work can be found in Fig. 4-6 in terms of the smooth curves which can be drawn through the experimental points despite the fact that two separate runs were involved in obtaining the points for each curve. The agreement between the polarization measured at 15 ma/cm^2 at the start of each run and that measured at the same current density at the end of each run was usually within ±1 mv and at the worse ±3 mv.

Polarization data.—In Fig. 4-6 are presented typical cathodic polarization data for the simultaneous deposition of nickel and hydrogen from chloride and sulfate solutions for various temperatures, pH, and nickel salt concentrations. The ordinates represent cathode potentials (negative to S.C.E.) and include a small liquid junction potential. Variations in the junction potential with solution composition are believed to be small compared to the changes in the cathode potentials arising directly because of changes in the activities of the hydrogen and nickel ions. Current densities represented in these figures are based on the apparent areas of the cathodes.

Polarization measurements have been limited to apparent current densities of 10^{-3} to 10^{-1} a/cm^2 for the following reasons. At current densities below 10^{-3} a/cm^2, the predominant process is the discharge of hydrogen and the polarization values become somewhat nonreproducible, probably because of insufficient control of impurities. Under such circumstances, impurity effects are accumulative. At cur-

rent densities above 10^{-1} a/cm^2, concentration polarization becomes significant in solutions of relatively low nickel ion concentration and high pH.

Polarization curves for the discharge of nickel at 45°C are presented in Fig. 7-9 for various nickel ion concentrations, pH, and temperatures. These curves have been derived from the over-all polarization data and the efficiency data. At least part of the deviation from linearity at higher current densities is associated with concentration polarization, and perhaps all of it.

In Fig. 10-12 are the polarization curves for the discharge of hydrogen at various nickel salt concentrations, pH, and temperatures. As in the case of the nickel polarization curves, deviations from linearity can be explained in terms of concentration polarization. Mass transport problems should be particularly severe at the higher pH as is evident from the curve for pH 2.43 in the 0.5M $NiSO_4$ solution in Fig. 11.

The differential capacity of the nickel cathode was measured by the interrupter method in the 0.50M nickel sulfate solution at a pH of 2.0 and temperature of 45°C. The value was found to be 75 ± 3 μf/cm^2 of apparent surface area over the complete range of potentials represented in Fig. 4-6. If the value of 28.8 μf/cm^2 of true surface area as determined by Brodd and Hackerman (21) for nickel in 1M Na_2SO_4 at 30°C is assumed applicable at potentials negative with respect to the zero point of charge, the roughness factor is approximately 2.5. In Fig. 10, the hydrogen polarization exhibits little variation with the type or concentration of nickel salt. Likewise in Fig. 8, the nickel polarization exhibits only minor dependence on pH particularly in chloride solution. This implies that the roughness factor does not change to any appreciable extent with pH, salt type, or salt concentration. Little question exists as to the constancy of the roughness factor during a

* Bracketted values are dubious because of concentration polarization with respect to hydrogen ions or because of limited accuracy for the hydrogen discharge current. When the efficiency for nickel deposition is close to 100%, the errors in the hydrogen discharge current become quite significant.

given polarization run in view of the reproducibility of the initial and final polarization values at a total current density of 15 ma/cm^2.

In Table I are summarized the polarization data for the discharge of hydrogen and nickel ions in terms of the Tafel slopes (B), the logarithms of the exchange current i_o in a/cm^2 of apparent area, and αz, where α is the fraction of the potential effective in changing the energy of activation for the cathodic rate-determining step, and z is the charge of the species passing over the energy barrier. For hydrogen, $z = 1$, while for nickel, z can be assumed to be equal to 2 if the rate-determining step involves the transfer of a nickel ion from the solution to the metal phase. The coefficient α is approximately 0.50 for hydrogen discharge with no significant difference in this coefficient between the sulfate and chloride solutions within the limits of experimental error. Likewise, the average value for the coefficient αz for nickel discharge is 0.65 and does not appear to differ significantly between sulfate and chloride solutions.

The calculation of the values for log i_o requires a knowledge of the reversible potentials of the hydrogen and nickel electrodes in the particular electrolytic solutions involved in the present work. For hydrogen, this is not a problem since the potentials of the reversible hydrogen electrode in these electrolytic solutions vs. S.C.E. were determined directly as part of the adjustment of the solutions to particular pH values. In the case of nickel, however, the reversible potential vs. the S.C.E. is much more difficult to establish because the reversible potentials could not be measured directly under the present experimental conditions. Furthermore, the best literature values for the standard electrode potential for nickel are probably accurate only to 10 mv. Even with data for the standard electrode potential for nickel, the uncertainties concerning liquid junction potentials and single ion activities interfere with the accurate calculation of the potential difference between the reversible nickel electrode and the S.C.E. In the present work, this potential has been evaluated for both sulfate and chloride solutions on the basis of the following equation:

$$E = -0.470-(1.0\cdot 10^{-3})(t-25) + (0.9915)(10^{-4})\ T \log a_+ \qquad [1]$$

where a_+ is the activity of the nickelous ion and t and T are the temperature on the Centigrade and absolute scales, respectively. This equation is based on the data of Carr and Bonilla (22) for the thermogalvanic potentials of nickel in 0.1 and 1.0M nickel sulfate solutions. In using the above equation for chloride as well as sulfate solutions, the assumption has been made that the liquid junction potentials and the temperature coefficients are the same for the chloride solutions as for the sulfate solutions. This assumption is probably valid to within a few millivolts.

The activities of the nickelous ion have been calculated for the sulfate solutions from the mean activity coefficients evaluated by Harned and Owen (23) from the isopiestic vapor pressure data of Robinson and Jones (24), and for the chloride solutions (25) from the isopiestic vapor pressure measurements of Robinson and Stokes (26). For the nickel sulfate solutions, the activity coefficient of nickelous ion has been assumed equal to the mean activity coefficient. For the chloride solutions, the activity coefficient of the nickelous ion was set equal to the square of the mean activity coefficient on the basis of the Debye limiting law. Furthermore, the values for the activity coefficients at 45°C have been assumed to be the same as at 25°C, an approximation which appears justified in view of the limited accuracy of Eq. [1]. In the case of the nickel sulfate solutions of pH 1.49, the amount of sulfuric acid added in the course of adjusting the pH was appreciable compared to the nickel sulfate concentration (0.5M). This partially was taken into account in the activity coefficient calculations by using the mean activity coefficient of nickel sulfate solutions of the same ionic strength as that of the sulfuric acid-nickel sulfate solutions.

The accuracy of the values for the apparent exchange current i_o is limited more by the accuracy of the value for the Tafel slope than the reversible potential. The uncertainty in the Tafel slope is particularly great for solutions in which either the concentration polarization is appreciable or the current densities for hydrogen discharge are uncertain because only a small fraction of the total current is involved in hydrogen discharge, e.g., hydrogen polarization curve in Fig. 11 for 0.5M nickel chloride at pH 2.41. On the basis of the roughness factor of

2.5, discussed earlier, the quantity −0.4 should be added to log i_o values in Table I to obtain the logarithm of the exchange current per unit true area.

X-ray diffraction.—The x-ray diffraction studies indicated that all of the deposits at 45°C from chloride and sulfate solutions have a face-centered cubic lattice. The diffraction patterns show a tendency for two types of preferred orientations as well as small changes in grain size. These results are summarized in Table II on a relative basis. In no case was the tendency for preferred orientation strong. The lack of any preferred orientation at the low current densities is surprising, particularly since the preplate had a small tendency for the [100] plane to be parallel to the surface. At the higher current densities, the [110] plane tends to be parallel to the surface for the sulfate solutions.

The grain size is compared qualitatively on a scale of 1 to 4, where 1 represents the finest grain and 4 the coarsest for the samples which were examined. This scale is believed to have covered a small range of grain size with the variation in size between the limits of the scale estimated to have been less than 1 to 3. No consistent trend is evident with increasing current density, although the grain size was generally smaller with the nickel sulfate solutions than the nickel chloride solutions.

Table III. Hydrogen overvoltage data for nickel in hydrochloric and sulfuric acid solutions according to other workers

Interpretation of Experimental Results

In systems involving simultaneous electrode processes, the assumption is often made that the current densities associated with the individual processes can be calculated on the basis of a constant effective area for each process. In Fig. 7-12 for nickel and hydrogen discharge, the Tafel slopes are substantially constant over a tenfold change in current density in the instances where concentration polarization is not large. This constancy of the Tafel slopes supports the above stated assumption. Likewise, the hydrogen discharge appears to be independent of nickel deposition on the basis of the linearity in the Tafel plots for hydrogen as well as the minor and probably negligible effect which variations in nickel salt concentration appear to have on the hydrogen polarization curves (see Fig. 10).

The values for the derivative of the cathode potential with respect to pH at constant hydrogen discharge current, evaluated near the middle of the linear ranges in Fig. 11, are 0.11 and 0.10 for hydrogen discharge[4] from sulfate solutions and from chloride solutions, respectively, provided the curve for pH 2.41 in 0.5M nickel chloride is not considered. These values compare favorably with the value of $2.3RT/\alpha F$ predicted (28) for the dependence of the electrode potential on pH when hydrogen is deposited in acid solution in the presence of a neutral salt for the case where either the hydrogen ion discharge step or the electrochemical desorption step is rate-determining. This relatively close agreement however, is to be expected only in the absence of specific ionic adsorption.

Unfortunately, hydrogen overvoltage data are not generally available in the literature for purposes of comparison with the present data since it is necessary to duplicate both pH and ionic strength. Table III summarizes hydrogen overvoltage data of Bockris and Potter (29) and of Lukovzev, Levina, and Frumkin (30) for room temperatures. Values for the 0.01 and 0.013*N* hydrochloric acid solutions in Table III differ by small, although significant amounts from the Tafel slope of 0.123 and the log i_o value of −6.6 listed in Table I for the 0.5M nickel chloride solution of pH 2.0 at 25°C. Such differences might be anticipated in view of the large concentration of salt present during the codeposition of hydrogen with nickel as well as the dependence of the Tafel slope on the pretreatment of the nickel surface (27).

The Tafel slopes and log i_o, calculated from the graphs published by Reiser and Fischer (7), also have been listed in Table III. These values are based

[4] Values for −log i_o in Table I are far too limited in accuracy to permit the effects of varying pH on the kinetics to be examined in terms of the apparent exchange current density.

on polarization measurements obtained during the simultaneous deposition of hydrogen and nickel. They differ from those obtained by other workers in Table III as well as in the present investigation. Hydrogen overvoltage measurements in sulfuric acid by Bowden and Rideal (31), and Jefferys, Yeager, and Hovorka (27) also have been presented in Table III. It is interesting to note that the Tafel slope is higher in sulfuric acid containing an excess of potassium sulfate. If the Tafel slope for hydrogen on nickel in sulfuric acid tends, in general, to be higher in the presence of a salt, then this may explain the slightly higher slopes obtained for hydrogen overvoltage in the present work.

The heat of activation for the discharge process at the reversible potential of the hydrogen electrode may be calculated on the basis of the following equation:

$$\Delta H^* = \alpha z F[T(\partial\eta/\partial T)_i - \eta] \qquad [2]$$

provided α is independent of temperature. If this equation is applied to the data in Table I for the 0.5M nickel chloride solution at *p*H 2 and at temperatures of 25° and 45°, ΔH^* is approximately +12 kcal, averaged over this temperature range. Considerable question exists, however, as to the accuracy of this value. A change in the roughness factor between 25° and 45° would cause a relatively large error. It is to be compared with values of 6.9 kcal and 16.3 kcal obtained by Bockris and Potter for 0.1*N* and 1.0*N* hydrochloric acid solutions, respectively. A knowledge of the Tafel slope, the exchange current density, and the approximate energy of activation for hydrogen overvoltage on nickel has not proved sufficient to resolve the question (32, 33) as to whether the rate-determining step is proton discharge ($H^+_{aq} + e^- \rightarrow H_{ads}$) or electrochemical desorption ($H^+_{aq} + H_{ads.} + e^- \rightarrow H_2$).

From Fig. 7 to 9, it is evident that the polarization associated with nickel electrodeposition is substantially independent of *p*H and follows the Tafel type dependence on current density. Deviations from linearity at higher current densities are probably associated with concentration polarization. These results support the conclusion that the rate-determining step associated with the nickel deposition is independent of hydrogen discharge over the range of conditions represented in the present work.

The apparent lack of interdependence between nickel deposition and hydrogen discharge can be explained on the basis that the number of sites available for nickel deposition does not vary appreciably with *p*H or potential and that the total number of sites available for each process is very large compared to the actual number of sites involved at any instant.

On the basis of the Tafel slopes listed in Table I, the value for αz is approximately 0.65. Such a value appears reasonable in terms of the transfer of a nickel ion from the solution across an unsymmetrical potential energy barrier to the solid phase as the rate-determining step for the nickel polarization. If this is the case, $z = 2$ and $\alpha = 1/3$. The data in Fig. 7-9 do not appear compatible with rate-determining steps involving transfer of nickel from metastable surface sites to stable lattice sites. It is interesting to note that Yuza and Kopyl (1) in 1940 reported a Tafel slope corresponding to $\alpha \cong 1/2$ on the basis of oscillographic studies of nickel electrodeposition from a 1M nickel chloride solution buffered with boric acid. In 1935, Essin and Alfimova (14), primarily from current efficiency measurements, deduced a value of $\alpha = 0.39$ for nickel sulfate over a range of concentrations and temperatures. The Tafel slope calculated from the graphs of Reiser and Fischer (7) is approximately 0.09 at 40°C for the electrodeposition of nickel from a 1.0M $NiCl_2$ — 1.0M HCl solution as well as a 0.26M $NiCl_2$ solution buffered with boric acid to *p*H 4.4. This Tafel slope corresponds to $\alpha = 0.3$ for $z = 2$.

The variation of the cathodic potential with the nickel ion activity expressed as the derivative $(\partial E/\partial \log a_+)_i$ has been found to be 0.12 for both the chloride and the sulfate solutions on the basis of the data represented in Fig. 7. Nickel ion activities have been calculated on the same basis as described earlier in conjunction with the determination of the reversible nickel potentials. Unfortunately, present day treatments of the double layer structure are not adequate to permit a quantitative prediction of $(\partial E/\partial \log a_+)_i$ with relatively concentrated solutions of polyvalent electrolytes such as $NiCl_2$ wherein complexing occurs. Furthermore, considerable question exists as to the significance of single ion activities evaluated in such solutions by the procedure indicated earlier.

In general, the deposition of nickel from a chloride solution occurs at lower potentials with corresponding higher current efficiencies than from sulfate solutions of the same concentration. This difference between chloride and sulfate solutions is as would be predicted on the basis of the nickel ion activities for the solutions represented in Fig. 7. In the sulfate solutions, the nickel activity coefficients are considerably lower than in chloride solutions. Thus, differences between chloride and sulfate solutions are not evidence of any specific anion effects.

As in the case of the hydrogen polarization data, the energy of activation for nickel deposition may be calculated from Eq. [2], provided the surface roughness factor and α are substantially independent of temperature and the method of ascertaining the reversible potential for nickel relative to the saturated calomel reference electrode is reliable. On the basis of the apparent exchange currents listed in Table I for 0.5M $NiCl_2$ at *p*H 2.0 for 25° and 45°C, the activation energy for nickel is +21 kcal or approximately twice that for hydrogen discharge.

A detailed discussion of the kinetics of the rate-determining steps involved in the nickel deposition will not be given at this time but will be postponed until after the publication of later papers in this series involving the electrodeposition of nickel from mixed solvent systems and the anodic properties of nickel in simple chloride and sulfate solutions.

Streaming Potentials of Corundum in Aqueous Organic Electrolyte Solutions

D. W. Fuerstenau[1] and H. J. Modi[2]

Department of Metallurgy, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

The effect of certain 12-carbon anionic and cationic surface-active compounds on the zeta potential of corundum at different pH values has been evaluated from streaming potential measurements. These measurements, made under conditions of both positive and negative surface charge, indicate that long-chained ions are adsorbed appreciably only when the solid and organic ions are oppositely charged. An adsorption mechanism involving electrostatic attraction and hydrocarbon chain association is discussed using the Stern model of the double layer.

The structure of the double layer has been the subject of considerable interest during the past few years. Although most of the work published deals with theoretical considerations, a number of experimental studies utilizing electrokinetic or electrochemical techniques have also been reported. The effects of organic electrolytes on the properties of the electrical double layer are important in flotation and other processes dependent on surface properties, but still the technical literature on the subject is exceedingly scant. Streaming potential experiments on quartz have shown that aminium ions are strongly adsorbed and are able to change the sign of the electrokinetic or zeta potential, ζ, because ions adsorbed

[1] Present address: Kaiser Aluminum & Chemical Corp., Permanente, Calif.
[2] Present address: National Cash Register Co., Dayton, Ohio.

in the Stern layer associate through Van der Waals attraction between their hydrocarbon chains (1, 2) Aminium ions begin to associate at the quartz-solution interface at pH 7 when their bulk concentration is about one-hundredfold less than their bulk critical micelle concentration (2). The experiments with quartz were carried out with a negatively charged surface, but corundum offers the possibility of working with an oxide mineral that can be readily charged positively or negatively since the zero point of charge occurs at pH 9.4 (3). The object of this paper, therefore, is to present the results of an electrokinetic investigation of corundum in solutions containing long-chained organic ions under conditions of both positive and negative surface charge, and to discuss an adsorption mechanism in terms of experimental results.

Experimental Materials and Method

The preparation and treatment of crushed corundum and the equipment and general techniques used in this investigation have been described previously in detail (3, 4). Great care was exercised in using reagents of the highest purity. Dodecylammonium chloride was obtained from Armour and Company, Chicago, Illinois, and sodium dodecyl sulfate and sodium dodecyl sulfonate were both supplied by Colgate-Palmolive Company, Jersey City, New Jersey. A sample of pure sodium laurate was prepared by neutralizing a warm solution of recrystallized lauric acid (mp 43.3°C) in absolute alcohol with an equivalent amount of a warm solution of metallic sodium in absolute alcohol. The white, waxy precipitate which formed was filtered, washed with alcohol, and dried at 90°C.

Experimental Results

Since H^+ and OH^- are potential-determining ions for alumina (3-5), the pH was maintained constant for each series of experiments. At pH values below 9.4, the alumina surface is positively charged, and at higher pH values it is negatively charged. Thus, by controlling the solution pH it is possible to study the effect of an anion or a cation on the electrokinetic potential of a positively or negatively charged surface.

Anionic organic electrolytes.—Zeta potentials of corundum were determined in aqueous solutions of sodium dodecyl sulfate, sodium dodecyl sulfonate, and sodium laurate at pH 6.5. Sodium dodecyl sulfate and sodium dodecyl sulfonate are both completely dissociated in aqueous solutions in the concentration range investigated. Since the pK of lauric acid (6) is about 5.3 and its solubility is 1.2×10^{-5} moles per liter (7), at pH 6.5 the undissociated acid should precipitate from 2×10^{-4}M additions of sodium laurate. The critical micelle concentrations of these anionic organic electrolytes are the following: sodium dodecyl sulfate, 0.8×10^{-2}M; sodium dodecyl sulfonate, 1.0×10^{-2}M; sodium laurate, 2.4×10^{-2}M.

Experimental results are presented in Fig. 1 along with measurements for sodium nitrate added for comparative purposes. The zeta potential curves are characterized by certain common features. First, the

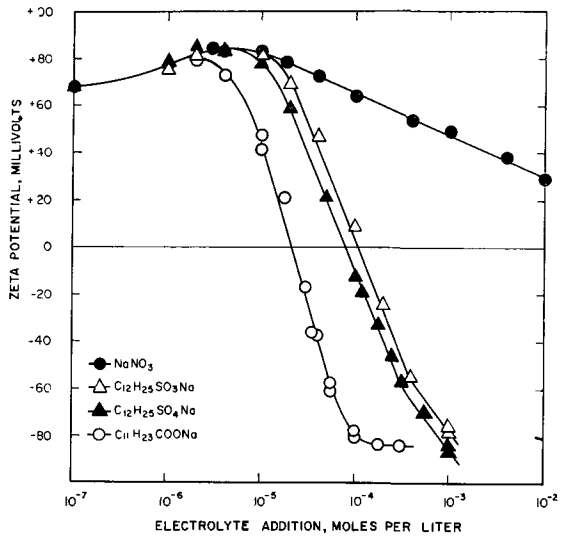

Fig. 1. Zeta potential of corundum in aqueous solutions of sodium laurate, sodium dodecyl sulfate, sodium dodecyl sulfonate, and sodium nitrate at pH 6.5.

experimental values of ζ indicate that all three organic electrolytes function like a simple 1:1 valent inorganic electrolyte (like $NaNO_3$) in dilute solutions. Second, sharp breaks occur in the curves for organic electrolytes with the zeta potential becoming negative, and third, the curves contain a portion where the slope decreases again. In the case of sodium laurate solutions, however, the slope is abruptly reduced to zero by the precipitation of undissociated lauric acid. The slope of the straight line portion of the ζ-log c curve for sodium nitrate is 17 mv, whereas for sodium dodecyl sulfate and sulfonate, it is 102 mv. For sodium laurate, it is 135 mv.

To illustrate the effect of the magnitude and sign of surface charge on the sharp break in the zeta potential curve, measurements were also made at pH 4 and 11 in sodium dodecyl sulfate solutions. In Fig. 2, ζ is plotted as a function of the concentration of both

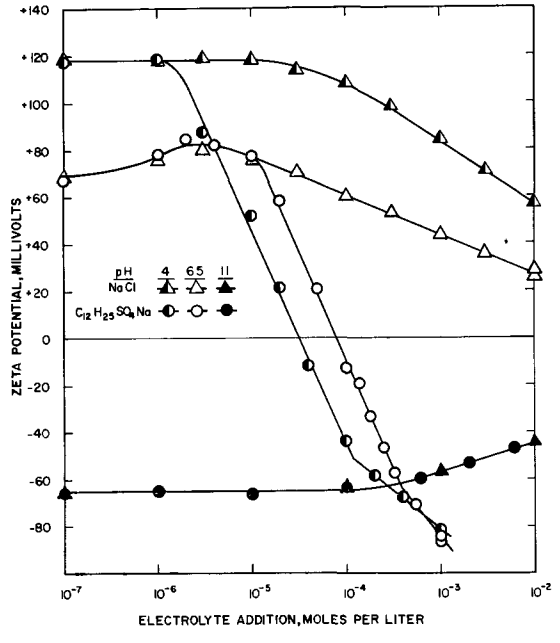

Fig. 2. Zeta potential of corundum in aqueous solutions of sodium dodecyl sulfate and sodium chloride at pH 4, 6.5, and 11.

sodium dodecyl sulfate and sodium chloride at pH 4, 6.5, and 11. It is seen that the sharp break in the ζ-log c curve occurs at nearly a tenfold greater dilution at pH 4 than at pH 6.5, but the slope $d\zeta/d$ log c is still 102 mv. In contrast, $d\zeta/d$ log c for the NaCl curves is only 17 mv and 27 mv at pH 6.5 and 4, respectively. Under conditions where corundum is negatively charged (pH 11), however, the two curves are nearly identical, the slope being —12.5 mv.

Cationic organic electrolytes.—Since anionic paraffin-chain electrolytes bring about an abrupt reversal in the sign of ζ when the surface is positively charged, it seemed reasonable that positively charged organic ions should produce similar changes under converse conditions. To study this experimentally, the zeta potential was determined in aqueous solutions of dodecylammonium chloride at pH 6.5, 10, and 11. The pK for the hydrolysis of dodecylamine is 3.4 and the solubility of dodecylamine is 2×10^{-5} moles per liter (8). At pH 10 and 11, the ratio RNH_3^+/RNH_2 is 4.3 and 0.43, respectively. The critical micelle concentration for dodecylammonium chloride is 1.3×10^{-2}M.

Experimental data are presented in Fig. 3 along with data for sodium chloride added for comparative purposes. At pH 6.5, when corundum is positively charged, dodecylammonium chloride behaves as an ordinary indifferent electrolyte, such as NaCl, because identical values are obtained in solutions of equal concentration. However, when corundum is negatively charged, dodecylammonium ions abruptly change the sign of ζ once a critical concentration is reached. For instance, in the ascending portion of the curve at pH 11, $d\zeta/d$ log c is nearly —350 mv. However, with further additions of dodecylammonium chloride the slope drops back to zero because of the precipitation of free amine. At pH 10, a similarly shaped curve is also obtained, although ζ becomes somewhat less positive as more dodecylammonium chloride is added. This results from the fact that, once the solubility of the free amine is exceeded, addition of dodecylammonium chloride at constant pH is equivalent to adding more NaCl, which increases the ionic strength and compresses the double layer, thereby reducing the zeta potential.

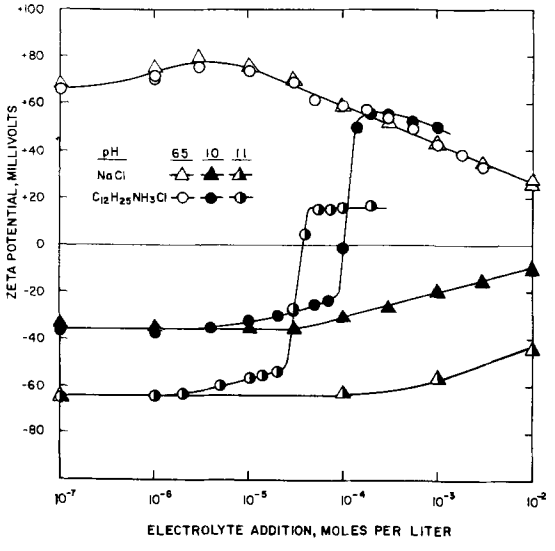

Fig. 3. Zeta potential of corundum in aqueous solutions of dodecylammonium chloride and sodium chloride at pH 6.5, 10, and 11.

Discussion of Results

Since H^+ and OH^- are potential-determining ions for corundum (3, 5), the surface potential, ψ_o, of corundum depends on the pH of the solution, and its value in volts can be calculated from

$$\psi_o = \frac{kT}{ve} \ln \frac{a_{H^+}}{a_{H_o^+}} = 0.059 \ [9.4 - pH] \qquad [1]$$

where a_{H^+} is the activity of H^+ in solution and $a_{H_o^+}$ is their activity at the zero point of charge, namely, pH 9.4 (3). In Eq. [1], k is Boltzmann's constant, T is absolute temperature in degrees Kelvin, v is the valency of H^+ (sign of charge included), and e is the electronic charge. The surface potential is +300 mv, +170 mv, —30 mv, and —90 mv at pH 4, pH 6.5, pH 10, and pH 11, respectively. In conductivity water, the values of ζ should approach ψ_o, but surface conductance has lowered the calculated value of ζ to +70 mv because the measurements were made with particles (10, 11). Experimental measurements of ζ with particles and capillaries made of the same glass have shown that data obtained with capillaries are 80, 50, and 17% higher in 10^{-6}, 10^{-5}, and 10^{-4}M KNO_3 solutions, respectively, than the values determined with particles (10). However, in the present investigation, we are essentially concerned with the conditions where ζ changes sign, and these conditions do not depend on particle size.

Monovalent inorganic electrolytes, such as NaCl or $NaNO_3$, reduce ζ to practically zero in highly concentrated solutions through compression of the electrical double layer (3), but under no condition do they change its sign. Monovalent organic ions, on the other hand, can change the sign of ζ provided they are charged oppositely to the surface. Under conditions wherein the organic ion and the solid surface are charged oppositely, ζ-log c curves indicate that organic ions are adsorbed as individual counter ions through coulombic attraction for the surface until a certain critical concentration is reached within the double layer when the hydrocarbon chains of the ions adsorbed in the Stern layer begin to associate and change the sign of ζ. Because of the analogy of this phenomenon to micelle formation in the bulk solution, the associated organic ions in the Stern layer have been called hemi-micelles (1, 2). The reduction of the slope of the ζ-log c curves at higher concentrations results either from monolayer coverage (in the case of dodecyl sulfate and sulfonate ions) or from precipitation of a neutral molecule (lauric acid or dodecylamine).

Stern first pointed out that the work W_i required to bring an ion from the bulk of the solution to a point in the double layer at potential ψ_i might involve not only electrostatic work

$$W_i = ve\,\psi_i \qquad [2]$$

but also chemical work, ϕ:

$$W_i = ve\,\psi_i - \phi \qquad [3]$$

If the adsorbed ion possesses a long hydrocarbon chain, Van der Waals association between hydrocarbon chains of similarly adsorbed ions will give rise to an additional work term, ϕ':

$$W_i = ve\,\psi_i - \phi - \phi' \qquad [4]$$

From the data presented in Fig. 2 and 3, it can be seen that reversal of ζ occurs only when the solid and organic ion are oppositely charged, meaning that the organic ions are adsorbed appreciably only when they can function as counter ions at the interface. Since these long-chained electrolytes affect ζ in a manner identical to any indifferent electrolyte under conditions of like charge, they have no chemical affinity for alumina and, consequently for this system, ϕ is zero. Thus, the inner Helmholtz plane will be empty and the heads of the adsorbed organic ions will lie in the outer Helmholtz or Stern plane. Under conditions represented by the initial portion of the ζ-log c curves, the force of adsorption is simply electrostatic and ϕ' is zero, whereas under conditions corresponding to the second and third parts of the curves, Van der Waals force of association between hydrocarbon chains becomes operative and ϕ' has a finite value. However, ϕ' is not constant and will depend on the orientation of the adsorbed organic ions in the Stern layer. Thus, the attractive force between the adsorbed organic ions will increase from zero to a value that is approximately the energy gained by taking the hydrocarbon chain out of water; namely, 1.1 kT per CH_2 group in the chain (9). The rate at which ϕ' becomes effective is illustrated qualitatively by any of the graphs.

Qualitatively, dodecyl sulfate ions change the sign of ζ at a lower bulk concentration than is required for dodecyl sulfonate ions, which is in accord with their relative critical micelle concentrations. However, even though the critical micelle concentration of sodium laurate is somewhat higher than that for sodium dodecyl sulfate, laurate ions begin to associate at the corundum-solution interface at a lower bulk concentration than is required for sodium dodecyl sulfate. At pH 6.5, the ratio of laurate ions to lauric acid molecules in solution is 16, that is, nearly 6% of the sodium laurate added is present as undissociated lauric acid. In the bulk solution this concentration of 12-carbon neutral molecules is not sufficient to lower the cmc (12), but it must be a major factor in adsorption at the solid-solution interface. If a laurate ion is anchored in the Stern plane, a lauric acid molecule can then be adsorbed through association of hydrocarbon chains. Another laurate ion can then be adsorbed through Van der Waals attraction between its hydrocarbon chain and that of an anchored lauric acid molecule. In this case repulsion between the charged laurate ion heads will be lower because of the intervening uncharged molecule. This is rpresented by F_{rep} in Fig. 4. If association of organic molecules with organic ions takes place before the Stern layer is sufficiently populated with enough organic ions for the ions to associate by themselves, ϕ' should already have a finite value when the curves begin to break sharply. Observation of Fig. 3 shows that the ζ-log c curves

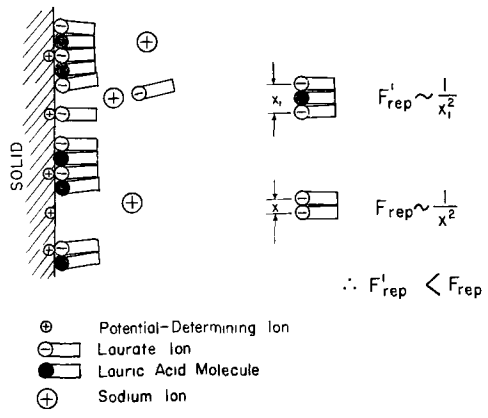

Fig. 4. Schematic representation of double layer when neutral molecules are present.

for dodecylammonium chloride (pH 10 and 11) begin to deviate from the curves for NaCl at concentrations above 2×10^{-6}M. This deviation increases gradually until it is 12 mv at the point where the ζ-log c curve breaks sharply. Thus, ϕ' for the system involving dodecylammonium chloride in alkaline solutions is zero only until 2×10^{-6} mole of the organic salt has been added. Because of the presence of the dodecylamine molecules, ϕ' begins to increase gradually for 2×10^{-6}M additions, but it increases sharply at the abrupt break in the ζ-log c curves. If the organic salt is a strong electrolyte, organic molecules are absent and the ζ-log c curves do not deviate from those of NaCl before the sharp break (Fig. 2).

Increasing the surface potential, that is, lowering the pH from 6.5 to 4.0, was found to reduce the bulk concentration of dodecyl sulfate ions which is required for the adsorbed ions to associate (Fig. 2). This results from the increased adsorption of counter ions. It should be pointed out that competition exists for sites in the double layer because the concentration of Cl^- is 10^{-4}M. At pH 11, sodium dodecyl sulfate affects ζ in a manner identical to sodium chloride. This indicates that the counter ions in each case are sodium ions and that dodecyl sulfate ions have no chemical affinity for corundum. In this case no association can take place because the concentration of dodecyl sulfate ions next to the surface is only about one-tenth of the bulk concentration.

A quantitative estimate of the value of ϕ' can be made by looking at the double layer under conditions where ζ is zero. For this quantitative treatment, the Stern plane must be assumed to coincide with the shear plane in streaming experiments in order that ζ equals ψ_s, the potential at the Stern plane. Under conditions where ζ is zero, all the counter ions occur in the Stern plane and consequently the double layer consists only of a molecular condenser.

The capacity C_s of the molecular condenser will be assumed to be constant and the relation with the surface charge σ where ζ is zero can be expressed by

$$\sigma = \psi_o\, C_s \qquad [5]$$

The charge of the Stern plane, σ_s, which is equal to but opposite in sign to the surface charge for this

Table I. Data for the calculation of ϕ' with Eq. [8a] when ζ is zero

Electrolyte	pH	ψ_o, mv	y	K'	c_o	ϕ', kT
Sodium dodecyl sulfate	6.5	+170	6.8	10.9	8.2×10^{-5}M	8.9
Sodium dodecyl sulfate	4.0	+300	12	10.9	3.3×10^{-5}	10.9
Sodium dodecyl sulfate	11.0	—90	—3.6	—	—	0

Sodium laurate	6.5	+170	6.8	22.2	2.5×10^{-5}	9.4
Dodecylammonium chloride	6.5	+170	6.8	—	—	0
Dodecylammonium chloride	10.0	—30	—1.3	21.2	8.9×10^{-5}	6.9
Dodecylammonium chloride	11.0	—90	—3.6	21.2	1.2×10^{-5}	9.5

model, is given by

$$\sigma_s = 2\ rnve \exp\left(\frac{\phi'}{kT}\right) \qquad [6]$$

when ζ is zero (13). In Eq. [6] r is the radius of the ion under consideration, that is, the head of the organic ion charged oppositely to the surface, and n is the number of such ions per cc of bulk solution.

For the molecular condenser:

$$\psi_o C_s = \sigma = -\sigma_s = -2\ rnve \exp\left(\frac{\phi'}{kT}\right) \qquad [7]$$

Multiplying both sides of the equation by ve/kT and rearranging terms gives

$$\frac{ve\,\psi_o}{kT} = -\left(\frac{ve}{kTC_s}\right) 2\ rnve \exp\left(\frac{\phi'}{kT}\right) \qquad [8]$$

$$vy = -K' c_o \exp\left(\frac{\phi'}{kT}\right) \qquad [8a]$$

where y is $e\psi_o/kT$ (ψ_o being evaluated from Eq. [1]), K' is $\frac{2\,v^2e^2r}{kTC_s}$ $(N/1000)$. Here N is 6.02×10^{23} molecules per mole, and c_o is the concentration in moles per liter of the organic electrolyte to bring the value of ζ to zero. Evaluation of ϕ' depends on the value and constancy of C_s, the mathematical identity of the Stern plane and the shear plane (obviously the shear plane exists outside the hydrocarbon chains of the adsorbed organic ions, but for use of Eq. [8] ψ_s must be zero when ζ is zero), and the presence or lack of a layer of water molecules between the adsorbed ions and the surface. For the present calculation, the large sulfate and sulfonate ion (2.9Å radius) will be considered to be dehydrated, and consequently the capacity of the Stern layer will be about 25 $\mu F/cm^2$. Because of the similarity in behavior between ammonium ions and the aminium ions (2), the aminium ions are probably separated from the surface by a layer of water molecules and C_s will thereby be about $15\mu F/cm^2$ (14). The value of r in Eq. [8] then must be the radius of the aminium head plus one water molecule, or a total of 4.2Å. Similarly, the relatively small soap ion (which would be 1.7Å when the tail is perpendicular to the surface) will be considered to be separated by a layer of water molecules from the surface. Consequently, the value of r in Eq. [8] will be 4.4Å and C_s will be $15\mu F/cm^2$.

The results of calculating ϕ' with Eq. [8] when ζ is zero are presented in Table I. The concentration of dodeclyammonium ions must be corrected to account for hydrolysis at pH 10 and 11.

In our picture of the adsorption mechanism, the adsorption potential ϕ' is zero until the organic ions in the Stern layer begin to associate, this being depicted by the deviation of the ζ-log c curve of an organic electrolyte from a surface-inactive inorganic electrolyte. For example, in the system involving corundum in aqueous solutions of sodium dodecyl sulfate at pH 6.5, ϕ' will be zero until the bulk concentration of sodium dodecyl sulfate reaches 10^{-5}M. Thereupon, ϕ' begins to increase as the adsorbed ions associate, reaching a value of about 8.9 kT when the bulk concentration is 8×10^{-5}M. Under these conditions ζ is zero. The value of ϕ' will continue to increase until the Stern layer is filled. Under these conditions ϕ' will approach 12 kT if all but the end CH_3 group is out of water. Beyond this point, adsorption probably will occur in multilayers. A plot of ϕ' vs. the logarithm of the concentration of sodium dodecyl sulfate yields a fairly straight line if ϕ' is zero at the first break in the ζ-log c curve (10^{-5}M), 8.9 kT when ζ is zero (8×10^{-5}M), and 12 kT at the second break in the ζ-log c curve (3×10^{-4}M). The slope of this curve $d\phi'/d$ log c is about 9 kT. A similar plot of the data at pH 4 shows that $d\phi'/d$ log c is reduced to about 7 kT. This reduction probably reflects the competition between dodecyl sulfate ions and chloride ions at the surface. For sodium laurate, $d\phi'/d$ log c is about 8 kT. Since the solubility limit of dodecylamine is rapidly reached, $d\phi'/d$ log c is over 300 kT (note the steep slopes in Fig. 3) for the systems involving dodecylammonium chloride at pH 10 and 11.

In this paper, the adsorption potential ϕ' which arises through association of hydrocarbon chains has been evaluated by considering the double layer as a molecular condenser when ζ is zero. Since ϕ' appears as an exponent in Eq. [8], its value does not change appreciably with the change in capacity of the Stern layer. However, adsorption measurements should be carried out to determine the actual value of the capacity of the molecular condenser in order to ascertain whether the organic ions are hydrated or not in the Stern layer.

Summary

The effect of 12-carbon organic ions on the zeta potential of corundum has been measured by stream-

ing potential techniques. Experimental data indicate that organic ions are adsorbed appreciably only under conditions where the solid and the organic ions are charged oppositely. Adsorption takes place as individual ions until a sufficiently high concentration is attained in the Stern layer to permit association of their hydrocarbon chains. This association results in increased adsorption which can be represented by an adsorption potential in the Boltzmann equation. By considering the double layer to be a molecular condenser when ζ is zero, the adsorption potential resulting from association of hydrocarbon chains was evaluated. The presence of uncharged long-chained molecules reduces the bulk concentration required for association next to the surface.

Acknowledgments

This research was made possible through the financial support provided by the Aluminum Company of America. The interest of Professors A. M. Gaudin and P. L. de Bruyn in this work is appreciated. The authors also wish to thank Dr. H. J. Harwood, Armour and Company, for a sample of purified dodecylammonium chloride and Dr. A. I. Gebhart, Colgate Palmolive Company, for samples of purified sodium dodecyl sulfate and sodium dodecyl sulfonate.

Manuscript received June 30, 1958. This paper was presented before the New York Meeting, April 27-May 1, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Capacities of Solid Metal-Solution Interfaces

J. J. McMullen[1] and Norman Hackerman

Department of Chemistry, University of Texas, Austin, Texas

ABSTRACT

An electric analog of the metal-solution interface was assumed and E vs. t changes were deduced mathematically for application of a square wave voltage. The analysis was verified using actual electric components, and it was demonstrated that the component of capacity could be measured readily. The method was applied with some success to each of the following systems: mercury in 0.1N Na_2SO_4, platinum, silver, copper, aluminum, and tantalum in 1N Na_2SO_4.

At various times investigators have attempted to determine roughness factors (ratios of true to apparent surface areas) of metal electrodes by means of capacity measurements. Assumptions usually made in these attempts included (*a*) that all metals have the same capacities at potentials slightly anodic (positive) to their hydrogen evolution potentials, and (*b*) that for mercury the apparent surface area is the true surface area. Thus if the capacity per square centimeter of apparent area for the metal M was C_M (at a potential just short of hydrogen evolution) and that for mercury C_{Hg} (at a similar potential) then the roughness factor of the metal M was C_M/C_{Hg}.

Assumption (*b*) is reasonable. However, assumption (*a*) is not entirely tenable. The small amount of information in the literature concerning capacities of solid metal electrodes shows wide discrepancies. Grahame (1) has published very useful papers concerning the differential capacity of mercury. Solid metal electrodes, however, have not been investigated systematically. Of course, differential capacities of solid electrodes cannot be checked by electrocapillary methods and as a result electrical double layer (edl) theory concerning solid metal electrodes has not been as extensively treated as has that of the mercury-solution system.

Several experimental techniques have been utilized to measure differential capacities of mercury-solution interfaces. The most sensitive method is the impedance bridge method. Grahame (1) has used this method extensively and reports an accuracy of better than 1%. The major drawback of this method is its inapplicability to large capacities. Bowden and Rideal (2) devised a method of measuring capacities by direct charging. They observed the potential change resulting from the passage of a known direct current for a known length of time. The potential changes involved, however, were of the order of 0.5 v, and the capacities calculated were, therefore, an

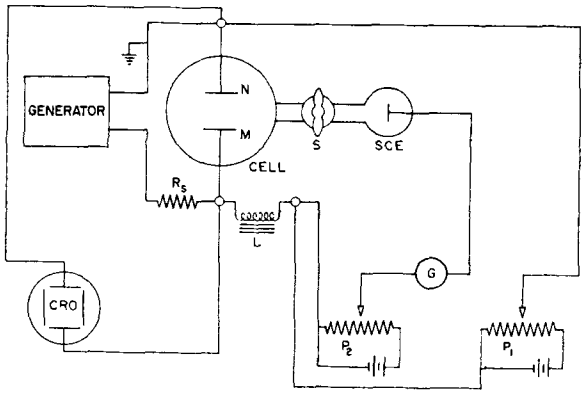

Fig. 1. Circuit diagram

average over a large potential change. Wagner (3) used a ballistic galvanometer to measure the charge required to polarize a silver specimen 0.1 v.

Methods involving direct charging all assumed that any current supplied to the electrode was involved in charging the edl. In effect, the assumption was made that the interface behaved as an ideally polarizable one.

Brodd and Hackerman (4) reported results obtained with solid metal electrodes showing a correlation between areas calculated from capacity data and areas measured by krypton adsorption. Their capacity data were obtained from time-potential traces observed when a square-wave signal was applied to the electrodes. This method has been modified and utilized here in an attempt to determine the differential capacity curves for several solid metal-solution interfaces.

Experimental

The circuit diagram is shown in Fig. 1. The source of the square wave voltage was a Model 202-A function generator manufactured by Hewlett-Packard. The generator applied a square wave voltage, across the series resistance, R_s, to the electrodes N and M. The potential change across the cell was observed on the cathode-ray oscilloscope, CRO. Potentiometer P_1 was used to polarize electrode M using N as an auxiliary electrode. Potentiometer P_2 measured the potential of M with respect to the saturated calomel electrode, SCE. L was an inductance placed in the circuit to keep the alternating current from the direct current parts of the circuit. For each measurement the CRO was connected to the generator to obtain a trace of the input square wave. Permanent records of the traces were obtained photographically.

The Pyrex cells used for measurements and for reservoir are, respectively, A and B in Fig. 2. The mercury electrode M was formed in a Pyrex cup with an inside diameter of 2.5 cm. The mercury level was controlled so that the top of the mercury meniscus was tangent to the plane at the top of the cup. A fresh surface was obtained by overflowing the mercury from the cup. A platinized platinum screen cylinder, N, suspended through the top of the cell and surrounding the mercury electrode, was in series with the mercury electrode in the a-c circuit. The area of the platinum screen cylinder was very large compared to that of the mercury; hence its capacity was large and its effect on the cell impedance should have been negligible. The saturated calomel electrode, SCE, was immersed in the solution in a small side cell connected to the main cell A through the closed stopcock S_2.

A ball joint and closed stopcock S_1 connected the main cell A with cell B. Cell B served as a pre-electrolysis cell and reservoir for solution. Pre-electrolysis with a current of 3 ma was carried out for at least 12 hr.

Bureau of Mines grade A helium, reported as 99.99% pure, was bubbled through a saturator and passed into cells A and B. The helium stirred the solution and provided an inert atmosphere. After pre-electrolysis and at least 4 hr of helium flushing, the helium pressure was used to force solution from B into A.

Distilled water was redistilled from alkaline permanganate to remove any organic matter. The mercury was triple-distilled instrument mercury. Other metals were used as wires put into the solution through the tip of the cell. Pretreatment of wires consisted of degreasing, washing with dilute sulfuric acid, and rinsing with distilled water.

The importance of avoiding grease contamination has been demonstrated (5). No grease was used in any part of the apparatus employed in these experiments.

Analysis of time-potential curve.—In the study of time-potential curves obtained with a square wave, it is helpful to consider the time-potential changes at the electrode surface in terms of an analogous electric circuit. Various simple and complex arrangements of resistors and capacitors have been utilized to represent the behavior of such an interface. One of the simplest, Fig. 3, consists of a condenser (C) in parallel with a resistance (R_p), both being in series with another resistance (R_e). In the present case the square wave passed through resistance R_s before entering the cell. The potential difference between points A and B was observed on the

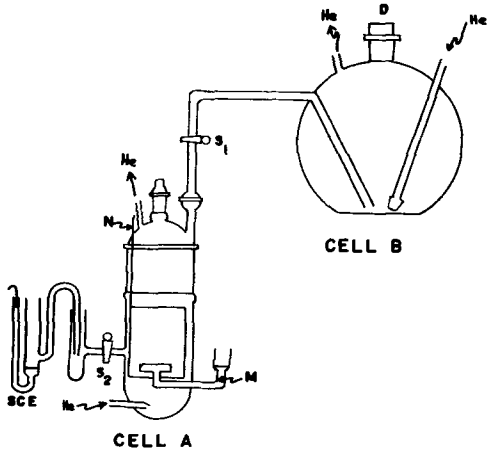

Fig. 2. Polarization cell and reservoir

CRO. Three cases were examined to determine the time-potential behavior to be expected under different conditions.

Case I: $R_p = \alpha$; $R_e = 0$

If the simplifying assumptions are made that the interface is an ideally polarizable one and that the resistance of the solution is zero, then R_p is infinite and R_e is zero. The equation for the change of voltage (E_c) between points A and B, in this case, is

$$E_c = E_i\,[1 - \exp\,(-t/R_sC)] \qquad [1]$$

where t is time and E_i is the input voltage. The value of E_c approaches the value of the input voltage, exponentially, with increasing time. At short time intervals, $t << R_sC$, the exponential in Eq. [1] was expanded to give

$$E_c = E_it/R_sC \qquad [2]$$

In this time interval E_c is a linear function of time. With reversal of the current, i.e., on the second half of the square wave cycle, another linear function, with slope of opposite sign, is obtained. The composite result for small time intervals is a triangular trace on the CRO.

Case II: $R_p \neq \alpha$; $R_e = 0$

If the interface is not an ideally polarizable one, R_p has a finite value. The equation for the change in voltage is now:

$$E_c = \frac{E_iR_p}{(R_s + R_p)}\left[1 - \exp\frac{\{-t(R_p + R_s)\}}{CR_pR_s}\right] \qquad [3]$$

At short time intervals, $t << CR_pR_s/(R_p + R_s)$, the exponential in Eq. [3] was expanded to give Eq. [2]. The form of the trace is thus the same as in Case I.

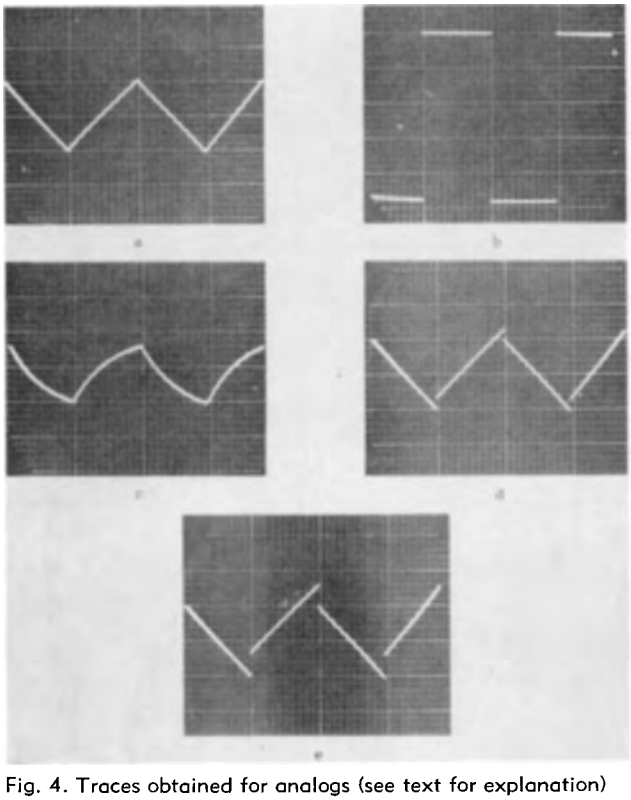

Fig. 4. Traces obtained for analogs (see text for explanation)

Case III: $R_p \neq \alpha$; $R_e \neq 0$

Introduction of R_e into the system results in discontinuities in the time-potential curve. These potential drops are representative of IR_e, where I is the current. The equation of each half-cycle obtained on the oscilloscope is thus:

$$E_c = IR_e + E_it/R_sC \qquad [4]$$

In all three cases, therefore, Eq. [2] gives the dependence of E_c on t for small values of time. Differentiating Eq. [2] with respect to time gives

$$dE_c/dt = E_i/R_sC \qquad [5]$$

If the frequency of the input square wave is selected to give a triangular trace on the oscilloscope, then the absolute values of the slope for each half-cycle is given by Eq. [5].

The three cases given above were studied experimentally by obtaining oscilloscope traces for the respective electrical circuits.

Figure 4a is a photograph of the CRO trace for the time-potential curve with the circuit described in Case I (Fig. 3). Here C was a 37μF commercial electrolytic condenser, R_s was a 15,000-ohm resistor, and the input voltage, E_i, was 100 cps square wave. A trace of the input voltage E_i, attenuated 100:1, is shown in Fig. 4b.

From the slope of the trace in Fig. 4a, and the known values of the input voltage (E_i) and of R_s, the capacity of condenser C can be calculated with Eq. [5]. The time for one half-cycle was 0.005 sec; the voltage rose 10 divisions in this time, giving the slope 2 x 10^3 div./sec. Therefore,

$$C = (dt/dE_c)\,(E_i/R_s) = \left(\frac{1}{2 \times 10^3}\right)\frac{12(100)}{15{,}000} = 40\mu F$$

This is in good agreement with 37μF measured by the conventional bridge method.

Figure 4c shows a trace obtained with a circuit described under Case II. Here, C was a 54μF condenser, R_p a 100-ohm resistor, R_s a 15,000-ohm resistor, and the frequency 50 cps. The time-potential curve is not a triangular wave. However, when the frequency of the input square wave was increased to 500 cps the output trace was triangular and the calculated capacity was 58μF. An increase in the amplitude of the input square wave, at this same frequency, resulted in a triangular trace with increased slope, and looked just like the trace in Fig. 4a. The product of the reciprocal of the slope and the input voltage remained constant, however, and the calculated capacity was again 58μF.

Figure 4d shows a trace obtained with a circuit described by Case III. Here C was a 54μF condenser, R_p 100 ohms, R_s 15,000 ohms, R_e 13 ohms, and the frequency 500 cps. The time-potential curve showed discontinuities between the linear portions. The calculated capacity was 58μF. The IR_e drop, (Fig. 4d), was 1.5 divisions. When R_e was doubled to 26 ohms, the discontinuity doubled in size (Fig. 4e) to 3 divisions. The calculated capacity remained the same, since the slope of the linear portions did not change.

Results and Discussion

Mercury.—The mercury-solution interface was investigated as another check, since the results could be compared with those of other workers. The Pyrex cup containing the mercury had an inside diameter of 2.5 cm. Assuming the surface of the mercury to be planar, the surface area was 5 cm^2. If the curvature of the surface were taken into consideration, the area could be as high as 6 cm^2. The former value was used here.

The solution used was 0.1*N* Na_2SO_4, and all experiments were conducted at 30° ± 1°C. The potential values given refer to the saturated calomel electrode. A 15,000-ohm resistor was used as the series resistance R_s throughout the rest of the experiments. Application of the square wave voltage, employed to carry out the capacity measurements, changed the potential of the electrodes somewhat. The change of potential was less than 10 divisions on the CRO. Since the sensitivity of the CRO was approximately 1.5 mv/division, the uncertainty in the measured potentials of the electrodes were less than 0.02 v.

Figure 5a is a photograph of a typical time-potential trace obtained with mercury electrodes. The potential of the mercury was −0.2 v in this case. The time-potential trace is a triangular wave with discontinuities between the linear portions. This type of trace corresponds to Case III. The calculated capacity was 154μF or 31$\mu F/cm^2$.

Capacity measurements were made at potentials varying from 0.0 to −1.0 v. These potentials were obtained by polarizing the mercury electrode with an auxiliary potentiometer. The differential capacity curve is shown in Fig. 6.

Grahame (1) found the potential at the zero point of charge (zpc) of mercury in 0.1*N* Na_2SO_4 to be −0.44 v. Therefore, for the purposes of discussion, the curve in Fig. 6 may be divided into three regions: (*a*) a region of potentials more negative than the zpc (cathodic branch of the curve), (*b*) a region of potentials more positive than the zpc (anodic branch of the curve), and (c) a region of potentials in the immediate vicinity of the zpc.

The capacity on the cathodic branch is independent of the potential and has a constant value of 19 $\mu F/cm^2$. This value would be 16$\mu F/cm^2$ if the higher surface area value were used. The constancy of the capacity along this branch of the curve has been verified experimentally many times. The value obtained here agrees with Proskurnin and Frumkin (6), Barclay and Butler (7), and Philpot (8). Grahame's experimental value was 16$\mu F/cm^2$.

The anodic branch of the curve does not show the broad flat portion found on the cathodic branch. However, for a narrow region of potentials, the curve has a slope close to zero. The average capacity in this region was about 33$\mu F/cm^2$. Grahame's curve shows such a "hump" at about 35$\mu F/cm^2$.

In the region of the zpc, a transitional portion of the curve occurs with capacities intermediate between those for the cathodic and anodic branches of the curve. In very dilute solutions (N/100 and less), this region exhibits a more or less sharp minimum. Even with 0.1*N* Na_2SO_4 Grahame found a minimum of the order of 1 or 2$\mu F/cm^2$. The sensitivity of the present measurements is insufficient to permit observation of such a shallow minimum in the curve.

Platinum.—In order to avoid the large solution resistance encountered in dilute solutions, the remaining experiments were conducted in 1*N* Na_2SO_4. The platinum electrodes were 20 cm in length and were cut from smooth wire having a diameter of 0.04 cm. The apparent electrode area was 2.5 cm^2.

A photograph of a typical time-potential trace obtained with platinum electrodes is shown in Fig. 5b. The time-potential trace is again of the type discussed under Case III above. However, the IR_e drop is considerably less than with mercury in 0.1*N* Na_2SO_4 (compare Fig. 5a and 5b).

Results of the capacity measurements, at potentials varying from 0.0 to 1.4 v, are shown in Fig. 7. The shape of the curve obtained is similar to that for mercury. Three regions are evident: a portion where the capacity is fairly constant at approximately 80μF, a narrow region having a capacity of

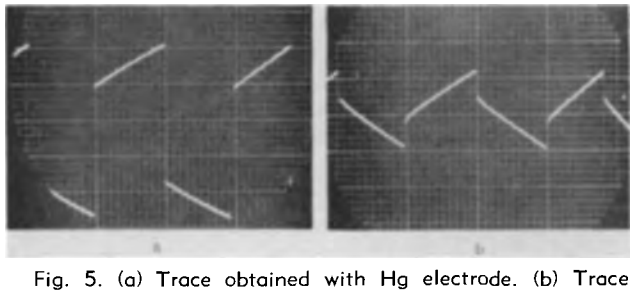

Fig. 5. (a) Trace obtained with Hg electrode. (b) Trace obtained with Pt electrode.

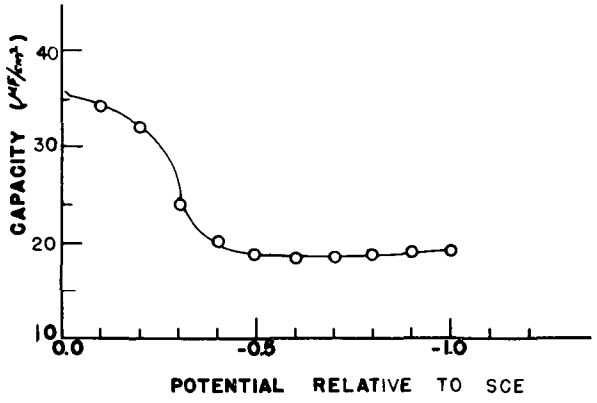

Fig. 6. Differential capacity curve for Hg-0.1N Na_2SO_4

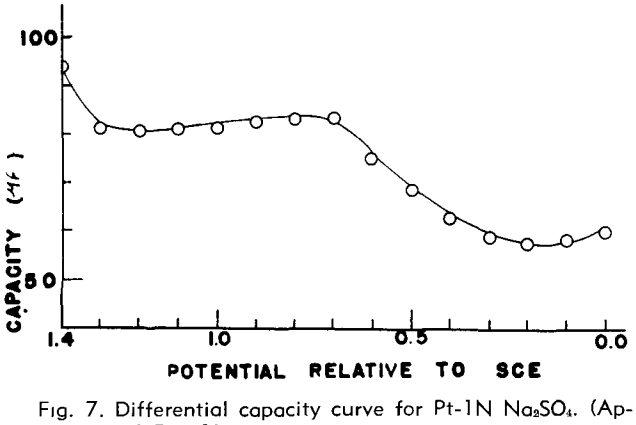

Fig. 7. Differential capacity curve for Pt-1N Na_2SO_4. (Apparent area 2.5 cm^2.)

approximately 58 μF, and a connecting portion with intermediate capacities.

These regions can be interpreted in the same fashion as for the curve obtained for mercury in 0.1*N* Na_2SO_4. The transitional portion of the curve is expected to be in the neighborhood of the zpc. Therefore, the zpc for platinum in this solution should be 0.5 ± 0.2 v. Robertson (9) has obtained a capacity minimum, for platinum in 1*N* HCl, at 0.79 v. A value of −0.04 v in acidified 1*N* Na_2SO_4 by contact angle measurements has also been reported (10).

The cathodic portion of the curve, with total capacities of the order of 54 μF, is the region of cation predomination in the double layer. Using the apparent area of the electrodes, the capacity was approximately 22 μF/cm^2. On the anodic portion the capacity was 32 μF/cm^2.

Silver.—The apparent area of the silver electrodes was 1.3 cm^2. The polarization caused by the square wave voltage was less than 15 mv.

The results of capacity measurements, at potentials of 0.0 to −1.2 v, are shown in Fig. 8. The shape of the curve is similar to that obtained for the mercury-solution interface. The zero point of charge has been reported for silver, in 0.1*N* KNO_3, as −0.233 v (11). A hump appears, in the vicinity of this potential, on the capacity-potential curve. Similar humps have been observed in the region of the zero point of charge for capacity-potential curves obtained for mercury in concentrated solutions. Grahame (1) has suggested that the humps arise from the mutual electrostatic repulsion of ions in the double layer. Watanabe, Tsuji, and Ueda (12) have suggested that this phenomenon is related more to mercury-ion interaction than to ion-ion interaction. The appearance of this phenomenon with silver and not with platinum seems to favor the latter suggestion.

The cathodic portion of the curve shows a capacity of approximately 58 μF. This would be the region of cation predomination in the solution side of the double layer. The capacity was approximately 45 μF/cm^2. This apparently high value of the capacity is not unreasonable. Wagner (3) has reported values of the order of 100 μF/cm^2 for "smooth" silver wires.

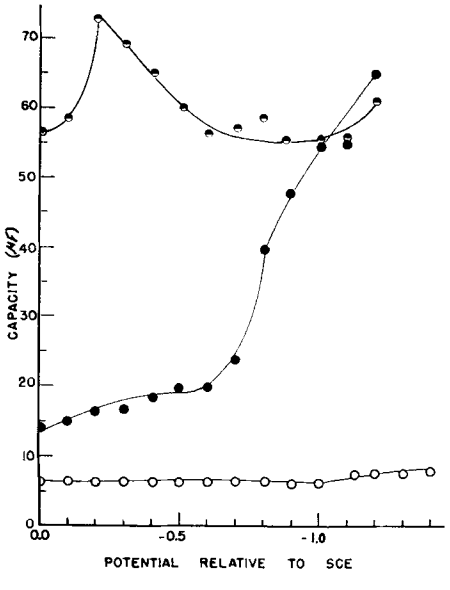

Fig. 8. Half-filled circle: Differential capacity curve for Ag-1N Na_2SO_4. (Apparent area 1.3 cm^2.) Open circle: Differential capacity curve for Al-1N Na_2SO_4. (Apparent area 2.5 cm^2.) Solid circle: Differential capacity curve for Al-1N Na_2SO_4 after cathodic treatment.

Aluminum.—The apparent surface area of the aluminum electrodes was 2.5 cm^2. The results of capacity measurements are shown in Fig. 8. The shape of this curve has no similarity to the curve obtained for mercury. The capacity is fairly constant over the range of potentials at which it was measured. The low values of the capacities, about 3 μF/cm^2 of apparent surface, are not surprising, since aluminum is normally covered with an oxide film. Rakov and Ershler (13) obtained 7 μF/cm^2 for an oxide covered electrode. The capacity of the oxide film is small compared to the capacity of the double layer. Therefore, the measured capacity would be primarily that of the oxide film. The capacity of the film is not dependent upon the potential. This explains the apparent nondependence of the measured capacity upon the potential.

Estimates of the thickness of oxide films on metals have been made by capacity measurements (14). Wanklyn (15) has used capacity measurements to study the protective character of oxide films on zirconium alloys. In these measurements the double layer capacity was neglected. Assuming the film substance to be γAl_2O_3, and using a value of 8 for the dielectric constant (16), the film thickness was calculated to be approximately 20Å.

A potential large enough to evolve hydrogen at the aluminum electrode was applied, momentarily, between it and an auxiliary electrode placed in the small side cell. The capacity was measured at potentials progressively more anodic. The results of these measurements are shown in the upper curve in Fig. 8. The capacity was found to be much higher after this treatment but decreased with time and the potential of the aluminum became progressively more anodic. The values of the capacity after cathodic treatment were in all cases substantially higher but fairly irreproducible. It is likely that the rise in capacity after cathodic pretreatment may be caused by the oxide film thinning due to the local increase in *p*H at the electrode.

Tantalum.—The apparent area of the tantalum electrodes was 1.6 cm^2. The results of the capacity measurements are shown in Fig. 9. The shape of this curve is very similar to that of aluminum. Tantalum, like aluminum, is normally covered by an oxide film. Therefore, the low values obtained for the capacities are in no way unusual. The average value of the capacity was approximately 9 μF/cm^2. Capacities were measured at progressively more anodic potentials to observe possible evidence of increased oxide formation. From Fig. 9 it can be seen that there is a continuous slow trend toward lower capacities. This lowering of capacity at more anodic potentials suggests the formation of more oxide on the surface of the tantalum.

Copper.—The apparent surface area of the copper

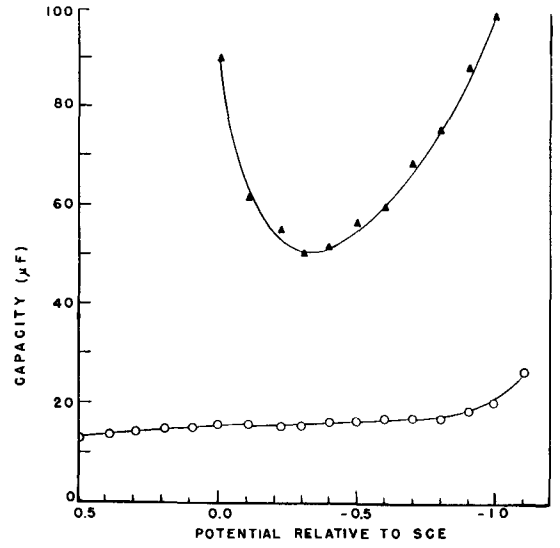

Fig. 9. Open circle: Differential capacity curve for Ta-IN Na_2SO_4. (Apparent area 1.6 cm^2.) Solid triangle: Differential capacity curve for Cu-IN Na_2SO_4. (Apparent area 2.4 cm^2.)

electrodes was 2.4 cm^2. The capacity-potential curve is shown in Fig. 9.

Since no value of the zpc could be found in the literature, an approximation method, as used earlier by Brodd and Hackerman (4), was tried. The work function for copper is 4.6 ev (17) and for mercury 4.5 ev (18). The difference between these two is 0.1 v. The zpc for mercury is −0.44 v; therefore, the zpc for copper is approximately −0.3 v. It is further noted that this approximation is made more approximate because of the variations in the values of the work functions found in the literature.

The capacity-potential curve (Fig. 9) shows a minimum of capacity at a potential of about −0.3 v. The shape of the curve is similar to that of mercury in that the capacity goes through a minimum. The anodic branch is similar to the anodic branch of the curves obtained for mercury in solutions containing anions which specifically adsorb (1). The results indicate that sulfate ion has specifically adsorbed on the copper.

The cathodic portion of the curve does not display a broad flat minimum as with mercury. The rise in capacity occurs with mercury but at much more cathodic potentials. This difference could be accounted for by the high hydrogen overvoltage on mercury and the smaller overvoltage on copper.

The minimum of capacity corresponds to 21 $\mu F/cm^2$. Winkler (19) reported a capacity of 23 $\mu F/cm^2$ for cathodic charging of copper.

Conclusions

The results obtained for electric analogs and the agreement of the results obtained for the mercury-solution interface with those of other workers attest to the reliability of the method.

The shapes of the differential capacity curves reported indicate that for most metals only a limited potential range is available for capacity measurements from which to estimate surface areas.

The capacity-potential curves obtained for film covered metals, aluminum and tantalum, suggests the applicability of the method to film formation and film removal studies. Further work along these lines is underway.

Acknowledgment

The authors are pleased to express their appreciation to the Office of Naval Research for the financial support of this work, and also to Dr. P. V. Popat for a number of very fruitful discussions.

Manuscript received June 6, 1958. This paper was prepared for delivery before the Washington, D. C. Meeting, May 12-16, 1957.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Preparation and Properties of Improved Protamine Collodion Matrix Membranes of Extreme Ionic Selectivity

Marc Lewis[1] and Karl Sollner

National Institute of Arthritis and Metabolic Diseases, National Institutes of Health, Public Health Service, U. S. Department of Health, Education, and Welfare, Bethesda, Maryland

ABSTRACT

Improved protamine collodion matrix membranes of extreme electrochemical activity were prepared by the adsorption of purified protamine from aqueous solutions on preformed highly porous collodion membranes whose porosity was subsequently reduced by drying. The most useful permselective membranes give rise to concentration potentials which agree with the calculated thermodynamic maximum potential in potassium chloride cells up to 0.1*N*/0.05*N* within the meaningfulness of the method. At higher concentrations the measured potentials become gradually less than the theoretical value. The more highly selective membranes have anion permeabilities which in 0.1*N* KCl are 250 to 450 times greater than the cation permeabilities and 2,000 to 12,000 times greater in 0.01*N* solutions. With solutions of $CaCl_2$ these ratios were at least two orders of magnitude greater. The ohmic resistances of the permselective membranes of highest selectivity (as measured in 0.1*N* KCl) may be adjusted from about 10 ohm-cm^2 upward.

The first membranes which combined a high degree of anionic selectivity with great stability and low resistance were the permselective protamine collodion matrix membranes described by Carr, Gregor, and Sollner (1-5).[2] They were prepared by the adsorption of protamine from buffered ($\cong$ pH 10.5) aqueous protamine sulfate solutions on collodion membranes of high porosity which were subsequently dried under carefully controlled conditions. The most important shortcoming of these membranes was their limited ionic selectivity; their permeabilities for anions even at concentrations as low as 0.01 and 0.001*N* were only 30-50 times greater than those for cations. This low ratio severely restricts the usefulness of these membranes in many studies.

Anion selective membranes of high resistance have been prepared by Albrink and Fuoss (6). Membranes of the permselective type were described in recent years by Bonhoeffer and Manecke (7), Winger, Bodamer, and Kunin (8), Wetstone and Gregor (9), and others (10-12). For our purpose these membranes have somewhat too low ionic selectivities, especially at higher concentrations, and too high unit area exchange capacities. Also the porosities and resistances of these membranes cannot be as readily adjusted at will as those of collodion matrix membranes.

Collodion matrix membranes of extreme anion selectivity which are free from these limitations and shortcomings were prepared some years ago in this laboratory by the adsorption from aqueous solution of poly-2-vinyl-N-methylpyridinium bromide (and several other basic synthetic polyelectrolytes) on preformed highly porous collodion membranes whose porosity was subsequently reduced by drying (13). The most useful of these membranes give rise to concentration potentials which agree closely with the calculated thermodynamic maximum potentials in potassium chloride cells up to 0.1*N*/0.05*N*. The more highly selective membranes have anion permeabilities which in 0.1*N* KCl are 500-1300 times greater than the cation permeabilities, and in 0.01*N* solutions 5,000-32,000 times greater. With solutions of $CaCl_2$ these ratios are two to three orders of magnitude greater. The ohmic resistances of these membranes as measured in 0.1*N* KCl may be adjusted from about 10 ohm-cm^2 upward (13). While otherwise fully satisfactory for many physicochemical investigations and model studies of biological interest, these membranes quite unexpectedly show a peculiarity which restricts their usefulness for certain purposes. The rates of self-exchange of critical ions between solutions across these membranes do not agree with those calculated from the Nernst-Einstein equation, whereas this equation describes satisfactorily the results of self-exchange studies with protamine collodion matrix membranes, or with (cation selective) oxidized collodion and sulfonated polystyrene collodion matrix membranes (14).

In order to prepare anion selective membranes of extreme ionic selectivity which behave in the manner postulated by the Nernst-Einstein equation with respect to the rate of exchange of ions across them, it seemed best to try to improve the ionic selectivity of the otherwise satisfactory protamine collodion

[1] Public Health Service Research Fellow; Present address: National Institute of Dental Research, Bethesda, Md.

[2] Protamines are simple strongly basic proteins, ordinarily derived from salmon sperm, with molecular weights of about 4000 in the hydroxyl form. They are of somewhat varying composition, most probably consisting of nineteen molecules of arginine, a dibasic amino acid with a pK of 10.5 to 11, and six or seven monobasic amino acids. The ionizable groups in the protamine molecule, which are not blocked by the formation of peptide linkages, are: one carboxyl group, one imino group, and nineteen guanidino groups.

matrix membrane. This seemed desirable also in view of the planned use of these membranes in studies of biological interest because the chemical nature of protamine is more similar to that of biological membranes than that of synthetic polyelectrolytes, such as poly-2-vinyl-N-methylpyridinium salts.

The looked for improvement, as previously indicated (1), must be presumed to consist either of the removal (or the chemical blocking) of the carboxyl group which is an inherent, terminal part of the protamine molecule, of the removal of acidic impurities contained in the commercial preparations, or of a combination of the two. If the presence of some acidic impurities in the protaminic preparations used is the cause of the deficient ionic selectivity of the membranes, the solution of the problem could be expected from a thorough purification of the protamine preparations.

Preliminary experiments with the commercial protamine preparations available at present regularly yielded membranes of higher ionic selectivity than those described previously, with considerable differences according to the particular batch of protamine used. Different samples of protamine were found to be of different purity as evidenced also by differences in color, from pure white to distinctly yellow, the least yellowish preparations generally yielding the best membranes. This observation also agrees with the results of earlier attempts to purify protamine in which the repeated dissolution and reprecipitation of commercial protamine preparations had led in some instances, but not in a satisfactorily reproducible manner, to membranes of greatly increased anionic selectivity (15).

Thus, the thorough purification of protamine was the obvious initial step in our attempt to improve the ionic selectivity of protamine collodion matrix membranes.

Preparation of Improved Permselective Protamine Collodion Matrix Membranes

A consistently successful method of purifying protamine to a degree adequate for our purpose is the following: Fifty grams of commercial protamine sulfate is extracted repeatedly with ethyl ether until a sample of the ether on evaporation does not leave any trace of residue. (With preparations already free of lipid-like ether soluble contaminants this step may be omitted.) The ether-wet protamine sulfate is dried, and a nearly saturated, approximately 6.5% aqueous solution is prepared (which in all instances proved to be very close to neutral). To remove all impurities of an acidic (anionic) character from this solution, it was passed through a column consisting of 1 kg of strong base anion exchange resin (Amberlite IRA —400) in the chloride form. While the protamine solution is run slowly through the column, the eluate is continuously tested with trichloroacetic acid and discarded until a positive test, a white precipitate, is obtained. After the last of the protamine solution has been run on the column, the column is slowly washed with distilled water and the eluate collected until it no longer gives a positive reaction with trichloroacetic acid. The solution containing the protamine (now in the chloride form) may either be diluted appropriately and used directly in the preparation of membranes, or dry protamine chloride may be obtained as a fine white powder by the conventional method of freezing and drying *in vacuo*. It might be added that this purified protamine chloride when reconverted to protamine sulfate on an ion exchange column yielded membranes which are significantly inferior in ionic selectivity to those prepared with the purified protamine in the chloride state.

The preparation of permselective membranes consists of casting collodion membranes of high porosity, followed by adsorption on the membranes of protamine from aqueous solutions, and controlled drying (1, 2). Three-layer membranes were prepared routinely at room temperature and at relative humidities between 20% and 50% from a 4.0% solution of Parlodion (Mallinckrodt) in 50:50 ether-alcohol containing 2% water. This solution was poured over 25 x 100 mm test tubes rotating in the horizontal position. Ordinarily, the first layer was dried 3.0 min, and the second 3.5 min; 4.0 min after the third layer was poured the membranes were immersed in water. When membranes of higher resistance were desired, these drying periods were each extended by 30 sec. After being washed for an hour in several changes of water, the membranes were slipped off their casting tubes and washed for 3 to 4 hr. They were then immersed in a solution containing 10 g of protamine chloride per liter, buffered to a pH of about 10.5 with a sodium hydroxide-sodium borate-sodium chloride buffer (0.05*N* NaOH, 0.05*N* $Na_2B_4O_7 \cdot 10H_2O$, 0.375*N* NaCl).[3] The membranes were kept in this solution for periods ranging from 12 to 48 hr depending on the resistance desired, shorter immersion times yielding membranes of higher resistance. Thereafter the membranes were washed for 5 min in distilled water, replaced on their casting tubes, and dried for 24 hr in a humidistat over saturated $CaCl_2$ solution, at a relative humidity of 31%. Next, the membranes were placed in water for 2 hr, removed from their casting tubes, and tied with linen thread to glass rings fitted into their open ends. They were again dried for 24 hr at 31% relative humidity and then placed in 0.1*N* KCl solution. After an aging period of several days in this solution, their properties are virtually constant. These test tube shaped membranes were about 30-40 μ thick, transparent, glass clear, and smooth.

The permselective membranes prepared with the purified protamine preparations, like the earlier types of protamine collodion matrix membranes, are very stable. They do not show any significant deterioration either in ionic selectivity or in mechanical strength over periods of a few years when stored in 0.1*N* KCl solution to which a preservative such as thymol was added for protection against mold growth. With respect to stability the protamine collodion matrix membranes are superior to the poly-2-vinyl-N-methylpyridinium collodion matrix

[3] These solutions of protamine could be used repeatedly with adjustment of pH as necessary. They were stored routinely in a refrigerator to prevent bacterial growth and other forms of deterioration.

membranes, some of which become very brittle in a period of two months.

Properties of Improved Protamine Collodion Matrix Membranes

For a series of survey experiments, six different sets of twelve membranes each were prepared under carefully controlled conditions and characterized by (*a*) anion-exchange capacity, (*b*) water content, (*c*) rate of osmotic water movement, (*d*) ohmic resistance in contact with 0.1N KCl solution, and (*e*) concentration potential in the cell 0.4N KCl | membrane | 0.2N KCl (see Table I).

Following the survey, membranes of the types most useful for physicochemical investigations were studied for their electromotive properties in KCl concentration cells over a wide range of concentrations, the concentration ratio being 2:1 (see Table II). One of these membranes was tested similarly in analogous cells with HCl, KNO_3, KIO_3, and K-Acetate (see Table III). The rates of exchange of critical ions (anions) and of noncritical ions (cations) across representative membranes at three concentrations, 1.0N, 0.1N, and 0.01N, were determined as a measure of their absolute permeabilities and ionic selectivities, and the corresponding ratios, the ionic selectivities of the membranes, calculated (see Table IV). In addition the bi-ionic potentials across several representative membranes were measured with various pairs of critical ions.

The anion-exchange capacity was determined with three or four membranes selected at random from each of the six sets. The membranes were slit open lengthwise, and 5.0 x 7.0 cm rectangles cut from the flat portions were placed in 0.1N KCl solutions which were changed several times during a week to assure that all accessible fixed charged groups were in the chloride form. The membranes were then washed with distilled water for several days until chloride could not be detected in the wash water. The chloride ions in the membranes were then displaced by immersing each group of three or four membranes in 20 ml of 0.5N $NaNO_3$ solution. After standing three days with occasional stirring, the $NaNO_3$ solutions were analyzed for chloride ion and the anion-exchange capacities of the membranes in μeq/cm^2 calculated. The dry weights of the membranes (see below) were used to calculate the anion-exchange capacities per gram of dry membrane.

The water content was measured with the flat membranes used in the anion-exchange measurements. They were reconverted to the chloride form, washed, blotted dry with filter paper, placed immediately in tared weighing bottles, and weighed in the wet state. They were then dried over phosphorus pentoxide *in vacuo*. The loss in weight was taken as the water content. The reproducibility of the measurements was about ±0.5 g, when the results are expressed as g water/100 g wet membrane.

The rate of osmotic water movement across a membrane was measured by filling the test tube shaped membrane with a 0.2M solution of sucrose (for which they are virtually impermeable), fitting it with a rubber stopper carrying a graduated capillary manometer tube, and placing it in a beaker of water at 25° ± 0.05°. After thermal equilibrium was reached, the rise of the liquid in the capillary gave

the rate of water transport, the reproducibility of these measurements being about ±10%.

The ohmic resistance of the membranes in 0.1N KCl solution, ρ^*, was measured at 25° ± 0.05° using the Kohlrausch method as previously described (16). From the measured resistance and the known free area of the membrane (about 50 cm²) the unit area resistance was computed.[4] The reproducibility of the membrane resistance from day to day was about ± 3%.

The concentration potentials of the membranes were measured at 25° ±0.05° using saturated calomel half-cells with saturated potassium chloride-agar bridges, except in the case of the HCl-cells in which Ag|AgCl electrodes, prepared by the method of Rule and La Mer, were used (17). Stirring had no effect at any concentration with membranes of ρ^* of several hundred ohm-cm² and more. With membranes having a ρ^* of about 100 ohm-cm², stirring was necessary at concentrations below about 0.2N/0.1N; otherwise, particularly at the lowest concentrations, the potentials were up to 0.5 mv too low. The majority of the potential measurements were reproducible within ± 0.05 mv except with the highest and lowest concentrations used, where the error may be twice as large.

From these raw data the true concentration potentials were obtained by the following two procedures. Where Ag/AgCl electrodes were used the difference of the two electrode potentials was computed from the Nernst equation using the known mean activities of the pairs of KCl solutions under consideration, and subtracting this computed value from the experimentally determined potential. In the case of the cells with which calomel half-cells and saturated KCl-agar bridges were used for the potential measurements, the corrections for the asymmetry of the two liquid-junction potentials, potassium chloride-agar bridge | electrolyte c_1 | electrolyte c_2 | potassium chloride-agar bridge, were determined by the following method which had also been used on prior occasions (4, 18). It is based on the assumption that it is possible to calculate with considerable accuracy (from the Nernst equation and known ionic mobility data) the liquid-junction potentials, $E_{1(calc.)}$, arising between solutions of the same electrolyte at different concentrations. These calculated liquid-junction potentials, $E_{1(calc.)}$ are compared with the experimental liquid-junction potentials, $E_{1(exp.)}$, in the membrane-free cells: saturated calomel electrode | saturated potassium chloride | saturated potassium chloride-agar bridge | electrolyte c_2 | electrolyte c_1 | saturated potassium chloride-agar bridge | saturated potassium chloride | saturated calomel electrode. The difference between these two values, $E_{1(calc.)} - E_{1(exp.)}$, is taken as the value of the asymmetry of two liquid-junction potentials at the tips of the agar bridges; it is applied as a correction to the concentration potentials measured across the membrane.

The values of $E_{1(exp.)}$ were measured with a simple W-shaped tube with a glass stopcock in the middle; otherwise the instruments used and the technique employed were the same as were used for the determination of the concentration potentials across membranes. The reproducibility of the $E_{1(exp.)}$ data, except at the lowest concentrations used, is better than ±0.05 mv. The various values for $E_{1(exp.)}$ and $E_{1(calc.)}$ are given in Table III for the neutral salts except KCl. With KCl cells with a concentration ratio of 2:1 (Tables I and II) the correction is —0.33 mv independent of the concentration. All data

[4] Dimensionally this resistance in ohm-cm², the reciprocal of the unit area conductance which is expressed in moh/cm². The designation of the unit resistance as ohm/cm² which is common in the literature (including some older publications from this laboratory) is dimensionally in error.

on membrane concentration potentials given in this paper are appropriately corrected.

The thermodynamically possible maximum values of the concentration potential were calculated in the conventional manner assuming that the only process occurring across an ideal membrane is the reversible transfer of the critical ions from the one solution to the other, and that the activity of the critical ions, the anions, at any given concentration is equal to the mean activity of the electrolyte ($a_- = a_\pm$). The activity coefficients were taken from Harned and Owen and from Robinson and Stokes, and converted from the molality to a normality basis (19, 20).

For the measurement of the rate of exchange of the anions a membrane filled with a KCl solution containing radioactive Cl^{36} was placed in a large volume of solution of nonradioactive KCl of the same concentration. Both solutions were stirred. Aliquots of the outer solution were withdrawn periodically and their radioactivity determined. The initial rate of anion exchange was calculated from the fraction of the radioactive chloride exchanging for stable chloride per unit time.[5]

The strictly comparable initial rate of exchange of the cations can be obtained from analogous experiments only with membranes of very low resistance and a significant leak because of the short half life ($t_{1/2}$ = 12.4 hr) of the available potassium isotope K^{42}. Instead, with the membranes of the extremely low cation leak of particular interest here, the rate of exchange of cations between an NH_4Cl and a KCl solution of equal concentration was determined by conventional microanalysis. The use of the data for these rates instead of those for the self-exchange of K^+ seems unobjectionable for the present purpose for the following reasons: (*a*) the behavior of NH_4^+ and K^+ ions in solution is very similar, and likewise, with cation selective membranes, as is evident from the fact that the bi-ionic potential, NH_4^+ | cation selective permselective membrane | K^+ is very low, at best of the order of a few millivolts; (*b*) the rates of exchange $K^{39+} \leftrightarrows K^{42+}$ and $NH_4^+ \rightleftarrows K^+$ across permselective poly-2-vinyl-N-methylpyridinium collodion matrix membranes have been found to agree satisfactorily in the case of those membranes with which both rates could be determined (14).

In addition, a few analogous experiments on the rates of exchange of critical and noncritical ions were carried out with $CaCl_2$ solutions in which the rates of exchange of the bivalent noncritical Ca^{++} ions were obtained by the use of Ca^{45} ($t_{1/2}$ = 152 days).

The bi-ionic potential in cells of the type 0.1*N* KCl | membrane | 0.1*N* KX where X may be any anion other than chloride, was measured (with all the precautions described recently elsewhere), using saturated calomel half-cells with saturated potassium chloride-agar bridges (21). The measurements were reproducible in general within ±0.5 mv. No corrections were made for the asymmetry of the liquid junction potentials at the tips of the two agar bridges.

Discussion

The exchange capacity per gram of membrane (Table I, column 2) is of interest primarily in correlation to certain aspects of the Teorell, Meyer-Sievers theory of the electrochemical behavior of membranes. This point will be touched upon later.

The exchange capacity per square centimeter of the membranes (Table I, column 3) is low, of the order of 1 to 2.5 μeq/cm² with the most useful of these membranes. Thus, in many types of experiments, it is possible to use membranes whose exchange capacities are low relative to the number of equivalents of ionic constituents in the surrounding solutions. This is of importance in many physicochemical investigations such as, for example, in the electrometric determination of ionic activities and in the study of Donnan equilibria.

The water content of the membranes (Table I, column 4) is the higher the longer the time of immersion of the membranes in the protamine solution and the less dried, that is, the more porous the membranes were during this immersion.

The rate of osmotic water movement across the membranes (Table I, column 5) is greater the higher the water content (cf. col. 4). The water movement across the membranes which is measured under a driving force corresponding to 50 m of water pressure is low except in the case of those with the highest protamine content. The low water permeabilities are helpful in studies where it is necessary to keep solutions of different water activity separate for long periods.

The resistances (Table I, column 6) of the membranes of a given type prepared under nominally identical conditions show substantial variations. Small increments in anion-exchange capacity are accompanied by great differences in resistance.

[5] A detailed account of the experimental technique is planned for a forthcoming paper on the exchange of ions across permselective membranes by Gottlieb and Sollner, in preparation (14).

The degree to which the concentration potentials (Table I, column 7) of the membranes deviate from the theoretical maximum at the 0.4/0.2*N* KCl concentration level can be estimated by comparing them with the calculated theoretical maximum potential, —15.95 mv.

The concentration potentials across the membranes with medium protamine contents approach the maximum theoretical potential more closely than do those with very low or very high protamine contents. The lower concentration potential obtained with the membrane with the lowest protamine contents is very probably due to the absence of charged groups at critical points in some of the pores of these membranes. With membranes of high protamine content the lower concentration potentials are undoubtedly due to the larger average pore size of these membranes which is correlated with their higher water content (cf. col. 4).

In connection with the Teorell, Meyer-Sievers theory (22, 23) it is of interest to look for a correlation of the selectivities of the various membranes as manifested by their concentration potentials and the equivalent concentrations of fixed basic wall groups (or exchangeable counter ions) in the pore water of the membranes. The latter values as derived from col. 3 and 4 of Table I, assuming all of the water to be available, are in order of increasing anion exchange capacity per gram of wet membrane, 1.7, 1.8, 2.2, 2.1, 1.3, and 1.4 equiv/l. These values are identical with the selectivity constants of the Teorell, Meyer-Sievers theory. The theory postulates the concentration potentials to be the higher the greater the equivalent concentration of active groups in the pore water of the membrane. The empirically found correlation is more of a general qualitative than of a quantitative nature.

Table II on the concentration dependence of the concentration potential in KCl cells shows that the potentials at the lowest concentrations are 0.15 — 0.28 mv below the calculated maximum; at 0.01/0.005*N* and 0.02/0.01*N* the agreement is perfect within the accuracy of the measurements, except possibly with the membrane of lowest resistance. With more concentrated solutions the deviations become greater. The electromotive behavior of the permselective protamine membranes in this series of concentration cells is virtually the same as that of the analogous strong-base type poly-2-vinyl-N-methylpyridinium bromide collodion matrix membranes (13).

Table III gives the calculated and the (corrected) experimental concentration potentials in cells with four different electrolytes, KIO_3, KNO_3, K-Acetate, and HCl, together with the calculated and experimental liquid junction potentials obtained with the three neutral electrolytes (on which the corrections of the measured potential values are based). In all instances, as above with the KCl cells, the agreement between the theoretical and experimental concentration potentials is best in a medium range of concentrations.

In order to facilitate visualization of the data on concentration potentials a part of the data of Table II and the data of Table III are represented graphically in Fig. 1. The deviations of the experimental values from the calculated ones at the higher concentrations do not require any comment; it is in full agreement with the fixed charge theory (22, 23). Deviations between the two sets of data at the lower and particularly the lowest concentrations, which are quite systematic and, with the neutral salts, far in excess of any probable error, are not explained by the fixed charge theory as commonly understood. They duplicate earlier observations with the older type of permselective protamine collodion matrix membrane (4) and with poly-2-vinyl-N-methylpyridinium collodion matrix membranes (13). Analogous deviations at the lowest concentrations were also observed with strong acid sulfonated polystyrene collodion membranes (24). We are inclined to attribute this effect to the ions of the water, specifically to the drift of the experimental cells toward the state of membrane hydrolysis predicted by the theory of membrane equilibria. Preliminary experiments support this view, without as yet definitely proving its correctness. We hope to report on this matter in the near future.

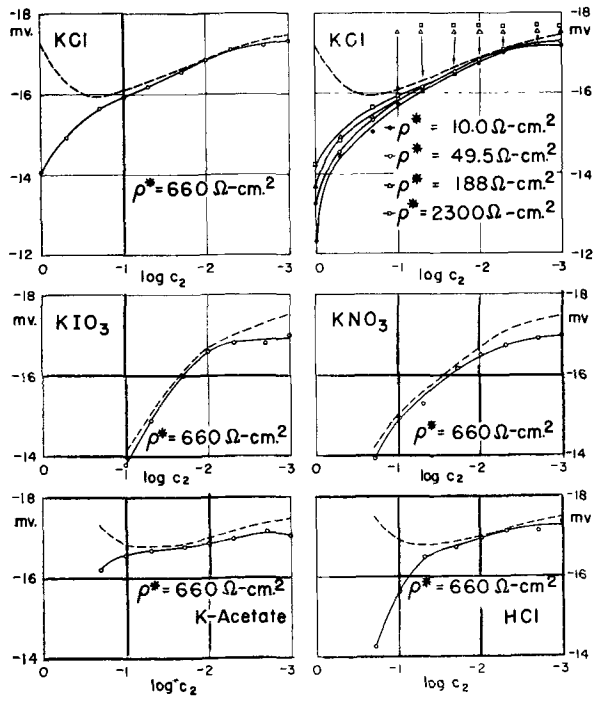

Fig. 1. Concentration potentials (c_1:c_2 = 2:1) of several electrolytes across typical permselective protamine collodion matrix membranes.

It was recognized some time ago that the deviations of the measured concentration potentials from the theoretically possible maximum values, particularly in the case of membranes of high ionic selectivity, do not furnish an adequate basis for a calculation of the numerical value of the ionic selectivities of such membranes (25). A variety of complicating factors is now generally recognized (26).

First, nonthermodynamic assumptions are made in the calculation of the theoretical maximum potential; and, likewise, in assigning a part of the measured potential of a concentration cell to the membrane concentration potential a nonthermody-

namic, at least semi-empirical correction procedure must be used, such as that outlined above. Second, there are definite limitations of the accuracy with which the potential measurements may be made. In particular, if a membrane is not of virtually ideal ionic selectivity and if the solutions are very dilute, the concentrations of electrolyte in the nonstirred, adhering water layers of the membrane may be significantly different from those in the bulk solutions. The measured potential would thus be lower than that which would arise if the concentrations in the adhering water layers and bulk solutions were the same. Expressed in another way, the true ionic selectivity of the membrane would be higher than that calculated in a straightforward manner from the measured concentration potential. Further, membrane hydrolysis may also lower the measured potential in dilute solutions of neutral electrolytes. In addition, the ions move across the membranes in a hydrated state, thereby transporting water of hydration from a compartment of lower to the compartment of higher water activity (and possibly some additional water by an electrophoretic effect). There may also be an opposing osmotic streaming of water which the diffusing critical ions must overcome. All these effects would tend to reduce the electromotive efficiency of the critical ions, thus reducing the concentration potential below the value which is calculated for the condition of no solvent transport between the two solutions. These latter possibilities, in recent years, have been the subject of intensive theoretical and experimental work (21, 26-29). Thus it is apparent that the degree of the ionic selectivity of highly ion selective membranes is better established by a more direct method, namely, on the basis of the relative permeabilities of the critical and noncritical ions as determined from the rates of self-exchange of these ions across a membrane (13, 14, 24, 25).

The initial rates of movement of critical ions, the anions, across the various membranes in the systems at 0.1*N* (Table IV, column 5) are inversely proportional to their standard resistances, ρ^*, (which is also measured with 0.1*N* solution) as postulated by the Nernst-Einstein equation for the rate of self-diffusion. With 1*N* and 0.01*N* solutions (columns 2 and 8 of Table IV) the rates of self-exchange of the critical ions show only a semi-quantitative inverse proportionality to the standard resistance of the membranes, ρ^*.

The initial rate of movement of the noncritical ions, the cations, (columns 3, 6, and 9 of Table IV) shows a considerably steeper inverse relationship with the standard membrane resistance than that observed with the critical ions.

The rates of exchange of the critical ions across a given membrane in 0.01 and 1*N* solutions differ by a factor of about 2 with the membrane of the highest standard resistance to a factor of about 15 with the membrane of lowest resistance. The rate of exchange of the noncritical ions varies over the same concentration interval by a factor of about 430 for the membrane with the highest resistance, to a factor of about 2500 for the lowest resistance membrane.

The ionic selectivities of the various permselective membranes, that is, the ratio of the initial rates of exchange of the critical to those of the noncritical ions (columns 4, 7, and 10 of Table IV) are very much greater at the lower than at the higher concentrations, in agreement with all previous experience.

The correlation between membrane resistance and selectivity is not straightforward; the best membrane with a selectivity of 12,000:1 in 0.01*N* KCl solution is of medium resistance. The degree of ionic selectivity of the permselective protamine collodion matrix membranes closely approaches, but does not quite reach, that of the analogous permselective poly-2-vinyl-N-methylpyridinium collodion matrix membranes (13).

The small "leaks" of noncritical ions which correspond to these high ionic selectivities (numerically their reciprocals) circumscribe the conditions under which these membranes can be used without significant disturbances due to this imperfection.

The selectivities of the improved permselective protamine collodion matrix membranes, in the presence of univalent anions and bivalent cations (not shown in the tables) as determined with 0.1*N* $CaCl_2$ solutions containing radioactive Ca^{45}, and membranes of 10, 23, 108, and 402 ohm-cm^2 in 0.1*N* KCl were found to be 10.400, 15.000, 48.000, and 151.000 ohm-cm^2, respectively. With more dilute solutions these selectivities can be safely assumed to be considerably higher.

The bi-ionic potentials across the permselective collodion matrix membranes prepared with purified protamine preparations, as may be expected *a priori*, are very similar in magnitude to those obtained earlier with membranes made with less pure preparations (30). Some of the bi-ionic potentials, E_{bip}, obtained (with 0.1*N* solutions) across a membrane with a standard resistance, ρ^*, of 660 ohm-cm^2 were: NaCl || NaSCN, + 31.4 mv; NaCl || $NaNO_3$, + 21.1 mv; NaCl || NaI, + 16.3; NaCl || NIO_3, − 38.3 mv; NaCl || Na-acetate, − 46.0 mv; and NaCl || Na-propionate, − 52.5 mv, the signs referring to the charge of the solutions on the right side.

The improvement in the ionic selectivity of the membranes prepared with purified protamine over those prepared with the commercial preparations obviously must be ascribed to the removal of some strongly adsorbable impurities of acidic character which are removed by the treatment with the ion exchange resin since it can hardly be assumed that the treatment with an ion-exchange column alters the chemical structure of protamine itself. As is evident from the data, the carboxylic end groups of the protamine molecules do not affect adversely the ionic selectivity of the membranes to any significant extent, in spite of the fact that they represent about 5% of the potentially dissociable groups of the protamine molecule.

Several factors should be considered to account for the functional ineffectiveness in the membrane of the carboxylic end groups of the protamine molecule. First, many of these groups may be blocked functionally by combination with a basic group

either of the same or of some other protamine molecule. Second, the cationic counterions of the sparsely distributed acidic groups, even if dissociated completely off the latter,[6] would have to migrate past numerous interposed positive wall groups. Being strongly repelled by these groups of the same charge, the cations are unable to move from the vicinity of one of the acidic groups to the next and thus are more or less permanently confined to the location which they had occupied when the membrane was prepared.

The high ionic selectivities of the improved protamine collodion matrix membrane which are evident from Tables I-IV demonstrate that the purpose of this investigation has been achieved, namely, to produce membranes which are free of the main shortcoming of the previous protamine membranes, their inadequate degree of ionic selectivity, and which fulfill the predictions of the Nernst-Einstein equation with respect to the correlation of their resistance and the rate of self-exchange of ions across them.

[6] Due to the mode of preparation of the membranes, the carboxyl groups may be present in the hydrogen state with the hydrogen ion dissociated off to a very limited degree only.

Manuscript received June 16, 1958. This paper was presented at the New York Meeting, April 27-May 1, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

December 1959 Discussion Section

A Discussion Section, covering papers published in the January-June 1959 JOURNALS, is scheduled for publication in the December 1959 issue. Any discussion which did not reach the Editor in time for inclusion in the June 1959 Discussion Section will be included in the December 1959 issue.

Those who plan to contribute remarks for this Discussion Section should submit their comments or questions in triplicate to the Managing Editor of the JOURNAL, 1860 Broadway, New York 23, N. Y. *not later than September 1, 1959.* All discussions will be forwarded to the author(s) for reply before being printed in the JOURNAL.

Electrochemical Kinetics of the Anodic Formation of Oxide Films

Pierre Van Rysselberghe

Department of Chemistry and Chemical Engineering, Stanford University, Stanford, California

and Herman A. Johansen

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

The total electric potential difference between a metal and a solution across an oxide film being built up by a constant anodic current is decomposed into three contributions: differences at the interphases metal-oxide and oxide-solution, both subject to activation overvoltage, and the difference across the oxide layer. For one or the other of the interphases the case of linearity of overvoltage with the logarithm of the current (in the range of large currents) and that of proportionality of overvoltage with current (in the range of small currents) are examined in some detail, and previously obtained experimental data for three types of titanium, for hafnium, and for tantalum are analyzed in terms of the proposed theoretical treatment. Numerical values are obtained for the various parameters appearing in the equations: thickness of the interphase, exchange current, electric potential difference, and electric field at zero current. Possibilities for refinement and extension of the treatment are mentioned.

The theory advanced by Cabrera and Mott (1) on the basis of earlier work by Mott (2) to explain the rate of growth of oxide films on metals usually has been regarded as directly applicable to the case of anodic oxidation. The present authors and their collaborators (3-5) have applied it to the interpretation of data obtained in the anodic oxidation of several metals. From the evolution with time of the potential of the metal (measured against an unpolarized electrode) during oxidation at constant current they were able to verify that the unitary rate of change of potential, $(1/I) \cdot (\partial E/\partial t)_I$, in which I is the apparent current density, E the relative potential of the metal, t the time, corresponding to the flats in the curves $\log(\partial E/\partial t)_I$ vs. $\log t$ at constant I was, over the range of currents utilized (1 to 100 μa/cm^2), a linear function of $\log I$. This situation is implied in the Cabrera-Mott theory which thus was regarded as essentially verified.

In a more detailed analysis of our recently published data (5) on the anodic oxidation of Al, Cr, Hf, Nb, Ta, Ti, and V in saturated ammonium borate at 25°C, it was found interesting to interpret these data on the basis of an electrochemical approach involving the use of the current-overvoltage relationships of electrochemical kinetics at the metal-oxide and at the oxide-solution interphase. Regardless of the detailed circumstances of the passage of the current through the oxide film itself, it appears probable that, at the metal-oxide interphase, the net process is the transfer of metallic ions from the metal to the oxide and that, at the oxide-solution interphase, the net process is the transfer of oxide or hydroxyl ions from the solution to the oxide. The treatment presented here does not depend on an *a priori* decision as to which process (that across the metal-oxide interphase, that across the oxide itself, or that across the oxide-solution interphase) is rate-determining. In a steady state, with the same current passing through the three portions of the over-all metal-solution system, the evaluation of the velocity of one of the three processes serves for the two other processes as well. This has been the guiding idea of one of us in previous treatments of overvoltage phenomena (6).

Following Cabrera and Mott (1) and Vermilyea (7) we shall neglect the possibility of the presence of a space charge anywhere in the over-all interphase, the electric field being then constant from the bulk of the metal to the bulk of the solution.

Electrochemical Theory of Anodic Oxidation

Consider a metallic phase α separated from an electrolyte solution β by a film γ of oxide (Fig. 1). Between the terminal plane a' of the metal and the oxide in bulk there is a transition layer a'a and between the oxide in bulk and the solution in bulk there is a transition layer bb'. The oxide has the thickness X from a to b. The thicknesses a'a and bb' are called x_a and x_b, respectively, and will be regarded as independent of time. We shall restrict ourselves to values of X large enough to prevent any overlapping or mutual influence of the transition

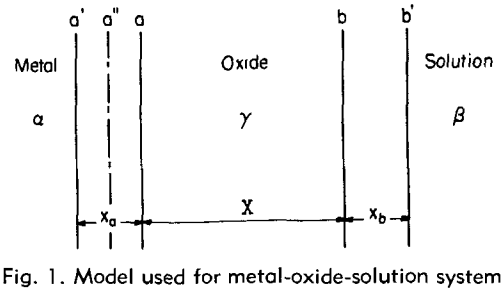

Fig. 1. Model used for metal-oxide-solution system

regions a'a and bb' but small enough to remain in the range of thin films.

The electric potential difference from metal to solution is given by

$$\phi_a - \phi_\beta = (x_a + x_b + X) \cdot F \qquad [1]$$

in which F represents the electric field. Calling w the mass of oxide formed per coulomb and d the density of the oxide we have

$$X = X_o + wIt/d \qquad [2]$$

In electrochemical terms the situation at the a'a interphase can be described as follows. It should be clear that this analysis is equally applicable to the interphase bb'. We shall consider the two extreme cases of: (a) a Tafel relation between current and overvoltage, and (b) proportionality between current and overvoltage. In this latter case, as well as in the intermediate one corresponding to proportionality of current with the hyperbolic sine of $zF\eta/2RT$ (z being the number of Faradays F carried by one gram-ion, η the overvoltage, R the molar gas constant, and T the absolute temperature; the transfer coefficient is taken as equal to ½ for both the anodic and the cathodic direction) the net current is the resultant of a forward anodic current and of a reverse cathodic current. Such a situation may conceivably occur at very low net currents both in a'a and in bb', even though the anodic current through the oxide itself might still be unopposed.

Case 1.—We have the following Tafel relation:

$$(\phi_{a'} - \phi_a)_I = (\phi_{a'} - \phi_a)_{I=0} + \frac{RT}{\tau_a zF} \cdot \ln \frac{I}{I_{0a}} = x_a \cdot F \qquad [3]$$

in which τ_a is the transfer coefficient (equal to the ratio of distance a'a" to distance a'a in which a" is the activated position of the metallic ion moving across the barrier from a' to a), ln represents the natural logarithm, and I_{0a} is the extrapolated exchange current at the a'a barrier. Since

$$\phi_a - \phi_\beta = (x_a + x_b + X_0 + wIt/d) \cdot F \qquad [4]$$

we have, combining with Eq. [3] and differentiating with respect to t at constant I, E differing from $\phi_a - \phi_\beta$ by a constant:

$$\frac{1}{I} \cdot \left(\frac{\partial E}{\partial t}\right)_I = \frac{RTw}{\tau_a dx_a zF} \cdot \ln \frac{I}{I_{0a}} +$$

$$(\phi_{a'} - \phi_a)_{I=0} \cdot \frac{w}{dx_a} = \frac{w}{d} \cdot F \qquad [5]$$

an expression independent of t which thus is expected to be valid only along the horizontal portions of the experimental plots of $\log(\partial E/\partial t)_I$ vs. $\log t$ for constant I. This situation is that which we actually verified with several of the metals previously reported on (3-5). Equation [5] was found to apply satisfactorily from current densities of 100 μa/cm^2 down to 1. However, plots of unitary rates vs. I rather than vs. $\log I$ (8) indicated a definite possibility that the lower current densities, from 5 to 1, might be in or very near the range of applicability of Case 2.

Table I. Data on anodic oxidation of Ti, Hf, and Ta in saturated ammonium borate at 25°C

Metal	Oxide	Density of oxide	x_a, Å	I_{0a}, μa/cm^2	$(\phi_{a'} - \phi_a)_0$, mv	F_0, 10^6 v/cm	F_{100}, 10^6 v/cm
Ti (iodide)	TiO_2	4.22	8.7	1.7	205	2.3	3.0
Ti (Kroll)	TiO_2	4.22	7.1	2.5	176	2.6	3.2
Ti (cold worked)	TiO_2	4.22	7.9	1.1	214	2.5	3.4
Hf	HfO_2	9.68	8.0	1.5	225	2.8	3.6
Ta	Ta_2O_5	8.5	6.0	1.7	94	1.6	2.3

Case 2.—When the cathodic counter-current in a'a cannot be neglected the net current is given by a difference between two Tafel expressions which, upon expansion and limitation to first power terms in the overvoltage (a procedure justified when $\tau_a F\eta/RT$ becomes sufficiently smaller than 1) gives:

$$(\phi_{a'} - \phi_a)_I = (\phi_{a'} - \phi_a)_{I=0} + \frac{RTI}{(\tau_a + \tau'_a) zFI_{0a}} = x_a \cdot F \qquad [6]$$

Instead of Eq. [5] we now have:

$$\frac{1}{I} \cdot \left(\frac{\partial E}{\partial t}\right)_I = \frac{RTwI}{(\tau_a + \tau'_a) dx_a zFI_{0a}} +$$

$$(\phi_{a'} - \phi_a)_{I=0} \cdot \frac{w}{dx_a} = \frac{w}{d} \cdot F \qquad [7]$$

an expression which, like Eq. [5], is time-independent and which we may expect to find verified along the horizontal portions of the plots of $\log(\partial E/\partial t)_I$ vs. $\log t$ for sufficiently small values of I. Let us note that Eq. [7] leads to the possibility of determining the field at zero current from the intercepts of the linear plots of $(1/I) \cdot (\partial E/\partial t)_I$ vs. I. This is of course not possible with the linear plots of $(1/I) \cdot (\partial E/\partial t)_I$ vs. $\log I$ corresponding to Eq. [5]. However, by combining information obtainable from Eq. [5] and [7] and on the basis of plausible assumptions concerning d, τ_a, and τ'_a we can arrive at numerical values for all the quantities appearing in these two equations. We have done this for a number of metals by applying Eq. [7] to the range of 5 to 1 μa/cm^2, taking the slope provided by these two points to be the coefficient of I in Eq. [7]. In two cases out of five [the first two of Table I, see (8)] the plots were linear in the range 1-5-10 μa/cm^2, while in the other three cases a hyperbolic sine type of behavior appears to hold in the 5-10-20 range.

Application to Titanium, Hafnium, and Tantalum

In Eq. [5] and [7] the experimental quantities are the unitary rate $(1/I) \cdot (\partial E/\partial t)_I$, the temperature T and the current density I. In addition these equations contain the constants R, w, z, and F. We assume that the density d of each oxide is equal to that of the oxide in bulk, that τ_a and τ'_a are both equal to 0.5. On this basis it is readily seen that the coefficient of ln I in Eq. [5] immediately will give us the value of x_a. Introducing this value of x_a in the coefficient of I in Eq. [7] we obtain the value of I_{0a}. It is interesting to note, as is shown in Table I, that, in the

five cases for which these calculations were carried out, I_{0a} turns out to fall within the 1 to 5 μa/cm^2 range, an indication that this range either corresponds to the exact applicability of the proportionality between current and overvoltage or is one of transition from hyperbolic sine behavior to proportionality. Even if this second alternative were to be the more correct one, it appears to be of extreme interest to pursue the calculations on the basis of proportionality for the 1 to 5 range and thus to obtain from our measured unitary rates at least approximate values for quantities which otherwise would not be accessible: exchange currents, electric potential differences across a'a or bb' interphases and electric fields at I equal to or different from zero.

Another indication in support of our procedure is the following: the term $(\phi_{a'} - \phi_a)_{I=0} \cdot (w/dx_a)$ should have, for internal consistency between Eq. [5] and [7] and their respective ranges of validity, the same value in these two formulas. We verified that this was practically the case by transporting into Eq. [5] the value of $(\phi_{a'} - \phi_a)_{I=0} \cdot (w/dx_a)$ derived from Eq. [7] and calculating the value of I_{0a} required for verification of Eq. [5]. In the case of hafnium, for instance, I_{0a} obtained from Eq. [7] is 1.5 μa/cm^2, while the value obtained from Eq. [5] by the procedure just outlined is 0.9, a very satisfactory agreement in view of the fact that a verification of the order of magnitude was all that had been expected.

The results of the calculations described above are given in Table I for three kinds of titanium (iodide process, Kroll process-annealed, Kroll process-34% cold worked), hafnium, and tantalum. The experimental details concerning these and other metals have been given earlier (5). The formula of the oxide, its density, the thickness x_a, the exchange current I_{0a}, the electric potential difference $(\phi_{a'} - \phi_a)_{I=0}$, the field F_0 at zero current and the field F_{100} at $I = 100$ μa/cm^2 are given for each metal.

Our calculations have been carried out without introducing any roughness factor because of the lack of any reliable information concerning its value and also because its theoretical role in the considerations developed here is by no means clear. It may be that the values of x_a empirically obtained in the calculations include an effective roughness factor. Using an arbitrary value of 2, for instance, the actual values of x_a would be those of Table I divided by 2.

Recall that the exchange current I_{0a} is proportional to exp $(-\Delta G^*/RT)$ in which ΔG^* is the chemical free enthalpy of activation, the electrical portion of the total free enthalpy of activation at zero net current having been separated in the first term on the right hand side of Eq. [3]. The values of I_{0a} and ΔG^* thus vary in opposite directions. It is interesting to note that, of the three kinds of titanium considered here, the Kroll process-annealed has the lowest ΔG^* and the Kroll process-cold worked has the highest, with the iodide process type having an intermediate ΔG^*, the total range of variation being about 500 cal/gram-ion.

In concluding we wish to stress that the calculations presented here should be regarded as having only qualitative significance. They should serve as illustrations for a theoretical approach which appears to be in the right direction and which could be refined without any major difficulty. In particular it would be a simple matter to introduce discontinuities in the electric field at the planes a and b and thereby to take into account the possible presence of space charges. The overvoltage-current relationships at the interphases a'a and bb' may each be, for a given current, of one of three possible types (Tafel, hyperbolic sine, proportionality) giving rise to a total of nine possibilities. In accordance with a recent study by one of us (9) on the dependence of reaction rates on affinities, which we are in the process of extending to electrochemical reactions, elementary reactions with rates varying exponentially with their affinities (here currents varying exponentially with the electrochemical affinities or overvoltages) are rate-determining, while elementary reactions with rates proportional to their affinities (here currents proportional to the electrochemical affinities or overvoltages) are regarded as practically reversible steps. If, in the cases discussed above, the current-overvoltage relationship applying to the thickness X of the oxide itself remains of the Tafel (or Cabrera-Mott) type throughout the whole range of currents, i.e., from 100 to 1 μa/cm^2, the corresponding step (passage of metallic ions from a to b, but, as a conceivable alternative, passage of oxide ions from b to a) is definitely rate-determining in the range of small currents, i.e., here 5 to 1 μa/cm^2. On the other hand, at the higher currents, the actual rate-determining step may be either the passage of metallic ions from a' to a or the passage of oxide ions from b' to b. In this latter case a variation with the composition of the solution of the parameters calculated in the present paper would be expected. In this manner it would become possible to examine the influence of the composition of the solution on the characteristics of the film-building process. Such an influence has already been detected experimentally in the case of zirconium and its alloys (10, 11).

Acknowledgment

The work reported in the present paper was part of a project carried out under a Research Fellowship granted to one of the authors (H. A. J.) by the Research Foundation of the Aluminum Company of America to which appreciation is hereby expressed. The experimental work (5, 8) on which the foregoing theoretical developments are based was performed in the Department of Chemistry of the University of Oregon at Eugene, Oregon.

Manuscript received Jan. 2, 1957.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Electrochemical Aspects of Stress Corrosion

D. K. Priest

Research Division, The Pfaudler Company, Rochester, New York

In recent years there has been some discussion of a "mechanical" mechanism for stress-corrosion cracking (1-5). In much of this work discussions of mechanism are based on the combination of a mechanical step and an electrochemical step, these being regarded as alternate and discrete actions which contribute to the total phenomenon. Those holding this viewpoint with respect to the mechanism of stress-corrosion believe that purely mechanical cracking is the major contribution toward stress-corrosion cracking and that electrochemical reaction or corrosion acts only as a means of triggering the mechanical cracking.

It is believed that some experimental evidence available indicates another, more logical mechanism for stress-corrosion, and this paper is devoted to discussion of a mechanism for stress-corrosion believed to be in best agreement with observable data.

Harwood, in a review of the phenomenon, discussed several theories of stress-corrosion (6). These theories can be divided into two main areas of belief, a mechanical mechanism, triggered at intervals by very local corrosive attack and an electrochemical mechanism in which corrosive attack occurs continuously as a primary contributing factor with the role of stress being that of causing local electrode potential changes. Such potential changes might be caused by stress-induced changes in filming mechanisms or by cold work of local metal volumes.

Brown and Dix (7) supported an electrochemical mechanism. Their work dealt primarily with intergranular stress corrosion, however, and strong evidence was presented for the existence of preferential paths for corrosion along grain boundaries. Extensions of the electrochemical theory into the area of transgranular stress-corrosion have been made by Logan (8), Priest, Beck, and Fontana (9, 10), among others.

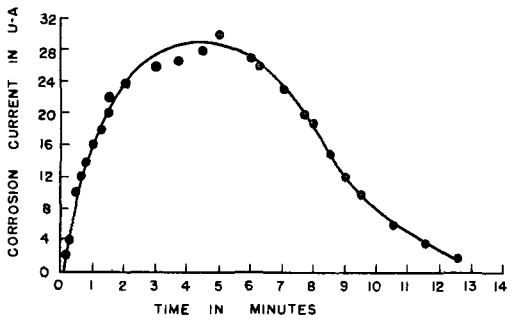
Although the mechanical theory was early expressed by Keating (1), in recent years Edeleanu (4), Harwood (5) and others have held similar although more sophisticated views wherein the electrochemical contribution to stress-corrosion was viewed as a triggering mechanism for a purely mechanical fracture. This expanded viewpoint was made necessary in view of the demonstration of the effectiveness of cathodic protection in preventing stress-corrosion cracking and in slowing or stopping stress-corrosion already in progress.

Loading Previously Cracked Specimens

Unpublished data and observations recorded by the writer some years ago are of interest in support of the electrochemical theory of stress-corrosion. In an investigation of stress corrosion in a magnesium-base alloy (9), several interesting experiments were performed. In one case stress-corrosion cracking of the J1 alloy (6% Al, 1% Zn, balance Mg) in an inhibited sodium chloride solution was allowed to proceed until the test specimen was cracked halfway through, at which time it was removed from the test solution, washed and dried, and subjected to additional stress. The imposition of additional stress resulted in no further cracking and caused only ductile bending of the remainder of the cross section. Such cracked specimens could only be cracked further in air by impact loading, in which case the surface appearance of the impact fracture was far different than the surface appearance of the fracture caused by stress-corrosion cracking.

Corrosion Current Measurements

A consideration of the mechanical triggering idea is that measured corrosion currents should assume different values according to whether or not mechanical failure or electrochemical corrosion is taking place within a given time interval. Thus, if purely mechanical cracking is occurring, the corrosion current should be zero or appreciably decreased and, if mechanical cracking is not taking place at the instant of time considered, then corrosion current should assume some maximum value.



The data presented in Fig. 1 were recorded for a transgranular stress corrosion failure of J1 alloy under testing and measuring conditions described in detail previously (9). The J1 alloy was made to crack in an inhibited sodium chloride solution and, using an electrode physically separated from the anodic crack as cathode, corrosion currents were measured. The data of Fig. 1, recorded at intervals of a minute or less, indicate that the measured currents did not fluctuate and did not increase or decrease in a step-wise manner. Further, continuous visual observation of the microammeter revealed no needle "flicker" or other evidence of changing current. This behavior of the corrosion current suggests that the electrochemical nature of stress-corrosion process is continuous and that purely mechanical cracking plays no role in the mechanism.

Cathodic Protection

Harwood (5) suggests that at some point in the cracking process, the influence of mechanical cracking might be too great to counteract with cathodic protection. In contrast, the writer's experiments indicate that application of cathodic protection to a specimen undergoing stress-corrosion controlled the *rate* of stress-corrosion at all stages of cracking.

Figure 1 presents typical corrosion current-cracking time data obtained for transgranular stress corrosion cracking with the magnesium-base alloy, J1. The data cover the total cracking of a specimen from crack initiation to essentially complete failure. Current values were measured as described previously. The shape of the curve in Fig. 1 is due to the fact that the specimens were stressed by the constant deflection method so that stress values at the crack base varied from zero (before initiation) to a maximum (when crack was halfway through the specimen cross section) to zero (as relief occurred because of the ductile behavior of the reduced cross section of the nearly completely cracked specimen). At any stage in the cracking process, the amount of cathodic protection current needed to stop the attack was proportional to the corrosion current being generated at the time of application of protection. Further, at all stages of the process the addition of lesser amounts of cathodic protection current slowed the stress corrosion cracking so that "failure time" was increased.

Corrosion Rates

Complete cracking of a specimen 3/16 in. thick took place in about 20 min, but the major portion of the cracking occurred in approximately 10 min and, during this time, two-thirds or about ⅛ in. of the specimen was cut through. During the fastest cracking period, therefore, a rate of 0.0125 in./min was attained. This is approximately 6500 in./year, a very high corrosion rate.

It should not be assumed that the explanation for this very large corrosion rate lies in proposing extensive mechanical cracking. On the contrary, corrosion can account for all of the metal loss necessary to produce such rapid cracking. If a crack width of 100 unit cells is assumed, a transgranular stress corrosion crack along the basal plane of the magnesium-base J1 alloy would be approximately 520Å or 5.2×10^{-6} cm in width. Since, experimentally, the average rate of crack propagation during its actively cracking period was of the order of ⅛ in. in 10 min (0.03 cm/min), then in 1 min the volume of metal lost in a crack the width of the 3/16-in. specimen (0.4763 cm) would be 7.43×10^{-6} cc. Using 1.8 g/cc for the density of the J1 alloy, the weight loss would be 1.34×10^{-7} g.

Another approximation of weight loss can be made by using measured corrosion current values (Fig. 1). During the active portion of cracking, corrosion current flow was at least 20 μa or 1.2×10^{-3} coulombs/min. By Faraday's law, the weight of metal lost should be 1.51×10^{-7} g.

These two weight loss approximations reduce to corrosion rates of 6,210 ipy (7.79×10^{6} mdd) and 7,000 ipy (8.77×10^{6} mdd), respectively, for cracks 100 unit cells in width.

Corrosion rate values thus derived strongly support the idea that electrochemical action is the primary cause and reason for the stress-corrosion cracking. These calculations, while admittedly approximate, could be considerably in error and still demonstrate the existence of extremely large corrosion rate values.

Visual Perception of Stress Corrosion

Still another area of discussion may clarify the essentially electrochemical nature of stress corrosion cracking. Reference has been made by Harwood (5) to the motion picture produced by Priest, Fontana, and Beck (9) with respect to visual evidence of the noncontinuous nature of stress-corrosion cracking. While the motion picture does show that the crack progresses nonlinearly with time, this does not necessarily indicate a series of sharp mechanical failures triggered by corrosion. It is the writer's belief that cracking is going on continuously, but is perhaps not always continuously visible. It must be remembered that this motion picture provides only a two-dimensional view of something occurring in three dimensions. With this in mind, it is evident that noncontinuous crack propagation observed on a surface could be caused by continuous cracking taking place beneath the viewed surface. As soon as this unseen cracking progressed far enough, the surface in view would tear quickly and do so in a semiductile fashion, that is, in the manner typical of ductile metal failure at the base of a notch. This analysis is compatible with the observations recorded in the film, and it is concluded that the plastic deformation revealed in the motion picture is the result of crack

propagation and not the cause of crack propagation. The role of stress, then, is that of maintaining film-free areas or, by very local deformation, causing an anodic change in electrode potential at the tip of an advancing stress corrosion crack.

Summary and Conclusions

Much of what has been discussed refers specifically to the author's work with the Jl alloy, but the fact remains that the electrochemical nature of stress corrosion has been demonstrated for other systems as well as the work discussed in this paper. In view of experimental evidence with regard to crack corrosion rates, cathodic protection and the nature of measured corrosion currents, it seems unlikely that purely mechanical cracking plays any discrete part in the stress corrosion process unless a distinctly brittle phase exists.

It is concluded that in ductile materials transgranular stress corrosion takes place only under the driving force of a continuous electrochemical action which causes very localized removal of metal by corrosion. The site of metal removal (the crack tip) and the direction of cracking are determined by stress acting to cause localized potential differences through the interruption of film forming mechanisms or by intense, localized plastic deformation.

Evaluation of the Homogeneity of Germanium Single Crystals by Photovoltaic Scanning

J. Oroshnik and A. Many[1]

Research Laboratories, Sylvania Electric Products Inc., Bayside, New York

It is well known (1, 2) that photovoltages due to resistivity gradients in the bulk can exist in semiconducting crystals. This phenomenon is generally referred to as the "bulk photovoltaic effect." Resistivity inhomogeneities constitute small junctions throughout the material which allow charge separation to take place. These junctions give rise to easily observed photovoltages generally of the order of hundreds of microvolts. Photovoltages due to p-n junctions are usually in the range of tenths of a volt.

Consider, for example, an n-type germanium sample having rectangular shape with contacts at the ends. If this crystal is illuminated at some point along its length where $(d\rho/dx) > 0$, a voltage will be observed across the sample with the right-hand contact (at $x = k$) positive (left-hand contact at $x = 0$ grounded). Similar reasoning holds for p-type material, in which case the voltages are reversed.

Since the photovoltage depends on the existence of a resistivity gradient, it is a derivative quantity. Therefore, the integrated signal corresponds qualitatively to the changes in resistivity.

This phenomenon can be used as a sensitive and rapid tool for exploring the homogeneity of single-crystal germanium samples that may otherwise appear to be very uniform. The experimental arrangement is shown schematically in Fig. 1. A low-speed

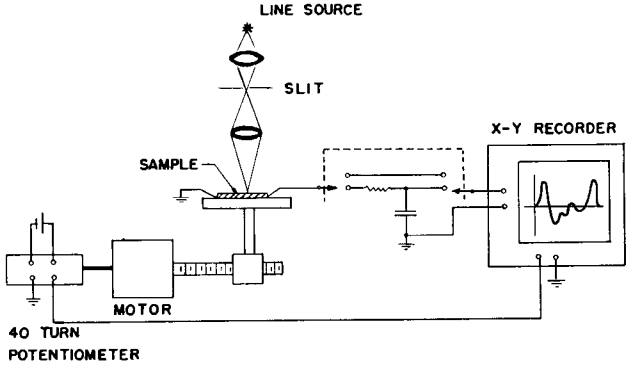

Fig. 1. Schematic of photovoltage scanning system

motor drives the crystal sample under a narrow band of white light focussed on the surface. A 40-turn potentiometer is driven simultaneously, and the voltage from it drives the x-axis of the recorder. Either the direct photovoltage signal, or the integrated photovoltage as desired, is, after suitable amplification, fed into the y-axis of the recorder. A direct plot of signal versus position is thus obtained for any sample.

Figure 2 shows the experimental results for an n-type germanium sample that would ordinarily be considered as being fairly uniform over a significant part of its length. The upper curve is the photo-

[1] Present address: The Hebrew University, Jerusalem, Israel.

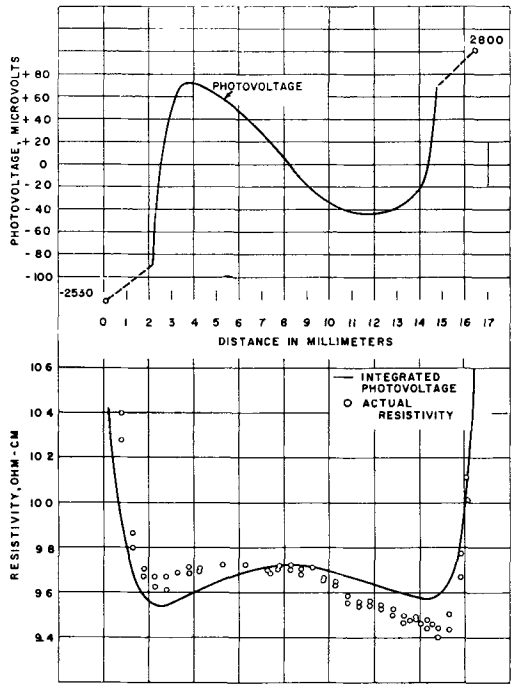

Fig. 2. Photovoltage and resistivity scan of on n-type germanium sample.

voltage scan—microvolts vs. distance along the sample in millimeters. This curve shows three points where the signal is zero, indicating that a combination of three maxima and minima will occur in the resistivity curve. The lower diagram represents the resistivity scan for this sample. The solid curve is the result of integrating the photovoltage, while the circles represent the actual resistivity measurements. The resistivity measurements were taken with a two-point probe. An electrometer was used to measure voltages, and a constant-current generator supplied the sweep current to the sample. Reasonably good agreement is apparent. In the central portion of the crystal, that is, around 8 mm, the resistivity changes are of the order of 0.1%, while the photovoltages in the same region are large and distinct. It is also clear that the zero photovoltage signals coincide exactly with the maxima and minima of the resistivity curve.

To explore a crystal wafer, deep trenches are cut into the crystal on one of the large faces, in the vicinity of the contacts. This procedure greatly reduces the effective lifetime of the minority carriers in the vicinity of the contact and alleviates troublesome photosignals that may arise.

Figure 3 is a diagram of such a (p-type) germanium wafer. A contact is soldered continuously along the left- and right-hand edges of the wafer. The pair of vertical lines at each end represent the trenches. A set of direct and integrated photovoltage scans (as in Fig. 2), were taken on this wafer from $x = 0$ to $x = 22.5$ mm, and $y = 0$ to $y = 19.8$ mm.

The integrated values of the photovoltage signals are plotted directly, and a resistivity map of the wafer is then prepared. The heavy lines in this map are lines connecting points of equal resistivity *change,* plotted in terms of microvolts. For convenience, let us call these lines *isorhos.* This mapping is still a very qualitative picture of the wafer. However, sufficient information can be gleaned from such a diagram so as to determine the region from which a sample having the highest uniformity can be obtained. For example, the section of the wafer in Fig. 3 between $x = 0$ and $x = 3$ mm indicates small resistivity changes as compared to other possible sections.

The section between $x = 0$ and $x = 3$ mm was cut out of this wafer and the measurements on it are shown in Fig. 4. The upper curve is the photovoltage scan, and the lower solid curve is the direct integration of it. As before, the circles represent the actual resistivity measurements. The fit between the two is clearly good.

This evaluation method has some distinct advantages over probe methods. First, it is fast; the photoscan and integration can be made in less than 1 min. Second, it is the only way known of making a detailed estimate of the homogeneity of a wafer before cutting it. Third, the photo method of estimating resistivity changes is applicable under conditions where probe methods are very difficult, as, for example, when the sample is held at liquid nitrogen temperatures.

Thus far there has been reasonable success in obtaining relative values of resistivity changes by photoscanning. By taking into account such important factors as the lifetime of the material, the photo-

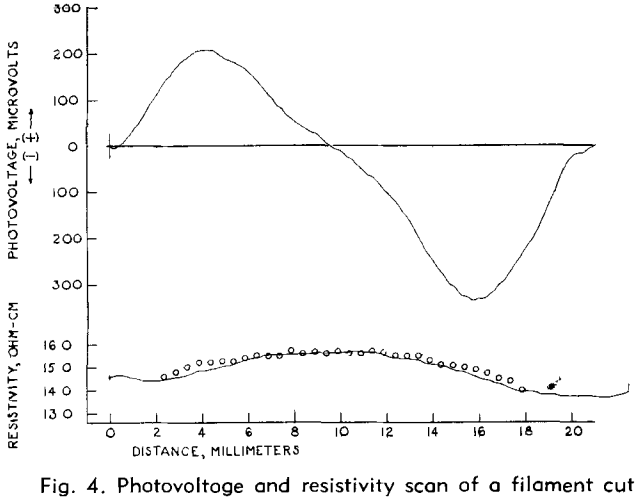

Fig. 4. Photovoltage and resistivity scan of a filament cut from the wafer of Fig. 3.

voltaic scanning method should be suitable for approximating the actual values of the resistivity changes in ohm-centimeters.

Acknowledgment

The authors are particularly indebted to Mr. Alfred Willis, of this laboratory, for the preparation of samples and his assistance in performing this work; to Mr. M. Adler, of the Design Group for the design of the mechanical components; and to Mr. M. Thomsen and Mr. A. Piorkow of the machine shop for the fabrication.

Technical Feature

Production of Electrolytic Copper Powder

Frank Wills

Technical Department, American Metal Climax, Inc., New York, New York

E. J. Clugston[1]

Amco Research Inc., Subsidiary, American Metal Climax, Inc., New York, New York

ABSTRACT

A detailed description of the operation, equipment, and quality control used in the commercial production of electrolytic copper powder[2] is presented. The effect of electrochemical and mechanical variables on the physical characteristics of electrolytic copper powder is also reviewed.

Roll has discussed (1) the advantages and improved properties obtainable by the use of electrolytic metal powders. The present paper describes the production of electrolytic copper powder. The plant[3] is an integrated copper smelter and refinery which processes concentrates, blister and scrap to fire refined, electrolytic and OFHC[4] brand copper. In addition to electrolytic copper powder, the plant also produces atomized copper-lead based powders as well as solder and tin powders.

Electrolytic copper powder, based on the work of Drouilly (2), has been produced by the refinery for twenty-five years. During this period the production capacity of copper powder was increased from 20,000 to over 1,000,000 lb/month. Simultaneously, with increased production capacity, many improvements have been made in production and control techniques, resulting in a better and more uniform product.

The physical characteristics such as particle size, apparent density, flow rate, and dimensional change on sintering of electrolytically deposited copper powder are affected by a number of factors. The most important of these are the current density, copper and acid content and the temperature and circulation rate of the copper sulfate electrolyte. Although electrochemical variables can be controlled to produce a powder within a relatively narrow range of physical properties, they cannot be controlled sufficiently to yield a product which meets the rigid specifications required by the consumer. Consequently, further processing operations on the washed powder are required such as furnacing in a controlled atmosphere, grinding, screening, and blending.

The basic electrochemical theory of electrorefining and electroplating is identical to that of electrolytic powder deposition. The electrochemical conditions affecting the type of deposit, however, are controlled in powder production so as to yield a deposit which is the opposite of that desired in refining and electroplating where a hard, dense and smooth, adherent cathode is the object. An excellent paper on the theories covering metal powder deposition has been presented by Mehl (3). Wranglen (4) also defines the three basic factors responsible for the formation of powdery and spongy deposits as low metal overvoltage, depletion of the metal content of the cathode film, and the formation of basic material in the cathode film. Only the first two factors are of importance in this case.

While the generalities noted above do produce spongy deposits, it is necessary to control the following variables to produce a powder within a specified range of physical properties. These are: (*a*) electrolyte composition (acid and copper content); (*b*) electrolyte temperature; (*c*) electrolyte circulation rate; (*d*) current density; (*e*) size and type of anode and cathode; (*f*) electrode spacing; and (*g*) brush-down interval.

The last variable is very important since it not only controls the type of deposit which builds up on the cathode, but also prevents excessive variations

in the cathode area, with consequent lowering of the current density. Tables I, II, and III indicate the effect of three of the above variables on the apparent density and the per cent dimensional change on sintering.

Electrolytic Operations

A section of the regular electrolytic copper refining plant, or tank house, is used for the production of electrolytic copper powder. The powder section uses the same type of cell as is found in the regular tank house and is also supplied with direct current from the main power plant. Electrolyte and electrical conditions for the two units are different, but by suitable alteration of piping and bus bars, sections can be switched from electrolytic copper refining to powder production and vice versa. This flexibility allows for considerable leeway in operating capacity of the two units.

At the present time, six sections or groups of cells, containing 16 cells each, are available for powder production. In addition, copper powder is also produced by four-cell liberator sections which control the electrolyte copper content by plating from the electrolyte solution instead of from copper anodes. The cells of four of the regular sections are constructed of wood, with adjacent cells having common side walls. The dimensions are 11 ft long by 3½ ft wide by 4 ft high (I.D.). These tanks are completely lined with 8-lb, 6% antimonial lead. The remaining two regular sections and the liberators are made of individual self-supporting, glass-fiber reinforced, polyester cells. The plastic cells are superior to the lead-lined cells from an electrical viewpoint, since stray currents and current leakage are minimized. To evaluate plastic tanks for use in the powder plant several different design and fabrication methods were used. While several units have demonstrated excellent serviceability, other tanks have developed leaks due to separation of the fiber-glass laminations. Repairs to these tanks is an arduous task since it is difficult to determine where the leak originates in the laminated structure.

All cells are supported by concrete piers standing in the basement floor. For electrical insulation from the ground, the columns are capped with glass and are protected from electrolyte leaks by plastic shields. Each cell is equipped with a solution outlet 15 in. from the bottom for partial draining. This outlet, in conjunction with a stand pipe which controls the solution level in the tank, is also used as an outlet for the circulating electrolyte. Another outlet in the cell bottom is used for complete draining.

Originally the sections were built on two levels so that the electrolyte flowed from the tank in the upper tier to the lower lying parallel tank before returning to storage for recirculation. Due to the change in both copper content and temperature of the electrolyte in flowing through the two tanks, powder deposited in the lower section was much coarser and heavier. To overcome this nonuniformity in powder production, all sections are now built on the same level and each tank has individual circulation. Electrolyte is pumped from basement storage tanks to an elevated head tank. From there it flows to manifolds on each section by gravity, and then into the back and the top of the cell. Thus circulation of electrolyte in the tanks is top to bottom. This yields a finer, more homogeneous powder than bottom to top circulation. Electrolyte returns to the basement storage by gravity.

The cathodes, which have been the subject of considerable experimentation, are now 6% antimonial lead, 24 x 34 x ⅜ in. and weigh about 150 lb each. Polished copper, aluminum, stainless steel, rolled and cast lead, as well as carbon, have been tried but none proved as satisfactory as the presently used material. For better contact, these cathodes are cast directly on the ½ x 1½ x 46 in. copper bars by which they are suspended. The lead cathodes have an average life of several years.

Each cell is loaded with eighteen lead cathodes at a spacing of 7 in. centers, and nineteen copper anodes which are hung between the cathodes. The electrodes in each cell are in parallel with each other, and the cells and sections are in series with each other. The bus bars from which the electrodes hang are notched, which prevents the electrodes from shifting and also gives better contact, permitting 20% higher amperage operation.

Power is supplied to the cells by a 1500 kw motor generator set at 10,000-13,000 amp, the power being conducted to the cells by a 21 square inch bus bar. At 12,000 amp, the current density on the anodes is 50 amp/ft^2.

During electrolysis, some of the deposited powder sloughs off and falls to the bottom of the cell. To prevent short circuiting between anodes and cathodes, causing a decrease in cathode current density and deposition of large particles, the cathodes are brushed down periodically with a long handled rubber squeegee. Several other methods such as continuous vibrating, shaking, and hammering have been tried, but none has been practicable.

At the end of the three-day operating cycle the power is turned off in that particular section. The electrolyte is drained to a level just above the top of the powder. The anodes and cathodes are washed down and removed from the cells by an overhead crane which services the entire powder section. The bottom outlet is opened and the remaining electro-

lyte drained from the tank along with a small amount of powder which is later cleaned from the solution launders.

The powder is scooped from the bottom of the cell by a motorized clam-shell bucket attached to the overhead crane. Damage to the cell bottom is prevented by wooden or plastic boards placed in the cell.

The subsequent powder washing operation is one of the most important steps in the whole production cycle. All traces of electrolyte must be removed from the powder, otherwise an impure and easily oxidizable material will be produced. In addition, any sulfate remaining in the powder will cause repeated breakdowns in the electrically heated furnaces used in the finishing operation. Until several years ago, a 40-in. batch type Tolhurst centrifuge was used to remove the electrolyte from the wet powder, followed by a clean water wash. Due to the high speed of the centrifuge, the powder was compacted causing particles to densify, making production of low density powder impossible. Production of low density powder was possible only by percolation washing in wooden boxes. Due to channeling, washing was frequently poor, and consequently time-consuming to achieve complete removal of electrolyte.

A system of washing and dewatering has been developed which improves the copper powder operation immensely. The present system, which is operating very efficiently, involves dumping of the powder from the clam-shell bucket into a 400 cubic foot tank. Water is added to slurry the powder which is then pumped by a Wilfley centrifugal pump to one of two 400 cubic foot surge tanks. Here, the slurry is adjusted to the proper consistency and then pumped to a 60 in. diameter horizontal Oliver continuous filter. The filter dewaters the slurry, washes it twice with clean water, and then dewaters it to about 20% moisture. A rotating screw removes the moist powder from the filter.

Since the density ratio of powder to solution is approximately 8:1, special precautions must be taken to prevent settling of powder in pipes, tanks, pumps, valves, etc. Although considerable preliminary test work was done to determine critical velocities and powder characteristics after pumping, a lengthy start-up period was needed in the plant before trouble-free operation was obtained. The irregular structure of the powder complicated matters even more, since once powder starts to settle out in the system, the powder particles interlock resulting in a very solid and hard-to-remove plug.

All equipment external to the cells is constructed of stainless steel type 316 and has given satisfactory service.

Because of the low acid content and relatively low temperature of the electrolyte, as well as the high resistance of the lead cathodes and high current density used, the power consumption is considerably higher than for copper refining. The average voltage per tank is 0.9-1.1 v compared to normally less than 0.25 v for copper refining. The ampere efficiency at the anode is in excess of 95%, but at the cathode it is somewhat less than 90% because of the deposition of hydrogen and relatively rapid redissolution of fine copper powder.

Preparation

The wet powder, which oxidizes readily because of its finely divided state and active surface, is now ready for the finishing operations. Certain of its properties, especially the apparent density and the dimensional change on sintering, have been produced in the powder during electrodeposition. To produce an acceptable grade of powder, however, a furnacing operation followed by grinding and screening with subsequent blending of the finished powder is needed.

As in the electrolytic operations, considerable improvements have been made in the processing division. When operations were begun in 1932, 6-in. tube furnaces were used to treat the powder. Small boats held the wet powder and were pushed through the furnace by hand. As demand increased and better equipment became available, the first of a series of four chain-driven pan furnaces was installed in 1937. These furnaces are 60 ft over-all in length having a three-section, 30-ft electrically heated zone and a 30-ft water jacketed cooling zone. Manually filled and compacted paper-lined copper pans were used to hold the powder. In order to meet increasing demand and to achieve improved production methods, a mesh belt furnace was installed in 1951 to supercede the pan-type furnaces. Various other improvements were also made in the grinding and classifying system.

Due to the location of the electrolytic production unit and the processing plant, the filtered product must presently be transported to the finishing division. A ten-ton fork lift truck which carries three boxes per trip is used for this job. Pumping has been considered, but, because of the difficulties encountered in even the short distance pumping in the tank house, improved systems must be developed before this will be feasible. Added factors are the possible and very probable detrimental changes that long distance pumping will have on powder characteristics.

Powder is dumped from the transfer boxes into the charge hopper of the mesh belt furnace. Dimensions for this furnace are identical to the above described pan furnaces. The continuous mesh belt, made of Cambriloy 25-20 alloy wire, is driven by a variable speed drive and operates at 1-7 in./min. To prevent wet powder from falling through the belt, a continuous high wet strength paper sheet is interposed between the belt and the powder. A roller after the charge hopper compresses the powder to improve heat transfer and to prevent loose powder from falling off the belt. After the belt enters the furnace and all water has been driven off, the paper burns, but by this time the powder has sintered sufficiently to prevent any of it from falling through the meshes of the belt.

Furnace atmosphere is produced in exothermic gas producing units.[5] Natural gas and air are burned in a ratio of approximately 1:6 to give a gas con-

[5] General Electric Co.

taining 17% H_2, 12% CO, 4% CO_2, balance N_2. Refrigeration lowers the dewpoint to 30°-40°F. Gas is fed to the furnace counter-currently, which improves reduction and improves cooling of the cake.

The furnace operation accomplishes the following: (*a*) drying the powder; (*b*) reducing oxide; (*c*) sintering the fines; (*d*) altering physical properties including apparent density and sintering characteristics.

By varying furnacing temperature between 900°-1450°F and concurrently varying furnacing time by changing the belt speed, large changes in the amount of fines, the apparent density, and to some extent the dimensional change characteristics can be effected. This furnacing operation is consequently the second point where powder properties can be changed to meet final specifications.

Depending on furnace conditions, the sintered powder discharges as a soft to a hard cake which cannot be broken by hand. Discharge temperature is maintained low enough to prevent re-oxidation of the powder. As the cake discharges, it is broken by grappling hooks and given a preliminary crushing in a 40 hp hammer mill to ¼ in. The crushed cake is next lifted to the main grinding system by a bucket elevator.

Fine grinding is done by Mikro-Pulverizers. These are high-speed water-cooled hammer mills equipped with Stellite faced hammers. Feed rate to the mills, the mill speed, and the screen opening under the mill can all be varied to obtain the desired powder characteristics. Normal operating conditions are: (*a*) 3000 - 4500 rpm; (*b*) 500 - 1000 lb/hr mill; (*c*) 1/16 - 3/32-in. screen opening; (*d*) screen hole shape: round, elliptical, slots.

The grinding operation becomes the third operation where powder characteristics can be changed. Each grinding system consists of two Mikro-Pulverizers in series. One or both units can be used to grind the powder, depending on the type desired. The ground powder is then moved to screen hoppers. These discharge into Sprout Waldron bolting reel screens equipped with a beater arm. Oversize powder from the screen is returned to a secondary grinding system which again consists of two Mikro-Pulverizers and screen. The minus 100 mesh powder is next classified in a Gayco air classifier. Fines from this unit are collected in 24-gal drums and moved to the blending floor. Oversize from the air classifier can either be removed from the system or, if desired, be again returned to the grinding system.

The grinding and classifying system consists of seven banks of Mikro-Pulverizers, screens, air classifiers, and the necessary bucket elevators and screw conveyors. Ground material starts in the first unit, and oversize, or material for regrinding to change its characteristics, is then ground and classified progressively through the whole system. The product from the final unit has been worked considerably and represents the highest density material produced. Its apparent density is above 3.5 g/cc and its application is for specialized uses. Oversize from this system is rejected and sent to the casting building for remelting.

Powder that discharges from the system is stored in closed drums to which silica gel containers are added to control humidity and prevent oxidation. Each drum of powder is sampled and its weight, apparent density, flow, and screen characteristics recorded.

To produce a lot of finished powder to meet customer specifications, the correct type of powder is selected from the storage drums and mixed in one of three Gemco double cone blenders. The lot size is generally 20,000 lb/blender charge and, before a lot is withdrawn from the blender into shipping drums, all specifications have been checked by the Control Department and approved for shipment.

In order to control all phases of the operation, a well-equipped production control laboratory is maintained. The control laboratory checks both electrolytic and finishing operations and the following samples are taken and tested.

1. Daily composite of cell powder: Tested for particle size distribution, flow, and apparent density.
2. Electrolyte sample: Tested for copper content and acidity.
3. Daily composite of filtered powder: Tested for washing, particle size, flow, apparent density, dimensional change on sintering, and sintered strength.
4. Hourly furnace discharge cake: Tested for temperature.
5. Shift composite of discharge: Analyzed for oxygen content.
6. Daily composite of furnace production: Tested for particle size distribution, apparent density, oxygen content, dimensional change on sintering, and sintered strength.
7. Daily composite of finished production lots: Tested for chemical assay: Cu, Pb, O_2, C, S, HNO_3 insol., grease.
8. Daily composite of main finished powder production: Tested for screen analysis, flow, apparent density, and dimensional change on sintering.

Table IV. Powder specifications

Type	Apparent density, g/cc	Flow, sec/50g	Screen analysis		Dimensional change, %	Chemical analysis %		
			+100 mesh	−325 mesh		Cu	H_2 loss	HNO_3 insol.
LC	1.5-1.75	(Scott)	0.1 Max.	90 Min.	—	99.0 Min.	0.75 Max.	0.03 Max.
C	2.1-2.5	(Scott)	0.1 Max.	90-95 Min.	—	99.0 Min.	0.75 Max.	0.03 Max.

U	2.5-2.6	35 Max.	0.2 Max.	55-65	0.3-1.8	98.4	0.40 Max.	0.03 Max.
HM	2.6-2.7	35 Max.	0.2 Max.	60-70	—	99.25	0.50 Max.	0.03 Max.
AJL	3.5-4.0	24 Max.	0.8 Max.	35-45	—	99.25	0.30	0.03 Max.

9. Monthly composite of finished production lots: Tested for tensile strength and green strength.

10. Production lots: Tested for screen analysis, apparent density, flow, dimensional change on sintering, green strength, and chemical assay.

This amount of testing has been found necessary to give a satisfactory degree of control over all operations and to assure consistent uniform powder production.

Table IV shows some of the types of powder produced. These range from the very light and fine LC type to the heavy and coarse material which is designated AJL. All other grades produced lie between these types.

To supplement the control section, a fully equipped powder research laboratory is also maintained. This unit has the responsibility of developing and improving production methods and to assist the operations generally. Since the United States Metals Refining Company also produces other powders, the laboratory has units for producing atomized powders, and an electrolytic section which consists of electroplating tanks which range in size from battery jars to full size units. The laboratory is also fully equipped with presses and sintering furnaces to study the effect of all processing variables on finished product characteristics. Process variables can consequently be fully evaluated in the laboratory before large scale tests are made in the production unit.

Manuscript received Oct. 13, 1958. This paper was prepared for delivery before the Buffalo Meeting, Oct. 6-10, 1957.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Brief Communication

The Structure of AgO

Alvin J. Salkind and William C. Zeek

The Electric Storage Battery Company, Research Center, Yardley, Pennsylvania

The structure of silver oxide (AgO) has been of interest to members of the Society as evidenced by recent articles (1) in the *Journal*, and by discussions at the Ottawa Meeting.

We would like to draw the attention of readers of this *Journal* to a group of researchers whose earlier contributions to this field are often overlooked. We refer to the work of Vladimiro Scatturin and his associates at the University of Padua. Their most recent paper was entitled "The Crystalline Structure of AgO" (2).

They investigated the crystal structure of AgO using both copper and iron radiation and listed in their paper 36 reflections obtained with Fe Kα radiation. They were able to index all these reflections by the Ito method and concluded that the compound was monoclinic, Space Group C_2^6 h = C 2/C with the following parameters.

$a = 5.85_2$Å	$b = 3.47_8$	$c = 5.49_5$
$\beta = 107°30'$	$V = 106.7$Å^3	$Z = 4$

The authors also discussed the position of the atoms and concluded that with the atoms as follows:

4 Ag in ¼, ¼, 0; ¾, ¼, ½; + (000; ½, ½, 0)

4 O in 0, Y, ¼; 0, Y, ¾; + (000; ½, ½, 0)

the most probable value for the parameter Y was 0.084.

Comparisons are also drawn with the spacings commonly found in other silver compounds.

Oxidation of Aqueous Ferrous Sulfate by Glow Discharge

H. A. Dewhurst, J. F. Flagg, and P. K. Watson

Research Laboratory, General Electric Company, Schenectady, New York

A variety of chemical reactions may be produced in aqueous solution by "glow discharge electrolysis." The observed chemical effects have been attributed to ions which are produced in the vapor phase by the discharge (1-3). It is well known that in glow discharges several chemically active species are formed in addition to the ions. These include atoms, radicals, metastables, as well as photons, all of

which can, under favorable conditions, produce chemical reactions in aqueous solution. We have recently carried out experiments which were designed to differentiate between the effectiveness of the positive ions and of the electrically neutral species in the glow discharge oxidation of ferrous sulfate. The portion of the total oxidation attributable to charged species was determined by interposing a platinum grid between the discharge point and the solution. The grid was used as the negative electrode in the cell so that it collected the positive ions from the discharge. However, because of its open construction, it had very little effect on the electrically neutral species.

The discharge cell was similar to that used by Hickling and Linacre (2) with the exception of the grid and the fact that the platinum cathode was placed directly in the aqueous solution. The anode was a stainless steel hypodermic needle situated approximately 1.0 cm above the surface of the solution. Deaerated 0.01M ferrous ammonium sulfate solutions (5-10 ml) 1.0*N* in H_2SO_4 were used. The amount of oxidation was determined by spectrophotometric measurement of ferric ion at 305 mμ (4). The total current was measured with a Keithley electrometer. Oxidation yields are reported in terms of the number of equivalents of ferric ion produced per Faraday of charge. Experiments were carried out at about 25 mm pressure under which conditions the discharge operated in water vapor. Other experiments were conducted at 760 mm pressure with either a static or flowing (3 liters/min) atmosphere of pure nitrogen. The results of these experiments are shown in Table I.

Table I. Glow discharge oxidation of aqueous ferrous sulfate
Fe^{2+} = 0.01M in 1.0N H_2SO_4

Pressure, mm Hg	Voltage, kv	Current, μamp	Fe^{3+} Ions/Faraday Grid*	No Grid
25 (Static)	1.1	100	0.6	25
	1.2	1000	0.3	11
	0.65	4200	0.2	11
760 (Static)	10.5	50	5.5	13.5
760 (Flow)	4.2	8.5	0.8	8.7†
	4.8	50	1.4	9
	7.0	100	0.9	10

* 3 mil wire, 80 wires/in.
† Current was 4.0 μamp.

Results at low pressure show that species removed by the grid account for at least 95% of the observed oxidation. The inverse dependence of the oxidation yield on current will be discussed in a later publication. We note that yields under our conditions are greater than yields observed by Hickling and Linacre (2).

Results at 760 mm pressure under static conditions show that about 60% of the oxidation could be accounted for by species removed by the grid. Under flow conditions, however, the grid prevented about 90% of the oxidations. We attribute the decreased effectiveness of the grid under static conditions to the presence of water vapor in the discharge region. In other experiments it was observed that under flow conditions presaturation of the nitrogen with water increased the yield to that obtained under static conditions.

In connection with these studies we have also examined the effect of various gases, ferrous sulfate concentration, and polarity on the yields. An oscillographic study has been made of the electrical characteristics of the discharge, under conditions used in these experiments. Details of these and related studies will appear in a subsequent publication.

The Anodic Oxides of Lead

Jeanne Burbank

U. S. Naval Research Laboratory, Washington, D. C.

ABSTRACT

The anodic oxides formed on lead under varying potential and *p*H were identified by x-ray and electron diffraction. Pure lead specimens were anodized at selected constant potentials to develop anodic coatings of sufficient thickness to give strong x-ray patterns. The domains of occurrence of: α and β PbO_2, yellow and red PbO, and the intermediate oxides, Pb_3O_4, and PbO_x were determined for acid and alkaline electrolytes. The intermediate oxides are not believed to be direct anodic oxides, but to represent chemical reaction products. The occurrence of certain of the oxides may be attributable to an initial electrochemical oxidation of water. The identifications have been presented in potential-*p*H phase diagrams.

Coincident with a study of the positive grid corrosion of the lead-acid storage cell, the anodic oxides formed on lead at various potentials in H_2SO_4 were identified by x-ray and electron diffraction (1, 2). Considered in the light of the potential-*p*H phase diagrams for the system (3), it became evident that certain aspects of the diagrams could be verified by application of diffraction techniques to anodic products formed on lead under controlled conditions of potential and *p*H. Furthermore, it was of interest to know which of the many oxides of lead occur as direct anodic products.

The potential-*p*H diagram is an isothermal phase diagram showing the various valence states of a metal, solubilities of oxides and salts, areas of thermodynamic stability of solid phases, ionic species, and their homogeneous and heterogeneous equilibria. The original presentation of the diagrams for the lead system (3) was based on available thermodynamic information. This present study was undertaken to identify the solid oxide phases appearing on lead as anodic products and to expand the usefulness of the diagrams by verification of the stable and metastable equilibria. In addition, it was desired to clarify the apparent thermodynamic anomaly of the simultaneous occurrence of the two crystallographic modifications of PbO_2 and of tetragonal PbO as anodic products on lead in acid solutions, and relate the known corrosion domains to those predicted on the basis of the diagrams.

Lead forms a number of oxides and Table I presents selected references (4-24) and the designations used in this report. An exhaustive listing has not been attempted. The hydrated lead monoxides have not been included because these materials are not well-established crystallographic identities. Bystrom (25) has presented a survey of the sterochemistry of the lead oxides.

Previous studies have indicated that the corrosion processes on the lead anode in H_2SO_4 at selected positive potentials included a group of reactions quite distinct from the reversible PbO_2, $PbSO_4$ and Pb, $PbSO_4$ electrode reactions (1, 2, 26-28). In order to clarify further the anodic corrosion reactions on lead, this detailed identification of the anodic products was undertaken.

Experimental

The anodic deposits formed on lead at controlled potential and *p*H were determined by polarizing pure lead sheet under fixed conditions and identifying the anodic products by x-ray and electron diffraction patterns taken by reflection from the anodized surfaces. The standard diffraction patterns used for identification are found in the X-ray Powder Data File (29) or in one or more of the references cited for each oxide in Table I.

The electrolytes used in this study were made from C. P. chemicals and distilled water. In the solutions near neutral limited amounts of CO_2 did not interfere with the observations. In order to check this a few experiments were carried out with freshly boiled distilled water and KOH very low in CO_2, in a closed cell. The results of these anodic tests were identical with those obtained in fresh solutions with nominal concentrations of CO_2. Fresh KOH solution was prepared for each run in which it was used. Values of reference electrode potentials were taken from the literature (30-33).

A Beckmann *p*H meter using a glass electrode, saturated calomel reference electrode, and standard buffer solutions were used to monitor the *p*H of the electrolytes. Solutions were made with C. P. reagents to approximate values and their actual *p*H's determined. Whenever feasible, the reference electrodes were used in the same solutions during anodization to eliminate liquid junctions. In sulfuric acid solutions, the electrode was Hg_2SO_4, Hg and in KOH solutions, HgO, Hg. Potentials were converted to the standard hydrogen electrode for this report.

Anodizations were carried out in glass cells, and usually only a few hours were required to develop coatings sufficiently heavy to give excellent x-ray diffraction patterns. Some specimens were anodized for longer periods of time, and as much as one week. The constant potential regulator described by Work and Wales (34) was used as the source of polarizing potential. A negative electrode of Pb or Pt gauze

was of such area that a constant positive polarization potential was obtained.

C. P. lead sheet to be anodized was annealed at 100°C for six weeks, cleaned of its air-formed oxide film by washing in saturated ammonium acetate solution, rinsing in water and inserting into the electrolyte while wet. Anodic polarization was begun simultaneously with insertion into the electrolyte, and the first few minutes of polarization was monitored carefully with a bench potentiometer and reference electrode to determine that the desired anodic potential was applied to the positive electrode.

At the termination of polarization, the electrode was removed from the solution, and rinsed in water, blotted dry on tissue, and placed immediately in the diffraction apparatus. The patterns were recorded as soon as possible after mounting.

GE-XRD-5 x-ray diffraction equipment was used with copper and iron targets, and electron diffraction examination was carried out with the diffraction attachment of an RCA-EMU-2 electron microscope.

In order to determine whether the two polymorphic forms of PbO_2 were readily interconvertible by crystallization from alkaline or acid media several tests were made on C. P. βPbO_2. Beta PbO_2 was dissolved in KOH solution, in concentrated HNO_3 solutions, and filtered with water aspiration. Water was added dropwise to the filtrates and, when sufficient material had hydrolyzed, it was collected on a filter and identified by x-ray diffraction examination.

C.P. βPbO_2 was treated with solid KOH and sufficient water to form a slurry. After several days' digestion at room temperature, large water-clear crystals formed up to 2 cm in diameter. These were washed free of excess PbO_2 with distilled water, and then placed in contact with a few drops of *N* KOH solution. They were slowly converted to dark brown powder which was examined by x-ray diffraction. The residual unconverted PbO_2 was also examined by diffraction.

Large clear crystals up to 6 mm in diameter formed from C.P. PbO_2 when treated with concentrated HNO_3. These were washed free of excess PbO_2, and placed in contact with dilute HNO_3 at room temperature. They were converted gradually to a brown powder that was examined by x-ray diffraction.

Essentially identical potential arrests are reported in many polarization studies of lead anodes in alkalies and only a few are cited here (35-38). Consider-

ation of such reports enabled judicious choice of the potentials used for the anodic treatments of this study.

Table II is a list of the electrolytes, and the potentials, employed in these anodization studies. Certain experiments were rerun many times in order that the identification should be conclusive. Certain other areas, where there seemed no possibility of question, were identified with only a few runs. The anodic products formed on lead in H_2SO_4 solutions have been reported earlier (1,2).

Some anodic coatings were laminated, and the material at the solution interface was removed by wiping the electrode with dry tissue, or by scoring around the edge of the electrode and lifting off the outer layer.

By using spot tests (39) it was possible to detect the appearance of a highly oxidizing material on the electrode surface considerably below the potentials where PbO_2 or the intermediate oxides became apparent in the x-ray diffraction patterns from specimens anodized in the strong acid range. Sheet lead specimens were anodized in H_2SO_4 solutions at carefully monitored potentials within a range ± 0.1 v to the theoretical reversible O_2,H_2O potential. After anodizations as long as 24 hr, the electrodes were removed from the electrolyte and dropped into the selected reagent: acetic acid when the benzidine test was used and starch-KI solution when this was used.

In order to verify the reported deposition of α and β PbO_2 as residues from the intermediate oxides, Pb_3O_4 and PbO_x were extracted with H_2SO_4, $NH_4C_2H_8O_2$ (saturated solution), HNO_3, and $HC_2H_3O_2$. The residues were rinsed in water, sucked dry on a filter, and the diffraction patterns recorded.

Neutral, acid and alkaline solutions of lead were electrolized between platinum electrodes. The potentials at which lead dioxide first deposited on the anode were observed, and the initial and final deposits were examined by x-ray diffraction.

αPbO_2 was heated in air at temperatures between 150° and 400° and the decomposition followed by x-ray diffraction examination of the products. The temperature range between 290°-305° was examined in steps of 2° with heating times of 48 hr. The decomposition was compared with that reported and verified for C.P. βPbO_2 (6, 13, 17).

Results and Discussion

The solid anodic products formed on lead at fixed pH and potential are divided into two categories: (*a*) the product of the anodic reaction at the solution interface; and (*b*) the product of the anodic reaction at the metal interface. These may be the same or different reactions, and there may or may not be other reactions between cell components. Thorough familiarity with the potential-pH diagram originally published (3) for the system is assumed, and this report deals mainly with the solid oxide phases associated with certain conditions of potential and pH at room temperature, but does not include solubility data.

Free energy values have been used to calculate the equilibrium potentials of this report in conformity with the original presentation of the potential-pH diagram; however, the free energy of formation of PbO_2 used by Delahay, Pourbaix, and Van Ryssel-berghe was only −50.86 kcal. Latimer gives a value of −52.34 kcal (40).

The domain of thermodynamic stability of metallic lead may approach that of PbO_2, and the equilibrium expected between the metal and this oxide has been calculated (28)

$$\beta PbO_2 + 4H^+ + 4e^- = Pb + 2H_2O \qquad [1]$$
$$E = 0.6775 - 0.0591\ pH$$

However, it is known that metallic lead usually tends to dissolve in the presence of PbO_2 and will be oxidized in a mixture containing excess higher oxide; or if metallic lead is in excess, the higher oxide will be discharged (41, 42). The electrochemical instability of PbO_2 in strong H_2SO_4 solutions at potentials below the reversible $PbSO_4$, PbO_2 electrode has been discussed by Lander (28). But at the potential of reaction [1], metallic lead is thermodynamically stable in the presence of PbO_2. However at this potential PbO_2 is not thermodynamically stable with respect to PbO_t or Pb^{++}. Therefore when the potential of a lead anode is raised above that of reaction [1], any formation of PbO_2 from metallic lead would tend to undergo the reaction

$$PbO_2 + 2H^+ + 2e^- = PbO_t + H_2O \qquad [2]$$
$$E = 1.107 - 0.0591\ pH$$

until the reversible potential for this reaction is exceeded. At potentials above those of reaction [1], metallic lead is unstable with respect to both PbO_t and PbO_2.

Anodic oxides at the solution interface.—It has been reported and was verified in this study that electrolysis of Pb^{++} solutions between platinum electrodes develops deposits largely of βPbO_2 from acid and αPbO_2 from alkaline solutions. Either or both polymorphs may be deposited from certain solutions depending on current density (potential) (23, 24).

Figure 1 shows the anodic oxides identified in this study at the electrode-solution interface on lead polarized in solutions of varying pH at several potentials. The lines for the oxidation of water to ozone and H_2O_2 have been added for reference. The effect of anions other than sulfate has not been indicated on the diagram; however, the corresponding salts will precipitate at the solution interface. The accumulations of solid products on the anode surfaces appear as oxides or hydrated oxides intermixed with the salts owing to depletion of the anolyte in anions.

The areas designated as PbO_y, βPbO_2, and the hydrous oxides (43) indicated on the diagram, Fig. 1, are not at thermodynamic equilibrium. Lead dissolves in solutions of pH less than 9.4 as the divalent Pb^{++} to form a saturated solution adjacent to the electrode, and when the rate of solution exceeds the rate of diffusion of anions from the bulk of the electrolyte the oxide crystallizes as a chemical deposit from this solution. The deposits designated in Fig. 1 of the hydrous oxides and the yellow glistening crystals of orthorhombic PbO_y are in this category and form normal and basic salts with anions present.

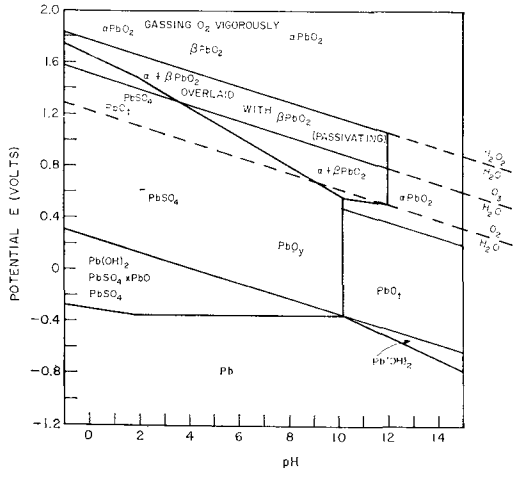

Fig. 1. Anodic oxides on lead at the solution interface. This diagram indicates the areas of occurrence of the solid oxide phases identified by x-ray and electron diffraction, and obtained on anodization of lead metal at fixed pH and potential. The lines for the following equilibria have been added

$$O_3 + 6H^+ + 6e^- = 3H_2O$$
$$E = 1.51 - 0.0591\ pH \quad P_{O_3} = 1\ atm$$
$$H_2O_2 + 2H^+ + 2e^- = 2H_2O$$
$$E = 1.77 - 0.0591\ pH \quad a_{H_2O_2} = 1M$$

Anions present in the electrolytes will form normal and basic salts with the lower oxides as indicated in the original potential -pH diagram of the system (3).

The open-circuit potential of the lead electrode is controlled by the amount of Pb^{++} in solution and is independent of pH. Above pH of 9.4 lead passes into solution as biplumbite ion, and the reaction has a slope 0.089 vs. pH. By impressing anodic potential on the system, more and more salt and oxide will be deposited unless a uniform coherent coating forms on the surface (passivation). These phenomena have been described in detail by Wolf and Bonilla for a large number of anions (44).

The crystals of PbO_y deposit in platelets shown by x-ray diffraction to be parallel to the c_o face typical of solution-grown crystals of this material. It does not form dense passivating films but grossly crystalline deposits. It is an anodic oxide in the sense that it is the solid deposited from saturated lead ion solutions.

At more elevated potentials such an electrode becomes covered with a layer of PbO_t in which the crystals of PbO_y are embedded. The domains of solubility of the two polymorphs of PbO_2 intrude into this area at higher pH, and a mixture of the four oxides is obtained. It is in this area that the intermediate oxides Pb_3O_4 and PbO_x as chemical reaction products will form after a time, but the electrode does not passivate. Only above the line indicated in Fig. 1 corresponding to the theoretical reversible O_3/H_2O reaction does passivation appear. The corrosion reaction of the metal surface is primarily a divalent one up to a potential corresponding to the reversible ozone reaction, while the deposition of tetravalent oxide takes place at the solution interface, resulting in a mixture of di- and tetravalent products.

In solutions of pH 12 and higher, a lead anode becomes covered with a deposit of hydrated lead oxide designated as $Pb(OH)_2$ in Fig. 1, and subsequently with a tetragonal oxide designated as PbO_t. If the potential is increased, plumbate ion is formed in the solution, and the surface of the electrode becomes covered with a layer of αPbO_2. There is an underlying layer of PbO_t which may react with the αPbO_2 formed at the solution interface to produce the intermediate oxides.

It may be possible to limit the deposition of αPbO_2 from alkaline solutions to a rate comparable to its chemical reaction rate with PbO_t and thereby obtain a deposit at the solution interface of the intermediate oxides, but such a condition was not observed in this work during anodization. Self-discharge may also produce such a surface. These intermediate oxides do not appear to be deposited directly from oxidation-reduction reactions, but from chemical combinations, i.e.

$$\left.\begin{aligned} PbO + PbO_2 &= Pb_2O_3 \\ 2PbO + PbO_2 &= Pb_3O_4 \end{aligned}\right\} \text{designated } PbO_t \cdot xPbO_2$$

An infinitude of stoichiometries is possible in such anodic products.

X-ray diffraction examination shows that βPbO_2 is obtained by hydrolysis of both acid and alkaline solutions of tetravalent lead ion, and is the main product deposited electrolytically from acidic Pb^{++} solutions at elevated potentials. Anodization of metallic lead, however, produces a mixture of α and βPbO_2 at elevated potentials. The anodic deposition of βPbO_2 in alkaline solutions occurs simultaneously with the evolution of O_2 gas. It therefore probably deposits by hydrolysis at the local areas on the anode where alkalinity is reduced by the gassing reaction.

Anodic oxides at the metal interface.—The x-ray and electron diffraction examination of the anodic products developed on Pb at various pH and potential conditions showed that the metal-coating interface exhibited the same oxides throughout the pH range, at the same potentials relative to the reversible hydrogen electrode in the same solutions (not the standard electrode). This means that the anodic reactions have slopes of 0.059 vs. pH. The solid phases identified in this study are indicated in Fig. 2.

When the potential of a lead surface exceeds the line bounding the lower extent of the area designated as $Pb(OH)_2$, a film of the solid hydrous oxide forms on the metal surface.

When the potential of a lead anode is raised above the line representing the reaction:

$$PbO_t + 2H^+ + 2e = Pb + H_2O \qquad E_o = 0.248$$

in Fig. 2, the lead becomes covered by a layer of PbO_t. This oxide has a tetragonal lattice showing a characteristic combination of sharp and diffuse lines in its diffraction patterns (6,13, 14). It is considered more reactive than either of the normal monoxides, and it appears on a lead anode in both acid and alkaline media. Katz described this as orthorhombic pseudotetragonal PbO (6). In alkaline solutions heavy coatings of this material appear yellow when wet with electrolyte, but are pale peach in color when dry and may form beautiful glossy coatings on a lead electrode. It has been described as a yellow

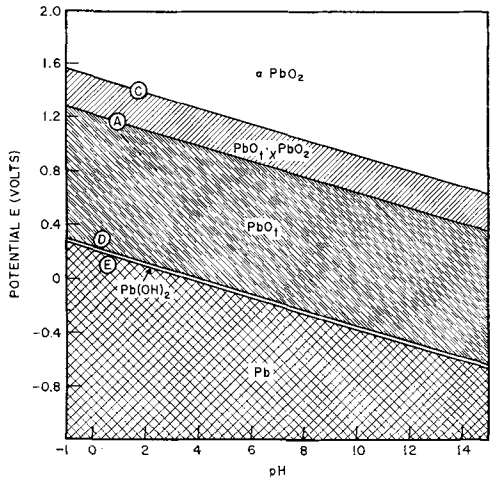

Fig. 2. Anodic oxides of lead at the metal interface. This diagram indicates the areas of occurrence of the solid oxide phases obtained at the metal-coating interface on anodization of lead at fixed potential and pH. The reactions represented by the lines D and E bounding Pb and the phases $Pb(OH)_2$ and PbO_t will be recognized from the original diagram (3), and were found to occur at essentially their reversible potentials throughout the pH range. The exception is the boundary between PbO_t and PbO_2. The intermediate region labeled $PbO \cdot xPbO_2$, representing oxides and mixtures of oxides of di- and tetravalent lead, was found to appear between the reversible oxygen and ozone potentials, lines A and C. Above line C, αPbO_2 is the principal anodic oxide at the metal interface. The reactions are represented as follows

(A) $O_2 + 4H^+ + 4e^- = 2H_2O$
$E = 1.228 - 0.0591\ pH \qquad P_{O_2} = 1\ atm$

(C) $O_3 + 6H^+ + 6e^- = 3H_2O$
$E = 1.51 - 0.0591\ pH \qquad P_{O_3} = 1\ atm$

(D) $PbO_t + 2H^+ + 2e^- = Pb + H_2O$
$E = 0.258 - 0.0591\ pH$

(E) $Pb(OH)_2 + 2H^+ + 2e^- = Pb + 2H_2O$
$E = 0.242 - 0.0591\ pH$

scum (37). Thermodynamically this oxide is stable up to a potential described by the reaction:

$$PbO_2 + 2H^+ + 2e = PbO_t + H_2O \qquad E_o = 1.107$$

The area associated with PbO_t is one of rapid corrosion of the anode unless there is a passivating layer of salt at the solution interface that permits establishment of metastable equilibrium. In sulfuric acid $PbSO_4$ serves this purpose, but in alkaline solutions no passivation occurs and the anode continues to corrode at high rates.

The area designated in Fig. 2 as $PbO \cdot xPbO_2$ is determined by both diffraction examination and spot tests. In this area PbO_2 as such is not detected by diffraction examination at the metal interface. In acid solutions the product is PbO_t giving a spot test for a highly oxidizing material after polarization above a potential corresponding to the theoretical reversible oxygen potential. The highly oxidizing material is considered in this report to be tetravalent lead. It appears immediately above the O_2/H_2O electrode potential and is not observed in the area where H_2O_2 could form from O_2 reduction. In neutral and alkaline solutions a mixture of the oxides Pb_3O_4, PbO_x, and PbO_t is observed. The reason for the difference in anodic materials developed in highly acid and in neutral or alkaline solutions is that PbO_2 varies in solubility with the pH at the solution interface. It is discharged in strong acid solutions, preventing accumulation of significant amounts of tetravalent lead. Both forms of PbO_2 are formed at the solution interface at higher pH so that larger amounts of tetravalent material do accumulate. In the alkaline solutions of $pH > 9.4$, the electrode is covered with a gray or black film of PbO_2 which is loose and may be lifted off the electrode revealing a layer colored bright orange, yellow, and peach giving the diffraction patterns for PbO_t, Pb_3O_4, and PbO_x. Lead is corroding under these conditions by a divalent mechanism (26, 28, 35, 36) forming PbO_t, part of which is being oxidized to PbO_2, and acted on at the solution interface by plumbate ion. The anodic products designated $PbO_t \cdot xPbO_2$ at the metal interface represent the mixture obtained by chemical reaction of these materials.

The existence of this area is belived to be caused by the relative rates of these several reactions

$$Pb + H_2O = PbO_t + 2H^+ + 2e^-$$

$$2H_2O = 2(O)_{aq} + 4H^+ + 4e^-$$

$$PbO_t + (O)_{aq} = PbO_2$$

$$\left.\begin{aligned} PbO_t + PbO_2 &= Pb_2O_3 \\ 2PbO_t + PbO_2 &= Pb_3O_4 \end{aligned}\right\} \text{Designated } PbO_t \cdot xPbO_2$$

The following mechanism is suggested: The anodic current may take two paths: (*a*) it corrodes Pb to form PbO_t or divalent products; (*b*) it oxidizes H_2O to $O_{2(aq)}$ which reacts with PbO_t to form the intermediate oxides (6, 13). Lander (26, 28) showed that within experimental limits all the current went to a divalent corrosion mechanism up to a potential of 1.58 v in acid solutions, and only above that potential did a tetravalent corrosion mechanism become significant. Grube and Glasstone (35, 36) showed a similar divalent corrosion mechanism in NaOH solutions up to a corresponding potential. It is suggested that the kinetics of the electrochemical reactions determine the anodic corrosion rate, and above potentials expressed by line C, Fig. 2, PbO_2 is present directly on the metallic surface. Line C corresponds to the reversible oxidation potential of water to ozone.

$$O_3 + 6H^+ + 6e^- = 3H_2O \qquad E_o = 1.51$$

The fact that the passivation of Pb in both acids and alkalies occurs just above this potential, that the reaction has a slope of 0.059 vs. pH, that it exceeds the potentials for formation of PbO_2 from Pb and PbO_t indicates that the corrosion reactions occurring at this potential may be related to water oxidation reactions.

The kinetic analyses of Lander (26) show that when lead is polarized above the potential for oxidation of water to O_2, the reaction mechanism changes. It was further determined that the anodic corrosion rates were related to the square of the water activity up to a potential corresponding to the maximum in the rate. Above this potential the relationship of the corrosion rate to water activity has values "ranging between two and four" (27). The water oxidation reactions to give O_2 and O_3 depend on the square and cube of the water activity, respectively.

The steps in the over-all water oxidation mechanisms are not known at the present time. The relation of the oxidation processes of the lead anodes to the water activity does not prove that $O_2(aq)$ or $O_3(aq)$ is liberated in these reactions; however, it does suggest that the anodic processes depend on the simultaneous reaction of two and more water molecules. It is possible that Pb or PbO_t catalyzes the water oxidation reaction, and that the subsequent step is reaction of Pb and PbO_t with the water oxidation product to form the intermediate oxides rather than molecular gas evolution.

If the lead anode in alkaline solutions is disturbed while in the laminated condition, before polarization above line C, Fig. 2, so that PbO_2 is mechanically brought into physical contact with the base lead metal, oxygen gas begins to be evolved at a potential lower than it will be from an undisturbed electrode. This effect, described by earlier workers (35), was verified in this study. With this positive identification of the anodic materials, it is concluded that PbO_2 must be in direct contact with the metal surface for the oxygen gas liberation reaction to take place and that the reaction may be associated with oxidation of H_2O or $(OH)^-$ to H_2O_2.[1]

It should be emphasized that this is a study of the dynamic anodization of lead under the potential and pH conditions indicated. Polarization of lead within the area designated $PbO \cdot xPbO_2$ does not establish a passivating coating on the surface, and anodic corrosion rates are high. Deposition of PbO_2 at the solution interface does not comprise a protective coating.

The area indicated at αPbO_2 in Fig. 2 is characterized by a heavy deposit of this material directly on the electrode, providing other reactions do not interfere. This material has not been well characterized chemically, and is probably the low-temperature polymorph (45).

X-ray diffraction examination of the residues obtained on air ignition of αPbO_2 at temperatures corresponding to those reported for thermal degradation of βPbO_2 (6, 17) showed evidence that prior to decomposition α converted to βPbO_2. The conversion temperature lies between 296° and 301°C. Subsequent thermal decomposition, determined by x-ray diffraction examination, follows the same path as βPbO_2.

It may be concluded from this examination of the oxides occurring at the metal-coating interface on anodic lead specimens that the oxides formed are: $Pb(OH)_2$; PbO_t and αPbO_2. The potentials for these reactions have a slope of 0.0591 vs. pH and are believed to represent the electrochemical reactions of lead with water and its oxidation products.

The reaction of metallic lead with water to form PbO_t takes place near the calculated reversible potential. Arrests appear near the theoretical potential in both acid and alkaline solutions on both anodic and cathodic treatment, and PbO_t is observed by diffraction examination of the surface. This indicates that the oxidation proceeds by direct reaction with water molecules or hydroxyl ions at the electrode interface and that no preliminary oxidation of water occurs in this reaction. But the reaction forming PbO_2 at the metal interface should probably be written to indicate that water is first oxidized to an oxygen species and the solid anodic products result from secondary reactions. This suggests that the anodic studies of lead may offer a method for kinetic analysis of the water, oxygen electrodes.

Anions and passivation.—As pointed out previously and discussed extensively by Wolf and Bonilla (44) anions present in the solutions will react with the lead ion and/or the lower oxides, and the corresponding salt will be deposited at the solution interface. If the anion is suitable, a tight passivating film is deposited on the anode surface [i.e., $Pb_3(PO_4)_2$, PbI_2, $PbSO_4$] (44, 46), and continued polarization of the electrode will result in the characteristic anodic oxide at the metal-coating interface. If the lead salt of the anion is not passivating, the electrode process may be changed by only very high current densities or cell potentials (47).

A picturization of a cross section of an anodic lead surface is shown in Fig. 3. This indicates the reaction products identified on the anode surface at pH = 0, and the reference potentials are presented in the left margin. The cross section is schematic;

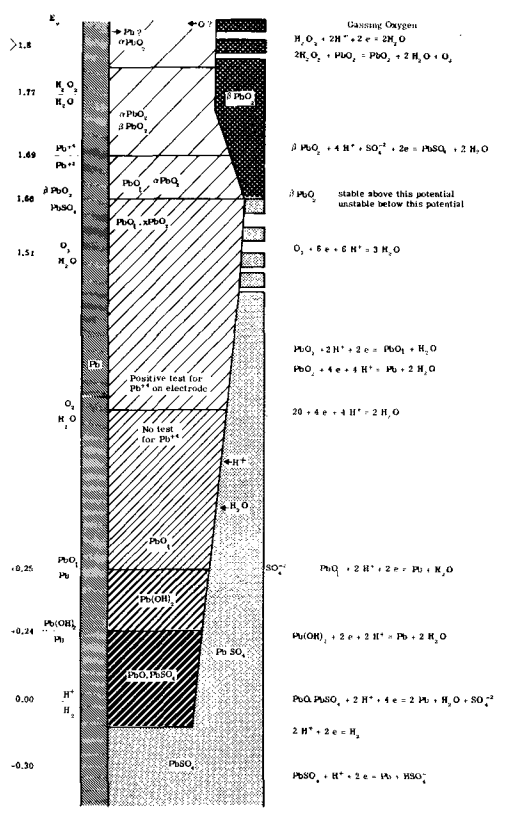

Fig. 3. Schematic cross-section of an anodic lead surface in H_2SO_4 at pH = 0. Anodic products identified by diffraction techniques on a lead surface held at constant potential in sulfuric acid are indicated. Electrochemical reactions are shown at the right within the areas where they were observed to occur. Some E_0 values are indicated at the left for orientation purposes. At the potential 1.8 v oxygen gas is evolved, and a hydrogen peroxide reaction mechanism is indicated as suggested by the potential. At this potential lead is represented as corroding by either migration of Pb or O in the film. The mechanism of this corrosion process is not known at the present time.

[1] The reactions in alkaline solution may be written with $(OH)^-$ rather than H^+, and the HO_2^- reactions have different slopes, but for simplicity these are not included in this discussion.

however, it indicates that as the potential is increased the $PbSO_4$ coating appears to become thinner while the PbO_t layer becomes increasingly thicker. Some suggested reactions are indicated at the right of the drawing. The solid phases identified by diffraction examination are indicated within the potential ranges where they were observed. Areas corresponding to high corrosion rates are indicated as porosity in the outer coating. These rates were determined by Lander under constant potential anodization (26, 28). Several reactions appear near their reversible potentials, exhibiting little polarization, and it is thought that the superficial $PbSO_4$ coating is permeable to H^+ ion and water, but not to SO_4^- ion (26, 44). The action of this passivating film is to permit establishment of pseudo equilibrium in an electrochemical reaction in an environment where the reaction would normally be driven in a destructive direction. This, of course, describes the condition called metastable equilibrium.

As the potential is increased, the lead sulfate present on the surface may be converted to βPbO_2. Electron diffraction examination of the anodic products indicates that the βPbO_2 is a polycrystalline coating at the solution interface. Beneath this is a thin layer of a mixture of the two polymorphs of PbO_2 (1, 2). These materials are believed to arise from two reactions forming PbO_2, one from the base lead and PbO_t and the other from $PbSO_4$.

The oxygen gassing reaction at elevated potentials has been indicated as going by way of the formation of H_2O_2 (possible at these potentials) and being decomposed catalytically by the PbO_2. This is merely a representation and suggestion of a possible oxygen liberation mechanism which potential appears to be related to the peroxide reaction in both acid and alkaline solutions (48, 49). The lead metal is represented as corroding by migration of an oxygen species in and lead outward through an αPbO_2 coating at very elevated potentials. Lead exhibits an increased corrosion rate (26, 28), and αPbO_2 comprises the major portion of the anodic product at these potentials, but it is not known whether the mechanism involves attack of the lead through fissures in the coating or migration through a continuous film.

Conclusions

The areas of occurrence of the anodic lead oxide phases are indicated on the potential-pH phase diagrams of Fig. 1 and 2. There appear to be two sets of anodic reactions, producing different anodic products. Some of the observed oxides are believed to be electrode species, and some deposits from saturated solutions and chemical reactions.

The occurrence of αPbO_2 as an anodic product on lead in acid solutions has been attributed to oxidation of PbO_t and lead metal by the preliminary oxidation of water.

It is suggested that the corrosion rate of lead depends on the kinetics of these water reactions, and that inhibition of corrosion depends on the imposition of a "corrosion" current and potential that results in a steady-state condition in which PbO_2 is maintained in direct contact with the base metal. Upon anodic polarization of a clean lead surface, it is necessary to "overshoot" the steady-state potential and current in order to generate the required materials, but once the materials are formed in the solution and on the electrode surface then only a minimal current is required to maintain passivation. The low corrosion rate of telephone battery service (50) is believed to be a reflection of this requirement.

The passivation domains originally outlined to correspond to the domains of thermodynamic stability of PbO_2 and $PbSO_4$ (3) should be modified to indicate two areas of passivation: one where the composite coating of $PbSO_4$ and PbO_t is protective below line A in Fig. 2; and the other above line C. These passivation domains are separated by an area of intense corrosion believed to be caused by the electrochemical oxidation of water at the metal interface at a rate insufficient to maintain a passivating coating of PbO_2 on the metal surface.

X-ray diffraction examination of calcined αPbO_2 suggests that it is the low-temperature polymorph and is converted to βPbO_2 at approximately 300°C in air.

The potentials associated with gassing oxygen from a PbO_2 electrode indicate that the reaction may go by way of peroxide in both acid and alkaline media.

Manuscript received Mar. 24, 1958. This paper was prepared for delivery before the Buffalo Meeting, Oct. 6-10, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Evidence for a Logarithmic Oxidation Process for Stainless Steel in Aqueous Systems

Milton Stern

Metals Research Laboratories, Union Carbide Metals Company, Division of Union Carbide Corporation, Niagara Falls, New York

ABSTRACT

Upon immersion of a passive stainless steel electrode into an oxidizing ferrous-ferric aqueous solution, the mixed potential of the electrode gradually approaches the reversible redox potential of the solution. During this period, an oxidation process occurs, the rate of which decreases with time. The process is most likely oxidation of metal since the potential range over which it occurs is more active than the estimated reversible oxygen potential for the system, and no other oxidation reaction is likely. The kinetics of oxidation of stainless steel are similar to kinetics reported for anodic oxidation of metals which form thin amorphous oxides. Therefore, it is believed that evidence has been obtained for growth of a similar type of oxide on stainless steel. At constant potential, the oxidation process can be described closely by a logarithmic oxidation equation. Also, the kinetics are consistent with equations which describe ion current through thin oxides as a function of the field across the oxide.

A study of ferrous-ferric electrode kinetics on stainless steel surfaces has been reported (1). The data supported theoretical equations which describe potential-current relationships for such a system. All rate measurements were conducted on electrodes whose potential, with no applied current, was very close to the reversible ferrous-ferric potential. However, it was also shown that stainless steel does not exhibit this potential immediately after immersion in the oxidizing solution. The electrode is initially more active than a platinum electrode in the same solution and slowly approaches the platinum potential over a period of several thousand minutes in a manner already illustrated (1). No effort was made to explain the processes occurring during this time interval; however, pertinent data were obtained which, at that time, were not particularly clear. A better understanding of the nature of the system now provides a reasonable explanation of this initial potential-time dependence, and the purpose of this discussion is to describe the kinetics of the processes which occur.

Experimental

The experimental procedure was described earlier (1, 2) and only pertinent details are repeated. The environment was either a mixture of ferrous and ferric sulfate in water or a mixture of ferrous and ferric chloride containing sodium nitrate as a pitting inhibitor. Solutions were oxygen-free. Platinized platinum was used as reference and as auxiliary electrodes during polarization. The material was commercial Type 304 stainless steel. Sample preparation involved thorough degreasing, activation in concentrated HCl until hydrogen evolution was ob-

served, a rinse in distilled water, brief (approximately 5 sec) immersion in concentrated HNO_3, a second rinse, and immediate introduction into the cell. This treatment produces a passive surface prior to immersion in the electrolyte. The initial potential-time behavior was recorded using a L&N pH meter which drove an appropriate potential recorder. Since platinized platinum was used as a reference, the approach of the stainless steel electrode to the reversible potential could be observed readily by watching the approach of the recorder indication to zero. During this time interval, a measurement not reported earlier was conducted. It involved periodic anodic polarization of the sample to the platinum potential and determination of the current required to do this. The procedure required a maximum of about 10 sec and did not affect the normal potential-time behavior significantly. To minimize the time during which the sample was polarized, an anodic current was applied to produce a zero recorder reading, after which the polarizing circuit was opened. The value of current required to polarize to the platinum potential was determined by substituting a shunt for the cell in the series polarizing circuit and measuring current through the series circuit without the presence of the cell. Values of resistance in the circuit were high so that the current was not significantly affected by introduction or removal of the effective resistance represented by the cell. This procedure was repeated periodically from the first few minutes after the electrode was introduced into the solution to the time when the potential was essentially stationary.

These measurements were not conducted with a view toward interpretation in the manner presented below. Rather, they were done to determine whether it was possible to measure the instantaneous corrosion rate of the material by a method described by Vetter (3). He reported that the corrosion rate of passive iron in concentrated nitric acid can be determined electrochemically by polarizing the surface anodically to the potential of platinum in the same solution. The current required to polarize is equivalent to the corrosion current. Measurements of this type were discontinued when it was realized that very special electrochemical conditions, described elsewhere (4), are required for the method to work. A sufficient number of experiments of this type were conducted to provide convincing evidence that the observations described below are correct for stainless steel. Since, qualitatively, similar potential-time behavior was observed for other materials, it is possible that the analysis presented below could well apply to the various other surfaces which were used to study ferrous-ferric oxidation-reduction kinetics. However, data for these other metals are not available.

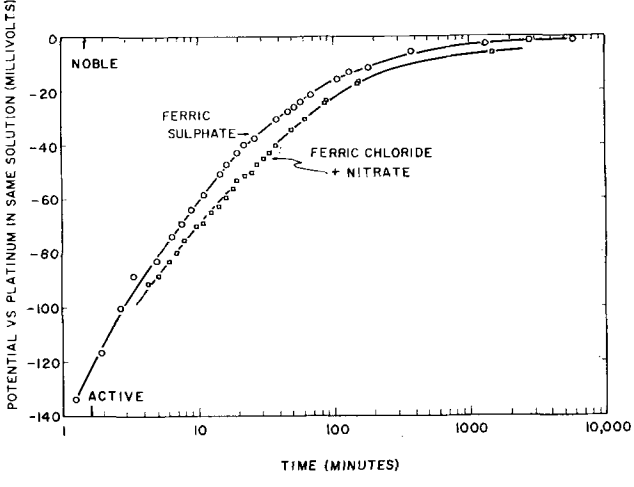

Fig. 1. Potential as a function of time for stainless steel

Time-Potential Measurements

Figure 1 illustrates the potential-time behavior described above. The circles represent data in ferric-ferrous sulfate and are the data reported earlier (1) without explanation. The squares apply to a ferrous-ferric chloride system containing nitrate. Kinetic data for oxidation and reduction of ferrous and ferric ions have already been reported for these systems. In the sulfate solution with a ferrous-ferric reversible potential of +0.770 v, the exchange current, i_o, is 0.045 μamp/cm^2; the Tafel slope for reduction of ferric ions, β_c, is 0.123 v; the Tafel slope for oxidation of ferrous ions, β_a, 0.102 v. For the chloride system (2) with a reversible potential of +0.824 v, i_o, is 0.063 μamp/cm^2; β_c is 0.146; β_a is 0.165. These measurements were made after the electrodes had come to a steady-state potential very close to the reversible ferrous-ferric potential.

Anodic Polarization Measurements

It is assumed that the above kinetic parameters apply to the system very soon after the electrode is immersed and that they do not change during the time the potential approaches that of platinum. Justification for this important assumption is presented later. If this assumption is correct, another oxidation reaction, in addition to oxidation of ferrous ions, must be occurring during this time. According to the theory of the mixed potential, the system must satisfy the following relation:

$$\overleftarrow{i_{Fe^{++}}} + \overleftarrow{i_m} = \overrightarrow{i_{Fe^{+++}}} \qquad [1]$$

where $\overleftarrow{i_{Fe^{++}}}$ (μamp/cm^2) is the rate of oxidation of ferrous ions; $\overleftarrow{i_m}$ is the rate of oxidation of a second oxidation process, and $\overrightarrow{i_{Fe^{+++}}}$ is the rate of reduction of ferric ions. Equation [1] simply states that there can be no net oxidation or reduction in the system and holds at any time where no external current is applied. The most likely process represented by $\overleftarrow{i_m}$ is oxidation of metal, particularly since potentials involved are more active than the reversible oxygen potential and oxygen evolution is not likely.

Upon anodic polarization to the potential of platinum ($\eta = o$), with an applied current, $\overleftarrow{i_p}$, the equation satisfied is:

$$\overleftarrow{i_p} = (\overleftarrow{i_{Fe^{++}}} + \overleftarrow{i_m}) - \overrightarrow{i_{Fe^{+++}}} \qquad [2]$$

but at $\eta = o$, $\overleftarrow{i_{Fe^{++}}} = \overrightarrow{i_{Fe^{+++}}} = i_o$, so that

$$\overleftarrow{i_m} = \overleftarrow{i_p} \qquad [3]$$

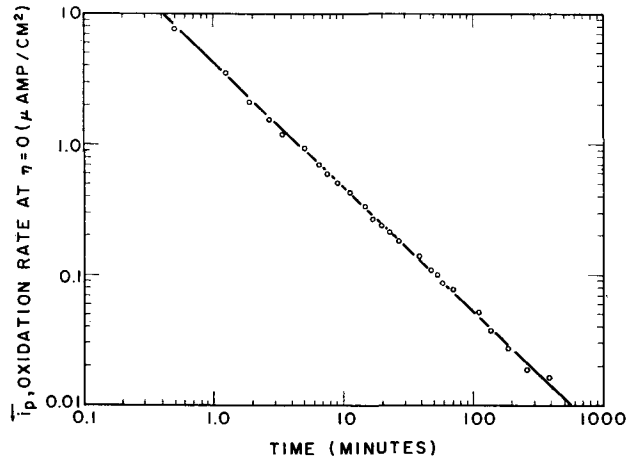

Fig. 2. Oxidation rate at zero overvoltage as a function of time for stainless steel in a ferric-ferrous sulfate solution with reversible potential of +0.770 v.

As described above, $\overleftarrow{i_p}$ was measured as a function of time. Consequently, the kinetics of metal oxidation *at constant potential* can be described in considerable detail solely from this type of measurement. Since the data range over three orders of magnitude, it is convenient to plot them on logarithmic scales. Data for sulfate solution are given in Fig. 2. The points fall on a good straight line, the slope of which is close to minus one. This means that $\overleftarrow{i_m}$ is inversely proportional to time.

$$\overleftarrow{i_m} = \frac{k'}{t} \qquad [4]$$

Consider that $\overleftarrow{i_m}$ represents the rate of oxidation of metal to form an oxide of some type in accordance with a process similar to $M + H_2O \rightarrow MO + 2H^+ + 2e$. Then $\overleftarrow{i_m}$ is proportional to the rate of growth of oxide thickness

$$\overleftarrow{i_m} = \frac{k''dx}{dt} \qquad [5]$$

where x is the oxide film thickness. Therefore,

$$\frac{dx}{dt} = \frac{k}{t} \qquad [6]$$

and upon integration a logarithmic oxidation equation is obtained

$$x = A + B \log t \qquad [7]$$

Whether one considers x an oxide film thickness or simply the weight of metal oxidized, it is quite clear that the kinetics of the process at constant potential closely approximate the general logarithmic oxidation equation.

Generally, Eq. [7] applies to oxidation at low temperatures when thin films are formed.

Relation to Other Work on Oxidation of Metals

Considerable work has been reported on oxidation kinetics of metals such as aluminum, tantalum, columbium, and zirconium, where amorphous oxide films are formed. Much of the experimental work has been directed toward determination of the applicability of the Mott and Cabrera (5) type of equation which relates ionic current through an oxide film with the field, F, across the film.

$$i = \alpha e^{\beta F} \qquad [8]$$

For example, Charlesby has worked with aluminum (6) and zirconium (7) and reports general agreement with Eq. [8]. Van Rysselberghe and co-workers (8) extended work with zirconium to much thinner films than those investigated by Charlesby and also found Eq. [8] valid. Young (9) reports that results for columbium may be expressed by this equation. Vermilyea (10) has conducted extensive studies on the formation of anodic oxide films on tantalum and finds that at constant temperature results are described by an equation similar in form to [8]. However, detailed work has shown that the Mott and Cabrera theory is not adequate for describing all observed phenomena, and efforts to provide modifications or new theories have appeared (11-14).

It is not the purpose of this work to evaluate any of these detailed descriptions. Rather, an effort will be made to show that observed kinetics of stainless steel anodic oxidation are very similar in form to observed kinetics for anodic oxidation of aluminum, columbium, tantalum, and zirconium where amorphous oxide films are produced.

At constant potential, Eq. [8] [where i is proportional to dx/dt and $F = E/x$] may be put in the form of the so-called inverse logarithmic equation by making suitable approximations (5).

$$\frac{1}{x} = a - b \log t \qquad [9]$$

It is particularly difficult to distinguish experimentally between Eqs. [7] and [9]. Measurements over better than two orders of magnitude in time are required. This is described clearly by Vermilyea and illustrated by his data for anodic oxidation (10) and dry oxidation (15) of tantalum. Thus, it is possible that the thickness-time relation observed here for stainless steel could also fit the inverse logarithmic equation and be consistent with Eq. [8].

Charlesby (6) in work with anodized aluminum tried to determine whether his data best fit Eq. [8] or whether they are best described by the strong field emission formula of Fowler and Nordheim (16).

$$i = \alpha F^2 e^{(-B/F)} \qquad [10]$$

He also illustrates the difficulty involved and further reports that the Guntherschulze and Betz' (17) data for tantalum fit Eqs. [8] and [10] equally well. Charlesby's data of particular interest here involve decay of current with time at constant potential, exactly the experimental conditions used for stainless steel in Fig. 2. He shows mathematically that for systems described by Eq. [8], $(d \log i)/(d \log t)$ varies with βF. Over a range of βF values from 10 to 50, which should cover many real systems, $(d \log i)/(d \log t)$ varies from −0.87 to −0.96. For Eq. [10], with B/F values from 10 to 30, $(d \log i)/(d \log t)$ varies from −0.984 to −0.998. These values are closer to −1 than the corresponding values for Eq. [8] and may serve to distinguish between the

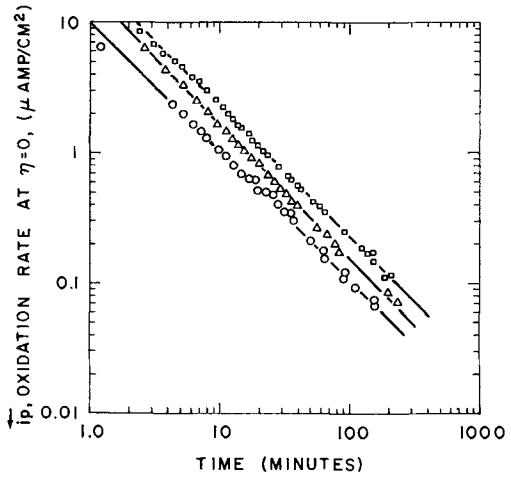

Fig. 3. Oxidation rate at zero overvoltage as a function of time for stainless steel in ferric-ferrous chloride solutions containing nitrate with reversible potentials of +0.824 v (circles), +0.823 v (triangles), and +0.809 v (squares).

two. Charlesby favored Eq. [8] for his data, but reported the results as inconclusive.

The line drawn through the points on Fig. 2 has a slope, $(d \log i)/(d \log t)$, of −0.96. Although values of B and F are not known for the stainless steel system, these data alone indicate that Eq. [8] may apply. However, similar data for three chloride systems are shown in Fig. 3. The circles are for the ferrous-ferric chloride system illustrated in Fig. 1. The squares and triangular points are for stainless steel in a similar solution with reversible ferrous-ferric potentials of +0.809 and +0.823 v, respectively. The straight lines drawn through the three sets of data have slopes of −1.0 (circles), −1.0 (squares), and −0.97 (triangles).

It is evident from the above discussion that the oxidation kinetics observed for stainless steel at constant potential in the oxidizing aqueous environments investigated can be considered to comply reasonably well with either the logarithmic or inverse logarithmic oxidation equations. Also, the data can be considered reasonably consistent with either Eqs. [8] or [10] describing ion current as a function of field across an oxide.

Dependence of Metal Oxidation Rate on Potential

For Eq. [8], which is favored by most work on anodic oxidation, $dF/(d \log i)$, is a constant[1] which is often referred to as the Tafel slope by Dewald (11) and Young (9). Thus, at constant film thickness, $dE/(d \log i)$ is a constant. The rapid (~10-sec) anodic polarization measurements described above for determination of $\overleftarrow{i_p}$ may be considered polarization at constant film thickness. Thus, one would expect a straight line relation between potential and log $\overleftarrow{i_m}$ at any time t. While extensive data showing the variation of $\overleftarrow{i_m}$ with potential at constant time cannot be obtained by the methods used, two points at any time have been measured. This is best described with the aid of a schematic

[1] There is now evidence that β in Eq. [8] is not strictly independent of field (14, 18). However, for the situation described, the change in field is quite small, and this relation may be considered to apply.

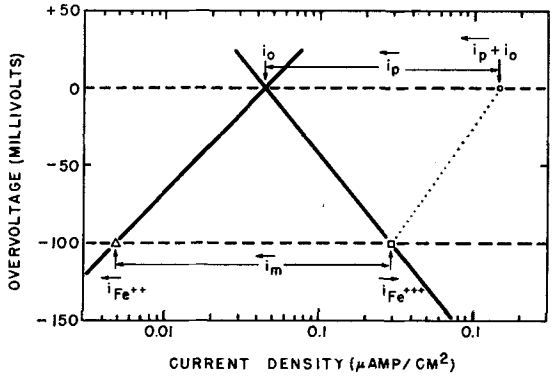

Fig. 4. Schematic polarization diagram showing the position of partial currents during the approach to a steady-state potential.

polarization diagram using the assumption (described above) that the ferrous-ferric oxidation-reduction kinetics are constant with time. With the measured kinetic parameters in sulfate solution used as an example, Fig. 4 illustrates the relation between the various partial currents during the approach to a steady state. Potentials are referred to platinized platinum in the same solution. The two solid Tafel lines represent the rate of oxidation and reduction of ferrous and ferric ions as a function of potential. Since these do not vary at any time (t) during the approach to the platinum potential, the magnitudes of $\overleftarrow{i_{Fe^{++}}}$ and $\overrightarrow{i_{Fe^{+++}}}$ are known from a knowledge of the mixed potential. For example, when the potential is −100 mv, $\overleftarrow{i_{Fe^{++}}}$ is about 0.005 μamp/cm² and $\overrightarrow{i_{Fe^{+++}}}$ is about 0.30 μamp/cm². These values are shown as the triangles and squares on Fig. 4. From Eq. [1], $\overleftarrow{i_m}$ is the difference between these values or approximately 0.30 μamp/cm². Therefore, the point representing $\overrightarrow{i_{Fe^{+++}}}$ also represents $\overleftarrow{i_m}$ when $\overleftarrow{i_{Fe^{++}}}$ is negligible and, in any case, represents the total anodic current.

Upon rapid anodic polarization to the potential of platinum, another value of $\overleftarrow{i_m}$ is determined as shown by Eqs. [2] and [3]. At this potential, $\overleftarrow{i_m} + \overleftarrow{i_{Fe^{++}}}$ represents the total anodic current. Since $\overleftarrow{i_m} = \overleftarrow{i_p}$ and $\overleftarrow{i_{Fe^{++}}} = \overleftarrow{i_o}$, $\overleftarrow{i_p} + i_o$ also represent the total anodic current. Therefore, the dotted line on Fig. 4 connecting $\overleftarrow{i_p} + i_o$ with $\overrightarrow{i_{Fe^{+++}}}$ represents the total anodic polarization curve of the system when the mixed potential is −100 mv. As described above, when the potential is far from the reversible potential, $\overleftarrow{i_{Fe^{++}}}$ is negligible and the dotted line represents the change of $\overleftarrow{i_m}$ with potential. At longer times, when η is small, $\overleftarrow{i_{Fe^{++}}}$ can no longer be neglected, and an analogous dotted line would represent the sum of two logarithmic curves which, over the small potential increment considered, may also be represented by a single Tafel line (19).

As described above, $\overleftarrow{i_p}$ was measured periodically during the approach of the sample potential to that

of platinum in the same solution. The exchange current and Tafel lines were measured after the electrode had reached a steady potential value. Constructing a similar plot to Fig. 4, the data for the sulfate system are shown in Fig. 5. The square points which lie along the Tafel line for ferric reduction are measured potentials at various times during the approach to zero overvoltage. They are the same points illustrated in Fig. 1 and are placed on this figure using the assumption that ferrous-ferric kinetics are independent of time. The circles are values of $\overleftarrow{i_p} + i_o$, where $\overleftarrow{i_p}$ is also measured during the approach to zero overvoltage. The solid lines connecting circles and squares represent data obtained at the same time (within about 10 sec), the time after immersion in the cell being indicated along the appropriate line. The lines are not exactly parallel, those at the shorter times exhibiting a higher slope. The lines at short times should more nearly represent $\overleftarrow{i_m}$ as a function of potential since $\overleftarrow{i_{Fe^{++}}}$ is insignificant, while the lines at long times are influenced by $\overleftarrow{i_{Fe^{+++}}}$. Unfortunately, for short times, the interval during which the sample is anodically polarized is significant in respect to the total time, so that these data cannot be considered as accurate as those for which the sample has been immersed for long times.

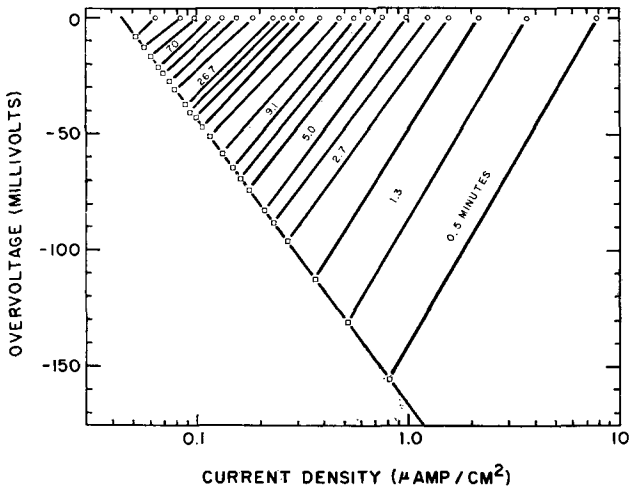

Fig. 5. Total anodic polarization curve for stainless steel as a function of time during the approach to a steady-state potential in ferric-ferrous sulfate with a reversible potential of +0.770 v.

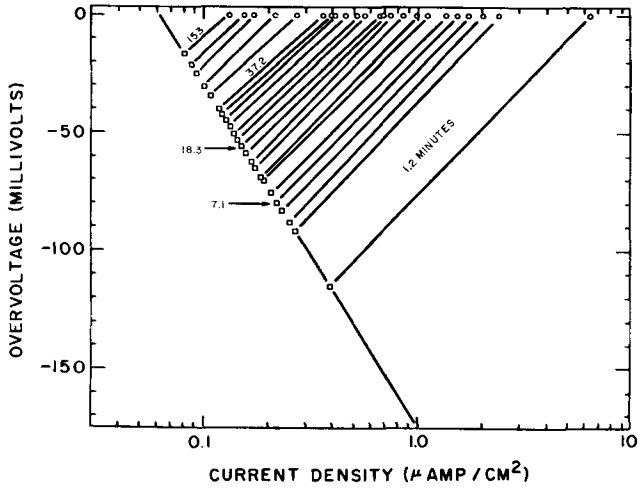

Fig. 6. Total anodic polarization curve for stainless steel as a function of time during the approach to a steady-state potential in ferric-ferrous chloride containing nitrate with a reversible potential of +0.824 v.

Figure 6 shows a similar plot for the chloride system. Here the total polarization lines are all more nearly parallel.

Regardless of whether one considers the family of total polarization curves parallel or not (and one would not expect them necessarily to be parallel since two different processes, $\overleftarrow{i_m}$ and $\overleftarrow{i_{Fe^{++}}}$, with possibly different β values are involved), it is evident that $\overleftarrow{i_m}$ appears to be a logarithmic function of potential as required by Eq. [8].

Potential-Time Behavior

The initial potential-time behavior is explained readily in terms of the processes described above. The potential decreases in the manner shown in Fig. 1 because an anodic Tafel line (representing $\overleftarrow{i_m}$ as a function of E) sweeps from right to left across the polarization curves of $\overleftarrow{i_{Fe^{++}}}$ and $\overrightarrow{i_{Fe^{+++}}}$. The mixed potential at any time is that value at which the sum of all the rates of oxidation ($\overleftarrow{i_{Fe^{++}}} + \overleftarrow{i_m}$) equals the rate of reduction ($\overrightarrow{i_{Fe^{+++}}}$). At short times, $\overleftarrow{i_{Fe^{++}}}$ is negligible and the potential is determined primarily by $\overleftarrow{i_m}$ which is changing rapidly. When $\overleftarrow{i_m}$ approaches $\overleftarrow{i_{Fe^{++}}}$, the potential is determined by the sum of these two currents. In this interval, $\overleftarrow{i_m}$ is changing less rapidly. Finally, when $\overleftarrow{i_m}$ becomes negligible in comparison to $\overleftarrow{i_{Fe^{++}}}$, the total anodic current is essentially $\overleftarrow{i_{Fe^{++}}}$. In this condition, $\overleftarrow{i_{Fe^{++}}} = \overrightarrow{i_{Fe^{+++}}}$ (or the exchange current), and the metal exhibits the reversible ferrous-ferric potential of the solution where $\eta = o$. The potential no longer changes with time.

Oxide Film Thickness

The oxidation kinetics observed for stainless steel during the approach of its mixed potential to that of platinum in ferric-ferrous solutions are similar to kinetics observed for anodic oxidation of metals which are known to form thin amorphous films. This is evidence that similar films are formed on the iron-chromium-nickel alloy.

An estimate of the thickness of the film formed at constant potential may be made by determining the number of coulombs involved in the observations reported in Fig. 2. Integrating the current-time relationship between 1 min and 400 min produces a value of 1.3 (10^{-3}) coulombs/cm^2. Considering the relationship applies from 1 sec to 1000 min increases this value to 2.5 (10^{-3}) coulombs/cm^2. Using 2 (10^{-4}) g/coulomb for the electrochemical equivalent for oxidation of the alloy, gives a value of approximately 5 (10^{-7}) g/cm^2 for the weight of metal oxidized after 1000 min. Assuming the oxide has the formula M_2O_3 with average molecular weight of 150 and metal atomic weight of 55, the weight of oxide

produced is approximately 7 (10^{-7}) g/cm^2 or 0.7 μg/cm^2. With a surface roughness factor of 2.5, this value is reduced to 0.3 μg/cm^2. This may be compared with Rhodin's (20) values of 0.5 to 1.0 μg/cm^2 obtained by weighing oxides stripped from stainless steels. Assuming an oxide density of 5 g/cm^3, the oxide thickness grown in the oxidizing solution after passivation in nitric acid is 6Å, a value which could easily be in error by a factor of two, considering the assumptions which are involved.

The calculation is made primarily to show that experimental values of current are consistent with a process involving logarithmic growth of thin oxide films.

General Discussion

The important assumption made in this entire analysis is that the ferrous-ferric kinetics remain constant with time during the approach of the potential to the reversible redox value of the solution. No absolute proof for the validity of this assumption can be presented. However, it appears quite reasonable, and the entire kinetic description based on this assumption is quite self-consistent.

It should perhaps be mentioned that construction of Fig. 5 and 6 to produce a family of curves which are so nearly parallel provides a very severe test of both the assumption involved and the experimental data. Note, for example, the points along the platinum potential are values of $\overleftarrow{i_p} + i_o$, where i_o is quite significant in respect to $\overleftarrow{i_p}$ for an appreciable fraction of the total anodic curves shown. If i_o or β_c for the ferric-ferrous system were to change appreciably with time, it would be highly unlikely that construction of Fig. 5 and 6 would have produced such a parallel array of anodic curves. This perhaps provides some justification for the assumption. Further, the assumption is consistent with a redox process occurring on an oxide surface, since one would not necessarily expect redox kinetics to change as the oxide becomes thicker provided the rate is not limited by the rate of electron transfer through the oxide.

Perhaps anodic oxidation kinetics for stainless steel, similar to that described here, have not been heretofore reported because stainless steel exhibits a transpassive potential region. That is, at relatively noble potentials, stainless steel dissolves rapidly, whereas oxides on other metals can support much higher fields. Also, overvoltages for oxygen evolution on metals like tantalum, zirconium, columbium, and aluminum are relatively high in comparison to the overvoltage for the process on stainless steel. Thus, the potential range where such kinetics can be observed for stainless steel is much more limited than that which exists for metals which can be anodized readily. Since the oxide on stainless steel apparently cannot support high fields, the thickness cannot readily be built up to the interference color range.

In most work on anodic oxide films, the field required to produce growth is applied externally, whereas here the redox system is considered to provide the field. This is consistent with considerations of Young (9), Dewald (11), Vermilyea (10), and Van Rysselberghe (8), who all have taken into account the field produced by electrochemical processes in solution as well as the field created by an applied potential.

Acknowledgments

The author would like to acknowledge critical discussions with Drs. N. D. Greene, A. C. Makrides, and H. Wissenberg. Dr. Makrides pointed out that the kinetics observed at constant potential can be described by a logarithmic oxidation equation. This led to the interpretation presented here.

Manuscript received Nov. 18, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Role of Thiourea in the Electrodeposition of Copper

Bacon Ke, John J. Hoekstra,[1] Bienvenido C. Sison, Jr.,[2] and Dan Trivich

Department of Chemistry, Wayne State University, Detroit, Michigan

ABSTRACT

Single crystal spheres of copper were used to study the effect of thiourea on the plating of copper from an acid bath and the adsorption of thiourea on copper. By x-ray diffraction methods, it was found that instead of the normal tendency of copper to receive single-crystal deposits on the (111) regions from the acid bath, the presence of thiourea caused a uniform bright polycrystalline deposit to be received over the entire sphere. By the use of thiourea labelled with S-35, it was found that thiourea was strongly but fairly uniformly adsorbed on the spheres. It is concluded that the adsorption of thiourea is general with no preference for any crystal face of copper and that the adsorbed thiourea interferes with the crystal growth of the copper electrodeposit.

During the development of modern electroplating practice, it was found that the inclusion of small amounts of the proper addition or brightening agent in the plating bath results in marked changes in the nature of the deposit obtained from the bath. In most cases addition agents are used to obtain smooth bright deposits although they also may be used in some cases to improve other properties. In some cases addition agents permit the use of higher current densities and, as is the case particularly with some bright nickel baths, produce a leveling action, whereby the plated surface is smoother than the original surface. The amount of addition agent required to produce these effects is surprisingly small, and the action of the addition agent is often specific for a particular bath.

The advent of bright plating represents a considerable commercial advance in the field of electrodeposition. In particular, substantial savings in cost and effort have been made since a good deal of the hand finishing previously used can be eliminated.

The early history of bright plating has been reviewed by Rubinstein (1) and by Henricks (2). The discovery of the brighteners used in the various plating baths was accidental in some cases, and in others was the result of painstaking experimentation, almost invariably by means of repeated test platings on a small scale. However comparatively little research effort has been devoted to incisive inquiry into the mechanism of bright plating. Henricks (2) reviewed several theories proposed for the mechanism of bright plating. The most prominent of these theories are the reducing menstruum theory of Kern (3), the adsorption theory of Bancroft (4) [cf. Blum (5)], the complex theory of Mathers (6), and the cathode interference theory of Hunt (7). Each of these proposed theories explains some of the phenomena associated with brightener action, but none of these completely explains all of the facts observed. While the explanations of the mechanism of bright plating are still obscure, the prevalent opinion among more recent workers (8) is that some form of adsorption is involved. The development of a satisfactory theory of bright plating will be of importance in bringing about the development of further bright baths of commercial utility.

A successful theory of bright plating must explain most or all of the following aspects of bright plating: the refinement of the deposit in regard to crystal size and the production of bright, smooth surfaces; the frequent accompaniment by leveling action; the extension of the current density range; the specific nature of the structure of the brightener; inclusion of the brightener or its reaction products in the deposit; the accompaniment of polarization; and the possible change of orientation in deposits.

The specific action of particular agents in certain baths is one of the characteristics that is hardest to explain. It is puzzling that some small variations in the structure of a brightener can ruin its brightening ability and that often there is little carry-over of the brightening power of a particular compound from one bath to another. This suggests that a proper theory of brightening should take into account this specificity in the nature of the brightener and its relation to the metal being plated.

In the face of these facts, we agree with the prevalent hypothesis that brightening is primarily the result of some form of adsorption. Our assumption of this point of view is based particularly on the fact that the molar concentration of the brightener is always much less than the molar concentration of the metal ion. Clearly then it is not possible for a small amount of brightener to form a complex with any substantial fraction of a large amount of metal ion. The most plausible mechanism in which such small amount of brightener can control the disposition of a large amount of metal must require that its action be localized principally at a surface. While it is possible that a brightener is carried into the cathode film in the form of a complex, or that it may exist at or near the electrode surface as a complex, this appears to us to be incidental to the real mechanism.

One could postulate several variations of adsorption mechanisms. One we shall call "structure-sen-

[1] General Motors Fellow at Wayne University, 1954-5.

[2] General Motors Fellow at Wayne University, 1954.

sitive," i.e., the adsorption of the brightener is selective, so that only molecules of a certain size, shape, and chemical structure can be adsorbed on the metal surface. This corresponds to something like chemisorption and may require a suitable spacing between metal atoms on the surface of the electrodeposit to hold the organic molecules. To test this, single crystals of copper were used in this investigation to carry out the adsorption studies. Plating tests were also made with the single crystals, and x-ray studies were made of the deposits on the various faces of the crystal obtained in the absence as well as in the presence of the brightening agent.

Another type of adsorption that could be postulated might be called "current density sensitive," or better "shape sensitive," i.e., the adsorption of the brightener molecules on the cathode surface occurs under electrolysis conditions regardless of the nature of the crystalline structure of the cathode but dependent on the surface contour of the electrode. Here primary consideration is given to the leveling action in certain bright baths, in which the expected low current density areas grow faster than the high current density areas, suggesting the possibility that the high current density areas are blocked preferentially by these compounds. It should be mentioned here that leveling is a microscale phenomenon and that the high and low current density areas being referred to here are micro protrusions and recesses. Relatively less attention was given to the leveling aspect of the subject in the present work. Some investigations of this aspect are in progress and will be reported later. The subject of leveling has recently been reviewed by Leffler and Leidheiser (19).

These types of adsorption may be viewed as physically independent but not necessarily always separate. There could be situations where one type of mechanism operates to the entire exclusion of the others and *vice versa,* but it would be more likely that any real situation would show some contribution from each. The degree to which each mechanism would be represented will probably vary from case to case. It should be mentioned that these postulated variations of an adsorption mechanism are not original with the present authors and that suggestions reminiscent of them can be found in the work of a number of other authors [e.g. (8, 19-24)].

The bath chosen for initial investigation was the acid copper bath using thiourea as a brightener, since this bath appeared to be simpler than others which might have been chosen. Typical compositions for bright acid copper baths are given by Blum (8a), Clifton and Phillips (9), and Beaver (10).

Electrodeposition Studies on Copper Single Crystal Spheres from the Acid Copper Bath

In the structure-sensitive hypothesis, it was suggested that adsorption processes might be operative in which a particular match would occur between the interatomic distances in the brightener molecule and those in the metal crystals of the surface of the electrodeposit. It appeared that such processes could be studied to good advantage by the use of large single crystals of metals.

The desirability of using metal single crystals in any studies in which the metal surface is concerned has been well demonstrated by Gwathmey, Leidheiser, and co-workers (11). Since an ordinary metal specimen is composed of many small crystallites which may have random orientations, the value of a measured surface property of such a specimen is a composite and variable average value of contributions due to exposed crystallite surfaces of many orientations. Such a surface is not readily reproducible and is not suitable for incisive studies of adsorption and other surface phenomena on metals. For such investigations metal single crystals can provide a more readily reproducible surface of better known character and can allow one to choose surfaces parallel to particular crystal planes for study. Single crystal spheres are useful in metal surface studies because a sphere permits all possible crystal faces to be exposed for study in any given experiment and under competitive conditions.

In the present research, two types of studies employing copper single crystals were made. The first type was the electrodeposition of copper on single crystal spheres from plain acid copper plating baths and from acid copper baths containing thiourea as a brightener. The second type was the study of the adsorption of the brightener, thiourea, on copper crystal spheres by means of radiotracer techniques. Plating studies are presented in this section and the radiotracer adsorption studies are presented later. The object of both types of experiments was to determine the relation between crystal structure of the copper metal and brightener action.

Experimental

Copper single crystal rods were grown by the Bridgman method in a resistance furnace which is a modification of one described by Gwathmey and Benton (11a) and also by a method using an induction heated stationary graphite crucible, developed here (12). The copper used was Baker's C.P. shot and also "high-purity" rods.[3] The single crystal rods obtained were machined into spheres by means of a lathe attachment and method developed here (13). Following the machining operation the spheres were first polished mechanically with abrasive papers and then electropolished until etching showed that all worked material had been removed. In general, the procedure followed was that outlined by Gwathmey and Benton (11a). The crystal spheres were further annealed at 1000°C in a nitrogen atmosphere for approximately 12 hr using a Lindberg CF-1 tube furnace. The area of the spheres was determined from micrometer measurements for current density calculations.

Plating experiments were conducted in 1-liter beakers which were immersed in a 25°C thermostat. The experimental electrolyte used was a standard acid copper bath: 205g/l $CuSO_4 \cdot 5H_2O$ and 50 g/l conc. H_2SO_4 (sp gr 1.84).[4] Trace organic impurities which had been found to cause poor results were removed by stirring some activated charcoal[5] into the

[3] Obtained from the American Smelting and Refining Co.

[4] Both chemicals were Baker and Adamson Reagent Grade.

[5] Darco Red Label grade.

solution at 60°C, allowing the solution to stand a short time, and filtering to remove the carbon. The anodes were thin, high-purity copper rods.[3] The single crystal sphere as cathode was immersed in the center of the cell.

Two series of plating experiments were performed; one series in a plain acid copper bath and the other in a bright acid copper bath, run at a fixed current density of 5 amp/dm^2 at 25°C for plating times of 1, 5, 10, and 20 min, corresponding to approximate deposit thicknesses of 1, 5, 10, 20 μ. The bright plating bath was the same as the plain bath, but contained 0.01 g/l of thiourea (Matheson, further purified by recrystallization from alcohol) in addition. At the beginning of a plating experiment the sphere was again electropolished for 5 min to remove oxide films; then the sphere was rinsed with water and immediately placed in the plating bath. Plating was begun at the current calculated to give the desired current density. The plating bath was agitated by bubbling filtered air through it. Immediately after plating, the spheres were rinsed with water, dried carefully with tissue paper, and then lacquered by dipping in a 4% solution of Saran F-120 in methyl ethyl ketone. The lacquer coating was advisable to preserve the deposit from oxidation to allow subsequent examination by x-ray diffraction. The appearance of the deposit was observed and in some cases photographed.

X-ray diffraction photographs were taken of the deposits on various crystal faces using the back reflection technique. Some early experiments were done with a General Electric XRD-3 x-ray diffraction unit but most of the work reported here was done with a North American Phillips model 5001 unit, using a copper target tube and one of the pin-hole ports. The camera was a Sachs type back reflection camera consisting of a cassette and pin-hole system.

The crystal sphere was mounted in a two-circle goniometer which enabled positioning the desired crystal face normal to the beam and 3 cm from the film. The white radiation necessary for the examination of single crystal structures was obtained by running the copper tube at 48 kv, 16 ma. In the case of polycrystalline deposits, usually two x-ray diffraction patterns were taken, one with white radiation and one with monochromatic radiation which accentuate the single crystal and the polycrystalline structures, respectively. The monochromatic radiation was the copper K-α line, which was obtained by running the tube at 30 kv, and 24 ma and using a 0.00075-in. nickel filter at the window of the x-ray tube. The film used was Eastman Kodak "No Screen" medical x-ray film and the exposure time was 1-1½ hr.

Results

It should be mentioned that the single crystal spheres before plating were bright and uniform in appearance following the polishing and electropolishing procedures. Plating these spheres with copper from the plain acid bath resulted in the development of characteristic patterns of striking symmetry [as first observed by Gwathmey and co-workers (11c)]. The deposit in the (100) region consisted of a matte area in the form of a square, while the deposit in the (111) region consisted of a bright triangle. There were six such square areas parallel to the faces of a cube and eight such triangles perpendicular to the body diagonals of a cube. Further we have found that this same pattern was obtained over a substantial range of temperatures and current densities (14). As a matter of fact, the patterns are so characteristic of copper electroplates on good single crystals from a pure bath that they may be used as a test of good procedures. The adequacy of the preparation, handling, cleaning, and plating conditions could be judged by the distinctness of the electroplated patterns obtained. For example, electropolishing insufficient to remove worked surface would result in an irregularly patterned deposit. The annealing treatment of the single crystals and the activated carbon treatment of the plating baths were instituted because such plating tests indicated their advisability. Many plating tests were made and the ones quoted are representative.

The structure of the electrodeposits on the single crystal bases plated in the plain acid copper bath is shown by the x-ray diffraction patterns in Fig. 1. In the bright (111) region, the patterns characteristic of a single crystal structure were obtained for plating times up to 10 min. Even a 20-min plate showed strong preferred orientation. In the matte (100) region, the structure is shown to be polycrystalline at a much earlier stage in the course of plating.

In contrast to the patterned deposits from the plain bath, the bright deposit obtained from a bath containing thiourea was bright and uniform over the entire sphere with no indication of the structure of the underlying single crystal base. Also, x-ray

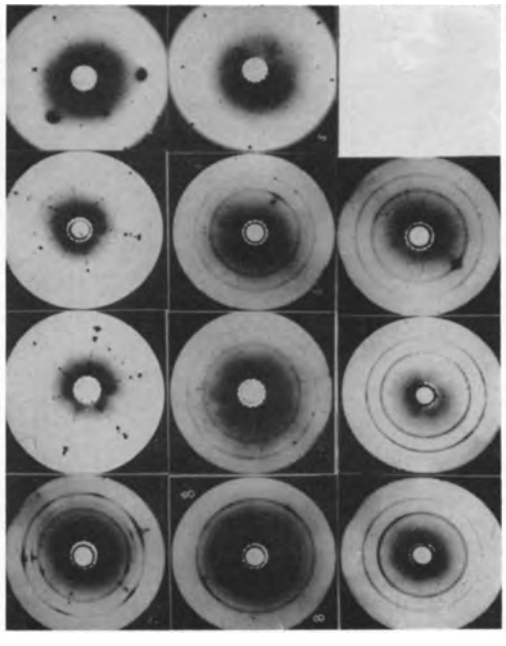

Fig. 1. X-ray diffraction patterns for copper electrodeposits of various thicknesses on copper single crystal spheres plated in an acid copper bath. First column is for white radiation on (111) face; second, white radiation on (100) face; and third, monochromatic radiation on (100) face. Plating times at 25°C at 5 amp/dm^2 from top to bottom: 1, 5, 10, and 20 min.

diffraction studies showed the deposit to have the same structure over the entire sphere. In this case the bright deposit was found to have a polycrystalline structure even in very thin deposits, in contrast to the single crystal bright deposit obtained on the (111) region from a plain acid bath.

Discussion of Plating Results

These results show that under normal plating conditions electrodeposition from the acid copper bath has the greatest tendency to continue the structure of the base crystal on the (111) faces. On the (100) faces, the process is sufficiently less favorable that a polycrystalline deposit is obtained. In a related study by Leidheiser and Gwathmey (11e), it was found in the electrodeposition of nickel from a Watts bath on copper single crystals that the favored direction for continuation of the single crystal structure was on the (100) face. The preferential direction of growth of metal crystals in electrodeposition is probably a composite effect of the influence of a number of variables, including the base crystal, bath composition, and plating conditions. It is well known that this same tendency for the electrodeposit from some baths to continue the structure of the base metal exists even in the case of polycrystalline metal bases when properly prepared [cf. (8a) p. 89].

Under the usual plating conditions on a polycrystalline base metal of doubtful cleanliness, the orienting influence of the base becomes less important, and the observed orientation in electrodeposits is more likely to be determined by bath composition and plating conditions. Electrodeposits from comparatively simple salt solutions frequently have a preferred crystal orientation and commonly exhibit a fiber structure perpendicular to the base metal and extending in the direction of the current flow (15). Fischer (8c) has evolved an extended classification system of crystal structures in electrodeposits and has also dealt extensively with the effect of inhibitors on electrodeposition, Microscopic examination of coarser deposits such as from the acid copper bath reveals a predominance of long columnar grains, One might expect that the long direction of such crystals would be the same as the preferred direction for the continuation of single crystal structure and thus establish a correlation to the preferred orientation in the polycrystalline deposits. Some support for this point of view can be found in the results of Leidheiser and co-workers who found that the Watts nickel bath gives a preferred (100) orientation in polycrystalline deposits (16) and that it continues the single crystal structure on (100) faces of a single crystal (11e), although this conclusion is clouded by the fact that the single crystal base was of copper.

The more striking results of the experiments of this section are the profound effects of the thiourea on the electrodeposition of copper. The most important effect is the ability of the thiourea to interfere with the normal tendency of the acid copper bath to continue the propagation of a metal single crystal on the (111) faces. Similarly the interference operates on the growing crystals on the (100) faces of the single crystal sphere limiting their growth also, as evidenced by the fact that the matte coarsely crystalline deposits normally obtained in these regions from the plain bath becomes refined into a finely crystalline bright deposit from a bath containing thiourea. Thus the copper electrodeposits from a bright bath on single crystals show a uniform polycrystalline structure with no trace of influence from the base single crystal.

It would be expected that copper electrodeposits made on a polycrystalline base would also show the inhibition effect of brighteners. Microscopic examination was made of copper electrodeposits from a standard acid copper bath and from bright acid copper using thiourea as a brightener. The nonbright deposit exhibited the typical coarse, grainy structure with some tendency toward a columnar structure. In the bright deposit there was no evidence of graininess and columnar growth. While no grain structure can be resolved, bright deposits are crystalline as shown by our x-ray results and as shown for nickel by Denise and Leidheiser (16), and others. It is interesting to note that the bright copper deposit obtained from an acid bath containing thiourea exhibits the laminar structure which is frequently, if not invariably, found in bright electrodeposits.

It is not possible from these plating results to decide whether thiourea exercises its inhibiting action on only certain crystal faces. While grain refinement could occur in the case of the electrodeposition of a metal of such highly symmetrical crystal structure as copper if adsorption were to occur on only certain crystal faces, one cannot exclude the possibility that inhibition could occur on several types of faces and perhaps even on all faces indiscriminately. One possible method of deciding between these various possibilities is a direct meaurement of adsorption using tracer methods.

Radiotracer Studies of the Adsorption of Thiourea on Copper Single Crystals

In the preceding section it was shown that the presence of thiourea in the acid copper bath profoundly influenced the crystalline structure of the copper electrodeposit and that this influence, or at least the effect of this influence, appeared to be greater on (111) faces than on the (100) faces. It was suggested that the adsorption of thiourea on copper might be selective on the various crystal faces. In order to make a direct experimental test of this possibility, radiotracer studies were undertaken.

Metal single crystals in the form of spheres are well suited to studies of this type because the surface of a single crystal sphere presents all possible crystal planes and all possible interatomic distances to the reaction medium being studied. If the reaction of the medium with the metal is a function of crystal face and spacing, a definite macroscopic pattern will develop on the surface of the crystal sphere. Gwathmey, *et al.* (11) have shown numerous examples of this pattern development such as those resulting from the etching action of a solution of cupric chloride in hydrochloric acid on copper single crystal spheres, the deposition of carbon on nickel crystal spheres during the thermal decomposition of car-

bon monoxide, oxidation films, wetting by lubricants, electrodeposition, etc.

Accordingly, if thiourea is adsorbed selectively on particular crystal faces of copper because of a preference for a particular interatomic spacing, then it is reasonable to expect that the adsorbed material would be arranged in such a regular macroscopic pattern on the crystal sphere. If thiourea-S^{35} is employed in the adsorption study, by means of the appropriate radioactivity detection technique, it should be possible to determine whether or not a radioactivity pattern corresponding to an adsorption pattern occurs. Since the films of interest would be expected to be monomolecular, sensitive detection methods are required.

Experimental

Electrolytically polished single crystal spheres such as described in the preceding section were used to carry out the adsorption studies. Immediately after they were taken out of the polishing bath and washed in running water, the spheres were dipped in solutions containing carrier-free thiourea-S^{35} which had been synthesized according to the procedure of Bills and Ronzio (17). Two types of solutions were used; one being an aqueous solution containing 0.01 g/l thiourea-S^{35} and the other being a typical acid copper plating bath of the composition used in the preceding section to which 0.01 g/l thiourea-S^{35} had been added. The time of immersion in the solution was usually 30 min to insure the attainment of equilibrium. Exposures were also made of short flash electrodeposits as well as simple immersion without current.

Gas phase adsorption experiments were conducted in a glass tube similar to the outside jacket of a vacuum sublimator. The crystal was suspended from a glass hook at the bottom of the solid ground glass stopper used to close the tube. A small amount of radioactive thiourea was dropped into the tube which was then evacuated at room temperature. After evacuation, the temperature of the whole tube was raised by means of an infra-red lamp operated through a transformer. At 50°C, the adsorption was allowed to continue for about 12 hr, while for a temperature of 100°C it was heated for 30 min and 1 hr in two experiments.

Two methods were employed for the detection of radiation on the spheres which had been exposed to the thiourea-S^{35} in various media. One was an autoradiographic method and the other a method employing a two-circle goniometer and a Geiger counter with scaler. These two methods with their results will be treated separately below.

The autoradiographic detection method of the present work is based on the fact that a photographic emulsion is darkened by the β-particles from the S^{35} in the thiourea-S^{35}. The location of the blackening on development serves as a means of determining the location of the adsorbed thiourea. The procedure used, patterned after that described by Gomberg (18), is as follows. After the adsorption procedure, each sphere was coated with a thin, chemically inert coating of Saran by dipping the sphere into a 4% solution of Saran F-120[6] in methyl ethyl ketone. This coating prevents the subsequent photographic emulsion from reacting with the copper base, and at the same time it is transparent to all radiations coming out. The 4% solution leaves about 2.5 μ of protective plastic coating. After this coating was dried, the photographic emulsion was applied over it.

The emulsion used was du Pont's DH dehydrated emulsion which was prepared, applied, and developed according to the instructions of the manufacturer. All handling, dissolving, coating, and processing steps were carried out in a photographic darkroom equipped with a du Pont S-55x safelight. The emulsion was applied by simply dipping the crystal sphere into the emulsion and rotating the sphere to spread the emulsion evenly over the entire surface. After the application of the emulsion the spheres were placed in a rack in a well closed dark box for exposure. Exposure times were determined from the β-count per unit area per unit time of the individual sphere and the emulsion requirement of 5×10^6 emissions per cm^2 for suitable contrast. The emulsion dried during the first part of the exposure period, and after exposure the film was developed and fixed without peeling it from the sphere.

The experimental results using the autoradiographic technique all turned out to be quite similar. All of the emulsion coatings developed to be uniformly dark over the surface of each sphere. In no case could any gradation be detected in the darkening, and certainly no regular pattern of localization of any kind was evident. The only conclusion that could be drawn was that the adsorption was uniform and that no preferential adsorption of thiourea on the copper single crystal spheres occurred. Several factors existed which gave a basis for doubting the validity of the autoradiographic results, among them possible migration of sensitive material in the emulsion during drying and subsequent exposure time, saturation and reversal effects in the exposure, and imperfect insulation of the emulsion from the base copper by the Saran coating allowing catalytic non-exposure reduction of the silver. These were proved to be unnecessary worries by further tests on blanks and graded exposures, but it was felt desirable in any case to proceed with an independent method of radiation detection employing the two-circle goniometer and Geiger counter.

The apparatus shown in Fig. 2 was used to count directly the emissions from various locations on the sphere. It consisted of a two-circle goniometer for fixing the position of the sphere and a TGC-2 mica window (2.3 g/cm^2) Geiger counter tube (Tracerlab, Inc.) which was used with a Raychronix Model A-4 64-scaler.

The crystal sphere was held in the goniometer clamp in such a position that the axes of both vertical and horizontal rotation passed through the center of the sphere. The crystal holder could be rotated 360° about its own axis and simultaneously through 180° about the vertical axis. Thus, any point on a hemisphere of the crystal sphere could be located

[6] Dow Chemical Co. vinyldene chloride.

Fig. 2. Apparatus used for scanning the radioactivity on copper single crystal spheres having adsorbed thiourea-S^{35}.

with respect to a chosen reference point which, in this case, was the pole of the horizontal axis opposite the handle of the crystal.

The Geiger tube was held horizontally on a ring stand. In front of and parallel to the Geiger tube window, 8 mm away, was a ⅛-in. lead sheet, in the middle of which was a small hole of known size, so positioned that the hole was in the horizontal plane through the horizontal axis and along a radius through the vertical axis. When the Geiger tube and lead shield were fixed in position, the crystal sphere could be so rotated that all positions on the hemisphere could be located and its emissions counted. The surface of the sphere was about 1 mm from the load shield so that emissions from the surface would give a fairly true representation of the number of counts from an area of the order of that of the hole in the lead sheet.

A typical set of counting results is shown in the polar projection of Fig. 3. The size of the black dots is proportional to the number of counts. The number of counts is referred to a pin-hole area of 0.0914 cm². The background count is subtracted. The locations of the various crystallographic regions on the crystal are also projected on the chart.

The direct counting method in the main substantiated the results of the autoradiographic method. While a finer discrimination in the detection of the degree of adsorption was possible, in that the counts varied from 50 to 90 over different points, again no definite pattern of adsorption could be detected. As shown in Fig. 3, no correlation can be found between strong and weak adsorption and crystallographic position.

The important result of the experiments of this section is that thiourea is strongly adsorbed on the various faces of a copper single crystal sphere. Contrary to the predictions of the structure sensitive hypothesis, no localization of adsorption was found which might have resulted if a specific fit were required between the brightener structure and interatomic distances on the metal crystal surface.

The differences in the amount of adsorption on the various parts of the single crystal spheres were not large in that they covered only a twofold range of variation. Such small variations might have been due to differences in metal surface areas or to migration of the brightener during the drainage and drying periods. In any case the differences were too small to differentiate between the various crystal faces in terms of adsorption power so that the present results lead to the conclusion that the adsorption of the thiourea is uniform on the various crystal faces.

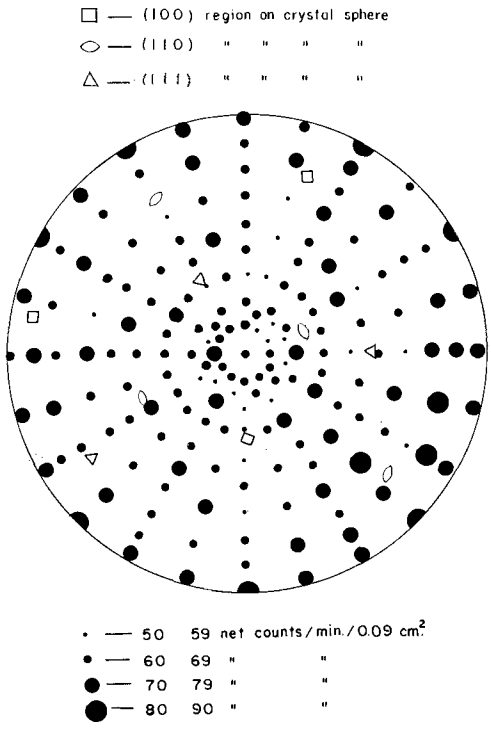

Fig. 3. Polar projection plot of radioactivity from adsorbed thiourea-S^{35} on a copper single crystal sphere. Smallest circles represent 50-59 counts/min/area of 0.09 cm²; next, 60-69; then, 70-79; and largest, 80-90. Crystallographic regions are represented: (100) by squares, (110) by ellipses, and (111) by triangles.

However, while these results are valid for the conditions used, there remains a lingering suspicion that other methods of carrying out the experiments might reveal a preferential adsorption. Perhaps in the present experiments, the adsorption is sufficient to saturate all faces, indicating that the media studied here have plenty of thiourea available for even the presumably weakest adsorbing faces of the copper to take on substantially the saturation amount of thiourea. This possibility suggests further experiments such as a mapping of the entire concentration vs. adsorption curve for thiourea on copper, or adsorption studies similar to the ones done here but in a medium with insufficient material to give saturation, or selective desorption studies by washing with various solvents, by heating, etc., performed on a saturated single crystal.

Summary and Conclusions

It has been shown by direct tracer measurements that thiourea is strongly adsorbed on the surface of a copper metal crystal or electrode. This adsorption takes place even in the absence of applied potential or electrolysis conditions, but this does not exclude the possibility of modification and perhaps enhancement of the adsorption under conditions of electrolysis.

The effect of the thiourea on the metal electrode during electrodeposition of copper from the acid bath is to modify the crystal structure of the deposit severely. The action of the brightener is one of inhibition of the crystal growth process so that there is a relative enhancement of the nucleation process. This results in a finer grained deposit. The adsorption process appears to have no selectivity for the various crystal faces of the metal so that the inhibition must be a general one governed by conditions other than crystal character of the metal.

Manuscript received Sept. 3, 1957. Most of the work was performed under Contract DA-20-018-ORD-12079 between Wayne University and the Office of Ordnance Research, U. S. Army, during the period of February 1952 to January 1954. Some later confirmatory work is included. Further details are given in Ref. (25).

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

The Source of the Nitrogen Impurity in Electrodeposited Chromium

N. Ryan and E. J. Lumley

Aeronautical Research Laboratories, Department of Supply, Commonwealth of Australia, Melbourne, Victoria, Australia

ABSTRACT

High-purity chromium deposited from chromic acid electrolytes containing either sulfate or fluoride catalysts invariably contains small amounts of nitrogen as an undesirable impurity. The amount of this nitrogen impurity is shown to be increased by increased nitrate ion concentration in the electrolyte but not affected by dissolved atmospheric nitrogen or ammonium compounds. It is demonstrated that the nitrate impurity is decomposed at the cathode by reduction with hydrogen to form ammonia as the major product. Some of the atomic nitrogen which is possibly formed at a stage during this reduction is probably adsorbed continuously into the electrodeposited metal.

The nitrogen content of high-purity chromium produced by the electrolysis of chromic acid electrolytes varies according to the bath conditions (1-3). In the chromium prepared at these laboratories it is usually present in the range 0.001-0.004%. Investigations into the ductile-brittle behavior of chromium and its alloys have revealed that small increases in the nitrogen impurity can influence the mechanical properties detrimentally to a remarkable degree (4,3). Hence there is a strong need to eliminate, as far as possible, this nitrogen impurity and for this reason to trace its source.

Possible sources of primary nitrogen contamination immediately apparent are: (*a*) atmospheric nitrogen dissolved in the electrolyte, and (*b*) nitrogen-containing compounds dissolved in the electrolyte.

If atmospheric nitrogen were the main source of

the nitrogen contamination it would be expected that chromium deposited by electrolysis in an atmosphere free from nitrogen would have a low nitrogen content, while that produced under high nitrogen concentrations would have a higher value.

Regarding the second source, the most commonly occurring nitrogen impurity in chromic acid is the nitrate ion, probably arising from the nitric acid wash during manufacture. The nitrate impurity is present in amounts usually of the order 0.004%. This appears a relatively small value, but represents 0.003 g of available nirogen in 1 liter of a 300 g/l chromic acid solution. If 5 g[1] of chromium containing 0.003 wt % nitrogen is deposited from this solution, only 0.00015 g of the 0.003 g of available nitrogen is used. Therefore, it is possible that the nitrogen contamination of electrodeposited chromium could originate from the nitrate impurity in the electrolyte. If this is the case, an increase in the electrolyte nitrate impurity should result in increased nitrogen contamination of the electrodeposited metal.

The experiments here described were carried out to test the above hypotheses.

In general, electrolysis in the sulfate- and fluoride-containing electrolytes was carried out for 5-hr and 1-hr periods, respectively. Because of the higher current efficiencies when using the fluoride electrolytes (2),[2] hourly runs produced sufficient chromium for analysis.

Apparatus

The apparatus, basically a completely enclosed glass vessel, was designed primarily to investigate the effect of dissolved atmospheric nitrogen and was subsequently employed for all experiments. It consisted of two sections: (i) the cell section for 300 ml of electrolyte, cathode, and anode, and (ii) the upper section connected to the cell via a ground glass socket joint. This section contained inlet and outlet arms for (*a*) introduction of the electrolyte, (*b*) anode and cathode connections, and (*c*) a reflux condenser (through which passed gases generated during electrolysis) to reduce evaporation losses.

The chromium was deposited on ½ in. diameter, 2 in. long copper tubes which were subsequently removed by digestion in nitric acid. Pure lead anodes were used in sulfate electrolytes, and 0.5% tin-lead anodes in the fluoride electrolytes. The nitric acid extraction does not influence the nitrogen content of the chromium as it has been found that chromium chipped from the electrode has the same value as that extracted in the nitric acid. Power to the cell was supplied by a 60-amp capacity selenium rectifier.

It has been found (2) that only slight contamination of the electrolyte with SiF_6^{--} occurs when using the fluoride electrolytes in glass vessels.

Chemical analysis.—The chromic acid used contained between 0.002-0.004% nitrate impurity together with the following nominal impurities 0.02% SO_4, 0.01% Fe, and 0.1% Na.

The oxygen content of the chromium deposits was determined using the "Adcock" method and the nitrogen content was determined by a semi-micro Kjeldahl procedure using a colorimetric finish for the low nitrogen values and an acid-alkali titration finish for the high nitrogen values.

Results

Effect of electrolyte atmosphere.—The conditions of electrolysis and the composition of the electrolytes used in these tests are recorded in Table I.

In the first test series, no precautions were taken to exclude air contamination, and these runs are recorded in Table I as having been deposited in an air atmosphere. This however is not entirely correct as the oxygen and hydrogen produced during electrolysis rapidly replaces the air above the electrolyte in the enclosed vessel. Results had been obtained previously for chromium deposited from open vats under otherwise similar conditions, and these showed the same gas content as the chromium produced "in air" in the experimental cell. In the second series of tests a rapid stream of nitrogen was bubbled through the electrolyte during plating.

To investigate deposition under nitrogen-free conditions the apparatus was completely evacuated and flushed with pure hydrogen. The electrolyte was introduced from an attached reservoir, into the evacuated vessel while the current was applied through the electrodes. The oxygen and hydrogen generated were free to escape through the reflux condenser via a water seal, once the internal pressure exceeded that of the external atmosphere.

Analyses of the chromium deposit obtained under the above conditions are recorded in Table I. It is apparent that dissolved nitrogen has an insignificant

[1] The approximate weight of chromium deposited from 1 l of electrolyte during a normal production run in the chromic acid-sulfate electrolyte.

[2] For brevity, the terms "fluoride electrolyte" and "sulfate electrolyte" are used to denote chromic acid solution containing fluoride and sulfate additions, respectively. "Fluoride chromium" and "sulfate chromium" similarly refer to the products of these electrolytes.

influence on the amount of nitrogen codeposited with the chromium.

Effect of nitrate impurity in the electrolyte.—Chromium was deposited under the conditions detailed in Table II from 300 g/l as-received chromic acid solutions containing either 4 g/l sulfate or 5.4 g/l fluoride as the active catalyst, the nitrate impurity being 0.012 g/l and 0.006 g/l, respectively. The chromium obtained from these tests was found to contain 0.002 wt % and 0.001 wt % nitrogen, respectively. These deposits were used as comparison standards.

In order to vary the nitrate impurity, nitric acid was added to electrolytes of similar composition to the above, and electrolysis was carried out under the conditions described in Table II. These deposits were analyzed for both oxygen and nitrogen, and results showed that the nitrogen content of the chromium was increased markedly.

Effect of electrolyte temperature.—Investigations into the production of high purity chromium from various electrolytes have given some indication that reduction in nitrogen content of the chromium occurs with increasing electrolyte temperature (2). In these experiments chromic acid with only trace amounts of nitrate impurity was used. Chromium deposited from an electrolyte containing sulfate at 100°C was found to contain less than the chemically detectable amount of nitrogen, but, as shown in Table III, the current efficiency was only 2.5%.

For a further series of tests, an electrolyte containing 300 g/l CrO_3, 5.3 g/l F, and 1 g/l NO_3 was prepared. This was electrolyzed at 1000 amp/ft² for 1-hr periods at 70°, 85°, 92°, and 100°C. Analyses of the chromium deposits obtained from these experiments are recorded in Table III. They indicate that the nitrogen content was unaffected by electrolyte temperature.

Effect of ammonium compounds in the electrolyte.—It is well known that ammonia is produced during the electrolytic reduction of nitrates. In order to find the effect of this ammonia on the nitrogen content of the electrodeposited chromium, the following tests were performed. Normal chromic acid electrolytes in which the active catalyst radicals were introduced as the corresponding ammonium salts were electrolyzed under the conditions listed in Table IV. The results indicate that the ammonium ion does not influence the nitrogen content of the chromium to any significant extent since the nitrogen values obtained lie within the usual scatter found in successive chromium deposits during normal production.

Electrolytic reduction of nitrate impurity.—In the preceding sections of this paper it has been demonstrated that there is a definite relationship between nitrate additions to the chromic acid electrolyte and the increased nitrogen content of the electrodeposited metal, while molecular nitrogen and ammonium compounds are without effect. The manner in which this contamination takes place is a matter for speculation and has been discussed briefly in a previous report (5). Nitrogen is obviously introduced into the chromium at some stage during the electrolytic reduction of the nitrate electrolyte impurity.

In order to study this relationship more closely a solution containing 300 g/l CrO_3, 5.84 g/l F, and 2.7 g/l NO_3 was prepared. This solution was electrolyzed at 100°C and 1015 amp/ft² current density. Chromium deposits were plated from this electrolyte for consecutive time intervals of 1 hr, ½ hr, ¾ hr, and ½ hr. Fresh cathodes were used for each successive electrodeposition. These deposits were analyzed to determine the nitrogen content, and samples of the electrolyte, after each succeeding deposit,

were analyzed to determine ammonia and residual nitrate, i.e., during the 1-hr deposition the nitrate was reduced from 2.7 to 0.052 g/l and so on. Results are recorded in Table V and Fig. 1.

It can be seen that the nitrate content decreased rapidly during the first hour of electrolysis and then more steadily with time, the ammonia content showing a corresponding increase. The nitrogen content of the chromium samples decreased with the nitrate content of the electrolyte.

Discussion

The main conclusions to be drawn from this investigation are that dissolved nitrogen and ammonium salts in the electrolyte do not influence the nitrogen contamination of electrodeposited chromium, but that nitrate impurities markedly raise the nitrogen pickup. Increasing the electrolyte temperature does not in any way effect a reduction in the nitrogen impurity, at least in electrolytes containing fluoride and considerable amounts of nitrate. However, the limited evidence from the sulfate electrolyte could suggest a decrease in nitrogen content with increasing electrolyte temperature. It has been shown in Table V and Fig. 1 that the progressive electrolytic reduction of nitrate results mainly in production of an equivalent amount of ammonium ion, and that the reaction follows a typical reaction rate time curve, asymptotic to the time axis. This implies long times for substantially complete conversion of nitrate to ammonia.

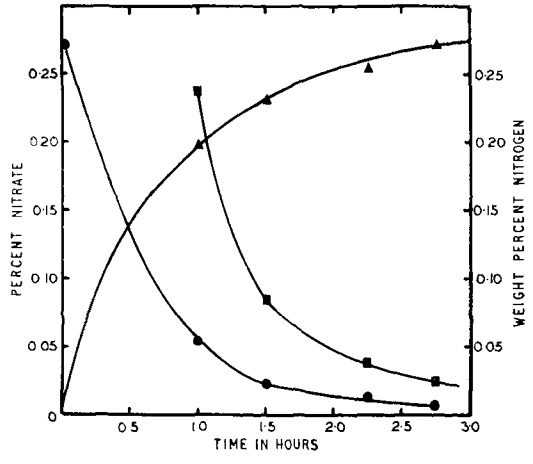

Fig. 1. ●—Reduction in nitrate during electrolysis; ▲—increase in ammonia in electrolyte expressed as equivalent nitrate; ■—nitrogen content in successive chromium deposits.

The manner by which nitrogen enters the chromium is not definitely known. The nitrogen impurity in the chromium is obviously introduced at some stage during electrolytic reduction of the electrolyte nitrate impurity. It is possible that atomic nitrogen is formed at some stage during this reduction, and that a portion of this nitrogen enters the electrodeposited chromium (5). The electrochemical reduction of nitrate is known to be complex (6), and many nitrogen-containing compounds can be formed depending on the various cathode conditions.

It is obvious that if some means could be found of eliminating the nitrate impurity in chromic acid electrolytes the nitrogen content of electrodeposited chromium could be reduced to a much lower level than is normally obtained at present. It is suggested that the impurity could at least be substantially reduced by electrolyzing solutions of chromic acid for long periods under conditions favoring the generation of large volumes of hydrogen at the cathode without any recoverable chromium deposition. Low concentrations of nitrate may however be very difficult to remove. Low-nitrate chromic acid could also be produced by replacing the nitric acid wash during manufacture by hydrofluoric acid, or by repeated recrystallization.

Acknowledgments

The authors wish to express their thanks to Mr. A. R. Edwards for his helpful criticism in the preparation of this paper which is published by permission of the Chief Scientist, Department of Supply, Australia.

Manuscript received Aug. 25, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.

Electroplating on Thorium

John G. Beach and Glenn R. Schaer

Battelle Memorial Institute, Columbus, Ohio

ABSTRACT

A method was developed for treating thorium whereby adherent electroplates of most metals can be applied. The method involves anodic pickling in hydrochloric acid and chemical pickling in sulfuric acid prior to plating. Factors affecting the adherence and protective qualities of the coatings are discussed.

The use of thorium in nuclear reactors prompted an interest in coatings that could provide desirable surface properties. Thorium, like magnesium, uranium, and zinc, oxidizes easily and corrodes readily in boiling water.

Coatings on thorium that could prevent oxidation and corrosion, or that would aid joining to other metals, for example by soldering, were deemed desirable. A process for plating on thorium has been worked out (1), and electroplated and conversion coatings that protect thorium in boiling water were studied briefly (2).

A review of the known properties of thorium and its compounds plus its electrochemical activity suggested that the problems involved should be similar to those encountered in plating on aluminum, magnesium, and uranium. The principal problem was the preparation and activation of the thorium surface. When the thorium was properly prepared, most metals could be electrodeposited satisfactorily by established procedures. Known methods for preparing aluminum, magnesium, and uranium for electroplating did not provide satisfactory adherence of electrodeposits on thorium. However, the method developed in these studies for plating on thorium is also applicable to aluminum.

Method of Electroplating on Thorium

Pretreatment of thorium.—Anodic and chemical pickling were used to activate thorium for electroplating. The procedure is as follows: descale mechanically (abrasive blast, machine, etc.); degrease (trichlorethylene); cathodic alkaline clean, conventional multipurpose alkaline cleaner, 180°F, 25 amp/ft^2, 2 min; cold-water rinse; anodic pickle, hydrochloric acid, 1.2*N* HCl, HCl (1.19 g/cc)—10% by volume, 80 = 10°F, 50 amp/ft^2, 5 min; chemical pickle (without rinsing), sulfuric acid, 3.6*N* H_2SO_4, H_2SO_4 (1.84 g/cc)—10% by volume, 80 = 10°F, immersion 5 min; cold-water rinse; electroplate (immerse with the current on).

Electroplating on pretreated thorium.—The above pretreatment permitted adherent electroplating of aluminum, chromium, copper, gold, indium, iron, lead, nickel, silver, tin, and zinc directly on thorium. The listing below describes the types of solutions that were used.

Metal Plated	Type of Solution
Aluminum	Aluminum chloride—lithium chloride—ether (3)
Chromium	Chromium acid—sulfuric acid (4)
Copper	Copper sulfate—sulfuric acid (4)
Iron	Iron sulfate—chloride—formate (5)
Nickel	High *p*H bath (6) (used for direct plating on aluminum)
Gold	Cyanide (4)
Indium	Cyanide (4)
Silver	Cyanide (4)
Zinc	Acid sulfate (4)
Lead	Complex alkaline tartrate (7)
Tin	Alkaline stannate (4)

Although most types of plating baths are suitable for plating on thorium not all plating baths were satisfactory. For example, chloride-containing baths that had a *p*H lower than 4 were unsatisfactory. Also, the high-temperature chromic acid solution for depositing low-contraction chromium was unsuitable for direct deposition on thorium.

Stripping of electrodeposits.—Most electrodeposits could be stripped, with little or no attack on the thorium, by immersion of the plated thorium in 50% nitric acid or by anodic treatment in a caustic solution.

Electropolishing (Anodizing) of Thorium

Electropolishing was tried as a means of improving the thorium surface for plating. Thorium treated anodically under the following conditions was smoothened uniformly but retained a film that prevented uniform activation for plating. However, the film presumed to be thorium phosphate also provided protection against oxidation and corrosion.

Sulfuric acid	9*N* H_2SO_4
Phosphoric acid	11*N* H_3PO_4
130°F	150 amp/ft^2

1500 amp-min/ft^2/mil of surface metal removed

Heating the electropolished thorium in vacuum at 600°F for about 30 min increased the protective quality of the anodized film.

Evaluation of Coatings on Thorium

Qualitative adherence, solderability, thermal-cycling, and corrosion tests were made to provide data for engineering design of protective coatings on thorium.

For the research reported here, "adherence" is narrowly defined as the attachment at the basis metal-electroplate interface. The term "bond strength" (8) is used to indicate the force required to separate the electroplated metal from the basis metal regardless of the location of fracture. Bond strength is of ultimate importance and whether or not a given bond strength is satisfactory is, of course, governed by the end use.

Adherence.—The adherence of the above electroplates to pretreated thorium was excellent. In no case could the electroplated metal be peeled from the thorium at the electroplate-thorium interface by the tests described below.

Adherence tests for copper, nickel, and silver-plated thorium were made by: filing and/or grinding across the interface (in a direction to drag the plate away from the thorium); chiseling along the interface; and bending a flat 40-mil-thick specimen around a ¼-in. mandrel, reflattening, and bending back around the mandrel. A minimum thickness of 1 mil of electroplate was deposited for the above tests.

Solderability.—Soldering copper- or nickel-plated thorium pieces together with a lap joint and separating by flexing the joint fractured the sample in the soft solder. Thus the adherence of the plate exceeded the strength of the soft solder, about 6000 psi.

Cyclic heating and cooling.—Copper-, nickel-, and silver-plated thorium specimens were cyclicly heated (in argon) for 15 min at 100° intervals up to 700°C successively and quenched through air into cold water. Zinc-plated thorium was heated only to 400°C.

Bend tests were made to find the temperature at which diffusion alloying would degrade the bond strength. The bond of zinc-plated thorium was satisfactory after heating to 400°C (19°C below the melting point of zinc). The bond of copper-, nickel-, and silver-plated thorium was satisfactory up to 500° or 600°C. Since thorium metal or alloy remained firmly attached to the electroplates when the samples were bent after heating to 600° or 700°C, the bond failure was attributed to the interfacial alloy layers that were weaker than the electrodeposited metal or the thorium.

Thorium is known to alloy with most metals. Interdiffusion of the electroclad metal and the thorium, along with the melting point of the clad or eutectic alloys formed, appears to establish limiting conditions for the use of plated thorium at elevated temperatures.

Corrosion.—Thorium corrodes readily in hot water, oxidizing and/or hydrating to form a layer of loose powdery corrosion products that can be brushed off easily. Corrosion weight changes of +72 mdd to −14 mdd have been reported. No doubt the variance in data is due to retention or removal of loose corrosion products for obtaining the weight-change data.

Table I. Corrosion rate in distilled water at 203°F (95°C)
Duration of test: 6 weeks

Surface coating on thorium	Corrosion rate in mdd
None*	−7.4
Anodized*	−1.7
Anodized and heated*	−0.7
Copper electroclad†	+0.9

* Loose corrosion products removed before weighing.
† Copper was plated in several steps with intermediate burnishing (to close porosity) and periodic heat treating in vacuum at 400°C (to decompose hydrides and remove entrained hydrogen). Copper tarnished during corrosion.

Anodizing (electropolishing) and heat treating or copper electrocladding appreciably reduced the corrosion of thorium. The corrosion data are presented in Table I. The corrosion of thorium was reduced about 90% by anodizing and heating to form a protective thorium phosphate film. The slight weight gain for copper-electroclad thorium was attributed to tarnishing of the copper and possibly to entrapment of water in the copper cladding.

Conclusions

Thorium surfaces pretreated by anodic pickling in hydrochloric acid and chemical pickling in sulfuric acid can be electroplated with coatings of most metals. The adherence of the plated coatings is excellent and passes all the conventional adherence tests. Electroplated metals on thorium can protect thorium in boiling water and can aid soldering and/or joining to other metals. The use of electroclad metals on thorium for high-temperaure applications will depend on the proper selection of metals that form suitable alloys with thorium by interdiffusion.

Copper, iron, nickel, and silver directly on thorium offer promise for protecting thorium. However, further data on the diffusion of the electroplated metals and thorium along with the properties of the alloys formed are needed.

Electropolishing (anodizing) of thorium and heat treating imparts a protective coating that resists hot-water corrosion.

The Effect of Magnesium Salts on Nickel Plating Baths

Ahmad Geneidy[1] **and W. A. Koehler**

Department of Chemical Engineering, West Virginia University, Morgantown, West Virginia

and Willi Machu

Department of Chemical Engineering, Cairo University, Cairo, Egypt

ABSTRACT

The effect of magnesium salts was measured in Watts-type and Wesley all-chloride type nickel plating baths. The deposition potential of nickel was lowered (metal became more noble), polarization was reduced, and results on decomposition potentials were inconclusive. Nickel deposited from all baths under test had a face-centered cubic lattice, and magnesium was present only in spectroscopic traces. It was found that addition of magnesium salts increased cathode current efficiency, improved throwing power, and reduced porosity of the nickel, as revealed by the ferroxyl test. At low concentrations of magnesium salts the mechanical properties of nickel deposits were not changed materially, but at high concentrations deposits were harder, more brittle, and had a higher tensile strength. The effect on residual stress in nickel deposits was not measured.

It has been shown that properties of electrodeposited nickel are dependent on a number of factors. One of these is the nature and concentration of the so-called "conducting salts"; the most common of these salts are those of sodium, ammonium, and magnesium.

Addition of magnesium salts to nickel baths has aroused a controversial issue in the plating industry, since many beneficial and some harmful effects have been observed and reported. Opinions expressed by scientific workers as well as by practical platers were, in many cases, conflicting. Data to support both sides of the argument have appeared in the literature. However, no systematic study confirmed with quantitative data has yet been conducted. Needless to say, the presence of such data will, undoubtedly, help the plater to control behavior of the bath as well as properties of the deposit. To this end the present investigation was directed. Carefully controlled tests were made to determine the net effect of magnesium salts on the operation of nickel baths and on the properties of nickel deposit, and whether or not these effects are due to codeposition of magnesium.

The chief advantage of adding conducting salts to nickel plating baths is to increase the conductivity of the baths. Apart from the economic advantage of increasing the conductivity, better conductivity usually leads to better deposits, prevents formation of trees and rough deposits (1), and improves the throwing power (2-4). The effect of magnesium salts on the conductivity of nickel plating baths was reported by Hammond (5) and by Nicol (6). Reactions, functions, and mechanisms of magnesium and other conducting salts were discussed at length (8-11).

As a conducting salt, magnesium sulfate was added to nickel baths since the very beginning of the nickel plating industry. Adams, who commercialized nickel plating in Boston in 1869 (12), introduced in the following year his well-known patent (13) of a nickel bath containing magnesium salts and in 1899 Kugel established another patent (14).

The first study on the effect of magnesium was conducted in 1902 by Coehn (15) followed by Siemens in 1904 (16). Since then, magnesium sulfate additions have been recommended for nickel baths used in various fields of applications; for commercial rapid (17-20) and barrel plating (21) and also for plating on iron and stainless steel (22), as well as on nonferrous metals and alloys, particularly zinc and zinc base die castings (23-32) aluminum and is alloys (33-41), and lead (42).

Magnesium sulfate additions have also been reported in nickel baths recommended for producing a rust-resisting nickel plate (43, 44), a detachable and elastic nickel film on a nickel base (45), and for plating phonograph records (46). Magnesium sulfate has also been added to improve throwing power (47), to produce mat silver-white deposits (48) that are free from pitting (49).

Nickel deposited from baths containing magnesium sulfate is soft, easy to buff (50), and can be bent, twisted, or rolled without stripping or peeling off the plate (51). However, Makar'eva (52) found that the addition increases hardness and produces a deposit that is more lustrous and more uniform in texture, and that changed very little with change in current density or temperature. The effect of magnesium on stress is not yet agreed upon (53, 54).

Robinson (55) considered magnesium sulfate as the most suitable conducting salt in nickel baths. Baths containing this salt kept up their metallic concentration, produced even anode corrosion, and showed no pitting. Nickel deposited from such baths were whiter, resisted action of acids and did not rust as quickly, retained their luster longer, and were

[1] Present address: Cairo University, Cairo, Egypt.

more readily cleaned and polished than deposits obtained in the absence of magnesium sulfate. Thirteen years later, Barrows (56) confirmed Robinson's findings relative to that "indifferently recognized aid to better plating."

In spite of reported beneficial effects of adding magnesium sulfate to nickel plating baths, some objections against its use had been raised (57-59).

Magnesium chloride additions are also common, although to a lesser extent. The function is either to increase conductivity (60) or to increase anode corrosion in sulfate baths (61-65) or as a halogen carrier in a bright bath (66).

In addition to being introduced intentionally as magnesium slats, magnesium can be also introduced in small amounts from nickel salts (67), nickel anodes (68-71), water (72-74), and from chemicals added to introduce ions or radicals other than magnesium (75-77).

Experimental

Purification and preparation of the test baths.— This was effected in a Pyrex glass cylindrical container. Heating was accomplished by immersing the container in a constant temperature water bath while agitating by bubbling purified compressed air through a perforated Pyrex glass coil which rested on the bottom of the container. Air was purified by passing it through columns packed with glass wool and charcoal to capture any entrained oil.

Concentrated solutions of plater's grade nickel sulfate and of nickel chloride were prepared and to each solution 2 ml of 30% hydrogen peroxide was added per liter of solution. The temperature was raised to 70°-75°C (158°-167°F), and the *p*H was then raised to 5.8 by slow addition of a freshly prepared slurry of nickel carbonate. Solutions were stirred vigorously at that temperature and *p*H for 2 hr, after which the precipitates were allowed to settle. After filtration, the solutions were electrolyzed at low current density. Due to the limited available quantity of electrolytic nickel, platinum anodes were used; cathodes consisted of thin nickel sheets to avoid the possibility of introduction of impurities at very low current density areas, as might be the case if steel or nickel plated steel were used. Electrolysis was continued at 0.2 amp/dm^2 (2 a.s.f.) until 120 amp-hr/gal were passed, and then at 0.5 amp/dm^2 (4.6 a.s.f.) until at least 30 amp-hr/gal had passed. Finally, the solutions were electrolyzed at 5 amp/dm^2 (46 a.s.f.) for 6 hr. The hot and well-agitated solutions were then treated with 7.5 g/l (1 oz/gal) of activated carbon. After allowing the solutions to stand for a few hours, they were filtered.

The effectiveness of this purification cycle was tested by spectroscopic analysis of a nickel sheet deposited nonadherently on a stainless steel cathode at the specified operating conditions. After thus purifying the separate concentrated solutions of nickel sulfate and nickel chloride, test baths shown in Table I were prepared by mixing and/or dilution of purified concentrated solutions.

Baths chosen for this investigation are the Watts sulfate and Wesley all-chloride types of nickel baths since they are the two most commonly used baths apart from the bright ones. Of the different types of Watts baths, the one selected was chosen because it is very widely used in actual practice; it has nearly the same nickel content as the Wesley bath, and it has been subjected to some investigations.

Since anions have a decided influence on the character of the deposit, it was decided to add magnesium sulfate to Watts bath and magnesium chloride to Wesley bath. Furthermore, in order to permit a fair comparison of the effects of magnesium ions in the two baths, magnesium salts were added in equinormal amounts rather than in equal percentages. Concentrations of the magnesium salts were selected to cover the range of usual additions. In order to facilitate reference to the different test baths, a bath symbol was assigned to each type; the letter S (sulfate) is a symbol of the Watts sulfate bath while C (chloride) indicates the Wesley chloride bath. The bath symbol is followed by a numeral which indicates the normality of the magnesium salt added.

Operating conditions. — Operating conditions chosen for this investigation were as follows: current density, 4.3 amp/dm^2 (40 a.s.f.); temperature, 60°C (140°F); *p*H (electrometric) 2.

Measurement of cathode and decomposition potentials.—Measurements of the deposition potentials were effected in a small rectangular glass trough measuring 15 x 6 x 6 cm. The two anodes and the cathode measuring 6 x 1.0 x 0.1 cm each were cut from electrolytic nickel sheet and placed 5 cm apart. Although dimensions of the electrodes did not allow ideal conditions of uniform density, results thus obtained were in agreement with those obtained by Wesley and Roehl (78) with measurements made in a box similar to Haring cell which provides better means for measuring electrode potentials. The close

agreement between the two data indicate the reliability of the measurements carried out in the previously mentioned manner. Moreover, we were chiefly concerned with reproducible relative values rather than exact absolute ones. The potential of the cathode was measured against a saturated calomel electrode. Connection with the cathode was effected through a glass U-tube, one stem of which was drawn to a capillary, which was bent through 90° and pressed against the cathode.

The electrolysis cell, containing 400-500 ml of solution under test, was immersed in a constant-temperature water bath at 50° ± 0.1°C, while the calomel electrode was at room temperature. The solution was not stirred. No difference was observed when the solutions were tested as prepared or after being boiled to expel dissolved oxygen. After recording the static potential, a very small current was applied for a sufficient length of time to attain equilibrium. Equilibrium was assumed to exist if two consecutive readings of the potential made 4 or 5 min apart differed only by a fraction of a millivolt. Usually equilibrium was attained within 20 min.

Decomposition potentials were made in the same cell and in the same manner except that the electrodes were all made of platinum sheet. No effort was made to measure decomposition potentials with great precision.

Cathode current efficiency and throwing power.—Cathode current efficiencies were determined by the increase in weight of a nickel cathode. Measurements were made in a rectangular glass trough 12 x 7 x 6.5 cm (4¾ x 2¾ x 2½ in.). The two anodes and the cathode were all cut from thin nickel sheet 1 mm (0.04 in.) thick. With the cathode placed midway between the two anodes and the area of all electrodes exactly filling the cross section of the trough, a uniform current density was secured on the cathode.

Measurements were made in triplicate with the efficiency cell at 60°C while a copper coulometer connected in series was at room temperature. For each bath, the current efficiency was determined at three current densities: 2.1, 4.3, and 6.4 amp/dm^2 (20, 40, and 60 a.s.f.). Results were reproducible to ±1%.

Throwing power determinations were made in the same troughs. The anodes were perforated with 3/32 in. holes. Determinations were made at two primary current distribution ratios: 5:1 and 2:1. In calculating the current density, only the areas of the two sides of the cathode facing the anode were considered. A run lasted usually 45 min.

Mechanical properties.—For testing mechanical properties, a sheet of nickel 0.25 mm (0.01 in.) thick was prepared from each bath by plating nonadherently on a stainless steel sheet, type 302, about 0.079 mm (0.031 in.) thick. The cathode measured 20 x 18.7 cm (8 x 7.5 in.)

The plating jar consisted of a rectangular glass trough measuring 20.6 cm long x 36.5 cm high x 16.2 cm wide (8¼ in. x 3 in. x 6.5 in.). The anode consisted of electrolytic nickel which was analyzed by spectroscopic methods and was enclosed in a high-quality cotton bag. One anode and one cathode were used, both filling the cross section of the plating jar. The pH of the solution, which always tended to rise, was kept constant at the required value by allowing acid to drip from a buret. Agitation of the solution was effected by two electrically driven propeller-type glass rods. Pitting was prevented by adding 0.4-0.5 ml of 30% hydrogen peroxide to every liter of the bath. Decomposition of the hydrogen peroxide was ascertained by testing with a dilute solution of potassium permanganate.

The electroformed nickel sheet obtained from each bath was cut into 2.5 cm (1 in.) strips with the long dimension corresponding to the horizontal dimension of the original sheet. Strips were then machined to the form recommended by A.S.T.M. specifications E8-46 for thin sheet material, except that the length of the strip was 18.7 cm (7.5 in.) instead of 20.3 cm (8 in.). Specimens were tested in a Baldwin hydraulic testing machine. After the tensile strength test was completed, the zone where fracture occurred was noted and the dimensions of that zone, previously measured, were used in the calculation of the cross-sectional area. The per cent elongation was calculated by the increase of a 5 cm (2 in.) gauge length. Usually two sets of gauge marks were made in the reduced section of the specimen so that the fracture would very likely take place with one, if not both pairs. However, in some specimens the fracture occurred just near or even outside the gauge marks; in such cases no elongation measurements were obtained. At least five specimens of each type of deposit were tested. Reproducibility of the tensile strength measurements was within 10% while that of the elongation measurements was very much poorer, although all specimens were free of pits and microscopic defects.

Hardness measurements were made by an Eberbach microhardness tester using a load of 323.2 g. Indentations were made on the cross section of the deposit (cross-sectional hardness) as well as on the inner surface of the deposit which was adjacent to the basis metal (surface hardness). Usually, at least seven hardness measurements were taken for each type of deposit. Reproducibility of the results was within 10%.

Structure.—To obtain samples for metallographic examination, two small pieces were cut from the electroformed nickel sheet; one of these pieces was mounted in Bakelite in such a way that the cross section perpendicular to its plated surface was exposed. The other piece was mounted so that the surface originally adjacent to the stainless steel cathode was exposed. Electrolytic etching using different electrolytes under varying conditions did not give satisfactory results. Good results were obtained through using the "flat solution," consisting of a mixture of equal volumes of concentrated nitric and glacial acetic acids. The structure was photographed in a Bausch and Lomb metallograph.

X-ray patterns were obtained by the powder method in a North American Philips Diffraction unit using a cobalt tube and an iron filter.

Porosity.—Samples for porosity were obtained by coating a thin layer of nickel 0.025 ± 0.0025 mm (0.001 ± 0.0001 in.) thick on low carbon (0.15% C)

steel pieces measuring 18.7 x 20 cm (7.5 in. x 8 in.). Steel cathodes were prepared according to the A.S.T.M Designation B 183-49 (79).

The corrosive solution used was that recommended by Thon, *et al.* (80) which consists of 50 g/l of potassium ferricyanide and 0.2 g/l sodium chloride. The test was carried out in the manner mentioned in the British Standard 1224-1945. At least five determinations were made from each bath.

Determination of magnesium. — Spectrograms were obtained by shaping two pieces of the electroformed nickel sheets from each bath to form the two electrodes for the spectrograph. These were then excited by a d-c arc at 5 amp for 60 sec. The nickel standard was excited for 5 sec only. Analysis was then conducted in the usual manner using the internal standard method.

Results

Cathode potentials and cathode polarization curves are shown in Fig. 1, 2, and 3. Figures 4 and 5 show the effect of magnesium on the cell voltages and on the decomposition potentials of the different baths.

Results of cathode current efficiencies are shown in Fig. 6 and 7.

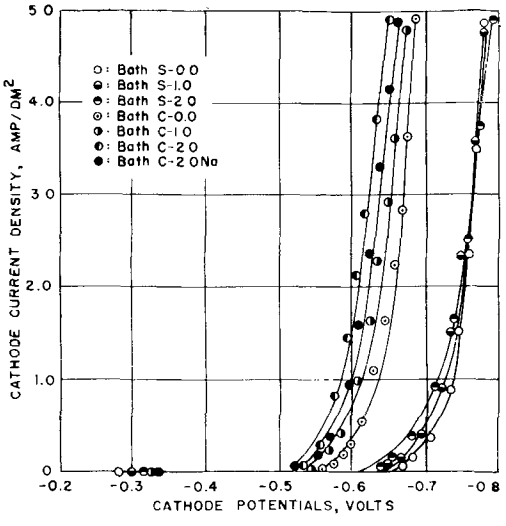

Fig. 1. Cathode potentials for nickel baths at 50°C against a saturated calomel electrode.

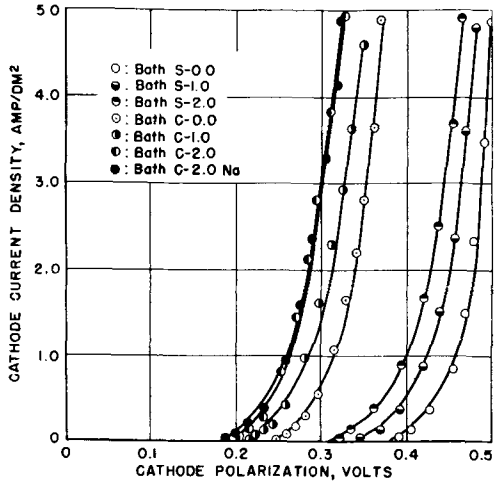

Fig. 2. Cathode polarization in nickel baths at 50°C

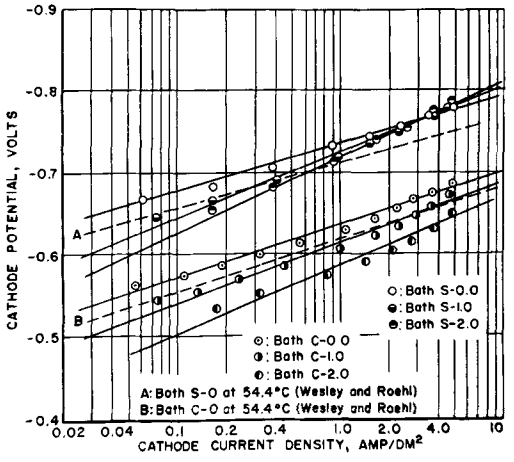

Fig. 3. Cathode potential vs. current density curves for nickel baths.

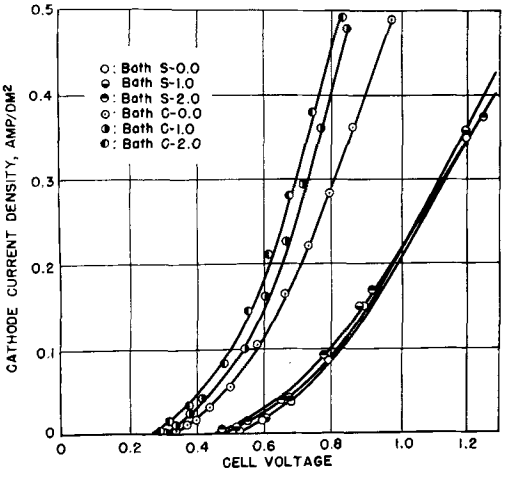

Fig. 4. Cell voltages in nickel baths

Throwing power data are plotted in Fig. 8. Data are submitted on the three scales: Haring and Blum scale (3), Heatley's modification (81), and the British Standard Institution (B.S.I.) scale. Each point on each curve is the average of three determinations.

Mechanical properties data are plotted in Fig. 9, 10, and 11. In Fig. 10, the elongation value corresponding to bath S-0.1 was not included since the fracture of the specimens occurred either outside the gauge marks or just adjacent to them.

Photomicrographs of the various deposits are shown in Fig. 12, 13, 14, and 15. X-ray patterns for the Wesley baths are shown in Fig. 16.

Corrosion resistance data are plotted in Fig. 17. Corrosion resistance is expressed as the reciprocal of the number of spots revealed by the ferroxyl test per square decimeter of the tested deposit.

Figure 18 shows spectrograms obtained from the standard nickel specimen and deposits from Wesley-type baths.

Table II summarizes some of the important data obtained in this investigation.

Discussion

Deposition potential, polarization, and decomposition potential.—Deposition potential and polarization data were investigated since they influence the

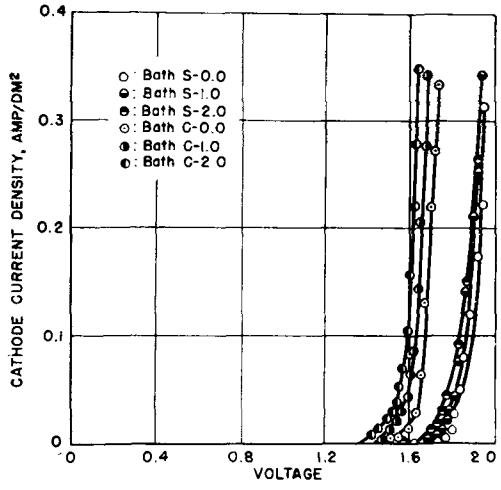

Fig. 5. Decomposition potentials for nickel baths at 50°C

following four characteristics (82): (*a*) structure of the deposit; (*b*) cathode current efficiency; (*c*) throwing power; and (*d*) alloy deposition.

It has been shown by others that there exists a relation between cathodic polarization and the structure of the deposit (1, 83-85). In some cases, the relation was not verified (86-90). This led to the introduction of the "interference" concept (91). However it is believed by some investigators that there must be some connection between cathode potentials and formation of electrodeposited metal (92).

Concerning throwing power, high cathodic polarization improves that important property (93, 2, 94). In this respect, the significant criterion is the slope of the cathode potential vs. current density curve.

Cathodic polarization affects alloy deposition in the same manner as it affects hydrogen evolution.

In the present study it is evident from Fig. 1 and 2 that addition of magnesium slightly makes the potential of nickel more noble and lowers cathodic polarization. That this effect is not due to formation of insoluble magnesium hydroxide is shown by the fact that bath C-2.0Na showed the same trend as the other baths.

The previous result is not in agreement with that of Thompson (27) who reported that magnesium increased cathodic polarization and cathodic current

efficiency as well. Thompson attributed these two contradictory phenomena to the common ion effect and to increased density and viscosity of the solution due to addition of magnesium salt. If this is the case, addition of magnesium chloride to a nickel chloride bath should also increase cathodic polarization. However, this was not verified by Verdick, *et al.* (95) who found that, at high concentrations of magnesium chloride, nickel was deposited more easily. These workers tried to explain this and similar phenomena by a theory involving complex ion formation.

It seems that the problem is open to more fundamental study to establish the possibility of complex ion formation and to reveal the part played by the degree of dissociation and solvation of molecules and similar factors which govern the very nature of the delicate process of deposition.

Figure 3 shows that the addition of magnesium increases the slope of the cathode potential vs. current density curve. This should tend to improve the throwing power of the baths.

Curves of Fig. 5 indicate that addition of magnesium causes a slight decrease in the over-all potential. This decrease may be entirely due to decrease in resistance of the bath.

Cathode current efficiency.—Cathode current efficiency is significant as it determines the useful portion of electric power consumed, liberation of hydrogen, maintenance of a constant pH during plating, and throwing power of plating baths.

Figure 6 shows that the baths under test have high cathodic current efficiencies. There is, however, a slight increase in these efficiencies after addition of magnesium. This is in agreement with results obtained earlier (27).

Concerning the rate of change of cathodic current efficiency with current density which affects throwing power, Fig. 7 indicates that there is no consistent change in one direction or the other, and differences observed are within the reproducibility of results and experimental errors. It is concluded, therefore, that this factor will have very little, if any, effect at all on the throwing power of the nickel baths under test under the conditions of this investigation.

Throwing power.—Good throwing power is a desirable property in plating solutions since it is generally found that a bath with a good throwing power

usually yields a good smooth deposit. It helps to give uniform thickness of plate with subsequent economic advantage. It is also important in plating more electronegative metals and alloys.

Figure 8 shows that there is a small but consistent increase in throwing power with increasing concentrations of magnesium. There was contradiction in the results of earlier investigations (27, 59). However, magnesium sulfate was usually added to improve the throwing power in nickel baths (47, 50).

The effect of magnesium can be predicted by analyzing its effect on the three factors which determine throwing power, namely, conductivity, rate of change of cathode potential and of cathode current efficiency with current density. By referring to Fig. 4 and to the work of Hammond (5) and Thompson (27) it will be clear that addition of magnesium sulfate increases the conductivity of nickel baths. Also, it was previously shown that addition of magnesium increases the slope of the cathode potential vs. current density curves. The third factor is not affected as has already been stated. It may be concluded therefore that addition of magnesium improves the throwing power partly due to an increase in conductivity of the bath and partly due to an increase in the rate of change of cathode potential with current density.

Mechanical properties.—Mechanical properties are of prime importance in determining the engineering qualities of electrodeposited metals. The tensile strength indicates the amount of distending force per unit area that the deposit can withstand before its fracture. Ductility is important if the plate is subjected to deformation or to machining operations. Elongation is associated with ductility and is usually taken as a measure of the latter. Hardness is also important in determining the ease of polishing and buffing. It is related to the resistance of abrasion.

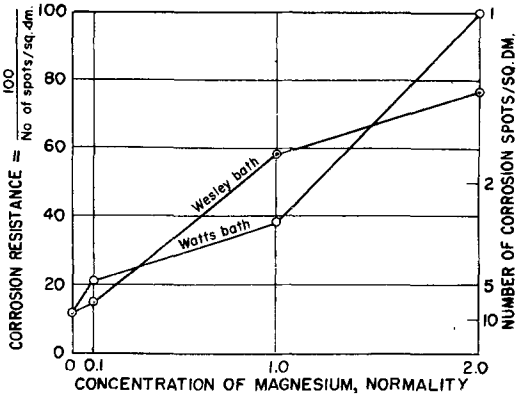

Fig. 17. Effect of magnesium content of nickel baths on the corrosion resistance of the deposits.

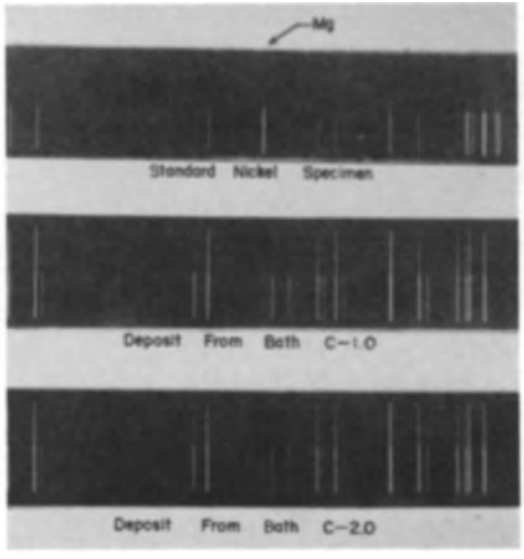

Fig. 18. Magnesium lines in the spectrum of nickel deposited from Wesley bath containing different concentrations of magnesium chloride.

Mechanical properties are affected by a large number of factors and many theories have been propounded to account for the net influence of these factors, the latest being that of Brenner and his associates (96).

Figures 9, 10, and 11 show that up to a concentration of one normal of magnesium salts, there is no appreciable change in the mechanical properties. When the concentration of the salts is twice normal, the resultant deposit has a higher tensile strength, is less ductile, and is harder. Opinions concerning the effect of magnesium are quite contradictory (97, 52, 73, 50). The recent investigation of Brenner and his associates (96) has proved that addition of 0.5*N* sodium sulfate or potassium sulfate to Watts-type bath did not result in any appreciable effect on mechanical properties. This has been shown, in the present investigation, to be true also in the case of magnesium salts up to a concentration of 1*N*. It is also found that the effect of magnesium is almost independent of the anion associated with it. The effect of high concentration of magnesium could not be attributed to codeposition of magnesium since this metal was found only in spectroscopic amounts as will be demonstrated later. The effect may be attributed to different factors such as increased density and viscosity of the solution, changing the rate of arrival of hydrogen and nickel ions to the cathode surface, or changing the nature and thickness of the cathode film. Unfortunately, our present knowledge based on available data is not quite sufficient to clear out this point.

Figure 11 shows that there is some difference between the cross-sectional and surface hardness with a general trend toward greater hardness on the surface. A similar phenomenon was observed by Cuthbertson (98) who attributed it to the anisotropic nature of electrodeposits, but it may also be due to the finer grain size of the deposit first laid down.

Structure.—The structure of electrodeposits is quite significant because of the relation which exists between it and mechanical properties. The structure was studied in the two directions parallel to the two different directions of linear crystallization, i.e., parallel to and normal to the cathode.

The effect of magnesium on structure has not been reported except in very few general statements (7, 99). In the present investigation, some modification in the structure was noticed usually at higher concentration of magnesium. In Fig. 13, for example, it is seen that the surface structure of the deposit obtained from bath S-2.0 is somewhat finer than that obtained from bath S-0.0. Also, in Fig. 14, the deposit from bath C-2.0 has a more pronounced needle-like structure. It has already been demonstrated that this modification in structure is accompanied by a change in hardness.

Structure by x-ray diffraction.—X-ray diffraction methods were conducted to examine the influence of magnesium on the crystal structure of electrodeposited nickel, and to detect the presence of magnesium or nickel-magnesium alloys if they were present in a fairly large percentage, as was reported earlier.

X-ray diffraction patterns, Fig. 16, show that the addition of magnesium has not changed the crystalline structure of nickel which is deposited from all baths under test with a face-centered cubic structure. It has been reported previously that, according to conditions, nickel can be deposited with a face-centered cubic structure or a hexagonal close-packed structure or a combination of both (100-102).

The patterns show also that magnesium lines do not appear. It is concluded, therefore, that nickel deposits do not contain magnesium or nickel-magnesium alloys, at least not in appreciable amounts. This necessitated further analysis of the deposits for trace amounts by spectroscopic methods.

Porosity.—Porosity determines to a large extent the protective value of nickel in ordinary atmospheres. Many methods have been used for determination of porosity. While atmospheric exposure tests are the most reliable, the ferroxyl tests are extensively applied and, in many cases, they give the best reproducible results which are parallel to those obtained by atmospheric exposure tests. In the present investigation, porosity was determined by hot water and ferroxyl tests. The former did not give consistent results.

Figure 17 shows that there is no essential difference in the porosity of deposits, expressed as corrosion resistance, between the Watts- and Wesley-type baths. However, the addition of magnesium to both baths has resulted in a marked increase in corrosion resistance of the resultant deposit. Increased corrosion resistance may be the result of the lower deposition potential mentioned before. This may have reduced the tendency for the nickel deposits to be pitted.

Magnesium in nickel deposits.—Early investigators had reported that magnesium was codeposited with nickel at fairly high percentages (15, 16, 103, 97), which may amount to as high as 10%. These results had led to the belief that magnesium is codeposited with nickel from aqueous solutions and that changes in the nature (104) and whiteness (29) of these deposits are attributed to such deposition. Later investigations could not verify these earlier claims (27, 59, 105) and neither does the present investigation. Table II shows that magnesium is found in deposits from baths containing magnesium but only in spectroscopic amounts. There is, however, a gradual increase in the magnesium content following concentration of magnesium in the bath. The source of the magnesium present may be either from occluded solution or from magnesium hydroxide inclusions which may have been precipitated at the high *p*H prevailing in the cathode film.

Conclusions

As a result of the present investigation, it is concluded that addition of high concentration of magnesium to nickel baths makes the deposition potential of nickel more noble, reduces cathode polarization, does not change the face-centered cubic lattice of nickel, codeposits only spectroscopic traces of magnesium, increases cathode current efficiency slightly, improves the throwing power, reduces porosity, and makes nickel deposits harder, stronger, and less ductile.

In the plating industry, use can be made of the effect of magnesium additions to nickel baths. It is shown that by addition of 2*N* magnesium sulfate to the Watts bath, properties of the new bath, bath S-2.0, lie nearly midway between those of Watts and Wesley baths. This can be realized easily by inspection of Table II. It is true that the same effect can be brought about by increasing the chloride content of the Watts bath, but addition of magnesium sulfate has certain advantages:

1. Magnesium sulfate is less expensive than nickel chloride.
2. The corrosive nature of the Watts bath will not be increased, whereas it will be much increased if the nickel chloride content is increased. In the latter case, additional precautions against corrosion of the equipment will be necessary.
3. In the presence of magnesium salts, nickel baths hold their metallic concentration better than they do without magnesium salts; addition of acid to correct the *p*H is less often needed.
4. Addition of magnesium sulfate will improve the corrosion resistance of the deposit, whereas increasing the nickel chloride content will not improve that property. An evidence of this is the fact that the Wesley bath, which is made solely of nickel chloride, gives deposits having corrosion resistance identical to that of deposits obtained from the Watts bath. This result was found by Wesley and Carey (106) and was confirmed in the present work.

It is worthy to note that the above point stimulates the necessity of further research to determine whether or not addition of still higher concentration of magnesium sulfate to Watts bath will result in deposits having mechanical properties closer to those of deposits obtained from Wesley bath without the disadvantage of higher tensile stresses characteristic of these deposits.

Acknowledgment

Acknowledgment is made to the International Nickel Company, Inc., for furnishing materials used in this investigation.

Manuscript received Feb. 21, 1957.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1959 JOURNAL.
