Wave-Length Dependence of the Quantum Efficiency and Absorption of Powder Phosphors

Yasuo Uehara, Iso Masuda, and Yoshimasa Kobuke

Matsuda Research Laboratory, Tokyo Shibaura Electric Company, Kawasaki, Japan

ABSTRACT

A number of powder phosphors have been measured by a direct optical method. Results are compared with other published values. Although slight discrepancies are found for magnesium and calcium tungstate at the 2537Å position, the maximum quantum efficiency for magnesium tungstate is in good agreement with the published values. Good agreement is also found for impurity-activated phosphors. New data are presented for a number of orthophosphates. The quantum efficiency curves decrease more rapidly than the absorption curves toward both longer and shorter wave lengths from the peak position. The peaks of the quantum efficiency curves lie at longer wave lengths than those of the absorption curves. Reasons for these differences are discussed.

Knowledge of the wave-length dependence of the quantum efficiency and absorption of phosphors provides an important foundation for the theoretical interpretation of luminescent properties as well as for the development or technical application of phosphors.

The quantum efficiency of powder phosphors has been measured by several methods (1), i.e., by direct optical, lamp efficiency calculation, calorimetric, and comparison methods. The second method used by Thayers and Barnes (2) and others (3-6) consists of comparing the measured luminous efficiency of a fluorescent lamp with its calculated maximum efficiency. This method involves some ambiguous assumptions concerning the optical characteristics of the phosphor layer in the fluorescent lamp. With the third or calorimetric method (1, 7) it is difficult to carry out the measurement over a wide range of exciting wave lengths, because an intense source of ultraviolet radiation is required but not available. The comparison method (1, 6, 8) is unsuitable to determine the absolute value of the quantum efficiency. In the present investigation, therefore, the first or direct optical method (9-11) was used to measure the wave-length dependence of many powder phosphors.

Experimental Apparatus

The arrangement of the experimental apparatus is similar to that reported by Botden and Kröger (10) and is shown schematically in Fig. 1. The radiation from a low-pressure hydrogen lamp L is reflected by two concave mirrors A and B, then falls on the entrance slit of a Beckmann type monochromator MN. The monochromatic beam from the exit slit is projected on the layer of phosphor P or magnesium oxide Q through a 5-mm circular hole in the ellipsoidal aluminum mirror M of 100 mm diameter. The samples are placed interchangeably on the first focus of the mirror whose position is 2 mm from the plane of aperture of the mirror in order to concentrate the entire flux of reflected light from the sample onto the second focus of the ellipsoidal mirror. The phosphor sample consists of a 3-mm thick layer prepared by compressing the phosphor powder into a rectangular recess of approximate size 3 x 10 x 18 mm which is cut or machined into a rectangular metal block of slightly larger size. The layer of magnesium oxide powder is in turn covered with a freshly smoked layer of magnesium oxide. Thus the thickness of the magnesium oxide layer is also about 3 mm. The two samples are interchangeable by 180° rotation about the rotation axis of the sample holder R. Their geometrical positions are adjustable so as to be accurately identical after rotation.

The radiation reflected from the phosphor or magnesium oxide is concentrated by the ellipsoidal mirror onto a photomultiplier PM (RCA 1P28) placed at the second focus of the mirror. With a phosphor in the measuring position, filters with a cut-off at about 3500Å or 4000Å are inserted between the photomultiplier and sample in order to separate the fluorescent light from the reflected radiation. The spectral sensitivity of the photomultiplier was determined by comparing it with a vacuum thermopile at various wave lengths in the spectral region from 2200 to 8500Å. In this experiment, a 500-w Xe lamp (Osram XB0501) and an incandescent lamp with a tungsten ribbon filament

L, light source A, B, and C, concave mirrors; D, quartz prism; MN, Beckmann type monochromator; M, ellipsoidal aluminum mirror; P, phosphor layer; Q, plaque of smoked magnesium oxide; R, axis of rotation of sample holder; F, filter; and PM, photomultiplier.

were used as the source for ultraviolet and visible radiation, respectively.

For the measurement of the spectral energy distribution of fluorescence, a Zeiss Three Glass Prism Spectrometer combined with a photomultiplier (RCA 1P22) was used, as reported in a previous paper (12). All of the experiments mentioned above were made at room temperature.

Experimental Procedure

In order to measure the relative reflectance of the aluminum mirror M, a fragment cut from its flange was placed at the position of sample P in Fig. 1, and the intensity of monochromatic radiation reflected by it and then by the ellipsoidal mirror was measured at various wave lengths relative to that of monochromatic radiation projected directly onto the photomultiplier. The relative spectral reflectivity of the plaque of smoked magnesium oxide was measured in the same manner. Let i, i_A, and i_o be the photocurrents produced by the incident monochromatic radiation, by the monochromatic radiation reflected from the piece of the aluminum mirror, and from the plaque of magnesium oxide, respectively, then the relative spectral reflectance of the aluminum mirror R_M and that of magnesium oxide R_1 are determined by the following relations:

$$R_M \equiv K_1 R_A = \left\{ \frac{i_A}{i} \right\}^{1/2} \qquad [1]$$

and

$$R_1 \equiv K_2 R_o = \frac{i_o}{i R_M} \qquad [2]$$

where R_A and R_o are the absolute values of the spectral reflectance of the aluminum mirror and magnesium oxide, respectively, and K_1 and K_2 are proportionality constants. In these equations, the influence of the multiple reflection between the samples and the mirror on the radiation reflected by the samples and then by the mirror was neglected. The measured results are shown in Fig. 2. Curve (2) for magnesium oxide shows no noticeable selectivity over a wide range of the spectrum from about 3500 to 6000Å, in contrast to curve (1) for the aluminum mirror. This result suggests that the influence of the multiple reflection on the measurement is negligibly small, as assumed above.

In order to determine the quantum efficiency of pure phosphors such as magnesium tungstate, it is necessary to know the absolute value of the spectral reflectivity of magnesium oxide, which is known to be close to unity in the visible region of the spectrum (13). One can, therefore, accept the spectral reflectivity of magnesium oxide normalized to unity as the absolute one with a probable error of about 0.2% (13).

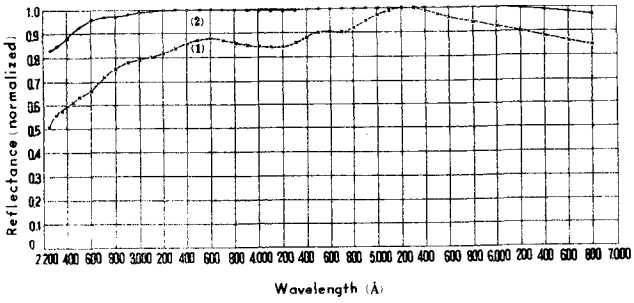

Fig. 2. Normalized reflection curves of aluminum mirror, 1, and magnesium oxide, 2.

It was verified by experiments that the transmittance for ultraviolet and visible light through a 3-mm thick layer of samples was practically zero. For such a layer, the relation between reflectivity R and absorptance A is given by

$$A = 1 - R \qquad [3]$$

Using this relation, one can determine the spectral absorptance by measuring the spectral reflectivity. The spectral reflectivity of unactivated phosphor base, of pure phosphor, and of impurity-activated phosphor is given by the following relations, respectively

$$R_b = \frac{i_b}{i_o} \cdot R_o \qquad [4a]$$

$$R_p = \frac{i_p}{i_o} \cdot R_o \qquad [4b]$$

and

$$R_a = \frac{i_a}{i_o} \cdot R_o \qquad [4c]$$

where i_b, i_p, *and* i_a are, respectively, the photocurrents produced with the layer of unactivated phosphor base, of pure phosphor, and of impurity-activated phosphor. Putting these relations in Eq. [3], the spectral absorptance of the pure and the impurity-activated phosphor is determined as follows:

$$A_p = 1 - R_p = \frac{i_o - i_p \cdot R_o}{i_o} \qquad [5a]$$

and

$$A_a = R_b - R_a = \frac{(i_b - i_a) R_o}{i_o} \qquad [5b]$$

Referring to Eq. [5b], it should be noted that A_a expresses the spectral absorptance due solely to the activators in the impurity-activated phosphor.

We shall define the quantum efficiency of the pure and the impurity-activated phosphors by the ratio of the emitted quanta to the quanta absorbed by the pure phosphor and by the activators in the impurity-activated phosphor, respectively. Then, the wave-length dependencies for the quantum efficiency of the pure and the impurity-activated phosphor are given by

$$\eta_p = \frac{i_{f,p} \cdot R_M \cdot S}{i_a / R_o - i_p} \times \frac{\int_o^\infty \lambda/\lambda e \cdot E_p \cdot d\lambda}{\int_o^\infty R_M \cdot S \cdot E_p \cdot d\lambda} \qquad [6a]$$

and

$$\eta_a = \frac{i_{f,a} \cdot R_M \cdot S}{i_b - i_a} \times \frac{\int_o^\infty \lambda/\lambda e \cdot E_a \cdot d\lambda}{\int_o^\infty R_M \cdot S \cdot E_a \cdot d\lambda} \qquad [6b]$$

where E_p and E_a are the respective energy distributions of the fluorescent emission, S is the spectral sensitivity of the photomultiplier, $i_{f,p}$ and $i_{f,a}$ are,

respectively, the photocurrents produced by the fluorescent emission with the pure and the impurity-activated phosphor, and λ and λ_e denote the wave length of the fluorescent and exciting radiation, respectively.

Since the spectral distribution of the emission of the phosphors measured was practically independent of the wave length of exciting radiation from 2200 to 4000Å, the integration of Eq. [6] can be carried out easily by numerical calculation. In order to measure the wave-length dependence of the quantum efficiency due to sensitizer and activator in the sensitized phosphors such as calcium halophosphate activated with Sb and Mn, the measured fluorescence spectrum was resolved into two bands due to sensitizer and activator. For example, the relative energy distribution curve of the Sb-band in calcium halophosphate activated with Sb and Mn was determined so as to fit it with that of the phosphor activated with Sb alone. By subtracting this curve from the energy distribution curve of the sensitized phosphor, the energy distribution of the Mn-band was determined.

In Eq. [6], the effect of absorption loss of fluorescent light through the powder on the measured quantum efficiency was neglected. Taking into account the absorption loss in the powder, Bril and Klasens (14) have already given the following approximate formula for the intrinsic quantum efficiency of fluorescence:

$$\eta_i = \frac{2}{1 + R_\infty}\eta_m \qquad [7]$$

where η_i and η_m are, respectively, the intrinsic and the measured quantum efficiency, and R_∞ is the reflectance of the thick phosphor layer for its fluorescent light. If the value for R_∞ is larger than 0.9, the correction factor according to Eq. [7] is less than 5%. On the other hand, the experimental errors in this experiment were about ±5%. The correction by Eq. [7], therefore, will be necessary only for phosphor layers whose reflectance in the visible region of the spectrum is smaller than 0.9.

Preparation of Phosphors and Experimental Results

Magnesium tungstate phosphors.—Three types of magnesium tungstate phosphors were measured. The first and second type had compositions of $MgWO_4$ and Mg_2WO_5, respectively. They were prepared by firing together the required proportions of magnesium nitrate and ammonium tungstate $[(NH_4)_2O \cdot 7WO_3 \cdot 6H_2O]$, with or without Pb and Cd in amounts of 1 mole %. Firing was at 980°C for 30 min followed by intimate grinding and a second firing at 1000°C for 1 hr. The third type phosphors were commercial products obtained from Sylvania Electric Products Inc. and from our factory.

Results for the first series of phosphors with and without Pb are shown in Fig. 3. The data for the second and third types of phosphors without added impurities were practically identical with those labeled (1) in Fig. 3, except for the Sylvania product whose quantum efficiency was about 5% smaller than that of the other magnesium tungstate phosphors. Addition of 1 mole % Cd to magnesium

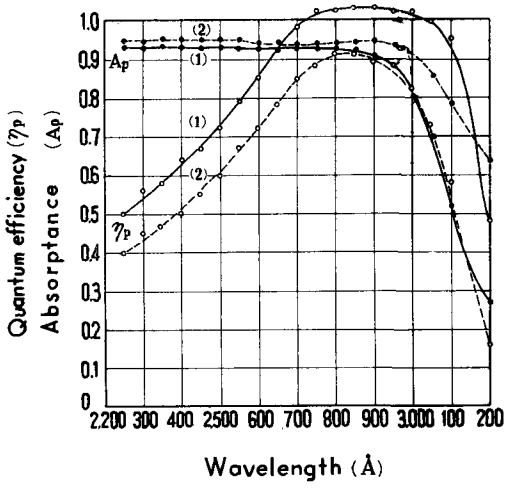

Fig. 3. Wave-length dependence of quantum efficiency and absorption for magnesium tungstate phosphors with or without Pb. 1, $MgWO_4$; 2, $MgWO_4$:Pb (10^{-2} mole).

tungstate of composition Mg_2WO_5 gave essentially the same curves as (2) in Fig. 3. Considering the experimental errors, the quantum efficiency of magnesium tungstate without added impurities is thus practically independent of its composition and close to unity in the spectral region from about 2750 to 3000Å. It is 0.75-0.80 at wave length 2537Å.

Calcium tungstate phosphors.—Six samples of calcium tungstate phosphors were measured. They were prepared by firing mixtures of 1 mole calcium nitrate and 1/7 mole ammonium tungstate with or without 0.4 mole calcium sulfate or 0.01 mole lead fluoride for two half-hour periods at 1000°C with intimate grinding between firings. In order to investigate the existence of nonluminescent compounds in the phosphor which absorb ultraviolet radiation uselessly (15), two samples of calcium tungstate phosphors with or without added calcium sulfate were washed with 5 wt % hot ammonium hydroxide aqueous solution.

Results for calcium tungstates are shown in Fig. 4. The phosphor with 0.4 mole calcium sulfate gave almost the same curves as those labeled (1) in Fig. 4. Washing with ammonium hydroxide decreases

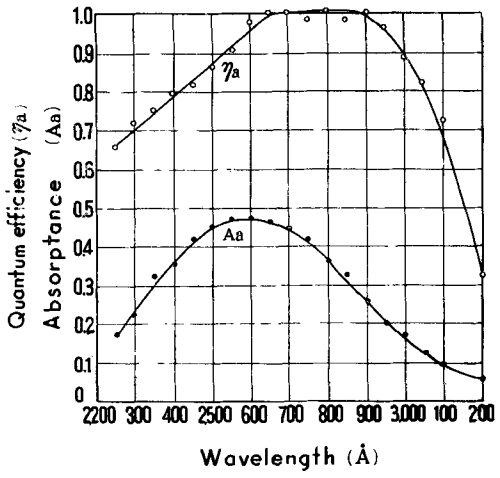

Fig. 5. Wave-length dependence of quantum efficiency and absorption for β-calcium orthophosphate activated with Cu, i.e., β-$Ca_{2.7}P_2O_8$:Cu (5×10^{-3} moles).

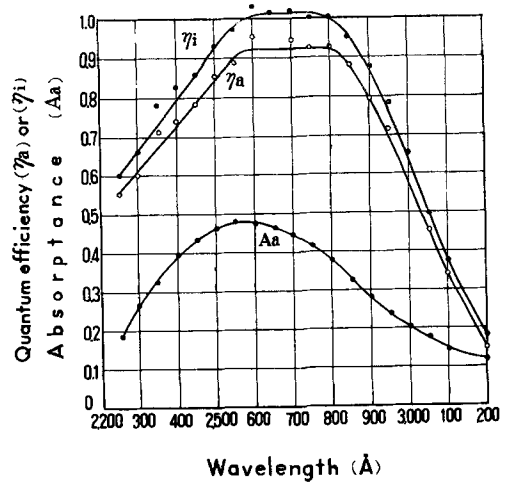

Fig. 6. Wave-length dependence of quantum efficiency and absorption for β-calcium-zinc orthophosphate activated Cu, i.e., β-$Ca_{2.7}Zn_{0.2}P_2O_8$:Cu(5×10^{-3} moles). η_a and η_i denote the measured and the intrinsic quantum efficiency, respectively.

the absorption of calcium tungstate phosphors with or without calcium sulfate slightly, while the quantum efficiency of both phosphors is increased by 5-10%. The maximum quantum efficiency of pure calcium tungstate phosphors, including the washed samples, is 0.50-0.62 at about 2537Å. The addition of 1 mole % Pb produces a remarkable increase in absorption and in the quantum efficiency in the spectral region above about 2500Å. In the spectral region below 2500Å, the quantum efficiency is slightly lowered by the addition of Pb. The maximum value of the quantum efficiency of calcium tungstate sensitized with Pb is about 0.77 at 2700Å.

Cu-activated β-calcium orthophosphate and related phosphors.—Data for Cu-activated β-calcium, β-calcium·magnesium, and β-calcium·zinc orthophosphate, together with those for pure orthophosphates without activators (used for the measurements) are shown in Fig. 5 and 6; the phosphors were prepared as reported in a previous paper (12).

The quantum efficiency of Cu-activated β-calcium orthophosphate is close to unity in the spectral region from about 2650 to 2900Å, as shown in Fig. 5, while that of Cu-activated β-calcium·zinc orthophosphate is about 0.92 in the same spectral region, as shown by the η_a-curve in Fig. 6. The spectral reflectivity of Cu-activated β-calcium and β-calcium magnesium orthophosphate averaged over the entire visible region of the spectrum was about 0.94, while that of Cu-activated β-calcium·zinc orthophosphate was about 0.81. Using Eq. [7], the intrinsic quantum efficiency of the latter phosphor was calculated. It is shown by the η_i-curve in Fig. 6. The curve for calcium·magnesium orthophosphate is quite similar to the η_i-curve in Fig. 6, but it is slightly lower; the maximum quantum efficiency of this phosphor is 0.99 around 2700Å. The absorption curve of this phosphor is in good agreement with that shown in Fig. 6.

Tin-activated calcium orthophosphate and related phosphors.—β-calcium orthophosphate phosphors activated with Sn and with Sn and Mn were prepared by firing mixtures of 1 mole calcium hydroxide, 2 moles dibasic calcium phosphate and 0.1 mole stannous chloride with or without 0.1 mole manganese carbonate for 30 min in air at 950°C and 1100°C, respectively, followed by firing in a reducing atmosphere (mixture of 25% H_2 and 75% N_2) for the same period and at the same temperature after an intimate grinding between firings. Pure β-calcium orthophosphate without activators was prepared by the same method.

Results are shown in Fig. 7. The curve for the quantum efficiency of the Sn-activated phosphor resembles somewhat that of the Cu-activated material, while the absorption curves are noticeably different. On the other hand, the absorption curves of the Sn and the (Sn + Mn) activated orthophosphate are quite close to each other, while the wave length dependencies of the quantum efficiencies are remarkably different.

As reported by Butler, the α-form of Sn-activated calcium orthophosphate is easily produced by firing at temperatures above 1175°C with low amounts of Sn, while the transition from the β- to the α-form of the phosphor is inhibited by the addition of

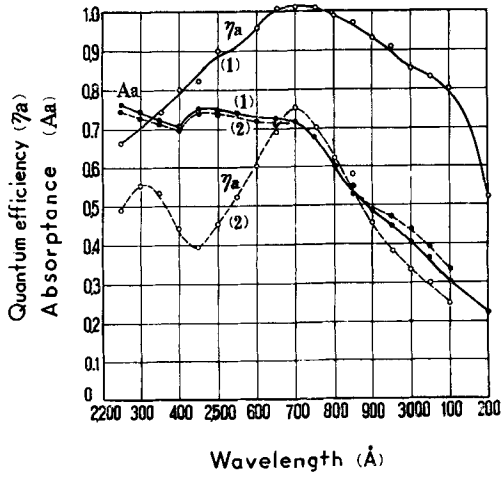

Fig. 7. Wave-length dependence of quantum efficiency and absorption for β-calcium orthophosphate phosphors activated with Sn and Mn.
1, $Ca_3P_2O_8$:Sn (0.1 mole); 2, $Ca_3P_2O_8$:Sn (0.1 mole), Mn (0.1 mole).

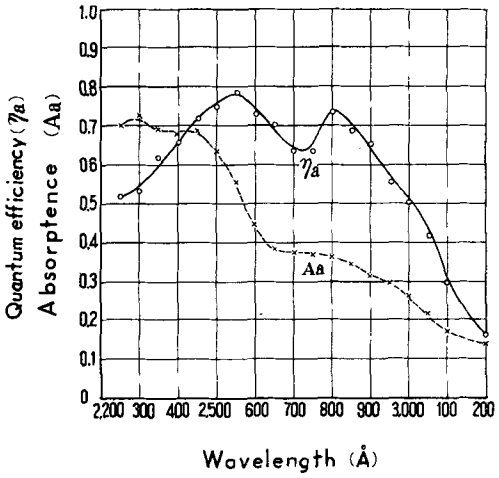

Fig. 8. Wave-length dependence of quantum efficiency and absorption for α-calcium orthophosphate activoted with 4 mole % Sn and containing 0.45 mole silica, fired at about 1200°C.

rather large amounts of Sn of the order of 4 mole %. It was found by the present authors that the conversion from the β- to the α-form with rather large amounts of Sn was promoted by the addition of silica during the preparation of phosphors. A series of Sn-activated calcium orthophosphate phosphors containing various amounts of silica were prepared by firing mixtures of 2 moles dibasic calcium phosphate, 0.9 mole calcium carbonate, silica in various amounts from 0.01 to 0.8 moles, and 0.04 mole stannous chloride for 30 min at about 1200°C in air, and then in a reducing atmosphere for the same period and at the same temperature after an intimate grinding between firings. Pure α-calcium orthophosphates without activators were prepared by the same method.

Results for Sn-activated α-calcium orthophosphate containing 0.45 mole silica are shown in Fig. 8. It was proved by x-ray analysis and by measurement of the fluorescent spectrum that it was typical α-calcium orthophosphate. The wave-length dependence of the quantum efficiency for Sn-activated α-phosphors is practically independent of the amount of added silica. It is quite different from that for the Sn-activated β-phosphor and resembles the curve for β-calcium orthophosphate activated with Sn and Mn. The absorption curves for Sn-activated α- and β-phosphors are rather different, and the intensity of the absorption band peaking at about 2800Å for α-phosphor is lower than that for β-phosphor.

Calcium·cadmium silicate phosphor activated Pb *and* Mn.—Calcium·cadmium silicate containing less than 30 mole % Cd and activated with Pb and Mn was described by Schulman (16). The phosphors used for the present measurements were prepared by firing a mixture of 0.8 mole calcium carbonate, 0.2 mole cadmium carbonate, and 1.2 mole silica with or without 8 x 10^{-3} mole lead fluoride and 0.1 mole manganese chloride for two 2-hr periods at 1180°C with an intimate grinding between firings. Results are shown in Fig. 9. Also shown as a dotted line (2) is the corresponding curve for the total (Pb+Mn) emission of calcium silicate activated with

2, calcium silicate: Pb, Mn (observed by Botden and Kroger).

Pb and Mn, as reported by Botden and Kröger (10). The two curves for the quantum efficiency are in good agreement in the spectral region above about 2650Å.

Calcium halophosphate phosphors activated with Sb or with Sb and Mn.—Calcium halophosphate phosphors of composition $3\,Ca_x\cdot P_2O_8\cdot 0.6\,CaF_2\cdot 0.4\,CaCl_2$ ($x = 2.7 - 2.8$) and activated with 0.3 mole Sb and various amounts of Mn ranging from 0 to 0.18 moles per mole calcium halophosphate, together with pure halophosphate without activators, were prepared by firing calcium carbonate and dibasic calcium phosphate with or without added Sb or Mn for two half-hour periods at 1100°C, with intimate grinding between firings.

Results for typical samples are shown in Fig. 10 and 11. The quantum efficiency of the phosphor

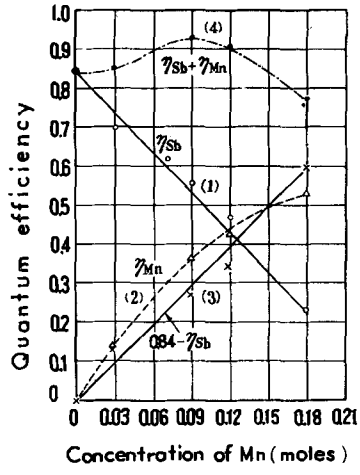

Fig. 12. Relation between quantum efficiency and concentration of Mn for calcium halophosphate phosphors activated with 0.3 mole Sb and various amounts of Mn from 0 to 0.18 mole per mole phosphor, excited with 2537Å. η_{Sb} and η_{Mn} denote the quantum efficiencies for the individual Sb- and Mn-bands.

activated with Sb alone is close to unity at wave lengths around 2750Å and 0.84 at 2537Å.

The relation between quantum efficiency and concentration of Mn for phosphors excited with 2537Å is shown in Fig. 12. With increasing concentration of Mn, the quantum efficiency for the Sb-emission, η_{Sb}, decreases almost linearly, while that for the Mn-emission, η_{Mn}, increases nonlinearly. Thus the total quantum efficiency of fluorescence, $\eta_{Sb} + \eta_{Mn}$, depends on the concentration of Mn. The straight line given by $0.84 - \eta_{Sb}$ expresses the concentration dependence of the quantum efficiency for the Mn-emission which might be obtained if the excitation energy absorbed by the Sb-centers were transferred to the Mn-centers with the same efficiency as that of Sb-centers alone. By comparing the observed with the calculated $(0.84-\eta_{Sb})$ values, it is seen that a part of the excitation energy, which is dissipated as heat energy in the Sb-centers, is transferred to Mn-centers in the sensitized phosphor and it leads to Mn-emission at concentrations below 15 mole % Mn; when the concentration of Mn ex-

ceeds 15 mole %, it is partly dissipated as thermal energy by the action of concentration quenching in the Mn-center. The absorption spectrum of these phosphors shown in Fig. 11 resembles that of Sn-activated α-calcium orthophosphate.

Discussion

Values for the measured quantum efficiency are summarized in Table I, compared with values reported in the literature. Our value for the quantum efficiency of magnesium tungstate at 2537Å is somewhat smaller than that reported by Fonda (9). This discrepancy does not seem to be due to phosphor differences but mainly due to the accuracy of measurements since the quantum efficiency of pure magnesium tungstate phosphors was independent of the samples used, as mentioned before. The maximum quantum efficiency and its wave length showed rather good agreement with the values reported by Fonda (9). The discrepancy of the quantum efficiency around 2537Å may be ascribed to the errors of the calibration of the photomultiplier or photocell used in these measurements. Furthermore, it should be noted that the quantum efficiency obtained by the lamp efficiency calculation method is likely to turn out too high because of neglect of the contribution of mercury lines other than the line 2537Å, for example, the line at 1850Å, to the luminous flux of the fluorescent lamp (18). Our value of the quantum efficiency of pure calcium tungstate is also somewhat smaller than that reported by the other authors. This discrepancy between these values may be due to the same reason as that for magnesium tungstate. The quantum efficiency of magnesium tungstate was decreased by the addition of Pb or Cd, while that of calcium tungstate was increased remarkably by the addition of Pb, as mentioned before. This fact is theoretically interesting with respect to the configuration of the luminescent center of tungstate phosphors.

In the impurity-activated phosphors, the quantum efficiency should be defined by the ratio of the emitted quanta to the quanta absorbed solely by activators, as shown by Eq. [6b]. Such a caution is especially important for the case in which the phosphor base shows a rather strong absorption in the ultraviolet region. It should be noted that the quantum efficiency of impurity-activated phosphors, based on the above definition, can be measured only by the direct optical method. Considering the sample differences, the quantum efficiency of halophosphate activated with Sb and with Sb and Mn shows good agreement with that reported by the other authors. The measured quantum efficiencies for the other impurity-activated phosphors seem to be reasonable.

In general, the quantum efficiency curves decrease more rapidly than the absorption curves at both longer and shorter wave lengths compared with the peak. For example, in the typical cases of magnesium and calcium tungstate, the quantum efficiency curves decrease gradually in the short wave-length region in which the absorption curves are flat, as shown in Fig. 3 and 4. The peaks of the quantum efficiency curves lie at a longer wave-length region than those of the absorption curves.

In principle, the wave-length dependence of the quantum efficiency of phosphors containing a single emitting state in the activator center should be flat over a wide range of the absorption spectrum, if the absorption is allowed only between the ground and the emitting state. If the absorption spectrum contains other absorption bands which are not responsible for the emission, the quantum efficiency should be reduced to small values in the corresponding spectral region. The rapid decrease of the quantum efficiency at longer wave lengths may be thus explained.

The decrease of the quantum efficiency at short wave lengths, however, seems to be attributable to another mechanism. It may be explained by a mechanism similar to that suggested by Dexter, Klick, and Russell (19) as an explanation for the low efficiency of F-center emission in alkali halides. We assume that the higher the vibration state in the excited state to which an electron makes a transition from the ground state, the larger becomes the nonradiative quenching of the excited state. The quantum efficiency will then decrease in the shorter wave-length region of the absorption spectrum. As a result, the peaks of the quantum efficiency curves will shift toward long wave lengths.

Acknowledgment

The authors wish to express their sincere thanks to Dr. Tsuneo Harada, the Director of Matsuda Research Laboratory of Tokyo Shibaura Electric Co., for his continuous support and encouragement. Part of this paper was presented at the Spring Meeting of The Physical Society of Japan, Fukuoka, April 9-11, 1957.

Manuscript received April 13, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Microscopic Observations on Electroluminescent Phosphors

A. Kremheller

Sylvania Research Laboratories, Bayside, New York

ABSTRACT

The electroluminescent brightness of single phosphor particles is studied microscopically in liquid dielectric cells. A simple visual technique in conjunction with a microscope permits one to analyze the brightness distribution within and among electroluminescent particles. Some experimental results are presented on the nonuniformity of the emission, the influence of ball milling and acid etching on the brightness, the improvement of brightness by particle separation, the analysis of the integrated light output as a function of the processing temperature, and the brightness changes due to particle orientation, contact, and irradiation.

Many investigations which aim at improving the brightness[1] of electroluminescent (EL) lamps are concerned with the integrated light output in evaluating the influence of the processing parameters in phosphor preparation. Although this approach is useful in testing and comparing finished products with each other, one does not learn much about the behavior of the single particles composing the EL layer. Even if one observes that a certain treatment improves the integrated light output, it is not evident how the improvement affects the phosphor particles, e.g., does an increased number of particles become electroluminescent, does every particle become brighter, or does the brightness distribution of particles change in some other way. These questions can be answered by observing the single EL particles. In this way, it is hoped that the analysis of the components of the integrated light output will finally lead to improved EL lamps by means of synthesis of the improved components. This paper shows in several examples that such an improvement can be attained by the microscopic study of single phosphor particles.

Experimental

Various EL phosphors have been studied in liquid, plastic, and glass dielectric cells. Some phosphors are of an experimental nature, while others are commercially available. Most brightness measurements are conducted with an adjustable-gap sandwich cell using castor oil as the liquid dielectric. The study of particle orientation, contact, and alignment is facilitated by using a gap-like cell. Its electrodes are about 0.5 mm high to avoid excessive edge effects with respect to the electric field.

[1] "Electroluminescent brightness" as used here is a measure of the luminous flux per unit emissive area of a single particle. (See also the definition of "brightness" in American Institute of Physics Handbook, Dwight E. Gray, New York, 1957, page 6-3.)

The particle brightness is determined by a method similar to that described by Zalm, Diemer, and Klasens (1) and has been adapted for our purpose. In this method, a relative estimate of the EL brightness of phosphor particles is obtained by employing photographic, neutral-density step filters in conjunction with a microscope. The filter is inserted into the optical path of the microscope until the EL particle remains just visible to the adapted eye; the step number is then a measure of the particle brightness. The opacity of the filter doubles with every two filter steps, so that 20 steps correspond to a change in particle brightness B by a factor of $2^{10} = 1024$. The logarithmic sequence of the opacity facilitates the plotting of log B if $2^{1/2}$ is used as the base of the logarithms. This simple visual technique permits comparison of the brightness from various regions within a single particle and among phosphor particles.

Nonuniformity of EL Emission

The importance of studying the EL brightness of single phosphor particles becomes apparent when an EL lamp is viewed under a microscope, and the considerable brightness variations from particle to particle are observed (Fig. 1). Only a minority of particles electroluminesces brightly, while some particles do not emit any EL light and others appear fairly dim.

Microscopic investigation of single particles permits one to measure their brightness and to produce a frequency diagram of the EL brightness (Fig. 2). The diagram indicates the degree of brightness variation. Since the base $2^{1/2}$ is used for log B, the brightness range is such that the brightest particles are about 50 times brighter than the dim ones. Actually, there are about 20% of the particles which do not

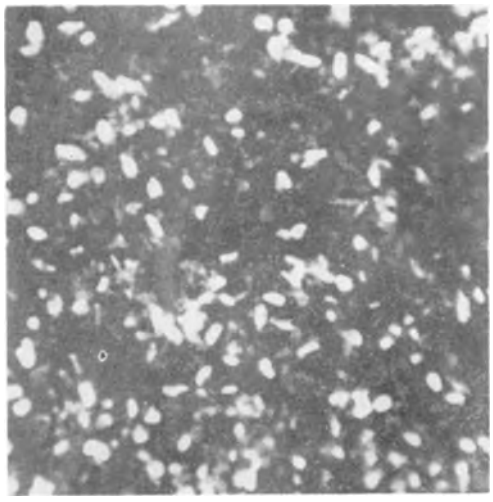

Fig. 1. Brightness variation among particles. Average particle diameter about 25 μ.

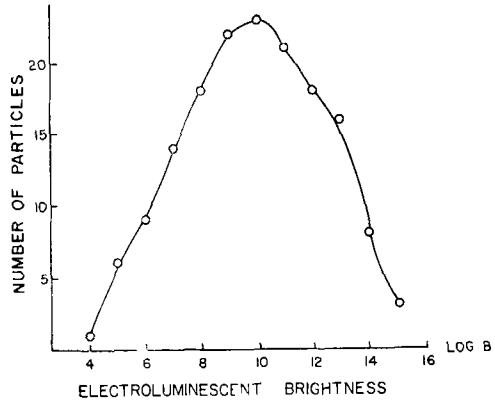

Fig. 2. Brightness distribution of electroluminescent phosphor particles; log B to the base $2^{1/2}$.

electroluminesce at all. Some of these "dead" particles do not show up in the photograph, others get some light from adjacent bright particles and can be seen. There is a most frequent particle brightness which is about 8 times the lowest brightness measured. The brightness-frequency diagram varies somewhat from phosphor to phosphor. In some cases a relatively flat peak or even 2 maxima have been observed.

Besides the brightness nonuniformity among particles, considerable brightness variation also occurs within single particles, as shown in Fig. 3. The emission seems to originate from particle regions[2] (usually the edges of particles) which appear opaque in transmitted visible light; it is also observed that the same opaque regions become photoluminescent under ultraviolet irradiation. The photoluminescence is, however, somewhat more uniform than the electroluminescence, as pointed out by other researchers (2). In addition to electroluminescent emission from extended areas, there is emission from spots (3); this spot emission is not observed during photoluminescence. The spot emission predominates at high frequencies (several kc) of the applied electric field. The spots occur usually in line arrange-

[2] In the review of this paper it was indicated that "the emission is, very likely, created only in small spots, and that the area emission is simulated mainly, or exclusively, by multiple reflections inside the crystals." The author feels that this statement is definitely valid at high frequencies, although primary area emission may occur at very low frequencies of the applied electric field.

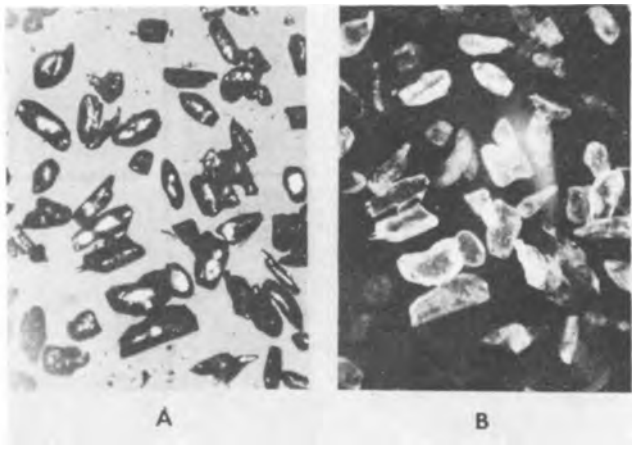

Fig. 3. Microscopic observation of phosphor particles: (a) in transmitted light; (b) under their own EL illumination. Average particle diameter about 120 μ.

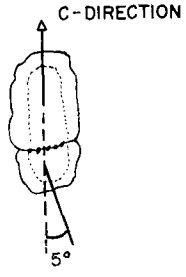

Fig. 4. Disorientation and spot emission along crystallite boundary.

ments, apparently located in fissures parallel to the c-plane (or 111-plane for cubic structure). It appears that these fissures separate contiguous crystallographic regions which are in many cases disoriented. The misalignment often amounts to 5° (Fig. 4), as the difference in extinction angle between crossed nicols indicates. Sometimes emission colors from spots and from areas are different; for instance, some (Zn,Cd) (S,Se) : Cu,Cl phosphors emit greenish-orange area and greenish-blue spot electroluminescence. It is possible that these color differences are caused by the nonuniformity of the electric field (4), or by the preferential optical absorption of the short-wavelength light in the bulk of the crystallite.

Ball Milling and Acid Etching

Another series of EL phosphors differs in that they have been ball milled prior to a final thermal treatment. Microscopic observation indicates that the milled phosphors exhibit an improved uniformity in EL brightness among and within single particles. The integrated light output increases in a typical case by 30% due to milling. As an attendant effect, milling introduces enough damage to particles to make most of them appear opaque in transmitted light. It is plausible that the particle damage during milling may contribute to an improved activator distribution (5) in the thermal processing step. In addition to this effect, it appears that surface damage increases the EL brightness by facilitating light emission which is otherwise lost by absorption due to internal multiple reflections.

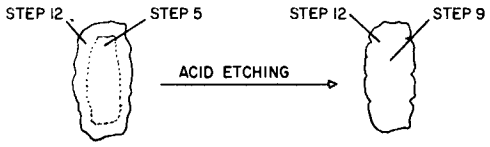

Fig. 5. Increase of emission uniformity by acid etching; the opacity values of the step filter indicate the relative brightness.

This hypothesis has been tested by acid etching of phosphor particles. A single phosphor particle (Fig. 5) is observed in a gap cell in castor oil. It is found that the edge has about 10 times greater EL brightness than the center region of the particle. The particle is removed from the cell, etched with concentrated HCl for a few minutes, and returned into the cell. The opacity of the center region in transmitted light is considerably increased by acid etching. The center region is now 4 times brighter electroluminescent than in the case of the original grain. The use of the step filter permits an estimate of the brightness improvement of the center region as a result of the acid treatment. The acid etching is not uniform over the whole grain; there is some preferential dissolution along grain boundaries, strained regions, and in strongly birefringent regions.

An increase in brightness and uniformity is also indicated by the slight shift of the brightness distribution (Fig. 6), which represents a large number of particles in the test cell. While there is no change in the maximum particle brightness, one obtains a slight increase in the most frequent brightness. The integrated light output is also measured, and an increase of 30% is observed which is due to the acid etching.

Particle Separation

Since the EL brightness of individual particles differs widely, attempts have been made to select bright particles for separate examination. This selection is sometimes comparatively simple; for instance, the bright particles may differ in size from the rest. A Zn(S,Se):Cu,I phosphor exhibited an unusual frequency diagram of the brightness distribution in that 2 peaks are observed (Fig. 7). The peak at high brightness is mainly due to the bright large particles. This green EL phosphor is fractionated so that particles above 80 and below 20 μ could be studied separately, since microscopic

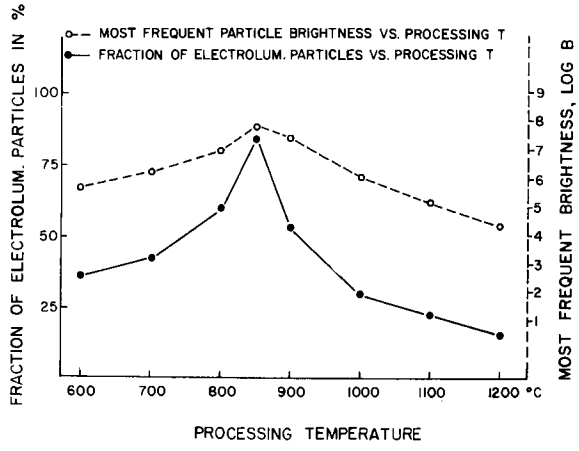

Fig. 9. Components of integrated light output vs. processing temperature.

observations had indicated that the large particles were brighter than the small ones. Measurements on the fractionated material show that the integrated light output from a liquid dielectric sandwich cell containing the coarse particles is up to 5 times as high as that from a cell containing the same weight of the fine particle size fraction (Fig. 8).[3]

Analysis of Integrated Light Output

Microscopic observation of single particles also permits analysis of the brightness characteristics as

[3] Measured by Dr. P. Goldberg of our laboratory.

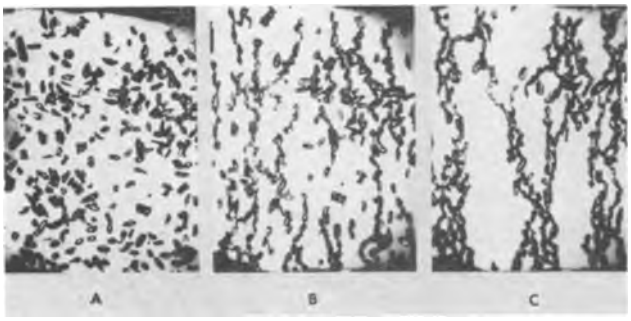

Fig. 10. Influence of electric field and irradiation on particle orientation: (a) random particle distribution, (b) orientation due to electric field, and (c) re-alignment due to irradiation with visible light. Average particle diameter about 70 μ.

a function of processing parameters, such as the preparation temperature. A series of blue-emitting EL phosphors has been studied for which the thermal treatment had been carried out at various temperatures between 600° and 1200°C. The integrated light output had been shown to be at a maximum for the material processed at 850°C. The study of the brightness of single particles reveals that this maximum in integrated light output results from optimization in two respects at this temperature, as indicated in Fig. 9. First, the fraction of particles which are electroluminescent peaks sharply at 850°C, and second, the most frequent particle brightness of the various frequency-brightness distribution curves is also at a maximum at this temperature.

Particle Orientation, Contact, and Irradiation

Phosphor particles in castor oil dielectric cells are readily oriented by electric a-c and d-c fields (6, 7). A change in voltage or frequency causes motion and reorientation of particles; some particles exhibit translational and rotational motion even at constant voltage and frequency. Especially the very small particles move erratically and appear to be charged and discharged by collisions with other particles. Randomly distributed particles (Fig. 10a) are oriented in an electric field; Fig. 10b shows the orientation with 1250 v/cm applied at 500 cps. During the orientational motion some particles become attached to one electrode while most particles become attached to other particles. The particles form oriented chains, with their elongation parallel to the electric field, and aggregates between the electrodes. Alignment and contact increase the EL brightness of many particles; although some particles remain nonelectroluminescent, others turn brightly electroluminescent. A brightness increase by a factor of 4 can be observed readily in many cases.

Although most particles align themselves with their elongation parallel to the applied electric field, there are some internally misaligned particles (some with adjacent crystallite regions disoriented by up to 10°, cf. Fig. 4) which align themselves with their aggregate elongation perpendicular to the electric field. It appears that this mode of alignment occurs when there is only little electrical contact between adjacent, elongated single crystal regions, which are consequently aligned with their single crystal elongation parallel to the electric field. This anomalous particle orientation is also connected with a marked increase in the EL brightness of such particles.

Irradiation with ultraviolet or visible light facilitates particle alignment and changes the brightness distribution. The threshold field for particle alignment under strong irradiation is considerably below that for the start of alignment in the dark. When partially aligned particles (Fig. 10b) are irradiated with visible light, the alignment as well as chain and aggregate formation continue until a new, fairly stationary arrangement is achieved, as shown in Fig. 10c. Besides this re-alignment, irradiation causes a redistribution of the local light emission from the phosphor particles in the test cell. The electroluminescence emission from single particles and particle regions frequently increases or decreases. It appears likely that most of these brightness changes, due to various parameters discussed above, are caused by the concomitant changes in the local electric field.

Summary and Conclusions

A simple visual method employing a logarithmically graded, neutral-density step filter enables one to study microscopically the brightness variation among and within single EL phosphor particles.

It has been shown that a relation exists between the opacity and the light emission from single particles, in that acid etching increases both. Sometimes it is possible to make use of the nonuniformity of light emission in improving the lamp brightness, for instance by particle separation. The integrated light output as a function of processing temperature is analyzed, and it is found that the phosphor sample of optimum integrated brightness contains the largest fraction of EL particles and the maximum brightness value for the most frequent particle fraction. Particle orientation, particle-to-particle and particle-to-electrode contact enhance the electroluminescence emission. External irradiation with visible or ultraviolet light exerts also a marked influence on the brightness distribution within and among single phosphor particles.

Microscopic studies consequently can contribute to the preparation and selection of bright particles, so that the integrated light output of EL lamps can also be increased. The method is that of analysis and synthesis. That is, one looks first at single particles and attempts to optimize the components contributing to the integrated light output. The second step is then the synthesis of the optimized components which leads to the improvement of the brightness of EL lamps, as has been demonstrated above in some typical cases.

Hydrothermal Preparation of Two-Component Solid Solutions from II-VI Compounds

A. Kremheller, A. K. Levine,[1] and G. Gashurov

Sylvania Research Laboratories, A Division of Sylvania Electric Products Inc., Bayside, New York

ABSTRACT

The hydrothermal synthesis of binary solid solutions of inorganic phosphors and photoconductors is described. This method depends on the increased reactivity between the components and ease of crystal growth in an aqueous solution maintained at high temperature under a confining pressure. The hydrothermal method offers the advantages of a sealed system and easily reproducible experimental conditions. Solid solutions of ZnS-HgS, CdS-HgS, and ZnS-CdS have been prepared by this method. Results of optical absorption measurements, x-ray analysis, microscopic studies, and the spectral photoresponse of the solid solutions formed are presented.

The conventional preparation of binary solid solutions from group II—group VI systems recently has been of interest (1,2), since these materials (such as zinc-inter-chalcogenides, zinc sulfo-and seleno-tellurides) permit one to study the correlation between crystal structure and their electronic behavior as photoconductors and phosphors. The usual synthesis (3) of stoichiometrically controlled two-component solid solutions is difficult if the vapor pressures of the compounds involved differ greatly, so that preferential evaporation occurs. In such cases solid solution is sometimes achieved by a vapor phase process in high-pressure furnaces (4), or by coprecipitation in aqueous solutions (5).

Utilizing processing techniques introduced by Allen and Crenshaw (6), Kremheller and Levine (7) succeeded in hydrothermally preparing electronically active II-VI compounds, such as photoconductive cadmium sulfide and various related luminescent materials. This paper reports on the extension of these investigations to the synthesis of binary solid solutions of II-VI compounds. The hydrothermal method was chosen because it employs a lower temperature than is required in dry processing. Low-temperature synthesis is possible under hydrothermal conditions because the formation of mixed crystals is effected by solution transport, whereas in conventional processing crystal formation and growth take place mainly by vapor transport.

Experimental

The hydrothermal method has been described in some detail in previous publications (7); therefore, only a brief account of the method is given here. Hydrothermal synthesis employs aqueous or liquid solution of the component materials, sometimes with certain additives, at temperatures considerably above the normal boiling point of the solution and under pressures of several hundred atmospheres.

Hydrothermal synthesis is carried out by placing the finely divided component solids, say zinc sulfide and mercuric sulfide in a typical case, into a quartz vial which then is filled partially with deionized water and sealed. The quartz vial is enclosed in a high-pressure steel autoclave which also contains water. As long as there is a liquid phase in equilibrium with a vapor, the pressure will depend only on the temperature and not on the amount of each phase. Therefore, at temperatures below the critical temperature, the pressure outside of the quartz vial can be equal to the pressure inside even though the degree of filling of the autoclave is not the same as that in the vial. For example, the temperature-density diagram for water shows that two phases are present at 350°C as long as the degree of filling is in the range of about 20 to 50% (8). The autoclave is put in place, and its temperature is raised very slowly so that the temperature of the water in the vial is almost the same as that of the water outside it. Under these conditions the pressure inside the sealed quartz vial is sufficiently close to that in the autoclave so that the quartz vial neither explodes nor implodes. After the desired time at temperature, the autoclave is cooled slowly until the pressure is atmospheric; the vial is taken out and the processed material is removed. A large number of vials can be processed at the same time under identical conditions without danger of sample-to-sample contamination.

Results

Most experiments were carried out at temperatures around 350°C and under pressures of several

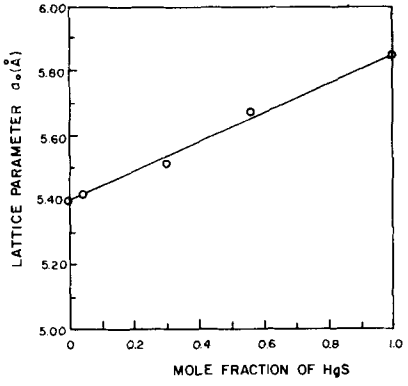

Fig. 1. Lattice parameter as a function of composition, ZnS-HgS system.

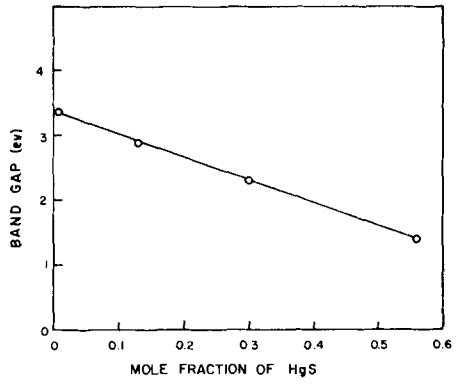

Fig. 2. Band gap as a function of composition, ZnS-HgS system.

hundred atmospheres. It was found that heat-treatment under these conditions for two or three days was sufficient usually to produce solid solutions of ZnS-HgS, CdS-HgS, and ZnS-CdS. In some experiments, equilibrium was reached in shorter time.

Solid solutions of ZnS-HgS.—Since the solubility rather than the vapor pressure is responsible for the formation of solid solutions by the hydrothermal processing technique, it is feasible to prepare quantitatively controlled solid solutions of components exhibiting greatly different vapor pressures under conventional processing conditions. For example, attempts were made conventionally to prepare solid solutions of (Zn,Hg)S by mixing ZnS with HgS and heating. However, after 30 min at 800°C, it was found that all the mercuric sulfide had volatilized leaving only ZnS. When a mixture of ZnS and HgS was processed hydrothermally for 50 hr at 350°C, solid solutions of (Zn,Hg)S were obtained, as indicated by the results of x-ray diffraction analysis of a series of such solid solutions (Fig. 1). These solid solutions are of the zinc blende structure, and within the limit of experimental error they exhibit a change of lattice constant with chemical composition in agreement with Vegard's law. A further proof of the formation of solid solution for the ZnS-HgS system was obtained from optical reflection measurements which show a shift in the absorption edge toward longer wave lengths as the mercury content increases. The reflection measurements were made with a Beckman Model DU Spectrophotometer with a MgO cell as the standard. The change of the energy band gap determined from these measurements

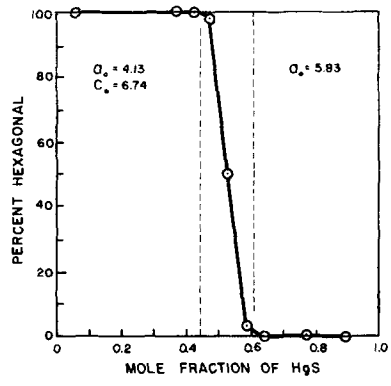

Fig. 3. Results of x-ray analysis, CdS-HgS system.

is shown in Fig. 2. The values of the band gap were calculated from the wave lengths corresponding to the intersection of the straight-line extrapolation above and below the short wave length knee of the reflectance curve, i.e., the same procedure was used as that employed by Larach, Shrader, and Stocker (2).

Solid solutions of CdS-HgS.—Solid solutions of (Hg,Cd)S can also be prepared readily by the hydrothermal synthesis. Figure 3 shows x-ray results for the CdS-HgS system. For HgS additions up to 43 mole % all the samples were of the wurtzite structure, and within the limit of experimental error no shift in the lattice parameters could be detected, the lattice parameters being essentially those of hexagonal CdS. The energy gap change in these samples (Fig. 4) indicates that formation of solid solutions was achieved, and it appears that CdS takes up HgS without any apparent structural changes.

For HgS additions of 60 mole % and higher only the zinc blende structure could be detected in CdS-HgS samples, and these cubic solid solutions have the same cell constant of 5.83Å. There is also an intermediate region in the CdS-HgS system extending from 43 to 60 mole % of HgS in which both the hexagonal (a = 4.13Å, c =6.74Å) and the cubic (a = 5.83Å) phases are present. The ratio of hexagonal phase to cubic appears to change gradually with the change in composition so that the sample to which 53 mole % of HgS were added contains both phases in equal amounts. To investigate further the nature of the intermediate region, microscopic observations were made on CdS-HgS samples and some results are given in Fig. 5. Figure 5a shows the sample con-

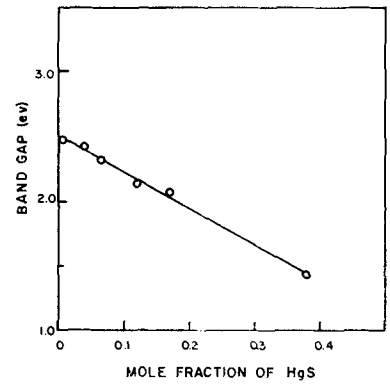

Fig. 4. Band gap as a function of composition, CdS-HgS system.

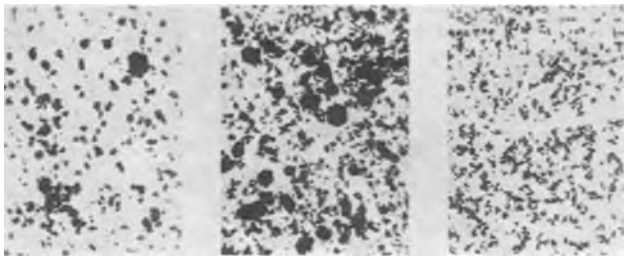

Fig. 5. Photomicrographs of CdS-HgS preparations: (a) (left) 43 mole % HgS (hexagonal), (b) (center) 53 mole % HgS (hexagonal:cubic, 1:1), and (c) (right) 77 mole % HgS (cubic). Figures have the same magnification; largest particle diameter about 50 μ.

taining 43 mole % of HgS in which only the hexagonal phase was found by x-ray analysis. One observes that the sample consists of large hexagons and small particles of indefinite shape. Under higher magnification it is observed that the small particles are also either hexagonal in shape or that they are fractions of large hexagons. The sample 5c containing 77 mole % of HgS consists of small particles which are found by x-ray analysis to be aggregates of cubic crystallites. The sample shown in the center, Fig. 5b, in which both hexagonal and cubic phases were found in equal amounts, consists of hexagons similar to those in Fig. 5a and small particles of the same kind as those in Fig. 5c. It appears that the sample containing 53% of HgS is a physical mixture of two solid solutions: the hexagonal (a = 4.13Å, c = 6.74Å) and the cubic (a = 5.83Å).

Solid solutions of ZnS-CdS.—Self-activated (Zn,Cd)S solid solutions have also been prepared by hydrothermal synthesis. The single crystallites exhibit good crystallinity; they are below 5μ in diameter, which is considerably smaller than the size of particles prepared by dry processing. Their luminescence and photoconductivity properties are comparable to those of conventionally prepared solid solutions. Luminescence under ultraviolet excitation (3650Å) shifts from blue to red with the increase in CdS concentration, while photosensitivity decreases with increasing ZnS concentration.

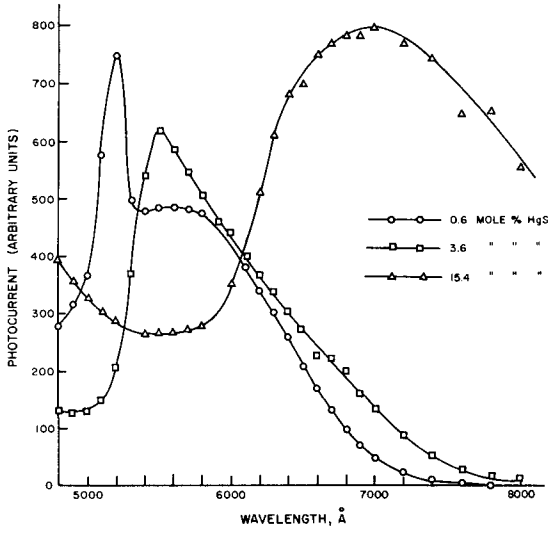

Fig. 6. Spectral response of photoconductive (Cd,Hg)S:Cu, Cl.

Activated solid solutions.—Solid solutions of (Zn,Hg)S, (Zn,Cd)S, and (Cd,Hg)S were made photoconductive or luminescent by proper activation. Activation was accomplished by adding copper or silver together with chlorine or aluminum to the host components. The luminescence of (Zn,Hg)S solid solutions under ultraviolet excitation (3650Å) shifts from green to red with the increase in HgS concentration. No visible photoluminescence is exhibited by (Zn,Hg)S solid solutions containing over 30 mole % of HgS because of a shift to the infrared. (Cd,Hg)S solid solutions were found to show photoluminescence and photoconductivity. Figure 6 shows the spectral response curves for this system. In every case 0.3 mole % of copper, 1 mole % of chlorine, relative to the sulfide was added to the solution in the vial. The photoconductivity peak shifts toward longer wave lengths with increasing HgS, as one would expect from the decrease in the width of the energy gap (Fig. 4). The photosensitivity in general decreases and the dark current increases with increase in HgS concentration.

Conclusions

Complete solid solution is obtained throughout the whole range for the ZnS-HgS system. These solid solutions appear to show a linear variation of lattice constant with composition. Corresponding to the continuous range of solid solution in this system, there occurs a linear variation of the energy gap at least up to 56 mole % of HgS. It is clear, however, that the energy gap cannot vary linearly in the whole range since the straight line in Fig. 2 extrapolates to a negative value for the band gap of pure cubic HgS.

HgS and CdS form solid solutions over the entire range, but the crystal system depends on the composition. Hexagonal solid solution of the wurtzite structure is obtained in the 0-43 mole % HgS range, while cubic solid solution of the zinc blende type is obtained for HgS additions above 60 mole %. Within the limits of experimental error neither of these solid solutions showed any shift in lattice parameters with composition. Hexagonal and cubic solid solutions are present in the 43-60 mole % region, the ratio of cubic to hexagonal solid solutions increasing continuously with increasing HgS concentration. These results agree essentially with those reported by Rittner and Schulman (5), who obtained (Cd,Hg)S solid solutions by coprecipitating CdS and HgS in concentrated ammonium sulfide solution. Solid solutions of (Zn,Hg)S, (Zn,Cd)S, and (Cd,Hg)S were made photoconductive and luminescent by proper activation.

Acknowledgment

Grateful acknowledgment is made to V. A. Brophy for carrying out the x-ray determinations, and to J. T. Ragusin and S. Faria for valuable assistance with the experimental work.

Tin-Activated Alkaline-Earth Pyrophosphate Phosphors

R. C. Ropp and R. W. Mooney

Chemical and Metallurgical Division, Sylvania Electric Products Inc., Towanda, Pennsylvania

ABSTRACT

The preparation and properties of the Group II metal pyrophosphates activated by tin are described. It is shown that the fluorescent emission is strongly dependent on the matrix shifting toward higher wave lengths with increasing size of the cation of the pyrophosphate. Excitation and emission spectra of many of the phosphors are given. The most useful of these phosphors is $Sr_2P_2O_7$:Sn, a very efficient blue phosphor emitting at 452 mμ.

During the past few years there have been several investigations of tin-activated phosphates. These phosphors present certain problems in preparation since the tin atoms function as activators only when in a partially reduced state, commonly thought to be the Sn^{2+} oxidation state. Except for this minor problem, the tin-activated phosphates are easily prepared and a wealth of new phosphors may be obtained by changing the cationic constituent of the lattice and the crystal structure if the compound exists in polymorphic forms.

The tin-activated orthophosphates were studied in detail by Butler (1) and several efficient phosphors discovered. Starting from titanium-activated barium pyrophosphate (2), Ranby and co-workers (3) made a study of the tin-activated alkaline-earth pyrophosphates giving the visually detected luminescent colors obtained by varying the ratio of one cation to another in the three binary systems and the spectral energy distributions of selected pyrophosphates activated by tin and manganese. All three alkaline-earth pyrophosphates were found to be polymorphic, but only in the barium pyrophosphate system did a change in structure from the low-temperature to the high-temperature form produce a change in emission, specifically from green to red. The high-temperature forms (commonly referred to as the α-forms) and the low-temperature or β-forms of calcium and strontium pyrophosphate both were stated to fluoresce blue under 254 μ excitation. A concurrent study of the tin-activated strontium and barium pyro- and tetraphosphates by McKeag and Steward (4) yielded several different phosphors in the barium system, but the blue emission of the strontium system was relatively unaffected by changes in the Sr/P ratio or firing temperature.

The present study was undertaken to investigate in greater detail the optical properties of the tin-activated alkaline-earth pyrophosphates and modifications thereof, especially with regard to the effects of crystal structure changes on the emission and excitation spectra of these phosphors. It will be shown that the spectral properties are even more dependent on crystal structure than was previously realized, thus leading to the discovery of several new phosphors. The most useful phosphor in this system is $Sr_2P_2O_7$:Sn, a deep-blue emitter, which has found practical application in fluorescent lamps.

Experimental Method

The pyrophosphates of calcium, strontium, and barium were readily obtained by ignition of their respective secondary phosphates. The compounds $CaHPO_4$ and $BaHPO_4$ were precipitated by the usual methods of adding a solution of $(NH_4)_2HPO_4$ to a solution of $CaCl_2$ or $BaCl_2$, each solution having been previously purified by sulfide separation of the heavy metals. Anomalies in the precipitation of $SrHPO_4$ led to an investigation of this material from which it was found that $SrHPO_4$ is dimorphic with each polymorph exhibiting slightly different behavior on ignition (5). In general, a slight excess of phosphate ion was used and the tin concentration varied from 0.01-0.20 gram-atom tin per gram-mole of pyrophosphate. It was found that phosphor characteristics were independent of activator concentration over this range, and therefore all phosphors were prepared at the same added concentration of 0.05 gram-atom tin per gram-mole of pyrophosphate. For the magnesium- and zinc-modified phosphors, the compounds $MgNH_4PO_4$ and $ZnNHPO_4$ were precipitated by standard techniques (13). The firing techniques used in the preparation of these phosphors followed the methods described in detail by several previous authors (1-3) and are not described here, except to state that various requisite

temperatures were employed to form the diverse polymorphic crystalline forms.

The crystal structures of the phosphors were determined by conventional x-ray diffraction techniques using CuKα radiation from a Philips Norelco unit. In the majority of cases, identification was made by means of Debye-Scherrer powder patterns taken on large diameter (114.6 mm) cameras. In a few cases, diffractometer tracings were taken on a Norelco wide-range goniometer at a scanning speed of ¼°/min. As would be expected, the two methods were in excellent agreement.

The excitation-emission radiometer[1] used for the measurements of excitation and emission spectra will be described in detail elsewhere (6). Basically, it is a double monochromator system with a high-pressure xenon arc source and a 1P28 photomultiplier detector. A combination of optical and electrical components provides for constant-energy-level illumination of the sample during excitation measurements and gives an emission spectrum which is proportional to the true energy output of the sample regardless of source fluctuations or detector sensitivity as a function of wave length. The relative efficiency measurements were made on a plaque tester of conventional design (7).

Experimental Results in Single-Component Pyrophosphates

Spectral characteristics of the tin-activated polymorphic modifications of calcium, strontium, and barium pyrophosphate are summarized below. In general, there were no changes in spectra with tin content.

Calcium pyrophosphates.—Excitation and emission spectra of β- and α-$Ca_2P_2O_7$:Sn are shown in Fig. 1. (λ_x refers to the wave length of excitation, and λ_e, the emission wave length at which the excitation was measured.) No fluorescence was observed for γ-$Ca_2P_2O_7$:Sn.

The low-temperature or β-form of $Ca_2P_2O_7$:Sn is primarily an ultraviolet emitter with a broad band peaking at 369 mμ. The excitation spectrum is also broad with the primary band peaking at 238 mμ. Both the emission and excitation spectra suggest the presence of a second band in each at lower energies. However, the emission spectrum remained essentially as shown in Fig. 1 for all energies of excitation which gave fluorescence. These results agree with the emission spectrum for β-$Ca_2P_2O_7$:Sn presented by Bril and Klasens (8).

As the crystal structure changed from β-$Ca_2P_2O_7$ to α-$Ca_2P_2O_7$, the high-temperature form, the spectra also varied. With high excitation energies, the emission spectrum closely resembled that of β-$Ca_2P_2O_7$:Sn with the peak shifted very slightly to higher energies at 364 mμ. The excitation spectrum for this band was, however, different with the strongest absorption band at 254 mμ and a weaker band at about 232 mμ. As the energy of excitation decreased, a second band appeared in the emission spectrum at about 430 mμ until with $\lambda_x = 276$ mμ the fluorescent spectrum shown in Fig. 1 was obtained. The excitation spectrum obtained for emission in this band also showed two peaks, the stronger at 240 mμ and the weaker at 260 mμ. An inspection of Fig. 1 shows that the positions of the bands in the excitation spectra are not equivalent for the two different emission bands.

[1] Built by the Perkin-Elmer Corporation, Norwalk, Conn.

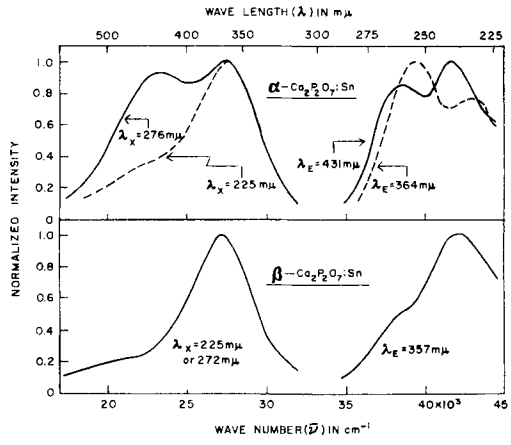

Fig. 1. Excitation-emission spectra for $Ca_2P_2O_7$:Sn phosphors. Firing temperature, 1300° and 1175°C, respectively.

Strontium pyrophosphates.—The low-temperature or β-form of $Sr_2P_2O_7$:Sn is also primarily an ultraviolet emitter (see Fig. 2) with its main band at 364 mμ and evidence of another weaker band in the visible. Its excitation spectrum has two bands, the stronger peaking at 234 mμ and the weaker at about 260 mμ. The similarities between the excitation and emission spectra of β-$Ca_2P_2O_7$:Sn and β-$Sr_2P_2O_7$:Sn are striking with the bands shifted very slightly to higher energies for β-$Sr_2P_2O_7$:Sn.

The α-form of $Sr_2P_2O_7$:Sn has a single emission band peaking at 464 mμ and the usual two excitation bands at 256 mμ and approximately 238 mμ. Again, a similarity may be noted between α-$Sr_2P_2O_7$:Sn and the lower-energy emission band in α-$Ca_2P_2O_7$:Sn with the spectrum of the strontium compound shifted to lower energies. The bands in the excitation spectra of α-$Sr_2P_2O_7$:Sn and α-$Ca_2P_2O_7$:Sn for $\lambda_E = 431$ mμ occur at almost identical energies although the relative intensities of the bands are reversed.

Barium pyrophosphates.—The low-temperature form of $Ba_2P_2O_7$, which Ranby (3) has designated as α-$Ba_2P_2O_7$ has a single weak emission band peaking

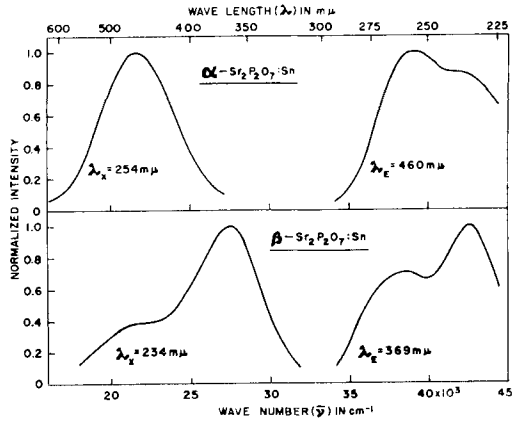

Fig. 2. Excitation-emission spectra for $Sr_2P_2O_7$:Sn phosphors. Firing temperature, 1100° and 650°C, respectively.

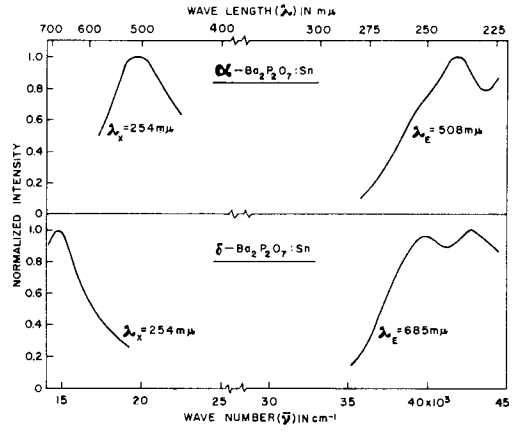

Fig. 3. Excitation-emission spectra for $Ba_2P_2O_7$:Sn phosphors. Firing temperature, 650° and 980°C, respectively.

at 505 mμ (see Fig. 3). The main excitation band peaks at 239 mμ and there is evidence of a weaker band at lower energies in the general vicinity of 256 mμ. Thus this phosphor also has spectral characteristics in common with α-$Ca_2P_2O_7$:Sn and α-$Sr_2P_2O_7$:Sn with the emission peak shifted to lower energies, but the positions of the two excitation bands relatively unchanged.

The δ-$Ba_2P_2O_7$ structure is unique and has no simple relationship to the other alkaline-earth pyrophosphates. Therefore, it is not surprising that the phosphor δ-$Ba_2P_2O_7$:Sn is also unique having a single emission band peaking in the deep red at 676 mμ and two excitation bands at 233 mμ and 250 mμ.

Experimental Results on Binary Metal Pyrophosphates

The effect of varying the ratio of one cation to another in the three possible binary combinations of the alkaline-earth pyrophosphates is shown in Fig. 4 in which the relative red and blue plaque readings, using Corning 2424 and 5543 plus 3389 filters, respectively, (7) are plotted against composition. The data given in Fig. 4 represent three separate systems. On the right is shown the binary combinations of the strontium calcium pyrophosphates activated by tin. The section in the middle represents barium strontium pyrophosphates activated by tin, and the left hand section represents barium calcium pyrophosphate activated by tin. In general, the combination of a pair of red and blue plaque readings represents the response of a single phosphor composition. Changes in fluorescent color were observed, and these changes are represented at the top of the figure. An increase or decrease in blue or red plaque readings should be correlated together to determine the relative chromaticities of the three systems to each other. The firing temperature was selected to give the high-temperature modification of each pyrophosphate, i.e., the α-modifications of $Ca_2P_2O_7$ and $Sr_2P_2O_7$ and the δ-modification of $Ba_2P_2O_7$ since the high-temperature forms were more efficient, visually, than their low-temperature modifications. Data on each system are summarized below.

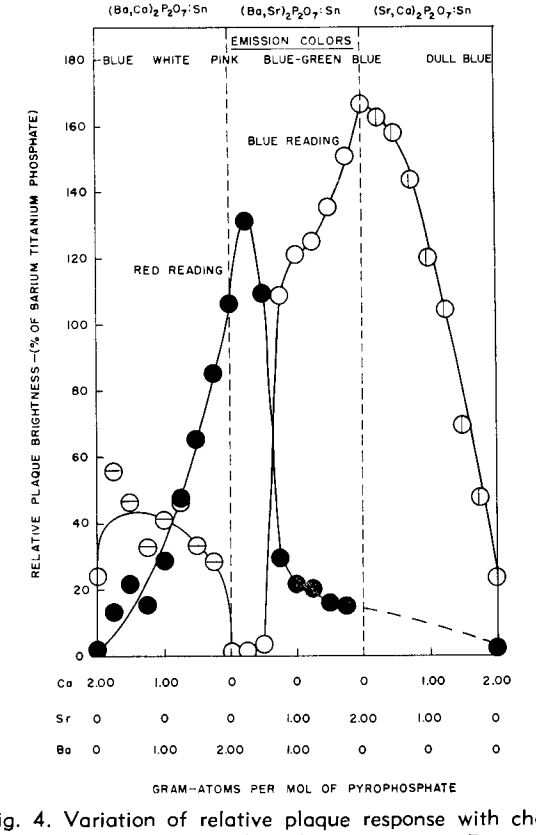

Fig. 4. Variation of relative plaque response with change in cationic constituents in three binary systems. Firing temperature, 1100°C.

Calcium-strontium pyrophosphates.—The plaque data of Fig. 4 show a continuous increase in blue emission as the Sr/Ca ratio is increased in $(Sr,Ca)_2P_2O_7$:Sn (right portion of Fig. 4). Identification of the compounds present by x-ray diffraction showed that the phosphors were mixtures of α-$Ca_2P_2O_7$ and α-$Sr_2P_2O_7$ with the relative amount of each being determined by the relative amounts of the cations. Therefore, it was not surprising that the emission spectra also showed the ultraviolet emission band at about 361 mμ characteristic of α-$Ca_2P_2O_7$:Sn and the visible band at about 464 mμ characteristic of α-$Sr_2P_2O_7$:Sn. Again, the amount of each emission band present was determined by the relative amount of the particular compound in the mixture. The excitation spectra were not examined in detail.

Strontium-barium pyrophosphates.—The fluorescent color of $(Ba,Sr)_2P_2O_7$:Sn changed from blue to blue-green to pink in agreement with Ranby, *et al.* (3) as the Ba/Sr ratio increased (middle portion of Fig. 4). It is evident that there is a sharp change in fluorescent color in going from $Sr_{0.75}Ba_{1.25}P_2O_7$:Sn to $Sr_{0.50}Ba_{1.50}P_2O_7$:Sn. The emission spectra of the system exhibited only a single band whose peak wave number varied with the alkaline-earth ratio. The discontinuity mentioned above is readily shown in Fig. 5 where the peak emission energy is plotted against this ratio. The x-ray data paralleled the optical measurements. Thus the diffraction pattern showed a continuous change from α-$Sr_2P_2O_7$ to a pattern closely resembling α-$Ba_2P_2O_7$ in going from $Sr_2P_2O_7$ to $Sr_{0.75}Ba_{1.25}P_2O_7$. Phosphors with higher barium contents than the latter had essentially the δ-$Ba_2P_2O_7$ structure and the characteristic red emission of δ-$Ba_2P_2O_7$:Sn. The data of Fig. 4 seem to imply that the phosphor $Sr_{0.25}Ba_{1.75}P_2O_7$:Sn has more emission in the red than δ-$Ba_2P_2O_7$:Sn. However, this result is due to the greater sensitivity of the photo-

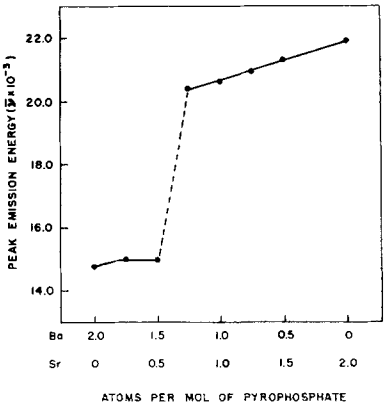

Fig. 5. Peak emission changes in the $(Sr,Ba)_2P_2O_7$:Sn systems.

multiplier as the peak emission shifts toward the green. In this system also, there was no detailed study of excitation spectra.

Barium-calcium pyrophosphates.—It is apparent from the results given in Fig. 4 (left portion) that the $(Ba,Ca)_2P_2O_7$:Sn phosphors are low in efficiency. For this reason, and since they melted very easily giving fused materials, this sytem was not studied in detail.

Other binary pyrophosphates.—With two exceptions, other Group II binary pyrophosphates activated by Sn were generally inefficient and uninteresting. The exceptions were $(Sr, Mg)_2P_2O_7$:Sn and $(Sr,Zn)_2P_2O_7$:Sn. These phosphors displayed a decrease in blue plaque efficiency similar to that shown in Fig. 4 for $(Sr,Ca)_2P_2O_7$:Sn as the Sr/Mg or Sr/Zn ratio decreased. Measurements of emission spectra disclosed that although $Mg_2P_2O_7$:Sn and $Zn_2P_2O_7$:Sn are essentially inert, the addition of small amounts of strontium produces ultraviolet-emitting phosphors. As an example, the emission and excitation spectra of $Mg_{1.75}Sr_{0.25}P_2O_7$:Sn and $Zn_{1.75}Sr_{0.25}P_2O_7$:Sn are given in Fig. 6. Both have a strong emission band peaking at 333 mμ and evidence of the α-$Sr_2P_2O_7$:Sn band appearing at lower energies. As the Sr/Mg ratio or Sr/Zn is increased, this band at about 464 mμ increases in intensity while the one at 333 mμ decreases. The excitation spectra are composed of two bands, on at about 248 mμ and a second at about 226 mμ. X-ray identification showed the presence of α-$Sr_2P_2O_7$ as well as compounds having diffraction patterns similar, but not identical, to $Mg_2P_2O_7$ and $Zn_2P_2O_7$. A comparison of the emission spectra data in Fig. 1 and 2 with those in Fig. 5 reveals no interrelation or similitude to previous data.

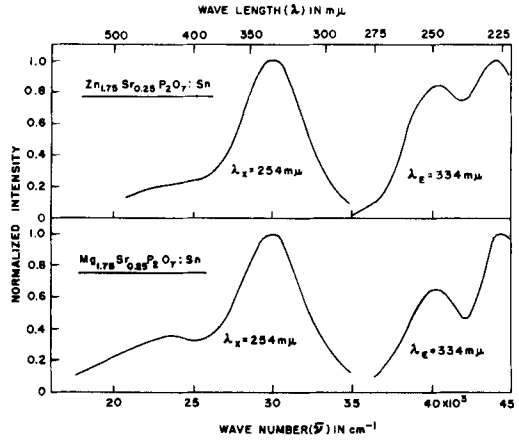

Fig. 6. Excitation-emission spectra for $(Mg,Sr)_2P_2O_7$:Sn and $(Zn,Sr)_2P_2O_7$:Sn phosphors. Firing temperature, 1120°C.

Discussion

The results of this investigation are in general agreement with those reached earlier by Ranby, *et al.* (3), namely, that the emission spectra are determined primarily by the crystal structure of the matrix. This conclusion is also applicable to the excitation spectra. However, while there is general agreement with previous work, there are several areas in which previous views must be modified. For instance, the tin-activated calcium strontium pyrophosphates exhibit considerable change in emission in going from $Ca_2P_2O_7$:Sn to $Sr_2P_2O_7$:Sn and in going from the β-form to the α-form. Thus, both β-$Ca_2P_2O_7$:Sn and β-$Sr_2P_2O_7$:Sn are primarily ultraviolet emitters, but neither is very efficiently excited by 254 mμ excitation. On the contrary, α-$Sr_2P_2O_7$:Sn is a blue phosphor and is very efficiently excited by 254 mμ, while α-$Ca_2P_2O_7$:Sn is both a blue and an ultraviolet emitter, but the blue band is only weakly excited by a low-pressure mercury-vapor arc. Therefore, under this excitation the $(Sr,Ca)_2P_2O_7$:Sn phosphors show changes in relative intensity but little change in position of the emission bands. The band at 464 mμ attributed to α-$(Ca,Sr)_2P_2O_7$:Sn (3) is therefore, in reality, due to α-$Sr_2P_2O_7$:Sn as shown in Fig. 2. The emission data on the barium pyrophosphates are in fair agreement with previous results (3,4).

The $(Sr,Ba)_2P_2O_7$:Sn system is interesting in view of its continuous change in the position of the emission peak with composition as shown in Fig. 5. Starting from α-$Sr_2P_2O_7$:Sn and replacing strontium by barium, the emission peak energy decreased linearly approaching that of the α-$Ba_2P_2O_7$:Sn phosphor. The d-spacings in the x-ray diffraction patterns showed a similar continuous shift, and therefore it is concluded that $Sr_2P_2O_7$ and $Ba_2P_2O_7$ form a continuous series of solid solutions up to an alkaline-earth content of 75% barium. At this point, the α-phase is no longer stable and the δ-$Ba_2P_2O_7$:Sn phosphor is formed as evidenced by the x-ray diffraction pattern and the spectra. It should be noted that the most efficient phosphors having the blue-green emission characteristic of α-$Ba_2P_2O_7$:Sn are prepared by stabilizing this structure with strontium as, for instance, in the phosphor $Ba_{1.25}Sr_{0.75}P_2O_7$:Sn, since it is difficult to prepare α-$Ba_2P_2O_7$:Sn with high efficiency due to the tendency to form δ-$Ba_2P_2O_7$:Sn at temperatures necessary to promote the requisite crystallinity and ultraviolet response of the phosphor.

The $(Sr,Ba)_2P_2O_7$:Sn system is therefore very different from the $(Sr,Ca)_2P_2O_7$:Sn, $(Sr,Mg)_2P_2O_7$:Sn, and $(Sr,Zn)_2P_2O_7$:Sn systems where the x-ray diffraction patterns of each individual component are readily discernible and where the emission spectra of both components appear, as for example the bands due to α-$Sr_2P_2O_7$:Sn and α-$Ca_2P_2O_7$:Sn in $(Sr,Ca)_2P_2O_7$:Sn. One is therefore led to believe that in these systems the phosphor components

Table I. Ultraviolet emission bands

Phosphor	Peak wave length in mμ		
	Emission	Excitation	
β-$Ca_2P_2O_7$: Sn	369	260	238
β-$Sr_2P_2O_7$: Sn	364	260	234
α-$Ca_2P_2O_7$: Sn	362	253	232

Table II. Visible emission bands

Phosphor	Peak wave length in mμ		
	Emission	Excitation	
α-$Ca_2P_2O_7$: Sn	429	261	240
α-$Sr_2P_2O_7$: Sn	463	256	238
α-$Ba_2P_2O_7$: Sn	505	256	239

exist as separate species, in contrast to the $(Sr,Ba)_2P_2O_7$: Sn system.

It was noted earlier that the emission spectra of the β-forms of $Ca_2P_2O_7$: Sn and $Sr_2P_2O_7$: Sn were similar and apparently related to one of the bands in α-$Ca_2P_2O_7$: Sn. This relationship is easily seen by a compilation of the peak energies.

Inspection of Table I shows that the peaks in the emission and excitation bands occur at almost identical energies. A corresponding tabulation of the peak energies of the α-forms of calcium, strontium and barium pyrophosphate is given in Table II. These three forms are closely related structure-wise and have orthorhombic symmetry (3).

For the visible emission bands there is a definite trend toward lower energies with increasing size of the alkaline-earth cation; however, again the excitation bands peak at almost identical energies.

The relative heights of the two excitation bands given in Tables I and II vary for each phosphor. If one assumes that the lower-energy emission bands, i.e., the visible, are associated with the lower-energy excitation bands, and the higher-energy emission bands, i.e., the ultraviolet, are associated with the higher-energy excitation bands, one obtains a direct correspondence between the strong excitation and the strong emission bands with both strontium systems and with β-$Ca_2P_2O_7$: Sn. However, the correspondence is very poor for α-$Ba_2P_2O_7$: Sn where the phosphor absorbs in the higher-energy band and emits in what we have arbitrarily called the lower-energy band, i.e., at 505 mμ. A similar, but even more puzzling anomaly exists in the α-$Ca_2P_2O_7$: Sn system where, considering only the excitation data, one would predict that irradiation with low-energy ultraviolet would yield the ultraviolet band. Actually, just the reverse results were obtained for the emission spectra, i.e., irradiation with 225 mμ energy gave the ultraviolet band and irradiation with 276 mμ energy gave both ultraviolet and visible bands. Thus the emission data are, by themselves, consistent with the other calcium and strontium systems.

In order to illustrate the trends in emission spectra with changes in structure, the peak emission energies of all phosphors are plotted against the alkaline-earth cationic radii in Fig. 7. The grouping

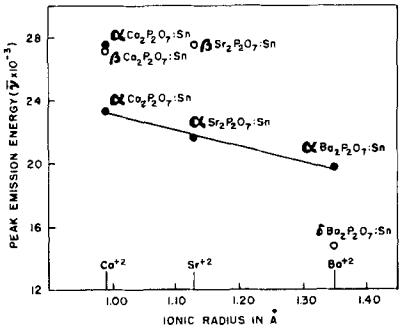

Fig. 7. Effect of cationic radius and structure on emission of tin-activated alkaline-earth pyrophosphate phosphors.

together of the ultraviolet bands is obvious as is the linear relationship between the peak energies in the α-pyrophosphates vs. cationic radii. The emission of δ-$Ba_2P_2O_7$: Sn falls into neither grouping. It is very apparent from Fig. 7 that there is an over-all trend toward lower emission energies or longer wave lengths with increasing cationic size. Unfortunately, this is in direct conflict with the results on several other phosphor systems as summarized by Fonda (9). However, with three exceptions all of the phosphors listed by Fonda were activated by manganese either as a primary or secondary activator. These exceptions were the alkaline-earth sulfides activated by europium (10), the self-activated vanadates of the alkaline-earth metals (11), and the alkaline-earth orthophosphates activated by tin (1). However, in the latter case the results were conflicting since, in one case, an increase in cationic size shifted the emission to shorter wave lengths, whereas in the other a shift to longer wave lengths was observed.

Fonda also points out several exceptions to his general rule that the spectral position of the emission band should shift to longer wave lengths as the lattice spacing is decreased. For these exceptions, the activators are thallium, silver, copper and in two cases, manganese. It is interesting that, ignoring the two manganese cases above, all of the other activators together with tin share the property that their bonding electrons are s-electrons, not d-electrons as is the case with manganese and europium. We are, therefore, led to agree with Fonda that the effects of polarizability lead to the reversal of his general rule stated above, but going a step further we believe that the effects of polarizability are more apt to be found in systems with activators whose bonding electrons are symmetrical s-electrons than in those whose bonding electrons are d-electrons, as for instance, manganese. The results on the tin-activated alkaline-earth pyrophosphates are explained, therefore, by assuming that the tin in a barium site has a greater effective radius than in a calcium site and is, therefore, more easily polarizable leading to a greater overlapping of the electronic orbits and a consequent shrinkage in the energy difference between the excited and ground states. Generalizing, it would appear that it is dangerous to treat all activator centers as identical and, specifically, it is very dangerous to use manganese-activated systems as typical. This conclusion is equally applicable to properties other than optical spectra

since, for instance, it has been shown that the tin- and manganese-activated phosphates do not exhibit the same type of variation of fluorescent efficiency with temperature (12).

Finally, one might assign the visible emission bands in the α-structures to the $^3P_1^0 \rightarrow {}^1S_0$ transition of the tin center and the ultraviolet emission bands to the $^1P_1^0 \rightarrow {}^1S_0$ transition. Corresponding assignments in the reverse direction could also be made to the excitation bands, although there are many unexplained phenomena that do not correspond exactly to these assignments.

Voltage Dependence and Particle Size Distribution of Electroluminescent Phosphors

Willi Lehmann

Research Department, Westinghouse Electric Corporation, Bloomfield, New Jersey

ABSTRACT

The particle sizes of electroluminescent zinc sulfide phosphors prepared by common firing techniques usually range over broad distributions which always have the same shape. Every phosphor of this "normal" particle size distribution shows a voltage (V) dependence of electroluminescent brightness (L) which, over many decades of L, can closely be described by $L = L_o \exp [-(V_o/V)^{0.5}]$. Every deviation of the particle size distribution from the "normal" form also causes a deviation of the measurable $L(V)$ dependence from this expression. Measurements on phosphor particles and on uniform phosphor films indicate that the basic excitation mechanism of electroluminescence follows the voltage dependence $L = L_o \exp [-(V_o/V)]$ and that the square root in the exponent of the usual equation is due mainly to the broad particle size distribution of regular phosphors. This view is supported also by a mathematical analysis.

The time-average of the emission intensity, L, of electroluminescent (EL) zinc sulfide powders generally increases rather rapidly with increasing amplitude of the exciting alternating voltage, V. Based on rough theoretical considerations, Destriau originally proposed to describe this dependence by

$$L = L_o \exp [-(V_o/V)] \qquad [1]$$

with L_o and V_o as constants (1). It developed, however, that the fit of this equation to experimental results is not too good, and a great variety of other mathematical forms have been proposed by various workers since that time (2-17). One of them

$$L = L_o \exp [-(V_o/V)^{0.5}] \qquad [2]$$

differs from Eq. [1] only by the square root in the exponent, and its agreement with experimental results is amazingly good in many cases and can extend over six or more decades of L. This agreement has repeatedly been considered to be a proof for the validity of the exhaustion barrier theory (9, 18-20) from which Eq. [2] originally was deduced (9). It cannot be denied, however, that deviations from Eq. [2] have been observed frequently.

The suggestion by Lehmann (21) that Eq. [2] is a result of the well-known nonuniformity of the emission in a phosphor powder could not, at that time, be supported by experimental results.

A somewhat unexpected answer to the problem came from investigations of particle size effects on

EL. If a common phosphor having the usual broad particle size distribution is separated into fractions of different mean particle sizes, then these fractions also show different $L(V)$ dependences. The first reliable experimental results in this respect apparently were reported by Milch and Mazenko (22). They separated their phosphor into fractions of fairly small distribution widths and used a generalized modification of Eq. [2]

$$L = L_0 V^n \exp\ [-(V_0/V)^{0.5}] \qquad [3]$$

to describe their measured $L(V)$ dependences. They found that not only L_0 and V_0 in Eq. [3] depend on the mean particle size, but also that a proper fit could be obtained only with values of the exponent, n, ranging between $n = -11$ and $n = +0.67$. Later, Goldberg (23) and Lehmann (24) independently made similar experiments with apparently less sharply separated phosphor fractions and described the $L(V)$ dependence of these fractions by Eq. [2]. They found, too, that both constants in Eq. [2], L_0 and V_0, depend on the mean particle size of the phosphor.

These experimental results immediately permit a conclusion. If the $L(V)$ dependence of a single phosphor particle depends in some fashion on its size, and if a phosphor has a broad particle size distribution (which is normally always the case), then the $L(V)$ dependence of the whole phosphor must be determined not only by the $L(V)$ dependence of a single particle but also by the form of the particle size distribution of the phosphor. In other words, there must be a correlation between the particle size distribution of a phosphor and its measurable $L(V)$ dependence, i.e., the $L(V)$ dependences of two otherwise identical phosphors, one of a broad and the other of a narrow particle size distribution, should be different even if the mean particle sizes of both samples are equal. The $L(V)$ dependence of normal phosphors with broad particle size distributions can be described fairly well by Eq. [2]. Consequently, a phosphor with a very narrow particle size distribution can be expected to show an $L(V)$ dependence which does not closely follow Eq. [2]. The significance of an experimental confirmation of this conclusion for all theoretical efforts to understand the mechanism of electroluminescence is obvious.

Particle Size Distributions of Regular Phosphors

Particle size distributions of normal phosphors, as obtained by common preparation procedures, were determined by means of a projection microscope. The approximate diameters of some 200-300 particles of each sample were measured. The resulting distributions of all these phosphors had essentially the same shape. An example in the form of a frequency-diameter histogram is shown in Fig. 1. Such a typical distribution curve has been shown earlier by Leverenz (25). It is not symmetrical and cannot be described closely by a Gaussian function, but a relatively good fit was obtained empirically by the function

$$y = ax^2 \exp\ (-2x/x_0) \qquad [4]$$

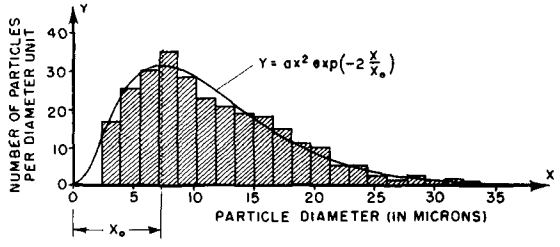

Fig. 1. Typical particle size distribution of a normal (i.e., unseparated) phosphor.

where x is the particle diameter, x_0 that particular particle diameter which corresponds to the peak of the function $y(x)$, a is a constant, and ydx is the number of particles between the size limits x and $x + dx$. The close fit of this function to the experimental distribution is shown also in Fig. 1. Variations of the several parameters of preparation (e.g., firing temperature and time, concentration of impurities, etc.) seem to cause only a shift of the peak size, x_0, to smaller or larger values but do not alter the general form of the particle size distribution. To what extent Eq. [4] may find a theoretical foundation (possibly in statistical considerations) is unknown. Nevertheless, it is at least a good approximation.

The $L(V)$ dependence of the phosphor sample whose particle size distribution is shown in Fig. 1 is given in Fig. 2. The agreement of the experimental points with straight lines, i.e., the agreement of the $L(V)$ dependence with Eq. [2], is almost exact over the whole measured range.

Behavior of Phosphor Fractions of Very Narrow Particle Size Distributions

The most desirable goal, fractions of almost uniform particle sizes separated out of common phosphor powders, could not be reached because of a lack of available techniques. There seems to be no

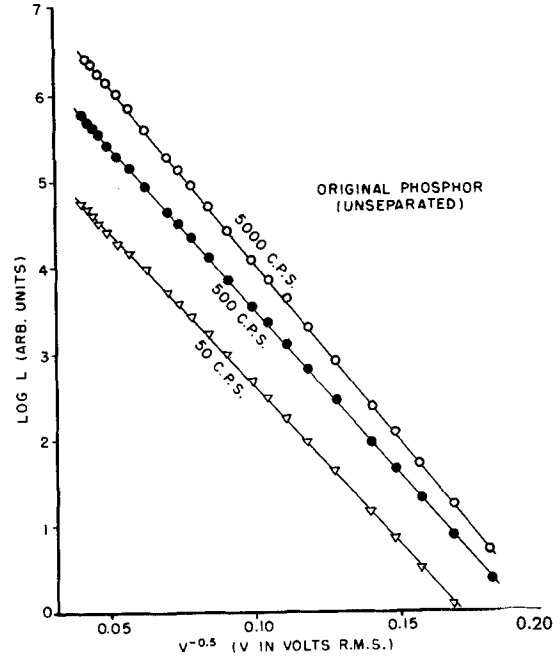

Fig. 2. The L(V) dependence of a normal phosphor can closely be described by Eq. [2].

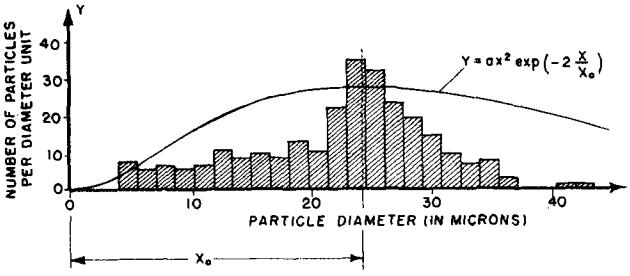

Fig. 3. Particle size distribution of a small fraction separated out of the normal phosphor of Fig. 1.

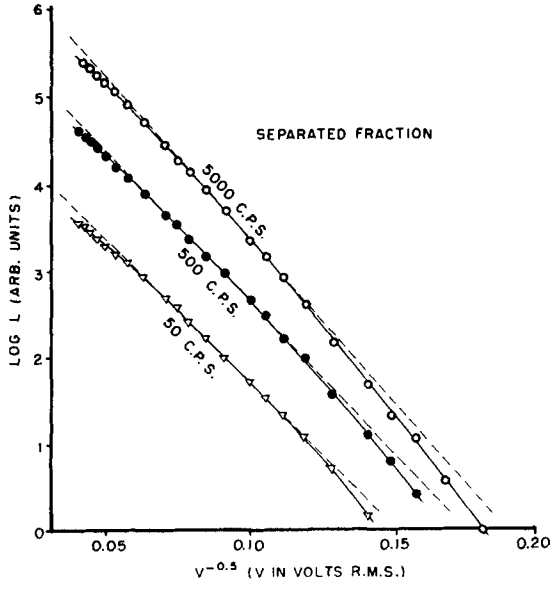

Fig. 4. The L(V) dependence of the separated fraction of Fig. 3 cannot closely be described by Eq. [2].

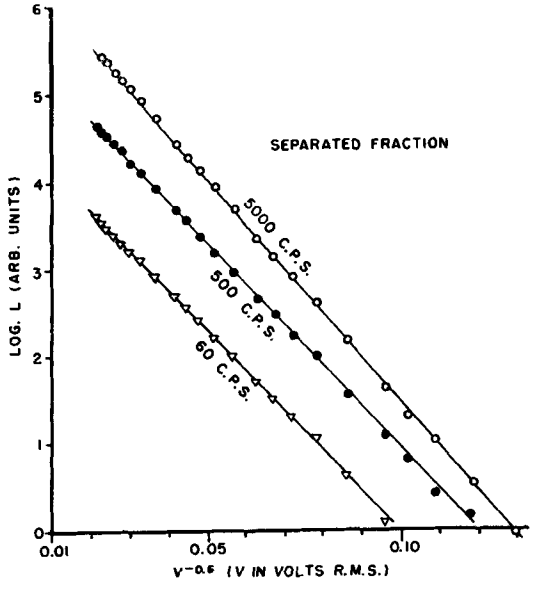

Fig. 5. The L(V) dependence of the separated fraction of Fig. 3 can closely be described by Eq. [5] with $\alpha = 0.6$.

known method permitting such narrow separations. As an example of what actually could be obtained in these experiments, Fig. 3 shows the distribution of a fraction of large diameter separated out of the phosphor whose original distribution is shown in Fig. 1. Although the distribution of Fig. 3 still has a considerable width, it is much smaller than that of the original, and it is obvious that there is no longer agreement with Eq. [4] as shown by the smooth curve in Fig. 3. The $L(V)$ dependence of this separated fraction is given in Fig. 4 as log L as a function of $V^{-0.5}$. The experimental points are not on straight lines here, so that this $L(V)$ dependence cannot be described closely by Eq. [2]. But if Eq. [2] is arbitrarily generalized by replacing the exponent 0.5 by an arbitrary constant

$$L = L_0 \exp\left[-(V_0/V)^{\alpha}\right] \qquad [5]$$

it turns out that $\alpha = 0.6$ now gives a good fit, much better than $\alpha = 0.5$, as shown in Fig. 5. This value of $\alpha = 0.6$, of course, is purely incidental and has no physical meaning except that it indicates the influence of the still present width of the particle size distribution on the $L(V)$ dependence of the phosphor.

An extrapolation may be permitted here. If the $L(V)$ dependence of the original phosphor with its broad particle size distribution can be described by $\alpha = 0.5$ while the separated sample with the smaller but still considerable particle size distribution gives a better fit with $\alpha = 0.6$, then a phosphor with a still narrower particle size distribution probably would require a still higher value of α. An approach to $\alpha = 1$, i.e., toward Eq. [1], for ideally uniform particles seems likely but cannot, of course, be deduced rigorously from an extrapolation.

Behavior of Single Phosphor Particles

Most of all the geometrical complexity of a phosphor powder can be eliminated by consideration of single particles. However, a part of the complexity remains here also. Real single particles always have somewhat irregular shapes, may contain lattice disorders, and may be differently oriented with respect to the direction of the electric field. It is also known that the emission inside the phosphor crystals mainly originates from relatively small spots (5, 26, 27), and microscopic examination shows that every particle may contain one or more such emitting spots. Sometimes, the spots appear to be extended to lines, and the direction of these lines seems to follow the direction of some striped pattern, probably stacking faults (28-30), which can be seen when the crystal is illuminated by white light. Figure 6 shows a typical example of such nonuni-

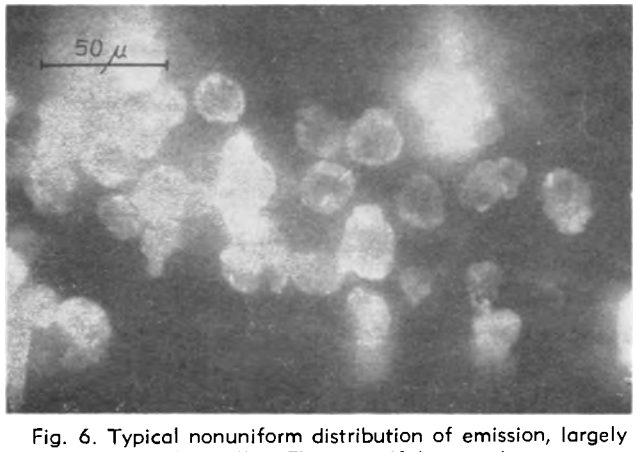

Fig. 6. Typical nonuniform distribution of emission, largely concentrated in "spots," of EL zinc sulfide particles.

form emission, largely concentrated in spots of single phosphor particles. Despite these complications, an $L(V)$ dependence of single particles somewhat simpler than that of complete phosphor powders can be expected.

The light emission of one single phosphor particle is too weak to be measured over a wide range by usual photomultipliers. Therefore, a visual method was used in these experiments. The phosphor to be measured (a few particles only) was placed in an oil cell and viewed through a microscope with low magnification. The starlike image of one luminescent particle was compared with the controlled and calibrated brightness of an artificial star (a pinhole in a piece of black paper illuminated by an incandescent lamp). Since a judgment of equality of the visual brightnesses of the two spots, even if they are visible side by side, always has a considerable uncertainty, each measurement was repeated ten times and the final value obtained by the arithmetic average of the ten single values. This technique gave fairly accurate results but was rather tiring to the eyes and time consuming so that only six single particles were completely measured.

The results obtained differ somewhat from particle to particle and are somewhat in contrast to results reported by Waymouth and Bitter (5) and by Zalm, Diemer, and Klasens (26). One particle out of the six had an $L(V)$ dependence which, over the whole measured range, can be described by Eq. [1] but not by Eq. [2] (see Fig. 7). Three other particles had $L(V)$ dependences which could not be described completely by either Eq. [1] or [2] but which can be understood easily by a superposition of two terms each of which has the form of Eq. [1]. Obviously in these three cases the curves are due to two emitting spots, with different voltage characteristics, inside the particles. Finally, the last two particles had $L(V)$ dependences which could be described in either way, by two terms of Eq. [1] or by one term of Eq. [2]. Since it seems unlikely that two totally different excitation mechanisms would be present in different particles of the same phosphor, we draw the conclusion that the emission of these two particles was due to two (or more) emitting spots inside the particles.

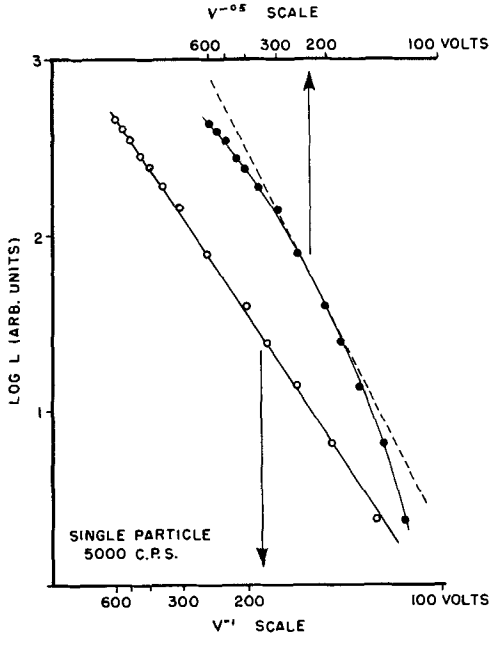

Fig. 7. The L(V) dependence of one single particle measured can closely be described by Eq. [1] but not by Eq. [2].

Behavior of Thin Phosphor Films

A uniform continuous film is obviously the simplest geometrical structure an EL phosphor can have. Its "particle size" is identical with its thickness, and variations of the thickness have the same effect as a finite particle size distribution of a powder phosphor; they cause a nonuniform distribution of the emission over the film area. The over-all emission of such nonuniform films in many cases can be described also by Eq. [2] fairly well, although deviations from this dependence occur rather frequently (31).

Most significant in this respect is, of course, the behavior of highly uniform films. Results obtained on specially selected uniform films[1] are shown in Fig. 8 and 9. These particular films (blue and green-emitting ZnS:Cu,Cl) were relatively thin (1 or 2 μ) and directly in contact with both electrodes (evaporated aluminum and the SnO_2 layer of conducting glass). The films appeared uniform and glassy under the microscope. Their electroluminescence was also uniform over their whole areas and without any emitting "spots" as are observed in powder phosphors. The experimental points deviate strongly from straight lines in Fig. 8 where log L is plotted as a function of $V^{-0.5}$. The points are on straight

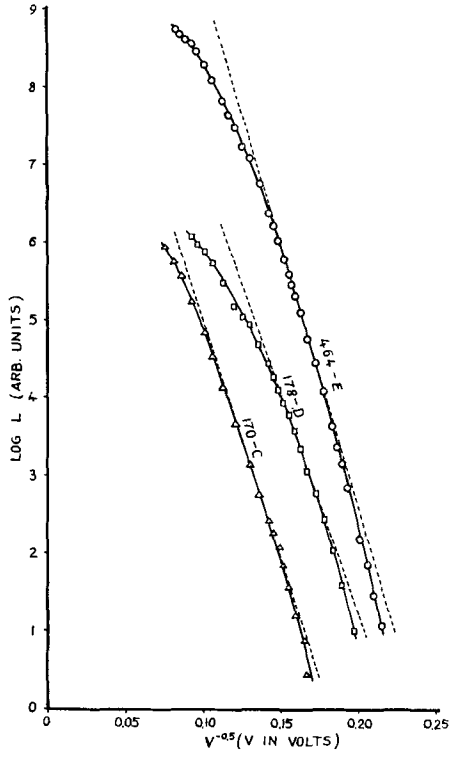

Fig. 8. The L(V) dependences of uniform zinc sulfide films do not follow Eq. [2].

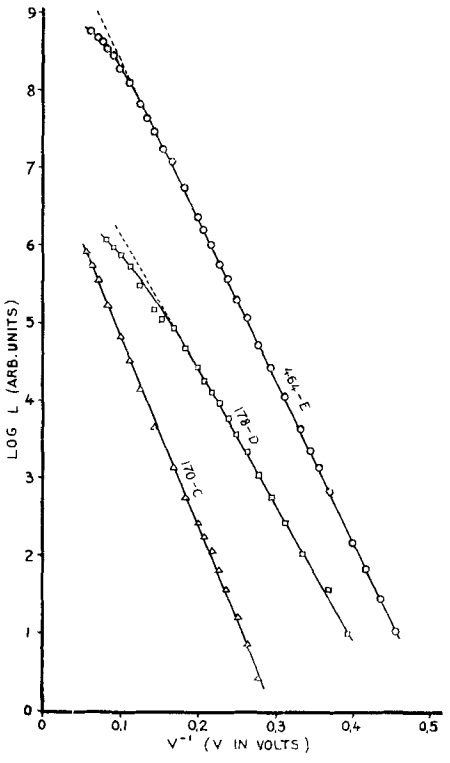

Fig. 9. The L(V) dependences of uniform zinc sulfide films follow Eq. [1] over many decades of L.

lines[2] in Fig. 9 over many decades of L, however, if log L is plotted as a function of V^{-1}.

Mathematical Treatment

The above experimental results indicate that, most likely, the process of excitation and emission of electroluminescence closely follows Eq. [1] if geometrical complexities are eliminated, and that the square root in Eq. [2] results only by the nonuniform geometry of the phosphor, i.e., mainly by the finite particle size distribution. Neglecting other possible reasons of nonuniformity (e.g., irregular particle shapes, orientations of stacking faults and barriers, etc.), it is possible even to draw a direct mathematical connection between the distribution function [4] and the emission function [1] on the one hand, and function [2] on the other hand.

A model phosphor may have a particle size distribution according to Eq. [4]. Every particle of this model phosphor may emit a light intensity described by

$$l = l_o \exp\ (-v_o/v) \qquad [6]$$

where l_o and v_o are constants and where v denotes the voltage drop across the whole particle. The two equations [1] and [6] are essentially identical concerning the voltage dependence. The particle size dependence enters Eq. [6] in two terms. The pre-exponential factor, l_o, may depend on the particle size, x, in a way which approximately may be described by $l_o = cx^m$ where c is a constant and where m is in the order of unity. Much stronger, however, seems to be the dependence v (x) since it enters Eq. [6] in the exponent. The ratio of the particle voltage, v, to the cell voltage, V, is essentially the ratio of the particle size, x, to the cell spacing, S, modified only by a factor, K, in the order of unity denoting the influence of the different dielectric constants of phosphor and embedding material

$$Kv/V = x/S \qquad [7]$$

The emission intensity of the whole phosphor is given by the integral

$$L = \int_o^\infty y(x)\ l(x,V)\,dx \qquad [8]$$

and introduction of [4], [6], and [7] into [8] gives

$$L = ac \int_o^\infty x^n \exp\left[-\left(2\frac{x}{x_o} + \frac{Kv_oS}{xV}\right)\right]dx \qquad [9]$$

where $n = m + 2$.

No simple analytical solution of this integral seems to exist, so a numerical integration was made with the assumption of reasonable values for the constants. The assumed values were $x_o = 8.7\ \mu$, and $(Kv_oS) = 2.3 \times 10^4\ v\mu$ (this corresponds, for instance, to $v_o = 100$ v, $S = 100\ \mu$, and $K = 2.3$). The value of the factor ac in Eq. [9] is unimportant. With these values, the integrand in Eq. [9], i.e., of

$$Y = x^n \exp\left[-\left(2\frac{x}{x_o} + \frac{Kv_oS}{xV}\right)\right] \qquad [10]$$

was computed for different values of n and of V. It develops that the value of the exponent, n, is only of very minor influence so that the presentation of the case $n = 2$ in Fig. 10 may be sufficient here (the curves for the cases $n = 0$, 1, or 3 are almost the same). The results of the numerical integrations are shown in two different ways, in Fig. 11 as log L as a function of $V^{-0.5}$ and in Fig. 12 as log L as a function of V^{-1}. In Fig. 11, the curves very closely approach straight lines over many decades of L, almost independent of the particular value of n. The curves deviate from straight lines at the highest voltages,

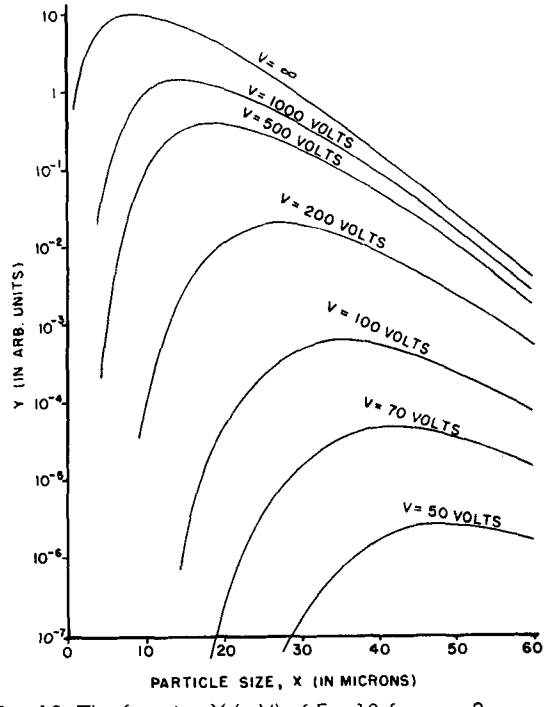

Fig. 10. The function Y (x,V) of Eq. 10 for n = 2, x_o = 8.7 μ, and Kv_oS = 2300 Vμ.

[2] The deviation of two curves at the highest voltages in Fig. 11 is probably due to thermal quenching. The films became noticeably warm under the highest loads and the emission changed from blue to greenish.

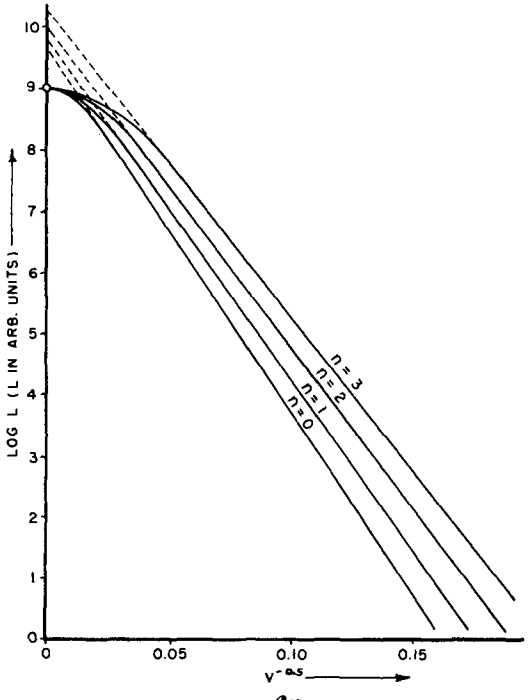

Fig. 11. The function $L = \int_0^\infty Y dx$ (Eq. [9]) approaches Eq. [2] very closely for low and moderate voltages.

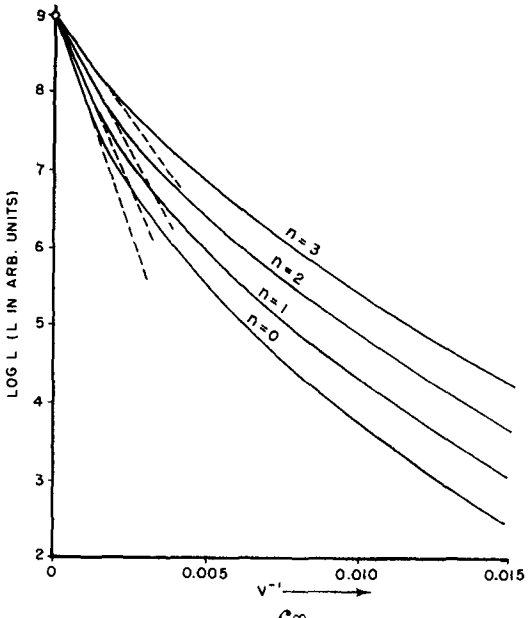

Fig. 12. The function $L = \int_0^\infty Y dx$ (Eq. [9]) does not closely follow Eq. [1] except at the highest voltages.

however, approaching "saturation" values considerably below the intersections of the straight lines with the axis $V = \infty$ (i.e., below the constant L_0 in Eq. [2]). In Fig. 12, on the other hand, the curves do not approach straight lines at all except at the very highest voltages. This behavior is in agreement with experimental observations (15, 21).

Figure 10 also shows another effect, namely, a shift of these particle sizes which contribute most to the over-all light emission with a variation of the voltage, V. At low voltages, only the few largest particles contribute noticeably to the over-all light emission while the many fine particles are still practically dead. Increasing voltage causes the emission from the fine particles to increase faster than that from the coarse particles so that the fine particles dominate at high voltages because they are more numerous. This different contribution of the particles of a real phosphor at different voltages is qualitatively well known (3, 27).

Conclusions

The main results outlined in this paper permit the following conclusion:

(*a*) There is a correlation between the particle size distribution of an EL phosphor and the form of its $L(V)$ dependence. The particle size distribution of common EL zinc sulfide phosphors can be described closely by Eq. [4], and the $L(V)$ dependence of such phosphor follows closely Eq. [2] over many decades of L. Every deviation of the particle size distribution from Eq. [4] also causes a deviation of the $L(V)$ dependence from Eq. [2]. It is possible by a suitable form of the particle size distribution to obtain, within certain limits, any desired form of the $L(V)$ dependence of a phosphor.

(*b*) The fundamental process of electroluminescence, if geometrical complexities are eliminated, most likely follows Eq. [1].

Gallium-Arsenide Diffused Diodes

J. Lowen and R. H. Rediker

Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts

ABSTRACT

Gallium arsenide has been used to fabricate variable reactance and computer diodes which compare favorably with the best commercially available of germanium and silicon. The diodes have been fabricated by zinc diffusion into n-type gallium arsenide. Ohmic contact to the n-type material has been made with an antimony-gold alloy and to the p-type side with indium. Etching is used to remove the p-type diffused skin from everywhere but under the indium contact, thereby forming the mesa and defining the p-n junction area. Rectification ratios (at 2 v) as high as 10^{10} have been achieved. The diodes have been operated successfully in a variable reactance amplifier at S-band (2800 mcps) and in millimicrosecond-switching computer circuits.

Gallium arsenide, because its energy gap is larger than that of silicon, its electron mobility larger than that of germanium, and its dielectric constant smaller than both germanium and silicon, is a very attractive material for use in high-frequency as well as high-temperature devices. Recently it has been reported (1) that the electron lattice scattering mobility in GaAs may be as high as 12,000 $cm^2\ v^{-1}\ cm^{-1}$ and that material with electron mobilities as high as 6000 $cm^2\ v^{-1}\ cm^{-1}$ is now being produced. Point-contact gallium arsenide microwave diodes have been reported by Jenney (2) and Sharpless (3). These point-contact diodes have operated efficiently as first detectors at 6 Kmc (2), and at 11 Kmc and 60 Kmc (3). Jenney (4) has described the very low lifetime of the minority carriers in presently available gallium arsenide and the consequent difficulties in the fabrication of conventional bipolar transistors from the material. This very low lifetime, however, is one of the reasons for the very short switching times (10^{-9}-10^{-10} sec) reported (2, 3) for the point-contact gallium arsenide diode.

This paper describes the fabrication techniques and electrical properties of gallium arsenide diffused diodes. These diodes were designed for use as variable capacitors in parametric amplifiers. Because of the low lifetime for minority carriers in the gallium arsenide, the diodes also could be used in high-speed computer applications, since their switching times were in the order of 10^{-9} sec. The rectification ratios for these diodes are orders of magnitude larger than those for point-contact (2, 3) or alloy junction (5) gallium arsenide diodes previously reported.

Fabrication

The fabrication of the gallium arsenide diffused diodes can be divided into two sets of processes, the first set related to the diffusion step, the second including the assembly of the diode and the making of the ohmic contacts.

Diffusion is accomplished in a sealed quartz ampoule as shown in Fig. 1. All components are carefully etched and washed before being introduced into the ampoule. Referring to Fig. 1, the n-type gallium arsenide wafer which is about 0.050 cm thick has been cut from single crystal material so that its faces are perpendicular to the <111> direction. The face sitting on the flat quartz plate has been polished with 600 mesh SiC, but the exposed face has been polished to a mirror finish, the final abrasive being 0.1 μ alumina. The flat quartz plate is used to avoid the possibility of producing strains in the wafer during the diffusion cycle. About 250 mg of coarse crushed gallium arsenide is added below the quartz plate to provide an arsenic atmosphere and preserve the mirror-like finish during the diffusion. Without this added gallium arsenide the surface becomes stained and under extreme conditions of temperature and vacuum shows droplets of gallium. About 200 millionths of a gram of zinc, the p-type dopant, has been weighed into a quartz capillary which is inserted into the ampoule with due precaution to prevent contact between the zinc and the gallium arsenide. The quartz ampoules which have been used have a volume of about 20

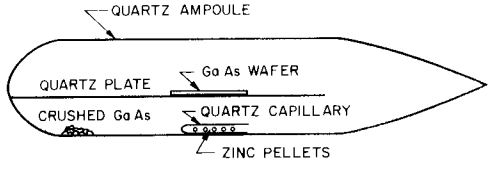

Fig. 1. Sealed diffusion ampoule just prior to being inserted into furnace.

ml; thus, the concentration of zinc in the vapor phase during diffusion is approximately 10^{17} atoms/ml. The loaded quartz ampoule is attached to a high vacuum system, pumped down to about 5 x 10^{-7} mm Hg, and then sealed off under vacuum. The heating cycle is programmed to heat to temperature rapidly, remain at that temperature for the desired period of time, and to allow for a slow cool down, between 1-2°C/min. Diodes have been fabricated from gallium arsenide indiffused with zinc at 650° and 700°C, and times of diffusion have been varied from 3 to 72 hr. There are indications that temperatures as low as 600°C can be used. For a 66-hr diffusion run at 650°C, we measured a junction depth of 8 μ, using a potassium hydroxide, potassium ferricyanide etch to delineate the junction.

The zinc indiffused gallium arsenide wafer then is diced and the rough side lapped to remove the p-type skin and to reduce the wafer thickness to between 0.003 to 0.005 in. Ohmic contact to this n-type side is made by bonding in a hydrogen atmosphere at about 450°C to an antimony gold plated Kovar rod. Ohmic contact to the p-type skin is made by alloying in an indium sphere 0.003-0.005 in. in diameter at 250°-300°C in a hydrogen atmosphere with aluminum chloride as a flux. The wafer is cleaned and then etched with a solution of equal parts of HNO_3, HAc, and HF. In this etching the p-n junction area is defined since the p-type skin is removed from the die everywhere but where it is masked by the indium alloy contact. An artist's conception of a section through a completed diode is shown in Fig. 2. This figure shows a pressure contact to the indium.

Electrical Properties

The voltage-current characteristic of a diode fabricated as described above is shown in Fig. 3. This characteristic has been plotted to logarithmic scale to show clearly the operating range of the diode. Note that below 5 v the reverse current is less than 2 x 10^{-11} amp and at 2 v the rectification ratio is about 10^{10}. For the diode of Fig. 3, the current in the forward direction obeys to a close approximation an $I = I_o \exp(qV/2kT)$ law between 10^{-11} and 10^{-2} amp. Larger area diodes have exhibited forward characteristics where, as the current is increased the exp $(qV/2kT)$ relationship changes to exp (qV/kT) before the ohmic series resistance masks the junction properties. This change in exponential behavior is consistent with the theory of Sah, Noyce, and Shockley (6).

The variation of diode capacitance with voltage is illustrated in Fig. 4. Plotted as abscissa is the applied voltage plus an assumed junction built-in-potential of 1.2 v. This assumed built-in-potential has been determined from the internal contact potential calculated from the impurity distribution. It is well known, however, that for germanium (7) and silicon the built-in-potential is usually less than this internal contact potential. The capacitance-voltage data is not sufficiently detailed to exclude by reason of poor fit to a power law the use of built-in-po-

tentials as low as 0.6 v. Using 1.2 v as shown in Fig. 5, the capacitance can be approximated by

$$C = \frac{C_o}{(V + 1.2)^{0.42}} \qquad [1]$$

indicating that the p-n junction is intermediate between an abrupt junction where the $V^{-1/2}$ law applies and the linear junction where the $V^{-1/3}$ law applies. If a built-in-potential of 0.7 v is used, on the other hand, the capacitance-voltage data can be fit by a $V^{-1/3}$ law.

Use as a Variable Capacitor

A figure of merit that has been proposed (8) for variable reactance diodes is the cutoff frequency

$$f_c = (2\pi R_s C_{min})^{-1} \qquad [2]$$

where C_{min} is the diode capacitance (given in Eq. [1]) just short of breakdown and R_s is the semiconductor series bulk resistance through which the capacitance charging current must flow. This cutoff frequency is the highest frequency for which the quality factor Q of the variable reactance can be unity or larger. The intrinsic value of gallium arsenide as the semiconductor in variable reactance diodes lies in its high electron mobility even at high doping levels, which makes possible lower values of series resistance, R_s, than can be achieved in either germanium or silicon. The ratio of the cutoff frequency for diffused diodes of different semiconducting materials but of identical geometry and impurity concentration is

$$\frac{f_{c1}}{f_{c2}} = \frac{\mu_1}{\mu_2} \cdot \frac{\epsilon_2}{\epsilon_1} \qquad [3]$$

where ϵ is the dielectric constant and μ is the mobility of majority carriers in the bulk material. The cutoff frequency should be larger for GaAs than for Si or Ge because (*a*) the dielectric constant of 11 for GaAs is smaller than the values of 12 for Si and 16 for Ge, and (*b*) the electron mobility in GaAs is significantly larger, and for very heavily doped material ($n > 10^{18}$ cm^{-3}) almost an order of magnitude larger, than that in germanium and silicon. The comparison of cutoff frequencies has been given in Eq. [3] assuming the breakdown voltage for a given impurity distribution is independent of the semiconducting material. Actually, for the more heavily doped material ($n > 10^{18}$ cm^{-3}) diodes made of gallium arsenide seems to exhibit a higher breakdown voltage than similar diodes of germanium or silicon.

The diode whose electrical characteristics are shown in Fig. 3 and 4 has been used successfully in a variable reactance amplifier at S-band (2800 mcps). It had a cutoff frequency measured at 5 v reverse bias of about 30 Kmc which corresponds to a series bulk resistance of about 6.5 ohms. This value of resistance can be explained in terms of a true bulk resistance alone if one remembers that near the diffused junction the resistivity is much higher than the 0.04 ohm-cm resistivity of the starting material and that it is in this region (which is in the mesa) that the diode cross section is limited. On the other hand, contributions to the resistance by the contacts cannot be excluded.

By further refinements of technique we have been able, using the same resistivity material, to fabricate diodes with about 3 times the high frequency capabilities of the diode described above (9). This resistivity, however, is by no means optimum for diodes to be used as variable capacitors. For a given semiconductor the figure of merit, given in Eq. [2], is related to the material properties by

$$f_c \propto n^{1/2} \mu \qquad [4]$$

where n is the net impurity concentration and μ is the mobility. Lower resistivity gallium arsenide than has been used here should yield significantly better figures of merit. The full exploitation of the advantages of this relatively new intermetallic semiconductor for variable capacitors and other applications awaits a more abundant supply of good single crystal gallium arsenide of controlled resistivity. One application, however, for which present day gallium arsenide with its very low minority carrier lifetime is eminently suited is the fast-switch computer diode.

Use as a Computer Diode

Because of the very low lifetime in the GaAs now available, minority carrier storage which limits the switching speed in most germanium and silicon diodes is minimized. Diodes, which were fabricated as described above primarily for use as variable capacitors, when used in computer circuits have had switching times of the order of millimicroseconds. Figure 5 is a photograph of the reverse recovery transient as seen on a traveling wave oscilloscope of the diode whose characteristics are illustrated in Fig. 3 and 4. The diode was switched from 10 ma forward current to 5 v reverse bias with a loop impedance of 120 ohms. The time to recover to 1 ma reverse current is less than 3 mμsec.

Acknowledgments

The authors wish to thank Mrs. M. Barney and F. Sullivan for help in fabricating the diodes, and R. H. Kingston for evaluating the diodes in his S-band variable reactance amplifier. For our supply of single crystal gallium arsenide we are indebted to the RCA Semiconductor Division and the RCA Laboratories and to the Wright Air Development Center and the Air Materiel Command who sponsored their work, as well as to P. Moody and Mrs. C. Kolm of our laboratory.

Purification of $SiCl_4$ by Adsorption Techniques

H. C. Theuerer

Bell Telephone Laboratories, Inc., Murray Hill, New Jersey

ABSTRACT

Silicon tetrachloride may be purified using adsorption columns filled with hydrous oxides or silicates. Hydrogen reduction of this purified halide leads to higher purity silicon than is obtainable otherwise. Data for the adsorption efficiency of various materials are presented using infrared spectroscopy and radioactive tracer techniques as the basis of comparison.

Several methods currently in use for the preparation of high-purity silicon require silicon tetrachloride as a source material. The quality of the silicon obtained depends on the purity of the silicon tetrachloride used, boron and phosphorus chlorides being the residual impurities of most concern. Removal of these impurities usually has been accomplished by distillation methods in conjunction with complexing additives (1-3). Such additives react with boron and phosphorus chlorides to form low vapor pressure compounds which remain in the still during distillation.

A new method for the purification of silicon tetrachloride using columns filled with hydrous adsorbents has led to significantly better results. It has been found that boron and phosphorus, as well as heavy metal chlorides, are removed efficiently by adsorption. Hydrogen reduction of the purified silicon tetrachloride to produce silicon rods, followed by floating-zone refining, has resulted in p-type crystals with resistivities above 8000 ohm-cm and minority carrier lifetimes of 1 msec. Using distillation methods for purification, comparative rods have resistivities of about 1000 ohm-cm and lifetimes of the same order as those obtained with the purer silicon.

In establishing the best adsorption techniques for the purification of silicon tetrachloride, it was necessary to evaluate various classes of adsorbents. Since hydrogen reduction and floating-zone refining are time consuming, several analytical methods were developed for these evaluations. Infrared absorption spectroscopy was used for the detection of BCl_3 and PCl_3 in $SiCl_4$. In the case of phosphorus, PCl_3 containing radioactive P32 with a half life of 14 days also was used for detection.

Evaluation of Adsorbents by Infrared Analysis for BCl_3 and PCl_3 in $SiCl_4$

Infrared spectra revealed that BCl_3 had a characteristic band at 1313 cm^{-1}, and PCl_3 had a series of bands at 1415, 1368, and 1345 cm^{-1}. $SiCl_4$ does not absorb in these regions. For calibration purposes, a series of $SiCl_4$ standards containing known amounts of BCl_3 and PCl_3 was prepared and analyzed. Strict adherence to Beer's law was not observed due to molecular interaction between BCl_3 and PCl_3, and the results are therefore semiquantitative with a detection sensitivity of 0.01%. Using this detection method and working with $SiCl_4$ containing 1% each of BCl_3 and PCl_3, it was possible to evaluate the relative efficiencies of various adsorbents for the removal of these impurities. Although the concentrations of impurities normally found in $SiCl_4$ are much lower than the detection limit of 0.01%, the above method gave much valuable information concerning the purification efficiency of various adsorbents.

In initial experiments, silica gel, activated alumina, coconut charcoal, and "molecular sieves" (sodium-calcium-alumino silicate) were evaluated for

Table I. Purification of $SiCl_4$ containing 1% PCl_3 and BCl_3 by various adsorbents

Adsorbent	First 10 cc eluted		Remaining drainable fractions	
	BCl_3, %	PCl_3, %	BCl_3, %	PCl_3, %
Silica gel 6-16 mesh	<0.01	<0.01	<0.01	<0.01
Activated alumina 8-14 mesh	<0.01	<0.01	<0.01	<0.01
Coconut charcoal 6-14 mesh	<0.01	0.1	0.1	0.1
Molecular sieves (sodium calcium alumino silicate) 1/16 in. pellets	1.0	<0.01	1.0	1.0

the removal of BCl_3 and PCl_3 from $SiCl_4$. Prior to use, the adsorbents were activated by treating in air at 270°C for 16 hr. The adsorbents then were added to 50 ml burettes to form columns 0.4 in. in diameter and 10 in. long. Thirty milliliters of $SiCl_4$ containing 1% each of BCl_3 and PCl_3 were allowed to drip into the columns at the rate of 1 ml/min. After standing 1 hr, 10 ml samples were drained from the burettes at a rate of 0.8 ml/min. A second set of samples comprising the remaining drainable $SiCl_4$ (approximately 12 ml) was collected also. All samples then were analyzed by the infrared absorption technique, with the results shown in Table I. It is apparent from these results that the hydrous oxides of silica and alumina are quite effective for removal of BCl_3 and PCl_3 from $SiCl_4$, the other adsorbents being relatively ineffective.

In addition to the above, various classes of adsorbents, including ion exchange resins, were tested for adsorption of BCl_3 and PCl_3 from $SiCl_4$ using the infrared technique. In a number of instances desired materials were not readily available, and in these cases, they were prepared specially. Where possible, the adsorbents were precipitated in gelatinous form for maximum surface area. The methods of preparation used are listed in Appendix I.

In the case of ion exchange resins, while $SiCl_4$ solutions are essentially nonionic, physical adsorption of impurities on these resins seemed possible, since they are porous and have a high surface area. Because such resins normally are furnished in a moist condition, prior to use with $SiCl_4$, it was necessary to remove the water by drying in a vacuum desiccator. After several days of pumping, these materials no longer hydrolyzed $SiCl_4$ and were then in satisfactory condition for adsorption studies.

In testing the adsorption efficiencies of the various materials, 5 cc of solid adsorbent, activated as listed in Table II, were added to 20 ml of $SiCl_4$ containing 1% each of BCl_3 and PCl_3. The mixtures were shaken intermittently for 1 hr, after which the $SiCl_4$ was filtered through glass wool and analyzed by infrared spectroscopy. Results are summarized in Table II.

It will be seen that hydrous oxides and silicates adsorb both BCl_3 and PCl_3 from $SiCl_4$. Those materials which were in gel form were most effective, probably due to their large surface area. Dehydration of several of the active oxides destroyed their adsorption efficiency, suggesting that chemisorption involving OH groupings is at least a part of the purification mechanism. Ion exchange resins were inoperative for the removal of boron and phosphorus chlorides.

Adsorption Studies Using Radioactive PCl_3 and PCl_5 in $SiCl_4$

In determining the effectiveness of adsorption columns for the removal of phosphorus chlorides

from $SiCl_4$, solutions containing 0.001% by volume of PCl_3 containing radioactive P32 were used. Where desired, the PCl_3 was converted to PCl_5 by the addition of Cl_2 to the $SiCl_4$ solution. In these studies, samples of the eluent were analyzed, and autoradiographs of the columns were made. The detection sensitivity for phosphorus in the $SiCl_4$ was initially 1×10^{-8} mole %. In this work, activated alumina and silica gel were used as the adsorbents; these were activated by heating in air prior to use at 270°C for 18 hr. The initial exploratory work was done with 0.4 in. diameter x 10 in. long columns in 50 ml burettes using 6-14 mesh adsorbents. In these experiments, autoradiographs showed that the PCl_3 was dispersed throughout the adsorbents, suggesting that channeling of the liquid was occurring in the columns resulting in some elution of PCl_3. To prevent channeling, finer adsorbents were required, and all subsequent experiments were done with 80-200 mesh adsorbents. For these experiments, columns, such as the one shown in Fig. 1, were used. With these columns, the $SiCl_4$ was allowed to drip through the adsorbent at a rate of about 1 cc/min until a liquid head formed in the top of the tube. The column then was allowed to equilibrate for several hours before sample collection was begun at a rate of 1 ml/min, controllable with the Teflon valve in the apparatus. Radioactivity measurements on samples of eluent taken during the purification, and autoradiographs of the columns were made at the end of each experiment. Table III gives a summary of the analytical data obtained with variations of the adsorption practice. It will be seen that using 60-200 mesh silica gel or activated alumina eliminated the channeling found with the 6-14 mesh adsorbents, and in consequence, better phosphorus removal was obtained. Autoradiographs of the columns containing the finer adsorbents showed that the phosphorus was banded for a distance extending 3 in. down from the top, no phosphorus being detected below this point.

In the course of this work, as shown in Table III, it was found that best results were obtained when the $SiCl_4$ contained free chlorine or a combination of chlorine and aluminum chloride prior to adsorption purification. In these cases, 10 ml of liquid chlorine per liter of $SiCl_4$ were added; where $AlCl_3$ was used, 30 g/l of granular anhydrous $AlCl_3$ were added. After standing overnight, the undissolved $AlCl_3$ was filtered off. The purpose of the chlorine addition was to convert PCl_3 to PCl_5. The use of $AlCl_3$ results in the formation of the coordination compound, $PCl_5 \cdot AlCl_3$ (2, 4). Using either of these pretreatments, with activated alumina as the adsorbent, no phosphorus was detected in the eluent after 3525 ml had passed through the columns. In both cases tight banding of the phosphorus was observed at the top of the columns. The width of this band increased with the quantity of $SiCl_4$ eluted and after 3525 ml had passed through extended down from the top of the column for a distance of about 1 in. For phosphorus removal, no advantage was found in adding $AlCl_3$ in conjunction with the chlorine. However, for reasons not completely understood, use of the combination of $AlCl_3$ and Cl_2 in the purification of $SiCl_4$ leads to silicon lower in boron. It has been observed that both PCl_3 and PCl_5 form coordination compounds with BCl_3. The complex $BCl_3 \cdot PCl_5$ has a solubility of about 0.033 mole % in $SiCl_4$ and sublimes below 100°C. It may be that the $AlCl_3$ breaks this complex by forming $AlCl_3 \cdot PCl_5$, thus freeing the BCl_3

* 10 ml of liquid chlorine per liter, and 30 g $AlCl_3$ per liter of $SiCl_4$ were used.

for more effective adsorption. These complexes of phosphorus and boron chlorides also may be the source of the difficulty normally encountered in distillation procedures for the removal of these impurities.

Removal of Heavy Metal Chlorides and Sulfur Compounds from $SiCl_4$

In operating adsorption columns, such as shown in Fig. 1, filled with either activated alumina or silica gel, it is observed that after several liters of $SiCl_4$ have been eluted, a brown band forms at the top of the column for a distance of about ½ in. This band gradually broadens with continued use. Spectrochemical analysis of the adsorbent in the banded region shows traces of B, Cu, Fe, Mn, and Mg. These impurities are not detected lower in the column and are not detectable in hydrolyzed samples of the initial $SiCl_4$. These results clearly indicate that the adsorption technique is quite effective in removing heavy metal chlorides from $SiCl_4$.

Commercially available $SiCl_4$ may contain sulfur compounds at mole ratios as high as 1.1×10^{-4}. These compounds, probably $SiCl_3HS$ and $SiCl_2S$, liberate H_2S on hydrolysis of the $SiCl_4$, and this may be used as a basis of detection. While adsorption methods remove these compounds, it is expedient to reflux the $SiCl_4$ with copper turnings for 16 hr prior to column purification, which effectively removes the sulfur. Sulfur compounds in $SiCl_4$ react with copper to form black CuS. In the absence of sulfur, the copper turnings remain bright.

Summary

It has been shown that adsorption columns filled with hydrous oxides or silicates offer an attractive method of purifying $SiCl_4$ for use in the preparation of very high-purity silicon. In using the method, the $SiCl_4$ is first refluxed with copper turnings to remove sulfur compounds. It is then preferably treated with $AlCl_3$ and Cl_2 and passed through an adsorption column containing either activated alumina or silica gel. The purified $SiCl_4$ contains Cl_2 which, if objectionable, may be removed by refluxing in a stream of dry nitrogen or hydrogen. On reduction of the purified $SiCl_4$ in hydrogen on tantalum tubes, polycrystalline rods suitable for floating-zone refining are obtained. After removal of the tantalum, such rods, if given several zone passes in dry hydrogen, are n-type with a resistivity of 50-100 ohm-cm in the region of the crystal where refining does not occur. Subsequent zone refining to eliminate the donors, principally phosphorus, results in p-type silicon with resistivities above 8000 ohm-cm. After two zone passes, the lifetimes of the crystals are of the order of 1 msec and no evidence of trapping centers is found. Subsequent refining does not further improve the lifetime.

The source of the phosphorus in this silicon is not known. It is unlikely that the phosphorus originates from the purified $SiCl_4$ in view of the radioactivity results, which show tight banding of phosphorus at the top of the column and no detectable phosphorus in the eluent. It seems probable that the donors are introduced during the reduction process either from the reactants or the apparatus itself.

Although a detailed study has not been made, exploratory experiments indicate that column methods using hydrous oxides as adsorbents can purify other halides such as $SiHCl_3$ and $GeCl_4$ effectively. Attempts to purify SiI_4 by passing through a heated column, or by dissolving the iodide in n-heptane or toluene prior to column elution, have not been promising. SiI_4 reacts with the adsorbents tried (activated alumina and silica gel) with the liberation of iodine.

Acknowledgments

The author is greatly indebted to a number of his colleagues at Bell Telephone Laboratories for much of the work in this investigation. D. L. Wood and J. P. Luongo were responsible for the infrared spectroscopy; J. D. Struthers was responsible for the radioactive tracer analyses; J. E. Jamieson purified the silicon tetrachloride and made the hydrogen reduced silicon; and D. D. Bacon did the zone refining work.

APPENDIX I

Method of Preparing Various Adsorbents

Silica gel from hydrolyzed $SiCl_4$.—Fifty milliliters of $SiCl_4$ were hydrolyzed in 500 ml of deionized water at 0°C. An opalescent liquid was obtained which set to a gel in about 2 hr. After aging overnight, the gel was broken up and washed copiously to remove the HCl formed during hydrolysis. The gel was dried for 2 days in a vacuum desiccator followed by air drying at 100°C for 24 hr and activation at 270°C for 18 hr.

Silica gel anhydrous.—Commercial silica gel, 6-14 mesh, was deactivated at 1000°C for 18 hr in air with a weight loss of 5.2%.

MgO *and* $Mg(OH)_2$.—Anhydrous MgO powder was heated for 18 hr at 120°C prior to use as an adsorbent. To hydrate this oxide, a batch of the above MgO was dissolved in 6*N* HCl and filtered. The clear solution was made alkaline with ammonium hydroxide to precipitate $Mg(OH)_2$. This was filtered, washed, and dried at 120°C. The resulting hard cake of $Mg(OH)_2$ was crushed in an agate mortar and dried for 4 hr at 120°C before use.

Titania gel.—Twenty-five milliliters of tetraisopropyl titanate were stabilized against rapid hydrolysis with 5 ml of 12*N* HCl. To the above solution, 75 ml of H_2O were added and the mixture heated to 80°C. Ammonium hydroxide then was added until a curdy gelatinous precipitate formed. After standing for several hours, the gelatinous mass was made strongly alkaline with ammonium hydroxide. The curd then was aged overnight, washed free of ammonia, and dried for 24 hr in a vacuum desiccator. This was followed by air drying at 120°C and activation for 18 hr at 270°C.

$Fe(OH)_3$ *gel.*—$Fe(OH)_3$ was dissolved in a small excess of 6*N* HCl and the solution filtered. This was made strongly alkaline with NH_4OH precipitating gelatinous $Fe(OH)_3$. After aging overnight, the precipitate was filtered, washed free of NH_4OH and NH_4Cl, and dried overnight. It then was dried for 24 hr at 120°C and activated at 270°C for 4 hr

Purification of Tantalum Obtained by Vacuum Arc Melting

M. L. Torti

National Research Corporation, Cambridge, Massachusetts

ABSTRACT

The purest commercially available tantalum powder was consolidated by a single, vacuum, consumable-arc melting operation yielding ingots of considerably higher purity than the original powder. Interstitial and metallic impurity analyses are presented for a large number of heats made under consistent conditions of ingot and electrode size, arc current, and furnace pressure. The effect of carbon addition to an oxygen-rich starting material was investigated, and the optimum carbon-oxygen ratio for maximum refinement has been located approximately. Under favorable conditions, the oxygen content is reduced by approximately one order of magnitude.

Tantalum metal has traditionally been produced by the powder metallurgy route in which a lengthy high-temperature vacuum sintering treatment is utilized for refining to the purity necessary for fabrication.

The general extension of vacuum arc melting as a method for consolidating the refractory metals has prompted a wide interest in the arc melting of tantalum. Although fabricable ingots have been produced from tantalum powder of conventional purity, the purity and ductility of these ingots has not matched good sintered bar material. Indeed, doubt is commonly expressed as to whether any refinement at all occurs during arc melting.

When a relatively pure tantalum powder became commercially available the arc melting procedure gained new promise. Ingots are now being produced by a single melt which can be fabricated cold from ingot to 0.0005 in. thick strip without intermediate anneals. The excellent ductility and superior purities are due in a large degree to the initial purity of the tantalum powder. However, substantial purification does occur during arc melting with respect to both interstitial and metallic impurities.

Description of Equipment and Procedure

All melting was done in a conventional cold-mold arc furnace. Power was supplied by a bank of welding generators capable of supplying 5600 amp. A 1000 CFM mechanical-booster high-vacuum pump, backed by a 100 CFM mechanical pump, comprised the pumping system. This system blanks off below 1 μ and has a pumping speed of over 1000 CFM between 10 and 1000 μ. A nominal 4 in. diameter cold mold was used. Since double extra heavy copper pipe was installed as the mold liner, the actual inner mold diameter was 3.5 in. Melt stock was National Research Corporation melting grade tantalum powder −12 +325 mesh. Bars 1¾ to 2 in. in diameter were hydrostatically pressed from this powder. These bars were given a quick premelting treatment in which direct resistance heating was used to heat the bars to 1500°C for approximately 1 min in vacuum. This operation dimensionally stabilizes the bars and improves the already excellent green strength. No significant purification is obtained for such a short heating period. The bars are then welded into the electrode using a tungsten permanent electrode in an argon atmosphere. Strong, ductile welds are obtained on high-purity powder. Brittle welds may occur if powder containing over 1000 ppm total interstitial impurities is used.

Melts were run at 30 v, 4500-5000 amp under 2-5 μ pressure measured in the furnace body. A melting rate of 0.5 lb/min resulted. This corresponds to a power input of approximately 4.5 kwh/lb. The molten pool was stirred by a 500 turn d-c adjustable-amperage stirring coil. Normally 3 amp was sufficient to stabilize the arc and gently stir the pool without undue agitation. At that amperage the measured magnetic field in the center of the empty mold is 40 gauss.

During melting the arc is observed visually. A thin film of deposited vapor is seen above the melt. This layer is partially driven ahead of the melt level and partially redissolved in the melt, resulting in the higher impurity levels reported for the ingot tops.

The 70-90 lb ingots are lathe conditioned, then slices are cut from the top and bottom for analytical samples. Chunks from the interior of the samples are used for the oxygen and nitrogen samples. Dry drillings are used for the other samples. For some elements both spectrographic and wet analyses are reported, and two spectrographic procedures were employed.

Experimental Results

Table I reports carbon and oxygen analysis for 2-in. diameter pressed-bar electrodes and the resulting 3½ in. diameter ingot. In this series no carbon was added to the melt stock. Note that signifi-

cant amounts of oxygen are removed, particularly at the ingot bottom. The oxygen is probably removed as tantalum oxides which deposit on the mold wall above the melt. Since this oxide film must be either driven up or redissolved in the melt it is not surprising that the oxygen level at the ingot top, although slightly lower than the melt stock, is double the oxygen content at the ingot bottom. The carbon present in the melt stock is decreased to or below the analytical limits indicating that some carbon removal, probably as carbon monoxide, is occurring. Occasional analyses report higher oxygen content for the ingot than for the melt stock. This is attributed to individual sampling and analytical determination errors, and indicates the necessity for averaging the results from a large number of heats.

Table I also reports analytical data for 1¾-in. diameter electrodes to which fine graphite powder was added. Since the melt rate, pressure, ingot condition, and metallic refinement were the same as for the 2-in. diameter electrodes, it is assumed that except for the carbon addition, melting conditions for this series are identical to those for the 2-in. electrodes. The initial carbon content of the tantalum was 10-20 ppm. Additional carbon in the form of fine graphite powder was thoroughly mixed with the tantalum powder. Sufficient carbon was added to raise the carbon-oxygen ratio to 50% of the stoichiometric ratio for carbon monoxide.

The average oxygen content in the electrode was 239 ppm, the average oxygen content in the ingots was 65 ppm top and 34 ppm bottom. The total carbon in the electrode was 111 ppm which was reduced to 23 ppm top and 30 ppm bottom for the ingots. Thus an average of 73% of the oxygen content of the electrode was removed at the top of the ingots and 85% at the ingot bottom. This compares to a 25% oxygen reduction at the ingot top and 67% at the ingot bottom for the melts (Table I) to which no carbon was added. Furthermore, carbon additions appear to cut down the fluctuations in oxygen content from ingot to ingot.

Table I. Tantalum vacuum arc melting

I. Oxygen and carbon refinement for no carbon addition, average of 14 melts

	O (ppm)		C (ppm)	
	Top	Bottom	Top	Bottom
Electrode	140		10-20	
Ingot	106	46	<10	13

II. Oxygen and carbon refinement with 50% stoichiometric carbon addition, average of 11 melts

	O (ppm)		C (ppm)	
	Top	Bottom	Top	Bottom
Electrode	239		111	
Ingot	65	34	23	30

III. Oxygen and carbon refinement with 100% stoichiometric carbon addition, average of 2 melts, high oxygen powder used

	O (ppm)		C (ppm)	
	Top	Bottom	Top	Bottom
Electrode	950		800	
Ingot	120	—	360	—

IV. Other impurity refinement (ppm), average of 25 melts

	N	Fe	Cr	Ni	Nb	Si
Electrode	28	95	86	111	112	<250
Ingot	27	30	14	28	40	30

The final carbon-oxygen ratio appears quite good, particularly at the ingot bottom. Earlier in the program tantalum powder of 1000 ppm oxygen content was mixed with sufficient carbon to bring the carbon-oxygen ratio to 100% of the stoichiometric ratio for carbon monoxide removal. Table I shows the results of two melts. Considerable oxygen was removed, but the final carbon content was 2-3 times that of the oxygen. When one of these ingots was remelted, the decrease in oxygen was less than expected.

Table I reports analytical data for several other elements. The ingot analyses were taken at the ingot top. Three analytical procedures are used; wet chemical, pellet spectrographic, and carrier spectrographic.

Very little difference is noted between the nitrogen analysis for the ingots and electrodes so that it appears that little, if any, nitrogen removal occurs during melting at the low nitrogen levels encountered in this program.

Iron is definitely removed on melting, being reduced by a factor of two or three. The amount of refinement is somewhat vague for several melts due to the starting concentration being below the level of detection for the method used.

Nickel is present in the same amounts as iron and is removed to the same degree.

Chromium is quite volatile and considerable refinement occurs, generally resulting in an ingot content below the level of detection.

The data indicate a removal of niobium on the same level as iron and nickel. This is somewhat surprising since the vapor pressure of niobium is considerably lower than that of iron at the tantalum melting point. Two possible mechanisms may be postulated. The vapor pressure of the niobium suboxides may be higher than that tantalum suboxide vapor pressure resulting in the preferential removal of niobium oxides. Unfortunately, values of the vapor pressures have not been reported in the published literature. Iron and nickel form intermetallic compounds with tantalum while niobium does not. Thus the activity coefficient of niobium in tantalum may be higher than that for iron or nickel in tantalum. The resulting impurity partial pressures may then be more nearly equal.

The data for silicon unfortunately do not locate the silicon level in the electrode until the last few runs. However, these rather sparse data do indicate significant removal during melting.

Hydrogen analyses were not always run, but the electrode hydrogen content varies between 25 and 50 ppm, while the ingot hydrogen varies between 1 and 5 ppm.

Conclusions

Consumable arc melting of tantalum can, under favorable conditions, result in considerable refine-

ment of the metal. Oxygen can be removed both as tantalum oxides and as carbon monoxide. Of the combinations studied, the lowest, most uniform oxygen analyses in the ingot result when the carbon in the electrode is 50% of the stoichiometric carbon-oxygen ratio for carbon monoxide removal.

Nitrogen is not significantly reduced at the low nitrogen levels encountered. Metallic impurities with vapor pressures equal to or greater than nickel are significantly reduced. Niobium appears to be partially removed although the mechanism is not completely clear.

Heat Transfer Rates of an Argon Plasma Jet

C. S. Stokes, W. W. Knipe,[1] and L. A. Streng

The Research Institute of Temple University, Philadelphia, Pennsylvania

ABSTRACT

Heat flux measurements were made on a small argon plasma jet. Experimental values as high as 4.5 kcal/cm² sec were obtained for the transient-heating rate of a small copper slug. The heat-flux variation with energy supplied and the energy distribution to cathode, anode, and plasma are presented.

Arcs have been of interest as high-temperature sources for a number of years. The development of the plasma jet has provided a convenient tool for studying gases at these temperatures, without electrode interference. A number of investigators (1-3) have devised plasma-jet apparatus of various kinds. This paper presents the measurements of the heat transfer rates of an argon plasma jet.

Apparatus and Procedure

A drawing of the plasma generator is shown in Fig. 1. The generator consists of a water-cooled ⅛ in.-2% thoriated tungsten cathode with an annulus for feeding the argon gas. The copper anode, which has a 0.157 in.-hole for the plasma jet, is water cooled. A ¼ in.-Teflon gasket insulates the anode from the cathode.

A 600-amp d-c welder was used as the power source. Appropriate electrical meters guided the operation. Argon[2] was metered through a Fisher and Porter flowmeter. The plasma jet was approximately 1 in. long and expanded to a diameter of about ¼ in.

The heat transfer measurements were made with a transient probe consisting of a piece of copper ⅛ in. in diameter and ¼ in. long, embedded in a ⅝ in.-diameter piece of "Transite" ½ in. long. This assembly was placed in a 1½ in.-diameter by 1 in.-long piece of laminated fiberglass (see Fig. 2). The probe was mounted on a high-speed air-piston cylinder which thrust the probe into the jet approximately 1 mm below the anode. A 30-gauge iron-constantan thermocouple was inserted into the copper slug 0.050 in. from the back surface.

Two separate high-speed measuring apparatus were used to obtain the time-temperature curves for

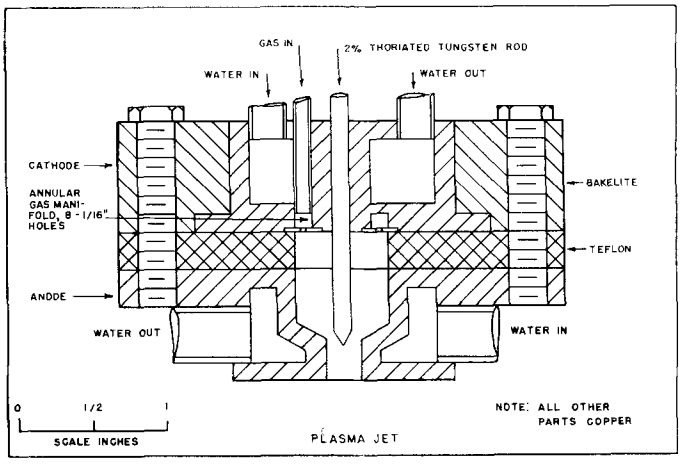

Fig. 1. Schematic of plasma jet apparatus

the copper slugs. One consisted of a d-c-modulated high response time potentiometer. The low voltage from the thermocouple modulated a 160-kc carrier wave which was shown on an oscilloscope with a triggered-sweep duration of 2 sec. The other system used was a Tektronix type-533 oscilloscope with a type-53/54D calibrated high-gain d-c preamplifier.

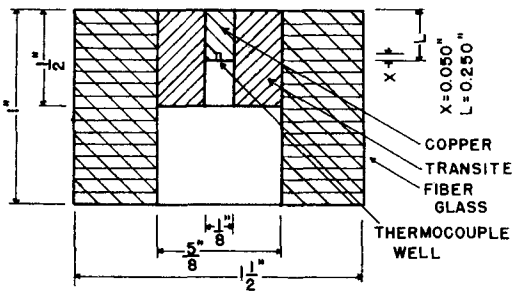

Fig. 2. Transient heat probe

[2] Obtained from Air Reduction Co.

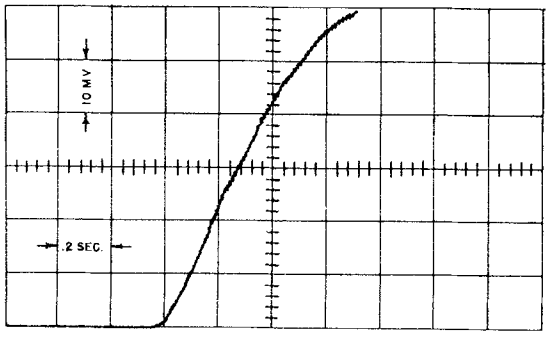

Fig. 3. Trace of the tektronix system. Ordinate, 10 mv per large division; abscissa, 0.2 sec per large division.

Both systems produced similar results. The modulation system cut out most of the "noise" produced by the arc but was more difficult to calibrate than the other. A typical trace of the Tektronix system is given in Fig. 3.

Calculation of Heat Transfer Rates

The general method of data reduction used is described by Sutton (4).

The equations for a transient one-dimensional system are:

$$\frac{T - T_o}{Q} = \frac{L}{K} Z \qquad [1]$$

$$Z = 2\sqrt{X} \sum_{0}^{\infty} (\text{ierfc } z + \text{ierfc } z') \qquad [2]$$

$$X = \frac{Kt}{dL^2 C_p} \qquad [3]$$

$$N = x/L \qquad [4]$$

$$z = (2r + 1 - N)/2\sqrt{X} \qquad r = 0, 1, 2, \ldots$$

$$z' = (2r + 1 + N)/2\sqrt{X}$$

Where: Q is heat transfer rate; T_o, initial temperature; T, temperature after time t; L, length of slug; K, thermal conductivity; N, position ratio; d, density of slug; C_p, heat capacity of slug at constant pressure; and x, distance of thermocouple from back of slug. Tables of Z have been tabulated by Kaye and Yeh (5) as a function of X and N.

The change in temperature was read from the photographs for the time increment 0.1 to 0.2 sec, making t equal to 0.1 sec. Values of X and N then were calculated and Z was read from the tables. From this value Q was computed. An example follows for the copper slug described previously: For copper: K, is 0.842 cal/cm sec °C; d, 8.94 g/cm^3; C_p, 0.1057 cal/g °C; L, 0.635 cm; x, 0.127 cm; t, 0.1 sec;

X is $\dfrac{(0.842)(0.1)}{(8.94)(0.1057)(0.635)^2} = 0.222$; and N, $\dfrac{0.127}{0.635} = 0.20$.

For the above values of X and N, $Z = 0.095$. Therefore,

$$\frac{T - T_o}{Q} = \frac{L}{K}(0.095) = \frac{(0.635)(0.095)}{0.842} = 0.0715$$

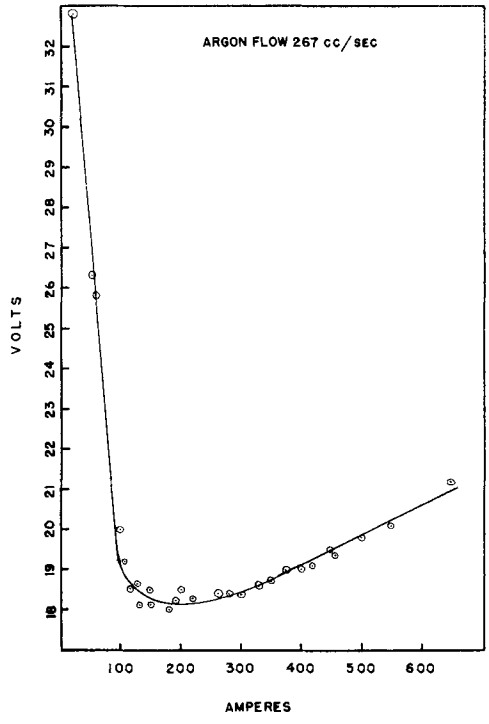

Fig. 4. Electrical characteristics of the argon plasma jet

letting $\Delta T = T - T_o$

$$Q = 1.4 \times 10^{-2} \Delta T \text{ in kcal/cm}^2 \text{ sec}$$

where ΔT is in °C.

Figure 4 shows the electrical characteristics of the arc jet. It will be noted that the high-intensity region starts at approximately 200 amp. Measurements of heat flux were made only in the high-intensity region because the jet becomes unsteady on the low-intensity side.

Results

The results of the heat transfer measurements are given in Fig. 5 and Table I. As can be seen, for the range of power used and for an argon flow of 16 liters/min, the heat flux falls between 0.5 and 4.5 kcal/cm^2 sec. These values are about 4 or 5 times those obtained from rocket motors and make possible tests on the stability of materials at extremely high temperatures and high heat fluxes. The values obtained are compared with the theoretical heat balance of the arc as shown in Fig. 6. The theoretical

curve was calculated by dividing the power to the plasma in kcal/sec by the average cross-sectional area of the plasma jet in cm². Experimental values fall below the theoretical as would be expected, since some of the energy is dissipated by radiation and other processes. The energy in the plasma was arrived at by evaluating the losses to the water-cooling system. It was found that approximately 56% of the total energy to the arc goes into the plasma jet, 5% to cathode heating and the remainder to heating the anode. Figure 7 shows the experimental points.

By using the Saha ionization equation (6), average plasma temperatures were calculated. These

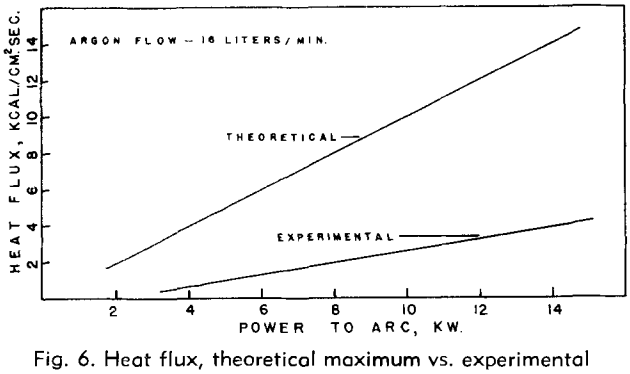

Fig. 6. Heat flux, theoretical maximum vs. experimental

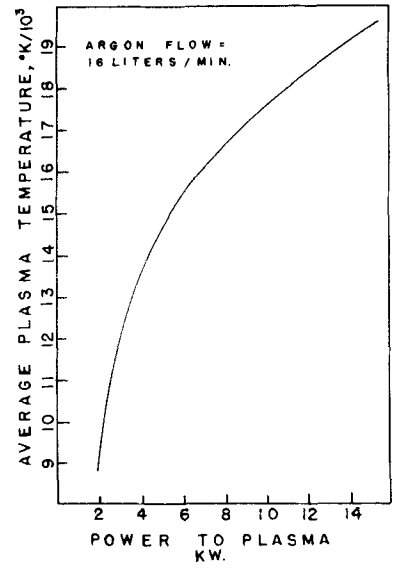

Fig. 8. Calculated temperature of the arc

temperatures are based on the total argon flow and the amount of energy actually in the plasma (56%). Figure 8 shows the results of these calculations. The temperatures range from 9000°K at 2 kw to 19000°K at 14 kw. There is some doubt whether these temperatures are actually the true ones, because a "frozen" composition of the jet is required by the Saha equation.

The Preparation of a New Crystalline Modification of Boron, and Notes on the Synthesis of Boron Triiodide

L. V. McCarty[1] and D. R. Carpenter

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

Boron triiodide has been made in yields as high as 70% from boron and iodine at 900°C. An equilibrium apparently limits the yield to 49% at 1050°C. An approximate free energy equation, $\Delta F^\circ_T = -43{,}000 + 31\ T$ cal/mole of BI_3, has been derived for the reaction $B_{(c)} + 3/2\ I_{2(g)} \leftrightarrows BI_{3(g)}$. Molybdenum metal may catalyze the reaction.

A new and denser form of crystalline boron has been deposited on tantalum in the temperature range 800°-1000°C from boron triiodide. Small portions of the deposit occur as red crystals with a density of 2.459_5 at 22.6°. The main impurity is 0.04% iodine. The red boron is composed of units of nearly regular icosahedra in a slightly deformed cubic close packing.

The preparation and properties of pure boron prior to 1942 have been reviewed by Laubengayer, Newkirk, and Brandauer (1). A short time later Laubengayer, Hurd, Newkirk, and Hoard (2) published their preparation of pure boron by the hydrogen reduction of purified boron tribromide. This technique probably makes the purest boron that has been described to date.

At least three other methods have been described since. These include sodium reduction of boron trichloride or boron trifluoride (3, 4), the electrolytic reduction of fused salt baths of fluoborates and alkali borates (5), and the hydrogen reduction of boron trichloride on hot carbon (6, 7) or titanium (7) rods. The first two of these three and the deposition on titanium lead to contamination of the boron with other metals which can be leached from the samples at least in part. Boron prepared on carbon rods may have as much as 5% carbon contamination, which is difficult to remove.

One of the chief advantages of the hydrogen reduction of boron tribromide is that it can be accomplished at temperatures as low as 600°C, and contamination by alloying with the filament substrate is not as serious a problem. Thermodynamic estimates indicate that boron triiodide would not be reduced as readily, but it would be expected to decompose directly to iodine and boron below 1000°C.

A possible advantage might be realized in the purification of boron triiodide (bp 209.5°C) by distillation. Aside from tetraiodoethylene (bp 187°C) iodine is the next lower boiling material (bp 184.35°C). The possible presence of tetraiodoethylene cannot be dismissed lightly because of the importance of carbon as an impurity, but its formation seems unlikely in our method of preparing boron triiodide. Phosphorus triiodide (bp approx. 220°C) is the nearest higher boiling iodide. Its removal may be difficult because there is only a 10° or 11° difference in the boiling points. During the decomposition of boron triiodide, phosphorus might react to form boron phosphide which would not volatilize as readily as elemental phosphorus. The next higher boiling compound anticipated is silicon tetraiodide (bp 301.5°C) which should not be difficult to remove.

Since phosphorus will not affect the electrical properties as much as silicon or carbon, its presence in our product is perhaps not as serious as the latter two. Efforts to make very pure boron from fractionally distilled boron triiodide resulted in a new crystalline modification some of which occurred as small, transparent red crystals.

Preparation and Purification of Boron Triiodide

Boron triiodide was made from the elements according to the method described by Moissan (8). U.S. Borax crystalline grade boron was placed in vertical reactors, and reagent grade iodine was vaporized slowly by boiling into a stream of about 50 cc/min of argon.

Boron triiodide vapor attacks quartz and alumina reactors at the optimum temperature of preparation. This problem was solved only partially by lining

† Boron contained in vertical quartz reactor 1⅛ in. OD by 12 in. with graphite liner ¾ in. ID.

quartz reactors with molybdenum sheet, because a brittle molybdenum boride was formed which crumbled eventually in use. Graphite was also used, but it is so porous that it did not protect the quartz. Thermodynamic estimates indicate that beryllia reactors might be stable to boron triiodide, but these were not tried.

The product contained considerable quantities of unreacted iodine which was stripped off in preliminary distillations in a 30-plate Pyrex distillation column. Material remaining in the still pot was weighed as crude boron triiodide.

Table I presents data from several runs. In the series with boron batch No. 1 the yield of crude boron triiodide goes through a maximum at 900°C. We interpret the decrease in yield at 1050° to be the result of having achieved equilibrium conditions for an exothermic reaction. An identical yield was observed with another grade of boron powder at 1050°C. As the temperature increases for an exothermic reaction the equilibrium constant normally decreases. By combining these data with Brewer's (9) estimate of the free energy of formation of crystalline boron triiodide, an approximate free energy equation

$$\Delta F^\circ_T = -43{,}000 + 31\,T \text{ cal/mole of } BI_3$$

(T = °K; range 298°-1323°)

can be derived based on the reaction $B_{(c)} + 3/2\ I_{2(g)} \leftrightarrows BI_{3(g)}$, after allowing for the decrease in molecular iodine concentration due to dissociation.[2] Equilibrium constants calculated from this free energy equation indicate that our yields at 900°C could be improved upon.

Boron batch No. 3 was somewhat less reactive than batch No. 1 in the usual reactors, but astonishingly less reactive in larger reactors and graphite lined reactors. Molybdenum is quite likely acting as a catalyst even though it is one of the most inert materials toward iodine attack.

Several lots of crude boron triiodide were combined in a 2-liter Pyrex distillation flask which could be attached to a 1-in. OD Pyrex distillation column by means of a Teflon gasketed standard taper joint. The remaining parts of the column were sealed together in such a way that liquid boron triiodide was delivered through a heated tube to a receiving flask with a nitrogen blanket maintained around the connection. The column was packed with helices and had an estimated efficiency equivalent to about 30 theoretical plates. The reflux ratio was never less than 30/1. About 10-15% was taken off in the first cut which was rejected and 60-70% in the heart cut for decomposition to boron.

Purified boron triiodide was discolored by the presence of iodine which seemed to form in small amounts throughout the distillation. The still pot became very dark colored and essentially opaque during distillation. Undoubtedly it contained the B_xI_y, where $x > y$, that Schumb, Gamble, and Banus (10) described. Little, if any, of this latter compound appeared in the distillate which sublimed cleanly and completely in the experiments described below.

Decomposition of Boron Triiodide

The decomposition reaction occurs on an electrically heated wire or rod in an evacuated apparatus similar to that used for the decomposition of silicon tetraiodide (11, 12). Temperatures were read with an optical pyrometer and have not been corrected for transmission of quartz or emissivity of the boron. The temperature of the boron triiodide was adjusted to maintain estimated vapor pressures in the range 0.1-1.0 mm.

Tantalum, molybdenum, and tungsten as deposition substrates.—Previous work (2, 7) is in conflict with respect to tantalum as a satisfactorily nonreactive surface for the preparation of very pure boron. Conditions in this work differ from the work with boron tribromide or trichloride in that hydrogen was not used in the reduction. Hydrogen might influence the formation of tantalum boride indirectly, so three kinds of wires were coated with boron in order to determine their suitability for iodide boron deposition. Hairpins formed from 20 in. of 10-mil diameter wires were heated to 1000° for 1 hr in boron triiodide vapor coming from a reservoir at 0°C (vapor pressure of the order of 0.1 mm). About 17-18 mg of boron was deposited on each wire. They were sectioned, polished, and a photomicrograph of each was prepared.

In Fig. 1 two distinct layers have formed on the tantalum. The inner zone is quite well defined and is very probably a tantalum-boron alloy, but no work was done to try to identify it. Other evidence obtained later indicates that the outer, rather irregular zone is pure boron. It is so brittle that it has fractured rather badly during the sectioning. A close examination indicates the boron has a crystalline appearance.

Figure 2 is a similar photomicrograph for boron on molybdenum filaments. The alloy zone is much broader, and relatively little free boron is evident. Figure 3 shows the results obtained with tungsten. No adherent alloy zone is evident, and the nature of the material that has separated from the tungsten sur-

[2] The authors are indebted to Mr. A. C. Loonam for suggesting the correct method of calculating the free energy from the equilibrium constant at 1050°C.

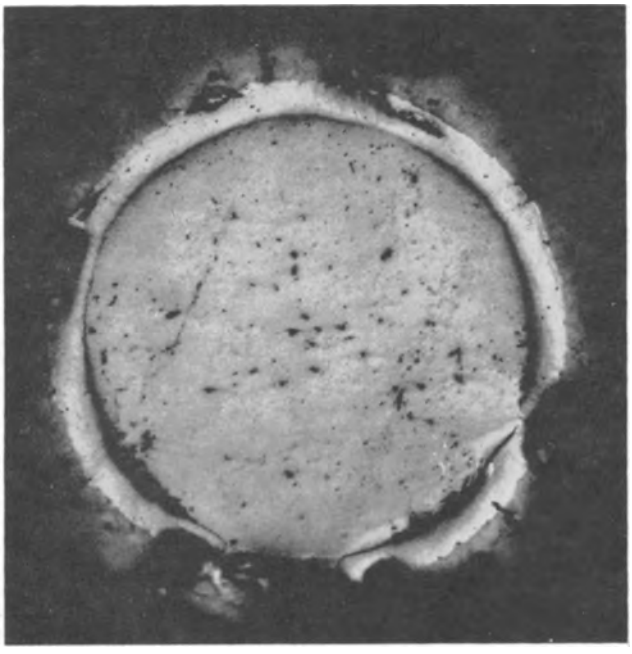

Fig. 1. Section of iodide boron deposit on 10-mil tantalum wire.

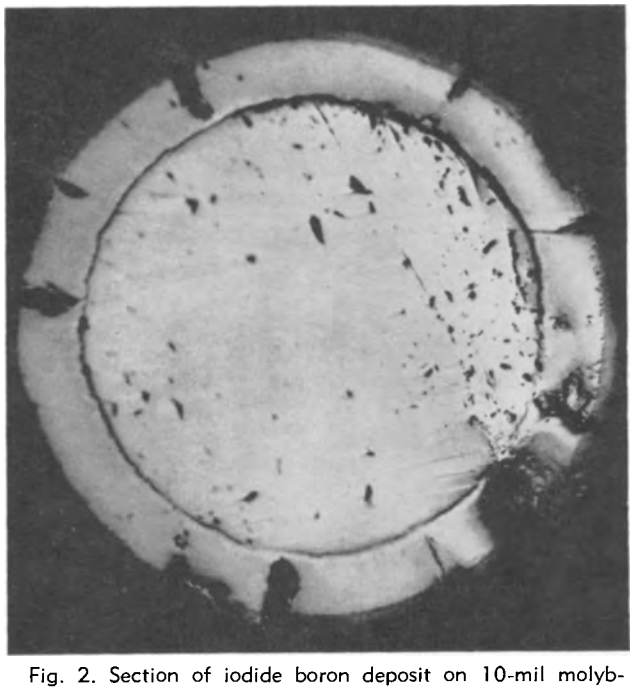

Fig. 2. Section of iodide boron deposit on 10-mil molybdenum wire.

face is unknown. Later work with tantalum at a lower temperature produced a similar flaky deposit that contained substantial amounts of tantalum. Since a densely adherent deposit was desired, the flaky type of product was unattractive.

Tantalum metal is not an ideal deposition substrate for this work, but it seems to be the best of the three refractory metals investigated. Tungsten might make a satisfactory surface at higher temperatures, but it would require further investigation.

Deposition of iodide boron on tantalum wire.— Two 4½ in. pieces of 3-mil tantalum wire were heated at 1000°C for 4½ hr in the vapor from boron triiodide kept at room temperature. The wire grew

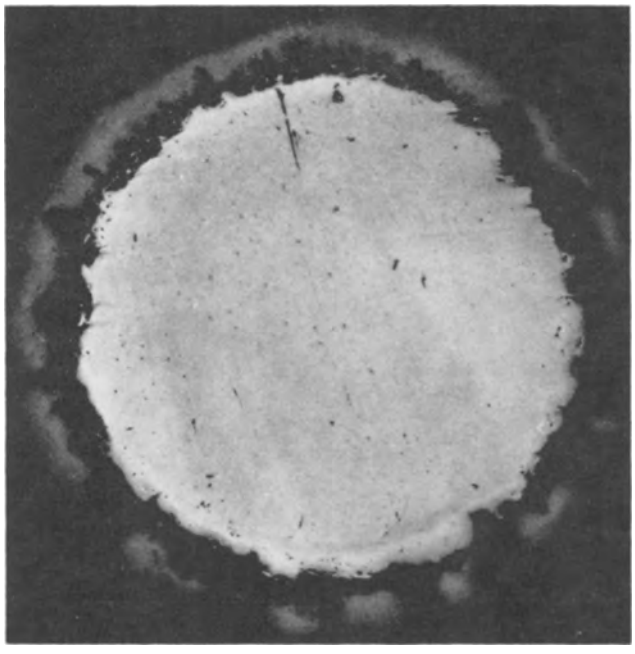

Fig. 3. Section of iodide boron deposit on 10-mil tungsten wire.

to approximately 70 mils in diameter when it broke revealing a cluster of red crystals surrounding the tantalum wire which were clearly visible to the unaided eye. In this same sample Horn (19) found a wedge-shaped band of orange-colored boron in a fractured portion of the rod which started as a narrow band at the tantalum core and expanded as it grew out to the surface. Neither the orange-colored band nor the red crystals were evident from the external appearance.

Deposition of iodide boron on tantalum rods.— Boron was deposited from boron triiodide on ⅛-in. x 36-in. tantalum rods in the form of a hairpin at the three temperatures shown in Table II. The deposit at 800°C was black, or nearly so, and very flaky. It peeled off the rod throughout the run and fell into the boron triiodide reservoir. X-ray powder photographs disclosed the presence of two components in this material: a low temperature crystal form of boron (13, 14), and considerable amounts of a tantalum boride. X-ray emission analysis of this sample confirmed the presence of approximately 78% tantalum, which was unexpected. The original purpose in preparing this sample was to compare its x-ray powder pattern with the 900°C sample which

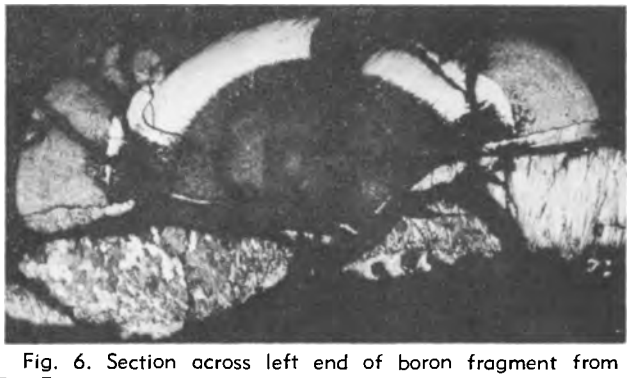

Fig. 6. Section across left end of boron fragment from Fig. 5.

was actually prepared first. There was no difference in the powder pattern from the boron, but the 900°C sample had only a very small amount of tantalum boride in it.

The boron sample prepared at 900°C adhered to the rod well during deposition and exhibited several features not seen at higher or lower temperatures. Two kinds of very regular growths about 0.060 in. in diameter developed on the surface of the boron during the run which are shown in Fig. 4 and 5. The two kinds of growth are probably related, but those shown in Fig. 4 have not been investigated for their structure. The central portion of the kind shown in Fig. 5 appeared to be a dark-colored glassy phase when viewed from above. A fracture in the boron deposit across one of the spots permitted examination of a cross section of the growth. The most dramatic feature revealed was that the glassy layer was clear red by transmitted light.

This particular sample was mounted by the Metallography Section of the G.E. Research Laboratory, polished, and photographed as shown in Fig. 6. The boron is so brittle that it has fractured during the polishing operation, but enough of the structure remains so that the chief features are easily discerned. The glassy layer referred to previously is the well-defined curved portion near the top about 4 mils in width.

The major portion of the exterior of the boron deposited at 900°C had a dull, matte-like texture with a brownish, slightly purple cast to it which contrasted sharply with the more metallic, crystalline appearance of the hemispherical growths of Fig. 4 and deposits made at higher temperatures.

The sample was subjected to several kinds of analysis after removing it from the tantalum rod by wrapping it in a polyethylene sheet and flexing gently. The analytical results are: carbon, 0.007 $\pm 0.002\%$;[3] tantalum, 0.03%; iodine, present by x-ray emission analysis; nickel, trace by x-ray emission analysis, but not detected by spectrographic emission analysis, $<0.01\%$. The tantalum was estimated from an uncalibrated x-ray emission analysis.

The sample of boron deposited on the tantalum rod at 1000°C warped the hairpin so badly that it moved close to the quartz wall of the deposition chamber and would have touched it if the experiment had continued. The experiment was interrupted to reposition the tantalum rod and then continued. The boron was removed from the tantalum by wrapping in aluminum foil and flexing in order to eliminate polyethylene as a source of carbon contamination. The carbon content of this sample was determined as $0.003 \pm 0.002\%$.

X-ray powder photographs of the 1000° sample showed some differences in line intensities compared to the 900°C sample, but the characteristic phase seemed to be the low temperature form of boron. Horn (19) found that the solid seemed to consist of several phases when examined under a microscope. By leaching with warm concentrated nitric acid he recovered red sandy, red glassy, and red microcrystalline material. Clear red crystals about 0.25 mm long were collected from this product. When examined by x-ray emission the red crystals showed about 0.04 wt % of iodine, but no other impurities of atomic number 13 or larger in concentration greater than 0.001% (the limit of detection for the amount of sample available). The density was measured as 2.459_6 at 22.6°C which is considerably greater than the density of the high temperature rhombohedral form obtained from melted boron, 2.33 at 22.6°C (13).

X-ray powder patterns of the various types of colored crystals present showed no significant differences (19), but there are very large differences in the electrical resistivities (15). The red colored crystals of the low-temperature rhombohedral form of boron apparently have impurities occupying very shallow levels near the band edge which contrasts with the deeper levels found in boron made at higher temperatures. The black portions of the deposits of low-temperature rhombohedral boron are probably more impure than the clear red crystals.

Kasper and Decker determined the crystal structure (14) of the red boron which is composed of units of nearly regular icosahedra in a slightly deformed cubic close-packing. The space group is $R\bar{3}m$ with $a_o = 5.07$Å and $\alpha = 58°1'$. The theoretical density calculated from the dimensions of this structure agrees very well with Horn's experimental values.

[3] Carbon analyses performed by a combustion-conductimetric technique fluxed with iron in a commercially available apparatus.

Discussion

The marked amount of tantalum contamination observed in the 800° deposition (cf. Table II) contrasts sharply with the experience of Laubengayer, Hurd, Newkirk, and Hoard in their work on the hydrogen reduction of boron tribromide (2). The formation of tantalum boride at 800°C in the present work may involve the formation of a tantalum iodide compound that is unstable at higher temperatures, while the corresponding tantalum bromide may simply never form because of the reducing action of hydrogen.

On the other hand, the small amount of contamination experienced in the 900° and 1000°C deposits on tantalum contrasts just as markedly with the experience of Stern and Lynds [cf. Table II, ref. (7)], who observed considerable diffusion of tantalum into boron at 975°-1025°C. Greater temperature gradients in the latter work could have increased the rate of diffusion in the solid phases, and, logically, at least comparable amounts of tantalum should have been found in Stern and Lynds' 1200°-1250°C sample, but it is not reported. It is difficult to reconcile the various observations on the basis of a physical mechanism such as simple diffusion. The chemistry of the various phases that can form at the tantalum surface may depend very strongly on the particular halide used and the presence or absence of hydrogen.

Among the elements not covered by our analytical techniques, the most probable contaminants are nitrogen and oxygen. Nitrogen should not be a problem during the deposition of the boron in an evacuated system. Richter (16) has shown that evaporated boron films will react with nitrogen of the air, however, to form crystalline boron nitride. It would not be surprising to find a surface film of nitrogen on most boron samples.

Oxygen is more of a problem because of the difficulty of removing water vapor completely from a quartz vessel. The reactor and boron triiodide container was prepared for use by flaming it with an air-gas mixture while it was being flushed with dry nitrogen with a dew point of less than −50°C. Boron triiodide vapor would be expected to react with most of the residual water vapor at or near the walls of the vessel. The work of Kaiser, Keck, and Lange (17) on the quantity of oxygen dissolved in floating zone purified silicon, suggests that iodide boron may contain less than 0.001% oxygen.

The band gap in the high-temperature rhombohedral boron formed from the melt is about 1.6 ev (18), and this kind of boron should be transparent to visible light in the far red end of the visible spectrum when pure enough. The "low-temperature" form of boron obtained as clear red crystals in this work may have a band gap as high as 2 ev (15), which could be the chief reason for the red transparency. It is true that high purity may be necessary too, but the purity requirements are, perhaps, not as stringent as for the "high-temperature" form in order to insure red transparency.

The red crystals observed within the deposit on the 3-mil tantalum wire were clustered around the wire core in such a way that the presence of the tantalum may have influenced the nature of the deposit. From the analysis of the red crystals of another deposit it seems clear that no significant amount of tantalum is necessarily present in the crystals. There remains the possibility that tantalum may be acting as a "getter" for impurities and thus promoting the growth of a red phase locally. Again, the presence of tantalum is not a necessary condition for the red glassy phase was observed in the center of the "bull's eyes" which grew on the exterior of the deposit as shown in Fig. 5.

The question of why the various kinds of growth and different colors occur in these deposits is a fascinating subject for speculation. The color of the crystals is very likely related to the impurity content. Apparently only one crystalline phase is involved, yet there must be subtle differences in the way the crystals grow in order to cause the segregation observed.

Acknowledgment

The authors are indebted to F. H. Horn for his interest and work on the properties of "red" boron. J. S. Kasper and Mrs. B. F. Decker performed most of the x-ray crystallographic work. A. E. Newkirk has been interested in the morphology of boron deposits for many years. His advice and encouragement were extremely valuable.

Manuscript received June 12, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Electrolytic Reduction of Thorium Oxide

L. H. Meyer

Savannah River Laboratory, E. I. du Pont de Nemours & Company, Aiken, South Carolina

ABSTRACT

Thorium metal was prepared by electrolytic reduction of thorium oxide in two systems, a fused KF-ThF_4 mixture and a fused NaCl-KCl-$ThCl_4$ mixture. The average decomposition potential measured in both systems was 1.92 v. Electrolysis in the fluoride melt proved to be a superior process, the metal product having higher purity and larger average particle size than the product from the chloride melt. In addition, the recovery of thorium from recycle streams proved to be much simpler in the fluoride process than in the chloride process. The feasibility was demonstrated for all the essential steps of a complete process for production of the metal in the fluoride system.

A satisfactory method for production of thorium metal requires (*a*) a simple preparation of feed material, (*b*) a successful reduction of the thorium feed compound to thorium metal, and (c) an efficient recovery of the metal after reduction. A simple recycle of nonrecoverable metal fines and other thorium-containing materials is also frequently desirable. Existing techniques utilize electrolytic or metallothermic reduction of a thorium halide as a means of producing the metal. However, preparation of an anhydrous thorium halide suitable for feed to a continuous reduction process is at best a difficult operation. Production of thorium metal through reduction of its oxide offers the advantage of eliminating the halogenation step and substituting for it the relatively simple preparation of thorium oxide.

This investigation was undertaken to determine the feasibility of a process based on electrolytic reduction of thorium oxide. This technique, which is closely analogous to the Hall process for producing aluminum, was suggested as a possible method for thorium production in a 1931 patent by Driggs (1). Electrolytic rather than metallothermic reduction of the oxide was selected because the former lends itself more readily to continuous operation and because other attempts (2) at the latter have resulted in a product with an average particle size of only 7-8 μ. Previous work (3) indicated that electrolytic reduction should produce a metal having larger particle size and lower impurity content.

The results of this experimental study form the basis for a proposed process for producing thorium metal by electrolytic reduction of its oxide. All steps essential to continuous operation have been demonstrated.

Experimental

Apparatus.—Electrolysis cells.—The cells, which also served as the anodes during electrolysis, were CS-312 graphite crucibles, 18 in. high and 5 in. in diameter with 0.5-in. walls. They were obtained from the National Carbon Company. During operation, the cell was inserted into a stainless steel sleeve to prevent loss of the melt in event of cell rupture.

Housing.—The cell was contained in a dry box provided with equipment to handle the internal manipulations. During operation the box atmosphere could be maintained at 99+% helium.

Instrumentation.—The instrumentation was standard. The Pt-Pt, 10% Rh thermocouple was housed in a stainless steel well which was immersed in the melt.

Materials.—Potassium thorium fluoride.—The compound $KThF_5$ was prepared by the method of Driggs and Lilliendahl (4). The anhydrous double salt precipitated upon adding an excess of aqueous potassium fluoride to aqueous thorium nitrate. The precipitation of Th^{+4} from the solution was virtually complete, the filtrate analyzing $<6\times10^{-6}$M Th^{+4}.

Thorium chloride.—The anhydrous NaCl-KCl-$ThCl_4$ mixture was obtained from Horizons, Inc., Cleveland, Ohio.

Thorium oxide.—Fisher Scientific Co. C. P. thorium oxide was used in all runs.

Cathode metals.—Six-millimeter molybdenum rod was used as cathode material in most of the electrolyses. The molybdenum and the tantalum were obtained from the Fansteel Metallurgical Corporation, North Chicago, Illinois. Titanium was obtained from Rem-Cru Titanium, Inc., Midland, Pennsylvania; and the thorium used for cathodes was obtained from the Atomic Energy Commission.

Procedures.—Electrolysis.—Prior to each electrolysis, the cell was filled with salt plus the desired quantity of oxide. The cathodes were hung on racks, and all electrical connections were made. The front window then was put in place, and the helium purge and heating were started simultaneously. Two to three hours were required to reach operating temperature.

After thermal equilibrium at the desired temperature had been attained, the cathode was immersed in the melt and electrolysis started immediately. At the conclusion of the electrolysis, the cathode was withdrawn slowly to allow maximum drainage of the molten salt. The cathode with its metallic deposit was hung on a rack to cool. A second cathode then

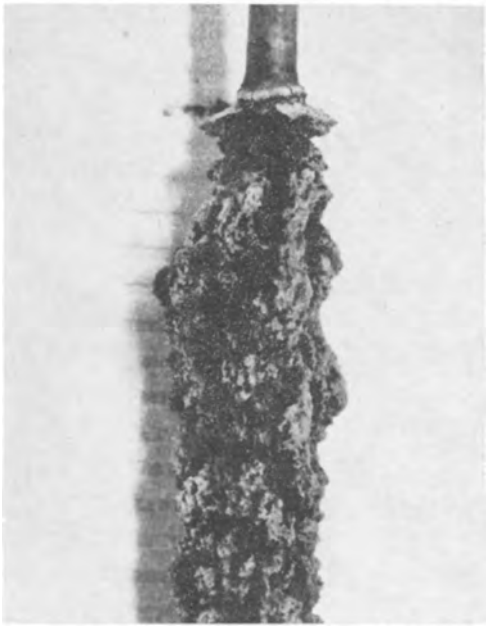

Fig. 1. Typical cathode deposit obtained by electrolysis of ThO_2 in a KF-ThF_4 melt.

could be immersed and the process could be repeated. A helium atmosphere was maintained throughout the cooling period to prevent oxidation of the deposited metal. Figure 1 is a photograph of a typical cathode deposit.

Metal recovery.—Fluoride system.—The metal produced by electrolysis in the fluoride system was recovered by stripping the deposit from the cathode, crushing, screening, and leaching. After the deposit was crushed, 20 to 40% passed a 200-mesh screen. This fraction, containing from 5 to 14% of the metal, was not processed further. The +200 mesh fraction was leached for 10 to 20 min in boiling aqueous aluminum nitrate (~1M). A white or gray near-colloidal dispersion formed in the supernatant liquor during the leaching operation. This dispersion, which consisted of finely divided thorium oxide and thorium metal, could be coagulated and precipitated by centrifugation. After the leaching operation, the metal was visibly free of salt, as shown in Fig. 2.

Metal recovery.—Chloride system.—The recovery scheme following electrolysis in the chloride melt differed from that for the fluoride system. The procedure consisted of stripping the deposit from the cathode, crushing, and leaching with water. Screening yielded no effective separation of metal from salt due to the very small average particle size of the metal. Leaching was accomplished easily, since the chloride salts of the melt are all highly soluble in water.

Cathode pretreatment.—During the course of the experimentation, it was found that pretreating the cathode decreased the porosity and improved the adherence of the metallic deposit. This pretreatment consisted of sanding to roughen the surface, degreasing with trichloroethylene vapor, and pickling for 3-5 min with an agent suitable for the cathode material. Following the pickling, the cathodes were washed in distilled water and dried in air.

Results and Discussion

Electrolysis of thorium oxide.—The composition of the anode gas evolved during electrolysis in both the fused fluoride and the fused chloride systems established thorium oxide as the compound undergoing decomposition. The oxygen resulting from decomposition of the oxide was liberated at the graphite anodes as carbon dioxide and carbon monoxide. The large increase in the oxide content of the gas surrounding the anode during electrolysis is evident from the analyses listed in Tables I and II. The anode gas contained no fluorine or chlorine compounds. The presence of such compounds would have been observed had the halides been decomposed during the electrolysis.

Decomposition potential.—The decomposition potential of thorium oxide in both systems was determined

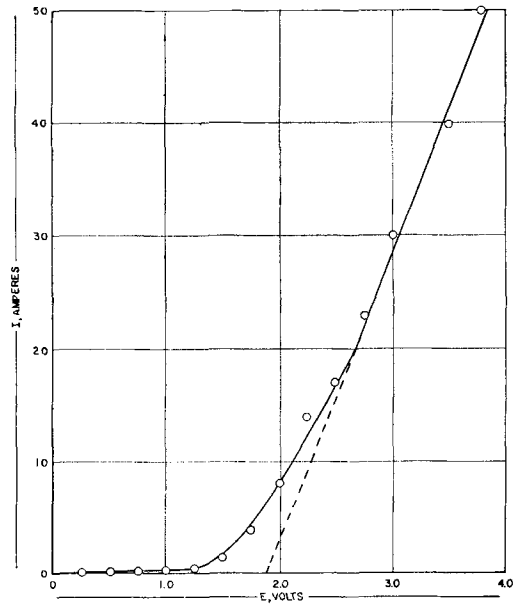

Fig. 3. Current-voltage curve for electrolysis of ThO_2 in o KF-ThF_4 melt.

in the conventional manner from current-voltage graphs. A typical plot is shown in Fig. 3. A variation from 1.67 to 2.15 v was found over fourteen independent determinations in the fused fluoride system, yielding a value of 1.92 ±0.11 v. Ten determinations in the fused chloride system gave a value of 1.92 ±0.27 v.

Solubility of thorium oxide.—The solubility of thorium oxide in a KF-ThF_4 melt, 70% ThF_4 by weight, was found to be approximately 1%. No reliable result was obtained for the solubility of thorium oxide in the NaCl-KCl-$ThCl_4$ melt.

Leaching agents.—A solvent was required for the constituents of each of the melts in order to leach the occluded salt from the metal. No problem was encountered in the chloride system, since all the salts in the melt are water soluble. Thorium fluoride and its double salts with potassium fluoride are insoluble in water but dissolve satisfactorily in boiling aqueous aluminum nitrate.

Product purity.—The product was identified as thorium metal by x-ray diffraction. Determination of the HCl-insoluble content yielded the amount of dissolved or occluded thorium oxide, which averaged 0.63% in the product from the fluoride process, but ran as high as 12.2% in the product from the chloride process. One complete spectroscopic analysis of the metal produced by electrolysis in the fluoride melt (Run 3D) is listed below:

600 ppm Al	35 ppm Mg
9 ppm B	40 ppm Mn
90 ppm Ca	300 ppm Ni
<0.5 ppm Cd	400 ppm Si
700 ppm Cr	<1 ppm U
250 ppm Cu	80 ppm Zn
1000 ppm Fe	<50 ppm Zr

Remainder Th

The source of impurities was assumed to be the fluoride salt.

Operating and performance data.—*Fused fluoride system.*—Table III lists the operating and performance data for seventeen electrolyses carried out in the fused fluoride system. Runs with a common numeral were made in the same salt bath. The recovery efficiency listed in the table is the per cent recovery of the metal theoretically deposited by the passage of the given charge, assuming a quadrivalent thorium ion in the molten salt solution. The HCl-insoluble content indicates the quantity of oxide dissolved in the metal.

Examination of the data reveals that the first electrolysis with each salt bath resulted in poor yields. This effect is ascribable to impurities in the salt, the presence of which decreases the mean particle size

(5) and consequently the recovery efficiency. The first electrolysis with each bath apparently served as a scavenging run, after which performance improved.

From the data in Table III the superiority of molybdenum as a cathode material over the other metals tested is apparent. If the results of the scavenging runs are discounted, the recovery efficiency, based on a quadrivalent thorium cation, for the electrolyses with molybdenum cathodes varied from 8.2 to 41.0%, averaging 18.3%.[1] The ratio of the weight of the recovered metal to the total weight of the deposit (including occluded salt and ThO_2) averaged 39.3%, with a total variation from 18.2 to 67.9%. An average of 61.7% of the recovered metal exceeded 40 mesh in size, and the amount of metal fines in the −200 mesh fraction ranged from only 2 to 7% of the total weight of the deposit. The HCl-insoluble content varied from 0.10 to 2.30%, averaging 0.63%. Performance with thorium, titanium, and tantalum cathodes was much less satisfactory. In particular, the particle size distribution of the product was less favorable than with the molybdenum cathodes, since much larger fractions of the thorium metal were produced as irrecoverable fines with the other three cathode materials tested. Figure 4 illustrates the differences in particle size distributions for the four cathode materials.

Current density was varied from 35 to 380 amp/dm² for the electrolyses listed in Table III. No good correlation was observed, however, between current density and any of the performance criteria. Figure 5 shows the particle size distributions for electrolyses run at different current densities.

Beginning with Run 3A, the cathodes were given a pretreatment with a pickling agent in an attempt to improve the adherence of the deposit. Improvement was not pronounced; however, the metal particles plated on pickled electrodes had a firmer structure, which facilitated separation of the metal from the salt.

Operating and performance data.—Fused chloride system.—Fourteen electrolyses were performed in the chloride system. Recovery efficiency, based on Th^{+4} in solution, varied from 13.9 to 55.0%, averaging 27.2%. The ratio of the weight of recovered metal to the total weight of the deposit averaged 22.5%, ranging from 10.9 to 43.3%. The HCl-insoluble content was high, 1.92 to 12.2%. The particle size distribution was considerably less favorable than that resulting from the electrolyses in the fluoride system. In only one of the fourteen runs did any of the metal particles exceed 80 mesh in size. Virtually all the product was −100 mesh, with sizable fractions in the 10 to 50 μ range.

Comparison of Processes in the Fluoride and Chloride System

The experimental results indicate that the production of thorium metal by electrolysis of thorium oxide in the fused fluoride system is superior to the analogous process in the chloride system. The chloride melt has a lower fusion temperature (~800°C) than the fluoride system (~1000°C), plus a high water solubility of the bath constituents, which facilitates the leaching operation. However, these advantages are inadequate to compensate for the lower purity and smaller particle size of the product. Moreover, there is no simple technique for recycling the occluded chloride salts that are removed with the cathode deposit. Unless methods can be found for depositing larger metal particles from the chloride melt, electrolysis of thorium oxide in this system does not appear to be competitive with the fluoride process.

Flowsheet for Proposed Process

Figure 6 is the proposed flowsheet of the complete process for the production of thorium metal in the fused fluoride system. A brief discussion of each of the steps is presented below.

[1] A sizable loss resulted from lack of proper equipment to strip the tightly adhering thorium deposit efficiently from the cathodes.

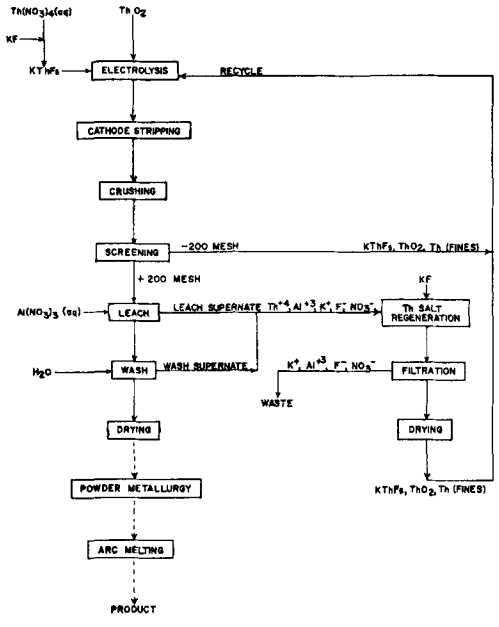

Fig. 6. Proposed flowsheet for production of thorium metal in fused fluoride system.

Electrolysis.—Electrolysis is performed in graphite-lined cast iron cells. The liners, serving as anodes, are replaced as they are consumed. An inert atmosphere chamber must be provided for removal and cooling of the cathodes following electrolysis.

Cathode stripping.—Conventional techniques and equipment are available for stripping the deposit from the cathodes.

Crushing and screening.—The gross physical separation of metal from salt is based on the fact that the salt crystals are reduced in size easily by crushing, while the metal particles are not. It is proposed that the metal in the +200 mesh (U. S. Standard Series) fraction, which contains 80 to 95% metal by weight, be leached, while the −200 mesh fraction which averages only 15% metal be recycled.

Leaching.—The salt not removed by the physical separation can be dissolved in hot aqueous aluminum nitrate. Boiling 10 to 20 min in 1M aluminum nitrate gives satisfactory removal of salt.

Metal processing.—After the leaching operation, the metal is separated from the supernatant liquor by decantation. The metal then is washed with water and air dried. The drying step is followed by a powder metallurgical forming of electrodes for subsequent arc melting.

Recycle (−200 mesh screening fraction).—The composition of this fraction averages 15% thorium metal, 0.4% thorium oxide, and the remainder salt. Two alternatives are available for treatment of these fines. An oxygen roast converts the metal to thorium oxide, after which this fraction can be returned to the electrolysis cells; or the −200 mesh fraction may be recycled directly to the cells, and a periodic oxygen sparge may be employed to re-oxidize the thorium metal. The latter alternative is favored, since an oxygen sparge is probably necessary to re-oxidize the nonadhering metal product, which collects at the bottom of the cells during electrolysis. Any such treatment with oxygen requires careful control to prevent excessive attack on the graphite liners.

Recycle (leach and wash supernatant liquors).—The leach and wash supernatant liquors contain thorium in the form of soluble Th^{+4} ion plus dispersed oxide and metal fines. The dissolved thorium can be recovered by adding KF in quantity sufficient to precipitate all the thorium as $KThF_5$. Some care must be observed in order not to precipitate any of the potassium aluminum fluorides. Control is not too critical, however, since less than 80% of the KF required for incipient precipitation from a blank 1M aluminum nitrate solution precipitates essentially all of the Th^{+4} from a 1M aluminum nitrate solution saturated with $KThF_5$. A well-agitated precipitation should succeed in coagulating and carrying down the dispersed particles as well. Following filtration, the precipitate is dried and recycled to the electrolysis cells.

Waste.—The only waste stream in the process is the filtrate from the $KThF_5$ regeneration step. Thorium concentration in this stream is less than 10^{-5}M.

Mass Transfer at the Streaming (Jet) Mercury Electrode

Theoretical Calculation of Limiting Currents

Kameo Asada, Fumio Hine, Shiro Yoshizawa, and Shinzo Okada

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Kyoto, Japan

ABSTRACT

Mass transfer at the streaming or jet mercury electrode has been studied theoretically. Momentum equations for both the mercury jet and the surrounding solution layer have been solved simultaneously on the assumption of laminar flow in both mercury jet and surrounding solution envelope. Limiting currents were measured for the reduction of Tl^+, Pb^{++}, and Zn^{++} at 25°C with 0.1M KCl as supporting electrolyte. Experimental results are in good agreement with predictions based on theoretical analysis.

The streaming or jet mercury electrode has been studied and used in various forms of polarography (1-12). Its application to routine analytical purposes is restricted by the large amount of mercury consumed, the high charging currents, and the inconvenience in reproducing stream geometry. On the other hand, the streaming electrode, if used along with the dropping electrode, appears promising in studies of kinetic currents (6, 7) and irreversible electrode processes (12). Furthermore, the rapid renewal of the mercury surface makes it useful in studies of the mercury-solution interface (2, 4, 8, 11). Toshima and Mizuno (13) successfully applied a mercury stream to the production of caustic soda from crude brine.

It is of interest to know how the mercury jet drags the solution around it and how the rate of mass transfer of the ions (limiting current) is related to the conditions of operation, such as flow rate of mercury, length of jet, etc. Ríus, *et al.* (8) obtained an expression for the limiting current based on the assumption that the radius of the mercury jet is constant, the curvature negligible, and the velocity of the jet and of the adjacent solution uniform everywhere. Weaver and Parry (12) showed the invalidity of these assumptions and presented a semi-empirical equation for the limiting current, using observed values of the jet diameter, interfacial velocity, and velocity gradient. The present paper gives an analysis of jet characteristics by methods of fluid dynamics, which have already been applied successfully to many instances of ionic mass transfer (14-17), and describes methods for the calculation of limiting currents without the use of empirical information on jet geometry.

Stream Characteristics

Theoretical.—Although the turbulent flow of gases from nozzles (18) and the breakup of liquid streams (19) have both been considered in fluid mechanics, no theory adaptable to working conditions of the streaming mercury electrode was available. Throughout this paper it will be assumed that (*a*) the flow of the mercury within the capillary is laminar (Hagen-Poiseulle flow without slip), (*b*) the mercury jet, after leaving the capillary, and the solution boundary layer formed around it are cylindrical and undergo laminar flow, and (c) there is no slip between the mercury jet and the solution boundary layer. The cylindrical coordinates are chosen as shown in Fig. 1, z being the logitudinal distance from the capillary tip and r the radial distance from the center of the jet.[1] The mercury jet and the solution flow are distinguished from each other by subscripts m and s, respectively.

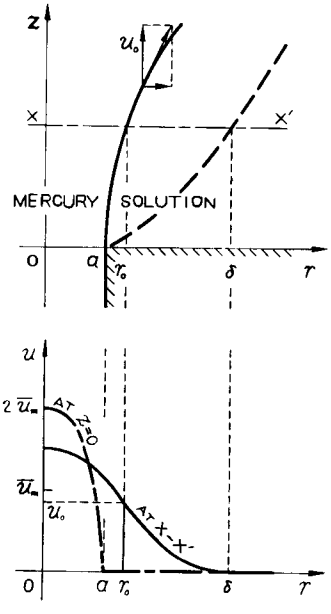

Fig. 1. Model for theoretical analysis; coordinates and velocity profiles.

As a rigorous simultaneous solution of the Navier-Stokes equations and the continuity equations for noncompressible fluids is very difficult, the Kármán momentum equation method (20, 21) is applied, a boundary layer of definite thickness being assumed. In order to simplify the mathematical model, parabolic velocity profiles are assumed, that is, the ve-

[1] A glossary of symbols is given at the end of this paper.

locity components in the z direction, u_m and u_s, are expressed by

$$\left.\begin{aligned} u_m/u_o &= 1 + [(\mu_s/\mu_m)r_o/(\delta - r_o)][1 - (r/r_o)^2] \\ u_s/u_o &= [(\delta - r)/(\delta - r_o)]^2 \end{aligned}\right\} \quad [1]$$

which satisfies the following conditions

$$\left.\begin{aligned} &\text{at } r = 0,\ \partial u_m/\partial r = 0 \\ &\text{at } r = r_o,\ u_m = u_s \equiv u_o \text{ and} \\ &\quad \mu_m \cdot \partial u_m/\partial r = \mu_s \cdot \partial u_s/\partial r \\ &\text{at } r = \delta,\ u_s = \partial u_s/\partial r = 0 \end{aligned}\right\} \quad [2]$$

In the above μ is the dynamic viscosity, r_o the radius of the mercury stream, δ the thickness of the boundary layer measured from the center of the stream ($r = 0$), and u_o the interface velocity component in the z direction. The last three quantities are unknown parameters dependent on z alone and are determined by the momentum equations

$$\left.\begin{aligned} &-d[\rho_m \textstyle\int_0^{r_o} u_m^2\, r\, dr]/dz + g(\rho_m - \rho_s)r_o^2/2 \\ &= -\mu_m r_o(\partial u_m/\partial r)_{r=r_o} = -\mu_s r_o(\partial u_s/\partial r)_{r=r_o} \\ &= d[\rho_s \textstyle\int_{r_o}^{\delta} u_s^2\, r\, dr]/dz \end{aligned}\right\} \quad [3]$$

and by the equation of conservation of mass for the mercury stream

$$d[\textstyle\int_0^{r_o} u_m r\, dr]/dz = 0 \quad [4]$$

ρ being the density and g the acceleration due to gravity (g is negative when the stream flows upward).[2] In Eq. [3] the bracketed terms are equivalent to the momenta of the mercury jet and of the solution envelope. The third and fourth terms correspond to the shearing stresses per unit length. Hence Eq. [3] implies that the momentum of the moving mercury jet, after ejection from the capillary, is consumed by work against gravitational force (or *vice versa*) or is transferred to the surrounding solution through the shearing stress at the interface. The second equality in Eq. [3] means absence of slippage at the interface [assumption (*c*)] and so perfect momentum transfer. It follows from assumption (*a*) that the boundary conditions in the z coordinate are

$$\text{at } z = 0,\ u_m/\bar{u}_m = 2[1 - (r/a)^2] \text{ and } u_s = 0 \quad [5]$$

where u_m is the mean velocity of the mercury jet and a the inner radius of the capillary.

Equation [1] is introduced into Eqs. [3] and [4], which then are integrated with respect to r and Eq. [5] is taken into consideration. One obtains

$$\left.\begin{aligned} &dM_s/dz' = 3(u_o/\bar{u}_m)\mu'\phi/(1 - \phi) \\ &M_m + M_s = 1 + g' \textstyle\int_0^{z'} (r_o/a)^2\, dz' \\ &(r_o/a)^2(u_o/\bar{u}_m)[2 + \mu'\phi/(1 - \phi)] = 2 \end{aligned}\right\} \quad [6]$$

where

$$\left.\begin{aligned} &z' = \nu_m z/a^2\bar{u}_m,\ \mu' = \mu_s/\mu_m,\ \rho' = \rho_s/\rho_m,\ \phi = r_o/\delta \\ &M_m = \tfrac{1}{4}(r_o/a)^2(u_o/\bar{u}_m)^2 \cdot \\ &\quad [3 + 3\mu'\phi/(1 - \phi) + (\mu')^2\phi^2/(1 - \phi)^2] \\ &M_s = (\rho'/20)(r_o/a)^2(u_o/\bar{u}_m)^2 \cdot \\ &\quad (1 - \phi)(1 + 5\phi)/\phi^2 \\ &g' = \tfrac{3}{4}(1 - \rho')\, ga^2/\nu_m\bar{u}_m \end{aligned}\right\} \quad [7]$$

ν being the kinematic viscosity ($=\mu/\rho$). The quantities M_m and M_s are the momenta of the mercury jet and of the solution envelope, respectively, expressed as fractions of the initial momentum of the mercury on ejection from the capillary.

The ratios r_o/a and $u_o/\bar{u}_m$ may be eliminated from Eq. [6] if the gravity term of the second expression is left in the integral form. When the effect of gravity is assumed negligible ($g' = 0$), one has an ordinary differential equation with separable variables, whose numerical integral is available (22) if values of μ' and ρ' are specified. Calculations including the gravity term may be carried out by means of successive approximations.

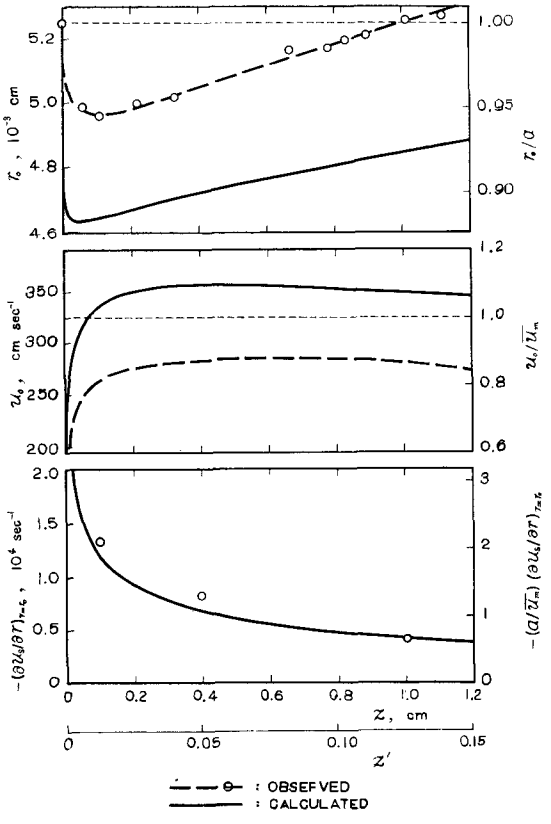

Fig. 2. Mercury jet diameter, interface velocity, and interface velocity gradient, from top to bottom; comparison between calculated and observed results for an upward mercury jet with $a = 0.0052_5$ cm and $\bar{u}_m = 325$ cm sec^{-1}. (Although the dashed curve in the middle figure is not for u_o but for the interface velocity, there is no appreciable difference except near the base of the stream.)

Results and Discussion

The above analysis was applied to some practical systems, and the results were discussed in comparison with experimental findings of Weaver and Parry (12). These authors obtained the jet diameter photographically, the interface velocity by measurements of charging currents, and the interface velocity gradient at the solution side by adding aluminum dust therein. Theoretical results for the foregoing three quantities for a 0.1M KCl solution at 25°C[3]

[2] Equations [3] and [4] may be obtained by integration of the Navier-Stokes equations and the equations of continuity.

[3] The following values were adopted for the physical properties of this system: $\mu_s = 0.008298$ g cm^{-1} sec^{-1}, $\mu_m = 0.01527$ g cm^{-1} sec^{-1}, $\rho_s = 1.0018$ g cm^{-3}, and $\rho_m = 13.534$ g cm^{-3} (from International Critical Tables and Landolt-Börnstein Tabellen).

(the gravity term is neglected) are shown in Fig. 2 together with the experimental values of Weaver and Parry.

Qualitative agreement is good and supports the model described by Eqs. [3]-[5]. The initial increase of u_o is simply a result of acceleration of the outer slow layers of the mercury jet by the inner fast ones through viscous shear. This means that the velocity distribution within the jet becomes more and more uniform; hence the mercury jet should tend to contract in order to conserve its mass velocity, so far as its momentum remains unchanged. But, since momentum transfer from the mercury jet to the solution envelope occurs gradually, the jet slows down and its diameter enlarges because, in the extreme example of infinitesimal momentum, an infinitely wide stream alone can sustain definite mass velocity.

Quantitative failure in the values of r_o and u_o arises in part from the parabolic velocity distribution approximation (Eq. [1]).[4] Since momentum is being transferred at the interface, the deceleration of the mercury jet due to drag of the solution moves from the interface into the interior; thus the velocity distribution profile should have an inflection point. Attempts to improve the velocity distribution function through introduction of higher terms (definite in number) led to a discontinuity in Eq. [5]. However, the momentum equation method is not designed to give individual values for r_o and u_o but is designed to yield products such as $r_o^2u_o$ and $r_o^2u_o^2$. Since the rate of reversible reduction (mass transfer) of ions at the streaming mercury electrode depends chiefly on the former product (12) and since the theoretical values of this product are in reasonable agreement with the experimental (Table I), this failure does not preclude an application of the analysis to problems of mass transfer (and thus to electrochemical measurements).

Although gravitational force was considered as a variable in the original analysis, its effect on an actual situation is negligible. For example, consideration of the gravity term raises r_o by 0.3% and reduces u_o by 0.6% at $z' = 0.14$ in the case of Fig. 2.

Limiting Current

Theoretical.—Limiting currents were evaluated by the following four methods:

1. The approximate solution of the problem by Ríus and his coauthors [(8) see also (16)]

$$I = 4n\mathbf{F}C_o a(\pi D\bar{u}_m l)^{\frac{1}{2}} \qquad [8]$$

[4] Although the experimental values are not specified as to temperature, minute change in physical properties does not account for such a large deviation.

where I is the limiting current, n the number of Faradays per mole or gram-ion reacting, **F** the Faraday, C_o the bulk concentration of the reactive species in moles per cubic centimeter, D its diffusion coefficient, and l the effective length of the jet or streaming mercury electrode.

2. Introduction of the jet characteristics observed by Weaver and Parry (dashed curves on Fig. 2) into their rigorous equation (12)

$$I = \pi n\mathbf{F}DC_o\left\{2\int_0^l r_o^2u_o[\pi D\int_o^z r_o^2u_o dz]^{-\frac{1}{2}}dz + l + \tfrac{1}{2}\int_o^l (r_o/u_o)(\partial u_s/\partial r)_{r=r_o}\,dz + \ldots\right\}^{-\frac{1}{2}} \qquad [9]$$

3. Introduction of the calculated characteristics (solid curves on Fig. 2) into Eq. [9],

4. Solution of the equation of mass transfer with an approximate method similar to that applied to the stream, as shown in the following.

A profile of the concentration C of the reactive species

$$C/C_o = 1 - [(\delta' - r)/(\delta' - r_o)]^2 \qquad [10]$$

is adopted, where δ' is the thickness of the diffusion layer in the same sense as $\delta(\delta' < \delta)$. If Eq. [1] and [10] are put into

$$d[\int_{r_o}^{\delta'} u_s(C - C_o)r\,dr]/dz = -Dr_o(\partial C/\partial r)_{r=r_o} \qquad [11]$$

one obtains (the gravity term on Eq. [6] is neglected)

$$\frac{60\psi}{\sigma(1-\psi)} = \frac{d}{dz'}\cdot\left\{\frac{(1-\psi)}{[2(1-\phi)+\mu'\phi](1-\phi)\psi^4}\cdot [5\psi^2(1+3\psi) - 4\phi\psi(1+3\psi+6\psi^2) + \phi^2(1+3\psi+10\psi^3)]\right\} \qquad [12]$$

where $\sigma = \nu_m/D$ and $\psi = r_o/\delta'$. Equation [12] can be solved numerically (22), and limiting currents are calculated through

$$I = n\mathbf{F}D\int_o^l 2\pi r_o(\partial C/\partial r)_{r=r_o}\,dz \qquad [13a]$$

or

$$I' = I\nu_m/4\pi n\mathbf{F}DC_o a^2\bar{u}_m = \int_o^{l'} \psi(1-\psi)^{-1}\,dz' \qquad [13b]$$

where $l' = \nu_m l/a^2\bar{u}_m$.

The dimensionless group I' in Eq. [13] corresponds to a Nusselt number divided by the Reynolds number of the mercury stream within the capillary. The mass transfer correlation is expressed as a relationship among the dimensionless parameters I', l', σ, μ', ρ', and g', the last three being of minor influence. It is not easy to measure a and $\bar{u}_m$ separately, but they appear both in I' and l' as the product $a^2\bar{u}_m$, which may be replaced by the mass velocity

$$\bar{m} = \pi\rho_m a^2\bar{u}_m \qquad [14]$$

Experimental, Results and Discussion

Valenta (9) reported that the limiting current was proportional to the square root of $\bar{m}l$ in accordance with Eq. [8], while Weaver and Parry (12) demonstrated that this proportionality required some correction with their equation, Eq. [9] above.

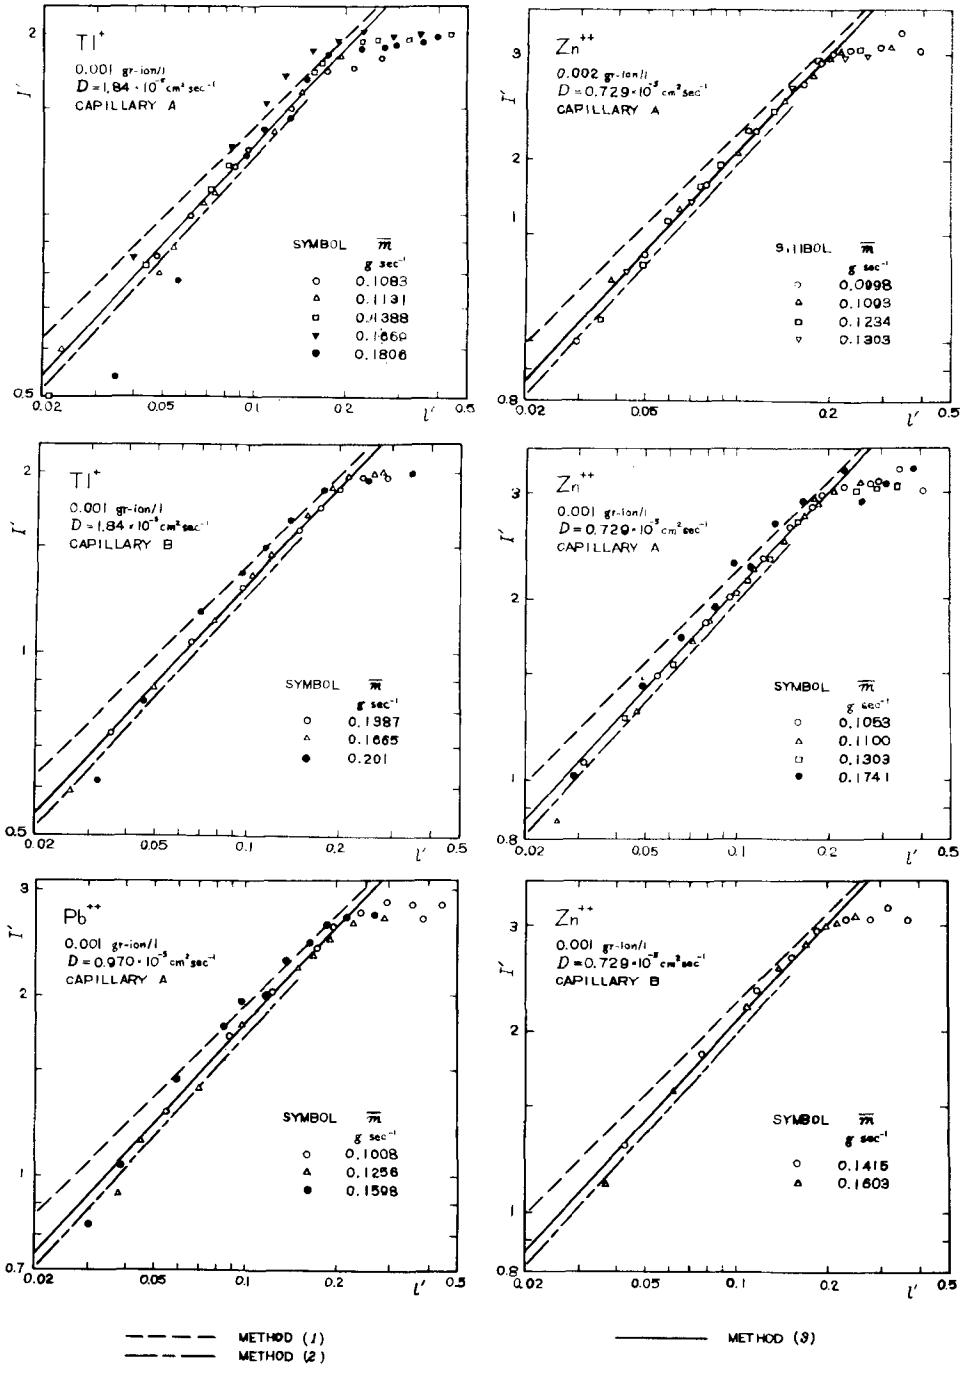

Fig. 3. Mass transfer correlation. Open symbols refer to laminar mercury streaming; solid symbols, to turbulent.

As neither of these data was specified as to temperature, measurements were made with an apparatus essentially similar to that used by Bieber and Trümpler (5), mounted in a bath controlled at 25°C. The solutions studied were 0.1M in KCl and 0.001 or 0.002M in TlCl, $PbCl_2$, or $ZnCl_2$. These systems were chosen since diffusion coefficients of the tracer ions of the reactive species are known: 10^5D (cm^2 sec^{-1}) = 1.84 (Tl^+), 0.970 (Pb^{++}), 0.729 (Zn^{++}) in 0.1M KCl (23). The limiting current I was measured at different values of the mass velocity $\overline{m}$ and the electrode length l, and the results are summarized in Fig. 3 in a dimensionless correlation between I' and l'.

In measuring I, a polarographic apparatus was not employed because anodic polarization and ohmic drop were large. Since charging currents are relatively high at streaming mercury electrodes (7), it was necessary to evaluate them separately. This was achieved by making measurements on solutions with and without the reactive species present.

The mercury mass velocity $\overline{m}$ is dependent both on the characteristics of the capillary and on the mercury head. Two capillaries designated A and B were used; although the mercury flow rate for B was almost twice as large as that for A under the same pressure head, no differences between A and B appear in Fig. 3. $\overline{m}$ was measured by weighing the ejected mercury, and results were plotted against the pressure head in order to check linearity between them or to confirm assumption (*a*). If this assumption is valid, assumption (*b*) is expected to be true, for the path of the mercury stream is rather short. On Fig. 3. open symbols refer to runs within the limit of laminar flow, while solid symbols refer to runs in

which $\overline{m}$ was larger and the mercury stream was turbulent. In the latter case the data were scattered.

The length l (more precisely speaking, the length of the upward mercury jet between the capillary tip and the solution level) was varied from 0.05 through 2.5 cm and measured by use of a cathetometer. When l was very small, polarization curves had discontinuities due to disappearance of charging currents. According to Valenta (9) it is caused by slippage at the interface, and so has a close connection with assumption (c) (accordingly, with Eq. [3]). Slippage at the mercury solution interface is dependent on surface tension; application of surface active agents has been supposed necessary to prevent it, in connection with polarographic maxima (24) and the rotated dropping mercury electrode (25). Although no surface active agent was added in the present study, the discontinuity was observed rather rarely, and besides the experimental results in Fig. 2 show clearly the drag of the solution; hence, slippage would not invalidate the theory. But rather low results for runs for $l' < 0.05$ may be due to this slippage (9). Although slipping was no serious problem, another trouble appeared. The solution coned up around the mercury stream above the solution level (9, 12) and some correction (reduction) was required for observed limiting currents. When l was too large or $\overline{m}$ too small, the limiting current increased no more because of decay and breakup of the stream. The critical value of l' was found to be around 0.2 at −1.4 v vs. S.C.E.

Within these restrictions (turbulence, and upper and lower limits of l'), the observed values ranged themselves on a single correlation for a species, justifying the choice of the dimensionless groups.

The limiting current was calculated by the four methods listed in the theoretical part and represented on Fig. 3 and Table II (method 4 was applied only to reduction of thallous ions). Equation [8] by Ríus and his coauthors (method 1) gives values which are too high. Methods 3 and 4, based on theoretical stream characteristics, gave results within about 2% of each other, suggesting that the approximations used are of fairly high reliability. Methods 2 and 3 give curves which, although nearly parallel, deviate from each other by about 6%. The experimental data follow well curves for these two methods. But no correction for coning of the solution was applied to the measured I values. The fractional correction should vary with the electrode length (larger as l' becomes smaller). It is not easy to obtain the magnitude of the "tail-cone correction," but Weaver and Parry estimated it at about 5-7% for $l' = 0.126$ in 0.1M KCl solution. In conclusion, the present theory of the stream characteristics allows prediction of limiting currents with an accuracy of a few per cent at worst.

Table II. Comparison of methods for calculating l' (reduction of Tl^+, $D = 1.84 \times 10^{-5}$ cm² sec⁻¹)

GLOSSARY OF SYMBOLS

a — radius of capillary (cm)
C — concentration of reactive species (moles/cm³)
C_o — bulk concentration of reactive species (moles/cm³)
D — diffusion coefficient of reactive species (cm²/sec)
$\mathbf{F}$ — the Faraday (amp sec/eq)
g — acceleration of gravity (cm/sec²)
g' — modified Froude number, defined by Eq. [7] (dimensionless)
I — limiting current (amp)
I' — reduced limiting current, defined by Eq. [13] (dimensionless)
l — electrode length (cm)
l' — reduced electrode length, defined by Eq. [13] (dimensionless)
$\overline{m}$ — mass velocity of mercury stream (g/sec)
M — fractional momentum, relative to that possessed by the mercury jet on ejection from capillary (dimensionless)
n — number of Faradays per mole or gram-ion (eq/mole)
r — radial distance (cm)
r_o — radius of mercury jet (cm)
u — velocity component in the z-direction (cm/sec)
u_o — interface velocity component in the z-direction (cm/sec)
$\bar{u}_m$ — mean velocity of mercury jet (cm/sec)
z — distance in the direction of streaming (cm)
z' — $= \nu_m z/a^2\bar{u}_m$ (dimensionless)
δ — thickness of boundary layer (cm)
δ' — thickness of diffusion layer (cm)
μ — dynamic viscosity (g/cm-sec)
μ' — $= \mu_s/\mu_m$ (dimensionless)
ν — kinematic viscosity ($= \mu/\rho$) (cm²/sec)
σ — $= \nu_m/D$ (dimensionless)
ρ — density (g/cm³)
ρ' — $= \rho_s/\rho_m$ (dimensionless)
ϕ — $= r_o/\delta$ (dimensionless)
ψ — $= r_o/\delta'$ (dimensionless)
$_m$ — mercury (jet)
$_s$ — solution (flow)

On the Parabolic Rate Law

W. B. Jepson

Department of Chemistry, University of Exeter, Exeter, England

ABSTRACT

The parabolic rate constant k_p is reformulated in terms of the defect concentration at one interface only by introducing the free energy change of the oxidation reaction ΔG. The pressure dependence of k_p then follows naturally, and k_p is shown to have an exponential dependence on ΔG.

Of the various rate laws which have been found to describe the oxidation kinetics of metals, the parabolic relation

$$X^2 = k_p t \qquad [1]$$

connecting the thickness of the layer of reaction product X with the time of oxidation t is probably the most familiar and widely applicable. The relation between the parabolic rate constant k_p and the mobility of the moving particles has attracted considerable interest, and there have been a number of derivations (1-5).

The purpose of this paper is to re-formulate k_p in terms of the defect concentration at one interface only.

We consider a metal whose rate of oxidation is controlled by the rate of diffusion of metal ions across the oxide layer; the attacking gas is oxygen and any simultaneous anionic diffusion is assumed to be negligible. The derivation by Mott (4, 5) of k_p is easily extended to give, for an n-type oxide, the result:

$$k_p = AD_i[n_i(\mathrm{O}) - n_i(\mathrm{X})]$$
$$\mathrm{A} = 2(z+1)\Omega \qquad [2]$$

for an interstitial ion of valence z where D_i is the diffusion coefficient of the interstitial ion, Ω is the volume of oxide per metal ion, and $n_i(\mathrm{O})$ and $n_i(\mathrm{X})$ are the concentrations of interstitial metal ions at the metal/oxide and gas/oxide interface, respectively. In deriving Eq. [2], the following assumptions are made: (*a*) the regions of space charge at the two interfaces can be neglected (4); (*b*) the problem can be treated as one of steady-state diffusion through a slab of constant thickness (6, 7); and (*c*) the dissolved metal atoms are fully dissociated into ions and quasi-free electrons which in turn form an ideal-dilute solution in the oxide; to the same approximation the concentration gradient of interstitial ions across the oxide layer is linear.

Now the defect concentrations at the two interfaces are determined by the equilibria:

$$2\mathrm{M} = 2\mathrm{M}_o^{z+} + 2ze \qquad [3]$$

$$\frac{z}{2}\mathrm{O}_2 + 2\mathrm{M}_o^{z+} + 2ze = \mathrm{M}_2\mathrm{O}_z \qquad [4]$$

at the metal/oxide and gas/oxide interfaces, respectively, the symbol M_o^{z+} denotes a metal ion occupying an interstitial position. It is easy to show that

$$2\ln n_i(\mathrm{X})n_e^z(\mathrm{X}) - 2\ln n_i(\mathrm{O})n_e^z(\mathrm{O}) = \Delta G/RT \qquad [5]$$

where $n_e(\mathrm{O})$ and $n_e(\mathrm{X})$ are the concentrations of quasi-free electrons at the metal/oxide and gas/oxide interfaces, respectively, and ΔG is the free energy change per mole of the oxidation reaction

$$2\mathrm{M} + \frac{z}{2}\mathrm{O}_2 = \mathrm{M}_2\mathrm{O}_z \qquad [6]$$

at temperature T and an oxygen pressure of p atm. By assumption (a), $n_e = zn_i$ so that, after simplifying Eq. [5] and inserting in Eq. [2], we obtain:

$$k_p = AD_i n_i(O)\left[1 - \exp\left\{\frac{\Delta G}{2(1+z)RT}\right\}\right] \quad [7]$$

which shows the dependence of k_p on the driving force of the reaction.

Since $n_i(O)$ is determined by the equilibrium represented in Eq. [3], the only pressure dependent term in Eq. [7] is ΔG,

$$\Delta G = \Delta G_o - \frac{z}{2} RT \ln p \quad [8]$$

where ΔG_o is the standard free energy change per mole of the oxidation reaction. Hence

$$k_p = AD_i n_i(O)[1 - \alpha p^{-s}] \quad [9]$$

where

$$\alpha = \exp \frac{\Delta G_o}{2(1+z)RT}$$

$$s = \frac{z}{4(1+z)} \quad [10]$$

If the metal ions are diffusing between vacant cation sites then, making the same approximations as before, the result is

$$k_p = AD_v n_v(X)\ [1 - \alpha p^{-s}] \quad [11]$$

where D_v is the diffusion coefficient of the vacancy (of valence z) and α and s are as defined in Eq. [10]; $n_v(X)$ the concentration of vacant cation sites at the gas/oxide interface is determined by the equilibrium:

$$2M^{z+} + 2ze + \frac{z}{2} O_2 = M_2O_z + 2M^{z+}\square + 2ze\square \quad [12]$$

where $M^{z+}\square$ and $e\square$ denote a vacant cation site and a positive hole, respectively. Equation [12] is sometimes formulated with the oxygen in the adsorbed state (12). By Eq. [12],

$$n_v(X) = n_v^{\circ} p^s \quad [13]$$

where n_v° is the concentration of vacant cation sites in equilibrium with an oxygen pressure of one atmosphere. Equations [11] and [13] give

$$k_p = AD_v n_v^{\circ} p^s (1 - \alpha p^{-s}) \quad [14]$$

The relations in Eq. [9] and [14] are of course equivalent to the alternative formulation (8) in terms of the partial pressures of oxygen at the metal/oxide and gas/oxide interfaces, but in the author's opinion they have two advantages: the dependence of k_p on the driving force of the reaction ΔG is clearly brought out (cf. Eq. [7]) and both the pressure dependence of k_p for an n-type oxide and what may be termed the additional pressure dependence for a p-type oxide follow naturally from Eq. [8]. Thus if $\alpha << p^s$, k_p will either be independent of pressure [n-type oxide] or will vary according to p^s [p-type oxide].[1] Values of α are given in Table I for some metal oxidation reactions which satisfy the parabolic rate law and whose pressure dependence has been examined. For the first three examples it is clear that the term αp^{-s} is negligible except at very low pressures: taking nickel oxidation as an example, the term αp^{-s} is only 0.076 with $p = 10^{-3}$ atm. For copper oxidation on the other hand, $\alpha = 0.163$ and k_p is not proportional to p^s (with $p = 10^{-2}$ atm., $\alpha p^{-s} = 0.290$); the procedure adopted by Baur, Bridges, and Fassell (12) of plotting log k_p against log p to determine s as an experimental quantity is therefore incorrect. It would also appear that the generalized rate expression for pressure sensitive oxidation reactions, developed by the same authors, should be modified to include the term in αp^{-s}.

Finally, it is of interest to note that if ΔG is sufficiently small for the exponential term in Eq. [7] to be written

$$\exp\left\{\frac{\Delta G}{2(1+z)RT}\right\} = 1 + \frac{\Delta G}{2(1+z)RT}$$

the parabolic rate constant becomes

$$k_p = A \frac{D_i n_i(O)}{2(1+z)RT} (-\Delta G)$$

so that k_p is now proportional to the driving force of the reaction or alternatively to the electromotive force of the equivalent electrical cell, a result equivalent to that derived by Hoar and Price (3) for a film substance of constant specific conductivity.

Manuscript received July 13, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Magnetism of the Electrodeposited Films as Revealed by Electron Diffraction

S. Yamaguchi

Institute of Physical and Chemical Research, Tokyo, Japan

The path of an electron beam is deflected in a magnetic field as the result of the Lorentz effect. This phenomenon is observable in electron diffraction of a ferromagnetic substance. The magnetic induction of a ferromagnetic film was measurable from the diffraction pattern obtained from it.

Experimental

A process of double exposure was utilized in order to measure the deflection of an electron beam caused by a ferromagnetic specimen. The diffraction pattern from a nonferromagnetic substance (gold foil) was photographed beforehand, and then that of a ferromagnetic specimen was superposed on it. In this process the wave length of the electrons applied as well as the position of the photographic plate were kept fixed. Diffraction rings from these two substances were not cocentric, because the specimen had the Lorentz effect on the electrons, whereas the nonferromagnetic gold foil showed no magnetic effect on them.

Nickel Film

Nickel was deposited electrolytically on a foil of brass from an aqueous solution of nickel sulfate (1). The deposited layer of nickel was divorced from the brass foil with a dilute solution of nitric acid. The area and thickness of the nickel film prepared for the experiment were 10 x 10 mm and about 5 μ, respectively. The specimen was magnetized as illustrated in Fig. 1a. A small piece of permanent magnet (size: about 0.5 mm, coercive force: 400 Oersted) was attracted at the edge of the film. An electron beam passed through a pin hole (about 0.1 mm) found in the nickel film (see Fig. 1a). Such pin holes were formed frequently in an electrodeposited film. Figure 2a was obtained by the double exposure process with the specimen and with a nonferromagnetic gold foil. In this double diagram it is recognizable that the diffraction rings from the specimen and those from

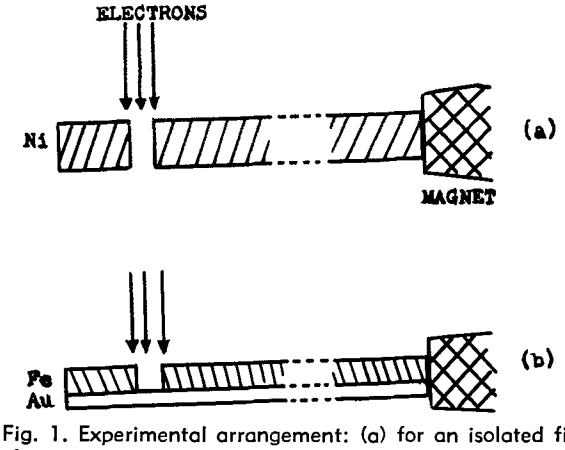

Fig. 1. Experimental arrangement: (a) for an isolated film, (b) for a composite film.

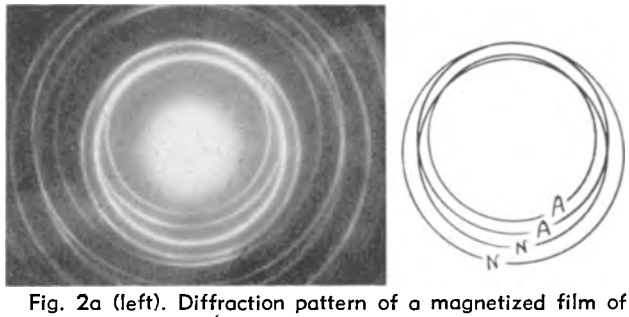

Fig. 2a (left). Diffraction pattern of a magnetized film of nickel and that of gold are superposed. The diffraction rings are eccentric as the result of the Lorentz effect. Wave length: 0.0327Å; camera length: 495 mm: Positive enlarged 2.3 times before reduction for publication. Fig. 2b (right). The main rings corresponding to Ni and to Au in (a) are indicated. N: Ni. A: Au.

the gold foil are eccentric as the result of the Lorentz effect. The main rings corresponding to the two substances are indicated in Fig. 2b (N: the nickel specimen, A: gold).

The deflection ΔZ of the incident beam caused by the magnetic specimen is measurable from the ring

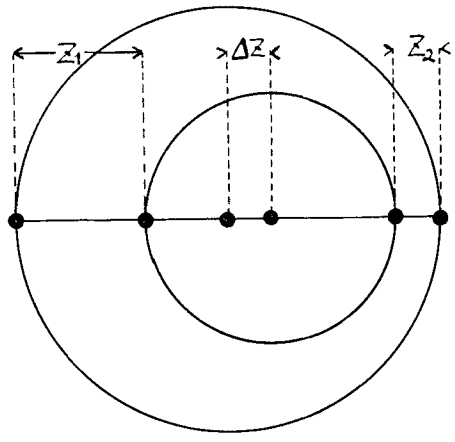

Fig. 3. Illustration for the calculation of the magnetic deflection ΔZ of the incident beam from the ring eccentricity.

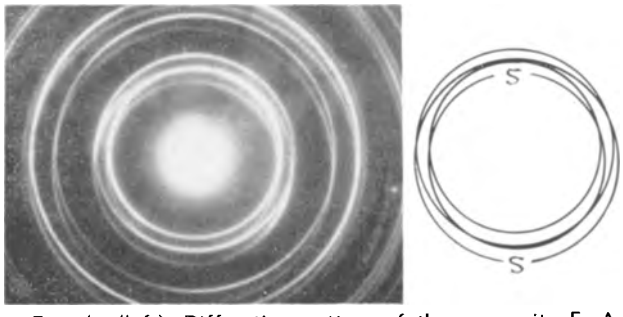

Fig. 4a (left). Diffraction pattern of the composite Fe-Au film and that of gold are superposed. Wave length: 0.0332Å. Lorentz effect. Fig. 4b (right). S shows the rings from the Fe-Au film.

eccentricity, as illustrated in Fig. 3. That is

$$\Delta Z = \frac{1}{2}(Z_1 - Z_2)$$

Under the experimental arrangement in Fig. 1 and 2 we have a relation between ΔZ and the magnetic induction B:

$$\Delta Z = \frac{eL}{mv}\int_0^l Bdl = \frac{eL\lambda}{h}\int_0^l Bdl \qquad [1]$$

where e is electron charge (1.6×10^{-20} emu), m is electron mass, v the velocity of the electrons, L the camera length (495 mm), λ the wave length of the electrons, and l the magnetic field region traversed by the electron beam. λ was determined with the diffraction rings of gold observed in Fig. 2. As seen from Fig. 1, l is approximately equal to the film thickness of the specimen (5 μ). In Fig. 2 we measure $\Delta Z = 0.142$ cm and $\lambda = 0.0327$Å. We obtain, therefore, $B \cong 7 \times 10^3$ gausses for the nickel film according to Eq. [1].

Iron Film

Iron was electrodeposited on a gold foil from an aqueous solution of ammonium ferrous sulfate. A composite Fe-Au film thus prepared, in which the thickness of the iron layer and that of the gold film were about 10^4Å and 5×10^2Å, respectively, was readily investigated by the present process (see Fig. 1b). Figure 4a is a double diagram obtained with the specimen and with a single film of gold. In Fig. 4b the main rings from the specimen are indicated with "S." In this diagram we recognize the ring eccentricity resulted from the magnetic effect. Here we measure $\Delta Z = 0.109$ cm and $\lambda = 0.0332$Å. According to Eq. [1], therefore, we obtain $B \cong 3 \times 10^4$ gausses.

Discussion

Figure 4 shows mainly the existence of the diffraction rings from gold. In this figure it is difficult to determine the rings characteristic of iron. This is because the electrodeposited layer of iron is not so crystalline as the gold film. In the present process, the magnetic state of the ferromagnetic layer is studied indirectly through the diffraction rings from the crystalline gold layer in the composite film. This method is suitable for the study of the magnetism of an amorphous film.

The magnetic inductions of the nickel and the iron film here measured (7×10^3 and 3×10^4 gausses) coincide with the known saturation inductions of these two substances (2). As seen from Eq. [1], it is possible to measure the thickness l of a film if the induction B of the film is known.

The successful result of a blank test for the present magnetic analysis was already shown with the two nonferromagnetic substances, i.e., here all diffraction rings were cocentric in a double exposure diagram (3).

It is of significance that the B-values determined in the present process are absolute, because Eq. [1] contains only the universal constants.

Manuscript received Oct. 20, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Polarography in Formamide

I. Some Transition Metal Ions, Zinc and Cadmium Ions

Glenn H. Brown and Hsiao-shu Hsiung

Department of Chemistry, University of Cincinnati, Cincinnati, Ohio

Formamide is a good solvent for a large number of inorganic salts as well as organic compounds. It has a very high dielectric constant (109.5 at 25°C) (1), a convenient liquid range (freezing point 2.5°C, boiling point 193°C), a very low vapor pressure (1 mm Hg at 70.5°C), and its solutions have a moderate electrical resistance. Formamide is very easily deoxygenated thus making it a good solvent for use in polarography. Moreover, formamide with anhydrous sodium perchlorate as a supporting electrolyte has a decomposition potential of −1.6 v vs. a saturated calomel electrode. Even though this voltage does not allow the voltage range of usefulness afforded by N-N′-dimethylformamide (2) (−2.4 v vs. a mercury pool) it is nevertheless a sufficiently high voltage to make it a useful solvent for polarography of many inorganic salts. The solvent has a high viscosity (3.359 cp at 25°C), but this is not a serious objection to its use.

Formamide is a very good solvent for a large number of different kinds of inorganic compounds; Colton and Brooker (3) have obtained solubility values for 47 salts. Although we have not made quantitative measurements of solubility for our polarographic studies, we have found that perchlorates are quite soluble in formamide. Also, the salts K_2NbF_7, K_2ZrF_6, K_2TaF_7, and K_2HfF_6 are all somewhat soluble in the solvent.

There appear to be only four papers in the literature concerned with the polarography of inorganic salts in formamide. Zan'ko and Mannsova (4) studied the polarography of cadmium sulfate, lead nitrate, tin (II) chloride, and zinc chloride. No supporting electrolyte was used in this study since the authors report that there is sufficient ammonium chloride (origin in synthesis of formamide) in the formamide to function as a supporting electrolyte. Letaw and Gropp (5) investigated the polarography of organic compounds such as acetophenone and anisaldehyde in formamide. They also obtained polarographic data on zinc sulfate, thallium (I) sulfate, and lead nitrate. Their supporting electrolyte was 0.1M KCl for the zinc and lead and 0.1M KNO_3 for thallium. Hook, Letaw, and Gropp (6) studied these same metal ions in formamide-acetamide mixtures. Their $E_{1/2}$ values in formamide are close to those for the same ions in water, and those in the mixed solvent are close to those in formamide.

Bruss and DeVries (7) in a study of the effect of solvents on the polarographic reduction of cations observed the $E_{1/2}$ values of bismuth, cadmium, chromium (III), and zinc ions against a silver-silver chloride electrode in a number of different solvents of which formamide was one. Their values for cadmium and zinc ions check with ours when one considers the different reference electrodes used. However, they did not report on $E_{1/2}$ value for Cr (II) to Cr (0), but did report an $E_{1/2}$ value for Cr (III) to Cr (II). We found the wave for the Cr (III) to Cr (II) to be ill-defined but were able to assign an approximate value of −0.9 v vs. S.C.E. to this transition which is close to the value of −0.83 v vs. Ag-AgCl electrode reported by Bruss and DeVries.

This paper deals with the polarography of some transition metal ions, zinc and cadmium in formamide. In this study we chose the hydrates of the salts of the electroreducible ions instead of anhydrous salts. Further studies of stability constants in nonaqueous solvents are now in progress using different ligands with some of the ions reported herein. When these studies are completed, data on the anhydrous salts will be discussed in light of the systems under observation.

Experimental

Materials.—The practical grade of formamide, obtained from Matheson Company, Inc., was purified by double vacuum distillation (2-3 mm Hg, bp 90°C). However, small amounts of water do not alter the decomposition potential of the solvent. It was found in this work that up to 3 ml of water in 25 ml of formamide did not change the decomposition potential of the formamide.

Anhydrous sodium perchlorate was used as the supporting electrolyte in this study. Anhydrous sodium perchlorate of "reagent" quality purchased from the G. Frederick Smith Chemical Company was used without further purification. The decomposition potential of a 0.2M solution of sodium perchlorate in formamide is −1.6 v vs. a saturated calomel electrode.

All perchlorates used in this study were "reagent" quality, obtained from the G. Frederick Smith Chemical Company and were used without further purification. These salts were dried in a current of dry air and dissolved as the hydrates. The cadmium sulfate was the "Baker Analyzed" reagent manufactured by the J. T. Baker Chemical Company. It was used without further purification.

In a few cases, maxima occurred in the polarographic wave and when these were found, they could be depressed by the use of gelatin.

Apparatus.—All polarograms were obtained using a L&N recording "Electro-Chemograph." The electromotive force recorded by the instrument was

checked with a "Queen Model" E-3040, three-range potentiometer manufactured by the Gray Instrument Co., Philadelphia, Pennsylvania. All diffusion currents were corrected for residual current, which never exceeded 1.5 μamp for any potential at which the diffusion current was measured.

The polarographic cell was constructed according to one described by Kolthoff and Coetzee (8) in order to eliminate the transference of water or potassium chloride into the electrolysis cell during the time required to complete the polarogram. The half-wave potentials were measured against a saturated calomel electrode.

All diffusion currents were corrected for iR drop across the electrolysis cell. The resistance of the solutions was measured with an Industrial Instruments, Inc., Model R C 16 conductance bridge. A 0.2M sodium perchlorate solution in formamide gave a resistance of 9600 ±50 ohms. In the iR corrections average values of i and R were used.

The capillary was made of Corning marine barometer tubing, which has a capillary of 28.4 μ radius, and was 10 cm in length. The capillary (open circuit) had the following characteristics: $m = 1.01$ mg/sec, and $t = 5.83$ sec/drop for $h = 64$ cm. The relationship of $m^{2/3}t^{1/6}$ was studied as a function of applied voltage for the capillary. These values for several applied voltages are: −0.4 v, 1.34; −0.8 v, 1.33; −1.20 v, 1.31; and −1.60 v, 1.26. These values were used at the appropriate places in the handling of the data.

The cell was immersed in a water bath at a temperature of 25 ±0.5°C. The electrolytic solutions were deaerated by bubbling tank nitrogen, obtained from the National Cylinder Company, through them.

Results and Discussion

Well-defined waves were obtained for the metal ions considered in this investigation. The concentrations of the electroreducible ions were varied from 0.6 to 4 mM in 0.2M $NaClO_4$ as the supporting electrolyte. In all cases the diffusion currents were proportional to the concentration. If one uses the criterion that an experimental value of the slope of a

$$\text{plot of } -E_{d.e.} \text{ vs. } \log \frac{i}{i_d - i} \text{ is } \frac{0.0591}{n} \text{ volts at } 25°C$$

and must agree with the theoretical value within 3-5 mv for a system to be reversible (9), then only one of the ions studied undergoes a reversible process (i.e., manganese). Zinc and cadmium approach reversibility while each of the other ions shows irreversibility in its electroreducible process. The copper reduction gave only a one-step wave, the same as in water.

The polarographic data on the ions investigated are to be found in Table I. The I_d values were calculated using values for t which were taken at the decomposition potential of the particular ion.

In formamide, as in water, the reduction stage of iron which gives a true curve is that from iron (II) to iron (0). On starting with iron (III) the first wave is not a true one since the reduction of iron (III) sets in at a potential which is more positive than the anodic dissolution of mercury.

Chromium (III) ion gives a stepwise reduction to chromium (II) and then to chromium (0). The first wave is not well-defined and makes the determination of the $E_{1/2}$ (approximately −0.9 v) for this step uncertain. Also, it might be pointed out that the height of the second wave is somewhat greater than twice that of the first. The chromium (II) to chromium (0) wave is well defined and can be used for evaluation of polarographic data.

Table I. Polarographic characteristics of some transition metal ions, zinc and cadmium in formamide (0.2M $NaClO_4$ as supporting electrolyte).

Salt	conc, mM/l	I_d	$-E_{1/2}$ v vs. S.C.E.	D cm²/sec x 10^5	0.059/n

Technical Review

Fabrication, Properties, and Applications of Some Metallic Silicides

R. D. Grinthal

American Electro Metal Division of Firth Sterling Inc., Yonkers, New York

Recent requirements for higher and higher operating temperatures in the rocket and missile field, nuclear reactors, and many other applications have led to the consideration of the so-called "refractory hardmetals" for use as one class of structural materials in the temperature ranges where today's superalloys are no longer useful.

The term refractory hardmetals includes compounds of the transition metals with boron, carbon, nitrogen, silicon, and sulfur. These materials are characterized in general as hard, brittle interstitial compounds which have very high melting points. They differ from the corresponding oxides mainly in their electrical and thermal behavior which is distinctly metallic. They are good conductors of electricity and heat. Many are even better in this respect than austenitic stainless steel and titanium which are among the poorer conducting metals. Thus the term refractory hardmetals serves to distinguish this class of materials from high melting metals such as tungsten and molybdenum and from the more refractory oxides.

Table I. Physical properties of some metallic silicides.

Silicide	Crystal structure	Density g/cm³	Melting point, °C	Hardness, kg/mm² (100 g load)	Electrical resistivity, microohm-cm
Ti_5Si_3				986	170
$TiSi_2$	Orthorhombic	4.4	1540	618	123
$ZrSi_2$	Orthorhombic	4.9	1520	1030	161
V_3Si	Cubic	5.7	2000		
VSi_2	Hexagonal	4.7	1750	1090	9.5
$NbSi_2$	Hexagonal	5.3	1950	1050	6.3
$TaSi_2$	Hexagonal	8.8	2400	1560	8.5
Cr_3Si	Cubic	6.5	1730	1100	43
CrSi	Cubic	5.3	1600	1230	139
$CrSi_2$	Hexagonal	4.4	1570	1150	600
Mo_3Si	Cubic	9.0	2100	1310	
$MoSi_2$	Tetragonal	6.2	1870	1260	21.5
WSi_2	Tetragonal	9.3	2150	1090	334
$ThSi_2$	Tetragonal	7.8	1600	1120	
USi	Orthorhombic	10.4	1600		
$USi_2(\alpha)$	Tetragonal	9.0			
$USi_2(\beta)$	Hexagonal	9.2	1700		
YSi_2	Orthorhombic	4.5	1500		
$LaSi_2$	Tetragonal	5.0	1500		
$EuSi_2$	Tetragonal	5.5	1500		
$GdSi_2$	Orthorhombic	6.4	1500		
$DySi_2$	Orthorhombic	6.8	1500		

Their stability in oxidizing atmospheres at high temperature falls between that of the refractory metals and the oxides. Some of these hardmetals have excellent resistance to oxidation at elevated temperatures while others must be protected or used in nonoxidizing atmospheres. This discussion is concerned only with metallic silicides, which are among the most stable of the refractory hardmetals under oxidizing conditions.

Table I lists physical properties of some silicides of the transition metals and metals of the lanthanide and actinide series. A great variety of crystal structures are encountered in these materials, from the orthorhombic $TiSi_2$ through the cubic V_3Si, tetragonal $MoSi_2$, and hexagonal $CrSi_2$. While most monocarbides and mononitrides are isomorphous with each other and most diborides are isomorphous with each other, this is not true of the silicides.

The melting points of the silicides which are known are quite high, although not as high as the corresponding borides or carbides in most cases. The disilicides in particular, however, have outstanding chemical stability, and resistance against oxidation and attack by acids is maintained over large temperature ranges.

Production

Silicides are produced by several methods, the most important of which are as follows.

Direct combination of the metal and silicon.—This can be accomplished by either fusion or sintering. Fusion temperatures are extremely high, necessitating electric arc or carbon tube furnaces. Sintering of mixtures of powders produces a violently exothermic reaction at temperatures ranging from 900°-1500°C, depending on the material. In many instances the metal hydride can be substituted for the metal powder. Protective atmospheres of argon, hydrogen, or vacuum are necessary to prevent oxidation.

Reduction of metal oxides with silicon.—Silicon can reduce metal oxides in the same manner as boron or carbon, but extremely high temperatures (above 1500°C) are necessary, and the silica which forms as a reaction product is difficult to remove completely. If the reduction is carried out in vacuum, however, the silica contamination is held to a minimum by

removal of the more volatile SiO before it can condense on the furnace charge.

Reaction between metal oxides and silica in the presence of carbon.—This process is similar to direct reduction with silicon except that the carbon serves to reduce both the metal oxide and the silica, forming CO and CO_2 which do not contaminate the reaction product. This process is best carried out at high temperature in an electric arc furnace.

The aluminothermic process.—The reaction of metal oxide, quartz, and either aluminum or magnesium, performed in clay crucibles in the presence of sulfur, yields fused silicides which can be treated chemically to remove undesirable reaction products. The sulfur serves to form a liquid slag which is decomposed readily by water.

Reaction of metal with silicon halide.—Silicon tetrachloride, when passed over heated metal powder in the presence of hydrogen, reacts to form the metal silicide and HCl at temperatures ranging from 1100°-1800°C, depending on the material. This method is also used to siliconize metal surfaces and produce protective coatings in place.

Fused salt electrolysis.—By electrolysis of fused alkali fluosilicate baths containing metal oxides, silicide crystallites are deposited on the cathode.

Fabrication

Bodies may be fabricated from the silicide powders by several powder metallurgical methods. Hot pressing (simultaneous application of heat and pressure) is done in graphite dies and produces dense parts. Limitations of this process, however, only allow production of fairly small, simple shapes which have regular cross section, no undercuts, and no thin walls. Since the graphite dies cannot be used more than once or twice, this is not a means of achieving high production rates.

Cold pressing followed by sintering allows the use of steel or carbide dies and can be adapted for fairly high volume production. The same limitations in size and shape apply here as were described for hot pressing. Long time sintering in a protective atmosphere consolidates and densifies the part, but the shrinkage which occurs makes it more difficult to hold close dimensional tolerances. This can be compensated for in long run production by allowing for shrinkage in the die design. Cold pressed and sintered parts may have slightly different mechanical properties than hot pressed parts.

Extrusion of the silicide powder after it has been mixed with plastic is also possible. This method is limited to simple cross sections which have straight sides, but for certain parts it can be a high volume production process. The sintered piece may be slightly porous due to voids left when the plastic burns out, but this is not a serious drawback in most cases.

Slip casting is a ceramic process which is currently being applied successfully to metal powders. The shape of the part produced by this method is far more unrestricted than any previously described, but the process at present is in a developmental state and, although some materials are produced in quantity, most would require considerable experimentation before usable parts could be produced on a volume basis. Using this method, however, re-entry angles, undercuts, thin-walled sections are all possible. Size is restricted only by the weight that the green piece can support without collapsing during sintering.

Another fabrication method which may be employed in special cases is flame spray forming. Here the silicide is extruded into rod, which is sintered, then fed through a flame spray gun and deposited on a pattern as a coating. The coating is built up to any desired thickness and the substrate removed chemically, leaving a strong, formed body which does not require further sintering. Density is 80-90% of theoretical. If this is not satisfactory for the application, it can be improved somewhat by sintering. This method may also be used, of course, to produce protective coatings on substrate materials which are subjected to oxidizing conditions which they cannot withstand normally. The coatings are slightly porous and quite brittle, but the porosity is not interconnected and is usually sealed by the protective silicate which forms during high-temperature oxidation.

Properties

The mechanical properties of these materials are generally similar. They are hard, brittle, and have appreciable compressive and transverse rupture strength which is retained at temperatures up to 1000°-1200°C. Like most interstitial compounds, they are sensitive to impact loading and cannot be relied on in applications where tensile strength is necessary. The properties of any given material can be varied somewhat by changes in the fabrication method or by the presence of small amounts of impurities which may come from various methods of preparation. Porosity exerts a major influence in this respect and, since most test samples are prepared by powder metallurgical methods, some porosity is almost always present.

Some of the properties of $MoSi_2$, chosen here as a typical example, are listed in Table II. This material is perhaps the best known silicide and may be closest to having real commercial application. The figures given should be taken only as representative values, since the properties can vary over a wide range when variations in fabrication technique or impurity content are employed.

Modifications

Several attempts have been made to apply the cermet principal to the hardmetals and improve impact strength by addition of a third metal, which is intended to act as a binder as in the case of WC-Co

Table II. Mechanical properties of $MoSi_2$

Hardness		80-87 RA
Compressive strength		100-350,000 psi
Modulus of elasticity		59×10^6 psi
Modulus of transverse rupture	20°C	36-67,000 pst
	1000°C	51-86,000 psi
Tensile strength	1300°C	41,000 psi
Stress to rupture (100 hr life)	1000°C	13,000 psi
Oxidation resistance	Excellent to 1700°C	

and TiC-Ni. These two cases, however, have proved to be the exception rather than the rule. Several factors must be considered in choosing a metal addition to a silicide system. First, the metal to be added should be one which does not form silicides readily and, second, the silicide should be the lowest possible in the system. If, for instance, copper should be added to $MoSi_2$, the result would not be a two-phase system consisting of $MoSi_2$ in a copper matrix. The copper would react with the $MoSi_2$ forming a copper silicide and leaving a lower molybdenum silicide such as Mo_5Si_3 or Mo_3Si. These materials are all brittle and, in addition, do not have the excellent oxidation resistance of $MoSi_2$. The same results are obtained when cobalt, platinum, nickel, chromium, or titanium are added to $MoSi_2$. When metallurgical equilibrium is obtained, the starting materials are never present in their original form but always react to form new compounds, solid solutions, or ternary compounds which are sometimes even more brittle and less stable than the original materials.

Several investigators have worked with the silicide-silicide systems which, in many cases, act like binary systems between elements. It is possible in this manner to produce modifications of some silicide structures by addition of only a few mole per cent of a second silicide. For instance, $TiSi_2$ and $MoSi_2$ are not isomorphous, and $TiSi_2$ is practically insoluble in $MoSi_2$. However, a few mole per cent $MoSi_2$ added to $TiSi_2$ changes the orthorhombic structure to a hexagonal one which is intermediate between $TiSi_2$ and the tetragonal $MoSi_2$. The two compounds form a third phase which has a wide range of homogeneity and, although similar to the parent compounds, it possesses unique properties of its own.

$MoSi_2$ and WSi_2 are isomorphous, and behavior similar to the above was also noted with $TiSi_2$ and WSi_2. $CrSi_2$ and $MoSi_2$ are mutually soluble in one another in very large amounts, with a narrow two-phase region between them in the center of the diagram. Other pseudobinary systems investigated include $ZrSi_2$-$TiSi_2$, WSi_2-$CrSi_2$, VSi_2-$TiSi_2$, $CrSi_2$-$TaSi_2$, USi_2-$MoSi_2$, $MoSi_2$-WSi_2. The last pair forms a complete series of solid solutions. Investigation of systems like these may lead to methods of changing physical, electrical, or mechanical properties of these materials so that they can be tailored to suit specific applications.

Applications

Many of the silicides have been tested for potential applications in various fields. $MoSi_2$ is perhaps the best known of the group and the one closest to commercial use. A new type of heating element has been developed which is based on this material. It can be heated in air for long periods at temperatures up to 1650°C without damage. The excellent stability of $MoSi_2$ has led to its use as a protective coating for molybdenum. This coating can be applied by flame spraying or by siliconizing a molybdenum surface. It has also been found to be resistant to corrosion by molten boron oxide at elevated temperatures. Other potential applications where impact loading is not a factor may be in rocket nozzles, afterburners (as a coating), or as refractory brick.

Some investigation has been carried out concerning the possible use of solid solutions of $MoSi_2$ and USi_2 as nuclear fuel elements. This may allow high reactor temperatures and minimize the distortion usually encountered when uranium metal or alloys are used as fuel elements.

A great deal of interest has developed lately in the use of the so-called refractory metals molybdenum, tungsten, tantalum, and niobium for very high-temperature applications. If the atmosphere is oxidizing, these materials must be protected, and the possibility of coating each with its corresponding silicide is certainly an interesting one.

$CrSi_2$ and $TiSi_2$ may find applications where the combination of high temperature stability and light weight are of interest.

Among the rare earth silicides, gadolinium disilicide has been considered as a possible control rod material, dysprosium disilicide has been used as a counter for neutron flux density measurements, and europium disilicide has been fabricated for a nuclear application.

As more information is compiled about these materials, other applications will undoubtedly be suggested and investigated, and one or two will find commercial outlets. When this happens, the whole class of hardmetal materials will begin to come into more popular use, and it is hoped that the fear of using brittle materials will subside finally.

Manuscript received June 4, 1959. This paper was prepared for delivery before the Philadelphia Meeting, May 3-7, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Brief Communication

Nodule Growth on Al_2O_3 Coatings

R. J. Jaccodine

Bell Telephone Laboratories, Incorporated, Allentown, Pennsylvania

This communication concerns the growth of nodules or hillocks on surfaces of heaters sprayed with Al_2O_3 coatings.

In studying heater-cathode breakdown phenomena, the method used (1) involved helically winding a bare tungsten heater or other bare metals about the Al_2O_3 coated heater: these were pumped and sealed off at 10^{-5} mm Hg. A variable heater voltage then was applied to both heaters to obtain the desired thermal conditions (Al_2O_3 coated heater at 1200°C optical and bare tungsten heater 900°C optical), and a d-c voltage of 180 v with coated heater positive was applied between both heaters to set up a potential gradient. During the course of this study, it was observed that nodules or hillocks of Al_2O_3 surface to the outside tungsten heater. These growths appeared gradually over a period of several months. The size of the nodule seemed to be limited by the gap formed between the outside base tungsten heater and the alumina surface. Figure 1 shows the hillock growth with the helically wound outside heater in place. Figure 2 shows the nodules with the outside heater removed. As can be noted, the nodules are aligned helically and occur only under the outside heater. The tops of the hillocks appear loosely packed and powdered as compared to the more substantial-looking base region. However, upon probing with a fine metal probe, the whole hillock and the region immediately adjacent to and under its base was found to be powdered, less adherent, and more loosely packed than adjacent normal regions of the coating.

Fig. 1. Hillock growth with helically wound outside heater in place.

Fig. 2. Nodules with outside heater removed

The presence of hillocks might be explained by several possible mechanisms. There may be an Al_2O_3-W (or impurities in W) reaction; bulk and/or surface diffusion under the influence of thermal and electrical gradients and also reaction involving vapor phase constituents.

The question of an Al_2O_3-W reaction at elevated temperatures remains open. Brewer and Searcy (2) claim Mo and W are nonreactive toward Al_2O_3. Wartenberg (3) and also Ackermann and Thorn (4) claim Al_2O_3 and W do react at high temperatures and form AlO.

Vapor phase reactions have been noted by various workers. Brewer and Searcy (2) give data on the Al-Al_2O_3 system, particularly the pressure of gaseous species over liquid Al_2O_3 and over liquid Al and solid Al_2O_3 mixture. Webb and Forgeng (5) account for the growth of single crystal Al_2O_3 whiskers by a vapor phase reaction in which AlO is adsorbed on an aluminum oxide surface where disproportionation takes place according to the reaction

$$3AlO(g) = 3AlO(surface) = Al_2O_3(s) + Al(l)$$

They noted globules of aluminum metal at the tips of their Al_2O_3 single crystal whiskers.

There seems a good possibility that the nodules grow as a result of an interaction of the above mechanisms. A reaction of Al_2O_3 with tungsten or the impurities in tungsten (carbon, for example) to give AlO and other vapor species, and the chemical disproportionation might be indicated by the identification of aluminum which coats in spots the wound outside heater and after longer periods slightly darkens the inside of the tube bulb. Chemical identification of these bright metallic spots was made by removing the outside tungsten heater and having qualitative spectrochemical analysis made of these areas. In Fig. 1, some of these spots can be seen on the outside base tungsten heater. Diffusion mechanism can be invoked to aid in the buildup of the nodules and could account for the observation that the regions immediately adjacent to the base of the nodules are loosely packed and in some instances are concave or moat-like.

These hillocks have also been observed in tubes in which the outside "heater" was made of nickel.

Manuscript received Sept. 3, 1959.

The Reaction of Germanium with Aqueous Solutions

II. Dissolution Kinetics in Electrolytes and the Role of Specific Adsorption

Walter W. Harvey and Harry C. Gatos

Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts

ABSTRACT

The dissolution of single-crystal germanium has been studied in electrolyte solutions containing dissolved oxygen. The following electrolytes were considered: KF, KCl, KBr, KI, $NaNO_3$, Na_2SO_4, CsCl, $BaCl_2$, and $LaCl_3$. In the range 10^{-6} to 1.0N, the dissolution rate typically goes through a maximum as the electrolyte concentration is increased. The concentration corresponding to maximum dissolution rate is different for the various electrolytes but, in general, is less than $10^{-2}N$. In the case of KF, two distinct maxima were observed; in $BaCl_2$ solutions the maximum is followed by a minimum. The activation energy for the reaction in O_2-saturated KCl solutions was found to be about 19 kcal/mole. At very low oxygen partial pressures, the activation energy was less than 5 kcal/mole, indicative of diffusion-controlled kinetics.

For single-crystal as well as for powdered germanium samples, the reaction rates were not altered measurably by changes in mobile-carrier concentration brought about by doping or illumination. The experimental results are related to germanium electrode behavior and can be interpreted on the basis of specific adsorption rather than solution conductance and oxygen solubility. The interaction of germanium surface atoms with aqueous solutions is discussed in terms of probable electronic configurations.

In a previous communication (1) it was reported that, in the absence of dissolved oxygen, germanium is inert to water and nonoxidizing electrolytes up to 100°C and over a broad range of *p*H. In oxygen-saturated water, the germanium dissolution rate at room temperature is approximately 1 $\mu g/cm^2/hr$, and the reaction is controlled by the activated reduction of oxygen. The dissolution mechanism was found to be the same for the various surface orientations, although the absolute dissolution rates decreased in the order {100} > {110} > {111} [see also Ellis (2)].

An unusual feature of the surface chemistry of germanium is that its common oxide, hexagonal GeO_2, is moderately soluble in water and aqueous electrolytes [forming metagermanic acid (3)], whereas germanium itself is not attacked by nonoxidizing acids (including HF) and bases. As a result, it is possible to follow the reaction of properly prepared germanium surfaces with mild oxidizing agents in aqueous solutions without the complicating effects of surface oxides. Germanium surfaces prepared by conventional etching techniques, however, generally are covered with an oxide layer consisting at least in part of an insoluble modification (possibly tetragonal GeO_2). With the chemical polishing agent CP-4[1] difficultly soluble surface oxide is likely formed by continued reaction of the etchant on removal of the germanium from the etching bath [cf. Ellis (4)]. The formation of the difficultly soluble oxide is avoided by displacing the etchant[2] with a large volume of water or dilute HF. It is believed that in this way, oxide-free germanium surfaces are obtained, whose subsequent behavior is independent of their prior etching treatment.

The obvious advantages of studying the surface properties of a semiconductor without the complicating effects of a surface oxide, as well as the continued importance of surface reactions in the science and technology of semiconductor materials, motivated this study of the influence of electrolytes in the reaction of germanium with aqueous solution. Elucidation of the role of the adsorptive properties of various ions was considered of particular importance. Our earlier finding (1), that changes in the mobile carrier concentration in germanium are without effect on the kinetics of the reaction with water containing dissolved oxygen, in contrast to the results reported by Schwab (6), was confirmed using both single-crystal and powdered germanium samples. Furthermore, no mobile-carrier effect was found in the presence of added electrolyte.

Experimental

The experimental techniques employed were, in many respects, similar to those described earlier (1). The reagent grade salts employed were not further purified, since consistent results were obtained with such salts from different sources. The KHF_2 was purified by recrystallization. Certain improvements in the procedure for single-crystal samples, as well as the technique employed with powdered samples, will be described briefly.

Powdered samples.—These experiments were performed using a conventional Warburg apparatus.

[1] CP-4 consists of conc. HNO_3 (5 parts by volume), glacial CH_3COOH (3 parts), 48% HF (3 parts), and Br_2 (0.06 part).

[2] A similar technique has been employed for cleaning silicon surfaces (5).

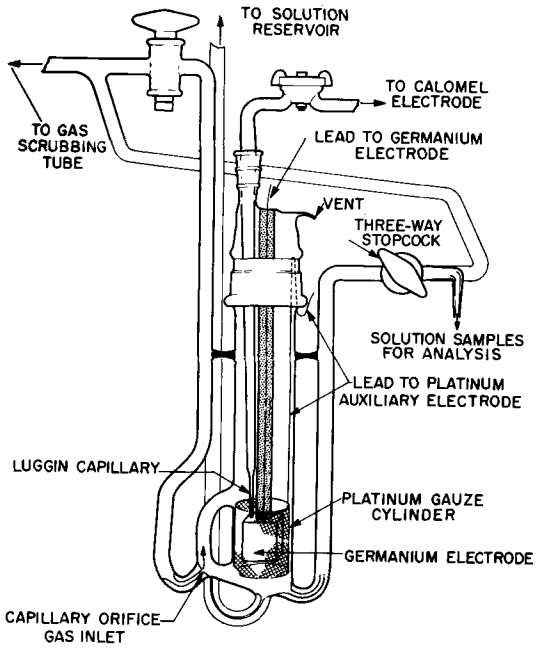

Fig. 1. Cell for dissolution and electrochemical measurements.

The method is similar to that employed by Schwab, *et al.* (6). Consumption of oxygen gas during the reaction was measured by means of a differential micromanometer to within 1 microliter. Our illuminating source consisted of two fluorescent lamps, providing an incident intensity of about 6500 meter-candles, or a photoflood lamp providing approximately 20,000 meter-candles. Radiation from the latter source was filtered through 1 in. of water.

The powdered samples were prepared by crushing germanium crystals of known type under water in an agate mortar. The particle size varied up to several hundred microns; extremely fine particles were removed by washing. For certain runs, powders of nearly uniform particle size were obtained by sieving. In a number of cases, on completion of the run, the solution was analyzed for total dissolved germanium for the purpose of comparison with the total amount of oxygen consumed.

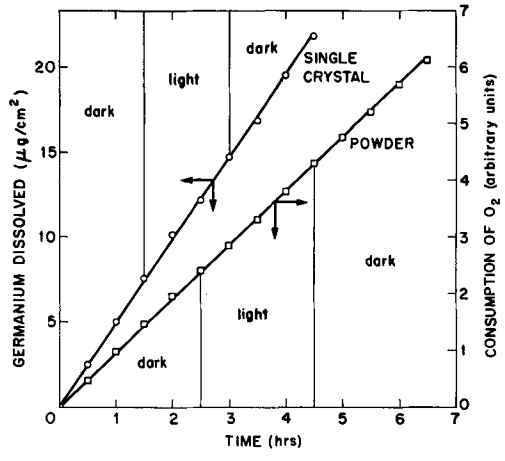

Fig. 2. Typical results of photo experiments with single-crystal and powdered germanium samples in oxygen-saturated solutions at 30°C and pH 6. ○ = 10^{-4}N Na_2SO_4; □ = 10^{-4}N KCl.

Single-crystal samples.—The single crystals employed were rectangular parallelepipeds measuring initially 1.5 x 1.5 x 2.5 cm, all faces having {100} orientation. This geometry was chosen for convenience. An electrical lead was soldered to the crystal, which was mounted as shown in Fig. 1. A thin layer of Apiezon W wax held the sample against the flat end of a heavy-walled capillary tube, through which the electrical lead passed. The saturating gas was introduced through a side tube so as to provide vigorous circulation of the solution past the specimen without permitting direct contact between gas bubbles and germanium. The partial pressure and, hence, the concentration of dissolved oxygen was varied by means of metered admixtures of nitrogen. A platinum auxiliary electrode made possible electrolytic pretreatment of the germanium whenever this procedure was required for the establishment of a stable rest potential. During pretreatment and subsequent equilibration, the solution in the cell was replaced continuously with presaturated solution from the reservoir.

Dissolution rates were obtained by withdrawing portions of solution periodically and analyzing for germanium. At least four samples were taken for each rate reported. For investigating photoeffects, sequences of three stages of alternating darkness and strong light were used in order to distinguish illumination effects from occasional small variations of rate due to other causes. Under the conditions of the experiment, illumination resulted in a considerable enhancement of the minority carrier densities.

Results

Role of mobile carriers.—In agreement with our earlier findings with single-crystal samples, no change in dissolution rate resulted from illumination of either n- or p-type germanium powder. This was the case not only in water, but also in 0.1*N* and 10^{-4}*N* KCl. Similarly, light was without effect on the reaction of n- and p-type germanium single crystals in electrolytes generally. In the latter experiments, total bulk carrier densities ranged from 5 x 10^{13} (intrinsic) to about 10^{18} carrier/cm^3. Typical results are shown in Fig. 2.

It is also significant that the average activation energy for the dissolution of powdered samples was found to be 20 kcal/g-atom, in agreement with the value previously reported for single-crystal samples (1). Furthermore, absolute dissolution rates for the sieved powders were the same as for single crystals, within the uncertainty of estimating actual surface areas. The ratio of moles of O_2 consumed to gram-atoms of germanium dissolved had an average value of 0.85 in 13 runs. However, in view of the experimental uncertainties in the quantitative determination of oxygen consumption, no significance is attached to the deviation of the average value from unity.

Influence of solution variables.—In a given electrolyte solution, as in pure water, the germanium dissolution rate remained constant with time for periods exceeding those employed in this study. With increasing electrolyte concentration, the dissolution rate goes through a maximum, as shown

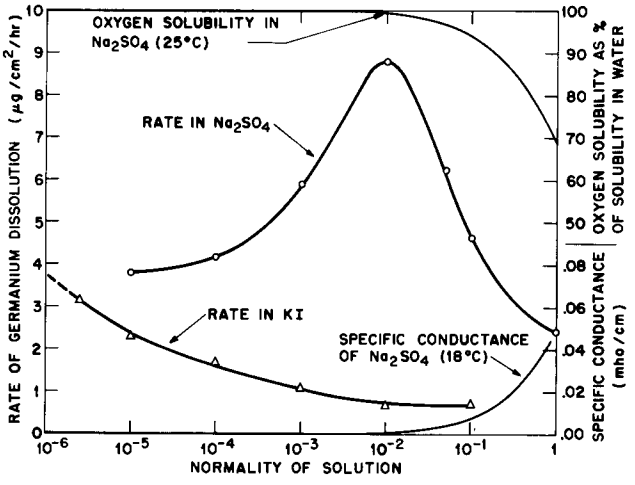

Fig. 3. Germanium dissolution rate, oxygen solubility, and specific conductance in Na_2SO_4 solutions. Oxygen solubility data from ref. (11). Conductance data from ICT 6:231, 236, 240. The maximum rates in KI and Na_2SO_4 solutions occur at the lowest and highest concentrations, respectively, of the electrolytes studied.

in Fig. 3 for Na_2SO_4 solutions. In addition to the dependence on electrolyte concentration, the effects of *p*H, oxygen partial pressure, and temperature were studied systematically with the following results.

It was found that the dissolution rate of germanium is not affected by *p*H changes below approximately *p*H 6. Above this value, the dissolution rate increases with increasing *p*H, as shown in Fig. 4(b) for O_2-saturated 0.1*N* KCl. The average of 12 determinations in the *p*H range 3 to 6.5 was 1.09 ± 0.11 μg/cm²/hr. (This value also indicates the degree of reproducibility of the data generally.) There is evidence that in certain more concentrated solutions, e.g., 1*N* CsCl, the rate in alkaline solutions is even more strongly dependent on *p*H, but this behavior was not studied in detail. Since working at low *p*H values would preclude consideration of very dilute salt solutions, all studies were carried out at *p*H 6.0 ± 0.1, unless otherwise specified.

The dependence of the dissolution rate on the concentration of dissolved oxygen is shown in Fig. 5 for 0.1*N* and $10^{-4}N$ KCl. Although rates are higher

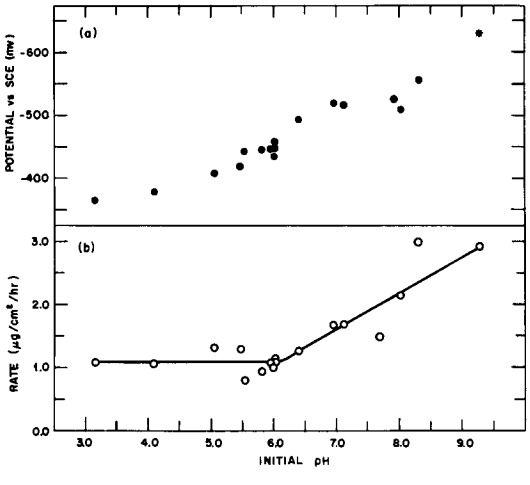

Fig. 4. Variation of (a) mixed potential and (b) dissolution rate with pH in 10^{-1}N KCl at 30°C.

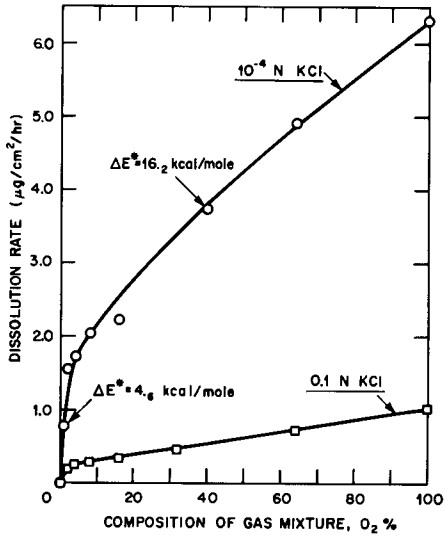

Fig. 5. Effect of oxygen partial pressure on the dissolution rate in 10^{-1}N and 10^{-4}N KCl at 30°C and pH 6.

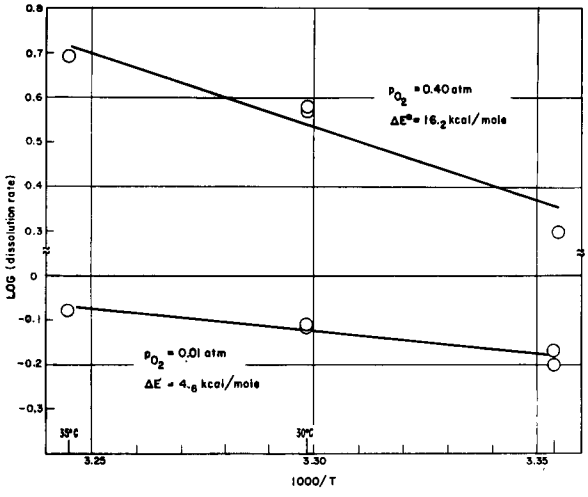

Fig. 6. Temperature dependence of the dissolution rate in 10^{-4}N KCl at two concentrations of dissolved oxygen.

in the latter, the general features of the oxygen dependence are the same in the two solutions, namely, an approximately linear decrease of rate with decreasing oxygen partial pressure, down to about 0.04 atm, and a more rapid decrease (to zero) below this value.

The temperature dependence of the reaction rate in $10^{-4}N$ KCl is shown in Fig. 6 for two values of P_{O_2}. The activation energy at 0.4 atm was 16 kcal/mole, in contrast to the value of less than 5 kcal/mole at 0.01 atm. These results indicate that diffusion is rate limiting only at low concentrations of dissolved oxygen.

Nature of the electrolyte.—The nature of the anion has a marked influence on the dissolution kinetics, as illustrated in Fig. 7 for the potassium halides. In view of the fact that in pure water the dissolution rate is 0.7 μg/cm²/hr at the same temperature, the maximum for KI evidently occurs at concentrations below $10^{-6}N$.[8] Considering for the present only the second of the two maxima in KF

[8]Actually, the maximum occurs below 10^{-7}M I⁻, as found by extending the concentration range to this value using H_2SO_4, rather than HI, for adjusting the pH to 6. The dissolution rate at 10^{-7}M I⁻ was 5.4 μg/cm²/hr.

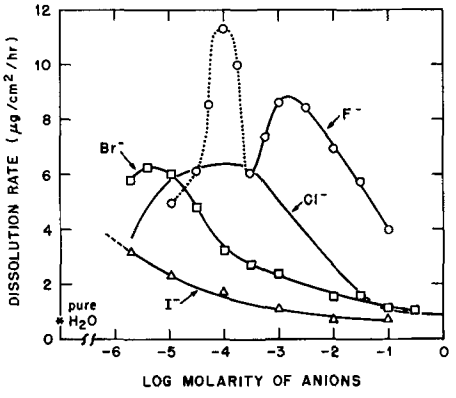

Fig. 7. Specific effects of halogen ions on the dissolution rate-oxygen-saturated solutions of potassium salts at 30°C and pH 6. The anion molarities have been corrected for additions of the corresponding acids in pH adjustments. The experimental points for KCl, omitted for clarity, are included in Fig. 8.

(full line in Fig. 7), a systematic shift of the maximum rate toward higher concentrations occurs in going from KI to KF.

The influence of the nature of the cations present was studied in a series of chlorides (Fig. 8). With the exception of $BaCl_2$, the maximum rates occur at nearly the same Cl^- ion concentration. There is, however, a significant variation in the absolute value of the maximum rate. It is also of interest to note that for $BaCl_2$, the dissolution rate does not decrease indefinitely with concentration after the initial maximum.

Electrode potential measurements.—The electrode behavior of germanium in aqueous solutions presents

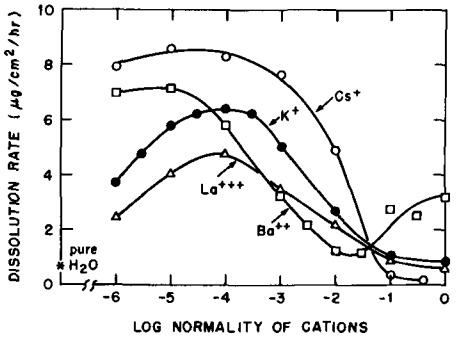

Fig. 8. Specific effects of cations on the dissolution rate-oxygen-saturated chloride solutions at 30°C and pH 6.

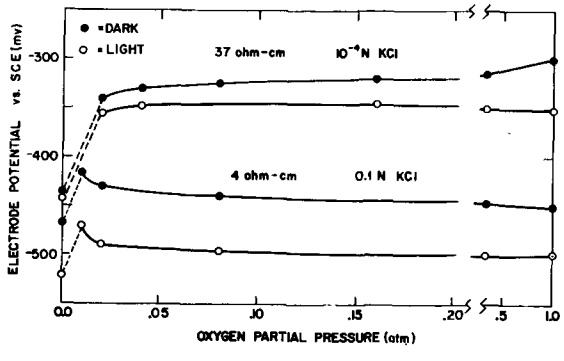

Fig. 9. Variation of the steady-state electrode potential with concentration of dissolved oxygen for n-type germanium electrodes and the effect of illumination.

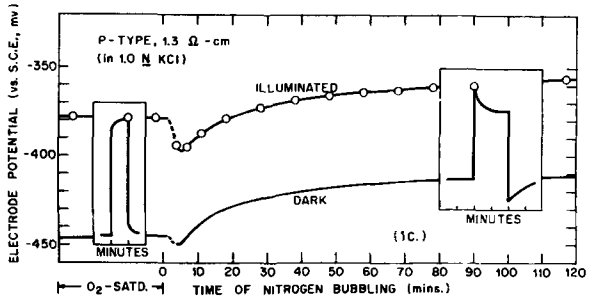

Fig. 10. Transient behavior of the photopotential of a p-type germanium electrode in moderately concentrated electrolyte.

certain aspects peculiar to semiconductors. Effects of oxygen and electrolytes on certain electrical properties of the surface have been described elsewhere (7). Some observations pertinent to the electrochemistry of the dissolution reaction are presented here. In dilute electrolytes, the steady-state mixed potential becomes more cathodic with increasing partial pressure of oxygen, as shown in Fig. 9 for an n-type electrode in $10^{-4}N$ KCl. The photopotentials obtained in the same solutions under steady illumination also are shown in Fig. 9. In more concentrated electrolytes, however, the steady-state potential becomes somewhat more anodic with increasing oxygen partial pressure, following a cathodic shift at very low oxygen partial pressures (illustrated in Fig. 9 for an n-type electrode in $0.1N$ KCl).

From Fig. 10 it will be noted that the combination of p-type electrode and moderately concentrated electrolyte results in a mixed potential which becomes more cathodic with light (i.e., the surface region is more n-type than the bulk). In the example shown, the potential under steady light in nearly oxygen-free solution undergoes a relaxation with a time constant of the order of tens of seconds. Comparably slow changes of the photopotential under no external polarization were not observed in dilute electrolytes for germanium of either type.

The mixed potentials recorded during steady-state dissolution in $10^{-4}N$ KCl at various pH's are plotted in Fig. 4(a) above the corresponding dissolution rates. The dependence of mixed potential on pH was studied more quantitatively in O_2-satu-

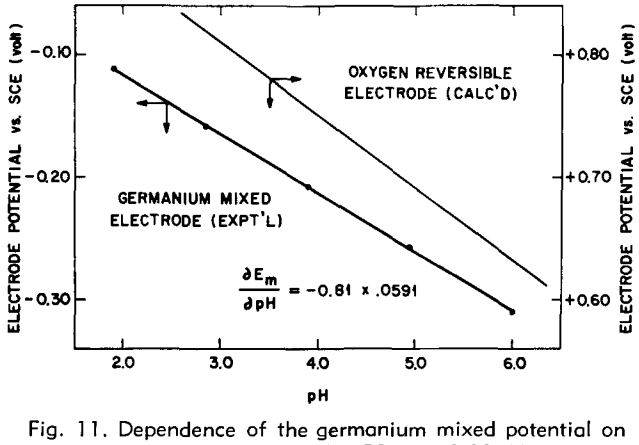

Fig. 11. Dependence of the germanium mixed potential on pH in oxygen-saturated 1.0N Na_2SO_4 + 0.001M GeO_2 + H_2SO_4.

rated 1.0N Na_2SO_4 solutions (sulfate-bisulfate buffers). Here the potential varied linearly with pH (Fig. 11) with a slope equal to −0.0478 v/pH unit at room temperature. It will be noted that the mixed potential is far removed from the oxygen reversible potential in these solutions.

Discussion

Comparison with Metal Behavior

The dependence of the germanium dissolution rate on the concentration of inert electrolyte resembles the behavior of metals in similar environments. In the case of metals, however, the maximum in dissolution rate occurs in the vicinity of 0.5N (8) and is attributed by Akimov (9) to the combined effects of solution conductivity and oxygen solubility. Thus, the increase in rate with increasing electrolyte concentration is ascribed to the increase in solution conductivity, leading in turn to an increase in the corrosion current. The subsequent decrease in rate in concentrated solutions is attributed to a decrease in oxygen solubility with electrolyte concentration. Evans (10) treats the subject in a more quantitative way but on a similar basis.

In the case of the germanium dissolution reaction, the maxima in rate occur at electrolyte concentrations below $10^{-2}N$. In this range, the solubility of oxygen is the same to within less than 1% as that in pure water (11), so that the decrease in rate with increasing concentration of electrolyte cannot be ascribed solely to diminishing oxygen solubility, although this is a contributory factor at concentrations greater than approximately 0.1N It is also unlikely that solution conductance alone is responsible for the initial increase of rate with concentration, since, at very low concentrations of electrolyte, marked differences in dissolution rate are observed in solutions of comparable conductivity.[4] Furthermore, for a given electrolyte, a maximum in rate is reached while the solution conductance continues to increase and the oxygen solubility remains essentially unchanged. This is shown in Fig. 3 for Na_2SO_4 and KI solutions, which represent the extremes of behavior observed in our experiments.

Clearly, the interpretation proposed for the dependence of the corrosion rates of metals on the concentration of electrolyte (9, 10) cannot account for the present findings. In fact, it appears that, even in the case of metals, it is inconsistent with some experimental results. For example, Schaschl and Marsh (12) have found recently that in inert electrolyte solutions at concentrations as low as $10^{-3}N$, the dissolution of iron is controlled by the amount of dissolved oxygen and is independent of conductivity and pH.

Specific Adsorption of Anions

In view of the dependence of the dissolution rate on the nature of the anion (Fig. 7) and the fact that the electrolytes considered are chemically inert toward germanium and oxygen, we believe that anions influence the kinetics of the dissolution process through specific adsorption. Specifically adsorbed anions are considered to be bonded covalently to the metal surface (13). The present results suggest that specific adsorption of anions onto germanium may be represented as follows

$$Ge\cdot + X^- \rightarrow Ge\text{-}X + e^- \qquad [1]$$

where Ge· is a surface atom having an unpaired electron (dangling bond) resulting from termination of the covalent lattice. The transfer of the anionic charge according to Eq. [1] presumably facilitates the reduction of oxygen at an adjacent site. Adsorbed anions regain their charge on detachment of underlying germanium atoms and in essence function as catalysts for the reduction of oxygen. With increasing concentration of adsorbable anions, however, competition for active surface sites between anions and oxygen molecules results eventually in a decrease in the number of sites available for the adsorption and reduction of oxygen and, hence, in a decrease in the dissolution rate. The more strongly adsorbed the anion, the more dilute the solution in which the maximum dissolution occurs. Based on this argument, the data of Fig. 3 and 7 indicate that the anions studied adsorb onto germanium in the order

$$I^- > Br^- > Cl^- > F^- > SO_4^=$$

(in the case of F^- ions the maximum occurring at $10^{-3}N$ is considered as the pertinent one in this regard, as will be discussed below). The same order of specific adsorbability of the halides has been found for mercury (14) and platinum (15). The tendency of sulfate ions to adsorb less than the halogen ions is consistent with data on other solid surfaces (16). In nitrate solutions, the position of the maximum dissolution rate was poorly defined. The unsatisfactory reproducibility of the measured rates may have been due to the presence of adsorbable impurities, especially NO_2^- ion. Nevertheless, the data indicate that the adsorbability of NO_3^- ion on germanium is close to that of Cl^- ion.

Fluoride Solutions

While it is generally considered that F^- ions are not specifically adsorbed on mercury (17), it is possible that they adsorb on germanium, especially since not only the tetrafluoride but also stable fluogermanates (18) are known. The possibility exists that one of the two maxima in KF solutions is associated with a change in the anodic mechanism, e.g., oxidation of germanium to H_2GeF_6 rather than H_2GeO_3. However, this is unlikely in view of the fact that measured solubilities of high-purity GeO_2 in 0.1N solutions of KI, KBr, KCl, KF, as well as in $10^{-4}N$ KF, all at pH 6, were the same as that measured in pure water. The absence of complexing action by the principal anions considered is thus indicated.

It is likely that the "anomalous" maximum occurring at $10^{-4}N$ in KF solutions is associated with specific adsorption of HF molecules rather than HF_2^- for the following reasons: (*a*) the residual bonding power of the HF molecule is indicated by the formation of H_2F_2 in the vapor and pure liquid and by the formation of HF_2^- in F^- solutions, and

[4] The conductivity of germanium is orders of magnitude greater than that of very dilute electrolyte solutions. At room temperature the conductivity of intrinsic germanium is 0.02 mho/cm.

(*b*) in the solution considered, the concentration of HF is about $10^{-7}N$ while that of HF_2^- is about $10^{-10}N$ (Table I). The subsequent increase of dissolution rate at higher KF concentrations probably results from displacement of adsorbed HF. At still higher concentrations, adsorption of F^- ions results in the eventual decline of the dissolution rate (Fig. 7).

The displacement of adsorbed HF is considered to result from association with F^- to form HF_2^-

$$HF_{(adsorbed)} + F^- \rightarrow HF_2^- \qquad [2]$$

The postulated interface reaction corresponds to the association of HF and F^- in the solution phase. Adsorption and displacement of HF may be considered as the net result of competition between F^- ions in the double layer and surface atoms having an unshared electron pair (—Ge:$^-$ or $\diagup\diagdown$Ge: —see below.)

The foregoing interpretation was tested with solutions of KHF_2. In the range 10^{-5} -10^{-3}M F^-, the concentrations of HF and HF_2^- are greater in the KHF_2 solutions than in the corresponding KF solutions and, moreover, increase much more rapidly with increasing $[F^-]$ (Table I). Accordingly, it was found that the anomalous maximum shifted from $[F^-] = 10^{-4}$M in KF to $F^- < 10^{-5}$M in KHF_2. The "normal" maximum also was observed in KHF_2 solutions, but could not be mapped accurately owing to chemical attack of the glassware.

Specific Effects of Cations

Figure 8 shows that the nature of the cation modifies the influence of the anion on the kinetics of the germanium dissolution reaction. No differences were observed between Na^+ and K^+ ions. The case for specific adsorption of inorganic cations is not nearly as well established as that for anions. Owing to the greater polarizability of anions, however, it is likely that their electrical centers are displaced closer to the electrode surface than those of cations. Thus, the larger the charge and the closer the approach of the cation, the greater is its effect in opposing the transfer of anionic charge and, hence, the smaller is the rate of oxygen reduction for equal concentrations of the same anion. For the cations considered, the charge-to-radius ratios are in the order $La^{+++} > Ba^{++} > K^+ > Cs^+$. The data for Cs^+, K^+, and La^{+++} are consistent with this interpretation over a very wide range of concentration (Fig. 8).

Of the cations considered, Cs^+ ions are most likely to undergo specific adsorption (19) and in the present case this seems to occur at concentrations greater than about 0.05*N*. The sharply reduced dissolution rates may be accounted for by specific adsorption of Cs^+ ions leading to increased polarization of the cathodic step, i.e., increase in the potential barrier for electron transfer to oxygen (or hole transfer to germanium).

The minimum in the dissolution rate at about $10^{-2}N$ $BaCl_2$ suggests a change in sign of the electrical double layer such as encountered in the coagulation of collodial particles by electrolytes. Since there is nothing unusual in the chemistry of Ba^{++} ion, its unique behavior suggests specific interaction with the germanium surface. A further study of this phenomenon could prove of special interest.

In view of the predominant role of adsorption in the kinetics of the germanium dissolution process, it is clear that solution conductance can have no more than a minor effect. Rather, it is suggested that in the case of metals, the dissolution rates in inert electrolytes containing dissolved oxygen are not entirely controlled by solution conductance and oxygen solubility, but are also influenced by specific adsorption. Recently, in fact, a correlation has been made between adsorption of anions and the pitting corrosion behavior of stainless steels(20).

Chemical Model of Interactions at Germanium Surfaces

Surface atoms[5] triply bonded to the lattice ($\diagup\diagdown$Ge· or, simply, Ge·) are considered to have each of their four valence electrons in sp^3 hybrid orbitals, three of which are involved in bond formation and the fourth constituting a "dangling bond." Doubly bonded surface atoms ($\diagup\diagdown$Ge: or, simply, Ge:) are usually described as possessing two dangling bonds; however, it is probably more accurate to consider their electrons as being in sp^2 hybrid orbitals, with two electrons forming a lone electron pair [cf. Handler (21)].

[5] Taking into account irregularities of atomic dimensions, any real germanium surface must consist of atoms doubly and triply bonded to the lattice; atoms attached to the crystal by a single bond are probably capable of only transitory existence at a surface in contact with an aqueous solution.

Table I. Composition of fluoride and bifluoride solutions*

KF (pH adj. to 6.0)				KHF_2			
M_{KF}	[HF]	$[HF_2^-]$	$[F^-]$	M_{KHF_2}	[HF]	$[HF_2^-]$	pH

* Calculations are based on the equilibrium data of Broene and DeVries, *J. Am. Chem. Soc.*, **69**, 1644 (1947).

Processes such as trapping, generation, and recombination of carriers can be visualized more readily in terms of triply bonded surface atoms and will be described accordingly. Conduction electrons and/or holes may be captured by surface atoms having unpaired electrons; an atom capturing both an electron and a hole functions as a recombination center:

$$\underset{\text{electron trap}}{\text{—Ge}^{+}} \; e^{+} \; \underset{\text{recombination center}}{\text{—Ge}\cdot} \; e^{-} \; \underset{\text{hole trap}}{\text{—Ge}^{-}}: \qquad [3]$$

Charged surface atoms may trap electrons or holes, as in Eq. [3], and so constitute localized surface states. Surface states on clean germanium generally are considered to be "fast," whereas "slow" states are believed to lie either in the oxide layer or at the oxide-gas interface (22). Long-time changes in the photopotential (Fig. 10) in moderately concentrated electrolytes[6] indicate that slow states may also result from adsorptive interaction of ions with an oxide-free surface.

In water or very dilute electrolyte solutions, oxygen makes the germanium electrode potential more cathodic and the surface more p-type (Fig. 9); this behavior is consistent with the nature of the oxygen molecule as an electron acceptor. The tendency of dissolved oxygen to drive the surface p-type is opposed by anions of the electrolyte (ref. 7 and Fig. 9 and 10), suggesting that nonoxidizing anions behave as electron donors during the dissolution reaction. This result further supports the view that adsorbed anions are covalently bonded to the lattice; adsorption of anions without transfer of charge would lead to changes in electrode potential and surface conductivity opposite to those observed.

Mechanism of the Dissolution Reaction

The insensitivity of the rates to changes in carrier concentration as brought about by illumination and doping indicates that holes and electrons are in adequate supply for the reaction of germanium with dissolved oxygen in aqueous solutions. Actually, the highest rates observed correspond to a corrosion current density of only about 15 μamp/cm^2, which is well below the region of measured limiting carrier currents (23). Moreover, the existence of an electron-limiting current recently has been disputed (24, 25).

Evidently, the rate-limiting step of the over-all dissolution reaction lies in the activated transfer, rather than supply, of electrons to oxygen. Although formal mechanisms can be written for the reduction of O_2 at Ge· and Ge: sites, the decrease in surface recombination velocity on adsorption of O_2 from aqueous solution (7) indicates that the former sites are involved in the first stage of the reduction.

The following mechanism[7] is compatible with the results of the previous discussion, including the pH dependence of the dissolution rate and mixed potential:

$$\text{acid solution} \begin{cases} O_2 + H^+ + e^- \rightarrow -O_2H & \text{(cathodic)} \quad [4] \\ Ge\cdot + H_2O \rightarrow Ge\text{-}OH + H^+ + e^- & \text{(anodic)} \quad [5] \end{cases}$$

$$\text{alkaline solution} \begin{cases} O_2 + H_2O + e^- \rightarrow -O_2H + OH^- & \text{(cathodic)} \quad [6] \\ Ge\cdot + OH^- \rightarrow Ge\text{-}OH + e^- & \text{(anodic)} \quad [7] \end{cases}$$

where $-O_2H$ represents the surface intermediate $\begin{matrix} H\text{—}O \\ | \\ \text{—Ge—O} \end{matrix}$. Subsequent steps in the mechanism can lead to the formation of metagermanic acid, $OGe(OH)_2$ [or $HGeO_3^-$ in alkaline solution (3)]. In this mechanism, the intermediate formation of GeO or GeO_2 is not essential [cf. Rösner (26)].

Provided the equilibrium between holes and electrons in the germanium is not disturbed, as by carrier injection or illumination, the measured potentials are the same for n-type and p-type electrodes. Hence, the quantity $\partial E_m/\partial pH$ (Fig. 11) measures the same variation of potential as for a metal electrode, irrespective of possible changes of the space charge potential drop inside the germanium. Generalizing the treatment given by Ammar and Riad (20) for the dependence upon pH of the mixed potential of a metal corroding by reaction with dissolved oxygen, we obtain for the case of activation controlled kinetics:

$$\partial E_m/\partial pH = -\frac{(\nu_c - \nu_a)}{n_c\beta_c + n_a\beta_a} \times \frac{RT \ln 10}{\mathbf{F}} \qquad [8]$$

where ν's are the chemical coefficients of H^+ (negative for OH^-) in the rate-determining anodic and cathodic steps; n's, the numbers of electrons transferred; β's, the corresponding symmetry factors; and $RT \ln 10/\mathbf{F} = 0.0591$ at room temperature. Assuming symmetrical energy barriers ($\beta_c = \beta_a = 0.5$), the mechanism represented by Eq. [4] and [5] or by [6] and [7] gives $\partial\epsilon_m/\partial pH = -0.0591$ v/pH unit. The experimental slope (Fig. 11) is -0.81×0.0591. The experimental value of $\partial E_m/\partial pH$ can be reconciled with the mechanism proposed and Eq. [8] if the reasonable assumption is made that the energy barrier for germanium dissolution is lower than that for the reverse process.

From a study of the anodic dissolution of germanium, Turner (27) concluded that the rate-determining step involves the capture of two holes. This has been considered improbable by Beck and Gerischer (28), who propose that one hole and one OH^- are required in the limiting step during anodic dissolution. These mechanisms are not discussed further here, since the anodic partial process of the reaction with O_2 and H_2O is not necessarily identical with the mechanism of electrolytic anodic dissolution. Moreover, we have made no attempt to distinguish on the basis of purely chemical evidence between the roles of conduction and valence electrons in the dissolution mechanism.

[6] Depending on the type and resistivity of the electrode and the composition of the solution, transient behavior can be more complicated than for the system shown in Fig. 10.

[7] The symbol e^- in the equations is used for valence as well as conduction electrons. It is recognized that holes can be consumed by the anodic reaction and that holes may be injected by the cathodic reaction, but these features are not essential to the present discussion.

The increase of dissolution rate with increasing pH (Fig. 4) is ascribed to depolarization of the cathodic reaction in alkaline solutions as a result of specific adsorption of OH^- ions on sites adjacent to those of adsorbed oxygen:

$$\begin{matrix} Ge\cdot + O_2 & & Ge-O_2H & \\ & + H_2O \rightarrow & & + OH^- \\ Ge\cdot + OH^- & & Ge-OH & \end{matrix} \qquad [9]$$

This is similar to the scheme proposed earlier in this discussion for the accelerating effect of anions. However, since both $-O_2H$ and $-OH$ are consumed in the formation of H_2GeO_3, it is readily understandable that the germanium dissolution rate increases continuously with increasing OH^- concentration in contrast to the behavior with other anions. Actually, experiments showed that differences in rate for the various electrolytes virtually are eliminated in strongly alkaline solutions.

The only previously published work on the reaction of germanium with oxygen in aqueous solutions is that reported by Schwab (6), who proposed that the reaction takes place according to

$$Ge \rightarrow Ge^+ + e^- \text{ and } O_2 + e^- \rightarrow O_2^- \qquad [10]$$

This mechanism does not account for the dependence of mixed potential on pH, and in other respects is incompatible with the results of our experiments.

The barrier-layer theory of chemisorption (29), applied with considerable success to reactions at the semiconductor-gas interface, leads in charge-transfer adsorption to a coverage whose magnitude is determined by the carrier density in the semiconductor bulk. For the reacting system germanium-aqueous solution, on the other hand, our results indicate that the steady-state surface configuration in a given environment is the same for n- and p-type germanium [cf. Bohnenkamp and Engell (30)], at least under mildly oxidizing conditions. In fact, for the reactions studied, the arrangement and predominantly covalent character of the bonds in the germanium crystal are of considerably greater significance than its semiconductor properties.

Corrosion Mechanisms in the Reaction of Steel with Water and Oxygenated Solutions at Room Temperature and 316°C

Mary Boehm Strauss and M. C. Bloom

U. S. Naval Research Laboratory, Washington, D. C.

ABSTRACT

The corrosion products developed by steel when reacting with water of varying oxygen content at room temperature and at 316°C are described. The reaction was carried out in sealed steel capsules and followed by pH measurement of the solution and by microscopic, x-ray, and electron diffraction analysis of the corrosion product films. Data on the transformation behavior of the corrosion products involved and a summary of some of their physical properties are included.

Although the literature dealing with aqueous corrosion in ferrous systems is discouragingly voluminous, the amount of material dealing directly with the nature of the corrosion product films formed has, until recent years, been rather meager. A literature review (1) in 1955 indicated that the available information was far short of that needed for analysis of corrosion mechanisms of interest in connection with naval and nuclear steam generation problems, and a long-range program for obtaining some of the needed data was undertaken. This is a report of the preliminary explorations of that program. The conditions chosen for this preliminary exploration were room temperature (25°C) on the one hand and 316°C (600°F) on the other, a choice dictated by the practical considerations of naval and nuclear power steam generation applications.

Before discussing the experimental work, it may be useful to recall a few of the properties of the corrosion products with which we are concerned. These properties are listed in Table I. Neglecting FeO, with which we will not be concerned in this work, we see that color can sometimes be useful in distinguishing various forms. The structures are readily distinguishable by diffraction techniques with the exception of the two spinels Fe_3O_4 and γ-Fe_2O_3 which are built on the same framework. It may be noted that these two oxides are the only ferromagnetic species in this corrosion product system.

Experimental Techniques

The technique which was the major basis of the experiments was the use of mild steel specimens in the form of sealed capsules completely filled with the solution under test (17). The test specimens were prepared from mild steel tubing the composition of which appears in Table II. Attention is directed to the manganese content which will come into discussion later. Before fabrication into capsules, the steel tubing was hydrogen annealed 1 hr at 875°C, cooled

Table I. Corrosion products of iron

Composition (Mineral name)	Color	Structural type (3)	Magnetic character	Electrical resistivity	Density	Thermal behavior
$Fe_{0.950}O$ to $Fe_{0.833}O$ (Wustite) (2)	Black	NaCl	Paramagnetic (4)	Semiconductor (3)	5.4-5.73 (2, 11)	Melts at 1371°-1424°C. Below 570°C decomposes to Fe and Fe_3O_4 (2)
$Fe(OH)_2$	White	$Mg(OH)_2$ (Brucite)	Paramagnetic (5)	Insulator*	3.40 (12)	Decomposes at about 100°C to Fe_3O_4 and H_2† (14)
Fe_3O_4 (Magnetite)	Black	Spinel	Ferromagnetic (4)	Electronic conductor (8)	5.20 (4)	Melts at 1597°C (2)
γ-FeOOH (Lepidocrocite)	Orange	γ-FeOOH (Lepidocrocite)	Paramagnetic (6)	Insulator*	3.97 (13)	Dehydrates to‡ γ-Fe_2O_3 at about 200°C (16)
α-FeOOH (Goethite)	Yellow	α-FeOOH (Goethite)	Paramagnetic (6, 7)	Insulator (9)	4.20 (13)	Dehydrates to‡ α-Fe_2O_3 at about 200°C (16)
γ-Fe_2O_3 (Maghemite)	Brown	Spinel (with vacancies)	Ferromagnetic (4)	Semiconductor to insulator (10)	4.88 (4)	Transforms to‡ α-Fe_2O_3 above 250°C (16)
α-Fe_2O_3 (Hematite)	Brick red to black	Al_2O_3 (Corundum)	Paramagnetic (4)	Insulator (10)	5.25 (4)	Decomposes to magnetite at 1457°C and 1 atm (2)

* Color indicates that these are insulators.
† In contact with traces of oxygen $Fe(OH)_2$ is unstable at room temperature and transforms to γ-FeOOH, α-FeOOH, or Fe_3O_4 depending on the conditions of the system (15).
‡ Presence of water causes conversion to α-Fe_2O_3 at lower temperature.

in the hydrogen atmosphere to 60°C and then removed to the atmosphere of the room; subsequently, the tubing was annealed 1 hr at 875°C in a vacuum furnace maintained at a pressure of less than 10^{-5} mm Hg and cooled to room temperature in the furnace. The electron diffraction pattern obtained from the metal after this treatment was that of α-iron with occasional traces of the 311-line, the strongest line of the spinel pattern.

The prepared capsule specimens were exposed in sets of 6 to 12 each. The specimens were prepared, treated at room temperature for selected lengths of time, and then opened. Additional capsules were treated at room temperature for specific times, then placed in an oven at 316°C for one week, or twelve weeks, cooled to room temperature, and opened immediately thereafter. A typical capsule is shown in Fig. 1. The capsules were opened by carefully filing one corner until the metal was so thin that it could be punctured with a stainless steel syringe needle. The liquid was removed from each capsule into a glass syringe and the *p*H of the liquid measured promptly to avoid reaction with carbon dioxide from the atmosphere. The *p*H measurements were made using a Beckman "one drop" glass electrode and Model G *p*H meter. The individual measurements showed considerable scatter. The value reported is the average. In some cases samples of the liquid were dropped on copper electrodes coated with Apiezon wax, evaporated to dryness under an infrared lamp, and analyzed by emission spectroscopy. When liquid was withdrawn from a capsule, a magnet was used to test suspended solids for the presence of the spinel type oxides, Fe_3O_4 and γ-Fe_2O_3, which as previously indicated are the only ferromagnetic species in this corrosion product system. Solids suspended in the capsule liquids were collected on a Millipore filter and dried in a desiccator over Drierite (anhydrous calcium sulfate), x-ray diffraction patterns being obtained from the dry solids.

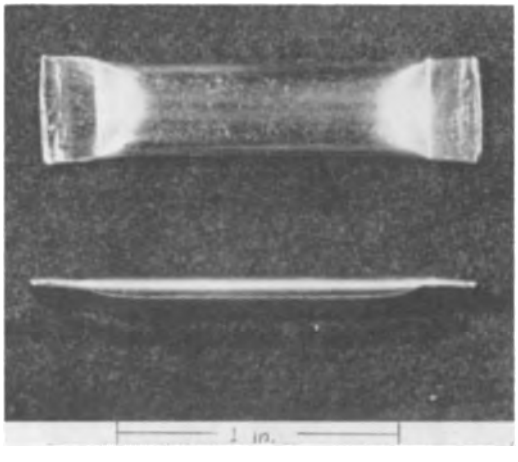

Fig. 1. Typical capsule

After removal of the liquid from the capsules, the walls were prepared for examination by filing away the lengthwise edges and shearing the transverse edges to yield two opposite wall surfaces. These were examined by use of a Geiger counter x-ray spectrometer using cobalt $K\alpha$ radiation as well as by use of the diffraction attachment of an RCA (EMU-2) electron microscope. The x-ray patterns served to characterize the bulk of the corrosion product film when this film was thick enough. The electron diffraction patterns served for characterization of very thin films on the metal surfaces and of the exterior surface layers of thicker corrosion product films.

The corroded capsule walls also were examined microscopically to determine the character and extent of the corrosive attack as well as the appearance of the corrosion products.

In most cases, no attempt was made in this exploratory work to distinguish between Fe_3O_4 and γ-Fe_2O_3.

Corrosion Products Generated in Air-Saturated Distilled Water

The data obtained in the characterization of the corrosion products formed at room temperature in capsules initially filled with distilled water are shown in Table III. Each *p*H value reported in this and subsequent tables is the average of a number of measurements usually 6-12. An indication of the scatter can be seen from the following which show typical scatter for data in Table III:

Measured *p*H after 6 hr: 9.48, 9.72, 9.57, 9.40, 8.91, 9.30, average 9.4; after 1 week: 9.7, 9.4, 10.1, 10.0, 9.7, 9.6, average 9.8; after 52 weeks: 9.93, 9.96, 9.90, 9.71, 10.02, average 9.9.

The water was initially air-saturated and the small variation in *p*H at the outset is probably due to differences in the carbon dioxide content of the laboratory atmosphere. It may be noted that after 6 hr the *p*H has risen to 9.4. This is approximately the *p*H of a saturated solution of $Fe(OH)_2$. This rise in *p*H indicates that all the oxygen has been consumed (20). The *p*H thereafter steadily rises to 9.9 where it is found one year later. The rise to so high a *p*H puzzled us for some time, but seems explicable as due to the simultaneous presence of $Fe(OH)_2$ and $Mn(OH)_2$. Using the known solubility product data for these two hydroxides one may calculate the *p*H in the presence of both to be 9.92. A calculation of the amount of manganese required (5.5×10^{-7} g) to produce this amount of $Mn(OH)_2$ shows that 10^{-4} g of steel would be required to be dissolved to give this quantity of manganese. This seems a very reasonable quantity to expect to have been dissolved in the 12 week period where this *p*H is shown to be developed. An independent series of experiments confirmed the conclusion that the calculated equilibrium of 9.92 would be achieved by allowing mixtures of carbonyl

Table III. Corrosion products formed by the action of water* in mild steel capsules at 25°C

Solution pH before reaction†	Time metal was exposed to solution	Solution pH after reaction†	Appearance of solution	Appearance of metal	Corrosion products on metal
5.9	1 hr	8.5	Yellow tinge	Speckled with brownish yellow islands	γ-FeOOH
5.6	6 hr	9.4	Clear, colorless	Same as above	γ-FeOOH and possibly spinel
6.0	24 hr	9.5	Clear, colorless	Same as above	γ-FeOOH and spinel
6.0	1 wk	9.8	Clear, colorless	Same as above	γ-FeOOH and spinel
6.0	12 wk	9.9	Clear, colorless	Thin gray brown film	Spinel and some γ-FeOOH
6.0	52 wk	9.9	Few particles of spinel	Continuous black film	Spinel

* The water was initially air saturated.
† Each value represents the mean of 6 capsules.

Table IV. Corrosion products formed by the action of 0.2% H_2O_2 in mild steel capsules at 25°C

Solution pH before reaction	Time metal exposed to solution	Solution pH after reaction†	Solid corrosion products filtered from solution	Appearance of metal	Corrosion products on metal	Residual oxygen pressure
5.9	1 hr	7.1	*	Yellow islands on shiny metal	γ-FeOOH	Yes
5.9	24 hr	6.8	Spinel and some γ-FeOOH	Same as above	γ-FeOOH and spinel	No
5.8	1 wk	7.4	Spinel	Yellow islands on black film	Spinel and some γ-FeOOH	No
5.8	4 wk	8.6	Spinel	Few yellow islands on black film	Spinel and some γ-FeOOH	No
5.7	52 wk	10.0	Spinel	Nearly covered with brownish-black film	Spinel	No

* Insufficient material for analysis.
† Each value represents the mean of 8 to 12 capsules.

Table V. Corrosion products formed by the action of 1% H_2O_2 on mild steel capsules at 25°C

Solution pH before reaction	Time metal exposed to solution	Solution pH after reaction*	Solid corrosion products filtered from solution	Appearance of metal	Corrosion products on metal	Residual oxygen pressure
5.8	1 hr	6.9	None	Yellow islands on shiny metal	γ-FeOOH	Yes
5.9	24 hr	7.3	γ-FeOOH	Same as above	γ-FeOOH	Yes
5.7	1 wk	8.0	α-FeOOH	Yellow film covers metals	γ-FeOOH and α-FeOOH	Yes
5.9	4 wk	8.2	α-FeOOH	Same as above	γ-FeOOH and α-FeOOH	Yes

* Each value represents the mean of 8 to 12 capsules.

Table VI. Corrosion products formed by the action of 4% H_2O_2 in mild steel capsules at 25°C

Solution pH before reaction	Time metal exposed to solution	Solution pH after reaction*	Solid corrosion products filtered from solution	Appearance of metal	Corrosion products on metal	Residual oxygen pressure
5.8	1 hr	7.1	None	Shiny metal	γ-FeOOH	Yes
6.0	24 hr	7.3	γ-FeOOH	Nearly covered with yellow film	γ-FeOOH	Yes
5.9	1 wk	8.2	α-FeOOH	Same as above	γ-FeOOH and α-FeOOH	Yes
5.9	4 wk	8.6	α-FeOOH	Same as above	γ-FeOOH and α-FeOOH	Yes
Not measured	61 wk	8.5	α-FeOOH	Same as above	α-FeOOH and trace of γ-FeOOH	Yes(?)

* Each value represents the mean of 8 to 12 capsules.

iron and electrolytic manganese to corrode in water. These metals had a total metallic impurity content of the order of 100 ppm and a nitrogen content in the neighborhood of 20 ppm. In these experiments, metallic powders were allowed to remain in sealed platinum-lined capsules for 3 weeks at 25°C prior to sampling. The solutions then gave the following pH values

Powder	Observed pH	pH Calculated for saturation
Fe	9.37	9.32
Mn	9.95	9.92
Fe-Mn mixture	9.95	9.92

Next, attention is called to the fact that the initial product of reaction is γ-FeOOH. The approximately 8 ppm of oxygen introduced with the air-saturated water apparently has produced the ferric ions necessary for its formation. This phase shows up as islands on the otherwise unattacked metal.

Finally, it may be noted that within 24 hr, the spinel phase has made its appearance and eventually spreads over the entire surface of the specimen. The fact that the pH of the solution has reached 9.4 [approximately the equilibrium pH of $Fe(OH)_2$] at the time that the spinel phase appears suggests that $Fe(OH)_2$ is present also, and the rise to 9.9 is taken as an indication of the presence of solid $Mn(OH)_2$ along with the $Fe(OH)_2$. Linnenbom (18) has shown that under these pH conditions $Fe(OH)_2$ does not break down to form Fe_3O_4 in impurity-free solutions, but Evans and Wanklyn (19), as well as Shipko and Douglas (14), have shown that impurities may catalyze the reaction

$$3Fe(OH)_2 \rightarrow Fe_3O_4 + 2H_2O + H_2$$

and this would appear to be what is happening here unless nuclei of Fe_3O_4 formed by reduction of γ-FeOOH are serving a similar catalytic purpose.

Tables IV-VI show some data concerning the effect of the presence of more oxygen in these systems. The data were obtained by utilizing solutions of H_2O_2 in the capsules. These solutions decompose readily in the presence of ferrous or ferric ions to liberate oxygen and thus provide a simple means for introducing oxygen into the capsules. When the capsules were opened, fluid squirted out whenever the residual oxygen pressure was in excess of atmospheric and this phenomenon was used to give a qualitative indication of oxygen exhaustion inside the capsules. The column marked residual oxygen pressure is based on this criterion.

Table IV shows the data obtained using 0.2% H_2O_2 solutions at room temperature. The pH of 5.7 to 5.9 exhibited by the solution before reaction is undoubtedly due to absorption of carbon dioxide from the atmosphere. No explanation is offered for the apparent drop in pH during the first 24 hr. Perhaps this is experimental error. Attention is, however, called to the fact that no residual oxygen pressure was observed after 24 hr and that thereafter the solution pH began to rise as it did previously in the case where no peroxide was added. It may be noted that γ-FeOOH is the initial reaction product which gives way to spinel as the oxygen content decreases and the pH increases finally reaching the vicinity of the 9.9 associated with oxygen-free solutions.

Table V exhibits analogous data obtained with a 1% H_2O_2 solution. It may be observed that a residual oxygen pressure in excess of atmospheric was present in all cases. We note that the pH again rises with time of exposure but that now a new corrosion product, α-FeOOH, appears when the pH reaches 8. Data obtained using a 4% solution of H_2O_2 are shown in Table VI. Again we note the appearance of α-FeOOH when the pH gets above 8, and we may now note that the pH seems to reach a plateau in the neighborhood of 8.5-8.6 which it maintains even after a year of exposure.

The following explanation is suggested for the arrest of the pH in the 8.5 region when oxygen is present. In the presence of oxygen, saturation of the solution with $Fe(OH)_2$ is not attained due to oxidation of Fe^{++} (20) and the consequent generation of FeOOH instead of $Fe(OH)_2$. FeOOH is so insoluble (21) that a pH in excess of 7 would not be anticipated from this source.

In the manganese system we might expect that analogously $Mn(OH)_2$ would be oxidized by dissolved oxygen as this is the basis of the Winkler test (22) for dissolved oxygen in water. However, the nature of the corrosion product generated and the corresponding pH has apparently not been investigated. Therefore, a brief exploration was undertaken of the corrosion of manganese by dissolved oxygen at room temperature. For this purpose fragments of electrolytic manganese were immersed in water in a quartz-glass flask and exposed to an atmosphere of oxygen which had been purified by being passed through sulfuric acid, water, and basic barium chloride. At weekly intervals the pH of the water was measured. Starting at 6.4, the pH of the water rose to 8.8 in the first week and remained there for 2 additional weeks. The major corrosion product which accumulated out of contact with the metal was a brown powder with an x-ray diffraction pattern not included in the ASTM card index. It has similarities to the pattern of γ-FeOOH and is perhaps the manganese analogue of that structure.

It seems probable therefore that the pH arrest noted in the capsules in the region of pH 8.5-8.6 was due to the genesis of manganese oxidation products.

As an aid to interpretations of observations from the capsule corrosion studies, exploratory studies of the transformation behavior of the various oxides and hydroxides were conducted. Samples of the desired compounds, obtained from commercial sources, (see Table VII) were subjected to the following treatments: (*a*) treatment in mild steel capsules at 25°C in the presence of water, (*b*) treatment in platinum-lined capsules at 316°C in the presence and absence of water, (*c*) treatment in mild steel capsules at 316°C in the presence and absence of water. The nature of the transformation products was determined by x-ray diffraction, chemical analysis for Fe(II) and Fe(III) and observation of the presence or absence of ferromagnetism. The results of these experiments are shown in Tables VIII-X. The data indicated that when in contact with corrod-

Fe_3O_4	Heated with H_2O	24 hr	Black	Yes	Unchanged
Fe_3O_4	Heated dry with air	24 hr	Black	Yes	Unchanged

Table X. Summary of observations on products formed when iron oxides and hydrated oxides are heated in sealed mild steel capsules at 316°C

Substance	Treatment	Time at 316°C	Color of product	Ferromagnetic	Result of treatment
γ-FeOOH	Heated with H_2O	Up to 4 hr (before cracking)	Red-brown	Partially	Converted to α-Fe_2O_3 and some Fe_3O_4
γ-FeOOH	Heated with H_2O	(All capsules tested cracked and leaked within 6 hr)			
γ-FeOOH	Heated dry with air	24 hr	Red	No	Converted to α-Fe_2O_3 and trace Fe_3O_4
α-FeOOH	Heated with H_2O	24 hr	Black-red	Yes	Reduced to Fe_3O_4 with trace α-Fe_2O_3
α-FeOOH	Heated dry with air	24 hr	Brick-red	No	Converted to α-Fe_2O_3 with trace Fe_3O_4
γ-Fe_2O_3	Heated with H_2O	24 hr	Black-brown	Yes	Converted to α-Fe_2O_3 and Fe_3O_4
γ-Fe_2O_3	Heated dry with air	24 hr	Brown (unchanged)	Yes	Slight reduction to Fe_3O_4 at Fe interface
α-Fe_2O_3	Heated with H_2O	24 hr	Brick-red (unchanged)	No	Slight reduction to Fe_3O_4
α-Fe_2O_3	Heated with H_2O	7 days	Very dark red	Partially	Considerable reduction to Fe_3O_4
α-Fe_2O_3	Heated dry with air	24 hr	Brick-red (unchanged)	No	Unchanged
Fe_3O_4	Heated with H_2O	24 hr	Black (unchanged)	Yes	Unchanged
Fe_3O_4	Heated dry with air	24 hr	Black (unchanged)	Yes	Unchanged

ing steel at room temperature, anhydrous oxides were more resistant to reduction to Fe_3O_4 than the hydrous ones and that the α-Fe_2O_3 was most resistant to this action. This reduction could be a reaction with corrosion-generated hydrogen or a precipitation reaction involving divalent iron from the corroding steel and dissolved species from the trivalent solids. A probable mechanism is the following: $Fe^{++} + 2FeO_2^- \rightarrow Fe_3O_4$. Evidence of rapid direct reaction of this kind is found in the experiments of Forrest, Roetheli, and Brown (23) in which "gelatinous precipitates of ferrous and ferric hydroxides" were mixed to produce Fe_3O_4.

It may be noted that at elevated temperatures in the absence of corroding steel the transformation of all trivalent species to α-Fe_2O_3 is markedly accelerated by the presence of water in accord with the observations of Gheith (16). The reduction of all trivalent oxides to Fe_3O_4 at the elevated temperature is most probably due to reduction by corrosion-generated hydrogen. The fact that γ-Fe_2O_3 did not transform to α-Fe_2O_3 when heated at 316° in the dry state is undoubtedly due to stabilization by the presence of the aluminum present as an impurity (24). The cracking of the capsules when heated with γ-FeOOH slurries was shown to be a stress corrosion phenome-

Table VIII. Behavior of iron oxide and hydrated oxide slurries in mild steel capsules at room temperature

Iron compound in prepared slurry	Solids present in slurry after 48 hr	Solids present in slurry after 4 wk
Fe_3O_4	Apparently unchanged	No change
γ-FeOOH	Apparently unchanged	γ-FeOOH and spinel*
γ-Fe_2O_3	Apparently unchanged	γ-Fe_2O_3 and traces of Fe_3O_4
α-FeOOH	Apparently unchanged	α-FeOOH and spinel*
α-Fe_2O_3	Apparently unchanged	Unchanged

* Chemical analysis was not used for these cases since Fe_3O_4 seems to be the only spinel species which could be developed. In both cases, prior experimentation (16) indicates complete stability to dehydration up to temperatures in the neighborhood of 100°C. Thus γ-Fe_2O_3 could not be developed by dehydration of γ-FeOOH. In the case of α-FeOOH, even dehydration would produce only the stable α-Fe_2O_3. Thus the only feasible way in which the spinel structure could be developed here is by reduction to Fe_3O_4.

non induced by the presence of a chloride impurity. This will be discussed in a subsequent publication.

All the data thus far discussed are summarized in Table XI, and the results of heating capsules to 316°C after 24 hr of room temperature exposure are shown in Tables XII and XIII.

The following conclusions may be drawn:

1. Steel in contact with air saturated water at 25°C in these capsules develops γ-FeOOH within an hour. This γ-FeOOH appears as islands on the metallic surface. The pH rises within 24 hr from an initial value of about 6.0 to 9.5, approximately the equilibrium value in contact with $Fe(OH)_2$, and continues to rise to 9.9 where it apparently remains indefinitely. This pH of 9.9 is the equilibrium pH of a solution in contact with both $Fe(OH)_2$ and $Mn(OH)_2$. This rise in pH is accompanied by the gradual elimination of γ-FeOOH and its replacement with a spinel which eventually covers the entire specimen as the oxygen is used up and the pH rises.

2. Steel in contact with H_2O_2 solutions under these conditions also develops γ-FeOOH which appears as islands on the metal within an hour. The rise in pH in this case, however, is much more gradual. With sufficient oxygen present ($\geqq$ 1% H_2O_2) γ-FeOOH is at first produced, and then as the pH rises with time to a value of 8.0 or above, α-FeOOH appears. With sufficient oxygen present the pH reaches a plateau in the neighborhood of 8.5.

3. On long standing (1 year) with exhaustion of oxygen, the spinel phase appears and the pH rises to the vicinity of 9.9, the equilibrium value in contact with $Fe(OH)_2$ and $Mn(OH)_2$.

4. On heating at 316°C, any $Fe(OH)_2$ or γ-FeOOH generated by room temperature exposure of steel to water is converted to magnetite within 24 hr with a corresponding drop in pH to the neutral region.

5. On heating at 316°C, any γ- or α-FeOOH generated by room temperature exposure in H_2O_2 solutions is converted to α-Fe_2O_3 within 24 hr with a corre-

Corrosion of Nickel Coated Mild Steel

B. C. Banerjee[1]

National Chemical Laboratory, Poona, India

ABSTRACT

A dissolution rate study of iron from mild steel disks coated with electrodeposited nickel having (100), (10$\bar{1}$0) + (211), (110), and (210) orientations has revealed that, in hydrochloric acid solution, coatings with (210) orientation gave the best protection to the iron. On the other hand, in neutral sodium chloride solution appreciable difference in the dissolution rate has not been observed. These results have been discussed with reference to the precipitation of basic iron salts, the electrochemical anisotropy of different faces of a single crystal, and also to the texture of the deposits.

The corrosion of a metal can be minimized by a coating of a nobler metal, for example, by electrodeposition of nickel on iron. Under the conditions of electroplating used in practice, the coating will be more or less porous and the protection efficiency is supposed to depend largely on the porosity of the coating (1, 2). It may be mentioned in this connection that the polycrystalline nickel coating is made up of a large number of single crystals. Such a coating may, however, develop different crystal orientations under varying conditions of deposition (3, 4) and thus affect the corrosion rate of the base metal due to electrochemical anisotropy of different faces of a single crystal (5-8). It was previously thought (3, 4) that the lateral growth of electrodeposited metals of the f.c.c. type, defined by the orientation of the more densely packed atomic planes such as (111), (100), or (10$\bar{1}$0) + (211) parallel to the substrate surface gives better protection than the outgrowth type of deposits defined by (110) or (210) orientations. For industrial electroplating, bath conditions corresponding to the former were therefore recommended (4). In what follows some preliminary results of dissolution of iron from a mild steel disk coated with electrodeposited nickel suggest a different type of behavior.

Experimental Results

Mild steel disks of 2 cm diameter were made out of a rod supplied by "TISCO" (India). They were carefully polished and the nonsignificant portions were thickly plated with nickel, and then covered with collodion. The significant surfaces (area 3.14 cm^2) of one set of such disks were hand polished with emery of different grades ranging from 1F down to 4/0 and the surfaces of another set were machine polished on a polishing cloth containing jeweller's rouge soaked with a continuous supply of xylene as lubricant. Machine polishing of different sets of disks also was carried out with jeweller's rouge soaked continuously with benzene, toluene, dioxane, decaline, etc., respectively. The machine polished disks contained no visible scratches, but a few scratches could be seen in hand polished disks. The surfaces thus obtained were cleaned thoroughly with acetone (A.R. grade) and distilled water to make them free from grease, etc., and then coated with nickel from a bath consisting of 280 g/l of nickel sulfate, 48 g/l of nickel chloride, and 31 g/l of boric acid. All chemicals were of C. P. grade. The bath was purified initially by electrolyzing the solution at a low current density, with a dummy brass cathode and a very pure nickel foil as anode. The *p*H of the bath was adjusted by adding an appropriate quantity of the acid or nickel carbonate. The solutions thus prepared were filtered to remove any suspended matter in them. In order to prevent possible leakage of iron through nonsignificant surfaces of a disk during experiments, thick coatings of beeswax also were applied on them. The deposit orientations, (210), (100), and (10$\bar{1}$0) + (211) were obtained at 25°C at *p*H of 2.1, 3.9, and 5.1, respectively, whereas the (110) orientation was developed at any one of the *p*H's at 60°C. The current density was 10 ma/cm^2 in all the above cases of deposition. The time of deposition which ensured an average thickness of 5.75 μ of nickel coating was noted from reference curves, previously determined for each one of the crystal orientations, by a method suggested by Blum and Hogaboom (1). The orientations were checked from electron diffraction patterns (reflection type, ~55 kv electrons, camera length ~50 cm).

The experiments on dissolutions of the plated disks were carried out in Pyrex beakers containing 40 cc of 0.5% HCl (*p*H $\approx$ 1) or 5% NaCl (*p*H $\approx$ 7) at 25°C with the disks immersed vertically for the specified time intervals in the stagnant solutions, kept open to air all the time. The disk was washed with distilled water, dried with filter paper, and dipped in a fresh solution every time. The solutions containing iron mostly in the form of Fe^{2+} ions were oxidized to the Fe^{3+} state by adding 3 cc of 4*N* nitric acid and boiling for 5 min. Then the concentration of iron was estimated spectrophotometrically after adding KCNS solution with a Unicam spectrophotometer using a light of $\lambda = 500$ mμ (10).

Figure 1 presents results for the dissolutions in 0.5% HCl solutions at 25°C when the initial surface was hand polished, Fig. 2 for machine polished surfaces (jeweller's rouge soaked with xylene as lubri-

[1] Present address: Department of Physics, Pennsylvania State University, University Park, Pa.

cant), and Fig. 3 for dissolution in 5% NaCl solution from the machine polished plated disks. However, results similar to Fig. 1 also were obtained with machine polished plated disks if benzene, toluene, dioxane, decaline, and many other similar hydrocarbons were used as soaking liquid for jeweller's rouge during machine polishing of initial surfaces of mild steel disks instead of xylene. In all the above cases averages from five different experiments are given. It may be seen that the rate of dissolution as given by the slope is higher initially and becomes steady after a few minutes. In the case of (210) orientation the initial rate of dissolution is higher compared with other orientations (Fig. 1 and 2), but later the rate becomes the lowest of all, irrespective of the method of polishing of the initial iron surfaces. This indicates that (210) orientation of nickel coating or the texture of the coating obtained under the stated bath conditions on mild steel ultimately gives the better protection from corrosion in the wet environments studied above.

In the salt solution (Fig. 3), however, no appreciable difference in the corrosion rates was observed

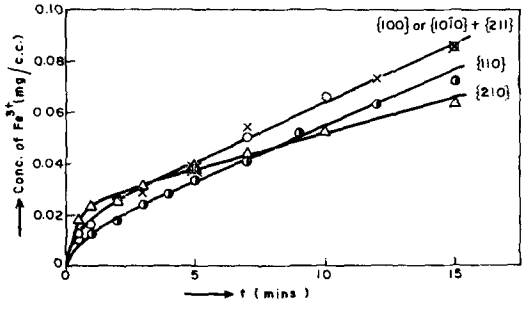

Fig. 1. Dissolution of Fe from hand-polished disk, coated with orientated nickel in 0.5% HCl solution.

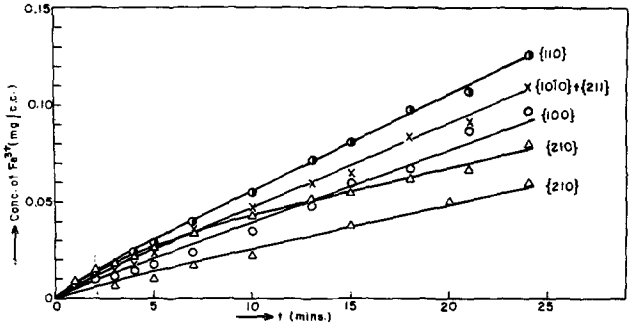

Fig. 2. Dissolution of Fe from machine-polished disk (xylene as soaking liquid) coated with orientated nickel in 0.5% HCl solution, (the lowest curve 0.25% HCl).

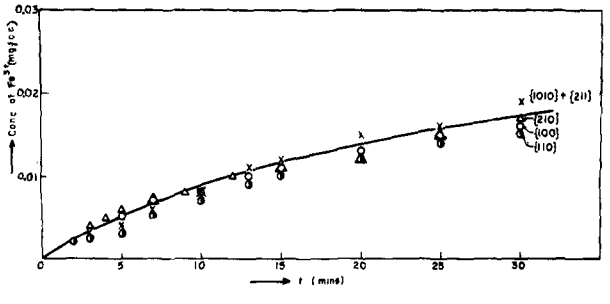

Fig. 3. Dissolution of Fe from machine-polished disk, coated with orientated nickel in 5.0% NaCl solution.

for the various crystal orientations. The higher dissolution observed in the case of hand-polished, compared to machine-polished, coated disks is obviously due to more irregularities on the surface leading to a less efficient protection by the coating.

Discussion

The corrosion of metals in acid solution involves essentially the transfer of one or more electrons by the metal atom to another species, followed by solvation in the aqueous solution. It could be assumed that the rate of dissolution will, *inter alia,* be dependent on the area of the exposed iron. The important question of the texture of the deposit involving such considerations as size, grain boundaries, orientations, and mutual arrangement of the discontinuities of the intercrystallites should be considered primarily (7-9).

It may be inferred that bath conditions depositing nickel with (210) plane parallel to the substrate surface might have produced the least porous surface. However, qualitative estimates of porosity by the usual hot water dip and ferrocyanide methods reveal that deposits with (210) and (1010) + (211) orientations are distinctly more porous and the results are in agreement with those of Rotinyan (13). This also can be appreciated in view of the fact that appreciable evolution of hydrogen occurs during the deposition of nickel with (210) crystal orientation and small gas bubbles would stick to cathode surface when the deposition is carried out (3-5). Although the above tests for porosity (1) do not give any quantitative estimate of the total area exposed as a result of discontinuities, etc., in the deposits, it is enough to suggest that the dissolution rate (vide Fig. 1 and 2) is not determined entirely by this exposed area, and the crystal orientation might have influenced the results (7-9).

It may be noted that the dissolution behavior as represented in Fig. 1 for (110) and (100) orientations of nickel coating is completely reversed in Fig. 2. This may be due to the adsorption of xylene (in some form or other) on the iron surface during machine polishing and the adsorbed matter could not possibly be removed by washing. Thus during electrodeposition of nickel on such surfaces, the adsorbed matter might have been trapped in the pores or other forms of discontinuities of nickel deposits and hence in the local corrosion cells during dissolution experiments. These trace quantities of trapped impurities (12) might have been responsible for influencing anodic and cathodic processes in each corrosion cell, ultimately giving the reversal effect.

It is well known that different single crystal faces have different electrochemical potentials (5, 6) and hence the oxidation and reduction rates differ considerably between them (7-9). We can visualize the existence of local cells at each pore consisting of large cathodes (oriented nickel) and small anodes (polycrystalline iron). The potentials of such cells are dependent on the orientations of nickel to such an extent as to affect the rate of dissolutions in the order suggested by our results. Further, the significant influence of other textural features as mentioned earlier cannot be ruled out.

Evans (2) pointed out that the combination of a large cathode and small anode gives rise to intense attack by corrosive agents. This will lead to a higher current density in the local corrosion cells favoring the dissolution of iron. In the prevailing stagnant condition of the acid solution in the pore, there will soon arise high anodic polarization due to the accumulation of Fe-ions which will oppose dissolution of iron progressively. Further, owing to the discharge of hydrogen at the cathode the liquid in the nickel/solution interfacial region will tend to be alkaline. Since the anode and the cathode are so near each other, iron/solution interface also will be at a pH much higher than that of the bulk solution. The precipitation of basic salts of iron in the pore thus are facilitated, and this decreases the dissolution rate with time. The absence of any appreciable difference in dissolution behavior of specimens having different crystal orientations in 5% sodium chloride solution in contrast with their behavior in dilute hydrochloric acid solutions may be attributed to the instantaneous formation of a protective oxide coating on the exposed areas in presence of neutral solution in the pores.

Acknowledgments

The author expresses his gratitude to Dr. A. B. Biswas for various suggestions and encouragements during the progress of the work and to Drs. A. P. B. Sinha, M. K. Gharpurey, and Hira Lal for stimulating discussions.

Manuscript received May 28, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

The Kinetics of the Corrosion of Low-Hafnium Zirconium in Aqueous Sulfuric Acid Solutions

Tennyson Smith

Atomics International, Canoga Park, California

ABSTRACT

The rates of corrosion of low-hafnium zirconium in aqueous sulfuric acid solutions, over the concentration range 9-97% by weight, have been studied. Corrosion was detected by measuring the concentration of zirconium in solution with a radioactive tracer, Zr^{95}. The samples first were etched in an aqueous hydrofluoric-nitric acid solution, then placed directly into the sulfuric acid solution. The initial corrosion followed a parabolic rate law which was followed by a constant rate. Corrosion during the constant reaction rate period was faster, by an order of magnitude or more, than rates reported in the literature (1-4) for unetched samples under similar conditions. This is thought to be due to the removal of the protective oxide film on etching and the subsequent growth of some less protective film in the sulfuric acid solution.

The corrosion rate was found to be first-order with respect to undissociated sulfuric acid over the concentration range 0.2-9M, "undissociated sulfuric acid," [31.4 to 81.1% H_2SO_4 by weight (5)]. An equation relating the corrosion rate and the concentration of undissociated sulfuric acid at 44°C and with pre-etching, is: $R = 4.0 \times 10^{-5} \times (H_2SO_4) + 1.0 \times 10^{-5}$, g cm^{-2} hr^{-1}. An approximate value for the activation energy determined over the temperature range 20°-72°C, is 7-8 kcal mole^{-1}. A discussion of possible mechanisms is given with suggestions for further research.

This paper reports the second part of a study to elucidate the kinetics of the corrosion of low-hafnium zirconium in aqueous acid solutions. Part one of this study has been reported previously (6) and concerned the dissolution of zirconium in aqueous hydrofluoric acid solutions.

Little has been reported in the literature about the kinetics of the corrosion of zirconium. Most of the work has been reported as engineering data, that is, spot checks at various temperatures and acid concentrations. The work reported here, although preliminary in nature, throws light on the mechanism of the corrosion of zirconium in sulfuric acid solutions and points the way to further experimentation.

To help understand the mechanism of the corrosion phenomenon, it is important to know the concentrations of the various species in solution. Much work has been done to identify the species present in aqueous sulfuric acid solutions. Most of the work has been done with the use of Raman spectra. It has been found that different species have characteristic lines, which are peculiar to them alone, the intensity of which is proportional to the concentration. Although most of the work has been concerned with identifying the Raman spectra with the individual species, two publications have been made which report the concentrations of the various species (H^+, $SO_4^=$, HSO_4^-, and undissociated H_2SO_4, hereafter represented as H_2SO_4) as a function of the stoichiometric sulfuric acid concentration. In 1949, Young and Blatz (5) reported calculations, based on the work of Rao (7), of the specific concentration of H^+, $SO_4^=$, HSO_4^-, and H_2SO_4 in aqueous sulfuric acid solutions. In 1951, Young (8) reported later work on the concentrations of these species.

The following reaction rate data are analyzed in terms of the specific concentrations of the various species in solution.

Experimental Procedure

Low-hafnium zirconium samples 5 x 5 x 0.32 cm had been irradiated with neutrons at the Oak Ridge National Laboratory. The isotope Zr^{95} (half life 65 days) was used as a tracer in these experiments. A detailed description of the zirconium history and the isotope detection apparatus is given in a previous paper (6). In brief, weighed samples were taken from the zirconium plates and were dissolved in hydrofluoric acid solutions. These solutions were used as standards for comparison with unknown concentrations of zirconium in solution. The apparatus, which continuously recorded the zirconium concentration in the hydrofluoric acid work (6), was not used because of the extremely slow corrosion rates in sulfuric acid below 80%.

The solutions were made with conductivity water and reagent grade sulfuric acid. All concentrations recorded in per cent refer to per cent by weight.

Four zirconium samples were suspended by polyethylene strings in four separate beakers which were in a constant temperature bath. Each beaker contained 750 ml of the appropriate sulfuric acid solution. Initial experiments showed that the corrosion of unetched zirconium samples in aqueous sulfuric acid solutions was too slow to be studied in the time available with the proposed experimental technique. Even samples that had been etched in aqueous hydrofluoric acid solutions, then rinsed in distilled water, corroded very slowly. Except for a few initial experiments, the zirconium samples were first etched for 1 min in a 4% hydrofluoric, 30% nitric acid, aqueous solution to remove any oxide film. The sample was then placed immediately into the sulfuric acid solution. Experiment showed that a sample etched then placed immediately into water put about 1 x 10^{-4} g of zirconium in solution as reaction products from the etchant. After placing samples in the sulfuric acid solution, samples of the solution were taken immediately and at regular time intervals and counted in the scintillometer. The amount of zirconium (1 x 10^{-4} to 2 x 10^{-4} g) in the first solution-sample then was subtracted from subsequent measurements, to determine the amount of corrosion.

In many of the initial experiments the solution was stirred at various rates (stirrer speed 0 to 1500 rpm), since no effect from stirring could be detected over the concentration and temperature range of the experiments stirring was discontinued.

Results

Figures 1, 2, and 3 show a few examples of 42 experiments that were made over a range of 9 to 97% sulfuric acid. Figure 1 shows the amount of zirconium that dissolved in a 16.9% solution of sulfuric acid as a function of time. Nine independent experiments were made at this concentration. Experiments 1, 2, 3, and 4 in Fig. 1 illustrate a phenomenon that occurred only a few times during the study, that of a sudden increase in the rate, or break away for a period of time, after which the corrosion rate returned to approximately the original value. These four experiments were started at the same time and were all in the same constant temperature bath. For simplicity, only curves showing trends are drawn through the points.

Figure 2 illustrates the shape of the curves that resulted when the weight of dissolved zirconium vs. time was plotted for 24.4% sulfuric acid solutions at 44°C. In most of the experiments, a constant rate was observed after the initiation period.

Figure 3 shows a plot of the corrosion of zirconium in 31.4% and 55% sulfuric acid over a period of 800 hr. The temperature was changed during some of the experiments to find the effect on the reaction rate. It is seen that the corrosion of zirconium in sulfuric acid, under the conditions of these experiments, is linear with respect to time over long periods.

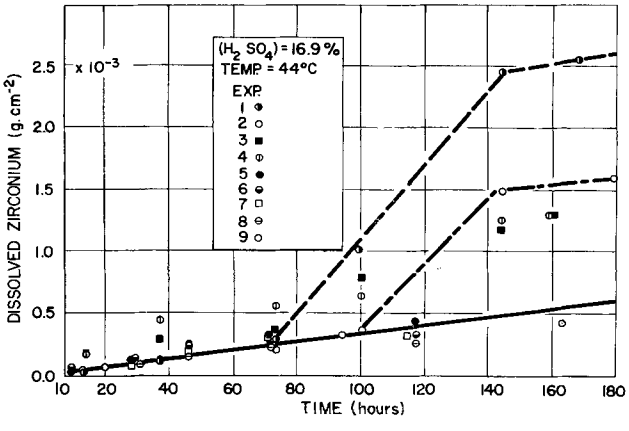

Fig. 1. Dissolved zirconium vs. time for a 16.9% sulfuric acid solution at 44°C. Shows break-away phenomenon.

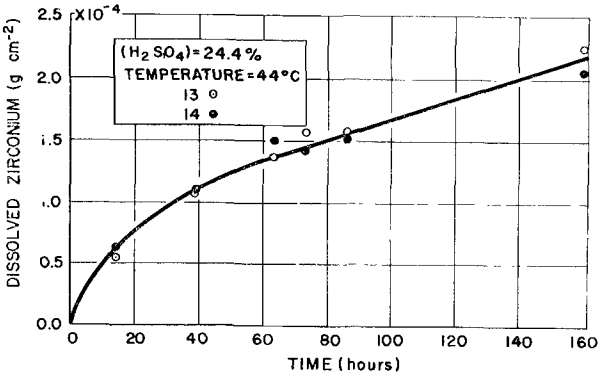

Fig. 2. Corrosion of zirconium in a 24.4% sulfuric acid solution at 44°C. Initial reaction follows the parabolic rate law.

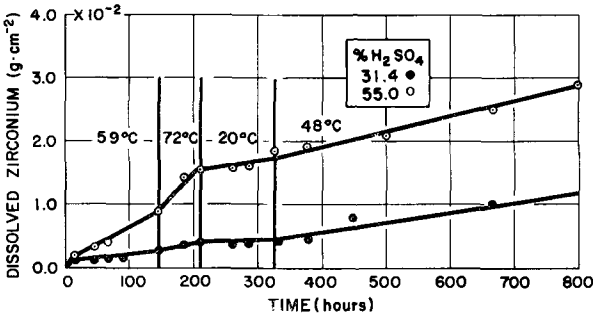

Fig. 3. Corrosion of zirconium in a 31.4 and 55% sulfuric acid solution, as a function of time and temperature.

Figure 4 is an Arrhenius plot for two experiments, one at 31.4% and the other at 55% sulfuric acid. An estimate of the activation energy from the experiment at 31.4% and 55% is about 7-8 kcal/mole.

Recorded in Table I is the rate of corrosion of zirconium at various concentrations of sulfuric acid, in weight per cent. The molarity of the sulfuric acid and the corresponding concentrations of the H^+, HSO_4^-, $SO_4^=$, and H_2SO_4 also have been recorded. These concentrations were estimated from the data given in the two reports by Young and Blatz (5) and Young (8) mentioned above.

Corrosion in solutions 9% or less was too slow to be detected in the time of the experiments. Between

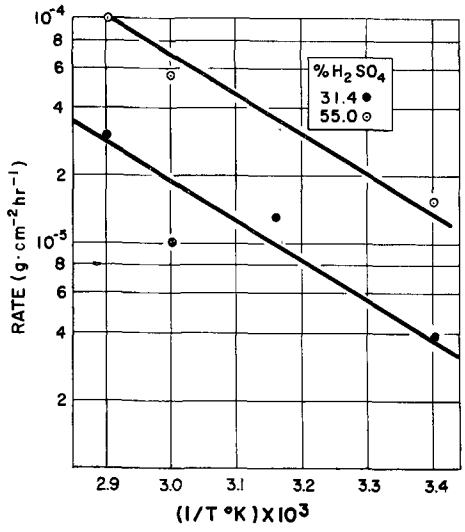

Fig. 4. An Arrhenius plot for zirconium corrosion in a 31.4 and 55% sulfuric acid solution.

9 and about 80% sulfuric acid the reaction rate was rapid at first then slowed down with time to a steady state. The samples had a clean metallic appearance while corrosion occurred, but were not bright. They appeared to have a very thin film that dulled their luster. At higher concentrations (around 80% or above) a white layer formed; some of this was scraped off and analyzed by x-ray diffraction. The x-ray diffraction pattern matched that of zirconium disulfate tetrahydrate as reported by Startzky and Singr (9) and also later by the National Bureau of Standards (10). At the highest concentrations (above 80%) the reaction rate was very fast and not reproducible. Black films formed that spalled and flaked off. The black material proved to be amorphous, giving broad peaks on x-ray analysis; many of the major peaks matched well in "d" value with those reported for ϵ zirconium hydride (ϵ-ZrH) by Hagg (11).

A weighed sample of zirconium turnings was reacted to completion in 96% sulfuric acid; the gas that evolved was collected and tested by infrared spectroscopy and by Orsat analysis. The gas proved to be

pure hydrogen; the amount was stoichiometrically correct for the oxidation of zirconium to the +4 state. The product of the reaction in solution would be zirconyl sulfate tetrahydrate according to Blumenthal (12).

To determine if the rate was affected by oxygen concentration, an experiment was conducted for which the solution had been boiled, cooled in an argon atmosphere, and saturated with argon. No change in the rate could be detected by thus changing the oxygen concentration.

Many of the experiments were made stirring the solutions at different rates, but no effect on the reaction rate could be noted.

One experiment was conducted with a solution approximately 1.5% sulfuric acid, for about 3 hr at varying temperature and pressure to see if corrosion would increase appreciably. The temperature ranged from 38° to 177°C and the pressure from 200 to 800 psig. No corrosion could be detected for zirconium in this short time experiment, although the titanium liner of the autoclave showed marked dissolution, forming a blue complex in solution.

Pitting corrosion was not observed during this study.

Discussion

Very low corrosion rates for unetched samples is in accord with rates reported in the literature (1-4), and this is usually ascribed to a protective layer of oxide on the zirconium surface.

To help understand the mechanism by which the reaction between zirconium and sulfuric acid is inhibited, samples were placed directly from the aqueous hydrofluoric acid solution into the sulfuric acid solution. It was felt that in this manner any oxide film adhering to the zirconium would be stripped off in the etchant, leaving a clean surface for the initial corrosion in sulfuric acid. In this way, the growth of any new film could be followed by the rate zirconium dissolved in solution.

Although the reaction during the initial period (20-60 hr) was not very reproducible, the curves generally had the shape as shown in Fig. 2.

A log log plot of the data in Fig. 2 is linear with a slope of 0.5. The initial corrosion follows a parabolic rate law which can be associated then with the growth of a corrosion product film (13).

The greatly increased corrosion rates that followed the initiation period, as compared to rates reported in the literature, indicate that this film is not an oxide film as found on unetched samples, but much more pervious. An attempt to discover the structure or composition of the film by x-ray analysis of the surface of a flat plate of zirconium proved unsuccessful. One can speculate that the composition is similar to that found at the higher acid concentrations, zirconium disulfate tetrahydrate, or zirconium hydride. Another possibility might be the formation of a film with small amounts of fluoride which acts as a catalyst to promote corrosion. The few instances where break-away took place (1, 2, 3, and 4, Fig. 1) may be attributed to the formation of an unstable film which occasionally breaks down, causing higher corrosion rates for a short interval until the film reforms.

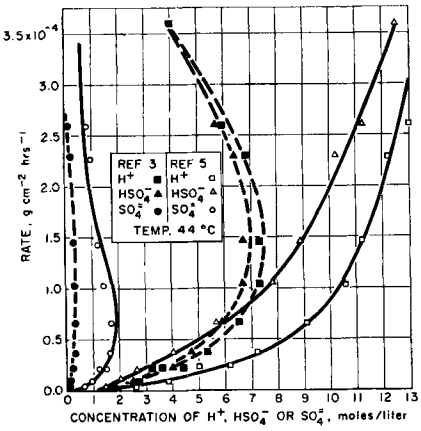

Fig. 5. Rate of corrosion of zirconium as a function of the concentration of H^+, HSO_4^-, and $SO_4^=$ ions.

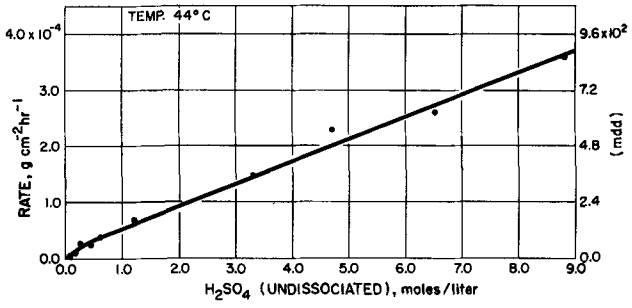

Fig. 6. Rate of corrosion of zirconium at various concentrations of undissociated H_2SO_4.

To find the effect of the individual ionic species on the rate of reaction, the steady-state corrosion rates were plotted as a function of the concentration of the ionic species separately in Fig. 5 and 6. The articles by Young and Blatz (5) and the later article by Young (8) report that, at low stoichiometric sulfuric acid concentrations, the major species are H^+ and HSO_4^-; at high acid concentrations H_2SO_4 increases rapidly. The article by Young and Blatz (5) reports that H^+, HSO_4^-, and $SO_4^=$ go through a maximum starting at a stoichiometric sulfuric acid concentration of about 6 to 7M. The later article by Young (8) gives the maximum for H^+ and HSO_4^- species at a much higher concentration, approximately 14M.

Figure 5 is a plot of the rate as a function of the concentrations of the H^+, $SO_4^=$, and HSO_4^- ions estimated from the two above mentioned articles. It is seen that, if the earlier report by Young and Blatz is correct, the rate is double valued for all of these species, and it can be concluded that the rate is independent of any of them. If the article by Young (8) is correct, the rate is still double valued for the sulfate ion and, although the curves for the H^+ and HSO_4^- ions are not double valued until much higher concentrations are reached, the shapes of the curves are such that it seems unlikely that the rate is a function of these ions in any case.

Figure 6 shows a plot of the rate as a function of the undissociated sulfuric acid concentration, based on the article by Young and Blatz (5). Within experimental error, the rate is directly proportional to the concentration of H_2SO_4. The points in Fig. 6 are

experimental, and the curve is a visual fit of these points.

Although the temperature at which Rao (7) did his work was not reported by him (he mentioned that he cooled his solutions by water), the temperature was probably close to room temperature or not far above this. Young (8) reported his later work was done at 25°C. The solutions used for the experiments reported in Table I were held at 44°C. In view of all the uncertainties involved, the values plotted in Fig. 5 and 6 probably have considerable error; however, the relative values and the shape of the curves should be reliable.

It seems reasonable to conclude that the species that controls the reaction rate is the undissociated sulfuric acid molecule, at least at the higher concentrations, and probably to as low as 0.5M. An equation for the linear portion of the curve in Fig. 6 is: $R = 4.0 \times 10^{-5} (H_2SO_4) + 1.0 \times 10^{-5}$ g cm^{-2} hr^{-1}, where R is the rate in grams of zirconium dissolving into solution per square centimeter of sample per hour.

By way of summary, the following observations have been made: under the conditions of these experiments the initiation reaction usually lasts from 20-40 hr and obeys a parabolic rate law. The initiation reaction is followed by a constant reaction rate which is somewhat higher than for unetched zirconium. The constant reaction rate appears to be a function of the undissociated H_2SO_4 concentration alone and is first order with respect to this species. At 44°C the specific reaction rate constant is 4.0×10^{-5} g cm^{-2} hr^{-1} moles^{-1} liter. The activation energy for the reaction slow step is 7-8 kcal mole^{-1}. No effect on the rate could be detected by stirring the solution or changing the oxygen concentration. No change in the appearance of the samples is detected until the solution becomes saturated with corrosion products, which crystallize as loose white crystals. The samples have a clean metallic appearance while corrosion occurs, but are not bright. They appear to have a very thin film that dulls their luster. Reaction of zirconium in solutions 80% sulfuric acid or higher gives rapidly increasing reaction rates, while loose films are formed that proved to be zirconium disulfate tetrahydrate. At the higher concentrations black films that flaked off are also formed; they are probably partly zirconium hydride. The gaseous reaction product is pure hydrogen; the amount evolved corresponds to that needed for zirconium to be oxidized to the +4 state.

Although these observations do not permit a very detailed account of the corrosion mechanism, they do allow the elimination of many of the possible mechanisms and point to further research which will narrow down the remaining possibilities.

The first order rate dependence on the undissociated sulfuric acid molecule and the low activation energy suggest the slow step to be some physical phenomenon involving this species, such as adsorption or diffusion. The initial reaction which follows a parabolic rate law indicates the growth of a reaction product barrier through which the reactants must diffuse. When the film reaches a limiting thickness, the reaction comes to a steady state as shown by the constant reaction rate which follows the initiation period. Another possibility could be that, as the reaction product film grows, it cracks, exposing only a small portion of the surface to reactants and that after the initiation period, exposure and closing off of reaction surface reaches a steady state.

Further experiments that would help elucidate the mechanism of corrosion of zirconium in sulfuric acid solution could be: electropolish the zirconium samples rather than etch them in hydrofluoric acid; weigh and measure the dimensions of both irradiated and unirradiated samples during corrosion, as a check on the tracer method, to see if irradiation affected the rate, and so that a material balance could be made accounting for the corrosion products that remained on the sample and that which dissolved in solution; investigate the reaction product film that adheres to the zirconium by electron diffraction and chemical analysis, if possible; and investigate the current potential relationships during the dissolution of zirconium in sulfuric acid solutions.

The Relationship between Brightness and Structure in Electroplated Nickel

R. Weil and R. Paquin

Department of Metallurgy, Stevens Institute of Technology, Hoboken, New Jersey

ABSTRACT

Nickel deposits of various brightnesses were plated from Watts baths containing several different addition agents. The as-plated surfaces of the deposits were examined by electron microscopy. All bright deposits had a very fine-grained structure. However, some fine-grained deposits showed surface crevices and were therefore not bright. A linear relationship between the fraction of the surface area having a roughness less than 0.15 μ and the logarithm of light reflected as measured with a photocell was found. There is no direct relationship between the degree of preferred orientation and brightness, but the fiber axis is related to the type of structure observed, i.e., platelet, equiaxed crystallite, or spiral-type, and the addition agents in the plating bath.

The relationship between the light-reflecting property generally referred to as the brightness and the structure of electrodeposits has been the subject of many investigations. These studies have led to two theories. One theory advanced by Kohlschütter (1), Liebreich (2), and others states that electrodeposits are bright if their microstructure consists of crystallites smaller than the wave lengths of visible light, i.e., smaller than 0.4 μ. However, Read and Weil (3) and Denise and Leidheiser (4) have shown that not all very fine-grained deposits are bright.

The second theory which, among others, Hume-Rothery and Wyllie (5) and Blum, Beckman, and Meyer (6) have formulated, states that the more oriented the grain structure, the brighter the deposit. Smith, Keeler, and Read (7) and Denise and Leidheiser (4) found this relationship not to hold.

Therefore, the need for further study to determine what structural features determine brightness was indicated and this investigation was undertaken.

Experimental Procedure

Nickel electrodeposits having a range of brightnesses from dull gray to specular were plated from Watts baths containing the various addition agents listed in Table I. The baths were agitated by pumping solution from the region near the cathode into the anode bag, which also served as a filter. Three deposits were plated from each bath to a thickness of about 50 μ; for two deposits, the starting cathode was electropolished copper sheet and for the third, mechanically polished, mild steel.

The microstructures of the as-plated surfaces were examined by electron microscopy. Collodion replicas made in the manner described by Weil and Read (8) and carbon replicas prepared according to the method of Grube and Rouze (9) were used. In view of the claims found in the literature (10) that the microstructure of bright deposits cannot be resolved by electron microscopy, a thin surface layer of the deposit was examined directly in order to eliminate possible extraneous structural features resulting from shadowing or the replicating medium.

The thin surface layers were obtained by partially immersing one of the deposits plated on copper sheet in a copper-cyanide bath immediately after removal from the nickel-plating bath and rinsing in water. A copper layer approximately 1000Å thick was deposited. After rinsing again, part of the copper-plated nickel deposit was immersed again in the

original nickel bath and a thin nickel film, approximately 100Å thick, plated over the copper layer. Thus, the surface of this sample consisted partly of the original nickel plate, partly of the thin copper layer, and partly of the second nickel deposit as schematically represented in Fig. 1. Collodion replicas from the surfaces of the original nickel deposit, the copper film, and the nickel film were examined electron microscopically as were carbon replicas from the original nickel deposit and the nickel film. The purpose of these examinations was to determine if the nickel and copper films had copied the structure of the original nickel deposit. When this was found to be so, the nickel film was stripped by dissolving the copper layer in an aqueous solution of 50 g/l H_2SO_4 and 500 g/l CrO_3.

The light-reflecting properties of the deposits were determined by directing a beam from a zirconium arc through a slit onto the specimen and measuring the reflected light with a photocell. The incident beam made an angle of 10° with the normal to the sample and the photocell was placed along a line 10° to the normal on the other side. The brightnesses of the three areas of the sample represented in Fig. 1 as well as of the other two deposits were measured. In spite of the polishing there were some irregularities in the starting-cathode surface which resulted in lower brightness measurements. Therefore, the maximum reading is recorded in Table II. The various deposits also were arranged in five classifications of brightness as judged by eye. These data are also included in Table II. The order of brightness by eye evaluation, with one exception, was the same as that obtained with photocell measurements.

* Brightness increases with group number.
† Part of deposit was hazy (a), part bright (b).
‡ s = strong, vs = very strong, m = medium, w = weak.

The fiber axis of the deposits was determined by x-ray diffraction. The nickel deposit first was stripped off the copper basis-metal by dissolving the copper in the sulfuric acid-chromium oxide mixture mentioned previously. The nickel deposit was bent into a convex shape through an arc of a circle of 10 cm radius and an x-ray beam was directed along its surface. The results of these determinations are recorded also in Table II.

For reasons which will be explained later, measurements to determine the fraction of the surface area which had a roughness less than 0.15 μ were made on electron photomicrographs of collodion replicas. Polystyrene latex spheres which were 0.514 μ ±0.011 μ in diameter, obtained from the Dow Chemical Company, Midland, Michigan, were placed on the replicas and palladium evaporated on them subsequently. The heights of the various structural components were determined from the ratio of their shadows to those of the latex spheres. The area occupied by those components of the structure more than 0.15 μ above or below the surface then was measured with a planimeter and the value subtracted from the total area of the photograph in order to get that fraction of the whole surface which was reflecting light. The results of these measurements also are included in Table II.

Experimental Results

Three structural types corresponding to the three different fiber axes were observed in the deposits plated in the baths containing the various addition agents. The type of structure was affected by the addition agent, but the structures of all deposits plated from a given bath were the same regardless of the basis metal.

The deposits having a (100) fiber axis[1] were found to consist of platelets. A number of platelets were stacked parallel to each other and comprised a colony. In most of the deposits exhibiting this type of structure, a depression in the surface resembling a grain boundary existed between colonies of platelets. The thickness and the spacing of the platelets within a colony varied widely between deposits from different baths. Figure 2 shows coarsely spaced and relatively thick platelets and a large colony size. Figure 3 shows a finer spacing and a smaller colony size. A structure with still finer platelets, although possessing a larger colony size than shown in Fig. 3, can be seen in Fig. 4. The x-ray diffraction patterns of the structures with the (100) fiber axis showed the anomalous intensity maximum at the meridian which Clark and Simonsen (11) explained on the basis of a twinning relation between the platelets. Structures with platelets were found in deposits

[1] The term, fiber axis is used here in the same sense as in Ref. (7).

from plain Watts bath and from baths with chloral hydrate, p-toluene sulfonamide, and saccharin additions.

The second structural type, which was associated with a (311) + (111) fiber axis, consisted of fine crystallites which appeared equiaxed in the surface plane of the deposits. Most of the bright deposits exhibited this type of structure, but so did some hazy ones. Figure 5 shows the structure of a specular deposit as seen by transmission through the thin nickel surface film. In hazy deposits with this type of structure, depressions in the surface were observed. These depressions appear as dark areas in Fig. 6, which is an electron micrograph of a negative collodion replica, shadowed with palladium. The raised portions in

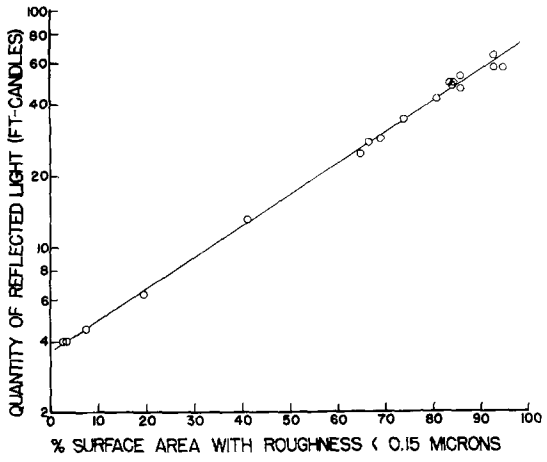

Fig. 8. Relationship between amount of light reflected and the fraction of the area with roughness less than 0.15 μ.

the replica result from depressions in the surfaces of the electrodeposit. Baths containing naphthalene disulfonic acid without chlorate hydrate and the bath containing the Harshaw Chemical Company proprietary brightener resulted in deposits of the second type.

Spiral growth was found in electrodeposits having a (110) fiber axis. This structure, represented by Fig. 7, was found in nickel plated from Watts baths containing aniline and benzoic acid. It is noteworthy that some deposits plated in an all-chloride bath without additives in connection with some other work performed by a graduate student at this institution also showed spiral-type growth. These deposits were found to have a (110) fiber axis. Banerjee and Goswami (12) reported the same preferred orientation under the same plating conditions. All deposits of this type were dull.

In attempting to relate microstructure and brightness, it was noted that all bright nickel samples in addition to having very small structural components also showed no crevices, deep grain boundaries, or protrusions which extended more than 0.15 μ from the surface plane. It therefore was assumed arbitrarily that only that fraction of the surface area with a roughness less than 0.15 μ specularly reflects light. This light-reflecting area was measured in the way previously described. A graph of brightness vs. fraction of surface area with a roughness less than 0.15 μ is shown in Fig. 8.

Discussion

It is apparent from Fig. 8 that the brightness depends on the degree to which the structural components of the surface of electrodeposits are in one plane. This, in turn, is determined by several factors such as grain size and orientation, the degree of preferred orientation, and codeposition of foreign substances. The grain size is important because the boundaries between large grains appear as deep crevices in the surface of electrodeposits. Structures composed of large platelets will show coarse steps between the plates. It is therefore necessary for bright deposits to be very fine-grained. However, it is also apparent from data in Table II that a small grain size is not a sufficient condition for brightness. The deposits showing spiral-type structures were dull even though some were fine grained because this type of growth results in crystals which have no light-reflecting plane parallel to the surface and consequently the tops of the grains protrude above the intergranular crevices. The orientation of the crystals which determines whether a light-reflecting plane is parallel to the surface therefore affects the brightness.

The size of the crevice between neighboring grains is certainly influenced by their relative orientations. It is expected that a group of crystallites with a common fiber axis would have very small crevices between them. As the degree of preferred orientation is only one of several factors which determines the surface roughness, it is not to be expected that there is a unique relationship between preferred orientation and brightness. Certainly, the findings previously cited (4, 7) that preferred orientation is not proportional to brightness have been substantiated. Even for a given fiber axis, no direct correlation has been found.

The smoothness of the surface has been shown by Beacon and Riley (13) to be dependent on the distribution of addition agents. By means of brighteners containing a radioactive atom, they showed that preferential codeposition takes place at protrusions, hindering crystal growth at these sites and thereby tending to eliminate the crevices. This could explain why there were no depressions in the surface with certain addition-agent concentrations.

The scatter of data for high light-reflecting values in Fig. 8 is probably due to the fact that, when most of the area has a roughness less than 0.15 μ, smaller changes in the morphology of the surface become significant. The photocell was also not as accurate at high light intensities as at lower ones. In the deposits with over 99% of their area having a roughness less than 0.15 μ, an increase in brightness and decreasing grain size was noted. The number of samples was not sufficient to definitely establish a relationship between brightness and grain size.

Conclusions

1. A direct relationship exists between the fraction of the surface roughness less than 0.15 μ and brightness in electroplated nickel.

2. The observations of others that fine-grained deposits need not be bright have been confirmed and explained.

3. A correlation between type of microstructure and fiber axis has been found.

4. There is no unique relationship between brightness and the degree to which the fiber axis is parallel to the corresponding crystallographic direction in each grain of the deposit.

The Adhesion of Electrodeposited Nickel to Chromium at Elevated Temperatures

Walter E. Reid, Jr. and Fielding Ogburn

Chemistry Division, National Bureau of Standards, Washington, D. C.

ABSTRACT

The use of a composite coating of electrodeposited nickel and chromium to protect molybdenum from oxidation at elevated temperatures has certain practical limitations. Examination of the composite coating showed that the problems of blister formation, weakening of the bond between nickel and chromium, and edge separation were interrelated. Blister formation was eliminated and edge separation reduced slightly by an improved treatment of the chromium surface prior to nickel plating. The weakening of the bond between nickel and chromium appears to be inherent in the coating system.

The application of a composite coating of electrodeposited nickel and chromium to protect molybdenum from oxidation at elevated temperatures has been described by Couch and co-workers (1). The use of this coating at elevated temperatures (800°-1200°C) has associated with it certain problems caused by the difference in the properties of the metals involved. Heating and thermocycling tests of the composite coating showed that (*a*) heating to 800° or 1000°C frequently, but not consistently, resulted in the formation of blisters between the chromium and nickel layers, (*b*) prolonged heating weakened the bond between the nickel and chromium layers, and (*c*) thermocycling between room temperature and 800° or 1000°C caused a separation of the nickel from the chromium, principally at sharp edges or corners.

An investigation of these three closely interrelated problems was necessary, since they represent practical limitations to the use of the coating system.

Blister Formation

Blister formation was observed on a number of specimens, electroplated with 0.007 in. of nickel over 0.001 in. of chromium, after they had been heated in a helium atmosphere to 850°C. These had been plated by the procedure described by Couch and co-workers. Examination of the blisters revealed that they always formed within the nickel-chromium diffusion alloy and not at the original nickel-chromium interface. Both nickel and chromium were detected chemically on the entire inner surface of the blister. Also the occurrence of blisters usually was accompanied by poor adhesion of the nickel to chromium on other parts of the specimen where blistering had not occurred.

Since blister formation is often caused by improper cleaning prior to plating, we examined a number of modifications in the plating cycle between the chromium and Watts nickel plating steps. Modifications included anodic and cathodic treatment of the chromium surface in different solutions, elimination of the water rinse, variation of current density for the nickel strike, and the immersion time in the nickel strike bath prior to electroplating.

The only change which eliminated blistering was the substitution of anodic etching in an acetic acid solution for the hydrochloric acid etch.

Acetic Acid Etch

Glacial acetic acid, to which had been added 10 to 15% H_2SO_4 by volume to increase the conductivity, constituted the etch solution. An inert cathode was used. Specimens were etched anodically in the solution at current densities of 3-7 amp/dm^2 until the surface of the chromium was covered uniformly with

a dark brown film. They were rinsed rapidly in water and placed in the Wood's nickel bath with electrical contact made beforehand so that plating began as the specimen was immersed. The specimens were plated at 25-30 amp/dm^2 for 2 to 4 min, then transferred directly to a Watts nickel bath.

A brief study of the etching process showed that an etching time of 5 min at 4 amp/dm^2 was usually sufficient. The time of exposure of the specimen to air after the water rinse and prior to insertion of the specimen into the Wood's nickel strike bath was not critical as long as it was brief and the specimen did not become dry. After adoption of this etch procedure in the plating cycle, blister formation was not encountered.

Adhesion

No difficulty was encountered with the adhesion of nickel to chromium in the "as plated" condition when either the plating procedure described by Couch and co-workers (1) or the acetic acid etch was used.

Heat treatment, however, caused a weakening of the bond between the chromium and nickel. This occurred when the nickel-chromium plated specimens were heated to 850°C in helium and held at this temperature for 1 hr. Very good adhesion was obtained with the acetic acid etch of chromium, even after extension of the heat treatment to 24 hr or with thermocycling (10 min in oven at 850°C, 10 min at room temperature) in air for 24 hr. Only a few such specimens were subjected to these more severe tests, but each one retained good bonding between the chromium and nickel.

A still more severe heat treatment of the same specimens, either at higher temperatures or for longer periods, resulted in a weakened bond. Thus, while it has been possible to improve the performance of the coating system with respect to bond failure, the problem still exists for prolonged heating at higher temperatures.

To gain additional insight into the weakening of the bond, a few experiments were conducted with short lengths of chromium plated nickel rods which were heat-treated to alloy the chromium and nickel. Additional nickel was plated over the chromium to serve as a grip for the measurement of the bond strength between the chromium and nickel rod by the Ollard method. Duplicate specimens were heated in helium at 850°C for 24 and 66 hr and compared with duplicate specimens in the as-plated condition. While the bond strength measurements were not highly reproducible, they showed a reduction in bond strength of 75 to 90%. This shows that bond strength is lost on heating when chromium is plated on nickel, just as when nickel was plated on chromium in the earlier experiments. Hence, it would appear that deterioration of the bond is an inherent property of the nickel-chromium system no matter how the nickel-chromium interface is prepared and is the result of the interdiffusion of nickel and chromium. The diffusion process leads to the formation of a weak layer which becomes the plane of separation. This weak layer could be simply an alloy of low tensile strength. It could also consist of a line of voids formed by the diffusion process (2) or a line of inclusions as observed by Couch and co-workers (1).

In summary, two factors can affect adversely the adhesion of the coating: (*a*) passivity of the chromium surface, and (*b*) alloying of the nickel and chromium. The first can be reduced by proper pretreatment of the chromium, but the second appears to be a property of the coating system.

Adhesion of Chromium to Molybdenum

As indicated above, the problem of blister formation was associated with the deposition of nickel on chromium. Usually, the adhesion of chromium to molybdenum was not a problem; however, an occasional lack of adhesion was encountered.

In the anodic etching of molybdenum in the sulfuric-phosphoric acid solution prior to plating, the metal becomes covered with a viscous film which is not entirely removed by simple rinsing in water. It was found that a subsequent short immersion in an acidified chromic acid solution (3) resulted in excellent adhesion. The composition of the immersion solution is given below. Other compositions were not considered, since no case of poor adhesion was encountered after adoption of this cleaning procedure.

Procedure.

1. Clean and anodically etch molybdenum in 1:1 H_2SO_4 (95%)-H_3PO_4 (85%) at 5-20 amp/dm^2 for 2 to 3 min.
2. Rinse thoroughly in water.
3. Immerse molybdenum for 3 min in an aqueous solution containing: 6% of CrO_3 by weight, 15% of H_2SO_4 by volume, and 15% of concentrated HCl by volume.
4. Rinse thoroughly in water.
5. Place in chromium bath about 30 sec before making electrical contact.
6. Plate in the chromium bath at 120 amp/dm^2 and 80° to 85°C.

"Edge Separation"

The resistance to thermal shock of a number of molybdenum specimens with a composite coating of chromium and nickel was evaluated by thermocycling them in air between room temperature and 800°-1100°C. The thermocycling was accomplished by lowering the specimens into a tube furnace at the desired temperature for 10 min and then withdrawing them to cool for 10 min. This cycle was repeated automatically for the duration of the test.

Microscopic examination of cross sections of specimens which had been cycled 6 times to 800°C revealed a slight parting within the coating in the immediate vicinity of a sharp corner or edge of a rectangular specimen. Specimens cycled for longer periods of time or at higher temperatures showed that the size of the void increased and also extended along the flat surfaces. In an extreme case, the separation of the coating extended over the entire circumference of a rod 0.25 in. in diameter after being cycled 16 times to 1100°C. The coating was intact, but was only very loosely held to the rod.

The "edge separation" always was observed as occurring within the nickel-chromium diffusion al-

loy. In view of this, the phenomenon of "edge separation" may be considered as another manifestation of the problem associated with the formation of a weak layer between the nickel and chromium.

Stresses due to Unequal Expansion of the Metals

A major factor contributing to the deterioration of the bond between the nickel and chromium when plated on molybdenum is the difference in the coefficients of expansion of the three metals. The expansion coefficient for nickel is about 2½ times that for molybdenum. Heating therefore would be expected to cause stresses which would tend to fracture the composite coating, especially where the radius of curvature is small. The equations used by Lander and Germer to explain spalling (4) also can be applied to this problem.

In these equations plastic flow is neglected and it is considered that a cylinder of metal A is plated with a metal B. They give for the normal pressure at the interface

$$P = \frac{2h}{d} (\alpha_B - \alpha_A) E_B t$$

and for the circumferential stress per unit area

$$S = (\alpha_B - \alpha_A) E_B t$$

where*: E is modulus of elasticity; α, coefficient of thermal expansion; d, diameter of cylinder; h, thickness of coating; and t, degrees Centigrade above room temperature. Though these equations do not include all the factors involved, they do help us to understand the stresses involved.

Since initial edge separation is governed by the stresses normal to the surface, the first equation is of primary interest. Consider a molybdenum surface with a radius of curvature of 0.3 in. plated with 0.008 in. of nickel over 0.001 in. of chromium. If this is heated to 800°C, the calculated normal stress is 5200 psi at the nickel-chromium interface and 1000 psi at the chromium-molybdenum interface. Thus the normal stress is greatest at the nickel-chromium interface and is of the order of the nickel-chromium (5) bond strength. The equation leads us to expect coating separation if the radius of curvature is small or the coating is thick.

These predictions are in qualitative agreement with the experimental evidence. Edge separation occurs initially at corners of rectangular specimens where the radius of curvature is small and at the chromium-nickel interface. If the corners are rounded off by increasing the thickness of chromium, edge separation is less likely. For example, two specimens were cycled 50 times to 980°C. One specimen had been plated with 0.004 in. of chromium and 0.006 in. of nickel, and the other with 0.001 in. of chromium and 0.006 in. of nickel. Edge separation occurred to a much greater extent on the specimen with the thinner layer of chromium.

The predicted low normal stress at the chromium-molybdenum interface is also verified by experiments for which rectangular molybdenum specimens were plated with 0.009 in. of chromium. After cycling 50 times to 980°C, no coating separation was observed.

Once the coating separation has been initiated, the analysis of the situation is different. Heating of the specimen causes the loose nickel layer to expand and the result is a high concentration of stress where the nickel joins the underlying metal. This stress concentration causes an extension of the void so that a peeling action of the coating occurs with continued thermocycling.

* The following quantities are used in the present discussion:

$\alpha_{Mo} = 5.5 \times 10^{-6}/°C$
$\alpha_{Cr} = 8.1 \times 10^{-6}$
$\alpha_{Ni} = 13.7 \times 10^{-6}$
$E_{Ni} = 30 \times 10^{6}$ psi
$E_{Cr} = 20 \times 10^{6}$ psi

Acknowledgment

Temperature and Space-Charge Effects in Liquid Hydrocarbons

R. Coelho[1] and M. Bono[2]

Laboratory for Insulation Research, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

Preliminary results on the residual d-c conduction and space-charge polarization in n-hexane and n-heptane under highly inhomogeneous field conditions (thin wire in coaxial cylinder) are presented. A residual current is observed under high applied voltage for either polarity of the test cell. At 20°C the current is one order of magnitude larger when the wire is the positive electrode. As temperature is increased, the residual current for the wire positive decreases and for the wire negative increases, until at 50°C it is about the same for both polarities. By heating only the wire, observations supporting and extending these findings were made. The gross features of the current-voltage characteristics can be explained by dissociation of polar impurities in the region of high field strength. The dependence on polarity can be explained by space-charge distortion of the field. For negative wire, field emission appears to occur from the wire, surrounding it with a current-limiting space charge.

For a number of years, work in this laboratory has emphasized the importance of field emission for certain types of electric breakdown in gases (1), liquids (2), and solids (3), and the role of space-charge buildup in front of the cathode as a means of providing the required gradient. Also, the charging-up of surface layers comes into play, as demonstrated impressively, for example, in the Malter effect (4) and in the work of Llewellyn Jones and co-workers (5).

The present investigation deals with space-charge phenomena in n-hexane and n-heptane, in continuation of the work by Green (2). His principal findings on d-c currents under nearly homogeneous field were that the current-voltage characteristics consist of a low-field region, dominated by the ions of the liquid, and of a high-field region in which the decisive role is played by the cathode as a source of field emission.

The main purpose of our measurements was to extend the study to a highly inhomogeneous electrode configuration (thin wire in large coaxial cylinder) that allows separation of anodic and cathodic effects.

Experimental

The test cell (Fig. 1) consisted of a platinum wire (1 mil diameter) stretched along the axis of a carefully polished platinum cylinder (about 10 mm diameter and 30 mm long) with ends rounded to avoid edge effects. The geometrical field strength on the wire is roughly 400 times greater than that on the cylinder surface. The cylinder was connected, through a 50-megohm resistor, to a reversible high-voltage 30-kv power supply (Beta Electric Co.) driven by a Sorensen a-c voltage regulator. The maximum ripple, observed with an oscilloscope, was less than 1.5 v peak to peak at 10 kv. The wire was connected to a vibrating-reed electrometer whose output was sent through a General Electric self-balancing potentiometer into an Esterline-Augus recorder (Fig. 2). The equipment in its shielded cage was tested up to 20 kv for the absence of corona.

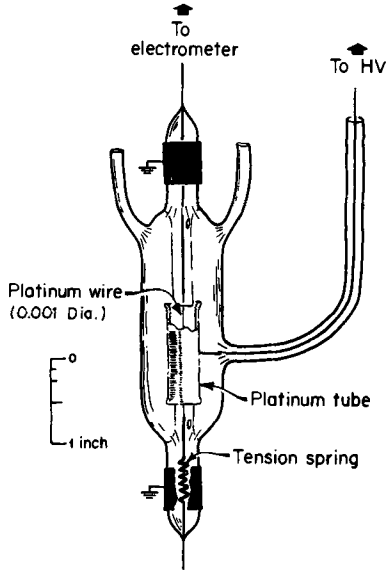

Fig. 1. Schematic drawing of the test cell

Test Samples and Procedures

"Pure grade" n-hexane and n-heptane (Philips Petroleum Co.) were repurified by passage through a 2-ft column of silica gel and an ultrafine fritted-glass filter; the initial fraction of the filtrate was discarded.

Ultraviolet absorption spectra, taken with a Cary spectrophotometer before and after treatment, show that bands initially observed around 2500Å are removed. This treatment seems to reduce the initial current slightly, but no significant change in residual current has been recorded.

Before final readings were taken, the cell was "conditioned" as follows.[3] After slowly raising the

[1] Present address: Laboratoire Central des Industries Electriques, Fontenay-aux-Roses, France.

[2] Present address: Torino, Italy.

[3] A similar technique has been used by House (6).

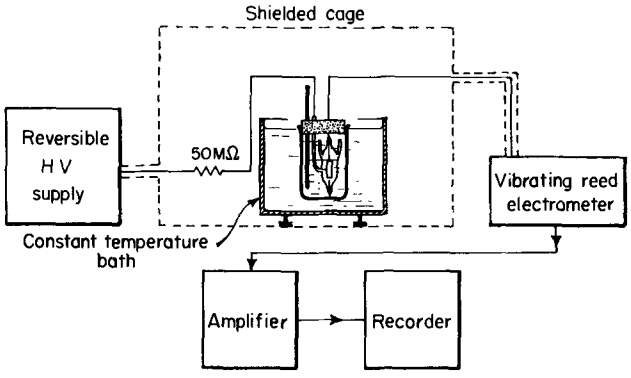

Fig. 2. Block diagram of the experimental setup

voltage to the onset of an erratic current, it was kept constant to permit the fluctuating current to decay gradually toward a steady state. Then the cycle was repeated three or four times until voltages of the order of 15 kv were reached. It is worth noting here that voltages up to 18 kv (which corresponds to 2.3 mv/cm at the wire for space-charge-free configuration) have been reached by this procedure. This treatment has a particularly strong effect in the negative-wire polarity (Fig. 3) supporting the belief that conditioning eliminates spots of high emissivity. The reproducibility of the final curves is shown by shaded areas which indicate the spread of the current values over a period of several weeks. The residual current is always noisy, especially when the wire is negative, and sudden fluctuations, superimposed on this noise, occasionally occur even after conditioning periods of 15 days. Hence, the current measured at intervals of several days was rarely reproducible within less than 40%.

In a second series of measurements, the test cell was thermostated to ±0.05°C and the steady current measured at constant voltage for various values of temperature as well as at constant temperature for different applied voltages.[4]

In a third series of experiments the wire alone was heated by a battery current and the average temperature of the wire estimated from its increment in resistance and the known temperature coefficient $d\rho/dt$ for platinum (4×10^{-3} ohm x cm x degree^{-1} between 0° and 100°C). In order to make sure that the leakage resistance to ground was not reduced when the heating current was turned on, the battery was connected permanently by one of its poles, and the whole circuit, including the switch, carefully insulated from ground. Potentials of 1.5, 3, 4.5, and 6 v were applied across the wire; at higher voltages the liquid at the wire surface started to boil. Since the volume of the wire is six orders of magnitude smaller than that of the liquid, only a very small fraction of the liquid near the wire surface is heated appreciably during the 1-min heating runs.

Time recordings of the charging and depolarization currents were also taken.

Behavior of the Residual Current

The residual current subsisting under both polarities after careful conditioning of the cell is shown in

[4] Since n-heptane is a liquid between −90.5° and +98.4°C, the data, thus far taken only over the range +13° to +50°C, should be extended. Some preliminary measurements in the wider range have been made but must be confirmed in detail before being reported.

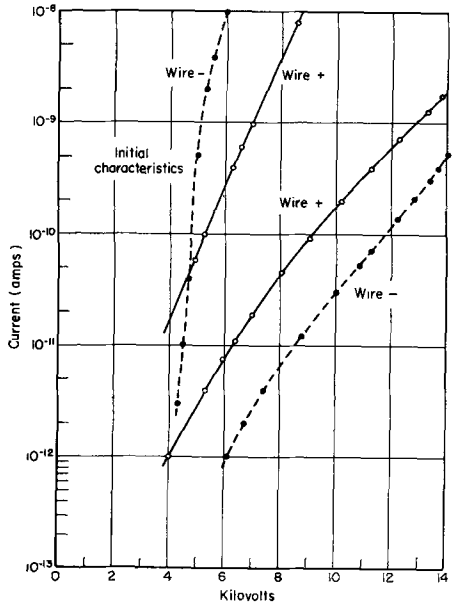

Fig. 3. Current-voltage characteristics in n-hexane showing the effect of conditioning. The shaded areas contain all the data taken over a period of several weeks, the points referring to the latest measurements.

Fig. 3 as a function of the applied voltage. The two curves, plotted on a log scale, are very similar in shape but the one corresponding to i_+ (positive wire configuration) lies above that corresponding to i_- (negative wire configuration).

Essentially the same results were obtained with a 1-mil diameter tungsten wire as the center electrode, although its surface roughness was much greater than that of the platinum wire. The residual current was larger under both polarities but the ratio i_+/i_- was nearly the same as for platinum (Fig. 4). Furthermore, fairly good agreement between the two sets of curves was obtained by scaling along the V axis. This seems to indicate that the highest field locally present in the cell, rather than the nature of the electrodes, is the significant factor.

The curves of Fig. 5, showing the temperature dependence of the current in n-heptane for various applied voltages, were obtained directly by varying the temperature under constant voltage. The same

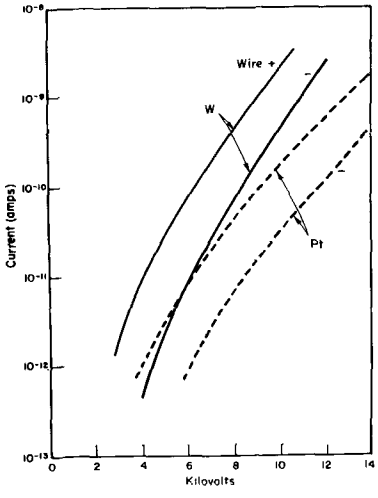

Fig. 4. Comparison of the current-voltage characteristics obtained with platinum and tungsten wire.

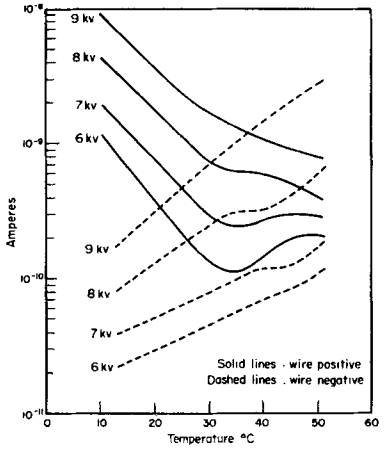

Fig. 5. Residual current vs. temperature in n-heptane for various applied voltages.

type of curves, constructed from a set of current-voltage characteristics at different temperatures, agree fairly well with those of Fig. 4. Although some details in the curves are not significant, the general trend shows that i_+ and i_- vary oppositely with temperature. While at room temperature i_+ is ten to twenty times larger than i_-, the two currents are of comparable magnitude at 50°C.

Current vs. Time (Wire Heated)

The results obtained when the wire was heated with 6 v applied are summarized in Fig. 6, which reproduces the essential trends of actual recordings. When the heating current is applied, the current drops suddenly regardless of polarity; then while i_+ keeps decreasing slowly, i_- tends to increase. When the wire current is switched off, the cell current rises sharply at first and then recovers its original value more slowly.

This effect is independent of the orientation (vertical or horizontal) of the test cell, the polarity of the battery, and the characteristics of the external circuit. Consequently, the sudden drop of the current must be caused by the heating of the wire and its immediate surroundings. However, transient phenomena related to the appearance of the thermal gradient are probably involved and complicate the interpretation. The slow variation, caused by the propagation of heat through the cell, is consistent

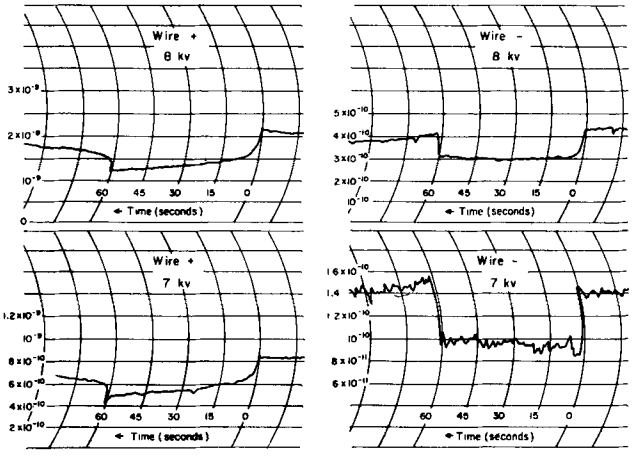

Fig. 6. Current recordings showing the effects of heating the wire alone.

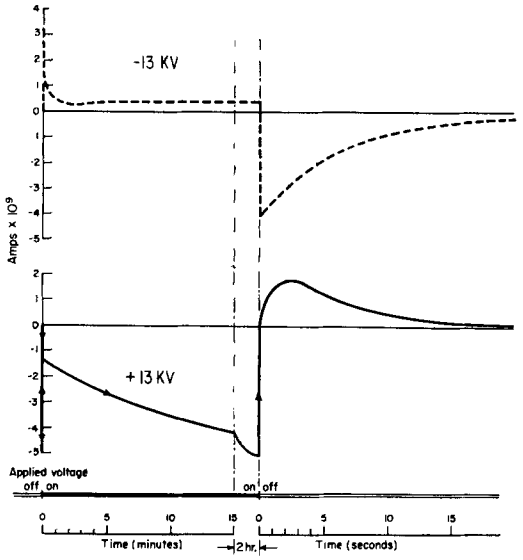

Fig. 7. Polarization and depolarization currents for both polarities.

with the results obtained by homogeneous heating of the whole cell. Table I shows the initial current drop in its relation to the wire temperature.

Polarization Currents

The cell generates a slowly decaying depolarization current when the applied voltage is removed after a steady state is reached. However, as Fig. 7 shows, the initial rise of this current is polarity dependent. When the applied voltage is restored, the current, after an initial jump, slowly recovers its initial value. It should be noted that i_+ increases significantly with time.

Discussion

The significant facts are: above a certain applied voltage, a residual current can be measured for both polarities. The current-voltage characteristics for i_+ and i_-, while of similar shape, vary oppositely when temperature is changed. The ratio i_+/i_-, of the order of 10 at 20°C, approaches unity around 50°C.

A detailed analysis, due to Onsager (7), of the influence of an external field E on the dissociation constant K of a weak electrolyte shows that for the high-field limit,

$$K(E) = K(O)\ (2/\pi)^{1/2}\ (8b)^{-3/4} \exp \sqrt{8b} \qquad [1]$$

where $8b = 77.2\ E/\kappa T^2$.

Table I. Initial current drop through the cell upon heating of the wire

Voltage across the wire, v	Current in wire, ma	Resistance of wire, ohm	Temperature at wire surface, °C*	Initial current drop through cell, %
0	0	13.40†	20.5 (R.T.)	0
1.5	102.5	14.65	38.7	7
3.0	189	15.90	64.0	12-22
4.5	260	17.30	77.5	18-22
5.95	318	18.75	97	27-30

* Calculated from the formula $R_T = 0.725\ R_{20.5}\ (1 + \alpha T)/(1 + \alpha \times 20.5)$. The factor 0.725 accounts for the difference between the temperature of the wire at its periphery and its average temperature. It was estimated from the fact that boiling started when the average temperature was about 135°C.

† Obtained by graphical extrapolation for zero current.

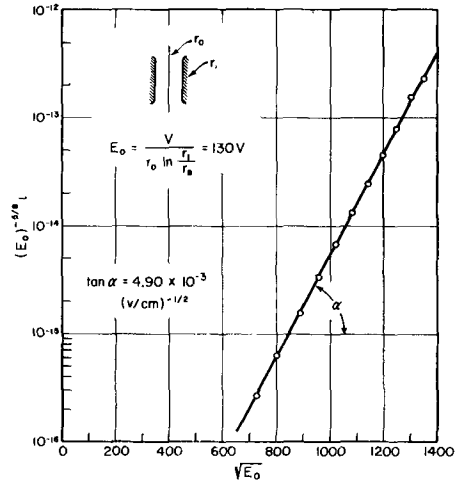

Fig. 8. Final characteristics of Fig. 3 (wire positive), plotted for a check of Onsager's theory.

Assuming that the dissociation products of both signs contribute equally to the current and that the mobility of the carriers does not vary in the field range of interest, the current is expected to vary with the field as $E\sqrt{K(E)}$, i.e. (in hexane at room temperature, $8b = 4.5 \times 10^{-4} E$), as

$$i \propto E^{5/8}\, 10^{1.6 \times 10^{-3} \sqrt{E}} \qquad [2]$$

In fact, if the residual characteristic for positive wire (cf. Fig. 3) is replotted on a log scale (Fig. 8) as $iE^{-5/8}$ vs. $\sqrt{E}$, the points fall on a straight line of angular coefficient 4.0×10^{-3}, as compared with the theoretical value of 4.6×10^{-3}. [5]

In view of the approximations involved in Eq. [1] and of the presence of the space charge which may distort the field at the wire, the agreement can be considered very good and strongly indicates that the carriers are created primarily by field ionization of impurities near the wire. Furthermore, the results obtained by other workers [in particular by House (6)] with more homogeneous field are consistent with this model. However, this mechanism fails to predict the temperature dependence of the residual current, in particular the effect of polarity (cf. Fig. 5). Since the polarization and depolarization currents (Fig. 7) suggest the presence of a different kind of space-charge for each polarity, it is logical to investigate whether the polarity effect can be ascribed to space-charge phenomena.

Let us call E_w^0 the field at the wire surface in the absence of space charge, and E_w^+ and E_w^- the actual field strengths at the wire positive and negative, respectively. If the wire is positive, a negative ionic space charge builds up at the wire surface, and $E_w^+ > E_w^0$ (Fig. 9). For increasing temperature the space charge expands by diffusion, hence E_w^+ decreases. For wire negative, field emission can occur. [6]

[5] The "effective radius" of the cell, defined as

$$\bar{r} = \int_{r_{in}}^{r_{out}} \left\{K[E(r)]\right\}^{1/2} r\,dr \Big/ \int_{r_{in}}^{r_{out}} \left\{K[E(r)]\right\}^{1/2} dr$$

with $E(r) = V/[r \ln(r_{out}/r_{in})]$ and $V = 9000$ v, has been calculated and found to be about twice the radius of the wire. Hence, no error in order of magnitude is made by using the geometric field $E(r_{in})$ in the plot of Fig. 7.

[6] E_w^0 is of the order of 10^6 v/cm for 8 to 10 kv applied. Surface irregularities make the field locally higher; furthermore, the potential barrier at the electrode is decreased by the dielectric.

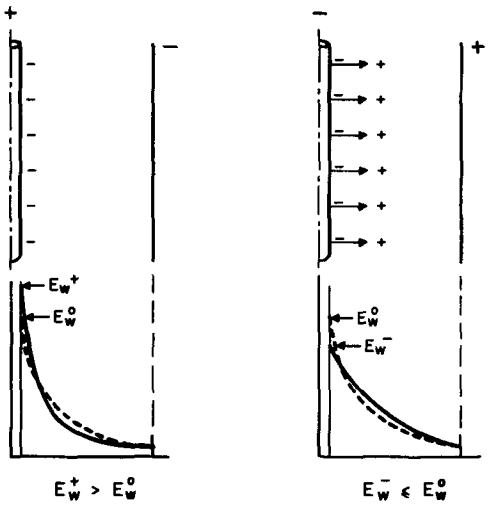

Fig. 9. Hypothetical model for the field distribution under both polarities (schematic).

The emitted electrons trapped by the liquid create a negative space charge, so that $E_w^- \leqq E_w^0$; as temperature increases, the space charge expands and E_w^- increases.

The inequality $E_w^- \leqq E_w^0 < E_w^+$ predicts the relative value of the current for both polarities, and the fact that E_w^- and E_w^+ become closer to E_w^0 as temperature increases is also in agreement with the observed temperature dependence.

To summarize, some evidence is given that the carriers are produced by field-induced dissociation and that the polarity dependence indirectly results from the fact that field emission is possible when the wire is negative. The species that dissociate under high field, the mobility of the charge carriers, and other problems of detail remain to be investigated. Experiments with other liquids and over a wider temperature range should help in clarifying the situation.

Acknowledgments

The authors are deeply grateful to Professor A. R. von Hippel for valuable discussions which contributed to the interpretation of the results, and to Mr. J. Kalnajs of this laboratory for his unfailing help in the realization of the experiment.

Manuscript received Sept. 16, 1959. This paper was prepared for delivery before the Philadelphia Meeting, May 3-7, 1959. Work on this paper was sponsored by the U.S. Office of Naval Research, Army Signal Corps, Air Force, and Atomic Energy Commission.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Silicon Nitride Thin Film Dielectric

Charles R. Barnes and Charles R. Geesner

Electronic Technology Laboratory, Wright Air Development Center, Wright-Patterson Air Force Base, Ohio

ABSTRACT

Thin adherent nonporous films of pure silicon nitride have been deposited from the vapor phase on hot molybdenum substrates by pyrolytic deposition. Such films, when incorporated between molybdenum plates to form capacitors, were found to maintain satisfactory dielectric properties up to and above 600°C. Silicon nitride coatings, deposited by the method herein described, also offer a convenient and effective method of encapsulation for protecting metal surfaces from atmospheric oxidation up to and above 1000°C.

As a result of the need for high temperature resistant electronic materials and miniaturized electronic equipment for use in space vehicles and satellites, thin films of silicon nitride were deposited pyrolytically and developed as a new dielectric material for capacitors capable of operating satisfactorily up to and above 600°C.

Pyrolytic deposition may be defined to include the following three chemical processes of deposition of materials on the surface of hot substrates: (*a*) the thermochemical decomposition of a properly selected chemical compound existing in the vapor state, (*b*) the reaction between two or more chemical vapors at the hot surface, and (*c*) the reaction of a vapor with the hot substrate itself. In the present case a process like (*b*) above was used.

The literature shows no record of the use of thin adherent nonporous films of pure silicon nitride as a dielectric for capacitors capable of satisfactory operation at 600°C. From the thermodynamic data of Kellogg (1), Brewer, Bromley, Gilles, and Lofgren (2), Powell (3) in a search for high-temperature protective coatings for metals predicted that silicon nitride might be vapor plated by means of the reaction of the combined vapors of silicon tetrachloride, hydrogen, and nitrogen at a substrate temperature of 1000°-1600°C. Powell further states that the probable deposit would be composed of a mixture of elemental silicon and silicon nitride.

In the present investigation it was imperative that a high temperature resistant dielectric material should not only be of high purity but should be pore-free in order to function properly in a thin film capacitor. To prevent the formation of pores in the deposit and to obtain a pure silicon nitride film the following precautions and requirements were adopted: (*a*) The metal substrate surface must be smooth and thoroughly cleansed. (*b*) Its temperature must be accurately controlled during the deposition. (*c*) A volatile silicon compound is required, such as silicon tetrabromide, capable of being relatively easily reduced to silicon which should react with nitrogen at temperatures below 1000°C to form pure Si_3N_4. (*d*) The reactant carrier gases, hydrogen and nitrogen, must be thoroughly purged of water vapor and oxygen.

Deposition of Silicon Nitride Dielectric

The silicon nitride dielectric films were deposited on smooth polished molybdenum disks 1 in. in diameter and 0.005 in. thick by means of the apparatus shown in Fig. 1. Before introducing the molybdenum disk into the plating apparatus, its surface is cleaned in succession with acetone, a hot water solution of sodium hydroxide, hot chromic acid, distilled water, and finally wiped dry with a fine clean grade of untreated tissue paper. The disk is then placed on the graphite core of the plating chamber (G), heated to the desired temperatures to be discussed later, deoxidized with hydrogen, and finally plated with silicon nitride dielectric.

In the actual plating process for silicon nitride dielectric illustrated in Fig. 1, commercial grades of hydrogen and nitrogen are allowed to flow through calibrated flowmeters (A) at the following flow rates expressed in milliliters per minute: 300 for hydrogen and 1100 for nitrogen. Both hydrogen and nitrogen gases then pass through deoxidizing units (B) and (C), respectively, for the purpose of removing con-

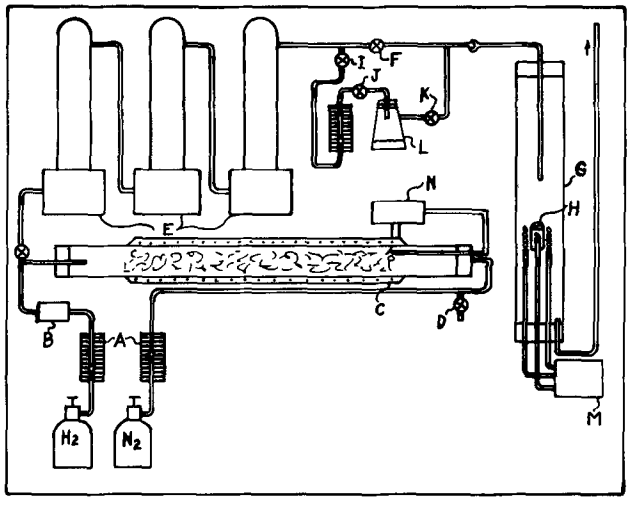

Fig. 1. Apparatus for depositing silicon nitride: (A) Flowmeters for hydrogen and nitrogen; (B) and (C) deoxidizers; (D) back-flush valve; (E) calcium hydride drying towers; (F), (I), (J), and (K) vapor control valves; (G) deposition chamber; (H) substrate; (L) silicon bromide evaporator; (M) induction heater with temperature controller; (N) deoxidizer temperature control.

taminating oxygen. For the hydrogen purification a Baker and Company Deoxo unit Model D is employed. The nitrogen gas is purified by passing over copper turnings maintained at a temperature of 750°C. The advantage of using a separate deoxidizing unit for the nitrogen is that the copper can be reactivated between runs by back flushing hydrogen through the hot oxidized copper turnings. As a result, a large quantity of water is removed from the system through outlet valve (D). This water would otherwise rapidly consume the drying agent in subsequent drying towers (E). The hydrogen and nitrogen both flow together through three drying towers each of which contains a bed of —4 to 40 mesh calcium hydride that is 7 in. in depth and 2 in. in diameter. The mixed purified carrier gases then flow through valve (F) and enter the plating chamber (G) through Vycor nozzle. Thus the carrier gases blow directly on the clean molybdenum disk substrate, the upper surface of which is maintained at a temperature of 960° ±2°C as measured by an optical pyrometer. The source of heat is a 7.5 kw induction heater whose water-cooled coils surround a cylindrical graphite core. By induction the graphite core is heated to approximately 1000°C which in turn heats the molybdenum disk substrate (H) resting on top. Finally the exhaust gases leave the heating chamber through the exhaust stack.

In starting the plating operation the carrier gases are allowed to flow until all air and moisture are flushed from the plating chamber. The induction heater is turned on and the temperature of the substrate raised to and maintained at 600°C for 10 min during which time the nitrogen flow is turned down to a trickle and hydrogen valve is opened to allow a flow of 1000 ml/min. The purpose of this short operation is to deoxidize and clean the substrate surface with hydrogen.

After the above purging operation the hydrogen and nitrogen flow rates are readjusted to 300 and 1100 ml/min, respectively, and the gas flow allowed to continue until equilibrium of the gas mixture is established in the Pyrex glass plating chamber. The temperatures of the graphite core and molybdenum disk are then increased until a substrate surface temperature of 960° ± 2°C is reached and maintained. To start the deposition of silicon nitride on the substrate, valves (I), (J), and (K) are opened and valve (F) is partially closed. By manipulation of valves (F) and (I) simultaneously the amount of carrier gas by-passed through the silicon bromide evaporator (L) is adjusted to 100 ml/min. As the gas mixture passes over the surface of the liquid, silicon bromide vapor is picked up and blown directly on the molybdenum disk substrate which is located 4¼ in. from the nozzle. Subsequently a deposit of silicon nitride (Si_3N_4) appears immediately on the molybdenum substrate discernible only by the moving rainbow formations which continue to grow as the deposition progresses. After continuing the deposition process for 1 hr, a silicon nitride dielectric film of 0.5 mil approximate thickness has grown on the molybdenum substrate. Finally, after turning off the silicon bromide vapor flow and in a few minutes shutting down the heater, the substrate with deposited film is allowed to cool and may be removed.

Although experiment showed that silicon nitride films can be deposited over a temperature span of 930°-1000°C, the best quality dielectric films were obtained at a substrate surface temperature of 960°C. These were smooth, clear, transparent, colorless, very adherent, free of pores, and suitable for capacitor construction. It was further determined that, by increasing the flow-rate of the carrier gases and silicon tetrabromide vapor, the deposition rate can also be increased. However, the best quality dielectric films were those which required at least 1 hr to obtain a thickness of 0.4-0.6 mil.

Construction of Silicon Nitride Capacitor

In order to measure the dielectric properties of silicon nitride a number of thin film capacitors were constructed and tested utilizing the dielectric films deposited on molybdenum disks as described above.

Before constructing the capacitor the molybdenum disk with a dielectric film of silicon nitride 0.5 mil thick on one side is turned over and plated on the opposite side with a coating of silicon nitride 0.3 mil thick which serves to encapsulate the molybdenum plate after it is incorporated in a capacitor.

Thickness of the films were measured by a metallurgical microscope with a mechanical stage graduated with one scale division equal to 1 μ of stage movement.

To construct the capacitor, a thin film of molybdenum of 0.5 mil thickness is plated on the silicon nitride dielectric which was previously deposited on the molybdenum substrate. As a source of molybdenum its pentachloride vapor carried by hydrogen gas to the substrate is employed, a procedure recommended by Powell (4). In the present case the apparatus of Fig. 1 is modified by removing the head assembly of the plating chamber and replacing with another (not shown) which contains an evaporator for furnishing molybdenum pentachloride vapor at a temperature of 195°C to the hydrogen carrier gas blowing at 1000 ml/min. The silicon nitride substrate surface temperature is 800°C. Five minutes are required to deposit a molybdenum film of 0.5 mil thickness. After cooling and removing the capacitor from the plating chamber the edge of the molybdenum film is etched back from the outer circumference for a distance of 1/32 in. Also a spot is etched away where it is desired to scratch through the silicon nitride dielectric in order to solder a lead to the base plate.

Platinum wire leads are then soldered with metallic gold, one to the molybdenum base plate and the other to the molybdenum film. To accomplish the gold soldering the capacitor is placed in the plating chamber and platinum wire leads are supported in such a manner that one tip of each rests against the bare molybdenum and adjacent to a tiny bead of gold placed at the attachment areas. Soldering is then accomplished in an atmosphere of hydrogen by heating the whole capacitor to the fluxing temperature of gold.

After the leads are attached the capacitor remains in the plating chamber and a final encapsulating film

Table I. Dielectric properties of silicon nitride

of silicon nitride 0.3 mil thick is plated over the molybdenum film and the attachment areas of the leads. The construction of an encapsulated high temperature thin film silicon nitride capacitor is now complete.

Summary of Dielectric Properties of Silicon Nitride

Several of the capacitors were recycled stepwise three times in a muffle furnace over a temperature range of 25°-600°C. Each capacitor was supported by two Vycor tubes through which the leads were passed. The tubes extended separately from the capacitor in the furnace through the port hole to the outside without touching each other or the walls of the furnace. Representative results of the temperature exposures up to 600°C are presented in Table I. Furthermore it is interesting to note that in one case a capacitor was heated to 1000°C in a flame without damage.

Manuscript received Sept. 18, 1959.

Tin-Activated Calcium Orthosilicate Phosphors

Richard W. Mooney

Chemical and Metallurgical Division, Sylvania Electric Products Inc., Towanda, Pennsylvania

ABSTRACT

A study of the tin-activated calcium orthosilicates disclosed two phosphors: a blue-emitting phosphor with a very broad excitation band having the β-Ca_2SiO_4 structure and a yellow-emitting phosphor with fair response to high-pressure mercury-vapor radiation having the α'-Ca_2SiO_4 structure. The β-Ca_2SiO_4: Sn phosphor is the more efficient of the two, comparing very favorably with other well-known blue phosphors. The efficiency of β-Ca_2SiO_4: Sn was studied as a function of activator concentration and compared with similar results for β-$CaSiO_3$: Sn. The difference in behavior between β-Ca_2SiO_4: Sn and β-$CaSiO_3$: Sn is attributed to differences in crystal structure.

The orthosilicates of calcium having the composition $2CaO \cdot SiO_2$ or Ca_2SiO_4 have been the subject of many investigations, since they are found commonly in blast furnace and open-hearth slags and used extensively in Portland cement and certain types of refractories. The present ideas on the chemistry and crystallography of dicalcium orthosilicate began in 1943 with the work of Bredig (1) whose ideas since have been confirmed and extended by many authors (2-6). It is now generally accepted that dicalcium orthosilicate occurs in four polymorphic modifications: namely, an alpha (α) or high-temperature modification stable above 1450°C; an alpha prime (α') modification occurring between 850° and 1450°C; a beta (β) modification, metastable at room temperature; and a gamma (γ) modification, which is stable at room temperature. The γ-, β-, and α'-modifications are found in nature and have the mineralogical names: calcio-olivine, larnite, and bredigite, respectively. It has been shown also that the additions of small amounts of many of the common oxides change the temperatures of both the α-β and the β-γ inversions, resulting in some cases in the stabilization of high-temperature forms (7, 8). For instance, less than 0.2 mole % of Na_2O will inhibit the β-γ transformation (9). Thus the specific crystallographic species formed by high-temperature solid-state reaction will be determined not only by the temperature of firing, but also by the particular modifying compounds present.

The only calcium orthosilicate phosphor previously reported was β-Ca_2SiO_4: Pb which, according to Studer and Fonda (10), emits at 334 mμ under 254 mμ excitation. The present investigation was undertaken as part of a general study of the tin-activated calcium silicates. The preparation and optical properties of the tin-activated calcium metasilicates were reported in a previous paper (11) while this paper gives corresponding data on the calcium orthosilicates activated by tin.

Experimental Procedure

Calcium carbonate and silicic acid were mixed in mole ratios which varied from 2CaO/0.95 SiO_2 to 2CaO/1.50 SiO_2 with 0.01-10.0 mole % of stannic or stannous oxide. The mixture was pebble-milled in a deionized water slurry, dried at 110°-120°C, and fired in silica trays at temperatures varying from 870°-1320°C. For maximum efficiency it was necessary to fire in a steam atmosphere, and since tin-activated phosphors luminesce only when the tin is in a lower valence state, a reducing atmosphere, usually a mixture of hydrogen, nitrogen, and steam, was maintained. All gas flows were controlled carefully in order to obtain reproducible results with optimum efficiencies being obtained at a nitrogen to hydrogen ratio of approximately unity.

The methods used for structure identification by x-ray diffraction, measurement of excitation and emission spectra, and determination of per cent tin by quantitative analyses were the same as those previously reported (11). In this paper the activator contents are expressed as gram-atom tin per gram-atom of calcium in the fired phosphor.

Relative efficiency measurments under 254 mμ excitation were made on a plaque tester of conventional design (12). Efficiency measurements under high-pressure mercury-vapor (HPMV) excitation were made on a similar instrument using as sources two General Electric C85H3 lamps with ultraviolet-transmitting envelopes. The predominant wave lengths present in the HPMV source were 313 and 365 mμ. The instrument was so constructed that efficiencies of various phosphors could be compared at room temperature, or the temperature dependence of fluorescence of a sample could be measured by raising the temperature of the sample at a constant heating rate of approximately 2°C/min. The output of a 1P21 photomultiplier detector was amplified by a Photovolt Model 520-M unit and fed into the Y-axis of a Mosely Autograf X-Y recorder. The signal from a chromel-alumel thermocouple imbedded in the phosphor sample was fed to the X-axis, thus giving a continuous plot of efficiency vs. temperature for a particular sample.

Results with β-Ca_2SiO_4:Sn

A deep blue-emitting phosphor having the β-Ca_2SiO_4 structure was formed over wide temperature and composition limits with temperatures between 1150° and 1230°C and compositions between 2.0 CaO/1.00 SiO_2 and 2.0 CaO/1.10 SiO_2 giving the best results. There was no evidence in any of the firings of the presence of γ-Ca_2SiO_4. The most efficient phosphors were produced at a SiO_2 content

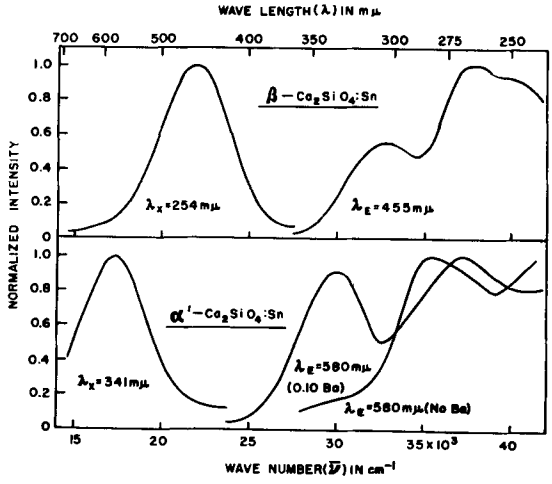

Fig. 1. Excitation and emission spectra of β-Ca_2SiO_4:0.003 Sn and α'-Ca_2SiO_4:0.003 Sn.

that gave a slight excess of SiO_2 over the theoretical Ca_2SiO_4 composition. The presence of a slight excess of CaO was extremely deleterious to phosphor brightness.

The excitation and emission spectra of β-Ca_2SiO_4:Sn are shown in the top half of Fig. 1. The emission spectrum consists of a single band peaking at 22,000 cm^{-1} or 455 mμ regardless of the energy of excitation. The excitation spectrum is broad, giving efficient excitation by both 254 mμ and HPMV radiation. The brightness of β-Ca_2SiO_4 compares very favorably with that of other blue-emitting phosphors. For instance, with 254 mμ excitation β-Ca_2SiO_4: 0.003 Sn is 25% brighter than $Sr_2P_2O_7$: Sn, which has its peak emission at 452 mμ, and under HPMV excitation it is 15% brighter than magnesium tungstate. Both comparisons were made at room temperature.

Results with α'-Ca_2SiO_4:Sn

As the firing temperature exceeded 1200°C for phosphors having a composition close to the theoretical Ca_2SiO_4 composition, there was a gradual decrease in blue emission and an equally gradual increase in yellow emission. This effect was most pronounced as the composition approached the Ca_2SiO_4 stoichiometric formulation and decreased as the excess SiO_2 increased. Concurrent with the shift in emission, there occurred a corresponding shift in the excitation spectrum with the yellow component being excited more easily by HPMV radiation than by 254 μ excitation. The yellow-emitting phosphor was identified by x-ray diffraction as α'-Ca_2SiO_4: Sn with emission and excitation spectra as given in the bottom half of Fig. 1.

The emission is dependent on the wave length of excitation, giving a single band at 17,300 cm^{-1} (578 mμ) when excited by 341 mμ. As the energy of the exciting wave length is increased, the position of the main emission band shifts from 578 mμ under 341 mμ excitation to 559 mμ under 268 mμ excitation, and in addition a very weak emission band develops at about 370 mμ. From the excitation data it is apparent that the intensity of the band in the neighborhood of 570 mμ is greatest at the peak in the excitation curve, i.e., under 285 mμ radiation.

It was also found that the substitution of small amounts of Mg, Zn, Sr, or Ba, in the range 0.10 gram-atom of modifying Group II metal, for an equivalent amount of Ca in the calcium orthosilicate formulation tended to promote the transition to the yellow-emitting α'-Ca_2SiO_4:Sn. A comparison of the results showed that the greater the difference in ionic size between calcium and the modifying cation, the greater the effect, i.e., barium and magnesium were more efficient in promoting the transition than zinc or strontium while cadmium had little, if any, effect. The most efficient yellow-emitting phosphor having the α'-Ca_2SiO_4 structure had the composition $Ca_{1.92}Ba_{0.08}SiO_4$:0.003 Sn. The excitation spectrum of the Ba-modified α'-Ca_2SiO_4:Sn phosphor as shown in the bottom half of Fig. 1 is very different from the unmodified sample as evidenced by the strong absorption of radiation at about 30,000 cm^{-1} (333 mμ) caused by the addition of barium. The addition of small amounts of alkali metals as, for example, 0.013 gram-mole of Li_2CO_3 to a Ba-modified Ca_2SiO_4:Sn phosphor was also effective in increasing the efficiency to HPMV radiation by increasing the absorption of 30,000 cm^{-1} radiation still further. Calcium orthosilicate phosphors fired at 1316°C displayed no evidence of fusion even in the presence of well-known fluxes such as Li_2CO_3 or $BaCO_3$.

Effect of Activator Concentration on β-Ca_2SiO_4:Sn

The effect of activator concentration, expressed as atom Sn found in the fired phosphor per atom Ca, on the relative efficiency of β-Ca_2SiO_4:Sn was studied and compared to similar results on the more efficient of the tin-activated calcium metasilicates, namely, β-$CaSiO_3$:Sn. The results for 254 mμ excitation for both β-Ca_2SiO_4:Sn and β-$CaSiO_3$:Sn are shown in the top half of Fig. 2. The normalized efficiency data were fitted to the equation

$$\eta = \frac{c(1-c)^z}{c + (\sigma/\sigma')(1-c)}$$

where η is the relative efficiency, c is the activator concentration in atom Sn per atom Ca, and Z and σ/σ' are adjustable parameters (13). The parameter σ/σ' is the ratio of the capture cross sections of non-activators to the capture cross sections of luminescent activators, while the parameter Z is defined as the number of lattice positions surrounding a given activator such that, if any one of these sites is occupied by another activator, luminescence is quenched. The efficiency of β-Ca_2SiO_4:Sn is relatively insensitive to activator concentration over the range 0.001-0.020 atom Sn/atom Ca for 254 mμ excitation, whereas the efficiency of β-$CaSiO_3$:Sn is sharply peaked at an activator concentration of about 0.001 atom Sn/atom Ca. The ratio of the capture cross section of nonactivators to activators is approximately constant for both phosphors, whereas Z increases by a factor of six in going from 10 for β-Ca_2SiO_4:Sn to 60 for β-$CaSiO_3$:Sn.

Since β-Ca_2SiO_4:Sn is also excited by HPMV radiation, the effect of activator concentration on the HPMV response was also studied, with results as given in the bottom half of Fig. 2. The efficiencies at elevated temperatures were calculated from the

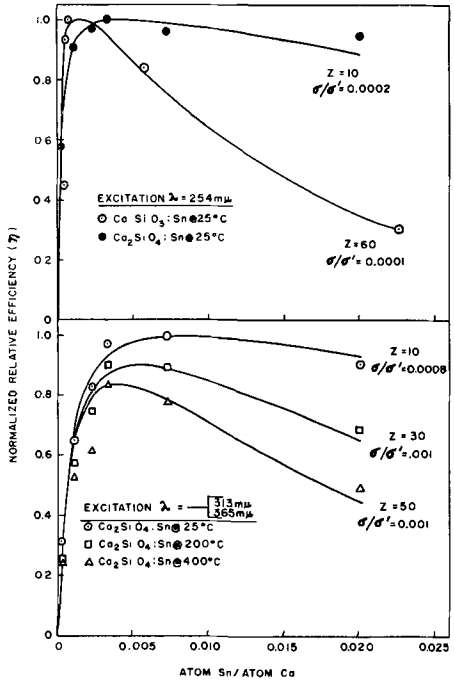

Fig. 2. Relative efficiency vs. activator concentration for β-Ca_2SiO_4:Sn with ultraviolet excitation.

room-temperature efficiencies and measurements of the temperature dependence of fluorescence. The β-Ca_2SiO_4:Sn phosphors showed a gradual decrease in efficiency with temperature with the phosphor having the highest tin concentration giving the greatest drop in efficiency. Since the decrease in brightness is very gradual, the error due to non-equilibrium measurements should be negligible. As would be expected the maximum in the plot of efficiency vs. activator content shifts to lower activator concentrations with increasing temperature.

Values of Z and σ/σ' for β-Ca_2SiO_4:Sn at 25°, 200°, and 400°C were calculated. The σ/σ' values for all three temperatures were approximately equal, i.e., about 0.001 or an order of magnitude greater than the σ/σ' values for 254 mμ excitation. The Z value found was the same at room temperature for low and HPMV excitation, but increased from 10 at room temperature to 50 at 400°C for HPMV excitation.

It is interesting that most of the tin added to the phosphor mix is lost during the firing process. Thus, for β-Ca_2SiO_4:Sn, 44% of the original tin present is retained at the lowest activator concentration. This amount decreases to a value of 13% in the neighborhood of the optimum activator concentration and then increases rapidly again to 40% for 0.10 gram-atom Sn added per gram-mole of Ca_2SiO_4. The per cent tin retained in β-$CaSiO_3$:Sn goes through a similar minimum starting at 45%, decreasing to a minimum of 2.5%, and increasing again to 42%.

Discussion

The predominance of the β-Ca_2SiO_4 structure and the complete lack of any evidence of the γ-Ca_2SiO_4 structure in the Ca_2SiO_4:Sn phosphors indicate that tin has a strong stabilizing effect on the metastable β-Ca_2SiO_4 crystal lattice. Another stabilizing influence on the β-Ca_2SiO_4 structure might be the small

particle size since Guinier and Yannaguis (5) found that, with crystals less than 10 μ in size, the β-phase only was stable. At very high temperature it is necessary to introduce a distorting cation whose radius is markedly different from that of calcium in order to promote the β-α' transition and stabilize the α'-structure at room temperature. The necessity of a slight excess of SiO_2 over the Ca_2SiO_4 composition for optimum efficiency is generally accepted in phosphor technology as is the use of reducing atmospheres for the firing of tin-activated phosphors.

It is interesting to compare the σ/σ' and Z values obtained on β-Ca_2SiO_4:Sn and β-$CaSiO_3$:Sn with those of another tin-activated phosphor, namely $Sr_{2.65}Zn_{0.20}(PO_4)_2$:Sn, recently studied (14). For 254 mμ excitation at room temperature, the σ/σ' values are all approximately constant, varying from 0.0001 and 0.0002 for the tin-activated silicates to 0.0005 for the tin-activated phosphate. The Z values of 10 and 60 for the silicates are higher than the previous $Z = 1$ value for the above phosphate, although a strict comparison of these figures is not entirely valid, since in the previous paper (14) the activator concentrations were expressed in terms of the unfired mix, whereas in the present paper they are given in terms of the tin actually present in the phosphor after firing. The latter method is much to be preferred due to the large and variable loss of tin during firing.

A comparison of the response of β-Ca_2SiO_4:Sn with $Sr_{2.65}Zn_{0.20}(PO_4)_2$: Sn under HPMV excitation gives similar results. Thus, σ/σ' is not changed very much, being in the neighborhood of 0.001 for the tin-activated silicates and varying with temperature from 0.003 to 0.005 for the tin-activated phosphate. The increase in Z with temperature is according to expectation, and at elevated temperatures there is good correlation between the Z value for $Sr_{2.65}Zn_{0.20}(PO_4)_2$:Sn of 36 at 377°C and the values of 30 and 50 for temperatures of 200° and 400°C, respectively, for β-Ca_2SiO_4:Sn.

Generalizing these results, it would appear that the ratio of the capture cross section of nonactivators to luminescent activators is relatively unaffected by environment, being a function largely of the activator itself and the energy of the exciting radiation. However, the parameter Z, which is related to the number of neighboring sites occupied sufficient to cause concentration quenching, is a function of the phosphor matrix.

More specifically, why is β-$CaSiO_3$:Sn with a Z value of 60 much more sensitive to activator concentration than is β-Ca_2SiO_4:Sn with a Z value of 10. One possible explanation for the difference lies in the fundamental difference in structure between wollastonite (β-$CaSiO_3$) and larnite (β-Ca_2SiO_4). Thus the structure of larnite has been shown by Midgley (15) to consist of isolated SiO_4 tetrahedra and Ca ions. On the other hand, the wollastonite structure has recently been reinvestigated (16, 17) and found to consist of infinite chains of Si_6O_{17} radicals arranged along endless columns of Ca-octahedra. Thus the activator sites in wollastonite, assuming isomorphous replacement of calcium by tin, are found in these Ca-octahedra columns, whereas the sites in β-Ca_2SiO_4:Sn are more or less randomly distributed among the isolated calcium sites in the crystal. It is proposed that the association of the activator sites by this column-type structure leads to a greater interaction between neighboring activators and therefore a greater sensitivity to concentration quenching as evidenced by a Z value of 60 for β-$CaSiO_3$:Sn vs. a Z value of 10 for β-Ca_2SiO_4:Sn.

The appreciable loss of tin during firing is undoubtedly explained by the work of Platteeuw and Meyer (18) who showed that at high temperatures SnO is a stable gas with an appreciable vapor pressure. The presence of H_2 in the gas mixture would undoubtedly favor the formation of SnO and thus lead to its subsequent dispersal through the system and partial loss to the surroundings. The presence of the activator in the vapor state might also explain the generally high efficiencies of tin-activated phosphors due to uniform incorporation in the lattice. The increase in the tin retained at the higher concentrations is evidently due to the inability of the phosphor to rid itself of excess tin during the period of firing used.

An analysis of the spectra of the Sn-activated calcium orthosilicates is considerably more difficult than that for the metasilicates. Studer and Fonda (10) found one emission band at 334 mμ for β-Ca_2SiO_4:Pb. However, recent measurements in this laboratory indicate that there are at least four emission bands with a corresponding number of excitation bands. As a consequence, it is completely impossible to relate the excitation or emission bands in β-Ca_2SiO_4:Sn to those in β-Ca_2SiO_4:Pb at this time.

Acknowledgment

The author is indebted to several of his colleagues for their help with the preparations and measurements. Specifically, he wishes to thank Dr. C. W. W. Hoffman for the x-ray identifications and Mr. G. J. Meisenhelter for the analytical determinations. The author also wishes to acknowledge the advice and encouragement of Dr. J. S. Smith during the progress of this work.

Manuscript received Aug. 26, 1959. This paper was prepared for delivery before the Philadelphia Meeting, May 3-7, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Luminescent Properties of Silver-Activated Magnesium Borate Phosphors

Yasuo Uehara, Yoshimasa Kobuke, and Isoo Masuda

Matsuda Research Laboratory, Tokyo Shibaura Electric Co., Ltd., Kawasaki, Japan

ABSTRACT

Silver-activated magnesium borate phosphors are extremely sensitive to reducing agents in the presence of water or moist air. With progressive reduction, the color of fluorescence turns from bluish white to green, yellow, orange, and red under excitation by 3650Å. At the same time the color of the phosphor powders changes from white to gray or black. Similar properties were found in some other crystals containing Ag. The characteristics of these phosphors show some similarities with photographic materials.

The fluorescence due to atomic silver in glasses and crystals containing silver has already been reported by Weyl and others (1). Reduction of the silver ions in these substances was effected by means of hydrogen, electron bombardment, and exposure to x- or γ-rays. It was found by the present authors that Ag-activated magnesium borate can be reduced by common reducing agents in the form of solutions and thus be made strongly fluorescent. These phosphors are extremely sensitive to reducing agents, and their fluorescence color under excitation by 3650Å radiation varies from an original whitish blue to orange or red with increasing degree of reduction; eventually they become nonfluorescent and dark gray. These phosphors are of interest in providing an analogy to photographic processes.

Preparation of Phosphor

Silver-activated magnesium borate phosphors of various compositions were prepared by firing mixtures of purified boric acid (H_3BO_3), basic magnesium carbonate ($3MgCO_3 \cdot MgO \cdot 4H_2O$), and silver nitrate with or without added aluminum hydroxide, for two 0.5 or 1 hr periods at 950°C. The initial firing was always made in air, and the second firing was carried out in various atmospheres, such as in air, oxygen, or nitrogen, after an intimate grinding between firings. Pure magnesium borates without added impurities were also prepared by the same method. The compositions studied were as follows: boric acid, 2 moles; basic magnesium carbonate, 0.5, 0.375, 0.25, and 0.125 moles; silver nitrate, $0\text{-}2\times10^{-2}$ moles; and aluminum hydroxide, $0\text{-}5\times10^{-2}$ moles. Furthermore, magnesium borates of composition $MgO \cdot B_2O_3$ containing 1 mole % Cu, Li, Be, Hg, Al, La, Tl, Ti, Ge, Zr, Sn, Pb, V, As, Sb, Bi, Se, Mn, Ce, Sm, U, and Th were prepared by the same method, except for phosphors with Ce and Sn which were fired in air or in a reducing atmosphere in the second heat treatment.

Reduction of phosphors.—A small amount of the phosphor is placed in a glass dish and wetted with an extremely dilute solution of a reducing agent. For most of the experiments, $10^{-5}N$ sodium sulfite ($Na_2SO_3 \cdot 7H_2O$) solution or the solution prepared by dissolving 1 cc Elon-Hydroquinon Borax (D-76) developer in 100 liters of water were used as reducing agents. With these dilute solutions of reducing agents, the fluorescence color of Ag-activated phosphors changes from an original whitish blue to green, yellow, orange, or red within a few minutes, while with concentrated solutions of reducing agents, such as D-76 developer itself, the phosphors turn into nonfluorescent black powders. On the other hand, pure magnesium borates of various compositions remained unchanged by the same reducing agents.

Filter paper or common white paper can also be used as convenient reducing agents. If a small amount of the dry phosphor powders is spread on a sheet of dry white paper in a layer of a few millimeter thickness, the reduction of the phosphor due to traces of reducing agents such as sulfite, which may be originally contained in the paper, occurs gradually and progresses from the interface between powder layer and paper to the upper layer of the powders. For example, the bluish white fluorescing phosphor spread on a sheet of paper turned completely into a green fluorescent phosphor during a few hours in air of about 70% relative humidity at room temperature, while the sample spread in a clean glass dish and wetted with distillated water showed no change of fluorescence color for a long time.

If the phosphor is first placed on a sheet of paper for several tens of minutes and then stored in a clean glass bottle, it turns into the reduced phosphor during a few months' time. Indeed, a phosphor spread on a sheet of paper for 30 min and then stored in a bottle in the dark for about five years turned into a dark gray powder producing only extremely weak red fluorescence under excitation by 3650Å, while the same phosphor stored from the beginning in a clean glass bottle turned into a strongly green fluorescent powder during the same length of time. The speed of reduction of the phosphor depends on temperature and moisture, as well as on the concentration of reducing agents. If the phosphor on a sheet of paper is moistened with hot steam, the color of fluorescence under excitation by 3650Å changes from whitish blue to green, yellow, orange or red, and finally to reddish dark gray within a few minutes. For the measurements of the optical properties of the reduced phosphor, the sample reduced on paper in air at room temperature was used since it was difficult to stop the reduction at the desired stage with reducing solutions.

Silver-activated phosphors reduced by electron bombardment or by means of hydrogen diluted with nitrogen in a third heat treatment at temperatures from 100° to 200°C showed weak fluorescence of various colors depending on the degree of reduction. When these phosphors were exposed to 2537 or 3650Å radiation and x- or γ-rays for 1 hr at room temperature they showed no changes of fluorescence color.

Emission and reflection spectra.—The spectral distribution of fluorescence under excitation by 3650Å and that of reflection were measured at room temperature by the same method as reported in a previous paper (2).

Experimental Results

Emission Characteristics

Silver-activated magnesium borate phosphors of approximate composition $MgO \cdot B_2O_3$:Ag (10^{-2} mole) and prepared by firing in air show a weak whitish blue fluorescence under excitation by 2537 or 3650Å, but not under excitation by cathode rays. The detailed hue of color and the intensity of fluorescence fluctuate from sample to sample, even when they are prepared under as nearly identical conditions as possible. This fluctuation of the luminescent properties may be due to slight differences of the atmosphere during preparation. The phosphors prepared by firing in oxygen or nitrogen in the second heat treatment are similar to those prepared by firing in air. At liquid air temperature, all of these phosphors produce strong bluish green or green fluorescence under excitation by 2537Å and 3650Å. The fluorescence of Ag-activated phosphors with different mole ratios of $MgO:B_2O_3$ was similar in color to that of the phosphor mentioned above, but weak in intensity. Pure magnesium borate showed no fluorescence under excitation by ultraviolet or cathode rays at room or liquid air temperature.

Silver-activated phosphors treated with reducing agents show a strong fluorescence whose color varies from bluish green to dark red depending on the degree of reduction of the phosphor, but only under excitation by 3650Å. The brightest fluorescence after reduction was obtained when the composition was $MgO \cdot B_2O_3$:Ag ($1\text{-}2\times10^{-2}$ moles). The fluorescent intensity of the phosphors emitting green, yellow or orange fluorescence is comparable to that of Cu-activated zinc or zinc·cadmium sulfide phosphors under excitation by 3650Å. Since the body color of the phosphor powder deepens from white to black with increasing degree of reduction, the intensity of the emerging red fluorescence of the gray colored powder is weak. The fluorescent intensity of Ag-activated phosphors of different mole ratios of $MgO:B_2O_3$ is weak after treatment with reducing agents as before. Pure magnesium borate without added impurities shows no fluorescence at all after reduction by the same reducing agents.

Among magnesium borates containing various elements other than Ag, several phosphors such as the ones containing Mn (red fluorescence under excitation by 3650Å or cathode rays), Tl (weak blue, 2537Å), Sm (orange, cathode rays), Ce(Ce^{3+}: strong violet, 2537Å) and Sn(Sn^{2+}: weak yellow white, 2537Å), produced fluorescence, but none of these phosphors showed a change of fluorescence color after treatment with the same reducing agents as before. Phosphors with 1 mole % Ag and increasing amounts of Al from 0.1 to 5 mole % showed a decreasing sensitivity to reducing agents as the Al concentration was increased. Thus a sample with 0.1 mole % Al was still strongly green fluorescent after the reduction, while one with 1% Al was already very weak.

The fluorescent spectrum of the bluish green phosphor obtainable by slight reduction on paper is shown by curve 1 in Fig. 1. After the phosphor was allowed to stand in air for 3 hr at room temperature, it gave the fluorescent spectrum shown by curve 2. As seen in this diagram, the normalized fluorescent spectra consist of at least two main bands peaking at about 4200 and 5300Å. With increasing degree of reduction, the intensity of the blue band decreases, while that of the green band increases.

The fluorescent spectrum of the green phosphor, which was reduced on paper in air, is shown by curve 1 in Fig. 2. The peak position is at about 5200Å in approximate agreement with that of the green band

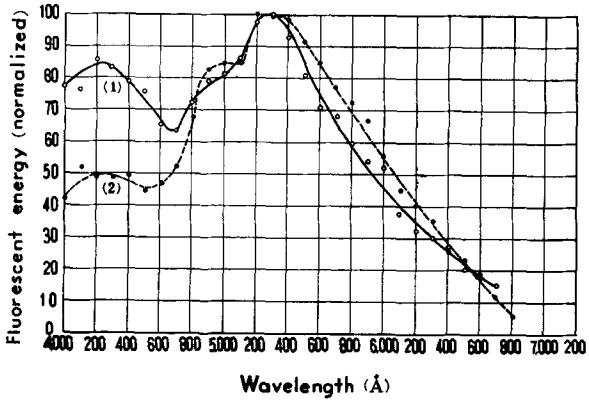

Fig. 1. Fluorescent spectrum of bluish white fluorescent magnesium borate phosphors with 1 mole % Ag, fired for two 0.5 hr periods at 950°C in air, under excitation by 3650Å at room temperature.

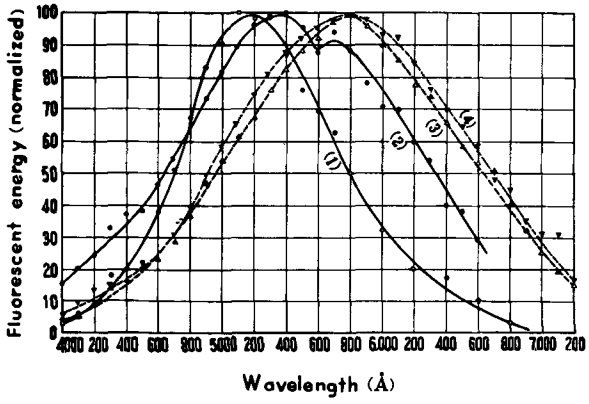

Fig. 2. Fluorescent spectrum of magnesium borate phosphors with 1 mole % Ag, fired for two 0.5 hr periods at 950°C in air, producing green (curve 1), yellow (curve 2) and orange (curves 3 and 4) fluorescence after reduction, under excitation by 3650Å at room temperature.

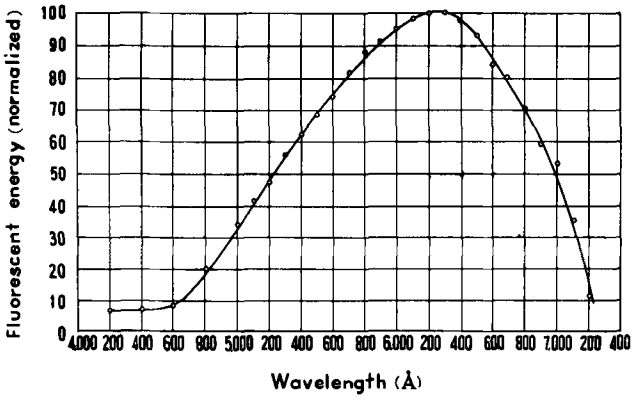

Fig. 3. Fluorescent spectrum of magnesium borate phosphor with 1 mole % Ag, fired for two 0.5 hr periods at 950°C in air, producing red fluorescence after reduction, under excitation by 3650Å at room temperature.

shown in Fig. 1. The fluorescent spectrum of the same phosphor exposed to 3650Å radiation for 6 hr in air at room temperature after the measurement of curve 1 in Fig. 1 is shown by curve 2 in Fig. 2. This spectrum shows two bands peaking at about 5400 and 5700Å which correspond to the bands peaking at about 5200 and 5800Å to be described below. The shift in peak position of the two bands may be due to the overlap of the two bands peaking at about 5200 and 5800Å.

The fluorescent spectra of samples which were allowed to stand in the dark in air for 24 hr, or for 18 hr followed by exposure to 3650Å for 12 hr, after the measurement of the spectrum shown by curve 2 in Fig. 2 was made, are shown by curves 3 and 4 in Fig. 2, respectively. The time required for the measurement of the respective fluorescent spectra mentioned above was about 30 min. The spectra shown by curves 3 and 4 in Fig. 2 are essentially identical and the peak wave length of the spectra is about 5800Å.

The fluorescent spectrum of a phosphor reduced on paper under irradiation by 2537Å for 30 hr at room temperature is shown in Fig. 3. The peak wave length of the spectrum is about 6300Å.

Reflection Spectra

The spectral reflection of pure magnesium borate of composition $MgO \cdot B_2O_3$ is shown by curve 1 in Fig. 4, relative to that of magnesium oxide. The reflection spectra of typical phosphors whose fluorescence spectra are illustrated by curve 1 in Fig. 1, by curves 1 and 2 in Fig. 2, and by Fig. 3 are shown by curves 2, 3, 4, and 5 in Fig. 4. All of these curves have a rather similar shape and show no narrow absorption bands over a wide range of the spectrum from about 2400 to 4800Å.

Discussion

Since the change of fluorescence color of phosphors treated with reducing agents was confined to the phosphors activated with Ag, the origin of this phenomenon must be ascribed to the presence of Ag. In Ag-activated magnesium borate phosphor prepared in oxidizing or neutral atmosphere, silver may be introduced into the matrix in the form of Ag^+ ions replacing Mg^{++} ions at the lattice sites. An O^{--} ion vacancy may be generated by the replacement of two Mg^{++} ions by two Ag^+ ions in order to satisfy the condition of charge neutrality in the phosphor, as has already been suggested for the Cu-activated calcium orthophosphate (2). The blue fluorescence band peaking at 4200Å may be ascribed to an Ag^+ activator center adjacent to an O^{--} ion vacancy.

Extending the assumption made above, the green, orange, and red bands in the reduced phosphor may be attributed to activator centers adjacent to O^{--} ion vacancies in which one, two, and three electrons are trapped, respectively. It is plausible to assume that one of the trapped electrons will combine with an Ag^+ ion and form an Ag-atom. If Ag-atoms aggregate into the colloidal form the phosphor powder will become gray or black colored.

It is further proposed that the surface O^{--} ions of the phosphor crystals react chemically with adsorbed reducing agents in the presence of water. For ex-

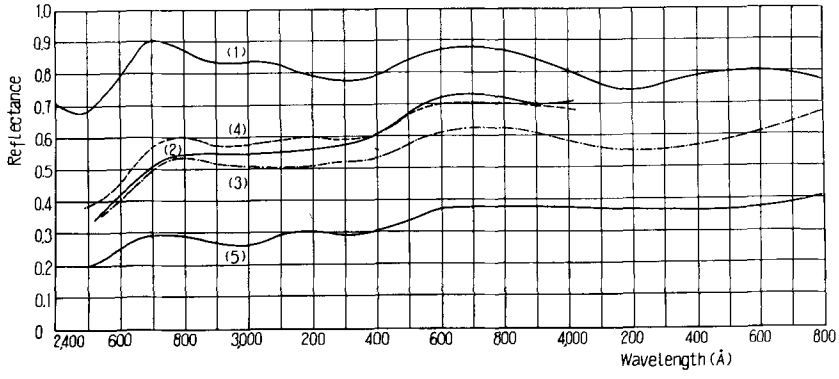

Fig. 4. Reflection spectrum of pure and Ag-activated magnesium borates: curve 1, pure magnesium borate; 2, bluish white fluorescent phosphor; 3, green fluorescent phosphor; 4, yellow fluorescent phosphor; and 5, red fluorescent phosphor.

ample, sulfite ions are thus oxidized to sulfate ions with the simultaneous release of free electrons. These free electrons then enter into the crystal via the conduction band and become trapped at O^{--} vacancies adjacent to Ag^{+} ions. This may lead to a reduction of Ag^{+} ions to Ag atoms. As a result, the concentration of surface O^{--} ions is greatly decreased. This establishes a steep gradient of O^{--} ion concentration in the region near the crystal surface, causing more O^{--} ions from the crystal interior to diffuse to to the surface. Repetition of these processes then leads to the progressive disintegration of the crystal until the last stage of reduction, namely the form of a black powder, is reached.

The strong interaction between activator center and lattice in the phosphor or the loose binding of trapped electrons with Ag^{+} ions in the activator centers will be responsible for the rather flat reflection spectra shown in Fig. 4. Since the intensity of fluorescence of the phosphors producing green to orange fluorescence is comparable with that of Cu-activated zinc or zinc·cadmium sulfide whose quantum efficiencies have been reported to be about 0.5 at 3650Å, the quantum efficiency of these Ag-activated magnesium borate phosphors will be close to unity at 3650Å. This is estimated on the basis of their much lower absorption of 3650Å radiation compared with the sulfides.

With the incorporation of aluminum into Ag-activated magnesium borate, the number of O^{--} ion vacancies will decrease, since aluminum will be introduced into the matrix as Al^{+++} ions replacing Mg^{++} ions at the lattice sites. The effect of aluminum in lowering the intensity of fluorescence of the reduced phosphor is thus explained.

The properties of these phosphors resemble somewhat those of Ag-activated alkali halides or of pure silver halides as reported by Weyl and others (1, 3), but they are more complicated. In addition to the phosphors described, a number of other Ag-activated phosphors were prepared and reduced by the same method. Many phosphors, such as Ca or Sr silicate containing Ag, showed similar properties, but their intensity of fluorescence after reduction was lower than that of Ag-activated magnesium borate. Furthermore, it was found that silver nitrate crystals purified by repeated recrystallizations and stored in a clean glass bottle for about five years in the dark developed a number of bright specks under excitation by 3650Å, while nonpurified silver nitrate crystals turned into nonfluorescent gray crystals under the same conditions. The color and intensity of the fluorescent specks in the pure crystals were similar to those of magnesium borate phosphors shown by curves 3 or 4 in Fig. 2. These crystals containing orange fluorescent specks turned into nonfluorescent dark gray crystals after reduction by the same reducing agents as mentioned before. The luminescent centers of these crystals, therefore, seem to be identical with those of Ag-activated magnesium borates. We suggest that Ag^{+} ions adjacent to negative ion vacancies in the phosphors correspond to the latent image in the photographic emulsion.

Acknowledgment

The authors wish to express their sincere thanks to Dr. Tsuneo Harada, the Director of Matsuda Research Laboratory, Tokyo Shibaura Electric Co., for his continuous support and encouragement. A major portion of this paper was presented at the Annual Symposium on Photochemistry, sponsored by The Chemical Society of Japan, The Photographic Society of Japan, and The Phosphor Circles of Japan, Tokyo, September 25, 1954.

Manuscript received April 22, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Chemical Etching of Silicon

II. The System HF, HNO_3, H_2O, and $HC_2H_3O_2$

H. Robbins and B. Schwartz

Hughes Semiconductors, Newport Beach, California

ABSTRACT

The kinetics of the reaction of silicon with solutions of hydrofluoric acid, nitric acid, and acetic acid are reported as a function of the composition of the etchant. The system qualitatively behaves in the same manner as the system hydrofluoric acid, nitric acid, and water, which has been reported previously. Quantitatively, the acetic acid diluted system shows a much higher tolerance for the diluent than does the water diluted system. The greater tolerance for acetic acid has been explained on the basis of the lesser ionization of nitric acid in acetic acid than in water. The reaction mechanisms postulated for the water diluted system have been found to apply equally well to the acetic acid diluted system.

Acetic acid is used widely as an additive to silicon etching solutions composed of hydrofluoric acid and nitric acid. This study was undertaken with the object of determining the role played by the acetic acid in the reaction, and also in the expectation that an understanding of the behavior of the acetic acid diluted system would lead to a better understanding of the water diluted system (1).

Experimental Procedure[1]

The kinetics of the system were determined by measuring the change in the dimensions of a silicon die, initially 0.125 x 0.125 in. in area and 0.025 in. thick, as a function of the composition of the etchant at constant initial temperature (25°C). The data were taken over the composition range where the decrement in die thickness exceeded 0.0001 in./min. The dice were n-type of approximately 3 ohm-centimeter resistivity; the two large surfaces were oriented along the (111) plane with an accuracy of approximately 90 min, whereas the remaining four surfaces were randomly oriented in the 111 zone. All surfaces were lapped with an abrasive grit; they were work damaged to an estimated depth of about ¼ mil.

The etching solutions consisted of mixtures, in various proportions, of nitric acid, hydrofluoric acid, and glacial acetic acid. No water was added to the solution. The only water in the solution was that contained in the concentrated hydrofluoric acid (51% H_2O) and nitric acid (30% H_2O). Before etching was begun, 20 ml of etching solution was placed in a small Teflon beaker and brought to 25°C in a constant temperature bath.

Two dice were placed in a small perforated polyethylene basket and etched simultaneously. Turbulent agitation was provided by rapidly swirling the basket through the solution, and quenching at the proper time was effected by rapidly transferring the basket to a large volume of water in a separate beaker. The decrement in die thickness was measured with a micrometer to ±0.0001 in.

The dice were etched three times, in separate portions of the same solution, and they were measured after each etch. The first etch was performed on an initially work damaged surface. The second etch was performed on a surface free from work damage, and the third etch was performed in the presence of a catalytic trace of sodium nitrite.[2]

Results and Discussion

Figure 1 depicts the etch rate corresponding to the catalyzed system as a function of the composition of the etchant. The solid curves correspond to the etching system in which acetic acid is the diluent, whereas the dashed curves correspond to the system in which water is the diluent. The curves are seen to converge on the zero diluent line, and to diverge as the amount of diluent is increased.

[1] Essentially the same experimental procedure was used here as was described in the first paper of this series.

[2] Small amounts of sodium nitrite have been found to enhance the rate of reaction in those instances where the supply of reagent by diffusion was not rate limiting (see below). Larger amounts of sodium nitrite caused inhibition of the reaction by formation of a protective film. This film is formed also in the presence of KNO_2 or NH_4NO_2, and on the basis of x-ray diffraction it has been identified as a fluosilicate.

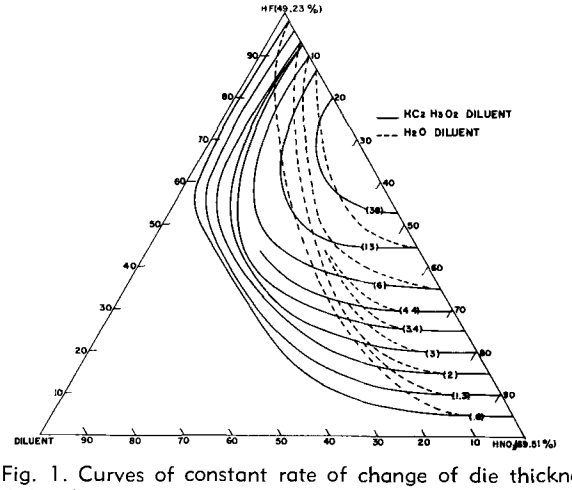

Fig. 1. Curves of constant rate of change of die thickness (mils/min) as a function of etchant composition in the system 49% HF, 70% HNO_3, and diluent.

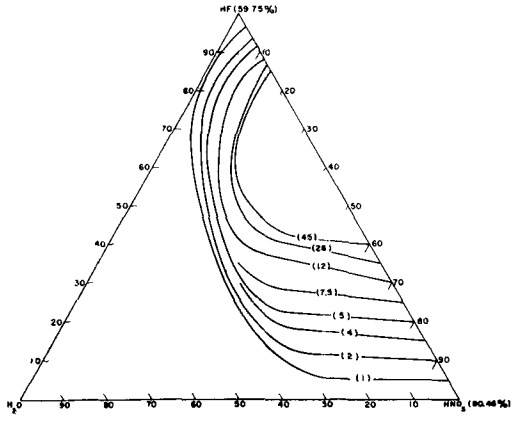

Fig. 2. Curves of constant rate of change of die thickness (mils/min) as a function of etchant composition in the system 60% HF, 90% HNO_3, and H_2O.

The etching behavior of the acetic acid diluted system is similar qualitatively to that of the water diluted system. The similarity is more striking when the acetic acid diluted system is compared with the more concentrated water diluted system shown in Fig. 2. There are three areas of general interest: the high nitric acid region, the high hydrofluoric acid region, and the region in the vicinity of the maximum etch rate. In the high nitric acid region the curves run parallel with lines of constant hydrofluoric acid, indicating that the hydrofluoric acid plays the kinetically important role here. In the high hydrofluoric acid region the course of the curves parallel with lines of constant nitric acid indicates that here the kinetically important reagent is nitric acid. In the region near the maximum etch rate both reagents play an important kinetic role.

The interpretation of the mechanism of the reaction in the water diluted system appears to be applicable also to the acetic acid diluted system. The mechanism involves a diffusion limited supply of reagents to the silicon surface, modified by autocatalytic factors as described earlier (1).

Effect of Diluent on the Reaction

The principal difference between the water diluted system and the acetic acid diluted system lies in the much greater tolerance of the latter for the diluent. Both systems initially show an indifference toward the addition of diluent in both the high hydrofluoric acid region and the high nitric acid region. When a critical amount of diluent has been added, however, the rates vanish rapidly upon the further addition of a small amount of diluent. In the high hydrofluoric acid region, the water diluted system of Fig. 1 already contains the critical amount of diluent so that no additional water can be tolerated if the etch rates are to retain their diffusion limited values.

Briner and co-workers (2, 3) have shown that the oxidizing power of nitric acid in concentrated solutions depends on the undissociated species, probably in the form of the pseudo acid $HONO_2$, which is involved directly in the oxidation. Cretella and Gatos (4) take a similar position with respect to the necessary role of undissociated nitric acid. They find that the rate of oxidation of germanium is proportional to the product of HNO_2 and undissociated HNO_3. They base their argument on the mechanism postulated by Vetter (5) as follows:

$$HNO_2 + HNO_3 \rightleftarrows N_2O_4 + H_2O$$

(slow and rate determining) [1]

$$N_2O_4 \rightleftarrows 2NO_2 \quad \text{(fast)} \quad [2]$$

$$NO_2 + e^- \rightleftarrows NO_2^- \quad \text{(fast)} \quad [3]$$

Here the active species is NO_2, which takes an electron from the germanium to form the nitrite ion. The nitrite ion then combines with a proton to regenerate the nitrous acid required for step [1]. This mechanism is in accord with the observed autocatalytic behavior of the reaction.

An additional possible interpretation of the mechanism is based on a paper by Schmid and Spahn (6) which considers the various equilibria involving nitrogen oxides and nitrous acid. The latter authors accept the basic ideas of Abel, *et al.* (7-9) that the active oxidizing agent is HNO_2 such that

$$2HNO_2 + R \rightarrow RO + 2NO + H_2O$$

(R = reducing agent) [4]

and that the formation of HNO_2 is rate determining.

$$HNO_2 + H^+ + NO_3^- \rightleftarrows N_2O_4 + H_2O$$

(slow, rate determining) [5]

$$N_2O_4 + 2NO + 2H_2O \rightleftarrows 4HNO_2 \quad \text{(fast)} \quad [6]$$

A portion of the HNO_2 is recycled through [5], and the remainder either reacts with the reducing agent to form more NO, which is again involved in the regeneration of HNO_2 as in [6], or diffuses away into the bulk of the solution. The net result is:

$$HNO_3 + R = RO + HNO_2 \quad [7]$$

On the basis of these equilibria which involve water, Schmid and Spahn come to the conclusion that there must be a maximum in the oxidizing ability of nitric acid at an optimum water content, since the removal of water past that point causes the reversal of Eq. [6] and thus a decrease in the concentration of the actual reactive species. As applied to the present research, this peak in the oxidizing ability of nitric acid would be leveled into a plateau by the diffusion mechanism, but would, in accord with our results to be discussed below, account for the ultimate falling off of the etch rates as the amount of water is decreased. We are not inclined to favor the point of view of Schmid and Spahn, since we have observed that in many instances the slowdown of the oxidation by nitric acid as the water content is decreased can be attributed to the formation of an insoluble film, and that in instances where the formation of the film does not take place, e.g., in the oxidation of substances such as sulfur, selenium, or phosphorus, the rates continue to increase monotonically as the amount of water is decreased. A further complication is the fact that the etching of silicon will take place in the presence of a slight excess of permanganate or cerate ions, which quantitatively remove all of the nitrogen existing in lower valence states, and which themselves attack silicon but slowly, if at

all. Under these conditions only the mechanism of Briner is possible. We are inclined to consider that it is this process that initiates the reaction, generating a surface concentration of catalyst that leads to the build-up of the etch rate to the steady-state value. In the steady state, the reaction probably takes a parallel path through the intermediate formation of HNO_2 within the boundary film in a mechanism similar to that postulated by Schmid and Spahn (6).

The difference between the two systems tolerance for diluent, shown in Fig. 1, reflects the difference in the basicity and dielectric constant of the diluents. Since the oxidizing power of nitric acid has been shown to depend on the undissociated HNO_3 molecule, the etch rates at constant nitric acid concentration should decrease as water is added to the system. However, as long as the reaction is diffusion governed, the reaction rates will remain constant in spite of the decreasing oxidizing power of the nitric acid as diluent is added. Upon the further addition of water, however, a point is reached ultimately where the oxidation potential has been reduced to the extent that the rate of oxidation of the suface during the induction period becomes slightly less than the possible rate of supply of reagents by diffusion. At this point, the reduction products of nitric acid begin to play a kinetically observable role, and, since the reaction is now sensitive to the catalyst concentration, there results a very rapid decrease in the rate of the initiation reaction on the further addition of only a small amount of diluent. Since a 49% HF solution already contains the critical amount of water, it is necessary to employ a 60% solution to observe this behavior.

When acetic acid is the diluent, it must be remembered that in the high HF region and at constant HNO_3 concentration, diluent is being substituted for an aqueous HF solution. Thus a very weak base of low dielectric constant is being substituted for a somewhat stronger base, water, and a substance having moderately acidic properties, HF. Initially this should result in a decrease in the dissociation of the nitric acid, since the solvent is initially more than 50% water. Because of the diffusion limitation, the etch rates do not respond to the increased free nitric acid concentration. On further dilution with acetic acid, the removal of HF, which is a stronger acid than acetic acid, probably counteracts the effect of the substitution of acetic acid for water, so that the concentration of undissociated HNO_3 probably goes through a maximum and then decreases. A critical composition with respect to diluent thus is reached ultimately, and the rates vanish on the slight further addition of acetic acid, for the same reason as in the water diluted system.

The same argument can be used to interpret the abrupt change of the curvature of the rate contours with increasing diluent in the high nitric acid region. The question may be raised that, if in the high HF region the reaction can be noncritical at 5% HNO_3, why does it become critical at 50% HNO_3 in the high nitric acid region of the acetic acid diluted system, and at a still higher value of HNO_3 in the water diluted system? We can only suggest that the difference lies in the nature of the silicon surface. In the high HF region the surface is essentially stripped of oxide, and the rapid decrease in the etch rate is the result of the slowdown of the oxidation reaction. In the high HNO_3 region the surface is essentially covered with an oxide mask. As the concentration of HNO_3 is decreased, this oxide becomes more tenuous, until a point is reached at which the HF reaction begins to slow down. The slowdown in the HF reaction causes a slowdown in the over-all reaction which then further affects the oxidation step through the mechanism of reduced catalyst production. This condition then requires an increased HF concentration to restore the etch rate to its previous value. It can be seen that in the critical region the rate contours run in the direction of constant acetic acid concentration, suggesting that the decrease in reactivity of the nitric acid as the latter is decreased in concentration may be compensated by the increase in the HF concentration. In this region the reaction is probably not strictly diffusion limited, since there is a finite surface concentration of both reagents. However, diffusion still plays a role in that the surface concentration does not equal the bulk concentration of reagents, and both the surface concentration of reagents and the nature of the surface itself affect the kinetics.

Chemical etching in solutions the compositions of which lie in the critical regions of Fig. 1 can be extremely frustrating. As an example, a mixture of 4.50 ml HF, 7.50 ml HNO_3, and 8.00 ml of $HC_2H_3O_2$ has always been found to etch a work damaged specimen, and etching always continued at the same rate even after all of the damage had been removed. A fresh solution did re-etch the specimen if the solution had been made up from 48.9% HF, but it did not re-etch the specimen if it had been made up from 48.5% HF. Furthermore, the addition of one drop of acetic acid to 20 ml of the solution that had been made up from 48.9% HF caused the solution to lose its ability to re-etch. The addition of a few milligrams of sodium nitrite then caused the solution to regain its etching ability. If an etching die were transferred to a fresh solution made up from 48.5% HF, it usually would continue to etch at the same rate, since a trace of catalyst reinitiates the reaction. If this die were transferred rapidly to a solution of the same composition, swirled to dissipate the catalyst, and then transferred to a third solution of the same composition, etching invariably would be quenched. In all cases, the etching rate was either in the vicinity of 1.8 mil/min or 0.

In view of this behavior, the reaction must proceed first through an induction period in which the autocatalytic factors cause a build-up of the etch rate to the steady-state value. The induction period depends greatly on the condition of the silicon surface. A work damaged surface has a short induction period, whereas an undamaged surface has a relatively long induction period, owing to the absence of catalyst initially. Whether or not the etch rate can build up to the steady-state value then depends on whether the catalyst can be conserved in the vicinity

of the surface in sufficient quantity to assure its involvement in the propagation of the reaction. The etch rates thus seem to be the result of a balance struck between the autocatalytic factors, which are explosive in nature, and some rate limiting mechanism. Since the rates are the result of the difference between these two large quantities, the system may be inherently unstable, and this may cause the measured etch rates to be nonreproducible.

Conclusions

The role of acetic acid in the etchant is primarily that of a diluent. As such it is able to provide control over the rate of the reaction by reducing the concentration of the kinetically important species. However, this function also can be performed with nitric acid as diluent in the compositions rich in nitric acid, or with hydrofluoric acid in the compositions rich in hydrofluoric acid. Excessive addition of acetic acid can cause the etch rates to become erratic and extremely critical with respect to small changes in composition. Water also can be used as a diluent, except that in the high hydrofluoric acid region the system is critical with respect to the addition of diluent.

The kinetics in the acetic acid diluted system are governed by the same factors that operate in the water diluted system. Thus the reaction rates are determined by the rate of diffusion of the kinetically important species to the surface of the specimen. The autocatalytic factors that operate in the water diluted system play the same role in the acetic acid diluted system. The quantitative differences between the two systems can be explained on the basis of the difference in the basicity and dielectric constant of the two diluents.

Manuscript received April 6, 1959. This paper was prepared for delivery before the Ottawa Meeting, Sept. 28-Oct. 2, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

High-Purity Silicon from an Iodide Process Pilot Plant

Carlyle S. Herrick and James G. Krieble[1]

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

Silicon tetraiodide is formed from commercial silicon and iodine in a fluid-bed reactor. Impurities are rejected by solvent recrystallization followed by fractional distillation. High-purity silicon is formed by thermal decomposition of the iodide on a silicon surface. Silicon made this way has a resistivity over a 1000 ohm-cm. Reproducible results are obtained which suggest the product quality is controlled by back-contamination from the decomposition and crystal growing steps. Data from the decomposition of silicon tetraiodide at 1000°C and low pressure are correlated by the relation:

$$\log p = 2.18 - \frac{m}{0.305}$$

where p = lb SiI_4 vapor feed/hr/ft^2 heated surface and m = fraction of $SiI_{4(g)}$ converted to $Si_{(s)}$. It is postulated that this reaction reaches equilibrium.

Iodide chemistry was developed by Van Arkel and de Boer (1) into a useful method for reducing the oxygen, nitrogen, or carbon content of such refractory materials as titanium, zirconium, hafnium, and silicon. Other impurities, aluminum, beryllium, boron, iron, and copper, are not rejected effectively by this simple iodide cycle and, as a result, further development of the iodide method has been necessary to produce the purity required in semiconductor silicon. The most fruitful approach has been to remove the iodide intermediate from the reaction system, subject it to additional purification, then decompose it to form a purer material.

Recrystallization (2), distillation (2-4), sublimation (5), and zone refining (5, 6) have been reported to be useful for the intermediate purification of sili-

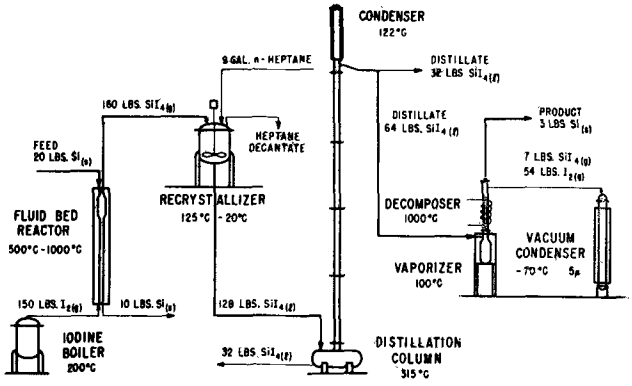

Fig. 1. Iodide process flowsheet

con tetraiodide. McCarty (2) in this laboratory has shown that silicon of 500 ohm-cm resistivity can be prepared by using a recrystallization step followed by a distillation step. The present work has been directed toward finding answers to the questions:

1. Can silicon of even higher purity be made by chemical means?
2. Can this silicon be made in large quantities?

Both questions can be answered in the affirmative when an iodide process is used.

Process Description

The flow sheet for this iodide process, Fig. 1, shows reaction of silicon and iodine to form silicon tetraiodide, purification of tetraiodide by recrystallization, then distillation, and decomposition to high-purity elemental silicon and iodine. This same sequence of events was used by McCarty (2); however the character of the reaction step, distillation and decomposition step used here have been modified substantially to improve their effectiveness.

Silicon tetraiodide is formed in a fluid bed reactor using commercial 99.9% silicon and research grade iodine at atmospheric pressure. The bed, charged with 44-100 μ diameter silicon powder is fluidized entirely by iodine vapor, although an inert gas diluent may be used if desired. Fluidization provides excellent heat transfer between particles and creates a uniform temperature throughout the bed. It has the advantage that an exothermic reaction involving a poor heat conducting solid can take place at constant temperature. Of course, constant reaction temperature means a constant reactivity for silicon and its impurities and a better separation between them based on reaction energies. Previously described small scale reactors have used the fixed bed principle and thus have not realized the full separating potential of the reaction step. Close observation of a fixed bed using iodine and silicon discloses that lack of temperature control causes a reaction zone to travel through the bed as a "hot spot," usually incandescent. Such lack of control is characteristic of fixed beds. Unreacted silicon enriched in impurities is discharged from the fluid bed at the end of an experiment.

Iodine residence time in the bed is short, 1-2 sec; however the reaction is rapid enough for the yield to be quantitative. As iodine is consumed from the vapor stream, the silicon tetraiodide product takes over the job of fluidizing the bed. Since the reaction appears to involve only iodine atoms and silicon, there is a 4 to 1 volume change during the reaction according to Eq. [1].

$$4\ I_{(g)} + Si_{(s)} \rightarrow SiI_{4(g)} \qquad [1]$$

This decrease in top-bed fluidizing velocity helps reduce powder entrainment.

Silicon tetraiodide leaving the reactor condenses in the recrystallizer where n-heptane is added in 1 to 1 mole ratio. The resultant slurry is warmed and then cooled to dissolve and recrystallize the tetraiodide. The n-heptane containing dissolved impurities is decanted, then the operation is repeated. The over-all yield for two recrystallizations is about 80%.

In the distillation column the tetraiodide is divided into a bottom fraction containing the less volatile impurities, a top fraction containing the more volatile impurities, and a second distillate of purified tetraiodide comprising 50% of the column charge.

This purified tetraiodide is fed to the vaporizer where evacuating and heating produce a low-pressure tetraiodide atmosphere around a heated silicon rod. Now the tetraiodide dissociates to the diiodide (7) and then to solid silicon according to reactions [2] and [3].

$$SiI_{4(g)} \rightarrow SiI_{2(g)} + 2\ I_{(g)} \qquad [2]$$

$$SiI_{2(g)} \rightarrow Si_{(s)} + 2\ I_{(g)} \qquad [3]$$

A deposit of high quality product silicon forms on the heated rod while the iodine atoms recombine after cooling and flow to the vacuum condenser along with unreacted tetraiodide. The diffusion rates of many impurities in silicon are comparable with the rate of product accumulation. Commercial semiconductor silicon was used for the heated decomposer surface to minimize diffusional contamination of the product silicon. The yield for this step was about 50%.

In the stoichiometry of Fig. 1, 20 lb of silicon and 150 lb of iodine are fed to the reactor for each 3 lb deposit of product silicon. It does not take account of the existing opportunities to reuse and recycle waste streams to bring consumption and production into better balance.

Except for impurities added during processing, it is assumed that impurities are present as iodides in silicon tetraiodide. Vapor pressure data from Brewer (8) and from Schäfer and Hönes (9) are shown in Fig. 2. Vapor pressures of Nb, Hg, Ga, Ge, Al, As, and Sb iodides fall in a band between those of tin and tantalum. Vapor pressures of most metal iodides are lower than for silicon tetraiodide so they will remain in the reboiler during distillation. Phosphorus and boron iodides are more volatile and must be removed at the top of the distillation column before purified silicon tetraiodide can be distilled overhead. At 1 atm CI_4 boils 19°C higher than SiI_4 and PI_3 63°C lower. The calculated relative volatilities are 3.4 for PI_3 with respect to SiI_4 and 1.4 for SiI_4 with respect to CI_4. Both volatilities are large enough to permit extensive separations with a moderate number of theoretical distillation plates.

This process scheme imposes stringent requirements on the materials of construction. Silicon tetra-

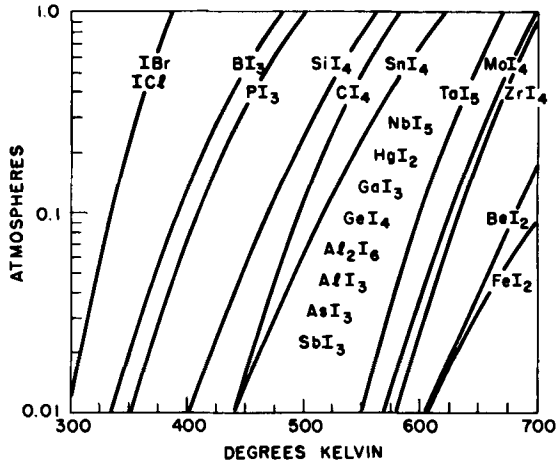

Fig. 2. Iodide vapor pressures

iodide in process is usually accompanied by some iodine and hydrogen iodide and this mixture is quite aggressive toward container materials at elevated temperatures. Quartz, due to its high chemical stability, was selected for the reactor, the distillation column, and the decomposer.

Process Equipment

The fluid bed reactor is a 4-in. diameter quartz tube 8 ft long mounted vertically in a furnace, Fig. 3. A porous-type gas distributor was used to eliminate stagnant zones and get uniform fluidization (10). Heat of reaction is removed from the bed by direct radiation to the furnace walls which are maintained about 50°C cooler than reaction temperature. The electric heating elements in the furnace are internally exposed to get maximum heat transfer and

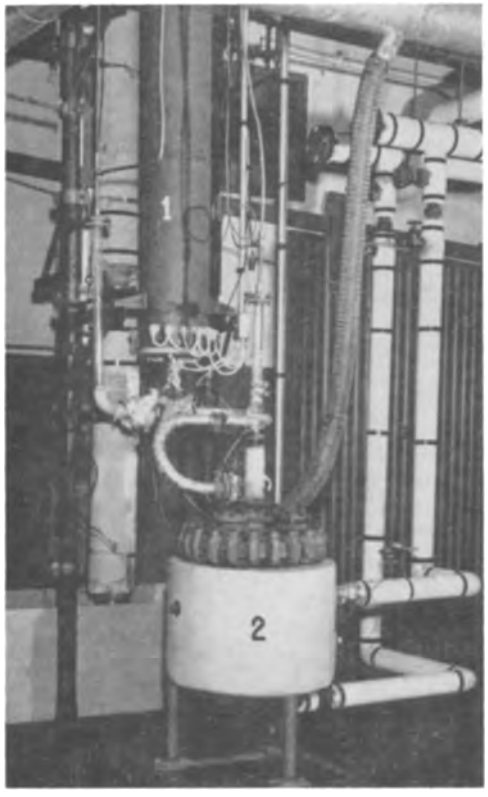

Fig. 3. Fluid bed reactor: 1, reactor furnace; 2. iodine boiler.

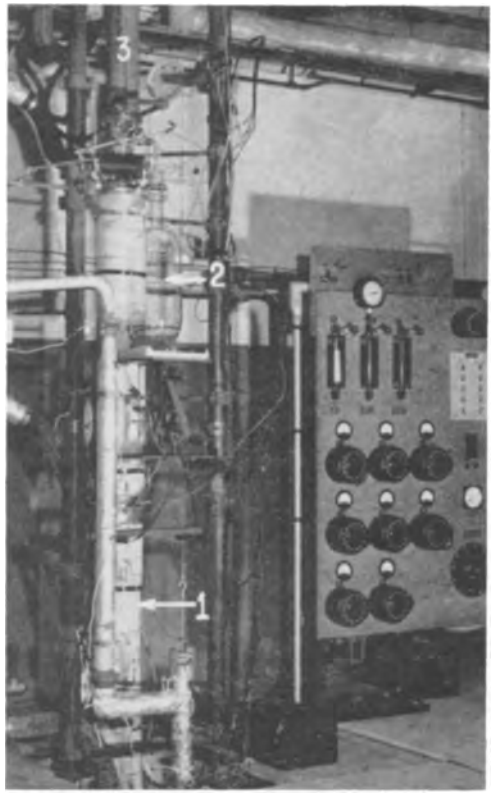

Fig. 4. Distillation column: 1, column upper sections; 2, product receiver; 3, condenser.

controllability. Iodine is vaporized in a 10-gal glass-lined steel iodine boiler jacketed with 230°C hot oil.

The recrystallizer is a 20-gal glass-lined steel agitated vessel jacketed for steam heating or water cooling. It is mounted on a base which permits weighing without disturbing the quartz piping connections.

The all-quartz distillation column consists of reboiler, four lengths of 3-in. diameter tubing, and a condenser, with an over-all height of 24 ft. At the bottom the 10-gal reboiler is heated by Calrod®[2] units inserted in quartz tubes sealed lengthwise through the lower sector of the vessel. Direct radiant heat transfer from heater to boiling SiI_4 gives fast response and minimum superheating.

At the top of the distillation column, Fig. 4, a 3-ft length of 4-in. tubing serves as a condenser. It is provided with a 6-in. stainless steel jacket and a circulating hot oil coolant system. Each of the four column sections is packed with ⅜-in. quartz rashig rings with quartz packing supports and distributor plates. The entire asesmbly is supported by a system of weights and pulleys and is arranged for adiabatic operation. Thirty-two theoretical plates were measured at 1 atm using a n-heptane methylcyclohexane test mixture (11) and the Fenske equation (12).

Silicon tetraiodide is removed from the column in a 3-gal quartz receiver and placed in the vaporizer to become the bottom portion of the decomposer assembly. Figure 5 shows a Pyrex receiver of the same size holding 45 lb of tetraiodide. The discoloration is caused by iodine released by a photochemical oxidation which has not yet been identified. Heating silicon tetraiodide from room temperature to 100°C

causes expansion forces strong enough to break glass or quartz containers. Melting the outer layer of the SiI_4 cake and reforming along one side of the vessel creates ample room for expansion without breakage.

The decomposer consists of a vertical 2-in. quartz tube mounted atop a 3 gal SiI_4 receiver just described. A silicon rod, $\frac{5}{8}$ in. in diameter and 14 in. long, mounted inside the tube, is heated to 1000°C by external coils connected to an induction heater, Fig. 6. As SiI_4 decomposes in contact with the heated surface, silicon deposits on the rod which increases in diameter. Adjustment of the heating coils along the rod is necessary to obtain a uniform deposit.

Figure 7 shows a typical deposit obtained by heating a 10 in. length of rod. It is 1.25 in. in diameter

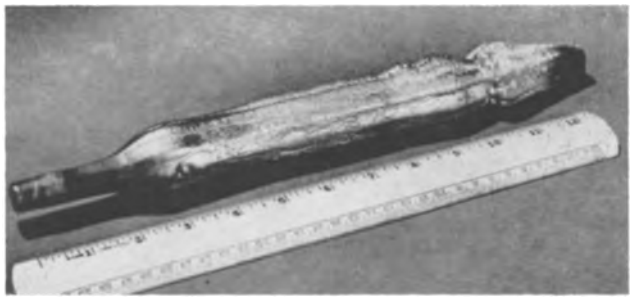

Fig. 7. Product silicon

and contains 1 lb of new silicon. Deposit and rod are separated by a sawing operation which produces sizes and shapes required for crystal growing.

Product Silicon Evaluation

Resistivity measurements were made on single crystals prepared by the Czochralski technique (13). The four point probe method (14) was used to measure resistivity profiles. Minority carrier lifetime was measured by the infrared photoconducting decay method (15).

Experimental results are listed in Table I. It should be recognized that the four point probe measurement is subject to large errors above 1000 ohm-cm. Furthermore, the crucible method of crystal growing contaminates the silicon, and at high resistivities this causes the seed end resistivity to change rapidly along the crystal so the region of maximum resistivity is difficult to locate. This effect is noticeable in Table I where resistivity values are reported at approximate 1-in. intervals along the crystals.

Resistivities as high as 3500 ohm-cm have not been reported previously for crucible grown silicon. Dissolution of quartz in molten silicon during crystal growth is known to occur (16, 17), and the accompanying impurities are expected to limit the maximum obtainable resistivity values. Practical values for such a limit have not yet been reported. Hannay (17) reports that the limit is higher than 300 ohm-cm p-type while Taft and Horn (16) report exceeding 300 ohm-cm in practice. The present work suggests that the practical limit is above 1000 ohm-cm p-type under the most favorable experimental conditions, i.e., minimum time elapses between the onset of melting and the cooling-off of the seed end of the pulled crystal.

Examinations in a cryostat for deep level compensation showed these effects to be absent. Each crystal did exhibit a photo-emf in ambient light; however, type reversals were not detectable by potentiomet-

ric probing or by applying an electric field to a barium titanate coated surface. The source of the photo-emf is not understood at present. While it did interfere somewhat with lifetime measurements, the values obtained are in a medium range for high-quality crucible grown silicon.

With all factors considered, it is concluded that the product silicon quality corresponds to a resistivity over 1000 ohm-cm. Measurements on crucible grown silicon in this resistivity range do not warrant a more quantitative statement at the present time.

The Table I data are a full sequence of lots without deletions or selections; thus the agreement between 3400, 3500, and 3200 ohm-cm resistivities is remarkable in view of the measurement uncertainties and may be fortuitous. The weight of evidence indicates to the authors, however, that this agreement is more real than circumstantial. It is believed to result from improved effectiveness and reproducibility in the processing steps and from skillful handling of the crystal growing problem.

Two different grades of silicon were used for the decomposer surface. One, the zone refined, had a resistivity of 130 ohm-cm; the other was a premelt rod of 2 ohm-cm commercial grade silicon. Both were prepared by the techniques of Taft and Horn (16). The low resistivity of product silicon in the second experiment correlates with the low resistivity of the silicon rod used in the decomposer. Since relative volumes of silicon and time of deposit were roughly equal in the four experiments, the data suggest that a proportional dilution effect controls product resistivity at about 27 times greater than the starting rod resistivity. It further suggests that the effect is roughly independent of resistivity over the range covered by the experiments.

Macroscopic examination of a transverse fraction in the product silicon gives the impresion of close-packed needlelike crystals with major axes radiating outward from the center of the rod. Hölbling (18) shows similarly oriented columnar crystals from the hydrogen reduction of SiI_4 on a carbon rod. Sangster, Maverick, and Croutch (19), on the other hand, show propagation of the original crystal structure when $SiBr_4$ is hydrogen reduced on a heated silicon filament.

The product silicon in this work was found to propagate the crystal structure of the original silicon rod. Figure 8 shows several crystal faces present after 2×10^5 atom layers of silicon have been deposited. The same crystal pattern was present in the rod before deposition. Microscopic examination of the product shows the individual crystals to have a large number of defects, presumably twins, Fig. 9. These twin lines are highly oriented in the growth direction. This degree of defect alignment would account for the observed fraction pattern as well as for the observation that the product material is much weaker when stressed in the transverse direction than is the original rod.

Impurity Separations During Processing

A resistivity of 3500 ohm-cm requires the electrically active impurity content of the silicon to be about 8 atoms per hundred billion atoms. The contribution of each process step to the total separation has been estimated in Table II to indicate whether this purity level is a reasonable achievement for the process. Impurity concentrations are indicated only as to order of magnitude which is about the accuracy warranted by much of the supporting data. The starting silicon was commercial acid-leached 99.9% silicon. Spectrographic analyses of this material gave results in agreement with those reported by Szekely (4). The most concentrated impurity was present less than 1×10^{-3} atoms per atom Si. Analysis of the SiI_4 product from the fluid bed reactor by the same means shows the maximum impurity concentration to be a few parts per million. Similarly after the recrystallization step the impurity content is below the sensitivity of the analytical method. It is interesting to note that detectable amounts of boron are rejected in the solvent.

An indirect approach is necessary to estimate distillation column output purity. Calculations for the PI_3-SiI_4 system using the Fenske equation (12) and a relative volatility modified to dilute solution conditions according to the experience of Green and

Table II. Impurity separating ability of process steps

Process step	Atoms of most concentrated impurity per silicon atom		Separation factor
	Input	Output	
Fluid bed reactor	1×10^{-3}	10^{-6}	10^{3}
Recrystallizer	10^{-6}	10^{-8}	10^{2}
Distillation column	10^{-8}	10^{-13}	10^{5}
Silicon surface decomposer	10^{-13}	10^{-11}	10^{-2}

Kafalas (20) indicate a maximum separation factor of 5.5 x 10^{6} for this column and feed. It is probable, however, that column performance is limited to a factor of 10^{5} by an aerosol entrainment mechanism according to Manowitz, Bretton, and Horrigan (21). This factor applies to all iodide impurities except CI_4. Since carbon is one of the elements most effectively rejected by iodide chemistry the lower separation factor for this compound has not caused special problems.

The decomposer separation factor calculated as the difference between known input and output impurity levels gives 10^{-2} or a hundredfold contamination. This is consistent with the observed dependence of product purity on silicon rod purity. Moreover, the magnitude of the effect is reasonable for the impurity level of this step.

Two conclusions can be drawn from this analysis. First, product silicon in the 10^{-11} impurity range is within the capability of this process. Second, improvements in the decomposition step will probably yield product silicon of still higher purity.

SiI_4 Decomposition

The experimental observations on the decomposition step made at the General Electric Research Laboratory including this work and that of McCarty are correlated in Fig. 10. Equation [4] expresses the linear correlating function.

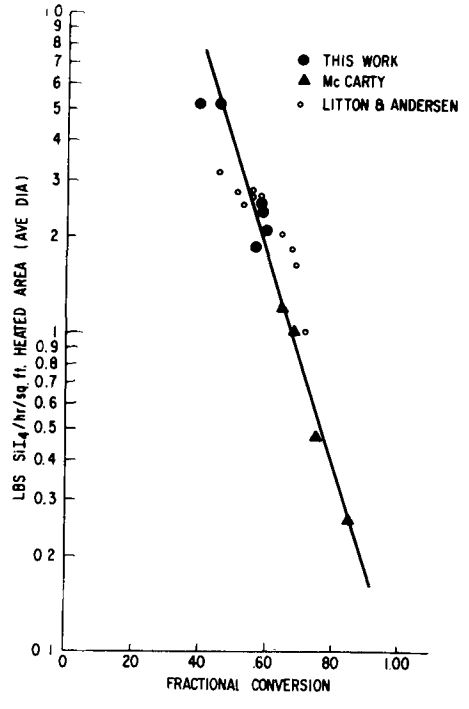

Fig. 10. Correlation of decomposition reaction data

$$\log p = 2.18 - \frac{m}{0.305} \qquad [4]$$

when p = pounds of SiI_4 vapor feed to the decomposer per hour per square foot of heated surface (arithmetic average) and m = fractional conversion of SiI_4 to Si.

The correlation holds for the over-all reaction of Eq. [5] at 1000°C and a condenser pressure of 1 to 10 μ.

$$SiI_{4(g)} \rightleftharpoons Si_{(s)} + 2\,I_{2(g)} \qquad [5]$$

The basic significance of this correlation is not understood at present, and no theoretical treatment exists to support it. Undeniably it correlates the data well. The results of Litton and Andersen (3), who have published the only data on thermal decomposition of SiI_4, have been recalculated and are compared with Eq. [4] in Fig. 10. Although the Litton and Andersen data show some scatter, the quantitative agreement is good. The decomposer vessels used in these three investigations differ widely in geometry. In this work decomposition occurred on a 5/8-in. diameter rod in a 2-in. diameter vessel. McCarty decomposed inside a 1.25-in. diameter cylinder while Litton and Andersen decomposed on a 0.1-in. diameter wire formed into an open helix inside a 2.75-in. diameter vessel. The fact that data taken under such widely different circumstances fit the same correlation suggests that chemical equilibrium exists in each type of equipment over the experimental range covered.

It is interesting to note that in all three studies each datum is really the average result of an entire experiment conducted at a continuously changing iodide vaporization rate, hence the instantaneous conditions corresponded with the average for a short time only. The form of the correlating equation $p = e^{m}$ is such that the derivative dp/dm is also equal to e^{m}. In this case, if the average diameter is replaced by the instantaneous diameter, the correlation will apply to the variables on an instantaneous basis. This condition is a prerequisite to having Eq. [4] represent an equilibrium relation.

One should note that the units, pounds per hour per square foot heated area, are actually unconventional units of pressure. Although no investigator has yet reported decomposer pressure measurements for reasons of contamination and corrosion, in principle sufficient data are now available to calculate an experimental equilibrium constant. The constant for equilibrium Eq. [5] is given by [6].

$$K_p = \frac{[I_2]^2}{[SiI_4]} \qquad [6]$$

In Table III experimental pressure values taken from the correlation have been recalculated to the more familiar units microns Hg. K_p has been calculated on the hypothesis that the experimental pressure is the total pressure in the system, i.e., the plug flow case or flow with no back-mixing. The variation between values of K_p is less than a factor

Table III. Experimental equilibrium constant

Lb SiI_4/hr/ft²	Pressure, μHg	K_p, mm
0.20	0.94	1.3×10^{-3}
0.30	1.4	1.2
1.0	4.4	1.4
3.0	13	1.9
6.0	25	2.2

of 2 which is firm evidence for equilibrium conditions during the decomposition reaction.

Acknowledgments

The authors appreciate the guidance and assistance of L. V. McCarty throughout the work, also C. B. Collins, F. H. Horn, and R. O. Carlson who took part in many helpful discussions. R. O. Carlson and G. W. Ludwig evaluated the product silicon, and W. C. Dash supplied silicon rods for the decomposer. R. J. Sullivan, R. L. Richard, and D. A. Reed assisted in carrying out the experimental work.

Manuscript received Jan. 22, 1959. This paper was prepared for delivery before the Buffalo Meeting, Oct. 6-10, 1957.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

The Preparation and Properties of Aluminum Antimonide

W. P. Allred, W. L. Mefferd, and R. K. Willardson

Battelle Memorial Institute, Columbus, Ohio

ABSTRACT

An improved method of growing single crystals of aluminum antimonide is described. Oxide from the aluminum has been eliminated by a vacuum heat-treating technique which also removes volatile impurities. The mobility of the positive carriers in AlSb at 300°K is found to be greater than 400 cm²/v-sec. Values as high as 5000 cm²/v-sec have been measured at 50°K. The p-type impurities have an activation energy of about 0.02 ev in AlSb. A maximum is observed at 4000 gauss in the magnetic-field dependence of the Hall coefficient at 77°K.

Considerable interest has been shown over the past few years in the development of semiconductors which are capable of operating at high ambient temperatures. The electrical properties of some of the Group III-V compounds are especially interesting for this application. Among these compounds, aluminum antimonide, with an energy gap of 1.6 electron volts (ev) shows particular promise. The major problem in producing device-quality aluminum antimonide is concerned with the removal of impurities from the compound or its constituents (1). Schell (2) reports that zone refining AlSb has produced p-type material with resistivities as high as 14 ohm-cm and carrier concentrations of 3 x 10^{15}/cm³. However, these samples have low carrier mobilities, 150 cm²/v-sec. Aluminum antimonide crystals with resistivities as high as 30 ohm-cm have been obtained by doping p-type AlSb with selenium (3). Again, the mobility of the positive carriers in the base p-type AlSb was low, about 100 cm²/v-sec. Resistivities as high as 200 ohm-cm have been obtained by adding lithium to aluminum antimonide (4). In this case, the mobility was extremely low, about 0.02 cm²/v-sec. While doping can produce interesting samples for optical studies, it drastically decreases the carrier mobilities and the purity of the

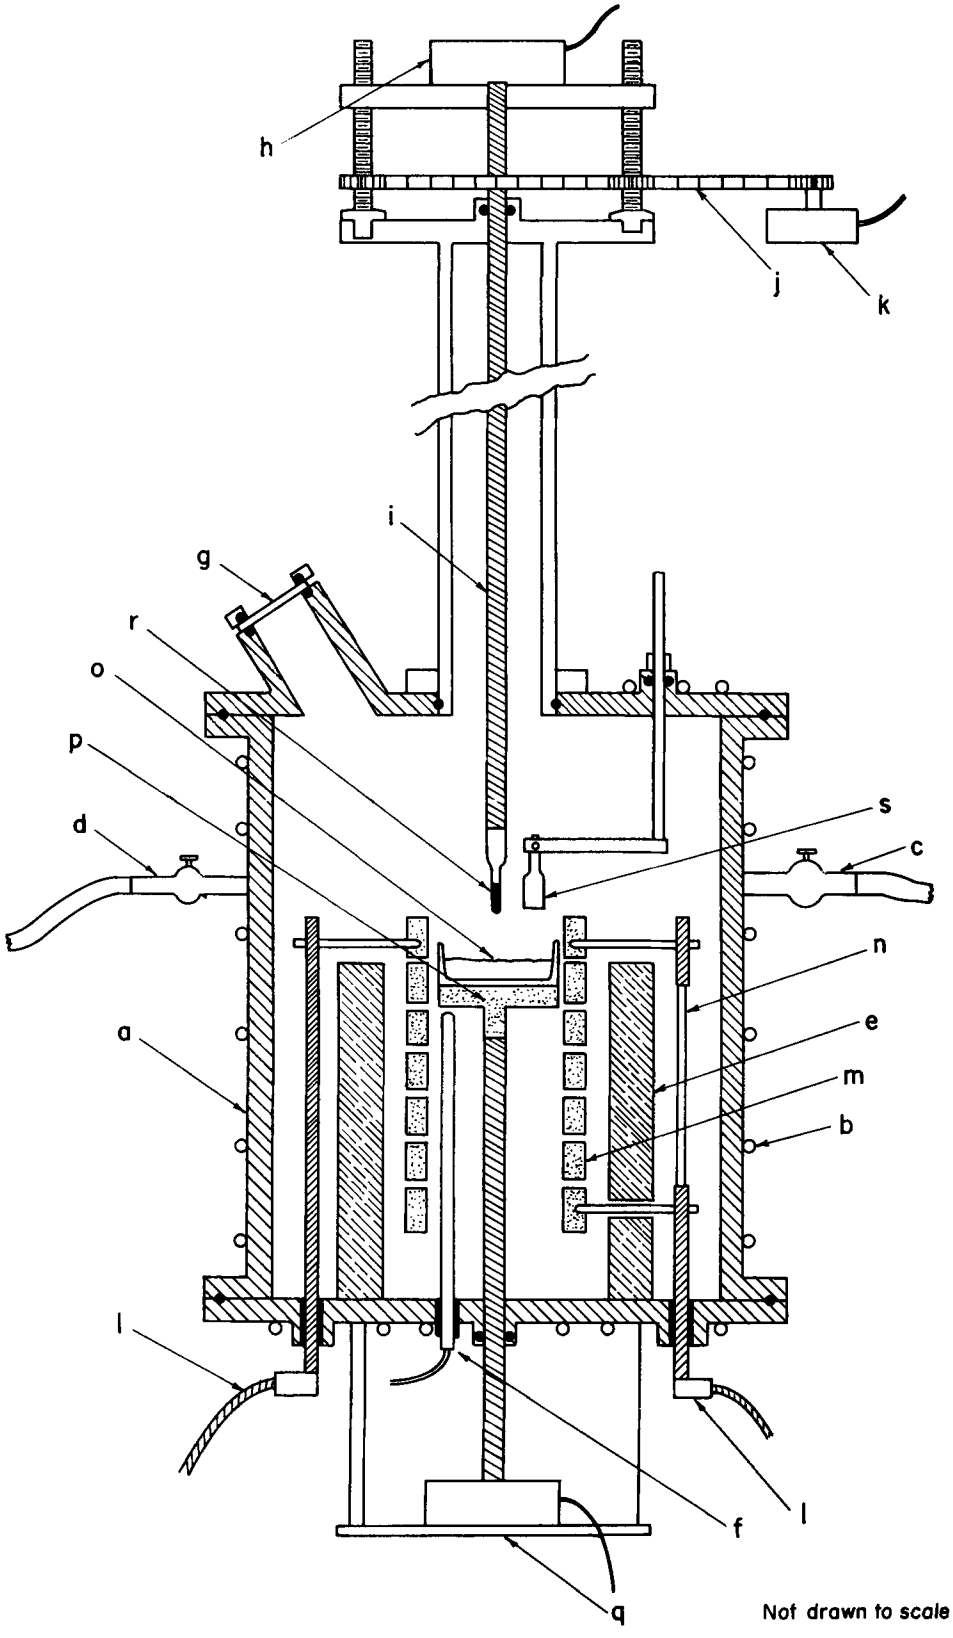

Fig. 1. Crystal growing furnace

aluminum antimonide. Nasledov and Slobodchikov (5) have prepared p-type aluminum antimonide with hole mobilities as high as 240 cm^2/v-sec and carrier concentrations of nearly $10^{18}/cm^3$.

Results of this investigation show that the majority of the p-type impurities found in aluminum antimonide come from the aluminum. It also shows that the concentration of the major p-type impurity in aluminum antimonide can be reduced by heat treating the aluminum at 1000°C in a vacuum. A relatively easy method for heat treating the aluminum and producing p-type aluminum antimonide single cystals with mobilities as high as 400 cm^2/v-sec and carrier concentrations in the $10^{16}/cm^3$

range is described. The purity of the aluminum antimonide is indicated by the temperature dependence of the Hall coefficient and the mobility data.

Growing of Single Crystals

The crystal-growing furnace shown in Fig. 1 is a steel vacuum tank (a) surrounded by cooling coils (b). Helium gas used for atmosphere while growing crystals enters the furnace through valve (c). A vacuum pump is connected to valve (d). Fused quartz is used for shielding (e) in this system, and the thermocouple well (f) is porcelain.

The viewing port (g) at the top is so located as to reduce condensation of volatile materials on the viewing glass. An electric motor (h) rotates the stainless steel seed holder (i). This motor is attached to a platform that is raised or lowered by the rotation of two long screws which are turned by a chain (j) driven by a variable-speed motor (k). The electrical feed-throughs (l) are stainless steel which contact the graphite heating element (m) through molybdenum rods. One side of the heating element is mechanically supported by a porcelain rod (n). The Morganite Al_2O_3 crucible (o) is mounted on an AUC graphite pedestal (p) and rotated counterclockwise by motor (q), while the seed (r) rotates clockwise. Both the seed and the crucible are normally rotated at 6 rpm, giving a net rotational rate of the seed with respect to the melt of 12 rpm.

Although aluminum is etched prior to its reaction with antimony, it still retains an oxide surface that floats on the aluminum antimonide melt and provides nucleation centers which produce additional crystals when the oxide particles come in contact with the seed or the crystal being pulled.

Originally this oxide was removed by lowering the aluminum oxide paddle (s) into the melt. The entire surface of aluminum antimonide was allowed to freeze to the paddle. Then this surface plus the oxide could be lifted out of the crucible, leaving a melt clear of oxide.

The oxide coating on the seed is a second source of nucleation. In order to minimize this nucleation, the crystal being grown is necked down to approximately ⅛ in. before it is allowed to grow out to the desired diameter. This necking down forces out crystals nucleated by the oxide on the surface of the seed.

During the pulling of aluminum antimonide crystals, it was observed that single crystals could not be grown when pulling at speeds above 3 in./hr. Pulling rates exceeding this value caused the ingot to grow as if pulled from a nonstoichiometric melt. This and other experiments indicate that the maximum pulling rate for single crystal growth depends on the magnitude of the deviation of the melt from the stoichiometric ratio. The greater the deviation from stoichiometry the more slowly the crystal must be pulled.

At pulling speeds less than ½ in./hr it was observed frequently that the ingot was covered with a yellow-white glasslike substance. This coating was identified as vitreous antimony trioxide by index-of-refraction measurements. The vitreous coating of Sb_2O_3 varied from 8 to 26 μ in thickness. It is expected therefore that all of the aluminum antimonide crystals pulled from the melt have a thin coating of antimony trioxide glass. Based on oxide coating thickness found at different pulling rates, ingots pulled at 2 in./hr would have a coating of Sb_2O_3 about 4 μ thick. This thickness would of course vary with the pressure of the inert gas and the amount of oxygen present.

Starting Materials

Since neither the antimony nor the aluminum was of sufficient purity as a starting material, purification by zone refining was attempted. The aluminum was given 20 zone-melting passes at 2 in./hr, while the antimony was given 20 passes at 1 in./hr. Both the aluminum and the antimony were zone refined in AUC graphite boats. Following the zone refining, both elements were etched to remove oxides from their surfaces. The aluminum was etched in a solution composed of 95% phosphoric acid and 5% nitric acid, and the antimony was etched in CP-4. Deionized water was used for washing the materials after etching.

In general, pulled aluminum antimonide crystals produced from zone-refined aluminum and antimony reacted in an aluminum oxide crucible contain p-type impurities on the order of $6 \times 10^{17}/cm^3$. Since high-purity indium antimonide can be made with antimony of the same quality as that used in the preparation of aluminum antimonide, the impurity content of the antimony is at least two orders of magnitude below this $6 \times 10^{17}/cm^3$ level.

To investigate the possibility of the melt being doped with contaminants in the aluminum oxide crucibles, two aluminum antimonide crystals were pulled from a high-purity, single-crystal sapphire crucible. These crystals showed no significant differences in electrical properties from the previously obtained material. It was concluded that this level of p-type impurities, i.e., $6 \times 10^{17}/cm^3$, does not come from the crucible.

Therefore, it is probable that the source of the observed impurities in aluminum antimonide is the aluminum. Various impurities which should act as acceptors in aluminum antimonide are found (spectrographically) in the aluminum. Significant quantities of magnesium and copper are among these impurities. An ingot of aluminum antimonide was pulled from a melt doped with 1 part magnesium to 10^4 parts aluminum. As would be expected, the acceptor concentration increased from 6×10^{17} to $2.5 \times 10^{18}/cm^3$. More significantly, little change in carrier concentration along the crystal was observed, indicating that magnesium segregates slowly in aluminum antimonide.

Heat Treatment of the Aluminum

The aluminum was heat treated in vacuum at 1000°C for several hours in an attempt to reduce the concentration of volatile impurities. Magnesium should be one of these impurities removed, since the vapor pressure of magnesium is quite high with respect to that of aluminum. After evacuating and flushing the system with dry helium several times, the system was maintained at 1×10^{-3} mm Hg. Then

Table I. Electrical properties of crystals pulled from AlSb Melts (300°K)

Crystal	Hall coefficient, cm^3/coulomb	Mobility, cm^2/v-sec	Number of carriers, n/cm^3	Preparation of aluminum
1	10.3	230	6.0×10^{17}	As received
4	11.0	230	5.6×10^{17}	Zone refined
8	14.6	250	4.5×10^{17}	Heat treat 1000°C for 7 hr
10	41.0	300	1.5×10^{17}	Heat treat 1000°C for 16 hr
16	53.3	340	1.2×10^{17}	Heat treat 1000°C for 40 hr
15	66.2	330	9.4×10^{16}	Heat treat 1000°C for 54 hr

the aluminum, in an aluminum oxide crucible, was heated to 1000°C for several hours. After heating the aluminum about 3 or 4 hr, the oxide skin which always appears on the aluminum began to disappear. The mechanism involved is probably the Al_2O_3 reduction by aluminum to Al_2O, which subsequently evaporates (6).

After the heat treatment of the aluminum, the system was filled with dry helium and a positive pressure of 10 psi maintained. The antimony which had been fastened to the aluminum oxide probe during the heat-treatment of the aluminum was lowered into the hot zone and allowed to melt into the crucible. This method allowed the aluminum and the antimony to react without the necessity of opening the system; a surface completely clear of oxide particles was produced.

Table I shows the electrical properties of crystals pulled from aluminum antimonide melts when using as-received, zone refined, and heat-treated aluminum. It is apparent from these properties that zone refining the aluminum does very little to reduce the p-type impurities in aluminum antimonide crystals. However, the crystals pulled from melts containing aluminum that had been heat treated had p-type impurity concentrations almost an order of magnitude lower than those observed for crystals made from as-received aluminum.

Figure 2 is a graphical presentation of a portion of the data in Table I. The concentration of p-type impurities in pulled aluminum antimonide crystals is plotted as a function of heat-treatment time of the

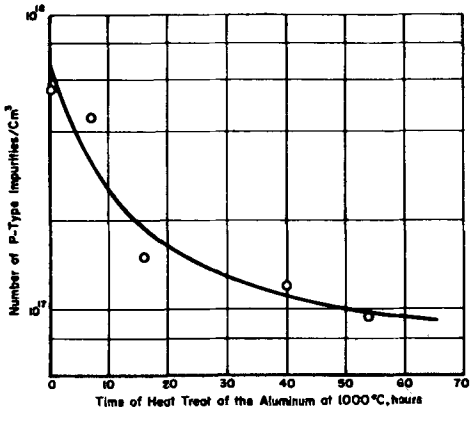

Fig. 2. Concentration of p-type impurities in pulled crystals of AlSb as a function of heat-treating time.

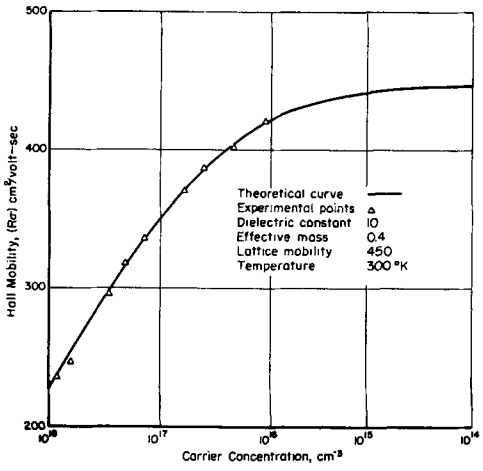

Fig. 3. Hole mobility at 300°K vs. carrier concentration of AlSb.

aluminum. As has been noted, initially the surfaces of the aluminum melts are covered with oxide, which gradually disappears as the aluminum is retained in the molten state. The vaporization of magnesium and other volatile impurities from the melt is inhibited undoubtedly by the oxide coating, which may be a cause of the scatter of points observed in the initial part of the curve in Fig. 2. Since the rate of the removal of p-type impurities seems to decrease rapidly at heat-treatment times above 16 hr, it is probable that most of the volatile impurities have been removed by this time and that the remaining impurities are not highly volatile and therefore are difficult to remove by this method. Such an impurity could be copper, which is known to be present in the aluminum also.

In Fig. 3 the mobility of the positive carriers in aluminum antimonide is shown as a function of carrier concentration. The theoretical curve was calculated on the basis of a dielectric constant of 10 for aluminum antimonide, an effective mass of 0.4 m_o, and a lattice mobility of 450 cm^2/v-sec at 300°K. The close agreement of the experimental points to the theoretical curve indicates that vacuum heat treatment of the aluminum significantly reduces the impurities in aluminum antimonide. The observed re-

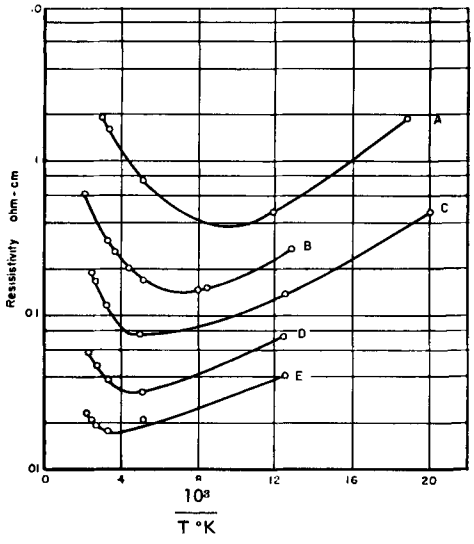

Fig. 4. Resistivity as a function of temperature for single crystals of AlSb.

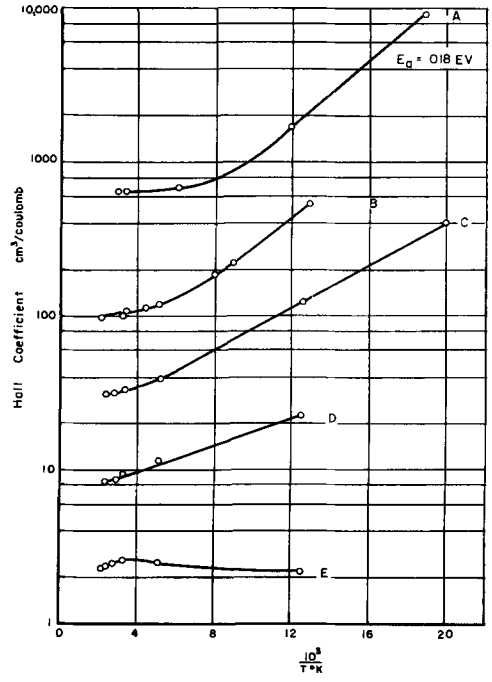

Fig. 5. Hall coefficient as a function of temperature for single crystals of AlSb.

duction in carrier concentrations therefore is not due to compensation.

Figure 4 shows the resistivity as a function of temperature of Hall samples cut from pulled aluminum antimonide crystals. Samples A, B, and C were taken from crystals pulled from melts containing aluminum that had been vacuum heat treated at 1000°C for 16 hr. Sample D is from an aluminum antimonide crystal made from aluminum that had been zone refined but not heat treated. Crystals grown from melts containing zone-refined aluminum show little, if any, improvement over crystals grown from melts containing aluminum in as-received condition. Sample E was cut from the aluminum antimonide crystal that had been doped with 1 part magnesium to 1 x 10^4 parts of aluminum.

Figure 5 shows the Hall coefficient as a function of temperature for the five crystals in Fig. 4. The slope of curve A was used to compute the energy level of the acceptor impurity. The energy level calculated from this slope is 0.018 ev. The minority impurity concentration calculated is consistent with the amount of compensation predicted by a comparison of the mobility data with the theoretical curve in Fig. 3.

The Hall sample cut from the magnesium-doped crystal giving curve E is degenerate throughout the entire temperature range of measurement. The critical concentration of p-type impurities in AlSb for which the ionization energy disappears is about 2 x 10^{18}/cm³, compared with 6.5 x 10^{18}/cm³ for silicon (7). It is expected that the effective activation energy will increase somewhat from 0.018 ev as the acceptor concentration is decreased and that it will be different for the various p-type impurities. However, it appears likely that the acceptor levels in AlSb are, in general, nearer to the valence band than those in silicon; probably the activation energies in AlSb are about a factor of two less than those in silicon.

Figure 6 is a plot of mobility as a function of temperature, as computed from the resistivity and Hall coefficient curves in Fig. 4 and 5. The mobility of the positive carriers decreases more steeply than $T^{-3/2}$ in the lattice-scattering range. In fact, the slope of the lattice mobility vs. temperature appears to be greater than T^{-2}. Magnetoresistance data suggest the presence of both light and heavy mass valence bands in AlSb. Thus, with the relatively impure samples presently available and the uncertainty in the values of r relating the Hall coefficient at a given magnetic field to the carrier concentration, the only conclusion possible is that the temperature dependence of the mobility in p-type AlSb is similar to that of p-type germanium and silicon.

Measurements of the Hall coefficient as a function of magnetic field between 600 and 20,000 gauss have

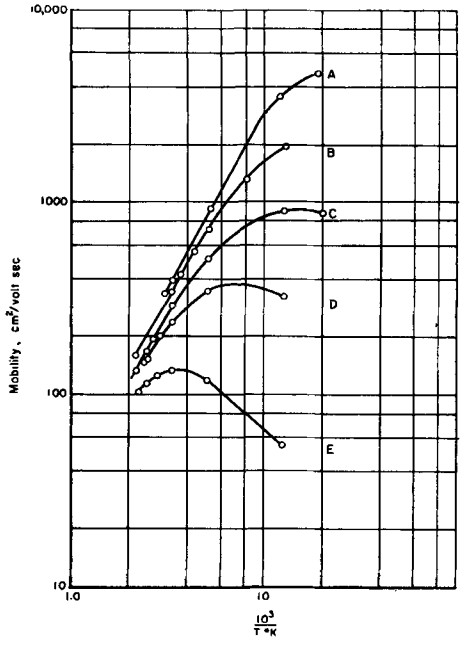

Fig. 6. Mobility as a function of temperature for single crystals of AlSb.

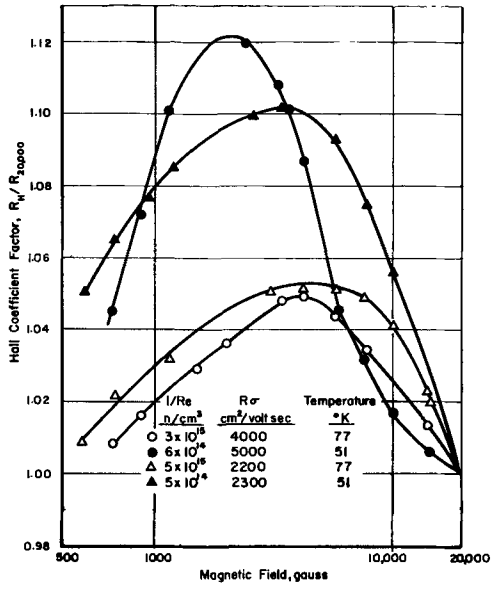

Fig. 7. Magnetic field dependence of the Hall coefficient in p-type AlSb.

been made at 77° and 51°K on a 1.6 ohm-cm sample of p-type aluminum antimonide with an $R\sigma$-value of 400 cm²/v-sec at room temperature. These measurements (shown in Fig. 7) indicate a maximum in the Hall coefficient at about 4000 gauss at 77°K and 2000 gauss at 51°K. A maximum also has been reported in the Hall coefficient of silicon at 77°K and a magnetic field of 20,000 gauss (8). In the case of silicon this maximum appears to be caused by a warping of the heavy mass band. One might expect a similar situation in p-type AlSb. It should be pointed out however that the maximum in the Hall coefficient occurs at a much lower magnetic field in AlSb. This could imply that the maximum in the Hall coefficient in p-type AlSb is related to the structure of the light mass band (9). Other factors, such as the polar character of the zinc blende structure, might affect the magnetic-field dependence of the Hall coefficient.

Summary

The p-type impurities in AlSb have been reduced by an order of magnitude by heat treating the aluminum. The major impurity remaining is probably copper; therefore, methods for removing minute amounts of copper and other nonvolatile impurities from the aluminum need to be developed. The oxide that hinders the growth of single crystals of aluminum antimonide can be eliminated completely by vacuum heat treatment of the aluminum. The activation energies of p-type impurities in AlSb are about one-half those for silicon. The mobility and the temperature dependence of the mobility of the majority carrier in p-type AlSb are almost identical with those in silicon. Finally, as in silicon, a maximum is observed in the magnetic-field dependence of the Hall coefficient in p-type AlSb.

A Phase Equilibrium Study of the System Na_2WO_4-Na_2CO_3-H_2O

R. L. Pilloton and G. E. Crawley, Jr.

Metals Research Laboratories, Union Carbide Metals Company, Division of Union Carbide Corporation, Niagara Falls, New York

ABSTRACT

A phase equilibrium diagram representing the binary system Na_2WO_4-H_2O between −7.5° and +35°C was constructed. This curve shows the regions of stability of the dihydrate and decahydrate of sodium tungstate. There is a eutectic point for the system ice-$Na_2WO_4 \cdot 10H_2O$ at −7.5°C and 30.1% Na_2WO_4, a transformation point for $Na_2WO_4 \cdot 10H_2O$-$Na_2WO_4 \cdot 2H_2O$ at 6.2°C, and 42.5% Na_2WO_4 and a metastable eutectic point for ice-$Na_2WO_4 \cdot 2H_2O$ at −13°C and 42.5% Na_2WO_4. Phase equilibria for the ternary system Na_2CO_3-Na_2WO_4-H_2O between −8° and +35°C are represented by a ternary diagram. Projections showing temperature contours and crystallization paths are given. The regions of initial crystallization of the various salts are presented. Applications of the diagram to fractional crystallizations are discussed.

Although solutions of sodium tungstate and of sodium tungstate plus sodium carbonate play an important part in the metallurgy of tungsten, information concerning phase equilibria of these systems is still incomplete. Published values for the solubility of sodium tungstate in water at low temperature (1, 2) are based on work done by Funk in 1900 (3). He indicated the existence of sodium tungstate decahydrate but did not study the exact range of stability of this salt. Furthermore, his solubility measurements are not sufficient to construct phase diagrams representing phase equilibria of the system Na_2WO_4-H_2O at low temperatures.

The only recent investigation of the ternary sys-

tem Na_2CO_3-Na_2WO_4-H_2O was reported by Sei and co-workers (4) in 1954 and concerns solubilities only at 19° and 29°C.

The first objective of the present work was to study the phase equilibria of the systems Na_2WO_4-H_2O and Na_2WO_4-Na_2CO_3-H_2O in the temperature and concentration regions close to those found in industrial applications. A second objective was to use the data for investigating the fractional crystallization of sodium carbonate from aqueous solutions containing both sodium carbonate and sodium tungstate.

General Procedures

To determine the solubilities, solutions of reagent-grade sodium carbonate and sodium tungstate containing an excess of one salt were agitated for several hours at constant temperature and the resulting solutions analyzed.

For experiments at or above 0°C, the samples were equilibrated in a water bath, the temperature of which was kept constant within 0.1°C. For experiments below 0°C, a glycol bath in a low-temperature chamber was used. After attainment of equilibrium, samples of the solution were withdrawn and filtered in the chamber at constant temperature. The length of time necessary to attain equilibrium was determined by analyzing aliquots from a number of solutions at regular intervals.

The densities of the solution samples were measured with a Westphal balance at room temperature. The dissolved sodium tungstate was determined by precipitating the tungsten as WO_3 in an acidified solution in the presence of cinchonine, igniting and weighing the oxide. Sodium carbonate was determined by weighing the $BaCO_3$ formed by absorption of the acid-displaced CO_2 in $Ba(OH)_2$ solution. Water was determined by difference. All analytical results were converted to weight percentages for the graphical representation. These results were found to be reproducible within a precision of 0.5%. The hydrate formulas were calculated from chemical analyses of the crystals which separated on cooling the solutions. Any solution attached to these crystals was carefully separated by absorption with filter paper. Crystals of ice were also analyzed to verify that they did not contain any Na_2WO_4 or Na_2CO_3.

In order to verify the course of crystallization, particularly in the "ice" region of the tungstate-carbonate diagram, a number of thermal analyses were made. In these experiments, solutions containing known quantities of Na_2CO_3 and Na_2WO_4 were cooled and time-temperature curves drawn. In most cases, a 4°C supercooling was observed. The temperatures of initial crystallization were determined from the curves.

Experimental results of the solubility measurements are given in Table I and represented by the phase diagram of Fig. 1.

The experiments showed that in most cases only crystals of $Na_2WO_4 \cdot 2H_2O$ were obtained even when saturated solutions of sodium tungstate were cooled to −5°C. The points representing the composition of the solution were then on branch FG of the curve in Fig. 1. However, by completely freezing a sodium tungstate solution at −15°C and then slowly raising the temperature to 0°C, long needles of a new hydrate were obtained. This compound was identified as $Na_2WO_4 \cdot 10\,H_2O$ by chemical analysis. The colorless crystals of this hydrate turned white and converted to $Na_2WO_4 \cdot 2H_2O$ and water at +6.2°C. By keeping the decahydrate at a low temperature, it was possible to prevent its decomposition and to

Table I. Solubility of Na_2WO_4 in water

use the crystals to seed other solutions. Branch EF of the curve was obtained by the procedure of seeding the solution after cooling below 6°C. Crystals of $Na_2WO_4 \cdot 10\,H_2O$ and $Na_2WO_4 \cdot 2H_2O$ are shown in Fig. 2 and 3.

The diagram shows that the freezing points of the solutions vary from 0 to −7.5°C along branch AE of the curve when the sodium tungstate concentration is lower than 30.1%. An aqueous solution containing 30.1% Na_2WO_4 by weight freezes invariantly at −7.5°C to give a binary eutectic E consisting of crystals of ice and of $Na_2WO_4 \cdot 10\,H_2O$. When the composition is lower than 42.5% and higher than 30.1% Na_2WO_4, crystals of $Na_2WO_4 \cdot 10\,H_2O$ may form between −7.5° and +6.2°C along branch EF of the diagram. However, in many cases, because of a "metastable supercooling" phenomenon, crystals of ice are formed along EG or crystals of $Na_2WO_4 \cdot 2H_2O$ along branch FG. Point F gives the temperature and

ments given in Table II is shown in Fig. 4. This diagram covers concentrations up to 35% Na_2CO_3 and 45% Na_2WO_4. Figures 5 and 6 are projections showing temperature contours and crystallization paths, respectively.

The different regions and the most important points and lines are lettered. Table III summarizes the state of the phases for various compositions with corresponding letters.

Peritectic reactions.—The "ice" region is a region of congruent crystallization; in other words, the composition of the solid phase being formed lies within the boundaries of its field of primary crystallization. On the other hand, solutions in the region corresponding to crystallizations of $Na_2CO_3 \cdot 10\,H_2O$ and of $Na_2WO_4 \cdot 10\,H_2O$ undergo incongruent crystallizations. Because of these phenomena, conversions of one crystal species into another are observed at the upper borders of these regions. For example, on cooling solution a in Fig. 6, crystals of $Na_2WO_4 \cdot 2H_2O$ are obtained first while the composition of the solution moves from a to b. From b to c, the crystals of $Na_2WO_4 \cdot 2H_2O$ are converted into $Na_2WO_4 \cdot 10\,H_2O$. At c, when all the dihydrate has been converted to decahydrate, the point representing the composition of the solution leaves the binary eutectic line and moves across the field $Na_2WO_4 \cdot 10\,H_2O$ to reach the binary eutectic

Table III. Salient features in the system Na_2WO_4-Na_2CO_3-H_2O

System composition	State of phases	Solid phases	Temp, °C
C	Binary eutectic	H_2O-$Na_2CO_3 \cdot 10H_2O$	−2.1
K	Binary peritectic	H_2O-$Na_2CO_3 \cdot 10H_2O$-$Na_2CO_3 \cdot 7H_2O$	31.2
E	Binary eutectic	H_2O-$Na_2WO_4 \cdot 2H_2O$	−7.5
F	Binary peritectic	H_2O-$Na_2WO_4 \cdot 2H_2O$-$Na_2WO_4 \cdot 10H_2O$	+6.2
H	Ternary peritectic	$Na_2WO_4 \cdot 2H_2O$-$Na_2WO_4 \cdot 10H_2O$-$Na_2CO_3 \cdot 10H_2O$	+5
I	Ternary eutectic	H_2O-$Na_2WO_4 \cdot 10H_2O$-$Na_2CO_3 \cdot 10H_2O$	−8
KLMHIC	One component saturation	$Na_2CO_3 \cdot 10H_2O$	−8 to 32
CIEA	One component saturation	H_2O	0 to −8
EIHF	One component saturation	$Na_2WO_4 \cdot 10H_2O$	−8 to 6.2
FHM	One component saturation	$Na_2WO_4 \cdot 2H_2O$	Above +5

line corresponding to crystallization of a mixture of $Na_2CO_3 \cdot 10\,H_2O$ and $Na_2WO_4 \cdot 10\,H_2O$. Upon further cooling, the invariant point I is reached, and the whole solution freezes solid to give a mixture of crystals of ice, $Na_2CO_3 \cdot 10\,H_2O$, and $Na_2WO_4 \cdot 10\,H_2O$.

Application to the crystallization of sodium carbonate.—The diagrams show that large quantities of sodium carbonate can be crystallized by cooling solutions containing both sodium tungstate and sodium carbonate in quantities comparable to those found in industrial sodium tungstate liquors. The course of the crystallization can be followed on Fig. 6. An example of a possible solution is represented by point P, which is in the Na_2CO_3-$10\,H_2O$ region. Upon cooling, the composition of the solution varies first from P to Q, while crystals of $Na_2CO_3 \cdot 10\,H_2O$ are formed. At Q, around −3°C, the binary eutectic line is reached, and a mixture of crystals of ice and of $Na_2CO_3 \cdot 10\,H_2O$ appears. More of these crystals form when the temperature is lowered further and the composition of the solution moves toward I along line QI. The temperature to each composition is found in Fig. 5. If cooling is stopped before a temperature of −8°C is reached at point I of the diagram, only crystals of ice and of sodium carbonate are formed, and there is no precipitation of sodium tungstate. Since sodium tungstate stays in solution, the amount of sodium carbonate and of water per gram of Na_2WO_4 before and after cooling indicates the yield of the crystallization. For example, point P of the diagram corresponds to the composition (by weight) $Na_2CO_3 = 10.2\%$, $Na_2WO_4 = 7.2\%$, water = 82.6%; consequently, there are 1.42 g of Na_2CO_3 and 11.5 g of water per gram of Na_2WO_4. At the end of the crystallization at, say, −7°C, the composition T is $Na_2CO_3 = 2.0\%$, $Na_2WO_4 = 28\%$, water = 70% which corresponds to 0.071 g of Na_2CO_3 and 2.5 g of water per gram of Na_2WO_4. The percentages of sodium carbonate and of water separated by crystallization are, respectively:

$$Na_2CO_3 \text{ .....} \frac{1.42 - 0.07}{1.42} \times 100 = 95.0\%$$

$$H_2O \text{ .....} \frac{11.5 - 2.5}{11.5} \times 100 = 78.3\%$$

The compositions of the final solutions and the percentages of water and of sodium carbonate removed by crystallization when solution P is cooled down to −4°, −5°, −6°, and −7°C are given in Table IV.

Table IV. Water and sodium carbonate crystallization from solution P (Fig. 6) at various temperatures

Final Temp, °C	Final composition, %			Removed percentage	
	Na_2WO_4	Na_2CO_3	Water	Na_2CO_3	Water
−3	8.5	5.0	86.5	56.5	11.3
−4	10.0	5.0	85.0	64.8	26.1
−5	16.0	4.4	79.6	80.6	56.7
−6	22.0	3.0	75.0	90.4	70.4
−7	28.0	2.0	70.0	95.0	78.3

If water is evaporated from the solution prior to cooling, the point representing the solution moves from P to R on line APR. The temperature at which crystallization of R starts is given by the temperature contour passing through R in Fig. 5. Upon cooling the solution, the composition follows paths RS and SI (Fig. 6).

Conclusions

This study of the solubility of sodium tungstate in water indicates that solid phases existing at temperatures between −7.5° and +35°C are ice, $Na_2WO_4 \cdot 10\,H_2O$, and $Na_2WO_4 \cdot 2H_2O$. The eutectic point for ice-$Na_2WO_4 \cdot 10\,H_2O$ is at −7.5°C and 30.1% Na_2WO_4, the peritectic point for $Na_2WO_4 \cdot 2H_2O$-$Na_2WO_4 \cdot 10\,H_2O$ at +6.2% and 42.5% Na_2WO_4, and the metastable eutectic point for ice-$Na_2WO_4 \cdot 2H_2O$ at −13°C and 42.5% Na_2WO_4.

The ternary diagram representing the system Na_2CO_3-Na_2WO_4-H_2O shows a ternary eutectic containing 2% Na_2CO_3, 27% Na_2WO_4, and 71% H_2O at −8°C. This diagram indicates that large quantities of sodium carbonate can be crystallized fractionally from solutions containing quantities of Na_2WO_4 and Na_2CO_3 comparable to those present in industrial liquors.

Manuscript received May 18, 1959. This paper was prepared for delivery before the New York Meeting, April 27-May 1, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Production of Thorium Powder by Calcium Reduction of Thorium Oxide

N. Fuhrman,[1] R. B. Holden,[1] and C. I. Whitman

Sylvania-Corning Nuclear Corporation, Bayside, New York

ABSTRACT

A process for the preparation of high-purity thorium powder by calcium reduction of thorium oxide has been developed, Calcined thorium oxide is reduced in an inert atmosphere at 950°C with high-purity calcium metal in the presence of calcium chloride. The reduction vessel is fabricated of type 446 stainless steel to avoid pick up of iron and nickel impurities and permit break out of the reduction cake. The thorium powder so produced has essentially the same purity as the thorium oxide starting material. Important factors controlling yield and quality of the thorium powder are discussed.

The purpose of this investigation was to examine the direct reduction of thorium oxide with calcium as a potential production process, to determine the yields and the quality of the metal so obtained, and to develop a standard procedure for preparing small batches of metal by this process.

Investigations of the calcium reduction of thorium oxide date back to the beginning of this century. Huppertz (1) suggested the use of calcium vapor, and Burger (2) employed this method with some success. Kuzel and Wedekind (3) subsequently patented a process using calcium vapor, and Wedekind (4) carried out further studies.

Results of the first critical study of thorium metal preparation were presented by Marden and Rentschler (5, 6) who, with the aim of producing a metal powder capable of being consolidated into homogeneous metallic bodies, conducted an investigation of calcium reduction of the oxide. Their method involved the reduction of thoria with a three-mole excess of calcium and one part of calcium chloride to one part of the oxide. The authors claim that after compacting and sintering, the solid metal assayed was 99.7 to 99.8% thorium.

Kroll (7) also investigated this process, essentially following the procedure of Marden and Rentschler. This method was also used on a large scale with some modifications in Germany during World War II, as reported by Espe (8, 9).

Rentschler, *el al.* (10) eliminated the calcium chloride in the charge and used a thin-walled molybdenum cup instead of the steel bomb. The reduction took place in a Vycor bell jar under argon at a maximum temperature of 1400°C, the heat being supplied by high-frequency induction. The thorium powder was recovered by leaching the charge directly out of the cup.

A variation of the above procedure was used by Marden (11) in the experimental preparation of several 12-lb batches of powder.

[1] Present address: Metallurgical Laboratories, Olin Mathieson Chemical Corporation, New Haven, Connecticut.

Meyerson (12) has described the development of the calcium reduction process in the U.S.S.R. Except for the production of thorium powder of much lower purity, his results are in agreement with those of the present work. Although the efforts were entirely independent, some of his reported procedures are similar to those developed here.

Process Description

The raw materials in the charge for reduction are: (*a*) thorium oxide, (*b*) redistilled calcium metal, and (*c*) anhydrous calcium chloride. Thorium fines may be added as a means of recycling the relatively impure metal powder which is not recovered as primary material in the leaching step.

The thorium oxide employed in the charge was supplied by the U.S. Atomic Energy Commission. A typical analysis of AEC thorium oxide is presented in Table I. It is apparent that special attention has been given to the removal of impurities of high thermal neutron absorption cross section. The overall quality of the material was fairly consistent from lot to lot. Raw thoria is fired for removal of absorbed carbon dioxide prior to preparation of the charge. Two methods have been used to accomplish this (*a*) continuous calcining at about 880°C in an experimental rotary unit, and (*b*) batch calcining in stainless steel boats for 40 hr or more at 800°C. The fired oxide is then handled in a CO_2-free atmosphere during the charge preparation and reduction. This procedure substantially reduces the carbon content of the metal product.

Redistilled calcium metal[2] was utilized as-received in the form of 6-mesh nodules. Typical analyses of the Domal and Nelco redistilled calcium indicate that they are of similar quality. Anhydrous calcium chloride, meeting the American Chemical Society specifications, is obtained in the form of 20-mesh granules and is used in the charge as-received.

The following charge composition is typical for the runs involving thorium fines recycle: 7000 g prefired ThO_2; 925 g thorium fines; 2800 g anhydrous $CaCl_2$; 2760 g redistilled calcium. The amount of $CaCl_2$ is 40% of the weight of ThO_2. The amount of calcium is 30% more than that required to react with the ThO_2. Whether or not thorium fines are recycled in this manner depends on the quality of thorium powder desired as a product.

The charge ingredients are weighed in an argon dry box into a 5-gal can which is then sealed and tumbled on a drum roller. Because of occasional poor yields of metal resulting from incomplete reduction, it is believed that blending may not be thorough enough with this equipment. An alternate blending method utilizes a 0.33 ft^3 double cone blender in which about half the charge is tumbled at one time. The latter procedure, on the basis of a limited number of experiments, appears to produce higher yields.

Fig. 1. Calcium reduced thorium oxide reduction cake. Type 446 stainless steel reduction vessel.

The blended charge is transferred to a tapered reactor fabricated of type 446 stainless steel. A flat reactor cover is secured to the reduction vessel, shown in Fig. 1, by means of a clamping ring. A pipe welded to the reactor cover admits argon into the reactor during the fastening operation as well as during the subsequent heating period, so that the reduction may take place in an inert atmosphere. An argon head of 5 in. of Hg is usually employed.

The loaded reactor is heated to 950°C by high-frequency induction heating and held there while the charge is soaked for about 5 hr. After reduction, the reactor generally is quenched in water to hasten the cooling process. The reduction product remains under argon until it is cold.

After cooling, the head is removed from the reactor and the reduction product or "cake" broken out by jolting the inverted reactor once or twice. A typical reduction cake is shown in Fig. 1.

Primary size reduction of the reduction cake is performed by crushing the cake between flat plates with a hydraulic press. Normally, about a 20- to 30-ton load is required to crack the cake. The large chunks are further reduced in size with a jaw crusher. A uniform crushed cake of about ¼ in. particle size is thus obtained.

A leaching apparatus consisting of a 55-gal stainless steel drum and a ½ hp "Lightnin" mixer, is used to disintegrate the crushed cake. First, the crushed reduction product is introduced into 35 gal of agitated tap water. After 15 to 30 min hydrogen evolution has almost ceased and agitation may be stopped. Any remaining unleached cake is allowed to disintegrate statically. After 2 hr the reduction cake is almost completely leached; however, in current practice, it is allowed to stand overnight. The supernatant liquor, containing suspended thorium fines, as well as $Ca(OH)_2$, is pumped to a settling tank for later recovery of the fines. The resulting thorium powder is then subjected to from three to five successive tap water washes to remove more of the $Ca(OH)_2$ leach product. These washes are carried out in a 20-gal stainless steel pot with agitation provided by a ¼ hp "Lightnin" mixer. After a settling interval of about 5 min, the supernatant liquor is pumped to the settling tanks. When practically all of the $Ca(OH)_2$ has been removed by this method, the thorium powder is ready for acid washing.

The powder is subjected to two successive washes of 1:8 nitric acid and then successive washes with demineralized water until the supernatant liquor is neutral. This treatment removes residual calcium and $Ca(OH)_2$ from the powder.

The wet powder is filtered and washed on a 9 in. diameter stainless steel Buchner funnel with three rinses of acetone followed by three rinses with petroleum ether (boiling range, 30° to 60°C) and then vacuum dried overnight at a pressure of <1 mm of Hg.

The wet powder can also be dried in a vacuum shelf dryer. The thorium powder is sufficiently dry when a vacuum of 35 μ of Hg is attained. It should be noted that in this drying method there is a possibility of obtaining an incompletely dried product which, because of its possible sensitiveness to ignition, is a safety hazard.

Thirty-seven reductions were carried out on an 11-lb. scale (the largest nominal batch size produced during the development program) with yields running as high as 91% of theoretical. The term "yield" refers to the coarse thorium powder obtained after the drying process. Early in this work it was shown that the yield of metal averaged over 99% when the metal fines were included and hence the conversion of oxide to metal is essentially complete.

The usual procedure for determining the quality of the thorium powder is chemical analysis. The following impurities are determined in each run: (*a*) carbon, (*b*) nitrogen, (c) hydrochloric acid insolubles (ThO_2), (*d*) iron, and (*e*) chromium. Occasionally, spectrochemical analyses are obtained, especially for elements with a high thermal neutron absorption cross section.

A typical spectrochemical analysis of the thorium powder produced is presented in Table I along with that of the ThO_2 starting material. A comparison of the two indicates that there is no substantial pickup of impurities in the process. In this case, an exception is magnesium which is readily removed, however, during consolidation by arc melting. Table II shows the chemical analyses of thorium powder produced during a series of ten consecutive runs on the 11-lb scale when the process was under control and before significant changes were made in the operating conditions. It is seen that the calcium reduction process is capable of consistently producing a high-purity thorium in good yield.

As a supplement to chemical analysis, another approach to quality measurement has been found useful, namely, the evaluation of the hardness and the surface appearance of arc melted buttons. For this evaluation, a 30-g sample of thorium powder is melted in an argon atmosphere of 7 in. of Hg absolute pressure in an arc furnace (button type). The Rockwell F hardness and button density are then determined. Since the button hardness is very sensitive to a small quantity of carbon and larger amounts

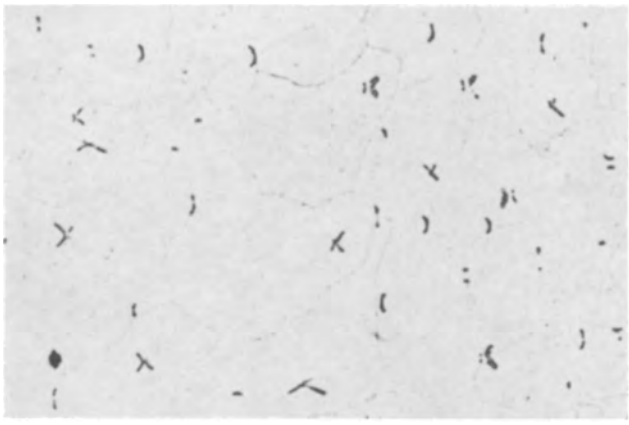

Fig. 2. Arc melted thorium button, run No. 58, bright field, 200X, 0.37% ThO_2.

of metallic impurities such as nickel, this method serves as a rapid means of determining relative quality. The presence of an unusually high oxide content is easily ascertained from the appearance of an oxide film on the button surface. Powder with a low oxide content (less than 0.3% HCl insolubles) normally results in a bright metallic surface. Button hardnesses of the material produced in the ten runs cited above are also shown in Table II.

A typical photomicrograph of an arc melted button is presented in Fig. 2. The main inclusion constituent is probably ThO_2, since chemical analysis indicates the presence of 0.37% HCl insolubles in the button.

To recover the very fine thorium powder which has been pumped to settling tanks during the leaching and acid washing steps for recycle through the reduction step, the settled thorium sludge is washed with 1:8 HNO_3. Enough nitric acid is added to insure the complete dissolution of $Ca(OH)_2$. After a 1-hr settling period, the supernatant liquor is pumped to the settling tanks. The supernatant liquor contains a small amount of dissolved thorium which may be periodically recovered as the hydroxide by precipitation with NH_4OH. The thorium fines are then washed with demineralized water at least three times to remove the acid. The fines are collected and dried by either of the two drying methods described previously.

Coarse thorium powder has been stored for periods as long as 4 months in air without any detectable deterioration. The usual practice is to store the powder from each run in a separate metal container. During the course of the development program described in this report, no case of spontaneous ignition of the powder was ever observed. However, at the termination of the project, a serious explosion did occur when some scrap fines were being burned in a disposal operation. It is suggested, therefore, that thorium powder be handled by procedures recommended for the handling of zirconium metal powders.

Various methods of consolidating thorium metal powder have been investigated extensively at this laboratory. These methods are: (*a*) consumable electrode arc melting (14), (*b*) hot compaction (15-17), and (c) cold compaction and sintering (17). By far, the most advantageous of these is the

first, since such impurities as calcium, magnesium, and hydrogen are reduced by a factor of about 10 during the arc melting. In addition, ingot densities as high as 11.69 g/cc [theoretical is 11.71 g/cc (18)] are obtained in a single melting operation.

Process Development

The standard operating procedure described in the previous section evolved from fifty-seven experiments made on a smaller scale. In these experiments the important factors controlling the yield and quality of thorium metal powder produced were ascertained. The most important results of these experiments are summarized below.

According to the thermodynamic data compiled by Coughlin (13), the equilibrium for the reduction of thorium oxide with calcium is favorable below the boiling point of calcium. It appears from our work that the reduction is not highly exothermic, i.e., there is no sudden increase in the temperature of the reactor as it is heated slowly to the reduction temperature. A calculation of the heat of reaction at 950°C predicts a value of −12.4 kcal for the reduction of a gram mole of thorium oxide with liquid calcium as follows:

$$ThO_2 + 2Ca \rightarrow 2CaO + Th$$

This small quantity of heat evolved is apparently easily dissipated.

In practice, a calcium metal excess of 25% or more is usually added to effect complete reduction. In addition calcium chloride is required to provide a fluid medium for contact between the reactants. It has been suggested by Marden and Rentschler (5) that the compound $CaO \cdot CaCl_2$ is formed (between the flux and the reaction product CaO), which removes the CaO as it is formed, driving the reaction to completion. This assumption cannot be entirely correct since it was found in the present work that complete reduction is attained with a relatively small amount of $CaCl_2$, much less than that contained in the compound $CaO \cdot CaCl_2$.

The subsequent leaching of the thorium metal from the reduction product releases heat through reaction of CaO and excess Ca metal with water and acid. For removal of this heat, some cooling mechanism must be provided; otherwise, local overheating may cause excessive oxidation of the thorium metal. The leaching and acid washing may be carried out with a large volume of water to dissipate the heat, or a cooling coil may be introduced into the leaching tank.

It was found that impurities in the calcium and calcium chloride such as nitrogen and aluminum would appear in the thorium metal product. The use of redistilled calcium and calcium chloride granules which conformed to American Chemical Society specifications reduced the nitrogen content from greater than 100 to less than 60 ppm and aluminum from greater than 2000 ppm to less than 10 ppm. Carbon in the thorium metal product was traced to the absorption of CO_2 from the atmosphere by thorium oxide raw material. For example, small samples of thoria were found to contain 80 ppm carbon immediately after calcining. This same material, after exposure to an air stream for 30 min was found to have increased in carbon content to 400 ppm. Either batch or continuous calcining of the thoria was found to be a suitable technique for reducing the carbon content in the thorium metal product to levels rarely exceeding 200 ppm.

The development of a suitable container for carrying out the reduction proved to be a major problem in this program. Ordinary steel is unsuitable because of its lack of oxidation resistance. When a nickel stainless steel or Inconel container was used, the reduction cake adhered so firmly to the container wall that it was necessary to leach the charge in place in the container. Also, the thorium metal produced generally contained several hundred ppm of nickel impurity. Lining of the reactor with overlapped sheets of molybdenum was not satisfactory in preventing nickel pickup. A calcium oxide liner was dissolved in the reduction melt. A graphite liner eliminated the breakout problem but resulted in carbon contents of about 500 ppm.

It was found eventually that the use of a tapered reactor of type 446 stainless steel (which contains no nickel) reduced the nickel content in the product to as low as 7 ppm and also permitted removal of the reduction cake by the simple process of inverting the container and jolting it on a hard surface. In addition, to minimize atmospheric contamination, it was found necessary to admit argon throughout the reduction process through a tube leading into the cover of the reactor.

Experiments were made with varying proportions of calcium and calcium chloride, reduction times, and reduction temperatures. In general, a longer reduction time resulted in an increased yield of thorium powder, probably through agglomeration of fine thorium particles into larger ones. This was counter-balanced by a slightly increased pickup of such impurities as iron and chromium from the reactor. When the excess of calcium was decreased from 50% down to 25%, it became necessary to increase the soaking time from 2½ hr to 5 hr to insure complete reduction of thorium oxide. An optimum temperature for reduction is 950°C because at higher temperatures breakout difficulty can be encountered and, in addition, impurities in the thorium powder increase.

It was noted that increased periods of agitation during the leaching of the reduction cake had an adverse effect on thorium yield because larger particles are comminuted to fines. Both impeller agitation and tumbling barrel techniques were satisfactory for leaching thorium powder.

A typical analysis of fines is illustrated in Table III. It should be noted that the impurity level is somewhat higher than in primary yield thorium powder. These fines can be recycled into the process in several ways. If necessary, fines can be dissolved, reprecipitated as thorium oxalate, and calcined to form thorium dioxide, although economically this is least attractive. As noted earlier, fines can also be introduced directly into the metal reduction charge and with good results. Finally, the fines can be consolidated directly with the primary yield coarse thorium

Table III. Chemical analysis of thorium fines

Nitrogen	0.010
Carbon	0.036
HCl insol.	0.83
Iron	0.012
Chromium	0.0058

powder at an apparent sacrifice in the quality of the metal produced. This was demonstrated in an experiment by comparing the button hardness of the product resulting from the two latter methods of recycle using the same lot of fines and a 15% recycle basis. The hardness of the metal produced by direct consolidation was R_F 58 and that prepared by recycle to the reduction step was R_F 47.

Conclusions

It has been shown that the calcium reduction of thorium oxide is capable of producing a high-purity thorium metal. This can be accomplished only through use of high-purity starting materials and by careful attention to charge preparation, reduction conditions, containers, materials, and powder leaching procedure. Extension of the process to manufacture of larger quantities should be straightforward.

Batteries with Solid Ion-Exchange Membrane Electrolytes

II. Low-Temperature Hydrogen-Oxygen Fuel Cells

W. T. Grubb and L. W. Niedrach

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

Hydrogen-oxygen fuel cells employing a commercial ion-exchange membrane as the electrolyte are described. Some performance data on this type of cell operating at room temperature with a cation membrane in the hydrogen form and with hydrogen and oxygen at 1 atm are presented. The open circuit EMF is about 0.3 v below the value of 1.23 expected for a reversible cell. This deficiency is found to be caused by the oxygen electrode which does not achieve the reversible half-cell potential. Equilibration of the membrane electrolyte with sulfuric acid prior to cell assembly results in improved polarization characteristics. Favorable features of these cells include their simple construction and their small unit thickness. In addition, the presence of as much as 67% CO_2 in the hydrogen feed gas is found to have little effect upon performance. Since the electrolyte is a cross-linked, water-saturated polymer, the electrolyte is locked into the structure and cannot be leached from the cell when it is operated within the stability limits of the polymer. No dilution occurs from the water formed at the oxygen electrode during cell operation because it is rejected from the saturated electrolyte.

In previous work (1), the behavior of ion-exchange membranes as electrolytes in cells employing metal electrodes was described. Their behavior suggests a strong analogy with aqueous solution elec-

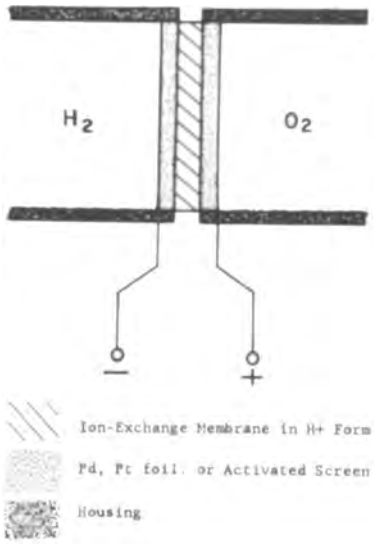

Fig. 1. Schematic diagram of ion-exchange membrane fuel cell.

Fig. 2. Type 1 ion-exchange membrane fuel cell, active area, 25 cm².

trolytes. Since the permeability of gases through ion-exchange membranes is low, they appeared to be ideally suited to serve as both the gas separator and the electrolyte in fuel cells (2, 3). The present work was undertaken therefore to study the properties of some simple systems of this type. This has resulted in a new type of low-temperature, hydrogen-oxygen fuel cell.

Experimental

Two types of cells were used in the experimental work. In both cases construction was such that the electrodes were in intimate contact with the electrolyte material as shown schematically by the diagram in Fig. 1. Immediately adjacent to the electrodes, gas chambers for the hydrogen and oxygen were formed by the cell housings.

A commercially available ion-exchange membrane was used in all of this work. For this purpose Amberplex C-1[1] was selected. This is a heterogeneous membrane consisting of particles of sulfonated, cross-linked polystyrene bonded into sheet form with an inert binder. These membranes, which were employed in the hydrogen form, have a conductivity that approximates that of a 0.1*N* H_2SO_4 solution (4). They are also stable chemically and have high flexibility and mechanical strength. Some electrochemical properties of Amberplex C-1 have been reported by Winger, *et al* (5).

Nickel screens activated by platinum black were used as the electrodes in most cases although a few experiments were performed with platinized platinum and palladium foil electrodes. Platinizing of the nickel screens was accomplished by simply immersing the screen into an acidified platinum chloride solution containing a trace of lead acetate (6). When palladium or platinum was employed, electrodeposition of the black was necessary, and the method of Reilly and Rae (6) was used.

A photograph of the simple cell (type 1) employed for the first experiments is shown in Fig. 2. The effective cell area was 25 cm² and the thickness of the electrolyte layer 0.06 cm to provide a cell constant of about 420. This type of cell was used with both screen and foil electrodes. Because of the relatively small area and the use of flat electrodes, good contact was obtained between the electrolyte and the electrodes with only the pressure of the flanges on the periphery of the housing.

In later work a larger version of the cell was designed. Two views of this cell (type 2) are shown in Fig. 3 and 4. In this model the electrodes were held in place against the membrane by backing plates with suitable baffles arranged to promote gas distribution. A uniform pressure was applied to the electrodes by placing rubber spacers between the backing plates and the face plates of the cell. These

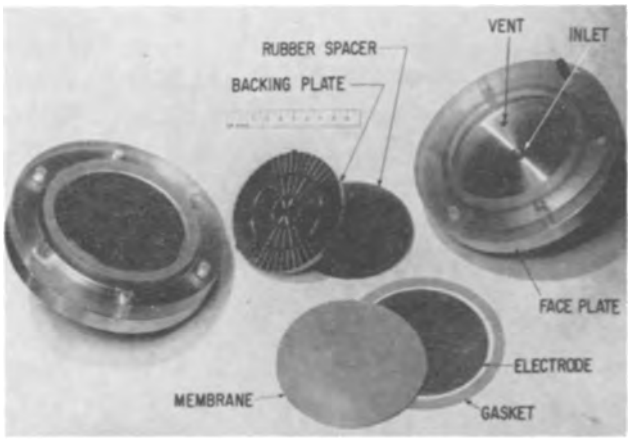

Fig. 4. Type 2 cell, not assembled

parts are shown in Fig. 4. In operation the feed gases were admitted through inlets on the axis of the cell. After radial distribution over the electrodes, the waste gases were then vented through the exit ports. Silicone rubber gaskets were employed as seals. Over-all diameter of the cell was 12.7 cm (5 in.) and the diameter of the electrodes was 8.3 cm (3¼ in.). Total active area was approximately 50 cm².

The cells were operated by admitting hydrogen and oxygen, respectively, to the two gas chambers and measuring the electrical output. In order to maintain ion exchange membranes in highly conducting form, they must be kept at 100% humidity, and this was accomplished by bubbling the input gases through water. Water formed by the cell in operation can help to maintain the hydration of the membranes. Actual dilution of the electrolyte cannot occur since the membranes reject water when they are saturated.

Polarization curves were obtained under various conditions by measuring currents with a sensitive galvanometer and cell potentials with a Rubicon potentiometer. In the initial work with the type 1 cells (Fig. 2), measurements were taken 10 sec after applying the load. This procedure has been recommended by Davtyan (7) and proved adequate for the purpose of comparing various modifications. In the work with type 2 cells, steady-state data were obtained. Establishment of equilibrium generally required several minutes after a change in load was made. All of the data were obtained at room temperature (25° ± 3°C).

In order to permit comparison of data obtained with the two types of cells, all current measurements were converted to current densities. This was done by dividing the measured current by the geometrical area covered by the circular electrodes.

Results and Discussion

The initial polarization curves, shown in Fig. 5, were obtained on type 1 cells with platinum foil electrodes. Platinized platinum foils as thin as 0.0002 cm (0.08 mil) were used in order to minimize diffusion effects through the metal. Only fairly low currents could be obtained from these cells. For this reason, attention was quickly directed toward cells with metal screen electrodes.

Polarization curves obtained with the type 1 cell using platinized screen electrodes are depicted in Fig. 6. All screen cells were found to afford higher currents than the foil types. The screen electrodes were made from nickel screen 150 x 150 (per inch) mesh. This mesh is woven from 0.0076 cm (0.003 in.) diameter nickel wire. The original screen thickness is 0.015 cm (0.006 in.) at the points where the wires of the mesh cross. The three curves were obtained with screens that had been rolled to different thicknesses before being platinized. It was observed that, as a result of the successive rolling, the surface of the screen became flatter and facilitated a larger area of contact between the electrode and electrolyte. This correlates with the fact that less polarization occurs with the more extensively rolled samples since lower effective current densities at the electrode surface would result from the better contact. The best type 1 cell achieved 60 ma at 0.75 v after 10 sec under load and a steady-state current of about 40 ma on the same load resistance.

Electrodes 500X 500 mesh nickel screen activated with platinum black.

The form of the polarization curves and the value of the open-circuit voltage both suggest irreversibility at one or both electrodes in this cell. In order to separate the effects of the anode and cathode, the hydrogen electrode was placed in a separate cell against a zinc electrode which is already known to behave reversibly (1). The following cell was used: zinc metal/zinc ion membrane/hydrogen ion membrane/platinized screen/hydrogen gas at 1 atm. The polarization curve of this cell is plotted in Fig. 7 along with that of the best cell of Fig. 6 for comparison. The emf of the H_2-Zn cell at zero current is observed to be 0.75 v, whereas in the analogous cell in which aqueous solutions at 25°C are employed with unit ionic activities the emf is 0.763 v (8). It is concluded that the H_2/platinized screen/H^+ membrane half-cell must be operating approximately at the reversible emf. The open-circuit emf of the H_2-O_2 cell is 0.90-0.96 v as compared with 1.23 v to be expected from the value of free energy of formation of water at 25°C. A deficiency of about 0.25-0.30 v at the O_2 electrode must therefore be present. This result is not surprising in view of published work on the behavior of platinum electrodes with oxygen at room temperature in sulfuric acid solutions (9).

The data presented above were obtained during short periods of operation using the type 1 cell of Fig. 2. It was of interest to consider performance under continuous operation. For this purpose a test run of approximately 15-hr duration was made on the type 2 cell of Fig. 3 and 4. In this run platinized nickel electrodes were used. In addition, the fuel gas was a mixture of 2 moles CO_2 to 1 mole of H_2. Flowing gases were used. At the start of the run the current was 45 ma at 0.69 v. After approximately 15-hr operation the cell current was 47 ma at 0.73 v. Initial and final polarization curves for this run are shown in Fig. 8.

Since it is known that ion-exchange membranes have a capacity for free acid, it was of interest to determine the effect of such acid on cell performance. For this purpose a membrane was equilibrated with 6M H_2SO_4 and after being blotted dry was assembled into a cell. The pronounced effect of the free acid on cell performance is shown by a comparison of the two curves in Fig. 9. The lower curve in the figure is representative of steady-state performance of cells operating with untreated membranes on pure hydrogen and oxygen.

While addition of free acid to the membrane does improve the cell performance, this does not appear to be a satisfactory, long range approach because of the corrosion problems that are thereby introduced. In addition, this acid can be leached from the membrane by the water produced in the cell reaction unless proper conditions are maintained to remove water by evaporation.

Summary and Conclusions

The use of ion-exchange membranes as the electrolyte in hydrogen-oxygen fuel cells is attractive. As solid, nonleachable electrolytes, these membranes permit the construction of cells that require a minimum of external components and controls, e.g., pumps, etc. Another important advantage of the ion-exchange membrane electrolyte is its very favorable geometry. The cells described here have a total active thickness of less than 1 mm. Such a favorable space factor helps to compensate for the lower current density of this cell relative, for example, to that of Bacon (3). In addition, because such membranes are used in their acid form, operation on gases containing large amounts of CO_2 is possible and has been demonstrated.

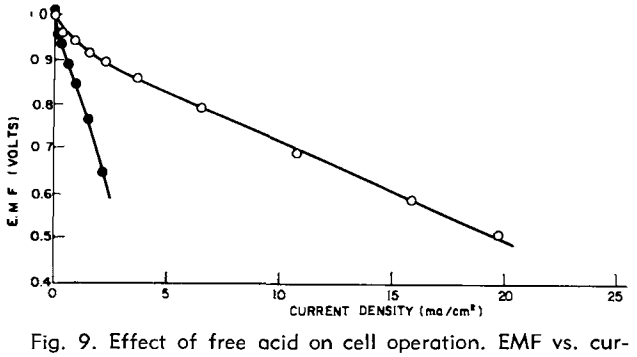

Fig. 9. Effect of free acid on cell operation. EMF vs. current density for type 2 cell with 200 x 200 mesh nickel screen electrodes (rolled to 0.002 in. thickness) platinum activated. ●, Leached membrane H^+ form; ○, membrane H^+ form in equilibrium with 6M H_2SO_4 and wiped dry superficially.

Saturation of the membrane-electrolyte with sulfuric acid improves the performance of the cell. The treatment has some disadvantage in that it causes corrosion problems and other complications related to the dilution and leaching out of the free acid.

The indicated directions of improvement for cells of this kind are in mechanical construction to improve the electrical contact between the electrodes and the membrane and in the oxygen electrode surface to provide a more nearly reversible O_2 half-cell.

The Influence of Cations on the Differential Capacity of the Dropping Mercury Electrode in Solutions of Electrolytes in Methanol and Ethanol

S. Minc and J. Jastrzebska

Department of Electrochemistry, University of Warsaw, Warsaw, Poland, and Department of Electrochemistry, Polish Academy of Sciences, Warsaw, Poland

ABSTRACT

Differential capacities of the electrical double layer of LiCl, NaCl, $MgCl_2$, and $SrCl_2$ in methanol have been measured. The capacities have been found to be higher in the presence of large cations (of low polarizability), which undergo chemisorption according to Frumkin's theory, by comparison with values observed in the presence of cations of high polarizability. In addition, the effect of concentration of the electrolyte on the differential capacity increases with decreasing polarizability of the cation. The solvent effect on the differential capacity has been found to be greatest near the zero charge potential, the decrease of the differential capacity relative to its value in water solutions being proportional to the decrease in dielectric constant.

In recent papers on electrocapillary phenomena, two different points of view have been advanced regarding the effect of cations on the structure of the electrical double layer. According to Grahame (1-3) the differential capacity of the inner part of the double layer is independent of the kind of cation if it is monatomic. Small differences of capacity observed for aqueous solutions in the region of strong cathodic polarization in the presence of different cations are due, according to Grahame's theory (4), to incomplete dielectric saturation of the solvent by some cations. There are more facts which could hardly be explained by Grahame's theory. For instance, it is known that the presence of large cations in the solutions increases the rate of electroreduction of some anions, e.g., $S_2O_8^{2-}$, and/or shifts the potential of desorption of anions toward more negative values (5-7).

Frumkin has concluded (6, 8) that some large cations, e.g., Rb^+, Cs^+, are chemisorbed at the surface of mercury. The aim of our work has been to contribute further experimental data to the solution of this problem (9). It was expected that the effects of chemisorption of cations ought to be more pronounced in some organic solvents. Methyl and ethyl alcohols have been chosen as solvents because of their high compressibility, high electrostriction in electrical fields, and their ease of dielectric saturation (10, 11). In consequence, the influence of cations on the structure of the double layer should be determined more precisely.

Experimental

An a-c symmetrical bridge was used in measurements of the differential capacity of the dropping mercury electrode. Our circuit differed from that of Grahame (12, 13) in that the stray capacitances of the bridge ratio resistors were balanced. A ferrite core choke or large inductance was introduced into the circuit (14). The application of balanced ratio

resistors and a large inductance in measurements with organic solvent solutions of low conductivity resulted in greater accuracy. The polarization of the dropping mercury electrode was achieved by a conventional polarographic technique.

Differential capacities were measured for potentials between —0.1 v and —1.8 v, with the aqueous saturated calomel electrode (S.C.E.) as reference. The surface area was evaluated by Grahame's method. The calculated differential capacity per unit area has been plotted against the potentials in Fig. 1-10.

Methyl and ethyl alcohols were distilled on a 30-plate column and the appropriate fractions collected. Water was distilled three times through a quartz condenser. Its specific conductivity was 4×10^{-6} ohm^{-1} cm^{-1}. Magnesium chloride, after being recrystallized from water, was heated in mixture with ammonium chloride at 360°C in platinum. Sodium chloride was brought down from a saturated solution by means of gaseous hydrogen chloride. Other salts were recrystallized from methyl alcohol and dried at 180°C to constant weight. Mercury was washed with dilute nitric acid, then with water, and finally distilled in vacuum. Nitrogen used for removing oxygen from the solutions was purified by means of activated carbon, potassium hydroxide solution, and silica gel impregnated with Cu_2O (15). The purity of solutions was checked polarographically.

Results and Discussion

Figure 1 shows differential capacity curves for 0.1M LiCl, 0.1M NaCl, and saturated KCl (about

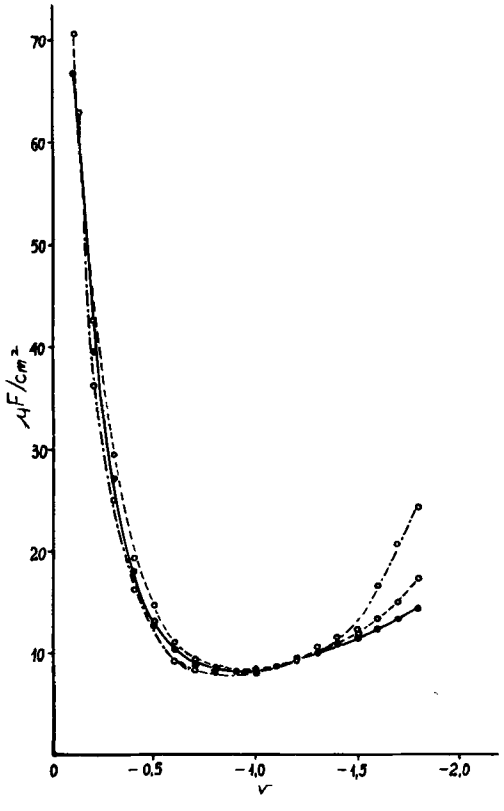

Fig. 1. •— 0.1M LiCl in methanol; o— — 0.1M NaCl in methanol; o- — satd. KCl in methanol.

Figs. 1-10. In the ordinate is the differential capacity of the mercury-solution interface in microfarads per square centimeter, the abcissa is the potential relative to the aqueous S.C.E., in volts.

0.05M) in methyl alcohol. In the region of high cathodic polarization the differential capacities differ in the presence of different cations and increase from Li^+ to K^+ in a manner similar to that observed for water solutions, except that the effect is more pronounced in alcohol. Similar curves determined for 0.1M methanol solutions of $MgCl_2$, $CaCl_2$, and $SrCl_2$ are shown in Fig. 2. The divalent cations affect the differential capacity only slightly and then only in the region of high cathodic polarization. In summary, it may be said that the differential capacity of the electrical double layer on mercury in the cathodic region is higher in the presence of cations of low polarizability (large radii). These ions, according to Frumkin's theory, undergo specific adsorption (chemisorption). There is no doubt that the high compressibility and electrorestriction of methyl alcohol molecules cause a more pronounced interaction of cations with the metal surface.

Results shown in Fig. 1 and 2 make it clear, however, that the differential capacity is affected not only by the nature of the solvent, as postulated by Grahame (11, 16), but also by the nature of cations, especially those of low polarizability. If Frumkin's hypothesis of specific adsorption of some cations is true, an unusually strong effect of concentration of the electrolyte on the differential capacity is to be expected when these cations are present in solution. The measurements performed to test this expectation are presented in Fig. 3-8. The differential capacities have been measured for aqueous, methanol, and ethanol solutions of LiCl and KF in the concentration range from 0.05 to 0.5M.

For aqueous solutions of LiCl and KF the effect of concentration on the differential capacity is small and nearly the same for both cations in the cathodic region (Fig. 3 and 4). This is in accordance with the

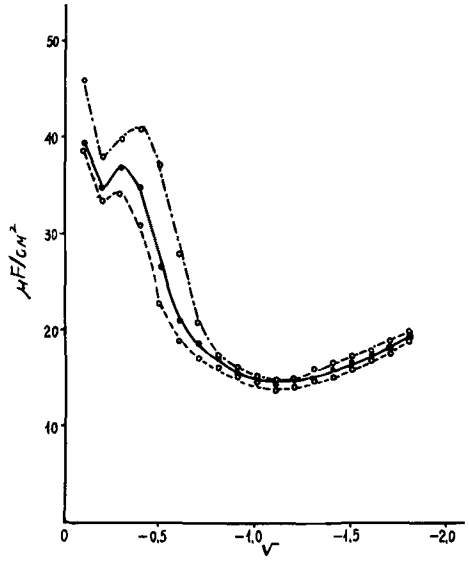

Fig. 3. Effect of concentration o— — 0.05 M LiCl in water; •— 0.1 M LiCl in water; o- — 0.5 M LiCl in water.

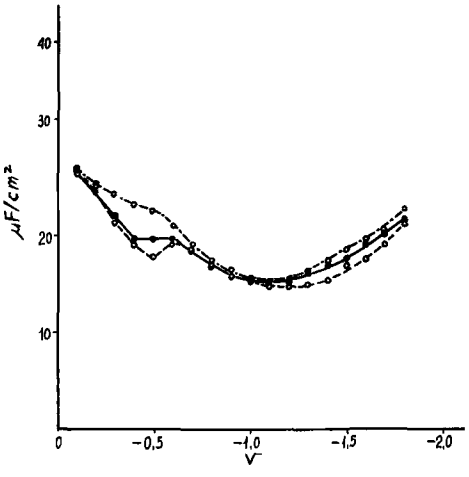

Fig. 4. Effect of concentration. o— — 0.05M KF in water; •— 0.1M KF in water; o- — 0.5M KF in water.

conclusion that neither Li^+ nor K^+ are chemisorbed on mercury from water. The small effect of concentration on the differential capacity of LiCl solutions in all three solvents (Fig. 3, 5, and 6) may be accounted for on the basis of the theory of electrostatic interaction of ions with metal surface developed by Grahame (1, 2, 11).

The marked concentration dependence found for high cathodic polarizations in alcoholic KF solutions (Fig. 7 and 8) cannot be due to the effect of concentration on the capacity of the diffuse part of the double layer as this effect could not be so different for the two cations investigated. It may be considered as evidence in support of the hypothesis of chemisorption of K^+ ion from methanol and ethanol.

Further measurements were undertaken to determine the desorption potentials of halide ions in methanol (Fig. 9 and 10). The only reason for the lower differential capacities in the cathodic region for saturated (about 0.05M) KCl in methanol as compared with 0.1M solutions of the potassium halides (Fig. 10) is evidently the difference in concentration. The differential capacities of saturated KCl (Fig. 1) and of 0.05M KF (Fig. 7) are practically the same. It is worth stressing that the desorption potentials found in this work for F^- and Cl^- ions in the presence of K^+ ion in methyl alcohol are nearly the same as those given by Grahame (11) for the same anions and solvent in the presence of NH_4^+.

In order to characterize the solvent effect, the curves for 0.1M LiCl in water (Fig. 3), methanol

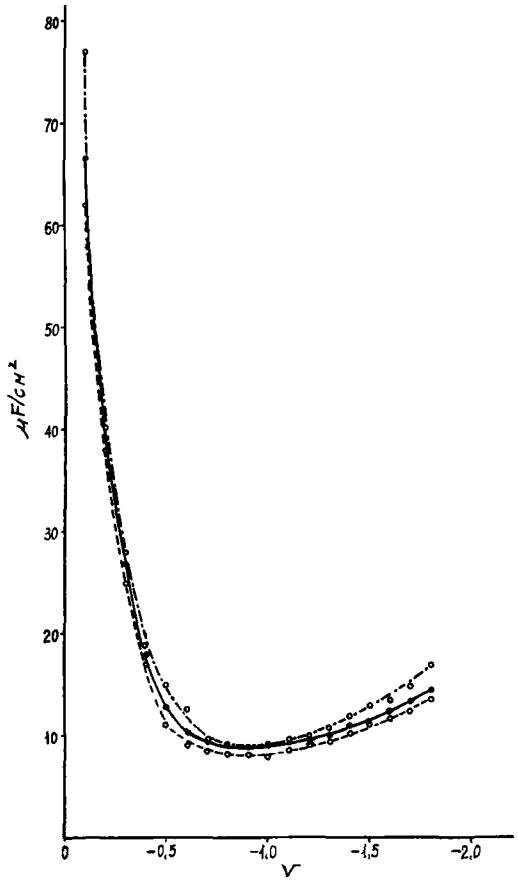

Fig. 5. Effect of concentration. o— — 0.05M LiCl in methanol; •— 0.1M LiCl in methanol; o- — 0.5M LiCl in methanol.

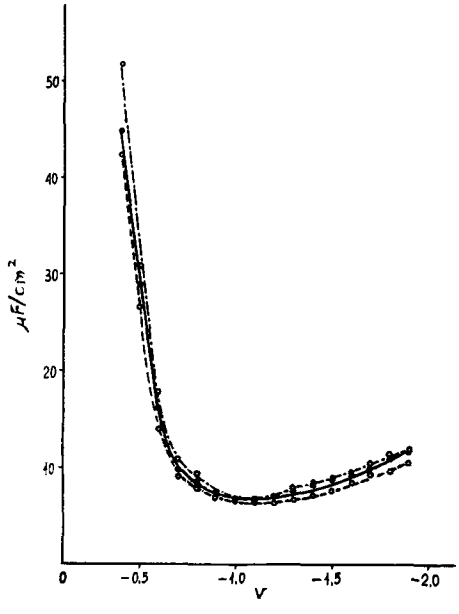

Fig. 6. Effect of concentration. o— — 0.05M LiCl in ethanol; •— 0.1M LiCl in ethanol; o- — 0.5M LiCl (satd.) in ethanol.

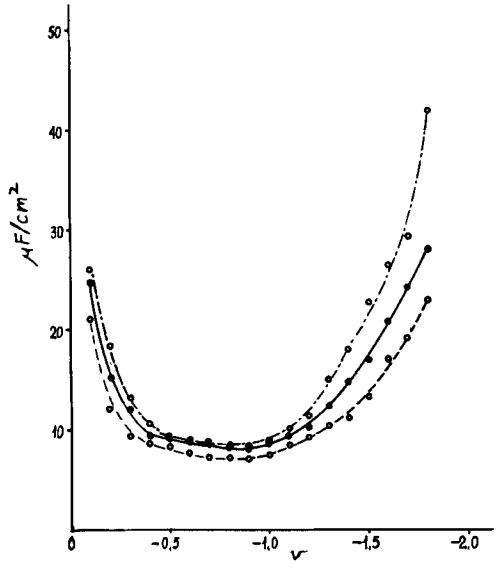

Fig. 7. Effect of concentration. o— — 0.05M KF in methanol; •— 0.1M KF in methanol; o- — 0.5M KF in methanol.

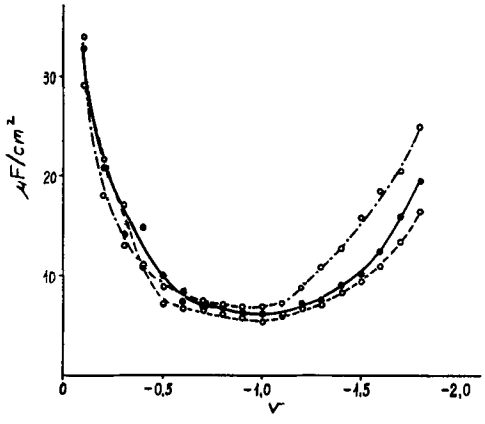

Fig. 8. Effect of concentration. o— — 0.05M KF in ethanol; •— 0.1M KF in ethanol; o- — satd. KF in ethanol.

(Fig. 1 and 5), and ethanol (Fig. 6) can be compared. The strongest effect of the solvent occurs near the zero charge potential (about —0.6 v). In this region, the decrease of the differential capacity when water is replaced by alcohol is nearly proportional to the decrease of the dielectric constant of the solvent. Also worth noting is the fact that the differential capacities of alcohol solutions show no peaks in the region of low anodic polarizations (about —0.3 to —0.4 v to S.C.E.); such peaks are observed in aqueous solutions (Fig. 3). This observation seems to favor the explanation given by Grahame (16) according to which this effect is due to the pseudocrystallic structure of water.

Technical Notes

Chloride Content of the Diffusion Layer at a Silver Anode

Paul A. Krasley[1]

Chemistry Division, National Bureau of Standards, Washington, D. C.

A technique for isolating the diffusion layer at an electrode was developed by Yannakopoulos and Brenner (1). It involves the drawing off of the diffusion layer through a microporous electrode. These authors applied the method only to the study of the decrease of metal concentration that occurred at a cathode during metal deposition. The study reported here is an extension of the method and deals with the depletion of chloride ion that occurs at an attackable anode of silver.

The diffusion layer that forms at a silver anode during electrolysis of a sodium chloride solution contains a lower concentration of salt than the body of the solution, and the lowest concentration exists at the interface of the solution and the anode. The reduction in concentration results from the precipitation of chloride ions as silver chloride and the migration of sodium ions toward the cathode.

Experimental

Preparation of a microporous silver electrode.— Yannakopoulos and Brenner used a microporous, cylindrical, stainless steel electrode in their experiments. This shape has the advantage of providing a large electrode surface and a small volume. Efforts to prepare a microporous cylinder from porous silver sheet were unsuccessful for several reasons. The pores in the silver sheet were closed through cold-welding during the fabrication of the cylinder, and the sheet was so brittle that it cracked in shaping. A silver plated stainless steel cylinder was unsatisfactory because the stainless steel was attacked anodically through the pores in the silver coating.

Plane microporous silver anodes 2 in. in diameter were made by placing "spherical silver powder" in a soapstone form, covering with a disk of soapstone, and sintering in a preheated furnace at 900°C for 0.5 hr. This procedure yielded disks having a ratio of voids to volume of 30-50%. Both acicular and electrolytic silver powder were also tried in the fabrication, but the spherical silver powder was most satisfactory.

Attempts to form the silver disks by the application of pressure alone, up to 2000 lb/in.^{2}, were not successful, because the silver did not cold-weld sufficiently to form a mechanically strong disk. The combination of compacting by pressure followed by sintering at 900°C had no advantage over heating alone.

The porous silver disks were made as thin as possible in order to reduce the amount of solution required to rinse the porous disks before collecting a sample of the interface of the bath. Disks having a thickness of about 0.09 in. were the thinnest able to withstand the handling in the cleaning procedure and the slight vacuum applied during sampling.

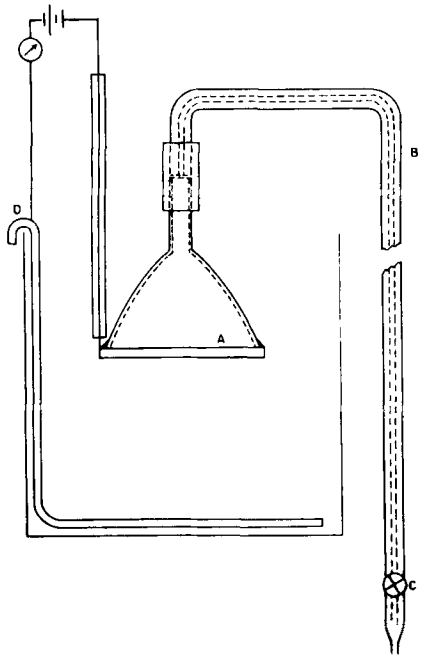

Fig. 1. Apparatus for desalting water: A, microporous silver anode; B, siphon; C, pinchcock; D, nickel anode.

[1] Present address: Bureau of Engraving and Printing, Washington, D. C.

Apparatus and Procedure

The apparatus shown in Fig. 1 consisted of a microporous silver anode, A, attached to an inverted funnel with Apiezon wax. The funnel was provided with a long capillary syphon, B. A pinchcock, C, regulated the rate of sampling of the interface. The nickel cathode, D, was bagged to minimize turbulence due to hydrogen evolution.

The apparatus was made ready for an experiment in the following way. The inverted funnel attached to the silver anode was filled with an organic liquid immiscible with water. To do this the anode assembly was partially immersed in water while the organic liquid was poured in from the top. An organic liquid more dense than water was chosen so that the aqueous solution subsequently collected would rise to the top. The following liquids were tried: a toluene-chloroform mixture (density 1.07^{20}), perfluorotriethylamine (density 2.7^{20}), and tetrabromoethane (density 2.95^{20}). Tetrabromoethane was used in most of the experiments.

The filled anode assembly was attached to the capillary syphon and was suspended in the bath. Electrolyses at various anodic current densities and rates of sampling were performed. Since the pores of the silver anode were filled with the water, the first several milliliters of liquid collected in an experiment were discarded before a sample representative of the electrode-solution interface was collected.

Results

The data in Table I represent typical results for the electrolysis of sodium chloride solutions. One disk was used for the 3% electrolysis and another disk was used for the 1% electrolysis. Because the formation of silver chloride plugged the interstices of the disk and caused a considerable increase in resistance both to current flow and to the flow of liquid, a single disk could not be used to make many successive experiments for determining effects of current density and of the rate of collection of the sample. For this reason the concentration of sodium chloride was reduced to 1%. The order of collection of data was the same as appears in Table I. Run No. 9 and definitely Run No. 10 can be attributed to the plugging of the disk. The plugging is accompanied by the evolution of gas which doubtless disturbs the diffusion layer.

Table I. Results of the electrolysis of NaCl solutions using porous silver anodes

Run No.	Conc. of electrolyte, %	Current density, amp/dm²	Rate of sampling of diffusion layer, min/ml	Reduction in chloride, %
1	3	2	3.3	17.8
2	3	3	3.3	24.5
3	3	1	7	39.4
4	3	2	7	45.6
5	1	0.25	7	18.5
6	1	0.50	7	34.3
7	1	0.25	14	32.2
8	1	0.5	14	73.0
9	1	0.75	14	80.9
10	1	0.75	17.5	27.0

Discussion

The investigation of the removal of chloride ion in the diffusion layer of a silver anode was carried only far enough to indicate that the process was theoretically feasible. The plugging of the silver disks showed that the use of this particular electrode was impracticable as a means of desalting water. However, it is possible that a more satisfactory electrode system can be developed.

Theoretically, a continuous desalting process could be devised which would utilize two porous silver-silver chloride electrodes. They would be placed close together, and initially the desalted water would be collected from one electrode. At intervals the direction of the current would be changed to regenerate the electrode and at the same time the collection of the desalted water from the other electrode would be started. If the two electrodes were placed close together to lessen resistance, the consumption of electrical energy would be small.

The desalting of water by the continuous collection of solution at the anode-solution interface differs in principle from the removal of chloride ion by use of a silver anode and cathode in a confined volume of solution. In the latter process, even though all the chloride ion were eventually removed by the silver anode, an equivalent content of sodium hydroxide would replace it, so that the solution would not be demineralized. The microporous electrode method, on the other hand, is envisaged to operate in a large volume of flowing solution, such as an ocean, so that the anode is always immersed in a solution of constant composition and the products formed at the cathode are swept away.

Murphy (2) has utilized silver-silver chloride electrodes to separate dissolved chlorides by an electro-gravitational method. His method is not directly comparable with the microporous electrode method, since its operation depends on the continued treatment of a solution for several hours either in a fixed volume or as it flows along the electrodes.

Oxidation Rates of K and Rb between -79°C and -20°C

J. V. Cathcart and G. P. Smith

Metallurgy Division, Oak Ridge National Laboratory, Union Carbide Corporation, Oak Ridge, Tennessee

A study of the oxidation characteristics of the alkali metals was undertaken as a part of an investigation of the factors which determine the degree of protectiveness of thin oxide films formed on metals. Previously published data (1) relative to the oxidation kinetics of Na indicated that in purified oxygen Na formed a highly protective oxide film at room temperature or below but that the film became nonprotective after long periods of oxidation in the vicinity of 50°C. A similar study of the oxidation rates of K and Rb between —79° and —20°C showed that these metals likewise formed protective films at low temperatures but that the transition from protective to nonprotective oxidation occurred at a lower temperature than for the case of Na.

Experimental Procedure

Oxidation rates of K and Rb were determined by measuring the changes in pressure in a closed reaction chamber as oxidation proceeded. A sensitive differential manometer served as the pressure sensing device. Samples of K and Rb were purified by careful vacuum distillation (2), and the oxidation specimens were prepared by depositing relatively thick films of K or Rb on the walls of the oxidation chamber at a pressure of approximately 10^{-7} mm Hg. Details of the apparatus and the experimental procedure have been described elsewhere (1).

Results and Discussion

Rate measurements were made for K at —79°, —50°, —20°C and for Rb at —79° and —50°C. Results of typical experiments are shown in Fig. 1 and 2. In each figure the number of moles of oxygen consumed per square centimeter of apparent surface area is plotted against the time of oxidation measured in minutes.

Both K and Rb exhibited a marked lack of reactivity in pure oxygen in the temperature range cited. If it is assumed that the oxide formed as a uniform surface layer on the specimens, the films produced on K at —50° and —79°C were not more than 100Å thick after 100,000 min (about 70 days) of oxidation. At higher temperatures, —20°C for K and —50°C for Rb, the maximum film thicknesses attained were probably between 2000 and 3000Å. More precise figures are not given for the film thicknesses because of the uncertainty as to the exact oxide compositions and because of the likelihood that thickness inhomogeneities existed in the films (3).

It will be noted that the oxide films formed on K at —50° and —79°C were almost completely protective, but at —20°C a transition from protective to nonprotective oxidation was observed. A similar transition occurred in oxide films formed on Rb at —50° and —79°C. These results are also consistent with the oxidation characteristics of Na for which a comparable behavior was observed at 48°C. Thus a transformation from protective to nonprotective oxidation occurred for all three of the alkali metals investigated, and the temperature at which this transformation was observed varied inversely with the electropositive character of the metals.

Because of the extreme thinness of the oxide films and their sensitivity to moist air, no satisfactory method has as yet been devised for determining their compositions. The super oxides, KO_2 and RbO_2 have been reported as the major products formed during the burning of K and Rb in oxygen (4). However, several other oxides have been reported in the literature for both K and Rb (5), although complete metal-oxygen phase diagrams are available

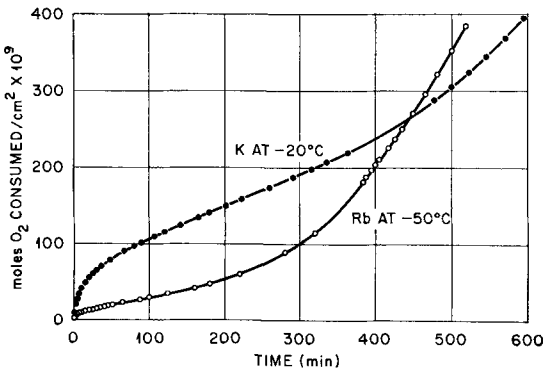

Fig. 1. Oxidation of K at —20°C and Rb at —50°C

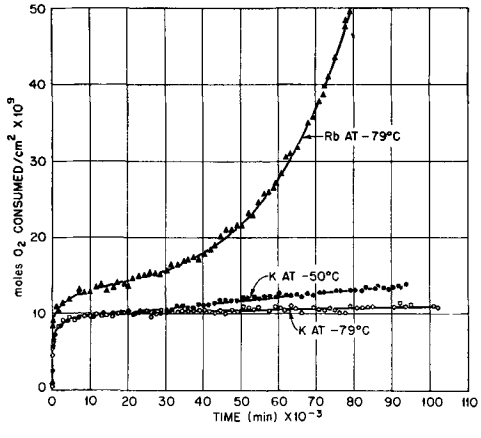

Fig. 2. Oxidation of K at —50° and —79°C and Rb at —79°C.

for neither. Since the metal was by no means completely consumed in the experiments reported here, it is probable that the oxide films consisted of several oxide phases in addition to the super oxides.

Efforts to determine rate curves at temperatures higher than −50°C for Rb and −20°C for K were unsuccessful because the rates of oxidation were too rapid to be measured with the manometric technique utilized in this research. At room temperature, actual burning of the metal occurred. It was noted, however, that, if the specimens were first exposed to oxygen at a lower temperature, e.g., −79°C, and then the system brought to room temperature, a drastic reduction in the oxidation rate occurred. Instead of the burning such as occurred when the clean metal was exposed to oxygen at room temperature, a slow uptake of gas was found to take place over a period of several days. Thus the oxidation rates of K and Rb, as is the case for many other metals, proved to be markedly dependent on the prior history, especially the surface condition, of the metal specimens.

The A-C Resistance of a Polarized Stainless Steel Wire Cathode

G. M. Schmid and Norman Hackerman

Department of Chemistry, University of Texas, Austin, Texas

Resistance measurements are used currently to determine the amounts of adsorbed gas on thin metal films (1). It also should be possible, in principle, to determine the growth of an oxide layer on a thin metal film in solution by this method. However, it is uncertain how the resistance of an electrode is affected by the solution and by a polarizing current.

The a-c resistance of palladium wires increases when the metal is in certain electrolyte solutions while being cathodically charged (2-4). Prolonged charging at higher current densities results in a resistance decrease. The increase is due to H_2 absorption and it has been suggested by Knorr and coworkers (5, 6) that the decrease is due to leakage through the surrounding electrolyte. Conductivity by way of the electrolyte must occur via a coupling which is provided by disturbing of the electrical double layer (edl). In order to eliminate the effect of H_2 absorption the a-c resistance of stainless steel electrodes was followed in this study. The structure of the edl was altered by passing a d-c polarizing current of 1-40 ma/cm^2.

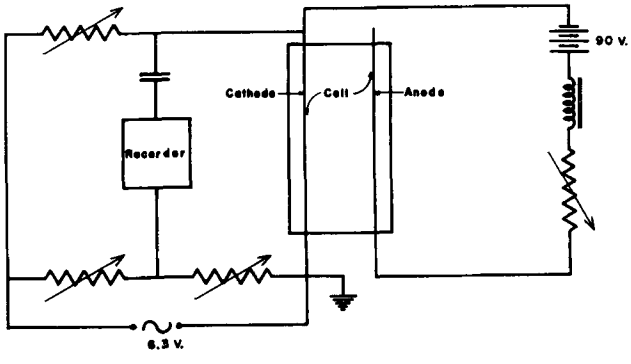

Fig. 1. Circuit diagram

Experimental and Results

The cell consisted of a glass tube and two straight type 302 stainless steel wires, 0.038 cm in diameter and 30-100 cm long (Fig. 1). The a-c resistance of the wire serving as the cathode was measured. The second wire was the anode and was held parallel to the first, generally more than 0.1 cm away. The electrolyte was 0.01-1.0M Na_2SO_4.

The resistance measurements, with or without d-c polarization, were obtained with a standard Wheatstone-Bridge, using 60 cps a-c. A Brown-Honeywell recorder with its converter stage by-passed was used as an automatic balancing instrument. Any d-c pickup was eliminated by the transformer in the automatic balancing unit of the recorder and by using a 100 μf capacitor in the circuit. The voltage drop along the grounded cathode was about 0.1 v. Resistance changes of 0.005 ohm could be measured easily. The polarizing current was furnished by a 90 v battery using a set of resistors to control the current and a 10 henry choke to minimize a-c pickup from the bridge circuit. In order to get significant resistance changes the cathode had to be polarized to the hydrogen evolution potential (at least to −1.1 v vs. SCE).

Addition of solution alone has no influence on the resistance of the cathode, causing changes of no more than 0.01 ohm, provided the anode was more than 1 mm away. On the other hand, Fig. 2 shows that the resistance of the cathode drops when polarized at current densities greater than 0.5 ma/cm^2, thus indi-

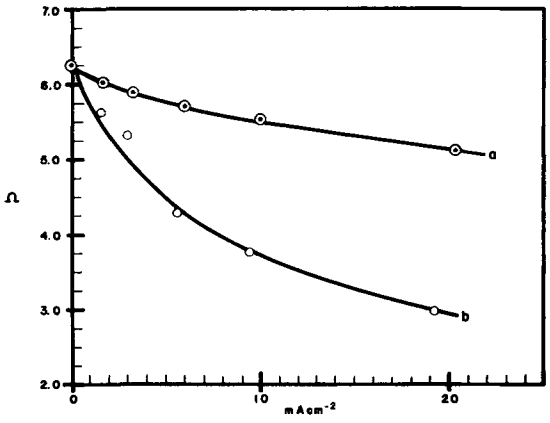

Fig. 2. Dependence of resistance on electrode-distance, cathode surface area 11.1 cm^2, 18-8 stainless steel, 1.0M Na_2SO_4. Curve a, electrode-distance 2.1 cm; curve b, electrode-distance 0.1 cm.

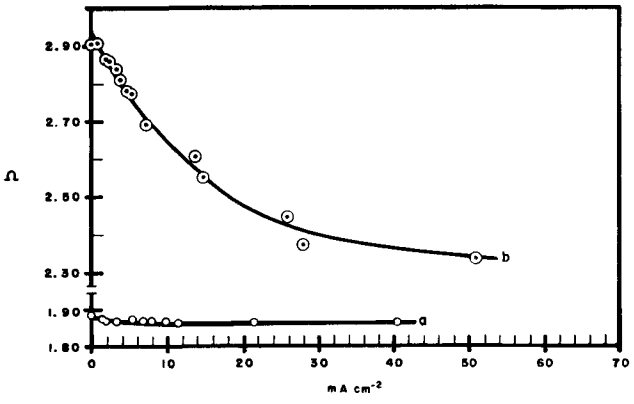

Fig. 3. Dependence of resistance on electrolyte concentration, electrode-distance 1.0 cm. Curve a, 0.01M Na_2SO_4, length of wire 29 cm, surface area 3.5 cm^2; curve b, 1.0M Na_2SO_4, length of wire 44 cm, surface area 5.2 cm^2.

cating additional conduction by the surroundings. The resistance changes are related nonlinearly to the length of the wire in solution.

Aside from immersed wire length, the resistance decrease at constant polarizing current density was influenced by the distance between anode and cathode. This indicates that the anode as well as the electrolyte is part of the a-c conducting system at small separations (Fig. 2). The influence of solution concentration is shown in Fig. 3. Under the same conditions except with 0.001M Na_2SO_4 there was no resistance change.

In all cases the resistance changes occurred in less than 2 sec, indicating the absence of hydrogen diffusion effects. The i^2R-effect was negligibly small, values obtained being steady over a 5-min period. The changes were reversible and, for a given electrolyte, a given distance between anode and cathode, and a given "air" resistance of anode and cathode, entirely reproducible.

Discussion

Coehn and Specht (7) carried out similar experiments on palladium and also observed drops in resistance proportional to the polarizing current. They explained their effects by the additional conductivity by hydrogen in the metal in excess of saturation concentration. This explanation is not suitable for stainless steel because of the rapid resistance changes and the rapid recovery of original resistance after switching off the d-c polarizing current. This makes diffusion effects highly improbable.

The transition resistance between cathode and surroundings seems to be very high as long as the cathode is not polarized. After the polarizing current has shifted the potential of the electrode to a high enough negative value, the a.c. is able to oxidize and reduce some species according to its own frequency, thus passing into solution. Moreover, with increasing current density, i.e., increasing negative potential, the cathode metal is sufficiently displaced from its zero point of charge so that there should be an adsorbed layer of cations and oriented water dipoles in close contact. This may cause a further drop in resistance.

The same effect, with reverse sign, should be expected at the anode, and this was verified experimentally. The resistance changes are in the same order of magnitude.

It seems therefore that the resistance of the system in a polarized state consists of the resistance of the cathode and the anode plus a transition resistance or coupling capacitance on either side plus the resistance contributed by the electrolyte. All these additional resistivities cannot be considered as parallel to the cathode but rather as diffuse and effective over the whole cathode surface. Thus a linear relationship between resistance change and length of the cathode should not be expected.

In order to get conclusive data concerning oxide films on thin working electrodes by observing its resistance change, one has to work in electrolytes of very low conductivity, otherwise the data taken during the flow of a d-c polarizing current are meaningless.

Further studies in this field should include the frequency dependence of the transition resistance and the effects of specifically adsorbed ions and surface active substances.

Brief Communication

Measurement of the Segregation Coefficients of Impurity Elements in Aluminum Antimonide

D. Hazelby and J. L. Parmee

B.T.H. Group Research Laboratory, Rugby, England

Some approximate figures have already been quoted (1) for segregation coefficients in aluminum antimonide, but it was considered necessary to obtain accurate values for those elements which influence the electrical properties of the compound, and also those which are common impurities.

The technique adopted was to use radioactive tracers, prepared by irradiating each impurity in the B.E.P.O. pile at Harwell. Since no suitable isotope of carbon could be made by this method, carbon-14 was obtained from the radiochemical center at Amersham. It was found convenient to measure activities with a liquid counter. As the energy of the beta radiation from carbon-14 and from sulfur-35 was too weak to be detected with this counter, they were precipitated with carriers as barium sulfate and carbonate, respectively, and measured with an end window Geiger counter. Magnesium was used in the inactive form and estimated with a mass spectrograph, although the accuracy of this method was somewhat less than would be obtained by the radiochemical method.

The impurity concentration at any point along an ingot produced by normal freezing is

$$C = kC_o\,(1-g)^{k-1} \qquad [1]$$

where C is the concentration at the point where a fraction g of the ingot has solidified, C_o is the original concentration in the melt, and k is the segregation coefficient.

At the front of the ingot, where g is almost equal to zero, the equation becomes

$$C = kC_o \qquad [2]$$

Thus, by measuring the concentration at the front of the ingot and the average concentration, k can be determined.

The conditions of our experiment did not conform strictly to those required for equilibrium segregation and so the measured values of k can be regarded only as observed values, i.e., as would be encountered in practice.

Milligram quantities of each impurity element were melted by high-frequency induction heating with 35 g of aluminum antimonide in a "Purox" alumina boat in an atmosphere of pure, dry argon. The melt was held at 1200°C for 5 min, during which time the stirring induced by the high-frequency field produced thorough mixing. The boat then was drawn out of the furnace at a rate of 5 in. hr^{-1}, causing normal freezing along the whole length of the charge.

The front 5% of the ingot was cut off, and this and the remaining piece weighed and dissolved in a mixture of hydrochloric and nitric acids. A suitable aliquot was taken from each solution and the activity was measured. The activity of the smaller piece gave the concentration of the front of the ingot C, and that of the larger piece was taken to be the average concentration C_o. The slope of the normal freezing curve at the front of the ingot is small for all values of k; there is thus no significant loss of accuracy in taking C to be the average concentration of the front 5%. The segregation coefficients of several elements are quoted in Table I.

It was noticed in some cases that an appreciable amount of activity was being lost by volatilization. Consideration of vapor pressures indicated that this was likely with zinc, cadmium, sulfur, selenium, and tellurium. This loss increased along the length of the ingot, being greatest at the end which was last to freeze, and so lowered the impurity concentration and hence the measured value of C_o. This gave a very high apparent value for the segregation coefficient, using Eq. [2].

In the practical use we are interested in the overall purification by both evaporation and segregation.

Table I.

Impurity element	Segregation coefficient	Purification factor
Magnesium	0.1	
Carbon	0.6	
Silicon	0.1	
Germanium	1.2	
Tin	1.0	
Iron	0.02	
Copper	0.01	
Manganese	0.01	
Cobalt	0.002	
Zinc		0.02
Cadmium		0.002
Sulfur		0.003
Selenium		0.003
Tellurium		0.01

This can be obtained by taking the ratio of the concentration of the activity in the front 5% of the ingot, to that of the impurity originally added, and gives an indication of the purification obtained under conditions in which volatilization is occurring. These ratios, which we have described as purification factors, are also given in Table I. Although they are clearly dependent on the conditions of the experiment, they do give an indication of the behavior of these impurities that could be expected on zone refining aluminum antimonide.

Observations on the Fe-Cr-O System

A. U. Seybolt

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

An isothermal phase diagram for the Fe-Cr-O system is presented for 1300°C which, with a minor modification, holds for 1000°C. It is observed that Fe-Cr alloys containing over 13% Cr are in equilibrium with Cr_2O_3 containing a little dissolved Fe_2O_3. Alloys of lower chromium content are in equilibrium with iron chromite of variable composition of the type $FeCr_2O_4$. Evidence is presented indicating that when the spinel forms next to the metal a pronounced internal oxidation occurs. However, higher chromium alloys with Cr_2O_3 next to the metal show no tendency for internal oxidation. An oxygen pressure-composition diagram for the entire system is also presented. Marker experiments made during the oxidation of 20% Cr and 30% Cr alloys suggest that Cr_2O_3 is formed almost entirely by cation (Cr^{+3}) diffusion.

Many investigators have been concerned with the oxidation kinetics of the industrially important Fe-Cr alloys. However, before the kinetics can be evaluated properly, the equilibria involved should be well established. The work of Yearian, Randell, and Longo (1), conducted between 700° to 1160°C, was primarily a kinetic study, but these workers presented an approximate phase diagram which agrees in many essentials with the present investigation and with the slightly later work of Woodhouse and White (2). The investigation of Yearian, *et al.* (1) as just mentioned was not primarily an equilibrium study, and in addition the scales they observed were influenced by the presence of significant amounts of manganese, silicon, and carbon in the commercial steels they studied.

The work of Richards and White (3), and in particular the closely related investigation of Woodhouse and White (2), presented considerable information on equilibria in this system. Only very little of the findings of Richards and White (3) can be compared directly with the present study since these investigators were more concerned with the effects of rather wide variation in temperature than with establishing phase boundaries at constant temperature, as in the present case. In addition, they studied equilibria which were stable in the partial pressure of oxygen in air. On the other hand, their qualitative findings relating to the M_2O_3-M_3O_4 equilibria are in agreement with results presented here.

However, the tentative isothermal phase diagram presented by Woodhouse and White (2) (for temperatures between 560°C and the solidus) can be compared directly and qualitatively with the present investigation. It should be emphasized that Woodhouse and White considered their Fe-Cr-O isothermal phase diagram as only semiquantitative. Considering the limited amount of information available to these investigators, it is remarkable that their estimation of the nature of the system should agree so well, on a qualitative basis, with the findings to be reported in the present investigation. This agreement is particularly remarkable in view of the fact that Woodhouse and White conducted no equilibrium studies involving a metal phase, but confined themselves experimentally to the study of oxide equilibria.

It would require an inordinate amount of space to review in detail the results of the various observations made on the oxidation of Fe-Cr type materials, including stainless steels. However, the nature of the scales observed in a few of the more significant papers might be listed briefly. Rickett and Wood (4) oxidized 12-28% Cr-Fe alloys in oxygen at 980° and 1090°C and found spinel ($FeCr_2O_4$) and Cr_2O_3 on the inside and Fe_2O_3 on the outside of the scale. The nature and number of the layers depended on chromium content and temperature. McCullough and Fontana (5) found that on stainless steels heated in oxygen to 980°C spinel formed next to the metal, but as the oxidation proceeded Fe_2O_3 was predominant in the scale. Caplan and Cohen (6) used commercial Fe-Cr alloys containing 11-26% Cr with 0.3% Si, and oxidized their alloys at 1600°F to 2000°F in dry and moist air. Cr_2O_3 and spinel in various proportions were observed as the principal scale components. No essentially pure iron oxides, such as Fe_2O_3, were observed apparently under the conditions of their experiments. Moreau (7) studied a wide range of Fe-Cr alloys at 800°-1250°C and is one of the few authors who reports FeO as a stable oxide (mixed with $FeCr_2O_4$) next to the metal. Moreau apparently observed this mixed scale regardless of the chromium concentration. Yearian, Randell, and Longo (1) found practically all possible oxides depending on the parameters of composition and temperature. Their main findings can be summarized as characterizing two kinds of scale: type A (low rates of attack) consisting primarily of Cr_2O_3 with some dissolved Fe_2O_3, and type

B scales where attack is severe. In the latter scales, the spinel of the type $FeCr_2O_4$ is predominant.

In reviewing the literature of the oxidation of Fe-Cr alloys, the somewhat confused summary just presented is quite typical. This lack of agreement is due primarily to the fact that the types of scale formed are a sensitive function of temperature, chromium content, atmosphere, time of exposure, impurities present, and possibly other factors. However, it seems reasonably clear that the following oxides can be present depending on composition and oxygen partial pressure: FeO, Fe_3O_4, Fe_2O_3, Cr_2O_3, and $FeCr_2O_4$. These last two oxides require additional discussion. It has been established by Wretblad (8) and by others that Fe_2O_3 and Cr_2O_3 form a continuous series of solid solutions. In addition, Yearian, *et al.* (1) and Caplan and Cohen (6) found evidence for some Fe_2O_3 dissolved in the Cr_2O_3-type scales. The spinel $FeCr_2O_4$ is not necessarily stoichiometric, but this cubic oxide forms a solid solution series with Fe_3O_4. This has been demonstrated very well by Yearian, Kartwright, and Langenheim (9) who found that the lattice parameter of these solid solutions is not a single valued function of the composition, due to lattice sites being occupied differently as Cr^{+3} ions are replaced by Fe^{+3} ions.

In the work which follows, the primary object has been to outline the isothermal sections at 1000° and 1300°C. The oxygen equilibrium pressure is in general different in different parts of the system.

Experimental Methods

Fe-Cr alloys in the range 1-70% Cr were made using Ferrovac (vacuum-melted electrolytic iron) and hydrogen-treated electrolytic chromium. In order to maintain good control over composition, the alloys were prepared as 50-g buttons in an inert arc furnace. After homogenizing heat treatments at 1000°C or above in a hydrogen atmosphere during the processing, the alloys were mainly finished as hot-rolled (600°C) strip 0.015 in. thick. Samples used for the oxidation treatment were usually ½ x 1 in. rectangles, whose flat surfaces were abraded with various grades of wet or dry carborundum paper. The 180 grade of paper was found to be better than some of the finer grits because the oxide formed subsequently during high-temperature oxidation treatments tended to be better anchored to the sample. It was desired to keep the oxide on the metal surface to secure equilibration with the metal phase.

The general procedure for oxidation was to form a thin oxide layer on the surface and then to "equilibrate" the oxide with the metal by heating at 1000° or 1300°C in an argon atmosphere. By forming a comparatively thin oxide layer on the surface, insufficient metal was used up in forming the oxide to change the alloy composition appreciably, at least in most instances. Where considerable oxidation occurred, the experiment was repeated or the sample was not used for determining a phase boundary. True equilibration between the metal and oxide phase would require accurate control of the oxygen partial pressure and, in general, each Fe-Cr alloy would require a different oxygen pressure. However, as will be demonstrated shortly, most of the alloys are in equilibrium with Cr_2O_3 containing a small amount of Fe_2O_3. Since the dissociation pressure of Cr_2O_3 is so low, about 10^{-16} atm at 1300°C, the rate of breakdown of Cr_2O_3 in pure argon would be very small. Hence, the practical difference between controlling the oxygen pressure at 10^{-16} atm and using argon is negligible for equilibria involving Cr_2O_3. This same reasoning can be applied to cases where $FeCr_2O_4$ or more accurately, $Fe\ Fe_{(2-x)}\ Cr_xO_4$ [$x=O-2$] solid solution, is stable. This is true for compositions near $FeCr_2O_4$ but not for spinels of low chromium content. In the vicinity of Fe_3O_4 or Fe_2O_3, the dissociation pressure is sufficiently high so that rapid breakdown of the oxides in argon occurs.

The primary object of the phase equilibrium study was to establish the tie lines between metal phase and oxide phase. While the identification of the oxide-oxide equilibria was of secondary importance, it was possible to establish these boundaries also.

Alloy-Oxide Equilibration Experiments

It is obvious of course that as long as one is using alloys far removed from a phase boundary, the amount of chromium removed from the alloy during oxidation is not critical. However, if one is close to a critical composition, one should not remove an appreciable fraction of chromium from the alloy if the phase boundary is to be located with a high degree of accuracy. The accuracy aimed at was about ± 1% Cr.

In general, the small ½ x 1 in. strips were oxidized briefly in 1 atm of dry oxygen for 1-5 min at temperatures ranging from 600° to 1000°C depending on chromium content. The higher chromium alloys required more severe oxidizing conditions to secure enough scale for Debye camera x-ray or electron diffraction identification. After a few milligrams of oxide were formed on the surface, the samples were transferred to a furnace operated at 1000° or 1300°C and equipped with a vacuum-tight mullite tube containing a stagnant argon atmosphere. The equilibration treatment was usually at least 24-hr long and sometimes over 65 hr in duration. The samples standing on edge on a ceramic boat could be pushed into or out of the hot zone without disturbing the argon atmosphere. The object of the equilibration was twofold: (*a*) to allow sufficient time for the composition of the oxide to adjust to the equilibrium composition of the metal phase, and (*b*) to smooth out local concentration gradients in the metal at the metal/oxide interface. Because the surface of the alloy was robbed to some extent of chromium to form a chromium-containing scale, the equilibration treatment served to reestablish a uniform chromium content across the thickness of the sheet.

For very low chromium alloys where oxidation was severe, or in cases where better control over the degree of oxidation was necessary, samples were

sealed in SiO_2 capsules. In these capsules, samples were mounted on molybdenum brackets to prevent contact with SiO_2. Also sealed into the capsule was a small amount of FeO wrapped in iron foil. The Fe/FeO equilibrium pressure at 1300°C is about 10^{-11} atm, which was more than enough to stabilize any equilibrium scale in the entire system. These capsules were partially filled with purified argon, after exhausting the air, to prevent collapse of the SiO_2 at 1300°C. Equilibrations usually were carried out on the encapsulated samples by again encapsulating them in a SiO_2 tube without the FeO.

Experimental Results

Oxidizing and equilibrating runs are summarized in Tables I and II, which give x-ray and electron diffraction results, visual and metallographic observations at 1000° and 1300°C, respectively. It will be noted that spinel solid solution ($FeFe_{(2-x)}Cr_xO_4$) was formed at low chromium concentrations, and that Cr_2O_3 constituted the scale at high chromium contents; this was true both at 1000° and 1300°C. However, at a chromium level centering about 13%, both Cr_2O_3 and the spinel were sometimes observed. It will be noted, however, that as the chromium content gradually increases, the spinel pattern becomes weaker, and the Cr_2O_3 pattern becomes correspondingly stronger. This is indicated in both Table I and II.

It was sometimes observed that the color of the scale could be a very sensitive indicator of composition, particularly since Cr_2O_3 and the spinel are so different in color. Note the visual observations in center of Table I near 14% Cr. According to this, the critical composition for spinel or Cr_2O_3 formation is between 12.8 and 13.6% Cr, whereas the x-ray data showed no Cr_2O_3 for the 13.6% Cr alloy. This last result is probably due to the fact that x-ray diffraction frequently fails to indicate a phase present in minor amount.

While in the absence of a subscale two oxide layers would signify lack of equilibrium, this is not true for the subscales formed here in the vicinity of 13% Cr. This is because, as will be demonstrated shortly, at this composition a three-phase field makes its appearance. This three-phase field widens with increasing oxygen content, and it is therefore to be expected that if much internal oxidation occurs, both spinel and Cr_2O_3 as well as the alpha solid solution can coexist.

However, for this same reason it was desired, in establishing the critical Fe-Cr alloy composition which divides Cr_2O_3 scales from the spinel scales, to avoid excessive oxidation, both external and internal. This was necessary in order to shrink the composition width over which both oxides coexist to a point on the Fe-Cr binary boundary of the isothermal phase diagram. In order to accomplish this aim the capsule experiment described above under experimental methods was used. In this manner, by the use of the decomposition pressure of iron-saturated FeO at 1000° and 1300°C, it was possible to form such a thin film of oxide (about 200 $\mu g/cm^2$) that an inconsequential amount of chromium was used up. Hence, concentration variations across the critical chromium content could be avoided, and

single equilibrium scales could be observed by electron diffraction as recorded in the last part of Tables I and II.

X-ray and electron diffraction observations on "equilibrated" oxide films may be summarized by stating that the transition between the spinel at low chromium content and Cr_2O_3 at high chromium contents lies at about 13% Cr ± 0.5% Cr.

Metallography

Besides the primary tool of scale identification by x-ray or electron diffraction and the occasional assistance provided by visual color observations, metallography was found to be only second in importance to x-ray diffraction. It was found possible to make a sharp division more readily between compositions which form Cr_2O_3 and those which form spinel by this technique than by use of x-rays. The pronounced separation between these two classes of alloys was made possible by the fact that alloys which form the spinel show very prominent internal oxidation, while the alloys richer in chromium, which oxidize to Cr_2O_3, do not. This is made clear in the following photomicrographs (Fig. 1-8).

The oxidized strips were given an evaporated silver coating and after a flash of copper were nickel plated to prevent washing out of the oxide layer during metallographic preparation. Four different compositions were chosen to show characteristic scales for both spinel-type and Cr_2O_3-type oxidation. Two compositions near 5 and 10% Cr in the spinel region, one near the critical 13% Cr composition and one well into the Cr_2O_3 region are shown. Figures 1 and 2 show a layer of alpha iron next to the nickel plate. The black layer between the iron layer and the beginning of the internal oxidation is spinel. The reason for the presence of an iron layer appears to be as follows: Because the chromium content is

Fig. 1. 4.95% Cr oxidized 1½ hr, 1000°C; equilibrated 64 hr argon, 1000°C. Note layer of internal spinel. Magnification 100X before reduction for publication.

Fig. 2. 9.94% Cr oxidized 1½ hr, 1000°C; equilibrated 64 hr argon, 1000°C. Note layer of internal spinel. Magnification 100X before reduction for publication.

fairly low in these two alloys, some iron oxide, perhaps both Fe_2O_3 and Fe_3O_4, are formed during the oxidation treatment in pure oxygen gas. These oxides form at the surface, while the more stable spinel forms next to the metal. During the subsequent argon "equilibration" treatment the iron oxides decompose to pure iron because their dissociation pressures are quite high and, hence, the kinetics tend to be fast. However, the spinel with its very low dissociation pressure and sluggish decomposition kinetics remains after heating in argon. It is interesting to note that Fig. 3 shows both the internal oxide and areas where only the surface scale of Cr_2O_3 is present; hence this sample represents a transition structure. Since Cr_2O_3 shows a brilliant green under polarized light, while the spinel appears red to yellow depending on thickness, it was easy to ascertain that the surface scale was essentially pure Cr_2O_3 while the internal oxide was mostly all spinel. Some samples showed very small particles of Cr_2O_3 as an internal oxide which occurred with the more massive and prominent spinel. The existence of spinel above 13% Cr or of Cr_2O_3 below this concentration was always insignificant in amount compared with the major oxide present.

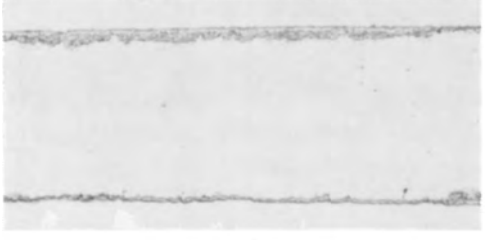

Fig. 3. 12.8% Cr oxidized 5 min, 1000°C; equilibrated 65 hr argon, 1000°C. Note transition scale: partly internal oxide, partly surface oxide. Magnification 100X before reduction for publication.

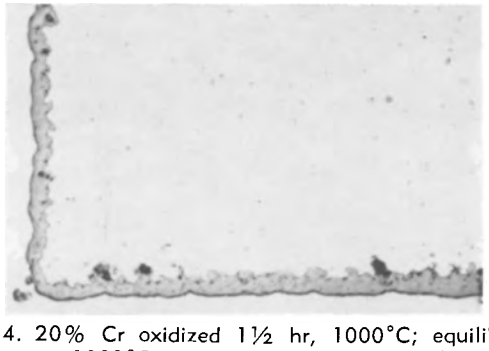

Fig. 4. 20% Cr oxidized 1½ hr, 1000°C; equilibrated 64 hr argon, 1000°C. All surface oxide. Internal oxide inclusions were present in sheet prior to oxidation. Magnification 500X before reduction for publication.

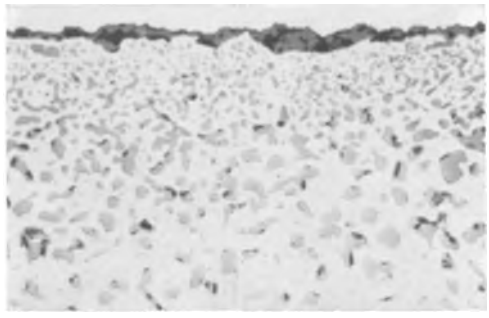

Fig. 5. 4.95% Cr oxidized 1 min, 1000°C; equilibrated 24 hr argon, 1300°C. Exaggerated internal oxidation apparently caused by some air leakage at 1300°C. Large particles are spinel. Magnification 500X before reduction for publication.

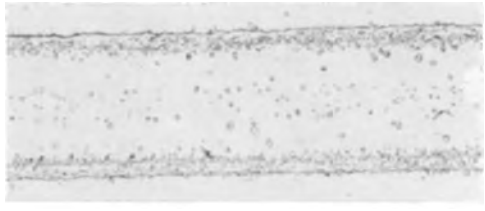

Fig. 6. 10.78% Cr oxidized 5 min, 1000°C; equilibrated 24 hr argon, 1300°C. Prominent internal oxidation. Oxide phase is spinel. Magnification 100X before reduction for publication.

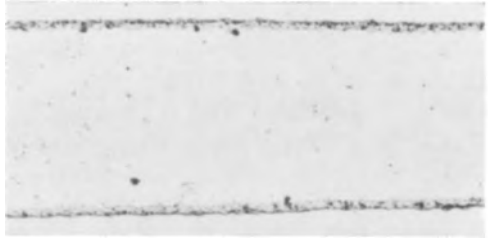

Fig. 7. 13.6% Cr oxidized 5 min 1000°C; equilibrated 24 hr argon, 1300°C. Note absence of internal oxidation. Magnification 100X before reduction for publication.

Therefore, it caused no confusion in interpretation, nor in allowing the choice of about 13% Cr as the critical chromium concentration. Although not shown here, there was essentially no difference in scale appearance nor in its kinetics of formation once the chromium content exceeded about 20%.

Figure 8 is of particular interest from the standpoint of oxidation mechanism. It is shown here that a 1-mil platinum wire spot-welded to a 30% Cr-Fe strip becomes covered with Cr_2O_3 during oxi-

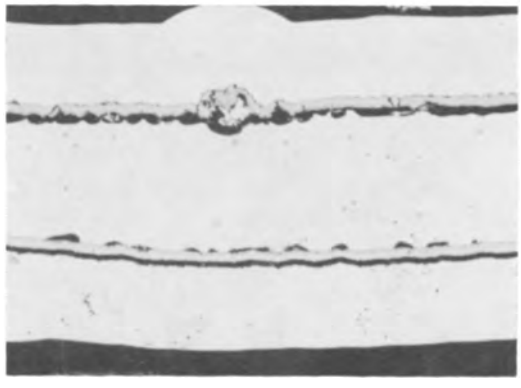

Fig. 8. 30% Cr oxidized 1½ hr, 1300°C; equilibrated 22½ hr argon, 1300°C. Note oxide covering platinum marker. Magnification 100X before reduction for publication.

Table III. Per cent Fe_2O_3 found in Cr_2O_3 scales

Alloy	Oxidation	Equilibration	% Fe_2O_3 in scale
1st sample 20% Cr-Fe	5 min 1000°C—O_2	1000°C—45 hr argon	2.7
			2.3 (check analysis)
	5 min 1000°C—O_2	1300°C—40 hr argon	0.32
		1300°C—40 hr argon	0.7 (check analysis)
2nd sample	5 min 1000°C—O_2	1000°C—64 hr argon	2.57
	5 min 1000°C—O_2	1300°C—16 hr argon	0.46

dation at 1300°C. It will be noted that many (Kirkendall) voids were formed just below the oxide layer, suggesting one-way diffusion of chromium to the scale without any countercurrent diffusion into the alloy. This observation corroborates the platinum marker behavior. Identical behavior was observed at 1000°C except that no voids just below the scale were observed. In addition, the same behavior was noted at both temperatures for a 20% Cr-Fe alloy. Since no oxide at all was formed underneath the wires, the tentative conclusion is that Cr_2O_3 on binary Fe-Cr alloys forms by cation (Cr^{+3}) diffusion, and that no appreciable diffusion of oxygen anions occurs from the gas phase. This mechanism is also suggested by the nature of the defect structure of Cr_2O_3 (10, 11).

Composition of the Two Equilibrium Scales

It has been shown above that from x-ray and metallographic evidence only two kinds of scale can be in equilibrium with binary Fe-Cr alloys: iron chromite or spinel below about 13% Cr, and Cr_2O_3 above this composition. So far, however, no evidence has been presented on the composition of these scales. To check the amount of Fe_2O_3 dissolved in Cr_2O_3, the following experiment was carried out. Two different samples of 20% Cr-Fe sheet were given a thin scale of Cr_2O_3 by a 5-min oxidation treatment in pure oxygen at 1000°C. The oxide film thus formed was equilibrated in argon at 1000° and 1300°C with the results indicated in Table III.

An alloy well over 13% Cr was chosen deliberately so that, in forming some Cr_2O_3 on the surface, the alloy would not be robbed of chromium to the point where spinel would make its appearance. However, on the basis of experience obtained in these experiments, it seems safe to assume that the nominal 20% Cr was not altered significantly by the very short oxidation treatments given this alloy. The reason for the lack of agreement between the check analyses at 1300°C must lie in the analytical technique since it was the same sample of scale. However, the main point is that if 0.5% Fe_2O_3 is taken as the average for the solubility of Fe_2O_3 in Cr_2O_3 on a 20% Cr alloy scale at 1300°C then there is an increase by a factor of five in Fe_2O_3 content by lowering the temperature to 1000°C.

The lattice parameters of the spinel phase from pure Fe_3O_4 to $FeCr_2O_4$ has been studied by Yearian, Kartwright, and Langenheim (9) as mentioned previously. While lattice parameters in this system cannot be used alone as an indication of composition, it can be used in conjunction with auxiliary information. For example, if the composition of the spinel is between approximately $Fe_{1.7}Cr_{1.3}O_4$ and $FeCr_2O_4$, one then can make use of the data of Yearian, *et al.* (9) to find the spinel composition. Fortunately, it developed that a key spinel composition fell within this range. Therefore, it was possible by suitable oxide phase equilibrations to determine all of the most important phase boundaries in the isothermal section. Before proceeding with the spinel equilibria and spinel compositions, it will be helpful to show the isothermal section of the Fe-Cr-O system at 1300° or 1000°C (Fig. 9). All of the evidence (except the maximum Fe_2O_3 solubility in Cr_2O_3) points to essentially no shift in phase boundaries between these two temperatures. At least any shift, if it occurs, seems to be less than 1% in composition. Starting at the top of the diagram, the first horizontal line joining Fe_2O_3 and Cr_2O_3 represents the continuous series of solid solutions formed by these two oxides. Just below it is the horizontal join between Fe_3O_4 and $FeCr_2O_4$; the latter composition is denoted at point S_3 in Fig. 9. The Fe_3O_4-$FeCr_2O_4$ join has a finite width according to the accepted Fe-O phase diagram and according to Yearian, *et al* (9). These authors find that $FeCr_2O_4$ contains a maximum of 0.002 cation vacancies per mole or about 2.9% vacancies, corresponding to somewhat less than 2 a/o maximum excess oxygen. Fe_3O_4 at 1300°C appears to have a homogeneity range of approximately 0.6 a/o oxygen (13). This indicates that the Fe_3O_4-$FeCr_2O_4$ join is actually a narrow band of something like 1 a/o oxygen average width. This width is indicated by the extra heavy line in Fig. 9.

The diagram can best be described by referring to the three, three-phase fields starting at the left with γ Fe, FeO, spinel and then proceeding to the right to the α Fe, γ Fe, spinel, and finally to spinel,

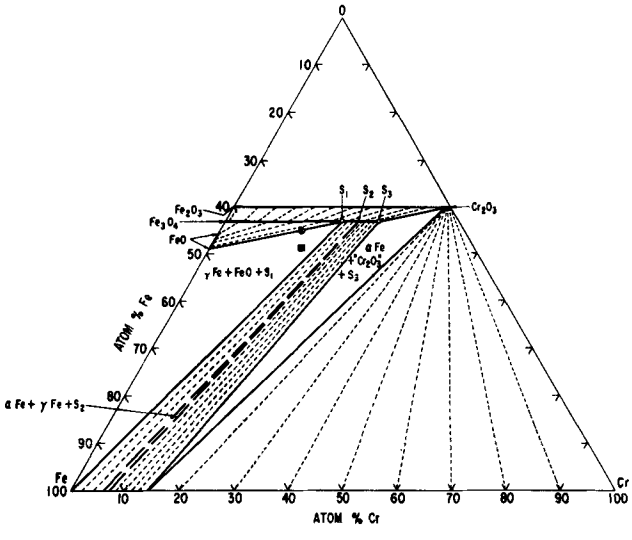

Fig. 9. Isothermal phase diagram at 1300°C for Fe-Cr-O system.

α Fe or (13 wt % Cr-Fe), "Cr_2O_3". The quotation marks around Cr_2O_3 refer to the fact that this oxide contains some Fe_2O_3 in solution. It has already been demonstrated that there are two kinds of two-phase equilibria involving the metal phase: Fe, spinel; and Fe, "Cr_2O_3." It will, of course, be understood that the spinel is of different composition in each of the three-phase fields mentioned above, and that its composition as a scale is a function of the alloy composition.

Spinel-FeO Equilibria and the Adjoining Spinel-FeO-Fe Equilibrium

The spinel composition S_1 corresponds to approximately $Fe_{1.5}Cr_{1.5}O_4$ or 21.4 a/o Cr as against 28.6 a/o Cr for $FeCr_2O_4$(S_8). The location of point S_1 was determined by heating together FeO (high iron) and $FeCr_2O_4$ at 1300°C. Samples were prepared by mixing −200 mesh FeO powder prepared by H_2/H_2O treatment of Fe_2O_3, and $FeCr_2O_4$ prepared by synthesis from FeO and Cr_2O_3. The starting composition was 50% by weight FeO and 50% by weight $FeCr_2O_4$. In one experiment the 2-g pressed compact was heated to 1300°C in argon for 20 hr with some FeO present to supply a small oxygen pressure. Metallographic examination and x-ray diffraction results showed a mixture of FeO and spinel of lattice parameter 8.398Å. The original lattice parameter of the $FeCr_2O_4$ used had a lattice parameter of 8.377Å which agrees with the value given by Yearian, *et al.* (9) for stoichiometric spinel. Yearian's curve shows that, if the composition is near $FeCr_2O_4$, a lattice parameter of 8.398Å corresponds to $Fe_{1.5}Cr_{1.5}O_4$ or 21.4 a/o Cr as indicated above. Chemical analysis of this oxide mixture yielded 49.5% total iron, 0% free iron, and 23.2% Cr. This analysis corresponds to 29.1 a/o Fe and 14.7 a/o Cr. If this composition is plotted on the isothermal section, it falls on the phase boundary between FeO and point S_1, as it should, at the spot marked with a circled X. Hence, the lattice parameter-located point S_1 agrees with the chemical analysis of the oxide mixture.

Two additional 50-50 wt % mixtures of FeO-$FeCr_2O_4$ were made at 1300°C but sintered in argon without using FeO to supply some oxygen. In these cases some decomposition of the FeO allowed the formation of free iron, resulting in one instance in the following analysis: free iron, 14.6%; total iron 51.6%; chromium, 24.7%. Plotting this point in terms of atom per cent results in the point in the three-phase field marked with an x inside a square. The lattice parameter (8.397Å) of spinel phase in all these three-phase compacts was within the experimental error the same as in the two-phase mixture.

Figure 10 shows the microstructure of the three-phase FeO + spinel + Fe specimen. The bright spots are iron and the lighter of the two oxide phases is the FeO phase. It will be noted that the dark chromite phase is completely surrounded by the FeO, and that it has many flat sides and sharp corners evidently indicating crystallographic growth from a liquid. Therefore, it appears that this composition touches the solidus surface at 1300°C. Not enough liquid was formed to allow deformation of the pressed compacts; there was no slumping or rounding off of sharp edges.

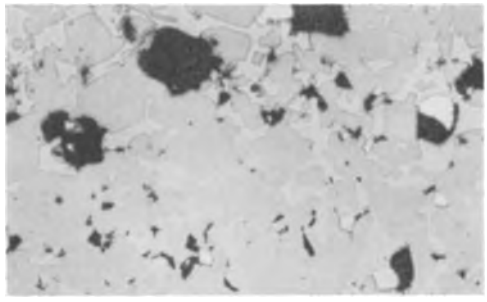

Fig. 10. αFe(γ at temperature), FeO, and spinel, demonstrating three-phase equilibrium. As polished. Black areas are voids. Magnification 250X before reduction for publication.

The FeO-$FeCr_2O_4$ experiments just cited seem to leave no doubt that the three-phase region of FeO, spinel, Fe exists as shown with the spinel composition as given above.[1] Furthermore, there appears to be no doubt that FeO of variable composition is in equilibrium with spinel of variable composition, as indicated qualitatively by the dotted tie lines. It must be emphasized, however, that these tie lines are purely qualitative, and are shown for purposes of illustration only; the precise location of these lines has *not* been determined.

Spinel-Rhombohedral Solid Solution Equilibria

The existence of this equilibria was first demonstrated by Richards and White (3), and was observed here by heating an equimolar mixture of Fe_3O_4 and Cr_2O_3 at 1800°C for 1 hr in a gas kiln. X-ray diffraction of the resulting body showed a mixture of iron chromite (spinel) and rhombohedral solution of approximately 50% Cr_2O_3 by weight. It was not possible to estimate the composition of the spinel phase from the x-ray pattern.

Figure 11 shows the microstructure of the spinel and rhombohedral solid solution compact. The black areas are voids (as in Fig. 10). The light phase which has formed on the boundary of the grains is the rhombohedral solid solution, and the darker of the two oxides is the spinel or chromite phase. Evidently at 1800°C the structure was principally spinel, but

[1] *Note added after MS preparation*: Birchenall (12) has evidence that in very dilute Fe-Cr alloys containing about 0.2% Cr, a FeO layer is formed *below* the spinel layer, e.g., next to the alloy. This evidently indicates a small amount of Cr solubility in FeO, and makes necessary a narrow two-phase region of gamma Fe solid solution—$FeO_{(Cr)}$ along the inside of the Fe-O side of the isothermal phase diagram (Fig. 9).

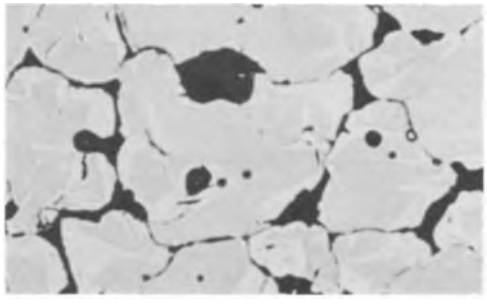

Fig. 11. Spinel (dark) plus Cr_2O_3-Fe_2O_3 solid solution (light). Black areas are voids. As polished. Magnification 500X before reduction for publication.

on cooling to lower temperatures the spinel becomes more susceptible to oxidation to the rhombohedral solid solution. Nucleation of the rhombohedral solution evidently occurred at the edges of the spinel grains where there was ready access to air, and as cooling progressed, the rhombohedral solid solution fingered into the interior of the cubic iron chromite (spinel) grains.

It has already been mentioned in connection with the spinel-FeO equilibria that the location of the tie lines were not determined but are only shown approximately for purposes of illustration. The same statement must be made about the spinel-rhombohedral solid solution equilibria. The tie lines could be established if it were possible to analyze either of these two equilibrium oxide systems for chromium, and both bivalent and trivalent iron. However, no current technique seems to be available for dissolving such oxide mixtures without oxidizing the Fe^{+2} to Fe^{+3}. In principle, probably it would be possible to obtain these tie lines merely from a knowledge of the chromium and total iron content together with lattice parameter measurements. This procedure, however, would have at least two drawbacks: (*a*) because of the lattice parameter of the spinel phase is not a single-valued function of composition, some trial and error would be involved, and (*b*) in some of the oxide mixtures the x-ray diffraction patterns may not be of sufficiently good quality to obtain the precision needed.

α Fe-γ Fe-*Spinel Equilibrium*

Spinel composition S_2 is the oxide in equilibrium with both ferrite and austenite as demanded by the Fe-Cr binary phase diagram.

In Fe-Cr binary alloys at 1300°C the alpha plus gamma region extends from about 6% Cr to 7% Cr as judged from the curve shown by Hansen's (13) recent review. Hence, there must be a three-phase triangle based on approximately 6% Cr and 7% Cr with the apex lying at some point S_2 on the spinel solid solution. An attempt was made to obtain a lattice parameter from the spinel "equilibrated" with an alloy lying near the critical chromium composition, but the grain size of the oxide was too fine to exhibit a satisfactory diffraction pattern. Hence, point S_2 in Fig. 9 is shown as lying approximately midway between points S_1 and S_3.

Equilibrium Oxygen Pressure as a Function of Composition

Figure 12 shows a pressure-composition diagram based mainly on data available in the literature, but to some extent on information obtained in this investigation. These data are marked with filled circles.

The pressure level of the α Fe-spinel-rhombohedral oxide equilibrium where log $Po_2 = -13$ was calculated from the equation given by Richardson, Jeffes, and Withers (14): $2FeCr_2O_4 = 2Fe + O_2 + 2Cr_2O_3$ $\Delta F = +131{,}600 - 24.2T$ and from the relation $\Delta F = -RT \ln K$. Although Richardson, *et al.*, were apparently not aware of it, this reaction should be written in some manner to indicate that it is not pure iron here, but a solid solution of 13% Cr in Fe.

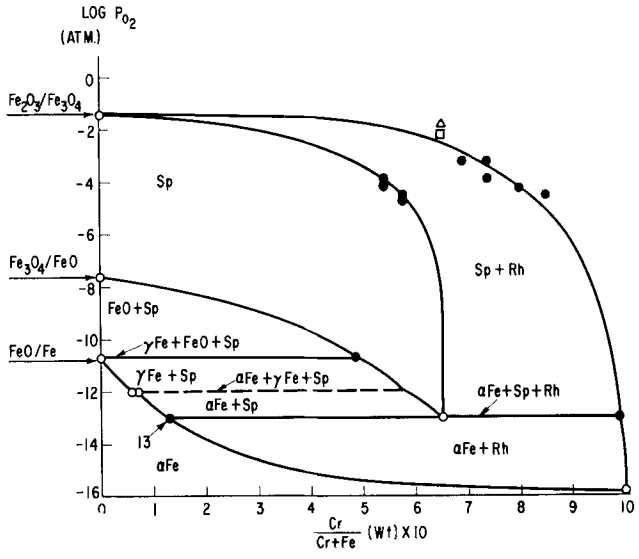

Fig. 12. Oxygen pressure-composition plot for 1300°C. Sp, spinel (based on $FeCr_2O_4$); Rh, rhombohedral (Fe_2O_3-Cr_2O_3) solid solution; αFe, pure bcc Fe or bcc Fe-Cr solid solution; •, this investigation; O, various sources, △, Schmahl; □, calculated from Richardson, et al.

This equilibrium is graphically shown as the lowest reaction horizontal in Fig 12. The left-hand terminus is the 13% Cr-Fe composition as explained above, and at the right-hand end is shown the 0.5% Fe_2O_3 in solution in Cr_2O_3.

It should be mentioned that the composition axis of this figure is the fractional weight chromium X10, referred to the metallic constituents only.

The α Fe, γ Fe, spinel equilibrium pressure has not been determined, but its left-hand terminus is at approximately 6-7% Cr at 1300°C as given by the binary phase diagram.

The top reaction horizontal corresponding to γ Fe, FeO, spinel equilibrium has a pressure level determined by the established Fe/FeO equilibrium pressure, and its right-hand terminus is at a value of 48.5% Cr or a Cr/Cr + Fe × 10 value of 4.85.

In the spinel + rhombohedral solution two-phase region in the top of the drawing, several experimental points are shown which were obtained by controlled pressure oxidation of $FeCr_2O_4$ (see Table IV). Small pellets of $FeCr_2O_4$ powder were heated to 1300°C for various periods of time using oxygen pressures varying from 15 μ to 500 μ, obtained by a variable vacuum leak.

The datum point (open square) near the curve describing stability for the rhombohedral solution

Table IV. Controlled oxidation of $FeCr_2O_4$ at 1300°C

O_2 pressure, microns	Log Po_2, atm	Oxidation time, hr	Lattice parameter (a_o) and Cr wt ratio a_o	$\frac{Cr}{Cr+Fe}$	Rhombohedral oxide Cr/Cr + Fe wt ratio based on high angle line measurements
15	—4.70	24	8.3851 ±.0005	0.575	Too diffuse
25	—4.48	8	8.3848 ±.001	0.575	0.85-0.90
50	—4.18	8	8.3909 ±.002	0.54	0.80-0.83
100	—3.88	8	8.389 ±.002	0.54	0.74
500	—3.18	24	Too weak		0.69
500	—3.18	3	No pattern		0.74

was calculated from the Richardson, *et al.* equation plus the following two:

$$2Fe_2O_3 = 4Fe + 3\ O_2 \text{ and } 2Fe_2O_3 \cdot 4Cr_2O_3 =$$

$$2Fe_2O_3 + 4Cr_2O_3$$

The free energy for this last equation was calculated on the basis of an ideal solution. In view of the fact that there is a complete series of solid solutions between Cr_2O_3 and Fe_2O_3, the assumption of ideality might be approximately correct. In any case, the free energy change involved in the formation of the $Fe_2O_3 \cdot 2Cr_2O_3$ solid solution must be small compared to the other processes involved.

By summing up the above equations of known ΔF, one arrives at the change in free energy for the following equation

$$2Fe_2O_3 \cdot 4Cr_2O_3 = 4FeO \cdot Cr_2O_3 + O_2$$

$$\Delta F = +124{,}250 - 68.7T$$

Solving for ΔF for 1300°C (1573°K) and substituting in $\Delta F = -RT \ln K = -RT \ln Po_2$, one finds $Po_2 = 4.48$ mm and log Po_2 in atmospheres is −2.23. This oxygen pressure is that required to oxidize completely the spinel of composition $FeO \cdot Cr_2O_3$ to the rhombohedral oxide of identical Cr/Fe ratio at 1300°C. In addition, Schmahl (15) has given an oxygen pressure for the dissociation of $Fe_2O_3 \cdot 2Cr_2O_3$ at 1323°C as 1.05×10^{-2} atm or log $Po_2 = -1.79$. This is plotted as an open triangle just above the open square point. Because his data refers to 1323°C, this point should be somewhat too high, as it is. Hence, it appears to be essentially in agreement with the Richardson, *et al.* point as calculated above.

It should be emphasized that the data plotted in this region are not of high accuracy, and in particular, the composition estimates of the rhombohedral solution from x-ray data are of poor accuracy, mainly because of poor x-ray photograms. However, the fact that these points cluster reasonably well to a smooth curve passing close to the other data (open points) offers some assurance that the experimental points may not be too far off.

The course of the curves bounding the two phase spinel + rhombohedral region provides the information necessary for establishing the tie lines between these two phases on the isothermal phase diagram, Fig. 9. However, in view of the questionable accuracy of these curves, it seems hardly worthwhile to attempt to draw in "accurate" tie lines. Anyone interested can do this readily from the information given.

Rate of Internal Oxidation in 5% Cr-Fe and in 10% Cr-Fe Alloys

Some measurements were made in the above two alloys on thick samples (about 0.2 in. thick) at 1000° and 1300°C. Fairly thick samples were chosen so that the diffusion distance would be small compared to the sample thickness. The samples were rectangular in shape and were encapsulated in SiO_2 with iron-saturated FeO as an oxygen source. The depth of penetration of the spinel subscale is shown in Table V.

Table V. Rate of penetration of spinel subscale

1000°C	Hours	Penetration, cm
5% Cr	20	0.0034
	40	0.0045
10% Cr	20	0.0031
	40	0.0048
1300°C		
5% Cr	1	0.0058
	64	0.0250
10% Cr	1	0.0071
	2	0.0071
	4	0.0150
	8	0.0155
	64	0.0451

Results at 1000°C are not very meaningful since the accuracy of measurement was poor. However, in the case of the 10% Cr alloy at 1300°C, it is possible to demonstrate that the data plotted as cm vs. $t^{1/2}$ yield a straight line which passes through the origin. If time is plotted in seconds, the slope is found to be about 7×10^{-8} cm²/sec. Evidently the rate of progress of the subscale layer is diffusion controlled, as would be anticipated. However, there is insufficient knowledge about concentration gradients in the layer to be able to calculate an oxygen diffusion rate.

Discussion

It seems clear that the disparity between various investigators' work in the results of Fe-Cr alloy scaling experiments lies in the nonequilibrium nature of such experiments. Evidently there was not always a full realization that very significant changes in alloy composition occurred during the progress of an oxidation run. These alloy composition changes are reflected in changes in the nature of the scale formed.

Another complication is caused by a tendency for the scale to separate from the alloy. When this can occur, the tendency for nonequilibrium scales is enhanced since there is poor contact between metal and scale. This means that a scale can exist in a higher state of oxidation than would be possible in contact with the alloy.

Thermodynamically, the scales of lowest oxygen pressure lie closest to the metal, and the scale nearest the gas phase must be of highest dissociation pressure. In a nonequilibrium experiment, if Cr_2O_3, "Fe Cr_2O_4," and Fe_2O_3 are all found in the scale, they must be present in the order listed from metal to gas phase. This order can be seen in Fig. 12. It can be seen also from Fig. 12 that during air oxidation one should not observe spinel as the outermost layer of scale for any Fe-Cr alloy because the spinel is only stable at very low oxygen partial pressures.

The actual scales observed will depend in large measure on the severity of the oxidation, which for any chromium level might be measured by the per cent chromium converted to various oxides. Yearian, *et al.* (1) recognized the so-called A and B types of scale representing a difference in the amount of oxidation. Under light oxidation, a 20% Cr alloy will only show the equilibrium Cr_2O_3 scale. With

more drastic conditions; higher temperature, longer time or possibly higher oxygen pressure, the chromium present is not adequate to prevent iron oxides from forming. In this case, one expects an outer layer of nearly pure Fe_2O_3, next a spinel layer, and finally a Cr_2O_3-Fe_2O_3 rhombohedral solid solution of variable composition.

The occurrence of different layers of variable composition will be expected, depending on the parameters just mentioned, plus specimen geometry. Therefore, there is no fundamental significance in reporting a specific series of layers in a scale unless all the variables are very closely specified, and unless the precise thickness and composition of each layer are well documented. This has not often been done in the past. What is needed at present in this and in other systems is a better characterization of the individual layers, including their defect structure and, of particular importance, their mode and rate of growth. This would probably entail controlling oxygen pressure so that the growth characteristics of a single layer could be studied.

From a practical point of view, the appearance of Fe_2O_3, or of iron chromite, during the oxidation of Fe-Cr base alloys is evidence of failure. Either the chromium content was too low, the temperature too high, or the time of exposure too long. There is good evidence that various small additions to the Fe-Cr type alloy can improve their oxidation resistance appreciably, but this will be reported elsewhere.

Finally, one must be cautious about translating results of oxidation behavior in pure oxygen to the behavior in air. The nitrogen content of air appears to play a significant role in the structures observed during the oxidation of Fe-Cr alloys. Chromium nitrides have been observed in Fe-Cr samples heated in air. This effect apparently has been little studied.

Summary and Conclusions

An isothermal section for equilibrium conditions at 1300°C in the Fe-Cr-O system has been presented. With the exception of a minor modification, this section also represents conditions at 1000°C. With the aid of this diagram, one sees that there are two types of equilibrium scale formed on Fe-Cr alloys: spinel or iron chromite below 13% Cr, and Cr_2O_3 containing a little dissolved Fe_2O_3 at higher chromium contents. With the additional information on the gamma iron-FeO equilibrium noted by Birchenall (12), this diagram agrees qualitatively with the one suggested by Woodhouse and White (2).

The oxidation mode for alloys in equilibrium with the spinel is mainly internal oxidation, at least at temperatures over 1000°C, while the oxidation mode for alloys over 13% Cr is formation of a surface oxide. This difference is of prime importance in regard to oxidation resistance. The rate of formation of the internal oxide at 1300°C is very rapid compared to the oxidation rate for surface Cr_2O_3. Since this is the case, alloys low in chromium content fail very rapidly, while the chromium-rich alloys are comparatively resistant to oxidation.

Platinum wire marker experiments seem to show that at 1000° or 1300°C the Cr_2O_3 on 20 or 30% Cr-Fe alloys forms almost entirely by cation diffusion. Oxygen diffusion from the gas phase apparently plays an insignificant role. This indicates that, to improve the oxidation rate of Fe-Cr base alloys, one should alter in some manner the rate of diffusion of Cr^{+3} in Cr_2O_3, such as by altering the nature of the defect structure of Cr_2O_3. The subject of the Cr_2O_3 defect structure cannot be expanded here, but for those interested in this subject the work of Hauffe and Block (10) and Fischer and Lorenz (11) should be mentioned.

Acknowledgments

It is a pleasure to acknowledge the general assistance of Mr. Leo Butler. The rather extensive x-ray data were obtained by Mrs. Rose DiCerbo and Mrs. Dorothy DeCarlo. Miss Eileen Alessandrini prepared many electron diffraction studies of the scales

Manuscript received July 31, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

A Model of the Mechanism of Electrochemical Conversion from Active to Passive States

W. A. Mueller

Physical Chemistry Division, Pulp and Paper Research Institute of Canada, Montreal, Quebec, Canada

ABSTRACT

A model is developed of the mechanism of passivation of metals by oxide films. It is based on the assumption of the formation of a passivating film caused by the reaction of OH^- ions with the metal surface. With increased potential the film-free area decreases exponentially and with a higher exponent than does the density of the anodic dissolution current. Thus in the conversion from the active to the passive state, the current density is reduced exponentially to the constant and very low value characteristic of the passive state. This mechanism of passivation is explained by equations which describe the density of the anodic dissolution current as a function of the pH and the potential difference between the metal and the electrolyte. Good agreement with the theory is shown by published data for iron, nickel, chromium, gold, and silver. A simple method is given to derive all the constants required for the mathematical formulation of the anodic dissolution current from experimental data. Flade's equation relating to the boundary potential between the active and the passive state of iron is discussed. The principles and formulas, although derived specifically for formation of oxide films, are considered also to be applicable to the electrochemical passivation by other films.

The mechanism of the reactions which cause the formation of a passivating film on metals is of basic interest in studying the nature of passivity. These reactions can be analyzed by means of partial polarization curves, if exact polarization curves in the potential range of the conversion from active to passive states are available. A detailed description of the analysis of polarization curves is being prepared for publication in another paper (1). This paper describes a model which allows an analysis of the density of the anodic dissolution current, particularly during the conversion from active to passive states. Equations are derived for the anodic dissolution current in the active state, for the conversion to the passive state and for the Flade potential (2) and these are used to interpret a series of pertinent empirical data.

The passivity of metals caused by the formation of an oxide film is the most important case of passivity; this is the case for which equations have been derived primarily. However, calculations for other types of passivating films of electrochemical origin may be made by using the same equations. Of primary importance is the inclusion of all known facts concerning the active and passive states.[1] These include the electrochemical properties of the anodic dissolution current from the active state through the Flade potential to the passive state.

Conditions for measuring accurate polarization curves in the potential range of the conversion from active to passive states have been derived before (3,4). Potentiostatic control prevents the state of instability expressed as a "jump of the potential." Accurate polarization curves measured potentiostatically in the potential range of the conversion from the active to the passive state were published previously for iron in a solution of 100 g/l NaOH and 35 g/l Na_2S (4). These curves, which were subsequently corroborated by Kesler (5), and Uusitalo (6), show an exponential increase of the current density with increasing potential in the active state (Fig. 1 and 3a). After reaching the maximum, the current density declines exponentially, thus demonstrating the conversion from active to passive states.

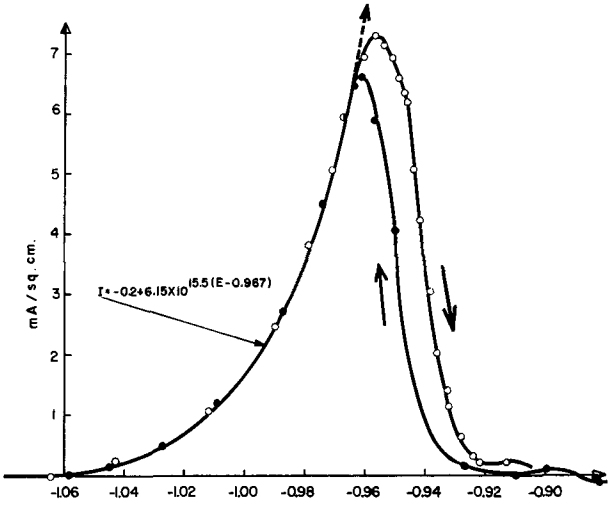

Fig. 1. Density of the anodic dissolution current of iron in a solution of 100 g/l NaOH plus 35 g/l Na_2S measured with reference to a saturated calomel cell. ○ Measured with increasing potential; • measured with decreasing potential.

[1] For a comprehensive survey of the literature on passivity the reader is referred to the symposium in Heiligenberg, 1957 [*Z. Elektrochem.*, 61, No. 6/7 (1958)].

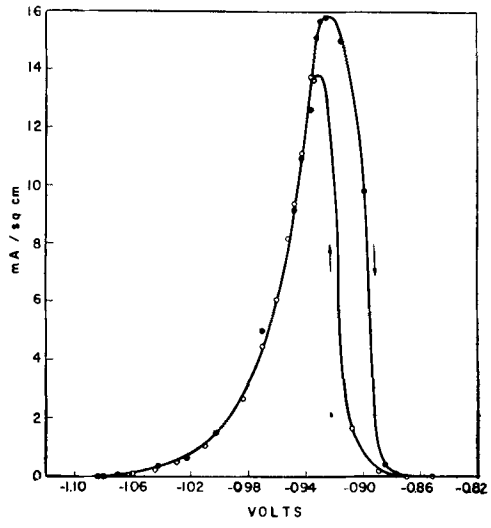

Fig. 2. Density of the anodic dissolution current of iron in a solution of 100 g/l NaOH + 35 g/l Na_2S + 30 g/l pyrogallol with reference to a saturated calomel cell. • Measured with increasing potential; ○ measured with decreasing potential.

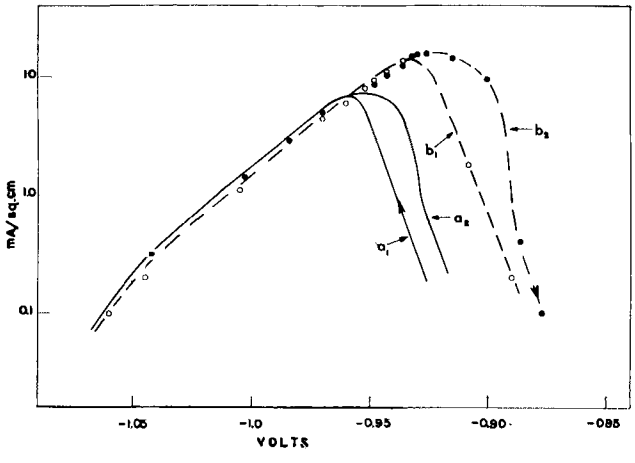

Fig. 3. Semilogarithmic plotting of the curves of Fig. 1a and b showing the exponential relations of both the increasing and decreasing current densities. The extended curves a_1 and a_2 represent the measurement without the addition of pyrogallol. The dotted curves b_1 and b_2 and the plotted points refer to the measurement in liquor containing pyrogallol.

An interesting change is noticed after adding 30 g/l pyrogallol to the above solution (Fig. 2 and 3b). The polarization curves recorded are identical with the previous curves in the range of exponentially increasing current density in the active state. However, the maximum current density is higher and is reached at a less negative potential. The decrease of the current density owing to passivation occurs also at less negative potentials. There are examples of several metals showing the same type of curves in different solutions given in recent publications (7-12).

The general equation of the anodic dissolution current I_a as a function of the measurable potential difference E between the metal and the electrolyte in the active state (1) is

$$I_a = I_o\, f(\mathrm{pH}) \exp \frac{\alpha_a n_a F}{RT} (E - E_o) \qquad [1]$$

where α_a is symmetry factor of the reaction of anodic dissolution amounting to unity or less, n_a is the valency of the determining dissolution reaction, which in the simplest case, but not generally, is the valency of the metal dissolving in the active state, $\alpha_a n_a$ is over-all electrochemical transfer coefficient, I_o and E_o are a couple of interdependent values of current density and potential at pH = 0, and f(pH) is the dependence of the Tafel relation on pH.

This equation is valid only if the rate of the reverse reaction, characterized by electrodeposition of the dissolved metal, is negligible in comparison to the rate of dissolution. In some cases, e.g., chromium in H_2SO_4, f(pH) = 1 (10). However, in the case of iron immersed in perchlorate and sulfate f(pH) $\neq$ 1 according to Heusler (9).

Pourbaix (13) has shown that the relation between equilibrium pressure and potential of iron is independent of the pH value in the pH range from 0 to about 9. Similarly the valency of the iron ions formed is assumed to be 2 (14). There is some evidence, however, that the dissolution of iron in alkaline solutions leads to the formation of Fe_3O_4 as was found in a dilute solution of $NaNO_2$ (15). This reaction also would explain the average valency 2 2/3 found in the dissolution of iron in (NaOH + Na_2S) solutions (4). For this reason; and in agreement with Pourbaix's diagram (13), it is assumed that at pH values higher than 9, Eq. [1] is still valid; however, the exponent $\alpha_a n_a$ might be different.

The Flade potential E_F (2), which represents the boundary potential between the active and the passive states, depends on the pH value. For iron in the range of pH 0 to 4 Flade discovered a relationship which can be expressed by

$$E_F = E_{F_o} - \frac{RT}{F} 2.3(\mathrm{pH}) \qquad [2]$$

where E_F is the Flade potential and E_{F_0} the Flade potential at pH = 0. Equation [2] has been verified by Franck (7).

The partial current density I_p of the anodic dissolution current in the passive state is independent of the potential difference between electrode and electrolyte in a considerable range of this potential (7-10). The iron ions formed in this potential range are trivalent. The anodic current density at high positive potentials (trans-passive range) is accompanied by the formation of FeO_3 and FeO_4^{--} (13).

Under the influence of a constant current density the conversion from the active to the passive state requires a time period which can be approximately expressed by the formula (7)

$$t_p = k/I - I_m \qquad [3]$$

where t_p is time during which the current passivates the metal, k constant, I current density, and I_m minimum current density sufficient for passivation. This relation was found to be valid also for metals other than iron; for gold for instance, in hydrochloric acid (16, 17), and for chromium in sulfuric acid (10). It is widely accepted (18, 8, 19-21) that the passivity of iron in many aqueous solutions is caused by an iron oxide film. The thickness of the film ap-

parently varies considerably between a film strong enough to be stripped from iron by dissolution of the backing metal (22, 23) on the one hand, and a film of molecular dimensions on the other (12, 24-27). In thick films, a layer of Fe_3O_4 adjacent to the iron surface is covered by one of Fe_2O_3 (19). At steady-state conditions the film thickness increases linearly with the potential (19-21). Visible deposits (28), usually of a bulky nature, are not considered typical features of the passive state as passivity is reached without these.

General Theory

Basic Concepts.—Since the formation of the passivating film is an electrochemical phenomenon, its rate on a film-free surface is an exponential function of the metal-electrolyte potential difference. This film originates from the reaction of anions, contained in the electrolyte, with the metal surface [Müller (29)]. For the present model the metal atoms of the film are assumed to maintain their original position in the metal lattice as surface atoms. The film is therefore very strongly bonded to the metal. In the case of iron, the electrostatic field which produces the passivating film is assumed to convert the iron atoms at the surface to the trivalent state. Thus a film is formed consisting of a monolayer of Fe_2O_3.

During the conversion from the active to the passive state, the film covering part of the surface reduces the rate of anodic dissolution because the rate of anodic dissolution is proportional to the ratio of film-free area to total area ("film-free" meaning free of the passivating film.) The corrosion rate of the film-free fraction is assumed to be undiminished.

The anodic current density in the passive state is usually very small and is caused by a very slow corrosion process. Since this current density does not depend on the potential, direct anodic dissolution is out of the question. The only alternative is to assume that a slow dissolution of the passivating film occurs continuously. The damage done to the film is immediately compensated by film reformation, which is basically an anodic process. For this reason, the anodic current-density in the passive state is proportional to the rate of film dissolution and is independent of the potential.

The variation of film thickness found empirically indicates film growth with increased potential from monomolecular dimension, reached initially by passivation at the Flade potential, to about 50 or 100Å. In agreement with Vetter (20) and Weil (21), it is assumed that the increase of the thickness of passivating films is caused by the migration of iron and oxygen ions in opposite directions across the oxide film under the influence of the potential gradient. The film thickness increases with increasing potential until the rate of film growth is reduced by the decreasing gradient of the potential to the value of the rate of film dissolution. Hence, under equilibrium conditions, the film maintains a thickness which increases linearly with the potential.

With decreasing potential, the gradient of the potential in the film is decreased and so is the rate of film formation by migration. The unchanged rate of film dissolution causes a decrease of the film thickness until stable conditions are reached, i.e., when the rate of film formation has become equal to the rate of film dissolution.

The validity of these derivations is limited by the assumption that the rates of possible reverse reactions of the anodic dissolution, i.e., electrode position of the dissolved metal, and of the formation of a passive film, characterized by rebreaking the bonds, are negligible. As the reverse reactions are substantial under certain conditions, their effect has been derived in another paper (30).

Formation of an Fe_2O_3 Film on Iron as an Electrochemical Process

The electrochemical reaction involved in the formation of an Me_2O_n film on a film-free metal surface can be formulated

$$Me + n(OH)^- \rightleftharpoons Me_2O_n + n/2\ H_2O + ne^- \quad [4a]$$

or

$$Me + n(OH)^- \rightleftharpoons Me(OH)_n + ne^- \quad [4b]$$

This reaction supplies n electrons per reacting metal atom to the metal. The rate of this reaction depends on the OH^- concentration and the potential difference between metal and electrolyte. Equation [4b] formulates the reaction in agreement with the chemical analysis of passive films on iron by Neilsen and Rhodin (31). Oxygen-free solutions will now be considered. The effect of dissolved oxygen will be discussed later.

The rate of film formation r_f on a film-free surface follows Tafel's relation and is proportional to $(OH^-)^{n_{OH}}$. As $(OH^-)^{n_{OH}} = \exp 2.3 n_{OH}\ (pH - 14)$, r_f can be formulated

$$r_f = r_{14} \exp\left[2.3\ n_{OH}\ (pH - 14) + \frac{\alpha_p\ n_p\ F}{RT}\ (E - E_{14})\right] \quad [5]$$

where α_p is the symmetry factor, n_{OH} order of the process with respect to (OH^-), n_p valency controlling the rate of Me_2O_3 formation on the metal, r_{14} the rate of film formation on a film-free iron surface at $pH = 14$ and $E = E_{14}$, and E_{14} characteristic value of E at $pH = 14$. Equation [5] takes into consideration only the forward reaction which forms metal oxygen bonds at the interphase. If the backward reaction of rebreaking the bonds is so strong that equilibrium conditions are approached, Eq. [5] is no more strictly valid (30).

For reasons of simplicity the calculation is better referred to $pH = 0$. Thus Eq. [5] is converted to

$$r_f = r_o \exp\left[2.3\ n_{OH}\ (pH) + \frac{\alpha_p\ n_p\ F}{RT}\ (E - E_o)\right] \quad [6]$$

where r_o is the rate of film formation on a film-free metal surface at $pH = 0$ and $E = E_o$.

Equation [6] defines the rate of the film formation on a film-free metal surface. The rate of the film formation in an area partly covered by film is proportional to the ratio of the surface area of film-free metal to the total metal surface. This part of the derivation follows the Langmuir adsorption theory and is similar to that of Franck (7) and of Gerischer

(8). At steady state the rate of film formation is equal to the rate of film dissolution. Hence

$$a_c\, r_c = a_f\, r_f \qquad [7]$$

where a_c is film-covered area, a_f film-free area, and r_c rate of film dissolution of metal oxide or hydroxide from a film-covered area. r_c is assumed to be independent of the potential as the dissolution goes without exchange of charges. It may also be stressed that Eq. [7] does not describe an equilibrium between film formation and dissociation of the film into the original components. The ratio of the film-free area to the total area a_t is given by

$$a_f/a_t = 1/1 + \frac{r_f}{r_c} \qquad [8]$$

Combining Eqs. [6] and [8]

$$\frac{a_f}{a_t} = \frac{1}{1 + \frac{r_o}{r_c} \exp\left[2.3\, n_{OH}\,(pH) + \frac{\alpha_p\, n_p\, F}{RT}(E - E_o)\right]} \qquad (9)$$

Eq. [9] shows the very rapid decrease of the film-free area with increasing potential and pH values.

Anodic dissolution current in the potential range of the conversion from active to passive state.—The density of the anodic dissolution current I_a at totally film-free areas is given by Eq. [1]. Only the film-free area is assumed to contribute to the anodic current in this calculation. The partial coverage of the surface by an insoluble film reduces this current density to an amount which is proportional to the ratio of film-free area to total area. Thus Eqs. [1] and [9] may be combined to calculate the anodic current density I_{af} on a partly film-covered surface

$$I_{af} = I_o \frac{f(pH) \exp \frac{\alpha_a\, n_a\, F}{RT}(E - E_o)}{1 + \frac{r_o}{r_c} \exp\left[2.3 n_{OH}\,(pH) + \frac{\alpha_p\, n_p\, F}{RT}(E - E_o)\right]} \qquad [10]$$

For the application of Eq. [10] the ratio r_o/r_c must be determined. In Eq. [3], t_p gives a reciprocal measure of r_o: however, since the potential changes continuously during the measurement, this must be regarded as approximate only. Accurate measurements of r_o should be made at constant potential in the passive state, e.g., at the Flade potential. There is, however, a clearcut relation between r_o/r_c and I_{po}/I_p ($I_{po} = I_p$ at pH = 0). When 50% of the surface is covered with the protective film, the current density $I_{0.5}$ becomes 50% of the value calculated for a film-free surface, and the potential becomes $E_{0.5}$. When $E = E_{0.5}$ in Eq. [10], I_o f (pH)-$2I_{0.5}$ and the denominator of Eq. [10] becomes 2. Thus

$$\frac{r_o}{r_c} \exp\left[2.3\, n_{OH}\,(pH) + \frac{\alpha_p\, n_p\, F}{RT}(E_{0.5} - E_o)\right] = 1 \qquad [11]$$

For the potential $E_{0.5}$ at pH = 0 the symbol $E_{o-0.5}$ may be used, and for the rate of film formation r_o at pH = 0 and $E_{o-0.5}$ the symbol $r_{o-0.5}$. According to Eq. [11] $r_{o-0.5}$ equals r_c when E_o equals $E_{o-0.5}$. Hence,

$$\frac{r_{o-0.5}}{r_c} \exp\left[2.3\, n_{OH}\,(pH) + \frac{\alpha_p\, n_p\, F}{RT}(E_{0.5} - E_{o-0.5})\right] = 1 \qquad [12]$$

The rate of film dissolution r_c at a completely film-covered area is proportional to I_p, the current density in the passive state, according to the given basic concept. At pH = 0, I_p becomes I_{po}, hence

$$r_{o-0.5}/r_c = I_{po}/I_p \qquad [13]$$

By substituting $r_{o-0.5}/r_c$ from Eq. [13] into Eq. [10] an equation results which contains only measurable quantities or constants as follows

$$I_{af} = \frac{I_o\, f(pH) \exp \frac{\alpha_a\, n_a\, F}{RT}(E - E_o)}{1 + \frac{I_{po}}{I_p} \exp\left[2.3\, n_{OH}\,(pH) + \frac{\alpha_p\, n_p\, F}{RT}(E - E_{o-0.5})\right]} \qquad [14]$$

The current density of the anodic dissolution current on a film-free surface as expressed in the numerator can be described by using any pair of related values of current density and potential to replace $I_o\, f(pH)$ and E_o, for instance, $2I_{0.5}$ and $E_{0.5}$. The second term of the denominator can be formulated

$$\frac{I_{po}}{I_p} \exp\left[2.3\, n_{OH}\,(pH) + \frac{\alpha_p\, n_p\, F}{RT}(E_{0.5} - E_{o-0.5})\right] \exp \frac{\alpha_p\, n_p\, F}{RT}(E - E_{0.5})$$

According to Eq. [12] and [13] this expression equals $\exp \frac{\alpha_p\, n_p\, F}{RT}(E - E_{0.5})$. Thus a simplified formula of the current density in the potential range of the conversion is derived

$$I_{af} = 2I_{0.5} \frac{\exp \frac{\alpha_a\, n_a\, F}{RT}(E - E_{0.5})}{1 + \exp \frac{\alpha_p\, n_p\, F}{RT}(E - E_{0.5})} \qquad [15]$$

The above derivation does not take into account the dissolution of the passivating film in the electrolyte which causes the flow of a small anodic current I_p at a completely covered surface. The partial current I_d which is caused by the film dissolution on a partly covered surface is proportional to the ratio film-covered area to total area. According to Eq. [9] and [11] the ratio film-free to total area amounts to

$$1/1 + \exp \frac{\alpha_p\, n_p\, F}{RT}(E - E_{0.5})$$

and the ratio film-covered to total area is put into Eq. [16] as factor of I_p

$$I_d = I_p \frac{\exp \frac{\alpha_p n_p F}{RT} (E - E_{0.5})}{1 + \exp \frac{\alpha_p n_p F}{RT} (E - E_{0.5})} \qquad [16]$$

In cases of typical passivity this partial current I_a is negligible in comparison with $I_{0.5}$. However, there are conditions under which I_a forms a substantial part of the combined current density I_c; then the calculation of I_c requires the addition of I_a to I_{at} as follows

$$I_c = \frac{2 I_{0.5} \exp \frac{\alpha_a n_a F}{RT} (E - E_{0.5}) + I_p \exp \frac{\alpha_p n_p F}{RT} (E - E_{0.5})}{1 + \exp \frac{\alpha_p n_p F}{RT} (E - E_{0.5})} \qquad [17]$$

Equation [17] covers the curve of the density of the anodic dissolution current as a function of the potential including the active and passive states. It is evident that Eq. [17] can be derived without special assumptions concerning type of metal and reacting ions and it is assumed to be valid if the assumptions about the mechanism of film formation are appropriate.

Comparison with experimental results.—From the above it is clear that the ratio $\beta = \alpha_p n_p : \alpha_a n_a$ determines the form of the curve of the anodic dissolution current. If β is unity the curve forms a polarographic wave, i.e., an S-shaped transition from current density 0 to a constant current density amounting to $2 I_{0.5} + I_p$ (Fig. 4). This is the shape of the curves found with silver (12) in (11M NH_3 + 1M $(NH_4)_2SO_4$), with gold (8) in 4.0*N* HCl, and with iron (8,9) in 1.0*N* H_2SO_4 at 25°C. However, this type of curve might also be caused by a film of salt, as this condition can cause the formation of a constant current density.

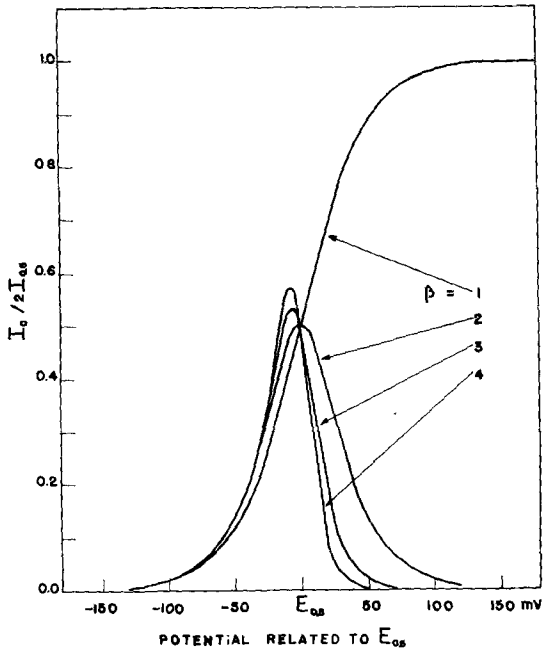

Fig. 4. Calculated curves characteristic of the density of the anodic dissolution current as a function of the potential. The ratio β of the exponent in the formula describing the anodic dissolution reaction to the exponent in the formula of the film forming reaction control the form.

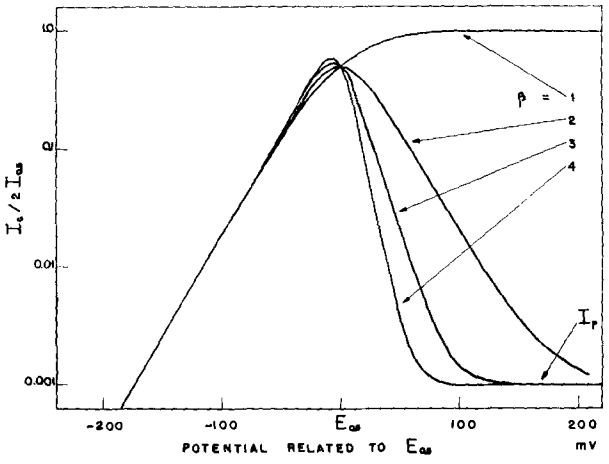

Fig. 5. Semilogarithmic plotting of the curves of Fig. 4 which shows the typical 3 ranges of nearly linear relation.

When $\beta = 2$ the curve is symmetrical, the branch covering the active state being the mirror image of the branch measured in the range of the conversion from the active to the passive state. When $\beta > 2$, the decrease of the current density in the range of the conversion from the active to the passive state becomes increasingly steeper than its increase in the active state. The curves of Fig. 1 and 2 show the typical form derived for $\beta = 3$ to 4.

In semilogarithmic plotting the calculated curve assumes a very simple form. When the second term in each numerator and denominator of Eq. [17] becomes negligible in comparison with the first term, the resulting equation in semilogarithmic plotting gives the straight line (Fig. 5)

$$\left(\frac{d \ln I_c}{dE}\right)_a = \frac{\alpha_a n_a F}{RT} \qquad [18]$$

Equation [18] is valid in the active range (subscript a). When the second term in the numerator and the first term in the denominator become negligible, another straight line is formed in semilogarithmic plotting as follows

$$\left(\frac{d \ln I_c}{dE}\right)_{a \to p} = \frac{(\alpha_a n_a - \alpha_p n_p) F}{RT} \qquad [19]$$

Equation [19] formulates the curve in the potential range of the conversion from active to passive state (subscript $a \to p$). When the first term of each nominator and denominator becomes small in comparison with the second term, I_c equals I_p.

The straight lines given by Eq. [18] and [19] cross at the coordinates $2I_{0.5}$ and $E_{0.5}$ and the second and third straight lines cross at the coordinates I_p and E_F. Thus a simple method of calculating all the characteristic constants of Eq. [17] from measured curves becomes evident. Kolotyrkin's (10) anodic current density potential curves in semilogarithmic plotting demonstrate these features. His curves obtained from chromium and nickel in H_2SO_4 consist of three straight lines representing the active state, the conversion to the passive state, and the passive state.

$E_{0.5}$ and the Flade Potential

For the current density as a function of pH a relation based on Eq. [14] and [16] can be formulated as follows

$$I_c = \frac{I_o f(pH) \exp \frac{\alpha_a n_a F}{RT} (E - E_o) + I_{p_o} \exp \left[2.3 n_{OH} (pH) + \frac{\alpha_p n_p F}{RT} (E - E_{o-0.5}) \right]}{1 + \frac{I_{p_o}}{I_p} \exp \left[2.3 n_{OH} (pH) + \frac{\alpha_p n_p F}{RT} (E - E_{o-0.5}) \right]} \quad [20]$$

Equation [20] shows the influence of pH and of the current density I_p in the passive state on the anodic dissolution current. The characteristic potential $E_{0.5}$ of their cross-point with the line of the active state is given by

$$E_{0.5} = E_{o-0.5} - \frac{RT}{\alpha_p n_p F} \left[2.3 n_{OH} (pH) + \ln \frac{I_{p_o}}{I_p} \right] \quad [21]$$

because at $E_{0.5}$ the second term of the denominator equals unity (Eq. [12] and [13]). $E_{0.5}$ is independent of the function f(pH). This might be expected because the potential at which the film covers 50% of the surface does not depend primarily on the rate of anodic dissolution. Typical features of the calculated curves are the following: in the active state there is one straight line in semilogarithmic plotting if the current density which is independent of pH (f(pH) = 1). The conversion to the passive state is shown by parallel straight lines for a variation of pH as demonstrated in Fig. 6. Kolotyrkin (10) gives a demonstration of these conditions from a study of the current density of the anodic dissolution of chromium in 1.0N, in 0.1N and 0.01N H_2SO_4. His curves in semilogarithmic plotting consist of one straight line of the current in the active state with straight lines of the conversion to the passive state branching off at potentials of 0.05 v difference.

It is also interesting to note that the alteration of the polarization curve found after the addition of pyrogallol (Fig. 1 and 2) might be caused by an increased solubility of the passive film which effects a change of I_p. This assumption agrees with the experimental result of MacLean and Gardner (32) who studied the corrosivity of wood extractives. These

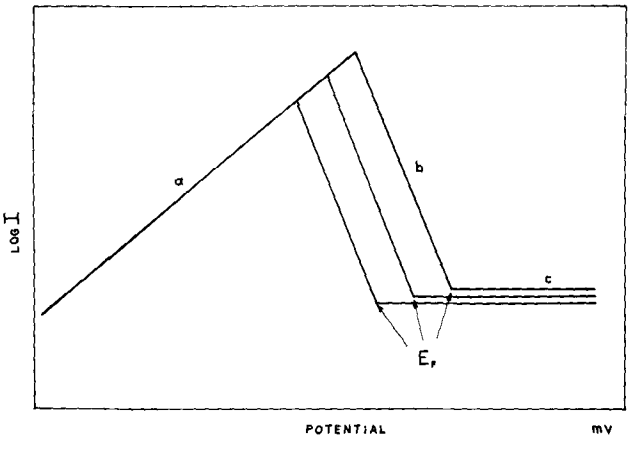

Fig. 6. Schematic semilogarithmic plotting of the density of the anodic dissolution current: (a) film-free active range, (b) conversion to the passive state, and (c) Flade potential E_F and the passive state.

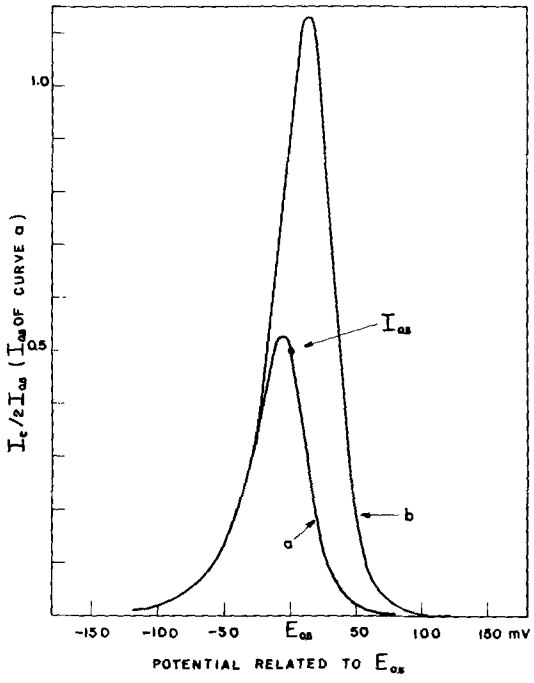

Fig. 7. Density of the anodic dissolution current calculated for a variation of the rates of film dissolution and film formation:

(a) $\frac{I_{p_o}}{I_p} \exp [2.3 n_{OH} (pH)] = 1;$

(b) $\frac{I_{p_o}}{I_p} \exp [2.3 n_{OH} (pH)] = 0.1$

authors suggested that the increased corrosivity of alkaline cooking liquor found by addition of 1,2 dihydroxybenzene and derivatives, such as pyrogallol, was due to increased solubility of ferric iron salts. Figure 7 demonstrates the calculated effect in two curves the shape of which agrees very well with that of Fig. 1 and 2.

Franck (7) on repeating Flade's (2) experiments, uses the expression "critical current density which causes the local activation" to describe the current density at the Flade potential. Franck does not indicate whether this critical value of the current differed at different pH values. Hence the definition of Franck's experimental values of the Flade potential is not exactly known.

In the present work, the Flade potential is defined as the potential at which the density of the anodic dissolution current I_{at} equals I_p, the density of the current in the passive state. It may be stated that this definition does not consider the Flade potential as an equilibrium potential for the formation and disintegration of the protective oxide film (19). According to the definition the two terms in the numerator of Eq. [20] are equal at E_F. Differentiation of the equation calculated for E_F with respect to pH results in the relation

$$E_F = E_{F_o} - (pH) \frac{RT}{F} \frac{2.3 n_{OH} - \frac{d \ln f(pH)}{d (pH)}}{\alpha_p n_p - \alpha_a n_a} \quad [22]$$

The meaning of Eq. [22] may be demonstrated in Fig. 8 which plots the current-potential relation on a semilogarithmic scale. The curve referring to pH = 0 is characterized by the crosspoints E_{F_o}/I_{p_o} and $E_{o-0.5}/2I_{o-0.5}$ ($I_{o-0.5} = I_{0.5}$ at pH = 0). According to Eq.

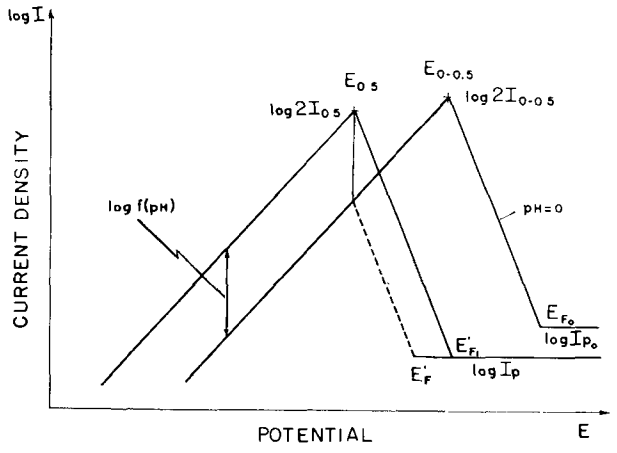

Fig. 8. Schematic semilogarithmic plotting of the anodic dissolution current showing the effect of f(pH) on the Flade potential (Eq. [22]).

[21], $E_{0.5}$ is independent of f(pH). If f(pH) equals unity the Flade potential is E'_F. If f(pH) increases with pH the resulting Flade potential $E'_{F'}$ reaches a value between E_{F_0} and E'_F. Equation [22] gives values of the same order of magnitude as Eq. [2]. However, exact values of the current-density-potential relation at varied pH are required for a definite decision on the validity of Eq. [22].

Comparison with Previously Developed Theories About Passivity

The theory presented is based on the accepted idea of a protective film, consisting of Fe_2O_3 in the case of iron. This theory leads to the conclusion that the electronic state of the metal surface influences the conversion process. A high value of β means a rapid decline from the maximum current density to the passive state, i.e., a typical passivity. An increase of the valency during the conversion from the active to the passive state increases β, because it means $n_p/n_a > 1$. Hence transition elements which increase the valency during the conversion are singled out as elements of typical passive behavior. Thus the original electron configuration theory (33,17,34) is corroborated, and the present theory forms a bridge between Faraday's protective film theory, and Schoenbein's theory (35) that passivation involves an essential alteration of actual metal properties.

The complementary relation between the presented theory and the theory of Vetter (20) and Weil (21) about the passive film is evident. The presented theory leads from an unprotected surface to one which is protected by a monolayer film. The growth of the film thickness is explained by their theory. Thus these two theories cover two neighboring potential ranges.

However, there is disagreement with certain previously published theories. Development of oxygen (7) or of an iron oxide higher in oxygen content than Fe_2O_3 (36) was assumed by some authors to be a necessary or characteristic condition for reaching passivity. This assumption probably has been stimulated by measurements with current controlled experimental arrangements which cause a jump of the potential from the active state over a large range of the passive state (3,4). Depending on the experimental conditions, the potential may reach stable values only in the transpassive state. With an adequate potentiostatic arrangement it is easily shown that the development of oxygen or of high iron oxides is not characteristic of the passive state of iron, but of the transpassive state.

The theory of Müller (28) assumes the deposition of porous metal salts on the rapidly corroding metal surface, particularly in strong acids. On the iron surface below the pores of the deposit, chemical passivity is assumed to be caused by the extremely high current density. Instead of this the present theory assumes that anions can form a salt film on metals. Corrosion rate and current density then are reduced to a value proportional to the solubility of the salt film. Once the potential for the formation of the oxide film is reached, the conversion from the salt-film-covered to the oxide-film-protected metal takes place.

Oxygen and oxidizing agents are well known promoters of passivity. Two different mechanisms were proposed to explain passivation by oxidation. By the first, formation of oxide films occurred by direct reaction between metal and oxygen or oxides. This is the mechanism of the formation of protective films of oxides during the exposure of metals to dry atmospheric oxygen. Dissolved oxidizing reagents, such as chromates, may also promote the formation of a protective film by direct reaction with the metal in the active state (18). By the second proposed mechanism, oxygen or oxides dissolved in water produce an electrochemical reaction between metals and oxidizing agents, consisting of removal of negative charges from the metal surface according to the equation (37)

$$\tfrac{1}{2}\,O_2 + 2e^- \rightleftharpoons O^{2-} \qquad [23]$$

An oxidizing process of this type involves a cathodic current-density according to Faraday's law. If this current density is higher than the maximum anodic current density in the active state, it causes a shift to the passive state. Thus, even though oxygen might contribute to the formation of a passive film, the decisive factors are pH and potential.

An explanation of passivity, and particularly of the Flade potential, has recently been given by Göhr and Lange (19). After a survey of the iron oxides and their properties, the basic chemical reaction involved in the formation of the Flade potential was formulated as follows:

$$Fe_3O_4 + \tfrac{1}{2}H_2O \rightarrow 3/2Fe_2O_3 + \tfrac{1}{2}H_2;\ U_H = +0.58\ v \qquad [24]$$

Even though the present theory assumes an Fe_2O_3 film in agreement with Göhr and Lange, the concept of the mechanism of film formation is different. According to the present derivation the Flade potential is not an equilibrium potential, it is a potential defined by a steady state condition as explained already.

The given derivation reaches from the active state over the range of the conversion from the active to the passive state and over the Flade potential to the passive state. The basic assumptions made and the results derived do not interfere with the theory and the facts known from Vetter (20) and Weil (21) about the neighboring passive state. At the Flade potential the proportion of film free to total area is extremely small and the film coverage almost literally complete. The present derivation studies the formation of a monolayer film. The growth of this film by inner migration which might begin before it covers the complete surface has been described by Vetter (20) and Weil (21).

Kinetics of the Dissolution of Copper in Aqueous Solutions of Aliphatic Amines

S. C. Sircar[1] and D. R. Wiles[2]

Department of Mining and Metallurgy, University of British Columbia, Vancouver, Canada

ABSTRACT

Studies of the rate of dissolution of copper in aqueous solutions of ammonia, and methyl-, ethyl-, and n-butylamines under a high pressure of oxygen have shown the reaction to occur in two stages: a rapid pre-equilibrium involving the free amine molecule, and a slower reaction step involving either the free amine molecule or its conjugate acid. This mechanism leads to a partial understanding of the passivity of copper surfaces in nearly neutral amine solutions.

Recent studies of the kinetics of the attack of various complexing agents on metallic copper have been extended to include the aliphatic amines. Earlier work on ammonia (1,2) and on some amine-type chelating agents (3) has suggested that the free base and its protonated form act to cause dissolution by independent paths, and that the reaction is first order in each species. Thus

$$\frac{d[Cu^{++}]}{dt} = k_1[A] + k_2[AH^+] \qquad [1]$$

where A represents the free amine, and AH^+ its singly protonated form.

The present study, involving methyl, ethyl, and n-butyl amines, was made with the thought of ob-

[2] Present address: Department of Chemistry, Carleton University, Ottawa, Canada.

serving possible variation in kinetic behavior among the members of this homologous series, and also of finding out how well ammonia would fit in as a first member of such a series.

Experimental

The apparatus and procedure used were the same as those described earlier (3,1). Briefly, these were as follows.

The reaction took place in a one-gallon autoclave, under a pressure of oxygen kept constant at about 8.0 atm. The solution, about 2 l in volume, was made up by diluting stock solutions of accurately known concentrations and was maintained at an ionic strength of at least 0.1M by addition of reagent-grade sodium perchlorate. The dissolution specimen was made from conductivity grade (99.97%) copper, heat treated to give small grains of nearly random orientation. This specimen, mounted in Bakelite, was supported in the solution with its exposed face tangential to the 8-cm-diameter cylinder swept out by the impeller blades.

The amines, of Kodak White Label grade, were used without further purification. Reaction solutions were made from calculated amounts of stock solutions of the amines and of reagent-grade perchloric acid. Concentrations of the amine stock solutions were determined by titration to a methyl red end point with sulfuric acid. The composition of each solution was checked by titration. During experiments, the reacting solutions were maintained at a temperature of 25.0° ± 0.1°C. Samples, withdrawn at intervals, were analyzed colorimetrically for copper by carbamate method (4).

Results

The amines used in this work are listed in Table I along with the constants for their acid dissociation in aqueous solution:

$$K_a = \frac{[A]\,[H^+]}{[AH^+]}$$

Unfortunately, the complexes formed by these amines with cupric ion (other than the complexes with ammonia) have not been investigated. It is reasonable to assume, however, that the copper is coordinated to four amine groups, which are most likely arranged in a plane square[3] around the central atom.

The rate plots ([Cu^{++}] vs. time) were found, as in the earlier work, to be linear. This once again demonstrates the absence of such effects as autocatalysis and progressive roughening of the copper surface. The observed dependence of the rate on the amine concentration did not support the anticipated first-order behavior, but was rather of the form shown for methylamine in the lower curve of Fig. 1. The same type of behavior was found for all the amines studied.

These data can be described quite well by an expression of the form:

$$R = \frac{d[Cu^{++}]}{dt} = \frac{k_1[A]\,S}{1 + k_1[A]} \cdot k_2[A] \qquad [2]$$

where S represents the exposed surface area of the copper sample. This is shown further in that a plot of $[A]^2/R$ vs. [A] gives a straight line, as would be expected from Eq. [2]. This is shown for methylamine in Fig. 2.

The observed effects of added acid, that is, the "aminium" form of the complexing agent, are such as not to support without qualification the view previously suggested (1) that the reaction of the protonated form follows an independent path. Figure 1 shows a family of curves for different values of the acidity. Some deviation from complete independence of reaction path is shown by the fact that the curves of rate vs. aminium concentration, although linear, have slopes which vary with amine concentration. These data are presented in Fig. 3.

The nature of this dependence suggests that the over-all rate equation may be of the form

$$\frac{d[Cu^{++}]}{dt} = \frac{k_1[A]\,S}{1 + k_1[A]} \{k_2[A] + k_3[AH^+]\} \qquad [3]$$

A careful re-investigation of the rate dependence in the ammonia system revealed that here, too, the reaction is not simply first order as had previously been reported (1) but follows the same pattern as was found for the amines. Since the deviation from

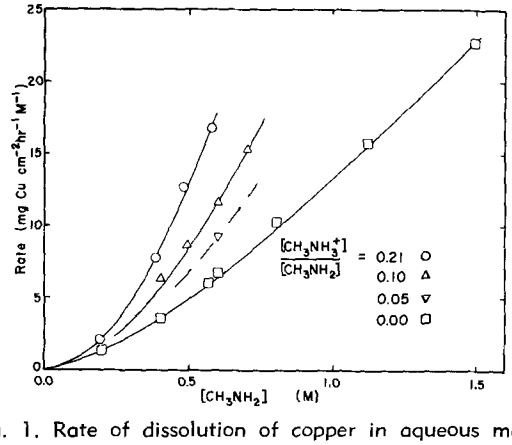

Fig. 1. Rate of dissolution of copper in aqueous methylamine solutions of various acidities.

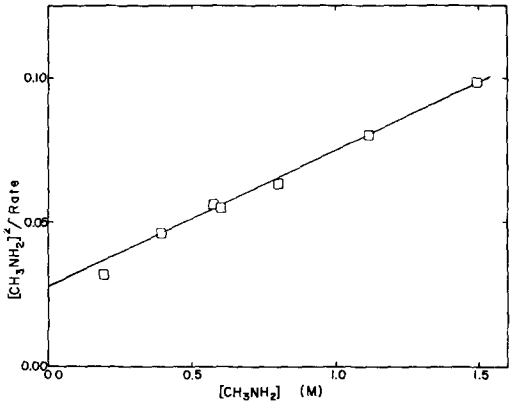

Fig. 2. Plot of $[A]^2/R$ vs. [A] for the dissolution of copper in aqueous solutions of methylamine.

[3] This assumption is based on the fact that most complexes of Cu^{++} which have been studied are square planar. See Ref. (6).

Table I. Amines used in this work

Amine	K_a*
Ammonia	5.68×10^{-9}
Methylamine	2.30×10^{-9}
Ethylamine	1.80×10^{-9}
n-Butylamine	2.46×10^{-9}

* Data adapted from Ref. (5).

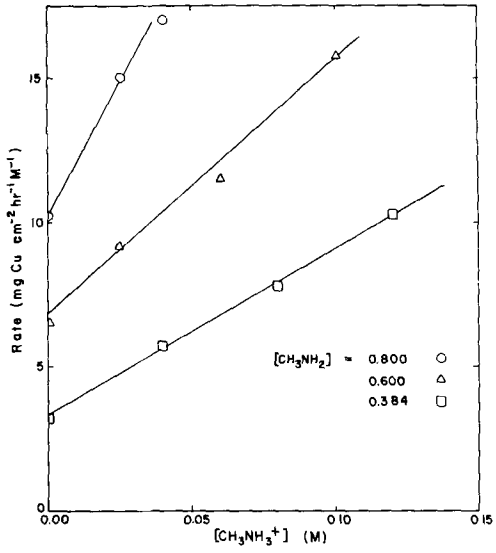

Fig. 3. Rate of copper dissolution in aqueous methylamine solutions as a function of the acidity, at constant concentration of free amine.

linearity is not great, this observation is not in disagreement with Halpern's original work, but is the result rather of a refinement in experimental sensitivity. Experimental data are summarized in Table II.

Values for the constants in Eq. [3] determined for ammonia and the various amines are presented in Table III

The form of Eq. [3] suggests that there is a pre-equilibrium involving adsorption of amine molecules on a saturable surface, producing "active sites." This equilibrium appears to be followed by reaction at the active sites via one of the two previously mentioned independent paths. The adsorption of oxygen on the surface is evidently very fast. The whole process, then, is envisioned as occurring in the following way: (The subscript $_s$ designates a species residing in the surface).

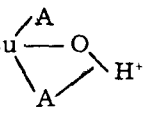
1. $Cu_s + \frac{1}{2} O_2 \xrightarrow{fast} Cu_s - O$

2. $Cu_s - O + A \overset{fast}{\rightleftarrows} Cu_s(A) - O$ $\quad k_1$

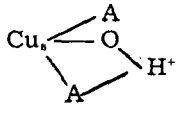
3a. $Cu_s(A) - O + A \xrightarrow{slow} Cu_s(A_2) - O$ $\quad k_2$

4a. $Cu_s(A_2) - O + H_2O \xrightarrow{fast} Cu(A)_2^{++} + 2\,OH^-$

3b. $Cu_s(A) - O + AH^+ \xrightarrow{slow}$ $\quad k_3$



4b.



$\xrightarrow{fast} Cu(A)_2^{++} + OH^-$

† Temperature: 25° ± 0.1°C; oxygen partial pressure: 8.2 atm; ionic strength adjusted with $NaClO_4$.

* No explanation has been found for these anomalously high rates.

Table III. Rate constants determined in this work

Amine	k_1*	k_2*	k_3*
Ammonia	4.7	80	2450
Methylamine	1.9	21	140
Ethylamine	2.3	20	90
n-Butylamine	1.9	23	90

* The units are: for k_1 liters per mole, and for k_2 and k_3 mg Cu^{++} cm^{-2} hr^{-1} $mole^{-1}$ liter. While the limits of error could not be determined accurately, it is felt that these values are correct to within about 5% for k_1 and k_2 and about 10% for k_3.

In the above, k_1 is an equilibrium constant, while k_2 and k_3 are the rate constants.

Since, under the conditions of the experiments, variation of the oxygen pressure makes no difference to the reaction rate, it can be assumed that the equilibrium in Step 1 is shifted very far to the right, so that the surface is completely covered with a layer of adsorbed oxygen atoms. It should be pointed out that there is no direct evidence to suggest that the oxygen adsorption precedes the amine adsorption. However, since the order of the first two steps is not at present important, the above arrangement is taken as satisfactory.

The values given in Table III for the rate constants show a marked reduction in reaction rate on going from ammonia to the amines. However, only k_3 shows any significant change as the length of the carbon chain is increased, and even here the change is not evident beyond ethylamine.

The results of the experiments done at constant total amine concentration, seen in Fig.4, in addition to confirming the nature of Eq. [3], may give some insight into the mechanism of passivation of copper in neutral or acid amine solutions. It appears that, as the concentration of free amine decreases, the position of the pre-equilibrium (Step 2) is moved far to the left, and the number of active sites is greatly reduced. Thus the reaction step (3a or 3b), involving either the free amine or its conjugate acid, is able to proceed only at a very slow rate.

The fact that the rates in nearly neutral solutions are much less than are expected from Eq. [3] (solid line in Fig. 4) cannot be accounted for on the basis of erroneous values for the rate constants. It seems possible that the surface may be closed by the adsorption of some inert species, or perhaps by the formation of an electrical double layer involving the aminium ion. Such a mechanism has been proposed (7) to explain the effect of chloride ion on the rate of dissolution of copper in acid chloride solutions.

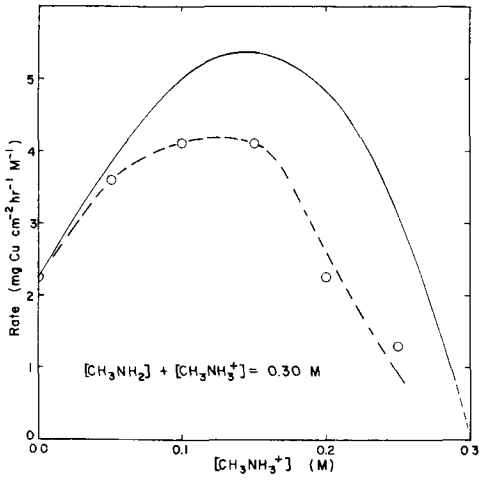

Fig. 4. Rate of copper dissolution in aqueous methylamine solutions as a function of the acidity, at constant concentration of total amine. Solid line calculated from Eq. [3], using the values given in Table III for the constants.

The Attack of Copper-Gold, Silver-Gold, Nickel-Copper, and Silver-Copper Alloys by Sulfur at Elevated Temperatures

Barry D. Lichter[1] and Carl Wagner[2]

Department of Metallurgy, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

Copper-gold alloys involving 10 and 33 mole % Au and Ag-Au alloys involving 12 mole % Au are attacked by liquid or gaseous sulfur above 400°C very rapidly with formation of a composite scale consisting of an outer homogeneous sulfide layer and an inner two-phase layer involving Au-rich alloy and sulfide in accord with theoretical considerations regarding the instability of a plane alloy-sulfide interface. The tendency to form a rugged alloy-sulfide interface decreases with higher Au contents especially at lower temperatures and the rate of attack by sulfur decreases accordingly. Silver-copper alloys involving 40 mole % Cu are also rapidly sulfidized at 400°C and yield a single sulfide layer of uniform thickness. Nickel-copper alloys sulfidized at 400°C yield a scale consisting of an outer layer which is supposedly digenite $Cu_{1.8}S$, and an inner layer which is supposedly a solid solution of Cu_2S in nickel sulfide.

In two previous papers (1,2), diffusion processes during the oxidation of alloys involving noble metals have been considered. In particular, a theoretical analysis of the interplay of diffusion processes in the alloy and the scale shows that a plane alloy-oxide interface is not stable if only one component of a binary alloy is oxidized and diffusion in the alloy is slow in comparison to diffusion in the oxide of the less noble metal (2). Thus a highly rugged alloy-oxide interface may be formed as has been found by various authors cited previously (2). To supplement available observations, the attack of Cu-Au and Ag-Au alloys by sulfur has been investigated. The experimental methods were weight gain measurements and microscopical examination of sectioned samples, supplemented by chemical analysis of detached scales and x-ray investigations. In addition, observations are presented on the attack of Ni-Cu and Ag-Cu alloys by sulfur involving sulfidization of both alloy constituents.

Copper-gold and Ag-Au alloys were chosen because the self-diffusion coefficients of silver and copper in their sulfides stable above 300°C are as high as 10^{-6} to 10^{-5} cm²/sec (3-6), whereas the interdiffusion coefficients in solid solutions Cu-Au and Ag-Au are much lower, e.g., 10^{-12} to 10^{-11} cm²/sec at 500°C (7-12). Moreover, the solubility of sulfur in silver and copper is very low (13). In particular, the solubility of S in Cu (coexisting with Cu_2S) at 600°C has been found to be as low as 10^{-3} a/o (atomic percent) (14). Thus internal sulfidization is not likely to interfere. While this investigation was conducted, however, it was found in accord with previous observations by Maclaurin (15) that solid Ag_2S-Au_2S solutions are formed and thereby certain complications not anticipated in the theoretical analysis (2) do occur. According to Maclaurin (15), Cu_2S also dissolves Au_2S but to a minor extent.

Figure 1 shows schematically a cross section through the scale which one may expect when Cu-Au alloys react with sulfur vapor of atmospheric pressure at 500°C. Under these conditions, only cubic Cu_xS ($1.7 \leqq x \leqq 2$) is formed supposedly, whereas at lower temperatures several sulfide phases may be formed as discussed below. In addition to an outer layer consisting of cuprous sulfide, Fig. 1 shows an inner two-phase layer consisting of penetrating sulfide zones interspersed with metallic trunks rich in gold.

As a limiting case, one may assume that copper diffuses in the metallic trunks only in a direction parallel to the original surface of the alloy, no plastic flow of the metallic trunks takes place, and thus the local gold concentration in the two-phase scale is equal to the initial gold concentration of the alloy.

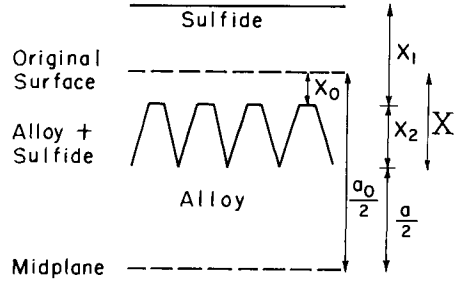

Fig. 1. Schematic section across a Cu-Au sample sulfidized at 500°C with a homogeneous layer of Cu_2S and a two-phase layer consisting of Cu_2S I and gold-rich alloy. (x_0 distance between outer boundary of the two-phase layer and initial surface, x_1 thickness of outer sulfide layer, x_2 thickness of two-phase layer, X distance between alloy-scale boundary and initial surface, a_0 initial thickness of the sample, a thickness of the unattacked core of the sample).

[1] Present address: Air Force Cambridge Research Center, Bedford, Massachusetts.

[2] Present address: Max-Planck-Institut für physikalische Chemie, Göttingen, Germany.

In this case, the outer boundary of the two-phase scale coincides with the original surface, i.e., $x_o = 0$.

In the sulfide phase, copper ions and electrons are supposed to diffuse outward, and plastic flow of the sulfide is supposed to take place so that the transition of copper from the metallic to the sulfide phase does not result in the formation of excessive voids.

Under these conditions, Cu-Au and Ag-Au alloys involving up to about 50 mole % Au are expected to be sulfidized at nearly the same rate as pure Cu and Ag with diffusion in the sulfide phase as rate-determining step.

The actual situation may deviate from the above limiting case in several respects.

1. Since metal ions and electrons move outward and plastic flow of the sulfide is limited, voids at the alloy-sulfide boundary may be formed in accord with observation by Czerski and Patzau (16), Billy and Valensi (17), Moore (18), and Rickert (19) on the sulfidization of pure Cu and Ag. In such voids, sulfur vapor originating from the dissociation of sulfide may diffuse and form sulfide farther inward whereby voids are filled at least in part.

2. Plastic flow of metallic trunks rich in gold may occur. Accordingly, the outer boundary of the two-phase scale is displaced by a distance x_o from the original surface as is shown in Fig. 1.

3. Side-branching of the penetrating sulfide zones may occur and produce a sponge-like network of gold-rich alloy.

4. In the case of excessive side-branching, individual gold-rich alloy particles in a sulfide matrix may be formed and move inward in the same fashion as inert markers move inward when a metal is oxidized and cations rather than anions migrate in the oxide. This also results in a displacement of the outer boundary between one-phase and two-phase scale toward the bulk alloy, i.e., $x_o > 0$.

5. Even under conditions where a plane alloy-sulfide interface is not stable, a nearly plane alloy-sulfide interface may occur on most of the alloy, but there may be pronounced local attack, especially along grain boundaries. Accordingly, the sulfur take-up of the sample is small, but the maximum depth of sulfide penetration may be high.

6. In the case of gold-rich alloys a plane alloy-sulfide interface, although theoretically not stable, may prevail without significant irregularities as, e.g., presumably in the case of the oxidation of Pt-rich Ni-Pt alloys (1,2). Under these conditions, diffusion of the less noble component of the alloy toward the alloy-sulfide interface becomes the rate-determining step.

7. In addition to diffusion, transfer of cations from the alloy to the sulfide may be an important rate-determining step according to recent observations by Rickert (19) on the sulfidization of pure Ag and Cu.

The experimental results reported below show that the systems investigated in this research exhibit considerable deviations from the limiting case conceived for theoretical calculations (2). In view of the complexities which have been found, results have qualitative rather than quantitative significance. No particular efforts have been made to obtain precise weight gain data because at the present stage the structure of the scale and the order of magnitude of reaction rates seem of primary interest. The discussion of the most characteristic features is stressed. Observations of seemingly minor importance are mentioned briefly but are not discussed at length.

Experimental

Materials

Copper.—Commercial Cu (99.94%) was available as 0.2 cm sheet. In addition, high-purity Cu (99.-999%) in rod form was rolled to 0.2 and 0.3 cm sheet.

Silver.—Ag shot (99.95%) was melted under nitrogen and sucked into 7 mm Vycor tubes whereby rods were obtained which were rolled to 0.2 and 0.3 cm sheet.

Nickel.—Commercial Ni (99.5% Ni, 0.32% Co, 0.15% Fe, less than 0.02% Pb) was obtained in the form of 0.1 cm sheet.

Copper-gold and silver-gold alloys.—Cu-Au alloys with mole fractions of gold $N_{Au} = 0.10$, 0.33, 0.61, and 0.74 and Ag-Au alloys ($N_{Au} = 0.12$, 0.35, and 0.56) were obtained from Baker & Co., Newark, New Jersey, where cast alloys were rolled to a thickness of 0.24 cm, annealed in nitrogen at 700°C for 15 min, quenched in water, and cross-rolled to a final thickness of 0.2 cm. These alloys are designated "as received" below. Microscopic examination of etched surfaces revealed the presence of effects of cold work and coring. To eliminate inhomogeneities and promote grain growth, samples of all alloys were annealed in a nitrogen atmosphere saturated with methanol for 100 hr approximately 100°C below the respective liquidus temperatures. The annealing time was sufficient to remove indications of a cored structure. These alloys are designated "annealed" below.

Nickel-copper alloys.—Ni-Cu alloys were prepared by J. D. Harrison. Reagent grade Cu and Ni were melted separately under hydrogen in order to remove oxygen. Alloys were prepared by vacuum melting in an induction furnace, admitting helium, and sucking samples into 9 mm Vycor tubes. The alloys contained 10, 29, and 58 atomic % Cu. Cast rods were rolled to 0.1 cm sheet.

Silver-copper alloys.—An alloy of eutectic composition ($N_{Ag} = 0.60$, $N_{Cu} = 0.40$) was prepared by melting high-purity Ag and Cu under nitrogen, sucking samples into 7 mm Vycor tubes whereby rods were obtained which were rolled to 0.3 cm sheet.

Sulfur.—U. S. P. sulfur powder was used without further purification.

Preparation of Samples

Samples were cut from the prepared sheet with a jeweller's saw, and a small hole was drilled at one end of each sample. The dimensions of samples were as follows: copper and silver, 0.5 x 1.0 x 0.2 or 0.3 cm; copper-gold and silver-gold, 0.5 x 1.0 x 0.2 cm; nickel and nickel-copper, 0.7 x 1.0 x 0.1 cm; silver-copper, 0.9 x 1.5 x 0.3 cm. The cut edges were abraided on emery paper to remove saw marks, and the large surfaces were further polished on emery

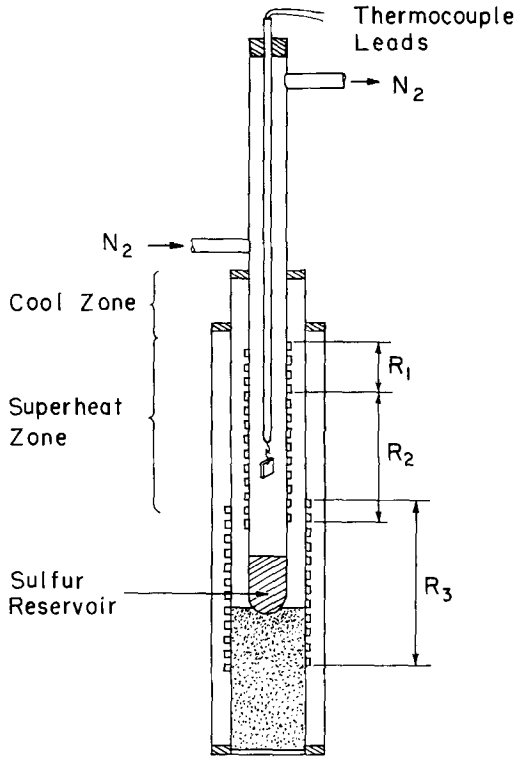

Fig. 2. Set-up for sulfidization in superheated sulfur vapor (500°-700°C) and in liquid sulfur (300°-400°C).

paper to 3/0 grade. Samples were washed with soap and water and rinsed in acetone or methanol. After surface preparation, samples were weighed immediately and inserted in the furnace.

Sulfidization Procedure

Reactions were studied (*a*) in sulfur vapor of atmospheric pressure (700°, 600°, and 500°C) and (*b*) in liquid sulfur (400° and 300°C). Figure 2 shows the set-up designed especially for tests in sulfur vapor. Power is supplied in three stages. The upper two stages ($R_1 = 8$ ohms, $R_2 = 15$ ohms) consisting of a single ribbon winding (1/16 in., "Chromel A", B and S number 28) cemented directly to the inner 25 mm Vycor tube with a common central lead were used to superheat sulfur vapor. The third stage ($R_3 = 5$ ohms) consisting of a ribbon winding ⅛ in., "Chromel A", B and S number 24) cemented to a 38 mm Vycor tube concentric with the inner tube was used to boil sulfur in the lower reservoir. A third concentric Pyrex tube was used as "storm window." Power was supplied from a constant voltage transformer and controlled by means of three variacs connected with the heating resistances R_1, R_2, and R_3. The maximum temperature which could be reached in the superheat zone was 725°C with a total electrical power imput of 1 kw. Temperature fluctuations were about ±5°C.

With the help of this design, it was possible to overcome initial difficulties which were encountered with a conventional two-stage furnace consisting of a ceramic tube surrounded by a thick packing of magnesia. When the conventional furnace was used, sulfur condensed at the upper end of the furnace and ran downward in a rather irregular manner because of the high peak of the viscosity of sulfur at 187°C (20). Applying sufficient power to the upper stage R_1 of the set-up shown in Fig. 2, liquid sulfur flowing downward was vaporized before it reached the superheat zone R_2 used for the sulfidization experiments. Boiling and recycling of sulfur and the location of the sample could be observed readily with this design.

To react samples with liquid sulfur, power was supplied only to the reservoir heated by R_3.

Samples were supported in the furnace by quartz hooks suspended on the sealed end of a Vycor tube which accommodated a thermocouple.

The samples and supporting hooks were weighed separately with a precision of 0.1 mg. At the completion of a run the Vycor tube was removed quickly from the furnace, and the sample was allowed to cool in air before weighing. For runs at 400° and 300°C, molten sulfur occasionally remained on the surface of the samples after withdrawal. The sulfur immediately ignited on contact with air and required from 5 to 10 sec for complete combustion. For most runs the weight gain was recorded as the difference in weight between the sample plus hook before and after reaction. Whenever it was possible to separate sample and hook, the weight gain was recorded as the difference in weight between the sample alone before and after reaction.

Evaluation of Weight Gain Measurements

To obtain results which are independent of the geometry of the samples and determined only by thermodynamic variables, it is necessary to conduct scaling experiments with sufficiently large samples so that the lateral dimensions are much greater than the thickness of the scale. If this condition is not satisfied, edge effects do occur, since the outer area of the sample increases and the area of the boundary between scale and metal decreases during the scaling process. Moreover, in view of local stresses, cracks within the scale and local detachment of the scale from the metallic core may occur as has been found especially in investigations on the oxidation and the sulfidization of iron (21-26).

Because of the high price of gold and the high reaction rates, it was not possible to use samples of sufficient size in order to prevent edge effects. Therefore, a definite rate law cannot be expected and, accordingly, no rate constants are reported. To represent results graphically, however, it was found expedient to plot weight gains per unit nominal area vs. the square root of time. In the calculation of the nominal area, only the large faces of the samples, approximately 0.5 x 1.0 cm, were taken into account; the smaller faces with a width of 0.1 or 0.2 cm were disregarded. Plots of this kind may in general be approximated by straight lines except when the reaction goes to completion.

Metallography

After reaction with sulfur, samples were cast in methylmetacrylate plastic. Powdered polymer was mixed with an equal volume of liquid monomer.[3] Hardening of the plastic occurs at room temperature without application of heat or pressure.

[3] Both supplied under the name "Casto-Mold" by Cosmos Products Inc., New York, N. Y.

Mounted samples were ground on a wet abrasive belt to approximately the center section. Next, samples were abraded lightly on wet silicon-carbide paper. Final polishing was performed on a "gamal" cloth wheel, using levigated gamma-alumina fine abrasive. A few samples were machine polished on lead laps, a standard procedure for preparing mineral specimens. These samples produced scale structures identical with those of manually prepared samples which indicated that the latter were representative. Samples were generally observed unetched except when it was desirable to observe the relation between the structure of the unattacked core and the structure of the scale. Unreacted samples were prepared similarly but were polished on broadcloth wheels with a coarse alumina abrasive before final polishing with "gamal" cloth. For grain size determinations a number of etchants were used. For "annealed" alloys, standard solutions of 10% KCN-2% KI and 5% $(NH_4)_2S_2O_8$ were applied separately with an eyedropper. The strength of the mixture was altered by dilution according to the gold content of the alloy. A 3% iodine solution in methanol, used (27) in studies with Cu_3Au (N_{Au} = 0.25), was found profitable only with a Cu-Au alloy with N_{Au} = 0.33. For as-received samples, the 10% KCN-2% KI and the 5% $(NH_4)_2S_2O_8$ etchant were used. Slightly better structures could be obtained with the help of staining etchants containing $FeCl_3$ or $K_2Cr_2O_7$. The latter revealed concentration gradients in as-received alloys.

Sulfidization of Cu-Au Alloys

Pure copper.—Weight gain curves of Cu samples reacted with sulfur at 300°, 400°, and 500°C are shown in Fig. 3. In view of the high rate of the reaction at 500°C, superheating of the samples may have occurred. Thus values for 500°C are only indicative for a very rapid reaction.

At 300° and 400°C, there may be formed three reaction products, (*a*) hexagonal chalcocite, Cu_2S II, with a variable deficit of copper, (*b*) face-centered cubic digenite with the approximate formula $Cu_{1.8}S$, and (*c*) hexagonal covellite, CuS (28-33).

At 500°C, CuS is unstable as its dissociation pressure exceeds 1 atm (34-36). Moreover, according to Hirohara (5), hexagonal Cu_2S II is unstable above 470°C. Instead, a face-centered cubic modification, Cu_2S I, is found. Its lattice is identical with that of digenite (5, 28, 29, 33). Tentatively, it may be assumed that the homogeneity of the phase Cu_2S I at 500°C extends from a Cu/S ratio of 2.0 to about 1.8. Thus face-centered cubic Cu_2S I is supposedly the only reaction product at 500°C.

Sectioned and polished samples which were sulfidized in part contained only gray sulfide. A thin outer blue layer of CuS becomes visible on samples sulfidized at 400°C only after much longer sulfidization, e.g., 24 hr. The gray sulfide may actually consist of two separate layers corresponding to hexagonal Cu_2S and digenite $Cu_{1.8}S$, or the respective transformation products formed on cooling. So far, however, no experimental evidence of Cu_2S II and digenite as separate reaction products has been obtained.

In accord with observations by Czerski and Patzau (16) and Rickert (19) sections of Cu samples sulfidized at 400°C showed numerous voids in the scale next to the metal whereas no voids were found in the outer scale. The porosity of the inner scale may be due to local detachment of the scale similar to that reported for the oxidation and sulfidization of iron (21-26).

Cu-Au *alloys.*—Weight gain plots for Cu-Au alloys involving 10 and 33 mole % Au are shown in Fig. 4 and 5.

Copper-gold alloys involving 10 mole % Au were sulfidized at about the same rate as pure copper as follows by comparing weight gain curves in Fig. 3 and 4. Microscopical examination of sectioned samples revealed an outer homogeneous sulfide layer and an inner two-phase layer consisting of sulfide

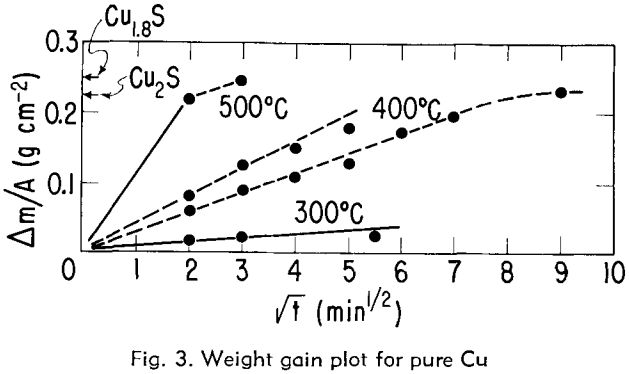

Fig. 3. Weight gain plot for pure Cu

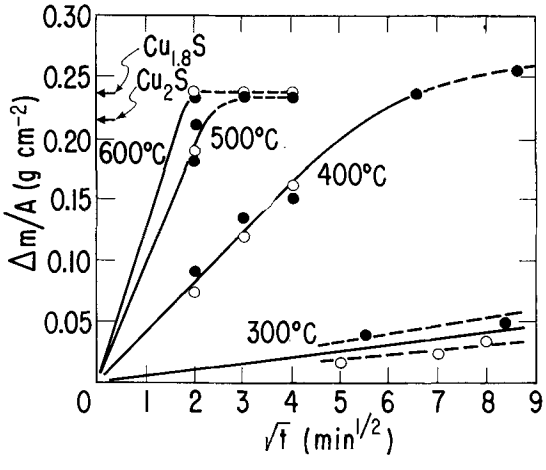

Fig. 4. Weight gain plot for Cu-Au alloy, N_{Au} = 0.10. ○ Annealed; • as-received.

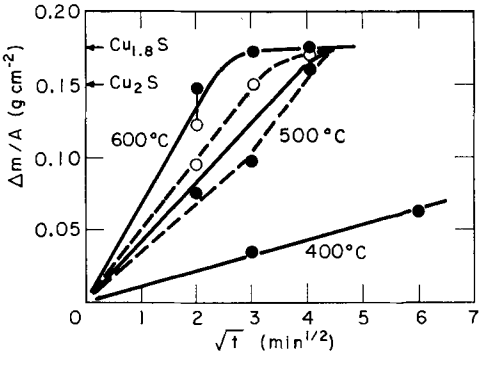

Fig. 5. Weight gain plot for Cu-Au alloy, N_{Au} = 0.33. ○ Annealed; • as-received.

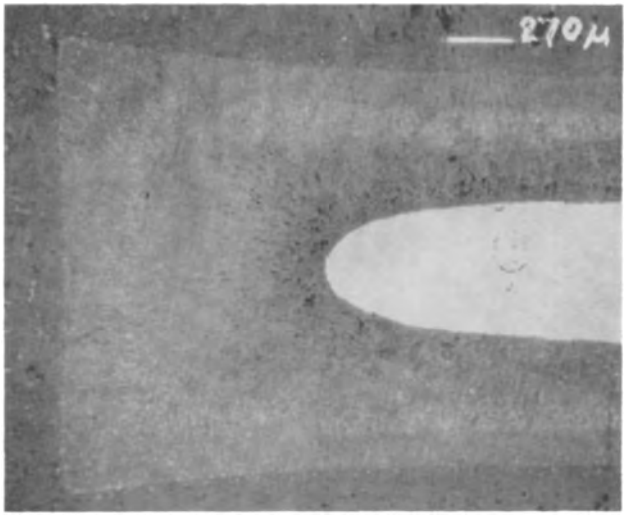

Fig. 6. Section of Cu-Au alloy (N_{Au} = 0.10, annealed) sulfidized at 500°C for 4 min. White region on the right-hand side is unattacked alloy, which is surrounded by a two-phase layer and an outer homogeneous sulfide layer shown only in part. Black spots in the two-phase layer are due to porosity. The width of the two-phase layer at the left-hand side is nearly equal to the original thickness. In the middle of the sample shown at the right-hand side, the two-phase layer has contracted.

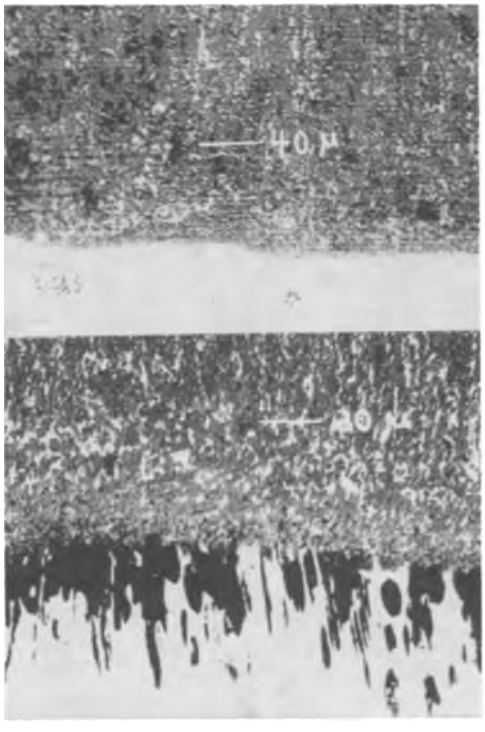

Fig. 7. Details of alloy-scale boundary of Cu-Au alloys (N_{Au} = 0.10) sulfidized at 500°C for 4 min. (a) (top) Annealed sample; (b) (bottom) as-received sample.

and metal. Figures 6 and 7a show that the boundaries between the various layers on annealed samples were remarkably well defined. In contrast, "as received" samples showed pronounced local sulfide penetrations presumably associated with copper-rich regions of the alloy, see Fig. 7b. Even in the outer scale, especially at the outer surface, gold particles were observed. Probably, these gold particles were formed when samples were cooled and solid Cu_2S-Au_2S solid solutions present at elevated temperatures decomposed. This interpretation is supported especially by the observation that the amount of gold in the outer scale increased when samples were stored at room temperature for a longer time.

Table I. Scale measurements for annealed Cu-Au alloys

N_{Au}	Temp, °C	t, min	x_1, mm	x_2, mm	X, mm	x_0, mm
0.10	500	4	1.1	0.6	0.7	0.1
	400	4	0.38	0.18	0.23	0.05
		9	0.60	0.32	0.39	0.07
		16	0.75	0.48	0.54	0.06
	300	25	0.08	0.07	0.07	—
		49	0.10	0.06	0.06	—
		64	0.10	0.06	0.06	—
0.33	500	4	0.3	0.35	0.35	—
		9	0.6	0.5	0.6	0.1
		16	0.65	0.9	1.0	0.1

Scale measurements for annealed alloys are presented in Table I. The thicknesses of the outer one-phase layer and the inner two-phase layer, x_1 and x_2, respectively, were measured approximately at the middle of the large faces of the sample with the help of a movable stage micrometer. In addition, the width a of the unattacked alloy was determined. By subtracting half the thickness of the unattacked alloy from half the initial thickness of the sample $a_o/2$, the distance X between the original surface and the boundary between the scale and the unattacked alloy was obtained, $X = a_o/2 - a/2$, see Fig. 1. Finally, the distance x_o between the original surface and the boundary between the outer one-phase and the inner two-phase scale was calculated as $x_o = X - x_2$. Finite values of x_o indicate either dissolution of gold in the sulfide, or a displacement of gold-rich alloy toward the middle of the sample either by plastic flow of the metallic trunks, or by inward movement of isolated gold-rich particles as has been mentioned above. From the values listed in Table I, one recognizes that the displacement x_o does not exceed 20% of the distance X to which the attack has penetrated.

Copper-gold alloys involving 33 mole % Au were sulfidized more slowly according to weight gain curves shown in Fig. 5. Microscopical examination of sectioned samples sulfidized at 400°, 500°, and 600°C revealed the same general type of scaling as that shown in Fig. 6, but with a rather abrupt change in the width of the single-phase regions in the two-phase scale. The width in the inner part of the two-phase region was much smaller than in the outer part. Scale measurements are listed in Table I.

Copper-gold alloys involving higher gold contents (N_{Au} = 0.61 and 0.74) were sulfidized at much lower rates. Even at 700°C, only minor weight gains were obtained, e.g., $\Delta m/A = 0.002$ g/cm² for $N_{Au} = 0.61$ after 16 min and for $N_{Au} = 0.74$ after 64 min.

Microscopical examination of sectioned samples which had been reacted at 700°C revealed the absence of a typical two-phase scale described above for alloys involving lower gold contents. Instead, there was found a thin uniform sulfide layer containing small amounts of Au which presumably was formed by decomposition of Cu_2S—Au_2S solid solutions present at elevated temperatures. For samples

involving 61 a/o Au, isolated patches of a two-phase scale were observed between the outer sulfide and the inner unattacked core. Comparison of the alloy grain size with the width of the single-phase constituent in the two-phase patches, together with observations at the scale-alloy boundary, suggest that a considerable amount of grain boundary attack is responsible for the appearance of the patches. No patches were observed for alloys involving 74 a/o gold. However, occasional penetration along grain boundaries was observed. At lower temperatures (600° and 500°C) only a uniform sulfide layer was observed.

Additional Observations on the Structure of the Scale.

The occurrence of a sponge-like network of gold-rich alloy within the two-phase scale has been confirmed directly for Cu-Au alloys involving 33 a/o Au. Upon dissolving the sulfide phase in a mixture of equal volumes of HNO_3 and H_2O with a small addition of KNO_2, a sponge-like network of gold-rich alloy could be isolated.

When the two-phase scale from an alloy involving 10 a/o Au was treated in the same way, the details of the structure were lost. This indicates that the two-phase scale of the latter alloy involved islands of gold-rich particles or sponge in a sulfide matrix rather than a coherent network of gold-rich alloy.

The width of the single-phase regions in the two-phase scale of gold-rich alloys ($N_{Au} = 0.10$ and 0.33) was found to depend markedly on temperature. The higher the temperature, the greater was the width. This is due at least in part to coarsening of the disperse structure while the sample was at temperature as follows from microphotographs shown in Fig. 8. Two Cu-Au samples ($N_{Au} = 0.33$) were reacted to completion in sulfur vapor at 500°C. A section of one of these samples is shown in Fig. 8a. A section of the other sample which was heated to 700°C for further 16 min, is shown in Fig. 8b. The width of the single-phase regions in Fig. 8b is considerably greater than that in Fig. 8a and similar to the width in a sample reacted to completion directly at 700°C, see Fig. 8c. This shows that the residual gold-rich alloy in the two-phase layer undergoes considerable structural changes. Au_2S is dissolved in Cu_2S to some extent (15) especially at higher sulfur activities. Thus gold can be transferred between different points of the sulfide-alloy interface involving different curvatures by virtue of local dissolution and redeposition corresponding to a decrease of the area of the gold-sulfide interface and the free energy of the system. In addition, gold atoms may migrate along the gold-sulfide interface.

At all temperatures, the width of the single-phase regions in the two-phase scale was found to be considerably smaller than the grain size of the original alloy. This indicates that transgranular penetrations of sulfide do occur in accord with observations on the attack of solid alloys by liquid metals which dissolve one component of the solid alloy preferentially (37).

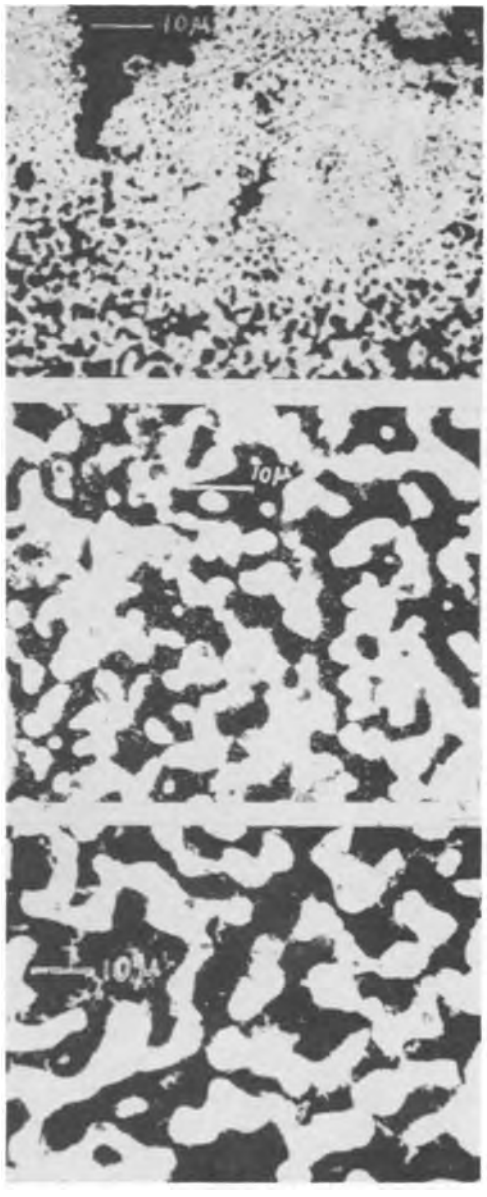

Fig. 8. Structures of two-phase layers obtained on Cu-Au alloys ($N_{Au} = 0.33$, as-received). (a) (top) Sample sulfidized at 500°C for 16 min; (b) (center) sample sulfidized at 500°C for 20 min and annealed in sulfur vapor at 700°C for 16 min; (c) (bottom) sample sulfidized at 700°C for 4 min.

Auxiliary Investigations

Chemical analysis of Cu samples completely sulfidized at temperatures ranging from 400° to 725°C yielded Cu/S atom ratios of 1.77 to 1.84 in accord with weight gain measurements. Somewhat higher Cu/S atom ratios, 1.86 to 1.89, were found in the scale detached from Cu samples which were incompletely sulfidized at 300° to 500°C. Ratios of 1.77 to 1.84 are characteristic of digenite (presumably identical with Cu_9S I) coexisting with sulfur vapor of atmospheric pressure above 500°C, or CuS below 500°C. The same Cu/S ratios were found in the scale detached from sulfidized Cu-Au alloys ($N_{Au} = 0.10$ and 0.33).

The composition of metallic particles in the two-phase scale formed on partially sulfidized Cu-rich alloys ($N_{Au} = 0.10$ and 0.33) was determined by x-ray diffraction investigations. Samples were sectioned parallel to the alloy-scale interface at several

positions in the two-phase scale. The diffraction patterns from the exposed surfaces, obtained with filtered copper radiation on a Norelco diffractometer, showed the spectra of pure gold to within $2\theta = \pm 0.2°$ where θ is the Bragg angle for Cu Kα reflections in the angular region $90° > 2\theta > 35°$. Even at that position in the two-phase scale practically adjacent to the interface between scale and remaining core of the copper-rich alloys, the spectra for virtually pure Au were observed.

Discussion

According to weight gain plots shown in Fig. 4 and 5 the rate of sulfidization of Cu-rich alloys is about the same for as-received samples and annealed samples, but there is a slight tendency for as-received samples to be sulfidized somewhat more rapidly than annealed samples as is indicated especially by results obtained for $N_{Au} = 0.10$ at 300°C shown in Fig. 4. Scale measurements are in accord herewith. In essence, however, the presence of inhomogeneities in as-received samples does not lead to a different type of attack but only modifies some characteristics of the attack found with annealed samples.

Upon extrapolating weight gain data and scale measurements for Cu-rich alloys ($N_{Au} = 0.10$ and 0.33), it follows that the final weight of a sample is reached after about the same time at which the core of unattacked alloy has disappeared. Hence most of the copper originally present in the two-phase layer is converted readily into sulfide, and accordingly the trunks of the remaining alloy consist mostly of gold. This has been confirmed by x-ray diffraction investigations reported above.

In accord with previous theoretical calculations (2), Cu and Cu-Au alloys containing 10 and 33 mole % Cu react very fast. With increasing concentration of Au, the rate of sulfidization of alloys containing up to 33 a/o Au decreases, although not considerably. To make a comparison without using a rate law explicitly, one may compare the times required for penetration of sulfide to a given depth X. For 500°C and $X = 0.05$ cm, one has $t \sim 3$ min if $N_{Au} = 0.10$ and $t \sim 5$ min if $N_{Au} = 0.33$. For 400°C and $X = 0.02$ cm, one has $t \sim 4$ min if $N_{Au} = 0.10$ and $t \sim 12$ min if $N_{Au} = 0.33$.

Gold-rich alloys ($N_{Au} = 0.61$ and 0.74) are sulfidized much more slowly than Cu-rich alloys. This is consistent with the absence of a typical two-phase scale. Thus one has a transition to the other limiting case involving a plane alloy-sulfide interface. Since diffusion in the sulfide phase is much faster than in the alloy, the activity of the sulfur at the alloy-sulfide interface is equal to that at the sulfide surface, the Cu concentration at the sulfide-alloy interface is virtually equal to zero, and diffusion of Cu toward the alloy-sulfide interface is the rate-determining step. According to Eqs. [16] to [20] of a previous, more general calculation (1) the distance x_i between the alloy-sulfide interface and the initial surface of the alloy is

$$x_i = 2u(D't)^{1/2} \qquad [1]$$

where D' is the interdiffusion coefficient of the alloy and the parameter u is determined by

$$\pi^{1/2} e^{u^2} \operatorname{erfc} u = 1 - N_{Au}^{(o)} \qquad [2]$$

The number of moles of metal contained in an alloy layer of thickness x_i *is* x_i/V' where V' is the molar volume of the alloy. Assuming the formula $Cu_{1.8}S$ as representative for the composition of the scale, sulfidization of 1 mole Cu corresponds to a weight increase of $M_S/1.8$ where $M_S = 32$ is the atomic weight of sulfur. Hence the weight increase $\Delta m/A$ per unit area is

$$\Delta m/A = x_i M_S/1.8\,V' = 2uM_S(D't)^{1/2}/1.8\,V' \qquad [3]$$

Equation [3] is evaluated for 500°C and $t = 1$ hr $= 3600$ sec with $D' = 2 \times 10^{-11}$ cm²/sec according to Jost (10), and values are compared with interpolated or extrapolated experimental values,

N_{Au}	0.33	0.61	0.74	
$\Delta m/A$ (calc.)	0.70	0.28	0.16	mg/cm²
$\Delta m/A$ (obs.)	300	2.4	1.2	mg/cm²

The experimental values $\Delta m/A$ are higher than the calculated values inasmuch as the alloy-sulfide interface was not plane under the conditions used in the present investigation. For Cu-rich alloys, the observed attack is especially high as compared to the calculated value. This illustrates the general conclusion that the instability of a plane interface may have a very large effect on the corrosion characteristics of an alloy. On the other hand, for Au-rich Cu-Au alloys for which a well-defined two-phase layer is not found and irregularities of the alloy-sulfide interface are not spectacular, the observed magnitude of attack is comparable to that calculated for a plane alloy-sulfide interface rather than to that of pure Cu or Cu-rich Cu-Au alloys.

Sulfidization of Ag-Au Alloys

Pure silver.—The reaction between pure Ag and sulfur is known to proceed very rapidly above 180°C because of easy migration of both cations and electrons in Ag_2S formed as reaction product above 180°C (38-40). In accord herewith, the time required for complete conversion of 2 mm Ag platelets into Ag_2S was found to be less than 4 min at 400° and 500°C. According to Czerski, Mrovec, Wallisch, and Werber (40) the rate is determined by a phase boundary reaction when the thickness of the Ag_2S layer is less than 0.1 cm, whereas diffusion control prevails with Ag_2S layers which are several centimeters thick according to Rickert (19).

Ag-Au *alloys.*—Weight gain curves for Ag-Au alloys involving 12 mole % Au are shown in Fig. 9. The sulfidization rate is remarkably high, although somewhat lower than for pure Ag. The total weight gain exceeds that for formation of Ag_2S alone and corresponds to the formation of a solid Ag_2S-Au_2S solution in accord with previous observations by Maclaurin (15). Microscopical examination of sectioned samples sulfidized at 400° and 500°C revealed an outer homogeneous sulfide layer and inner two-phase layer consisting of sulfide and Au-rich alloy, see Fig. 10. Scale measurements are shown in Table II. Samples sulfidized at 300°C showed only a homogeneous sulfide layer.

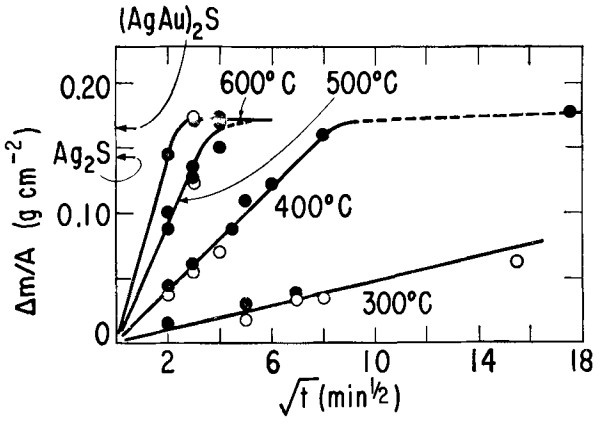

Fig. 9. Weight gain plot for Ag-Au alloy, $N_{Au} = 0.12$. ○ Annealed; • as-received.

Upon comparing microphotographs of sections of the scale in Fig. 10 and the original alloy in Fig. 11, it is clearly seen that the width of the single-phase regions in the two-phase scale is much smaller than the grain size in the original alloy. This illustrates the occurrence of transgranular attack.

According to Fig. 9, weight gain data for annealed alloys agree fairly well with data for as-received alloys. Sections of as-received samples showed a less well-defined boundary between two-phase scale and unattacked alloy, but the observed irregularities were much smaller than in the case of Cu-Au alloys shown in Fig. 7b.

Ag-Au alloys involving 35 mole % Au were found to react much more slowly. Weight gain curves are shown in Fig. 12.

Sectioned samples sulfidized at 700°, 600° and 500°C revealed considerable attack at grain boundaries together with transgranular attack. The resultant scale structure differs from that shown schematically in Fig. 1. Values of x_2 reported in Table II represent the average depth of penetration along grain boundaries. A thin two-phase region resulting from transgranular attack could be observed at the boundary between the outer sulfide scale (containing patches of alloy, presumably due to decomposition of Au_2S-Ag_2S solid solutions) and the core of the alloy. The thin two-phase layer follows the contour of the boundary between the alloy and the outer sulfide. The width of the thin two-phase layer is of the order of $x_2/10$. However, in the vicinity of a grain boundary, considerably more two-phase scale is formed, i.e., attack initiating at grain boundaries spreads into adjacent grains and results in formation of a two-phase scale.

Table II. Scale measurements for annealed Ag-Au alloys

N_{Au}	Temp, °C	t, min	x_1, mm	x_2, mm	X, mm	x_0, mm
0.12	500	9	0.92	0.31	0.65	0.34
	400	4	0.24	0.05	0.14	0.09
		9	0.37	0.06	0.20	0.14
		16	0.51	0.06	0.32	0.26
0.35	600	4	0.22	0.3	0.4	0.12
		16	0.43	0.4	0.6	0.22
	500	4	0.15	0.3	0.4	0.10
		16	0.25	0.4	0.4	0.12

Samples sulfidized at 400°C showed only a homogeneous sulfide layer. In view of the relatively low rate found at 400°C, the activity gradient of sulfur

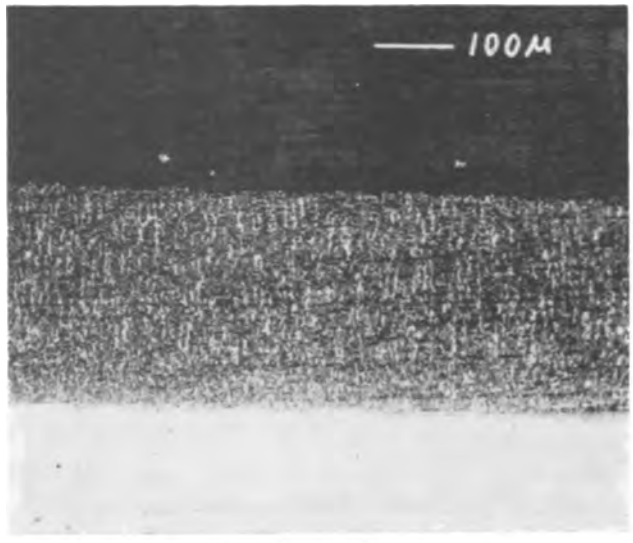

Fig. 10. Section of Ag-Au alloy ($N_{Au} = 0.12$, as-received), sulfidized at 500°C for 9 min with a homogeneous sulfide layer at the top, a two-phase layer in the middle, and unattacked alloy at the bottom.

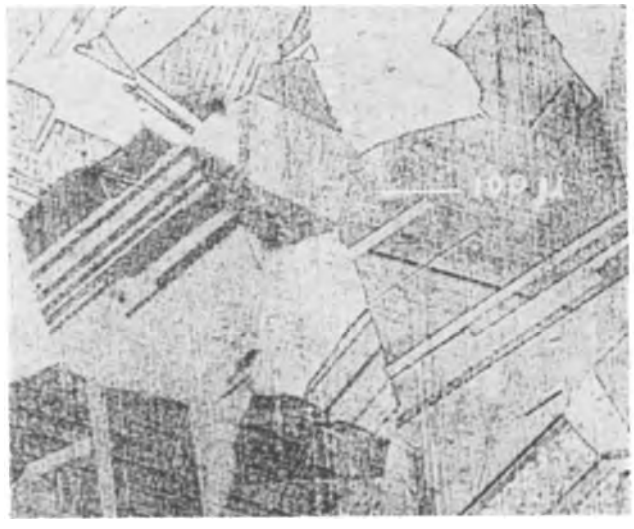

Fig. 11. Section of annealed Ag-Au alloy ($N_{Au} = 0.12$) etched with a mixture of a 10% KCN + 2% KI solution and a 5% $(NH_4)_2S_2O_8$ solution.

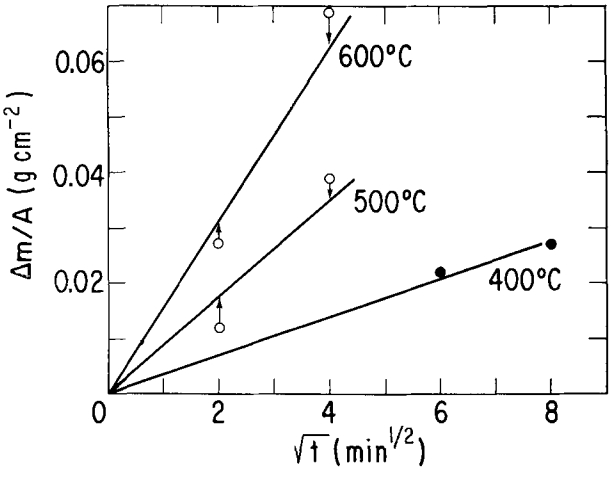

Fig. 12. Weight gain plot for Ag-Au alloy, $N_{Au} = 0.35$. ○ Annealed; • as-received.

in the sulfide must be small. Thus the activity of sulfur at the alloy-sulfide interface is nearly that of pure liquid sulfur, and accordingly a solid Ag_2S-Au_2S solution is formed.

Ag-Au alloys involving 56 a/o Au showed only slight attack. Even at 700°C, $\Delta m/A$ was as low as 0.0015 mg/cm² after 25 min. Microscopical examination of samples sulfidized at 500°, 600°, and 700°C revealed the presence of smooth sulfide layers with plane sulfide-alloy interfaces.

Discussion

In view of the formation of solid Ag_2S-Au_2S solutions (15), the behavior of Ag-Au alloys deviates from the behavior of Cu-Au alloys in several respects.

The structure of the scale may be similar to that found on Cu-rich Cu-Au alloys with an outer homogeneous sulfide layer and an inner two-phase layer consisting of sulfide and Au-rich alloy as shown in Fig. 10 for $N_{Au} = 0.12$. Since the attack is very rapid, there must be a significant gradient of the sulfur activity within the scale. The tendency for dissolution of Au diminishes with decreasing activity of sulfur, i.e., with increasing distance from the outer surface. Therefore, only little Au is dissolved at the boundary between the two-phase scale and unattacked alloy, whereas the outer parts of Au-rich alloy in the two-phase scale are gradually eaten away. Accordingly the outer boundary of the two-phase scale is displaced inward from the initial surface of the sample, i.e., $x_o > 0$, see Table II.

As an alternative, it is conceivable that Ag-rich Ag-Au alloys are sulfidized with formation of a sulfide layer of uniform thickness in which the Ag/Au ratio is virtually equal to that in the alloy. Since, the standard free energy of formation of Ag_2S is considerably more negative than that of Au_2S, the alloy coexisting with a solid solution Ag_2S-Au_2S of given composition has necessarily a much higher Au/Ag ratio than the sulfide phase. Thus there must be a thin zone of Au-rich alloy next to the sulfide phase.

To simplify calculations, it is assumed that the self-diffusion coefficients of Ag^+ and Au^+ ions in the sulfide phase are equal, and accordingly the Au/Ag ratio in the sulfide layer is independent of the distance from the surface. The driving force for outward migration of the cations is essentially a diffusion potential gradient resulting from the electrons which have a high mobility and, therefore, have the tendency to move ahead (41-43). Thus the rational rate constant k_r defined as the rate of metal transport in equivalents per unit area per unit time for unit thickness of the sulfide layer is (42)

$$k_r = (D''/2V_{eq}'') \ln a_S^{\circ}/a_S^{(i)} \qquad [4]$$

where D'' is the self-diffusion coefficient of the cations in the sulfide phase, V_{eq}'' is the volume of one equivalent of sulfide, $1/V_{eq}''$ is the cation concentration in equivalents per unit volume of the sulfide, a_S° is the sulfur activity at the outer surface, and $a_S^{(i)}$ is the sulfur activity at the alloy-sulfide interface.

The rate constant k_{PB} introduced by Pilling and Bedworth (44) is related to k_r as has been shown previously (38),

$$k_{PB} = (\Delta m/A)^2/t = k_r M_S^2/2V_{eq}'' \qquad [5]$$

From Eqs. [4] and [5] it follows that

$$\Delta m/A = (k_{PB}t)^{1/2} = (M_S/2V_{eq}'') [D''t \ln (a_S^{\circ}/a_S^{(i)})]^{1/2} \qquad [6]$$

Tentatively, chemical equilibrium at the alloy-sulfide interface is assumed. In view of the high degree of disorder of the cations in Ag_2S above 180°C (28), the sulfide phase may be supposed to be an ideal solution of $Ag^+ + 0.5\ S^{2-} = AgS_{0.5}$ and $Au^+ + 0.5\ S^{2-} = AuS_{0.5}$ (45). Thus, if the law of mass action is applied to the reactions

$$Ag\ (alloy) + 1/2\ S = AgS_{0.5}\ (sulfide) \qquad [7]$$

$$Au\ (alloy) + 1/2\ S = AuS_{0.5}\ (sulfide) \qquad [8]$$

the activities may be replaced by the respective mole fractions. Hence

$$\frac{1-y}{2_{Ag}^{(i)} [a_S^{(i)}]^{1/2}} = K_1 \qquad [9]$$

$$\frac{y}{a_{Au}^{(i)} [a_S^{(i)}]^{1/2}} = K_2 \qquad [10]$$

where y is the mole fraction of $Au_{0.5}S$, equal to the ratio of the number of Au^+ ions to the sum of the numbers of the cations, $1 - y$ is the mole fraction of $AgS_{0.5}$, $a_{Ag}^{(i)}$ and $a_{Au}^{(i)}$ are the activities of Ag and Au, respectively, which are determined by the composition of the alloy at the interface, and K_1 and K_2 are constants.

Upon subtracting corresponding sides of Eqs. [7] and [8] one has

$$Ag\ (alloy) + AuS_{0.5}\ (sulfide) = Au\ (alloy) + AgS_{0.5}\ (sulfide) \qquad [11]$$

with the equilibrium condition

$$\frac{a_{Au}^{(i)}\ (1-y)}{a_{Ag}^{(i)}\ y} = K_1/K_2 = K_{ex} \qquad [12]$$

where K_{ex} is the equilibrium constant of the exchange reaction in Eq. [11].

The value of K_1 may be calculated from the standard free energy of formation ΔF° for $1/2\ Ag_2S = AgS_{0.5}$ deduced from emf measurements (46). Hence

$$K_1 = \exp(-\Delta F^{\circ}/RT) = 75 \text{ at } 445°C \qquad [13]$$

Formulating Eq. [9] for the three-phase equilibrium alloy + sulfide + sulfur with starred variables and the special values $a_s^* = 1$ and $y^* \cong 0.5$ according to Maclaurin (14), one has

$$a_{Ag}^* = (1 - y^*)/K_1 (a_s^*)^{1/2} = 0.0067 \text{ at } 445°C \qquad [14]$$

corresponding to $N_{Au}^* = 0.95$ as mole fraction of Au in the alloy, according to equations interrelating mole fractions and activities in Ag-Au alloys recommended by White, Orr, and Hultgren (47).

The value of K_{ex} may then be obtained by formulating Eq. [12] for the three-phase equilibrium alloy + sulfide + sulfur,

$$K_{ex} = \frac{a_{Au}^*(1-y^*)}{a_{Ag}^* y^*} = 141 \text{ at } 445°C \quad [15]$$

whereupon in view of Eqs. [12] and [13]

$$K_2 = K_1/K_{ex} = 0.53 \text{ at } 445°C \quad [16]$$

With the help of Eqs. [12] and [15], one may readily calculate y for arbitrarily chosen compositions of the alloy at the interface, using activities according to White, Orr, and Hultgren (47). From a plot y vs. $N_{Au}^{(i)}$ one may read $N_{Au}^{(i)}$ for a given value of y which supposedly equals the bulk mole fraction of Au in the alloy. Finally, one may calculate the value of $a_S^{(i)}$ with the help of Eq. [10]

$$a_S^{(i)} = (y/K_2 a_{Au}^{(i)})^2 \quad [17]$$

For $N_{Au} = 0.35$ in the bulk alloy one has $y = 0.35$ and obtains $N_{Au}^{(i)} = 0.93$ and $a_S^{(i)} = 0.51$ at the alloy-sulfide interface, whereas in a system free of gold according to Eqs. [9] and [13] $a_S^{(i)} = 1.78 \times 10^{-4}$ at 445°C. Hence, in view of Eq. [4], the ratio of the rate constants for a Ag-Au alloy ($N_{Au} = 0.35$) and pure Ag is

$$k_r(N_{Au} = 0.35)/k_r(N_{Au} = 0)$$
$$= \ln 0.51/\ln (1.78 \times 10^{-4}) = 0.077 \quad [18]$$

Extrapolation of data reported by Rickert (19) yields

$$k_r(N_{Au} = 0) = 17 \times 10^{-6} \text{ equiv./cm sec at } 445°C \quad [19]$$

From Eqs. [5], [18], and [19] it follows that

$$\Delta m/A = 0.38 \text{ g/cm}^2$$
$$\text{for } N_{Au} = 0.35,\ t = 3840 \text{ sec at } 445°C \quad [20]$$

which is about 14 times greater than the experimental value obtained at 400°C, $\Delta m/A = 0.027$ g/cm². Since the various values involved in the calculation supposedly depend on temperature only to a minor extent, the divergence between the experimental and the calculated value is an indication that equilibria at the interfaces are not readily established. This is in accord with observations on the sulfidization of pure silver especially at 200° and 300°C (19). Since Ag is sulfidized very rapidly, one may conclude tentatively that the rate of transfer of Au from the alloy to the sulfide phase is the limiting factor.

If the gold content of the alloy exceeds the maximum content of Au_2S in the sulfide phase for a given activity of sulfur, ($N_{Au} > y^*$), it is also possible that a sulfide layer of uniform thickness is formed, but with accumulation of Au in the alloy near the alloy-sulfide interface. Then diffusion in the alloy determines the rate as is shown in what follows.

Fick's second law for diffusion in the alloy reads

$$\partial N_{Au}'/\partial t = D'\partial^2 N_{Au}'/\partial x^2 \text{ at } x > x_i \quad [21]$$

where N_{Au}' is the local mole fraction of gold in the alloy, D' the interdiffusion coefficient of the alloy supposedly independent of composition, x distance from the original surface, x_i distance of the alloy-sulfide interface from the original surface, and t time.

The initial condition is

$$N_{Au}' = N_{Au} \text{ at } x = 0, t = 0 \quad [22]$$

Since $D'' >> D'$, the gradient of the sulfur activity in the sulfide layer is very small, i.e., $a_S^{(i)} \cong a_S^\circ$ and, therefore,

$$y \cong y^* \quad [23]$$

$$N_{Au}'(x = x_i) \cong N_{Au}^* \quad [24]$$

As long as the alloy in the middle of the sample has virtually the original composition, equations for diffusion in a semi-infinite space apply. Thus the displacement of the locus of the alloy-sulfide interface is supposed to be in accord with the parabolic law

$$x_i = 2u(D't)^{1/2} \quad [25]$$

where u is a parameter calculated below.

Equations [21], [22], [24], and [25] are satisfied by

$$N_{Au}' = N_{Au} + [N_{Au}^* - N_{Au}] \frac{\text{erfc}\,[x/2(D't)^{1/2}]}{\text{erfc } u} \quad [26]$$

The molar volume of the alloy is denoted by V' and the surface area of the sample by A. The total number of moles of Ag and Au sulfidized per unit time is $(A/V')\ (dx_i/dt)$. Thus the number of moles of Au entering the sulfide layer per unit time is

$$dn_{Au}'/dt = y^*(A/V')\ (dx_i/dt) \quad [27]$$

According to Eq. [25] the alloy-sulfide interface moves by

$$dx_i = u\,(D'/t)^{1/2}dt \quad [28]$$

within the time dt. The amount of Au in the volume element Adx_i is $N_{Au}^* Adx_i/V'$ and must be equal to the sum of the amount of gold diffusing backward

$$(D'A/V')\ [-(\partial N_{Au}'/\partial x)_{x=x_i}]dt$$

and the amount of gold transferred from the alloy to the sulfide phase within the time dt. Hence, using Eqs. [27] and [28] and regrouping,

$$(N_{Au}^* - y^*)\ u\,(D'/t)^{1/2} = -D'\,(\partial N_{Au}'/\partial x)_{x=x_i} \quad [29]$$

Upon substituting Eqs. [25] and [26] in Eq. [29], it follows that

$$\pi^{1/2} e^{u^2} \text{erfc } u = (N_{Au}^* - N_{Au})/(N_{Au}^* - y^*) \quad [30]$$

whereby the parameter u is determined.

Equation [30] comprises Eq. [2] stated above for Cu-Au alloys with neglect of Au in the sulfide phase. Equation [2] is obtained from Eq. [30] by letting $N_{Au}^* = 1$ and $y^* = 0$.

Sulfidization of 1 mole of Ag (or Au) corresponds to pick-up of 0.5 g-atom of sulfur, with a weight gain of $M_S/2$. The total number n of moles of Ag and Au lost from the alloy is $n = x_i A/V'$. In view of Eq. [25], the weight gain per unit area is found to be

$$\Delta m/A = M_S x_i/2V' = u M_S (D't)^{1/2}/V' \quad [31]$$

Equation [31] involves the diffusion coefficient D' in the alloy, whereas Eq. [6] involves the diffusion

coefficient D'' in the sulfide phase. Since $D' << D''$, one has, therefore, to expect a sharp decrease in the rate of sulfidization when the mole fraction of Au in the alloy exceeds the upper limit of the mole fraction y^* of $AuS_{0.5}$ in the sulfide phase provided that diffusion control prevails.

To evaluate Eq. [31] for $N_{Au} = 0.56$ at 500°, the values $N_{Au}^* = 0.95$ and $y = 0.5$ valid for 445° are used as an approximation. Then Eq. [30] yields $u = 1.6$. Substituting $u = 1.6$, $V' = 10.3$ cm³/mole and $D' = 3.2 \times 10^{-12}$ cm²/sec according to Jost (8), one obtains from Eq. [31]

$$\Delta m/A = 0.6 \times 10^{-3} g/cm^2 \qquad [32]$$

for $N_{Au} = 0.56$ and $t = 3840$ sec at 500°C which is about 3.5 times less than the experimental value, $2.1 \times 10^{-3} g/cm^2$. The divergence between the calculated and the observed value is supposedly due in part to the approximations used in the calculation and in part to the occurrence of minor irregularities of the alloy-sulfide interface.

Sulfidization of Ni-Cu Alloys

At 400°C, Ni-Cu alloys involving 10, 29, and 58 a/o Cu were found to react with sulfur at a rate which is of the same order of magnitude as that for pure Ni, but much more slowly than pure Cu. Weight gain data are shown in Fig. 13. Results obtained with samples involving 58 a/o Cu showed a large scatter.Since local detachment of the scale is suspected as the reason for irregular results, the highest weight gains observed for different samples in runs lasting the same time are reported as representative values. The parabolic rate law is obeyed approximately in contradistinction to the linear rate law reported by Hauffe and Rahmel (48) for the reaction between pure nickel and sulfur vapor at pressures ranging from 10^{-2} to 1 mm Hg and 630°C.

Microscopical examination of sectioned samples revealed the presence of two distinct, essentially homogeneous sulfide layers, see Fig. 14. The alloy-scale interface and the interface between the two sulfide layers were essentially plane. Both sulfide layers, however, showed considerable porosity. According to chemical analysis, the Cu-Ni ratio in the scale was nearly equal to the Cu-Ni ratio in the alloy. The two sulfide layers could not be separated from each other. Therefore, the two layers have not been analyzed separately.

Since the ratio of the thickness of the outer sulfide layer to that of the inner sulfide layer increases with increasing copper content of the alloy, the outer sulfide layer is supposed to be mostly copper sulfide and the inner sulfide layer mostly nickel sulfide.

At 400°C the system Ni-S involves 4 intermediate phases which may be characterized by the approximate formulas Ni_3S_2, Ni_7S_6, NiS, and NiS_2 (13, 49). According to an investigation of the ternary system Cu-Ni-S by Köster and Malfinger (50), the phase Ni_3S_2 dissolves some Cu_2S but probably less than 1 mole % at 400°C.

A tentative schematic representation of the various diffusion processes is shown in Fig. 15 where the occurrence of different sulfides of Ni and Cu is disregarded. Copper and nickel (presumably as ions and electrons) enter the inner sulfide layer I of average composition Ni_yCu_zS and migrate outward. At the interface between the two sulfide layers, most of the arriving nickel ions, some copper ions, and electrons combine with sulfur ions from the outer layer II, Cu_xS, to form Ni_yCu_zS. In the outer Cu_xS layer, copper ions and electrons migrate to the surface and react with sulfur in order to form Cu_xS. In accord with experimental results, it is assumed that Cu and Ni enter the scale and migrate across layer I at the same ratio at which Cu and Ni are present in the alloy. Since the concentration of Cu in layer I is presumably much lower than the concentration of Ni, the mobility of Cu must be sufficiently greater than the mobility of Ni. This is

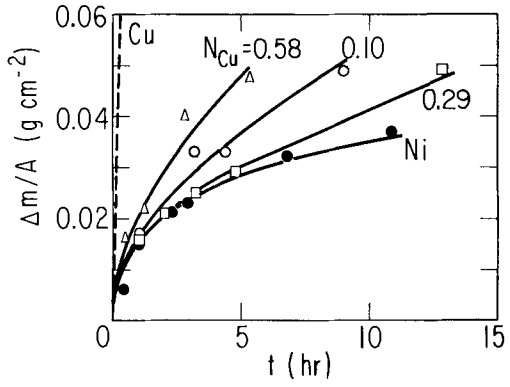

Fig. 13. Weight gain plot for Ni-Cu alloys sulfidized at 400°C.

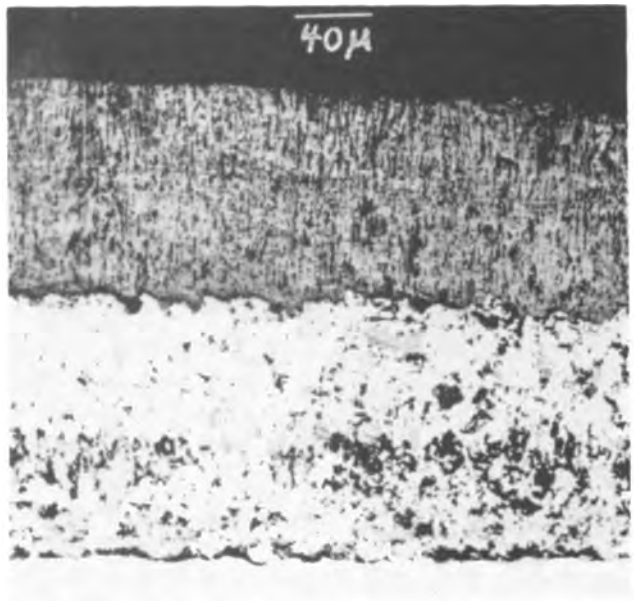

Fig. 14. Section of Ni-Cu alloy ($N_{Cu} = 0.58$) sulfidized at 400°C for 100 hr.

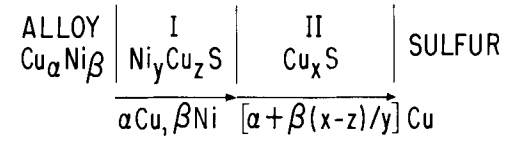

Fig. 15. Schematic representation of diffusion processes in the scale on Ni-Cu alloys exposed to sulfur at 400°C. Reaction at the Ni_yCu_zS-Cu_xS interface: αCu (in Ni_yCu_zS) + βNi in (Ni_yCu_zS) + $(\beta/y)Cu_xS = (\beta/y)\ Ni_yCu_zS + [\alpha + \beta(x-z)/y]$ Cu (in Cu_xS).

in accord with other observations according to which the mobility of monovalent ions is considerably greater than that of ions carrying a higher electrical charge.

Sulfidization of Ag-Cu Alloys

Samples of Ag-Cu alloy of eutectic composition are sulfidized in liquid sulfur at 400°C at about the same rate as the pure components. The size of the samples were 0.9 x 1.5 x 0.3 cm with a total initial surface area of 4 cm^2. The weight gains after 4, 9, 16, and 25 min were 0.369, 0.553, 0.565, and 0.660 g, respectively. The last sample was sulfidized completely. Microscopical examination of sectioned samples revealed a single sulfide layer with only minor irregularities at the alloy-sulfide interface.

Since the standard free energy of formation of Cu_2S is about twice that of Ag_2S, preferential sulfidization of copper may be expected. Actually, however, Ag and Cu enter the scale at the ratio at which they are present in the alloy as has been ascertained by chemical analysis. Presumably, the scale consists of solid solutions of the quasi-binary systems Ag_2S—Cu_2S and Ag_2S—$Cu_{1.8}S$. Various observations suggest considerable mutual solubilities (51, 52). However, complete miscibility is impossible since the terminal phases of these systems have incompatible structures at 400°C. Ag_2S has a body-centered cubic sulfur sublattice (28), Cu_2S II is hexagonal (29), and $Cu_{1.8}S$ has a face-centered cubic sulfur sublattice (28, 29).

Conclusions

High-temperature oxidation of pure metal yields, in general, oxide or sulfide layers of uniform thickness with diffusion in the scale as rate-determining step as an important limiting case. When an alloy rather than a pure metal is oxidized, one component of the alloy may be oxidized preferentially. In view of differential oxidation, diffusion processes take place in both the alloy and the scale. In special cases, the over-all ratio of the components in the scale may be the same as in the alloy, but the local ratio of the components in the scale may vary with distance from the outer surface. In addition to homogenous layers, there may occur two-phase layers either consisting of alloy enriched with respect to the more noble component and an oxide or sulfide of the less noble metal, or consisting of two oxides or sulfides of different metals. In the present research, typical examples from a large variety of possible situations have been found. The exploration of the decisive factors has been stressed. Many details have not yet been fully clarified.

Sulfidization of Cu-Au and Ag-Au alloys involving low Au contents, e.g., 10 a/o Au yields a composite scale consisting of an outer homogeneous sulfide layer and an inner two-phase layer involving Au-rich alloy and sulfide. This is in accord with theoretical considerations according to which a plane alloy-sulfide interface is not stable since the interdiffusion coefficients in the alloy are much lower than the diffusivities in the sulfide phases (2). At higher Au contents the tendency to form a rugged interface decreases especially at lower temperatures. At intermediate Au contents, local sulfide penetrations occur particularly at grain boundaries. Finally, Au-rich alloys may yield a nearly plane alloy-sulfide interface with only minor irregularities. The gradual change in the structure of the scale is reflected by a gradual decrease in the rate of attack. Alloys involving low Au contents are attacked very rapidly at about the same rate as the pure base metals since trunks of Au-rich alloy in the two-phase scale do not change the diffusion resistance of the sulfide to a large extent. In contrast, Au-rich alloys are attacked very slowly presumably with diffusion of Ag or Cu to the alloy-sulfide interface as the rate-determining step.

Silver-copper alloys also yield a sulfide layer of uniform thickness, in which the ratio of the components is the same as in the alloy in spite of the large difference in the standard free energies of formation of Ag_2S and Cu_2S. Thus only diffusion in the sulfide layer is essential and accordingly the rate of attack is about as high as that of pure Ag or Cu.

In contrast, Ni-Cu alloys immersed in liquid sulfur yield two sulfide layers. The outer layer is supposedly digenite $Cu_{1.8}S$, and the inner layer a solid solution involving nickel sulfide as solvent and Cu_2S as solute. The over-all Cu/Ni ratio in the scale is virtually the same as in the alloy. Thus only diffusion in the scale is essential. Both nickel and copper migrate presumably across the inner sulfide layer which grows by a displacement reaction between nickel ions, electrons, and copper sulfide.

Acknowledgment

This paper is based on a thesis submitted by B. D. Lichter in partial fulfillment of requirements for the degree of Sc.D. in metallurgy, Massachusetts Institute of Technology, Cambridge, Mass.

Research has been sponsored by the National Science Foundation and by Office of Ordnance Research, U. S. Army, under Contract DA-19-020-ORD-3661. The authors want to express their thanks to D. L. Guernsey for chemical analyses.

Manuscript received April 3, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Influence of Electrode Surface Conditions on the Electrical Strength of Liquified Gases

D. W. Swan and T. J. Lewis

Electrical Engineering Department, Queen Mary College, London, England

ABSTRACT

The strengths of liquified argon, oxygen and nitrogen are of the order of 1 mv/cm but are found to depend to a marked degree on the nature of the electrode surfaces. The strength can be changed in a regular manner (sometimes by as much as 50%) by changing both the electrode metal and the degree of surface oxidation. The important discovery is that the *anode* as well as the cathode has a strong influence on the strength. This surprising result has, as yet, no obvious explanation in terms of usual breakdown mechanisms but may be very significant, not only for theories of breakdown in these liquids but for hydrocarbon liquids as well.

Studies of the electric strength of liquid dielectrics have been concerned almost exclusively with organic materials because of their practical importance as electrical insulation. Insulating oils are mixtures of complex hydrocarbons in which trace compounds can have a strong influence and, in an endeavor to simplify the studies, less complex hydrocarbons such as pure n-paraffins have been investigated extensively (1). Even for these liquids, the molecules are complex, purification is complicated, and electrode conditions difficult to assess. In addition, discharges attendant on measurements of the electric strength cause gas evolution, carbon and other deposits, and seriously disturb the electrode surfaces. Because of these difficulties, the major discharge processes cannot be studied accurately in the liquid phase. There are, however, other much simpler dielectric liquids without these disadvantages in which breakdown mechanisms can be more easily understood, and which offer the opportunity for much more precise and controlled measurements. These are liquified gases and, although they are of no importance as practical insulants, much information can be gained from them which helps in understanding the processes occurring in the organic liquids.

Of the possible liquified gases, argon, oxygen, and nitrogen are most suitable for study since they may be easily obtained by condensation. Argon is ideal

because it has a simple atomic structure and is inert; other rare gases are not so convenient since they are more expensive and not easily liquified. Oxygen and nitrogen can also be obtained with reasonable purity and are simple diatomic gases with distinctive properties. All these should produce negligible by-products when electrical breakdown occurs because the discharge merely creates gas which then recondenses. In the case of oxygen, oxidation reactions may be caused on the electrodes and surface reactions may also occur with nitrogen, but the possible processes will be few compared with those in hydrocarbons. These three liquids also possess other advantages for breakdown investigations. Thus argon does not react with the electrode surfaces and electrons will remain free in it. Oxygen readily forms negative ions, thereby trapping electrons, and also encourages surface reactions at the electrodes, especially in the craters formed by previous discharges. Nitrogen is not inert but is only slightly reactive compared with oxygen. Each liquid, therefore, produces different discharge conditions, and there is also the possibility of investigating, for example, argon with a small admixture of oxygen, so reducing the number of free electrons in the argon.

The electric strengths of these liquids have been investigated on a limited scale already by Kronig and Van de Vooren (2) who obtained values between 860 and 1040 kv/cm depending on the electrode material. No other measurements of electric strength have been made, and there is only one measurement of natural conductivity at high electric stress for liquid oxygen by Pao (3). Induced conduction has been fairly well studied, however; the liquids being irradiated with x-rays or α particles (3-9). This work has given data on ion mobilities in these liquids and has clearly demonstrated that oxygen and also nitrogen can quench electron bursts in argon by forming negative ions of low mobility. A concentration of 0.7% oxygen in liquid argon was sufficient to quench all electron pulses, but a 15% concentration of nitrogen was required for the same effect. Clearly, electrons are not likely to remain free in liquid oxygen or nitrogen except, perhaps, at the highest fields approaching the electric strength when electron detachment may occur.

The work reported here represents an initial investigation into the strength of these liquids with the intention of estimating the role of the electrode surfaces in determining the strength. It is more extensive and of greater precision than that of Kronig and Van de Vooren (2). Techniques already used for reliable measurements on hydrocarbons have been employed. It will be shown that electrode effects are dominant in argon, and this may have important implications in the studies of breakdown in hydrocarbons.

Equipment and Procedure

A diagram of the test cell arrangement is shown in Fig. 1. It consists of a long glass tube, A, sealed at the lower end and flanged at the top. The electrode mounting B is rigidly fixed at one end of a stainless steel tube C which, in turn, is sealed to a metal flange D at the top. The vacuum sealed high voltage connection E is led through tube C and terminates in a small bushing at the lower fixed electrode. The other earthed electrode with its connector F is fixed to a stainless steel shaft, G, which can be moved vertically by a micrometer H. A vacuum seal is maintained by a metal bellows J joining G and D. The flanges D and A are then sealed by an o-ring joint which also locates the electrode assembly at the lower end of the cell. Gap adjustment between the 0.5-cm diameter spherical electrodes can be made to within $\pm$ 1 μ, i.e., with $\pm$ 2% error for a 50-μ gap, and is checked several times during an experiment in order to compensate for any temperature changes. Zero gap is obtained by using a sensitive detector as already described (10). Gas is admitted via K and caused to condense by placing liquid oxygen or nitrogen in the outer Dewar vessel L. The test cell is of sufficient length above the Dewar vessel for the top flange D and micrometer to remain at room temperature during experiments. By using liquid oxygen in L when condensing oxygen and liquid nitrogen for nitrogen condensation, it is possible to effect a slow and controlled condensation with adequate temperature control. Liquid argon, which has a small temperature range (84°-87°K) is obtained by boiling liquid oxygen in L at a controlled rate at reduced pressure. Normally the cell is filled with liquid to a level just below the lower edge of B and this requires only 15 cc of liquid, i.e., about 45 liters of gas at N.T.P. In all experiments equilibrium conditions were obtained by allowing 1 hr to elapse after condensation before making measurements.

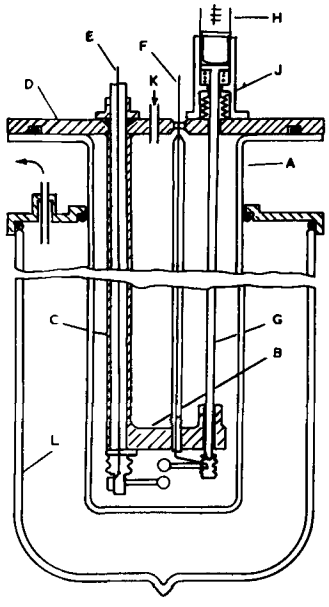

Fig. 1. Diagram of test cell

The temperature and pressure in the cell could be measured but, as Kronig and Van de Vooren have found, small pressure changes do not affect the strength. In the present series of experiments, the liquids were always in contact with their saturated vapors. For reasons given above, the temperatures were sensibly constant and are given in Table I.

The gas to be tested was passed through a P_2O_5 drying tube and a sintered glass filter of 1-μ pore

Table I. Data for gases used

	Argon	Oxygen	Nitrogen
Boiling point at atmospheric pressure, °K	87.3	90.2	77.3
Purity, %	99.95	99.5	99.9
Significant impurities, vpm	N_2 <500 O_2 <20 H_2 <10	H_2 <50 Carbon compounds <15	O_2 <10 Carbon compounds <15

size to remove dust particles. The purity of the gases is given in Table I and it is important to note that argon and nitrogen contained traces of oxygen. Since a slight internal positive pressure was maintained in the system, which was in any case vacuum tight, it is improbable that any further gas contamination occurred.

A 25 kv fully stabilized direct voltage source capable of very fine control was used for the measurements, and the voltage applied to the electrodes was measured by recording the current through a 1000 M ohm high stability resistor connected across the electrodes. The absolute error in voltage measurement was <2% and relative values could be obtained with much less error than this. When breakdown occurred the current flow was limited by using a fast electronic by-pass circuit of a type already described (10). This was capable of discharging the stored energy of the voltage supply within 1 μ sec of breakdown and so limited the energy dissipated in the liquid to the residual associated with the test cell capacitance. There was, therefore, minimum gas evolution and electrode damage. This permitted repeated measurements to be made on the same electrode surfaces without significant deterioration. Operation of the diverter also indicated breakdown without need for visual observation of the spark. Kronig and Van de Vooren report observing occasional very low electric strengths which they attribute to gas bubbles on the electrodes. Since they did not divert the discharge energy and low strengths have not been observed in the present work, their deduction seems correct.

The techniques adopted for electrode preparation were similar to those found to be reliable with hydrocarbons (1, 11). Surface scratches and previous discharge damage were removed by buffing the electrode on a rough mop with polishing compound. This was followed by further polishing on finer mops until the surface was smooth when viewed under a microscope of magnification X150. Polishing material was then removed by washing in hexane; then a soft mop, free of grease, was used to prepare the final surface. At this stage the surface was comparatively free of grease and heated by the polishing process so that initial oxidation occurred rapidly. Further oxidation could then be arrested by washing the electrodes in dust-free hexane (11). For certain measurements to be described, various oxidation thicknesses on oxidizing metals were required; these were obtained by delaying the wash in hexane and allowing the electrodes to remain for predetermined times in dry air in a dessicator. Oxidation times were then taken as measures of oxidation thickness, with zero time and minimum thickness arbitrarily chosen to correspond to that involved in directly transferring the electrodes from the final mop to hexane without delay.

The electrodes were then transferred to the test cell and washed again in dust free hexane. Finally, the whole test cell assembly was evacuated to a pressure of 10^{-5} mm Hg for a period of 18 hr to remove hexane vapors and other volatile impurities. Before condensing the gas to be tested, the cell was flushed with a sample of the same gas and re-evacuated for a short while.

Electric Strength

Electric strengths of the three liquids were measured using both stainless steel of zero oxidation

Table II. Mean strengths for liquified gases (mv/cm)

	Platinum electrodes		Stainless steel electrodes	
	from Fig. 2	from ref. (2)	from Fig. 3	from ref. (2)
Argon	1.10	0.86	1.42	1.00
Oxygen	2.00	0.93	2.38	1.04
Nitrogen	2.26	0.93	1.88	1.00

time, and platinum electrodes, in order to make direct comparison with the values obtained by Kronig and Van de Vooren. Results for a range of electrode spacings are given in Fig. 2 and 3, together with the earlier results. The coefficient of variation was found to be less than 10%. Mean strengths for the liquids, obtained from the slopes of the plots, are given in Table II. In the case of argon with stainless steel electrodes, which had been subjected to a glow discharge in hydrogen in order to reduce the oxide layer still further, a linear plot is not obtained, and the value shown in Table II is the slope for the smaller electrode spacings. The new values are higher than the previous ones in all cases. This may be due to the use of 0.5-cm diameter spherical electrodes rather than the 1-cm diameter sphere-plane arrangement used by Kronig and Van de Vooren, or to the use of the energy diverter; but, as will be shown below, the difference could be ascribed to electrode surface conditions. Argon has the lowest strength with either electrode material, but nitrogen is either stronger or weaker than oxygen according to whether platinum or stainless steel electrodes are employed (2). Good reproducibility of these results was obtained except for nitrogen with stainless steel electrodes. For this gas, results for different samples could not always be repeated even though the techniques were maintained constant. Values given in Fig. 3 are the most probable ones obtained from a large number of experiments. Similar difficulties have been found with electrical discharge measurements on nitrogen gas on a previous occasion (12), and at the moment there is no explanation of the effect. The nonlinear plot for argon and stainless steel suggests that the strength of argon for really large spacings ($> 100\ \mu$) would be much less than that quoted in Table II, and any increase for smaller spacings may be due to the influence of the electrodes, but more measurements are required to prove this.

In view of the earlier evidence from α-particle and γ-ray induced conductivity (3-9) it is expected that in argon, at least, a small percentage of oxygen (or somewhat greater amounts of nitrogen) should alter the pre-breakdown state by quenching avalanche discharges and causing electrons to attach to form negative ions. These ions would be transported to the anode and an ion concentration built up there. Although the ionization potential of oxygen (12.2 ev) is less than that of argon (15.8 ev), this does not appear to be important in deciding the strength of the liquid since addition of oxygen to argon raises the strength. For instance, addition of 20% oxygen to argon raised the strength from 1.66 to 2.42 mv/cm for a 40-μ gap with stainless steel electrodes. This is an increase of 45% but is still less than the strength of pure oxygen. In order to reveal any electrode effect in this process, stainless steel electrodes were rendered oxide-free by glow discharge and used to measure the strength of liquid argon both before and after a small quantity of oxygen had been added. Measurements of the strength at 1-min intervals showed a gradual increase amounting in all to nearly 30% over a period of 25 min. Addition of a much larger quantity of oxygen at the end of this period caused an immediate further increase of about 10%. These results suggest that the initial gradual increase could be associated with electrode oxidation and the later one with attachment processes in the bulk of the liquid.

Electrode Effects

It is obvious from the experiments described that a strong electrode influence exists. This has been further studied in two ways, both of which are described briefly. In the first, the influence of electrode metal prepared with a zero oxidation time was found for each gas. Plots similar to those of Fig. 2 and 3 were made for a range of electrode spacings and the electric strengths found as before. These strengths, given in Table III, can be changed by almost 100% by a change of electrode material. There is no correlation with work function; in fact, the order of increasing strength for the different metals is not the same for each gas even with electrodes of gold or platinum which should provide stable surfaces. Gold gives a higher strength than platinum for argon but not for oxygen or nitrogen. In any relationship between strength and cathode emission properties, platinum, having a higher work function than gold, might be expected to give a higher strength especially in argon which is inert. It is in this liquid, however, that the lower strength is found.

The next series of experiments, using argon because of its inertness, involved electrodes having various degrees of oxidation obtained by the method already outlined. Figure 4 shows the influence of this oxidation time. Each point is the mean strength found from plots similar to Fig. 2 or 3 and thus represents a large number of measurements. As expected, neither gold nor platinum produce any variation with oxidation time whereas stainless steel and brass, which oxidize readily, cause a large change. For these oxidizing metals the strength reaches a maximum after oxidation times of 15 and 70 min, respectively. Larger oxidation periods than these, i.e., greater thicknesses of oxide, cause a gradual decline in strength, and shorter times giving thinner layers also lower the strength.

The initial rise to the peak could be associated

Table III. Mean strengths as a function of electrode material

Electrodes	Work function, ev	Electric strength, mv/cm		
		Argon	Oxygen	Nitrogen
Stainless steel	—	1.40	2.38	1.88
Brass	—	1.01	1.44	1.62
Copper	4.47	1.40	1.81	—
Gold	4.58	1.16	1.24	1.50
Platinum	5.29	1.10	2.00	2.24

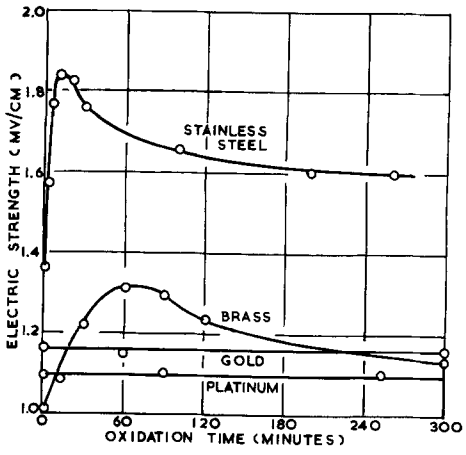

Fig. 4. Effect of electrode oxidation time on mean electric strength of argon.

with a decrease in electron emission resulting from an increase in work function caused by oxide growth. Any increase in work function in this way might be offset by a decrease caused by positive ions produced in the discharge processes coming back to this oxide layer (13). The over-all cathode emission would be determined by these opposing effects and, as the oxide layer thickened beyond a certain value, it is possible for the positive ion layer to increase in effectiveness because of the insulating properties of the oxide which would hinder ion neutralization.

For the whole range of oxidation times, therefore, the emission might initially decrease and then increase again, and if electric strength was directly related to emission, the curves in Fig. 4 are reasonable. This would be a plausible mechanism if the behavior were found to be independent of the anode, but unfortunately this is not the case. By using mixed electrodes, it has been possible to show an anode dependence also. For example, with a stainless steel anode and an aluminum cathode, the strength was practically the same as for two stainless steel electrodes, but reversal of the polarity gave a strength equal to that for aluminum electrodes. In other experiments using gold anodes and stainless steel cathodes, it was possible to change considerably the effect of oxidation time from that shown for stainless steel in Fig. 4. Thus, any mechanism of breakdown in liquid argon must include the role of the anode as being of great importance.

Conclusion

These results and others not reported indicate that the "intrinsic" strengths of the three liquified gases have not, in fact, been measured. It may well be that electrode effects will always prevent this being achieved with any certainty. The breakdown stresses are $\sim 10^6$ v/cm so that electron emission from the cathode might be expected, but it should be borne in mind that at temperatures of $\sim 90°K$ Schottky field-aided thermionic emission, which is considered to be significant for liquid breakdown at room temperature, will be negligible. At the same time the field strength does not seem to be large enough for appreciable cold field emission. Measurements of the natural conductivity of liquid argon at 10^6 v/cm confirms this since no detectable current was found. Nevertheless, individual microscopic sites might emit more freely and would then increase the probability of breakdown in these regions. The number and activity of the sites would depend on cathode material and preparation and on the incidence of positive ions generated by discharge processes as already outlined.

It is very much more difficult to suggest processes by which the anode conditions might influence the electric strength, especially when the emission from the cathode is feeble and probably confined to microscopic sites. The normal concepts of gas breakdown which we may tentatively employ here involve primary electron avalanche or α processes, followed by secondary mechanisms in the gas or at the cathode surface. In particular, positive ions produced by the avalanches may yield secondary electrons at the cathode (γ process). This mechanism does not, however, include the anode at all. If the anode is to be important, it is necessary that positive ions should be generated at the anode at a rate controlled by the conditions there and that the yield of positive ions from the rest of the liquid should be small. Two processes seem possible but there may be others. In both, the presence of oxygen in small amounts in the liquid is required in order that electrons emitted from the cathode have a good chance of forming negative ions. A negative ion approaching the anode creates a strong local field which will act across any oxide layer present, so increasing the probability either of ionization of any adsorbed molecules on the oxide layer (including neutralized oxygen ions), or of direct extraction of positive metal ions through the oxide as in an oxidation process. Ions created in this way then proceed to the cathode and by a γ process yield further electrons with the consequent possibility of a breakdown instability. An alternative process which requires positive ions to be produced by avalanches is as follows. The formation of negative oxygen ions serves to transport oxygen to the anode where the ions are neutralized. A concentration of oxygen will then build up in the immediate anode neighborhood to an equilibrium controlled by the availability of electrons and ease of neutralization of the ions. This oxygen-rich anode layer will now have a marked influence on positive-ion production which, according to avalanche growth, should be greatest in the same region. Both processes require the existence of negative ions which, for argon liquid, means the presence of an oxygen impurity. Further experiments on nitrogen and oxygen liquids need to be made to see whether anode effects are present in these liquids also.

The attachment properties of oxygen may also be responsible for the apparent intercept on the voltage axis found in Fig. 2 and 3. While this may be ascribed to the presence of a Paschen minimum as in gases, occurring for spacings of less than about 1 μ, it could also be due to an oxygen and oxygen ion layer at the anode of, perhaps, the same order of thickness. As the electrode spacing is reduced, so this layer exerts a proportionally greater influence on

the strength. It is significant that similar intercepts are found for hydrocarbon liquids containing oxygen (1).

The role of oxygen, therefore, seems the same for liquified gases and hydrocarbon liquids. The electrode effects found with the former may also exist for the latter. The present investigation is valuable in suggesting effects which may well be present in hydrocarbons, but which are masked by the more numerous side effects. Work is proceeding to discover whether this is so. Measurements in compressed gases similar to that already undertaken (14) would also be very valuable and should yield closely related information to that given here.

Acknowledgment

The authors are grateful for the generous financial assistance from the British Electrical and Allied Industries Research Association enabling equipment to be purchased. Thanks are also due to Professor M. W. Humphrey Davies for the facilities provided and for encouragement, and to the Department of Scientific and Industrial Research for a maintenance grant to one of us (D.W.S.). Dr. A. E. Guile was responsible for much of the early design of the test cell and his considerable help is acknowledged.

Manuscript received Nov. 2, 1959. This paper was prepared for delivery before the Philadelphia Meeting, May 3-7, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Molecular Structure and the Electrical Strength of Liquid Hydrocarbons

T. J. Lewis

Electrical Engineering Department, Queen Mary College, London, England

ABSTRACT

It is suggested that electrons moving through hydrocarbon liquids are able to excite molecular vibrations of infrared frequencies, and that this provides an effective energy loss mechanism. The relative magnitudes of this loss may be estimated for a wide range of hydrocarbons and other liquids and can be used in a criterion of breakdown. Thus the electrical strengths of these liquids measured under standard conditions may then be compared with their molecular structures. A good correlation is found.

In recent years the electric strength of a large number of hydrocarbon liquids has been measured using microsecond pulse and continuous voltages. The results published are reliable in that they are repeatable, but they do not represent the intrinsic strengths because of several influences, such as electrode effects, inherent in the measurements. In spite of this, the experiments have demonstrated that the strength is dependent on the molecular properties of these hydrocarbons and quite small changes such as that from hexane to heptane or to isopentane produce a significant effect. Because of the work of Sletten (1) of this laboratory, who has demonstrated that dissolved oxygen increases the strength of n-hexane considerably, it is now realized that the attainment of the highest strengths may not indicate the closest approach to the intrinsic value. As discussed below, many measurements already made must have been influenced strongly by oxygen in solution and, for this reason alone, it is timely to re-examine the relationship between electric strength and molecular structure. This has been discussed in various ways already (2-6) and in this paper the earlier ideas are re-stated concisely in a criterion which permits the molecular influence to be separated from the other factors. Any simple criterion of this sort is open to detailed criticism but, since the theory of breakdown is by no means clarified, the adoption of a simple criterion is advantageous. Having established the criterion, its validity will be examined using experimental results.

Basic Processes

The electric strength of a simple hydrocarbon liquid is considered to be determined by the onset of an instability initiated by the primary processes of electron emission from the cathode and electron multiplication or associated charge accumulation in the bulk of the liquid (2). These processes are

likely to be inter-related and secondary effects arising from impurities or from the measuring technique (7) may also occur. It is then difficult to separate the primary processes by measurements of the electric strength except under special conditions. Stresses greater than 10^6 v/cm are reached in these liquids before breakdown occurs, and it is commonly accepted that field extraction of electrons from the cathode must be occurring (8, 9): a major component of the infra-breakdown conduction current arising from these emitted electrons. Excluding impurities, the mode of conduction is then either by quasi-free electrons or negative ions formed by attachment and at the highest fields possibly by positive ions produced by collision ionization. The mobilities and energies of these particles depends on the collision characteristics of the liquid so that once an electron is emitted the subsequent processes are governed by the liquid and dependence on molecular properties may be expected.

Cathode Mechanisms

If the strength is to be related to liquid properties, the cathode should either play a consistent or else a negligible part in the breakdown process. Evidence from the literature suggests that the cathode effect may be both erratic and elusive, some authors reporting a dependence on electrode material and others not. The electrode surfaces in all cases is covered by complex and perhaps insulating layers of oxide, gas, and other adsorbed impurities. Charge transported to such surfaces can build up electric double layers strongly influencing the emission and preventing any direct relationship between it and the work function of the pure cathode metal. Green (8) has suggested that positive ions deposited on the cathode from the liquid are responsible for enhanced emission in n-hexane and has found a definite dependence on electrode metal and degree of oxidation.

The strengths achieved when measurements are made with pulse voltages of sufficiently short duration depends on the degree of electron availability, and cathode conditions are then important. This situation is analyzed by Ward and Lewis (7), and Hancox and Tropper (10) have also reported an effect of this kind in which cathode oxidation altered the impulse strength of transformer oil.

The relative importance of the control exercised by the separate cathode and liquid processes also determines the degree of electrode dependence. For breakdown both processes need to be above a certain threshold of activity. If the field strength required to promote the liquid mechanisms is high and at the same time the cathode is a good field-emitter, then the breakdown is liquid-controlled and cathode dependence is masked. On the other hand, a liquid of lower "intrinsic strength" with a poor cathode emitter would be expected to show cathode effects. Normal measurements might give either situation as the literature seems to indicate. In Fig. 1 these two conditions are shown by using a point-plane electrode system (11). When the liquid is relatively highly stressed, i.e., the plane negative, a cathode dependence is present, but this

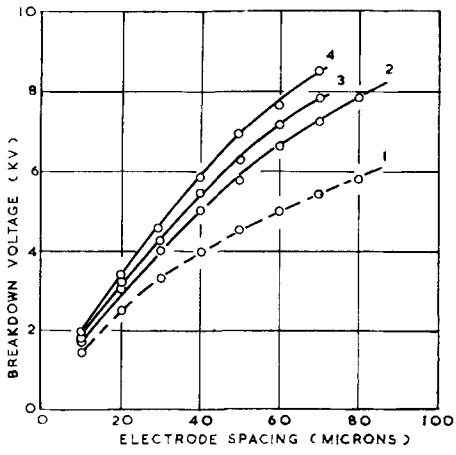

Fig. 1. Breakdown voltage of a point-plane electrode system in n-hexane, Ref. (11). 1. Point cathode, no dependence on electrode material; 2. plane cathode, aluminum electrodes; 3. plane cathode, copper electrodes; 4. plane cathode, chromium electrodes.

disappears when the polarity is reversed. A negative point insures a copious emission and the liquid, being less highly stressed, then controls the breakdown.

Since extensive experiments on various hydrocarbon series have demonstrated already that liquid effects may be observed in some detail it can be concluded that the cathodes were consistent in behavior and able to yield the required emission in these experiments. Any liquid influence on electron emission would remain reasonably constant because of the strong chemical and physical similarities in these hydrocarbon series.

Electronic Processes in the Liquid

As in gaseous or solid phases, an electron gains energy from the applied field and loses it in collisions with molecules. The efficiency of energy transfer in a collision is energy dependent and at low field strengths a stable condition is reached in which only electrons of low energy are accelerated by the field. Although the electron population will contain some electrons of much larger energies, the probability of energies sufficient for ionization will be insignificant. As the field is increased, the distribution will shift to higher energies and ionizing collisions will become more probable. Energy distributions and collision probabilities have long been known for gases (12). In liquids, the complexity of the molecules and the increased density can change the relative importance of various collisions so that these must be reconsidered. The major collision processes are:

(*a*) Elastic. At low field strengths the majority of collisions will be purely elastic involving little energy loss because of the high mass ratio of hydrocarbon molecule and electron.

(*b*) Vibrational. An energy loss, which may not be nearly so important in the gaseous phase unless the molecules are complex, arises from the excitation of molecular vibrations. The vibrations associated with the binding forces are usually in the infrared frequency band and energy quanta in the range 0.1-1 ev are involved. Vibrations excited in this way may couple to other molecules especially when

local order exists. This type of collision is considered to be a major loss process in solid breakdown.

(c) Attachment. Saturated hydrocarbons are not expected to be electronegative, but low-energy electrons could form ionic complexes or clusters by induced polarization of neighboring molecules. These clusters would behave as large ions at low fields, but the electron could be freed by thermal activation or field acceleration at higher fields, leaving the polarized molecular atmosphere behind as in the Wien effect.

(d) Excitation. Excitation transitions in the hydrocarbons requires energy quanta of several electron volts, and the excited molecule can subsequently either emit a photon or for the majority of hydrocarbons stabilize by dissociation (13). Even if photon emission occurred, it would be strongly absorbed by neighboring molecules and would not have the importance found in gas breakdown. The increased density together with the increased number of excitation and ionization levels of the complex molecules will cause the distinct energy gap between excitation and ionization of a gas to be lost in a liquid (14). Consequently, excitation will no longer form such an effective regulating mechanism to limit the ionization process as in gases.

(e) Ionization. Ionization energies are ~10 ev and decrease progressively as any particular hydrocarbon series is ascended. Positive ions of low mobility produced by the collision will disturb the field and cause enhanced emission at the cathode (8). These ions are important in causing a breakdown instability.

Apart from the major processes, electron collisions may also involve impurity molecules and give rise to a variety of effects but for conciseness, only a few of these may be mentioned. Organic impurities such as related hydrocarbons are not likely to upset the breakdown process in the pure liquid; others of a polar nature can induce a low strength. The cleaning techniques adopted reduce the effects of these latter impurities, but their presence in small controlled amounts may be useful in detecting certain breakdown processes. For instance, Darveniza (15) of this laboratory has shown that traces of anthracene cause n-hexane to emit visible light with a photon energy of about 2.5 ev when the breakdown field is approached, thus giving evidence for the presence of electrons of this energy. Water is an important impurity of which most is removed chemically, but some must remain as a trace. In dissociated form it can contribute to the conduction current and is probably regenerated at the electrodes as Plumley has suggested (16). Provided the accepted drying techniques are employed there is no evidence at the moment for it having any strong influence on breakdown.

Another important class of impurity is dissolved gas which introduces additional collision centers having energy levels which may be very different from those of the pure liquid. The excitation and ionization energies of oxygen and nitrogen, which are likely to be dissolved, are greater than the corresponding values for hydrocarbons such as n-hexane so that these transitions in the gases are not likely to occur. The most important effect to be expected is the strong electron attachment of oxygen which is discussed more fully below. The presence of an actual gas phase in the form of bubbles has been considered on many previous occasions especially for oils. Bubbles could easily initiate breakdown, but the majority of evidence suggests that the influence of dissolved gas in simple hydrocarbon liquids is through individual electron-gas molecule collisions rather than bubbles.

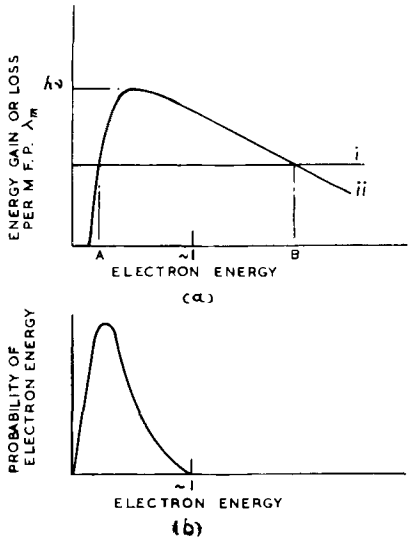

Fig. 2. Energy diagrams for vibrational collisions. (a) Energy balance below breakdown stress (i) energy gain from field E, (ii) energy loss in vibrational collisions of frequency ν; (b) electron energy distribution function corresponding to (a).

Vibrational Collisions

From the assessment above, it is concluded that vibrational collisions account for the major electron energy loss in pure hydrocarbon liquids replacing excitation collisions as the major control of collision ionization. The vibration collision loss can then be used to establish a breakdown criterion similar to that proposed for solids (14, 17). This may be done by reference to Fig. 2a which shows the hypothetical electron energy gain from the field E and loss to molecular vibrations per minimum mean free path λ_m for this collision. It is assumed that the vibration cross section reaches a peak $Q_m = (N\lambda_m)^{-1}$, where N is the number of molecules per cc, for an energy equal to a few multiples of the threshold value. Electrons in the range AB tend to shift in energy toward A, but this is opposed by thermal fluctuations repopulating the higher energy ranges. For a particular applied field below the breakdown value and constant electron emission and absorption at the electrodes, an equilibrium energy distribution is set up characterized by a severe curtailment in the excitation-ionization energy range ~ I(Fig. 2b). As the field is increased, point B moves down and more electrons will be capable of acceleration by the field toward ionization energies, but the increase will be small until the condition B = I is reached. At this field strength, many more electrons are available for acceleration. Thus the condition B = I represents the onset of a significant collision ionization or α process. At still higher fields the condition A = B will be

reached and electrons of any energy are then accelerated towards I.

The α process causes electron avalanches and, by analogy with gas breakdown, we require either that these should grow to a particular size or that an instability through secondary processes such as positive-ion emission enhancement at the cathode should occur. In any of these cases the necessary condition for an instability is that α should reach a minimum value. From Fig. 2, the condition can be expressed as

$$e\,E_m\,\lambda_m = Ch\nu \qquad [1]$$

where E_m is the breakdown field, C ($\leqq 1$) determines the required α value, and $h\nu$ is the energy quantum transferred in a vibration collision of frequency ν. This criterion, or variations, has been utilized by several authors (2-6, 18). It should be noted that C takes account of the experimental conditions (e.g., pulse or continuous voltage measurements) and would be affected by any electrode conditions capable of altering secondary processes and thereby requiring a new α value for an instability. Because of these effects, Eq. [1] is useful for comparing liquids only when C remains reasonably constant throughout the experiments. This seems to have been achieved for the alkanes and alkyl benzenes (2-6). Through Eq. [1] it is possible to relate strength to molecular structure.

Vibration Frequency ν and Minimum Free Path λ_m

Vibration frequencies of the hydrocarbons are restricted to a few bands. Characteristic wave-numbers, determined from infrared spectra, can be associated with the carbon-hydrogen groups and with the skeletal carbon-carbon bonds (Table I). It is well known that these are characteristic of the groups and independent of the rest of the molecules. As the electron energy increases, each mode of oscillation may be excited in turn, but from our concept of the breakdown process and knowledge of the infrared absorption intensities it is expected that the major energy loss will occur in exciting 2960 cm^{-1} vibrations of the CH_1, CH_2, and CH_3 groups. This requires an energy quantum of 0.37 ev. Vibrations of the carbon skeleton in alkanes require a lower energy, and the skeleton is screened by CH bonds so that it is likely to be less effective in causing loss. The same applies to the alkyl radical of the alkyl benzenes. The benzene ring itself is best considered as a single independent group having a highest frequency as in Table I.

The independent behavior of the various groups as shown by their infrared spectra suggests that these hydrocarbon liquids may be considered to a first approximation as dense gas-like phases of the group

Table I. Infrared vibrations of hydrocarbon groups

Group	Wave number, cm^{-1}	Energy quantum, ev
CH_1, CH_2, CH_3	~2960	0.37
CH_3, CH_2	1450	0.18
CH_3	1000	0.12
C-C skeleton	890-1090	0.11-0.14
Benzene ring (CH modes)	~3000	0.37

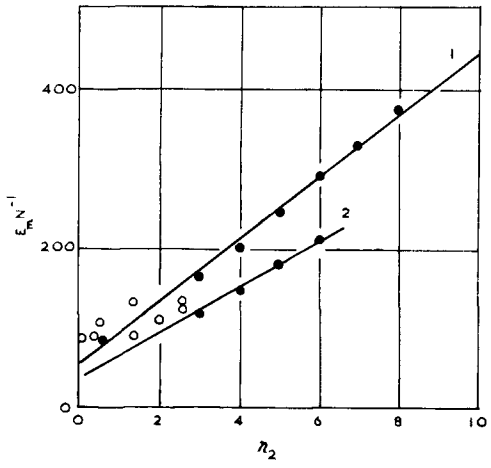

Fig. 3. E_mN^{-1} vs. n_2 for alkanes according to Eq. [4]. Curve 1, from short duration pulse measurements; curve 2, from direct voltage measurements. o Points marked thus are for branched chain alkanes containing the Q_1 cross section.

oscillators, each acting as an independent collision center and having a uniform distribution in the liquid. Thus (2, 4)

$$\lambda_m^{-1} = N\,\Sigma n_i Q_i \qquad [2]$$

where n_i is the number of i^{th} groups per molecule for which the maximum collision cross section for the 2960 cm^{-1} mode is Q_i.

Equation [1] may now be checked against the electric strength determinations reported by Sharbaugh, *et al.* and by Lewis (2-6) in which consistent techniques leading to a constant C were adopted in each series of measurements. Combining Eq. [1] and [2] and writing the constant k to include C and the common frequency of vibration ν then

$$E_mN^{-1} = k\,\Sigma n_i Q_i \qquad [3]$$

If i = 3, 2, 1 refers to CH_3 CH_2 and CH groups, then for n-alkanes C_nH_{2n+2}

$$E_mN^{-1} = k\,(n_2Q_2 + 2Q_3) \qquad [4]$$

i.e., E_mN^{-1} vs. n_2 should give a linear plot of intercept 2 k Q_3 and slope k Q_2 as is indeed confirmed for both sets of measurements in Fig. 3. Results for branched alkanes have been added to Fig. 3 and lie above the linear plot as expected because of the neglect of Q_1 in Eq. [4]. By plotting

$$(E_mN^{-1}n_1^{-1} - k\,n_3Q_3n_1^{-1}) \text{ vs. } n_2n_1^{-1}$$

for the isomers, the expected linear plot is again found which gives an estimate of k Q_1 and a check on k Q_2. It no longer appears necessary to place branched chain isomers on a separate characteristic and to ascribe a new characteristic frequency ν to them as suggested earlier (4). The relative magnitudes of Q_1, Q_2, and Q_3 agree well in the two sets of measurements in spite of the very simplified model.

For n-alkyl benzenes $C_6H_5-C_nH_{2n+1}$ Eq. [3] becomes

$$E_mN^{-1} = k\,(n_2Q_2 + Q_3 + Q_b) \qquad [5]$$

where Q_b is the cross section of the benzene ring. Results obtained by Sharbaugh, Crowe, and Cox (5) fit this law as in Fig. 4a (6, 19). Also in agreement

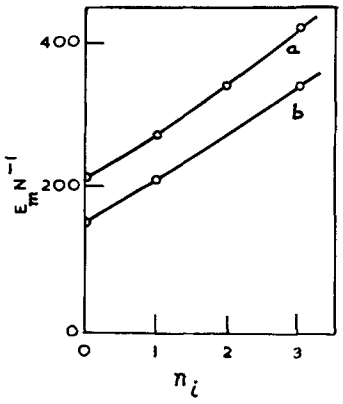

Fig. 4. $E_m N^{-1}$ as a function of molecular structure for alkyl benzenes. (a) n-Alkyl benzenes according to Eq. [5], $n_1 = n_2$; (b) branched-alkyl benzenes according to Eq. [6], $n_1 = n_3$.

with the criterion are the results for benzene, methyl benzene, and t-butyl benzene (Fig. 4b), fitting accurately the relationship

$$E_m N^{-1} = k\ (n_3 Q_3 + Q_b) \qquad [6]$$

Cross sections estimated from Fig. 4, show that Q_b is relatively large as might be expected but also that k Q_2 and k Q_3 are considerably greater (~100%) than estimates from the alkanes. This may be due in the first place to a shift in the breakdown criterion since there is no reason why C (Eq. [1]) should be the same in both series. Changes may also occur in the cross sections because the alkyl benzenes are polar with the ring negative. This would increase the interaction between the alkyl groups and electrons. It is also probable that the liquid structure differs in the two cases with a consequent effect on λ_m (see below).

Equation [1] is also supported by measurements on the dimethyl siloxane (silicone) liquids which have similar chain structures to the alkanes. The main skeleton consists of silicon-oxygen bonds, replacing the carbon-carbon bonds of the alkanes, and methyl side groups are added at the silicon sites to give a general formula $(CH_3)_3Si-[O\ Si(CH_3)_2]_n-O\ Si(CH_3)_3$. An important difference is that the silicone skeleton is relatively exposed at the oxygen sites and the silicon oxygen bonds are polar. Equation [3] becomes

$$E_m N^{-1} = k\ (n_3 Q_3 + n_o Q_o) \qquad [7]$$

where Q_o refers to the oxygen site. The strengths found with direct voltage for the first four members of the series again give a linear characteristic when plotted according to Eq. [7] (6), bearing in mind that the dimer exhibits exceptional behavior in many of its other physical properties (20). The value of k Q_3 so obtained is identical with that from the alkanes. It has been shown already that the CH_3 group in the silicones has a vibration of ~3000 cm^{-1} very close to that found in the hydrocarbons so that the agreement in the estimates of k Q_3 appears significant.

On the whole, therefore, experiments on a large number of simple liquids can be arranged systematically according to Eq. [1] based on individual molecular groups.

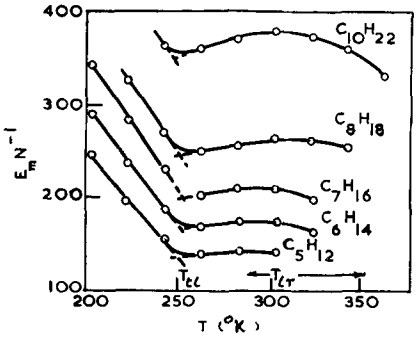

Fig. 5. Variation of E_m/N with temperature for n-alkanes showing transition temperatures.

Liquid Structure

The assumption of a uniform distribution of collision centers implies that the liquid is isotropic along individual electron paths. It is known that local order can exist in n-alkanes, however, and that this is temperature dependent. The liquid phases for pentane to decane are characterized by three states having transition temperatures T_{tl} and T_{lr} in the neighborhoods of 245° and 288°-355°K, respectively (21). Below T_{tl} the state is quasi-crystalline and the molecules pack with their long axes parallel to form crystallites. In the range T_{tl}-T_{lr} libration occurs about the long axes and above T_{lr} complete rotation is possible and local order disappears. Many physical properties change when taken through these transitions; Fig. 5 shows that the electric strength is no exception (22). By plotting $E_m N^{-1}$ against temperature in this figure normal density changes are annulled, structure effects are accentuated, and T_{tl} and T_{lr} become obvious. The change at T_{tl} is particularly abrupt. In a crystallite at low temperature the density of scattering centers due to CH_2 and CH_3 groups will be greater along the chain axis than perpendicular to it, and an electron with a trajectory along the axis will suffer the greater loss. This situation could occur as a result of field-induced orientation of the anisotropic molecule and will lead to a smaller value of λ_m in Eq. [1]. As the temperature is increased, both orientation and the crystallite size will decrease, so increasing λ_m and lowering the strength. In the range T_{tl}-T_{lr}, the onset of libration will increase the effective volume occupied by each molecular group and so increase the cross-section. The two opposing effects of decreasing orientation and increasing cross section would account for the small changes in E_m/N in this range. Normal results quoted in Fig. 3 are in this range. Above T_{lr} complete rotation is possible and the disordering processes already begun at lower temperatures cause a further fall in strength. Since the alkyl benzenes are polar, field orientation is likely to be stronger than in the alkanes and this may help to account for the increased effective cross sections found for the CH_2 and CH_3 groups in these liquids. A similar increase in orienting force would occur for the alkanes if ions attach in any way to the chain molecules.

Oxygen Effects

Account must now be taken of the study recently reported by Sletten (1) in which oxygen was shown

to have a marked influence on the strength of n-hexane (and presumably on other n-alkanes). His conclusion is that the results reported by Lewis, House, Sharbaugh, and others refer to liquids in which dissolved oxygen caused an increase in strength. He demonstrated that the strength of n-hexane may be increased from 0.9 mv/cm to the levels normally reported by dissolving oxygen in the liquid. Nitrogen did not affect the strength at all. It is necessary to determine whether the concepts in this discussion are in any way disturbed by this discovery. Because small changes in molecular structure influence the strength (2-6), even in the presence of oxygen, it is logical to seek a mechanism by which oxygen raises the strength without disturbing the controlling influence of the hydrocarbon vibrations.

Oxygen is electronegative and forms negative ions. According to the latest work (23) attachment in the gaseous phase involves a dissociative process, with the formative of an atomic ion, which has a peak at electron energies of about 6 ev lying between the vibrational and ionization energies of the hydrocarbons. If the same attachment process occurs when oxygen is dissolved, it will remove free electrons of energies above the vibration peak normally capable of contributing to the α process in the liquid. The conversion of electrons to low-mobility negative ions would also reduce the conduction current as observed (1). The attachment cross section (23) is, however, smaller than seems necessary to explain the large influence on the strength, but its effectiveness may be enhanced by transport of the oxygen ions to the anode. A layer of oxygen and oxygen ions will be built up there and brought to an equilibrium as regards oxygen concentration and electrical double-layer strength determined by the applied field. The layer would be strongly electronegative and therefore resistive to electron motion. Strong evidence for the existence of this layer on the anode has been provided recently by Ward of this laboratory who used an electrode with a layer formed in this way as the cathode in a pulse breakdown test on n-hexane. The strength was initially greater than 2.1 mv/cm and declined to the more normal value of 1.5 mv/cm as the layer diffused away and the cathode regained its emission properties. Oxygen will, therefore, tend to reduce α and restrict the volume for avalanche development. This can be accounted for in the present theory by an increase in the constant C of Eq. [1]. Further work on the role of oxygen and other gases is in progress.

The Adamczewski Theory

The theory given by Adamczewski (18) employs the same type of energy loss concept as here, but there are detailed differences which are important, especially as excellent agreement with pulse measurements (4, 5) have been obtained by him.

The major energy loss is ascribed to C—C bond vibrations of wave numbers 890 and 1090 cm^{-1}, either of which ultimately give strengths in close agreement with the pulse measurements. Reasons for not preferring this mode of vibration, which in the author's opinion cannot be overlooked, have been given already. The mean free path λ_m is also calculated differently. In the work of Sharbaugh, *et al.* (4) and Lewis (2) no attempt is made to estimate the absolute cross sections from bond dimensions and only relative magnitudes in terms of k are derived. Adamczewski, however, assumes the collision cross section to be a longitudinal geometrical section of the molecule. The n-alkane molecule is taken to be a cylinder of base radius r and length $l(n-1)$ where $2r$ (=4.9Å) is the mean distance between molecular axes, assuming crystal order as in the solid, l (= 1.23Å) is the C—C bond length projected on the axis and n is the number of carbon atoms. The collision cross section is then $Q = 2r\ l(n-1)$ or $\lambda_m = [2Nr\ l(n-1)]^{-1}$. This calculation neglects thermal motion by which the molecule may be orientated randomly to the electron path. It is also doubtful whether the molecular spacing should be taken as $2r$ in determining the collision cross section. The same cylindrical model is also used for branched-chain alkanes (by adjusting r to compensate for the reduction in l due to the side groups) and for the alkyl benzenes. In the latter case the benzene ring is not considered as an entity but is used to extend the length of the alkyl radical by including two carbon atoms of the ring as part of the radical. The remaining ring bonds and any side groups then influence r. Adherence to a cylindrical model does not seem justified in these cases.

Finally, Eq. [1] is used with C = 1, i.e., no account is taken of other mechanisms vital to the breakdown process. Neither the oxygen effect nor the lower strengths obtained with direct rather than pulse voltages can be accommodated in the criterion. There are, therefore, great difficulties in accepting the Adamczewski theory, but the close agreement with experimental values is intriguing and demands further study.

Conclusion

The discovery of the oxygen effect and the statistical concepts given in another contribution (7) should help greatly in separating cathode from liquid effects and in determining C in Eq. [1]. By employing oxygen and perhaps other additives in controlled amounts the basic processes should be capable of investigation. Further work is also required to clarify the orientation effect over a range of temperatures including the solid state. Permanently orientated molecules in the solid might show strong directional properties and higher strengths. In the meantime the present treatment using a simple model provides a consistent relationship between measured electric strengths and molecular structure of these hydrocarbons. Up to now the reported strengths of insulating oils have been lower than what might be expected by extrapolation from simple hydrocarbons of less complexity. Careful separation of the oil will not only indicate particular molecular species which lower the strength but also provide valuable information on the relationship between electric strength and molecular structure.

Manuscript received Nov. 2, 1959. This paper was prepared for delivery before the Philadelphia Meeting, May 3-7, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

A New Statistical Theory for the Breakdown of Liquid Hydrocarbons

B. W. Ward and T. J. Lewis

Electrical Engineering Department, Queen Mary College, London, England

ABSTRACT

Hitherto it has been accepted that breakdown under pulse conditions occurs in liquid hydrocarbons with an insignificant statistical time lag. Theories have been developed in which the whole of any time lag measured has been assigned to a formative time, but these theories are not at all satisfactory. The paper shows that (*a*) that a significant statistical time lag does in fact exist provided the experimental procedure is correctly interpreted and (*b*) that a proper statistical analysis of the previous pulse measurements together with a statistical theory of breakdown shows that these measurements provide clear evidence *for* rather than against, a statistical time lag. Experimental results are given to show how the statistical time lag depends on electric stress and on cathode conditions.

The electric strengths of pure simple hydrocarbons indicate the possible strengths for liquid dielectrics of more commercial interest and also provide data for the determination of the breakdown mechanism in liquids. Alkanes and certain aromatic hydrocarbons have received attention in this way, but, in spite of increasingly reliable experiments, no general theory for the whole breakdown process has emerged and many conflicting ideas exist.The present contribution has the aim of presenting a new statistical model for the breakdown process, and hypotheses, supported by experimental evidence, are advanced which will help to explain many of the apparent discrepancies.

Electric strengths have been measured with both continuous and short duration voltages, but here attention will be concentrated on the latter type of test. The liquids, of which n-hexane has been most frequently tested, are given preliminary chemical purification if necessary and then further cleaned in a closed system to remove water, ionic impurity, dust particles of size $> 1\mu$, and dissolved gas. However, as Sletten has shown recently (1), most results for n-hexane, at least, and probably for other hydrocarbons refer to liquids containing significant amounts of oxygen which raise and stabilize the strength. The oxygen in these cases must have come from the air during a final stage in the cleaning process or while being stored after cleaning. The test cell is frequently integral with the cleaning system and the electrodes are usually 1 cm diameter metal spheres at a spacing of less than $\sim 10^{-2}$ cm. Electrodes are highly polished and degreased beforehand and for the experiments reported here, were stainless steel.

With this preparation, the strength of n-hexane is in excess of 1.5 mv/cm for pulse voltages of 1.5 μ sec or less (2), and at this stress field emission of electrons from the cathode must be taking place and contributing significantly to the conductivity of the liquid. A typical plot of strength vs. pulse duration (3) is shown in Fig. 1. Any point is the mean of a set of measurements having a coefficient of variation of about 5%, and a measurement is made by applying successive pulses of constant duration and increasing amplitude until a breakdown occurs. A distinct change occurs for pulse lengths $< T_0$ and the times $T \leqq T_0$ have been considered to be a measure of the formative time of the breakdown process. If the

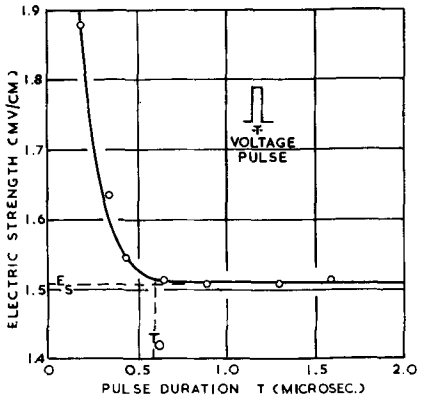

Fig. 1. Typical characteristics for a hydrocarbon liquid n-hexane (3).

pulse time T was greater than T_o, breakdown was considered to occur invariably at a time T_o provided the voltage was sufficient to cause a stress E_s (Fig. 1). This idea has been generally accepted (3, 4) and supported by statements that the statistical time lag was negligible, breakdown being easily initiated by ample electrons from the cathode (3-5). The times $T \leqq T_o$ have been related to the transit times of certain ions of mobility μ across the sphere gap d according to the law $T = d\ (\mu E)^{-1}$ (where E is the applied stress) and so compared with viscosity (4). This theory does not easily explain why the formative time should be influenced by the cathode material as observed, nor does it explain several discrepancies in published results (3-6).

There is also contrary evidence that the statistical time lag is not in fact zero from experiments using "step-function" pulse voltages in which the time lag to breakdown is measured directly for each voltage application. Strigel (7) using oil, and Saxe and Lewis (8) with n-hexane, have reported considerable random variations in the time lags even at stresses of 1.9 mv/cm. The work reported here confirms the existence of a statistical lag and also shows that it was almost certainly present in short-duration pulse experiments such as those leading to Fig. 1. By employing a statistical method, all these measurements become consistent and a physical interpretation is possible in which the roles of the liquid and cathode are clear. We begin by setting up a statistical model for the breakdown condition applicable to measurements with step-function and short duration pulse voltages.

Theory

The necessary assumptions for the model are (*a*) that electrons are ejected randomly from the cathode into the liquid with a mean rate I per second, and (*b*) that each electron has a probability W of initiating a breakdown process having a formative time t_f which is small. Cathode surface conditions will control I and liquid properties will determine W and t_f and all three quantities will be dependent on the field strength (see Fig. 2) and electrode geometry.

Step-function voltages.—If a step-function voltage is applied creating a mean stress E in the liquid, it may be shown [see (8) and references therein] that the probability of breakdown occurring within a

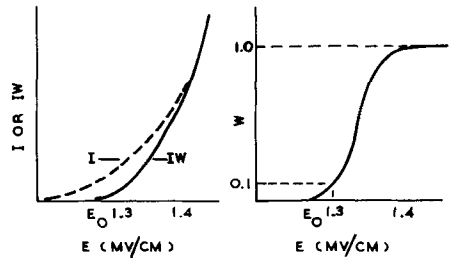

Fig. 2. I, W, and IW as functions of applied stress E. Values given are for a hypothetical liquid.

time interval t to $t + dt$ after the instant of voltage application is

$$P(E)\,dt = WI \exp\left[-WI(t - t_f)\right] dt \qquad [1]$$

From this the mean time lag before breakdown occurs, $\bar{t}$, is given by

$$\bar{t} = t_f + (WI)^{-1}$$

and the probability of a time lag $> t$ is exp $[-WI(t - t_f)]$. These expressions are valid for $t \geqq t_f$. Equation [1] shows that the shorter time lags are most probable and according to Fig. 2 there will be a threshold condition $E = E_o$, $W = 0$ below which P is zero. As the field strength increases, the mean time lag $\bar{t}$ will decrease in accordance with the field dependence of IW. Although the theory indicates that many time lags need to be measured to obtain an accurate estimate of P, experience has shown that reliable indications may be obtained from relatively few measurements.

Short-duration pulses.—The probability of breakdown occurring with a pulse duration T, producing a stress E is

$$p(E) = 1 - \exp\left[-IW(T - t_f)\right] \qquad [2]$$

which will be zero for $E < E_o$ and $T < t_f$ and will tend to unity as E increases. The usual procedure is to apply a succession of pulses of constant T and increasing magnitude in steps ΔE until a breakdown is recorded. If at each level of stress N pulses are applied, the probability of breakdown at a stress E_m is then, assuming $t_f = 0$ for the present,

$$P_m = 1 - (1 - p_m)^N = 1 - \exp\left[-I_m W_m T N\right] \qquad [3]$$

and the probability of a breakdown first occurring at a level E_n in any succession of pulses is

$$Q_n = Pn \prod_{m=0}^{n-1} (1 - P_m) \qquad [4]$$

The initial level corresponds to $m = 0$ and for most applications can be taken as E_o. Using Fig. 2, it is easy to show that Q_n increases from zero at E_o, passes through a maximum and then decreases as E_n becomes large; the exact form depending on IW.

For convenience in calculation it is better to transform to a continuous variable, replacing Q_n by $Q(E)dE$ which is defined as the probability of a first breakdown in the interval E to $E + dE$ and writing λ (instead of N) as the number of pulse applications in a unit interval of stress. It is found that

$$Q = \lambda p \exp\left[-\lambda \int_{E_0}^{E} p\, dE\right] \qquad [5]$$

The distribution Q need not be symmetrical since this depends on the form of IW. It will give a most probable breakdown stress E_p and an average stress E_{av} but unless asymmetry is great $E_p \sim E_{av}$.

The same model has been used for step-function and short duration voltages, but measurements might lead to very different conclusions in the same two cases. In the first, random time lags would be obvious immediately, but with the second Q might have little spread and E_p or E_{av} could be reasonably precise. Any fluctuations in this case might then be ascribed to extraneous influences rather than to the true breakdown process. It should be noted that E_0 will be the breakdown stress with continuous voltage and there will be a negligible chance of breakdown at this stress with pulses of microsecond duration. If the model is correct, measurements with either step-function or short duration voltages should yield information concerning the cathode and liquid function I and W. The most important result is that it gives an entirely different interpretation of the characteristic shown in Fig. 1 as will be demonstrated immediately.

Comparison with Experiment

As already mentioned, with E_p equal to 1.5 mv/cm or greater, the emission I is likely to be a field-aided thermionic process according to a Schottky law (9) which can be written as

$$I = B \exp\left(15\, E^{1/2}\right)$$

E is in mv/cm and B is a constant determined by the temperature and nature of the cathode surface. Other workers have proposed alternative field emission laws, but the exact nature is immaterial for the present argument since we require merely that I should increase rapidly with E. Making an arbitrary choice, $B = 0.01$, gives $I = 10^6$ electrons/sec for $E = 1.5$ mv/cm and using this with W for a hypothetical liquid, as in Fig. 2, in Eq. [2]-[5] it is possible to obtain Fig. 3. The formative time t_f has been neglected for ease in calculation, but it will be reintroduced below.

The agreement between the theoretical characteristic in Fig. 3 and the experimental one in Fig. 1 is striking. The parts AB and BC of the curve mainly depend on I and W, respectively, and the position of the curve on the axis of stress E_{av} may be shifted to conform with any specific liquid by adjustment of these. Adjustment on the T axis is not arbitrary however, and the discrepancy between Fig. 3 and Fig. 1 is due to the assumption $t_f = 0$ which causes the asymptotic value of T for large E_{av} to be zero in the theoretical case but not in the practical one. This can be rectified easily by including a nonzero t_f in the theoretical derivation.

The most significant result of the statistical theory is that the region of maximum curvature at B is not due to a formative time but is produced by the statistical requirements and the shape of the IW curve. Figure 3 also emphasizes that over the small range of T normally employed, the characteristic can appear to be independent of T in the range BC. Extrapolation to large T corresponding in the limit to tests with continuous voltage would yield a breakdown stress equal to E_0. It should be noted that for ethyl alcohol and water, a strong dependence on T has been found even when T was several microseconds (5).

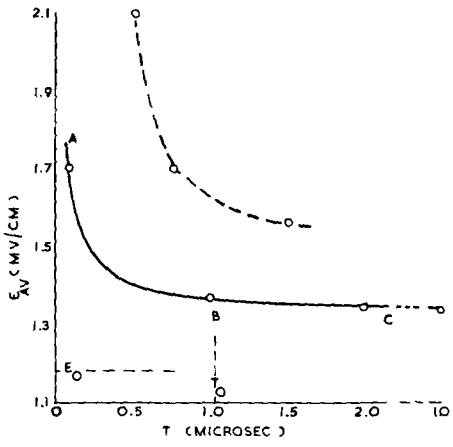

Fig. 3. Calculated breakdown stress E_{av} as a function of pulse duration for a hypothetical liquid. The region of maximum curvature at B is not due to a formative time which has been put equal to zero in the derivation.
- - - curve obtained from experiments on n-hexane similarly prepared to that employed for Fig. 4.

The procedure adopted has been to choose I and W and then derive the breakdown stress vs. pulse duration curve, but there is no reason why the procedure should not be changed and the experimental curve together with I used to determine W and t_f, for instance.

Direct support for the statistical model has recently been obtained in this laboratory. Using n-hexane and stainless steel spherical electrodes at

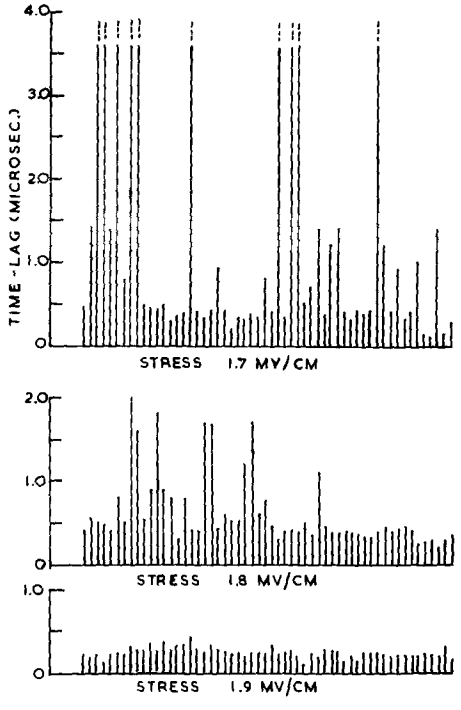

Fig. 4. Statistical time-lag sequences for n-hexane. Each vertical trace indicates the time lag for a particular step-function pulse. Electrodes were stainless steel with $d = 5 \times 10^{-3}$ cm.

a spacing of 5 x 10^{-3}cm, time lags have been measured directly using a "step-function" pulse having a front of 10^{-7} sec and lasting at maximum voltage for a time $> 10^{-4}$ sec. Time lags were recorded automatically using the technique of Saxe and Lewis (8). Figure 4 shows a series of these measurements. There is no doubt that the time lags are random and decrease in mean value as the stress is raised. At 1.7 mv/cm, lags well in excess of 3.5 μsec are recorded and even at 1.8 mv/cm lags greater than 1.5 μsec are not infrequent. These results give quite a different impression from that deduced formerly from short-duration pulses (2-6) under very similar experimental conditions. On the earlier theory, at a stress of 1.8 mv/cm, it would be considered that the time to breakdown could not exceed about 0.25 μsec, being due entirely to a formative process.

In order to confirm that Fig. 3 and 4 represent the same phenomena, measurements have been made on similar samples of n-hexane using short-duration rather than step-function voltages. All other conditions were identical. The pulses were produced by matched line techniques and increased in steps ΔE = 0.05 mv/cm with $N = 1$. Values of E_{av} obtained have been added to Fig. 3. The dependence on pulse duration is in general agreement with the theory and Fig. 1 and with other results (4, 5). The strength increases rapidly when the pulse duration is reduced sufficiently. Further comments concerning cathode influence on these results are given below. According to the theory, the distribution Q_n, (Eq. [4]), should shift to lower stresses when N is increased. To verify this, experiments were repeated with $N = 5$ instead of unity. The predicted shift occurred as the sample results in Table I indicate because if a procedure in which $N = 1$ had been adopted, all except measurement 4 and 5 would have resulted in higher breakdown stresses.

Thus, by comparing the theory with earlier work and by performing both types of test under otherwise identical conditions, it has been demonstrated that breakdown in n-hexane can be consistently described by the statistical model. It is inferred that the model will also be applicable to the other simple liquids tested. A few implications of this are now examined.

Discussion

Cathode effects.—According to the theory, cathode effects should predominate in the range AB (Fig. 3). Figure 5 reproduces measurements made by Crowe (3) with stainless-steel electrodes in n-hexane and other n-alkanes at two electrode spacings. Since all these liquids have common properties and the electrodes received a consistent preparation, it would be expected that the emission properties of the cathodes would be similar in all cases, i.e., that the characteristics would merge in the region AB. This is, in fact, seen to be the case in Fig. 5. Through W, liquid influences cause the curves to separate in the region BC. The differences found between the cathode regions in the experiments here (shown in Fig. 3) and those of Crowe and co-workers (2, 3, 6,) (Fig. 1) and other authors (4, 5) may be ascribed directly to differences in the emissive properties of the cathodes employed.

Table I. Influence of number of pulse applications on breakdown stress

	Breakdown measurement number							
	1	2	3	4	5	6	7	8
Breakdown stress, mv/cm	1.45	1.45	1.55	1.45	1.25	1.35	1.45	1.55
Number of pulse applications at the breakdown stress	4	5	2	1	1	2	4	2

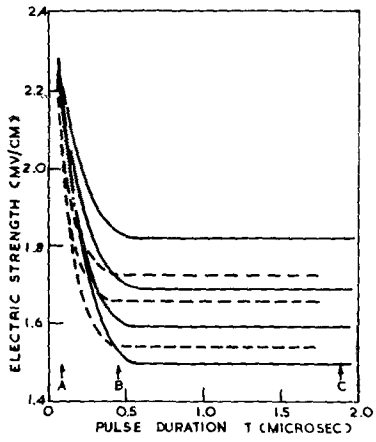

Fig. 5. Electric strength as a function of pulse duration according to Crowe (3). —— d = 6.35 x 10^{-3} cm; - - - d = 5.08 x 10^{-3} cm.

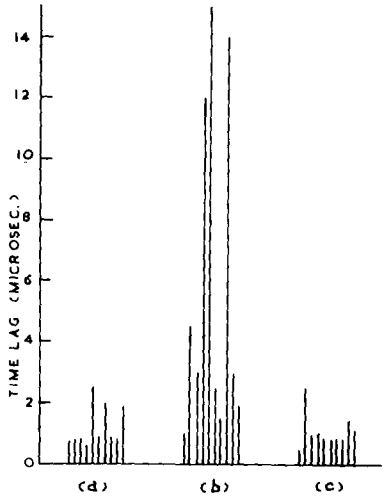

Fig. 6. Statistical time lags for n-hexane at a stress of 1.4 mv/cm, (a) and (c) roughened cathode, (b) polished cathode. Electrodes of stainless steel with d = 5 x 10^{-3} cm.

Conclusive evidence concerning the direct influence of the cathode on breakdown is shown by the time-lag measurements of Fig. 6. It is well known that an abraded metal cathode will exhibit considerably enhanced electron emission (10) and so should yield a much greater value of I than a normally polished one. Consequently, a pair of stainless steel electrodes were prepared, one being highly polished and the other roughened, and used to test n-hexane at a spacing of 5 x 10^{-3}cm. Measurements were made at a stress of 1.4 mv/cm; the polarity being reversed after every ten measurements. When the cathode was rough, time lags were short, but on reversal the

lags normally expected at that stress were obtained. A further reversal recovered the short lags once more. This experiment and others in which the degree of oxidation of the cathode was found to change the mean time lag clearly indicate the role of the cathode.

Liquid effects.—The W dependent region BC (Fig. 3) depends on the properties of the liquid and on the electrode spacing (3, 4) and thus from this region information pertaining to the breakdown mechanisms in the liquid phase may be found. Since formally T may be extended to very long times, liquid influence on pulse and continuous voltage measurements may be unified. These matters, together with the oxygen effect found by Sletten which does not alter the model proposed here, are discussed at length in a subsequent paper (11).

Formative time.—According to the statistical model, times $T < T_0$ are not measures of a true formative time t_f and even when t_f is zero (as assumed in Fig. 3) a finite T_0 exists. T_0 corresponds approximately to the stress at which W becomes unity and cathode conditions predominate but does not apparently have any further significance. The true formative time may be estimated at very high stresses from the experimental results because the statistical lag then tends to zero. Values estimated in this way from the work of Crowe as in Fig. 1 and 5 give t_f not greater than about 1×10^{-7} sec for a 5×10^{-3} cm gap. An estimate of similar magnitude may be made from the work of Edwards (5) and with certain reservations from that of Goodwin and Macfadyen (4). The time-lag measurements at 1.9 mv/cm, Fig. 4, also suggest a formative time not greater than 10^{-7} sec. This estimate is much less than those based on T_0 and helps to explain why certain discrepancies existed in earlier interpretations. For instance, Edwards found T_0 to be practically independent of the liquid but dependent on electrode separation in general agreement with Crowe and co-workers, whereas Goodwin and Macfadyen reported that T_0 increased with molecular chain length and viscosity. Goodwin and Macfadyen also found that the formative time as defined by them was influenced by the cathode material and thus difficult to explain.

If t_f is about 10^{-7} sec at a stress of 1.9 mv/cm and is ascribed to the transit time of a particle, the mobility is $\sim 3 \times 10^{-2}$ cm^2/v sec which is appreciably greater than ion mobilities measured at lower fields in these liquids by Adamczewski (12) although it is possible that the mobility will decrease as the stress decreases. Further investigations are required to determine t_f and ion and electron mobilities directly in the range above 1.5 mv/cm.

A fuller study of the nature of the statistical time lag is now being made which should permit the various cathode and liquid mechanisms to be understood in more detail. If the cathode influence is understood, greater progress can then be made in establishing a theory for breakdown in liquids comparable with that in gases. The statistical hypothesis should help greatly in achieving this.

Kinetics of the Oxidation of Antimony

A. J. Rosenberg A. A. Menna, and T. P. Turnbull

Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts

ABSTRACT

The oxidation of antimony has been studied between 265° and 385°C. The reaction is characterized by an initially parabolic growth rate, which degenerates into a time-independent rate, controlled by the gaseous diffusion of $(Sb_2O_3)_2$ from the surface region to the cold wall outside the sample furnace. The stationary rate decreases with increasing oxygen pressure and with increasing diffusion length. A compact layer of Sb_2O_3 forms on the antimony surface and supports a further overgrowth of Sb_2O_5. Kinetic data have been analyzed to obtain thermochemical parameters for the reaction which yields $(Sb_2O_3)_2(g)$ and agreement is obtained with known data for the equilibrium $2Sb_2O_3(s) \rightleftharpoons (Sb_2O_3)_2(g)$.

Several studies now in progress in these laboratories (1) deal with the oxidation of intermetallic compounds containing antimony as a principal element. To provide a suitable frame of reference, it has been necessary to examine the oxidation of elemental antimony itself. The present article is concerned with the kinetics of this reaction in the temperature range, 265°-385°C.

Experimental

Reaction rates were determined by following the oxygen pressure at constant volume. A thermistor manometer was used, permitting instantaneous pressure measurements in the range, 1-500 μ, with a precision of better than 0.1% (2).

Single crystals of 99.999+% antimony were used. Small wafers were cleaved normal to the (0001) direction, and this plane accounted for more than 75% of the exposed surfaces, which totaled 0.5 cm^2 per sample. The samples were cleaved in air and transferred directly to an 8 mm tube which was then connected to an adsorption apparatus of the type described earlier (2). A movable tube furnace which maintained the sample temperature to ± 1°C was then raised into position. Oxygen of spectroscopic purity was used throughout.

Results

Upon exposure to oxygen at 358°C, antimony reacts readily, but the rate rapidly decreases by two orders of magnitude and becomes constant (Fig. 1). During the reaction a yellow-white crystalline material deposits on the walls of the sample enclosure at the point where it leaves the furnace. The material can be displaced by raising the position of the furnace. It was established by both x-ray and electron diffraction that the entire deposit consists of senarmontite, the cubic form of Sb_2O_3 (3). If the oxygen in the sample chamber is evacuated during the experiment, Sb_2O_3 continues to evaporate from the sample. When this evolution ceases and oxygen is readmitted to the system, the kinetics of Fig. 1 are repeated.

If the sample is quenched during the reaction by removing the furnace, an irregular crystalline overgrowth, identified as Sb_2O_5 by electron diffraction,

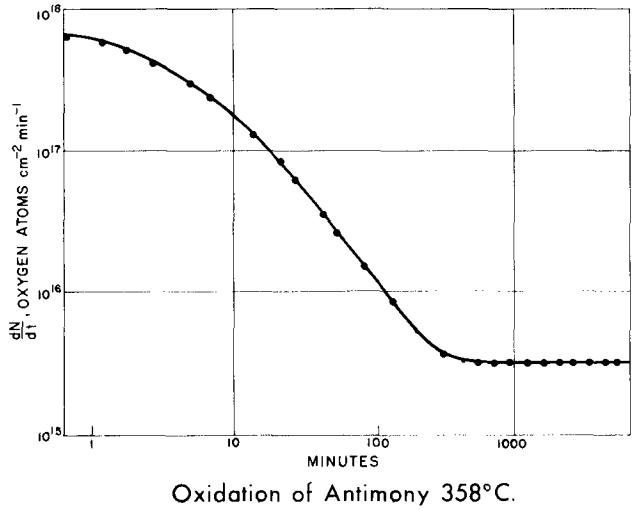

Fig. 1. Oxidation of antimony at 358°C. Oxygen pressure, 0.40-0.45 mm, surface area = 0.5 cm^2.

is observed on the surface of the sample. By sectioning the sample and scanning the exposed surface, it was further established by reflection electron diffraction that a layer of cubic Sb_2O_3 separates the Sb_2O_5 from the antimony substrate (Fig. 2).[1]

[1] Bound and Richards (4) observed the formation of senarmontite on antimony films heated in air above 250°C.

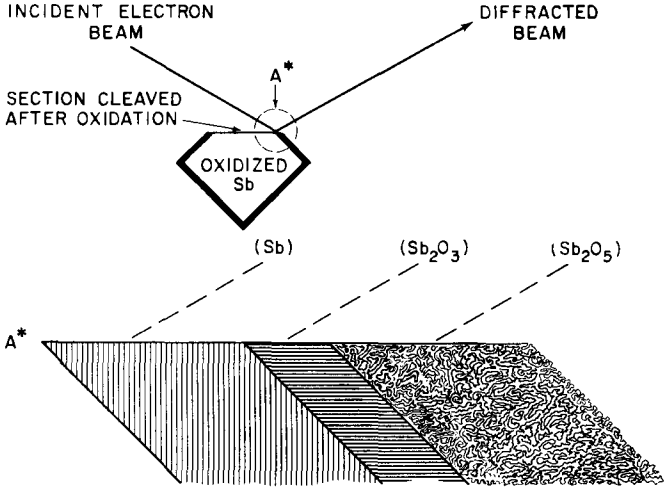

Fig. 2. Reflection electron diffraction by oxidized antimony

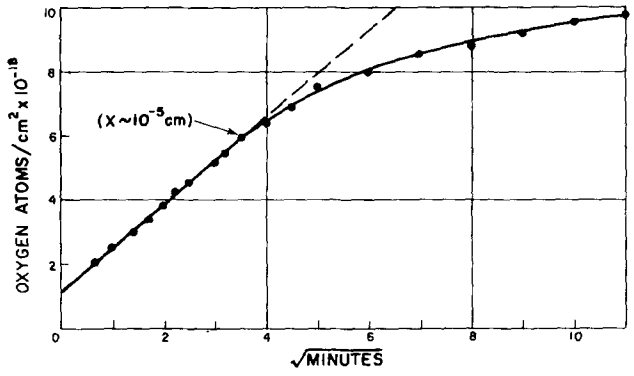

Fig. 3. Oxidation of antimony at 350°C. Oxygen pressure, 0.40-0.45 mm, surface area = 0.5 cm².

Clearly, the oxidation proceeds in at least two stages. The formation of an oxide film presumably controls the initial stage. Growth of the film requires that it be penetrated by either antimony or oxygen, so that the rate diminishes as the film thickens. Ideally, $dX/dt = kX^{-1}$ and $X = (2k)^{1/2} t^{1/2}$ where X is the film thickness, t is the reaction time, and k depends only on temperature and pressure. Figure 3 shows that the oxygen uptake does indeed increase linearly with $t^{1/2}$ during the first 15 min of reaction at 358°C. The rate then drops more rapidly than expected and approaches its stationary value.

When the steady state is attained the reaction rate is controlled by the distillation of Sb_2O_3 from the surface of the sample to the cold wall at the inlet to the sample enclosure. This is shown by two decisive results.

(i) The stationary rate varies inversely with the oxygen pressure, as shown in Table I. Accordingly, neither the primary oxidation reaction, nor the diffusion of oxygen or antimony through the oxide film, nor the diffusion of oxygen through the gas phase control the reaction since the rates of each should increase with pressure.[2] One may conclude, therefore, that oxygen acts by impeding the vapor phase diffusion of Sb_2O_3.

(ii) The stationary rate depends on the position of the sample in the furnace. Figure 4 shows that when the position of the sample relative to the top of the surrounding furnace is changed from 11 cm to 1.5 cm, the rate increases by almost an order of magnitude. Since the only effect of this manipulation is to shorten the gaseous diffusion path, the diffusion of Sb_2O_3 to the cold wall must control the rate.

[2] A chemical reaction of oxygen to inhibit vaporization of Sb_2O_3, e.g., through the equilibrium, $Sb_2O_3 + \frac{1}{2}O_2 = Sb_2O_4$ may also be disallowed since the negative pressure effect increases with increasing temperature in the range, 285°-360°C (Fig. 4). This would require that the inhibiting reaction be endothermic, and, since the entropy of any reaction which fixes gaseous oxygen is negative, the over-all free energy change would be positive.

Discussion

The high-temperature oxidation of antimony parallels that of germanium (5) in that the diffusion of a volatile oxide through the vapor phase leads to a stationary reaction velocity. In the case of germanium the volatile species is GeO; in the case of antimony, it is $(Sb_2O_3)_2$ (6). The rate at which $(Sb_2O_3)_2$ diffuses from a gas reservoir at concentration, C_o, can be estimated from kinetic theory. We shall follow the treatment given by Law and Meigs (5) for the diffusion of GeO. The rate is given by:

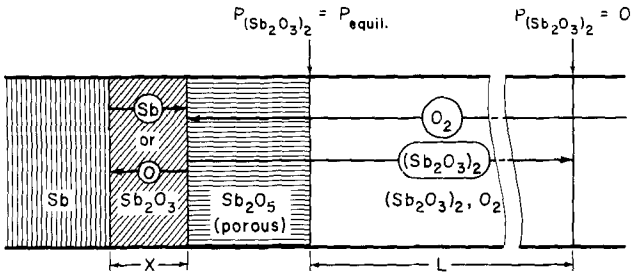
$$V = \frac{\lambda \Gamma C_o A}{\frac{\lambda \Gamma (L - \Delta)}{D} + 1} \qquad [1]$$

λ is the accommodation coefficient of $(Sb_2O_3)_2$ at the surface from which it arises; $\Gamma = (kT/2\pi m)^{1/2}$ where m is the molecular mass of $(Sb_2O_3)_2$; Δ is the mean free path in the vapor; L and A are the length and cross section of the path separating the reservoir from the cold wall where the pressure of $(Sb_2O_3)_2$ is virtually zero; D is the diffusion coefficient of $(Sb_2O_3)_2$ through oxygen. Ideally D should vary as $1/p_{O_2}$; in the present case, the dependence, while inverse, is not linear. For the present qualitative purposes we assume, as an approximation, that

$$D = D_o (T/273)^{1.75} (760/p_{O_2}) \qquad [2]$$

where D_o is estimated to be 0.04 cm^2/sec for $(Sb_2O_3)_2$ (5, 7).

Substituting $C_o = 1.0 \times 10^{18} PT^{-1}$ molecules/cc where P = pressure in mm of $(Sb_2O_3)_2$ in the reservoir, $\Gamma = 150T^{1/2}$ cm/sec, and $D = 1.7 \times 10^{-3} T^{1.75} p_{O_2}^{-1}$ cm^2/sec, Eq. [1] becomes



Model for High Temperature Oxidation of Antimony

Fig. 5. Model for the oxidation of antimony

$$V = \frac{1.5 \times 10^{20} \lambda A T^{-1/2} P}{9 \times 10^{4} \lambda (L = \Delta) p_{O_2} T^{-1.25} + 1} \quad [3]$$

$(Sb_2O_3)_2$ molecules/sec

Equation [3] is of the right form to account qualitatively for the negative effects of increasing p_{O_2} and L on the stationary oxidation rate. It is consistent, furthermore, with the fact that the relative effect of P_{O_2} increases with both T and L. Evaluating Eq. [3] at $L - \Delta \sim L = 11$ cm, $A = 0.5$ cm^2, $T = 600$°K, and $p_{O_2} = 0.05$ mm, we obtain

$$V\ (600°K) = \frac{3 \times 10^{15} \lambda P}{17\lambda + 1}\ (Sb_2O_3)_2 \text{ molecules/sec} \quad [4]$$

This is to equated to the rate of oxygen uptake by the sample, hence,

$$V(600°K) = \frac{1.1 \times 10^{21} \lambda P}{17\lambda + 1} \text{ oxygen atoms/min} \quad [5]$$

Since the effects of p_{O_2} and L are contained in the first term of the denominator of the rate expression, this term must be comparable with unity. Consistent with this qualitative calculation, we assume $17\lambda >> 1$ and obtain finally

$$V(600°K) \approx 6 \times 10^{18} P \text{ oxygen atoms/min} \quad [6]$$

The observed rate of oxygen uptake under these conditions (Fig. 5) is 5×10^{15} oxygen atoms/min, whence

$$P(600°K) \approx \frac{5 \times 10^{15}}{6 \times 10^{19}} = 8 \times 10^{-5} \text{ mm} \quad [7]$$

The purpose of this calculation is to decide whether $P = P_{equil.}$, where $P_{equil.}$ is the equilibrium vapor pressure of a plausible surface reaction yielding $(Sb_2O_3)_2(g)$. If this is the case, the standard free energy of the reaction will be given by $\Delta F° = -RT \ln(P/760)$, $= +19$ kcal/mole. The enthalpy of the reaction will be defined through Eq. [3], from which it is seen that

$$V \sim AT^{0.75} \sim BT^{0.75} \exp(-\Delta H/RT) \quad [8]$$
$$\sim C \exp(-\Delta H/RT)$$

where, C is constant for any small range of T. Thus the enthalpy corresponds approximately to the activation energy of the oxidation reaction. From Fig. 4 one obtains $\Delta H \approx +56$ kcal/mole in the range 270°-340°C for $p_{O_2} \sim 0.05$ mm, independent of L.

With the presence of $Sb_2O_3(s)$ and $Sb_2O_5(s)$ at the surface established by electron diffraction, the four reactions given in Table II must be considered as potential sources of $(Sb_2O_3)_2(g)$. The values of ΔH, $\Delta F°$, and $P_{equil.}$ for each reaction have been calculated from the data of Hincke (8), Simon and Thaler (9), and Coughlin (10). Reactions [1],[3], and [4] are inconsistent with the kinetic analysis, giving impossibly high or low values of $P_{equil.}$. Reaction [2], on the other hand, satisfactorily accounts for the predictions of both Eq. [7] and [8].

The results give compelling evidence that the vaporization of Sb_2O_3 goes to equilibrium in the region immediately surrounding the sample, yielding a regulated pressure of $(Sb_2O_3)_2$. Although Sb_2O_5 is the most stable oxide of antimony below 360°C, it does not participate in the equilibrium. Thus, the chemical interactions of $(Sb_2O_3)_2(g)$, $Sb_2O_5(s)$, and O_2 must be very slow compared to the over-all oxidation rate. This is consistent with the observations of many workers that the interconversions of the antimony oxides through the addition or loss of O_2 are extraordinarily slow reactions (9).

A model for the oxidation is illustrated in Fig. 5. The model assumes that the primary reaction of Sb + O_2 yields $Sb_2O_3(s)$ in an isothermal system below 350°C. Continued oxidation to Sb_2O_5 is much slower. A compact film of Sb_2O_3 forms at the surface and continued reaction of Sb requires that either Sb or O_2 diffuse through the film. The rate of oxidation thus decreases with $1/X$, as observed (Fig. 3). Simultaneously $(Sb_2O_3)_2$ evaporates from the surface of the film and escapes through the oxygen atmosphere to condense on the available cold wall. The rate at which it escapes is controlled by the difference between its pressure at the surface of the sample, P, and that at the wall. The latter is virtually zero, while the maximum value that P can have is $P_{equil.}$, the equilibrium vapor pressure above $Sb_2O_3(s)$. The Sb_2O_3 film thus will thicken to a point (about 10^{-5} cm) where the further diffusion of O_2 or Sb through it exactly matches the maximum rate at

Table II. Thermochemical parameters for formation of $(Sb_2O_3)_2$ vapor at 600°K, $p_{O_2} = 0.05$ mm, standard states $p_{O_2} = P_{(Sb_2O_3)_2} = 1$ atm

	Reaction	ΔH, kcal/mole	$\Delta F°$, kcal/mole	$P_{equil.}$, mm

which oxygen is removed from the sample as $(Sb_2O_3)_2(g)$.

When the rate of gaseous diffusion is altered through changes in $P_{equil.}$, D, or L, the rate of transfer of Sb or oxygen across the Sb_2O_3 film is altered identically by an adjustment of the film thickness. This is best illustrated by the transient effects which are observed when the pressure, hence D, is changed. When the pressure is raised, the rate of oxidation sharply increases before falling to the lower value characteristic of the higher pressure. Conversely, when the pressure is dropped, the rate only slowly rises to the higher stationary value.

While the reaction proceeds, Sb_2O_3 is slowly oxidized to the nonvolatile Sb_2O_5 which crystallizes as a porous overgrowth atop the Sb_2O_3 film. Its rate of formation is so small as to contribute only slightly to the over-all rate of oxygen uptake. Furthermore, it does not significantly impede the escape of $(Sb_2O_3)_2$ by either physical or chemical interaction. When the supply of fresh O_2 to the sample is interrupted, however, the Sb_2O_3 film will continue to evaporate. When it is exhausted the Sb_2O_5 will collapse on the antimony substrate and be dissipated through the reaction, $8Sb + 6Sb_2O_5 \rightarrow 5(Sb_2O_3)_2$.

The model accounts for the principal experimental features of the oxidation of antimony in the temperature range 265°-350°C. The shift in mechanism above this temperature (cf. Fig. 4) is probably related to the fact that the rate of oxidation of Sb_2O_3 to Sb_2O_4 becomes appreciable above 350°C (9).

Manuscript received Oct. 5, 1959. The work reported in this paper was performed by Lincoln Laboratory, a center for research operated by Massachusetts Institute of Technology with the joint support of the U. S. Army, Navy, and Air Force.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

CaS:Cu,Eu Electroluminescent Phosphors

A. Wachtel

Research Department, Westinghouse Electric Corporation, Bloomfield, New Jersey

ABSTRACT

Introduction of Cu into CaS:Eu does not interfere with the red Eu^{++} emission. Excitation of the blue CaS:Cu emission is more effective by 3650Å than by 2537Å. Firing with excess Cu gives rise to deposits of free Cu_2S which may cause an efficient system of contact electroluminescence. The electroluminescent properties depend on the physical characteristics of the phosphors, including its state of agglomeration. At moderate concentrations of Eu, the blue emission of CaS:Cu is entirely suppressed in electroluminescent excitation.

This investigation was performed as part of a program to study new electroluminescent (EL) phosphors with red emission. CaS:Eu was chosen for the following reasons:

1. The red emission of this phosphor (1-3) can be excited by contact-electroluminescence (4).
2. As in ZnS, Cu is an efficient activator of alkaline earth sulfides. Excess Cu_2S has been proposed as responsible for local field intensification in ZnS EL phosphors (4). Through the use of excess Cu, a system analogous, with respect to energy transfer, to ZnS:Cu,Mn was sought.
3. Other red-emitting alkaline-earth sulfide phosphors such as CaS:Ni (5), MgS:Mn (6, 7), and MgS:Sm (8, 9) were not considered as promising because of the high sensitivity to moisture of MgS and repeated failure on the part of the writer to reproduce the CaS:Ni phosphor. Some preliminary work indicated that BaS:Sb may show a weak red emission, while the orange-red emission of BaS:Cu (10) seemed to depend on the presence of oxygen and is yellow in pure BaS:Cu phosphors.

Experimental Technique

Preparation of Raw Materials

CaS.—Most of the phosphor preparation was performed with CaS prepared by reduction of $CaSO_4$ with H_2 at 1000°C (11, 12), followed by firing in dry H_2S (12). The $CaSO_4$ for this purpose was precipitated with reagent H_2SO_4 from hot $Ca(NO_3)_2$ solution, purified according to a previously reported procedure (13). The CaS thus obtained is very voluminous. Denser materials as obtained by firing of $CaCO_3$ or CaO in H_2S (14), either directly or after reaction with sulfur (15), were investigated only at a later stage of this project.

Fluxes.—The usual fluxes were generally available in sufficiently pure form either directly or in

the form of suitable precursors from which they could be prepared easily. Halides were often added as resublimed ammonium salts which are not hygroscopic and, on thermal decomposition during firing, readily react with CaS to form the corresponding calcium halide, while the NH_3 formed furnished a reducing atmosphere.

Europium.—A convenient dry addition of the necessarily small amounts of Eu consisted of drying a solution of 99.9% Eu_2O_3[1] in dilute HNO_3 slurried with a definite weight proportion of purified sulfur. Usually, a concentration of 5% Eu on S was employed. This form of Eu addition was considered more versatile than the well-known use of a definite flux as carrier of the activator. The presence of free sulfur during the first stages of firing was also considered advantageous from the standpoint of decreasing the reactive O_2 concentration in the interstices of the powder, which is otherwise difficult to replace by N_2.

Mixing.—The usual technique of mixing consisted of directing a gentle current of dry N_2 on the mortar. This enabled the handling of hygroscopic substances such as $CaBr_2$ or CaI_2, as well as minimized decomposition of CaS without resorting to the use of a dry box and its attendant inconveniences. Whenever desirable, the preparation of oxygen-free phosphors was accomplished most reliably by conducting at least the latter part of the firings in a current of dry H_2S.

Firing.—Firing was conducted in transparent silica tubes, 15 mm ID, 17 mm OD, 75 mm long, closed at one end and charged with 2-3 g of the powder such that an empty channel was present throughout the length of the tube. While this resembles the use of boats, it also enabled the simultaneous firing of more than one sample under identical conditions in cases where appreciable interaction through atmospheric convection was not anticipated. Purified N_2 at a flow rate of about 500 ml/min was used as a protective atmosphere. H_2S, where used,[2] was passed through dioctyl phthalate followed by Ba $(OH)_2$ solution, "Drierite" (anh. $CaSO_4$) and P_2O_5. The gas inlet tube for H_2S had an ID of ½ in. and was charged with granular CaS extending into the hot zone of the furnace. Gradual discoloration of this CaS showed that it absorbed residual heavy metal impurities as well as converting to H_2S any residual gaseous impurities (H_2O, HCl) by simple metathesis.

An alternate method of firing consisted of capping the silica tube with another tube also closed at one end, and whose ID is no more than 1-2 mm larger than the OD of the tube containing the phosphor. This arrangement effectively prevents spontaneous convection of the atmosphere over the phosphor with the surrounding N_2 and thereby minimizes losses of volatile components such as ammonium halides. For this reason, however, the atmosphere over the phosphor is not replaced by N_2 during the initial flushing and about 500 mg S is added to the charge to displace this atmosphere during the initial warm-up of the system. This method is hereafter referred to as firing in a sulfur atmosphere.

[2] Matheson "halogen-free" H_2S.

Measurements

It will be shown that the highly conducting nature of these phosphors introduced a considerable dependence of EL output on the resistance of the electrodes of the cell used for testing. Similarly, differences in conductivity between different phosphors were reflected in anomalous differences in EL output if such samples were operated simultaneously in a simple cell. It was therefore necessary to test each phosphor individually even at the expense of possibly imperfect reproduction of operating voltage and exact cell spacing. The power input with respect to the lateral dimension of the emitting area (25 mm diameter circle) was equalized by using an aluminized conducting glass of which only the necessary area of tin oxide was left uncovered. A 12 μ sheet of Mylar was laid on the conducting side of the glass by means of a thin film of castor oil. An oil-soaked paper spacer of about 110 μ thickness served to separate this from the solid Al electrode. Most measurements were performed with an applied voltage of 800 v at 10,000 cps.

All measurements were performed by means of a Spectra Brightness Spot Meter[3] which, except on rare occasions, was set on the "red" position to avoid any blue emission contributed by CaS:Cu. However, this was usually negligible.

The phosphor was screened through 200 mesh and mixed with castor oil in 1:1 weight proportion and placed between the cell electrodes. On application of the voltage, the EL output initially obtained tended to change due to simultaneous bridging (16) of the phosphor particles and decay of intrinsic EL. This resulted either in an initial increase followed by a decrease or a continuous decrease. In all cases, the maximum readings obtained were recorded.

General Conditions for Electroluminescence

Firing of CaS with Eu and more Cu than can be incorporated at a given halide concentration[4] results in discoloration due to formation of free Cu_2S and EL. Washing of the phosphor in alcoholic NaCN solution is possible without chemical decomposition other than removal of Cu_2S, but decreases EL.

In order to decrease the halide concentration present with Cu during firing and yet optimize the flux concentration with respect to enhancing the Eu emission, a two-stage procedure was found advantageous. A photoluminescent CaS:Eu phosphor is prepared, using the desired fluxes. The phosphor is slurried subsequently with anhydrous methanol containing the necessary amount of Cu as halide. Boiling causes deposition of the Cu as sulfide on the phosphor which is then washed with methanol until halide-free. After decanting, the phosphor is dried and refired either as is or with further additions. The refired phosphor is preferably again washed with methanol and then dried and screened.

The uniform deposition of Cu effected by this method is shown by almost complete disappearance of photoluminescence due to optical screening. Re-

[3] Photo Research Corp., Hollywood, Calif.

[4] Halide fluxes were usually preferred. As in ZnS, halides were noted to aid the incorporation of Cu in CaS (presumably as Cu^+) although this was not studied on a quantitative basis.

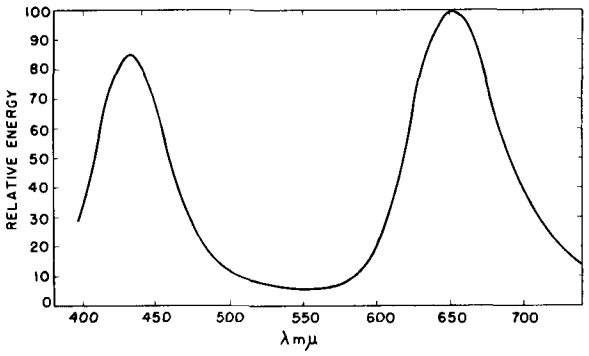

Fig. 1. Spectral distribution of 3650Å—excited emission of CoSi:Cu, Eu(0.01%) phosphor.

firing then causes a shrinkage of the precipitated layer into discrete particles of Cu_2S, and photoluminescence is restored. Electroluminescence shown at this point, when viewed through the magnification afforded by the Spectra-Meter, is seen to originate from discrete separated points which in the case of better specimens do not appear brighter but are more numerous.

Experimental Results

Photoluminescence

Introduction of Cu into CaS:Eu causes the well-known blue emission of CaS:Cu together with the red Eu^{++} emission. The Cu emission is well excited by 3650Å as shown in Fig. 1. The relative heights of the two peaks are incidental and depend on the Eu/Cu ratio and firing conditions. It is noteworthy that under 2537Å excitation, the Cu emission is largely suppressed in favor of stronger Eu emission. At low Eu concentration (0.01%),[5] the introduction of Cu, however, also enhances the otherwise weak 3650Å-excited Eu emission. This phenomenon may be analogous to the sensitized luminescence of CaS:Sm, Bi and CaS:Sm, Pb phosphors (17).

Introduction of Na^+ (and to a lesser extent Li^+) suppresses the red Eu^{++} emission. Because of the almost identical ionic sizes of Ca^{++} and Na^+, this phenomenon may well be regarded as charge compensation of substitutional Na^+ with Eu^{+++} which may thus be stabilized in the lattice. If this is so, then it tends to support Jaffe's (3) conclusion as to the divalent nature of Eu in alkaline earth sulfides. Heavier alkalies, if added as halides, do not have this effect, although the respective carbonates do.

At low Eu concentration, firing in H_2S also causes increased response to 3650Å excitation. Some of these observations are summarized in Table I which

[5] All percentages reported in this paper refer to mole or atom per cent.

shows measurements of the 6540Å peak height taken on excitation with two sources whose relative output was measured by the fluorescence of sodium salicylate. The figures refer to relative values normalized for equal number of quanta of incident 2537 and 3650Å radiation.[6] It should be mentioned that increased Eu concentration greatly increases the 3650Å-excited fluorescence, so that the low values of sample No. 4 in Table I are due to the effect of Na^+.

Effect of Phosphor Composition and Firing on EL

The effect of fluxes was investigated by firing CaS with 0.01 mole % Eu + 5 mole % flux at 1050°C in N_2 for 1 hr. The second firing was conducted with 1 mole % Cu for 20 min at 1050°C in N_2. Table II shows that $CaBr_2$ resulted in the brightest EL. CaI_2 suffers decomposition but yields similar results if used in larger quantity. The effect of alkali carbonates is the same as discussed in the previous section and, in addition, not even blue or green EL is observed. The brighter fluorescence of the green emission is probably only an effect of color. It appears to consist of a band peaked at 505 mμ as shown in Fig. 2 for a CaS:Cu,Eu,Na phosphor. Because of the halide-gettering effect of Na_2CO_3, this green center might consist of Cu^{++}. It may, however, also be identifiable with the green emission peaked at 495 mμ as obtained by Asano and Kishimoto (18) on 3CaS:$CaSO_4$:Cu,Na_2SO_4 phosphors, which these

[6] Under the simplified assumption of linear dependence of fluorescence on intensity of excitation.

authors ascribe to "CaS". The 10 mμ shift to longer wave lengths obtained here may be due to superposition of a portion of the Eu emission. Here again, 2537Å excitation tends to favor the excitation of the few Eu^{++} centers still present.

Figure 3 shows the result of increasing Eu concentration in similarly prepared phosphors fluxed with $CaBr_2$. The ratios of measurements taken through the different filters of the Spectra Meter show that, at low Eu concentration, there is an appreciable blue contribution of CaS:Cu. Spectral distribution measurements showed that in the neighborhood of maximum red output (0.04 mole % Eu) the blue emission is entirely absent. In Fig. 3, this can also be estimated by the leveling-off of the ratio curve whose residual height thereafter is a function of the response of the particular photometer to the Eu emission only.

The gradual disappearance of the blue CaS:Cu emission which occurs with increasing Eu concentration is analogous to the effect observed on introducing Mn into ZnS:Cu. Inasmuch as the red Eu emission is best excited by wave lengths much shorter than the Cu emission, one is probably not dealing with an optical cascade process. The same conclusion may be drawn from the strong excitability of the blue emission by 3650Å, alongside with the red Eu emission. The mechanism therefore involves sensitization as in ZnS:Cu,Mn (19) as well as many other doubly activated systems.

Inasmuch as the excess Cu_2S is thought to effect local field intensification, its particle size and distribution as well as the surface condition of the phosphor were considered to be critical. Figure 4 shows that this is probably affected by the refiring temperature in the presence of Cu which shows sharp optima with respect to EL output. Similarly, the prefiring temperature and amount of Cu added have a pronounced effect. This is shown in Table III. It will be noted that, with the exceptions of a few points showing what are believed to be accidental variations, the ratios of EL to fluorescence brightness tend to increase with increasing Cu addition and then level off in the neighborhood of maximum observed EL. This indicates that decreasing EL at higher Cu concentrations may be an optical effect due to darker body color.

It was generally noted that the parameters influencing EL output of this system appear to be more numerous than could be investigated within the scope of this study. Table IV gives a summary of some measurements taken on differently prepared phosphors. KBr as a flux was investigated because it resulted in particularly bright photoluminescent Eu emission (first firing), while $NH_4HB_4O_7$ has usually proven advantageous on EL if both firings are conducted in H_2S. It is now shown that either of these fluxes tended to reduce EL output, especially when used together.

An effort was made to shift the emission spectrum to shorter wave lengths and thus increase the visual output of these phosphors. This is known to occur upon partial substitution of Ca by Mg or Sr. In-

creased brightness was achieved, however, only on ultraviolet excitation. The substitutions generally introduced phosphorescence[7] and decreased or completely extinguished EL (20).

Additional attempts were made to optimize the nature of Cu_2S segregations. Of interest may be the effect of $CaBr_2$ or CaO in the second firing. This is shown in Fig. 5 and 6. In the case of $CaBr_2$, the effect was noted to depend on the use of H_2S and the sample size refired. Under optimum conditions, it may be postulated that partial incorporation of Cu^+ at the surface of the phosphor causes enhanced emission, while the particle size of the remaining Cu_2S is somewhat reduced. However, increased $CaBr_2$ retention (as in the case of large additions, N_2 refiring, or larger sample sizes) dissolves too much Cu. A particularly advantageous effect of the $CaBr_2$ at this stage consists of decreasing the fluxing action of the Cu_2S which is also well known in ZnS phosphors. The effect of CaO (Fig. 6) is of interest inasmuch as most if not all of this is converted to CaS during the firing in H_2S. The advantageous effect of low CaO addition, in this case, is therefore probably due to modified surface structure. Otherwise, it may be seen that oxygen in the finished phosphor is probably detrimental.

Effect of Physical Structure of CaS and Finished Phosphors on EL

A number of phosphors were prepared under conditions whereby the only variable consisted of CaS prepared by different methods and therefore differing in particle size and degree of agglomeration. Correlation of the results with microscopic examination of the phosphors showed that the highest brightness values were always obtained on phosphors consisting of thin, uniform, and fairly extended agglomerates, relatively free of fine background. No correlation of EL brightness with degree of crystallinity as obtained by x-ray powder diffraction patterns could be noted. Generally, the differences in EL output obtained here were as great as previously reported on as a result of varying phosphor composition and firing procedures. To illustrate this further, Table V shows four phosphors, each separated into two fractions 45-75 μ and <45 μ. It can be seen that the differences in EL output are considerable. Since the largest single crystals of phosphor rarely exceed 3 μ in size, it appears that the EL output of this system is a function of agglomeration.

Attempts to achieve this artifically were made by preparing phosphors from CaS derived from $CaCO_3$ or CaC_2O_4 of particle size up to 100 μ as obtained by

[7] The phosphorescence of CaS:Eu:$CaBr_2$ is quenched at Eu concentrations as low as 0.024 mole %. Most of the present phosphors were prepared with 0.04 mole % Eu.

3	1.2	0.26	4.6
4	1.0	0.33	3.0

homogenous precipitation with urea. These preparations were handled with sufficient care so as to avoid mechanical destruction of agglomerates whose outward shape remained, throughout all stages of preparation, that of the original crystals of $CaCO_3$ or CaC_2O_4. The EL output of these phosphors was, however, low and the dark body color suggested lack of penetration of the Cu beyond the outer surfaces of the agglomerates. Simultaneously prepared control phosphors obtained from finer CaS:Eu in which some agglomeration occurred during the second firing had a lighter body color and better EL performance.

Properties of CaS:Eu,Cu EL Phosphors

Chemical properties.—The chemical properties of the phosphors are essentially those of CaS, i.e., well-known. Slow decomposition as a result of exposure to atmospheric moisture has no noticeable effect on photoluminescence but does affect the EL. In connection with this, the effect of moisture absorbing additives was investigated. Table VI shows that the additives have an immediate detrimental effect. Its nature has not been determined.

EL properties.—Figure 7 and 8 show the voltage and frequency dependence of a typical phosphor. It can be seen that the voltage dependence is quite steep, possibly owing to the small intrinsic particle size of the phosphor (21). On the other hand, the frequency dependence is comparatively slight and better specimens can be excited to be readily visible at 60 cps. The luminous efficiency at 10,000 cps excitation of two phosphors is shown in Fig. 9. Under equal conditions of input (voltage and cell characteristics) the more efficient phosphor also consumed on the average 1.7 times as much power as the less efficient phosphor, i.e., was approximately 2.5 times brighter. The shape of the graphs suggests that maximum efficiency occurs at field strengths which are higher than can be achieved in practice. Somewhat similar but less reproducible results were obtained at 500 cps excitation.

Electrical properties.—As mentioned earlier, the conductivity of the CaS:Eu,Cu phosphor is very high compared to that of normal ZnS:Cu EL phosphors. Table VII shows the effect of electrode resistance on EL output of two phosphors. Under similar experimental conditions, no perceptible difference could be noted for the usual ZnS:Cu EL phosphor. Assuming a similar slope of log L vs. $V^{-1/2}$ as shown in Fig 7 and a voltage drop across the phosphor layer which is proportional to its effective resistance[8] under the particular conditions of cell operation, the respective resistances across the thickness of the 110 μ x 25 mm patch of phosphor suspension

[8] For simplicity, the calculation was made as for an ohmic resistance. Actually, the conductivity is purely an effect of ϕ, since an insulating layer of Mylar is used.

Table VI. Effect of moisture and additives on EL output

Additive	Time of exposure to 100% relative humidity 0	1 hr	20 hr
none	2.0	1.5	0.62
1% CaO	2.0	0.8	0.49
1% MgO	1.4	0.66	0.45

turn out to be about 1000 and 2000 ohms, respectively, i.e., very low values. Inasmuch as Fig. 9 suggests that a more conducting phosphor may also be more efficient (and much brighter) the difficulties in reproducible phosphor comparison with respect to different cell characteristics can readily be appreciated. It is for this reason that only values appearing within any one table or figure are comparative with each other.

Discussion

The observations made in this investigation suggest a model for the CaS:Eu,Cu EL phosphor consisting of a fine dispersion of Cu_2S particles in con-

Table VII. Effect of electrode resistance on EL output

tact with the surfaces of a red-emitting CaS:Eu,Cu phosphor. If the coated phosphor particles are agglomerated, there results increased EL output. The reason for this is not clear at present; however, one reason may be proposed on the grounds that penetration of the dielectric embedding material into the interior of the agglomerates may be poor, so that the bulk of the emitting material is subjected to greater than average field strengths. This would also explain the poorer performance of all systems in which the Cu_2S phase may be assumed to be in contact with the dielectric, i.e., either single crystal background or surface coated agglomerates.

The model is in some respects similar to the one proposed by Lehmann for ZnS:Cu EL phosphors (4) except that here one seems to be dealing with a more heterogeneous system. Phosphor formation in ZnS is associated with considerable crystal growth, and the formation of field intensifying disturbances is a process occuring during this growth and subject only to the over-all composition of the system and the firing procedure. In the present phosphor, however, there is little evidence of this, and special efforts must be made to obtain the desired physical structure by means other than relying on the usual (automatic) recrystallization process. It can, at present, only be estimated that at least one parameter responsible for high EL output should be identifiable with the concentration and state of dispersion of the Cu_2S phase on the surface of the CaS:Eu,Cu phosphor. Other parameters may be the crystallographic nature and electrical properties of the Cu_2S-CaS interface. It is probably in this respect that the comparison with ZnS:Cu EL phosphors breaks down, inasmuch as the brightness and efficiency obtainable in ZnS:Cu EL phosphors can only be explained in terms of highly specialized junctions.

The EL properties of CaS:Eu,Cu need not be regarded as an isolated case among alkaline-earth sulfides. Besides the blue-emitting CaS:Cu phosphor, yellow-emitting BaS:Cu EL phosphors were prepared successfully during preliminary phases of this study. Orange-red emitting $BaS:BaSO_4$:Cu (10) prepared with some nonincorporated Cu showed lower EL output, possibly due to presence of appreciable phosphorescence (deep traps). There is reason to believe that, under suitable conditions of preparation, any known semiconductor-type phosphor which may be coactivated by Cu may be amenable to similar treatment, provided that the phosphor tolerates the high activator concentration known to be advantageous for EL emission (22) and that deep traps can be reduced.

Summary

A method of obtaining EL in CaS:Eu has been presented, consisting of the introduction of Cu in concentrations greater than can be accommodated in the phosphor lattice. Among the various procedures tried, definite relationships have been found to exist between EL output and Cu concentration, firing temperatures and atmospheres, fluxes, and the physical nature of the raw material employed. The EL exhibited by this system appears to be a form of contact EL produced at more points than can be achieved by mechanical mixtures, and microscopic examination shows that the best specimens consist entirely of thin agglomerates of uniform size. In addition, it is visualized that the nature of the Cu_2S-CaS:Cu, Eu interface may influence the efficiency of EL produced at individual contact points. The parameters necessary to optimize this effect reproducibly are more numerous than could be investigated at present, and this difficulty is at least partially caused by the conductivity of the phosphor which influences its relative performance under slightly different conditions of excitation.

The absence of blue CaS:Cu emission shows that an energy transfer mechanism possibly analogous to that occurring in ZnS:Cu,Mn may take place. It is felt that the method can be adapted to other phosphors whose activator and trap distribution are such as not to interfere with the EL excitation process.

Acknowledgments

The writer is indebted to Miss I. Walinski for her aid in the performance of much of the experimental work, as well as to Mr. I. Meister and Drs. C. K. Lui-Wei, W. A. Thornton, and W. Lehmann for measurements. He also wishes to thank Professor E. Banks and Dr. W. Lehmann for helpful discussions and Dr. H. F. Ivey for reading and suggesting improvements in the original manuscript.

Manuscript received Aug. 27, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Influence of Crystal Size on the Spectral Response Limit of Evaporated PbTe and PbSe Photoconductive Cells

W. D. Lawson, F. A. Smith[1], and A. S. Young

Royal Radar Establishment, Malvern, England

ABSTRACT

Photoconductive layers of PbTe have been formed by evaporation on substrates at different temperatures. The size of crystals in the layers has been estimated from electron micrographs and x-ray diffraction, and a correspondence has been obtained between crystal size and the limit of spectral response. Sensitivity up to the long wave-length limit set by the energy gap is not achieved unless the crystals are greater than a critical size; for lead telluride this is about a quarter of a micron. A similar effect has been shown to occur with PbSe.

Photoconductive layers of PbTe are commonly prepared by an evaporation technique usually in a low pressure of oxygen, followed by a sensitizing heat treatment either *in vacuo* or in a low pressure of oxygen. PbS and PbSe cells can be made similarly, or the layers can be formed by chemical precipitation from solutions and this may or may not be followed by heat treatment. It is well known that the sensitivity and the spectral response of layers depend very markedly on the preparation process and on the subsequent heat treatment, and, although some very sensitive cells have been prepared, the processes employed are mainly empirical (1) and the precise effect of each stage in the treatment is not always clear. This note shows that the long wave-length limit of the spectral response of a layer is related to the size of the crystals in the layer and that full spectral response is not developed unless the crystals are of adequate size. Thus layers prepared initially with small crystals respond only to the shorter wave lengths and one effect of heat treatment is growth of the crystals with a corresponding extension of the response to longer wave lengths.

Preparation of Layers

The layers used in this investigation were all prepared by the evaporation technique described in detail by Young (2) for PbTe, in Dewar-type cell blanks fitted with sapphire windows. Powder from crushed single crystals was used as starting material and it was first evaporated onto the sapphire window of the cell blank in a good vacuum (10^{-6} mm Hg) and then transferred to the glass substrate which carried the electrode system, through a low pressure of oxygen (10^{-2} to 10^{-3} mm Hg). The thickness of the layers was about one micron and apart from the variables noted in Table I the conditions of preparation were as nearly identical as possible for all layers.

Measurement of Spectral Response

The measurements of spectral response were made using a Leiss double monochromator (3) fitted with sodium chloride prisms. The monochromatic radiation from the output slit was divided into two beams, one of which was deflected to the layer under test, the other to Hilger thermocouple. The path lengths of the two beams were made equal in order to eliminate the effects of atmospheric absorption.

The input radiation to the monochromator, from a Nernst filament source, was chopped at two frequencies by two independent rotating sectored disks. One frequency of 5 cps was suitable for the thermocouple response time, and the other of 800 cps was used in the photoconductive response circuit. The signal from the thermocouple, after amplification at 5 cps, was used in a servosystem to control the aperture of the input slit and so maintain a constant energy output from the monochromator over the wave-length range 1 to 7 microns.

The cell under test was connected through a series load resistor to a constant voltage source and the 800 cps signal developed was amplified in a tuned high-gain amplifier (4) and fed to a pen recorder.

[1] A.E.R.E., Harwell, England.

The wave-length scale on the chart was derived from calibration pips obtained from the monochromator prism drive. The response curves are reproduced as they were drawn by the recorder; the wave-length scale is not linear because the dispersion of the prisms is not linear with either prism drive or chart drive. The response scale is linear but arbitrary as we were not concerned in this study with absolute measurements of sensitivity.

The apparatus was arranged so that spectral responses could be monitored while the cells were being processed on the pumping system and all spectral responses were measured with the cells at 90°K.

Electron Microscope Examination of the Layers

At one micron the layers are too thick to be examined directly in a transmission electron microscope and replicas have to be used. Some photographs were taken in a reflection electron microscope, but they were difficult to interpret and the replica technique was found to be the best way of examining the structure of the layers. Preshadowed aluminum replicas about 250Å thick were used, prepared by first evaporating a layer of boric oxide onto the photoconductive layer, then the shadowing material, uranium or gold-palladium alloy at an angle of ~ 30°, and finally the aluminum layer evaporated from three directions simultaneously to ensure a continuous replica. The replicas were then floated off by immersing the specimen gently in water. The magnification of all the E. M. pictures is about 10,000 times; crystal sizes were measured from these photographs.

X-Ray Photographs

Back reflection x-ray Laue photographs of the layers were taken, with the front window of the cell removed, using radiation which consisted predominantly of the $K\alpha_1$ and $K\alpha_2$ lines of copper. A half-millimeter diameter collimator directed the beam on to the specimen, and the film-specimen spacing was 3 cm. Exposure times of 3-4 hr were required.

The x-ray photographs give an indication of crystal size (5) since the scattered beams from very small crystals are broadened and the broadening from crystals up to 300Å thick is sufficient to prevent resolution of the α doublet. Between 300Å and 1000Å broadening still occurs, but the doublet can be resolved and above 1000Å the doublet is fully resolved. Crystal sizes from 1000Å up to 10,000Å give continuous sharp diffraction rings, but above that there are insufficient orientations present in the irradiated region of the layer to give continuous rings which then begin to appear spotty.

Debye-Scherrer photographs taken on powder scraped from the layers confirmed that the material was PbTe with the same lattice spacing, 6.45Å, as the original crystals.

Results

Lead Telluride.—Figures 1 to 6 show x-ray and electron microscope photographs and measurements of spectral response at 90°K, obtained from a series of lead telluride layers prepared as described in

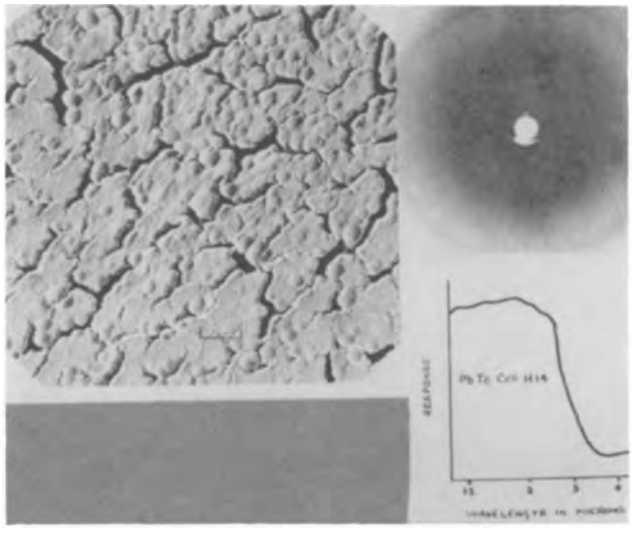

Fig. 1. PbTe cell H14 formed ot 90°K. Electron micrograph, x-ray Laue photograph, and spectral response.

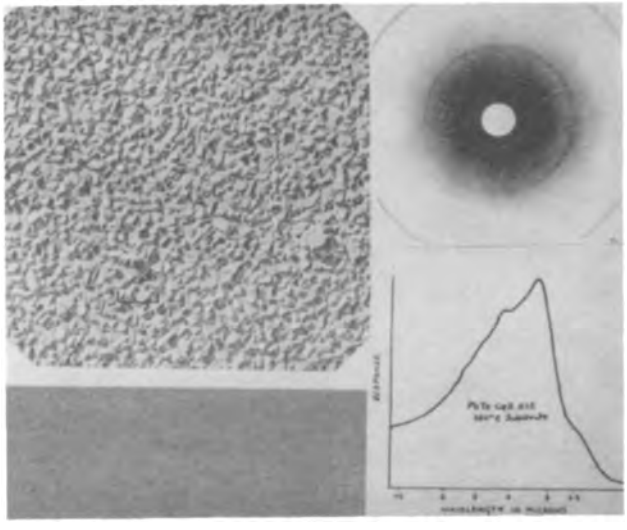

Fig. 5 PbTe cell H18 formed at 650°K. As Fig. 1

(2) but with the glass substrate held at different temperatures while the layers were being formed. Table I gives the substrate temperature at which each cell was formed and also the long wave-length limit of its photoconductive response and an estimate from the x-ray and electron micrographs of the mean size of the crystallites in the layer.

The oxygen pressure at which each layer was formed is also given in Table I, and it will be seen that the pressure has been increased with substrate temperature. This increase was found to be necessary in order to obtain a reasonable sensitivity in each layer, but we found that oxygen pressure by itself had no influence on the limit of response. The precise role of oxygen in the sensitizing process is not discussed in this paper. Jones (6) has shown in experiments on the oxidation of lead selenide that the amount of oxygen taken up in the sensitizing process is small (<2%).

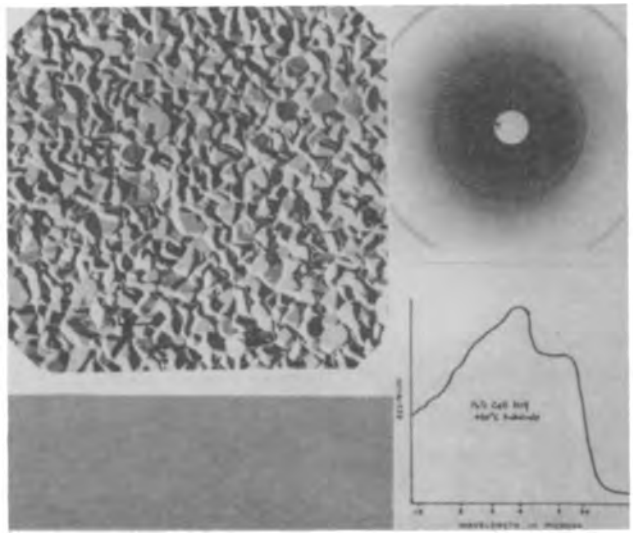

Fig. 6. PbTe cell H19 formed at 720°K. As Fig. 1

From absorption measurements on single crystals (7) lead telluride should give a photoconductive response at 90°K extending to 5.8μ on the long wave-length side, assuming correspondence between absorption and photoconductivity. It will be seen from Fig. 1-6 that the full spectral response is obtained only from layers formed on the hotter substrates and the limit of response in layers formed on the colder substrates occurs at shorter wave lengths. The reason becomes apparent from the electron micrographs. These show a progressive increase in crystallite size with increasing substrate temperature, as might be expected, and it is only those layers which have crystallites of adequate size which exhibit the full spectral response out to 5.8μ. The critical size is between a quarter and a half a micron; crystals smaller than that are apparently unable to absorb the longer wave-length radiation and the spectral response is limited correspondingly. This explanation is confirmed by the discrepancy between the measured absorption of layers (8) and single crystals (7). The layers gave an absorption edge at about 2μ (measured at 290°K), whereas the absorption edge of single crystals at the same temperature occurs at 4.5μ. The absorption edge of single crystals varies very little

[+] Before the layer had warmed up to room temperature.

with deviations from stoichiometry or with the state of strain of the crystal. The conditions of preparation of the layers in reference (8) are not given, so a comparison of their properties with ours is not possible.

The response of cell H18 formed at 650°K goes out as far as that of cell H19 formed at 720°K, but in the latter cell high sensitivity is maintained right out to 5.5μ whereas in H18 the sensitivity falls rapidly beyond 4.5μ. This again can be attributed to the difference in crystal size. An apparent anomaly occurs in the response of cell H14, prepared at 90°K, which goes to a slightly longer wave length than H22, formed at 193°K. These responses were, however, measured after each cell had been allowed to warm up to room temperature, cell H14 for a longer time than H22. Some increase in crystal size may occur at room temperature so that spectral responses measured after warming up are not truly characteristic of the temperature of formation. This is consistent with the result in Fig. 7 which shows the response curve of cell H14 taken immediately after the layer was formed at 90°K and before it had been allowed to warm up at all; the limit of response occurs at an even shorter wave length, 2.5μ. It was not possible to measure the characteristic crystal size corresponding to 90°K as an x-ray or replica could not be taken without letting the layer come to room temperature, but the result can again be explained in terms of crystal size since it is likely that the layer formed at very low temperature consists of very small crystals.

The response of H14 after a further anneal at 620°K is shown in Fig. 8 together with the x-ray and electron photographs. The doublet in the Laue diagram is now distinctly resolved, c.f. Fig. 1 showing that the crystals have grown and this is confirmed in the electron micrograph. The limit of photoconductive response has now moved out to about 5.8μ and sensitivity is well maintained to nearly 5.5μ.

The physical appearance of the layers in Fig. 1, 2, and 8 is characteristic of layers which are formed on substrates below room temperature. It is likely that the cracks develop through differential expansion during the period of warming up to room temperature.

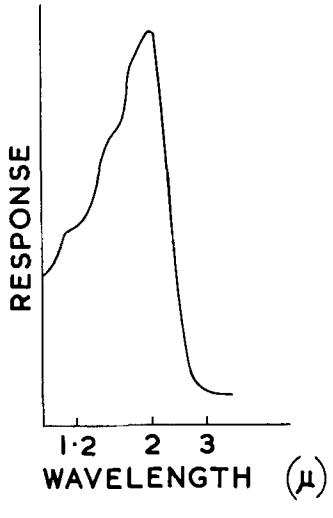

Fig. 7. Spectral response of PbTe cell H14 measured immediately after formation.

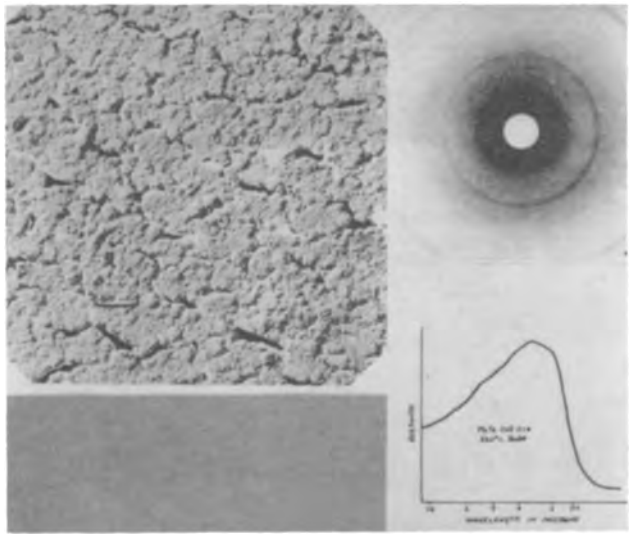

Fig. 8. Electron micrograph, x-ray Laue photograph, and spectral response of PbTe cell H14 after anneal at 620°K.

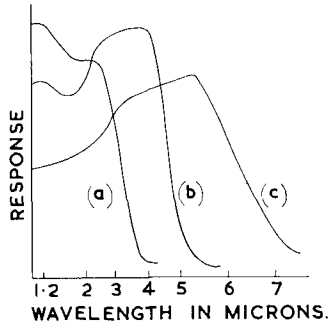

Fig. 9. Spectral responses of PbSe cells baked at different temperatures. (a) Cell H1 left at room temperature; (b) cell H3 baked at 420°K; (c) cell H8 baked at 570°K.

Lead selenide.—Lead selenide layers prepared in the same way by evaporation give similar results, and the dependence of spectral response on crystal size again occurs. The results are not given here in detail but Fig. 9 shows how the limit of response can be moved to longer wave lengths. Cell H1 was formed on a cooled substrate at 90°K through an oxygen pressure of 10^{-2} mm Hg, it was allowed to warm up to room temperature, and its response was measured (at 90°K) some time later. The response ends at about 3.5μ. Cell H3 was prepared similarly and subsequently baked *in vacuo* (10^{-6} mm Hg) at 420°K; its response extends to about 5.2μ. Cell H8 was baked instead to 570°K with a corresponding extension of response to about 7μ, the same as the limit at 90°K in single crystals (9). X-ray and electron micrographs of these layers again showed a gradual increase in crystal size with the temperature of the heat treatment.

Conclusion

The long wave-length limits of photoconductive response and absorption of evaporated layers of PbSe and PbTe are related to the size of the crystallites in the layer. By controlling crystallite size the response or the absorption of a layer can be made to terminate at any wave length up to the

limit fixed by the energy gap of the compound. Thus infrared filters and selective narrow-band filter-detector combinations can be constructed to operate anywhere within the spectral range of the material.

Acknowledgments

The authors are indebted to Miss A. E. Rennie for taking the x-ray photographs, Mr. A. A. Brooker for assistance with the preparation of cells, and Dr. C. S. Lees for helpful discussions on the electron microscope study. The paper is published by permission of the Controller, H. M. Stationery Office.

Manuscript received Sept. 9, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Relation of Some Surface Chemical Properties of Zinc Silicate Phosphor to its Behavior in Fluorescent Lamps

D. E. Harrison[1]

Luminescent Materials Laboratories, Lamp Metals and Components Department, General Electric Company, Cleveland, Ohio

ABSTRACT

The importance of the surface properties of zinc silicate phosphor to fluorescent brightness and lumen maintenance has been demonstrated. A phenomenological theory is developed which accounts qualitatively for some of the changes that occur during lamp burning. Inherent in this theory is the concept of a high-temperature surface phase which is a part of the zinc silicate crystal. The surface phase may be retained at room temperature by rapid quenching, but if the phosphor is cooled slowly the surface phase dissociates, probably into its constituent oxides. As a result Mn^{2+} can be oxidized, and Zn^{2+} can be reduced either by vacuum firing or by photolysis by u.v. light. Metallic zinc is produced as a consequence of lamp burning and it amalgamates with mercury. The zinc atoms on the phosphor surface act as vapor traps for mercury and cause it to distribute itself over the surface, probably as tiny droplets. The oxidation of Mn^{2+} and the reduction of Zn^{2+} can be prevented by formation of a protective layer on the phosphor surface, e. g. $ZnSb_2O_6$. It is thought that the surface properties of zinc silicate phosphor, particularly those which affect the extent and perfection of a protective coating, greatly influence the quality of lamps produced by identical procedures.

Zinc orthosilicate activated by manganese is a phosphor which has been the subject of numerous investigations (1-5). In addition to the usual green luminescent form, red and yellow phosphors have been prepared (6-9). The green luminescent form is of value as a lamp phosphor. Unfortunately however, when it is used in fluorescent lamps it exhibits poor maintenance. Lowry (10) showed that the maintenance could be improved substantially by the addition of small amounts of Sb_2O_3 to the phosphor; the best results were observed when the addition was made to the coating suspension. Merrill and Davis (11) demonstrated similar results by incorporation of small amounts of As plus Pb in the phosphor matrix during synthesis.

The practical advantages of Sb_2O_3 additions have been used for many years, but nevertheless seemingly identical phosphor preparations and lamp-making procedures yield different lamp results.

The subject is treated as a summarization of observations which seem pertinent to an understanding of the zinc silicate phosphor. Phase studies are considered to show that under equilibrium conditions phosphor compositions consist essentially of $(Zn, Mn)_2SiO_4$ plus SiO_2. The effects of the ZnO/SiO_2 ratio and phosphor synthesis temperature on lumen output are shown. Some of the surface chemical properties of zinc silicate phosphor are given, and evidence is presented for changes in the crystallographic structure of the surface. Finally a phenomenological mechanism of fluorescent deterioration of zinc silicate phosphors in fluorescent lamps is given.

Experimental Procedure

Raw materials used where silicic acid prepared by hydrolysis of tetraethylorthosilicate, New Jersey Zinc Company USP grade ZnO, Mallinckrodt reagent grade $MnCO_3$, Sb_2O_3, As_2O_5, $(NH_4)_2HPO_4$, SnO_2, TiO_2 H_3BO_3, and Reynolds $Al_2O_3xH_2O$. Compositions were mixed in a mortar with acetone until dry. Calcines were prepared in fused silica crucibles at temperatures ranging from 1200° to 1300°C. Heat treatments were done in silicon carbide electric resistance furnaces and platinum-wound resistance furnaces.

[1] Present address: Metallurgy Department, Research Laboratories, Westinghouse Electric Corp., Pittsburgh, Pa.

The *p*H values of water suspensions of zinc silicate phosphor were measured in the following manner: 60 ml of distilled water were adjusted to a *p*H of 6.0 by absorption of a small amount of CO_2. One gram of phosphor was added to the water and the mixture was stirred sufficiently to maintain the phosphor in suspension. The polyethylene beaker which contained the suspension was covered and a stream of nitrogen was passed over the cover in order to prevent CO_2 from diffusing in around the electrodes and stirrer. Measurements were obtained by means of a Beckman glass electrode *p*H meter. Results were reproducible to ± 0.05 *p*H units.

Lumen data were obtained from 40-w fluorescent lamps using standard lamp-making and photometry procedures.

Results and Discussion

Phase Studies

The system ZnO-SiO_2 was investigated by Bunting (12) who reported that Zn_2SiO_4 is the only compound which exists in the binary system. The absence of a metasilicate is surprising, for this compound is found in other systems of the type RO-SiO_2 where RO = CaO, MgO, SrO, BaO, or MnO. Leverenz (13) postulated the existence of a deficiency structure between the ortho-and meta-silicate compositions. This opinion was based on observations from x-ray studies that no new phases appeared with ZnO/SiO_2 ratios between the ortho-and meta-silicate compositions and that the Zn_2SiO_4 pattern remained unchanged when mixtures were prepared from ZnO and silicic acid.

Re-examination of the system confirmed the earlier results of Bunting that $ZnSiO_3$ does not exist. Microscopic and x-ray examination of compositions between Zn_2SiO_4 and SiO_2 (introduced as silicic acid) revealed that the silica is very reluctant to form a crystalline modification even on prolonged heating and that it does not occur as isolated particles but rather it appears to form a "cocoon" around the Zn_2SiO_4 crystals. X-ray and microscopic data show no evidence of solid solution between Zn_2SiO_4 and SiO_2.

Studies in the system ZnO-MnO-SiO_2 (14) showed that there is a binary join between Zn_2SiO_4 and $MnSiO_3$ and that $MnSiO_3$ is soluble in Zn_2SiO_4 in excess of 10 mole % at 1300°C, which is more than twice the amount of manganese normally used as an activator. Since there appears to be no solubility of SiO_2 in either Zn_2SiO_4 or $(Zn,Mn)_2SiO_4$, phosphor compositions can be regarded as essentially a two-phase system of $(Zn,Mn)_2SiO_4$ plus SiO_2.

In order to investigate the effects of the ZnO/SiO_2 ratio and synthesis temperature of the phosphor on lamp performance, the following synthesis technique was used: over-all compositions with the desired ZnO/SiO_2 ratios were prepared at 1200°-1250°C from ZnO plus silicic acid. The required amount of manganese was introduced as the carbonate in a second firing at either 1200°, 1250°, or 1300°C. This procedure yields a wide range of phosphor compositions which have high powder brightness. If $ZnO + SiO_2 + MnO$ initially are fired together, a firing temperature of 1300°C is required to develop full brightness unless a flux is used.

Zinc silicate phosphor is excited by 2537Å or 3650Å radiation but the response to 3650 develops after firing the phosphor at higher temperatures than are required for good response to 2537. This effect was demonstrated by thermal gradient firings in air. Zinc orthosilicate was prepared at 1200°C/4 hr. To this material was added the necessary amount of $MnCO_3$ and the mixture was fired in a thermal gradient furnace in the temperature range from 600° to 1350°C. At 1200°C the phosphor had 95% of the maximum fluorescent brightness observed when excited by 2537, but it had practically no response to 3650. 1220°C increased the response both to 2537 and 3650. The maximum brightness under 2537 was obtained between 1250° and 1300°, but at 1350°C there was marked sintering and a decrease in brightness. In contrast, the brightness under 3650 increased in a uniform manner from 1250° to 1350°C.

Relation of Phosphor Preparation to Lumen Output

The effect of various ZnO/SiO_2 ratios on lamp performance is given in Fig. 1. Test phosphors were prepared by first forming zinc silicate at 1200°C and then introducing the required amount of manganese in a second firing at 1200°C. A control phosphor was prepared by firing together $ZnO + MnO + SiO_2$ at 1300°C using a ZnO/SiO_2 ratio of 1.7/1.0. In all tests an addition of 0.1 wt % Sb_2O_3 was made to the phosphor coating suspension. A line on the ordinate opposite the ZnO/SiO_2 ratio indicates the spread in lumen values obtained from a seven lamp test at zero hours. The two curves shown per test represent the extremes per variation, as measured during the time of the test. The data show that a phosphor with a mole ratio of 1.9/1.0 is comparable in lumen performance to one with a ratio of 1.5/1.0, whereas a phosphor with a ratio of 1.7/1.0 is substantially better. By some means a certain excess of silica gives an improvement in lumen output, but too large an excess cancels the initial gain. Since silicic acid in contact with $(Zn, Mn)_2SiO_4$ is reluctant to form a crystalline modification even on prolonged heating, too large an excess of silica may have a deleterious effect on lamp performance as a result of carrying water into the lamp. However, the fact that some sort of surface protection is required strongly suggests that the surface properties of zinc silicate itself may be an important factor in phosphor depreciation.

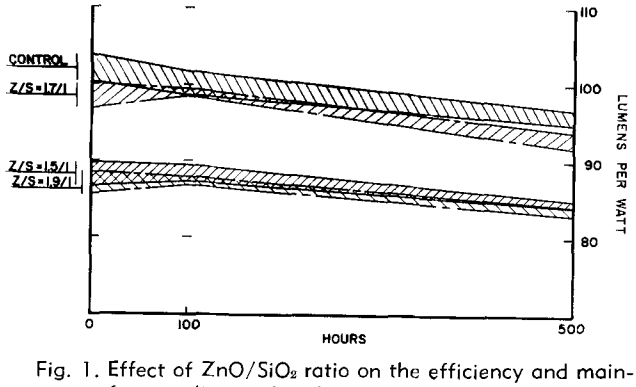

Fig. 1. Effect of ZnO/SiO_2 ratio on the efficiency and maintenance of zinc silicate phosphors.

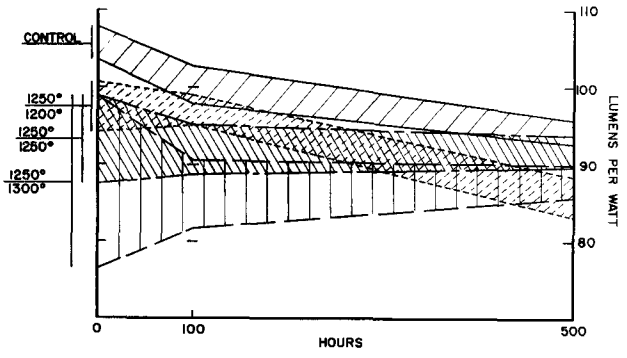

Fig. 2. Effect of firing temperature on the efficiency and maintenance of zinc silicate phosphors.

Further evidence of the possible effect of surface properties was given by the following test: zinc silicate was formed at 1250°C; the required amount of manganese was introduced in a second firing at either 1200°, 1250°, or 1300°C to yield compositions low in free silica, i.e., $(Zn_{0.90}Mn_{0.05})_2SiO_4$. Lamps were prepared from each of the three test lots; results are shown in Fig. 2. The lines on the ordinate opposite the firing temperatures and the two curves per test have the same meaning as in Fig. 1. It is seen that the spread within each group increases as the second firing temperature increases. As lamp burning progresses, changes occur which tend to minimize the differences initially present. Evidently higher firing temperatures produce changes in the phosphor which make it more susceptible to lamp making variables.

Evidence for the Formation of a Surface Phase

The suspicion that a surface alteration does occur in zinc silicate phosphor during synthesis is confirmed by comparison of x-ray and electron diffraction data. These data, which are listed in Table I, were obtained from a sample with a molar composition of $(Zn_{0.90}Mn_{0.05})_2SiO_4$ and fired three times at 1250°C/3 hr. The first column lists "*d*" values obtained from x-ray data which reflect the arrangement of atoms in the interior of the crystal. The fourth column lists "*d*" values calculated from electron diffraction data which gives the arrangement of atoms on the surface. Comparison of the two sets of "*d*" values shows that there is a shift in lattice spacing between the surface and interior of the crystal.

The surface phase cannot be accounted for by an accumulation of either ZnO, MnO, Mn_2O_3, Mn_3O_4, $ZnMn_2O_4$, or any of the crystalline modifications of SiO_2. Therefore, it appears that a distinct new phase develops on the surface of $(Zn,Mn)_2SiO_4$.

Zinc silicate phosphor can fluoresce either green, yellow, or red, or a combination of these colors depending on the method of preparation. As was mentioned earlier, zinc silicate phosphor develops a response to 3650Å excitation when fired at temperatures higher than about 1200°C. Since the green emission under 3650Å is the same as that under 2537Å, it appears that the development of a surface phase serves to introduce new absorption centers but not different types of luminescent centers. Comparison of the x-ray data of yellow luminescent powders studied by Rooksby and McKeag (7) and Pfeiffer and Fonda (8), respectively, and of yellow and yellow-green luminescent films examined by Feldman and O'Hara (9) showed no correlation with the surface phase postulated in the present study. The red fluorescent form is in a vitreous state as shown by Pfeiffer and Fonda.

Closely related to the phenacite structure of zinc orthosilicate is the spinel arrangement. The oxygen atoms in spinel are in a face-centered cubic order. The "*d*" spacings of a face-centered cubic structure were calculated on the basis of the strongest line observed in the electron diffraction data. The last column in Table I lists the calculated "*d*" values. There appears to be a reasonable fit between the calculated values and the "*d*" values obtained from electron diffraction data, particularly with the smaller "*d*" spacings. The data show that a surface rearrangement has occurred and that it seems to be a spinel-like structure.

The phenacite and spinel structures of A_2BO_4 compounds are similar enough that, in some cases, an increase in temperature can cause a phase transition. For example, Li_2SO_4 and Li_2MoO_4 are dimorphic with low-temperature phenacite and high-temperature spinel structures. Since bulk Zn_2SiO_4 does not have a spinel modification, and since, in general, reconstructive inversions show positive volume changes in the direction of increasing temperature, a spinel modification of zinc silicate could be expected to be stable at the surface of the crystal at temperatures nearer the melting point, e.g., 1200°-1300°C. Therefore, at some lower temperature, the postulated surface phase will become unstable and should ideally invert back to the phenacite arrangement. As will be developed later, it appears unlikely that a simple inversion occurs but rather that the surface phase dissociates into its constituent oxides.

Differential thermal analysis data seem to fit this general scheme: DTA curves of previously formed zinc silicate phosphors showed a small but reproducible exothermic effect on heating, beginning at about 1250° and exhibiting a broad maximum in the region of 1320°C. No heat effects were observed during cooling. High-temperature x-ray analysis by Hummel (15) demonstrated that the thermal effect is not the result of a "bulk" crystallographic

inversion. Since the phosphor was originally furnace-cooled from about 1250°C, a stable high-temperature surface phase has had an opportunity to invert to a low-temperature modification or to dissociate. The exothermic effect at 1250°C on reheating suggests a recombination reaction of the dissociated products of the high-temperature surface phase. If there were a simple crystallographic inversion, an endothermic rather than an exothermic effect would be expected. The sluggishness of a dissociation or inversion could prevent the appearance of any distinct thermal effects on cooling.

A rough estimate of the thickness of the surface layer can be made by comparing the patterns obtained by x-ray and electron diffraction techniques. For ionic crystals, the depth of electron penetration is of the order of 10Å (16), whereas, oxide films several hundred angstroms in thickness have insufficient volumes to produce x-ray lines. Since the x-ray pattern did not show even diffuse lines corresponding to the electron diffraction data, the surface phase may be from about ten to several hundred angstroms in thickness. A surface film with this order of volume could conceivably produce the thermal effect detected by DTA.

Some Surface Chemical Properties of Zinc Silicate Phosphor

Differences in the surface properties of the phosphor are reflected in measurements of *p*H and oxidizing potential. The data are shown in Fig. 3. Zinc orthosilicate, free of manganese, has a *p*H of about 6.80 and, of course, no oxidizing potential as evidenced by organic indicators such as benzidine (17). When the previously formed zinc silicate was activated by manganese to yield the composition $(Zn_{0.90}Mn_{0.50})_2SiO_4$, fired at 1250°C/4 hr, and cooled in the furnace, it exhibited marked oxidizing potential and a *p*H of 7.85. When this phosphor was quenched from temperatures above 1000°C, the oxidizing potential was lost and the *p*H dropped to 6.82.

Changes in *p*H and oxidizing potential can be explained on the basis of the properties of a surface structure. A phosphor preparation temperature of 1300°C will favor divalent manganese by the valency isobar effect. Since Mn^{3+} will substitute isomorphously for Zn^{2+}, rapid quenching of the phosphor should freeze in the surface structure in which Mn^{2+} is stable. Therefore, a quenched phosphor would have zero oxidizing potential and a *p*H similar to that of unactivated zinc orthosilicate. On the other hand, if the phosphor is cooled slowly, the surface phase has an opportunity to dissociate and as a result some of the divalent manganese is oxidized. Consequently the phosphor now exhibits high oxidizing potential. The higher *p*H over that of nonactivated zinc silicate is probably a result of the formation of $Mn_2O_3 \times H_2O$ or $MnO_2(OH)_2$ on the surface of the phosphor where it serves as another source of $(OH)^-$ ions.

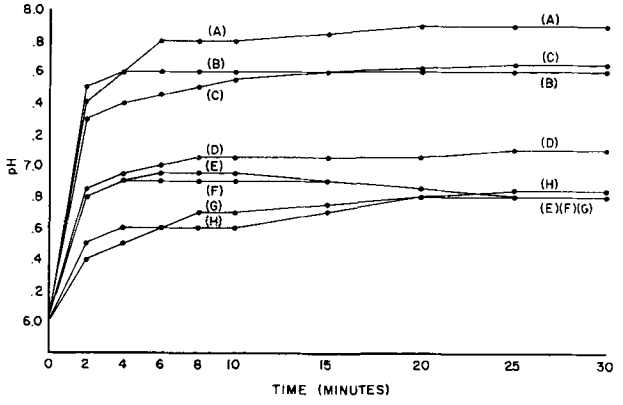

Fig. 3. Effect of surface treatment of zinc silicate phosphors on pH. (A) $(Zn_{0.90}Mn_{0.05})_2SiO_4$; (B) $(Zn_{0.90}Mn_{0.05})_2SiO_4:B_2O_3$; (C) ZnB_2O_4; (D) $(Zn_{0.90}Mn_{0.05})_2SiO_4:Sb_2O_3$; (E) $(Zn_{0.90}Mn_{0.05})_2SiO_4:P_2O_5$; (F) $Zn_3(PO_4)_2$; (G) Zn_2SiO_4; (H) $(Zn_{0.90}Mn_{0.05})_2SiO_4$ air quenched from 1050°C.

Froelich (18) concluded from his studies of Mn-activated silicate phosphors that oxidizing matter, presumably Mn^{3+}, is located at or near the surface of the phosphor crystals. Thus, he observed that Zn-Be silicate, which is isostructural with Zn_2SiO_4, activated by manganese acquired a tan coloration and high oxidizing potential when fired between about 350° and 1000°C. Experiments showed that the higher oxides of manganese did not develop during phosphor synthesis but only after the material was heated in the temperature range of instability previously mentioned. Summarizing, Froelich comments that, "it can be said that manganese-activated silicate phosphors, in particular Zn-Be silicates, have a rather unstable crystal surface which is subject to chemical deterioration and disintegration, depending upon the surrounding atmosphere and temperature. Small amounts of manganese oxide on or immediately below the crystal surface, held more or less loosely in the lattice, are fairly easily attacked by oxygen from the atmosphere or other oxidizing substances. They sever their bonds with the other oxides in the crystal lattice and are oxidized to free, brown manganic oxide, Mn_2O_3, giving rise to a change in the natural color and an apparent loss of fluorescent brightness. . ."

The oxidation of surface manganese can be avoided in other ways than by quenching. Refiring the phosphor with $(NH_4)_2HPO_4$ produces a film of zinc phosphate on the material at temperatures from 300° to 800°C. The oxidizing potential is lost and the *p*H is very nearly that of $Zn_3(PO_4)_2$ as shown in Fig. 3. Similar treatment of the phosphor with H_3BO_3 destroys the oxidizing potential and yields a material with a *p*H nearly that of ZnB_2O_4. However, the firing temperature is limited to 300°-500°C because of the volatility of B_2O_3. Refiring the phosphor with Sb_2O_3 produces a film of $ZnSb_2O_6$ as revealed by x-ray analysis, and again the oxidizing potential is lost.

Changes in the surface properties of zinc silicate phosphor can be produced at moderate temperatures in vacuum. The procedure was to place the phosphor sample in an alumina boat which then was sealed in a Pyrex tube and evacuated to 1μ. The tube was inserted in a furnace so that one end protruded from the furnace. Samples were heated at 600°C for 20 hr. Results obtained from untreated phosphor and phosphors with various surface modifications are shown in Table II. Zinc orthosilicate free of manganese was partially reduced, and metallic zinc collected on the cool portion of the tube. Manganese solid solutions in zinc orthosilicate substantially increased the reduction of zinc as evidenced by a darker gray powder and larger deposits of metallic zinc on the tube.

When zinc silicate phosphor is fired at 1200°-1300°C under neutral or reducing conditions, the powder turns gray in color and the fluorescent brightness is much decreased. Therefore, it appears that Zn_2SiO_4 itself may be subject to reduction quite apart from the effect of a surface phase. However, since the formation of metallic zinc can be prevented by suitable surface treatment, the surface structure of zinc silicate seems to play an important role in the process. Assuming that the surface structure does contribute directly to the formation of metallic zinc, the effect may arise from two causes. Under the same conditions of vacuum heat treatment zinc metal will distill from ZnO. Consequently the occurrence of zinc metal in the phosphor may be the result of the presence of ZnO from the dissociation of the surface at 600°C. Another possible cause may be from an oxidation-reduction reaction which occurs as a result of the instability of the surface phase. Since the coordination number of silicon in inorganic crystalline materials is invariably four, the postulation of a surface-spinel phase suggests the occurrence of a "normal" spinel structure. That is, a structure in which Si^{4+} ions are in fourfold and Zn^{2+} ions are in sixfold coordination positions. When zinc silicate which was prepared at a high temperature is reheated at a moderately low temperature, e.g., 600°C, the surface-spinel phase becomes unstable and attempts to form a phenacite structure. This requires that the Zn^{2+} ions change their coordination number from 6 back to 4 since all cation sites in the phenacite structure are fourfold coordination positions. Although the over-all cation/anion ratio has to be maintained in the structure transition, it may be that local surface conditions give rise to oxidation-reduction reactions between O^{2-} and Zn^{2+} ions. The loss of Zn and O_2 unbalances the stoichiometry so that dissociation of the surface phase results. As shown in Table II, Mn^{2+} substitutions for Zn^{2+} increases the amount of metallic zinc produced. However, consideration of the free energy changes shows that reduction of Zn^{2+} cannot result from the oxidation of Mn^{2+}. Therefore, it appears that manganese plays an indirect role in the reduction of zinc ions and it may serve to increase the instability of the surface phase. Examination of the relative field strengths of Mn^{3+} or Mn^{4+} and Zn^{2+} (where field strength is defined as ionic valence/ionic radius) shows that manganese ions have higher polarizing power than zinc ions. Consequently, oxidation of Mn^{2+} enables it to compete more successfully for oxygen ions than can Zn^{2+}. As a result, another disruptive force is introduced which would tend to cause dissociation of the high-temperature phase.

Table II. Stability of zinc silicate phosphor

Sample	Oxidizing potential	Body color after 600°C for 20 hr at 1μ Hg pressure	Deposit on tube	Fluorescent brightness (2537Å rad.) $(Zn,Mn)_2SiO_4$ at 100%
Zn_2SiO_4	—	Light gray	Zinc	—
$(Zn, Mn)_2SiO_4$	Positive	Dark gray	Zinc	72%
$(Zn, Mn)_2SiO_4: P_2O_5$	Negative	Dark gray	—	72%
$(Zn, Mn)_2SiO_4: As_2O_5$	—	White	—	102%
$(Zn, Mn)_2SiO_4: Sb_2O_5$	—	White	—	97%

The reactivity of zinc silicate phosphor is demonstrated by the ease with which it will react with other oxides to form a second compound on the surface of the phosphor. For example, Al_2O_3 will react with zinc silicate at 1000°C to form a layer of $ZnAl_2O_4$, a spinel. By suitable surface treatment both the oxidation of Mn^{2+} and the reduction of Zn^{2+} ions can be prevented. Re-firing the phosphor with Sb_2O_3 or As_2O_5 forms surface films of $ZnSb_2O_6$ and probably $ZnAs_2O_6$, respectively. As a result the phosphor body color remains white and the fluorescent brightness is maintained. Since $ZnAs_2O_6$ has low u.v. absorption and causes reduction of oxidized manganese present in the untreated phosphor to the divalent state, the powder brightness is somewhat higher than that of the untreated material. A surface film of zinc phosphate prevented zinc metal from volatilizing from the phosphor, but reduction still occurred as evidenced by a gray powder color and loss of fluorescent brightness (see Table II).

A fluorescent lamp provides a low-pressure environment for the phosphor and, during exhaust, temperatures in excess of 500°C. In addition there is the possibility of reducing Zn^{2+} by photolysis from u.v. radiation produced by the mercury arc. Kressin (19a) reports that graying occurs in zinc silicate phosphors on exposure to strong u.v. light. He has attributed the observed graying to the formation of elemental manganese. Two of the experiments on which Kressin (19b) bases his conclusions are the following:

(*a*) A weighed amount of gray irradiated phosphor was placed in a silica bulb and heated in the presence of a measured small amount of oxygen until the white color of the original phosphor was restored. The oxygen then was pumped off, burned with hydrogen to form water, and the latter determined by means of Karl Fischer reagent. The amount of oxygen used up by the phosphor then was found by difference. A blank sample of unactivated zinc silicate without manganese, carried through the entire process as before, showed no oxygen consumption whatever.

(*b*) Zinc silicate with manganese was settled on a quartz plate and irradiated in vacuum with a quartz lamp. During this experiment, the vessel was connected to a mass spectrometer, and the evolution

of oxygen could be detected with this instrument. A blank run with zinc silicate free of manganese did not show the evolution of any oxygen.

Kressin's data can be equally well accounted for by the formation of elemental zinc. Thus, the consumption of oxygen in experiment (*a*) and the evolution of oxygen in experiment (*b*) could be associated with the oxidation and reduction of zinc. The fact that the blank, which contains no manganese, did not show a similar reaction is probably a result of zinc orthosilicate having low absorption for u.v. radiation.

If metallic zinc is produced by photolysis or by the mechanism described earlier, it logically can be expected to react with mercury, probably to form an amalgam. To test this hypothesis phosphor was brushed from lamps after they had burned for 3000 hr. Mercury was separated from the phosphor by shaking a suspension of 5 g of the phosphor in an NH_4OH solution, which caused dispersion of the phosphor, until a ball of mercury collected at the bottom of the tube. The 4 mg of mercury which were recovered were washed with acetic acid to dissolve traces of Zn_2SiO_4. Chemical analysis revealed that the mercury contained 5 wt % Zn but no Mn. Microscopic examination of the zinc amalgam before chemical analysis revealed that it consisted of a mixture of liquid and well defined hexagonal platelets. These platelets are described by Mellor (20) as beta-zinc amalgam. Reference to the phase diagram of the system Zn-Hg (21) shows that Zn is soluble in Hg to 2.15 wt % at 20°C. Therefore, zinc in excess of this limit separates from the liquid as crystals of beta-zinc amalgam.

Relation of Surface Properties to the Accumulation of Mercury on the Phosphor

A mechanism of lumen depreciation is indicated in which zinc metal sites on the phosphor surface act as "vapor traps" which cause the mercury to distribute itself over the phosphor surface. Of the several factors responsible for lumen depreciation, adsorption of mercury is generally regarded as the principal cause (22). The condensation of mercury in tiny droplets on the phosphor surface has been considered by Froelich (22). If it is assumed that the normal 10-20% lumen drop is the result of shadowing by mercury droplets, the size of the droplets required lies between that necessary to cover a certain fraction of the lamp surface to that required to cover the same fraction of the geometric surface of the phosphor powder. Thus, a 40-w lamp with internal surface area of 1320 cm^2 would require spheres of 0.1 to 0.05 μ in diameter to shadow 10-20% of the surface area. A 40-w fluorescent lamp contains about 3.7 g of zinc silicate phosphor which has a surface area of 1.0 to 1.3 m^2/g. Therefore, the geometric surface area is in the order of 10^4 cm^2. Again assuming that the mercury condenses in spheres, droplets with diameters in the order 0.01 to 0.001 μ would be required to cover 10-20% of the geometric phosphor surface area.

Application of the well-known Thomson equation (23) shows that a mercury sphere with a 0.1 μ diameter would have about 10% higher vapor pressure than that over a flat surface. The equation is not valid for spheres with diameters 0.01-0.001 μ since the surface tension is no longer independent of the diameter. Such classical considerations do not take into account the effect of surface forces on the behavior of small droplets of mercury nor do they consider the effect of zinc atoms in "seeding" the condensation of tiny mercury droplets.

The behavior of excess silica with Zn_2SiO_4 suggests that surface forces are appreciable. As was described earlier, excess silicic acid used in the preparation of Zn_2SiO_4 is reluctant to form a crystalline modification and tends to form a cocoon around the zinc silicate crystals. In contrast, excess silicic acid used in the preparation of $CaSiO_3$ readily forms quartz crystals which tend to remain as isolated particles. Thus, it seems possible that small droplets or patches of mercury might be particularly stable on the surface of the zinc silicate phosphor. Unfortunately, electronmicroscopy has not resolved the problem so that the distribution of mercury is still a matter of conjecture.

It is instructive to note that a lamp which has burned for some time and then is reheated to about 300°C will regain substantially all of its lumen drop, but the rate of lumen decrease on re-burning is much greater than it was initially. Evidently the sites which cause deposition of mercury on the surface of the phosphor are not destroyed by heating to 300°C with the result that the lumen drop is much more rapid because of the greater number of sites operating. Such a description is in qualitative agreement with the observation that a gray colored phosphor, which had been removed from a lamp after some hours of burning, could not be bleached by acetic acid until the sample had been reheated to about 300°C. Heating zinc amalgam to this temperature will distill off the mercury and leave a residue of zinc. Since zinc amalgam is insoluble in acetic acid whereas zinc is soluble, it is necessary to decompose the amalgam before the zinc can be dissolved.

Relation of Phosphor Surface Chemistry to Lamp Brightness

The behavior of zinc silicate phosphor during lamp making and lamp burning is complicated. However, the observations discussed serve at least qualitatively to account for the major changes in phosphor brightness. Phosphor removed from a lamp immediately after lamp making is discolored and it has suffered about a 10% loss in brightness. Two factors contribute to this effect. Since the phosphor was furnace cooled, dissociation of the surface phase has led to higher oxidation states of manganese and consequently a tan coloration. The addition of Sb_2O_3 to the coating suspension has led to the formation of $ZnSb_2O_6$ which has high u.v. absorption.

As lamp burning progresses the phosphor suffers further losses in brightness as mercury collects on the surface of the material. The body color changes from a tan coloration to a dark gray color. Metallic zinc atoms are believed to serve as "vapor traps" which cause the mercury to be distributed over the

Table III. Effect of various additives on the lumen performance of zinc silicate phosphors

Sample	0 hr, LPW	100 hr, LPW	500 hr, LPW
$(Zn, Mn)_2SiO_4$	95.7	83.3	70.9
$(Zn, Mn)_2SiO_4$: P_2O_5	110.4	81.6	65.1
$(Zn, Mn)_2SiO_4$: 0.25 wt % As_2O_5	110.3	98.0	85.8
$(Zn, Mn)_2SiO_4$: 0.10 wt % Sb_2O_3	102.6	95.2	84.2
$(Zn, Mn)_2SiO_4$: 0.10 wt % As_2O_5 + 0.10 wt % Sb_2O_3	108.4	98.3	85.1
$(Zn, Mn)_2SiO_4$: special treatment	109.0	104.1	99.0

surface of the phosphor. Two factors can lead to the production of metallic zinc: the decomposition of the surface phase; and reduction of Zn^{2+} by photolysis. Both effects may operate, but it is nevertheless clear that prevention of the oxidation of Mn^{2+} and reduction Zn^{2+} should give substantial improvements in lumen output.

The benefit of a protective coating is demonstrated by the lumen data shown in Table III. The addition of either $(NH_4)_2HPO_4$, Sb_2O_3, or As_2O_5 was made to the coating suspension. As a result the development of a surface film most probably occurs only during lehring. Lamps prepared from untreated zinc silicate gave about 71 lpw (lumens per watt) after 500 hr of burning. The addition of P_2O_5 gave only 65 lpw. This result is consistent with the data given in Table II which show that, although P_2O_5 additions prevented oxidation of Mn^{2+}, reduction of Zn^{2+} did occur. The larger lumen decrease observed than for untreated phosphor may be the deleterious effect of additional H_2O in the lamp from unreacted H_3PO_4. As is well known, the addition of 0.1 wt % Sb_2O_3 to the coating suspension gives substantial improvements both in initial lumens and lumen maintenance so that after 500 hr lamps have about 84 lpw. A mill addition of 0.1 wt % Sb_2O_3 plus 0.1 wt % As_2O_5 was better at 100 hr than either Sb_2O_3 or As_2O_5 alone. The substantial gain in zero hour lumen achieved by adding As_2O_5 alone or in combination with Sb_2O_3 is probably the result of better formed $ZnAs_2O_6$ or $ZnSb_2O_6$ on the surface of the zinc silicate crystals. Evidently the surface layer is not entirely stable since the initial gain in lumens over Sb_2O_3 alone was lost after about 500 hr of burning. By special treatment of the phosphor it is possible to achieve 99 lpw after 500 hr. Thus, appropriate surface treatment of the phosphor improves not only the lumen output but also the lumen maintenance.

Ideally, $(Zn, Mn)_2SiO_4$ stabilized by a suitable surface film should be an optimum phosphor composition. However, a certain excess of silica is required as shown by the data in Fig. 1. A phosphor with a ZnO/SiO_2 ratio of 1.9/1.0 gave lower lumens than one with a ratio of 1.7/1.0. Since Sb_2O_3 was added to the coating suspension, a film of $ZnSb_2O_6$ could form only during lehring, that is, in the minute or two that the phosphor was above about 500°C. It seems likely that any factor which affects the kinetics of formation of $ZnSb_2O_6$ also will affect lamp performance. Similar results are shown by the data in Fig. 2. A particular phosphor composition had varying susceptibility to lamp-making conditions depending on the temperature at which the phosphor was prepared. Since it is shown that surface alterations do occur in zinc silicate, it is likely that different heat treatments will produce various degrees of surface alteration. The change in response to 3650Å excitation appears to be associated with alterations in surface structure which also could conceivably have a marked effect on the kinetics of the formation of $ZnSb_2O_6$. Thus, heat treatments which produce changes in response to 3650Å excitation also yield phosphors which give lamps with different lumen outputs. Consequently, it appears that the surface properties of a phosphor, particularly those which affect the extent and perfection of a protective coating, greatly influence the quality of lamps produced by identical procedures.

The proposed mechanism of zinc silicate phosphor deterioration does not explain why some lamps actually improved in maintenance from 100 to 500 hr (see Fig. 2). Also in need of an explanation is that although zinc-beryllium silicate and zinc silicate are isostructural the former is much more stable in lamps than the latter. However, in the case of zinc-beryllium silicate there is the possibility of forming a surface film of Be_2SiO_4 which may help prevent reduction of Zn^{2+}.These results emphasize that there are many other factors needing research to explain the maintenance of lamps.

Acknowledgments

Grateful acknowledgment is given to Miss Eileen Allessandrini of General Electric Company Research Laboratory for supplying the electron diffraction data, to Miss Mary V. Hoffman for obtaining some of the lamp data, to Mr. J. G. Rabatin for supplying the DTA data, to Mr. J. W. Hunter for analysis of the zinc amalgam, and to Dr. C. A. Brown for his many stimulating discussions.

Manuscript received Sept. 16, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

The System BaO-TiO_2-P_2O_5: Phase Relations, Fluorescence, and Phosphor Preparation

D. E. Harrison[1]

Luminescent Materials Laboratory, Lamp Metals and Components Department, General Electric Company, Cleveland, Ohio

ABSTRACT

The subsolidus phase relations were determined in the system BaO-TiO_2-P_2O_5 by using x-ray and petrographic techniques. Four compounds were isolated and individually prepared: $2BaO:TiO_2:P_2O_5$ melts congruently at 1197° ± 3°C; $BaO:TiO_2:P_2O_5$ has a rapidly reversible dimorphic inversion at 967° ± 5°C and it melts congruently at 1428° ± 3°C; $4BaO:3TiO_2:P_2O_5$ melts incongruently at 1302° ± 3°C; and $BaO:4TiO_2:3P_2O_5$ melts incongruently at 1368° ± 3°C. The only compound in the system which is of the self-activated type is $2BaO:TiO_2:P_2O_5$. It has an emission similar to that of $MgWO_4$. Compositions of maximum fluorescence are restricted to the join $2BaO:P_2O_5$-$2BaO:TiO_2:P_2O_5$ since compositions off this join contain either $BaO:TiO_2:P_2O_5$, $4BaO:3TiO_2:P_2O_5$ or TiO_2 which have high u.v. absorption but are nonfluorescent phases.

Henderson and Randy (1a) developed a phosphor with a composition of $2Ba_2P_2O_7$: 0.5 to 2.5 TiO_2. (In this paper, "activator concentrations" such as 0.5 to 2.5 TiO_2 refer to moles of material per mole of $Ba_2P_2O_7$.) This phosphor, which is excited by 2537Å radiation, has an emission similar to that of $MgWO_4$ and it is of the self-activated type. It is reported that maximum fluorescence occurs with a composition of $2Ba_2P_2O_7$: 1.0 TiO_2 but that relatively large increases in the concentration of titania only slowly decrease the intensity of fluorescence.

The system BaO-TiO_2-P_2O_5 provides an unusual opportunity to relate the ternary phase relations to the fluorescent properties without the uncertainties attending the introduction of small amounts of an activator as the fourth component. The purpose of this study was to determine the subsolidus phase relations and to show how the brightness of phosphor compositions is influenced by small amounts of nonfluorescing phases which necessarily occur as a result of the ternary phase relations. Subsolidus phase relations were determined by examining compatibility triangles and isolating compounds. It is hoped that the phase data and particularly the characterization of the fluorescent compound will prove useful in a fundamental study of this self-activated phosphor.

Experimental Procedure

Reagent grade $BaCO_3$, $BaHPO_4$, TiO_2, $(NH_4)_2HPO_4$, and BaF_2 were used as starting materials. Compositions were prepared by grinding the ingredients in a mortar with acetone until dry. Calcines were prepared in either fused silica or platinum crucibles at temperatures ranging from 700° to 1100°C for periods up to 3 weeks.

X-ray data were obtained from a General Electric, XRD-5, diffractometer using $Cu_{k\alpha}$ radiation (λ = 1.540Å) filtered with nickel.

The immersion technique was used to determine the refractive index of crystals. Indices up to 1.700 were determined to an accuracy of ±0.001, from 1.71 to 1.80 to an accuracy of ±0.005, and 1.84 to 2.00 to an accuracy of ±0.02.

Differential thermal analysis (DTA) data were obtained with an automatically recording apparatus, as described by Rabatin and Card (2).

The melting points of compounds were determined by a quench technique similar to that described by Shepherd, Rankin, and Wright (3). Thermocouples were calibrated using gold (mp, 1063°C), lithium metasilicate (mp, 1201°C), and diopside (mp, 1392°C). Since it was impossible to quench 20-g samples of ternary compound compositions to glasses, calcines were used as starting materials for quench studies.

Ultraviolet absorption was measured by determining the u.v. reflected from a sample. The detector consisted of a Corning 9863 filter, a layer of zinc silicate phosphor, a green filter, and a barrier layer photocell.

Relative fluorescent brightness was measured by a barrier layer photocell corrected to eye sensitivity.

Results and Discussion

Phase studies, binary systems.—The system BaO-TiO_2 was examined extensively by Rase and Roy (4). Five compounds exist: $2BaO:TiO_2$, $BaO:TiO_2$, $BaO:2TiO_2$, $BaO:3TiO_2$, and $BaO:4TiO_2$. The compound $BaO:2TiO_2$ has a lower limit of stability at 1210°C; below this temperature the composition is a mixture of $BaO:TiO_2$ and $BaO:3TiO_2$. Jonker and Kwestroo (5) discovered two new compounds which belong to the binary system. These compounds, $2BaO:5TiO_2$ and $2BaO:9TiO_2$, are stabilized by small additions of SnO_2 or ZrO_2. The system TiO_2-P_2O_5 was examined recently by Harrison and Hummel (6) who showed that $5TiO_2:2P_2O_5$ and $TiO_2:P_2O_5$ are the only compounds which occur in this system.

No complete phase diagram of the system BaO-P_2O_5 is reported, but a number of compounds are claimed. Glatzel (7) reports the occurrence of $BaO:P_2O_5$, and Ouvrard (8) shows the existence of $2BaO:P_2O_5$. A cubic form of $3BaO:P_2O_5$ is listed in the ASTM X-ray Diffraction Patterns, and a rhombohedral form is reported by Zachariasen (9). Recently, Langguth, Osterheld, and Karl-Kroupa (10) presented x-ray data for a new compound $3BaO:2P_2O_5$. Re-examination of the system confirmed the existence of the four compounds claimed. Further work was done on the new compound $3BaO:2P_2O_5$. Since it was not possible to quench the entire composition to a glass, conventional quench technique could not be used to determine the melting point. After fusion the quenched product always consisted of $3BaO:2P_2O_5$ plus glass. Therefore, it is concluded tentatively that the 3:2 compound melts congruently. DTA gave an endotherm at 900°C on heating and a second endotherm at 990°C followed by melting. The thermal effect at 900°C is the result of a slowly reversible dimorphic inversion which was found by static methods to occur at 870° ± 10°C. Microscopic examination showed that the low-temperature form has maximum and minimum refractive indices of 1.628 and 1.618, respectively. The high-temperature form is nearly isotropic with a refractive index of about 1.626. Typical x-ray patterns of the high- and low-temperature forms are given in Table II and compared with the data of Langguth, Osterheld, and Karl-Kroupa. Langguth, *et al.* fired their sample of 3:2 at 550°C/12 hr, whereas in the present work the low-temperature form was prepared at 800°C/24 hr. The differences in crystal development obtained at these firing temperatures may account for the discrepancies in the x-ray data.

Phase studies, ternary system.—Compatibility triangles were determined by comparison of x-ray and microscopic data of ternary compositions with data from the binary systems. Compositions investigated are shown in Fig. 1 and listed in Table I.

Since the temperature range examined was from 800° to 1100°C, $BaO:2TiO_2$ does not appear as a phase in the ternary system. Composition No. 28 consisted of a mixture of $4BaO:3TiO_2:P_2O_5$ + $BaO:TiO_2$ + $BaO:3TiO_2$ but not $2BaO:5TiO_2$. Therefore, it appears that $2BaO:5TiO_2$ does not occur as a stable phase in the ternary system in the temperature range studied. The sluggishness with which equilibrium is reached in the triangles $3BaO:P_2O_5$ — $2BaO:TiO_2$ — BaO and $4BaO:3TiO_2:P_2O_5$ — $BaO:3TiO_2$ — TiO_2 prevented determination of the phase relations within these triangles. However, the boundaries of the triangles are correct as drawn. No extensive solid solution regions exist in the ternary system. Four ternary compounds were discovered and individually prepared. A diagram of the compatibility triangles is given in Fig. 1 and the phase data are listed in Table I.

The compound $2BaO:TiO_2:P_2O_5$ has maximum and minimum refractive indices of 1.688 and 1.672, respectively. At 1197° ± 3°C, 2:1:1 melts congruently. DTA showed no thermal effects between ca. 100°C and the melting temperature. A characteristic x-ray pattern is listed in Table II.

The compound $BaO:TiO_2:P_2O_5$ has maximum and minimum refractive indices of 1.84 and 1.79, respectively, and it melts congruently at 1428° ± 3°C. DTA exhibits an endotherm at 970°C on heating and a exotherm at 905°C on cooling. The thermal effects are the result of a rapid-reversible-dimorphic inversion. High-temperature x-ray examination showed that the inversion occurs at 967° ±5°C. Characteristic x-ray diffraction data of the high- and low-temperature forms are given in Table II.

The compound $4BaO:3TiO_2:P_2O_5$ has a refractive index of about 1.71, and it melts incongruently at 1302° ± 3°C into a liquid and $3BaO:P_2O_5$. Comparison of the x-ray data of 4:3:1 and 3:1 shows that they are almost identical but differences in optical properties of these two compounds proved that 4:3:1 dissociates into 3:1 and a liquid. DTA shows no thermal effects from about 100°C to the melting temperature. A characteristic x-ray pattern is given in Table II.

The compound $BaO:4TiO_2:3P_2O_5$ has refractive indices between 1.88 and 1.92, and it melts incongruently at 1368° ± 3°C into a liquid and probably 1:1:1. X-ray examination of the dissociated product did not reveal a clearly defined phase but suggests that it might be a transition phase between the high- and low-temperature forms of 1:1:1. DTA showed no thermal effects from about 100°C to the melting temperature.

Fluorescent studies.—Reference to Fig. 1 shows that the composition region, $2Ba_2P_2O_7:0.5\text{-}2.5TiO_2$, of useful phosphors reported by Henderson and Ranby lies on the joins $2BaO:P_2O_5$-$2BaO:TiO_2:P_2O_5$ and $2BaO:TiO_2:P_2O_5$-TiO_2. Observation of the end members reveals that 2:1:1 fluoresces a blue color whereas 2:1 and TiO_2 do not fluoresce at all. The optimum phosphor composition claimed by Henderson and Ranby is $2Ba_2P_2O_7:1.0TiO_2$ or actually 50 mole % $2BaO:P_2O_5$ + 50 mole % $2BaO:TiO_2:P_2O_5$, since there is essentially no solubility between end members. Surprisingly, a composition with 50 mole % dilution by 2:1 fluoresces only slightly less brightly than the 2:1:1 compound. This may be explained by the relatively low u.v. absorption of $2BaO:P_2O_5$ and the method of measuring powder brightness. Powder brightness is measured from a sample which has effectively infinite thickness for u.v. light; therefore low absorbing, nonfluorescing particles behave as voids. In this regard it is interesting to examine the fluorescence of compositions in the compatibility triangles which terminate at the 2:1:1 compound.

Composition No. 31, for example, is a mixture of 35 mole % 2:1:1, 31 mole % 1:1:1, and 34 mole % 2:1. However, this composition has only 52% of the brightness of 2:1:1 or $2Ba_2P_2O_7:1.0TiO_2$ because of the presence of 1:1:1 which has high u.v. absorption but no fluorescence. A similar situation exists in composition No. 36 which is composed of 44 mole % 2:1:1, 28 mole % 4:3:1, and 28 mole % 2:1. Like 1:1:1, the presence of 4:3:1, which is a nonfluorescent, highly u.v. absorbing phase, causes this composition to have only 68% of the brightness of 2:1:1. Compositions Nos. 21 and 27 exhibit only 36 and 25% brightness, respectively, due to the presence of TiO_2 in addition to either 1:1:1 or 4:3:1. Absorption and brightness data are summarized in Table III.

Table III. Ultraviolet absorption and fluorescent brightness of Ba-Ti-phosphate compositions

27	57	—	26	—	17	96	25

Effect of phosphor composition on brightness.—Because of the low reactivity of TiO_2, the formation of 2:1:1 can be facilitated by using an excess of $2BaO:P_2O_5$. More satisfactory results can be achieved by employing a flux, such as BaF_2, as was used by Henderson and Ranby. Since chemical analysis shows that fluorine is lost on firing, the BaF_2 appears to be oxidized to BaO, apparently by a mass action effect. In order to remain on the 2:1 — 2:1:1 join or to arrive at the 2:1:1 compound, it is necessary to compensate for the additional BaO with P_2O_5. The use of SrF_2, as claimed in a recent patent by Uehara, Kobuke, and Tomishima (11), probably requires similar treatment, since it is likely that small amounts of Sr will substitute for Ba in the phosphor matrix.

A particularly effective method of introducing extra P_2O_5 is by use of $BaO:P_2O_5$. Conveniently, this compound melts congruently into a stable liquid at 843° ± 3°C. Since phosphor synthesis proceeds rapidly at about 1000°C, the combined effects of a fluoride flux and liquid $BaO:P_2O_5$ yield well-formed phosphor. The liquid initially produced by melting of $BaO:P_2O_5$ does not cause sintering, and a phosphor with small particle size is obtained.

The dramatic effect on phosphor brightness with compositions on either side of the 2:1:1 — 2:1 join is demonstrated by the following experiment: Three compositions were prepared (A) $4BaHPO_4 + 1.3TiO_2 + 0.07BaF_2$; (B) $4BaHPO_4 + 1.3TiO_2 + 0.07BaF_2 + 0.07BaO:P_2O_5$; and (C) $4BaHPO_4 + 1.3TiO_2 + 0.07BaF_2 + 0.14BaO:P_2O_5$. Composition (A) lies just off the join in the compatibility triangle 2:1 — 2:1:1 — 4:3:1. Composition (B) is on the join and composition (C) is again located off the join in the triangle 2:1 — 2:1:1 —1:1:1. All compositions were fired at 900°C for 2 hr, a second time at 930°C for 2 hr, and finally fired at 1000°C for 15 hr. The results of

Table IV. Relative fluorescent brightness of some Ba-Ti-phosphate compositions

F: 37.0 mole % 2:1:1 + 56.5 mole % 2:1 + 6.5 mole % 1:1:1

powder brightness measurements are given in Table IV. Assuming loss only of water and fluorine, the fired compositions are given in Table IV in mole per cent by compatible phases.

The brightness data show that as equilibrium is attained, composition (A) which contains 0.9 mole % 4:3:1, and composition (C) which contains 3.3 mole % 1:1:1 have only 80% of the brightness of composition (B) on the join 2:1:1 — 2:1. The loss in brightness of compositions (A) and (C) shows that 4:3:1 and 1:1:1 are more effective absorbers for u.v. radiation than their mole percentages would suggest. Examination of the reaction sequence reveals that the first phase to form is $2BaO:P_2O_5$ from the decomposition of $BaHPO_4$. $2BaO:P_2O_5$ reacts with TiO_2 to form $2BaO:TiO_2:P_2O_5$ and depending on composition either 4:3:1 or 1:1:1 form as equilibrium is reached. The reaction sequence is illustrated by composition (A). An initial firing at 900°C gave a product with 96% brightness but successive firings at 930° and 1000°C lowered the brightness to 82%. Composition (C) which has the additional fluxing action of liquid $BaO:P_2O_5$ approached the equilibrium value during the initial firing at 900°C. Thus, it seems likely that the 4:3:1 and 1:1:1 phases occur on the surfaces of the 2:1:1 and 2:1 phases where they can act as more effective absorbers for u.v. light than their mole percentages would indicate.

Three other compositions were selected similar to (A), (B), and (C). The additional compositions were prepared as follows (D) $4.0BaHPO_4 + 1.0TiO_2 + 0.15BaF_2$; (E) $4.0BaHPO_4 + 1.0TiO_2 + 0.15BaF_2 + 0.15BaO:P_2O_5$; and (F) $4.0BaHPO_4 + 1.0TiO_2 + 0.15BaF_2 + 0.30BaO:P_2O_5$. Fluorescent brightness data and compositions by compatible phases are given in Table IV. The results parallel those obtained from compositions (A), (B), and (C). In addition, it is demonstrated that doubling the amount of 4:3:1 from 0.9 mole % in (A) to 2.0 mole % in (D) only further decreases the brightness by about 10%. Thus it appears that doubling the amount of 4:3:1 increases the effective u.v. absorbing area by about 10%, which again suggests that 4:3:1 occurs as patches on the surface of the phosphor.

Conclusions

1. The subsolidus phase relations were determined in the system $BaO-TiO_2-P_2O_5$. Four ternary compounds were isolated: (*a*) $2BaO:TiO_2:P_2O_5$ melts congruently at 1197° ± 3°C, and it has maximum and minimum refractive indices of 1.688 and 1.672, respectively; (*b*) $BaO:TiO_2:P_2O_5$ melts congruently at 1428° ± 3°C, and it has maximum and minimum refractive indices of 1.84 and 1.79, respectively; (*c*) $4BaO:3TiO_2:P_2O_5$ has a refractive index of about 1.71, and it melts incongruently at 1302° ±3°C, and (*d*) $BaO:4TiO_2:3P_2O_5$ melts incongruently at 1368° ± 3°C, and the refractive indices lie between 1.88 and 1.92.
2. $3BaO:2P_2O_5$ exhibits a slowly reversible dimorphic inversion at 870° ± 10°C. The low-temperature modification has maximum and minimum refractive indices of 1.628 and 1.618, respectively. The high-temperature form is nearly isotropic with a refractive index of about 1.626.
3. $2BaO:TiO_2:P_2O_5$ is the only compound in the system which is of the self-activated type. It has an emission similar to that of $MgWO_4$.
4. Compositions with maximum fluorescence are restricted to the join $2BaO:P_2O_5$-$2BaO:TiO_2:P_2O_5$, since compositions off this join contain either $BaO:TiO_2:P_2O_5$, $4BaO:3TiO_2:P_2O_5$, or TiO_2 which have high u.v. absorption but are nonfluorescent phases.

Acknowledgments

The author thanks Professor F. A. Hummel of the Pennsylvania State University for supplying the high-temperature x-ray data, and J. G. Rabatin of the General Electric Company for obtaining the differential thermal analysis data.

Manuscript received Sept. 16, 1959.

An Apparatus for the Preparation of Semiconductor Grade Silicon by Film Boiling

Ray C. Ellis, Jr.

Research Division, Raytheon Company, Waltham, Massachusetts

ABSTRACT

A film boiling technique is used to increase the rate of thermal decomposition of silicon tetraiodide. The silicon is deposited molten on a submerged induction-heated graphite shape and is collected after its departure from the hot zone by flotation. Apparatus is described for the synthesis and purification of large quantities of silicon tetraiodide.

Depending on the semiconductor application, silicon of purity of as little as one part per billion is required. Zone segregation has been of limited use for silicon. Many difficulties have been encountered when melting and solidifying silicon in known crucible materials. The most effective method of zone segregation utilizes a floating zone (1).

Semiconductor grade silicon has been prepared by the reduction of silicon tetrachloride with zinc vapor (2), the reduction of a halogenated silicon compound with hydrogen (3-8), and by the thermal decomposition of silane (9) and of silicon tetraiodide (10, 11).

Recently it was shown that the rate of deposition of titanium from the thermal decomposition of titanium tetraiodide could be increased greatly if the geometry were changed from the Van Arkel-de-Boer (12) method to a film boiling geometry (13). This is the basis of the apparatus described below.

Silicon tetraiodide is a suitable starting material. The free energy change for the decomposition $SiI_4 \rightarrow Si + 2I_2$ at 1 atm becomes zero at about 1770°K. This figure may be in considerable error because of the uncertainty of the data available (14). At this temperature, K of the reaction, $I_2 \rightarrow 2I$, is about 8 $l/mole^{-1}$ with a contribution of −7.32 kcal/mole (15).

The partial pressure of iodine which limits the reaction is supplied by the decomposition. The rate of the decomposition by film boiling is most dependent on the removal of iodine from the reaction zone (11).

Silicon tetraiodide melts at 127°C and boils at 300°C, mp 122°-122.5°C, bp 301.5°C (16). Its density is greater than that of silicon and aids in the removal of the product from the reaction zone by flotation. Silicon tetraiodide can be prepared easily in large quantities (Appendix I) and can be purified in large quantities (Appendix II).

Experimental

Apparatus.—The apparatus for the decomposition consists of a graphite heater, A in Fig. 1, heated with coils, B, driven by a 20 kw rf generator. The heater is held at its base by two molybdenum wires, C, in an inner quartz liner, D. This liner assembly can be changed without disassembling the entire

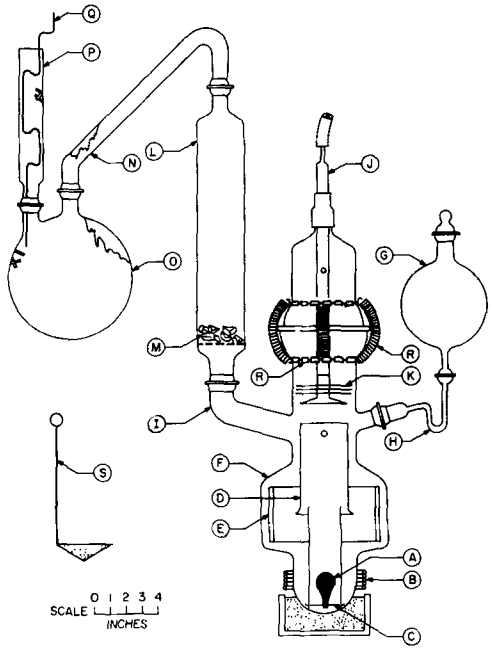

Fig. 1. Apparatus for the decomposition of silicon tetraiodide by film boiling.

apparatus. The inner liner and the outer quartz liner, E, are contained in the reactor, F, which has a total volume of about 10 l and rests in sand. The reactor is fitted with a 2-l feeding flask, G, and feeding tube, H, a sidearm, I, and a large upper joint. The upper joint contains a gas inlet tube, J, on which are hung a series of tantalum baffles, K. Attached to the side arm is the column, L, filled with quartz cullet, M. A condenser, N, leads from the top of the column to a 10-l receiving flask, O. Connected to the receiving flask is a vent or stack, P, in which is placed a cleaning crank, Q. All joints are held together with ball joint clamps except the large joint, which is held together with a chain and spring clamp, R. The chains on each side of the joint are held with springs of suitable number and strength. The chains distribute the pressure evenly.

Operation.—After the graphite heater has been put into place and about 3 l of liquid silicon tetraiodide have been added, the apparatus is flushed with an inert gas such as argon. The graphite then is heated to just below the decomposition temper-

ature (1800°C est.). The flushing gas is adjusted to the point where the heavy vapors of silicon tetraiodide just rise to the baffles. This keeps the large joint between the reactor and the top clean. As the boiling continues the condensing vapors rise in the column and heat it. This prevents clogging of the cold column later by iodine. The power put into the graphite is increased and decomposition begins. Iodine vapors obscure all the inner parts of the apparatus and the decomposition proceeds with iodine distilling out of the column and into the condenser and receiving flask. To prevent clogging, the condenser is heat-cycled periodically to melt the solidified iodine down into the receiver. The crystals in the stack are broken free with the crank.

The molten silicon builds up continuously on the graphite and breaks to the surface of the surrounding liquid in a bright display of molten droplets. The inner quartz liner directs the silicon droplets upward and dumps them out onto the surface of the liquid tetraiodide. The outer quartz liner prevents the molten droplets from floating into the side of the glass container. Very few droplets stick to any surface. Fresh silicon tetraiodide is added as it is needed during the decomposition to keep the liquid level up. This is accomplished by melting the solidified silicon tetraiodide in the feeding flask and through the feeding tube trap.

After several pounds of silicon have collected, the power is turned off, the top is opened, and the inner liner removed. The pellets then can be removed with a tantalum screen ladle (S, Fig. 1). The pellets are soaked in distilled water and then in hydrofluoric acid solution to rid them of any silica. After washing and drying, the pellets are ready for use.

In disassembling the apparatus the joints of the feeding tube and the condenser are loosened by heating and are separated. The top of the reactor is removed and the liquid contents of the reactor poured (usually with filtering) into a flask for storage. The glassware is cleaned by an overnight immersion in hot, 10% sodium hydroxide solution, followed by a scrubbing in Alconox solution and a rinse in demineralized water.

Heater.—Special attention must be paid to the surface on which the silicon deposits since naturally no contamination of the silicon by the surface material or its impurities is desired. The best material found was graphite.

The graphite selected has to be both pure and dense for this application. It was found that commercial graphite with a density of less than about 1.70 was completely disintegrated into silicon carbide by molten silicon. This destructive process was seen less frequently as more dense graphite was used. As silicon starts to form on a graphite surface a protective layer of silicon carbide forms. This prevents further reaction unless the graphite is porous. In this case the silicon runs into the pores, forming some silicon carbide. The volume of the silicon carbide is greater than that which the graphite originally occupied, resulting in a crack which relieves the strain. Silicon runs into this crack and the destructive process continues.

The shape selected for the graphite has smooth contours to encourage the least violent liquid and gas flow around it and to minimize the strains induced on its surface by the thin silicon carbide layer.

Unfortunately there is a finite solubility of carbon in molten silicon. Therefore the graphite (or silicon carbide) dissolves to an appreciable extent in the silicon that has formed. A very small amount of silicon carbide crystallizes out of the silicon pellets as they solidify. This amounts to about 0.1%. Occasionally a graphite heater had to be replaced because of extensive erosion.

Silicon carbide was used in several experiments and found to erode about as rapidly as the dense graphite samples.

Results

Product.—The product is a mass of various sized polycrystalline droplets of silicon ranging from ⅛ to ⅜ in. in diameter. Many of the droplets broke after solidification. The product is pictured in Fig. 2.

Rates as high as 120 g/hr have been observed. This corresponds to 10 g of silicon/hr/cm^2. By suspending the graphite in the vapor, a rate of 1.0 g/hr/cm^2 was obtained at about 1800°C. This tenfold increase in the rate by the introduction of film boiling compares with the factor of 100 found by Petersen (13) using titanium tetraiodide.

The purity of the prqduct was determined by drawing a test crystal from each batch and measuring its resistivity. The average resistivity of about a thousand runs was found to be about 5-10 ohm-cm, p-type. The impurity element was identified as boron by determining the segregation coefficient. The highest resistivities found were in the 300 ohm-cm range, but it is believed this was due to compensation.

Although the small carbon (or carbide) content in the silicon did not affect the resistivity, it interfered in the growth of single crystals by appearing as a dross on the molten product during crystal growing.

Several methods have been used to remove the silicon carbide from the product. The product has

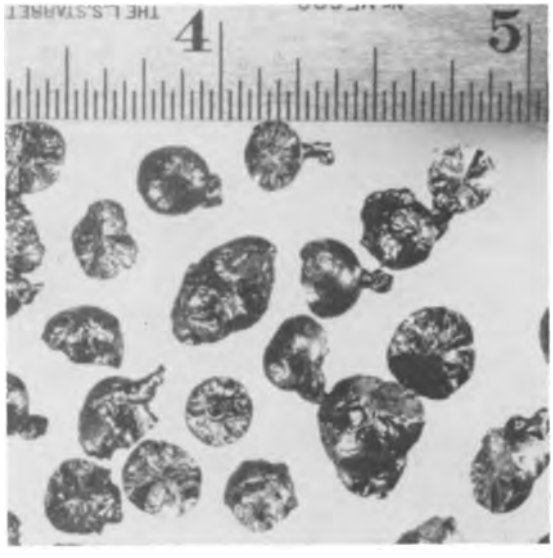

Fig. 2. The product: solidified droplets of silicon

been filtered through quartz wool and fritted quartz disks but these steps, while removing the carbide, introduce oxygen (17).

Temperature of decomposition.—The decomposition in this system starts suddenly because the sudden darkening of the contents of the reactor is seen when the temperature is increased by very small increments. Several methods have been used to estimate this temperature. Direct optical measurement was impossible because of the deep iodine color. Just prior to decomposition, the temperature is about 1700°C. When the graphite was heated in argon with the same power input as above, the temperature was about 150° higher. In one case where silicon tetraiodide was used, hydrogen was introduced just under the heater to obtain better visibility. The deep iodine color was dispelled everywhere except in the immediate neighborhood of the decomposition zone. It is interesting to note that under these conditions small quantities of triiodosilane distilled out of the column.

Placing a thermocouple inside the graphite and free from silicon tetraiodide vapors could not be accomplished without the disintegration of the thermocouple with silicon at temperatures somewhat below where the reaction appears to begin.

A further estimate of the decomposition temperature was attempted by observing the time it took the pellets to solidify. Knowing the heat of fusion and the heat capacity of molten silicon and assuming an emissivity as high as unity, one can calculate the time required for a pellet of a given size to solidify, assuming heat loss by radiation only. The calculated cooling time is still much larger than the observed, showing considerable heat loss by conduction.

Thermodynamics predicts an equilibrium decomposition temperature of 1770°K at 1 atm but this is very dependent on the iodine partial pressure. Reducing the iodine pressure reduces the temperature at which decomposition can take place. A discussion of this equilibrium has been made by Schäfer and Morcher (18, 19) and by Loonam (20). It is interesting to note that, with an adequate supply of iodine at a total pressure of 1 atm, the formation of silicon tetraiodide is self-sustaining, sometimes producing temperatures sufficient to soften quartz (Appendix I).

Summary

An apparatus has been used for the thermal decomposition of silicon tetraiodide by film boiling on a graphite surface to produce semiconductor grade silicon at a rate of 120 g/hr. The estimated decomposition temperature is 1800°C at 1 atm. The small solubility of carbon in silicon at this temperature does not affect the resistivity but does hinder the growth of single crystals from the product.

APPENDIX I

Apparatus for the Production of Large Quantities of Silicon Tetraiodide

Literature on preparation of metal halides by direct combination are too numerous to mention. Much of the preparative work on silicon halides has been done by Schumb, *et al.* (21). The following represents an improvement on Szekely's method (3) in that the apparatus can be run almost continuously and that the rate of the reaction is somewhat higher.

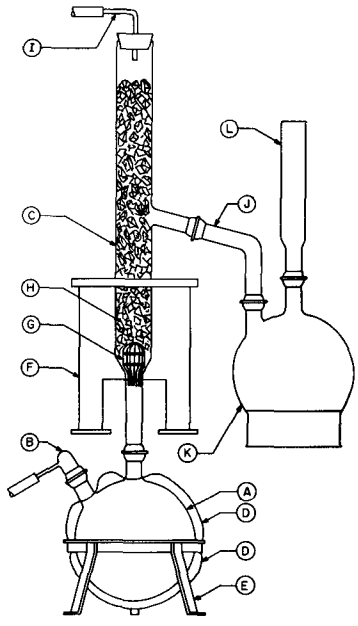

Fig. 3. Apparatus for the preparation of silicon tetraiodide

Experimental.—Resublimed iodine was purchased in 25-lb drums from J. T. Baker Chemical Company, Phillipsburg, New Jersey. The crude silicon (low aluminum grade) was purchased in 100 lb drums from the Electro-Metallurgical Division of Union Carbide and Carbon Corporation. The silicon was crushed to about 1 mesh before use.

The apparatus (Fig. 3) consists of a 5 l boiler flask, A, fitted with an inlet tube, B, and an opaque quartz burning tube, C. A heating mantle, D, surrounds the boiler and supports it. The assembly is supported by a sturdy tripod, E. The lower portion of the burning tube is surrounded by a resistance furnace, F. A tantalum or molybdenum wire plug, G, in the neck of the burning tube supports the silicon charge, H. A one-holed rubber stopper and a glass tube in the top of the burning tube act as a secondary inlet tube, I. The burning tube has a side arm which connects through an elbow, J, to a 5 l receiver, K. The receiver is fitted with an open tube, L, called a stack.

To ready the apparatus for use, the burning tube is filled with crushed silicon and the boiler is loaded with about 4 l (40 lb) of molten iodine. This material is generally iodine recovered from the decomposition of silicon tetraiodide. The system is swept with argon slowly through both inlet tubes.

The furnace is turned on and its temperature increased until the purple vapors appearing in the side arm and elbow change to a white aerosol of silicon tetraiodide. The boiler temperature is increased and the reaction proceeds vigorously as iodine distills up into the burning tube. Usually the furnace is turned off completely to avoid overheating as the reaction is self-sustaining.

As the reaction continues, the flushing gas is decreased to a very low flow rate. The necks of the receiver and the stack are heated periodically with a large soft flame to melt down any solid that has collected. Silicon in the burning tube is knocked down into the reaction zone by tapping the tube gently with a heavy wooden stick. To run the apparatus more or less continuously, the boiler and burning tube can be recharged and the receiver replaced. The washing procedure for the burning apparatus is identical to that used for the decomposition apparatus.

The impure product that distills into the receiver is usually a dark pinkish-brown liquid cooling to a brown waxy solid. The rate of production can be controlled by regulating the boiler temperature and averages 7.5

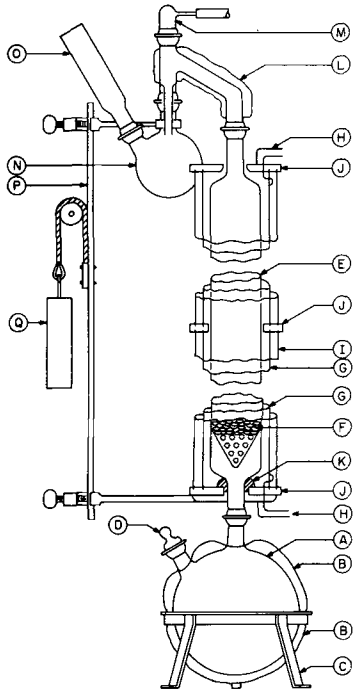

Fig. 4. Still for the distillation of silicon tetraiodide

lb/hr of crude product. The yield is essentially quantitative.

The rate of burning cannot be increased greatly because several times the opaque quartz tube had sagged dangerously because of over-heating. If pure silicon is used as the starting material, the reaction starts with great difficulty and the burning rate is quite slow.

APPENDIX II

Still for the Purification of Large Quantities of Silicon Tetraiodide

The still used for the purification is an easily built laboratory-scale still for handling of large quantities of a dense, high boiling material such as silicon tetraiodide. It is of the usual type with a few innovations for use with silicon tetraiodide. The weight of the column and receiver is counterbalanced so that a redistribution of weight during distillation will not strain the neck of the boiler flask. The thermometer was eliminated from the prototype still head because it was more convenient to take product cuts on an empirical basis.

Experimental.—The apparatus (Fig. 4) consists of a 12-l boiler pot, A, enclosed in a heating mantle, B. The mantle and flask are supported by a sturdy tripod, C. The boiler has a side arm, D, for the introduction of crude silicon tetraiodide. A column, E, 72 in. long and 3 in. in diameter is packed with ⅜ in. glass helices, F, and is connected to the boiler. The column is surrounded by two jackets. The inner jacket, G, is wound with nichrome wire, H, to balance the heat loss of the column. The outer jacket, I, is insulating. To facilitate the construction of the apparatus, the jackets were each made of two parts. The column assembly is held in position by three grooved Transite rings, J. The column rests in glass wool, K. The weight of the column assembly is supported by the bottom Transite retainer. The top of the column connects to an insulated still head, L, which is fitted with a gas inlet tube, M. The receiver, N, is attached to the still head and is fitted with a vent, O, called a stack. An internal extension on the head directs the distillate away from the joint between the head and the receiver. The column and receiver assembly is attached to a movable rack, P. The column, receiver, and rack are counterbalanced by a weight, Q, to prevent strain on the neck of the boiler flask.

Usually the charge of crude silicon tetraiodide is about 85 lb. It is contaminated largely with iodine. The first fraction is deeply colored with iodine, bp 184°C, and somewhat contaminated with boron triiodide. By the time the pure yellow distillate of silicon tetraiodide appears these impurities have been collected. The temperature of the upper part of the column is lowered slightly by decreasing the power in the winding of the upper, inner jacket. The throughput stops and the receiver is quickly changed. Product is similarly taken in batches. Crude silicon tetraiodide can be added as desired.

The distillation was carried out at 1 atm to avoid the use of vacuum equipment. This step did necessitate the introduction of suitable insulation and heating of the apparatus.

The reflux ratio during operation was about 3:1 and it is estimated that there were about seven theoretical plates.

The product is a yellow liquid or a white solid with the melting point found to be 127°C. The throughput of the column could be as large as 7 lb/hr, because there was good separation of impurities. The nearest boiling containment was boron triiodide with a boiling point of 210°C (16), a separation of 90°C from silicon tetraiodide. The product was analyzed spectroscopically and no impurities were found.

Manuscript received June 22, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Imaging-Furnace Developments for High-Temperature Research

Peter E. Glaser

Arthur D. Little, Inc., Cambridge, Massachusetts

ABSTRACT

The principles of imaging furnaces using the sun or a high intensity electric arc are presented. The performance of imaging furnaces with the two energy sources are contrasted and the relative advantages of each source are pointed out. Details on arc performance and construction are given. Advances in instrumentation for measuring and controlling temperature and heat flux are described. The function of a flux distributor to obtain larger uniformly heated area is explained.

The goal of high-temperature research is to obtain a better understanding of the behavior of materials under conditions of extreme temperatures. Therefore, means had to be found to generate high temperatures under controlled conditions in the laboratory. Among the approaches for generating high temperatures are those relying on heat transfer by a gas, induction heating, or resistance heating, and those using only radiant heating by means of an imaging furnace.

The imaging furnace, an optical system to concentrate radiation from a suitable heat source, has been found a useful research tool in studies of high-temperature phenomena. In an imaging furnace, the heat source is far enough from the sample to transmit heat by radiation only and not by conduction or convection. The advantages of this method are freedom from contamination of the sample (both by furnace vapors and a sample container), the possibility of studying the behavior of the material in either air or a controlled atmosphere, and the ease with which instruments can be brought close to the sample without being subjected to excessive heat.

Imaging Systems

During the past few years, solar furnaces, using the sun to provide radiant energy, have created considerable interest (1), although their dependence on the weather has restricted their applications. The substitution of an artificial source to permit the use of an imaging furnace inside a laboratory has been found to offer definite advantages (2). The development of new high-intensity electric arcs (3) has provided radiant-energy-producing capabilities beyond those found in a solar furnace.

Figure 1 shows the possible arrangements by which the source can be imaged onto a sample. A single paraboloidal mirror (4) and a paraboloidal mirror in combination with a flat mirror (5) have been used to image the sun onto the sample. Ellipsoidal-(6) and paraboloidal-mirror combinations (7) have been used in conjunction with electric arcs. An optical system using an ellipsoidal mirror with the source located at the major focal distance (8) produces a reduced image and the highest flux density, while a refractive system (9) is capable of giving a uniform image irradiation. The two-paraboloidal-mirror and two-ellipsoidal-mirror systems have found wide usage; two-ellipsoidal mirrors have some advantage in convenience of controlling the radiation.

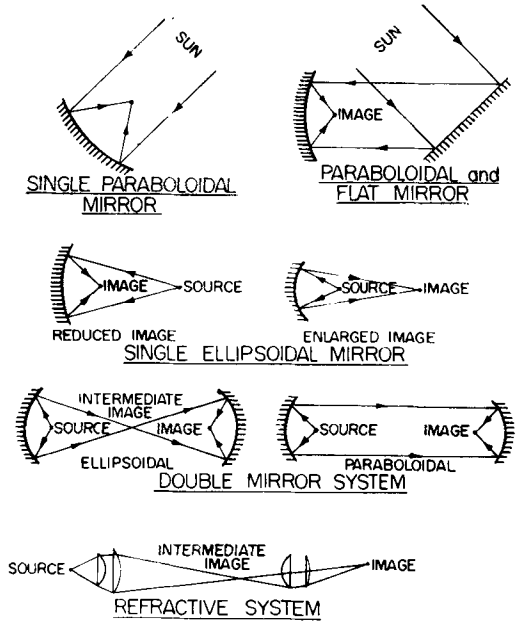

Fig. 1. Optical systems of imaging furnaces

The choice of optical system and imaging source depends on the desired characteristics of the image. A single mirror tends to have the least transmission loss, and, if the location of the source is transposed, either an enlarged or reduced image can be obtained. In addition to the type of image obtained (as determined by the optical system), the radiation flux density, distribution of the flux density at the focal zone, and fluctuation in the source output influence the usefulness of an imaging furnace.

When the sun is used as the radiation source, the flux density at the image is determined by the amount of radiation that reaches the collecting mirror system after absorption by the atmosphere (about 1.3 cal/cm^2/min). Because of the limited output of this radiation source, considerable effort had to be expended in establishing the optimum size and geometry (10) of the collecting mirrors so that a high image flux density could be attained.

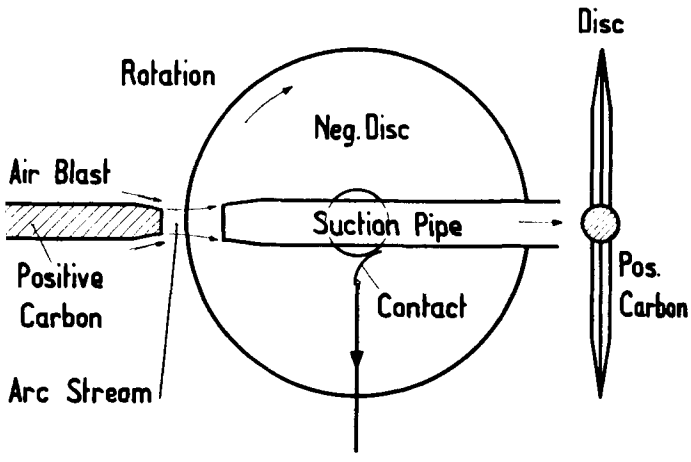

Fig. 2. Blown arc arrangement

Electric-Arc Sources

The electric arcs that have been used in imaging furnaces are of the Beck (11) type. The outstanding visible characteristic of this high-intensity electric arc is a jet of gaseous material ejected from the anode crater in the form of a vertical tail flame. The flow velocity and flow direction of this tail flame are determined by internal electromagnetic fields and thermal effects. These vaporized anode components, comprising atoms, ions, and possibly some diatomic molecules, radiate very strongly; their steady-state behavior depends on the current density. Much of the radiation that emanates from the gaseous materials of the tail flame is lost, since it cannot be concentrated into an image. A considerable improvement over the conventional high-intensity electric arc is represented by the Gretener (12) blown arc. Figure 2 shows the mechanism by which a blown arc is obtained. Tangential air jets surrounding the anode direct a conical stream of air inward toward the arc. In this manner, the gaseous materials are concentrated in the form of a cylinder of brilliantly glowing gases. In addition, the air jets surrounding the anode cool the outside surface thus allowing a higher current density without an increase in carbon consumption.

Operational Requirements

Operational requirements and experimental procedures may determine the type of source and optical system of an imaging furnace. The spatial distribution of the radiant flux density at the focal zone of the collecting mirror must be considered; it has been shown to follow approximately a Gaussian distribution (13). A useful parameter describing it is the radial distance from the optical axis at which the flux density has dropped to 90% of that measured on the axis. The nature of the optical system and the size and type of source determine what this radial distance will be.

Although a maximum image flux density is desirable, a constant flux density at the image plane is necessary. When the sun is used as the radiation source, nearly ideal constant conditions prevail at the image; no other source has been able to produce equivalent conditions.

Constancy of flux density is influenced by nonuniform composition of the arc electrodes, irregular burning of the electrodes (caused by the effects of magnetic fields), variations in the supply of voltage, unsatisfactory electrode feed devices and controls, and an unstable arc (caused by an excessive current density). The positioning of the positive carbon in the focal plane of the source mirror is critical; a movement of ⅛ in. from the electrode focal plane can cause a change of 10% in the flux density at the image.

The duration of an experiment to be performed in an imaging furnace may influence the selection of a source. Theoretically, the sun provides the longest daily operating time for an imaging furnace, but actually, this time depends on the location of the furnace and on the weather. In the northern latitudes, atmospheric conditions may limit the number of uninterrupted operating hours available; the electric arc offers a better alternative when continuous use of the imaging furnace is desired.

Considerable improvements have been made in the structure of electrodes (14) for improving the performance of electric arcs, particularly the blown arc. The improved carbon electrodes have a cored structure designed to prevent disturbing light fluctuations when the arc is being burned. A suitable electrode has a double-cored construction. The inner core contains rare earth compounds that provide a high intensity of light; the proportion of rare earth in the outer core is greater than that in the inner core. Experimentally produced electrodes using this construction allow a far greater current density to be employed and thus make possible a higher flux density.

At lower current densities, electrodes may have to be replaced in about 20 min, while at higher current densities, they may have to be changed in about 5 min. Disk cathodes can operate for several hours.

ADL-Strong Arc-Imaging Furnace

A double-ellipsoidal-mirror system has been designed on the basis of requirements posed by high-temperature research procedures. This system offers an excellent compromise between the requirements of high-radiation flux density, large image size, temperature control, duration of the radiation pulse, and flexibility for experimental measurements. Figure 3 is a diagram of the ADL-Strong arc-

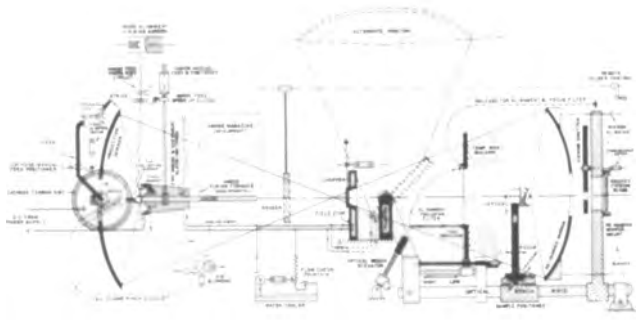

Fig. 3. Diagram of ADL-Strong arc imaging furnace

imaging furnace. The arc source is a Gretener-type arc with a 10-mm rod anode and a carbon-disk cathode. An auxiliary 6-in. diameter collecting mirror located behind the anode reflects a portion of the radiation to the main source mirror. Two ellipsoidal 21-in. diameter mirrors are used; these can be operated with the optical axis in either a horizontal or vertical position by the insertion of a flat diagonal mirror. With the optical axis in the vertical position, it is possible to melt powders and study liquid phases, with the parent materials forming the container.

Temperatures of the sample are controlled by a temperature modulator that consists of a sliding aperture with remote electric controls. An alignment and focusing disk forms part of the modulator and enables the mirrors to be aligned on the optical axis and a sample to be located in the focal plane. The sample is mounted on a positioner that permits tri-axial movement through remote electric drives. Two shutters are used, one located near the intermediate image, and the other just behind the opening in the collecting mirror. The purpose of these shutters is to permit the separation of incident and reflected radiation from the sample as well as to allow a specific radiation pulse to be obtained. The power required by the arc is 180 amp continuous to 300 amp intermittent at 75 v and is supplied by a selenium rectifier.

Measurement Techniques

Once the capability of generating high temperature with an imaging furnace had been developed, the need arose to have instruments available for the measurement of physical parameters, particularly heat flux and temperature.

Heat Flux

Calorimeter.—Figure 4 shows the cross section of the calorimeter (15), designed to meaure heat flux reaching the focal zone of the collecting mirror, where the energy arriving over a 140-degree solid angle is accumulated inside a black-body cavity

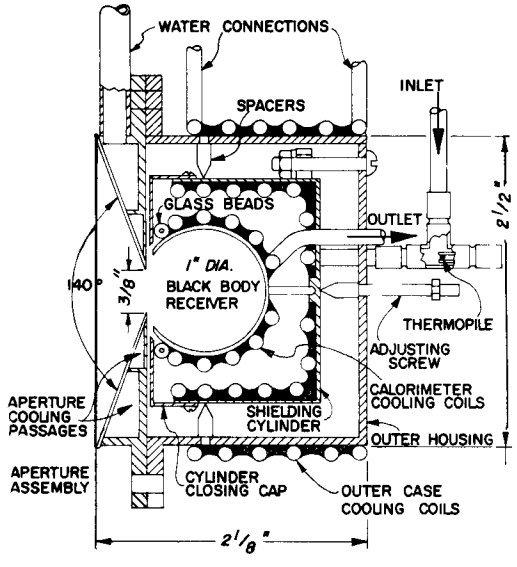

Fig. 4. Cross-section of calorimeter

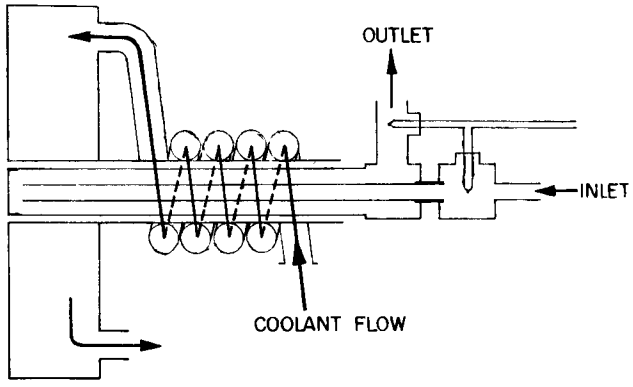

Fig. 5. Cross section of calorimeter

and transferred to the circulating water; this energy is calculated from measurements of the temperature rise and quantity of water flowing. The device is designed with an accuracy of ± 5% and has been used as our basic calibrating calorimeter.

Figure 5 shows a cross section of the water-cooled calorimeter used to measure the radiation over 180-degree solid angle. The measuring area of the calorimeter is blackened and water-cooled, and the temperature rise and quantity of water flowing is measured. This type of calorimeter requires calibration, since some of the incident energy is radiated again at the front surface.

Radiometer.—The two calorimeters described measure the total radiation received over a specific diameter at the focal plane. In some instances, it may be of interest to measure the maximum flux density (rather than the average flux density) as well as the flux distribution across the focal plane.

Figure 6 shows a circular-foil radiometer (16). The receiving area of this water-cooled radiometer is 0.9 mm in diameter. Since it has a very short time constant, the measurement of rapidly varying fluxes or of the continuous traversal of the focal plane can be accomplished. Figure 7 shows the cross section through the radiometer. A blackened, thin circular foil of constantan fastened to a water-cooled copper block absorbs the radiation, and a thin copper wire attached to the center of the circular foil measures the temperature rise at its center.

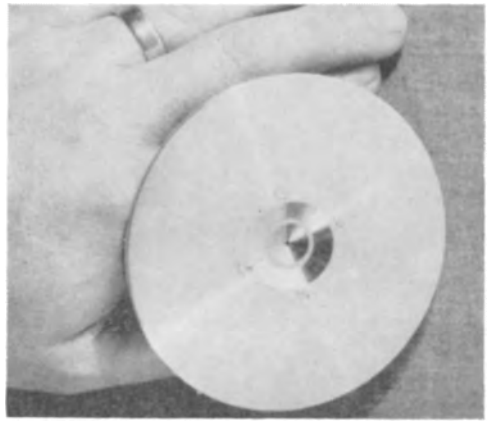

Fig. 6. Circular foil radiometer

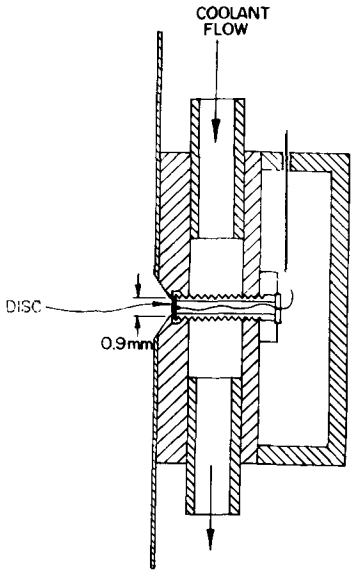

Fig. 7. Cross section of radiometer

The circular-foil radiometer calibrated with the absolute calorimeter can also measure the radiation flux density at the focal zone. Figure 8 shows the flux distribution obtained in both the solar furnace and the arc-imaging furnace with the radiometer. Also shown are the instantaneous flux variations recorded by the radiometer in the arc-imaging furnace; these variations are of the order of ± 5%. Improvements in the electric feeding device, the power supply, and the uniformity of the electrode are expected to further reduce the flux variations.

When a short-time radiation pulse is to be used, conventional calorimeters cannot be applied use-

fully. Instead, a copper disk is suspended by thin wires, and its temperature is measured by a thermocouple after calibration with the calorimeter (Fig. 9).

Table I shows the performace data of the ADL-Strong arc-imaging furnace. Although in prior work 4000°K (obtained from calorimetry) was reported as the highest value attained, the lower temperatures measured in the ADL-Strong furnace are partially attributed to the use of second surface-collecting mirrors.

Temperature Measurements

Conventional optical pyrometers measure accurately only the temperatures of a black body (17), a condition that few samples are able to satisfy. Although drilling small holes into the sample surface to approximate black body conditions is valid theoretically, this expedient raises questions concerning the uniformity of cavity temperatures and may not be feasible with some of the samples to be tested.

The optical pyrometer can be used for accurate temperature measurements in an imaging furnace if suitable shutters are provided for separating emitted and reflected radiation. Radiation emitted by, or reflected from, the sample is observed with an optical pyrometer sighted through a hole at the center of the collecting mirror (Fig. 3). The shutter located near the intermediate image position rotates about an axis that is slightly displaced from the optical axis of the ellipsoidal mirrors and periodically shields the sample from the arc radiation. An off-axis shutter behind the collecting mirror is provided with a small opening that coincides with the optical axis; it is driven in synchronization with the previous shutter by means of synchronous motors. The field coils of the motors are connected in such a manner that the two shutters can be either in phase or out of phase. In the in-phase position, only radiation emitted by the sample is observed, since all other radiation is prevented from reaching the sample. In the out-of-phase position, both emitted radiation and the arc radiation reflected from the sample are observed.

The apparent surface temperature of the sample is measured with the two shutters rotating in phase. A second temperature is then measured with the shutters out of phase. Kirchhoff's equation relating reflectivity to emissivity can then be used to deter-

mine the approximate spectral emissivity; once this is known, the true temperature can be calculated

$$\frac{1}{e^{C_2/\lambda T_{p1}} - 1} = K \frac{\epsilon(\lambda,T)}{e^{C_2/\lambda T_M} - 1} \qquad [1]$$

$$\frac{1}{e^{C_2/\lambda T_{p2}} - 1} = K \frac{\epsilon(\lambda,T)}{e^{C_2/\lambda T_M} - 1} + \frac{K[1 - \epsilon(\lambda,T)]}{e^{C_2/\lambda T_s} e - 1}$$

$$\epsilon(\lambda,T) = 1 - \frac{1}{K}\left(\frac{1}{e^{C_2/\lambda T_{p2}} - 1} - \frac{1}{e^{C_2/\lambda T_{p1}} - 1}\right)(e^{C_2/\lambda T_s} e - 1)$$

$$T_M = \frac{\lambda}{C_2} \ln^{-1}\left[1 + K\epsilon(\lambda,T)\,(e^{C_2/\lambda T_{p1}} - 1)\right] \qquad [2]$$

The first equation relates the in-phase apparent temperature of the sample to the true sample temperature. The second equation relates the out-of-phase apparent temperature to the sample temperature and to the effective temperature of the arc source. The last term in this equation represents the reflected arc radiation received by the pyrometer.

An effective arc temperature must be used in the equation in place of the arc temperature, because the mirrors of the imaging furnace are not perfect reflectors and do not have perfect geometry. These imperfections reduce the spectral brightness of the arc image. For determination of the effective arc temperature, a plain mirror is placed about 2 in. in front of the focal zone, and the apparent temperature of the arc image is measured with an optical pyrometer provided with suitable filters. These equations can then be solved simultaneously to give a value of the spectral emissivity. The value of the emissivity is then used with the first equation so that a true temperature accurate to 5% is obtained. A comparable measuring procedure has been used to measure cathode temperatures in a cavity (18).

A modified optical pyrometer allows the measurement of temperatures automatically and provides a record of temperature variations occurring as fast as 1/100 of a second.

Flux Uniformity

The optical system used in an imaging furnace determines the spatial distribution of the radiant flux density. With the two-ellipsoidal-mirror system, a high flux density over a limited image size is obtained (Fig. 8). At times it may be desirable to enlarge the image area and, instead of a Gaussian distribution, to obtain a uniform distribution over a larger area. The usefulness of defocusing (19) depends to a large extent on the type of optical system; defocusing is usually accompanied by a decrease in uniformity even as the image size increases. Although optical systems to obtain larger images with a uniform distribution have been developed (20) low flux densities usually result. To meet the requirements for either a high temperature over a small area or a uniform flux distribution over a large area, a flux redistributor was developed. This flux redistributor (Fig. 10) can be placed in front of the focal plane of the imaging furnace; it provides a uniform distribution over a fairly large image area. By using this instrument, we were able to concentrate 20 cal/cm²/sec over a ⅝-in. square area; Figure (11) shows the increased uniformity of burned patterns when the redistributor is used; Fig. 12 shows the pattern without the flux redistributor. This device intercepts the flux by means of four mirrors and redistributes it onto the sample plane in a uniformly illuminated area.

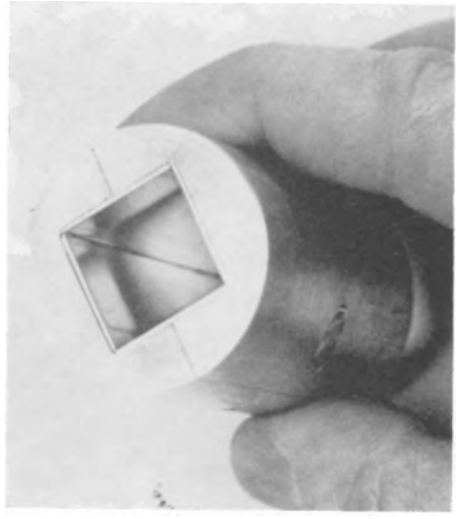

Fig. 10. Flux redistributor

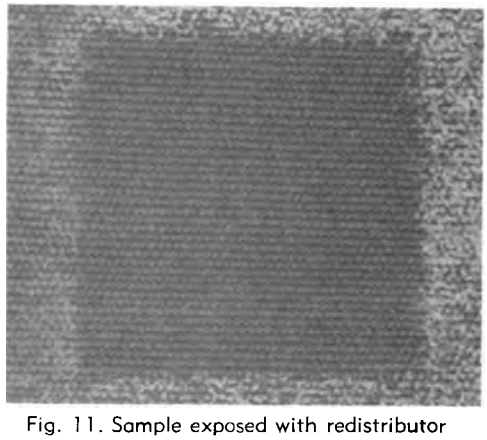

Fig. 11. Sample exposed with redistributor

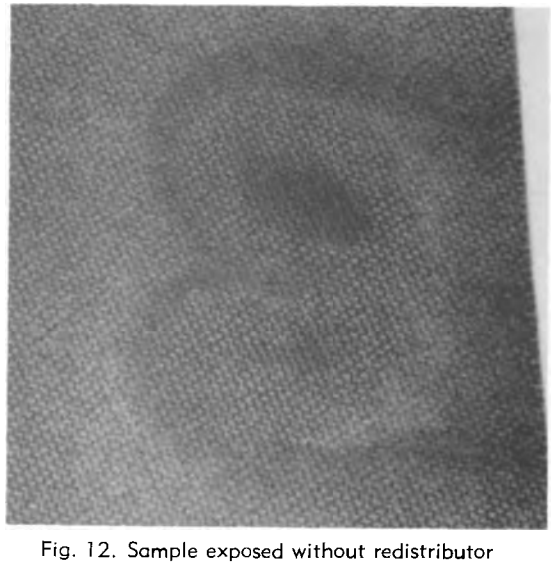

Fig. 12. Sample exposed without redistributor

The effect of a nonuniformity in the energy beam is almost completely eliminated by the use of the flux redistributor. If U_m is the maximum nonuni-

formity expressed as a percentage of the flux distribution without a flux redistributor, then with the redistributor the nonuniformity is given by:

$$U < \frac{S_a}{100} U_m$$

where S_a is a shadow attenuation function depending on the ratio of length to inside dimension and on the reflectivity of the inside surfaces of the flux redistributor.

Conclusions

The use of imaging furnaces for the radiant heating of materials has been of considerable interest to many researchers. Because of the newness of the device, however, the lack of instrumentation, and the nonexistence of well-defined experimental procedures, its applications have not as yet been widespread. As more information accumulates, its advantages and drawbacks will become more fully appreciated and its usefulness demonstrated in a greater number of research projects. As is the case with many new research tools, it cannot be expected to solve all high-temperature-research problems; rather, it will be applicable to those research projects where the ingenuity of the experimenter and experimental requirements make it invaluable.

Acknowledgments

The author would like to thank the members of the staff of Arthur D. Little, Inc., and Strong Electric Company, Toledo, Ohio, for their interest, help, and cooperation in the design, instrumentation, and manufacture of the arc-imaging furnace. Particularly noteworthy were the designs worked out by F. Chellis, the development of the flux redistributor by M. Chen, and the temperature-measurement methods developed by H. Blau. C. Warner, A. Camus, and J. Lund made valuable contributions to the measurements of heat flux and helped make the ADL-Strong arc-imaging furnace a safe and dependable research tool.

Metal Mists and Aluminum Losses in the Hall Process

Warren E. Haupin

Alcoa Research Laboratories, New Kensington, Pennsylvania

ABSTRACT

Reaction of aluminum with Hall cell electrolyte forms aluminum monofluoride and sodium which dissolve in some form to give the bath a reducing capacity equivalent to a free aluminum content of about one tenth per cent. The so-called "metal mist" forms in the presence of moisture and consists of hydrogen bubbles containing a small partial pressure of aluminum monofluoride, sodium, and sodium tetrafluoroaluminate. Increasing the NaF/AlF_3 ratio of the electrolyte increases the sodium and decreases the aluminum monofluoride partial pressure, but sodium has a much higher partial pressure; hence, a low NaF/AlF_3 ratio is desirable to minimize metal reoxidation. Carbon dioxide is abundant in the anode gas of a smelting cell and is soluble in the bath. It oxidizes the free metal both in and over the bath. The rate of this reoxidation appears to be controlled by the rate of diffusion and convection of dissolved metal away from the metal-bath interface.

Almost any oxygen-containing gas, including water vapor, is reduced when it is bubbled through Hall bath (87% $NaF-AlF_3$ of various NaF/AlF_3 ratios, 8% CaF_2, 5% Al_2O_3) when the electrolyte is contacting aluminum, thereby indirectly oxidizing the aluminum. The mechanism of the aluminum reoxidation, the composition of the "mist" or "fog" that forms, and even the question of whether acid bath (excess AlF_3 over the cryolite composition) or alkaline bath (excess NaF) causes the greater metal loss have, however, been the subject of considerable controversy (1-16).

Various investigators have reported the fog to be sodium (4-9), aluminum (10-13), aluminum monofluoride (16), aluminum carbide (19), hydrogen (14,15), or some combination of these. The apparent composition of the fog was influenced by the method used to identify the fog. Investigators immersing copper strips in bath, held over aluminum, picked up aluminum in the copper, which has a high solubility for aluminum. They interpreted this as indicating the mist was aluminum. However, investigators similarly using lead, which has a high solubility for sodium, found that the lead picked up sodium.

Composition of Mist

A mist must be a separate phase, but bubbles of sodium vapor or aluminum monofluoride vapor were ruled out by thermodynamic considerations, for these vapors cannot exist at 1 atm pressure at the bath temperature in contact with molten cryolite. Thermodynamics did not rule out the presence of these gases at a much lower partial pressure, but this presupposed the presence of some other gas. There was also the possibility of a mist of finely divided aluminum suspended in the cryolite, and mechanisms for obtaining such suspensions have been postulated (12,13).

To start the present investigation, it was thought desirable to extend Grjotheim's investigation (14) of metals which form a mist in Hall baths. At 980°C in a graphite crucible, it was found that a mist formed when magnesium, aluminum, sodium, or zinc was added to the bath. Sodium and zinc caused a violent bubbling when added, but a foggy appearance remained for 15 to 30 min after the bath became still. The bath remained clear when tin, nickel, lead, copper, or silver was added. The metals that made a mist were all metals capable of displacing hydrogen from water. Since sodium and zinc were above their boiling points, it might be claimed that the mist was vapors of these metals. The other mist formers, however, were well below their boiling temperatures.

Operators of the Hoopes-type aluminum refining cells claimed that the bath in their cells did not form a mist. To investigate this and to observe the effect of lowering the sodium ion concentration of the bath, melts were prepared of the following compositions by weight:

Bath 1—30% BaF_2, 21.5% AlF_3, 37.5% Na_3AlF_6, 11% MgF_2
Bath 2—18% BaF_2, 21% AlF_3, 45% Na_3AlF_6, 16% CaF_2
Bath 3—26% AlF_3, 58% Na_3AlF_6, 16% CaF_2
Bath 4—100% Li_3AlF_6

These baths all formed a mist when aluminum was added. The most logical explanation for the bath in commercial refining cells being free from mist is that the bath had a layer of molten aluminum floating on its surface and was thereby protected from absorbing moisture.

Local cell action.—The loss of aluminum when held under fused salts in Pyrex was studied. No loss of metal was found in pure NaCl-KCl eutectic at 750°C. With the addition of 10% Na_3AlF_6 both chemical and electrochemical solution of aluminum occurred. Electrochemical solution was obtained by placing a graphite rod into the bath and contacting the aluminum. The rate of electrochemical solution was controlled by polarization of the carbon and took a carbon area approximately six times the metal area to obtain double the rate of chemical solution. A

tenfold increase in metal loss was obtained with a carbon area roughly 30 times the metal area.

Loss in inert crucibles.—To determine if mist formation in the Hall bath was the result of electrochemical action and rule out the carbide mist theory, neutral Hall bath and bath No. 3 were each melted in crucibles of sintered alumina, silicon nitride, and magnesite, respectively. These baths formed a mist upon the addition of aluminum, regardless of the crucible used.

To eliminate completely any crucible effect or local cell action, a pool of molten bath was melted in a pile of powdered Hall bath using radiant energy from an electric arc in argon between tungsten electrodes. The molten bath held in solid bath was clear. A 0.1 mg piece of aluminum was dropped in the pool. It moved about by convection currents and left a trail of mist reminding one of the tail of a comet. Eventually, the aluminum was consumed. When a 1 mg piece of aluminum was added, it rested on the bottom and a mist rose in streamers. A 1-g piece completely fogged in the bath. Since no carbon was present in the system, these tests ruled out the carbide mist theory. They also indicated that no electrolytic cell action was necessary for mist formation. Based on the foregoing evidence Grjotheim's conclusion was accepted: that a mist of hydrogen forms by the reaction between free metal and moisture that dissolves in the bath.

Howard (18) has shown that a vapor of sodium tetrafluoro aluminate ($NaAlF_4$) exists over molten cryolite. Therefore, one must conclude that the hydrogen bubbles will have a small partial pressure of $NaAlF_4$.

Formation of a Hydrogen Mist

While the tests just described gave indirect evidence of a mist of hydrogen, they did not prove that hydrogen was the only source of mist. Grjotheim (15) suggested that polynuclear metal ions may cause a foggy appearance. A more quantitative test was designed therefore to ascertain if hydrogen was the only source of fog or mist. Baths of the desired composition were mixed as dry powdered reagent grade chemicals and added to a crucible at the bottom of a sealed retort, as shown in Fig. 1. The bath was dried at 200°C for 12 hr, then melted and held at 980°C. Dry argon was flushed continuously through the retort at 100 cc/min. The retort had a replaceable copper sleeve extending from the top of the crucible to the top of the retort, a distance of 12 in. Metallic vapors condensed and partially alloyed with this sleeve. Some metal condensed also on and in the gas inlet and outlet tubes. The top of the retort was water cooled to protect the "O" ring seals and to cool the upper part of the copper sleeve. The escaping gases passed consecutively through an electrostatic precipitator to remove particulate matter, sodium fluoride pellets to remove HF, magnesium perchlorate to remove moisture, ascarite to remove CO_2, hot copper oxide to oxidize CO to CO_2 and hydrogen to water, magnesium perchlorate to absorb the oxidized hydrogen, and finally ascarite to remove CO_2 oxidized from CO. The absorption chambers

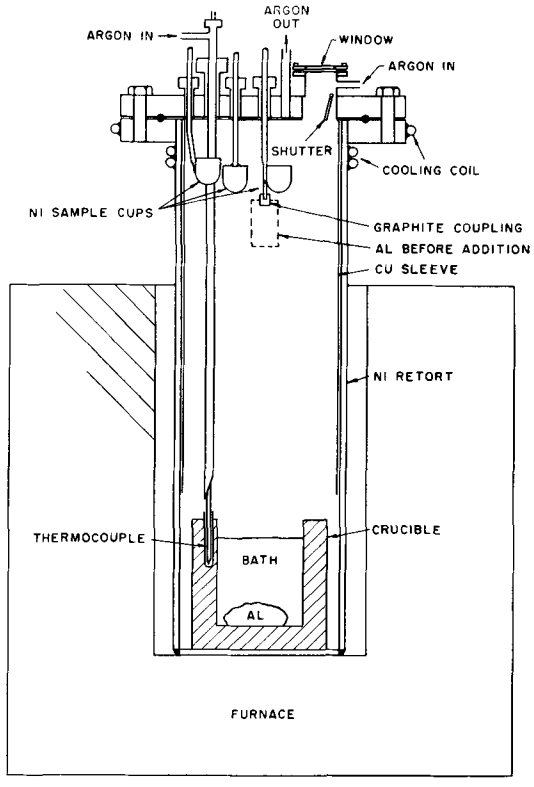

Fig. 1. Sealed system for metal mist tests

were weighed periodically during the test. Also, throughout the run, observations were made of the mist in the bath through a glass window equipped with a shutter and wiper operated through "O" ring seals. Bath samples were taken and metal addition made by control rods operated through "O" ring seals so that the system was never open to the atmosphere.

As soon as the bath became molten, bath sample No. 1 was taken. Then 100 g of aluminum were added to the remaining 750 g of molten bath. As soon as the metal melted, the bath became fogged and the surface was agitated by escaping gas bubbles. After ½ hr, the time of maximum hydrogen evolution determined by weight gain of the absorption bottle, bath sample No. 2 was taken. Since it was difficult to see clearly enough through the window to be sure of the complete absence of mist, duplicate runs were made of the first three tests. The retort was opened after 72 hr, at which time all measurable hydrogen evolution had stopped. The bath, at this time, was in each case found to be mist-free. The taking of bath sample No. 3, therefore, was set at 72 hr. Table I gives the results. The free metal in the frozen bath samples was determined by hydrogen evolution with HCl and is reported in equivalent per cent free aluminum. Both hydrogen and methane were frequently evolved. The methane, assumed to have come from Al_4C_3, represented 0-0.24% Al_4C_3 by weight in the bath. There was no correlation between the evolution of methane and the presence of mist or the NaF/AlF_3 ratio of the bath.

An attempt was made to analyze the frozen bath samples separately for metallic sodium and metallic aluminum by vacuum distillation and by mercury extraction. No free aluminum or sodium was found

Table I. Results of bath sample No. 3

Bath molten (length of time)	10 min	40 min	72 hr
Aluminum present under bath	No	Yes	Yes
Bath appearance	Clear	Fogged	Clear
H_2 evolution	None	0.2-0.25 ml/min	None

ND—Not determined.
[1] Weight loss is not accurate because of difficulty in separating adhered bath from aluminum.
[2] Did not want to sacrifice expensive crucible.
[3] Previous data appeared sufficient.
[4] Difficult to obtain in carbide system.
[5] Cu condensing sleeve became detached during run.

by either method, but this was attributed to faulty technique. It is planned some time in the future to make a more detailed study of these techniques.

An apparent separation of the aluminum and sodium was obtained by hydrogen evolution, using first water and then a sodium hydroxide solution. The first evolution was assumed to represent metallic sodium, again correcting for any methane evolution. When all evolution stopped, sufficient NaOH was added to the water to make a 10% NaOH solution. The second evolution was assumed to represent aluminum. Hall bath with a NaF/AlF_3 weight ratio of 1.5 showed 0.16% Na and 0.05% Al by this technique, while bath with a NaF/AlF_3 ratio of 1.3 showed 0.10% Na and 0.05% Al. These results were not exactly consistent with Table I or with theory. Theory would lead one to expect a higher aluminum concentration in the second bath sample, for AlF in the molten bath should decompose to Al and AlF_3 in the frozen bath samples. It was feared that water was giving some evolution from the aluminum. Because of this, no great reliance is placed in this method of separately analyzing for Al and Na.

A mist or fog was present only when hydrogen was being evolved. No second type of mist suspected by Grjotheim was found. No hydrogen was evolved until aluminum was added. Upon addition of aluminum, free metal was found in the bath and a mist formed. After 72 hr, hydrogen evolution had stopped, but the bath still contained free metal. Later we shall see that the free metal in solution creates a vapor pressure of aluminum monofluoride and sodium over the bath. The metal loss through reaction with moisture apparently depended on how dry the bath and crucible were initially.

Metal Losses

Table II gives the weight loss in grams of the aluminum and shows the various ways in which this aluminum was lost. The aluminum loss into the crucible was determined by a chemical analysis of the crucible for calcium, sodium, aluminum, fluorine, and aluminum carbide, all corrected for a blank of the crucible before the test. The aluminum loss into the crucible was taken as the excess of metal ions over the fluoride ion on an equivalent basis. The total carbide figure included both the carbide on the crucible and adhering to the aluminum. The aluminum loss by reaction with moisture dissolved in the bath was determined by the hydrogen evolution from the system. The aluminum loss as a vapor escaping from the bath was determined by chemical analysis of the copper shield and gas inlet and exit tubes and the condensate adhering to them. Both free aluminum and sodium were found. Naturally, much of the sodium condensing did not alloy with the copper and burned when the retort was opened. Care was taken to minimize the loss of sodium oxide fumes and the sodium that burned was determined from the sodium oxide formed.

Aluminum and Sodium Vaporization

Perhaps the manner in which the sodium and aluminum condensate varied with bath ratio, shown in Table II, is even a more significant finding than the composition of the fog. Metallic sodium in the vapor over the bath probably is accounted for by the equilibrium:

$$\underset{\text{(lig)}}{Al} + \underset{\text{(bath)}}{Na_3AlF_6} \rightleftharpoons \underset{\text{(bath)}}{3Na} + \underset{\text{(bath)}}{2AlF_3}$$

$$\downarrow\uparrow\ 3Na$$

$$\text{(p in argon)}$$

The vapor pressure of aluminum is too low to account for the transfer of aluminum. The most plausible explanation for the aluminum transfer is that the aluminum was carried as aluminum monofluoride vapor through the following sequence of reactions:

$$\underset{\text{(lig)}}{2Al} + \underset{\text{(bath)}}{AlF_3} \rightleftharpoons \underset{\text{(bath)}}{3AlF} \rightleftharpoons$$

$$\underset{\text{(p in argon)}}{3AlF} \rightarrow \underset{\text{(Cu alloy)}}{2Al} + \underset{\text{(solid)}}{AlF_3}$$

To check this theory a ⅛ in. diameter copper rod was sealed in a graphite capsule 1 in. OD x 2 in. long with ⅜ in. thick walls. The air in the pores and cavity of the capsule was replaced with argon by placing the capsule in the chamber, evacuating, and then filling with argon. The capsule was then

floated on molten bath for 24 hr. After the test the capsule was broken open. No bath penetrated the capsule, but the surface of the copper rod was covered with a white powder that was found by x-ray diffraction to be AlF_3. The copper rod had assumed the color of yellow brass and qualitative spectrographic analysis showed it to have picked up between 1 and 10% aluminum. This was taken as evidence of a sizable vapor pressure of aluminum monofluoride over the bath.

In the foregoing reasoning it was assumed that aluminum monofluoride and sodium were soluble in some form in the bath, otherwise there appeared to be no mechanism for carrying free metal from the pool of aluminum under the bath to the surface of the bath to generate a vapor pressure of aluminum monofluoride, and sodium. However, the dissolved species need not be aluminum monofluoride and sodium. Either would suffice, or any other appropriate species such as Al, Al^+, Na_2^+, or any combination of these. Through their respective equilibriums with the bath, these constituents would create a vapor pressure of aluminum monofluoride and sodium over the bath and give the bath an activity of aluminum monofluoride and sodium so that it would reduce carbon dioxide or moisture.

Since the argon flow was the same in all the metal holding tests, the ratio of the weights of aluminum and sodium condensed should, on a mole basis, be proportional to the partial pressures of the aluminum monofluoride and sodium over the bath. Even though the partial pressure of AlF was increased by a low NaF/AlF_3 ratio, sodium still had a higher partial pressure over the bath than AlF and apparently a higher activity in the bath. This to a large extent explains why acid baths give higher current efficiencies than neutral or alkaline baths.

The steps in the reoxidation of aluminum appeared to be: (*a*) a reaction at the metal-bath interface to give a solution of free metal or its equivalent in the bath, (*b*) diffusion and convection of the free metal away from this interface, (c) reaction between the free metal from the bath and carbon dioxide from the anode. Reoxidization of free metal by moisture cannot account for more than about 0.6% loss in current efficiency for unburned gas from commercial cells averages less than 1% hydrogen by volume.

Nozaki and Miyanchi (12), investigating industrial cells that were suddenly disconnected due to war action, found that the free metal concentration in the electrolyte varied from none near the anodes to the maximum near the metal pad. Bath samples taken in the static metal holding tests showed the equivalent of about 0.1% free aluminum. A sample of similar electrolyte taken 3 in. from the side of an anode and 3 in. above the metal pad of an operating cell showed only the equivalent of 0.02% free aluminum or about one fifth of the equilibrium value. A similar sample of electrolyte was taken and CO_2 determined as present. It appears from the concentration and distribution of free metal that the slow step in the reoxidation of aluminum in commercial cells is the transport of free metal from the cathode to the vicinity of the anode. This is confirmed further by the observation that greater anode-cathode separation improves current efficiency.

Solubility of CO_2 in Bath

Förland and Associates (17) have reported solubility of CO_2 in molten cryolite. This was confirmed by taking a quickly frozen sample of electrolyte, as described previously, from an operating cell and a similar sample as a blank from the sealed system. Both were heated to approximately 500°C in a vacuum and the gas evolved analyzed by a mass spectrograph. The 10-g sample of the bath from the reduction pot evolved approximately 21 μg of carbon dioxide. The sample from the sealed system evolved two micrograms of carbon dioxide. This was taken as confirmation of Förland's findings.

The fact that both sodium and carbon dioxide were present in the sample of electrolyte from a commercial cell indicates a highly nonequilibrium condition exists within the electrolyte. Apparently there are strata of dispersed and dissolved carbon dioxide and dissolved free metal which are being mixed and reacting.

Numerous other gases also were evolved from the sample of the electrolyte from the reduction pot. They are listed in Table III.

Other Sources of Aluminum Loss

Another major source of aluminum loss in these tests was the formation of aluminum carbide. There was some indication (Table II) that the carbide formation was more severe in acid baths, but the trend was not very distinct. The loss of free metal, probably mostly sodium, penetrating into the crucible accounts for most of the remaining metal loss.

Use of Crucibles Other than Carbon

A test in a boron nitride crucible showed an abnormally small aluminum loss. When the cell was opened and the bath poured, however, the metal pad was covered with a dark film. The test made in a silicon carbide (SiN bonded) crucible showed practically the same metal loss as in a graphite crucible. If the principal cause of metal loss were an electrochemical cell reaction between the aluminum and the carbon, then it would appear that the metal loss would be lower both with the SiC and BN crucibles because of the lower electrical conductivity of the crucibles. The fact that the loss was practically the same in SiC as in the graphite crucible would lead one to believe that, at least under the conditions of these tests, the solution of aluminum was predominantly chemical rather than electrochemical. Previ-

Table III. Gases evolved from a rapidly frozen 10-g sample of electrolyte from a reduction pot when reheated to 500°C in vacuum

Carbon dioxide	21 micrograms

ous tests in Pyrex, using fluorides diluted by chlorides, showed the metal loss was increased by electrolytic cell action. Perhaps in the present case, carbide formation on the graphite crucible inhibited local cell action, or it could be that straight chemical reaction was fast enough to maintain the equilibrium concentration in the bath. Carbon dioxide bubbling through the bath in a commercial cell certainly will remove the free metals from the bath at a much greater rate. Under these conditions cell action to form sodium may become a factor. In the present test, the lower metal loss in the boron nitride crucible appeared to be associated with the presence of a boride film over the surface of the aluminum.

Conclusions

Molten Hall bath in contact with molten aluminum develops a reducing capacity equivalent to about 0.1% free aluminum dissolved in the bath. The presence of sodium and aluminum monofluoride vapors over the bath indicates solution of free metal in some form in the bath. The visible mist, on the other hand, is hydrogen formed by reaction between moisture and free metal dissolved in the bath. Naturally the bubbles contain a small partial pressure of Na, AlF, and $NaAlF_4$. Aluminum monofluoride and sodium vapors are evolved even from a clear, mist-free bath. Increasing the NaF/AlF_3 ratio of the bath increases the sodium loss and decreases the aluminum monofluoride loss. The aluminum monofluoride loss, however, is small compared to the sodium loss even from an acid bath. In an operating reduction cell the free metal concentration in the bath does not reach its equilibrium value in the bulk of the bath but varies from a maximum near metal pad to a minimum near the anode. This indicates that the process of diffusion and convection of free metal in the bath is the rate-controlling step in the reoxidation of aluminum.

Anodic Precipitation of Tracer Manganese as Dioxide

Edward A. Heintz[1] **and L. B. Rogers**

Department of Chemistry and Laboratory for Nuclear Science,
Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

Quantitative recovery of carrier-free $10^{-9}M$ manganese (II) is possible from weakly acidic solutions. The use of lead dioxide as either a nonisotopic carrier or a chemical displacing agent makes possible high recoveries from more acidic solutions.

Electrolytic procedures for the recovery of radioactive tracers offer the advantages of being easily adaptable to remote control operation as well as being quite selective. The present study aimed to define conditions under which carrier-free manganese could be deposited quantitatively as the dioxide. In addition, the use of lead dioxide as a carrier (1) was examined because it enabled better recoveries to be made from solutions too acidic to permit deposition of tracer manganese dioxide alone.

The choice of lead as a carrier was also based on the ready availability of conditions (2) and mechanism (3) for its anodic deposition. The ability of thallium (III) oxide to carry manganese was investigated only briefly and was found, as expected, to be less satisfactory.

Results

Anodic behavior of manganese alone.—The only depositable species in solution was manganese (II) either as a radioactive tracer alone, at an estimated concentration of $10^{-9}M$ in $1.0M$ potassium nitrate solutions, or with added nonradioactive manganese up to millimolar. Figure 1 shows that, as the pH was increased, complete deposition of carrier-free manganese dioxide ($10^{-9}M$) was first attained at pH 4.

The decrease found at more anodic potentials has been attributed to formation of a higher valence state having greater solubility (1).

In general, the manganese could be deposited, stripped, and redeposited at will by choosing the proper potential, thereby indicating that removal from solution was primarily an electrochemical process. However, the contribution of adsorption was evaluated by measuring at open circuit the decrease in activity of a tracer solution with time. At *p*H values less than 7.0, adsorption was negligible, i.e., less than 3% in 12 hr. At *p*H 9.0, however, virtually all of the activity was adsorbed within an hour. It was surprising to find most of the radiomanganese on the electrode.

From *p*H 3.5 to 6.0, the curves (at the 50% level) shifted at a rate of 155 mv/*p*H unit. If the reaction were

$$Mn^{++} + 2H_2O \rightarrow MnO_2 + 4H^+ + 2e \qquad [1]$$

this shift should be 120 mv at 25°C. The discrepancy may indicate that some deposited manganese was not in the tetravalent state. However, some of the discrepancy can be attributed to *p*H changes during a run. For example, a series of points were obtained using solutions carefully adjusted to *p*H 6.10 before electrolysis at each potential. These showed a spread of ±0.03 v at the level of 50% deposited whereas a comparable study at *p*H 4.00 showed less than ±0.01 v variation. It is interesting to note that the extent of deposition was usually in agreement with an earlier estimate (4) of 10^{-54} for the apparent solubility product of manganese dioxide.

At a given *p*H, one would expect the completeness of deposition to increase with the concentration of manganese. When more tracer was present, a larger percentage of manganese precipitated under a given set of conditions. Thus, 95% precipitated when three times the normal amount of tracer was used compared to 80% from the normal amount. In addition, the deposition curve proved to be the same as that for the normal amount of radiomanganese plus $10^{-8}M$ of inert manganese (II) nitrate. Decreasing the tracer to one-half the standard amount resulted in only 60% coprecipitation. Inspection of the above data showed that, regardless of the initial amount of tracer present, approximately the same amount of tracer remained in solution at the completion of the deposition. The average concentration of manganese in the tracer calculated from these data was $1 \times 10^{-9}M$, the same as estimated from activity data. Exact agreement was fortuitous but did indicate that contamination of the tracer with nonradioactive manganese was not serious.

Higher concentrations of manganese were examined by adding nonradioactive manganese. Figure 2 shows that near *p*H 2.0 complete deposition was attained at $10^{-4}M$ and higher. From the tracer alone a maximum of 10% was deposited. This curve served as a "blank" for later coprecipitation studies.

Coprecipitation of trace manganese with lead dioxide.—The *p*H region in which carrier-free manganese dioxide precipitated completely was sufficiently high to incur interferences from a number of other elements if attempts were made to apply the method to mixtures. For that reason, coprecipitation from more acidic media (1) was investigated further.

Factors which affect the coprecipitation of radiomanganese with lead are applied potential, *p*H, and the amount of carrier. The lower limit of potential was that at which lead deposited as its dioxide. This limit depended on the initial concentration of lead (II), shifting approximately 30 mv in a cathodic direction with each tenfold increase in concentration. The upper limit was the potential at which oxidation of manganese to a higher, more soluble valence became significant. Both the upper and lower limits were *p*H dependent, shifting approximately 120 mv in a cathodic direction with each tenfold increase in *p*H.

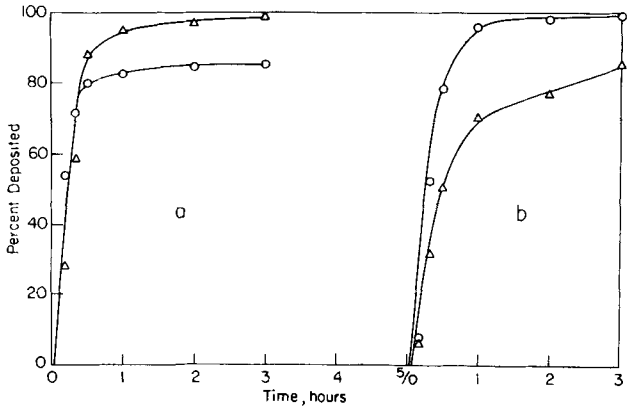

Fig. 3. Coprecipitation of manganese with 50 mg lead (II) carrier as a function of potential in 1.0M potassium nitrate at a pH of 2.0. (a) initial pH 2.00, final pH 1.85, E = +1.320 v vs. SCE; (b) initial pH 2.00, final pH 1.85, E = +1.275 v vs. SCE. Open circle, per cent manganese deposited, open triangle, per cent lead deposited.

Before starting studies of coprecipitation, depositions of lead or manganese alone were made at a number of different potentials using different initial concentrations. The relative rates later proved to be the same when both elements were deposited simultaneously.

Effect of applied potential and amount of carrier.—Figure 3 illustrates the effect of applied potential at a given pH. At the less anodic potential, lead deposited slower and gave a somewhat more adherent deposit. Use of a less anodic potential is analogous in an ordinary precipitation process to a slower rate of addition of reagent, a change which usually leads to larger and more nearly perfect crystals. However, the particles formed at both potentials were sufficiently large (greater than 1 μ) to give sharp lines on x-ray powder diffraction pictures.

At the less anodic potential, there was no reason for the potential to change the rate of deposition of the manganese because the potential was still sufficient to oxidize all of it to the tetravalent state. Hence, the net effect was greater coprecipitation for a given amount of lead. Table I shows that the effect was more striking for smaller amounts of carrier where the final fraction of manganese coprecipitated was usually smaller. The logarithmic distribution coefficient, λ, (5) was noticeably larger when the rate of deposition was slower although neither case gave a constant value during a run. For example, the values obtained for a run at +1.275 v decreased continuously from 6 to 2, whereas at +1.320 v they started at 2 and decreased to 0.3. The homogeneous distribution coefficient, D, (6) also changed during a run but it varied more than λ and in an apparently random fashion.

At potentials more anodic than +1.380 v, the efficiency of coprecipitation decreased markedly. At a potential of +1.425 v, lead was practically completely deposited at the end of 5 hr, while radiomanganese was only about one-third coprecipitated. For a similar deposition at +1.480 v only about 9% of the manganese coprecipitated. At these higher potentials, manganese was probably oxidized more or less to the more soluble heptavalent state in which form its tendency to coprecipitate should be smaller.

Table I. Effect of applied potential on the coprecipitation from 1.0M potassium nitrate of manganese-52 with lead dioxide after four hours

pH		Applied potential, v	Mg. lead present	Per cent lead deposited	Per cent manganese coprecipitated
Initial	Final

1.03	1.00	+1.350	5	100	10
2.05	1.89	+1.350	5	100	24

In order to determine whether the manganese was firmly bound in the deposit or held on the surface, 50 mg of lead (II) at +1.350 v was completely deposited along with 84% of the radiomanganese. The potential was then raised to +1.480 v and the increase in the amount of manganese in the aqueous phase determined. After 4 hr, only 4% of the total manganese had returned to the solution. If the tracer had been distributed equally throughout the deposit, the 4% removed would have come from the top nine layers of lead dioxide. However, since the true area of the electrode was undoubtedly at least ten times the geometrical area, the tracer must have been stripped only from the surface.

Effect of electrode size.—A small gauze anode having a geometrical surface area of 13 cm^2 and a platinum wire anode having a geometrical surface area of 4 cm^2 were substituted, in turn, for the 79 cm^2 gauze electrode. Solutions of 1.0M potassium nitrate with 50 mg lead (II) plus the standard amount of radiomanganese were used after adjustment to a given pH.

At pH 1.0, a greater fraction of radiomanganese deposited than lead. This seemed reasonable because, although the rates of deposition, as measured by depletion of the solution, were considerably slower than observed for the large gauze electrode, the rate at which lead was depositing at the small electrode after the first few minutes was actually higher in terms of millimoles per square centimeter per minute than in the more depleted solution having the larger electrode. The result is comparable to that obtained by using more carrier, or to that in which lead deposition was slowed by a change in the electrolyte (*vide infra*).

At pH 2.0, the situation was reversed, and a greater fraction of lead deposited. A change in the rate of lead deposition was observed consistently between pH 1 and 2, but no satisfactory rationalization can be suggested for its existence. Irregular behavior has also been encountered under other conditions (4).

Table II. Removal at +1.350 v of manganese-52 by successive additions of lead (II)

1.0 *M* $LiNO_3$	0.76	1.05	1.00	90

Successive additions of carrier.—Large amounts of carrier required great care in handling to avoid mechanical losses from the electrode. To decrease the total, a series using small successive additions of carrier was explored as being analogous to cross-current extraction (7). Data for successive 5 and 10 mg additions given in Table II show that, at a pH of 2.0, an approximately constant extraction factor, E, was obtained. Remembering that the extraction factor is defined as the ratio of the amount deposited to the amount remaining in solution of a given level of carrier, the ratio for 10 mg additions was 1:1, while for 5 mg additions it was about 1:3.

In contrast, at a pH of 1.0, E varied with each addition of lead such that for each 10 mg addition of lead about 20% of the *initial* amount of trace was removed; for each 5 mg, about 10% of the *initial* amount of trace present. Gordon (8) has described a type of coprecipitation in which the amount of tracer carried per unit weight of carrier was independent of the amount of tracer present initially. He attributed this to phase saturation. To test this, successive 10 mg portions of lead were added to a solution containing three times the normal amount of tracer. In this case, each 10 mg portion carried 8%, 7% and 8% of the initial tracer present. On a weight basis, the amount of tracer coprecipitated with a given amount of carrier was the same as before. Although it seems unlikely, the lead dioxide formed at pH 1.0 behaved as though it were saturated with manganese dioxide.

Effect of supporting electrolyte.—Table III shows the effect of a change in electrolyte on the deposition rates of lead and manganese. In each case lead was completely deposited, although the time required depended on the supporting electrolyte. Perchlorate generally led to faster depositions of lead than did nitrate, possibly due to inhibition by lead nitrate complexes of the type $PbNO_3^+$ (10), perchlorate having less tendency to form such complexes (11). Nitrite, at a concentration of 0.01*M*, had no effect. For a given anion, it appears that the rate of lead deposition was related inversely to the hydrated cationic radii (12) which decrease on going from lithium to potassium.

In addition to increasing the relative rate of lead deposition, perchlorate media could affect adversely the amount of radiomanganese coprecipitated in another way, especially when very concentrated supporting electrolytes were used. Thermodynamically, the reaction

$$Mn^{++} + ClO_4^- + 2H^+ \rightarrow Mn^{+++} + ClO_3^- + 2H_2O \quad [2]$$

is spontaneous as written, as it has a negative change in free energy of some 20 kcal. This was tested by observing that in a millimolar solution of manganese (II), which was 1.0*M* in sodium perchlorate and at pH 2.0, a brown precipitate formed after two days without noticeable change in the pH. At the trace level, some manganese could react in this way during a run and thus form a radiocolloid that would not deposit on the anode. Such a result was actually observed: in 5.0*M* perchlorate, only 26% of the tracer coprecipitated; in a mixture of perchlorate and nitrate, only 66% of the tracer coprecipitated (compared with 85% in the absence of the perchlorate). Even the deposition of millimolar manganese at a pH of 1.0 from 1.0*M* sodium perchlorate was only 80% complete at a potential of +1.300 v, whereas from 1.0*M* potassium nitrate solution under identical conditions, deposition was more than 99% complete.

Open-circuit studies.—Byrne (4) noted that, when an electrode was disconnected from the potentiostat following an incomplete coprecipitation and was allowed to stand overnight in the solution, almost all of the radiomanganese was found on the electrode in the morning. This phenomenon was easily checked as shown by the data run in Table IV. A similar study at pH 2.0 gave results that were virtually identical. In both cases, the change in potential was similar to that observed by Wynne-Jones and coworkers (13) for pure lead dioxide.

Thermodynamically, the reaction

$$PbO_2 + Mn^{++} \rightarrow Pb^{++} + MnO_2 \quad [3]$$

Table IV. Changes in solution characteristics with time that occurred on disconnecting the external potential (+1.350 v) from an anode in 1.0M potassium nitrate solution at pH 1.0

Time, hr	Potential, v	Per cent Mn deposited	Per cent Pb deposited
0.0	1.350	80	99
0.5	1.325	—	—
1.0	1.305	84	96
2.0	1.293	86	95
5.0	1.273	87	94
10.0	1.255	98	88

has a negative change in free energy of about 2.4 kcal. Postprecipitation of radiomanganese onto the electrode is, therefore, spontaneous and is quite probably due to chemical replacement rather than to adsorption, although some contribution from the latter cannot be entirely discounted.

Farradini and Haissinsky (14) had reported that a trace of protactinium-233 was deposited spontaneously on a freshly prepared lead dioxide electrode but not on one that had been aged overnight in distilled water. The difference between a "fresh" and an "aged" lead dioxide electrode was attributed to a layer of oxygen dissolved in the crystal lattice or held on the surface of the "fresh" oxide. After such an electrode had been stored in distilled water for 12 hr, the oxygen had escaped presumably. A comparable study for manganese-52 was undertaken so as to rule out this possibility. Both platinum and lead dioxide electrodes were examined.

Several lead dioxide electrodes were prepared by anodizing platinum gauze electrodes at +1.350 v in a 1.0*M* potassium nitrate solution containing 50 mg of lead (II) at a *p*H of 1.0. Some electrodes were used immediately ("fresh"); others were stored in distilled water overnight ("aged"). Whether the oxide was "fresh" or "aged" made no difference: about 65% of the trace manganese deposited at open circuit in the first hour; another 25%, in the next hour. The deposits reached 98% after a total of 6 hr indicating that surface oxygen was unimportant.

To rule out the unlikely possibility that oxygen alone on the surface of bare platinum could cause radiomanganese to deposit, a platinum electrode was anodized in the absence of lead. It was then disconnected from the potentiostat and a standard amount of radiomanganese added. After 4 hr, only a little more than 1% of the manganese had deposited on the electrode. To complete the circle, it was shown that if lead dioxide were deposited completely from 1.0*M* potassium nitrate at *p*H 1.0 before adding manganese tracer, further electrolysis at +1.350 v deposited only 8% of the manganese. Clearly, when lead was not depositing, the applied potential strongly deterred the deposition of manganese.

Coprecipitation of trace manganese with thallium (III) oxide.—The carrying ability of thallium (III) oxide was investigated briefly. Thallium was chosen because it provided a different type of oxide with regard to structure and atomic ratio. Also, thallium could be determined easily with a polarograph and its anodic deposition behavior had been noted (15). Coprecipitations were expected to be much less efficient because it presented a change in valence type.

At a *p*H of 1.0, thallium (III) oxide would not deposit on an anode from a solution containing 50 mg of thallium (I) in 1.0*M* potassium nitrate although thallium was oxidized, as evidenced by the high current flow. However, using 50 mg thallium (I) at a *p*H of 2.0, about 90% of the thallium could be deposited, presumably at Tl_2O_3, before the remainder precipitated into the bulk of the solution and ruled out further study. Approximately 6% of the manganese coprecipitated with the thallium (III) oxide that adhered to the electrode. The deposition was rapid, only 20 min being required to deposit 90% of the thallium. Because the time was rather short, it was thought that the tracer might not have had sufficient time to incorporate itself in the crystal, so a smaller electrode of 13 cm^2 geometrical area was used. As in the case of lead, somewhat more tracer deposited, but not enough to make thallium a useful carrier for manganese.

Discussion and Conclusions

The isolation and simultaneous concentration of $10^{-9}M$ carrier-free manganese-52 by anodic electrodeposition as dioxide is quantitative above *p*H 4. The potential must be limited so as to avoid low recovery due to formation of a more soluble higher valence state. A lower *p*H would probably be necessary to decrease the interference from other elements if they were present. In that case, coprecipitation with lead dioxide could be used to effect complete recovery of the manganese. The later separation of manganese from lead could be done in a variety of ways including cathodic deposition of lead into mercury.

Chemical displacement of manganese (II) from aqueous solution by reaction with electrolytic lead dioxide was slower than electrolysis but always quantitative. The use of powdered lead dioxide should make the replacement faster, but it would necessitate a filtration. Other techniques leading to slower but more nearly complete recovery for a given amount of lead dioxide are the use of smaller electrodes and of successive additions of small portions of carrier.

The mechanism for anodic coprecipitation of manganese and lead dioxide appears to be either anomalous mixed-crystal formation or internal adsorption, processes which are difficult to distinguish (16). Although the dioxides of lead and manganese crystallize in the rhombic and tetragonal systems, respectively, anomalous mixed-crystals might form. However, the fact that the logarithmic distribution constant, λ, did not have a constant value indicates internal adsorption to be the more probable mechanism.

Experimental

Chemicals.—Solutions of carrier-free six-day manganese-52 were prepared by dissolving deuteron-bombarded chromium in 10*M* sulfuric acid and distilling permanganic acid (17). Calculations from radioactivity data indicated that these solutions were about $10^{-9}M$ in manganese-52. Evidence has been cited to show that the concentration of total manganese was in the same range. Before use, all manganese-52 stock solutions were precathodized for 2

hr at a potential which insured that all of the tracer was in the divalent state. Other stock solutions, all of them nitrates, were a 0.0103*M* solution of manganese (II) standardized by the bismuthate method (18); a 50 mg/ml solution of lead (II) standardized as the sulfate (19); and a 50 mg/ml solution of thallium (I), standardized against bromate (20).

Apparatus.—Depositions were carried out using a volume of 150 ml in a glass cell 5 cm in diameter and 12.5 cm tall. A platinum gauze anode with a geometrical area of 79 cm^2 was used except in one set of experiments where a 13 cm^2 gauze and a platinum spiral with a geometrical area of 4 cm^2 were substituted. Electrodes were pre-anodized in 1.0*M* sulfuric acid. Nitrate or perchlorate salt bridges were used to connect the saturated calomel reference electrode and the isolated platinum cathode to the electrolytic solution. The solution was stirred by a magnetized Teflon-covered stirring bar. The temperature, unless otherwise specified, was maintained at 25.5° ±0.5°C.

The potential of the anode was controlled to at least ±2 mv using potentiostats (21). The potentials were adjusted at the beginning of each run and checked at intervals thereafter using a Rubicon potentiometer reading to ±0.1 mv. All pH measurements were made with a Beckman Model G pH meter.

A single-channel differential discriminator, coupled through a linear amplifier to a thallium-activated sodium iodide scintillator was used to obtain the gamma-ray spectrum in the characterization of the manganese-52 in the radiochemical studies. The same scintillator-amplifier combination coupled to a binary scaler was used to count samples withdrawn from the deposition cells.

Procedures

Electrolytic.—A typical electrolytic solution was prepared by adding 145 ml of a chosen supporting electrolyte to the deposition cell along with a predetermined volume of carrier solution, usually 0.1 to 1.0 ml from a Kirk micro-pipet. A standard volume of radiomanganese, from 1.0 to 4.0 ml, was then added so as to produce about 10,000 cpm above the average background of 250 cpm. Equilibrium was reached after 1 hr at a given potential whereupon a 500 μl sample was withdrawn for analysis and the potential adjusted for the next electrolysis. To define a curve for per cent deposited vs. potential, the potential was changed anodically in successive 50 mv increments. After reaching the desired limiting potential, the direction of change was reversed until all the deposit had been stripped off the electrode. This procedure tested both reproducibility and reversibility of the system.

Analytical.—The 500 μl sample was placed in a one-dram glass vial and counted for at least 1 min or until 10,000 counts above background had registered in order to minimize the counting error (22). In calculating the amount of tracer or carrier deposited at any given time, corrections were made for the amount of solution previously withdrawn and, in the case of the radiochemical measurements, for the background and the natural decay of the radionuclide.

Manganese was analyzed by the periodate method (23) when present in macro amounts (i.e., 10^{-4} to $10^{-3}M$). Lead and thallium were determined by conventional polarographic procedures (24, 25).

Mass Transfer and Current Distribution under Free Convection Conditions

Kameo Asada, Fumio Hine, Shiro Yoshizawa, and Shinzo Okada

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Kyoto, Japan

ABSTRACT

Correlation of mass transfer with current distribution, for deposition and dissolution of metals, on vertical electrodes, under free convection conditions, is discussed. The equation of mass transfer and the Laplace equation, determining the concentration and potential distributions, respectively, are solved simultaneously. The results explain most features of observed current distributions.

This paper is concerned with current distribution for deposition and dissolution of metals at vertical electrodes. The rate of metal deposition may be controlled mainly or partly by the rate of transfer of ions to the cathode. In the absence of agitation, ions are usually transferred by free convection, a process which has received much theoretical and experimental investigation (1-14). Owing to depletion of reactive ions, the density of the cathodic region becomes lower than that of the bulk of the solution; an upward flow of solution then results. (Circumstances at the anodic region are just reversed.) A diffusion layer formed around a body is generally thicker with increasing distance from the frontal edge of the body. Hence, under limiting current conditions the current density (or the reciprocal of the thickness of the diffusion layer) is inversely proportional to the *fourth* root of the distance from the bottom of the cathode, as confirmed by Wagner (3), Ibl (8), and Wilke (11).

Even at current densities below limiting ones, the same type of current distribution would be expected, if the interface concentration of the reactive species remains uniform. Such uniformity of the interface concentration is, however, not always the case, as discussed by Ibl (5, 10) and Wagner (13). In the case of rectangular cell with vertical electrodes on opposite ends, a reduction of the electrolytic current is accompanied by more uniform current distributions, because of the predominance of ohmic drop and chemical polarization over concentration polarization. Under such circumstances the thickness of the diffusion layer tends to be proportional to the *fifth* root of the distance from the bottom; this suggests that the mass transfer process is not exclusively dependent on hydrodynamic conditions.

This paper describes a theoretical approach to the intermediate domain between the extreme cases: uniform interface concentration and uniform current density. This requires simultaneous consideration of mass transfer and current distribution. These two problems have so far been studied rather separately. Effects of mass transfer on polarization characteristics were interpreted by using the thickness of the diffusion layer calculated from the limiting current, e.g. (14); this is not rigorous unless the polarization is uniform and of the nature of concentration polarization (13). On the other hand, it has been accepted that predominance of polarization over ohmic drop improves current distributions, e.g. (15). But this conclusion is based on the tacit assumption that the relationship between current density and polarization is the same for every point on the electrode. Such a condition applies to chemical polarization but is not always realized when mass transfer plays a part in polarization. It follows from these discussions, that mass transfer, electrode kinetics, and electrical resistance of baths and electrode materials are united through transfer of electric charge or current distribution.

An integration of mass transfer with the other two factors has been treated in related fields of science. Modern theories of polarography have systematically correlated electrode kinetics to diffusion (16); in addition the effect of ohmic drop on polarographic waves has been described (17). Heat transfer from a two-dimensional solid wall to a moving fluid has been analyzed (18). Levich (19) and the present authors (20) discussed current distributions over a flat plate electrode in a longitudinal flow under the condition of uniform polarization. This problem is mathematically identical to simple mass transfer processes such as the dissolution of nonelectrolytes studied by several authors (21-23). Weaver and Parry (24) estimated current distributions at a streaming mercury electrode under nonuniform polarization, by assuming that, in this case, resistance of solution is localized to the vicinity of the electrode surface.

Theoretical

The model to be treated is a cell of rectangular vertical section with vertical electrodes full-end on opposite sides. The x-axis is chosen as the cathode surface and x measures the vertical distance from the bottom of the cell. The y-axis is the bottom of the cell and y measures the horizontal distance from the cathode toward the anode.[1] The height and breadth of the cell are denoted by h, and b, respec-

[1] A glossary of symbols will be found at the end of the paper.

tively. The cathode ($y = 0$) and anode ($y = b$) are distinguished by subscripts c and a, respectively.

Distribution of concentration C is determined by a differential equation of mass transfer. The distribution of potential follows the Laplace equation

$$\partial^2\phi/\partial x^2 + \partial^2\phi/\partial y^2 = 0 \qquad [1]$$

Equation [1] is valid if there is an excess of indifferent electrolyte in the bath so that diffusion potential gradients are negligible in comparison with ohmic ones and the conductivity κ is uniform. The boundary conditions are common to both electrode surfaces and are expressed by

$$\begin{aligned} i &= i_e\{(°C/*C)\exp[-\alpha n\mathbf{F}(E-E_e)/RT] \\ &\quad - \exp[(1-\alpha)n\mathbf{F}(E-E_e)/RT]\} \\ &= n\mathbf{F}D|*C - °C|/\delta \\ &= \kappa(\partial\phi/\partial y) \qquad \text{at } y = 0 \text{ and } y = b \end{aligned} \qquad [2]$$

In Eq. [2], i is the local current density, i_e the exchange current density, α the transfer coefficient, n the number of Faradays per gram-ion reacting, $\mathbf{F}$ the Faraday, E the local electrode potential, E_e the equilibrium electrode potential, R the molal gas content, T the absolute temperature, °C and *C the concentration of the reactive species at the electrode surface and in the bulk, respectively, D the diffusion coefficient of the reactive species, and δ the differential thickness of the diffusion layer. Although not necessary for the problem, it is convenient to assume that the same kinetics operate at the cathode and anode; in other words, common values of E_e, n, i_e, and α are assigned to both electrodes. This problem was solved by means of successive approximation.

If distribution of i is given, the equation of mass transfer may be solved approximately and one obtains

$$\delta^5 = n\mathbf{F}Dki^{-2}\int_0^x i\,dx \qquad [3]$$

where k is a constant specific to the system. The derivation of Eq. [3] and an evaluation of k is described in the following section. When the anode is concerned, x should be replaced by $h - x$ in Eq. [3].

On the other hand, Eq. [1] was solved by expansion into a Fourier series. The origin of the potential ϕ was chosen to satisfy

$$\begin{aligned} \phi_{y=0} \equiv \phi_c &= -(E_c - E_e) \\ \phi_{y=b} \equiv \phi_a &= V - (E_a - E_e) \end{aligned} \qquad [4]$$

V being the terminal voltage (constant along any current flux). Equation [4] is self-consistent, if the potential drop within electrode material is negligible and if the equilibrium emf of the cell is zero. Equation [1], the last member of Eq. [2], and the additional boundary condition at the bottom and top of the electrolyte

$$\partial\phi/\partial x = 0 \quad \text{at } x = 0 \text{ and } x = h \qquad [5]$$

are satisfied by

$$\begin{aligned} \phi &= \bar{\phi}_c + \bar{i}y/\kappa \\ &\quad - (2/\kappa h)\sum_{s=1}^{\infty}\{\cos(s\pi x/h)[\sinh(s\pi b/h)]^{-1} \\ &\quad \cdot[\cosh(s\pi[b-y]/h)\int_0^h I_c \sin(s\pi x/h)\,dx \\ &\quad - \cosh(s\pi y/h)\int_0^h I_a \sin(s\pi x/h)\,dx]\} \end{aligned} \qquad [6]$$

where I_a, I_c are defined by

$$I_j = \int_0^x (i_j - \bar{i})\,dx \quad (\text{for } j = a, c) \qquad [6']$$

and where $\bar{\phi}_c$ is the mean cathode potential and $\bar{i}$ the mean current density.

A cycle of successive approximation is composed of: (i) specification of $\bar{\phi}_c$ as the given condition (instead of V), (ii) assumption of i_c and i_a, followed by calculation of $\bar{i}$, (iii) evaluation of ϕ_c and ϕ_a by means of Eq. [6], (iv) determination of i_c consistent with ϕ_c through Eqs. [2]-[4], and (v) simultaneous determination of i_a and V consistent with ϕ_a through Eqs. [2]-[4] and satisfying the condition: $\bar{i}_c = \bar{i}_a$. As the integration of i and the calculation of the resulting Fourier coefficients were done repeatedly, i_c and i_a were approximated by definite numbers of exponential and polynominal terms of (x/h), respectively. This led to no serious error except in the neighborhood of the lower edge of the cathode, where $|\partial i/\partial x|$ is very large. Such an analysis could be extended to more complicated geometry, if a prior application of conformal mapping is possible.

Thickness of Diffusion Layer

One of the special features of ionic mass transfer processes by free convection as compared with the corresponding heat transfer processes and those by forced convection is the behavior of species indifferent to electrode reactions. Those species contribute to the density difference to an extent nearly as large as the reactive ones; in this respect analysis by Wagner (3) appeared to be rigorous, and his treatment was followed. Cathodic deposition of copper from $CuSO_4 - H_2SO_4$ baths was taken as an example, with the same coordinates as in the preceding section. Wagner's analysis was modified in the following three ways. (*A*) The interface concentration °*C* was regarded as a variable with x instead of a constant. (*B*) Since the velocity profile used by Wagner gives values of the limiting current which are too high, the profile of Wilke (12) was employed,[2] and the thicknesses of the hydrodynamic boundary layer and the diffusion layers of all species present were assumed equal and denoted by δ'. (*C*) In order to take migration of H^+ into account Wagner differentiated the thickness of the H^+ diffusion layer from that of Cu^{++}. In the present paper, the concentration profile of Cu^{++} will be given by

$$(C - °C)/(*C - °C) = 2y/\delta' - 2(y/\delta')^3 + (y/\delta')^4 \qquad [7]$$

and a parameter ϵ will be introduced in the profile of H^+, *i.e.*, the latter profile will be given by a power series in y/δ' with the coefficients of the first, second, third and fourth power terms taken as $(2 + \epsilon/3)$, $-\epsilon$, $-(2 - \epsilon)$ and $(1 - \epsilon/3)$, respectively.

[2] Although the observation of boundary layers (uniform current density) by Ibl (10), published during the present study, is in favor of the former profile, discussion of the profile itself is outside the limits of this paper.

This gives a differential equation:

$$(1/8k) \cdot d\,[\delta^3\,(^*C - {}^\circ C)^2]/dx = 2(^*C - {}^\circ C)/\delta' = i/n\mathbf{F}D$$

where

$$k = 126\,(\nu D/g)/[9\beta_1 - \beta_2\,(18 - \epsilon)/(6 + \epsilon)]$$

$$\epsilon = -\,(90\,t - 30)/(15\,t + 2) \qquad [8]$$

In Eq. [8], ν is the kinematic viscosity, g the acceleration of gravity, t the transference number of H^+, β_1 and β_2 the density coefficients (*i.e.*, the relative increase in density caused by unit increase in the concentrations of $CuSO_4$ and H_2SO_4, respectively), and °C, *C and D refer to Cu^{++}. Equation [8] was solved for the following three cases, with the boundary condition for δ':

$$\delta' = 0, \text{ at } x = 0 \qquad [9]$$

(i) Provided the *interface concentration °C is independent of x*, the differential thickness of the diffusion layer δ and the limiting current density i_d are expressed by

$$\delta^4 = 4kx/3(^*C - {}^\circ C)$$

and

$$i_d = n\mathbf{F}D\ ^*C(3\ ^*C/4kx)^{1/4} \qquad [10]$$

respectively. Equation [10] is different from those presented by other authors (1-4, 12) only in the detail of the constant k and gives estimates of limiting currents in accordance with those observed by Wilke (11).

(ii) If the *functional dependence of i on x is known*, Eq. [8] leads to Eq. [3]. In the special case of uniform current density, it follows from Eq. [3] that

$$\delta^5 = n\mathbf{F}Dkx/\bar{i} \qquad [11]$$

which is similar to those presented by Sparrow and others (10, 13, 25).

(iii) When the *electrode potential E is uniform over the electrode*, one obtains from Eqs. [2], [7], and [8]

$$d\xi/d\mu = \mu^4\,(3\mu + 5)/(\mu + 1)^2$$

where

$$\mu = k_f\delta'/2D,$$

$$\xi = k \cdot k_f{}^5\,x/^*C\,D^4\,(k_f - k_b),$$

$$k_f = (i_e/n\mathbf{F}\ ^*C)\ \exp\,[-\alpha n\mathbf{F}(E - E_e)/RT]$$

$$k_b = (i_e/n\mathbf{F}\ ^*C)\ \exp\,[(1 - \alpha)n\mathbf{F}(E - E_e)/RT] \qquad [12]$$

which is solved as

$$\xi = \frac{3}{4}\mu^4 - \frac{1}{3}\mu^3 - \frac{1}{2}\mu^2 + 3\mu - 5\ln(1 + \mu) + 2\mu/(1 + \mu). \qquad [13]$$

At $\xi = 0$ and $\xi \to \infty$ Eq. [13] reduces to Eqs. [11] and [10], respectively. Current distributions calculated from Eq. [13] were used as the first approximation for the procedure described in the preceding section.

Experimental and Results

A methacrylate cell (5 cm width, 32 cm breadth and 15 cm depth ID) was filled with solution up to a level $x = 10$ cm from the bottom, and immersed in a bath controlled at 25°C. Copper electrodes (0.1 mm in thickness) were covered with polyvinyl chloride paint except for the electrode surfaces, which were 5 cm in width and 10 cm in depth. The cathode was placed in contact with one of the end walls. The anode was supported by grooves cut into the sides and bottom of the cell, at different distances y from the cathode. Local current densities were measured by weighing what deposited or dissolved. Since introduction of a Luggin capillary might disturb hydrodynamic conditions, local electrode potentials were measured in the following way: five holes (1 mm in diameter) were drilled on one of the side walls at different depths for each electrode position, and each hole was connected with rubber tubing to a glass vessel in which a saturated calomel electrode was inserted in turn.

As noted by Ibl (8), excess of indifferent electrolytes retards the establishment of diffusion layers typical for free convection, while shortage of indifferent electrolytes may invalidate the assumptions on which the theory is based. From these considerations a system, $0.1M$ $CuSO_4 - 1.5M$ H_2SO_4, was chosen. For this system theoretical and experimental values of current densities and electrode potentials were obtained. Typical results are represented in Fig. 1-4. The following physical properties are used in the calculation: $\kappa = 0.543$ mho/cm, $D = 5.99 \times 10^{-6}$ cm²/sec, $\nu = 1.15 \times 10^{-2}$ cm²/sec, $\beta_1 = 120.6$ cm³/mole, $\beta_2 = 53.5$ cm³/mole, and $t = 0.81$ (26-28, and International Critical Tables); kinetic data were estimated at $i_e = 10^{-1}$ ma/cm² and $\alpha = 0.5$ (20).

Figures 1 and 2 refer to the case of infinite distance between electrodes ($b = \infty$ in Fig. 1, calculated, and $b = 32$ cm in Fig. 2, experimental). Cathodic current distributions shift from an inverse fourth root dependence on x (Eq. [10]) to a virtually uniform shape, with decreasing mean current density. As already mentioned, this is attributable to the competition of concentration polarization with chemical polarization and the resistance of the bath.

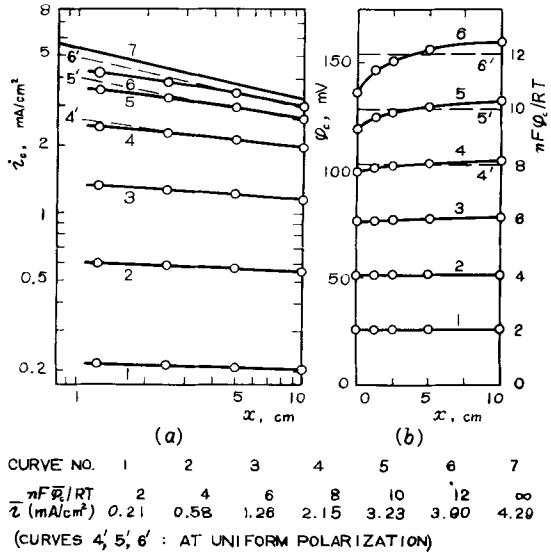

Fig. 1. Calculated distributions of (a) cathodic current density and (b) cathode potential, for b = ∞; x is the vertical distance from the bottom.

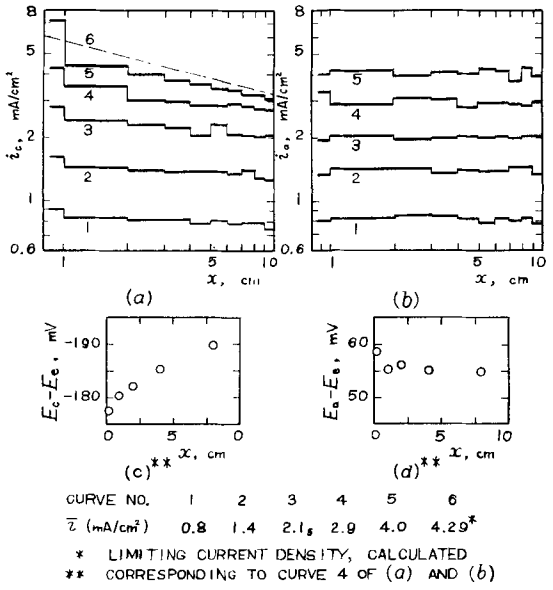

Fig. 2. Observed distributions of (a) cathodic current density, (b) anodic current density, (c) cathode potential, and (d) anode potentiol, for b = 32 cm.

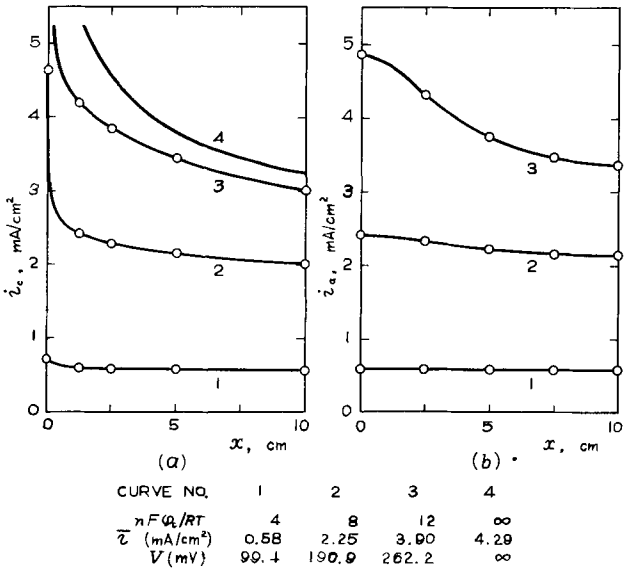

Fig. 3. Calculated distributions of (a) cathodic current density and (b) anodic current density, for b = 2 cm.

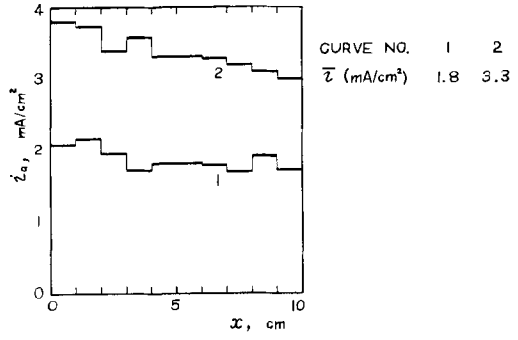

Fig. 4. Observed anodic current distributions, for b = 2 cm

The effect of the first two factors is seen separately in the dashed curves of Fig. 1, representing the case of uniform polarization [refer to (iii) of the preceding section]. The last factor results in much more uniform current distributions and nonuniform electrode potentials [see Fig. 1 (b) and Fig. 2 (c)].[3] Relatively low polarization around the lower portion of the cathode in association with relatively high current density shows plainly the peculiar effect of mass transfer on current distributions. This situation was observed also by Ibl (5). On the other hand, anodic current densities and potentials are virtually uniform (see Fig. 2), because anodic polarization is almost exclusively a chemical one as expected from Eq. [2].

Figures 3 and 4 refer to the case of finite distance between electrodes ($b = 2$ cm). The mutual influence of the cathode and the anode, whose current distributions were originally nonuniform and uniform, respectively, would cause better uniformity of current distribution at the cathode and worse uniformity at the anode. Distributions of cathodic current densities and potentials were, however, practically unaltered from the previous case ($b = \infty$) while marked change results at the anode; current densities at the anode, like those at the cathode, now become relatively high at near the bottom. This may be understood from the difference in polarization characteristics. Owing to the inclusion of concentration polarization, the slope $|\partial E/\partial i|$ of cathodic polarization curves is larger than that of anodic ones at the same current density. The larger the slope and the conductivity of the bath, the stronger is the buffering action against change in current densities (15).

Extension to Practical Conditions

The above discussions are concerned exclusively with 0.1*M* $CuSO_4$ — 1.5*M* H_2SO_4 solution at 25°C. In this system the effect of mass transfer on current distributions was remarkable, because the conductivity is high for the concentration of reacting ions. On the other hand, typical working conditions in industry are as follows: for electroplating, 0.8*M* $CuSO_4$ — 0.5*M* H_2SO_4, 20-30°C and 5-15 ma/cm²; for electrorefining, 0.6*M* $CuSO_4$ — 1.5*M* H_2SO_4, 50°C and 20 ma/cm² (29). The conductivities of these baths are not much different from those of the present study, and current densities may be less than one half of the limiting values. Such conditions would correspond to the curves on Fig. 1 numbered 4 or less. Hence failure in uniformity of current distributions due to mass transfer may be tolerable, and it would be overlooked because of probable predominance or superposition of geometrical effects.

Next, cells for testing plating conditions (such as Haring and Hull cells) are mentioned. The principle on which their use is based is such that current distributions in the vertical direction due to mass transfer are left out of consideration, and effects of polarization are interpreted in a unified way in terms of the throwing power. Such a cell is, however, operated by nature under more severe conditions than in practical plating. Indeed Ibl (5) reported that deposits appeared in a triangular form on the corner nearer to the anode and the bottom of a Hull cell. Moreover, Shreir and Smith (30) found that

[3] Except for the present case of a rectangular geometry, the resistance of the bath does not help the establishment of uniform current distributions, while chemical polarization always does.

quality of deposits was worse at the upper half of cathodes even under ordinary conditions.

Acknowledgment

The authors wish to express their appreciation to Asahi-kagaku-kogyo-shoreikai (The Asahi Association for Development of Chemical Engineering) for its support of the present study. They are grateful to Dr. R. W. Parry of the University of Michigan who read the manuscript and offered helpful suggestions.

GLOSSARY OF SYMBOLS

b — distance between electrodes (cm)
C — concentration of reactive species (mole/cm^3)
$^\circ C$ — concentration of reactive species at the electrode surface (mole/cm^3)
$^* C$ — concentration of reactive species at the bulk (mole/cm^3)
D — diffusion coefficient of reactive species (cm^2/sec)
E — electrode potential (volt)
E_e — equilibrium electrode potential (volt)
$\mathbf{F}$ — the Faraday (amp sec/eq)
g — acceleration of gravity (cm/sec^2)
h — height of electrodes (cm)
i — current density (amp/cm^2)
i_d — limiting current density (amp/cm^2)
i_e — exchange current density (amp/cm^2)
k — defined by Eq. [8] (mole)
k_f, k_b — apparent rate constants of the forward and backward reactions, respectively, defined by Eq. [12] (cm/sec)
n — number of Faradays per gram-ion reacting (eq/mole)
R — molal gas constant (joules/deg K mole)
t — transference number of H^+ (dimensionless)
T — absolute temperature (deg K)
V — terminal voltage (volt)
x — vertical coordinate parallel to electrodes measured from the bottom of the cell (cm)
y — horizontal coordinate perpendicular to electrodes measured from the cathode towards the anode (cm)
α — transfer coefficient (dimensionless)
β_1, β_2 — density coefficients (see text) (cm^3/mole)
δ — differential thickness of diffusion layer (cm)
δ' — integral thickness of diffusion layer (cm)
ϵ — parameter of migration for H^+ (dimensionless)
κ — conductivity (mho/cm)
μ — defined by Eq. [12] (dimensionless)
ν — kinematic viscosity (cm^2/sec)
ξ — defined by Eq. [12] (dimensionless)
ϕ — potential (volt)

subscripts

$_c$ — cathode
$_a$ — anode

Manuscript received Oct. 27, 1958. This paper was abstracted from the Dissertation of K. Akada, Kyoto University and was presented before the fall meeting of the Electrochemical Society of Japan, November 28 and 29, 1957.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Technical Notes

On the Influence of Combinations of Impurities on the Electrolysis of Zinc

Georg Steintveit and Hans Holtan, Jr.

Det Norske Zinkkompani A/S, Eitrheim, Odda, Norway, and Metallurgy Department, Norways Institute of Technology, Trondheim, Norway, respectively

It is a well established fact that the electrolysis of zinc sulfate solutions is very sensitive to impurities present in the electrolyte, and results of experimental investigations have been reported both in textbooks (1) and in the literature (2). In recent years the subject seems to have gained increased interest (3-12). Some investigators have also applied radioactive tracers in their studies (13-15).

Metallic impurities of known poisonous action are Ge, Sb, As, Sn, Co, Ni, Se, Te, etc. Further it is also assumed that organic materials affect zinc deposition. Of particular interest in this respect is beta naphthol or alpha-nitroso-beta-naphthol (16), as this reagent is found in some technical electrolytes. Combinations of the impurities mentioned are particularly harmful. Especially is the combined effect of Co and Sb known to be very dangerous (17, 18). Nevertheless, there seems to exist some confusion regarding the subject as at least one zinc producer (19, 20) keeps a high level of Co in solution and in addition adds amounts of Sb and beta naphthol to improve zinc deposition.

Our investigations comprised the *combined action of several of said impurities* in concentrations which may occur in actual plant operation.

The influence of as much as four impurities present simultaneously was investigated. It was found that there is no law of additivity for the influence of impurities. Thus the presence of only one of two impurities may not harm the electrolysis at all, but when they are present simultaneously they may be harmful. Similar findings were reported later by Turoshima and Stender (6). Angel and co-workers (21) have performed similar experiments on chlorine-caustic electrolysis. One of our results was the observation of the very bad influence of the combination Co,Sb and beta naphthol. Below are shown the results of a series of experiments performed under identical conditions in cells fed with the following solutions:

	Pure zinc sulfate solution	% current efficiency
1.	0.003 g Co/l	90.3
2.	0.050 mg Sb/l	91.7
3.	0.030 g beta naphthol/l	91.1
4.	0.003 g Co/l + 0.050 mg Sb/l	76.8
5.	0.03 g beta naphthol/l + 0.050 mg Sb/l	91.4
6.	Co precipitated from 10 mg/l to 4 mg/l by means of beta naphthol	81.6
7.	As 6 + 0.050 mg Sb/l	25.1

Conditions during electrolysis were: current density, 4.2 amp/dm^2; cell temperature, 30°C; zinc content, 130 g/l; cell acidity, approximately 90 g H_2SO_4/l; time between stripping cathodes, 48 hr.

We see that the influence of the combinations Co,Sb, and Co,beta naphthol are harmful and that the combination Co,Sb,beta naphthol is extremely unfavorable. In the latter case the deposits were heavily corroded and showed a characteristic appearance of pinholes and of spheres under which there were voids.

There is no doubt that a real corrosion takes place even if there is present a "cathodic protection" current of 4.2 amp/dm^2. This is clearly seen also in the simple case where Co is added as the only impurity. It then formed holes in the deposits, and these holes grow as the electrolysis is continued. When a good deposit is formed from a pure solution, it is possible to start corrosion of the deposit by adding the proper combinations of impurities to the solution. When beta naphthol was present as the only impurity, we observed tiny holes in the deposits. Lashkorev and Krynkova (22) have shown that the discharge of zinc and other ions is inhibited by beta naphthol. During electrolysis, hydrogen bubbles are probably attached to the beta naphthol, thus making the holes visible.

A theoretical investigation of the phenomenon is planned.

Dendritic Inclusions in AlSb Grown-Junction Diodes

H. C. Gorton

Battelle Memorial Institute, Columbus, Ohio

One of the disturbing factors in the development of solid-state devices is the anomalous behavior of individual units fabricated from material with seemingly homogeneous characteristics. One of the causes for such anomalies, found in grown-junction diodes of aluminum antimonide, has been the inclusion of impurities in the form of long filaments, which in some cases pass through the junction. The possibility of a similar mechanism for such anomalous behavior in other semiconductor devices also is suggested.

The peak inverse voltage of grown-junction AlSb diodes generally has been consistent with values expected for material of a given carrier concentration, and general uniformity has been observed in the electrical properties of different diodes cut from the same ingot.

In several AlSb crystals, p-n junctions were grown by adding tellurium or selenium to the melt after pulling had commenced. In each of the cases of interest, 0.5 a/o (atomic per cent) tantalum had been added to the melt prior to pulling the crystal (1). In one such crystal, the mobility and carrier concentration of the p-type material were 420 $cm^2\ v^{-1}\ sec^{-1}$ and $1 \times 10^{16}\ cm^{-3}$, respectively. Consequently, peak inverse voltages in excess of 150 v were expected. However, of seven diodes fabricated from single-crystal sections of the grown junction, five were linear and two broke down at about 5 v reverse potential.

Microscopic examination of the diodes, after having been etched in 1:1 $HCl:HNO_3$, revealed the presence of long, thin fibers about 1 to 5 μ in diameter oriented parallel with the direction of growth of the crystal and penetrating the junction. A powder Debye-Sherrer pattern of the filaments showed them to be Al_3Ta. The fortuitous fact that Al_3Ta happens to be insoluble in the etchant used to prepare the diodes made observation of the inclusions possible. Figure 1 shows a sectioned slice of an AlSb ingot containing a p-n junction. The increase in the density of the filaments toward the center of the crystals

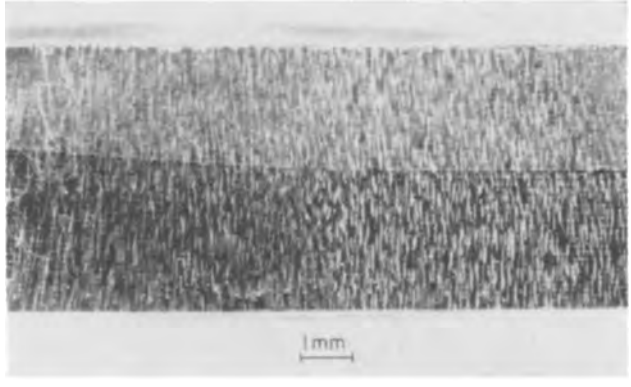

Fig. 1. Section of AlSb ingot with Al_3Ta inclusions showing p-n junction.

may be seen in the figure. Each of the two diodes mentioned above that showed some rectification was taken from near the edge of the crystal. The effect of the fibrous inclusions on the electrical properties of a p-n junction is readily apparent. The fibers appear to be shorter on the right than on the left, because they intersect the surface on the right at a slightly steeper angle.

As may be seen in Fig. 1, the growth of the filaments is inhibited at the p-n junction near the periphery of the crystal, evidently resulting from a physical disturbance due to the addition of the impurity. This discontinuity in the growth of the filaments is indicative of the fact that they are formed as the crystal is being grown and are not associated with solid-state diffusion processes subsequent to the formation of the crystal, such as the decoration of dislocations.

Figure 2 is a photomacrograph of the top side of the same specimen shown in Fig. 1. The bright spots on the dark background are the ends of the filaments protruding from the etched surface. Areas of higher and lower density of the filaments may be seen to have radial symmetry. The radial symmetry of the

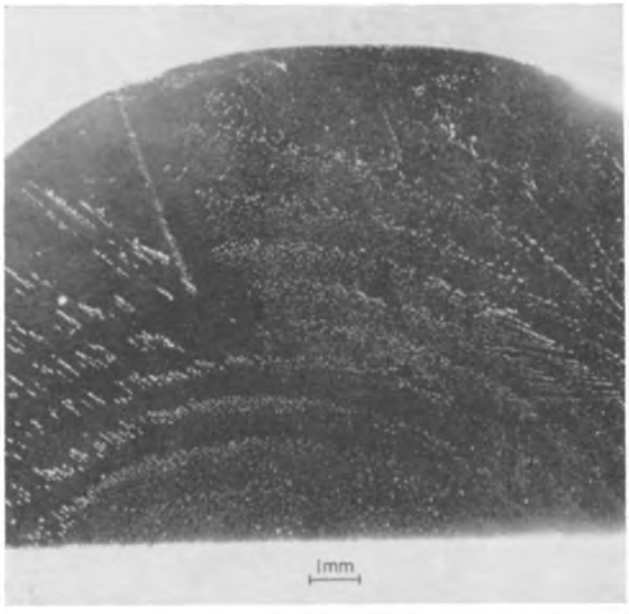

Fig. 2. Section of AlSb ingot showing filaments protruding from etched surface.

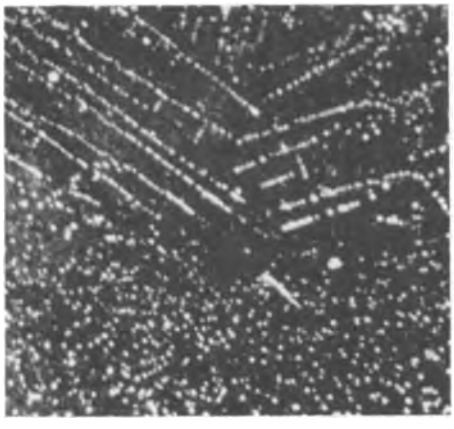

Fig. 3. Exploded view of section of Fig. 2 showing linear array of inclusions. Scale, 1⅜ in. = 1 mm.

grouping of the filaments apparently is associated with diffusion of the impurity to preferred sites at the solid-liquid interface. A detailed study of this phenomenon may lead to a greater understanding of the structure of the solid-liquid interface under various growth conditions. It is also interesting to note that such fibrous inclusions may grow in a single-crystal matrix, without themselves acting as nucleation centers for new crystallites.

A closer examination of Fig. 2 shows several areas of parallel linear arrays of the fibrous inclusions, which are superimposed on the annular areas of high and low density of impurities. These parallel linear arrays are localized to single crystal sections of the ingot. Figure 3 is an exploded view of a small section of the crystal shown in Fig. 2. Here the linear array of the inclusions is quite apparent. Such an array immediately suggests its similarity to dislocation etch pits in other semiconducting materials.

Billig (2) showed that crystals possessing the zinc blende structure solidify dendritically when freezing takes place at a rapid rate. It is here suggested that even with the relatively slow pulling rates associated with normal crystal-growing techniques, incipient dendritic growth takes place at the solid-liquid interface. Crystal growth therefore would initiate along preferred crystal planes from which it would extend dendritically in the plane of the solid-liquid interface. An incipient dendritic lattice at the solid-liquid interface therefore would be built up whose structure would be characteristic of the crystallographic plane presenting itself to the melt. Impurities in the melt with segregation coefficients less than one therefore would tend to be trapped in the interstices of the incipient dendritic lattice. Since the different crystallographic surfaces would propagate themselves into the interstices of the dendritic lattice, any imperfections in the crystal growth would tend to form dislocations in these areas also. In either case, if the dislocations were made visible as etch pits or if the impurities were made visible either as etch pits or as insoluble inclusions, they would show ordered arrays characteristic of the dendritic growth of the matrix.

It is further suggested that certain impurities, such as Al_3Ta, segregating to the interstices of the dendritic lattice would tend to propagate themselves along the direction of growth of the crystal. Visual observation of such inclusions would be rendered impossible, except as etch pits where they would intersect a surface, if they happened to be soluble in the etchants used to process the semiconductors. Such a situation may be a factor in accounting for the disturbing fact that some crystals whose bulk properties show acceptable electrical characteristics nevertheless are unsuitable for device application.

Ohmic Contacts to Semiconducting Ceramics

D. R. Turner and H. A. Sauer

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

Flaschen and Van Uitert (1) made a low-resistance ohmic contact to ferrite and semiconducting titanate ceramics with indium wetted with mercury or gallium rubbed on the surface. For investigative purposes and perhaps for some applications the low melting indium-gallium alloy is satisfactory. The difficulty of attaching terminals to indium-gallium, due to its susceptibility to physical deterioration by mechanical abuse and changes in its wetting properties, has spurred the search for a more practical contact material. This paper describes a method of preparing stable low-resistance ohmic contacts to titanate ceramics to which terminals can be soldered. The process can be used to make ohmic contacts to intermetallic compounds such as gallium-arsenide and thermoelectric semiconductors such as bismuth-telluride. The method consists of depositing metal contacts such as nickel on appropriate surfaces of the material and subsequently heat treating the contacts. Nickel is deposited most conveniently by chemical reduction, the "electroless" process (2). Electroless nickel deposition was used by Sullivan and Eigler (3) to make ohmic contacts to silicon, where a heat treatment may not be required.

Experimental

Most of the experimental work to be described here was done on lanthanum-doped barium titanate ceramics ($Ba_{0.998}La_{0.002}TiO_3$) which are n-type semiconductors. These materials exhibit large positive temperature coefficients of resistance (4). Two stable low-resistance ohmic contacts are required on devices for thermistor applications. The test specimens were wafers 1 cm in diameter and about 2 mm thick. The adhesion and surface coverage of the electroless nickel deposit on the titanate ceramic is improved if the surface is prepared by lapping, for example with No. 600 silicon carbide. The area to be coated with nickel is "activated" by dipping in stannous and palladium chloride solutions (5). This procedure deposits a thin layer of palladium on the surface which catalyzes the start of nickel deposition by chemical reduction in the "electroless" solution. Three minutes in the electroless nickel solution (solution temperature ~95°C) deposits a layer of nickel about 0.001 mm thick which is adequate for contact purposes.

Results and Discussion

The electroless nickel contact on the titanate ceramic is nonohmic as deposited. A low-resistance ohmic contact is obtained when the specimen is heat treated to at least 170°C for about 10 min. This is illustrated in Fig. 1 which gives the voltage-current curves obtained at room temperature on a typical titanate ceramic disk with electroless nickel contacts. The initial V-I curve is nonlinear, and at 0.7 v the

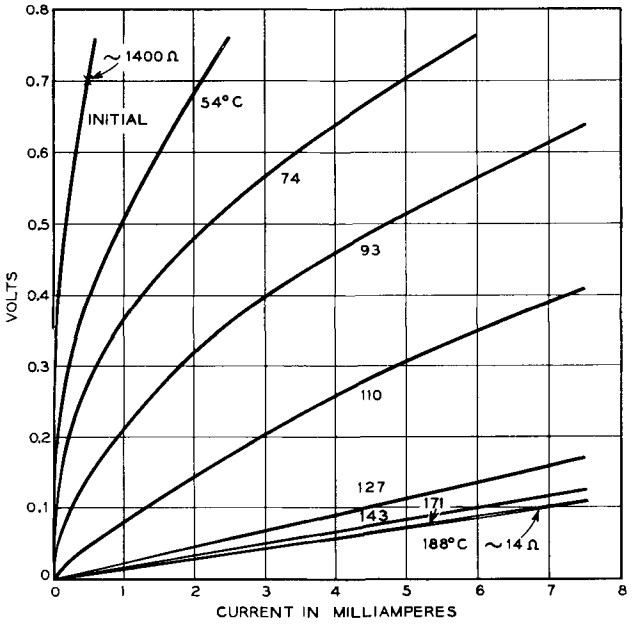

Fig. 1. Effect of heat treatment temperature on the voltage-current relation of a disk of lanthanum-doped barium titanate ceramic with electroless nickel contacts. Specimens measured at room temperature.

total resistance[1] is about 1400 ohms. After the ceramic has been heat treated for 10 min at 54°C, the contact resistance is decreased but it is still nonohmic. Higher heat treatment temperatures decrease the contact resistance still further. The contact resistance continues to decrease with increasing heat treatment temperature up to about 170°C where it approaches a minimum value. This may be considered a minimum processing temperature for obtaining low-resistance ohmic contacts. The total sample resistance of 14 ohms at this point is essentially the body resistance of the ceramic as determined by the four point probe method.

The resistance of the ohmic contact increases with time after heat treatment. This aging effect decreases if longer heat treatment times are used or the temperature of heat treatment is raised. It was found that, with heat treatment temperatures up to about 250°C, the time of heat treatment was an important factor. Longer heat treatment times decreased the rate at which the contact resistance increased with time. The time factor became less important as the heat treatment temperature approached 250°C. Above 250°C, heat treatments longer than 5 or 10 min did not change the aging characteristics of the ohmic contact. The most stable ohmic contacts were obtained when the specimen was heated to the highest temperature tried, 400°C.

[1] The total resistance includes the resistance of two contacts plus the body resistance of the sample.

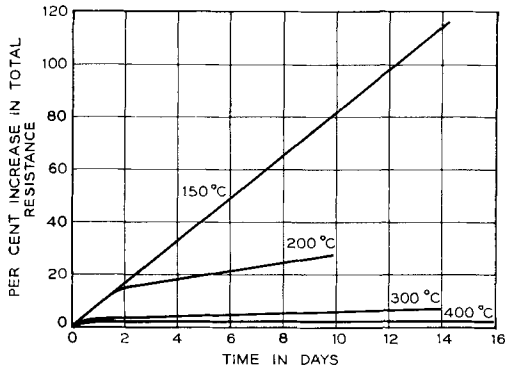

Fig. 2. Effect of heat treatment temperature on power aging of electroless nickel contacts on lanthanum-doped barium titanate disks. Samples measured at room temperature.

The effect of heat treatment temperature on contact resistance aging is shown in Fig. 2. For this experiment, electroless nickel contacts were applied to a series of 20-ohm ceramic disks and each group was heat treated at a different temperature. The heat treatment time was 30 min for 150° and 200°C and 10 min for 300° and 400°C. Those heated to 300° and 400°C were tinned with lead-tin solder to protect the electroless nickel from excessive oxidation. These aging tests were carried out at an elevated temperature of about 80°C since it was found that some heating accelerated the aging effect. The samples were heated electrically by passing either a.c. or d.c. current through the ceramics. Plotted in Fig. 2 is the per cent increase in total resistance as a function of aging time in days. The total resistance measurements were always made at room temperature. When heat treated at 150°C, the total resistance of the test pieces increased linearly with time and the resistance doubled in about 12 days. The contact resistance stability improved with higher heat treatment temperatures. At 400°C, there was a slight change during the first day after which no further resistance change was detected up to 16 days.

Long-time shelf aging tests indicate that electroless nickel contacts heat treated even at 400°C are not perfectly stabilized against increases in the contact resistance. If the contact resistance becomes too large, however, the low contact resistance obtained after the initial heat treatment can be renewed with another brief heat treatment.

The results obtained with titanate ceramics can be explained if it is assumed that the initial nonohmic behavior of electroless nickel is due to an adsorbed layer of oxygen between the ceramic and the nickel (6). The heat treatment removes the adsorbed oxygen presumably by reaction with the nickel. The deterioration of the ohmic contact is attributed to the re-formation of the insulating oxygen layer as the result of oxygen diffusion to the ceramic-nickel interface.

Electroplated nickel, copper, gold, indium, and silver have also been used to make ohmic contacts to titanate ceramics. Electroplated nickel gives the same results as electroless nickel, however, the latter is preferred over plated nickel since it is more convenient to use in this application. Indium provides an ohmic contact as plated but the adhesion is poor. Silver contacts must be heat treated in a vacuum or in an oxygen-free system to produce the ohmic contact. Oxygen diffuses through silver rapidly at elevated temperatures thus the oxygen layer at the semiconductor-silver interface is removed by chemical reaction on heating only in an oxygen-free ambient. Electroless nickel contacts on gallium-arsenide single crystals are made ohmic by tinning the nickel with a lead-tin solder. The heat treatment alone does not make the contact ohmic. Sharpless (7) has shown that tin is important in producing ohmic contacts to gallium-arsenide.

Preparation of InAs, InP, GaAs, and GaP by Chemical Methods

D. Effer and G. R. Antell

Research Department, Metropolitan-Vickers Electrical Company Limited, Trafford Park, Manchester, England

The formation of crystals of the arsenides and phosphides of indium or gallium by a vapor phase reaction between the lower valency halides of these metals and arsenic or phosphorus has been previously reported (1). This work has now been extended to show that these basic reactions may also be used to prepare the compounds by the following methods: (*a*) continuous flow vapor phase reaction in the presence of an unreactive carrier gas; (*b*) direct reaction in the liquid phase; (*c*) by passing AsH_3 or PH_3 into the molten chlorides; and (*d*) by a replacement reaction starting with $AsCl_3$ or PCl_3 and the metal.

The following equations illustrate the over-all reactions involved.

$$2\,MCl + Y \rightarrow MCl_2 + MY \qquad [1]$$

$$3\,MCl_2 + Y \rightarrow 2\,MCl_3 + MY \qquad [2]$$

where M corresponds to In or Ga and Y to As or P.

Of the possible reactions under each heading only those involving indium monochloride and gallium dichloride were investigated. Some of the reactions resulted in the formation of colored, solid complexes which decomposed at higher temperatures to give the appropriate III-V compound. Reference is made to the possible structure of these intermediates in the discussion section.

X-ray diffraction measurements were used to establish the identity of all the III-V compounds produced.

The various methods offer alternative routes to the ultimate purification of the compounds. In this respect it has been established that chlorine has little or no effect on the electrical properties of InAs, but we have not carried out any experiments to determine the effect of this element on the other three compounds under discussion.

Experimental

Examples of the reactions given under (*a*), (*b*), (*c*) and (*d*) above are as follows:

(*a*) A continuous flow vapor phase method was carried out by passing gallium dichloride and As vapor in pure nitrogen as a carrier gas through a heated quartz tube. The reactants were introduced into the main tube from separately heated compartments such that the composition of the final mixture was in the proportions given in Eq. [2]. After mixing, the vapors passed through a furnace set at approximately 800°C followed by another at 600°C. The latter furnace served to remove any unchanged reactants and volatile products. GaAs was deposited in powdery form in this furnace, and a 75% yield was obtained by a single passage through the heaters.

(*b*) Direct reaction in the liquid phase was carried out by heating gallium dichloride with arsenic powder under a pure nitrogen gas atmosphere, at approximately 500°C for 24 hr. The gallium arsenide formed was separated mechanically from the small amount of free gallium which resulted from the heating and finally baked out under vacuum at 600°C.

To prepare the phosphides of the metals, liquid yellow phosphorus was reacted with gallium dichloride or indium monochloride at substantially 300°C in a pure nitrogen gas atmosphere for 1 hr. Normally only a temperature sufficient to keep the chloride in a molten condition was necessary to produce the reaction. Colored complexes varying from yellow to red were obtained. On heating slowly to approximately 500°C, these decomposed to give InP or GaP.

(c) AsH_3 and PH_3 are relatively unstable gases, AsH_3 decomposing into its elements at about 230°C and PH_3 at 440°C. Passage of AsH_3, in a carrier gas of pure hydrogen, through gallium dichloride at approximately 300°C produced an orange-colored complex which decomposed on heating slowly to 600°C to give GaAs powder. GaP was similarly prepared by passing PH_3 in a nitrogen carrier gas through gallium dichloride at approximately 300°C, the yellow complex formed being slowly heated to 500°C under vacuum to give GaP powder.

Passage of PH_3, in a pure nitrogen carrier gas, through InCl at approximately 300°C produced a red complex which yielded InP on heating slowly to 500°C under vacuum.

(*d*) A variation of the basic reactions was carried out by employing $AsCl_3$ or PCl_3 and the appropriate metal. Using the reaction between $AsCl_3$ and In as an example, when these are heated in molecular proportions an exchange reaction occurs

$$AsCl_3 + In \rightarrow InCl_3 + As$$

If the reaction takes place using an excess of In, InAs is finally produced. It is assumed that a lower halide of In is formed at one stage by the reaction between $InCl_3$ and In and that this reacts with arsenic to form indium arsenide as in the basic Eq. [1] and [2].

All of the four compounds were produced in this way by heating the chlorides to their boiling point ($AsCl_3$ 130°C; PCl_3 76°C) with the metal in sealed evacuated quartz tubes arranged vertically. As the reaction progressed, the temperature was gradually increased to approximately 350°C. Finally, the tubes were placed horizontally in a furnace and heated

slowly to 600°C with what was originally the top end of the tube protruding in order to free the III-V compound from volatile products. The tubes were sealed off in the middle and drawn off. In the case of InAs and GaAs the powders produced were melted by dropping the tubes vertically at 4 cm/hr through a furnace. In all cases except InP the compounds were produced with efficiencies greater than 95% the single experiment with *InP* yielding 65%.

Of the reactions described under the four headings, reaction (*d*) is considered to be most worthy of further investigation with regard to the preparation of the semiconducting compounds in the state of high purity. The $AsCl_3$ or PCl_3 may be purified by careful fractional distillation and finally distilled into reaction capsules containing highly purified In or Ga which are then sealed off. On completion of the reaction as detailed above InAs and GaAs may be melted directly or injected into a "floating zone" or "hanging drop" of the molten compound.

InP and GaP powders produced from the reaction are more difficult to melt due to the high pressures of phosphorus produced at the melting points of these materials. Melting of InP may be attempted in ampoules of extra thick wall or by using an autoclave pumped up to a pressure equal to the dissociation vapor pressures produced by the molten compound. Alternatively the InP powder may be used as charge material for a crystal pulling apparatus.

Discussion

The composition of the colored complexes observed during some of the reactions was not elucidated. Gallium dichloride has been denoted as $GaCl_2$ but is actually dimorphic similar to indium dichloride. Evidence for the formulation of $Ga^{I}(Ga^{III}Cl_4)$ has been given by x-ray diffraction studies with crystalline gallium dichloride (2) and by Raman spectra of the fused compound (3). Further evidence for the formulation which may have a considerable bearing on the structure of the observed complexes has been obtained by passing H_2S through gallium dichloride (4). A solid complex containing Ga, Cl, and S was obtained of variable composition, the reaction occurring with the Ga^{I} ion. It seems possible that the reactions between gallium dichloride and AsH_3, PH_3, and liquid phosphorus behave in an analogous manner.

The Change in Open-Circuit Potential of the Manganese Dioxide Electrode on Discharge and the Discharge Mechanism

W. C. Vosburgh and James H. DeLap

Department of Chemistry, Duke University, Durham, North Carolina

ABSTRACT

Discharge of electrodeposited MnO_2 electrodes for successive short periods at *p*H 8, with time for reattainment of equilibrium, shows that the potential of partially discharged MnO_2 is a linear function of the amount of lower oxide formed over part of the discharge. With this relationship, some previous data on the overpotential of MnO_2 in acid electrolytes are interpreted more simply than before in terms of the discharge mechanism previously proposed. The overpotential is shown to be a linear function of the square root of the current density.

In previous attempts to measure the change in open-circuit potential of the MnO_2 electrode as the result of discharge, the time allowed for recovery from polarization was insufficient (1, 2). This was suspected at the time, but a compensating slow decrease in potential made longer times of doubtful value. The metal anode used in the discharge was probably responsible for much of the decrease (3), and in the present investigation this source of error was avoided. After a small discharge the potential increased for 4 to 40 days, depending on how much the electrode had been discharged previously. The final, nearly constant potential was an approximately linear function of the amount of discharge over the first quarter of the total capacity. The interpretation of some overpotential measurements with acid electrolytes (4) has been reconsidered in the light of this result.

Experimental

Electrodes.—MnO_2 was electrodeposited on graphite rods from a bath of 0.33M $MnSO_4$ and 0.67M H_2SO_4, or from a similar bath containing also 0.3M $(NH_4)_2SO_4$ at 90°C (1, 2, 5). The graphite rods were of 0.48 cm diameter and were covered for a length of 5.1 to 5.2 cm, and on one end, with MnO_2, giving an apparent area of 8 cm^2. Much of the bare portion of the rod was covered with glass sealed to the graphite by glyptal cement for protection from the electrolyte. The current in the electrodeposition was 25 ma (3.13 ma/cm^2) and the time 30 min, giving about 0.2 millimole of MnO_2. The MnO_2 formed in the bath without $(NH_4)_2SO_4$ was probably γ-MnO_2 (6). That deposited in the presence of $(NH_4)_2SO_4$ has been shown to differ in discharge characteristics from γ-MnO_2 (5) and was probably largely α-MnO_2.

After electrodeposition, the electrodes were washed by allowing them to stand in test tubes of 0.01M $(NH_4)_2SO_4$ acidified to *p*H 4.5, this solution being changed daily. Washing was continued until a test for Mn^{++} in the wash solution by oxidation to MnO_4^- with KIO_4 was negative. This usually required 2 to 3 weeks. Each electrode was then immersed in an electrolyte of 1M $(NH_4)_2SO_4$ buffered at *p*H 8 by NH_3. This portion of electrolyte was contained in a 125-ml bottle fitted with a rubber stopper bearing the electrode. By means of a ground-glass joint the electrode was mounted in the stopper in such a way that it could be transferred easily to and from a discharge cell. The stopper also had a hole for the salt-bridge of a saturated calomel electrode, and all of the important potential measurements were made with the electrode in the bottle. Measurements in the discharge cell were used for control only. New electrodes were kept in the bottles with frequent measurements until the potential was decreasing only very slowly; this period was about two weeks usually. The final potential attained was taken as the initial potential of the discharge curve.

Electrodes standing in electrolyte decreased more or less rapidly for a few days and then attained a steady rate of decrease of about 0.1 mv a day which was the same for all electrodes. Although γ- and α-MnO_2 electrodes had nearly the same potential at first, the α-MnO_2 electrodes decreased more rapidly initially and for a longer time, about 10 days. Thereafter the potential was around 70 mv lower than the γ-MnO_2 electrodes, but the slow decrease was at the same rate.

Discharge and subsequent potential measurements.—Tests showed that an electrode could be transferred from one bottle of electrolyte to another of the same electrolyte with no appreciable change in potential. It was concluded that removal of an electrode for discharge and returning it to the same bottle would have no effect other than that of the discharge. It was observed that removal to a discharge cell equipped with 8 graphite rods to act as the anode usually caused a small decrease in potential. The change indicated was considered negligible in comparison with the discharge.

The discharge cell contained about 250 ml of the 1M $(NH_4)_2SO_4$ electrolyte, *p*H 8. The electrode was placed centrally in the cell and was surrounded by 8 graphite electrodes connected together, which formed the anode. A calomel electrode allowed measurement of the changing potential during discharge by a recording potentiometer. A current of 2

Table I. Temperature coefficients of electrodeposited MnO_2 electrodes measured against S.C.E. at 10° to 35°C

Electrode	$\Delta E/\Delta t$, mv/deg C	
	pH 5	pH 8
γ-MnO_2 undischarged	0.07	0.50
γ-MnO_2 discharged 60 ma-min	0.15	0.58
α-MnO_2 undischarged	0.14	0.61
α-MnO_2 discharged 60 ma-min	0.16	0.58

ma from an outside source was passed for the discharge and was regulated by hand.

For discharge an electrode was given a final measurement in the storage bottle and transferred to the discharge cell. A current of 2 ma was passed for a measured time, usually 5 or 10 min. Then the electrode was transferred back to the storage bottle and measured occasionally against a saturated calomel electrode until the potential was increasing less than 1 mv a day. After the first discharge of a new electrode about 4 days was required. In later discharges the times required increased with the amount of total discharge to as much as 40 days. Electrodes of α-MnO_2 required more time than those of γ-MnO_2. All measurements were made at room temperature (in the vicinity of 25°C), and corrections made when necessary for both temperature and pH changes.

Temperature and pH corrections.—For the temperature corrections electrodes in bottles were measured at intervals from 10° to 35°C against a calomel electrode, with about 48 hr allowed at each temperature for the attainment of constancy. In addition to the pH 8 measurements some were made with a 1M $(NH_4)_2SO_4$ electrolyte buffered at pH 5 with pyridine and pyridinium sulfate. The changes in potential per degree are shown in Table I. These are averages for two electrodes which agreed within 0.03 mv/degree at pH 5 and 0.05 mv/degree at pH 8.

The change of potential with pH was determined by transfer of a number of electrodes from one electrolyte to another and measuring after equilibrium was attained. The average change was close to the theoretical 59 mv/pH unit at 25°C.

Test for Mn^{++}.—The solutions in the bottles were tested for Mn^{++} when the electrodes had come to equilibrium. The solution tested was replaced by a fresh portion of electrolyte in the bottle for the next discharge.

Results

The discharge curves determined as above are shown in Fig. 1. The more important are the curves for γ-MnO_2. The solid straight lines are shown to represent the discharges from 10 to 60 ma-min for three electrodes quite well. For a fourth electrode (not shown) which required longer preliminary washing than the others, the first 40 ma-min of discharge was straight. The dashed lines indicate deviations from the straight lines in the first discharge period and after 60 ma-min. No Mn^{++} was found in the electrolytes in which these electrodes were stored for recovery during the first 100 ma-min of discharge. After that an average of 0.12 mg/20 ma-min of discharge was found. Previously (7) in continuous discharges at pH 8 no Mn^{++} was found in the discharge cell until after 150 ma-min.

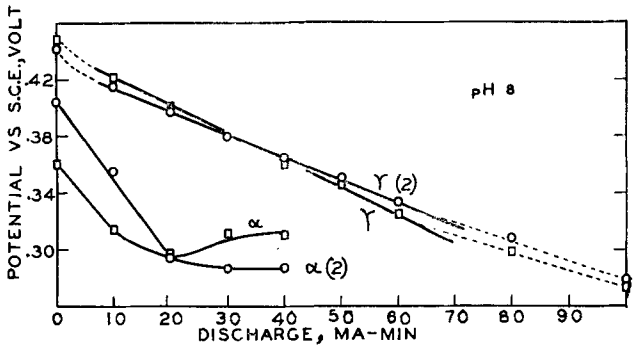

Fig. 1. Variation of equilibrium open-circuit potential with amount of discharge in electrolyte of pH 8; α- and γ-MnO_2. Circles represent averages for two electrodes.

The straight lines for γ-MnO_2 at pH 8 indicate that over a certain portion of the discharge the electrode potential decreases linearly with the increase in lower oxide formed. Deviations from linearity are found at the beginning and below a potential of 0.34 v against the saturated calomel electrode. Within the linear range no Mn^{++} is found in solution, and the entire reduction product remains on the electrode. During the recovery process the product, which is probably formed mainly in the outer portion of the MnO_2 (8, 9), appears to become distributed more uniformly. Even though this process may not have been entirely complete at the time of the final measurements, the amount of product in the surface layer must have been approximately proportional to the total product formed. It has been assumed previously that the electrode potential is determined in part by the composition of the surface layer, but it was thought that the relationship was logarithmic and similar to the Nernst equation (4). The present results indicate a linear relationship over a limited range of compositions. A similar linear relationship is apparent in the data of Kozawa (10) especially in his Fig. 7 showing the decrease in electrode potential when MnO_2 is reduced with varying amounts of Mn^{++}. Ruetschi, Angstadt, and Cahan (11) showed that there is a linear relationship between the potential of a PbO_2 electrode and the surface concentration of adsorbed oxygen.

The formation of Mn^{++} in solution during the later recovery periods (beyond 100 ma-min) after removal of the electrode to another container, does not seem to be in accord with the discharge mechanism proposed by Cahoon and co-workers (12, 13).

In the discharge of α-MnO_2 at pH 8 no Mn^{++} was found for the first 20 ma-min and the potential decreased more rapidly than for γ-MnO_2. The discharge reaction evidently does not penetrate as deeply in α-MnO_2 as in γ-MnO_2, giving a more rapid change in surface composition.

Discussion

The recovery curve.—The straight-line relation between electrode potential and discharge time over a limited range, as shown in Fig. 1, suggests a revision in the interpretation of some previous data (4). It was assumed previously that the electrode

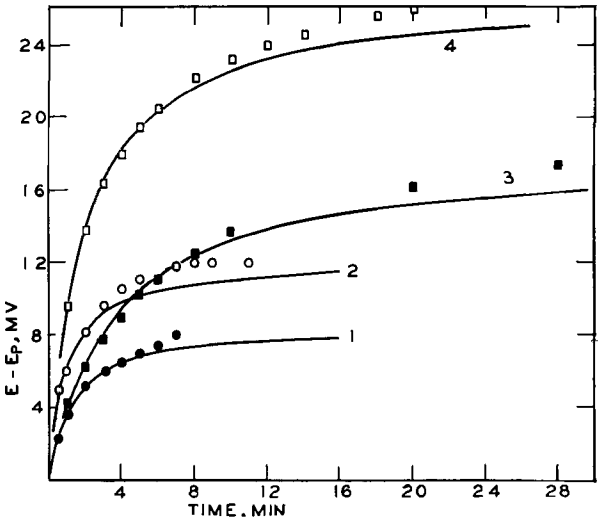

Fig. 2. Decay of polarization in acid electrolytes.

potential is related to the composition of the MnO_2 surface by a logarithmic relation of the form of the Nernst equation (4, 10).

In the discharge of electrolytic MnO_2 electrodes in H_2SO_4 solution containing $MnSO_4$ (4) the potential first decreases, then passes through a minimum and rises to a constant value, indicating a steady state of polarization. The steady state was ascribed to a balance between the lower oxide formed and that dissolved by the electrolyte per time unit. On breaking the circuit a relatively slow rise to a constant open-circuit potential takes place, as shown in Fig. 2.

The amount of polarization shown in Table II of the previous paper (4) was in all cases less than 60 mv, whereas the straight line portions of the γ curves in Fig. 1 extend over about 100 mv. Therefore, a linear relationship between the composition of the surface and the electrode potential may be expected to hold for the polarization in acid electrolytes.

Let E be the variable electrode potential during recovery from polarization, E_e the constant open-circuit potential after recovery, and E_p the closed-circuit potential in the steady state of polarization. If the iR drop and solution concentration polarization are negligible, E_p is also the open-circuit potential at the instant of breaking the circuit. Following the suggestion of Fig. 1, we may write

$$\Delta E = -k' \Delta L \qquad [1]$$

with L defined as a measure of the amount of discharge of product in the electrode surface. It may be somewhat approximate to apply this to the recovery process since the linear relationship may not hold all the way to E_e. However, we shall assume its validity and consider that $L = 0$ when $E = E_e$ which also is an approximation when the solution contains Mn^{++}. Then for the recovery process,

$$E_e - E = k' L \qquad [2]$$

The assumptions made previously that the primary discharge product is a Mn(III) oxide or hydroxide (for which we shall use the formula MnOOH), that the recovery reaction is a disproportionation as in Eq. [3] and that this reaction is rate-controlling are retained. We may add the newer concept that the lower oxide is formed both on and below the surface of the MnO_2 (8).

$$2MnOOH + 2H^+ = Mn^{++} + MnO_2 + 2H_2O \qquad [3]$$

For the velocity of this reaction at constant H^+ concentration we may write

$$-dL/dt = k'' L^2 \qquad [4]$$

This may be somewhat too simple because of the neglect of a reverse reaction, but it seems sufficient for testing the theory. Integration and evaluation of the constant for the condition $L = L_p$ when $t = 0$ gives

$$1/L - 1/L_p = k'' t \qquad [5]$$

with L_p standing for the concentration of product in the surface in the steady state of polarization. Combination of Eq. [2] and [5] gives

$$1/(E_e - E) - 1/(E_e - E_p) = k_1 t \qquad [6]$$

in which $k_1 = k''/k'$.

Equation [6] can be tested by recalculation of the data presented in Fig. 4 and 5 of Yoshiza and Vosburgh (4). Figure 2 gives the results of such a calculation. Curves 1, 2, and 4 represent the same data as the two lower curves of (4): Fig. 4 and the higher of Fig. 5, respectively. Curve 3 represents a different experiment from the lower curve of (4): Fig. 5, but carried out under the same conditions. The lines in Fig. 2 were calculated by Eq. [6] using the experimental values for E_e and E_p and an arbitrary value of k_1 determined for each curve from some of the experimental points. The experimental points shown were taken from recorder curves for the recovery process.

The agreement of the earlier experimental points with the calculated curves is good. The later points deviate from the curves in the direction of too rapid increase in E. It was pointed out above that the equation might not be exact when $E_e - E$ is small. The agreement of the calculated lines and the experimental points is better in curves 3 and 4 than in the corresponding curves of (4): Fig. 5. Curve 2 is not as good as the corresponding one in (4): Fig. 4, but curve 1 may be considered about equal to the lowest (4): Fig. 4 curve, since the earlier points in the latter are not on the curve.

Relation between overpotential and current.—A better test of the above theory is in the relation between overpotential and current in discharges in acid solution. The steady state of polarization in acid electrolytes is enough different from the equilibrium state of the electrode so that Eq. [2] should be a better approximation than for the recovery process.

For the MnO_2 electrode the overpotential has been defined as the difference between the equilibrium open-circuit potential after a discharge and the potential of the steady state of polarization (14). In acid electrolytes the overpotential is not a linear function of the logarithm of the current density (4).

In the steady state of polarization the rate at which lower oxide is formed, $i/\mathbf{F}$ equivalents/sec, can be set equal to the rate at which it is removed

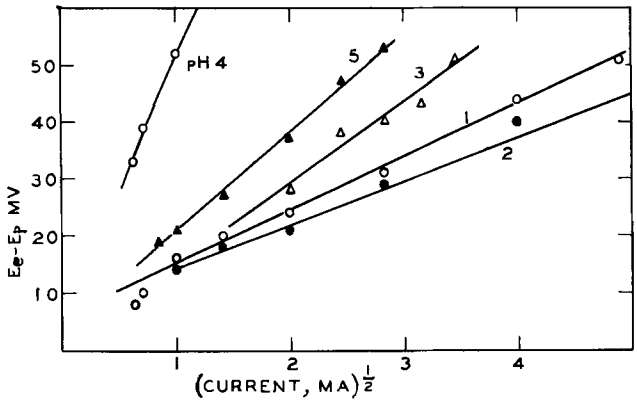

Fig. 3. Overpotential, E_e-E_p, plotted against the square root of the current. Numbers refer to electrolyte compositions (Ref. 4); 1, 1M H_2SO_4; 2, 0.5M; 3, 0.1M; 5, 0.01M; all 0.1M $MnSO_4$. Electrolyte pH 4, acetate buffer and no $MnSO_4$.

from the surface. According to Eq. [4] and the definition of L_p the rate of removal should be equal to $k''L_p^2$. Then

$$i = \mathbf{F}\, k''\, L_p^2 \qquad [7]$$

Combining with Eq. 2 when $E = E_p$ and $L = L_p$

$$i = \mathbf{F}\, k''(E_e - E_p)^2/(k')^2$$

$$E_e - E_p = k_2\, i^{1/2} \qquad [8]$$

Equation [8] predicts a linear relationship between overpotential, $E_e - E_p$, and $i^{1/2}$. Figure 3 shows that this is true over the entire range of currents tried by Yoshizawa and Vosburgh (4). Four different electrolytes, Nos. 1, 2, 3, and 5, give satisfactory straight lines within the limits of error. There was insufficient data for electrolyte 4. An electrolyte of pH 4 gave a slightly curved line. Some of the overpotentials for this electrolyte (not shown in Fig. 3) were so large that the validity of Eq. [1] might be questioned. The data plotted are from (4): Tables II and III.

According to Eq. [8] the lines of Fig. 3 should pass through the origin. However, most of them would pass above the origin, if extended. A constant term in Eq. [8] would be needed to express them. The points of lowest overpotential for the most acid solution in Fig. 3 deviate from the line in the direction to approach $\Delta E_e = 0$ at $i = 0$. This may be connected with the breakdown of the linear relationship between E and oxide composition when the lower oxide component is small.

The data on the growth of polarization of the previous paper have not been recalculated, since these involve the little understood phenomenon of the passage of the electrode potential through a minimum. A recalculation would not be likely to add materially to the older interpretation.

The experimental data and calculations of this paper are in agreement with the assumption made previously that the primary product of the reduction of MnO_2 is a Mn(III) compound formed within the MnO_2 structure, and that its formation is followed by a disproportionation. The assumption of primary reduction to Mn(II) would lead to a linear relationship between overpotential and current, which is not found. However, recent work has shown a linear relation to hold for PbO_2 and TiO_2 electrodes, for which no disproportionation reaction is possible. This work will be reported later.

Acknowledgment

This work was supported in part by a James B. Duke Fellowship and in part by the Office of Ordnance Research. The authors are indebted to Mr. Bruce C. Tyson, Jr., for measurement of the change of potential with pH.

Manuscript received Aug. 14, 1959. This paper was prepared for delivery before the Columbus Meeting, Oct. 18-22, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Effect of Adsorption of Polar Organic Compounds on the Reactivity of Steel

Howard F. Finley[1] and Norman Hackerman

Department of Chemistry, The University of Texas, Austin, Texas

ABSTRACT

Rate studies were made for the oxygen-free reaction between steel powder and 1*N* H_2SO_4, both uninhibited and inhibited. In particular, it was shown that the retardation of the reaction by organic polar compounds was influenced more markedly by molecular structure than by molecular weight or area.

This study is a continuation of the work reported by Hackerman and Cook (1) on the adsorption of polar organic compounds on steel and their effect on its reactivity in acid solution. A comprehensive theory of the general adsorption of organic inhibitors and subsequent inhibition of acid dissolution by polarization of the anodic reaction was given by Hackerman and Makrides (2). The investigations undertaken here were for the purpose of obtaining additional information as a basis for confirming or denying the theory as stated.

Experimental

The essential features of the experimental approach have been described (1). The principle used was to determine gravimetrically the increase in weight of a sample of steel powder on being exposed to a solution of benzene containing the organic inhibitor. The metal used was SAE 1010 steel powder purchased from the Vanadium-Alloys Steel Company. It had a composition of 0.10 C, 0.10 Si, 0.24 Mn, 0.012 P, 0.012 S, and test Fe. It was purchased as powder which passed No. 100 sieve mesh and further sieved, the 140 to 200 range being used.

The benzene was thiophene-free, C.P. grade and was free also from H_2S, CS_2, and SO_2. The polar organic compounds were obtained from several sources. Hexamethylenimine and heptamethylenimine were obtained from Dr. P. D. Gardner, The University of Texas. Diallylamine, 1,4,4, trimethylpiperdine, and 1-benzylpiperdine were obtained from Dr. N. J. Leonard, The University of Illinois; tetrahydrothiophene from Delta Chemical Works, and four alkyl aryl sulfonate salts from Dr. A. H. Roebuck, Continental Oil Company. The remainder of the compounds were of the best grade of Eastman chemicals. In all cases, except for the sulfonate salts, the compounds were liquids and were redistilled. The sulfonate salts were 99.5% pure as received.

In making solutions of the inhibitors, two liters of 0.0100M solution were made and then solutions of 0.005, 0.0025, 0.00125, 0.00063, 0.00031M prepared by dilution of the proper aliquotes.

The relative inhibitor efficiency was determined by measuring the reaction rates in 1*N* H_2SO_4 of the steel powder either untreated or previously exposed to the benzene solutions of the inhibitors. The acid was prepared in 4-liter quantities from stock concentrated C.P. H_2SO_4.

The data are good in general to 5%.

Procedure.—The procedure for determining the amount of polar organic compound adsorbed on the steel has been described (1). There were, however, some modifications made in the method of determining relative inhibitor efficiencies. The apparatus used was essentially the same, with one or two minor alterations, but the technique of treating the data was completely different. Previously the results were compiled as a relative activity based on the time required to liberate 36, 81, and 126 ml of hydrogen gas or the time for the dissolution of 1.6, 3.4, and 5.2% of the metal. Basis time for reaction on clean steel was taken as an average from a number of different runs made on different samples. There are two objections to this procedure. The first is that there is only a relatively small amount of inhibitor on the surface of the steel, and after a short time of reaction it can be expected to be swept away or undermined so that it no longer protects the metal. The second is that unreduced steel powder already has a considerable surface oxide layer, and reaction rates with acid are both low and erratic from sample to sample.

It was believed that the following procedure would eliminate these objections. The powder was reduced in 150-g sample lots under hydrogen for 24 hr at 600° ± 25°C, both inhibited and uninhibited samples being treated alike. Individual curves were run for each sample lot and the inhibited samples were compared with these. Plots were made of volume of hydrogen evolved against time of reaction. The slope of the curve at zero time was obtained by extrapolation and a graphical method. The procedure used was to stand a small mirror on edge on the curve in such a way that the curve was continuous with its reflection. The base of the mirror was then normal to the curve at point of contact. Check values obtained with curves of known slope were never in error more than 2 or 3%. This approach is versatile and readily provides volume vs. time, rate vs. time, and rate vs. volume curves.

[1] Present address: Creole Petroleum Corporation, Cabimas, Edo. Zulia, Venezuela.

The relative inhibitor efficiency, y, was calculated from the equation

$$y = \frac{R_p - R_I}{R_p} \qquad [1]$$

where R_p is the reaction rate at zero time for the plain steel and R_I that for the inhibited steel.

Reaction rate data.—Typical hydrogen evolution data from uninhibited steel samples are shown in Fig. 1. These curves were not immediately amenable to analysis. The data were first plotted as volume vs. square root of the time and seemed to give a fair fit. However, the upper and lower ends of the curves deviated somewhat (Fig. 2). A better fit was obtained by plotting hydrogen volume against the square of the natural logarithm of the time. This is shown for the same data in Fig. 3. The equation for the curves is then

$$V = k_o \ln^2 t + k_1 \qquad [2]$$

The rate equation becomes

$$\frac{dV}{dt} = 2k_o \frac{\ln t}{t} \qquad [3]$$

Figure 4 shows the data of the 30°C curve from Fig. 1 plotted as reaction rate vs. time and compared with the function $(k\ln t/t)$ normalized to $(k\ln t/t) = 3.5$ at $t = 2.5$, one of the actual data points.

This time dependence of the hydrogen volume is somewhat difficult to interpret. There was a slight increase in pH as the reaction proceeded but nothing of magnitude sufficient to explain the great decrease in reaction rate. Various investigators (3-5) have solved the square root dependence curve in the case of dry oxidation of metals, basing their solution on the diffusion of reactants through the oxide layer formed on the surface of the metal. Figure 5 shows that there is a general similarity between the shape of a $t^{1/2}$ and a $\ln^2 t$ curve. From this the tentative conclusion concerning the latter curve is that it is due to barrier layer formation.

The hydrogen volume-time dependence of the inhibited samples failed to show the same relationship. A typical curve is shown in Fig. 6 compared with a rate curve for plain steel. The rate increases slowly at first, reaches a peak at about 10 min, and then begins to decrease. The final rate is somewhat lower than that for plain steel, but its rate of change with time is about the same.

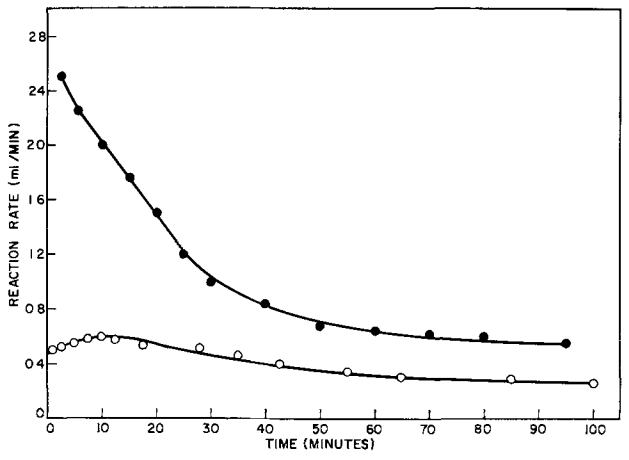

Fig. 6. Hydrogen evolution from steel in 1N H_2SO_4. •, Unhibited; o, inhibited.

The first 10 min the preadsorbed inhibitor is being removed from the surface by undermining, and fresh surface is being continuously exposed. At the same time a barrier layer is forming over the surface of the steel. After about 10 min of reaction the effect becomes predominant and the reaction rate begins to decrease. Thus protection of the steel functions simultaneously through two mechanisms: adsorbed inhibitor and barrier layer formation.

Adsorption and inhibitor efficiency data.—The data for the adsorption of the polar organic compounds are shown in Table I and that for the relative inhibitor efficiencies in Table II. The sulfonate salts were found to be extremely insoluble not only in benzene and water but also in all the usual solvents. For this reason adsorption curves could not be obtained for these compounds. However, they were slightly soluble in 1N H_2SO_4 so that relative inhibitor efficiency curves could be obtained with the inhibitor *in situ*. These data are also given in Table II.

A typical adsorption isotherm and a relative inhibitor efficiency curve are shown in Fig. 7.

The adsorption of the heterocyclic amines, pyrrolidine, piperdine, hexamethlenimine, and heptamethylenimine was not dependent on the number of carbon atoms in the molecule and only slightly on the molecular cross-sectional area. The approximate cross-sectional areas of all compounds studied were determined from Stuart and Briegleb atom models (obtained from Arthur S. LaPine and Company, Chicago), and are given in Table III. Photographs were made of each model with the camera lens in the position of a metal surface atom onto which the polar molecule had adsorbed. Line drawings were made from the photographs and the cross-sectional area calculated assuming that the molecule was free to rotate about the center of its electron density. A plot of the amount of imine adsorbed vs. area is shown in Fig. 8. It is seen that the large molecule adsorbs less but only slightly so. From the areas per molecule and the nitrogen adsorption area of the metal, it was calculated that approximately two layers of inhibitor adsorbed in each case.

There is a marked difference between the adsorption behaviors of these cyclic imines and the high molecular weight aliphatic amines studied earlier (1). Both adsorption data and relative inhibitor efficiency data show that all the imine is irreversibly adsorbed (note the plateaus in Fig. 7). The aliphatic amines adsorbed in every case about the same

amount irreversibly and an additional amount, easily desorbed, that increased with the molecular weight of the amine. This difference can be attributed to two things: (*a*) the secondary nitrogen atom of the imines has a greater electron density for coordinating with metal surface atoms, and (*b*) the short, rigid, nearly planar hydrocarbon tails of the imines do not intertwine and lead to physical adsorption. The amines chemisorb less to begin with and their longer, less rigid hydrocarbon tails probably form a loose, haphazard arrangement on top of the chemisorbed layers.

The small amount of adsorption of the 1-benzyl piperdine is due to its large cross-sectional area. In addition the electrophylic phenyl group tends to reduce the electron density on the nitrogen atom. The high degree of adsorption of the tetrahydrofuran is due to its small cross-sectional area. There were evidently areas on the surface available to it that were not available to the other molecules.

Tetrahydrothiophene exhibited a surprisingly small degree of adsorption. However, the compound is extremely volatile. The simple adsorption equipment used in these experiments was not designed for use with volatile compounds.

The relative inhibitor efficiency of the heterocyclic imines is a function of the number of carbon atoms in the ring. This is shown in Fig. 9 and for comparison the data for the n-aliphatic amines taken from Hackerman and Cook's data. The amines also show a linear dependence on the number of carbon atoms for octylamine through tetradecylamine but decidedly less protection for hexadecylamine and octa-

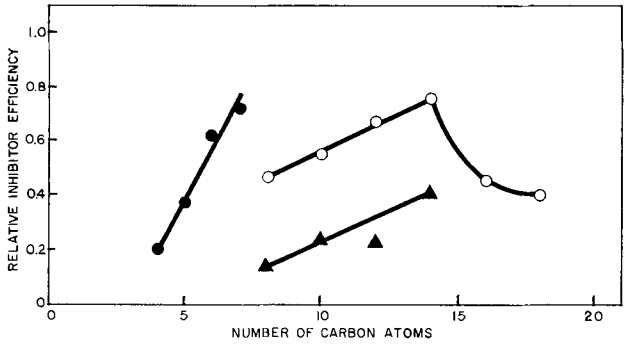

Fig. 9. ●, Heterocyclic imines; ○, aliphatic amines; ▲ alkyl aryl sodium sulfonates.

decylamine. Levine and Zisman (6) found similar behavior for n-aliphatic acids, alcohols, and amines. They noted a marked change in the kinetic coefficient of friction and contact angle for those of 14 or more carbon atoms and attributed this to a transition between monolayers which were liquid condensed and those which were solid.[2] It is seen that the imines increase in efficiency about 20% on the addition of a methyl group, while the amines below hexadecylamine increase by only about 5%.

The imines are relatively good inhibitors. This is in consonance with the fact that secondary amines inhibit better than primary amines. An additional increase in efficiency in going to the tertiary compound can be seen by comparing 1,4,4-trimethylpiperdine with piperdine. It should be noted that there is a greater increase on adding a methyl group to the ring than to the nitrogen atom. Thus,

$$\text{piperdine} < \text{1,4,4-trimethylpiperdine} < \text{hexamethylenimine}$$

The data for the two oxygen compounds is not straightforward. The high relative protection of the tetrahydrofuran is because of the high degree of adsorption observed. The relative inhibitor efficiency of the tetrahydrothiophene was very good even without considering the reduced adsorption of the compound due to its volatility. If the ratio of efficiency to amount adsorbed is considered, the order is

$$\text{tetrahydrofuran} < \text{pyrrolidine} < \text{tetrahydrothiophene}$$

In analyzing the data for the alkyl aryl sodium sulfonates two things must be considered: (*a*) the inhibitor is in the solution and not preadsorbed, and (*b*) the sulfonate salts are very insoluble compared to the other compounds studied. A plot of relative inhibitor efficiency against the number of carbon atoms in the alkyl chain is shown in Fig. 9. Like the amines, the increase is about 5% per methyl group.

Thus we see that homologous series of three types of compounds: heterocyclic imines, aliphatic amines, and alkyl aryl sulfonates exhibit a linear dependence of relative inhibitor efficiency on the number of carbon atoms in the molecule. This cannot be attributed

[2] At first glance, it seems that the sharp drop for hexadecylamine and octadecylamine amine could be ascribed to micelle formation in the solution or to reduced solubility. However, it should be noted that the adsorption increased regularly with molecular weight and what is shown in Fig. 9 is a reduction in effect. Similarly, Levin and Zisman (6) describe a reduction in effect, as did Marsh (7), in connection with a discontinuous change in oil wetting properties. Therefore, the reason could just as well lie in a two-dimensional phase change for instance. In any event, this is a problem which is outside the scope of the present work.

to an increase in barrier layer resistance due to longer chain length on ascending the homologous series, since the amines would then be expected to show a greater effect than the imines. The explanation lies in a more fundamental property of the molecule.

One possible explanation lies in the charge-transfer-no-bond adsorption complex theory advanced by Matsen, Makrides, and Hackerman (8). This postulates that on chemical adsorption a surface complex is formed between adsorbate and adsorbent whose ground state is characterized by a linear combination of wave functions for a no-bond state and a dative state. The dative state lies above the no-bond state by an amount equal to $I_B - (E_A + E_C)$ where I_B is the ionization energy of the adsorbate, a Lewis base, E_A the electron affinity of the metal, a Lewis acid, and E_C the coulombic interaction energy. For a given metal with a series of polar inhibitors, the value of $(E_A + E_C)$ should be constant, but the value of I_B will vary from inhibitor to inhibitor. A lower value of I_B results in a lower value of the energy of the dative state and consequently a lower value of the energy of the ground state. A lower ground state energy is reflected in a stronger bond of chemisorption and a greater relative inhibitor efficiency.

A nucleophylic methyl group tends to increase the electron density on the polar group of organic inhibitors. This is observed as a decrease in ionization potential of each higher member of a homologous series. Data for the compounds studied here are not available, but values of the ionization potentials of some low molecular weight amines were made available by Matsen (9). These values are:

Group	Mono	Di	Tri
Methyl	8.97±0.02	8.24±0.02	7.82±0.02
Ethyl	8.86±0.02	8.01±0.01	7.50±0.02
Propyl	8.78±0.02	7.84±0.02	7.23±?
Butyl	8.71±0.03	7.69±0.03	

A plot of these is shown in Fig. 10. Thus it is seen that the change in ionization energy in ascending a homologous series of amines is about the same per methyl group but that the value of the ionization energy is dependent on whether the amine is primary, secondary, or tertiary.

The inductive effect of a methyl group, with its attendent decrease in ionization potential of the polar group, is thus a possible explanation of the linear dependence of relative inhibitor efficiency on the number of carbon atoms in the molecule. In the heterocyclic imines the change in relative inhibitor efficiency per methyl group is almost 20% reflecting the fact that each carbon in a ring compound is able to exert an inductive effect along both sides of the chain back to the terminal group. The value of 5% for the amines results from the decrease in inductive effect as additional carbon atoms are interspersed in the chain. The same is true for the alkyl aryl sulfonates. The para polarized benzene nucleus.

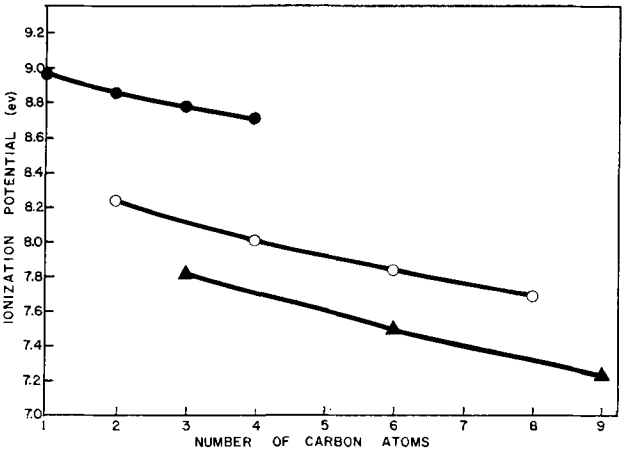

Fig. 10. •, Primary amines; ○, secondary amines; △, tertiary amines.

hydrocarbon chain +  – polar group

is such that the inductive effect is transmitted across it, even though the benzene ring is an electrophylic group.

Conclusions

1. In these experiments the rate of hydrogen evolution from reduced plain steel powder in 1*N* H_2SO_4 is a function of $(\ln t/t)$. Also, the steel was protected by barrier layer formation and by adsorbed inhibitor simultaneously, when the latter was present.

2. The heterocyclic nitrogen, oxygen, and sulfur compounds investigated here exhibit chemisorption under the experimental conditions imposed.

3. Over a range of molecular weights in an homologous series of heterocyclic imines, aliphatic amines, and alkyl aryl sulfonates, the relative inhibitor efficiency is a linear function of the number of carbon atoms in the molecule.

4. A possible explanation of this is the inductive effect of a methyl group with its attendent decrease in ionization potential of the polar group.

Mechanism of the Iron-Hydrogen Sulfide Reaction at Elevated Temperatures

Hans Arm,[1] Paul Delahay, Charles Hudgins,[2] Fritz Hügli,[3] Lester Hulett,[4] and Mohsin Qureshi[5]

Coates Chemical Laboratory, Louisiana State University, Baton Rouge, Louisiana

ABSTRACT

The mechanism of the iron-hydrogen sulfide reaction was studied in the 500°-760°C temperature range for a total gas pressure of 1 atm. The rate of attack was essentially constant (linear law), and the corrosion scale was composed of two layers: a thin dense layer adjacent to the metal and a porous layer with a coarse crystalline structure. These two features which differentiate this reaction from the iron-sulfur vapor reaction are interpreted on the basis of two main effects: (*a*) partial blocking of reaction sites by hydrogen produced during attack, and occurrence of a reaction at a constant number of reaction sites; and (*b*) continuous recrystallization of the dense scale into a porous scale offering no barrier to transport of reactants. This mechanism is self-regulating.

The following evidence is presented: (*a*) linear Arrhenius plots were obtained; (*b*) essentially the same rate of attack was observed for hydrogen-hydrogen sulfide and helium-hydrogen sulfide mixtures having the same partial pressure of hydrogen sulfide; and the dependence of rate on hydrogen sulfide pressure was accounted for; (*c*) the attack rate was not affected by the coating of specimens with a dense layer of varying thickness obtained by preliminary attack in sulfur vapor; (*d*) the iron-sulfur reaction, which obeys the parabolic law of attack, was inhibited by hydrogen diffusing from the back of the specimen surface; (*e*) recrystallization of the dense layer into the porous one was observed for specimens aged in helium; and (*f*) aging of iron sulfide with a fine crystalline structure (prepared by sulfur attack) in the corresponding hydrogen-hydrogen sulfide equilibrium mixture caused the scale structure to become somewhat coarse.

Discussion of experimental methods covers the following points: (*a*) measurements of the rate of attack with a quartz spring balance in hydrogen-hydrogen sulfide and helium-hydrogen sulfide mixtures; (*b*) techniques for attack in sulfur vapor followed by hydrogen sulfide attack; (*c*) use of a mild steel cartridge containing lithium aluminum hydride in the hydrogen diffusion studies; and (*d*) scale thickness studies.

The iron-hydrogen sulfide reaction at elevated temperatures has two unusual features which distinguish it from most other metal-gas reactions with solid scale formation: (*a*) the rate of attack becomes constant after a short time (a few minutes above 500°C), i.e., the attack follows a linear law; and (*b*) a scale composed of two layers is formed, the layer adjacent to the metal having a fine crystalline structure and the outer layer being of a porous and coarse structure. [See review of previous work in the recent paper of Dravnieks and Samans (1).] In contrast, the iron-sulfur reaction, according to Hauffe and Rahmel (2), follows the normal parabolic law of attack (corresponding to a diffusion controlled process) with formation of a single homogeneous scale having a fine crystalline structure. The same product of attack, iron sulfide, is obtained in both reactions, and yet the kinetics are very different. An interpretation for these differences is given here.

Recent kinetic investigations of this problem were made by Dravnieks and Samans (1) and by Haycock (3). The manuscript of the former authors was available at the onset of our work while Haycock's manuscript became available in the fall of 1958. Dravnieks and Samans postulate a mechanism controlled by a surface reaction which they assume to be the dissociation of hydrogen sulfide at the scale surface. They account for the two-layer scale by assuming two different processes, namely diffusion of sulfide ions in the dense layer and diffusion of ferrous ions in the coarse layer. Haycock postulates mixed control by diffusion of sulfide ions across the dense layer and recrystallization of the dense layer into the porous layer. A linear law is observed when the dense layer reaches a constant thickness. Continuous recrystallization is greatly accelerated by hydrogen produced in the iron-hydrogen sulfide reaction. Haycock concludes from marker experiments that sulfide ion is the diffusing species. This is accounted for by the assumption that the diffusion rate

[5] Postdoctoral fellow, 1958-1959. Present address: Department of Chemistry, Muslim University, Aligarh, India.

for ferrous ions is decreased because of the formation of "E-centers." By analogy with other cases (4), Haycock assumes that E-centers are formed by trapping of hydrogen in cation vacancies of the lattice.

Our purpose was to design experiments to discriminate as unambiguously as possible between control by a surface reaction and that by a diffusion process and to determine whether hydrogen plays a role in recrystallization of the dense layer into a coarse layer (not observed when hydrogen is not present). The following studies were made: (*a*) confirmation of the linear law at different temperatures and determination of the heat of activation; (*b*) attack in mixtures of hydrogen sulfide and hydrogen or helium; (*c*) attack of iron in sulfur vapor followed by hydrogen sulfide attack; (*d*) study of the effect of hydrogen on the iron-sulfur vapor reaction, hydrogen being supplied by diffusion through the iron from the unexposed face of the corroding specimen; and (*e*) determination of the scale thicknesses and effect of aging on the two-layer scale.

Experiment (*a*) would give an indication of mixed control by two processes having different heats of activation if a nonlinear Arrhenius plot were obtained. The combination of experiments (*b*), (*c*), and (*d*) should allow discrimination between control by a surface reaction and by diffusion. Experiment (*e*) should provide direct evidence of recrystallization.

Experimental Methods

Attack in Hydrogen Sulfide and Hydrogen Sulfide-Hydrogen or Hydrogen Sulfide-Helium Mixtures

Rates of attack were determined from the increase in specimen weight. The specimen in the lower Vycor reaction chamber (Fig. 1A) was suspended on a fine Vycor fiber attached to a quartz spring (obtained from Worden Laboratories, Houston, Texas). The quartz spring extended only in the upper Pyrex chamber and was essentially at room temperature; i.e., no temperature correction in the calibration was necessary. The elongation of the spring was measured with a cathetometer (Gaertner, Chicago) with an error not exceeding 0.05 mg for specimens weighing approximately 0.5 g.

The chamber with its gas preheater coil was connected to a gas mixing system which could supply hydrogen and mixtures of hydrogen sulfide with either hydrogen or helium. Traces of oxygen in the electrolytic grade hydrogen (Matheson) were removed by passing the gas through a "Deoxo" catalyst cartridge (obtained from Engelhard Industries, Inc., Newark, N. J.). Hydrogen sulfide and helium were used as supplied in tanks (Matheson). The composition of the gas mixtures was constantly controlled (*a*) from the individual flow rates, as measured with differential pressure manometers, in the determination of the heat of activation, and (*b*) by a sensitive thermal conductivity cell in the comparison of attack rates for hydrogen-hydrogen sulfide and helium-hydrogen sulfide mixtures. A gas reservoir with twice the capacity of the reaction chamber was inserted between the chamber and the mixing system. The gas reservoir was used in the initiation of the reaction. The reaction chamber was bypassed during the adjustment of the gas mixture composition.

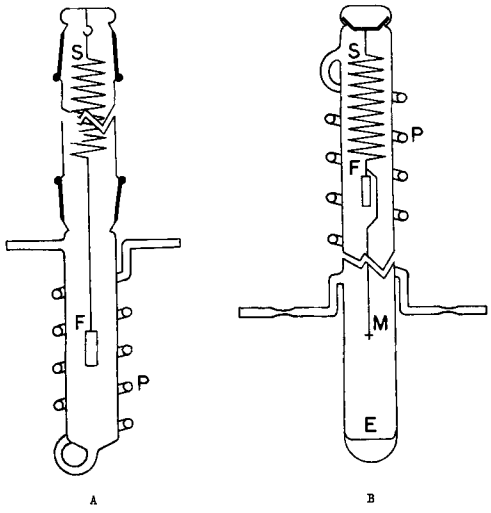

Fig. 1(A). Apparatus for the study of the reaction of iron with hydrogen sulfide and mixtures of hydrogen sulfide and hydrogen or hydrogen sulfide and helium. F, specimen; S, quartz spring; P, gas preheater coil. Fig. 1(B). Apparatus for mixed attack experiments and for hydrogen diffusion experiments. F, iron cartridge or other specimen; S, quartz spring; E, sulfur pool; P, gas preheater coil; M, platinum wire marker.

Specimens were made of spectroscopically pure iron sheets, for which the suppliers (Jarrell Ash Co., Newtonville, Massachusetts) gave the following analysis: 4 ppm Mn; 2 ppm Ni, Si, Mg; 1 ppm Cu, Ag, Na, Li; other metals were not detected spectroscopically. The specimen dimensions of approximately 0.05 x 0.7 x 1.4 cm were determined accurately with a micrometer. Specimens were washed in petroleum ether and acetone before use.

After introduction of the specimen in the reaction chamber the entire flow system was evacuated to a pressure below 1 mm. The absence of leaks was ascertained, and the system was flushed repeatedly with hydrogen and finally evacuated again. Hydrogen then was passed through at a rate of approximately 200 ml/min (linear velocity of approximately 1 cm sec^{-1}), and the furnace was brought to the desired temperature. Reduction of traces of oxide on the specimen followed for 2 hr at 500°C or a higher temperature. After removal of hydrogen by evacuation, the gas mixture was passed through the chamber at the rate of 200 ml/min, and the attack was followed as described above.

Mixed Attack

Experiments in which attack by sulfur vapor was followed by hydrogen sulfide attack involved one difficulty, namely, that to avoid condensation, no part of the apparatus could be colder than the vessel in which sulfur was vaporized. The Pyrex chamber of Fig. 1B was constructed with the upper end open. Sulfur was introduced, and the specimen, suspended on a quartz spring, was hung on an inverted U-rod. The top of the chamber then was sealed. Procedures

for the purging and reduction were the same as for the hydrogen sulfide attack. After reduction of the specimen, the chamber was filled with helium and sealed at the constricted sections of the side arms, the upper part of the chamber being maintained all the time at 575°C. The lower furnace was raised around the sulfur reservoir and heated to 230°C. Vaporized sulfur condensed in the section of the chamber (between the two furnaces), approximately 2 in. in length, which remained cool during the warm-up of the lower furnace. Heater sleeves were slipped over the side arms to avoid sulfur condensation. After the lower furnace reached 230°C, a heater clamp was placed around the exposed midsection, and attack of the specimen was initiated. This method reduced the uncertainty of the zero time to a few minutes.

After the desired increase in weight, as followed by the cathetometer, had been reached, sulfur attack was stopped by removal of the lower furnace, the upper furnace remaining at 575°C. The heater sleeves were removed and the gas flow system, discussed above, was connected to the sidearms with thick-walled Tygon tubing. The system then was evacuated and purged with hydrogen. The hydrogen-hydrogen sulfide mixture of previously adjusted composition was introduced in the chamber by the snapping of the sidearm tips inside the Tygon tubing at the inlet and outlet. Rates of attack were determined from cathetometer readings at a gas flow rate of 200 ml/min.

Influence of Diffusing Hydrogen on the Iron-Sulfur and Iron-Hydrogen Sulfide Reactions

The effect of hydrogen diffusing from the back of the specimen surface during attack in sulfur vapor was studied. The specimen was a mild carbon steel cartridge, 4 x 20 mm with a bore of 2 mm diameter, containing 20 mg of lithium aluminum hydride. The air in the cartridge was flushed with helium while the mouth was crimped together. The cartridge was immediately sealed with an acetylene torch, the lower part of the cartridge being kept cold in water. A platinum wire was attached to the top of the cartridge for suspension purposes, and the wire and sealed portion of the cartridge were masked with a porcelain cement (Saureisen). The cement was allowed to harden in air for at least 24 hr before the cartridge was used. Immediately before use, the cartridge was polished with Behr-Manning 400A sandpaper and jeweler's rouge cloth and then washed with acetone and petroleum ether.

The cartridge and a long platinum wire were suspended on a quartz spring inside a Pyrex tube whose bottom had been filled previously with sulfur (Fig. 1B). This Pyrex tube was provided with an inlet and outlet for hydrogen. The tube then was sealed at the top and placed in a furnace. The cartridge was reduced for 2 hr in a stream of hydrogen, the lower part of the reaction tube remaining at room temperature. After reduction, the furnace was cooled and the tube was removed. The hydrogen remaining in the tube was replaced with helium, and the gas inlet and outlet were sealed off and shortened so that they would not protrude outside the furnace.

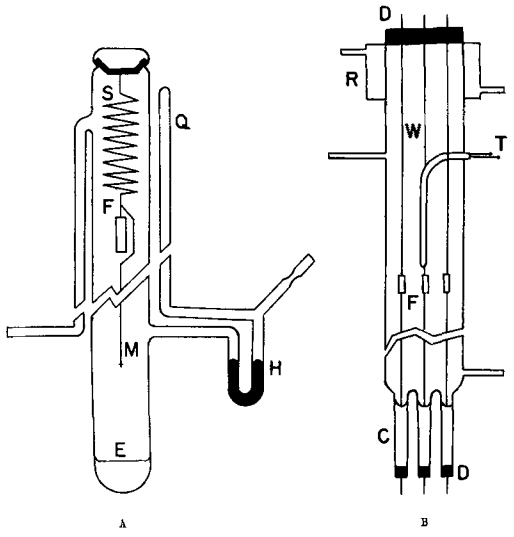

Fig. 2(A). Apparatus for measuring rates of hydrogen diffusion through iron and iron sulfide. S, quartz spring; F, cartridge; E, sulfur pool; M, platinum wire marker; H, differential pressure manometer; Q, tube containing the reference volume of gas at the same temperature as the cartridge. Fig. 2(B). Apparatus for scale studies. F, specimens; W, chromel wires; T, thermocouple; C, detachable casting tubes containing sulfur; D, rubber stoppers; R, cooler.

Sulfur attack followed according to the procedure described in the previous section.

In some experiments with blank cartridges, i.e., without lithium aluminum hydride, the reaction tube was evacuated after hydrogen reduction and kept at a pressure of 0.02 mm for 8 hr to remove the hydrogen which had diffused into the metal.

Experiments on the effect of hydrogen diffusion on hydrogen sulfide attack involved the same procedure as described above for spectroscopically pure specimens except that cartridges were utilized.

Diffusion of Hydrogen in Iron and Iron Sulfide Scale

Rates of hydrogen diffusion through iron with or without ferrous sulfide scale were obtained with the chamber of Fig. 2A. The initial steps were the same as in the preceding section. After reduction, hydrogen was replaced by helium in the chamber. The side arm on the left was sealed off close to the wall of the chamber, and the small sidearm protruding from the U-tube was sealed off at the constriction. Condensation of sulfur was prevented by a specially shaped heater. Sulfur vapor attack was carried out at 500°C all the time. The U-tube was connected, after removal of its heater, to a vacuum system with a thick wall Tygon tube. A small glass bulb containing 5 ml of mercury was also connected near the U-tube and in parallel with the vacuum system. The tip of the sidearm in the Tygon tube was snapped and the reaction chamber was evacuated with the forepump. The sulfur reservoir was sealed off to eliminate subsequent errors in pressure measurements as a result of gas release from the sulfur. Evacuation to 1 μ was continued with an oil diffusion pump. Mercury from the small reservoir was poured through the sidearm and into the U-tube, and the sidearm was sealed. An all glass, completely sealed system with a built-in differential pressure mano-

meter thus was obtained. Pressure variations in the reaction chamber resulting from hydrogen diffusion through the cartridge wall were measured with a cathetometer.

Scale Thickness Studies

A special reaction vessel was designed for scale thickness studies to allow rapid casting of specimens in molten sulfur. Five specimens (only three shown in Fig. 2B) were suspended on chromel wire by means of insulating glass hooks. The wires were strung through rubber stoppers. The casting tubes were filled with sulfur chips which were melted with a clamp heater just before the casting of a specimen. After attack in a hydrogen sulfide-hydrogen mixture, the specimen was lowered into the molten sulfur, and the casting tube was allowed to cool. The five specimens could be cast at different times. The reduction in hydrogen before attack and the attack were conducted as above.

The tendency of the scale to peel off as a result of the temperature change was minimized by the use of curved specimens as suggested by Haycock (3). The scale remained quite adherent on the concave side.

Mounted specimens were cut with a high-speed, glass-cutter's saw. The cross section was polished with graded emery cloths and levigated alumina on a metallographic polishing wheel. A Bausch and Lomb metallographic microscope was used for examination and photography.

Specimens obtained in mixed attack and aging experiments and cartridges from experiments with hydrogen diffusion were mounted in an EPON resin.[6] The procedure was as follows: Add 9 parts EPON 828 to 1 part curing agent (DTA); mix well; pour into mold around the specimen; allow the EPON to cure for 24 hr at room temperature.

Aging of Scale in Hydrogen-Hydrogen Sulfide Mixture

Specimens were attacked in sulfur vapor as in the mixed attack experiments. After attack, hydrogen was introduced in the chamber much in the same way as hydrogen sulfide was introduced in the mixed attack studies, and the pressure in the chamber was adjusted slightly above atmospheric pressure. The equilibrium partial pressure of hydrogen sulfide, in the conditions of this experiment, was quite insignificant in comparison with the hydrogen pressure (see below, influence of diffusing hydrogen on sulfur vapor attack), and this allowed the use of pure hydrogen rather than the equilibrated mixture hydrogen-hydrogen sulfide. After aging, the chamber was allowed to cool slowly to room temperature before the specimens were removed. Specimens then were mounted in the EPON resin.

Mechanism of the Iron-Hydrogen Sulfide Reaction

Postulated Mechanism

The results of attack in helium-hydrogen sulfide mixtures and mixed attack experiments led us to postulate a mechanism for the iron-hydrogen sulfide reaction which was further confirmed by experiments on sulfur attack with hydrogen diffusion and experiments on aging of the scale. The mechanism is as follows:

Hydrogen produced by the iron-hydrogen sulfide reaction remains in large part adsorbed (or associated in some other fashion) with iron sulfide. The number of reaction sites available for attack by hydrogen sulfide is considerably decreased as a result of hydrogen adsorption, and attack occurs at an essentially constant number of reaction sites, i.e., a linear law of attack is observed. Furthermore, diffusion is not rate controlling (at least at sufficiently high temperatures, i.e., above 500°C approximately) because of continuous recrystallization of the scale into a coarse layer which offers no diffusion barrier. The thickness of the thin layer is not sufficient to cause diffusion control.

This mechanism is self-regulating in that a decrease (or increase) in rate would result in a decrease (or increase) in the rate of hydrogen production and, consequently, in an increase (or decrease) in the number of reaction sites. The latter effect then would compensate the initial decrease (or increase) in rate that caused it.

Supporting evidence will now be presented.

General Characteristics and Effect of Temperature[7]

The two essential characteristics of the iron-hydrogen sulfide reaction, linear law of attack and formation of a two-layer scale, are apparent from Fig. 3 and 4. The slope of the log-log plot in Fig. 3 is quite close to unity, i.e., the law of attack is linear. In the early stage of attack (5-15 min) the rate is somewhat larger than the constant rate observed afterwards. This effect causes the slope of the log-log plot in Fig. 3 to be somewhat smaller than unity. The initial high rate possibly results from the difference in the metal and scale areas.

At temperatures below 500°C, plots of the increase in specimen weight vs. time exhibit a marked

curvature [cf. Dravnieks and Samans (1) and Haycock (3)] which is probably due to partial diffusion control.

Arrhenius plots for the data on Fig. 3 and similar data for a 4:1 hydrogen-hydrogen sulfide mixture are linear (Fig. 5). Mixed control of kinetics by two processes having rather different heats of activation is ruled out by the linear plot of Fig. 5. The corresponding heat of activation is 30 kcal/mole, as compared to 20 kcal/mole according to Dravnieks and Samans (1) and 12 kcal/mole according to Haycock (3). The variation from 30 to 12 kcal/mole is possibly due to differences in hydrogen coverage. (This point was suggested to us by Dr. Haycock.) Indeed, the values of 30, 20, and 12 kcal/mole were obtained, respectively, in pure hydrogen sulfide at 1 atm, in hydrogen at 1 atm with a relatively low partial pressure of hydrogen sulfide, and in hydrogen at 600 p.s.c. with hydrogen sulfide at 0.6 p.s.c. If one assumes that hydrogen desorption is the rate-determining step, the foregoing heats of activation correspond to the heats for hydrogen adsorption. The values of 30 to 12 kcal/mole then are of the right order of magnitude, and their variation with coverage is in the right direction. Compare for instance with the heat for hydrogen adsorption on nickel which, according to Beeck (5), decreases from approximately 30 kcal/mole near zero coverage to 17 kcal/mole near full coverage. The iron sulfide scale probably behaves as a metal for hydrogen adsorption because of the high density of free electrons (high conductivity of scale).

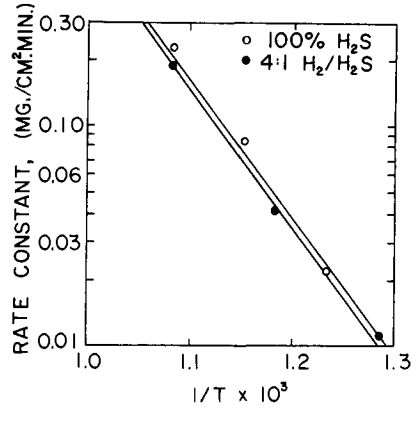

Fig. 5. Arrhenius plots of the rate constant for attack in hydrogen sulfide and in hydrogen-hydrogen sulfide mixture.

Attack in Hydrogen Sulfide-Hydrogen and Hydrogen Sulfide-Helium Mixtures[3]

It is well established that the rate of attack of iron in hydrogen-hydrogen sulfide mixtures depends on the partial pressure of the gases [cf. Dravnieks and Samans (1) and references therein]. The effect can be accounted for by thermodynamics, and there is little doubt that near equilibrium a thermodynamic interpretation holds. Hydrogen, however, might act primarily as a diluting agent in the attack of iron in hydrogen-hydrogen sulfide mixtures not near equilibrium. Essentially the same rate of attack then should be obtained with hydrogen-hydrogen sulfide and helium-hydrogen sulfide mixtures having the same partial pressures of hydrogen sulfide, if variations in hydrogen coverage did not complicate matters. Figure 6 shows that the same rates are indeed observed with mixtures having the same partial pressure of hydrogen sulfide. (Incidentally, the decrease in rate at low partial pressures of hydrogen sulfide is not caused by depletion of reactant.)

These observations preclude interpretation based on a Wagner model for the kinetics of attack, since such a model presupposes equilibrium attainment at the metal-scale and gas-scale interfaces. Very different rates of attack would be obtained for a reaction obeying a Wagner model when hydrogen is replaced by helium, especially for low partial pressures of hydrogen sulfide. The data of Fig. 6 do not eliminate diffusion as a partial or total rate-controlling factor, but it can be concluded from them that equilibrium is not reached at the metal-scale and/or scale-gas interfaces. Of course, departure from equilibrium does not necessarily imply control by a surface reaction since the surface reaction might be too fast to be rate-controlling.

Since, according to our interpretation, the rate of attack depends on hydrogen coverage, Fig. 6 im-

[3] This section based on the work of C. Hudgins, F. Hügli, and L. Hulett.

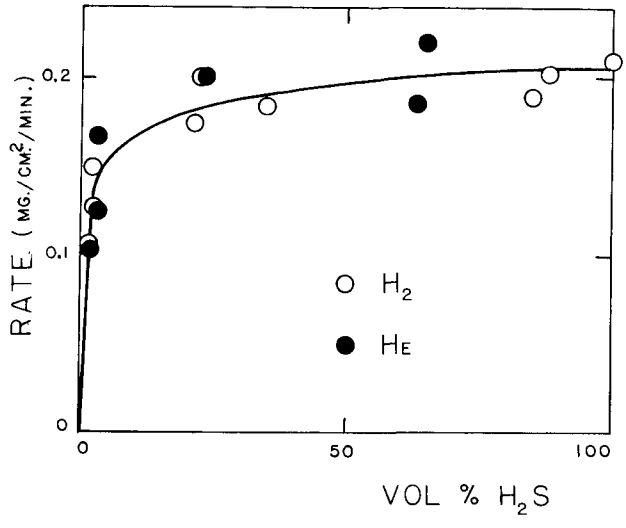

Fig. 6. Rate of attack at 649°C against volume per cent of hydrogen sulfide for mixtures of hydrogen sulfide with hydrogen or helium.

plies that this coverage remains essentially the same when helium is substituted for hydrogen. Of course, coverage by hydrogen for adsorption equilibrium would be affected by such a substitution unless full coverage were achieved for the lowest partial hydrogen pressure. One then must assume that adsorption equilibrium is not reached for hydrogen.

The data of Fig. 6 can be interpreted on the basis of the postulated mechanism. It is assumed (*a*) that the attack rate is proportional to the partial pressure of hydrogen sulfide and (*b*) that the rate is proportional to the number of reaction sites, i.e., the "free area." Thus

$$v = kp(1-\theta) \qquad [1]$$

where v is the attack rate, k a proportionality constant, θ the "coverage" by hydrogen, and p the partial pressure of hydrogen sulfide. The coverage by hydrogen increases with the rate of production of hydrogen, i.e., with v. A rigorous relationship between v and θ would be complicated because it would include the adsorption isotherms for hydrogen and hydrogen sulfide, or kinetic terms corresponding to these isotherms, and possibly other considerations for the interaction between hydrogen and the scale [Haycock's E-centers (3)]. Furthermore, the dependence of θ on p should be considered. This dependence is quite minor for the data of Fig. 6, if the foregoing analysis is accepted. It will suffice for the present purpose to assume without any claim to rigor that

$$\theta = k'v \qquad [2]$$

By elimination of θ from Eq. [1] and [2] there follows an equation in the form of a Langmuir isotherm (but the similarity ends with the form of the equation)

$$v = \frac{kp}{1 + kk'p} \qquad [3]$$

It follows from Eq. [3] that a plot of p/v against p should be linear. This is the case (Fig. 7) for the data of Fig. 6.

Dravnieks and Samans (1) also noted that the dependence of attack on pressure obeys a Langmuir isotherm type of equation, and, in fact, they reported linear plots of p/v against p. Their explanation, however, is different from the one offered here.

Mixed Attack[6]

Rather conclusive proof of the absence of diffusion control was obtained from mixed attack experiments. Data for attack in hydrogen-hydrogen sulfide mixtures (4:1) are given in Fig. 8 for specimens with different initial thicknesses of iron sulfide scale (as obtained by preliminary attack in sulfur vapor). After an initial period, which is interpreted below, the same rate of attack prevails regardless of the thickness of the initial scale of iron sulfide. This conclusion holds even for the experiment in which the initial scale was approximately twice as thick as the scale formed during hydrogen sulfide attack. An interpretation of the iron-hydrogen sulfide reaction based on control by diffusion in the scale is inconsistent with these observations.

[6] This section based on the work of H. Arm, L. Hulett, and M. Qureshi.

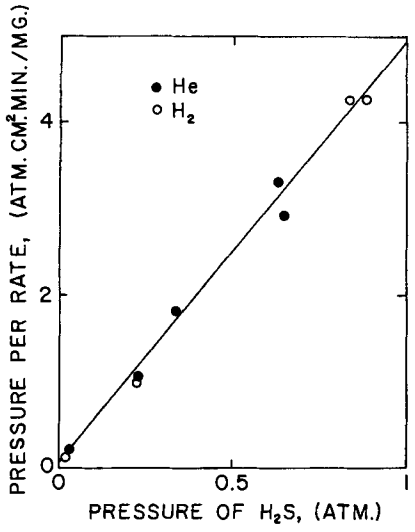

Fig. 7. A verification of Eq. [3] for the data in Fig. 6

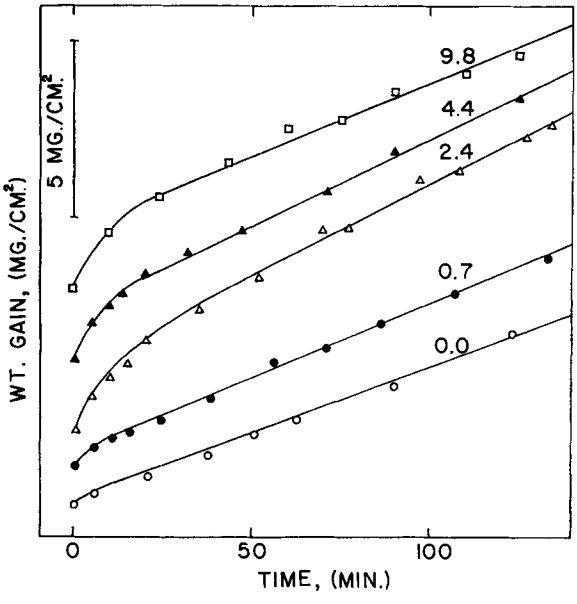

Fig. 8. Increase of weight against time for specimens previously attacked in sulfur vapor. Number on each curve is weight of iron sulfide in mg/cm² formed during sulfur vapor attack. Temperotures: molten sulfur during sulfur vapor attack, 230°C; specimen during sulfur vapor and hydrogen sulfide attacks 575°C; curves are shifted for clarity.

It could be argued that the scale underwent some transformation during the initial hydrogen sulfide attack and that the rate became constant when the thin dense layer obtained in the usual hydrogen sulfide attack was formed. Examination of the scale (Fig. 9) did not confirm this view. The outer scale exposed to hydrogen sulfide was composed of large crystals, but the bulk of the scale had remained quite compact and homogeneous. Furthermore, the initial rate of attack in hydrogen sulfide was higher than the constant value reached at a later stage, and yet the initial scale (formed in sulfur vapor) had a fine crystalline structure.

The initial rapid attack can be interpreted in terms of the postulated mechanism. Thus, the area at the gas-iron sulfide interface before hydrogen

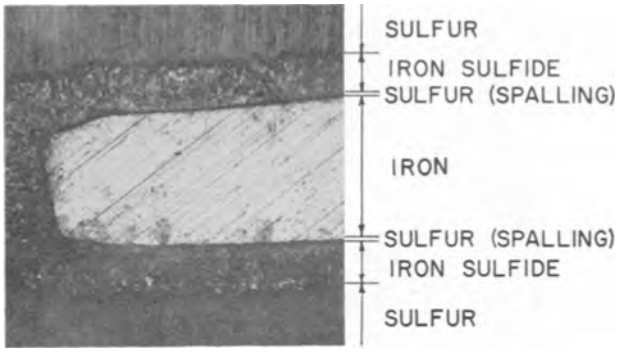

Fig. 9. Photomicrograph of section of specimen after attack by sulfur vapor followed by hydrogen sulfide attack. Temperature: 575°C. Magnification, 200× before reduction for publication.

sulfide attack was larger than for the metallic surface corresponding to the same projected area. Hence, rates of attack by hydrogen sulfide were initially larger than for a metallic specimen without prior sulfur attack. However, the self-regulating mechanism soon brought the rate to a constant value. Note that the curves of Fig. 8 for the three thicker scales appear to be the same, i.e., the initial process was independent of the scale thickness once a sufficiently thick scale had been produced.

Influence of Diffusing Hydrogen on Sulfur Vapor Attack[10]

Since hydrogen, in our interpretation, is supposed to block in part the surface for attack in the iron-hydrogen sulfide reaction, it was thought that a similar effect might be observed in the iron-sulfur vapor reaction if hydrogen were allowed to diffuse from the back of the specimen surface. The data of Fig. 10, obtained by the cartridge technique, confirm this inference. The parabolic law was confirmed for the blank cartridges which had been left in vacuum for 8 hr after hydrogen reduction. An induction period was observed for blank cartridges which had not been vacuum treated, and an even longer induction period was observed for cartridges containing lithium aluminum hydride. In all cases, sulfur attack resumed its normal course after a sufficiently long time. The interpretation is as follows:

Hydrogen produced in the lithium aluminum hydride cartridge diffused toward the outside surface of the cartridge and greatly reduced the attack by sulfur vapor. Nevertheless, an iron sulfide scale slowly built up. The diffusion rate for hydrogen through the compact scale (no leaks!) was lower than through iron, as shown[11] in Fig. 11, and consequently, coverage of the scale by hydrogen decreased as the scale became thicker. This resulted in a progressive increase in rate of attack until the film had become so thick that diffusion was practically stopped. Attack then resumed its normal course. Complete decomposition of lithium aluminum hydride cannot be invoked for resumption of normal attack because of the respective amounts of this substance and diffused hydrogen that were involved.

[10] This section based on work of L. Hulett and M. Qureshi.

[11] One calculates from the rate of diffusion of hydrogen for the cartridge without scale the approximate inner pressure of hydrogen of 2 atm on the basis of the permeability data of Jost (7).

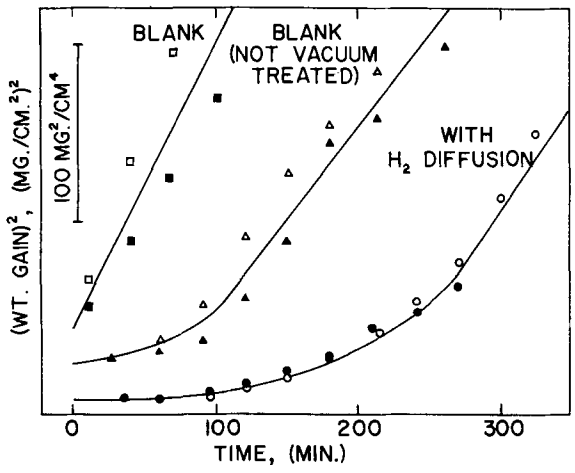

Fig. 10. Plots of the square of the weight gain against time for iron cartridge during attack by sulfur vapor. Temperatures during attack: molten sulfur, 230°C; cartridge, 500°C. Curves are equally shifted at the origin by 20 mg^2/cm^4.

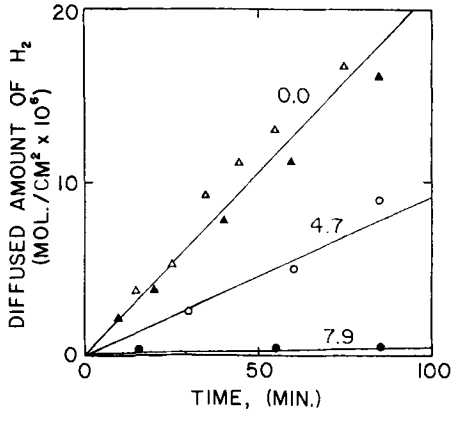

Fig. 11. Data for hydrogen diffusion through iron or iron coated with iron sulfide scale. Number on each line is the weight of iron sulfide in mg/cm^2. Temperature: 500°C.

The same interpretation holds for the blank cartridges which had not been vacuum treated. Hydrogen which had diffused in the metal during reduction then hindered attack in sulfur vapor until it could no longer appreciably cover the scale surface.

Further confirmation of the above interpretation was obtained by similar experiments in which the blank cartridge and a lithium aluminum hydride filled cartridge were attacked in hydrogen-hydrogen sulfide mixture (4:1). The same rate of attack was observed in both cases, and no induction period due to the presence of hydrogen was observed.

An alternative explanation, based on thermodynamic considerations, namely that iron attack by sulfur did not proceed in the presence of hydrogen, is ruled out. Thus, one calculates from the data of Rosenqvist (6) that the equilibrium constant for the reaction $FeS + H_2 \rightleftharpoons Fe + H_2S$ at 500°C is 2×10^{-4}. The amount of hydrogen sulfide formed in one of the experiments was in fact determined by passing the gas through a detection tube used in air pollution studies.[12] A maximum amount of 6×10^{-6} moles of hydrogen sulfide was formed in the reaction chamber. Since the amount of hydrogen sulfide produced is so small, the retarded sulfur attack is

660	7.7	1
720	8.9	1

definitely not due to reduction of iron sulfide by diffusing hydrogen.

Another possible interpretation according to which Haycock's E-centers (3), resulting from the presence of hydrogen in the film, decrease diffusion by cation vacancy does not account for the resumption of attack. Thus, the scale, at least in its inner layer, retained a relatively high concentration of E-centers because of the vicinity of hydrogen supply. This layer would have offered a permanent barrier to vacancy diffusion, i.e., attack would never have resumed unless the film had cracked. The latter explanation, however is invalidated by the very low diffusion rate of hydrogen through the scale (Fig. 11). Of course, one could say that sulfide ion is the diffusing species, but the role of hydrogen then remains unexplained.

Recrystallization of the Scale[18]

It is well established [see Dravnieks and Samans (1) for review of literature] that the thin dense layer reaches an essentially constant thickness. The data on Table I confirm this, but it should be noted that initially (30 min) the thin layer had not reached its constant thickness although a linear law was already observed. This seems to preclude, with other arguments discussed above, control by diffusion through the thin layer.

Since the thin layer reaches a constant thickness, there must be a continuous transformation of the thin dense layer into the porous one (Fig. 4). We observed that aging of the two layer scale in a helium atmosphere causes a progressive disappearance of the dense layer. Since such a transformation is not observed for iron sulfide produced by the iron-sulfur vapor reaction, hydrogen or hydrogen sulfide must be responsible for recrystallization. Haycock (3) suggested a tentative mechanism for the recrystallization process, and he showed that hydrogen greatly enhanced the sintering rate of powdered iron sulfide. Powdered ferrous sulfide with a large initial surface area did not appreciably sinter when left in a vacuum for 5 hr at 500°C. In the presence of hydrogen at the same temperature the surface area was reduced by half after only 2 hr, and the powder had visibly sintered to a porous plug.

Haycock's experiments were corroborated by studies on aging of iron sulfide, prepared by sulfur attack, in the equilibrium hydrogen-hydrogen sulfide mixture (see Experimental Methods). The outer crystalline structure of the scale became somewhat more coarse upon aging (Fig. 12).

[18] This section based on the work of L. Hulett and M. Qureshi.

Fig. 12. Photomicrograph of section of specimen, attacked in sulfur vapor at 500°C (vessel with liquid sulfur at 230°C), after a 48-hr aging in hydrogen at a pressure slightly above 1 atm. Note EPON resin around metal contour as a result of scale spalling. Magnification, 200× before reduction for publication.

Conclusion

It is concluded that the linear law of attack for the iron-hydrogen sulfide reaction at elevated temperatures (above 500°C approximately) results from two main effects: (*a*) partial blocking at reaction sites by hydrogen produced during attack, and (*b*) continuous recrystallization prevents the formation of a thick dense scale that would become a real diffusion barrier for sufficient thicknesses. The blocking of reaction sites is self-regulating and the linear law is thus obeyed.

Acknowledgment

The support of the American Petroleum Institute is gratefully acknowledged. The authors are indebted to the following members of the Subcommittee on Corrosion, Division of Refining, of the American Petroleum Institute for helpful discussions: Messrs. E. B. Backensto, E. A. Camp, and R. J. Hafsten. Discussions with Drs. A. Dravnieks and E. W. Haycock were most fruitful. Messrs. E. G. Smith and G. F. Mathes of the Mechanical Engineering Department, Louisiana State University, kindly provided equipment for the photomicrographic studies.

X-ray equipment used in some structure studies was purchased in part with a grant from the National Science Foundation.

Manuscript received July 30, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Nickel-Aluminum Alloy Coatings Produced by Electrodeposition and Diffusion

Dwight E. Couch and Jean H. Connor

National Bureau of Standards, Washington, D. C.

ABSTRACT

Nickel-aluminum alloy coatings were produced by diffusion of aluminum electrodeposited over nickel. The aluminum was plated from baths operated at 25°-1000°C. The alloys were much harder than nickel and were superior to nickel coatings in salt spray, atmospheric exposure, and air oxidation tests. Attempts to codeposit the two metals were not successful.

Nickel-aluminum alloys are very resistant to oxidation in air at temperatures of 500°-1100°C. They are hard and resistant to corrosion at normal temperatures. Alloys of this type have been prepared by metallurgical methods (1, 2) but, because the alloys are brittle, they are difficult to use in the manufacture of intricately shaped objects. Electrodeposited coatings of these alloys should provide valuable protection to other metals. In previous studies (3) coatings of nickel-aluminum alloys were formed by the electrodeposition of aluminum, from a fused cryolite bath, on nickel. Beck (4) used a cryolite bath to form nickel aluminide coatings on nickel-plated molybdenum and identified the various phases of the alloy diffusion layer. Many objects that require coating cannot withstand a temperature of 1000°C at which the cryolite bath is operated; therefore, other baths that may be used at lower temperatures were investigated. Fink and Solonki (5) studied several aluminum chloride alkali chloride baths with a 1 to 1 mole ratio. Collins (6) used a higher aluminum chloride content and obtained smooth deposits. A review of aluminum coating processes was given by Murphy (7).

Electrodeposition of Nickel and Aluminum from Organic Type Baths

All of the known organic-type baths (8-13) for plating aluminum were investigated to see if nickel could be codeposited with aluminum. In general, nickel salts were only slightly soluble in the organic solvents used to prepare the baths and no alloy deposits were produced. Electrodeposition of nickel from other organic solvents also was investigated, since the desired alloy would be predominantly nickel. Ductile nickel deposits could not be obtained from any of the organic baths. Thin, coherent, highly stressed, lustrous deposits were obtained sometimes. These contained only 85% nickel, the remaining 15% probably was occluded organic material. Table I lists organic solvents and nickel salts used in the experiments. Since pure nickel could not be electrodeposited from organic solvents, this approach was abandoned.

The ether-hydride bath (8) was used successfully to produce coatings of aluminum that could be alloyed with nickel. However, an intermediate coating of zinc or copper was required to give necessary adhesion and to prevent blistering of the aluminum

deposit during the heat treatment at 550°C required to alloy the aluminum with the nickel.

Fused Salt Baths and Conditions of Operation

Several fused-salt baths for the electrodeposition of aluminum were studied, and the following were found to be the most satisfactory: potassium chloride-sodium chloride-cryolite, aluminum chloride-sodium chloride.

The composition and optimum operating conditions for these baths are as follows:

Potassium chloride-sodium chloride-cryolite: sodium chloride, 440 g; potassium chloride, 560 g; cryolite, 150 g; temperature, 700°-800°C; current density, 2-10 amp/dm^2; anodes, graphite; container, graphite.

Aluminum chloride-sodium chloride: aluminum chloride (anhydrous), 900 g; sodium chloride, 200 g; temperature, 160°-180°C; current density, 1-4 amp/dm^2; anodes, tungsten or graphite; covered container, glass (Pyrex or equivalent).

Potassium chloride-sodium chloride-cryolite bath.—This bath was contained in a graphite crucible and operated at temperatures from 650° to 900°C. At the higher temperature the graphite crucible oxidized rather rapidly, and at 650°C the aluminum diffused into nickel rather slowly. Therefore, most of the deposits were made at 700°-750°C. At this temperature the aluminum deposit was liquid and alloyed with the nickel.

Samples (0.1 x 3 x 6 cm) to be plated were placed in the bath and allowed to heat up to bath temperature before electrolysis. Excellent adhesion was obtained on nickel, iron, and previously prepared Ni-Al alloys. No precleaning of the specimen was necessary. At 700°C an aluminum deposit 6 μ thick could be produced by using a current density of 7 amp/dm^2 for 5 min. When the electrolysis was continued under these conditions for more than 5 min, the aluminum was electrodeposited faster than it could diffuse into the nickel, and free aluminum was produced on the surface of the sample. Thicker deposits could be produced by using a lower current density for a longer time, or by operating at a higher temperature. Deposits 25 μ thick were prepared at 700°C by the following schedule: 7 amp/dm^2 for 5 min, 4 amp/dm^2 for 20 min, and 2 amp/dm^2 for 90 min.

The cathode current efficiency for plating aluminum on nickel cathodes is shown in Fig. 1. The efficiency was about 90% at 15 amp/dm^2, but decreased, as the current density decreased. At 0.5 amp/dm^2 the solution rate of the alloy equaled the deposition rate, thus giving an efficiency of zero. The efficiency at current densities greater than 15 amp/dm^2 could not be determined because the aluminum deposited more rapidly than it could diffuse into the nickel and was lost as molten aluminum into the bath. Nickel and Ni-Al alloy slowly dissolved in the bath. Nickel dissolved at a rate of about 0.6 mg/cm^2/hr, and the Ni-Al alloy dissolved at approximately 1.6 mg/cm^2/hr.

Alloy deposits 25 to 75 μ thick[1] produced from the

[1] The thickness referred to here and at all later places in this paper is the thickness of the electrodeposited aluminum as determined by the increase in weight of the sample as a result of the aluminum deposit. Therefore it is not a measure of the actual thickness of the alloy layer formed.

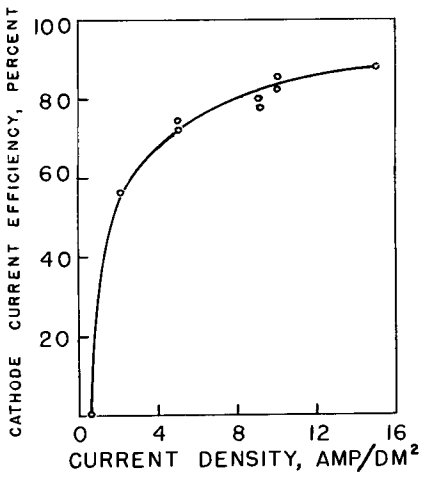

Fig. 1. Cathode current efficiency of aluminum electrodeposited from potassium chloride-sodium chloride-cryolite bath at 700°C.

potassium chloride-sodium chloride-cryolite bath contained from 43 to 52% Al. This represents an average composition of 1 mole Ni to 2 moles Al. No attempts were made to identify the separate phases of this alloy system.

Occasionally, deposits produced at the higher current densities showed traces of free aluminum on the surface. Excess aluminum was removed with 2.5M aqueous sodium hydroxide. This solution dissolved the alloy at a rate of about 0.005 mg/cm^2/hr.

Aluminum chloride-sodium chloride baths.—This bath was operated at a temperature where very little diffusion of aluminum into nickel took place. Therefore, it was necessary to heat the samples after plating to form the alloy. Temperatures of 700°C could be used for thin coatings 5 μ thick, but coatings 25 μ thick melted, and only a small fraction of aluminum diffused into nickel, the remainder formed a metallic bead at the edge. The approximate time required for various thicknesses of aluminum to diffuse into nickel at 700° and 550°C are shown in Fig. 2. Values for 700°C were obtained on flat specimens that were held horizontally to prevent run off of molten aluminum.

If the aluminum chloride-sodium chloride mole ratio was less than 1.5, as in the baths described by Fink and Salonki (5), and operated at 160°-180°C,

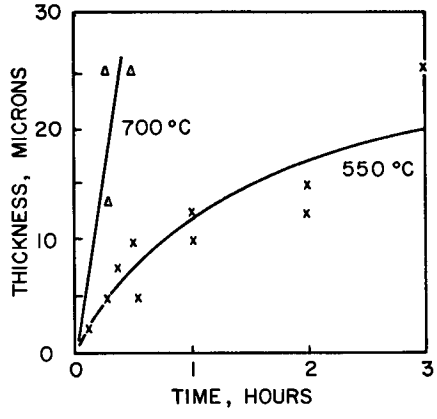

Fig. 2. Time required to completely alloy aluminum with nickel at various temperatures. Aluminum was plated from $AlCl_3$-NaCl bath, or ether-hydride bath.

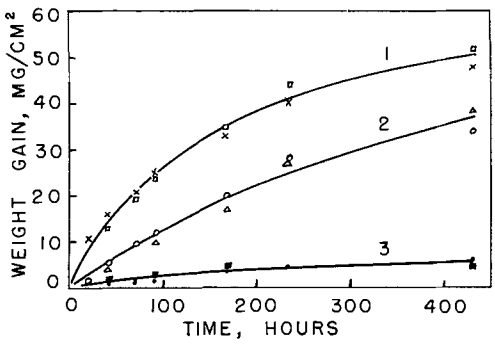

Fig. 4. Oxidation of nickel and nickel-aluminum alloy at 1000°C. Curve 1. □, x, pure nickel, duplicate samples; 2. o, △, alloy coating, approximately 8 μ, duplicate samples; 3. ●, ■, alloy coating, approximately 25 μ, duplicate samples.

the maximum thickness of satisfactory deposits was about 5 μ. Thicker deposits were rough and powdery. Electrodeposits up to 25 μ thick were obtained from a bath similar to that given by Collins (6). However tungsten was used for anodes instead of aluminum.

Figure 3 shows the cathode current efficiency of aluminum chloride-sodium chloride bath. Chlorine liberated at the insoluble anode apparently dissolved in the bath in sufficient amounts to slowly dissolve aluminum deposit, thus accounting for the decrease in cathode efficiency at the lower current densities. Moisture that reacted with aluminum chloride produced some hydrogen chloride that attacked the aluminum deposit.

When aluminum electrodeposited from this bath was overplated with a second layer of aluminum, the adhesion was very poor. Aluminum deposits that were allowed to stand in the bath showed surface attack and formation of a thin black film. This film prevented adhesion of the second deposit. Anodic treatment of the panel in the bath caused a similar condition regardless of current density (1-15 amp/dm^2). If the sample was heated to alloy the first aluminum deposit with nickel, a second layer could be deposited with sufficient adhesion to allow heat treatment to alloy it with the first layer.

Codeposition of nickel and aluminum from fused salt baths.—Aluminum and nickel can be codeposited from a bath containing sodium chloride, potassium chloride, cryolite, and nickel chloride at current densities of 100 amp/dm^2 or greater. These deposits contained 30 to 50% Al. Unfortunately, they were produced only as very thin deposits, and attempts to form deposits 25 μ thick resulted in thin coherent layers covered with a black noncoherent material. At current densities of less than 100 amp/dm^2, the deposits contained no aluminum. Nickel anodes were insoluble and were coated with a tan-colored material that was also insoluble in the bath. This was presumably an oxide or oxychloride of nickel. Other fused-salt systems studied are listed in Table II. No alloy deposits were obtained from these baths. Although aluminum could be electrodeposited from most of them, nickel only could be electrodeposited after the addition of nickel salts.

Evaluation of Deposits

Oxidation.—In air at 550°C, Ni-Al alloy coatings on steel oxidized at a slower rate than nickel-coated steel. Similar results were obtained at 1000°C using nickel panels as a basis metal. Nickel panels, 6 x 3 x 0.1 cm, were cut from rolled sheet nickel. Two of these panels were used as controls while five others were plated in the fused aluminum chloride-sodium chloride bath to the following average thicknesses: 8, 8, 10, 25, and 25 μ. Two panels (8 and 10 μ aluminum) were heated in air at 750°C for 30 min and others were heated in helium for 15 hr at 550°C to alloy the aluminum; all panels showed a slight gain in weight of about 3 x 10^{-5} g/cm^2. Oxidation curves are shown in Fig. 4. The oxide of one panel spalled in large flakes when cooled after heating for 20 and 44 hr. This oxide was weighed and added to the total weight gain of the panel. This panel had oxidized at about the same rate as the pure nickel. A coating of

8 μ Al reduced the amount of oxidation at 1000°C about 40%, curve 2, while a coating of 25 μ Al reduced the oxidation by about 80%, curve 3. Heating samples in an inert atmosphere to alloy aluminum with nickel did not affect the rate of oxidation.

The oxide layer that formed on the Ni-Al alloy was gray, while that formed on the nickel was vitreous and black in color. A gray oxide formed on specimens with a coating of 8 μ Al, but after heating about 100 hr at 1000°C, the surfaces of the panels were black. Those specimens with 25 μ Al retained their gray color for 300 to 400 hr before the black nickel oxide covered a significant amount of the surface.

Figure 5 shows that alloy coatings 25 μ thick do not give satisfactory protection to steel at 900°C. The iron diffused through the coating, resulting in rapid oxidation. Thicker coatings are required to protect steel at these temperatures.

Salt spray test.—Salt spray tests were made on steel (6 x 3 x 0.1 cm) coated with Ni-Al alloy. Samples were first nickel plated, then separated into groups in random fashion. One group was used as a control, while the alloy was formed on the other group. In this way the influence of the nickel plating process was minimized. The most corrosion-resistant coatings were produced by plating aluminum from the sodium chloride-potassium chloride-cryolite bath and subjecting these coatings to oxidation at 500°-600°C prior to testing. Rapid temperature cycling of these panels did not affect their corrosion resistance. The coatings were more resistant if the aluminum thickness was less than 50% of the total thickness of the coatings (see Table III). In the salt spray tests, 5 or more samples were used for each thickness tested and the average time required for the first rust to form on the surface is given in Table III.

Evaporated aluminum coatings[2] 0.1 μ thick, which were alloyed with nickel by heating in air, caused a decrease in the corrosion of nickel-plated steel. Although they showed the first rusting at the same time as the control panels (5 hr), the surface area was 7% rusted after 75 hr as compared to 30% on the control panels.

[2] Panel size in these tests were 10 x 15 x 0.1 cm.

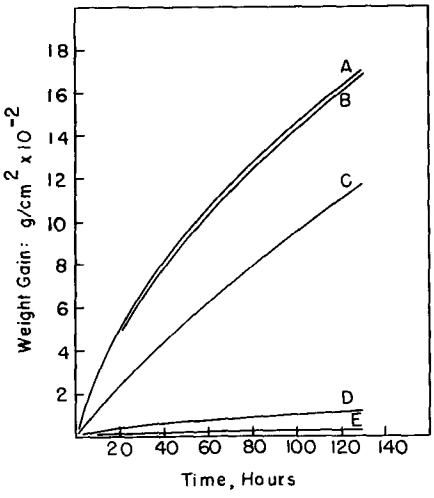

Fig. 5. Oxidation at 900°C in air of alloy-coated steel and nickel. Coatings were prepared in cryolite bath at 1000°C. Curve A, steel; B, 25 μ of nickel on steel; C, 25 μ of nickel plus 25 μ of aluminum on steel; D, wrought nickel; E, 25 μ of aluminum on wrought nickel.

Sprayed aluminum coatings[2] were also effective in reducing corrosion by salt spray. Although small areas of uncoated nickel could be seen through the sprayed coating, these areas could not be detected after the sample was heated. The sprayed coating was initially about 20-30 μ thick, but after heating for 30-45 min at 550°C, which was sufficient time to produce an alloy layer about 10 μ thick, the samples were treated with 2.5M aqueous sodium hydroxide to remove the excess aluminum. They then were subjected to salt spray tests. These samples showed rust after 30 hr and were 2% rusted after 75 hr. The control[2] samples showed the first rusting after 5 hr and were 30% rusted after 75 hr.

Corrosion studies conducted on atmospheric exposure racks at Washington, D. C., correlated well with the salt spray tests. Steel panels coated with 25 μ Ni and 5 μ Al did not show rust at the end of one year of exposure, while coatings with 12 μ Ni plus 4 μ Al showed traces of rust after eight months of exposure. Nickel-plated control panels tested simul-

taneously with the above samples showed rust after four months and one month, respectively.

Metallographic examinations.—Figure 6 shows a deposit prepared from low-temperature fused aluminum chloride-sodium chloride bath at 160°C, then alloyed with nickel by heating at 500°-600°C for a few hours. Figure 7 shows a deposit produced from potassium chloride-sodium chloride-cryolite bath, after heating for 2 hr at 1000°C. No structure could be developed on the alloy in the as-plated condition.

The Knoop hardness of the Ni-Al alloy produced from the chloride-cryolite bath was 620 for thin films and 700-725 for thicker coatings (50 μ). The hardness of deposits produced from the all-cryolite (3) bath varied from 611 to 788.

The coatings were brittle, and, if 25 μ thick, they could be separated from the basis metal by repeated bending. Thin coatings 5 μ thick fractured when bent, but did not separate from the basis metal. Results of bending samples of two different thicknesses around a 0.6 cm diameter rod are shown in Fig. 8.

Effect of Addition Agents on Tungsten Codeposition

J. S. Sallo[1] and R. D. Fisher

Magnetic Research Department, The National Cash Register Company, Dayton, Ohio

ABSTRACT

Small quantities of certain addition agents will prevent the codeposition of tungsten with iron, nickel, or cobalt. Data are presented comparing addition agent concentration with the amount of tungsten in a nickel-tungsten codeposit. Polarographic data indicate that addition agents which prevent tungsten codeposition are capable of being adsorbed at a Hg cathode and form complexes with the codepositing metal ion. These complexes are more readily reduced than is the original codepositing species. The cathode potential of the deposition process is lowered to a more positive potential by the addition agent. Structural studies show that the deposit does not consist of alternate layers of tungsten and codeposited metal as is required by the catalytic reduction mechanism. It is shown that the addition agent effect can be explained by a mechanism of codeposition involving complex formation.

Many claims have been made for the deposition of pure tungsten from aqueous tungstate solution (1-3). Subsequent investigation of these processes has shown that the deposits always contain iron, nickel, or cobalt (codepositing metal ion) (4), and that deposition ceases when these impurities are exhausted from the plating solution. When no such impurities are present in the plating solution, oxides of tungsten may be deposited at the cathode; however, under these conditions reduction of tungstate to tungsten has not been observed.

Many baths have been developed for the codeposition of tungsten with iron, nickel, or cobalt. The most successful of these are the complex ammoniacal baths which have been developed by Brenner (5) and by Holt (6). Brenner's baths allow the codeposition of sound Ni-W deposits containing 20% tungsten. Iron-tungsten deposits containing 50% tungsten can be plated from such baths. Two mechanisms have been proposed to explain the codeposition process. These are the catalytic reduction mechanism and the complex formation mechanism.

The catalytic reduction mechanism proposes that laminations observed in the codeposits are alternate layers of tungsten and the codeposited metal (iron, nickel, or cobalt) (7). The codeposited metal acts as a catalytic surface on which, in the presence of hydrogen, the tungstate anion is reduced chemically and electrochemically to metallic tungsten. When a layer of tungsten has covered this catalytic surface, the deposition ceases and the formation of a fresh layer of catalytic codeposited metal begins.

The complex formation mechanism describes the codeposition as taking place from some complex of tungstate and the codepositing metal ion (7). The function of the codepositing metal ion is to provide a reducible tungstate complex. The major disadvantage of the complex formation mechanism is that no complex of tungstate with ions of iron, nickel, or cobalt has been observed.

The effect of addition agents on tungsten codeposition and data indicating that the codeposits are solid solutions are discussed in this paper.

Experimental

Deposition studies.—All chemicals used were C.P. reagent grade and were not further purified.

The plating bath used for the nickel tungsten deposition was as follows: $NiCl_2 \cdot 6H_2O$, 28 g/l (0.12 mole/l); $Na_2WO_4 \cdot 2H_2O$, 32 g/l (0.036 mole/l); NH_4Cl, 50 g/l (0.94 mole/l); sodium citrate, 100 g/l (0.39 mole/l); H_2O and NH_4OH to 1 liter at a *p*H of 8.5. For the iron-tungsten and cobalt tungsten codeposits 0.12 mole/l of $FeCl_3 \cdot 4H_2O$ or $CoCl_2 \cdot 6H_2O$, respectively, were used in place of $NiCl_2 \cdot 6H_2O$.

The cathodes for deposition were 0.003 in. thick sheets (2 x 2 in.) of phosphor bronze to which were welded copper wires for electrical contact. The copper contacts were kept well above the solution level. The cathodes were cleaned cathodically in an alkaline medium, followed by an acid dip (1:1 HCl), and a distilled water rinse. Sheets or rods of pure tungsten were used as anodes. The temperature of the bath was controlled at 90° ± 0.5°C by means of a glascol heating mantel. The current density was 2 amp/dm^2. The volume and *p*H of the solution were maintained by continuous addition of a NH_4OH, H_2O solution through a peristaltic action pump.

In the studies leading to the determination of the minimum concentration of addition agent required to prevent tungsten codeposition completely, a fresh plating system was used for each addition agent concentration. In the studies showing the decrease of tungsten content in the nickel-tungsten deposit with increasing addition agent concentration, successive additions of the addition agent were made to a single plating system.

Cathode potential studies.—Cathode potentials were determined at varying current densities on the following three baths:

1. $NiCl_2 \cdot 6H_2O$, 28 g/l (0.12 mole/l; NH_4Cl, 50 g/l (0.94 mole/l); and sodium citrate, 100 g/l (0.39 mole/l) H_2O and NH_4OH to a *p*H of 8.5.

2. Same as 1 except 32 g/l $Na_2WO_4 \cdot 2H_2O$ (0.036 mole/l) added.
3. Same as 2 except 0.1 g/l (0.0013 mole/l) thiourea added.

Cathode potentials during deposition from the above baths were determined by the direct method.

The cell consisted of a 2-liter beaker with a heating mantle and contained a platinum cathode (0.95 x 1.01 x 0.022 cm) and two platinum anodes (2.2 x 2.2 x 0.022 cm). The distance between the anodes and cathode was 4.75 cm. The flat platinum cathode was coupled with an external Beckman saturated calomel electrode by means of a bridge made from 6.3 mm Pyrex tubing with one end drawn out to a capillary tip 1 mm in diameter and 1 cm long. The tip was bent at 90° and placed near the face of the cathode. To measure the potential, a L&N type K-3 potentiometer supplied a balancing emf, and a Kintel Microvoltammeter served as a Null detector. The potentials were measured commencing with the initial static potential emf. The readings of the emf were taken at various current densities. The current was measured with a Simpson milliammeter (Model 373). Sufficient time (2-3 min) was allowed for each measurement to enable the potentials to reach a steady value. Individual determinations were reproducible within ± 5 mv. No correction was made for the *IR* drop between the capillary tip and the surface of the cathode. Also, a nonuniform current density results with a parallel electrode system since the current density is highest at the edges. These factors and others make the absolute cathode potential measurements somewhat uncertain. The *p*H and volume of each bath were maintained by continuous additions of NH_4OH and H_2O, and temperature was controlled at 90° ± 1°C.

X-ray diffraction.—X-ray diffraction was performed on a North American Phillips type diffractometer. In all cases copper K α radiation was used, the potential was 35 kv, the current was 20 ma, the scanning rate was 2°/min, and the Geiger counter voltage was 1385. The time constants were 8, 2, and 16 sec for nickel, tungsten, and nickel-tungsten, respectively.

X-ray fluorescence.—The plated samples were analyzed for Ni, Co, Fe, and W, respectively on a Norelco x-ray spectrograph. The unit was operated with a W x-ray tube at 50 kv and 50 ma. Fixed count operation was employed, i.e., the times were recorded to obtain 512,000 counts for Ni; 256,000 counts for Co; 128,000 counts for Fe; and 32,000 counts for W. These readings were converted to counts/second for each element. A LiF crystal was used and first-order peaks of the elements were used as follows: Ni $K\alpha_1$ at 48.61° 2θ, Co $K\alpha_1$ at 52.74° 2θ, Fe $K\alpha_1$ at 57.45° 2θ, and W $L\alpha_1$ at 42.99° 2θ.

Since the use of a W x-ray tube means that a W count will be produced even if the sample is free of W (background), the point at which no W appears in the deposit for each series of samples was double-checked using a Norelco x-ray spectrograph employing a Mo x-ray tube, operating at 50 kv and 40 ma. In this case a NaCl crystal was used and a scan was made over the W $L\alpha_1$ peak in the second order (at 63.13° 2θ). The absence of W in the end-point samples was confirmed for all series.

Several nickel-tungsten samples were prepared in accordance with the instructions of previous workers (5). These were used as standards for the x-ray spectrometer. The graph of % W in the deposit vs. addition agent concentration is shown in Fig. 1.

Since the composition of the standard was not checked by chemical analysis, the accuracy of the values given is doubtful. However, the relative values of the concentrations in different specimens are probably valid.

Polarographic studies.—The polarographic studies were carried out using a L&N "polarotron" and a type-E electrochemograph. Polarograms were determined in a 1M NH_4OH, 0.2M NH_4Cl supporting electrolyte with 0.005% gelatin. Chemicals were C.P. grade.

Results

Many of the addition agents which were studied in this program were found to prevent the codeposition of tungsten with iron, nickel, or cobalt. These are thiourea, thiosulfate ion, thiocyanate ion, thioacetamide, and water soluble substituted thioureas. Among the addition agents which have no effect on the composition of tungsten codeposits are gelatin, saccharine, and urea. No criteria for the structure required of an addition agent for the prevention of tungsten codeposition can be established at this time; however, all successful addition agents investigated contained sulfur.

The effect of varying quantities of sodium thiosulfate, potassium thiocyanide, and thiourea on the approximate composition of the nickel-tungsten codeposit is shown in Fig. 1. The cut-off concentrations of other addition agents which prevent tungsten codeposition are shown in Table I. These cut-off concentrations were determined by an x-ray fluorescence unit with a molybdenum source.

It has been observed that the concentration of thiourea necessary to prevent tungsten deposition increases with increasing current density. That is, increasing the current density decreases the effectiveness of the thiourea. This decrease in effectiveness with increasing current density may be explained by the desorption of the thiourea with increased negative potential, or it may be due to in-

creased decomposition of the thiourea with increased negative potential. The latter seems more likely since depletion of thiourea has also been observed. For example, a deposit was made from a bath containing the minimum quantity of thiourea (3 mg/l) required to prevent tungsten codeposition with nickel for a period of 4 hr at 2 amp/dm^2. After this period, a fresh deposit was then made from this bath and tungsten was found in the deposit. The thiourea concentration necessary to prevent W codeposition increases with Ni, Co, and Fe, respectively. In all cases investigated the concentration of addition agent necessary to prevent tungsten codeposition is larger when cobalt is the codepositing metal rather than nickel.

The potential required for the deposition of the tungsten alloys is more noble than the potential required for the deposition of the metal (Fe, Ni, or Co) by itself (8-10). According to data published by Markwell and Holt (11), a criterion for tungsten deposition is that the dynamic cathode potentials of the codepositing ion (Ni, Co, Fe) solutions, with and without tungsten ion, must be within 85 mv of each other. Therefore, it was of interest to determine the effect of thiourea on the cathode potentials of nickel and nickel tungstate solutions. The cathode potential, E_c (vs. SCE) at 2 amp/dm^2 of pure nickel solution was −1100 mv, while the solution containing nickel and tungstate ions had a cathode potential of −970 mv. When 0.1 g/l of thiourea was added to the nickel-tungstate solution, the cathode potential was −880 mv. This value is 90 mv below the cathode potential of the nickel-tungstate solution and 200 mv below the cathode potential of the nickel solution (Table II).

The polarographic method was employed to study the addition agent effect. The half-wave potential ($E_{1/2}$) of the cathodic nickel waves was determined in 1M NH_4OH, 0.2M NH_4Cl, supporting electrolyte and using 0.05 g/l of gelatin as a maxima suppressor. The results of these polarographic measurements are given in Table III. All effective addition agents cause a shift in the half-wave potential of the Ni wave. This is attributed to complex formation between the addition agent and the nickel species.

Except for the thiosulfate, the effective addition agents are seen to form complexes which are more easily reduced than is the original nickel species. This conclusion was also confirmed for thiourea by cathode potential studies.

Since, in general, complex formation makes an ion more difficult to reduce and shifts $E_{1/2}$ to a less

noble potential, the observed behavior in this case probably results from the high overvoltage normally associated with the reduction of $Ni(H_2O)_x^{++}$ or $Ni(NH_3)_x^{++}$.

The suppression of the polarographic maximum, as by gelatin, occurs by adsorption of a surface active species at the cathodic mercury drop. Table IV indicates the effectiveness of addition agents as suppressors of the maximum of the cathodic nickel wave. All results are in the absence of gelatin or any other known surface active material. Therefore, it is concluded that all effective addition agents are adsorbed at the cathode. However, there is no quantitative correlation between their effectiveness as maxima suppressors and as tungsten deposition inhibitors.

The catalytic reduction mechanism states that the structure of the deposit consists of alternate layers of tungsten and the codeposited metal. If this is the case, x-ray diffraction should show a phase of nickel and a phase of tungsten, and the diffraction pattern obtained should consist of the superimposed diffraction patterns of pure nickel and pure tungsten. It has been reported that the diffraction pattern of the codeposit is that of a solid solution (5); however, the x-ray data which led to this conclusion was not published. Results obtained in the present investigation are shown in Table V. It is clear from the table that no tungsten phase is present. Instead the codeposit contains only nickel peaks shifted in the direction expected for a solid solution of tungsten in nickel. That the codeposit is a solid solution of tungsten in nickel, and not alternate layers of nickel and tungsten, is thereby confirmed.

Discussion

The addition agents which were found to prevent tungsten codeposition with nickel have several features in common. They all contain at least one sulfur atom, lower the cathode potential of the deposition process, can form bulk complexes with the co-

Table IV. Polarographic adsorption data

Complexing agent	Molar conc. × 10^3	Approximate % adsorption[a]

depositing metal ion, and are adsorbed at a dropping mercury cathode. The addition agents which were found to have no effect on the composition of the codeposit were either not adsorbed (i.e., urea) or formed no complexes (i.e., gelatin) with the codepositing metal ion.

It is likely that the formation of a complex between the codepositing species and the addition agent is essential for the prevention of tungsten codeposition. All such complexes are more easily reduced than is the original nickel species, as is shown by the shift to more noble values of the half-wave potentials and of the dynamic cathode potentials. It has also been shown that all addition agents which prevent tungsten codeposition are capable of being adsorbed at the mercury cathode. The fact that very small quantities of addition agent prevent the codeposition and the observed depletion of the addition agent supports the hypothesis that this adsorption is also essential for the prevention of codeposition. As further evidence for this, it has been observed that tungsten will deposit normally from a solution containing 3 mg/l of thiourea (enough to completely prevent codeposition) provided an excess (0.8 g/l) of gelatin is added. This indicates a competition for adsorption between gelatin and thiourea and further demonstrates that adsorption of the addition agent is essential for the prevention of tungsten codeposition.

If one may assume that the behavior of the plating solution at a tungsten alloy electrode is not grossly different from that of the polarographic solution at a mercury cathode, then a plating mechanism consistent with these observations can be formulated. It would involve the adsorption of the addition agent at the cathode and its formation of complexes with the codeposition metal ion[2] as it approaches the cathode. During the formation of this new complex, the original complex between the codepositing ion and the tungstate ion dissociates, and tungsten deposition is prevented.

The x-ray diffraction data negate the mechanism involving alternate layers of the two metals, as does the lack of any periodicity in the plating voltages (12).

Paquin entitled "The Relationship between Brightness and Structure in Electroplated Nickel" which appeared in the February 1960 JOURNAL, on page 88 in Table II the data for the quantity of reflection light and the eye evaluation brightness group for Specimen 3006a belong to Specimen 3006b and vice versa.

The Mechanism and Efficiency of Electroluminescence in ZnS Phosphors

F. F. Morehead, Jr.[1]

Lamp Research Laboratory, General Electric Company, Nela Park, Cleveland, Ohio

ABSTRACT

This work describes the application of a model of the electroluminescent process to the photon emission and power consumption of insulated electroluminescent phosphors as a function of voltage and frequency. The model represents an extension of one described earlier. The model leads to a convenient summary of such data and an increased understanding of their significance. An upper limit to the efficiency of impact electroluminescence in insulated particles is proposed on the basis of the implications of the model.

One of the difficulties encountered in correlating data for electroluminescence in ZnS phosphors is that there does not exist an adequate model of the process. The lack of such a model makes impossible a convenient summary of the variation of brightness and power dissipation with voltage, frequency, and temperature. Comparisons of the properties of the electroluminescence of different phosphors are difficult to describe in meaningful terms and even more difficult to relate to differences in the fundamental properties of the phosphors. The purpose of this work is to present as complete an approach to an adequate model based on the collision excitation mechanism as is possible at present.

This model, to be described in the following section, is consistent with the relevant experimental data reported in the literature (1-6) although not in entire agreement with their interpretation [cf. (2, 3)]. The major premise is that of delayed recombination, which, despite alternative suggestions (7) remains unambiguously demonstrated (1, 2, 6). Further, the model is a straightforward extension of work by the present writer (1) with some changes suggested by consideration of efficiency. It is similar in concept but more detailed and more accurate than one described by Lehmann (5).

Finally, the model yields a phenomenological approach toward estimating maximum efficiencies that can be achieved with electroluminescence produced by impact ionization. The primary consideration is the relation between the way in which light emission and power consumption increase with voltage in insulated particles.

A Model of the Electroluminescence Process

The principal features of this model have been described previously (1); the same notation will be retained. The electrons participating in the electroluminescence process in a given particle are divided into two populations: n_e "mobile" electrons, which emerge from and return to a "high-field region" in each voltage cycle and N_T "trapped" electrons in the particle bulk which do not succeed in returning to this region. The origin of the high-field region in which carrier acceleration and impact ionization occur is discussed in a following section. It is assumed that all of the participating electrons have been ionized from the lattice and that the resultant holes are localized in the high-field region at N_+ recombination centers, so that

$$n_e + N_T = N_+ \qquad [1]$$

Of the n_e mobile electrons a fraction α recombine at the emission (recombination) centers and a much larger fraction β are trapped. These βn_e electrons are field-ionized by the succeeding voltage half-cycle and accelerated such that $F\beta n_e$ ionizing collisions occur, where $F \sim e^{-\frac{const}{E}}$ and E is the effective field in the high-field region. We have then

$$\alpha + \beta = 1 \qquad [2]$$

and

$$\alpha n_e = F\beta n_e \qquad [3]$$

to maintain a steady-state condition with respect to ionization and subsequent recombination. We further define Ψ as the fraction of the total number of electrons, $n_e + N_T$, which are in the particle bulk at the beginning of a voltage half-cycle, and which fraction returns to the high-field region

$$\Psi = n_e/(n_e + N_t) = n_e/N_+ \qquad [4]$$

The fraction α is of course proportional to the number of ionized recombination centers, which, as mentioned above, are localized in the high-field region

$$\alpha = N_+X \qquad [5]$$

where X is a capture cross section for these centers relative to trapping.

With the assumption $\alpha << \beta$, algebraic combination of Eq. [1], [2], [3], [4], and [5] gives the following

$$\alpha \sim F$$
$$n_e \sim \Psi F/X$$
$$B/f \propto \alpha n_e \sim \Psi F^2/X \qquad [6]$$

where B/f is the light emission/voltage cycle.

[1] Present address: Research Laboratory, International Business Machines Corp., Poughkeepsie, N. Y.

Trapping and retrapping in the phosphor bulk delays the return of the ionized electrons to the recombination region, which return is facilitated by a field opposite in direction to the ionizing field. Ψ is then a function of the frequency and amplitude of the voltage and of the temperature. The form of this function has been given in previous work (1) for a sinusoidal voltage V of frequency f

$$\Psi = 1 - e^{-\mu}$$
$$\mu = k_\mu \frac{V}{f^{0.6}} e^{-E_0/kT} \quad [7]$$

For a distribution rather than a single trap depth E_0, a weighted sum of terms of the form $e^{-E_{0i}/kT}$ applies.

Application of the above model to the electroluminescence brightness (time-averaged for photons) yields

$$B = B_\infty f \Psi F^2 \quad [8]$$

where B_∞ is a constant.

The motion of the n_e mobile electrons as well as that of the N_T trapped electrons under the influence of the applied field leads to an increase in both the real and imaginary capacitance of the cell C′ and C″ over the value of these constants in the absence of a carrier-producing process in the insulated phosphor particles C'_0 and C''_0. The power dissipated by the cell W, the stored power VAR, and the cell current i are given by

$$W = \omega C'' V^2$$
$$VAR = \omega C' V^2$$
$$i = \omega \mid C \mid V \quad [9]$$

where

$$C = C' + iC''$$

The increase in C′ and C″ arising from the electroluminescence process is proportional to the increase in the two populations of electrons, n_e and N_T, so that we can write

$$C' = C'_0 + \bar{C}'_1 n_e + \bar{C}'_2 N_T$$
$$C'' = C''_0 + \bar{C}''_1 n_e + \bar{C}''_2 N_T \quad [10]$$

where $\bar{C}'_1$ and $\bar{C}''_1$ are constants containing geometric and mobility or polarizability factors and $\bar{C}'_2$ and $\bar{C}''_2$ are similar constants of lower magnitudes representing the more limited excursions of the trapped electrons. One should emphasize here that the lossy motion of a trapped electron is conduction between traps rather than displacement within a trap. The designation "trapped" simply indicates electrons which do not succeed in returning to the recombination region within a half-cycle. Substituting in Eq. [10] from [6] gives

$$C' = C'_0 + C'_1 \Psi F + C'_2 (1 - \Psi) F$$
$$C'' = C''_0 + C''_1 \Psi F + C''_2 (1 - \Psi) F \quad [11]$$

The model thus leads to the expectation of a fairly direct correlation between photon brightness B and power consumption W.

Experimental Technique

A demountable cell was used for most experiments consisting of a circular copper block for one electrode and a circular conducting glass plate for the other. The latter makes contact at its periphery with a metal ring attached through an insulator to the copper electrode, providing a fixed separation of the electrodes. The phosphor powders were mixed with a viscous liquid, #1254 Aroclor (a chlorinated biphenyl, Monsanto Chemical Company), to give a desired volume loading. The mix first was deposited on the conducting glass plate, freed of admixed air in a vacuum chamber, and then pressed against the copper electrode, which was covered with a ¼ mil Mylar film to elminate electrolytic processes that might otherwise occur in the liquid medium. The experimental results reported below are not corrected for the effect of the Mylar film, since this correction does not significantly alter the results relative to the purposes of this work.

The cells were operated by means of a wide range oscillator, a 60 w audio amplifier, and a transformer. This combination of units provides up to 450 v rms above 100 cps to beyond the 5 kc frequency to which the measurements were limited to avoid a significant contribution of the resistance of the conducting glass to the power absorption. For measurements at lower frequencies a d-c amplifier which was limited to below 250 v rms was used.

The power consumption and current were measured with a Model 102 electronic wattmeter (John Fluke Engineering Co.) which was checked periodically against known resistances and capacitances.

Cell brightnesses were measured with a 1P21 photomultiplier tube whose output current was read with an electrometer. In each case the output of the photomultiplier was compared with the cell brightness in footlamberts as measured with a Photo Research Corporation "Spectra" brightness spot meter (Model UB) at each of the frequencies employed.

To obtain the cell output in lumens, the brightness in footlamberts was multiplied by the cell area in square feet. To convert the photomultiplier output to a relative photon count in those cases in which the wave-length distribution of the electroluminescence shifts with frequency, several procedures were used. The emission spectra of a ZnS,ZnO:Cu,Cl phosphor were measured at 100 cps and 5 kc, and plotted as relative amount of radiant power (for equal frequency intervals) $dW/d\nu$ vs. photon energy $h\nu$. The S-4 response of the 1P21 photomultiplier was obtained in response for equal radiant power at each photon frequency R_ν. The following integral gives the relative photomultiplier response/photon/second for the particular emission spectrum characteristic of the frequency f

$$(PMR)^{h\nu}_f = \frac{\int \left(\frac{dW}{d\nu}\right)_f R_\nu \, d\nu}{\int \left(\frac{dW}{d\nu}\right)_f \frac{d\nu}{\nu}}$$

For the phosphor described above we had from numerical integration of the above

$$\frac{(PMR)^{h\nu}_{5\text{ kc}}}{(PMR)^{h\nu}_{100\text{ cps}}} = 1.44$$

which is the correction factor by which the photo-

multiplier readings at 5 kc must be divided to obtain the number of photons emitted relative to 100 cps.

Similar calculations give the relative photomultiplier response/watt for each frequency

$$(\mathrm{PMR})^{w}_{f} = \int\left(\frac{dW}{d\nu}\right)_{f} \mathrm{R}\nu\, d\nu \;\Big/\; \int\left(\frac{dW}{d\nu}\right)_{f} d\nu$$

such that for the ZnS,ZnO: Cu,Cl

$$\frac{(\mathrm{PMR})^{w}_{5\ \mathrm{kc}}}{(\mathrm{PMR})^{w}_{100\ \mathrm{cps}}} = 1.42$$

The luminous equivalent of the emission at each frequency can be calculated in similar fashion with the use of the standard eye response curve, which equivalents are 296 lpw for 5 kc and 395 at 100 cps. The ratio of the sensitivity of the photomultiplier in lumens/unit deflection at 100 cps to that at 5 kc will therefore be

$$\mathrm{SR}(100\ \mathrm{cps},\ 5\ \mathrm{kc}) = 1.42\,\frac{395}{296} \sim 1.9$$

This value compares reasonably well with the sensitivity ratios for this phosphor (ZnS,ZnO: Cu,Cl) measured directly as described above with the brightness spot meter, about 1.75 ±0.2. Thus as a rough rule of thumb, one can estimate the correction necessary to convert photomultiplier outputs to relative photon counts as being approximately

$$[\mathrm{SR}(f_1,f_2)]^{0.6}$$

As a final procedure a set of filters were arranged to cover the electroluminescent cell in such a fashion as to give a linear photon count response (when combined with the S-4 1P21 response) in the wavelength range of 4400 to 5600Å. Calculations of the relative cell area assigned to each filter were based on their measured transmission curves. Satisfactory agreement with the results of the above procedures was obtained.

Experimental Results

Figure 1 shows the agreement of the measured photon emission of an electroluminescent cell of a

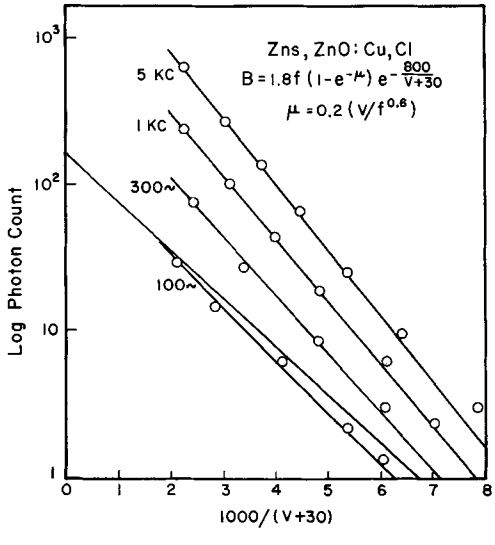

Fig. 1. Log photon count vs. $\dfrac{1000}{V + V_0}$ for ZnS, ZnO:Cu, Cl

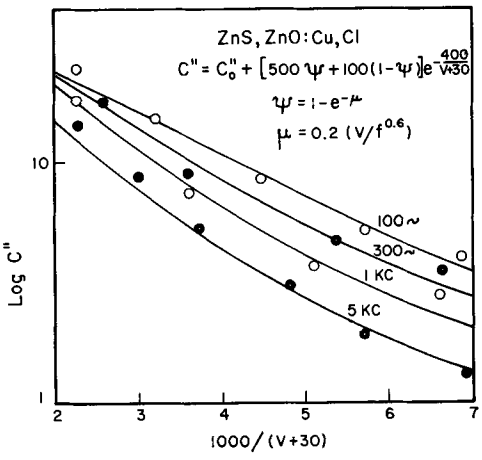

Fig. 2. Log imaginary cell capacitance vs. $\dfrac{1000}{V + V_0}$ for ZnS, ZnO:Cu, Cl.

ZnS,ZnO: Cu,Cl phosphor as a function of voltage and frequency with the form dictated by the model, Eq. [8]. The ionization efficiency F has been given the form

$$\mathrm{F} = e^{-\frac{\hat{c}}{V+V_0}} \qquad [12]$$

The reasons for choosing this form are given in the following section. The straight lines are not exactly the theoretical curves but are drawn through calculated points at $\dfrac{1000}{V + 30} = 2$ and $\dfrac{1000}{V + 30} = 6$ for each frequency. The heavy line is the relation between emission and voltage that would obtain at 100 cps for $\Psi = 1$. Figure 2 shows the agreement of the measured values of the imaginary cell capacitance in $\mu\mu$f with the form predicted by the model, Eq. [11]. Ψ and F are taken from the light measurements (Fig. 1) and C''_0, C''_1, and C''_2 then chosen to give a good fit of the solid (calculated) lines with the experimental points. (C''_0 is about 15 $\mu\mu$f in most cases.) Higher losses than those expected invariably are experienced at the highest voltages. This extra consumption is believed due to nonelectroluminescent processes, possibly associated with the presence of moisture (5).

Variation of cell thickness d and phosphor volume loading N_p give within experimental error the expected changes in the various parameters, viz.

$$B_2 = fB_{\infty 1}\frac{d_2}{d_1}\frac{N_{p2}}{N_{p1}}(\Psi)e^{-\frac{2c_1(d_2/d_1)}{V+V_{01}(d_2/d_1)}}$$

$$\frac{d_2}{d_1}C''_2 = C''_0(N_{p2}) + \left(\frac{N_{p2}}{N_{p1}}\right)\left[C''_{11}\Psi + C''_{21}(1-\Psi)\right]e^{\frac{c_1(d_2/d_1)}{V+V_0(d_2/d_1)}}$$

$$\Psi = 1 - e^{-\mu}$$

$$\mu = k_{\mu 1}\frac{d_1}{d_2}\frac{V}{f^{0.6}}$$

where the subscripts 1 and 2 refer to the parameters appropriate to cells of thicknesses d_1 and d_2 and phosphor volume loadings N_{p1} and N_{p2}.

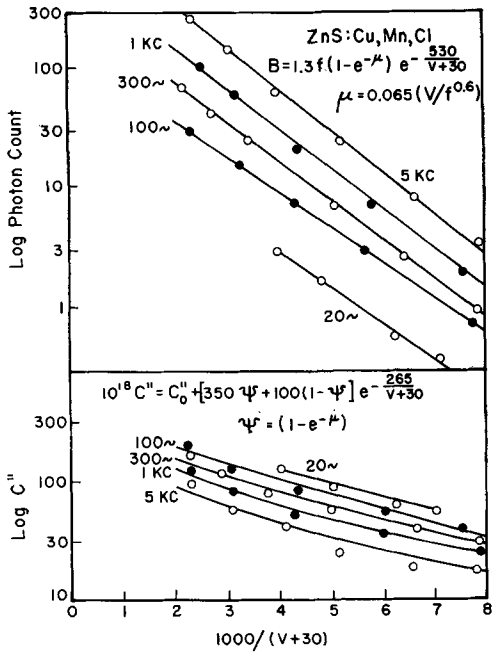

Fig. 3. Log photon count and log imaginary cell capacitance vs. $\frac{1000}{V + V_o}$ for ZnS:Cu, Mn, Cl.

Figure 3 shows the agreement of the model with the brightness and power data for a yellow-emitting ZnS:Cu,Mn,Cl phosphor. There is, of course, no shift in the emission spectrum with frequency. The green- and blue-emitting centers are impact ionized as in the previously described phosphor, but on recombination, the excitation energy is transferred to the yellow-emitting Mn-center, by means of a quantum mechanical resonance process (8, 9). The ground state and excited state of the Mn center are both thought to be below the top of the valence band, so that direct collision excitation rather than ionization of this center can occur (2). This latter mode of excitation of this center occurs significantly only at much higher currents than those characteristic of "normal" ionization electroluminescence and dominates only in cells that allow continuous current flow at very low frequencies or for d-c voltages.

A further distinction of the Mn-phosphor is the very low value obtained for k_μ in the expression for Ψ. This difference results in a much larger contribution of the N_T trapped electrons (a lower value of Ψ) to the power consumption of the cell, which increases rapidly with frequency. Thus if one measures a maximum phosphor efficiency (neglecting C''_o) of 6.0 lpw at 100 cps and 100 v, the equations shown in Fig. 3 predict a maximum efficiency of 8.4 lpw at 20 cps and 80 v. The solid lines shown in Fig. 3 for photon emission and C" at 20 cps were plotted on the basis of measurements made between 100 cps and 5 kc. The agreement with the experimental points shows that one may accurately extrapolate on the basis of the model outside of the actual range of measurements. By contrast, if one measures a maximum phosphor efficiency of 6.0 lpw at 100 cps and 140 v for the ZnS,ZnO:Cu,Cl phosphor, one can expect a maximum efficiency of only about 6.2 lpw at 20 cps and 100 v on the basis of the model and the experimentally determined parameters.

The reason for the low value of k_μ for the Mn-phosphor is not wholly understood. There is no evidence for the presence of deep traps, which would give a lower value at room temperature to $k_\mu = k_{\mu} e^{-E_0/kT}$, in either the thermoluminescence or the temperature dependence of the electroluminescence. The answer perhaps lies in a greater concentration of traps with consequently greatly increased retrapping and a slower rate of return at a given applied voltage and frequency. Similar consideration may also apply to the Ni-quenched phosphor discussed below.

ZnS:Cu, Al phosphor have even higher values of k_μ at room temperature than those coactivated with chlorine. A value as high as $k_\mu = 0.66$ has been measured, giving a very nearly linear frequency response to the phosphor at the higher voltages. A further advantage of the phosphor is the absence of color shift with frequency (2).

Interesting variations in the model parameters are produced by firing longer at higher temperatures to yield a higher mean particle size. One such ZnS,ZnO:Cu,Cl phosphor gives the following results (a correction for the greater cell thickness required to accommodate this phosphor has been made)

$$B = 0.32 f \Psi \left[e^{-\frac{255}{V+20}} \right]^2$$

$$C'' = C''_o + [500\Psi + 250\ (1 - \Psi)]\ e^{-\frac{255}{V+20}}$$

$$\Psi = 1 - e^{-\mu}$$

$$\mu = 0.18 \left(\frac{V}{f^{0.6}} \right)$$

A comparison of this phosphor with the usual ZnS,ZnO:Cu,Cl under a microscope shows the former to have roughly twice the average particle size of the latter The change in the parameters contained in the expression for photon emission (cf. Fig. 1) as a result of the increased particle size correlates reasonably well on the basis of Lehmann's work (10). He found that B_∞ (Eq. [8]) varied inversely as the square of the mean particle size. The present results correlated on this basis with a size ratio of 2.3.[2] His experiments also show that the equivalent of the threshold voltage c (Eq. [12]) varied inversely with the 0.7 power of the mean particle size. Lehmann's analysis of the latter constant is in terms of the 1.0 power rather than 0.7, but the former value cannot explain phenomenologically the decrease in maximum efficiency with increasing particle size which he observed, and 0.7 is in better agreement with his data than 1.0. From the ratio of the c-values then, one obtains a particle size ratio of $\left(\frac{400}{255} \right)^{\frac{1}{0.7}} = 1.9$, in reasonable agreement with the above figure.

Lehmann's analysis was based on the following relation between brightness, voltage, and frequency

$$B = A f \exp\ (-\sqrt{G/V}$$

while we have been using an expression which, at sufficiently low frequencies, reduces to

$$B = B_\infty f \exp\,(-2c/(V + V_0))$$

Although no attempt at a rigorous mathematical analysis has been made, it has been the experience of the present author that, at low frequencies, a set of data which fits the equation used by Lehmann above will also be consistent with the second expression above, with the following approximate relations between the constants

$$B_\infty = 0.10\ A;\ 2c = 0.12\ G;\ V_0 = 0.05\ (2c) = 0.006\ G.$$

Therefore any functional relationship between the constants A and G and parameters such as particle size, cell thickness, etc., will also apply, within a constant factor, to the constants B_∞ and c.

The coarse phosphor is also considerably less efficient than the normally sized phosphor, by a factor of about 1.6. On the basis of the model discussed above one would predict this for at least two reasons. First, the variation of c inversely as the 0.7 power rather than 1.0 power of the mean particle size indicates that a smaller fraction of the total voltage appearing across the particle is concentrated in the high field for large particles than for small. Hence proportionally more useless energy is dissipated in the low field volume by the "mobile" electrons. Second, the relative value of C''_2 to that of C''_1 is greater for the larger particles, indicating, quite reasonably, that in large particles the trapped electrons are subjected to displacements over larger distances within the high-field region in their unproductive agitation by the applied field.

The invariance of C''_1 with particle size suggests that the polarizability per available conduction electron at $V = \infty$ (the number of which is proportional to B_∞) varies directly as the square of the particle size. k_μ is also relatively invariant with particle size, which tends to confirm its association with the average field in the phosphor particles rather than the high-field region. It should be realized, however, that the above analysis is based mostly on data from a single phosphor sample.

The introduction of a killer such as Ni into a phosphor of the ZnS,ZnO:Cu,Cl type produces a quenching of the emission which depends on frequency alone (11). To determine the value of k_μ associated with such a phosphor one can use the change in slope at a particular voltage of ln B vs. $\frac{1}{V + V_0}$ (Fig. 1, 3) as a function of voltage, viz.

$$\frac{d \ln B}{d\left(\frac{1}{V + V_0}\right)} = \frac{d \ln \Psi}{d\left(\frac{1}{V + V_0}\right)} - C$$

$$= \frac{(V + V_0)^2}{V} \frac{\mu}{e^\mu - 1} - C \qquad [14]$$

$$\mu = k_\mu \frac{V}{f^{0.6}}$$

[2] That exact agreement is not to be expected is shown by the somewhat different particle size correlations reported by Goldberg (11).

The results of such an analysis on a ZnS,ZnO:Cu,Cl, Ni phosphor are

$$B = \frac{B_\infty}{Q} (\Psi)\, e^{\frac{710}{V+30}}$$

$$C'' = C''_0 + [500\,\Psi + 150\,(1 - \Psi)]\, e^{-\frac{355}{V+30}}$$

$$\mu = 0.1 \frac{V}{f^{0.6}}$$

f:	100	300	1000	5000 cps
$1/Q$:	1.0	1.17	1.60	2.0

The value of $1/Q$ has arbitrarily been set at 1.0 for 100 cps. The addition of the Ni has also had the effect of reducing the value of k_μ (more traps?) as well as quenching the emission at the lower frequencies, compared to the ZnS,ZnO:Cu,Cl phosphor (Fig. 1, 2). Thus a Ni-quenched phosphor can be sublinear, as well as superlinear or linear with frequency at a fixed voltage.

The analyses of the phosphors described above, other than the Ni-quenched material, have been made on the assumption of the absence of quenching. Using Eq. [14] to determine k_μ for ZnS,ZnO:Cu,Cl yields a value of 0.16, compared with 0.2 (Fig. 1), suggesting a small but significant amount of quenching. Trace amounts of Fe, Ni, or Co are undoubtedly present in this phosphor.

It should be mentioned also in this section that for all the phosphors examined, the dependence of the real part of the cell capacitance on voltage and frequency was such that, within experimental error, $C'_1 \sim C''_1$ and $C'_2 \sim C''_2$. Thus of the total energy absorbed by a conduction electron falling through a given potential, roughly half is stored as potential energy and returned to the field on field reversal.

Efficiency of Electroluminescence in Insulated Particles

The efficiency η with which the insulated electroluminescent phosphor converts the electrical power it absorbs from the applied field into luminous flux is proportional to (Eq. 8, 9, 11)

$$\eta \propto \frac{B}{W} = \frac{B f \Psi F^2}{\omega V^2 F[C_1'' \Psi + C''_2(1 - \Psi)]} \qquad [15]$$

The power absorbed by the cell dielectric and phosphor in the absence of electroluminescence, $\omega C''_0 V^2$, has been neglected, since we wish here to estimate the limiting efficiency of the electroluminescence process alone.

For most phosphors, at sufficiently low frequencies, $C'' \Psi >> C''_2 (1 - \Psi)$ so that

$$\eta \propto \frac{F}{V^2} \qquad [16]$$

Maximum efficiency then occurs at that voltage V_m for which

$$\frac{d \log F}{d \log V} = 2 \qquad [17]$$

The form of the maximum phosphor efficiency obtainable from insulated particles can be written

$$\eta_m = \frac{n_e\,(2.5\epsilon) F_m}{n_e (V_e\,\epsilon)} \qquad 400 \text{ lpw} \qquad [18]$$

2.5ϵ is the energy of a typical visible photon; V_e the voltage through which a typical "mobile" electron falls; $F_m = F(V_m)$. (Acceptable "white" luminescence with a luminous equivalent greater than 400 would be difficult to achieve.) One-third is a reasonable guess for the value of $2.5/V_e$ at η_m. V_e is the product of two factors: the average field over the path of the electrons and the mean path of the electrons. Both factors are assumed proportional to the applied field V, so that Eq. [18] is in fact dimensionally consistent with [15] and [16]. For most phosphors the average field across the cell, and hence across the phosphor in a liquid dielectric (5), is about 1.5 v/μ peak at the voltage of maximum efficiency. For $V_e = 3 \times 2.5 = 7.5$ v, the mean path of the electrons in this field is 5 μ, which is not unreasonable. If, as indicated above, half the absorbed energy is stored and later returned to the field, and in the absence of competing, nonradiative recombinations, an upper limit to the maximum phosphor efficiency may be set at

$$\eta_m = \frac{2}{3} F_m \qquad 400 = 267\, F_m \qquad [19]$$

The value of F_m depends on the form of the voltage dependence of $F(V)$. If we apply the usual form $F = \exp(-\text{const}/\sqrt{V})$, which is presumed to arise from the formation of an exhaustion layer (Eq. [2]), we have $F_m = e^{-4} \sim \frac{1}{50}$, which, substituted in Eq. [19], gives $\eta_m < 5.3$ lpw. Measurements have been published which exceed this by approximately a factor of three (10). If these are correct, then the expression $F = \exp(-\text{const}/\sqrt{V})$ does not give a reasonable characterization of the voltage dependence of F. Furthermore, the formation of an exhaustion layer requires the movement of a considerable quantity of charge before an ionization field is obtained, so that the maximum efficiency of such a process would have an even lower limit than 5.3 lpw. For these reasons, consideration of the formation of an exhaustion layer was eliminated from the model description.

Application of the form $F = \exp(-\text{const}/V)$ yields $F_m = e^{-2} \sim \frac{1}{7}$ or $\eta_m < 38$ lpw, a value high enough to explain efficiency obtained experimentally thus far. Such a voltage dependence can arise from, among other possibilities, the intrusion of elongated "spikes" of a conducting phase, such as Cu_2S, into the ZnS phosphor particle interior (13). The field at the tip of such an intrusion can easily be an order of magnitude greater than the average field. The ratio of the high field at the tip of the spike to the average field is given roughly by the ratio of the length of the spike to its cross-sectional diameter (14). This ratio undoubtedly increases with particle size. In such a case the value of the exponential constant c in the expression for $F = \exp -(c/V)$ is a monotonically decreasing function of particle diameter a, $c = c(a)$, and the effective value of F that applies to the rather wide particle size distribution encountered with electroluminescent phosphors is an integral or summation of the form

$$F = \sum_i f_i e^{-\frac{\bar{c}(a_i)}{V}} \qquad [20]$$

where the subscript i applies to a narrow range of particle sizes of mean diameter a_i and relative frequency f_i. The form $\exp(-\text{const}/\sqrt{V})$ has been shown to approximate the behavior of Eq. [2] except at the highest applied voltage (15), which makes it possible to use $\exp(-\text{const}/\sqrt{V})$ to describe the dependence of electroluminescence brightness on voltage. A more suggestive approximation to Eq. [20] is (16-18).

$$F = e^{-\frac{c}{V+V_0}} \qquad [21]$$

where the relative value of the constant V_0 is considered as simply a measure of the dispersion of a_i, particularly in the direction of larger than average particles. (Much smaller than average particles do not contribute much to brightness or power absorption at voltages in the neighborhood of maximum phosphor efficiency; only a small fraction of the particles that are absorbing power will be operating at the voltage of maximum efficiency for that fraction, so that the effective value of F_m will be less than e^{-2}. In fact, application of Eq. [17] to Eq. [21] for $V_0 \cong 0.10c$, true for the phosphors described above, yields

$$F_m = e^{-2.7} \sim \frac{1}{15}$$

Therefore to test the "limit" of about 38 lpw, one would have to use a phosphor of both uniform and small particle size since, as indicated in the discussion of the coarse phosphor, smaller particles concentrate a larger fraction of their total voltage across the high-field region, and on the basis of this model would be expected to operate more efficiently.

Finally, it should be mentioned that for the relations developed earlier in this paper between photon emission and power consumption to apply accurately to the assembly of particle sizes present in a typical electroluminescent phosphor, one must hope, applying Eq. [20] to [8] and [11], that the following is a good approximation

$$\frac{\sum_i f_i e^{-\frac{2\bar{c}(a_i)}{V_1}}}{\sum_i f_i e^{-\frac{2\bar{c}(a_i)}{V_2}}} \sim \left[\frac{\sum_i f_i e^{-\frac{\bar{c}(a_i)}{V_1}}}{\sum_i f_i e^{-\frac{c(a_i)}{V_2}}} \right]^2$$

for any values of V_1 or V_2 within the range of interest.

Acknowledgment

The writer wishes to thank the following persons for many helpful suggestions as well as the preparation of most of the phosphors: Dr. I. L. Smith, Dr. M. Aven, Dr. R. M. Potter, and Mrs. M. S. Jaffe.

Manuscript received Oct. 15, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

SYMBOLS

α — Fraction of n_e "mobile" electrons that recombine with emission each half-cycle.

β — Fraction of n_e "mobile" electrons that are trapped in high-field regions each half-cycle.

ϵ — Electron charge.

η — Electroluminescence efficiency.

μ — A constant in expression for Ψ: $\mu = k_\mu \dfrac{V}{f^{0.6}}$

Ψ — $\dfrac{n_e}{n_e + N_T} = (1 - e^{-\mu}) = \Psi$

ω — $2\pi f$

a — Effective particle diameter

B — Photon emission/cycle, arbitrary units.

B_∞ — Photon emission/cycle extrapolated to $V = \infty$.

$c, \bar{c}$ — A constant in one expression for $F = e^{-\frac{c}{V+V_0}}$ for the cell; $F = e^{-\bar{c}/(V+V_0)}$ for particles of a given diameter.

C_0', C_0'' — The real and imaginary parts of the cell capacitance in absence of electroluminescence.

C'_1, C''_1 — Constant coefficients in expression for real and imaginary capacitance contributed by "mobile" electrons.

C'_2, C''_2 — The same for "trapped" electrons.

d — Cell thickness.

$\mathbf{E}$ — Effective ionizing field.

E_0 — Trap depth.

F — Probability of impact ionization of a secondary electron by a primary electron in high-field region.

f — Frequency in cps.

f_i — Relative frequency of occurrence of particles of mean diameter a_i.

i — Cell current

k_μ — A constant in expression for μ.

n_e — Number of electrons that return to the high-field region each half-cycle.

N_+ — Steady-state number of ionized centers in high-field region.

N_T — Steady-state number of electrons that remain trapped in phosphor bulk.

$(PMR)_f^{h\nu}$ — The 1P21 photomultiplier response to a given number of photons/second distributed according to emission spectrum of a given phosphor at frequency f.

$(PMR)_f^{w}$ — Same for a given radiant power.

Q — Quenching factor by which the emission expected in the absence of quenching is divided.

R_ν — Relative response of the 1P21 photomultiplier for equal radiant power at each photon frequency.

$SR(f_1,f_2)$ — Response of the 1P21 photomultiplier to a given number of lumens emitted by a phosphor at a frequency f_2 relative to that at a frequency f_1.

T — Absolute temperature.

V — The rms voltage.

V_0 — A constant in the expression for F.

V_e — Potential through which a typical electron falls in the electroluminescence process.

N_p — Fraction of cell volume occupied by phosphor.

VAR — Stored power, $VAR = \omega C' V^2$.

W — Consumed power, $W = \omega C'' V^2$.

X — A constant proportional to capture cross section of the ionized activators.

Electroluminescence under Pulsed Square Wave Excitation

ABSTRACT

The slow return of an electroluminescent cell to its equilibrium state following a field excitation has been studied for a blue-green emitting Zn(S,O): Cu,Cl phosphor and for a yellow-emitting ZnS: Mn,Cu phosphor. The light pulse emitted upon the rise of a square voltage pulse was measured as a function of repetition rate and of temperature between —130° and 150°C. Relaxation times encountered varied between 10^{-2} sec and 10^{5} sec. The temperature dependence of the relaxation rate exhibits effective activation energies of about 0.4, 0.7, and 0.6 ev, respectively, for the blue, green, and yellow emission bands. The results do not seem to favor the mechanism of delayed recombination. An alternative mechanism is suggested whereby the number of filled deep donors is assumed to control the electroluminescence emission via the number of field-ionizable electrons available for collision-excitation of centers. Observations were also made on some other effects associated with square wave excitation.

A complete picture of the microscopic processes involved in the light emission from insulated zinc sulfide crystals under high electric fields (1) has not yet been established firmly, although various models have been more or less successful in accounting for different aspects of the phenomenon. The present work was undertaken to obtain further insight into the nature of electroluminescence.

This paper describes some observations on the electroluminescence of two zinc sulfide phosphors under pulsed d-c voltage excitation and their interpretation in the light of proposed mechanisms. Square wave voltage excitation is in some ways simpler than the extensively studied sine wave excitation and yields information not readily obtainable from studies of brightness wave forms under sinusoidal voltages.

When a square wave pulse is applied to an electroluminescent cell two pulses of light emission are generally observed (2-5), one upon application of the external field and the other upon removal of that field. The first light pulse reaches its maximum shortly after the voltage rise is completed, then decays in roughly exponential fashion until the inception of the second light pulse at the removal of the voltage. A typical time dependence of luminescence and applied voltage is shown in Fig. 1.

[1] Present address: Gordon McKay Laboratory, Harvard University, Cambridge, Mass.

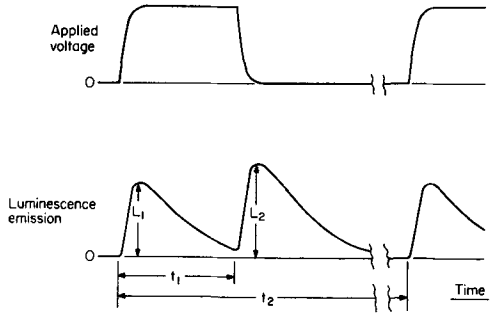

Fig. 1. Typical brightness waveform under square wave voltage excitation: t_1 = pulse width; t_2 = repetition interval; L_1, L_2 = peak intensities of the two light pulses.

In this work measurements were made of the emitted light pulses and their decay characteristics as a function of the two time parameters of the pulsed square wave voltage excitation: pulse width and repetition interval. These effects were studied in the temperature range of —130° to 150°C. The yellow emission band of a manganese-activated phosphor and the blue and green emission bands of a copper-activated phosphor (isolated by means of optical interference filters) were studied. The voltage dependence of emission intensity was checked and found to fit closely to exp $[-b/V^{1/2}]$ as has been widely observed for sine wave excitation (2).

Experimental

The preparation of the phosphors is shown in Table I and the panel construction in Fig. 2. Chlorine was included as a charge compensating coactivator in the copper-activated phosphor. Monovalent copper ions substitutionally replacing zinc ions in the crystal are more easily incorporated if chlorine is present simultaneously to substitute for sulfur (6). It has also been proposed (7) that chlorine promotes the formation of sulfur vacancies thought to be necessary for luminescence in ZnS. Preparation of the manganese-activated phosphor did not require

a coactivating halide flux since manganese replaces zinc as a divalent ion in the lattice so that charge compensation is unnecessary (8). Some copper was also included in this phosphor since it has been found to promote electroluminescence (9). The numbers given for the thickness of the various layers are representative. A rough check on the measured phosphor layer thickness was given by the capacitance of the panels which was about 10^{-9} farads in each case. The phosphor powder was mixed with a binder and sprayed onto the conductive surface of a Pyrex plate serving as the transparent electrode. A second layer of binder containing powdered barium titanate was applied to the back of the phosphor layer. This insulating layer was found to be useful in preventing breakdown across thinner portions of the phosphor layer without sacrificing much of the voltage drop across the latter due to the large dielectric constant of barium titanate. An aluminum backing evaporated onto the barium titanate layer served as the rear electrode. Silver paint around the edges of the glass plate allowed contact to be made between the conductive coating electrode and a copper strip pressed against the front of the plate. The aluminum electrode was held against the surface of a copper block kept at ground potential, which also served as the thermal reservoir used in controlling the temperature of the phosphor.

The experimental arrangement is shown schematically in Fig. 3. Tektronix units of the 160 series provided the square wave signals which were fed into an amplifier capable of delivering outputs up to 2000 v with a rise time in the vicinity of 10 μ sec. An RCA 6199 photomultiplier was used to monitor the luminescence. The time dependence of the exciting voltage and of the emitted light were displayed on a Tektronix 545 oscilloscope equipped with a dual trace preamplifier.

The panel was enclosed in a stainless steel chamber fitted with a quartz window for viewing the luminescence. A copper rod connected to the copper block in contact with the panel's aluminum backing led outside the housing through a Teflon insulator. This rod could be immersed in a refrigerant or in a heating coil to vary the temperature of the electroluminescent cell. Temperature was measured by an iron-constantan thermocouple with one junction located on the surface of the copper block next to the panel.

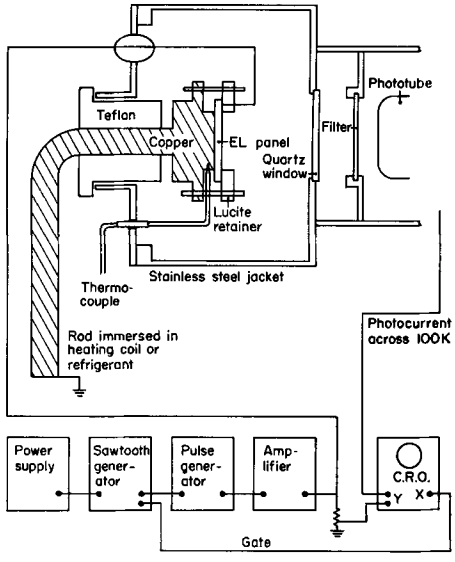

Fig. 3. Schematic diagram of the experimental arrangement.

Procedure and Measurements Performed

The aluminum backing electrode was kept at ground potential while the transparent electrode was driven back and forth between ground and a high negative potential. By means of a Balzers graduated interference filter serving as a crude spectrometer in the visible it was determined that the yellow-orange emission of the manganese panel consisted of the characteristic single broad band peaked around 5800Å. The copper-activated panel exhibited the well-known blue-green emission which changes in spectral content with varying operating conditions, e.g., becomes bluer with increasing frequency. The overlapping emission bands of this phosphor were separated by two Balzers interference filters transmitting 4610Å and 5300Å with peak transmissions of 30% and half widths of 100Å. Because of the reduction in intensity in selecting such narrow spectral ranges for investigation, the measurements on the Zn (S,O): Cu,Cl panel were made at higher exciting voltages and greater phototube sensitivity than were used in the measurements on the ZnS: Mn, Cu panel.

Detailed measurements were made on the variation of the two peak intensities, L_1 and L_2, with the repetition interval t_2, and with temperature. 400-v pulses of 10 msec duration were used in the ZnS: Mn, Cu studies, 700-v pulses of 1 msec duration for

the Zn (S,O):Cu, Cl. The pulse widths chosen were the smallest times needed to allow the first light pulse to decay to a value small relative to L_2. The output photocurrent of the photomultiplier was passed through a 10^5 ohm resistor and displayed on the oscilloscope. When L_1 and L_2 were widely different ($L_1 << L_2$), the signal was fed into both channels of a dual trace preamplifier with each channel set at a scale convenient for measuring one of the peak heights. For long repetition intervals the peak heights were taken from a photograph of the scope trace.

Measurements were made of the decay of the second light pulse after removal of the applied field (L vs. t from L_2 on). For the ZnS: Mn, Cu panel, 400-v pulses of 10 msec duration and 10 cps repetition rate were used in making these measurements. For the Zn (S,O): Cu, Cl panel, 700-v pulses of 1 msec duration and 10 cps repetition rate were used. The delaying sweep circuit of the oscilloscope was employed for these measurements. This decay characteristic was studied at various temperatures.

Qualitative observations were made on the brightness wave forms of the luminescence emission with very small pulse widths. This turned up some interesting effects which will be discussed.

Results

Luminescence emission occurs on the rise and on the fall of the applied voltage, giving the two light pulses L_1 and L_2. For a given voltage amplitude and for the low duty cycles normally employed ($t_1 << t_2$), it was found that L_1 depends on t_2 and L_2 on t_1. This is to be expected if the dominant factor in determining the state of a phosphor at a particular temperature is the time elapsed from the last preceding excitation, i.e., the last preceding voltage shift (3). Thus it is not surprising that the second light pulse is insensitive to the repetition interval and that the first light pulse is unaffected by the duration of the applied voltage following it.

Figures 4 and 5 are log-log plots of the variation in peak intensity of the first light pulse with repetition interval for the two phosphors at several temperatures. Figure 5 consists of the two sets of curves for the green and the blue emission of the copper-activated phosphor. Any small drift in either the applied voltage amplitude or the phototube sensitivity would be expected to change both L_1 and L_2 by the same factor. In order to compensate for such variations the data are normalized by plotting the peak height ratio, L_1/L_2, as the dependent variable.

In all cases the peak height ratio is of the order of unity for small t_2 and falls off as t_2 increases. At low temperatures the drop-off is slower than at high temperatures. At —125°C this variation is well frozen out, with very little change in L_1/L_2 occurring in times less than an hour. For the manganese-activated panel the ratio falls until a terminal value of the order of 10^{-1} to 10^{-2} is attained at a particular value of t_2, and then remains constant. For the copper-activated panel the ratio falls to 10^{-3}, the limit of measurement, without exhibiting any saturation effect. The blue emission of this panel possesses a faster decrease of L_1 with t_2 than does the green emission, al-

though the latter decay seems to catch up with the former at very long repetition times. Waymouth and Bitter (4) measured the integrated light output of a blue-green phosphor upon removal of an applied voltage of long duration. They observed a slow decay with increasing duration time similar to that reported here for increasing repetition time, with the blue decay occurring more quickly than the green decay. Their results are compared to ours in the following section.

The temperature dependence of L_1 (t_2) is interesting since such a thermally controlled process can yield information on energy levels of electrons involved in the excitation or recombination processes taking place in electroluminescence. An analysis and interpretation of this temperature dependence is discussed in the next section.

Figures 6 and 7 show the time decay of the second light pulse upon removal of the applied field for the two phosphors at three of the temperatures studied, the latter figure giving both the blue and the green decays of the Zn (S,O): Cu,Cl panel. The ZnS: Mn, Cu data do not exhibit any appreciable systematic temperature shift whereas the Zn (S,O): Cu,Cl curves exhibit a minor systematic change with temperature. The initial slope of the decay at −125°, 25°, and 150°C gives decay rates of 17, 14, and 8×10^3 sec^{-1}, respectively, for the blue and 11, 8, and 5×10^3 sec^{-1} for the green emission. In addition to this decrease of the initial rate of decay, these curves also become more exponential in shape (linear on a semi-log plot) with increasing temperature so that after long times the emission is lower and the decay rate greater for high temperatures than for low. This produces the cross-over of the decay curves shown in Fig. 7. The initial decay rate of the ZnS: Mn,Cu data is 0.9×10^3 sec^{-1} and the shape of this decay does not change with temperature.

Figure 8 shows some brightness waveforms obtained by application of voltage pulses of short duration. For the manganese-activated phosphor, equal increments of emission occur at the rise and fall of the applied voltage except with pulse widths less than about 0.5 msec for which the second increment becomes smaller than the first. Nudelman and Matossi (5) report a very similar behavior for the blue component of a ZnS: Cu,Pb phosphor with a critical pulse width of 0.7 msec. The blue emission of our copper-activated phosphor also exhibits equal increments of emission, but at pulse widths down to 0.2 msec. For the green emission of their phosphor, Nudelman and Matossi report equal peak heights at the voltage rise and fall for pulse widths greater than 0.7 msec. Our observations are similar, except that the critical time observed is about 0.2 msec.

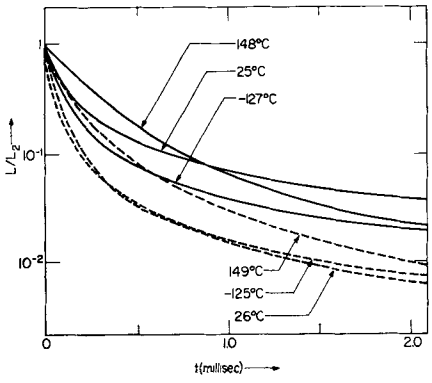

Fig. 7. Decay of light emission L on removal of the applied voltage for the Zn(S,O):Cu,Cl panel. Green emission: solid lines; blue emission: dashed lines.

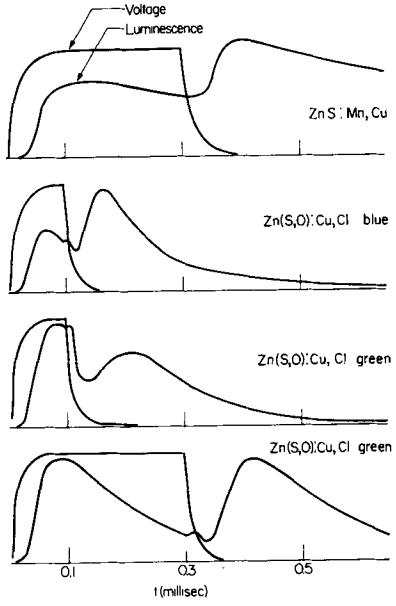

Fig. 8. Brightness waveforms using short pulses

Some interesting effects were observed in the Zn (S,O): Cu,Cl panel. The blue emission exhibits a very small peak preceding the build-up of the second light pulse. This stimulation peak appears at small repetition intervals and is insensitive to pulse width. The green emission also reveals this effect. In addition, however, at short pulse widths this emission shows a sharp dip upon the start of the voltage drop. This quenching dip precedes the build-up of the second light peak but follows the stimulation peak. Some representative brightness waveforms are shown in Fig. 8. The two effects are independent. The stimulation peak is most noticeable at short repetition times and long pulse widths, but as the pulse width is reduced the quenching dip becomes dominant. Nudelman and Matossi observed stimulation peaks, but for the green emission only. They did not find quenching dips in their phosphor.

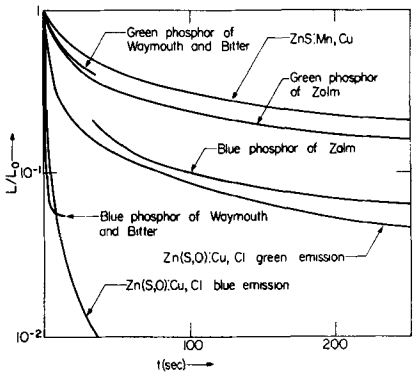

Fig. 9. Room temperature data on the dependence of the emitted light L after an elapsed time t from the preceding voltage shift. L_0 is the value of L for t = 0.

Both of these effects were absent in our manganese-activated phosphor.

Discussion

In Fig. 9 the room temperature curves of Fig. 4 and 5 are replotted on semi-log paper along with some data of Waymouth and Bitter (4), and of Zalm (2), who also noticed this slow return of an electroluminescent cell to its original state following a field excitation. These curves demonstrate that this decay does not follow an exponential law. Rather, the log-log plots are suggestive of the power-law decays encountered in phosphorescence (10). Such decays may be accounted for in terms of the emptying of a collection of filled traps of various depths. For example, it has been shown (11) that a uniform trap distribution, that is, an equal number of traps of all depths, gives a decay with a t^{-1} dependence at long times. It is interesting that the blue emission decay approximates this hyperbolic relationship at the higher temperatures. A trap distribution varying exponentially with trap depth, that is, $dN_E/dE = A \exp[-\alpha E]$, gives a decay going as t^{-n} for long times (11), where $n = \alpha kT + 1$. If a t^{-n} law is assumed and compared with the steepest slopes encountered in Fig. 4 and 5, n is found to vary linearly with temperature from 0° to 150°C, going from 0.7 to 1.8 for the green emission, from 0.5 to 1.2 for the blue emission, and from 0.4 to 0.8 for the yellow emission. These observations suggest that the mechanism responsible for the behavior of L_1 with time and temperature is the thermal release of trapped electrons (or holes). The existence of traps in zinc sulfide phosphors has been widely demonstrated by means of glow curves and other methods (12).

The above reasoning may be summarized by the following syllogistic argument: (*a*) temperature dependent phosphorescence has been accounted for in terms of electrons thermally ejected from traps; (*b*) the decay curves of L_1 vs. t_2 resemble reported temperature dependent power-law phosphorescence decays; (*c*) therefore, the present measurements may reasonably be explained by the thermal release of trapped electrons.

In order to characterize the temperature dependence of the data, the following method has been employed. A particular value of L_1/L_2 is first selected, and then the value of t_2 corresponding to this level of the peak height ratio is noted for each of the various temperatures studied. The reciprocal of this arbitrarily defined relaxation time is plotted against reciprocal temperature on semi-log paper (hoping, of course, to obtain a straight line). This calculation is repeated for several choices of peak height ratio. The rationale for this procedure is the assumption that the extent to which the phosphor has retrogressed toward its equilibrium condition at a particular time following a field excitation is more or less defined by the value of L_1/L_2 at that time. The reciprocal of the time needed for the relaxation to proceed to a given stage is then taken as a measure of the rate of the relaxation process.

The results are shown in Fig. 10 and 11. Despite the crudeness of the approach and the expected complexity of the actual trap distributions, reasonably good straight lines were obtained. The activation energies corresponding to the slopes of the lines are listed in Table II. The effective trap depths obtained fall in the range of 0.3-0.5 ev for the blue emission, 0.5-0.8 ev for the green emission, and 0.6 ev for the yellow emission. For each emission band the effective trap depths increase with decreasing choices of L_1/L_2. Thus the deeper traps control the later stages in the relaxation process, which is reasonable as it is to be expected that the shallow traps empty first.

Before resuming this discussion of the role of traps in this phenomenon, a brief digression on the nature of the electronic states of the luminescence centers involved may be useful. It is generally agreed that the manganese centers give rise to perturbed ionic states lying well below the top of the valence band (13). Accepting the collision-excitation hypothesis, a ground-state electron interacts with a conduction electron accelerated to optical energies by the electric field in a localized high-field region of the crystal and is raised to a bound excited state from which it drops back to the ground state after a characteristic time, giving off a photon

in the process. Ionization does not occur. This picture is consistent with our observations on the yellow emission band. The temperature independence of the decay of the light pulse (Fig. 6), as well as the absence of stimulation or quenching effects, indicates that bound states are involved. The equal increments of emission on the rise and fall of the external field may be understood on the basis of equal effective fields [the field at the voltage fall is due to polarization charges (3-5) to be discussed later] exciting equal numbers of centers which are simply added to the excited centers left over from previous excitations. This latter statement contains the assumption that the number of centers excited at any time is a small fraction of the total so that the number available for excitation remains essentially constant.

In copper-activated zinc sulfide, it is generally assumed that the emission process for both green and blue bands involves transitions between perturbed crystal states lying within the forbidden gap, and either conduction electrons (14) (Schön-Klasens model) or valence band holes (15) (Lambe-Klick model). The green emission exhibits equal peak heights with rise and fall of voltage, as well as sharp quenching dips upon field removal which may be due to charge carriers being swept out of a region in which they had been participating in radiative recombination with ionized activators. In addition, the shape of the light pulse decay is temperature dependent (Fig. 7). These observations favor the belief that excitation of the green centers involves ionization and production of mobile charge carriers. The situation is ambiguous for the blue band since this emission resembles that of the manganese in giving equal increments upon field application and removal, while it possesses a temperature dependence of the light pulse decay similar to that of the green band.

It has been reported (3) that an internal polarization is present which develops upon application of an external field and which decays upon removal of that field with a time dependence similar to that observed for L_1 vs. t_2. This polarization may result from the trapping of charge carriers in regions removed from their place of origin due to migration under the action of the field. It shall be assumed that both this internal polarization and the L_1 dependence arise from the same trapping mechanism within the phosphor.

Waymouth and Bitter (4) propose the trapping scheme shown in Fig. 12 in terms of the Schön-Klasens model. Upon application of the field, electrons are collision-ionized from activator centers into the conduction band whence they are swept by the field to another part of the crystal. Here they are held until field removal, whereupon they return and recombine radiatively with the empty activator centers. During the interim, however, the ionized centers may thermally release their trapped holes to the valence band where they may subsequently be retrapped by deeper quenching centers. Electron-hole recombination occurring at these quenching centers is assumed to be nonradiative at high temperatures, while at low temperatures light of longer wave length is emitted. This process reduces the light pulses emitted in the blue and green bands upon removal of the field, and also accounts for the temperature quenching of the photoluminescence.

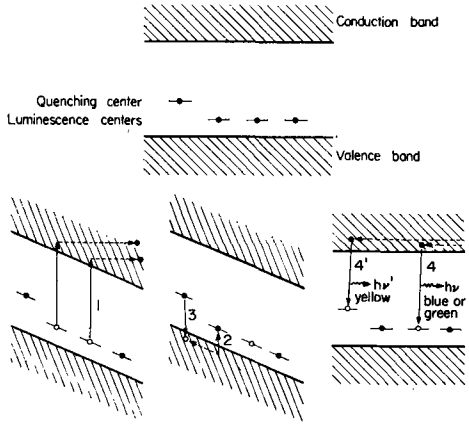

Fig. 12. Schon-Klasens model applied to electroluminescence (after Waymouth and Bitter).

Waymouth and Bitter, from temperature dependence measurements of L_2 vs. t_1, obtained activation energies of 0.29 and 0.21 ev for the green and blue bands, respectively, which they interpret as giving the separation between the vacant activator levels and the top of the filled band. Garlick and Gibson (16), from measurements of temperature quenching, obtained 0.95 ev for green-emitting ZnS:Cu and 0.59 ev for yellow-emitting ZnS:Mn. Activation energies observed here are about 0.7 ev, 0.4 ev, and 0.6 ev for the green, blue, and yellow bands, respectively.

Although this model is consistent with observations on the decrease of the burst of light emitted on removal of an applied field with increasing time of application of that field, there remain some objections to it. It does not appear to account for the decay of the light pulse emitted on aplication of the field with increasing time elapsed from the previous field excitation (our measurements of L_1 vs. t_2). As mentioned above, it seems likely that excitation of the green luminescence band, with emitted radiation (transition 4 in Fig. 12) of about 2.4 ev photon energy, involves ionization of an electron into the conduction band (or a hole into the valence band). Since the band gap of zinc sulfide is about 3.8 ev (17), the depth of the traps involved (transition 2 in Fig. 12) should be about 1.4 ev, much greater than observed values. This failure of the measured activation energies to give the band gap when added to the energy of the emitted radiation contradicts the picture shown in Fig. 12. It is tempting, but doubtful, to explain this discrepancy by invoking Schön's hypothesis of widely different energy levels for thermal and optical processes (18).

In connection with Fig. 12, it may be worthwhile to mention the related concept of delayed recombination proposed by several workers (2, 3). According to this model, electrons removed from ionizable activators by collision excitation on application of a high field are quickly swept to the positive side of the crystal where they are held until removal of the field releases them for radiative recombination with empty centers. Thus excitation of luminescence centers is thought to occur only on the rise of an applied d-c voltage pulse while luminescence emission occurs primarily at the fall of the voltage as only then may electrons return to recombine with ionized centers. Frequently quoted evidence for this theory is the observation that $L_1 << L_2$. However, Fig. 4 and 5 reveal that $L_1 << L_2$ only for long repetition intervals and high temperatures. Over wide ranges of operating conditions, e.g., for t_2 up to an hour at $-125°C$, L_1 and L_2 are approximately equal. These measurements do not favor delayed recombination. In addition the delayed recombination mechanism is not applicable to activators for which the excited state is a bound perturbed ion state and the electron is never physically removed from the center, e.g., manganese.

In view of the difficulties with this model, we will propose a mechanism by which we hope to account for, among others, these experimental findings: (*a*) the light pulse emitted on application or removal of voltage decays with the time elapsed from the preceding field excitation (voltage shift); (*b*) temperature dependence of (*a*) resembles the emptying of trap distributions of depths between 0.3 and 0.8 ev; (c) there is a component of internal polarization which builds up and decays in synchronism with the above effect.

When an external field is applied to a phosphor, there is evidence (3) that large voltage drops are concentrated across small regions of the phosphor due to the existence of barrier layers or rectifying junctions. It is in these high field regions that electroluminescence takes place. Electrons are field-ionized from deep traps and then accelerated to optical energies by the field. Some of these "hot" electrons collide with activator centers and lose all or part of their kinetic energy in raising electrons to excited states from which radiative transitions back to the ground state may later occur. It is natural to assume that the number of luminescence centers excited will be proportional to the concentration of energetic free electrons which, in turn, should strongly depend upon the number of "loose" electrons (electrons thermally excited to or injected into the conduction band, or electrons in traps shallow enough to be directly ionized by the field) originally present to initiate the process. It is hypothesized here that the experimental facts listed above are due to time variations in this population of loose electrons. Thus we consider changes in the number of centers excited rather than changes in the efficiency of the radiative recombination to be the dominant factor.

It is proposed here that the light emissions L_1 and L_2 are independent luminescence events produced by separate excitations at the rise and fall of applied voltage, and that a difference in their intensities reflects a difference in the number of centers excited in each case. Application of the external field establishes a space charge as electrons are swept out of the high field region. The time required for the development of this polarization is of the order of the critical pulse width mentioned earlier (5). Some of the free electrons produced by the applied field are trapped in a normally unoccupied trap distribution. When the external field is removed, part of the polarization charge decays quickly in a time similar to the build-up time. However, that portion of the space charge consisting of electrons in deep traps decays very slowly at a rate determined by the thermal release of trapped electrons. This accounts for the last of the experimental facts listed above, viz., the "frozen-in" component of polarization observed by Waymouth and Bitter.

Consider an electroluminescent phosphor in an equilibrium condition ($t_2 \rightarrow \infty$) at a certain temperature. Application of a field finds a certain number of loose electrons available for acceleration and collision-excitation of luminescence emission L_1. Let us denote this value of L_1 for a first voltage application, i.e., L_1 for $t_2 \rightarrow \infty$, as $L_1°$. Removal of the external field momentarily leaves an unopposed polarization field which causes a second excitation of luminescence, L_2. However, this field finds a larger number of field-ionizable electrons as traps were

filled on the voltage rise. This increases the resultant number of hot electrons to take part in collision-excitation. Thus we may understand the situation whereby $L_1 << L_2$ without recourse to delayed recombination.

A second similar voltage pulse applied after a short time finds the same nonequilibrium concentration of loose electrons so that for short repetition intervals we find $L_1 \approx L_2$. A voltage pulse applied after a considerable elapsed time ($t_2 >> t_1$) will find the phosphor partially relaxed towards thermal equilibrium so that $L_1^\circ < L_1(t_2) < L_2$. From Fig. 4 and 5 we note that L_1° is about one-twentieth of L_2 for the manganese-activated phosphor, while for the copper-activated phosphor L_1° is below the limit of measurement, i.e., less than one-thousandth of L_2. Thus we may interpret (*a*) in terms of a return to thermal equilibrium of the number of field-ionizable electrons via the thermal emptying of an overpopulated trap distribution. The temperature dependence mentioned in (*b*) then follows naturally from Boltzmann statistics. These trapped electrons comprise the slowly decaying component of polarization mentioned above so that this polarization decays in synchronism with L_1, as stated in (*c*).

Although this mechanism accounts for the above experimental behavior it is not without its difficulties, a normal situation among electroluminescence theories. Since L_1 is assumed to vary with the number of occupied deep donors in the crystal, the effect should be largely independent of the particular luminescence center involved for a given host phosphor. However, we obtained different activation energies for the green and blue emissions of the copper-activated phosphor. Further assumptions may be needed to explain these observations in terms of our model. Another objection might be that filling of traps does not seem to occur to any great extent during electroluminescence as evidenced by the very weak glow curves following voltage excitation (9). This result may be due to the fact that electroluminescence is confined to just a small fraction of the phosphor volume. Also, other observations re-emphasize the importance of traps (19).

Summary

Measurements of the temperature-dependent decay of L_1 with t_2 suggest a process involving the thermal emptying of donors of depths between 0.3 and 0.8 ev. This phenomenon has been reported to be correlated with a polarization charge. We therefore attribute the traps to the host crystal rather than to the luminescence centers. The mechanism of delayed recombination does not appear to account satisfactorily for the data. An alternative suggestion is proposed whereby the number of filled deep donors is assumed to control the electroluminescence emission via the number of field-ionizable electrons available for collision excitation of centers.

Anodization of InSb

J. D. Venables and R. M. Broudy

Research Laboratories, National Carbon Company, Division of Union Carbide Corporation, Cleveland, Ohio

ABSTRACT

The dependence of the constant current anodization curve on crystallographic face and illumination is reported for monocrystalline InSb. It is shown that illumination changes the film formation rate, either increasing or decreasing it depending on certain experimental conditions. Photovoltages similar to those reported for other anodic films have been observed.

The work of Dewald (1) on anodization of InSb indicates that this material is in some ways particularly suited to a study of the general oxidation process. InSb forms in the zincblende structure which, although cubic, does not possess a center of inversion; therefore, opposite directions are not necessarily equivalent. This geometrical polarity, which also can be revealed by etching (2,3), is an important factor in the experiments of Dewald (1) in that he finds that (111) faces anodize at a faster rate than the $(\bar{1}\bar{1}\bar{1})$ faces.[1] In the present account we show the crystallographic dependence of the constant current anodization curves.

In the previous literature, several authors have reported a photodependence of the oxidation process for various materials such as Ta (4-6), Si (7), Cu (8), and Al (6). We have found that photoeffects also exist in the InSb system; several associated phenomena are reported here.

Apparatus

The experimental arrangement is shown in Fig. 1. An appropriately masked sample[2] with either the (111) or $(\bar{1}\bar{1}\bar{1})$ face exposed is made the anode in a 0.1*N* KOH solution held at constant temperature. An electronic constant current source serves as a power supply to provide current densities in the neighborhood of 200 μa/cm^2. Voltages which represent the drop across the anode film are monitored using a reference electrode of InSb connected to a recording voltmeter with a high input impedance.

The samples are x-ray oriented, cut, and then mechanically polished with various grades of alumina down to 0.1 μ which produces a mirror-like finish on the selected face. After masking, they are pre-anodized to 10-20 v and then immersed in concentrated HF which removes the oxide film but does not attack the InSb substrate. This process (pre-anodizing and film removal) is repeated until the anodization curves are completely reproducible.

[1] Allen (2) has made the correlation between anodization rates and etch pits. Pits appear on the $(\bar{1}\bar{1}\bar{1})$ face.

[2] The masking agent used was either polystyrene in toluene (1) or G.E. 1202 baking varnish. The latter is more durable.

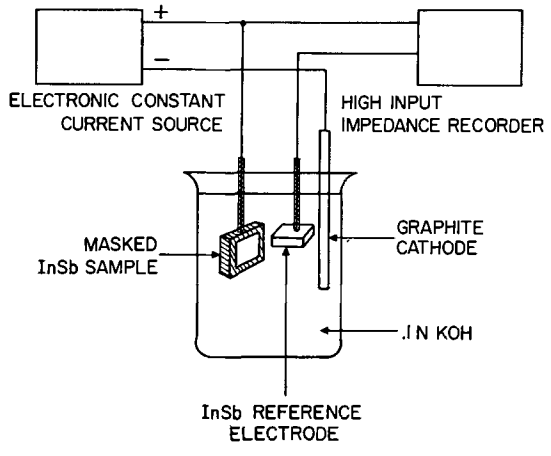

Fig. 1. Experimental arrangement for constant current anodization studies on InSb.

Anodization Curves

In Fig. 2 typical recorder curves of the voltage drop across the film on the (111) and $(\bar{1}\bar{1}\bar{1})$ faces are shown as a function of time at constant current. There are several features of the curves which are of interest: (*a*) the initial region of the two curves is similar and nonlinear, tending to curve upward until the turnover point is reached. The nonlinearity is perhaps a consequence of the formation of space charge in the oxide layers during anodization (9); (*b*) the turnover voltage is different for the two faces and is always greater for the $(\bar{1}\bar{1}\bar{1})$ face than for the (111) face, under identical experimental conditions. This unusual crystallographic dependence indicates that the turnover probably is not a

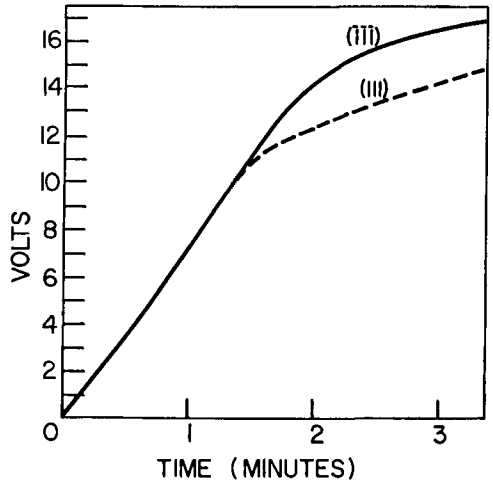

Fig. 2. Constant current anodization curves for (111) and $(\bar{1}\bar{1}\bar{1})$ faces of InSb.

consequence of the structure of the oxide film (porosity, cracks, etc.) but that the metal-oxide interface plays some role in the process.

When a piece of InSb is anodized with both the (111) and ($\bar{1}\bar{1}\bar{1}$) faces exposed, it is observed by means of interference colors that the film thickness is the same on both faces until the turnover region is reached. As anodization continues beyond this point, the interference colors indicate that a thicker film forms on the (111) face than on the ($\bar{1}\bar{1}\bar{1}$). By means of the following experiment we have shown that this is due to a redistribution of current density which takes place when the (111) face reaches its turnover point. The experimental arrangement is shown in Fig. 3. Two InSb samples with {111} faces of equal area but of opposite crystallographic sign are connected to a common constant current supply through separate ammeters. Since the voltage drop across the solution and cathodes is negligible, this is equivalent to anodizing a single sample having both crystallographic faces exposed, except that now the current through each face can be monitored separately. Initially both meter readings are the same; however, as soon as the (111) face reaches its turnover voltage for the currents involved, its resistance ceases to increase. Eventually most of the current flows through the (111) face producing a thicker film on it than on the ($\bar{1}\bar{1}\bar{1}$) face. Apparently this redistribution occurs because the electric field required for ion flow cannot be maintained across the film on the ($\bar{1}\bar{1}\bar{1}$) face after the (111) face attains the turnover voltage.

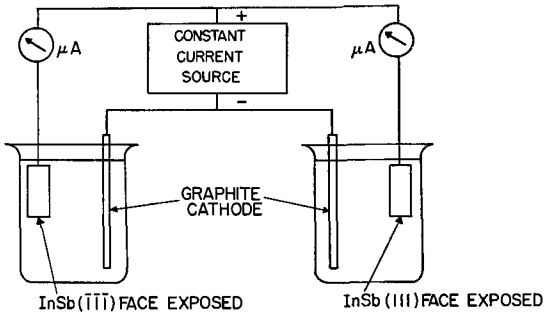

Fig. 3. Experimental arrangement to monitor current through (111) and ($\bar{1}\bar{1}\bar{1}$) faces separately.

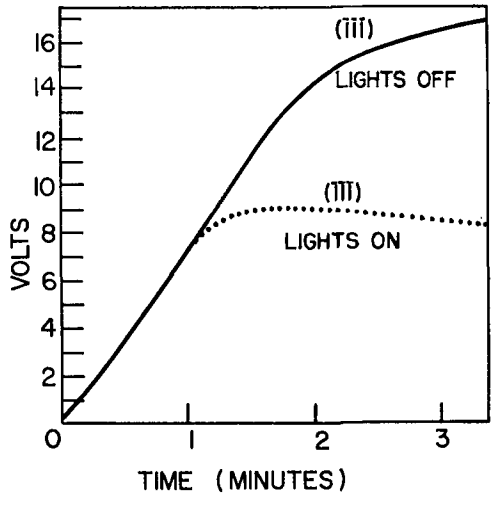

Fig. 4. Effect of illumination on constant current anodization curves.

Photoanodization

When a sample undergoing anodization is irradiated with visible light of wave length shorter than approximately 5200Å, it is observed that the initial part of the anodization curve remains unaffected but that the turnover voltage is decreased. The illumination from a 300-w slide projector produces the effect shown in Fig. 4. Accompanying this reduction in turnover voltage under the two sets of experimental conditions described below, there occurs a change in the film formation rate.

Condition No. 1.—The exposed face of an InSb sample is illuminated evenly and anodized under constant current conditions beyond the turnover point. The relative thickness of the film formed is measured using the step gauge method described by Dewald (1). The film is removed with HF and the sample, now in total darkness, is anodized again using the same value of current for the same length of time. Step gauge measurements show that the illuminated film is thinner than the one formed in darkness, indicating that the efficiency of film formation is lowered when the sample is illuminated.

Condition No. 2.—In this experiment, only half of the exposed InSb face is illuminated during anodization. The process is carried out past the turnover point and it is observed that the above situation is reversed. At first glance it appears that here the light increases the efficiency of film formation since the illuminated section is now thicker than the dark section. We have shown, in an experiment similar to the one discussed in the previous section, that this is actually due to a redistribution of current density which takes place when the illuminated section reaches the turnover. Figure 5 depicts the experimental arrangement. Two identical faces are anodized, one with illumination and the other without. The two samples are connected to a common constant current supply through separate meters.

Again it is observed that initially both meter readings are the same; however, as soon as the illuminated face reaches the light-induced turnover voltage its resistance ceases to increase with time and most of the current flows through that face. This produces a film on the illuminated face which is considerably thicker than the one which is formed

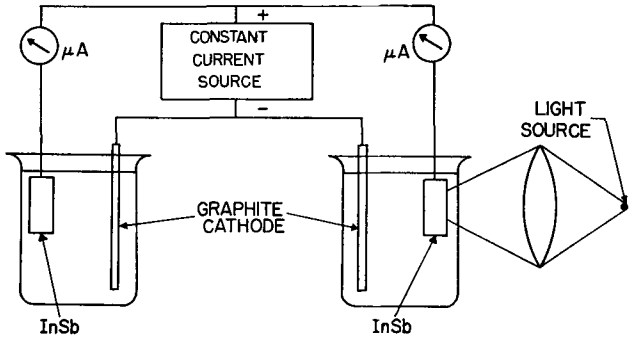

Fig. 5. Experimental arrangement to monitor current through illuminated and nonilluminated faces of InSb separately.

in darkness. A device which utilizes this photoanodization effect to record an image projected on the face undergoing anodization has been described elsewhere (10).

Photovoltages

When InSb of any orientation is anodized beyond the turnover point (it makes no difference whether the turnover is light-induced or not) and then removed from the circuit, it is found that a voltage appears across the film when illuminated. This photovoltage, which incidentally has the same polarity as the anodizing voltage, saturates at approximately 1.5 v and is similar in many respects (time constants, decay, internal impedance, etc.) to photovoltages found in Ta_2O_5 films by van Geel, Pistorius, and Winkel (8). Because of this similarity, no further description is given here. We do wish to point out, however, that the photovoltage demonstrates the existence of light-induced carriers (electrons or holes) in the system. We speculate that perhaps it is these carriers which serve to lower the film forming efficiency during photoanodization by providing electronic (or hole) conduction in addition to the ionic current.

Summary

The phenomena observed during our preliminary studies on the InSb anodic system have been presented at this time because of their unique character. No attempt has been made to interpret the data theoretically since several questions which are raised by this initial work remain to be clarified. For example, we do not know whether the crystallographic dependence of anodization rate as observed by Dewald (1) exists during the initial stages of the anodic process or occurs only near the turnover point as our initial experiments seem to indicate. In addition it is not known why the turnover occurs at all or why illumination changes the turnover point; it is possible that space charge effects which have been discussed by Dewald (9) and light-induced space charge effects which were hypothesized by Vermilyea (11) may be responsible for the observation phenomena.

Acknowledgments

The authors wish to thank Dr. R. G. Lye, Dr. W. Ware, and Dr. S. Senderoff for many helpful discussions of this work. They are also indebted to R. E. Hart, Jr. for his help in sample preparation.

Manuscript received Aug. 13, 1959.

Lifetime Preservation in Diffused Silicon

M. Waldner[1] and L. Sivo

Semiconductor Products Department, General Electric Company, Electronics Park, Syracuse, New York

ABSTRACT

Minority carrier lifetime in silicon which has been diffused in BCl_3 plus nitrogen at 1100°C may be in excess of 100 μsec. Diffusion at 1200°C may give lifetimes in excess of 25 μsec. The lifetimes are significantly higher than the values obtained by heat treatment without the BCl_3. A similar effect is observed if chlorine or PCl_5 is added to the nitrogen ambient. Some lifetime preservation after extended heat treatment following the BCl_3 treatment indicates that the glassy layer deposited during the treatment plays a significant role in the process.

Several methods for lifetime preservation during the heat treatment of silicon, such as is incurred during a diffusion process, have been reported. These include slow cooling (1), vacuum heat treatment (2), and gettering by a metal-silicon liquid phase on the silicon surface (3). The purpose of this paper is to show that relatively high lifetime may be maintained in silicon that has been diffused with boron, even with fairly rapid cooling, and that the diffusion process, using BCl_3 gas, plays a significant role in this lifetime preservation; furthermore, that chlorine gas or PCl_5 as well as the BCl_3 also give the effect of lifetime preservation.

The use of BCl_3 as a carrier for boron during diffusion has been noted by Fuller and Ditzenberger (4). Moreover, Prince (5) has noted that during the diffusion of boron in such a process lifetime regeneration of previously diffused silicon may be observed on thin samples.

Experimental Procedure

The diffusion and heat treatment were carried out in a dual tube furnace with 1⅛ in. ID quartz tubes. The silicon was in a 5-15 ohm-cm resistivity

[1] Present address: Hughes Products, Semiconductor Division, Newport Beach, California.

range with initial lifetimes in excess of 100 μsec. The silicon wafers were supported either horizontally in a separate quartz half tube or vertically in a slotted quartz holder. The wafers were from 35 to 60 mils thick. One of the quartz tubes was used to run control samples in a nitrogen gas flow of 10 ft³/hr.[2]

Three programs were used during the introduction of the BCl_3. They were as follows: Program A—The samples were introduced into the furnace, with only a nitrogen flow, followed by a BCl_3 flow of 0.04 ft³/hr with 18 ft³/hr of nitrogen, for 30 sec, 0.04 ft³/hr of BCl_3 and 10 ft³/hr of nitrogen for 30 sec, 0.04 ft³/hr of BCl_3 and 4 ft³/hr of nitrogen for 4 min, and 10 ft³/hr of nitrogen only for the rest of the run; Program B—The samples were introduced into the furnace, with only a nitrogen flow, followed by a BCl_3 flow of 0.04 ft³/hr with 10 ft³/hr of nitrogen for 30 sec, 0.04 ft³/hr of BCl_3 with 4 ft³/hr of nitrogen for 4 min, and 10 ft³/hr of nitrogen only for the rest of the run; Program C—A BCl_3 flow of 0.04 ft³/hr with 4 ft³/hr of nitrogen was established before introduction of the samples, which were then held at approximately a 500°C zone of the furnace for 1 min, a 900°C zone for 1 min, and at 1100°C for 4 min, followed again by a 10 ft³/hr flow of nitrogen only for the rest of the run.

The first of these programs, with the high initial nitrogen flow, was chosen to minimize back diffusion of air into the furnace. However, the programs which allowed higher initial BCl_3 concentrations, especially at low temperatures as in program C, gave the best results.

The PCl_5 was introduced by placing several grams of PCl_5 in the quartz tube at a point where the temperature was about 180°C. The PCl_5 gradually sublimed in the nitrogen carrier gas.

The chlorine heat treatment involved a chlorine flow rate of 0.04 ft³/hr for 4 min, mixed with 4 ft³/hr of nitrogen, followed by a chlorine flow rate of 0.01 ft³/hr, mixed with 10 ft³/hr of nitrogen, for the remainder of the run.

In most of the experiments the sample was cooled by turning the furnace off after the heat treatment. The resulting cooling cycle ("slow cool") is shown in Fig. 1. Two other cooling cycles were used. One involved cooling the sample by withdrawing it from the furnace during a 15-min period ("fast cool"); the other was a rapid withdrawal from the furnace ("air quench").

The pellets were prepared for diffusion by soaking in 48% nitric acid (to remove a nickel plate used in preliminary lifetime measurements), followed by three successive etches in "white" etch (4 parts HNO_3, 1 part HF), followed by a soak in HNO_3 and final rinses in deionized water and distilled water.

[2] All flow rates are given in air equivalent at 14.7 psi and 70°F.

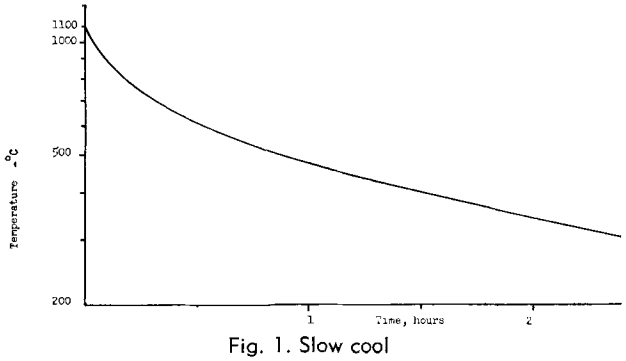

Fig. 1. Slow cool

The lifetime of the samples were determined by a measurement of the photoconductivity decay following excitation of excess carriers by a sparked light source (6). For all but the very short lifetimes, the illumination was through a 1.6 mm thick silicon filter. For measurements on the short lifetime samples either a 0.2 mm filter or no filter were used. Because trapping may have been present in the very low lifetime samples, the true lifetime may in some cases be less than the measured decay times which are given here. On the higher lifetime samples, with junctions, photovoltaic measurements (7) on several samples confirmed the spark data. For two samples an attempt was made to estimate the lifetime from the amplitude of the collected signal in the usual drift mobility experiment (8). These checks indicated that the measured lifetime in the n-type control samples was correct, but that the lifetimes measured on p-type control samples was much too high.

In many of the samples the minority carrier diffusion distance was so great that a very large correction, due to surface recombination, needed to be applied to the measured values. For this reason both the measured decay times and the corrected values are given.

Experimental Results

Lifetime Preservation

Below are listed the results for a number of experiments with the boron trichloride process, at 1100° for ½ hr, with "slow cooling." The boron diffused junction depth was about 0.04 mil. The control runs listed were run simultaneously with the listed boron diffusion of the same run number.

M2592: p-type Czochralski, 5-8 ohm-cm, approximately 7×10^3 dislocations/cm²
* No observable lifetime from drift mobility measurement.
† These measurements were made with no filter or a thin filter. At least half of the samples showed evidence of trapping in the shape of the decay curve.

Both high dislocation density floating zone and low dislocation density Czochralski n-type material gave consistently high lifetimes well above those obtained with the control samples. Control sample lifetimes were usually about 4 μsec, although one exceptional value of 14 μsec was observed during the experiment. Some variation would be expected in the control results because of the expected dependence upon cleanliness.

The results with p-type material have been somewhat more erratic. However, use of the program C has resulted in lifetime values comparable to those observed in n-type material. Furthermore, although the listed values for the control lifetimes are similar to those reported for the n-type material, many of these samples showed evidence of trapping. An effort to correlate the results with those of a drift mobility measurement, which was successful with one n-type sample, failed with the p-type sample. Consequently, it is likely that the measured decay times for these control samples are not characteristic of the recombination process but are dominated by trapping effects.

The lifetime in a larger number [36] of diffused junctions on lower resistivity, 0.5 to 1 ohm-cm, n-type silicon was measured by means of the photovoltaic effect. The median lifetime on these samples was in excess of 10 μsec.

The results with chlorine and PCl_5 added to the nitrogen are tabulated below. Slow cooling was used.

Run	Material	Measured t, μsec	Corrected t
11	M2455 (n-type)	45	74
11	M2455 (n-type)	22.5	76
33	M2455 (n-type)	21	26
16	M2455 (n-type)	16.5	20
32	M2455 (n-type)	21	26
31	XP3223 (p-type)	2.9	2.9
32	XP3223 (p-type)	7.1	7.1
41	M2455 (n-type)	5	5
(Chlorine for 4 min only)			
Control (vs. chlorine) 1100°C for ½ hr			
11	M2455 (n-type)	7	7
11	M2455 (n-type)	12.5	14
16	M2455 (n-type)	5	5
31	XP3223 (p-type)	2.5	2.5
PCl_5 at 1100°C for ½ hr			
37	M2455 (n-type)	29	58
37	XP3223 (p-type)	3.1	3.1

For both the chlorine and PCl_5 ambient the lifetimes, at least in n-type material, were higher than those of the control samples. When the chlorine was run only for a few minutes at the beginning of a run, as in run 41 above, no marked lifetime retention was observed. This is in contrast to the results with BCl_3.

In the case of the chlorine treatment, a significant difference in lifetime in several samples run together was noticed. For instance, for three samples placed vertically and directly behind each other in the gas flow at 1100°C the corrected values were 74, 52, and 29 μsec in order from the upstream end. This effect, if present, was much less pronounced with the BCl_3 process. The values in a corresponding experiment with the BCl_3 were 90, 90, and 72 μsec.

The tabulation below shows the results obtained when the diffusion time at 1100°C was extended, or the temperature raised to 1200°C. N-Type material was used.

Time and temperature	Measured t, μsec	Corrected t
2 hr at 1100°C	43	80
2 hr at 1100°C	37	60
21 hr at 1100°C	11.5	13
21 hr at 1100°C	19	24
21 hr at 1100°C Control	3.4	3.4
½ hr at 1200°C	26	38

Lifetimes in excess of those resulting from the heat treatment alone may be obtained during extended diffusion, or at 1200°C. In order to obtain the results quoted at 1200°C it was necessary to apply the boron from the BCl_3 at 1100°C and then raise the temperature to 1200°C. If the BCl_3 is introduced at 1200°C, the adherent glassy deposit otherwise obtained on the silicon surface is not observed. Instead, layers which were cracked and chipped were found.

The effect on the final lifetime of the three cooling cycles which were tried is shown below. N-type silicon diffused for ½ hr at 1100°C, with program A, was used. The fast, 15-min cooling was without

Cooling	t Measured, μsec	t Corrected
Slow cool	48	125
Fast cool	37	90
Air quench	7.5	7.5

serious effect, although the air quench did give much lower lifetime.

Lifetime Regeneration

An experiment was performed on several diffused silicon p-n junctions (provided by F. E. Gentry) to determine the feasibility of lifetime regeneration with the BCl_3 process. These samples had been diffused with gallium to a junction depth of about 3 mils. These samples were run through program C with slow cooling. The low-temperature step changed to 700°C for 1 min. Two samples were subjected to a control cycle with nitrogen ambient only. The photovoltaic method was used to measure the lifetime before and after the processing. Values quoted below may be taken only as relative values for this particular experiment because the boundary conditions imposed by the deeply diffused junctions are not those for which the photo-voltaic equipment was calibrated. Results are tabulated below.

Process		Initial t, μsec	Final t
Program C		1	6.8
		2.7	24.3
		3.6	11.9
		3.0	6.1
	Average	2.6	12.3
Control		3.4	2.3
		2.7	2.0

These results substantiate Prince's observation (5) that lifetime regeneration may be obtained in this way.

Discussion

The above data show that lifetimes of 20 to over 100 μsec may be obtained in diffused p-n junctions formed by the diffusion of boron from a BCl_3 carrier. The similar results obtained with PCl_5 and chlorine suggest that the chlorine liberated by the decomposition of the boron trichloride and phosphorus pentachloride plays a part in the process. However, good results can be obtained with BCl_3 even though the gas flows only a few minutes, while with chlorine a continuous flow is necessary. This suggests that the adherent glassy deposit formed on the silicon surface during the BCl_3 flow also plays a part.

Chlorine is known to attack many metals at elevated temperatures. Indeed, during the PCl_5 and chlorine experiments there was some attack even on the silicon. It may be that the chlorine provides an effective in-site etching and cleaning of the presumably contaminated silicon surfaces. Moreover, because of such an etching action, the chlorine may act as an impurity getter at the silicon surface during the diffusion. The results with BCl_3, despite the short application of the gas, suggest that the glassy surface layer may act as an impurity getter, or at least mask the silicon against the in-diffusion of impurities coming from the carrier gas or the walls of the furnace.

As has been described, a BCl_3 program that had beneficial effects on the n-type material did not work as well on the p-type material. It was necessary to modify the process to obtain markedly improved results on p-type material. This suggests that, at least under the conditions of these experiments, an impurity (not necessarily the only one) was present which was particularly effective in reducing the lifetime in the p-type material, and was particularly difficult to remove from the system.

Acknowledgments

The writers wish to thank R. E. Hysell for his assistance and instruction in the lifetime measurements, J. P. Dietz for making the dislocation density estimates, J. E. Greever and D. C. Jillison for supplying the silicon crystals, and J. F. Elliott for discussions of his related work which initially suggested this study.

Manuscript received Sept. 18, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Electrolytic Reduction of Nitro- and Dinitrotetralins

R. N. Boyd, A. A. Reidlinger, and M. J. Sher

Department of Chemistry, Washington Square College, New York University, New York, New York

ABSTRACT

The polarographic reduction of mono- and dinitrotetralins was studied in buffered solutions at four different *p*H values. The reduction became more difficult and was less complete with increase in *p*H. The relative heights of the multiple waves were interpreted in terms of certain electron changes, and these were checked by coulometric measurements at controlled potentials. The first stage in reduction in the tetralin series appears generally to be a four-electron change as it is in the benzene series.

In the course of other work in this laboratory it was found necessary to prepare most of the isomeric dinitrotetralins. From a search of the literature it became evident that a study of the polarographic behavior of the dinitrotetralins would be a logical extension of the work carried out by Pearson (1) on various dinitro compounds in the benzene series.

For the sake of completeness all four possible dinitrotetralins as well as the two known mononitrotetralins were prepared; 5 x 10^{-4}M solutions of the nitro compounds in 80% ethanol were studied in four buffered solutions. The compounds were also studied by constant potential coulometry to determine the number of electrons associated with each polarographic wave.

Experimental

6-Nitrotetralin (2), 5-nitrotetralin (3,4), 5,6-dinitrotetralin (2), and 5,7-dinitrotetralin (2) were prepared by methods given in the literature.

5,8-Dinitrotetralin.— 5-Aminotetralin (5) was nitrated (2) to give a low yield of 8-nitro-5-aminotetralin. One gram of the nitroamine was stirred into a mixture of 4 ml trifluoracetic acid and 0.5 ml 90% hydrogen peroxide (6); the solution was kept below 50° for 1 hr. At the end of this time the reaction mixture was poured over ice. The solid dinitro product was filtered off and recrystallized from ethanol. Yield, 0.1 g, mp 88.0°-88.1° [Literature: 87-88° (7)].

6,7-Dinitrotetralin.—6-Aminotetralin (3, 4) was transformed by nitration (2) to give 7-nitro-6-aminotetralin. One gram of the nitroamine was oxidized by trifluoroacetic acid and 90% hydrogen peroxide as described previously. The dinitro product was recrystallized from methanol. Yield, 0.3 g, mp 109.0°-109.2° [Literature: 108° (2)].

Polarographic procedure.—The polarograph employed was a Fisher Elecdropode which had been calibrated against a Type K L&N potentiometer. The electrolysis cell was a modified H-type cell. At a drop time of 4.0 sec with an open circuit and using an alcohol solution buffered by acetic acid and sodium acetate, the drop weight was 6.5 mg. The electrolysis cell was immersed in a thermostat maintained at 25°± 0.2°, and a saturated calomel electrode was used as the anode. Dissolved oxygen was removed by bubbling prepurified nitrogen through the solution for 20 min; the gas was previously passed through another sample of the solution under test. The polarographic curves were plotted as the experimentally determined currents minus the blanks. The half-wave potentials were corrected for *IR* drop.

The solutions were made by adding 10.0 ml of the proper buffer solution to 40.0 ml of 95% ethanol which was 6.25 x 10^{-4}M in nitro compound and then adding sufficient 95% ethanol to give a total volume of 50.0 ml. The apparent *p*H values of the solutions were measured using a Beckman *p*H meter Model G.

The buffer solutions were the following: for *p*H 2.1, 0.800M potassium chloride, 0.100M hydrochloric acid; *p*H 6.4, 4.00M sodium acetate, 3.00M acetic acid; *p*H 9.4, 1.00M triethylamine, 0.500M hydrochloric acid; *p*H 11.0, 1.00M phenol, 0.500M sodium hydroxide. All buffers were also made 0.050% in methyl cellulose. C.p. chemicals were used in each case.

Coulometric procedures.—Electrolyses were performed on 2-5 x 10^{-4} solutions of the nitro compounds in 80% ethanol. Initial currents were low due to low solubility of the nitro compounds and were generally of the order of 20 to 50 ma. The reductions were usually allowed to proceed to zero current (or at most 0.1-0.5 ma) and they generally lasted for 2-4 hr.

Electrolyses were carried out at a stirred mercury cathode at *p*H 2.1. Potentials (vs. SCE) were maintained constant (±15 mv) by means of a Lingane-Jones potentiostat (8) at values which were read from the polarographic curves. Those values were selected which appeared to offer the best chances for step-wise reductions.

The electrolytic cell consisted in the main of a standard three-neck one-liter round-bottom flask to which an extra neck had been added. One neck was fitted with a nitrogen bubbler which extended to the bottom of the flask and a 4-ft length of 6-mm tubing which served as an outlet. The center neck was fitted with the portion of the cell that served as the anode compartment; it consisted of a piece of an 8-in Pyrex test tube to which an 18-mm fritted-glass filter of medium porosity was fused. The anode was a silver gauze in contact with nearly saturated aqueous potassium chloride. A third neck

[a] Estimated to nearest integral number of electrons from wave heights of the polarographic curves.

was fitted with a glass-sealed platinum wire through which contact was made to the 50 ml of triply distilled mercury which served as the cathode. The remaining neck was fitted with a saturated potassium chloride salt bridge (9) that was in contact with the cathode and led to the same calomel electrode that was used in determining the polarographic curves. Stirring was done by a magnetic stirring motor and a Teflon-covered stirring bar.

A silver coulometer of the usual design (10) was placed in series with the electrolysis cell.

In operation, 500 ml of buffer solution were introduced into the flask and deaerated for 30 min with prepurified nitrogen. The electrolysis of the buffer solution was carried out at −1.03 v (vs. SCE) until the current dropped to approximately 0.2 ma, and then the circuit was opened. Twenty to thirty milligrams of nitro compound were introduced, deaeration was resumed, and stirring was maintained for ½ hr to insure complete dissolution. The coulometer was then placed in series with the cell, and the circuit was closed. The electrolysis was allowed to proceed at the desired potential until the current dropped to a negligible value. It was found necessary to have a vigorous stream of nitrogen bubbling through the cell at all times during an electrolysis in order to prevent atmospheric oxygen from diffusing into the system.

Coulometric values obtained from the nitro- and dinitrotetralins are listed in Table I.

Large-scale reduction of 1,3-dinitrobenzene.—The anode compartment was a 150-ml porous cup, the anolyte was 20% sulfuric acid, and the anode was a carbon rod. The entire assembly was suspended in a 400-ml beaker which served as the cathode compartment. A pool of mercury covering the bottom of the beaker was used as the cathode. Its potential was controlled by a Lingane-Jones potentiostat (8) just as in the coulometric procedure. The cathode compartment was fitted with a nitrogen bubbler. The catholyte was stirred with a Teflon-covered stirring bar and a magnetic stirring motor.

Dissolved oxygen was removed from the catholyte by bubbling nitrogen through the solution for 20 min. Pre-electrolysis of the catholyte, consisting of 250 ml of the buffer solution (pH 6.4), was carried out at −0.60 v (vs. SCE) until the current dropped to a negligible value (2 ma). This took about 20 min. The circuit was opened and 1,3-dinitrobenzene (1.5 g) was introduced, and nitrogen was bubbled through the cell for 30 min. At the end of this time, the circuit was closed again, and the electrolysis was allowed to proceed at −0.50 v vs. SCE (value chosen from the polarogram). The initial current was 0.150 amp, and the electrolysis was allowed to continue until the current dropped to 2 ma.

The solvent was removed at reduced pressure, and the orange-yellow residue was recrystallized twice from benzene. The yield was 0.8 g of N-(3-nitrophenyl)hydroxylamine, mp 119°-119.5° [Literature: 118°-119° (11)].

The same product was obtained from a reduction at −0.55 v (vs. SCE) in which a nickel gauze cathode and a platinum anode were used.

Discussion

Pearson (1) has claimed that the first of the multiple waves obtained from the polarographic reductions of dinitro compounds is usually that corresponding to a four-electron change, the transformation of a nitro group to a hydroxylamino group. Present coulometric data amply confirm this conclusion for the nitro- and dinitrotetralins.

The polarogram obtained by Pearson (1) from *m*-dinitrobenzene is very similar to the one that he obtained from 2,4-dinitrotoluene and to the one obtained in the present work from 5,7-dinitrotetralin. Large-scale electrolytic reductions of *m*-dinitrobenzene at controlled potentials and at pH 6.4 show that N-(3-nitrophenyl)hydroxylamine is indeed the first reduction product, the result of a four-electron change. *m*-Dinitrobenzene rather than a dinitrotetralin was chosen for a test of the coulometric procedure at controlled potentials because it gives an intermediate that is stable enough to be isolated and identified.

It is shown conclusively by coulometry that reductions in acid lead to complete reduction with the formation of polyamines (for a dinitro compound this requires twelve electrons). At pH 9.4 complete reduction becomes more difficult, and the final product may be a bis-hydroxylamine (an eight-electron change) or an aminohydroxylamine (a ten-electron change). At pH 11 the curves are rather diffuse and difficult to interpret simply. The diffuseness may be due to secondary electrode processes involving reduction of condensation products.

It can be seen from Table II that as the pH increases the separation between the component waves also increases. Pearson (1) suggested for the dinitrobenzenes that this was due to a decrease in salt formation in alkaline media, and the same seems to hold in the present case.

It can also be seen that 5-nitrotetralin is more difficult to reduce than 6-nitrotetralin. This is in good agreement with the findings of Pearson (1) that o-nitrotoluene is more difficult to reduce than either *m*- or *p*-nitrotoluene. It may also be mentioned that when a mixture of 5-nitrotetralin and 6-nitrotetralin is allowed to react with a limited amount of sodium hydrogen sulfide, only 6-nitrotetralin will be reduced.

[a] The values of $E_{1/2}$ are in volts vs. SCE, and those of i_d/C are in μa/mmole/l. A question mark indicates that the wave is too indefinite to assign values with any degree of certainty.

An examination of Fisher-Hirschfelder molecular models showed that the three atoms of the nitro group in *o*-nitrotoluene or 5-nitrotetralin cannot so easily lie in the plane of the aromatic ring as in the other isomers. As a result of the probable steric inhibition of resonance, the hindered nitro group should be expected to be more like an aliphatic nitro group which, in general, is the more difficult to reduce (12).

Finally, as might be expected, present results with the dinitrotetralins present a striking concordance with the work of Pearson (1) on *ortho-*, *meta-*, and *para*-dinitro compounds in the benzene series.

Acknowledgment

The authors wish to thank Dr. R. T. Schenck for his suggestions concerning some of the apparatus used in this work. They are also grateful to the Minnesota Mining and Manufacturing Company for the gift of trifluoroacetic acid, and to the Becco Chemical Division of the Food Machinery and Chemical Corporation for the gift of 90% hydrogen peroxide.

Manuscript received Aug. 20, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Decomposition of Uranyl Fluoride between 700° and 950°C

L. M. Ferris and F. G. Baird[1]

Chemical Technology Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee[2]

ABSTRACT

The thermal decomposition of uranyl fluoride was studied by a thermogravimetric technique between 700° and 950°C. At temperatures below 900°C, the main decomposition reaction is

$$3\ UO_2F_2 \rightarrow 2/3\ U_3O_8 + UF_6 + 1/3\ O_2$$

In an atmosphere of dry helium, the rate of decomposition was first order with respect to uranyl fluoride. The rate constants, determined with a constant helium flow rate of 270 cc (STP)/min, were $k = 3.72 \times 10^{11} \exp(-71{,}800/RT)$. Sublimation of uranyl fluoride, as a parallel, first order process, occurred at temperatures above 825°C.

Previous investigators (1) have reported that uranyl fluoride undergoes thermal decomposition at temperatures as low as 300°C. Several decomposition products, which include the uranium oxides U_3O_8 and UO_2, and uranium tetrafluoride were found under various conditions, but the data were insufficient to determine the exact stoichiometry. In contrast, preliminary data obtained in this laboratory (2) indicated that uranyl fluoride was quite stable in a dry atmosphere below 700°C. Above this temperature slow decomposition occurred, apparently according to the reaction $3\ UO_2F_2 \rightarrow UF_6 + 2/3\ U_3O_8 + 1/3\ O_2$. Further work performed in this laboratory, which supports the preliminary data, is presented in this paper.

Experimental

Materials.— High-purity uranyl fluoride was prepared by the ion exchange method of Higgins, Roberts, Hancher, and Marinsky (3). Details of the method are given in Fig. 3 of their article. The product was quite hygroscopic and initially contained 4.5 w/o (weight per cent) water. During the course of the investigation, the water content increased to about 6.2 w/o. It was demonstrated, however, that complete dehydration could be achieved at 150°-250°C without causing pyrohydrolysis. The purity of the dehydrated uranyl fluoride was 99.4 ± 0.3%. The major impurities were uranium dioxide and uranium tetrafluoride.

All gases used in the study were of high purity. Before use they were dried carefully by passage through ta charcoal bed, held at −196°C, and two Drierite bulbs.

Apparatus.—Weight loss data, used in determining the stoichiometry and rates of decomposition, were obtained with a semi-automatic, recording thermobalance. The thermobalance provided a continuous plot of the sample weight vs. time. Details of this instrument and its operation may be found elsewhere (4).

Procedure.—At the start of each experiment, a 2-g sample of the hydrated uranyl fluoride was weighed accurately into a small platinum basket. This sample was then transferred to the thermobalance reaction chamber where it was dehydrated by heating to about 230°C in a stream of dry helium. Reaction rates were obtained by continuously recording the isothermal weight loss due to decomposition at several predetermined temperatures. A gas flow rate of 270 cc (STP)/min was used in each experiment.

Determination of the Stoichiometry

Prior to initiation of the experimental work, estimates were made of the standard free energy changes of the following reactions which include all the decomposition products reported by other workers (1):

$$UO_2F_2 \rightarrow UO_2 + F_2 \qquad [1]$$

$$2\ UO_2F_2 \rightarrow UO_2 + UF_4 + O_2 \qquad [2]$$

$$3\ UO_2F_2 \rightarrow UF_6 + 2/3\ U_3O_8 + 1/3\ O_2 \qquad [3]$$

$$4\ UO_2F_2 \rightarrow UF_4 + U_3O_8 + 2\ F_2 \qquad [4]$$

$$3\ UO_2F_2 \rightarrow 2\ UO_2 + UF_6 + O_2 \qquad [5]$$

A plot of $\Delta F°$ vs. temperature for reactions [1]-[4] is found as Fig. 2, Ref. (2). For reaction [5], $\Delta F°$, in kcal, can be computed from the equation $\Delta F° = 109\text{-}0.085\ t$ where t is °C. The free energy change is positive for all the reactions; however, that for reaction [3] is the least positive of the others and could be expected to be the main reaction in a dry system.

In accordance with the thermodynamics, uranouranic oxide (U_3O_8) was the only decomposition product which could be identified by x-ray analysis at temperatures below 880°C. At 900°C, a small amount of uranium dioxide was present in the product.

Reaction [3] was shown to be the main decomposition reaction by comparison of the calculated weight losses and chemical analyses expected from reactions [1]-[5] with those obtained by decomposing uranyl fluoride at 880°-900°C until constant

19	880		41.4	83.6	38.7	0.10

[a] Weight losses and composition of the residues were calculated for complete decomposition according to reactions [1]-[5].
[b] In each case the decomposition was essentially complete, i.e., the residue had attained a constant weight.
[c] Analysis is obviously low.

weight was obtained (Table I). Reactions [1], [2], and [4] may be eliminated from consideration at the outset on the basis of weight loss alone. Comparison of the uranium (IV) analysis of the residue with that expected from reactions [3] and [5] leaves no doubt that reaction [3] is the main decomposition reaction.

A rapid loss in weight, corresponding to complete dehydration, occurred at temperatures below 250°C. Any further weight loss was attributed to the decomposition of uranyl fluoride. In all cases, the per cent weight loss due to decomposition was slightly greater than expected from reaction [3]. As indicated by the uranium (IV), fluoride, and x-ray analyses, reaction [2] may also have occurred to a slight extent. In most cases the residue was found to be virtually pure U_3O_8; therefore, it was concluded that the excess weight loss was due primarily to simultaneous sublimation of uranyl fluoride. It is important to note that if reaction [2] occurred to a significant extent the weight loss would be less than expected from reaction [3] alone.

Rates of Decomposition in Dry Helium

If it is assumed that the following parallel, first order reactions

$$UO_2F_{2(s)} \xrightarrow{k} 2/9\ U_3O_{8(s)} + 1/3\ UF_{6(g)} + 1/9\ O_{2(g)} \quad [3]$$

$$UO_2F_{2(s)} \xrightarrow{k_v} UO_2F_{2(g)} \quad [6]$$

account for the total loss in weight when a sample of uranyl fluoride undergoes decomposition, the following equation is easily derived

$$\frac{-dw_s}{dt} = (fk + k_v)\ w \quad [7]$$

In Eq. [7], w_s is the sum of the weights of uranyl fluoride and urano-uranic oxide, i.e., the weight of the sample at any time, w is the weight of uranyl fluoride at any time, and f is a stoichiometry factor defined by

$$f = \left[1 - \frac{2/9 M_{U_3O_8}}{M_{UO_2F_2}} \right] = 0.3925 \quad [8]$$

in which M is the molecular weight of the respective compound. Since

$$w = w^\circ \exp\left[-(k + k_v)t\right] \quad [9]$$

Eq. [7] may also be expressed as

$$\frac{-dw_s}{dt} = (fk + k_v)\ w^\circ \exp\left[-(k + k_v)t\right] \quad [10]$$

For convenience, define

$$X = fk + k_v \quad [11]$$

$$Y = k + k_v \quad [12]$$

Then, integration of Eq. [10] with the boundary condition that $w_s = w_s^\circ$ at $t = 0$ yields

$$w_s - w_s^\circ = \frac{Xw^\circ}{Y}\left[\exp\left(-Y\,t\right) - 1\right] \quad [13]$$

Rearrangement of Eq. [13] and conversion to common logarithms gives

$$\log\left[\frac{Y(w_s - w_s^\circ)}{Xw^\circ} + 1 \right] = \frac{-Yt}{2.303} \quad [14]$$

Equation [14] contains the two desired quantities, k and k_v, in terms of experimentally measurable quantities, but it cannot be used directly. However, the rate constants may be evaluated by the following method, if the assumptions made above are valid. The quantity X may be computed from the initial slope of a plot of sample weight vs. time, i.e., at $t = 0$, Eq. [10] reduces to

$$\frac{-dw_s}{dt} = Xw^\circ \quad [15]$$

Once X is known, Y may be evaluated from Eq. [14] by successive approximations using the experimentally determined weight-time data. Arbitrary values for Y are used in the calculation of the logarithmic portion of Eq. [14]. This logarithmic quantity is then plotted vs. time. If the value chosen for Y is not the correct one, a curved plot will result. Successive approximations are continued until the plot becomes linear. Then, as required by Eq. [14], the value of Y used in the calculation of the logarithmic term will equal that calculated from the slope of the line. The rate constants k and k_v can then be obtained by solving Eq. [11] and [12] simultaneously.

For the special case where no sublimation occurs, Eq. [14] reduces to

$$\log\left[\frac{w_s - w_s^\circ}{f w^\circ} + 1 \right] = \frac{-kt}{2.303} \quad [16]$$

Here a plot of the logarithmic term vs. time should be linear with k evaluable from the slope.

Figure 1 contains several examples of the type of first order plot which results when the rate of sublimation is negligible, i.e., k_v is approximately zero. The lower curve in Fig. 1 illustrates the marked deviation from linearity which results if

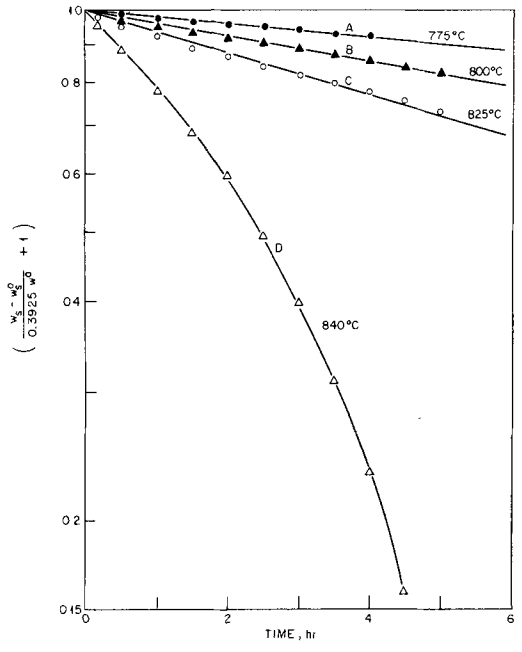

Fig. 1. Decomposition of UO_2F_2, showing a single first-order process below 825°C.

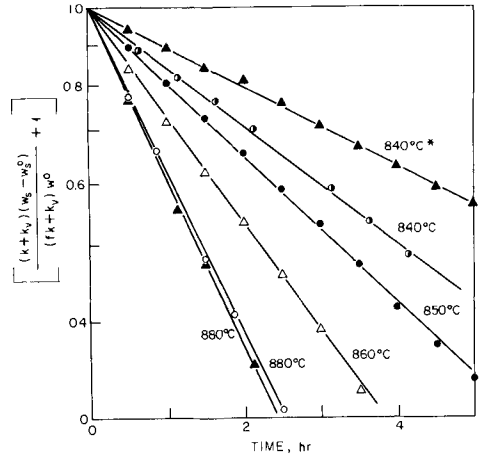

Fig. 2. Representative plots obtained when decomposition and sublimation of UO_2F_2 are considered parallel, first-order processes at temperatures above 825°C.
* Curve plotted from same weight-loss data as the lower curve in Fig. 1.

sublimation is ignored at temperatures above 825°C. Use of Eq. [14] to show that decomposition and sublimation are parallel, first order reactions is illustrated by Fig. 2. It should be noted that the upper curve in Fig. 2 was plotted from the same data used to plot the lower curve in Fig. 1. Table II contains the rate constants obtained over the temperature range of 750°-880°C., while a least squares plot of log k vs. $1/T$ is found in Fig. 3. The temperature dependence of the rate constant for the decomposition reaction is $k = 3.72 \times 10^{11} \exp(-71{,}800/RT)$.

Discussion of Results

Consideration of several other variables would be necessary before a detailed rate expression could be determined. Among the important variables omitted in this study were the effects of oxygen partial pressure, gas velocity, and gas density on the rate of decomposition. The results of preliminary

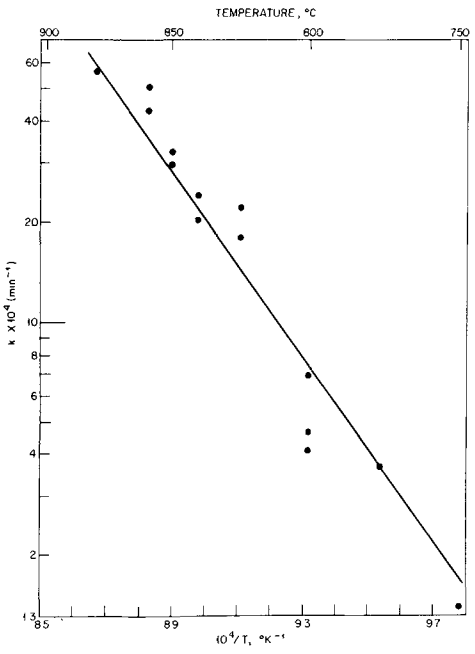

Fig. 3. Rate constants for the reaction 3 $UO_2F_2 \rightarrow$ 2/3 U_3O_8 + UF_6 + 1/3 O_2.

experiments (Table III) indicated that the rate of decomposition decreased with increasing oxygen partial pressure.

An attempt was made to estimate the heat of

sublimation of uranyl fluoride by assuming that the slope of a plot of log k_v vs. $1/T$ was equal to the heat of sublimation. However, the scatter in the values of k_v precluded any such estimation.

Acknowledgment

The authors are pleased to acknowledge Mr. I. R. Higgins for the preparation of the uranyl fluoride, and Mr. J. F. Land for his assistance in performing the experiments. Chemical and x-ray analyses were provided by the groups of Mr. G. R. Wilson, Mr. W. R. Laing, and Mr. R. L. Sherman, of the ORNL Analytical Chemistry Division.

Manuscript received Aug. 13, 1959. This paper was presented before the Nuclear Technology Subdivision, American Chemical Society, Boston, Mass., April, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Some Properties of Aluminum Nitride

K. M. Taylor and Camille Lenie

Research and Development Division, The Carborundum Company, Niagara Falls, New York

ABSTRACT

Aluminum nitride crystals in the form of six-sided prismatic needles, up to 0.5 mm in diameter by 30 mm long, and thin plates, 2-3 mm in diameter, have been prepared by vaporization of aluminum in a nitrogen atmosphere at temperatures ranging from about 1800° to 2000°C, and the properties of the crystals determined. Also, an aluminum nitride body, having a density of 98% of theoretical, has been prepared by hot pressing the fine powder, and a study made of its properties.

Aluminum nitride, AlN, consists of 65.81% aluminum and 34.19% nitrogen. Although aluminum nitride was prepared many years ago, its properties have not been well known. Early investigators considered it too unstable, especially with respect to moisture and oxidizing conditions, to be useful as a refractory. More recent work, however, has indicated that aluminum nitride, prepared at high temperature, is relatively inert and, therefore, may have applications as a refractory.

Reconsideration of the potentialities of aluminum nitride as a refractory appears to have started with a publication (1) in 1956 by Kohn and associates of the U. S. Bureau of Mines. These investigators incidentally obtained small crystals of aluminum nitride while working at high temperatures on another project and reported that the crystals were inert to hot and cold mineral acids and alkali solutions. Other recent workers who found aluminum nitride a relatively stable material include Rey (2), Renner (3), and Long and Foster (4). Notwithstanding the considerable recent work on aluminum nitride prepared at high temperature, there is still disagreement on many of its properties such as melting point, hardness, color, and oxidation resistance.

Refractories based on aluminum nitride are not now commercially available, although Rey (2) has prepared aluminum nitride brick by a sintering process and Long and Foster (4) have made laboratory-size crucibles, also by a sintering method. In addition, Johnson (5) has prepared a composite aluminum nitride-cryolite body, and Taylor (6) has used aluminum nitride as a bond for other refractory materials. High density, impervious, essentially pure aluminum nitride ware, however, has not previously been made.

The objects of the present work were to study crystalline aluminum nitride further, especially those properties which are still in dispute, and to prepare and determine the properties of a high-density aluminum nitride body. In the latter instance, hot pressing was chosen as a method of fabrication because preliminary experiments indicated that it would yield ware of maximum density, and, therefore, of optimum physical properties.

Crystalline Aluminum Nitride

Formation of Crystals.—Two methods of forming the crystals were tried: (*a*) heating aluminum nitride powder in a nitrogen atmosphere at high temperatures to induce crystal growth by recrystallization, and (*b*) heating aluminum metal powder in a nitrogen atmosphere to sufficiently high temperatures to vaporize the aluminum and thus form crystals by a vapor phase reaction. The second method was more effective and was used to prepare most of the crystals described in this report.

Sintered aluminum nitride boats and crucibles were used as containers in vaporizing the metal. The reaction was carried out in a horizontal graphite tube resistance furnace or in a vertical induction furnace having a graphite susceptor. In the horizontal resistance furnace, it was possible, using an optical pyrometer with telescope, to follow the origin, growth, and development of the crystals and to measure the corresponding temperatures at the same time.

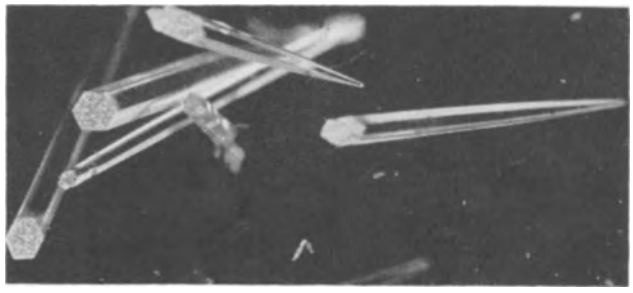

Fig. 1. Aluminum nitride crystals in the form of six-sided prismatic needles, obtained by nitriding aluminum vapors at 1850°C.

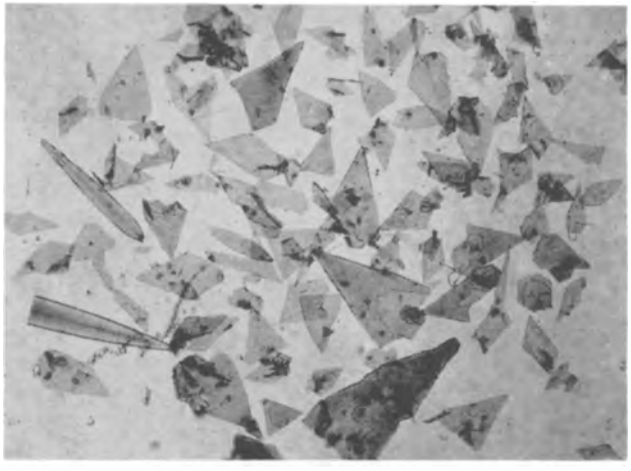

Fig. 2. Plate-like crystals of aluminum nitride formed by heating aluminum nitride powder in nitrogen at temperatures in excess of 1900°C.

It was observed that short, extremely fine filaments of aluminum nitride formed in the range of 1450°-1750°C, while at 1800°-1900°C the crystals were predominantly well-defined six-sided prismatic needles, some of which were about 0.5 mm in diameter and 30 mm long (Fig. 1). Some elongated plates also formed in this temperature range. At 1900°-2050°C, new growth appeared mainly as plates (Fig. 2), while above about 2050°C, previously formed crystals began decreasing in size very slowly due to vaporization. In the case of the prismatic needles shown in Fig. 1, the tapered end was the free end.

Color.—The color of the crystals varied from white to various shades of blue. Rey (2) states that pure aluminum nitride forms blue hexagonal crystals. Long and Foster (4) claim that pure aluminum nitride is water white and that the blue coloration results from the presence of about 7% aluminum oxycarbide (Al_2OC) in the crystals. They report that aluminum oxycarbide is isomorphous with aluminum nitride and that formation of solid solution between the two compounds is very likely. They suggest that Al_2OC results from a reaction between carbon monoxide, incidentally formed in the graphite lined furnace, and aluminum in the sample. In order to test these theories, aluminum nitride crystals were formed in carefully controlled atmospheres of (*a*) nitrogen only, (*b*) in nitrogen containing 0.5-2% of carbon monoxide, and (c) in nitrogen containing 1% of methane. Blue crystals formed only when carbon monoxide was present, the shade of blue becoming deeper with increasing amount of carbon monoxide in the nitriding atmosphere; 0.5% carbon monoxide resulted in light blue crystals, while 2% carbon monoxide produced dark blue crystals. Chemical analysis of the crystals showed the presence of carbon and oxygen in an approximately equimolecular ratio. The percentage of carbon varied from a few tenths of a per cent in the light blue crystals to about 2% in the deeper colored crystals. If carbon and oxygen are combined as aluminum oxycarbide, Al_2OC, as stated by Long and Foster (4), then the amount of this compound in the crystals prepared in the present study ranged up to about 14%.

Crystal structure and density.—Both the white and blue crystals have the hexagonal wurtzite structure. Other investigators have reported cell dimensions as follows:

Investigator	Type of material	Cell dimensions a_0	Cell dimensions c_0
Ott (7)	Powder	3.113	4.981
Stackelberg and Spiess (8)	Light gray powder	3.104±0.005	4.96±0.008
Kohn, Cotter, and Potter (1)	Blue crystals	3.10±0.01	4.965±0.01
Paretzkin (9)	Powder	3.114	4.986

In the present investigation, unit cell dimensions were determined by x-ray diffractometer back reflection techniques. Each sample was standardized independently with a spectrographically pure silicon sample. The National Bureau of Standards value of $a = 5.4301$Å for silicon was used.

The following values were obtained for light colored aluminum nitride: $a = 3.111$Å; $c = 4.980$Å.

A sample of the dark blue crystals containing approximately 2% carbon and 2.7% oxygen produced an x-ray diffraction pattern with broader reflections, some of which showed three distinct peaks. Most of these were shifted from the peaks of the light material. Values of 3.11-3.13Å for the *a* dimension and 4.93-4.98Å for the c dimension were obtained, depending on which peak was evaluated. Differences in reflections of the white and blue crystals were not detected when the usual film techniques were used. Possibly the blue samples contained enough pure AlN to overshadow the less prominent shifted reflections. Also, the general broadening would tend to produce the same geometrical center for the reflections of both the white and blue crystals.

The density of aluminum nitride, calculated from the cell dimensions $a = 3.111$Å and $c = 4.980$Å, is 3.26 g/cc.

Melting point.—The literature reports melting points in the range of 2000°-2400°C. Renner (3) observed strong vaporization of aluminum nitride at 2450°C, but no melting. The present investigation confirms Renner's conclusions. The experiments were carried out in a microfurnace (10) at atmospheric pressure in argon. Well-formed prismatic crystals, about 0.2-0.5 mm thick by about 2-5 mm long, were heated in a V-shaped tungsten crucible,

making observations with an optical pyrometer. The crystals were heated to 1800°C in 2-3 min, after which the temperature was increased at the rate of about 200°C/min. Some vaporization could be observed at 2300°C; at 2450°C vaporization was rapid, and after 1 min at 2500°C the crystals had completely disappeared without evidence of melting. In some experiments, crystals were heated to 2450°-2500°C in about 3 min and then immediately allowed to cool. The crystals had partially vaporized, but no evidence of melting was observed.

Hardness.—Hardness values on the Mohs scale ranging from 5 to between 9 and 10 are found in the literature. No accurate microhardness indentations have been reported. However, crystals obtained in the present research were sufficiently large that Knoop indentations could be made readily. All indentations were made with a load of 100 g, the force being applied perpendicular to the c or long axis of the crystal. Some indentations were made with the long diagonal of the indenter parallel to, and some perpendicular to the c axis of the crystal. Results varied somewhat with the direction, probably because of the anisotropic nature of the crystals. The over-all hardness of aluminum nitride appears to be approximately 1200. This is equivalent to a hardness of slightly higher than 7 on the Mohs scale. Detailed hardness data are seen in Table I.

Oxidation resistance.—Aluminum nitride crystals appear to begin to oxidize in air at about 700°C. This was investigated by heating colorless and blue crystals on a platinum lid in flowing air to various temperatures for 24 hr, and then carefully examining the crystals microscopically after each test. At between 700° and 800°C, the surface of clear transparent crystals became slightly foggy, indicating the beginning of oxidation. The oxidation rate of well-formed crystals, however, was slow even at much higher temperature, because of the formation of a dense adherent aluminum oxide film. Thus, after 24 hr at 1400°C, the cross section of crystals of about 1 mm diameter and 7 mm long showed an oxide surface film estimated to be 40 μ thick. The inside core of the crystal, however, was still clear and transparent.

Tendency to oxidize also was determined by heating 2-3 g samples of the finely milled powder, having an average particle size of about 5 μ, in a flowing stream of air. The weight gain, after 24 hr at 700°C, was 3.2%, corresponding to a conversion of 13% of the compound to aluminum oxide. When a new sample of the same powder was heated 24 hr in air at 800°C, the increase in weight was 9%, corresponding to a conversion of about 36% of the compound to aluminum oxide. In the latter case, x-ray diffraction clearly showed the presence of gamma alumina.

Corrosion resistance.—Crystals of aluminum nitride have been immersed in water at room temperature for several months with no apparent effect on the crystals. Some recent investigators (1, 3, 4) state that aluminum nitride is essentially unaffected by mineral acids. In the present research, it was observed that aluminum nitride crystals were dissolved slowly in a boiling mixture of one part concentrated hydrochloric and one part water. Thus, prismatic needles having a diameter of about 80 μ were dissolved completely in 80 hr. The corrosion rate, based on these experiments, is approximately 170 mils per year.

Table I. Hardness of aluminum nitride crystals

Indentation* No.	Knoop hardness, K_{100} White crystals	Blue crystals
1	1010	920
2	1075	970
3	1010	980
4	1115	1030
5	1000	1050
* Average	1042	990
6	1453	1415
7	1426	1510
8	1454	1450
9	1356	1445
10	1348	1530
* Average	1407	1470
Over-all average	1225	1230

* Indentations 1 through 5 were made with the long diagonal of the indenter parallel to the c axis of the crystal, 6 through 10 were made with the long diagonal of the indenter perpendicular to the c axis.

Hot Pressed Aluminum Nitride

Preparation of hot pressed aluminum nitride.—Aluminum nitride powder was prepared by direct combination of aluminum and nitrogen. Alcoa's No. 101 atomized aluminum powder was mixed with 1% sodium fluoride, which catalyzes the nitriding at low temperatures (11), and heated in purified nitrogen in a refractory crucible. The temperature was raised rapidly to 650°C and then increased slowly over a period of 40 hr to a maximum of 1800°C. In this way a porous sintered agglomerate was obtained. It was reduced readily by dry ball milling in a stainless steel mill with stainless steel balls to a light gray powder with an average particle size of about 5 μ. Chemical analysis of the milled aluminum nitride powder and also the calculated composition, based on this analysis, are shown in Table II. It will be noted that the aluminum nitride content is approximately 96%, and that the chief impurity is alumina. The density of the powder was 3.23 g/cc, compared with a density of 3.26 g/cc as calculated from the cell dimensions of the crystals.

Table II. Aluminum nitride powder
(Pure AlN: 65.81% Al; 34.19% N)

Chemical analysis		Calculated composition	
Al	64.8%	AlN	96.0%
N	32.8%	Al_2O_3	2.1%
C	0.2%	Other compounds	1.9%
Si	0.4%		
Fe	0.1%		
O	1.0%		

Particle size: 0.5 to 25μ
Density: 3.23 g/cc

Table III. Strength and elasticity properties of hot pressed aluminum nitride

Temp, °C	Modulus of rupture, psi	Modulus of elasticity, psi
25	38,500	50×10^6
1000	27,000	46×10^6
1400	18,100	40×10^6

Test specimens, 3 in. in diameter and 3 in. long, were fabricated by hot pressing the milled powder at 2000°C in graphite dies, applying pressures of about 5000 psi. Test bars, 3 x 0.5 x 0.25 in., were cut from the hot pressed pieces with a diamond wheel and then ground to produce smooth parallel surfaces. The test specimens were light gray in color and had a bulk density of 3.20 g/cc or about 98% of the theoretical for pure aluminum nitride. Using a load of 100 g, 10 Knoop hardness indentations gave values ranging from 1005 to 1240, with an average of 1130.

Strength and elasticity.—Data for modulus of rupture and modulus of elasticity at room temperature, 1000° and 1400°C, are presented in Table III. Four specimens, 3 x 0.5 x 0.25 in. were tested at each temperature, pressure being applied perpendicular to the direction in which the bars were hot pressed. These values compare favorably with those for other high-density ceramic materials, especially at high temperatures. For instance, hot pressed alumina is stronger at room temperature, but weaker at 1400°C. The modulus of elasticity of hot pressed aluminum nitride is about the same as that of hot pressed alumina at room temperature, but is higher than that of hot pressed alumina at 1400°C.

Long and Foster (4) reported a modulus of rupture of sintered aluminum nitride at room temperature of 11,500 psi. The exact density of the test specimens was not given but presumably was appreciably lower than that of the hot pressed material reported herein. Rey (2) reported the compressive strength of sintered aluminum nitride brick to be about 3000-4000 psi. Preliminary tests on the hot pressed material indicate a compressive strength of about 300,000 psi.

Thermal conductivity.—The thermal conductivity was measured by a linear flow comparative method, parallel to the direction of pressing, in an atmosphere of stagnant nitrogen, using Inconel as a standard. Values obtained over a temperature range of 200°-800°C are shown in Table IV. These results indicate that aluminum nitride is a good conductor of heat, being intermediate between dense silicon carbide, which is an excellent conductor, and alumina, which is a fair conductor. This is illustrated by the following comparative values for thermal conductivity expressed in cal/cm²/cm/sec/°C obtained by the same method:

Material	At 200°C	At 800°C
Dense SiC	0.24	0.10
Hot pressed AlN	0.072	0.048
Dense Al_2O_3	0.054	0.017

The present data are in sharp contrast to those of Long and Foster (4), who recently reported the thermal conductivity of sintered aluminum nitride at 25°C as 0.0042 cal/cm²/cm/sec/°C. The density of the specimens used by Long and Foster was not disclosed, but the density of some of their test specimens used for determination of electrical resistivity was as high as 2.66 g/cc. It seems probable, therefore, that the difference in density alone is not responsible for the great dissimilarity of the thermal conductivity values, but rather the difference in methods is mainly responsible. According to Kingery and co-workers (12) thermal conductivity at zero porosity can be calculated employing the following simplified relationship of Loeb:

$$k_s = \frac{km}{(1 - P_v)}$$

where k_s is the solid thermal conductivity (zero porosity); k_m, measured thermal conductivity; P_v, volume pore fraction.

Even if it is assumed that the thermal conductivity, $k_m = 0.0042$ cal/cm²/cm/sec/°C, measured at 25°C by Long and Foster, is for a specimen with 40% porosity, the thermal conductivity at zero porosity calculated according to above equation, will be only 0.007 cal/cm²/cm/sec/°C.

The accuracy of the present method has been checked by comparing the results obtained on some standard materials with data from other laboratories as illustrated in the following examples:

Laboratory	Material	Thermal conductivity, cal/cm²/cm/sec/°C 400°C	600°C
Carborundum	Inconel	0.049	0.057
National Bureau of Standards (13)	Inconel	0.049	0.058
Carborundum	Nickel	0.119	0.130
International Nickel Company (14)	Nickel	0.112	0.136

Thermal expansion.—The determination of thermal expansion was made by the dilatometer method, using a silicon carbide dilatometer assembly (15). Thermal expansion was measured parallel to the direction of pressing, on a bar 3 in. long and 0.5 in. in diameter. Values are given in Table V. These

Table IV. Thermal conductivity of hot pressed aluminum nitride

Temp, °C	Cal/cm²/cm/sec/°C	Btu/ft²/in./hr/°F
200	0.072	209
400	0.060	173
600	0.053	153
800	0.048	139

Table V. Thermal expansion of hot pressed aluminum nitride

Temperature interval, °C	Linear expansion, cm/cm/°C
25-200	4.03×10^{-6}
25-600	4.84×10^{-6}
25-1000	5.64×10^{-6}
25-1350	6.09×10^{-6}

check closely the results reported by Long and Foster (4) (4.8 x 10^{-6} cm/cm/°C in the range 20°-500°C) for the sintered aluminum nitride. The thermal expansion of hot pressed aluminum nitride is in the moderate range for a ceramic, being only slightly higher than that of silicon carbide.

Thermal shock resistance.—The high thermal conductivity and low thermal expansion of hot pressed aluminum nitride are conducive to good thermal shock resistance. Bars, 3 x 0.5 x 0.25 in., heated rapidly to 2200°C in an oxygen-acetylene torch and cooled rapidly, did not crack or spall when the test was repeated consecutively several times. The thermal shock resistance was evaluated also by measuring the loss in strength of hot pressed aluminum nitride bars after 30 cycles of heating in 2.5 min to 1400°C and rapidly cooling to room temperature in an air blast. The modulus of rupture before thermal cycling was 38,500 psi and after thermal cycling, 33,700 psi, or a loss of 12% of the original strength.

Stability in various atmospheres at elevated temperatures.—Test specimens, 0.25 x 0.5 x 0.5 in., were exposed to flowing air, oxygen, dry steam, chlorine, and hydrogen at elevated temperatures. Results are reported in Table VI. The last column shows the percentage of aluminum nitride converted to aluminum oxide or aluminum chloride according to the different conditions of the experiments. As can be seen from these data, the effect of air or oxygen at temperatures up to 1400°C or of steam at 1000°C after 30 hr is slight. At 1700°C in air, however, the rate of oxidation becomes rather rapid. It will be recalled from the discussion of the crystalline material that it was found that oxidation of aluminum nitride in air starts at about 700°C, but that the rate of oxidation is slow even at temperatures as high as 1400°C, because of the formation of a protective oxide coating. This coating also accounts for the slow rate of oxidation of the dense hot pressed material. Figure 3 shows a 0.25 x 0.5 in. cross section of a bar after exposure to air at 1400°C for 24 hr. The oxide layer is approximately 60 μ or 2-3 mils thick. At 1700°C, however, it was noted that the oxide coating tended to crack and no longer protected effectively the aluminum nitride against oxidation. The cracking of the coating at this temperature may be due to the appreciable difference in the thermal expansion of aluminum oxide and aluminum nitride.

Table VI. Stability of hot pressed aluminum nitride in various atmospheres of elevated temperatures (Test specimens, 0.25x0.5x0.5 in.)

Atmosphere	Temp, °C	Time, hr	Conversion to other compounds, %
Air	1000	30	0.3 Al_2O_3
Air	1400	30	1.3 Al_2O_3
Air	1700	4	10.6 Al_2O_3
Oxygen	1400	30	0.9 Al_2O_3
Dry steam	1000	30	0.3 Al_2O_3
Chlorine	500	30	<0.1 $AlCl_3$
Chlorine	700	30	19.2 $AlCl_3$
Hydrogen	1700	4	nil

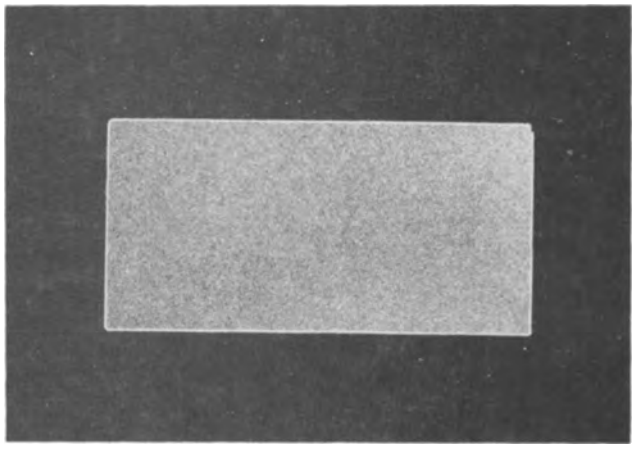

Fig. 3. Cross section of a hot-pressed aluminum nitride specimen showing the protective oxide coating after heating in air 24 hr at 1400°C.

It is of interest to note the difference in the oxidation rate of hot pressed aluminum nitride and the sintered material as reported by Long and Foster (4). Exposure to air for 1 hr at 1200°C of 1-cm cubes of sintered material resulted in a conversion of about 11% of the sample to aluminum oxide, whereas exposure to air for 30 hr at 1400°C of dense hot pressed aluminum nitride specimens of comparable size resulted in a conversion of only about 1% to aluminum oxide.

Table VI also shows that hot pressed aluminum nitride is not appreciably attacked by chlorine at 500°C, but that the reaction rate at 700°C is rapid. Furthermore, hot pressed aluminum nitride is practically unaffected by hydrogen at 1700°C for 4 hr.

Corrosion in water and mineral acids.—As in the case of the crystalline material, hot pressed aluminum nitride is slowly dissolved by hot mineral acids. The results of the corrosion tests are shown in Table VII. Specimens 0.25 x 0.5 x 0.5 in. were heated in a 600 ml volume of water and in the several mineral acids for 72 hr. With the exception of hydrofluoric acid, the tests were made at the boiling temperatures of the liquids. The corrosion rate in boiling water can be considered as low. Although dissolution in the mineral acids is slow, the rate is too great to classify hot pressed aluminum nitride as a corrosion resistant material in these acids. It will be recalled that

Table VII. Corrosion of hot pressed aluminum nitride in water and mineral acids (0.25x0.5x0.5 in. specimens in 600 ml liquid, 72 hr)

Corrosive liquid	Temp, °C	Corrosion rate, mils/year
Water	100	14
Conc. HCl acid	72	320
1 Conc. HCl acid: 1 H_2O	110	570
Conc. H_2SO_4 acid	305	180
1 Conc. H_2SO_4 acid: 1 H_2O	145	550
Conc. HNO_3 acid	120	150
1 Conc. HNO_3 acid: 1 water	111	200
1 HF: 1 HNO_3 conc. acids	57	160
1 Conc. HF acid: 1 water	57	215

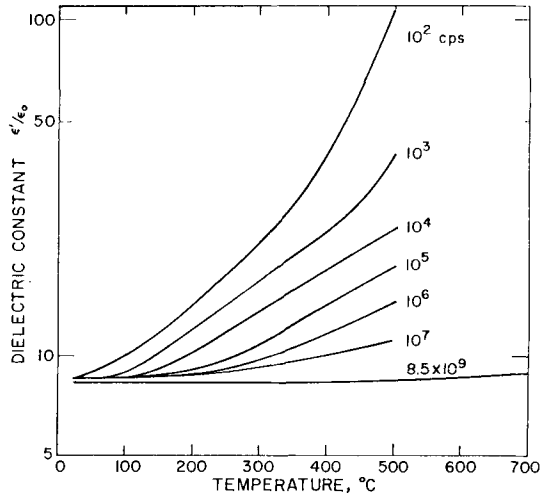

Fig. 4. Effect of temperature on dielectric constant of hot pressed aluminum nitride at several frequencies.

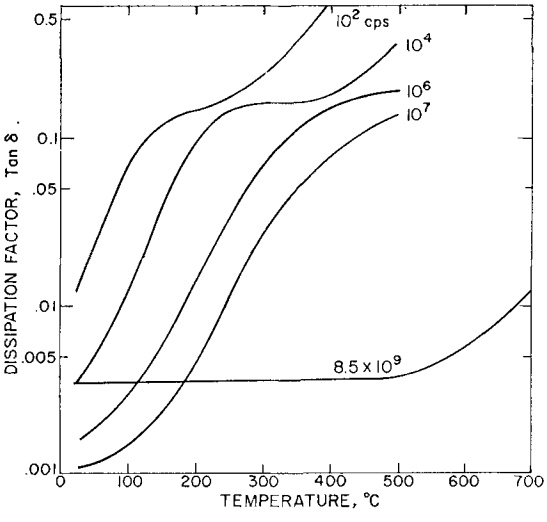

Fig. 5. Effect of temperature on dissipation factor of hot pressed aluminum nitride at several frequencies.

the corrosion rate of single crystals in a boiling mixture of 1 part concentrated hydrochloric and 1 part water was estimated to be about 170 mils per year.

Corrosion in cryolite and aluminum and in boric oxide.—Hot pressed aluminum nitride was heated in an inert atmosphere in a bath consisting of a mixture of molten cryolite and aluminum for 66 hr at 1200°C without visual evidence of corrosion. A piece of hot pressed aluminum nitride, 0.25 x 0.5 x 0.5 in., immersed in molten boric oxide for 4 hr at 1000°C, showed only very slight evidence of attack in the form of faint surface marking and a weight loss of 0.02%. This is equivalent to a corrosion rate of about 25 to 30 mils per year.

Electrical properties.—The electrical properties of hot pressed aluminum nitride appear to be similar to those of alumina, and especially to some of the high density hot pressed aluminas. Dielectric constant and dissipation factor were determined by the Laboratory for Insulation Research at Massachusetts Institute of Technology and also by our own laboratories, the results agreeing fairly closely. Data on dielectric constant are shown in Fig. 4. At room temperature the dielectric constant, over a wide range of frequencies, is about 8.5 compared with between 9 and 10 for many aluminas. The dielectric constant increases rapidly with temperature at low frequencies, less rapidly at high frequencies. At a frequency of 8.5 x 10^9 cps, the change with temperature is only slight. This behavior is also typical of the aluminas.

The dissipation factor at various frequencies and temperatures is shown in Fig. 5. At low frequencies, the dissipation factor increases rapidly with temperature. However, at the frequency of 8.5 x 10^9 cps, the change with temperature up to 500°C is slow. At room temperature the dissipation factor at the various frequencies is between about 0.01 and 0.001, while for the aluminas, the dissipation factor at this temperature is about 0.001 to 0.0001. At high temperatures (400°-500°C) and low frequencies (10^2-10^3 cps) the dissipation factor of hot pressed aluminum nitride and alumina are comparable, while at high temperatures and high frequencies the dissipation factor of the aluminas is appreciably lower.

The volume resistivity of hot pressed aluminum nitride as calculated from the dielectric constant and dissipation factor is shown in Fig. 6. Data for a hot pressed alumina at two frequencies are also shown in Fig. 6 for comparison. At a frequency of 100 cps, the resistivity of hot pressed aluminum nitride is about 2 x 10^{11} ohm-cm at room temperature and 7 x 10^7 ohm-cm at 500°C. Resistivity decreases with frequency; this is also typical for the aluminas and other ceramic insulators.

Summary

Pure aluminum nitride is white. Blue crystals are formed when the metal is heated above 1750°C in nitrogen containing small amounts of carbon monoxide.

Aluminum nitride does not melt under atmospheric pressure in argon, but vaporizes rapidly at about 2400°C. Its Knoop hardness, with a load of

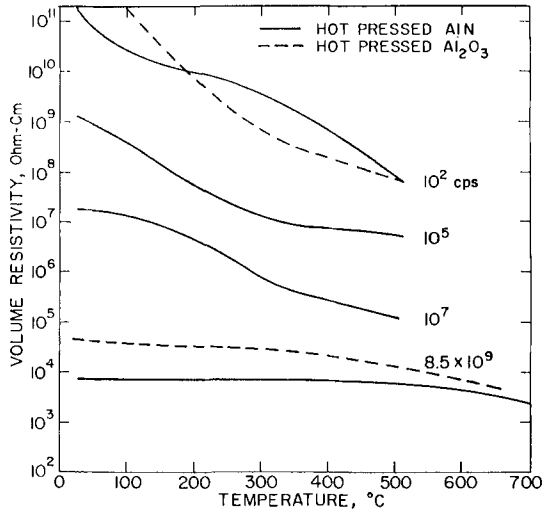

Fig. 6. Effect of temperature on volume resistivity of hot pressed aluminum nitride at several frequencies. Data for a hot pressed alumina at two frequencies are shown for comparison. (Data obtained from Tables of Dielectric Materials Volume V- Laboratory for Insulation Research, Massachusetts Institute of Technology.)

100 g, is approximately 1200, which is equivalent to seven plus on the Mohs scale.

Aluminum nitride starts to oxidize in air at between 700° and 800°C, but in the case of large crystals and the dense hot pressed material, oxidation is slow up to 1400°C because of the protective oxide surface layer formed. It is inert to hydrogen at 1700°C but is attacked by chlorine between 500° and 700°C.

Although aluminum nitride in the crystalline or hot pressed form does not dissolve readily in boiling mineral acids, it is not highly corrosion resistant to these acids. However, it has relatively good corrosion resistance to molten boric oxide and to a mixture of molten aluminum and cryolite in inert atmospheres.

Strength of hot pressed aluminum nitride is lower than that of high-density aluminum oxide at room temperature, but is higher at 1400°C. Compared with most ceramics, it has high thermal conductivity, low thermal expansion, and good thermal shock resistance. Its electrical properties, in many respects, are similar to those of aluminum oxide.

Acknowledgments

The authors are indebted to various members of the Research and Development Division of The Carborundum Company for help in obtaining data and also to Mr. W. B. Westphal of the Laboratory for Insulation Research, Massachusetts Institute of Technology, for measurements of electrical properties.

Manuscript received August 10, 1959. This paper was prepared for delivery before the Philadelphia Meeting, May 1-5, 1960.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Relative Rates of Electromigration of Different Ions of the Same Charge across Permselective Membranes

Ruth McClintock, Rex Neihof,[1] and Karl Sollner

Laboratory of Physical Biology, National Institute of Arthritis and Metabolic Diseases, National Institutes of Health, Public Health Service, Bethesda, Maryland

ABSTRACT

A theory is developed which correlates the ratio of the rates of electromigration across permselective membranes of two species of critical exchangeable ions coexisting in solution with the ratio of the rates of spontaneous exchange across the same membrane of the same two species of ions for a third ion in the other solution, and with the bi-ionic potential arising across the same membrane between solutions each containing one of the ions under investigation, at the same activity. The numerous factors which must be considered in electromigration experiments, particularly polarization, are outlined. With solutions in the range of 0.02-0.2*N* and with current densities of about 0.3-1.0 ma/cm², the agreement between the ratios predicted by the theory is closely approached, in many instances within the limits of the experimental errors. At lower current densities, the experimental flux ratios are markedly lower than postulated by the theory, for unknown reasons. At higher current densities, with increasing polarization, there is a gradual decline of these flux ratios, as predicted by theoretical considerations.

In a previous paper we demonstrated the occurrence of greatly different rates of exchange of ions of the same charge across porous membranes of extreme ionic selectivity (permselective membranes) (1). This effect was studied in systems such as System 1 which, in the case of exclusively cation-permeable, anion-impermeable membranes of ionic character, ←⊕→, are represented by:

Solution 1	←⊕→	Solution 2
A^+X^- B^+X^-	Membrane of extreme cationic selectivity	L^+X^-

[System 1]

Here A^+, B^+, and L^+ represent the exchangeable (critical) cations, X^- the nonexchanging, nonpermeating anions. Anionic systems with exclusively anion permeable membranes, ←⊖→, are analogous. Depending on the nature of the membranes, the ratio of the initial rates of simultaneous exchange of univalent ions, A^+ for L^+ and B^+ for L^+, can be as high as 1:100 and more.

These ratios of the rates of exchange, that is, the ratios of the net fluxes of any two species of critical univalent ions coexisting in Solution 1, $(\phi_{A^+}/\phi_{B^+})_{exch.}$, were shown to be correlated to the potentials arising with the same membrane in cells of the type:

Solution 1			←⊕→	Solution 2		
Calomel electrode	KCl conc.	c_1 A^+X^-	c_1 B^+X^-	KCl conc.	Calomel electrode

[Cell 1]

(and analogous cells with exclusively anion permeable membranes) (1). The sign and the magnitude of the potential arising in such cells, the so-called "bi-ionic" potential, $E_{bip.}$, as was pointed out by Michaelis (2), are determined by the relative ease with which the two critical ions penetrate the membrane: if in Cell 1 the cations A^+ of Solution 1 penetrate the membrane with greater ease than do the cations B^+ of Solution 2, then Solution 2 will be charged positive; if the converse is true, Solution 2 will be negative.

Expressing this concept quantitatively one may write

$$E_{bip.} = \frac{RT}{\mathbf{F}} \ln \frac{\tau^\circ_{A^+}}{\tau^\circ_{B^+}} \qquad [1]$$

where $\tau^\circ_{A^+}$ and $\tau^\circ_{B^+}$ represent the transference numbers of A^+ and B^+ within the membrane (the superscript ° being used throughout to indicate equality of activities) (3-6). The ratio of these transference numbers is considered to be a quantitative measure of the relative intrinsic abilities of the A^+ and B^+ ions to penetrate across the particular membrane.

If this holds true, the ratio of the transference numbers can be used to predict the ratio of fluxes of A^+ and B^+ ions across the membrane when present at equal activities in Solution 1, and exchanging for a third ion in Solution 2, as in System 1 (1). If this predicted ratio of fluxes derived from the bi-ionic potential is designated $(\phi^\circ_{A^+}/\phi^\circ_{B^+})_{bip.}$, we may write:

$$\left(\frac{\phi^\circ_{A^+}}{\phi^\circ_{B^+}}\right)_{bip.} = \frac{\tau^\circ_{A^+}}{\tau^\circ_{B^+}} \qquad [2]$$

Experimentally it was shown that in most instances these ratios, $(\phi^\circ_{A^+}/\phi^\circ_{B^+})_{bip.}$, agree within the limits of experimental error with the experimentally established ratios of exchange, $(\phi^\circ_{A^+}/\phi^\circ_{B^+})_{exch.}$ (1):

[1] Present address: Chemistry Division, Naval Research Laboratory, Washington 25, D. C.

$$\left(\frac{\phi^\circ_{A^+}}{\phi^\circ_{B^+}}\right)_{bip.} = \left(\frac{\phi^\circ_{A^+}}{\phi^\circ_{B^+}}\right)_{exch.} \quad [3]$$

If, in systems such as System 1, the ratio of the activities of any two species of exchangeable ions in Solution 1 was not 1:1, the ratios of their initial net fluxes across the membrane, $(\phi_{A^+}/\phi_{B^+})_{exch.}$, were shown to agree satisfactorily, usually within the limits of the experimental error, with the corresponding ratios derived from the bi-ionic potentials, $(\phi^\circ_{A^+}/\phi^\circ_{B^+})_{bip.}$, times the ratios of the activities of the two ions under consideration, $a_{A^+}{}^{[1]}/a_{B^+}{}^{[1]}$, according to the equation:

$$\left(\frac{\phi_{A^+}}{\phi_{B^+}}\right)_{exch.} = \frac{a_{A^+}{}^{[1]}}{a_{B^+}{}^{[1]}}\left(\frac{\phi^\circ_{A^+}}{\phi^\circ_{B^+}}\right)_{bip.} \quad [4a]$$

Combining Eq. [3] and [4a], we may write the expanded equation:

$$\left(\frac{\phi_{A^+}}{\phi_{B^+}}\right)_{exch.} = \frac{a_{A^+}{}^{[1]}}{a_{B^+}{}^{[1]}}\left(\frac{\phi^\circ_{A^+}}{\phi^\circ_{B^+}}\right)_{bip.} = \frac{a_{A^+}{}^{[1]}}{a_{B^+}{}^{[1]}}\left(\frac{\phi^\circ_{A^+}}{\phi^\circ_{B^+}}\right)_{exch.} \quad [4b]$$

Analogous considerations were shown to apply to systems with more than two species of critical ions in Solution 1.

After the ratios of the rates of spontaneous exchange across permselective membranes of coexisting species of ions of the same charge were thus correlated satisfactorily with the bi-ionic potentials arising with these ions across the same membranes, the next obvious step was to test whether analogous correlations exist with the ratios of the migration in an electric field of ions of the same charge across permselective membranes. This electromigration could be studied in cells such as Cell 2, which is essentially System 1 provided with electrodes:

	Solution 1		Solution 2	
		$\leftarrow\oplus\rightarrow$		
Anode	c_1 A^+X^- c_1 B^+X^-		c_2 L^+X^-	Cathode

Cell [2]

This matter, mentioned briefly at an earlier occasion (7), is the subject of the present communication.

When a positive current is passed through Cell 2 from left to right, A^+ and B^+ ions are transported simultaneously from Solution 1 through the membrane into Solution 2, the total number of equivalents of ions moved being identical with the number of faradays passed through the cell.

If the ratio $(\phi^\circ_{A^+}/\phi^\circ_{B^+})_{bip.}$ and the closely similar ratio $(\phi^\circ_{A^+}/\phi^\circ_{B^+})_{exch.}$ represent a measure of the ratio of the intrinsic competitive propensities of these two ions to penetrate across the membrane, the ratio in which the current is transported by the A^+ and B^+ ions across the membrane in Cell 2 may be expected to be the same, provided $a_{A^+}{}^{[1]}$ equals $a_{B^+}{}^{[1]}$. Denoting the ratio of these net fluxes of the A^+ and B^+ ions, which may also be considered as the ratio of their transport numbers in the membranes, as $(\phi^\circ_{A^+}/\phi^\circ_{B^+})_{elect.}$ we may write:

$$\left(\frac{\phi^\circ_{A^+}}{\phi^\circ_{B^+}}\right)_{elect.} = \left(\frac{\phi^\circ_{A^+}}{\phi^\circ_{B^+}}\right)_{bip.} = \left(\frac{\phi^\circ_{A^+}}{\phi^\circ_{B^+}}\right)_{exch.} \quad [5]$$

If the concentrations of A^+ and B^+ in Cell 2 are not identical, this is taken into account in the same manner as in the case of exchange studies (1) by the use of the more general equation

$$\left(\frac{\phi_{A^+}}{\phi_{B^+}}\right)_{elect.} = \left(\frac{a_{A^+}{}^{[1]}}{a_{B^+}{}^{[1]}}\right)\left(\frac{\phi^\circ_{A^+}}{\phi^\circ_{B^+}}\right)_{bip.} = \left(\frac{a_{A^+}{}^{[1]}}{a_{B^+}{}^{[1]}}\right)\left(\frac{\phi^\circ_{A^+}}{\phi^\circ_{B^+}}\right)_{exch.} \quad [6]$$

or its analogue for anionic cells.

The foregoing derivation of the flux ratio $(\phi_{A^+}/\phi_{B^+})_{elect.}$ implicitly makes the assumption that potentially complicating effects do not arise to a significant extent. Specifically it is based on the assumptions that:

1. the membranes are of ideal ionic selectivity;
2. equilibrium conditions at the membrane-solution interfaces are maintained;
3. the distribution of ions in the membrane has reached a stationary state;
4. polarization does not arise;
5. electrophoretic effects, particularly a coupling of the movements of different ionic species, are absent;
6. spontaneous net exchange of ions across the membranes is absent; and
7. osmosis, due to differences in the activity of the solvent at the two sides of the membrane does not occur.

Assumption 1 means that no significant quantity of noncritical ions penetrates across the membrane, a condition which is readily fulfilled by permselective collodion matrix membranes (8-10).

Assumption 2 implies that the distribution of ions at the membrane-solution interfaces during electromigration corresponds to the equilibrium distribution of ions which would exist without the flow of current, in the absence of any spontaneous net exchange of ions across the membrane. This assumption is closely linked to the problem of membrane polarization which is treated below, Assumption 4.

Assumption 3 states that the distribution of the ions in the membranes under the influence of the electric field has reached a stationary state. This condition would be fulfilled either if such a stationary state is the same as that with no current flowing, or if a current has been passed through the cell prior to the experiment proper for a period long enough to achieve the stationary state. Membranes having ion exchange capacities which are low compared with the total ionic content of Solution 2 would be expected to cause the least error even if Assumption 3, which is not readily tested by an independent method, should not be strictly fulfilled.

Assumption 4, that polarization at the membrane-solution interfaces does not arise, can be true only with infinitely weak currents, quite as in the case of metallic electrodes.

While polarization at metallic electrodes has been treated widely in the literature, membrane polarization has not been studied extensively. Polarization at

metallic electrodes is thus a useful starting point in discussing membrane polarization.

Electrode polarization is best known for nominally reversible electrodes in contact with single electrolyte solutions such as $CuSO_4/Cu$. Ordinarily one distinguishes (*a*) *chemical polarization* due to a slow step or steps involved in the discharge of the ions, such as their dehydration, and the deposition of the discharged material in a stable form at the cathode, or to the inverse processes in the anodic dissolution of a metal electrode; and (*b*) *concentration polarization* which is due to the slowness of the diffusion of ions in the solution. There is a decrease of the concentration in the solution in the immediate neighborhood of the cathode where ions are being discharged, and an increase near the anode from which metal dissolves and goes into solution in the form of ions. In a thin layer of solution there is always a concentration gradient from that of the bulk of the solution to the smaller or larger (for cathode and anode, respectively) value at the electrode; diffusion into or from the bulk solution tends to reduce these concentration differences near the electrodes. The layer in which this occurs is commonly referred to as the *diffusion layer*. The thickness of this layer can be reduced by stirring, but it cannot be eliminated entirely. With solutions at room temperature that are stirred thoroughly by ordinary mechanical devices a diffusion layer with an apparent thickness of 20 to 30 μ remains.

Before the ions can reach the cathode they must traverse the diffusion layer from the bulk solution; the rate at which ions reach the cathode is proportional to their concentration in the solution. Concentration polarization at a given current density can be reduced by the use of solutions of higher concentrations and by stirring, or by raising the temperature, but it cannot be eliminated entirely. Concentration polarization is less at lower current densities.

At the phase boundaries between two electrolytic conductors, such as an electrolytic solution and an ionic membrane, *chemical polarization* which involves the discharge of ions obviously does not occur except under the most extreme conditions (11).

Concentration polarization, however, does occur when a current passes across the phase boundary between two ionic conductors if the ratios of the transference numbers of cations and anions in the two phases are not the same, as pointed out first by Nernst and Riesenfeld (12) for the simple case of a uni-univalent electrolyte distributed between two liquid phases. Such polarization consists of an increase in concentration of electrolyte at the one side of the phase boundary and a corresponding decrease at the other. The ratios of the transference numbers, $t^{+[1]}/t^{-[1]}$ and $t^{+[2]}/t^{-[2]}$, are obviously not the same if Phase 1 is an electrolytic solution and Phase 2 an ionic membrane equilibrated with it (12-14).

With permselective membranes the situation is much simpler. In such membranes of practically ideal ionic selectivity either the cations or the anions have a transference number of zero. Only the counter ions of the fixed wall charges, the critical ions of the adjacent solution, move into the membrane phase or are released by it.[2] Thus, with permselective membranes the concentration polarization in a solution containing a single electrolyte is quantitatively the same as if the membrane were a reversible electrode on which the ion under consideration is deposited, or from which it is released by dissolution.

The cells investigated in this paper, such as Cell 2, contain two species of critical ions of the same charge in Solution 1, thus being analogous to electrolytic cells in which an alloy is deposited from a mixed solution. In the two solutions of such cells concentration polarization will arise with respect to all ions according to their respective transport numbers in the solutions and the membrane. Therefore, the degrees of concentration polarization of two ions of the same charge will, in general, be different. In other words, the ratio of the concentration of the two critical species of ions in the solution layers immediately adjacent to the membranes will be different from that in the bulk solution. In cells such as Cell 2, this effect would be disturbing particularly at the phase boundary between Solution 1 and the membrane, where the critical ions move from the solution into the membrane, thereby changing profoundly the most important parameter of the cell. If concentration polarization did not change the ratio of the concentrations of the two permeable ions but only their absolute concentrations, concentration polarization would be of little consequence in the present situation.

Assume, for instance, that the A^+ ions in Cell 2 represent potassium ions and B^+, lithium ions. The former have in free solution about twice the diffusion velocity and ionic mobility of the latter. In ordinary permselective membranes the ratios $(\phi^\circ_{K^+}/\phi^\circ_{Li^+})_{exch.}$ or $(\tau^\circ_{K^+}/\tau^\circ_{Li^+})_{bip.}$ are in most instances about six (1). Although the K^+ ions reach the interface about twice as fast as the Li^+ ions, they are removed by the current into the membrane about six times as fast as the Li^+ ions; thus a relatively stronger depletion of the K^+ ions than of the Li^+ ions would arise in Solution 1 at the membrane-solution interface.

The concentration polarization which we have considered so far is the polarization which arises in the solutions. On the membrane side of the interface, concentration polarization in the classical sense, a decrease or increase in total concentration of electrolyte, cannot occur with membranes of extreme ionic selectivity in which all movable ions are of the same charge. However, another type of concentration polarization may conceivably arise. In our discussion up to now the assumption was made (Assumption 2) that equilibrium with respect to the distribution of ions is always maintained between the surfaces of the membrane and the layers of solution immediately adjacent to it. The question arises whether or not the assumed ion exchange equilibrium on the surface of the membrane is maintained when two competing species of ions of the

[2] This is not true if the degree of polarization is extreme, and the concentration of the electrolyte in the diffusion layer immediately adjacent to the membrane becomes so low that the ions of the water, H^+ or OH^- ions, contribute significantly to the transportation of electricity across the membrane (14). Conditions under which this effect arises are not considered in this paper.

same charge are forced by the electric field into the surface of the membrane. There might be some processes associated with the transition of the ions from the solution into the membrane, such as partial dehydration, which are slow and occur at different speeds with the two species of critical ions under consideration. No information fully pertinent to this point seems to be available. It must be assumed that this type of polarization, if it should exist, would, like all other polarization effects, be more pronounced the higher the current density.

Assumption 5 states that there is no electrophoretic coupling of the movement of the A^+ and the B^+ ions in the membrane. Such a coupling may be visualized as being due to an electro-osmotic movement of liquid in the pores which is caused by the friction between the electromigrating ions and the solvent. With the two species of ions electromigrating in the same stream of liquid, the electrophoretic effect would always tend to equalize the experimentally observable fluxes, thus bringing the flux ratios, $(\phi_{A^+}/\phi_{B^+})_{elect.}$ nearer to unity than those predicted on the basis of the bi-ionic potentials or from exchange studies.

Assumption 6, that there is no significant spontaneous net exchange of ions by diffusion across the membrane, can be realized by the use of membranes of high resistance; the rate of exchange of ions across a membrane, *ceteris paribus,* being inversely proportional to its resistance.

Assumption 7 stipulates that movement of water caused by an inequality of the solvent activities at the two sides of the membrane is absent or negligibly small. The direction of this movement of water would depend on the composition of the two solutions or more correctly on the concentrations in the two layers of solution immediately adjacent to the membrane. If polarization occurs, this would result in a reduced concentration of this layer in Solution 1 and in an increased concentration on the side of the more dilute Solution 2. This effect would tend to alter the osmotically active concentration difference across the tested membrane. The use of fairly dense membranes of low water permeability, such as the permselective collodion matrix membranes, tends to minimize the errors due to osmotic solvent movement (8-10).

The conditions postulated by the various assumptions discussed above, except the absence of electrophoretic effects may be realized experimentally to an adequate extent, primarily by the use of low current densities and solutions which are not too dilute in cells with dense, high resistance membranes. The absence of electrophoretic effects, however, cannot be achieved as a matter of principle, except in the unique and trivial instance of equal mobilities within the membrane of the two competing species of critical ions. The mutual interactions between the two types of electromigrating critical ions, the charged pore walls, and the solvent are inherent in the electromigration experiments, independent of the current density. Only the experiments can show whether the simple theoretical approach which has led to Eq. [5] and [6] is justified by the facts.

A study somewhat similar to the present has been published by Bergsma and Staverman (15). Using technical membranes of fairly high water content, they found rather unsatisfactory agreement between theory and experiment. Gregor and Wetstone (16) and Bilberg and Brun (17) have briefly touched the same subject. From a more practical point of view some phases of the problem of the simultaneous electromigration of ions across membranes were taken up by Di Benedetto and Lightfoot (18) and by Partridge and Peers (19).

Design of the Experiments

The experiments were designed not only to fulfill adequately the requirements of the assumptions outlined above, but also to permit ease and accuracy of analysis. Pairs of ions were chosen which do not interfere analytically with each other. Further, to facilitate accurate measurement of concentration changes in the solution into which the ions were transported, Solution 2, the initial concentrations in that solution of the ions under study were made low. Various possible types of cells satisfy these conditions. We chose cells which fulfill the condition described by the Donnan membrane equilibrium:

$$\frac{a_{A^+}{}^{[1]}}{a_{B^+}{}^{[1]}} = \frac{a_{A^+}{}^{[2]}}{a_{B^+}{}^{[2]}} \qquad [7]$$

In cells with only strong uni-univalent inorganic electrolytes, it is adequate and more convenient to operate with normalities instead of activities, the ratios of which are for practical purposes identical with those of the corresponding activities, for example:

	Solution 1		Solution 2	
		$\leftarrow\oplus\rightarrow$		
Anode	$0.1N$ A^+X^- $0.1N$ B^+X^-	|	$0.001N$ A^+X^- $0.001N$ B^+X^-	Cathode

[Cell 3]

Before the passage of current, such cells are in equilibrium with respect to the distribution of the critical ions. No spontaneous net exchange of ions between the two solutions can occur until the flow of current has shifted the ratios of their concentrations away from the Donnan distribution.

Although Cell 3 is in equilibrium with respect to the distribution of the ions, it is not in equilibrium with respect to the solvent; there is an osmotic flow of water from Solution 2 into Solution 1. Such an osmotic flow would decrease by the same absolute value the speed of electromigration of the two critical ions across the membrane, and thus would increase the experimental flux ratios above the calculated ones. The influence of osmosis would be most noticeable in long duration, low current density experiments. The osmotic and the electro-osmotic effects in Cell 3 operate in opposite directions and thus tend to cancel.

The following considerations were applied in the detailed planning of the experiments. In order that the concentrations of the ions under study in Solution 1 and therefore also the ratio of their concentrations remain practically unchanged, the volume of this solution should be large and its concen-

tration high compared with that of Solution 2. The volume of Solution 2 should be small, so that a given small amount of electricity passed through the cell would bring about changes in concentration which are large enough to permit accurate analyses. To obtain a large concentration change in a short time with a given current density, it is desirable to have a high ratio of the membrane area to the volume of Solution 2.

To fulfill as far as possible Assumptions 1, 6, and 7 listed in the preceding section, the membranes chosen should be of virtually ideal ionic selectivity, of sufficiently high resistance to prevent significant spontaneous exchange of ions between the two solutions, and dense enough to prevent appreciable osmotic water movement. Further, the membranes should have low ion exchange capacities so that exchange of ions between them and the solutions cannot affect significantly the ratio of the ionic concentration of the solutions.

Permselective membranes except those with very low resistances have satisfactory ionic selectivities in solutions up to about 0.2*N*, they also have low ion exchange capacities (8-10). In general, membranes of higher resistance yield a lower rate of osmotic water movement. However, the resistance must not be so high as to make the exchange studies for the determinations of the $(\phi^\circ_{A^+}/\phi^\circ_{B^+})_{exch.}$ ratios too tedious, or to cause a significant amount of heat to be generated by the flow of the maximum current used. Although the concentrations of both species of critical ions in Solution 1 should be high, the total concentration of Solution 1 can be raised safely only to a certain extent (which depends on the membrane) because the ionic selectivities of the membranes are lower at higher concentrations (8-10).

Also, the current densities used should be low to minimize polarization. However, a certain total quantity of electricity must flow through the cell before analytical data of sufficient accuracy can be obtained. Low current densities therefore necessitate long experimental periods. Under these conditions the danger of a significant spontaneous exchange of ions is increased, due not only to the time factor but also to the less pronounced unidirectional flux of ions in the membrane. The range of current densities used must represent a compromise between these antagonistic requirements.

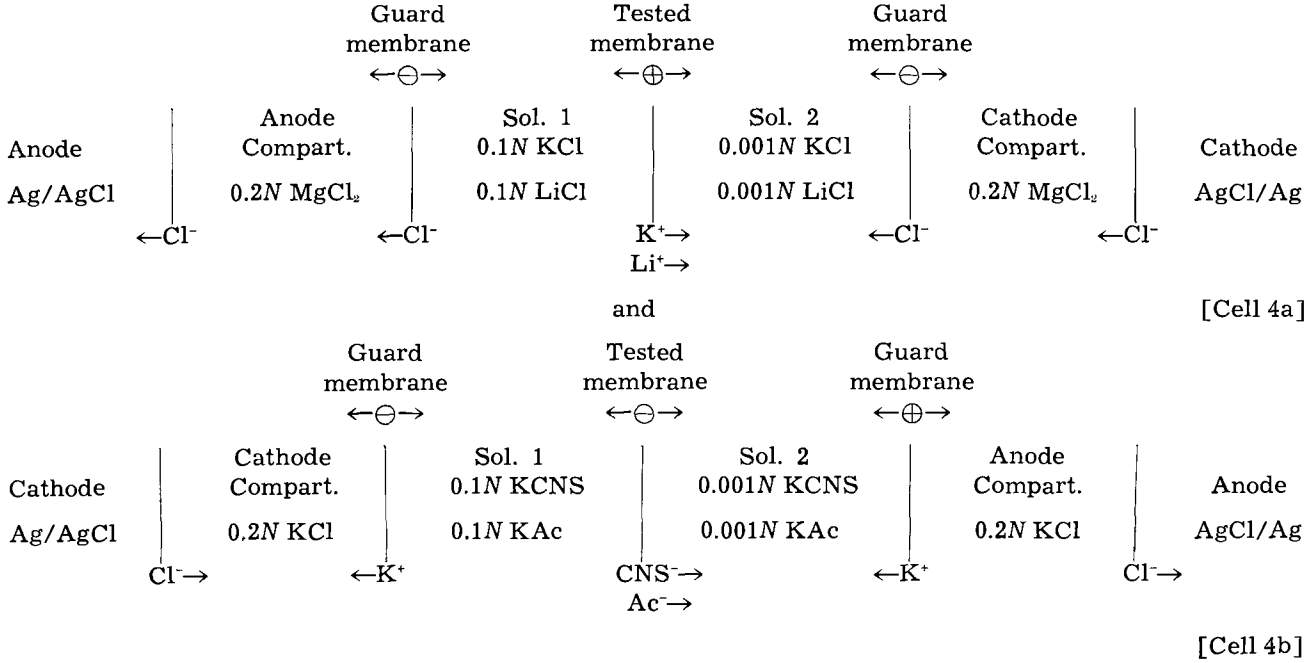
When a current is passed through Cell 3, the products of electrolysis developed at metallic electrodes, particularly H^+ and OH^- ions, would seriously affect the essential membrane processes. In cells with cation selective membranes and solutions of the halides, the use of silver-silver halide electrodes would considerably ameliorate this situation; however, disturbing electrode processes would still occur with the current densities used in many of our experiments. The difficulties due to electrode processes can be eliminated by using guard membranes of extreme ionic selectivity which separate the electrodes from Solutions 1 and 2 (15, 20). If the tested membrane is cation permeable the guard membranes must be anion permeable, and *vice versa,* as shown in Cells 4a and 4b.

It is evident which ions are transported by the current to and from the different compartments of Cell 4, how contamination of Solutions 1 and 2 from the adjacent electrode compartments is suppressed, and how electroneutrality is maintained in each compartment.

Apparatus and Procedure

The experimental cell, shown schematically in Fig. 1a, consisted of four Lucite sections clamped together by means of four bolts. The compartments so formed, A, B, C, and D, were separated from each other by the tested membrane and two guard membranes, mounted flat between Parafilm gaskets. The exposed area of each membrane was 23.7 cm^2.

The two end sections forming the electrode compartments A and D each had an air hole at the top and a tube at the bottom for introducing or draining



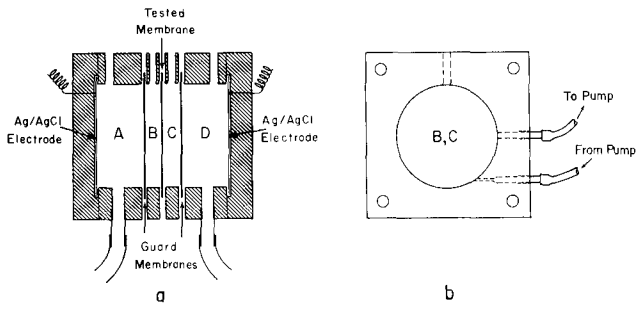


Fig. 1. Cell for the study of the electromigration of ions across membranes (schematic). (a) Cross section through the cell; (b) plastic section forming compartment B or C.

solutions, and contained an electrode, a silver disk on which silver chloride had been deposited by electrolysis from a chloride solution.

The two sections forming compartments B and C on either side of the tested membrane were machined as shown in Fig. 1b. Each had a hole at the top and was provided with a closed loop of polyvinyl chloride (Tygon) tubing. These loops passed through a peristaltic pump which circulated the solutions at a rate of about 100 ml/min. This stirring was vigorous enough that further increases in the rate of circulation made no significant difference in the experimental results. The volume of solution required for filling completely either compartment B or C including the loop of tubing was about 20 ml which, when necessary, was increased to about 200 ml by placing a reservoir in the pumping circuit.

The membranes were cut from the cylindrical parts of test tube-shaped permselective collodion matrix membranes, the preparation and properties of which have been described in detail (8-10). The cation selective membranes contained acidic polyelectrolytes as activating agents, polyacrylic acid (PAA) in the case of weak acid membranes and polystyrene sulfonic acid (PSSA) in the case of strong acid membranes (8). The anion selective membranes were made with basic polyelectrolytes, poly-2-vinyl-N-methyl-pyridinium halide (PVMP) or protamine chloride (9, 10).

The tested membranes had unit area resistances in 0.1*N* KCl, ρ^*, from 125 to 300 ohm-cm^2, the guard membranes from 250 to 900 ohm-cm^2. Membranes in these ranges of resistance are known to be of high ionic selectivity as determined from the measurement of concentration potentials or from leak studies, their permeabilities to the critical ions at 0.1*N* being about 400 to 2000 times that of the noncritical ions (8-10). They have ion exchange capacities of 0.4 to 2.0 μeq/cm^2, water contents of 6-13%, and are about 30 μ thick.

For measurement of the *bi-ionic potentials*, $E_{bip.}$, the compartments B and C on opposite sides of the tested membrane were filled with 0.1*N* electrolyte solutions, each containing one of the critical ions to be studied; the electrode compartments were left empty. The solutions, which were stirred continuously, were renewed repeatedly over a period of several hours to establish a stationary state across the membrane (4). Immediately after renewing both solutions again, the potential was measured using saturated calomel half-cells with saturated KCl-agar bridges, and the temperature recorded. This was repeated until successive readings agreed within ± 2%. These potentials were not corrected for the asymmetry of the two liquid-junction potentials at the tips of the bridges. The flux ratio, $(\phi^\circ_{A^+}/\phi^\circ_{B^+})_{bip.}$ was obtained using Eq. [1] and [2].

For the determination of the ratios of the *rates of exchange*, a reservoir was placed in the pumping circuit of one of the compartments adjacent to the tested membrane, B or C, and filled with Solution 1, a 0.2*N* solution containing equal concentrations of the two critical ions under study. The other compartment, without reservoir, was filled with Solution 2, 0.2*N* NH_4Cl if the tested membrane was cation permeable or 0.2*N* KNO_3 if it was anion permeable. Both solutions were circulated for stirring. A stationary state across the membrane was obtained, as described above, before starting the experiment proper with fresh solutions. The duration of the exchange experiments was chosen so that the concentrations of the critical ions in Solution 2 became sufficient for accurate analysis. The ratio of their concentrations gives the ratio of the exchange fluxes, $(\phi^\circ_{A^+}/\phi^\circ_{B^+})_{exch.}$. These experimental runs were repeated until two or more runs agreed within 5-10%.

To measure the *electrical fluxes*, the electrode compartments A and D were filled with about 50 ml of 0.2*N* $MgCl_2$ if the tested membrane was cation permeable, or 0.2*N* KCl if the tested membrane was anion permeable. One of the compartments adjacent to the tested membrane, B or C, was provided with a reservoir and filled with the more concentrated solution, Solution 1 [Cell 4]. The compartment on the other side of the tested membrane, without reservoir, was filled with the more dilute solution, Solution 2. Both solutions were circulated for stirring. The membrane was equilibrated with the solutions as described above. Before an experimental run, both solutions were changed, the more dilute solution three times. Finally, a measured volume of the dilute solution was placed in the compartment of Solution 2 and the flow of a direct current of the chosen intensity, 0.042-4.2 ma/cm^2, started. The duration of the experiments, 3-480 min, was adjusted so that the concentrations of the critical ions in the dilute solution increased sufficiently for accurate determination of the concentration changes. The currents passed were 1-100 ma; the total quantity of electricity in the individual runs was 0.2-0.6 x 10^{-3} faraday. The experimental runs at any given current density were repeated, usually two or three times with about 100% variation in their duration. The electrical flux ratios, $(\phi_{A^+}/\phi_{B^+})_{elect.}$, for each experimental run were obtained from the ratios of the increases in concentration of the two critical ions. These ratios were ordinarily reproducible within 15%.

As a routine check for satisfactory performance of the cell, the number of equivalents of critical ions transported was compared with the number of faradays of electricity passed, as determined by an iodine coulometer or as calculated from the magnitude and duration of the current. It also should be mentioned that the membranes did not change significantly during a series of experiments, as indicated

by the constancy of the exchange flux ratios and of the bi-ionic potentials. The sequence in which the experiments were carried out did not influence the results.

In numerous instances the positions of the solutions and the direction of the current were reversed with respect to the tested membrane; with the electrolytes used in the experiments reported below in detail, no significant effect was found.

The analytical determinations of anions were carried out by standard micromethods (21), ordinarily with an estimated error of ±1%. The cations were determined by means of a flame spectrophotometer, the error in analysis being in most cases less than ± 3%, never more than ± 5%.

Before presenting the results of the experiments which were carried out by the methods just outlined, several preliminary tests are described which were made to explore to what extent certain of the conditions assumed in the theoretical development are fulfilled in our experimental cells.

During the course of the electromigration experiments the ratio of the A^+ and B^+ ions in Solution 2 is changed from the Donnan equilibrium distribution shown in Cell 4, and spontaneous back exchange of ions tends to occur, contrary to our assumption.

Back exchange is not readily measured in the presence of the electric field applied in the electromigration experiments. We therefore have tested whether such an exchange of ions might occur in the absence of an impressed electric field. The membranes were of the same types employed in the electromigration experiments, with ρ^* of 175-275 ohm-cm^2. Solutions similar to the final solutions obtained in the electromigration studies were placed in the compartment of Solution 2 and allowed to exchange against Solution 1 while both solutions were stirred. At the end of the exchange periods, 2-16 hr, little or no change in the concentrations of the ions was found. There would have been even less back exchange during the electromigration runs: first, with current flowing, the back exchanging ions would have had to move against an electrical gradient; second, the concentration difference which would cause back exchange is initially zero and would be built up only in course of time. Thus it is certain that back exchange was quantitatively unimportant during the electromigration experiments.

To test whether osmosis due to differences in the activities of the solvent at the two sides of the membrane occurs, the rate of osmotic water movement was measured, as described previously (8-10), with 1.0*N* KCl against water. The same membranes were used as in the back exchange experiments. The rates of osmotic water movement were 2 to 6 mm^3/hr-cm^2. Since the rate of water movement is proportional to the difference in osmolar concentrations, the greatest rate to be expected with the solutions used in our electromigration experiments is approximately one-fourth as much.

The water transported per equivalent of ions moved was also determined for the same membranes. The experimental arrangement was similar to that for the measurement of osmosis, but with the addition of Ag/AgCl screen electrodes on either side of the membrane. The quantity of water transported per faraday depended on the critical ion and the resistance of the membrane. It was independent of the current density and essentially independent of the concentration, in the range of interest here. The values with acidic membranes were 3-4 moles of water per equivalent of K^+ and 6-8 per equivalent of Li^+; for the basic membranes, 4-5 moles per equivalent of Cl^- and 8-10 for Ac^-. The lower figures were obtained with the higher resistance membranes.

The difference in the number of moles of water transported by ions of the same charge may be taken as an indication that an electrophoretic coupling of the movement of such ions exists when they electromigrate simultaneously across a membrane. However, at present it does not seem possible to evaluate this effect quantitatively.

Another aspect of the electro-osmotic transportation of water of interest here is its correlation to the osmotic water movement, the two being opposed in direction to each other in the electromigration experiments. The electro-osmotic effects are proportional to the number of equivalents of ions transported, independent of the duration of the experiment. The osmotic effects, however, are proportional to the time and are thus proportionately less for the shorter experiments at higher current densities. The data indicate that the osmotic and electro-osmotic effects were of the same order of magnitude at the lowest current densities used in our electromigration experiments, 0.042-0.127 ma/cm^2; at the highest current density employed (4.2 ma/cm^2) the electro-osmotic effect was an order of magnitude greater than the osmotic effect.

The effect of the electro-osmotic and osmotic movement of water on the volume and therefore the concentration of Solution 2 must also be considered. At low current densities the two effects, being of about the same magnitude and opposite in direction, tend to cancel and produce little change in the volume of Solution 2. At high current densities where electro-osmosis predominates, a maximum of approximately 6 mM or about 0.1 ml of water is moved into Solution 2 during a single run. This is only about 0.5% of the initial volume of Solution 2, so that the volume change which results from the water movement and the concomitant effect on the concentration of ions in Solution 2 may be neglected.

Results and Discussion

Figures 2-4 summarize our experimental results. In the coordinate graphs the mean values of the ratios of the electrical fluxes for each current density studied are plotted and connected by straight lines. The length of the vertical line at each plotted point indicates the average deviation of the electrical flux ratio from the mean value of replicate experiments. This alternative is used to give an indication of the reproducibility of the experiments, since many more data would be necessary to make possible a meaningful statistical analysis.

To the right of each coordinate graph are two bar graphs, one showing the ratios calculated from

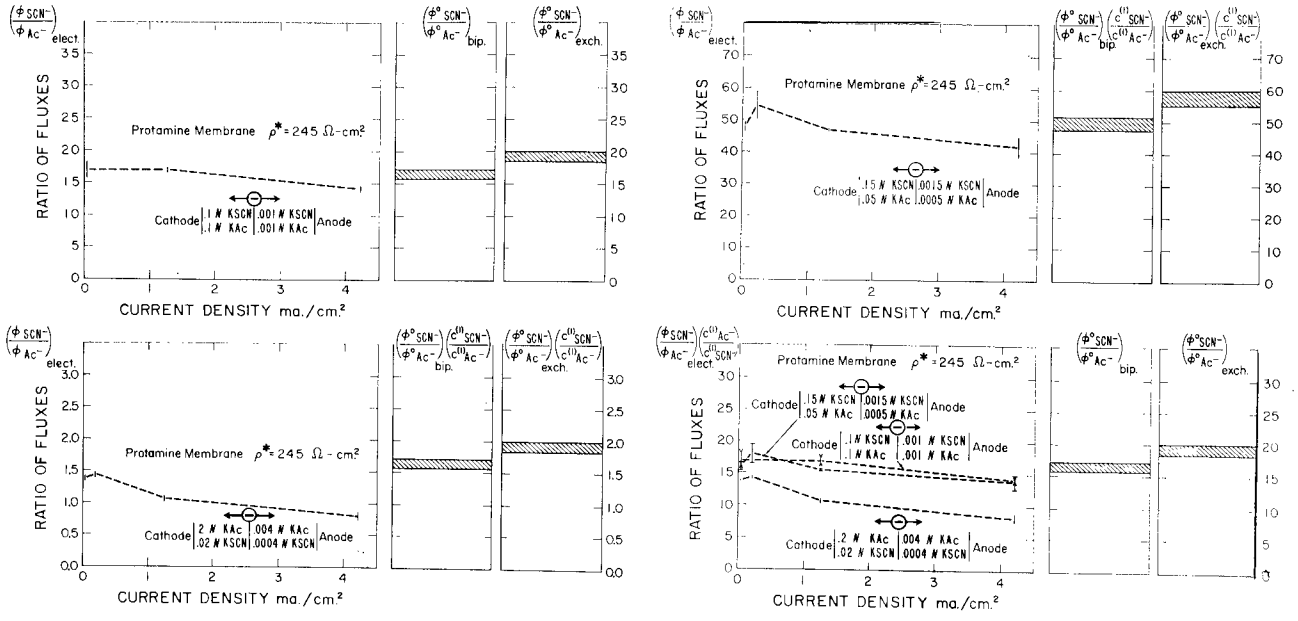

Fig. 2. A comparison of the ratios of fluxes of SCN^- and Ac^- ions (i) as transported by an electric current across an exclusively anion permeable permselective protamine collodion matrix membrane, $(\phi_{SCN^-}/\phi_{Ac^-})_{elect.}$, (ii) as calculated from the bi-ionic potential with the two ions separated by the same membrane, $(\phi^\circ_{SCN^-}/\phi^\circ_{Ac^-})_{bip.}$, and (iii) as measured in the simultaneous exchange of the two ions across the same membrane, $(\phi^\circ_{SCN^-}/\phi^\circ_{Ac^-})_{exch.}$.

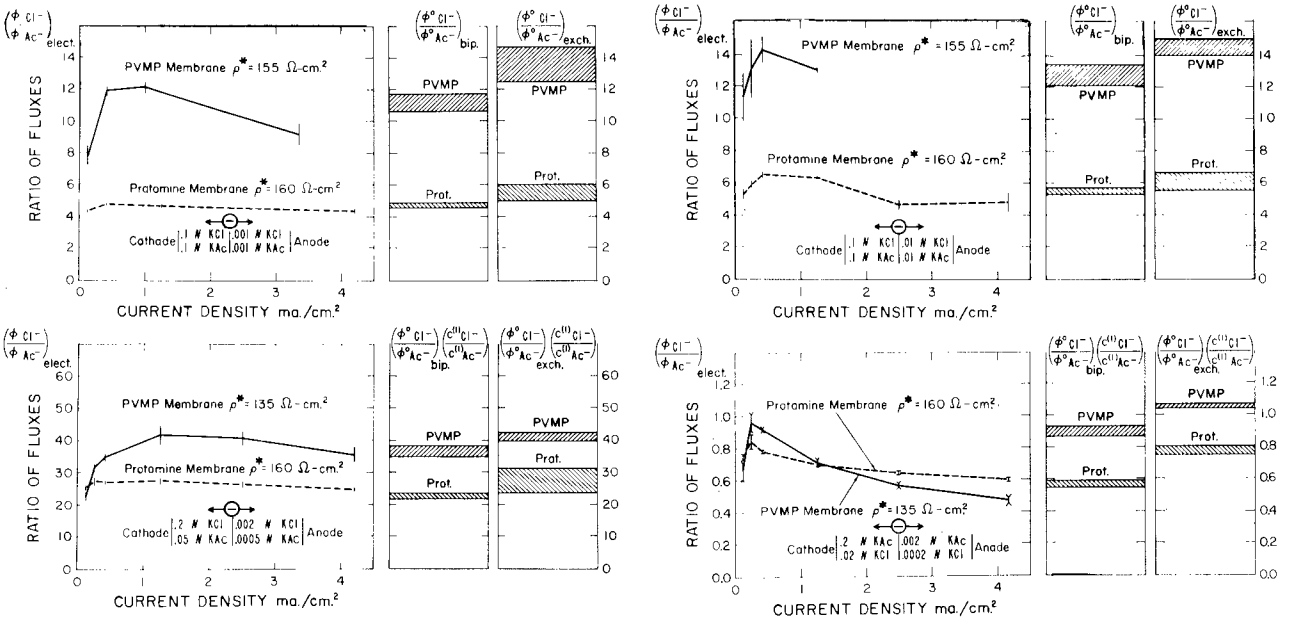

Fig. 3. A comparison of the ratios of the fluxes of Cl^- and Ac^- ions (i) as transported by an electric current across exclusively anion permeable permselective poly-2-vinyl-N-methyl-pyridinium (PVMP) and protamine collodion matrix membranes, $(\phi_{Cl^-}/\phi_{Ac^-})_{elect.}$, (ii) as calculated from the bi-ionic potential with the two ions separated by the same membranes, $(\phi^\circ_{Cl^-}/\phi^\circ_{Ac^-})_{bip.}$, and (iii) as measured in the simultaneous exchange of the two ions across the same membranes, $(\phi^\circ_{Cl^-}/\phi^\circ_{Ac^-})_{exch.}$.

the bi-ionic potentials, and the other, the exchange flux ratios. These graphs have the same vertical scale as the coordinate graphs. In the bar graph of the ratios derived from the bi-ionic potentials, the width of the shaded areas represents the estimated uncertainty in these ratios assuming the measurement of the bi-ionic potential to be accurate within ± 2%. Because the ratio is a logarithmic function of the bi-ionic potential, the width of the shaded areas increases exponentially with the heights on these bar graphs. In the case of the exchange ratios, the width of the shaded areas represents the average deviation from the means of replicate experiments.

Figures 2 and 3 show results obtained with exclusively anion permeable membranes, ←⊖→: Fig. 2 with a protamine membrane and SCN^- and Ac^- as critical ions; Fig. 3 with protamine and poly-2-vinyl-N-methyl-pyridinium (PVMP) membranes Cl^- and Ac^- ions. Figure 4 gives the results with exclusively cation permeable membranes, ←⊕→, polystyrene sulfonic acid (PSSA) and polyacrylic acid (PAA) membranes, with K^+ and Li^+ as critical ions.

A comparison of each pair of bar graphs shows that the flux ratios calculated from the bi-ionic potentials and from the exchange measurements agree

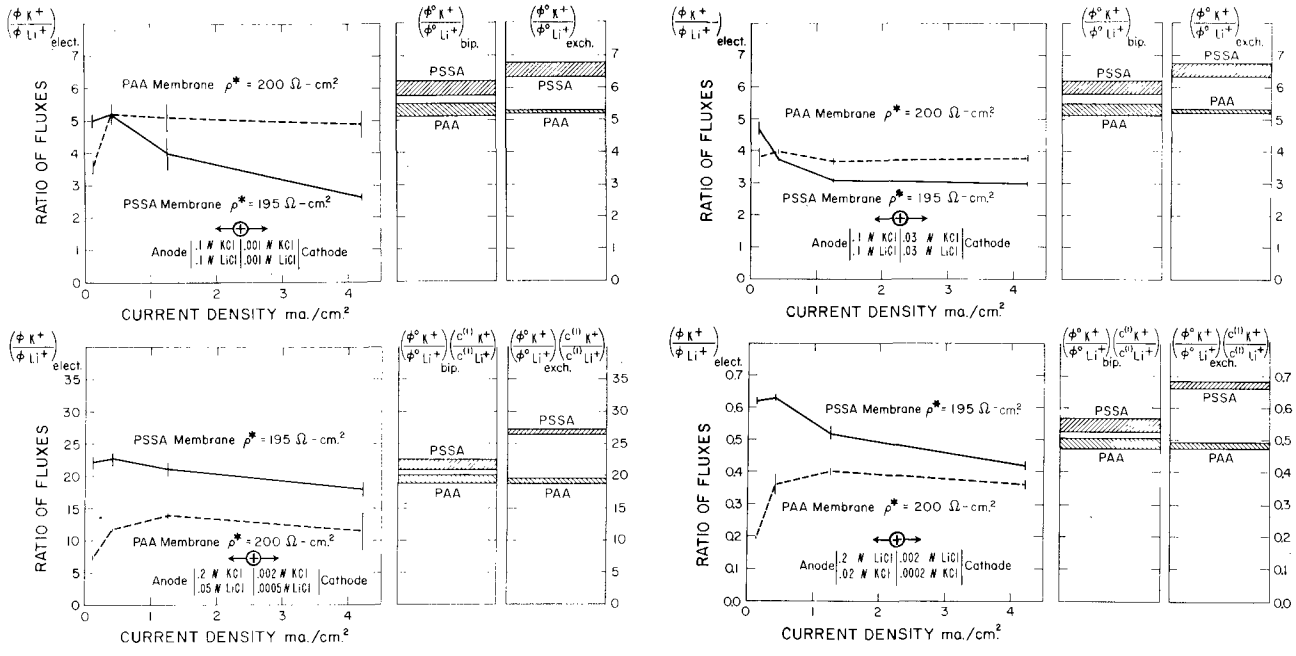

Fig. 4. A comparison of the ratios of the fluxes of K^+ and Li^+ ions (i) as transported by an electric current across exclusively cation selective permselective polystyrene sulfonic acid (PSSA) and polyacrylic acid (PAA) collodion matrix membranes, $(\phi_{K^+}/\phi_{Li^+})_{elect.}$, (ii) as calculated from the bi-ionic potentials with the two ions separated by the same membranes, $(\phi^\circ_{K^+}/\phi^\circ_{Li^+})_{bip.}$, and (iii) as measured in the simultaneous exchange of the two ions across the same membranes, $(\phi^\circ_{K^+}/\phi^\circ_{Li^+})_{exch.}$.

reasonably well with each other, the exchange flux ratios being somewhat higher than the ratios calculated from the bi-ionic potential. The agreement between the two ratios is similar to that reported by Neihof and Sollner (1).

The curves of the ratios of electrical fluxes versus current density in the coordinate graphs of Fig. 2-4 show in the majority of the investigated cells a maximum in the range of current densities of about 0.3-1.0 ma/cm². At higher current densities the ratios of the fluxes are lower, being lower the greater the current density. At current densities less than about 0.3 ma/cm² there is in nearly every cell a significant, in several instances a very marked, drop in the electrical flux ratio. The slope may in many cases be steeper than indicated by the graphs, since the experimental points at low current densities are not close enough together to define exactly the maximum of the curves.

This general shape of the curves is not to be anticipated on the basis of the theoretical treatment. The latter predicts only the observed lowering of the electrical flux ratios as the current density increases, primarily due to polarization and, secondarily, to an increasing preponderance of the electroosmotic over the osmotic liquid movement.

A comparison of the electrical flux ratios at the maxima of the curves with the ratios given by the corresponding bar graphs shows a fairly good quantitative agreement with most of the cells. An extrapolation to zero current of the parts of the curves between about 0.5 ma/cm² and 4.0 ma/cm² would yield an intercept which would show an even better agreement with the bar graphs. This extrapolation, however, seems questionable in view of the drop of the curves at the lower current densities.

The downward slope of the curves toward the side of the lower current densities is contrary to the theoretical expectation. Since this effect occurs quite regularly and is in magnitude far outside the limits of the experimental errors, it must be considered as real. The experiments on spontaneous back exchange reported above preclude an explanation on this basis of the low flux ratios obtained at low current densities. In some instances a spontaneous back exchange with no current passing was not detectable. The greatest back exchange with no current would correspond to less than one-third of the observed decrease in ratios. However, as mentioned previously, any back exchange during the electromigration runs must have been less. Attempts based on the conventional electrochemistry of permselective membranes to explain the lower electrical flux ratios at the lowest current densities have not yet been successful.

That the electrical flux ratios at the maxima of the curves, where polarization is still small, show satisfactory agreement with the theory, seems to indicate that the electrophoretic coupling of the electromigration across the membrane of two species of critical ions is not very marked—the available data are inadequate for any quantitative statement.

Thus the outlined theory seems justified in principle as a first approximation, although it is not adequate to describe the phenomena over more than a very limited area of current densities. Proof is lacking that such agreement between theory and experimental results would be found with membranes of higher porosity, in which each electromigrating ion transports a much greater number of water molecules (22) than in the rather dense membranes used in the present study.

Any more comprehensive and rigorous approach to the problem of the ratios of the electromigration across permselective membranes of two or more species of critical ions coexisting in solution will be confronted not only with the complexity of the membrane processes themselves, but also with the

problem of polarization. Polarization, as indicated by our experimental results, is a most important factor, at all but rather low current densities. The general approach to the theory of irreversible processes given by de Groot (23) and the more specific treatment of membrane processes along analogous lines by Staverman, Kirkwood, Schmid, Schlögl, Spiegler and others yield a useful conceptual framework (24-28). However, the practical obstacles to the use of this approach with experimental cells are formidable. Disregarding polarization in the solutions and assuming no complications such as slow reactions at the membrane-solution interfaces, the situation even with membranes of ideal ionic selectivity is highly complex. With three species of particles, A^+, B^+, and H_2O, which are movable with respect to the membrane, it would be necessary to determine six independent flux constants, which describe the interactions between these particles, in order to know their flux equations (28). However, a given set of constants applies only to a given ratio of A^+ and B^+ in the membrane and additional data, or permissible assumptions, are needed to describe any different A^+/B^+ ratio. Moreover all such constants apply only to the particular membrane under study; different constants pertain to each different membrane.

An approach along these lines to the problem of the ratios of the electromigration across permselective membranes of co-existing species of critical ions is an undertaking of a major magnitude. This prompts us, for the time being, to stop further work in this direction.

Manuscript received Aug. 13, 1959. This paper was prepared for delivery before the New York Meeting, April 27-May 1, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Surface Coverage during Hydrogen and Oxygen Evolution

P. Rüetschi, J. B. Ockerman, and R. Amlie

Research Center, The Electric Storage Battery Company, Yardley, Pennsylvania

ABSTRACT

The relation between surface coverage and electrode potential during hydrogen and oxygen evolution was studied with inert electrodes of very large surface area. Desorption of gas after interruption of current was followed with micro-volumetric techniques and overvoltage decay was measured simultaneously. The steady-state overvoltage varied linearly with the total amount of hydrogen or oxygen evolved after interruption of current. The true surface area of the electrodes was determined by the BET method, and the capacity was obtained from charging curves. Average effective charges in the double layer per desorbed reacting particle were calculated from these data.

A given (experimentally measurable) over-all Volta potential difference at an electrochemical interface may be established by an infinite number of different charge distributions in the electrode double layer. For the interpretation of transient electrode phenomena (experiments with voltage or current step functions, or a-c techniques) the time-dependence of the charge distribution along the coordinate vertical to the electrode surface, or of the double layer capacity, must be taken into account. Adsorption processes on electrodes are often relatively slow, and it is shown below that considerable time periods may be required to establish steady-state conditions.

Build-up of overvoltage at constant current is generally linear with time over voltage regions extending in some cases over several hundred millivolts if the double layer capacity remains constant during the time period involved (1-6). This is the case if the build-up of the double layer charge is due to accumulation of the same (reacting) species in the same average state (constant distance from electrode interface, constant dipole for adsorption bond) throughout. Changes in the electrode capacity during the charging period (nonlinear charging curves) could result from a variation in specific capacity of a particular species with total Volta potential difference (adsorption state, particularly average distance from the electrode surface varying with potential) or from adsorption of several different species with different specific capacities in such a way that the number of each species in the interface does not vary linearly with over-all Volta potential difference.

The decay of overvoltage after interruption of current becomes, after an initial time period, generally linear with the logarithm of time (1, 4, 6-11). This again can generally be expected only in potential regions where the double layer capacity is constant. This is the case if the number of each species contributing to the charge of the double layer decreases linearly with electrode potential, and if the specific average capacity (adsorption state, distance from electrode surface) is independent of the total Volta potential difference.

Overvoltage in general decays more slowly than expected for an ionic double layer without strong adsorption. The reacting species, maintaining the overvoltage, must be strongly (specifically) adsorbed. Electrodes have the characteristic of maintaining a nonequilibrium concentration of reacting species at the interface over considerable time periods (12). The persistence of nonequilibrium electrode potentials is manifested convincingly by experiments with reversed pulse technique (6). Speculations about the actual configuration of the intermediates (protons, hydrogen molecule ions, atomic hydrogen, surface metal hydrides, molecular hydrogen, for H_2 evolution; and oxygen ions, hydroxyl ions, hydrogen peroxide ions, atomic oxygen, surface oxides, molecular oxygen, for O_2 evolution) on the basis of current-voltage relations only, are not conclusive in view of the fact that (mixtures of) these species might be present in the interface together with foreign inert species, not taking part directly in the reaction. In this connection it is important to point out that there is no such thing as a neutral particle (atom, molecule) in an electrochemical interface. All the surface bonds must have substantial ionic components. This becomes particularly evident from the work function effects of adsorption on solid-gas interfaces (13). The differentiation between atomic and ionic species in the interface is therefore only one of degree and not clear-cut at all. It is the purpose of the present investigation to shed more light on the actual configuration in the electrode interface during hydrogen and oxygen evolution, to study the number and state of adsorbed (activated) species, and to determine the relation between surface coverage and overvoltage. Particular consideration is given to time effects due to slow adsorption phenomena.

Theory

The electrode reaction of gas evolution can be described approximately by the rate equation (13)

$$i = A \exp \{-\alpha Z_i e\, V/kT + \alpha Z_i e\, V_f/kT - (\epsilon^* - \epsilon^\circ)/kT\} \quad [1]$$

where i is the current density, A a factor independent of potential, α the transfer coefficient, $Z_i e$ the

charge of the reacting species in the interface, $V = \psi_I - \psi_{II}$ the Volta potential difference between electrode I and solution II, $V_f = (\psi_I - \psi_{II})_f$ the Volta potential difference at which the number of the reacting species in the interface becomes zero,[1] and $\epsilon^* - \epsilon^\circ$ the covalent adsorption energy of the reacting species.[2] The transfer coefficient α is given by $\alpha = (1/2)(1 - \gamma) = 1/2 - \gamma/2$, where γ is the fraction of the variation of electrode polarization due to inert foreign species according to the theory of Rüetschi (21). The factor A is given by $A = \nu Z_i e \delta n_i$, where ν is a jump frequency and δ the thickness of the reaction zone, and n_i the concentration of the reacting ions in the bulk of the solution (number per cm^3). The instantaneous current, during build-up or decay of overvoltage, is given by

$$i = C\, dV/dt = C\, d(\psi_I - \psi_{II})/dt \qquad [2]$$

where C is the double layer capacity. Combining [1] and [2] and integrating at constant C, one obtains

$$V = \frac{kT}{\alpha Z_i e} \ln \left\{ \frac{tA\alpha Z_i e}{CkT} \exp \left[\frac{\alpha Z_i e V_f}{kT} - \frac{\epsilon^* - \epsilon^\circ}{kT} \right] + \exp \left[\frac{\alpha Z_i e V_o}{kT} \right] \right\} \qquad [3]$$

where $V_o = (\psi_I - \psi_{II})_o$ is the Volta potential difference of the electrode at zero time (beginning of build-up or decay).

If the time t is sufficiently long, the second term in braces can be neglected, and the potential decays on open circuit linearly with logarithm of time.

$$dV/d \ln t = \pm kT/\alpha Z_i e \qquad [4]$$

During constant current charge, the potential increases linearly with time, if C is constant, according to Eq. [2].

$$V = it/C + V_o \qquad [5]$$

In the present paper Eq. [1] to [5] were tested experimentally for hydrogen and oxygen evolution. Deviations from these equations demonstrate the influence of voltage and time effects on the capacity C. Experiments on overvoltage decay were coupled with gas desorption measurements. Such measurements give information about the amount of partially or completely discharged reacting species in the interface.

It should be pointed out here that the behavior of an electrode interface can be described quite accurately with the simple model of a condenser. Each species on the electrolyte side of the interface contributes a characteristic charge to the double layer, and contributes through its specific average capacity in a characteristic way to the total Volta electrode potential difference of the electrode. The total charge is compensated on the electrode side of the interface by an excess or deficiency of electrons, depending on whether the electrode is on the negative or positive side of the zero charge potential. The double layer capacity remains constant only if each species has a constant specific capacity, independent of the total Volta potential difference, and if the number of each species varies linearly with total Volta potential difference.

Equations [1] to [5] imply a reacting species, with charge $Z_i e$, whose energy in the double layer can be compared with its energy in the bulk of the electrolyte. For hydrogen evolution in acid solution, it is convenient to define the proton as reacting species. The charge of the double layer on the solution side in sulfuric acid, e.g., is due to reacting protons, SO_4^{--} ions and overlapping electrons (partially discharged hydrogen ions, or polarized hydrogen atoms). Then $Z_i = 1$, and α is determined by the relative contribution of SO_4^{--} ions and electrons (and conceivably other charged species) to the variation of the electrode potential (21). After having defined the reacting species, Eq. [1] and [4] allow calculation of $\alpha = (1/2)(1 - \gamma)$ from experimental data. A priori, only the product αZ_i can be determined experimentally, but not the individual components γ and Z_i. Only after definition of the reacting species is γ determined. If, in the case of H_2 evolution, the variation in polarization is due to accumulation of reacting protons only, $\gamma = 0$ and $\alpha = \frac{1}{2}$.

For oxygen evolution in acid solution one can define the reacting species as the hypothetical O^{--} ion. On the solution side of the double layer, this ion can be associated with protons (producing OH^- or H_2O), or with overlapping electron holes (producing partially discharged species like O^-, O, O_2^{--}, O_2^-, O_2) or both, producing HO_2^-, and H_2O_2. The charge on the solution side is therefore due to O^{--} and associated foreign species (including SO_4^{--} and ions of the metal). If the variation in polarization due to foreign species were zero, then $\gamma = 0$ and $\alpha = \frac{1}{2}$. If the variation in polarization were due entirely to OH^- ions, each O^{--} is associated with *one* proton and $\gamma = -1$. Since $Z_i = 2$, $(\frac{1}{2})(1 - \gamma)Z_i = 2$ and $\alpha = 1$. To demonstrate that the choice of the reacting species is not arbitrary, one could assume OH^- as the reacting species and variation of polarization due to accumulation of OH^- ions only. Then $Z_i = 1$, $\gamma = 0$, $\alpha = \frac{1}{2}$, and thus $(\frac{1}{2})(1 - \gamma)Z_i = \frac{1}{2}$. This shows that α depends on the choice of the reacting species.

In the following discussion we shall adopt $Z_i = 1$ for hydrogen and 2 for oxygen, since these are the charges actually required to liberate one atom of the gases from their state in the bulk of the solution. The experimental results then yield values for γ, which is a measure of the contribution of foreign species (other than H^+ or O^{--}, respectively) to the variation of polarization for H_2 and O_2 evolution. The factor γ can theoretically assume any value between $-\infty$ and $+1$ (21).

Measurements of build-up of overvoltage at constant current give information about the total capacity of the double layer. Capacity is measured here by the voltage change produced by an external known current. During overvoltage decay, the instantaneous internal current cannot be measured directly, but it is reasonable to assume that it is adequately described by [1].

[1] The potential V_f was denoted V_{if_o} in an earlier theoretical paper (21).

[2] Only changes in $V = \psi_I - \psi_{II}$ are measured in overvoltage studies: $\Delta V = \Delta(\psi I - \psi II) = \Delta\eta$, where η is the overvoltage. In this paper the reference electrodes to which overvoltages are referred are the reversible $Pb/PbSO_4$ and $PbO_2/PbSO_4$ electrodes.

It is necessary to define the term capacity as the charge transferred per unit voltage change. During fast charging, an outer layer of ions is built up at the interface. As time proceeds, part of these ions are brought closer to the interface and are partially discharged. This results in an apparent increase in capacity. Only the gas actually leaving the interface does not contribute anything to the charge of the double layer. In the present paper, the capacities were determined from relatively slow charging curves, which means that they are essentially the capacities for an average adsorption state. On open-circuit decay, an ionic, outer double layer would require theoretically 2 or 4 electronic charges to produce one molecule of H_2 or O_2. Actually, less charge may be required for species already partially discharged in the interface. The amount of gas desorbed in excess of the amount expected for an ionic type double layer is a measure of the number and state of adsorbed and partially discharged reacting species. Thus, even for constant capacity (voltage changing linearly with current-time product) the amount of gas desorbed need not be linear with the amount of electricity passed, nor with the voltage change.

Experimental

To obtain measurable amounts of gas during overvoltage decay, inert electrodes of large surface are required. In the present study, the electrodes were sections of storage battery plates. The electrode for the hydrogen evolution studies consisted of pure metallic sponge lead, with a grid of a lead-calcium alloy (0.075% Ca by weight) and was 7.5 cm high, 3.6 cm wide, and 0.55 cm thick. The total weight of the electrode was 70.00 g. The electrode for the oxygen evolution studies was a PbO_2 sponge plate with a lead-calcium grid alloy (0.075% Ca by weight) and 4.0 cm high, 2.0 cm wide and 0.60 cm thick, weighing 44.02 g. It should be pointed out that PbO_2 is an excellent material for the study of oxygen overvoltage since it cannot be oxidized to a higher oxide and since it has a low electronic resistivity (*ca.* 10^{-4} ohm-cm).

The large-area electrode is shown in Fig. 1 at B. The electrolyte was 5*M* H_2SO_4 prepared from triply distilled water and purified acid. The electrolyte level (E) was adjusted to allow a minimum amount of dead space. Electrode potentials were measured against a sealed mercurous sulfate reference electrode in 5*M* H_2SO_4. The large-area electrodes were polarized by means of a polarizing electrode of pure lead (A). During polarization at constant current, both stopcocks in Fig. 1 were kept open. The electrodes were polarized at small current densities over prolonged time periods prior to the actual experiments on decay and build-up of overvoltage, to remove $PbSO_4$ from the surfaces.

Build-up of overvoltage at constant current and decay of overvoltage on open circuit were followed with an electrometer amplifier (General Radio Voltmeter Amplifier 1230-A) driving a high-speed recorder [Brown-Honeywell Model Y 153 X (19) VX 156] with a precision of 1 mv, current drains of less than 10^{-13} amp, and with a response of 1 mv in 20 msec. Constant current was obtained from an

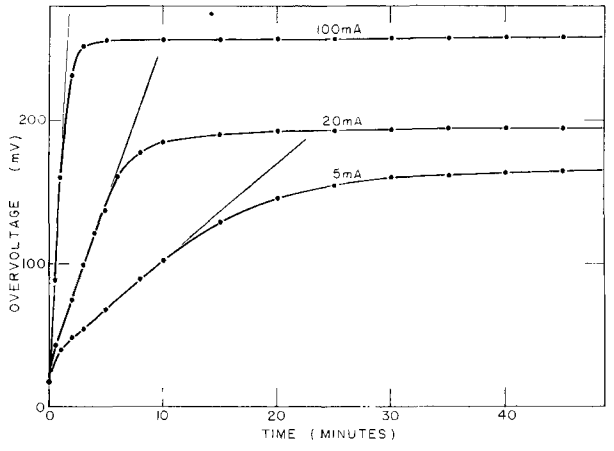

Fig. 2. Build-up of oxygen overvoltage on PbO_2 at constant currents, in 5.0M H_2SO_4 at 30°C.

electronic circuit described earlier (14). To minimize any changes in electrode surface, the electrode potentials were never allowed to reach reversible values. The reversible potential of the $PbO_2/PbSO_4$ electrode in 5*M* H_2SO_4 is 1.704 v vs. H_2 (or 1.111 v *vs.* Hg/Hg_2SO_4) in the same solution. During oxygen overvoltage decay the potential was allowed to reach a value of 1.717 v vs. H_2 (13 mv above the reversible $PbO_2/PbSO_4$ potential). At this point the charging current was switched on again and the constant current charging curves were obtained (Fig. 2). In this manner, specific adsorption effects due to SO_4^{--} ions were minimized. It is known that SO_4^{--} ions are adsorbed on PbO_2 between 1.70 and 2.0 v vs. H_2, and that above this potential adsorption does not change much (15). A similar procedure was followed during hydrogen overvoltage studies on metallic lead. The reversible potential of the $Pb/PbSO_4$ electrode −0.372 v vs. H_2 (or −0.965 v vs. Hg/Hg_2SO_4) in 5*M* H_2SO_4. During decay of overvoltage the potential was allowed to reach a value of −0.392 v vs. H_2 (20 mv more negative than the reversible potential). This decreased the effects of SO_4^{--} adsorption; however, these effects were nevertheless pronounced, which is understandable since the zero charge potential of metallic lead is at about −0.7 v vs. H_2 (16). Only at potentials negative to this value can the polarization be expected to be due predominantly

to accumulation of H^+ ions. In the case of the $PbO_2/PbSO_4$ electrode the zero charge potential in $5M$ H_2SO_4 is at +1.70 to +1.75 v vs. H_2 (17, 18). This indicates that SO_4^{--} adsorption is less noticeable for the oxygen overvoltage experiments. This was confirmed experimentally. Gas desorption from the electrodes was measured from the displacement of a dibutylphthalate drop in a 1 cm^3 Pyrex capillary, calibrated in units of 1/100 cm^3. After interruption of the polarizing current, the stopcocks were closed instantaneously and the position of the dibutylphthalate drop followed with time. Volume corrections for atmospheric pressure changes were made by simultaneously following a drop in a second capillary attached to a cell with the same dead-space, but without electrodes. The whole system was carefully thermostated to ± 0.05°C.

At the end of the measurements the electrodes were washed carefully with distilled water and ethyl alcohol and dried quickly in a vacuum desiccator containing $CaCl_2$. The surface areas of the electrodes were determined by standard BET techniques and yielded 35.2 m^2 for the PbO_2 electrode and 15.9 m^2 for the Pb electrode.

Overvoltage studies on porous electrodes can lead to different results from smooth electrodes due to the nonuniform current distribution over the true surface area (19). If the ohmic drop due to current flow in the pores cannot be neglected in comparison with the polarization at the interface, the porous electrode will show different polarization characteristics. According to Ksenzhek and Stender (20) the overvoltage η varies with distance x from the surface of the porous electrode toward the interior according to

$$\eta = 4b \tanh^{-1} [\exp (-x/\sqrt{b/2Si_o\rho}) \tan (\eta_o/4b)] \quad [6]$$

where i_o is the exchange current density, ρ the electrolyte resistivity, S the specific surface area of the porous electrode in cm^2/cm^3, and $b = RT/\alpha ZF$ (Tafel slope/2.303); η_o is the apparent overvoltage at the surface of the porous electrode, and η the true overvoltage at the reaction interface. The penetration depth x_e, where the true current density has fallen to $1/e$ of the apparent value, is $x_e = \sqrt{b/2Si_o\rho}$. For our experiments, with $b = 0.05$, $S = 50{,}000$ cm^2/cm^3, $i_o = 10^{-9}$ amp/cm^2, $\rho = 1$ ohm-cm, the penetration depth becomes 22.4 cm. This is 100 times the value of the half-thickness of our porous plates. This shows that pore-structure effects should be negligible in our experiments.

Results

The electrodes were polarized at constant current to a steady-state overvoltage. The corresponding Tafel plots are shown in Fig. 3. Here overvoltage is referred to the reversible $Pb/PbSO_4$ potential for hydrogen evolution, and to the reversible $PbO_2/PbSO_4$ potential for oxygen evolution. These are the stable electrode potentials the electrodes would actually reach on prolonged open circuit. The current densities refer to the total BET electrode surface. Hydrogen overvoltage increases slowly over many hours. If overvoltages are measured over short time intervals, the Tafel slope is 0.120 v i.e.,

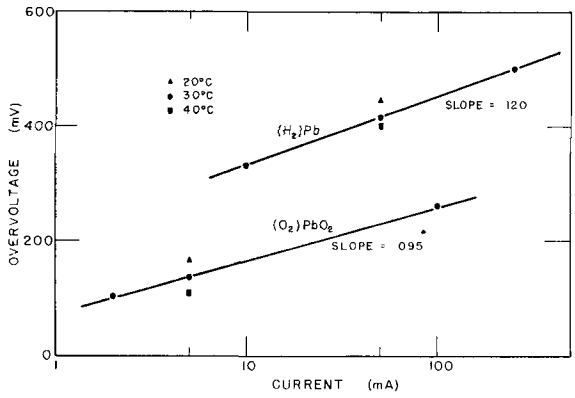

Fig. 3. Tafel curves for hydrogen overvoltage on lead and oxygen overvoltage on PbO_2. Overvoltage measured against reversible $Pb/PbSO_4$ and $PbO_2/PbSO_4$ electrodes, respectively, in 5.0M H_2SO_4 at 20°, 30°, and 40°C.

with $Z_i = 1$, $\gamma = 0$, and $\alpha = \frac{1}{2}$ (Fig. 3). The change in overvoltage from one current density to another is then simply due to accumulation of reacting species only, according to the theory of Rüetschi (21). If, on the other hand, the Tafel curve is taken slowly, allowing longer time periods for each current, the slope increases to 0.160 v in the voltage region of Fig. 3. This means that now slowly adsorbing or desorbing foreign species are contributing to changes in the charge of the double layer (desorption of SO_4^{--} ions), or that the reacting species have a smaller specific capacity (larger distance to the electrode surface) such that for a given number of reacting species in the interface, the electrode potential is higher than before. From the slope 0.160 v one obtains $\alpha = 0.37$ and $\gamma = 0.25$. The latter is the fraction of variation of polarization attributable to desorption of SO_4^{--} or changes in specific capacities of reacting protons (21).

In Fig. 3, oxygen overvoltage has a Tafel slope of about 0.095 v, depending again somewhat on the rate of taking the curve. However, adsorption effects are smaller than for hydrogen on lead, which can be explained on the basis of the relative position of the zero charge potentials. With $Z_i = 2$ one obtains from the Tafel slope $\alpha = 0.32$ and $\gamma = 0.37$. The latter fraction of voltage change from one current to another, is attributable to adsorption or association of foreign species, such as SO_i^{--} (along with the reacting species O^{--}), or changes in specific capacity of reacting species (21). Considering the large surface areas of the electrodes the true current densities are extremely low, in the order of 10^{-9} to 10^{-8} amp/cm^2. However, the exchange currents for hydrogen and oxygen evolution on these electrodes are in the order of 10^{-12} and 10^{-10} amp/cm^2, and therefore the experiments fall into the Tafel region. Measurements of the gas evolved at steady state showed that 97% or better of the current went into gas production, and therefore, no other charging reactions interfered.

Figure 2 shows oxygen overvoltage build-up at constant current. From the slopes of the linear portions one obtains a capacity of 44 farads for the double layer. With a BET surface of 35.2 m^2, this is 125 $\mu F/cm^2$, a relatively high value, which would be even higher if only part of the surface were elec-

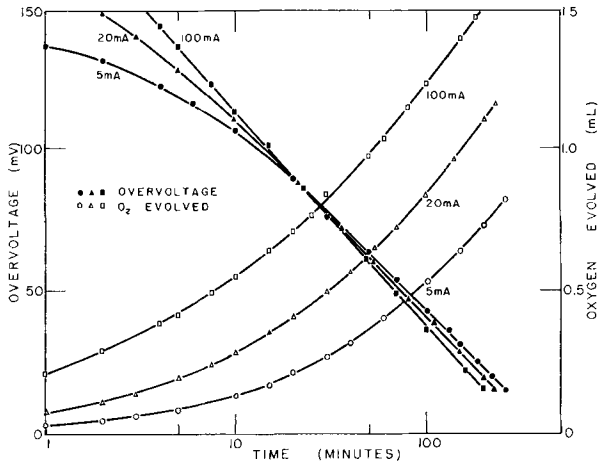

Fig. 4. Decay of oxygen overvoltage on PbO_2 for various prepolarizing currents and oxygen gas desorbed; temperature 30°C.

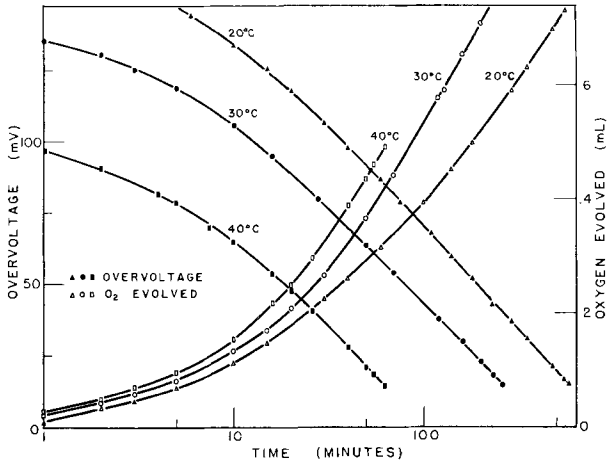

Fig. 5. Decay of oxygen overvoltage on PbO_2 at various temperatures and oxygen gas desorbed. Prepolarizing current 5 ma.

trochemically active. The high value for the capacity indicates strong adsorption of the reacting species. There is a slight bend in the initial portion of the charging curve indicating a small variation in capacity due to a different initial charge distribution.

Figures 4 and 5 show oxygen overvoltage decay on open circuit, and simultaneous gas desorption. Oxygen overvoltage decreases linearly with the logarithm of time, indicating a fairly constant capacity during decay. The decay slope is almost independent of temperature and of prepolarizing current. Figure 4 indicates that at the same temperature (30°C) a given voltage is reached in the same time, independently of prepolarizing current. According to Fig. 5 the desorption rate increases with temperature. In Fig. 6 the logarithm of the gas evolution rate in cm^3/min is plotted against $1/T$ for given overvoltage values. The slopes of the straight lines tend to become less steep with increasing overvoltage. If the rate of O_2 evolution could be set equal to the instantaneous internal current, then the slopes would be, according to Eq. [1], a measure for the term $-\{\alpha Z_i eV - \alpha Z_i eV_f + \epsilon^* - \epsilon^\circ\}/2.303\ k$. A plot of this term against overvoltage should then yield a straight line with a slope of $-\alpha Z_i e/2.303\ k$ $= 5010\ \alpha Z_i$. One could then determine the value of αZ_i by this method, but the accuracy of the measurements is not sufficient to obtain an exact value, although one obtains the correct order of magnitude ($\alpha Z_i = 1 \pm 2$). However, the instantaneous internal current cannot be set equal to the instantaneous gas evolution rate, at 2 electrons per H_2 and 4 electrons per O_2. The slope of the oxygen overvoltage decay curves in Fig. 4 and 5 is about 0.078 v, which is fairly close to the value of the Tafel slope. With $Z_i = 2$ this gives $\alpha = 0.38$ and $\gamma = 0.23$.

In Fig. 7 the results of Fig. 4 have been correlated in such a manner that the total oxygen evolved has been plotted against overvoltage. A voltage of +13 mv above the reversible $PbO_2/PbSO_4$ potential has been chosen arbitrarily for the endpoint of decay. It seems reasonable to assume that at this low value the same state of the electrode surface is reached, independently of prepolarizing current.

Since 1 cm^3 of O_2 at 700 mm Hg and 30°C corresponds to 15.5 amp sec, one can calculate how the voltage should decay, at 2 electrons per oxygen atom, if only a discharge of the double layer capacity of 44 farads were involved. One cm^3 of O_2 evolved should then decrease the potential by 350 mv. In Fig. 7, this theoretical slope has been plotted, marked with 2*e*. Other slopes, corresponding to 1*e* and 0.5*e* per oxygen atom are also indicated. It is

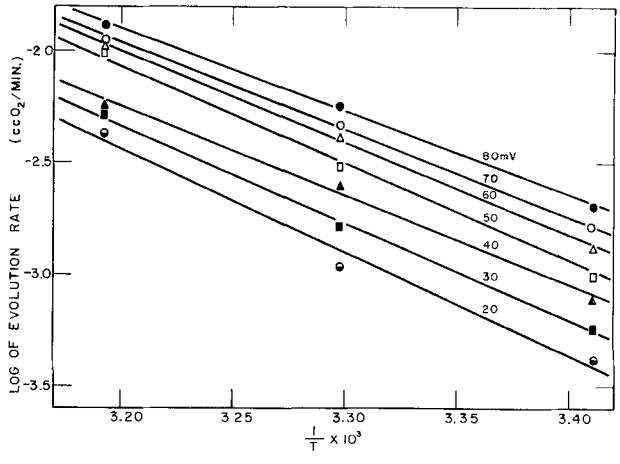

Fig. 6. Logarithm of oxygen gas evolution rates on PbO_2 on open circuit (in cm^3/min) as a function of $1/T$ for various fixed values of overvoltage.

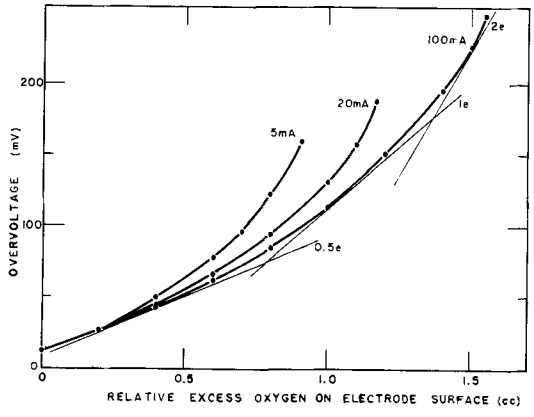

Fig. 7. Oxygen overvoltage decay on PbO_2 as a function of oxygen gas desorbed from the electrode at 30°C.

Table I. Observations on PbO_2 anode

Prepolarizing current, ma	Overvoltage, mv vs. $PbO_2/PbSO_4$	Oxygen atoms desorbed per BET cm^2
100	242	2.12×10^{14}
20	190	1.61×10^{14}
5	158	0.91×10^{14}

interesting to note that for the initial portions of overvoltage decay, the slope approaches the value for 2*e*. However, for later portions, the voltage decay is much smaller, the difference being a measure for the amount of oxygen already partially discharged. A slope of 2*e* could indicate the discharge of 2 OH^- or O^{--} in the outer double layer.

There is another important result in Fig 7. The slope of the plot of the steady-state overvoltage against the total amount of oxygen desorbed gives a straight line. The slope of this line could be interpreted theoretically by postulating the presence of oxygen species with an average charge of about 1*e* per atom in the double layer, although such an interpretation is not rigorous. If the total amount of oxygen desorbed is related to the BET surface of the electrode, one obtains the figures of Table I (1 cm^3 O_2 at 760 mm Hg, 30°C contains 4.84 x 10^{19} atoms).

Build-up of hydrogen overvoltage on lead at constant current is shown in Fig. 8. From the slope of the linear portion one obtains a capacity of 1.67 farad. With a BET surface of 15.9 m^2, this is 10.5 $\mu F/cm^2$, a small value, indicating that the charges are at considerable distance from the surface. Since the charging was done at relatively low rates, this capacity does probably include some changes in SO_4^{--} adsorption and adsorption capacities due to partially discharged protons.

Figures 9 and 10 give hydrogen overvoltage decay curves and gas evolution curves. Decay of hydrogen overvoltage is nearly linear with the logarithm of time, indicating a nearly constant capacity. The decay slope is almost independent of temperature and prepolarizing current. The temperature has a smaller effect on the rate of desorption than for oxygen. In Fig. 11, the logarithm of the hydrogen evolution rate (cm^3/min) is plotted against 1/*T*. The

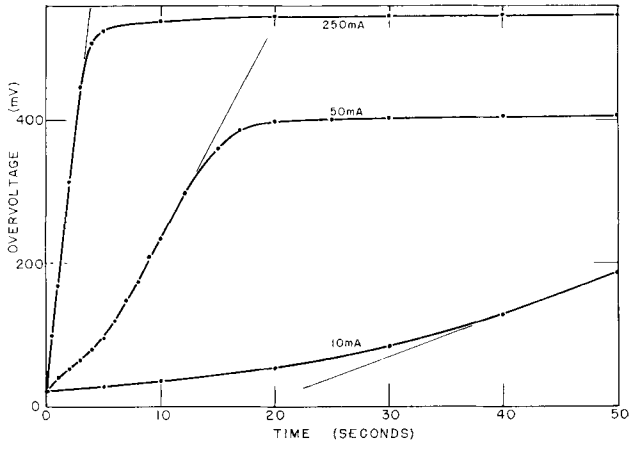

Fig. 8. Build-up of hydrogen overvoltage on Pb at constant currents. Electrolyte 5.00M H_2SO_4 at 30°C.

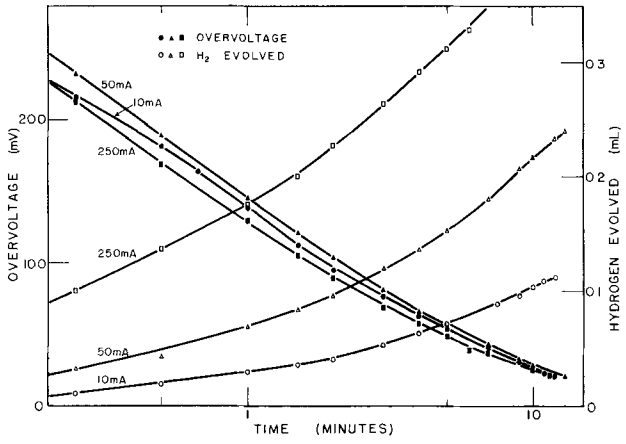

Fig. 9. Decay of hydrogen overvoltage on Pb and hydrogen gas desorbed, for various prepolarizing currents at 30°C.

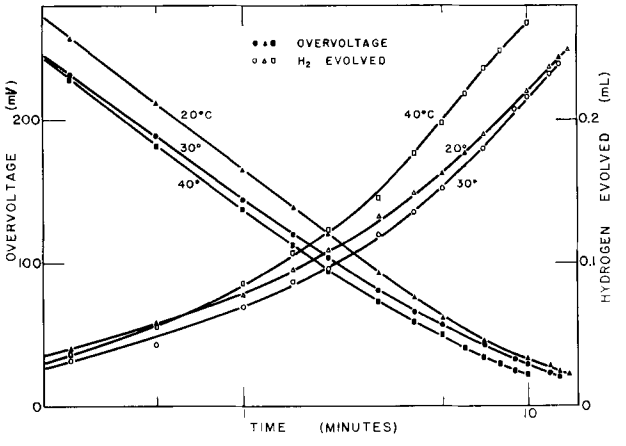

Fig. 10. Decay of hydrogen overvoltage on Pb and hydrogen gas desorbed at various temperatures; prepolarizing current 50 ma.

slopes of the lines are nearly equal but tend to decrease with increasing overvoltage. The variation in the slopes would be a measure for αZ_i if the instantaneous current were equal the rate of gas evolution, which is not exactly the case. One can derive however the right order of magnitude ($\alpha Z_i = 0.5 \pm 1$), although the method is not precise.

The slope of the hydrogen overvoltage decay curves in Fig. 9 and 10 averages 0.145, which is close to the slope of the Tafel curve, when it is taken slowly. The value 0.145 gives with $Z_i = 1$ values for $\alpha = 0.41$ and $\gamma = 0.17$. This shows that the variation in polarization due to foreign species (e.g., adsorption of SO_4^{--} during decay) or the influence of partially discharged hydrogen is not excessive, according to Rüetschi's theory (21).

In Fig. 12 the total amount of H_2 desorbed after interruption of current (to a potential 20 mv more negative than the $Pb/PbSO_4$ electrode) was plotted against overvoltage decay. At the end of decay, the same state of the electrode is reached, independently of prepolarizing current. Since 1 cm^3 of H_2 at 760 mm Hg and 30°C corresponds to 7.75 amp sec at 1*e* per H, one can calculate that 1 cm^3 of H_2 should discharge 1.67 farad by 4.65 v. This theoretical slope between the hydrogen evolved and overvoltage decay is shown in Fig. 12 as a line marked with 1*e*. This is the theoretical decay of the voltage if each

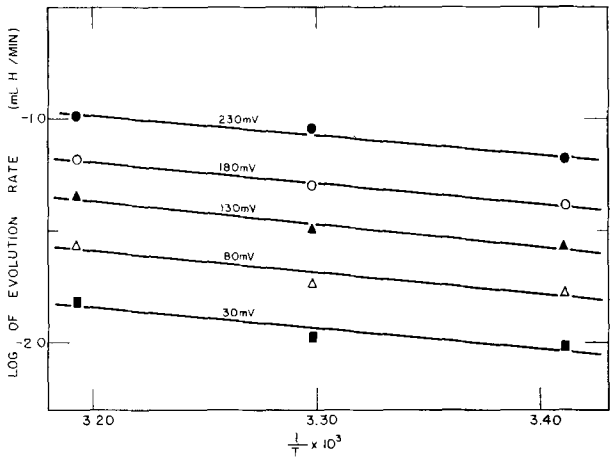

Fig. 11. Logarithm of gas evolution rates on Pb on open circuit (in cm^3/min) as a function of 1/T for various fixed values of overvoltage.

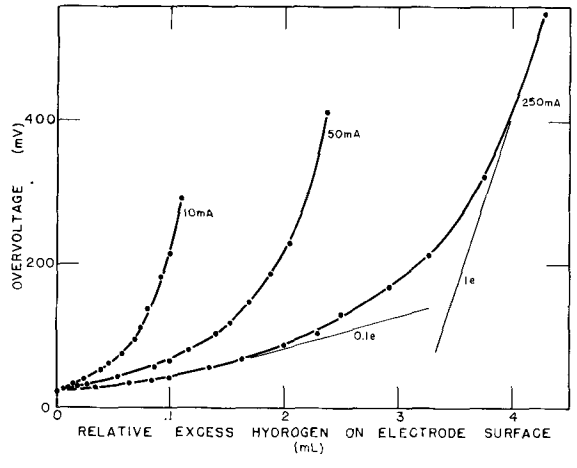

Fig. 12. Hydrogen overvoltage decay on Pb as a function of hydrogen gas desorbed from the electrode at 30°C.

hydrogen atom desorbed were to originate from a proton in a double layer with a capacity of 10.5 $\mu F/cm^2$. For the initial portion of the decay, the voltage decreases according to this theoretical slope. However, for later portions, the potential decreases much less. The difference between the theoretical slope of 1*e* and the experimental values is a measure of the already partially discharged hydrogen in the surface (overlap of H^+ and electron cloud). This hydrogen contributes to the charge of the double layer only by the heteropolarity of the adsorption bonds. Toward the end of the decay, the potential is determined largely by the adsorption of SO_4^{--} ions, as in the case of the oxygen overvoltage SO_4^{--} become the potential determining species at the reversible potential.[3]

During decay of H_2 and O_2 overvoltages, the potentials approach asymptotically the reversible $Pb/PbSO_4$ and $PbO_2/PbSO_4$ potentials, respectively, while H_2 and O_2 evolution are continuing at a small but steady rate since the $Pb/PbSO_4$ potential is negative to the potential of the hydrogen electrode and the $PbO_2/PbSO_4$ potential positive to the oxygen electrode (self-discharge).

[3] Note that the diffusion of adsorbed gas along the grain surfaces of the porous electrodes to the locations of bubble formation might be interfering with the simple interpretation of the results given in this paper.

Table II. Observations on Pb cathode

Current, ma	Overvoltage, mv, vs. $Pb/PbSO_4$	Hydrogen atoms desorbed per BET cm^2
250	553	13.0×10^{13}
50	410	7.2×10^{13}
10	293	3.3×10^{13}

The steady-state overvoltage prior to interruption of current varies, according to Fig. 12, linearly with the total amount of hydrogen evolved. The slope of this line corresponds roughly with the slope of a line calculated for a theoretical discharge of a double layer of 10.5 $\mu F/cm^2$ at 0.5 electron for each hydrogen atom desorbed. This could be interpreted as resulting from a mixture of adsorbed H atoms and protons in the double layer, or the presence of H_2^+. The significant fact is that more hydrogen is desorbed than one could expect from the discharge of a purely ionic type double layer, indicating the presence of partially discharged reacting species.

The total amount of H_2 evolved from the electrode during hydrogen overvoltage decay, down to a potential 20 mv more negative than the $Pb/PbSO_4$ potential, has been correlated to the BET surface. Since 1 cm^3 of H_2 at 760 mm Hg at 30°C contains 4.84 x 10^{19} atoms, the figures of Table II were obtained.

Basically, the same laws apply both to hydrogen and oxygen overvoltage. In either case, the electrode potential (overvoltage) seems to be determined essentially by the number of adsorbed activated species at the interface, these species being present in various states of discharge, and by adsorbed foreign inert species, not taking part directly in the electrode reaction (21). Desorption follows a Becker-Zeldovich equation, which is coherent with a Temkin isotherm (13).

A Study of the Factors Affecting the Electrical Characteristics of Sintered Tantalum Anodes

G. L. Martin,[1] C. J. B. Fincham, and E. E. Chadsey, Jr.

National Research Corporation, Cambridge, Massachusetts

ABSTRACT

Measurements were made of the electrical characteristics (d-c leakage, capacitance, and equivalent series resistance) of anodically oxidized sintered tantalum pellets, which were made from three tantalum powders of different purities, particle shapes, and particle size distributions. The apparent densities of the pellets after sintering were also measured. The effects of varying the pressed density of the pellets and the time and temperature of sintering were studied systematically, and the results were correlated in the form of empirical relationships.

A tantalum electrolytic capacitor is composed of three basic parts: the tantalum anode, the tantalum oxide dielectric, and the electrolyte which acts as the cathode.

The tantalum anode may be foil, wire, or a sintered porous pellet made from powder. The sintered pellet can give the highest surface area per unit volume and hence the highest capacitance per unit volume of the three types. The tantalum oxide dielectric is formed by anodic oxidation of the tantalum anode. The cathode is an electrolyte, which may be either liquid (e.g., aqueous solutions of sulfuric or phosphoric acids) or solid (e.g., manganese dioxide). References (1-3), for example, give more detailed descriptions of the construction and operation of tantalum capacitors.

This paper reports a study of some of the factors, especially sintering conditions, which affect the electrical properties of porous sintered tantalum anodes and their oxide films. The electrical properties studied were d-c leakage, which is defined as the current which flows when a specified d-c voltage is impressed across the anode and its oxide film; the capacitance, which varies with the surface area and thickness of the oxide film; and the equivalent series resistance (*ESR*), which was calculated from the measured dissipation factor (*D*) using the relationship

$$ESR = \frac{D}{2\pi f C}$$

where C is the capacitance (in farads), f is the frequency of the a-c signal (in cps), and *ESR* is given in ohms.

[1] Present address: Department of Chemistry, University of Alabama, University, Alabama.

Experimental Techniques

Pressing.—The tantalum powder was pressed into cylindrical pellets of 0.25 in. diameter in a floating-body steel die. No lubricant or binder was used. The pellets all weighed 1.8 g. Annealed 10-mil tantalum lead wires were pressed into the pellets.

Sintering.—The pressed pellets were sintered inside a closed tantalum can, in a modified NRC 2904 resistance-heated vacuum furnace. Temperature was measured with a tungsten-molybdenum thermocouple with the hot junction resting on top of the tantalum can. Temperatures measured in this way were probably lower than the true temperatures of the pellets in the can. The furnace was pumped, through a cold trap, to a pressure of about 5×10^{-6} mm Hg (and a leak rate of less than 10^{-3} mm Hg/min into a volume of about 40 liters) before the power was turned on. At the end of a run, the charge was allowed to cool to about 200°C under vacuum; then argon was admitted. The furnace was not opened to air until the charge temperature was less than 100°C.

Electrical testing.—The sintered pellets were anodized at a constant current of 35 ma/g up to 200 v, in an 0.01% phosphoric acid solution at 92°C. They were held at 200 v for 2 hr. The maximum voltage determined the thickness of the oxide film and hence its capacitance per unit area. At 200 v the thickness of the oxide film is about 0.3 μ (4).

The anodized pellets were washed for ½ hr in de-ionized water and dried in air overnight at room temperature.

Measurements of d-c leakage, capacitance, and dissipation factor were done using 10% phosphoric acid at room temperature as electrolyte.

Direct current leakage was measured after 2 min at 140 v. Capacitance and dissipation factor were measured at 120 cps with a 0.5 v a-c signal, using a modified General Radio 650-A impedance bridge. The signal source was a Hewlett Packard 205 AG audio signal generator, and a Hewlett Packard 400D vacuum tube voltmeter was used as the null detector.

Sinter densities.—The apparent densities of the pellets after sintering were determined by measuring the diameters and lengths of the pellet at several places on the pellet with a pointed end micrometer.

This method was found to give results agreeing well (within 1%) with measurements made by coating the pellets with nail polish and weighing them in air and water.

Materials

Three different tantalum powders were selected for study, and were given the designations E-11, SG-73R, and L-533. As discussed below, there were considerable differences between these powders in chemical purity, particle size distribution, and particle shape.

Chemical purity.—The analyses of the three powders are given in Table I. The impurities showing the widest differences in levels between the powders are O, C, N, Fe, Cr, Si, and Na. In general, SG-73R was the most pure, and L-533 the least pure, of the three powders.

Particle size measurements below 44μ were done using a Roller subsieve particle size analyzer.

Particle size distributions.—These are shown in Table II. Measurements of particle size above 44 μ were done by screen analysis, and below 44 μ by using a Roller subsieve particle size analyzer (5). L-533 differed from the other two powders in having a considerable amount of material in the greater than 74 μ range. In general SG-73R had the lowest average particle size, and L-533 the highest, of the three powders. However, in view of the particle shapes (see below) of L-533, the measurements of particle size for this material are of doubtful significance.

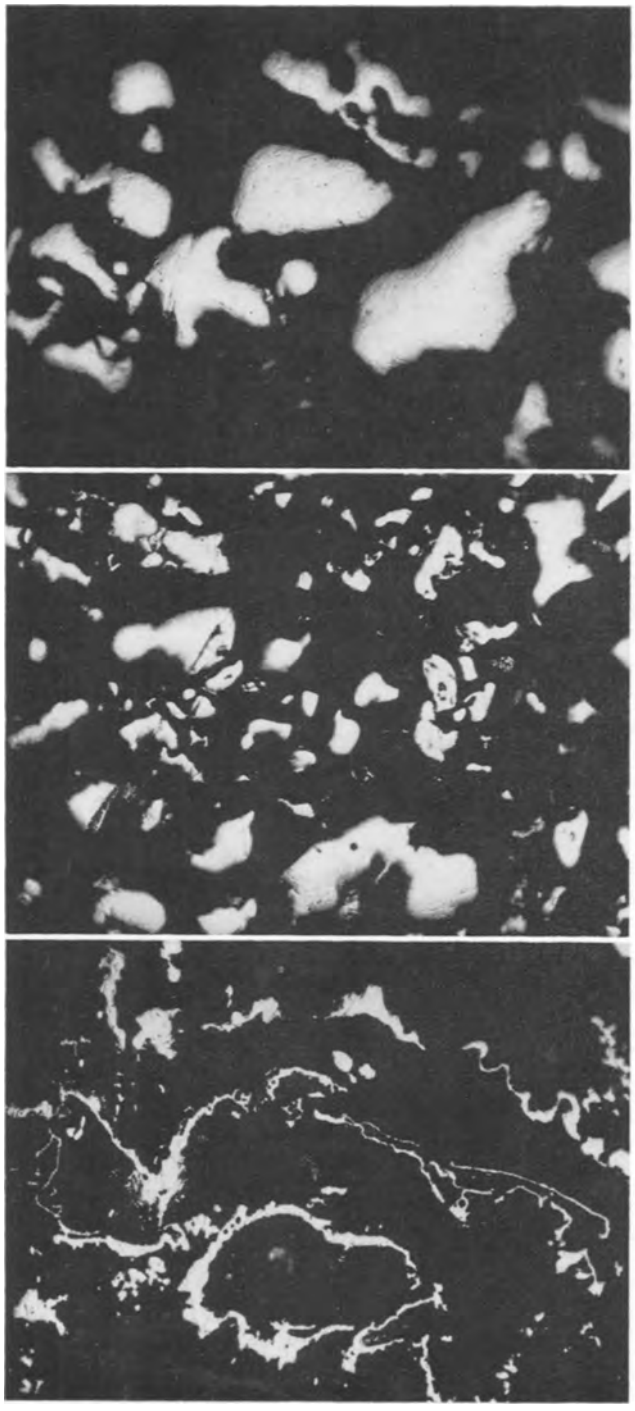

Fig. 1. Particle shape. Photomicrographs of powder particles mounted in plastic, sectioned, and polished. Top, E-11; middle, SG-73R; bottom, L-533.

L is d-c leakage at 140 v, in μa/g; *C*, capacitance at 120 cps, in microfarad/g (200 v formation); *ESR*, equivalent series resistance, in ohm/pellet; D_g, green density, in g/cc.
* Indicates one "wild" pellet out of six.
** Indicates two "wild" pellets out of six.

$$C = 3.75 \times 10^4/T - 3.50 \log (t + 6) - 32.47/(16.6\text{-}D_g) + 3.20 \qquad (T \text{ in } °K)$$

$$L/C = 0.09 \pm 0.02$$

Particle shape.—Samples of each of the powders were mounted in plastic, sectioned, and polished. Figure 1 shows photomicrographs of the sectioned particles, at a magnification of 500 x before reproduction. The particle shapes of E-11 and SG-73R were somewhat similar, in that the particles tended to be solid and regular in shape. L-533 had several different particle shapes, including hollow hemispheres and "strings." The particle size of such irregular shapes is not measured accurately by screening or by air elutriation in the Roller apparatus.

Results

The results of this study were obtained using the experimental techniques described above. In particular, the electrolyte used for measurement of leakage, capacitance, and equivalent series resistance was always 10% phosphoric acid. However, other work done in these laboratories has shown that, when liquid electrolytes are used, to a first approximation leakage and capacitance are independent of electrolyte. Equivalent series resistance is markedly dependent on the electrolyte, since part of the series resistance is due to the ohmic resistance of the electrolyte in the pores of the anode. Equivalent series resistance therefore varies with the specific resistivity of the electrolyte. The specific resistivity of 10% phosphoric acid at room temperature is about 15 ohm-cm (6, 7).

E-11.—Pellets pressed to three different green densities (9.5, 10.5, and 11.5 g/cc) were sintered at three different temperatures (1750°, 1900°, and 2050°C) for three different times (30, 90, and 180 min).

The electrical results obtained on these pellets are shown in Table III, together with results for a green density of 8.5 g/cc (see below). Each result is the average from four pellets, two from one sinter run and the other two from a second sinter run. The table shows the leakage per gram (*L*, in microamperes), the capacitance per gram (*C*, in microfarads), the equivalent series resistance per 1.8 g pellet (ESR, in ohms), and the leakage divided by the capacitance (*L/C*, in microamperes per microfarad).

It can be seen that both leakage and capacitance decreased as the green density and time and temperature of sintering increased, the over-all change for the range of conditions studied being about a factor of two. As the values of *L/C* show, *L* and *C* changed at the same rate, so that *L/C* was constant at 0.09 ± 0.02 μa/microfarad over the range of conditions.

It was found that the relationship between capacitance and sintering conditions could be expressed in the form of an empirical equation, with independent terms in green density, time, and temperature. This equation is

$$C = 3.75 \times 10^4/T - 3.50 \log (t+6) - 32.47/(16.6\text{-}D_g) + 3.20$$

where *T* is temperature, in °K, *t*, time, in minutes, D_g green density, in g/cc, and *C*, capacitance, in microfarads/g. The average difference between the value of *C* given by this equation and the measured value of C is 1.5%. The maximum difference is 4.9%. These differences are well within experimental error. The expression $(t+6)$ occurs in the term for time because *t* was measured as time at the designated temperature. The additional 6 min is an estimate of the extra effective time due to heating and cooling periods. The density of tantalum metal is 16.6 g/cc, and this number appears in the term for green density.

The equivalent series resistance results showed some scatter which tends to obscure the trends. However, it is clear that *ESR* increased markedly with increasing green density, and also to some extent with time. The effect of temperature is uncertain.

After the results described above were obtained and the capacitance equation derived, the study of E-11 was extended to a lower green density of 8.5 g/cc, at the same temperatures, but for two times only (30 and 90 min). The results are shown in Table III. The agreement between the measured capacitance and the capacitance predicted by the previously derived equation is excellent, the largest difference being 6%. Values of *L/C* also agree with

D_s is sinter density (g/cc) and Cvol. is capacitance per unit volume (microfarads/cc).

those previously found; however, a different kind of result was obtained with a few pellets sintered at the less severe sintering conditions. One, or at most two, of six pellets sintered under the same conditions started to "gas" violently during anodization, and on measurement were found to have leakages of the order of 400 μa/g. These values were termed "wild" leakages and are not included in the averages in the table. The reasons for this phenomenon are not clear, but it is associated with lower green densities and lower times and temperatures of sintering (see also the results for L-533 below).

The results for equivalent series resistance appeared to follow the same trends as those previously obtained.

The apparent densities of the pellets after sintering were measured for the pellets studied electrically. Results are shown in Table IV, together with the values for capacitance per unit volume, which were obtained by multiplying the capacitance per gram by the sinter density in g/cc. For practical purposes, in the manufacture of capacitors, the capacitance per unit volume is the important parameter, rather than the capacitance per unit weight.

The sinter density increased with time and temperature of sintering and also with green density, but the difference between green density and sinter density became less as the green density increased. The capacitance per unit volume was almost independent of green density, except at the highest green density (11.5), where there was some decrease. The capacitance per unit volume decreased with increasing time and temperature of sintering.

SG-73R.—A similar study to that made on E-11 was made with SG-73R, except that the data were not as complete and sinter densities were not measured.

The electrical results are shown in Table V, where the values are the averages from six pellets.

The trends of leakage and capacitance were very similar to those for E-11, and L/C was again found to be constant, although the value of 0.07 ± 0.01 μa/microfarad for SG-73R was slightly lower than that for E-11 (0.09 ± 0.02). The capacitance values could be expressed by an equation, in terms of green density, time, and temperature, of the same form as that used for E-11. The average difference between the values of capacitance given by this equation and the measured values was 2%. The maximum difference was 5.1%. The equation is $C = 4.83 \times 10^4/T - 3.72 \log (t + 6) - 46.56/(16.6\text{-}D_g) + 1.19$.

The measurements of equivalent series resistance showed less scatter than that found for E-11, partly because experimental technique had been improved. The equivalent series resistance increased with increasing green density and time, and slightly with increasing temperature.

L-533.—The study of L-533 was made over a range of green densities (7.0 to 10.5 g/cc) extending lower than that used for E-11. Only times of 30

$C = 8.04 \times 10^4/T - 7.34 \log (t + 6) - 94.0/(16.6\text{-}D_g) + 0.40$ (T in° K)
L/C not constant.

and 90 min were used. Electrical results are shown in Table VI, each number being the average from four pellets.

As with E-11 and SG-73R, the capacitance decreased with increasing green density, time, and temperature. However, leakage did not follow the same trend over the whole range of conditions, so that while *L/C* was essentially constant at 0.12 ± 0.02 μa/microfarad for green densities of 8.0 and 9.5, there was a definite increase in *L/C* at a green density of 10.5 and higher temperatures. There were also pellets showing "wild" leakage at the lower green densities and times and temperatures. These were not included in the averages.

The capacitance measurements fitted the same form of equation relating them with green density, time, and temperature as that found to apply for E-11 and SG-73R. The equation is

$$C = 8.04 \times 10^4/T - 7.34 \log (t+6) - 94.0/(16.6\text{-}D_g) + 0.40$$

This equation does not fit the data quite as well as did the equations for E-11 and SG-73R, the average and maximum differences between the measured and calculated capacitances being 3.4% and 9.2%, respectively. This may be due in part to the less complete data used in deriving it.

The equivalent series resistance increased with increasing green density, temperature, and time.

The results of sinter density measurements and the values of capacitance per unit volume derived from them and the capacitances per unit weight are shown in Table VII. Unlike E-11, the capacitance per unit volume of L-533 changed markedly with green density, decreasing with increasing green density. Capacitance per unit volume also decreased with increasing time and temperature.

Comparison of Results

Leakage.—The most significant differences between the leakage results for the three powders were, first, the constancy of *L/C* for E-11 and SG-73R compared with the increase in *L/C* for L-533 at higher green densities and temperatures, and second, the conditions at which the phenomenon of "wild" leakage occurred. Some pellets of E-11 had "wild" leakages at a green density of 8.5 and lower temperatures and times, whereas, under the same conditions, no pellets of SG-73R showed "wild" leakage. L-533 gave "wild" leakages only at green densities below those studied for the other two powders.

Capacitance.—For all three powders the relationship between capacitance and sintering conditions could be expressed by an empirical equation of the form

$$C = A \times 10^4/T + B \log (t + 6) + C'/16.6\text{-}D_g + D$$

There were, however, considerable differences in the values of the coefficients A, B, C′, and D for the three powders. These coefficients (shown in Table VIII) are a measure of the sensitivity of the capacitance to changes in sintering conditions. It can be seen that the capacitance of E-11 is the least sensitive to changes in conditions, and that of L-533 is the most sensitive. SG-73R is much closer in sensitivity to E-11 than to L-533, but is more sensitive

Table VII. Sinter densities and capacitance per unit volume, sample L-533

Table VIII. Comparison of capacitance equations

General form of equation:
$$C = A \times 10^4/T + B \log (t + 6) + C/(16.6\text{-}D_g) + D$$

Sample	A	B	C'	D
E-11	3.75	−3.50	−32.47	+3.20
SG-73R	4.83	−3.72	−46.56	+1.19
L-533	8.04	−7.34	−94.0	+0.40

C is capacitance, in microfarad/g (200-v formation); T, temperature, in °K; t, time, in minutes; D_g, green density, in g/cc.

to changes in temperature and green density than is E-11.

Figures 2, 3, and 4 show the changes in capacitance of the three powders with changing temperature (at constant time and green density), time (at constant temperature and green density), and green density (at constant time and temperature), respectively. Those graphs show not only the relative sensitivities of the capacitance of the powders to changes in conditions as described above, but also the effects of each of the separate variables

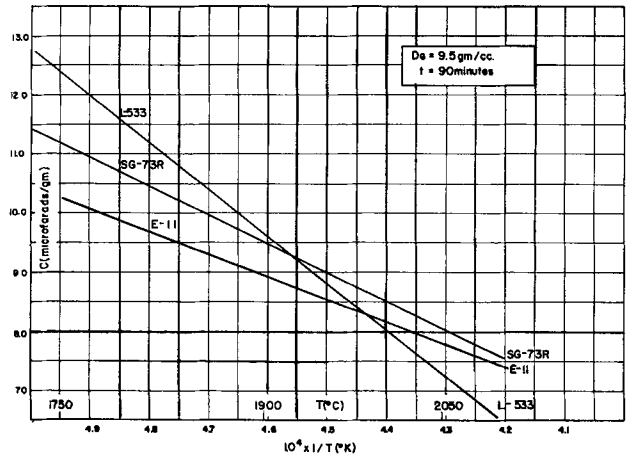

Fig. 2. Capacitance vs. temperature at constant time and green density.

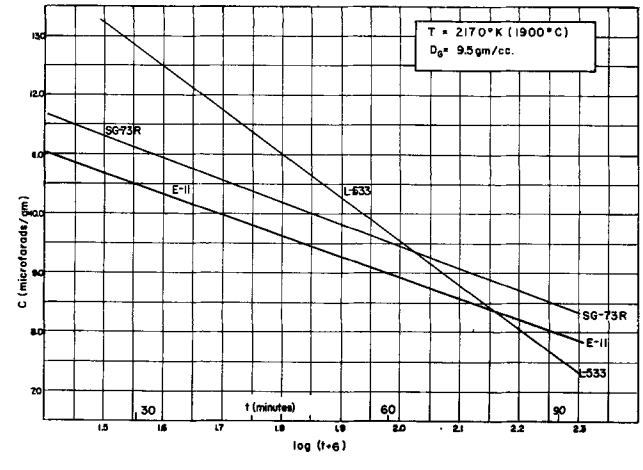

Fig. 3. Capacitance vs. time at constant temperature and green density.

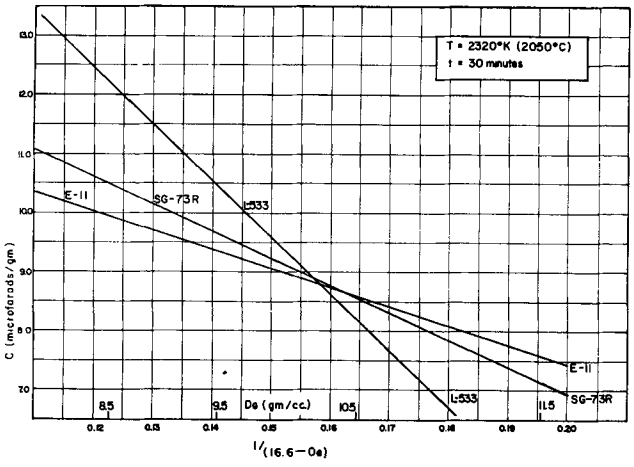

Fig. 4. Capacitance vs. green density at constant time and temperature.

(time, temperature, and green density) relative to each other. The changes in capacitance due to the separate effects of the over-all changes in each variable were approximately equal, over the ranges studied.

Equivalent series resistance.—The equivalent series resistance increased with green density and time for all three powders. It increased with temperature for SG-73R and L-533, but the effect of temperature for E-11 is uncertain. The *ESR* of L-533 was the most sensitive of the three powders to changes in sintering conditions, and also the highest in magnitude for a given set of conditions.

Conclusions

No attempt has been made to give speculative interpretations of the observed results, since it is thought that speculation could be more misleading than helpful when discussing such complex systems. Much more experimental work is needed in this field before, for example, any meaningful physical interpretation could be given for the form of the general capacitance equation, or the phenomenon of "wild" leakage could be explained. It is hoped that such work will be forthcoming.

Manuscript received June 22, 1959. This paper was prepared for delivery before the Philadelphia Meeting, May 1-5, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

The Growth of Anodic Oxide Films on Germanium

Solomon Zwerdling and Sumner Sheff[1]

Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts

ABSTRACT

Thick uniform germanium dioxide films of controlled thickness have been grown anodically on both n- and p-type germanium. The electrolyte used was a 0.25*N* solution of anhydrous sodium acetate in glacial acetic acid. The composition of the films was established by gravimetric and spectrometric methods. From the current efficiencies and the other parameters of the electrolysis, certain significant properties of the oxide films were calculated, i.e. differential formation field during growth, resistivity, and thickness. Furthermore, it was possible to determine changes in these quantities by evaluating them for different intervals of the electrolysis.

The presence of a thick oxide film on a germanium substrate is considered of importance in understanding the surface properties of semiconductors. Such specimens could be used for physical measurements involving electronic interactions between the oxide layer and the substrate, e.g., the influence of various gaseous ambients on the surface conductivity. Anodic electrolysis was selected to produce these films, since it readily permits obtaining pertinent electrochemical data for the films including differential formation field during growth, resistivity, and thickness. Furthermore, the oxidation rate may be controlled readily, and the films may be formed at room temperature, so that the electrical characteristics of the substrate are unaltered.

Anodic oxide film growth on electrodes has been studied rather extensively for metals in aqueous electrolytes (1-8), and several theories (4, 9-11) have been proposed according to which the formation current density should be dependent exponentially on the electric field across the oxide film. The data obtained for these systems have been essentially in agreement with theory. In recent years, the experiments have been extended to semiconductors, including germanium (12), indium antimonide (13), and silicon (14). In this paper, we will present the detailed results obtained for the electrochemical parameters of the anodic oxide film formation on germanium in a nonaqueous electrolyte.

Experimental

Apparatus.—The experiments for producing the oxide films were performed at room temperature in a three compartment electrolytic cell with the same electrolyte in all three compartments. The experimental arrangement is shown schematically in Fig. 1. Current was obtained from an electronically stabilized current supply having an equivalent source voltage of 100 kv. The anode was grounded and its voltage relative to a reference platinum electrode in the same electrolyte was measured and recorded continuously by a very high input impedance electronic potentiometer. The circuit was designed so that the current could be monitored on the same apparatus without interrupting the circuit.

Samples.—The samples were Ge wafers (approximately 2 × 1 × 0.1 cm) carefully lapped with No. 600 and No. 800 silicon carbide followed by a 1.5 min CP-4 etch.[2] Surfaces were examined in intense oblique light and were reprocessed if not satisfactory. For repeated anodic oxidations with the same electrode, only a 0.5 min CP-4 etch was used. Tygon paint (air-dried, then baked at 70°C overnight) was used to protect the lead soldered to the anode which was only partially immersed in the electrolyte.

The geometrical areas of the electrodes were determined to ± 1% by means of an optical comparator capable of reading dimensions to within 0.005 cm. A surface roughness factor of 1.3 was assumed based on measurements reported by Law (15). The depth of immersion of the Ge anode was determined from the boundary line of the oxidized portion of the electrode observed after the removal of the oxide film by immersion in 0.01*N* sodium hydroxide (aq.).

Electrolyte.—A large number of experiments showed that it was apparently impossible to grow oxide films on germanium using aqueous electrolytes, due to the appreciable solubility of the formed

[2] CP-4 consists of concentrated HNO_3 (5 parts by volume), glacial CH_3COOH (3 parts), 48% HF (3 parts) and Br_2 (0.06 part).

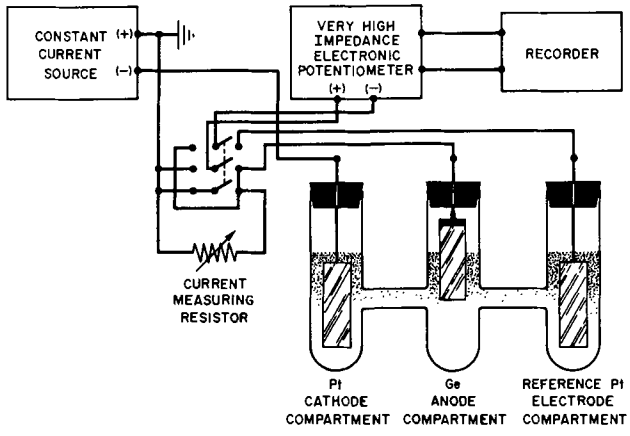

Fig. 1. Schematic diagram of electrolysis apparatus

[1] Present address: Semiconductor Division, Raytheon Manufacturing Company, Newton, Mass.

GeO_2 in water. Among many electrolyte systems tried a solution of anhydrous sodium acetate in glacial acetic acid (A.R.) was found suitable and it was employed in the present study. The optimum composition for producing satisfactory oxide films over the current density range from 50-400 $\mu a/cm^2$ was found to be 0.25*N* and it was employed throughout.

Anodically formed GeO_2 is essentially insoluble in the electrolyte (less than 0.2 γ/ml) as shown by a colorimetric procedure described below. The electrolyte had a specific conductivity of 43.7 $\mu mho\text{-}cm^{-1}$ at 24.3°C.[3]

Analytical.—A method for the determination of the amount of oxidized Ge in the anodic films was developed by a modification of the oxidized hematoxylin photometric procedure described by Newcombe, *et al.* (16). The modifications involved (*a*) dissolving the oxide film on the electrode by a 10-sec immersion with stirring in 0.01*N* aqueous sodium hydroxide, neutralizing with 0.04*N* aqueous sulfuric acid, and making up to standard volume with phthalate buffer of pH = 3.2, (*b*) using 10 ml aliquots of this solution to determine the Ge concentration, and (*c*) allowing 60 min for the reaction time between the Ge and the hematoxylin. The 10-sec immersion time was experimentally found sufficient to remove completely even the thickest film grown and make negligible any contribution due to further oxidation and dissolution of the electrode. A calibration curve was obtained by using β-GeO_2 standard solutions prepared by dissolving a weighed quantity of the oxide in 0.01*N* aqueous sodium hydroxide, neutralizing, and diluting to volume with the same reagents as above. Optical density measurements were made on a Beckman Model DU Spectrophotometer to a precision of ± 0.002 unit standard deviation.

Determination of Oxide Composition

A study was made in order to determine the composition of the anodic films. Since the electrolysis was performed in glacial acetic acid, the possibility that the films were germanium tetraacetate was investigated. This compound had been synthesized by Schmidt, *et al.* (17) and was reported to be soluble in benzene and acetone. These anodic films were found to be insoluble in those reagents.

To test the assumption that the films were GeO_2, experiments were performed to determine the stoichiometric ratio of germanium to oxygen. The ratio was calculated from the weight loss of germanium anodes after the film had been removed by dissolution in aqueous sodium hydroxide and from the amount of germanium found in the resulting solution. The films were grown on p-type germanium at 100 $\mu a/cm^2$ for 10 hr. They were freed of sodium acetate by ten 5-min rinsings in fresh portions of glacial acetic acid, and of acetic acid by pumping in a vacuum desiccator for several hours. Radiotracer experiments using Na^{22} tagged electrolyte indicated that this rinsing procedure was sufficient to remove completely all sodium ions possibly adsorbed on the film. By counting the aqueous sodium hydroxide solutions containing the dissolved film grown in the tagged electrolyte, it was found that no significant amount of sodium was incorporated in the film. Prior to weighing, the films were equilibrated at atmospheric pressure in a desiccator for 30 min. Weighings were made on a microbalance to a precision of $\pm 2\gamma$. A stoichiometric ratio of 1:2 corresponding to the empirical formula GeO_2 was found.

X-ray diffraction patterns were taken of the powder obtained by mechanically removing the film material grown on Ge anodes. A diffuse pattern was obtained indicative of an amorphous powder. After recrystallization from redistilled water, the diffraction pattern contained only the lines associated with the hexagonal form of GeO_2.

The composition of the anodically formed film was investigated further by determining its infrared absorption spectrum. Transmission measurements were made using two oxidized electrodes in series, corresponding to four film thicknesses, in the radiation beam. The spectral region from 2-20 μ was scanned. This was possible since bulk germanium is transparent in this region. Only the absorption bands of GeO_2 (18) were found and are shown in Fig. 2(a) and (b), thus confirming that the films were germanium dioxide.

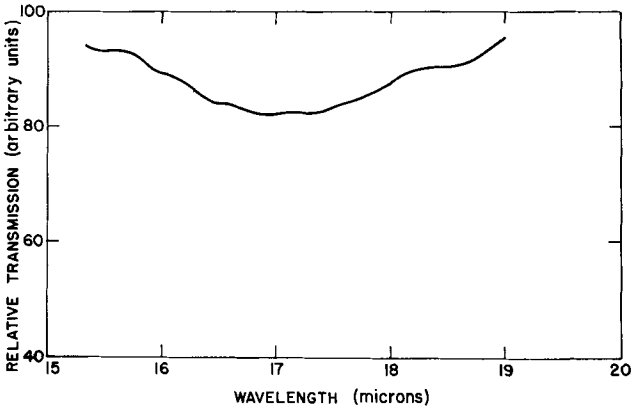

Fig. 2(a). Infrared transmission of GeO_2 films produced anodically on germanium (16 to 18μ band).

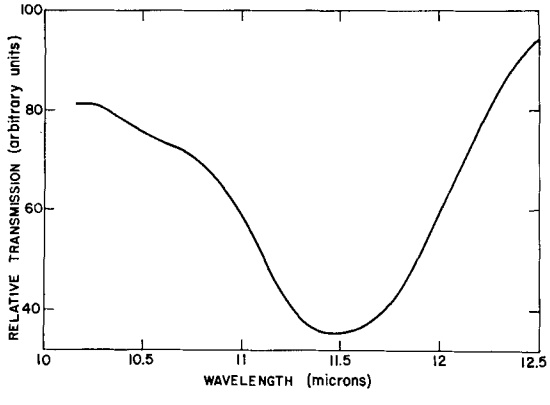

Fig. 2(b). Infrared transmission of GeO_2 films produced anodically on germanium (11.5μ band).

[3] A small quantity of the electrolyte was refluxed at 120°C for 1 hr with 0.6% of its weight of acetic anhydride to dehydrate it further. The resulting solution had a specific conductivity of 42.4 $\mu mho\text{-}cm^{-1}$ at 27.5°C as contrasted to a value of 49.5 $\mu mho\text{-}cm^{-1}$ for the original solution. Attempts to grow uniform oxide films on Ge anodically with the refluxed electrolyte were unsuccessful. Further investigations with this electrolyte may elucidate the reaction mechanism of the anodic oxidation.

Electrochemical Considerations of Film Growth

Certain pertinent properties of the oxide films were calculated from the parameters of the electrolysis, i.e., the total current, the anode area, and the increase of voltage across the oxide with time as the film grew thicker.

The differential oxide formation field at any thickness is defined as

$$E_d = dV/dx = dV/\beta dq_f \quad [1]$$

where E_d is the differential oxide formation field, v/cm; V the potential across the film, v; x the film thickness, cm; and β the centimeters of film thickness formed per amp-sec/cm^2 of charge q_f passed leading to oxide formation.

The thickness of the oxide film at any time t is given by

$$x_t = x_o + \beta q_f \quad [2]$$

where β is taken to be a constant, and x_o is the thickness prior to electrolysis. The density of the oxide formed on the Ge anode was assumed to be that of bulk hexagonal GeO_2 (4.28 g/cm^3) (19), so that a calculation for β yielded 6.35 x 10^{-5} cm^3(amp-sec)$^{-1}$, and for the average thickness of a GeO_2 layer 3.4Å. The current efficiency for oxide formation ϵ is defined as

$$\epsilon = i_f/I \quad [3]$$

where i_f is the oxide formation current density and I the total current density. If the current efficiency is a constant during a given electrolysis interval in the anodic oxidation of Ge to GeO_2, then

$$\epsilon = 4\mathbf{F}M_{Ge}/Q \quad [4]$$

where **F** is the Faraday constant, M_{Ge} is the number of moles of Ge anodically oxidized, and Q is the total charge passed during that interval. If the electrical resistivity of the oxide ρ_{ox} is a constant during the same interval, from Ohm's law,

$$\rho_{ox} = E_d/I \quad [5]$$

Since $i_f = dq_f/dt$, Eq. [3] may be combined with Eq. [1] to give

$$E_d = dV/\beta i_f dt = (1/\beta\epsilon I)\, dV/dt \quad [6]$$

and with Eq. [2] to give

$$x_t = x_o + \beta\epsilon It \quad [7]$$

Alternatively, the thickness of the film may be determined from

$$x_t = W_{Ge}\, G/D \quad [8]$$

where W_{Ge} is the quantity of oxidized Ge on the surface in g/cm^2, G is the gravimetric factor for GeO_2/Ge, and D is the density of GeO_2 in g/cm^3.

Because of the experimental method used, the current efficiency could be obtained only as an average over an interval of electrolysis. Therefore, it was only possible to evaluate the differential field for those intervals during which the current efficiency was constant. Since the electrolyses were performed at constant current density, such intervals would be expected to exhibit a linear rise of voltage with time. As the potential across the oxide was the only component of the measured anode potential that was expected to contribute primarily to its increase with time as the oxide grew thicker, the rate of increase of the latter was taken equal to the rate of increase of potential across the oxide dV/dt. This increase was assumed to be due only to the increase in the film thickness and not to any changes in the oxide already formed.

It was necessary to consider the possibility of the formation of a p-type "inversion" layer at the surface of n-type Ge when anodized in the sodium acetate-glacial acetic acid electrolyte. The effect was not observed in the electrolyses performed except at the highest current density used. For this case, the anode voltage rose abruptly to abnormally high values when the current was turned on, and within 1 min had fallen to the value normally obtained with p-type germanium under the same conditions. During further electrolysis, the behavior of the anode voltage with time remained normal. Evidently, the oxide film formed within 1 min of electrolysis was sufficiently thick to destroy the "inversion" layer by preventing the electrolytic double layer from affecting the normal electron and hole densities at the surface of the germanium substrate. Furthermore, an accumulation of electrolytic oxidation products near the anode might also have contributed to the rise of anode potential with time. It is likely, however, that this did not occur since the potential of a platinum anode substituted for the germanium was found to remain constant during prolonged electrolysis.

Results and Discussion

As a consequence of the above considerations, the criteria adopted for a successful anodic oxide film growth experiment were: (*a*) the film grown should be of uniform thickness as evidenced by the uniformity of the color it produced by optical interference in white light, and (*b*) for all intervals following the initial shorter one, the anode voltage should increase uniformly with time at constant current density.

For current densities between 66 and 240 μa/cm^2, uniform films appearing blue and yellow, respectively, in white light were obtained. The anode voltage vs. time curves satisfied criterion (*b*), although the onset and duration of the intervals varied with the current density. Plots of corrected anode potential vs. electrolysis time for both n- and p-type germanium are shown in Fig. 3.

The correction was chiefly due to the *IR* drop in the anolyte included in the measured voltage and depended on the geometry of the experimental cell. By substituting a platinum anode for the germanium and electrolyzing at various current densities in the range studied, these corrections were evaluated, the largest being about 4.5 v at the highest current density. The curves show the different linear intervals for the different current densities. The values of dV/dt which were used in calculating E_d from Eq. [6] for the different linear intervals were obtained from these curves. The current efficiencies for the different linear intervals were calculated from the charge passed during each interval

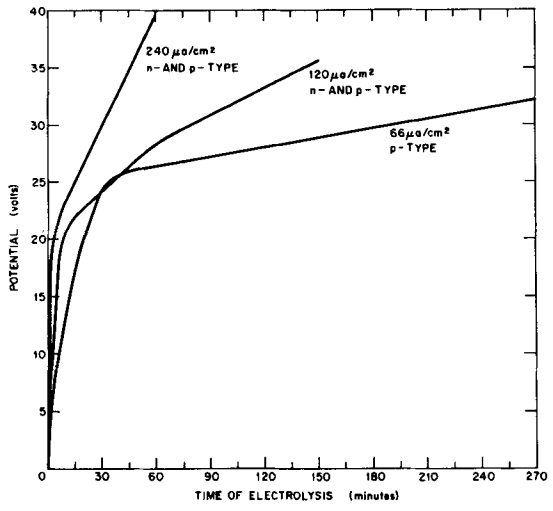

Fig. 3. Potential of Ge anodes vs. a reference Pt electrode during growth of anodic oxide films in 0.25N sodium acetate in glacial acetic acid (corrected for IR drop in electrolyte).

and from differences in the amounts of oxidized germanium found in films grown at the same current density for times equal to those at the beginning and end of each interval. From such differences, the values for M_{Ge} in Eq. [4] were obtained. It was established that the current efficiency actually was constant throughout a linear interval, by dividing each of two such intervals into two parts and obtaining the current efficiency for these parts. The results for two samples of both n- and p-type germanium are shown in Table I. The uncertainty of the efficiency determinations for the total interval in each case was ± 5%. Since the determinations for the intermediate intervals involve smaller differences between relatively large quantities of oxidized germanium than in the case of the corresponding total intervals, the uncertainty for the former was ± 10%. Consequently, within this experimental error the current efficiency was constant throughout a linear interval.

A comparison was made between the anodic oxidation parameters of the (111), (110), and (100) faces of p-type Ge with resistivities of approximately 30 ohm-cm. Experiments were performed for periods of 6 hr at various current densities in the range of interest. The results indicated that, within experimental error, there were no differences between the anodic oxidations of the various crystallographic planes.

Table I. Current efficiency for anodic oxidation of germanium

Material	Total current density, μa/cm²	Specimen	Interval, min	Current efficiency, %
n-type Ge (30 ohm-cm)	120	1	60-105	11
			105-150	11
			60-150	11
		2	60-105	12
			105-150	11
			60-150	11
p-type Ge (30 ohm-cm)	66	3	60-150	17
			150-270	16
			60-270	16
		4	60-150	17
			150-270	16
			60-270	17

The results of a series of determinations of the anodic oxide growth parameters for n- and p-type Ge of 30 ohm-cm resistivity, electrolyzed at the indicated current densities are shown in Table II. For the p-type Ge, the (111) face was used, and for the n-type Ge, the (111) and (100) faces were used. The values reported are the averages of determinations with each electrode as well as with different samples cut from adjacent sections of the same ingot. The current densities for repeated experiments could be reproduced only to within ± 3% on account of the partial immersion technique used for the Ge anodes. The reproducibility of the determinations of dV/dt was ± 5%, so that the values for E_d, ρ_{ox}, and i_f are reported with an uncertainty of ± 8%. Within this experimental error, both n- and p-type Ge showed the same behavior during anodic oxide film growth.

The average current efficiency values obtained for the oxidations during the initial nonlinear intervals at the various current densities were all approximately the same, about 24-26%. The duration of these nonlinear intervals was shorter the greater the corresponding current density. However, for the later intervals, there is a tendency for the efficiency to decrease with increasing current density. It is interesting to note that in all cases, the first pronounced change in slope occurred at a potential between 20 and 24 v (see Fig. 3). This might indicate a change in the anodic process which could arise from the onset of increased electron and/or "hole" conductivity in the oxide due to the field across it, or to a heating effect by the current passing. Since the current efficiency of oxide formation for any current density, following the change of slope, is less than during the initial interval as is evident from Table II, it follows that the electronic conductivity increases at this point probably accompanied by a decrease in ionic conductivity in the oxide since the total current density remains constant.

For the measurements taken at a current density of about 120 μa/cm², the values of the current efficiency and dV/dt are smaller for the third interval than they are for the second interval, but in approximately the same proportion. Consequently, the related values for E_d and ρ_{ox} are about the same for these intervals.Furthermore, the three different current densities employed resulted in E_d values for the later intervals that were approximately proportional to the respective current densities. Therefore, the corresponding resistivities, ρ_{ox} are again about the same. This indicates that the oxide films grown were alike.

Using the assumption for the oxide density stated earlier, the thicknesses of the oxide films were found to range from 220 to 1240Å. The amounts grown for specific intervals are shown separately in Table II.

In conclusion, we have shown that relatively thick oxide films may be grown on germanium by anodic electrolysis in the nonaqueous electrolyte system: sodium acetate-glacial acetic acid. It was not possible to deduce a simple relationship between the formation current density and the differential formation field in this case, as is usually found for metal-aqueous electrolyte systems. Likewise, no definite relationship between these parameters was reported for an analogous semiconductor nonaqueous electrolyte system by Schmidt and Michel (14) who studied the anodic formation of oxide films on silicon in a solution of 0.04*N* potassium nitrate in N-methyl acetamide. Similar curves for the increase in anode potential with time were obtained in their study and ours. Anodic oxide films on indium antimonide have been grown in the aqueous electrolyte 0.1*N* potassium hydroxide by Dewald (13) where, although the potential vs. time curves were similar to those found for Ge and Si, the data obtained could be fitted empirically to the relationship $i_f \propto \exp(E_f)$. In this work on InSb, it was indicated that the interpretation of the kinetic parameters derived from the experimental data was difficult, since the necessary mathematical formulations of the detailed theory of the oxidation of such a binary intermetallic electrode have not yet been developed. The interpretation of the data for the more complex system of a semiconductor electrode in a nonaqueous electrolyte must also await further theoretical and mathematical developments.

Acknowledgment

The authors wish to thank Dr. Harry C. Gatos of this Laboratory for many helpful discussions and assistance with the preparation of the manuscript. The x-ray measurements and crystallographic orientations were performed by Mr. Joseph W. Sanchez. The radiotracer experiments were performed with Mr. J. A. Kafalas, to whom the authors express their thanks.

Manuscript received July 2, 1959. The work reported in this paper was performed by Lincoln Laboratory, a center for research operated by Massachusetts Institute of Technology with the joint support of the U.S. Army, Navy, and Air Force.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Interpretation of Measurements of Potential Decay on Open Circuit

Paul C. Milner

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Observations of the change in electrode potential as a function of time on open circuit have proved a useful method for the study of electrode kinetics and double-layer capacitances. The interpretation of such observations may be complicated by capacitative effects resulting from competing faradaic processes. Consideration of these effects is included in a theory of open-circuit decay. In certain cases such effects are virtually indistinguishable from double-layer capacitances and they may be of surprising importance. The analysis of decay measurements is also considered, and a new method is described.

In view of recent interest in the decay of overpotential on open circuit in studies of electrode kinetics and of double-layer capacitances, it is pertinent to re-examine the theoretical basis for interpretation of observations. The simplicity of the measurement and its applicability to large electrodes should be recognized. Former interpretations of potential-decay data have depended on very simple theories. This has, in a number of cases, proved inadequate or led to erroneous results.

Early observations of hydrogen overpotential decay made by Baars (1) and Bowden and Rideal (2) were simply explained by Butler and Armstrong (3, 4) in terms of the discharge of a capacitor (electrical double layer) by a faradaic current which is an exponential function of the potential (Tafel current). On this basis, explicit potential-time relations are readily derivable and have been given by a number of authors (5-11). Where the faradaic reaction has equal anodic and cathodic Tafel slopes, expressions valid throughout the whole potential range have been derived (11, 12), and the situation near the equilibrium potential has also been considered (9, 13). When diffusion is a factor in the faradaic process, Grahame (10) and Scott (14) have shown the extreme complexity to be expected in any analysis of decay measurements.

The more general situation, in which more than one faradaic process occurs, is treated here. It has been approached only by Lukovtsev and Temerin (15) in their treatment of the discharge of the nickel oxide electrode by oxygen evolution without consideration of the electrical double layer.

General Equations

For any electrode

$$i_{ext} - \Sigma i_f = dq_{dl}/dt = C_{dl}\, dE/dt \qquad [1]$$

where i_{ext} is the external current, Σi_f is the sum of the currents for faradaic processes at the electrode, q_{dl} is the charge on the electrode side of the electrical double layer, t is the time, C_{dl} is the differential capacitance of the electrical double layer, and E is the potential of the electrode, measured with respect to an unpolarized reference electrode (Gibbs-Stockholm sign convention). In any given electrode system, C_{dl} is a function of potential, but its variation over short ranges of potential is generally small, and it may be treated as a constant to a good approximation. By analogy with mercury (16), C_{dl} may be expected to be of the order of 20 μf/cm^2 of true electrode surface.

The potential-time relation to be observed for any electrode can therefore be determined if the current-potential relations for the faradaic processes are known. Although the rates of many faradaic processes are influenced strongly by mass transport phenomena, such complex effects will be neglected here and all phases will be assumed homogeneous. The resulting simplification will be only an approximation to the state of affairs in a system where mass transport is important. Since sufficient homogeneity of a phase can be assured by adequate mixing, and since the extent of inhomogeneity in a real system depends markedly on geometrical as well as electrochemical considerations, the treatment given here will omit any specific discussion of these factors. The current-potential relation for a faradaic process is then determined entirely by activation control.

Close to the equilibrium potential E_e, the faradaic current intensity is given by

$$i_f = i_0 n\mathbf{F}(E - E_e)/RT \qquad [2]$$

where i_0 is the exchange current intensity (17) and n the number of electrons passed when the rate-determining reaction occurs once. Both i_0 and E_e are dependent on the concentrations of reacting species.

At potentials considerably removed from E_e, the current intensity is given by the Tafel equation

$$i_f = \pm\, i_0 \exp[\pm\alpha\mathbf{F}(E - E_e)/RT] \qquad [3]$$

where α is the anodic or cathodic transfer coefficient (17) and the upper signs are used for anodic processes, the lower for cathodic. The Tafel slope is $\pm 2.303\, RT/\alpha\mathbf{F}$.

Normally, investigations of electrode kinetics are made in systems which are buffered in an electro-

chemical sense. Hydrogen and oxygen evolution are usually studied in fairly acidic or basic electrolytes to prevent significant changes in pH during the course of an experiment. Problems associated with mass transport and ohmic solution effects are also reduced by this procedure. The faradaic current for a reaction in a system which is electrochemically well-buffered with respect to that reaction is then given by [2] or [3] with both i_0 and E_e constant.

However, the electrochemical buffering of a system with respect to one reaction often precludes the buffering of the system with respect to competing reactions which may occur. For example, it is possible to examine the kinetics of silver deposition in solutions containing both silver and hydrogen ions in large quantity, but the process of hydrogen evolution at silver electrodes cannot be studied in solutions containing appreciable quantities of silver ion without great difficulty.

In such a case, it is customary to buffer the system with respect to the reaction of interest and to eliminate as far as possible all other reactants. Even then, the measured steady-state current-potential relations will not refer to the desired reaction unless all the remaining possible reactions are either at equilibrium or so slow for kinetic reasons that they may be disregarded. Very slow reactions may be neglected in general, but it is necessary to consider the possibility of remaining unbuffered reactions which are at equilibrium under steady-state conditions.

For example, during hydrogen evolution at any metal electrode in an acid solution, there exists a finite equilibrium quantity of metal ion in solution at any given steady-state hydrogen overpotential. A change in potential changes the amount of metal ion required for equilibrium and results in a faradaic current corresponding to oxidation of, or reduction to, the metal. Current-potential relations for such an unbuffered reaction are complex, depending on the potential, the exchange current for the reaction, and the concentration of metal ion, all of which are interrelated and time dependent. However, if the unbuffered reaction is characterized by an inherently large rate constant, the process may be considered to take place under conditions close to thermodynamic reversibility, and a considerable simplification becomes possible.

In this case, the faradaic current may be related to the potential by

$$i_f = dq_f/dt = (dq_f/dE_e)\,(dE_e/dt) \qquad [4]$$

where dq_f is the positive charge carried by the faradaic process from electrode to electrolyte in time dt. Two classes of faradaic processes are of interest.

The equilibrium potential for the metal-metal ion couple $M = M^{z+} + ze^-$ is given by

$$E_e = E^\circ + (RT/z\mathbf{F}) \ln a \qquad [5]$$

where a is the activity of M^{z+} and E° is the standard electrode potential. If the activity can be approximated by the molarity c, the activity change resulting from a faradaic process is

$$da = dc = dq_f/z\mathbf{F}V \qquad [6]$$

where V is the volume of the solution in liters. With the assumption that E is not significantly different from E_e, i.e., that the electrode substantially maintains thermodynamic reversibility with respect to the metal-metal ion reaction, the faradaic current is given by

$$i_f = (z^2\mathbf{F}^2V/RT) \exp [z\mathbf{F}(E - E^\circ)/RT](dE/dt) \qquad [7]$$

For the reaction: reduced species = oxidized species + ze^-,

$$E_e = E^\circ + (RT/z\mathbf{F}) \ln a_o/a_r \qquad [8]$$

where a_o and a_r are the activities of oxidized and reduced species. Approximating activities by molarities c_o and c_r,

$$i_f = [z^2\mathbf{F}^2V(c_o + c_r)/4RT] \operatorname{sech}^2 [z\mathbf{F}(E - E^\circ)/2RT](dE/dt) \qquad [9]$$

As long as $E - E^\circ \leq -0.078/z$ volt, so that $c_o/(c_o + c_r) \leq 0.05$, Eq. [9] may be approximated within 10% by the simpler expression

$$i_f = [z^2\mathbf{F}^2V(c_o + c_r)/RT] \exp [z\mathbf{F}(E - E^\circ)/RT](dE/dt) \qquad [10]$$

which has the same potential dependence as the current for the metal-metal ion reaction. A similar approximation is valid when E is sufficiently greater than E°.

It will be noted that no kinetic parameters appear in these expressions for i_f since these unbuffered faradaic processes are assumed in effect to be infinitely fast. If, as is often the case, i_0 is large and dE/dt is not, the limitations introduced by such an assumption are probably less serious than those brought about by the neglect of mass transport phenomena. Quantitative considerations including diffusion and forced convection are prohibitively complex, but qualitatively it is apparent that inhomogeneity in the electrolyte may have a considerable effect, since then only the volume of electrolyte nearest the electrode remains in virtual equilibrium with it during a change in potential.

Potential-Time Relations

With an appropriate choice of current-potential relations, potential-time relations during open-circuit decay may be determined for any electrode. As a specific example, the decay of hydrogen overpotential at a metal electrode in a well-stirred acid electrolyte free from oxygen and other reducible material will be considered, so that the reactions which take place during the decay are $2H^+ + 2e^- \rightarrow H_2$ and $M \rightarrow M^{z+} + ze^-$. The unbuffered metal-metal ion reaction is assumed to be at equilibrium at all times.

Near the equilibrium hydrogen potential.—For this metal electrode in a potential region such that hydrogen evolution is occurring at a rate given by Eq. [2], Eq. [1], [2], and [7] give

$$i_{ext} - i_0 n\mathbf{F}(E - E_e^h)/RT - (z^2\mathbf{F}^2V/RT) \exp [z\mathbf{F}(E - E^\circ)/RT](dE/dt) = C_{dl}(dE/dt) \qquad [11]$$

where E_e^h is the equilibrium hydrogen potential. It is apparent that in a steady-state condition ($dE/dt = 0$), no current is carried by the metal-

metal ion reaction and only the first two terms are finite.

On opening the circuit, $i_{ext} = 0$ and integration yields

$$C_{dl} \ln [(E - E_e^h)/(E_0 - E_e^h)] + (z^2\mathbf{F}^2V/RT) \exp [z\mathbf{F}(E_e^h - E^\circ)/RT] \times \{Ei[z\mathbf{F}(E - E_e^h)/RT] - Ei[z\mathbf{F}(E_0 - E_e^h)/RT]\} = -(i_0 n\mathbf{F}/RT)t \quad [12]$$

where $Ei[x]$ is the exponential integral of x, t is the time on open circuit, and E_0 is the potential at the moment of opening the circuit ($t = 0$). If the circuit is opened from a steady-state condition in which the external current is i_i, Eq. [11] shows that $i_0 n\mathbf{F}/RT$ may be replaced by $i_i/(E_0 - E_e^h)$.

If $E^\circ >> E_e^h$, the second term in [12] may be neglected and ln $(E - E_e^h)$ becomes a linear function of time during the decay with a slope of $-i_0 n\mathbf{F}/C_{dl}RT$. Under this condition, the fraction of the current from the hydrogen evolution reaction used during the decay in forming metal ions is negligible, and a plot of $\ln(E - E_e^h)$ vs. t may be used in the determination of C_{dl}. If the measured potential at the moment of interruption of current is in error because of an ohmic potential drop in the solution between the electrode and the reference electrode, such a plot also provides a means of determining E_0. This type of behavior, which corresponds to the discharge of a capacitor through an ohmic resistance, has been predicted (9), observed experimentally (18), and used in the determination of capacitance (13).

On the other hand, when a negligible fraction of the current from the hydrogen evolution reaction is used in changing the charge in the electrical double layer, the first term of [12] may be neglected, and $Ei[z\mathbf{F}(E - E_e^h)/RT]$ is a linear function of t. When $z\mathbf{F}(E_0 - E_e^h)/RT$ is small, the difference between exponential integrals may be approximated by $\ln [(E - E_e^h)/(E_0 - E_e^h)]$, so that the relation between $\ln(E - E_e^h)$ and t is again linear. However, the slope is now $-(i_0 n/z^2\mathbf{F}V) \exp [z\mathbf{F}(E^\circ - E_e^h)/RT]$ and is unrelated to the capacitance of the electrical double layer.

In Fig. 1, log $(E_e^h - E)$ is plotted against t during the open-circuit decay of hydrogen overpotential at a 1 cm² metal electrode whose ions are divalent. As parameters typical of such a system, $i_0 = 10^{-8}$ amp, $n = 1$, and $C_{dl} = 20$ μf were chosen, and the volume of solution was taken to be 10^{-3} liter. Three cases are shown, each originating at the same value of $E_e^h - E_0 = 0.026$ v, but with different values of $E^\circ - E_e^h$.

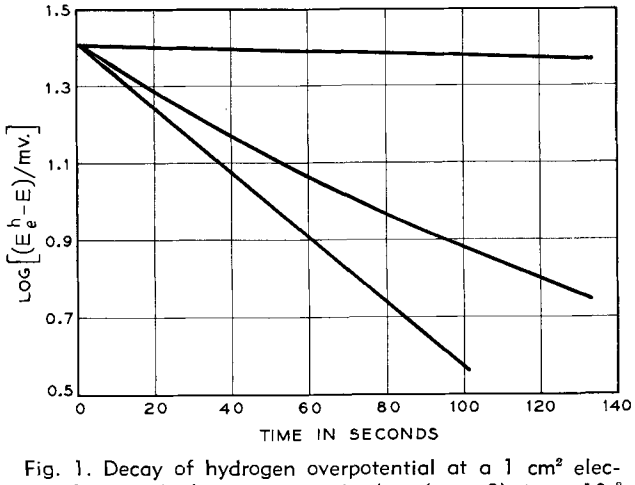

Fig. 1. Decay of hydrogen overpotential at a 1 cm² electrode of a metal whose ions are divolent (z = 2). $i_0 = 10^{-8}$ amp, n, = 1, $C_{dl} = 20\mu f$, V = 10^{-3} liter, E_e^h-E_0 = 0.026 v. Lower curve, E°-$E_e^h \geqq 0.313$ v; middle curve, E°-E_e^h = 0.254 v; upper curve, E°-E_e^h = 0.195 v.

The most rapid decay corresponds to $E^\circ - E_e^h \geqq 0.313$ v. In this case, the second term of Eq. [12] is less than 1% of the first term so that the slope of log $(E_e^h - E)$ vs. t is a measure of C_{dl}. The least rapid decay corresponds to $E^\circ - E_e^h = 0.195$ v. For this and any smaller values, the second term of [12] is at least 100 times the size of the first term so that the fraction of the current from the hydrogen evolution reaction changing the charge in the electrical double layer is negligible. The middle curve corresponds to $E^\circ - E_e^h = 0.254$ v, an intermediate case.

While the theory on which these plots are based is limited by the approximations made in its derivation, the large capacitative effect shown by faradaic process involving the metal-metal ion couple should be strongly emphasized. It can be shown readily that the oxidation of a metal in contact with a solution containing m moles of divalent metal ion corresponds to an apparent capacitance of the order of $1.5 \times 10^{13}\, m$ μf, and even in extremely dilute solutions this may easily exceed the capacitance of the electrical double layer.

In the Tafel region.—For the same metal electrode in a potential region where the current for hydrogen evolution is given by Eq. [3],

$$i_{ext} + i_0 \exp [\alpha\mathbf{F}(E_e^h - E)/RT] - (z^2\mathbf{F}^2V/RT) \exp [z\mathbf{F}(E - E^\circ)/RT](dE/dt) = C_{dl}(dE/dt) \quad [13]$$

On opening the circuit, $i_{ext} = 0$, and integration yields

$$C_{dl}\{\exp [\alpha\mathbf{F}(E - E_e^h)/RT] - \exp [\alpha\mathbf{F}(E_0 - E_e^h)/RT]\} + [\alpha z^2\mathbf{F}^2V/(\alpha + z)RT] \exp [z\mathbf{F}(E_e^h - E^\circ)/RT]\{\exp [(\alpha + z)\mathbf{F}(E - E_e^h)/RT] - \exp [(\alpha + z)\mathbf{F}(E_0 - E_e^h)/RT]\} = (i_0\alpha\mathbf{F}/RT)t \quad [14]$$

If $E^\circ >> E_e^h$, the second term in [14] may be neglected because a negligible fraction of the current from hydrogen evolution is used in forming metal ions. In this case, the equation may be rewritten

$$E = E_0 + (RT/\alpha\mathbf{F}) \ln \{1 + (\alpha\mathbf{F}i_0 t/RTC_{dl}) \exp [\alpha\mathbf{F}(E_e^h - E_0)/RT]\} \quad [15]$$

If the circuit is opened from a steady state in which the external current is i_i, Eq. [13] indicates that [15] may be simplified by replacing $i_0 \exp [\alpha\mathbf{F}(E_e^h - E_0)/RT]$ by $-i_i$.

If C_{dl} is independent of potential, the ratio i_0/C_{dl} is determined solely by the composition of the system, and Eq. [15] shows then that, at sufficiently large values of t, all decays in a system of constant composition become coincident, regardless of E_0 and electrode area. Furthermore, when t is large, the potential is a linear function of ln t with a slope of $RT/\alpha\mathbf{F}$.

Since Baars (1) and Bowden and Rideal (2) in 1928, many workers have observed such behavior. The experiments of Fedotov (19) are of particular interest, for the values of C_{dl} which he determined from measurements of the decay of hydrogen over-

potential on mercury agree well with the a-c determinations of capacitance at the same potentials. In certain cases, successive potential-time curves starting from different values of E_0 have been observed to cross by Hickling and Salt (20) and Kolotyrkin (21). This has been ascribed by the latter to changes in surface area, but this explanation is clearly inapplicable under the conditions in which Eq. [15] applies.

If a negligible fraction of the current from the hydrogen evolution reaction is used in changing the charge in the electrical double layer, the first term in Eq. [14] may be neglected and the equation may be rewritten

$$E = E_0 + [RT/(\alpha + z)\mathbf{F}]\ln\{1 + [i_0 t(\alpha + z)/z^2\mathbf{F}V] \times \exp[\alpha\mathbf{F}(E_e^h - E_0)/RT] \exp[z\mathbf{F}(E^\circ - E_0)/RT]\} \quad [16]$$

which corresponds to the result obtained by Lukovtsev and Temerin (15).

The similarity in form between Eq. [15] and [16] is striking and clearly indicates that in the Tafel region capacitative effects resulting from faradaic processes may well be indistinguishable from the capacitance of the electrical double layer. The essential difference is that the slope exhibited by a plot of E vs. ln t at large values of t is $RT/(\alpha + z)\mathbf{F}$ rather than $RT/\alpha\mathbf{F}$. It is interesting to note that in this case, a crossing of decay curves can be ascribed to changes in surface area, since the resulting change in i_0 is uncompensated by a corresponding change in V. The discrepancies observed by Hickling and Salt (20) between decay slopes and the negatives of the Tafel slopes measured by a direct method lend additional weight to this explanation of such behavior.

In Fig. 2, $E_e^h - E$ is plotted against log t during the open-circuit decay of hydrogen overpotential at the same 1 cm² metal electrode illustrated in Fig. 1. Again, typical parameters for such a system were chosen: $i_0 = 10^{-8}$ amp, $C_{dl} = 20$ μf, and the volume of solution containing divalent metal ions in equilibrium with the electrode was taken to be 10^{-3} liter. The transfer coefficient α was chosen to be ½, so that the Tafel slope is −0.118 v/tenfold change in current. Three decays are shown, each from the same value of $E_e^h - E_0 = 0.592$ v, but with different values of $E^\circ - E_e^h$.

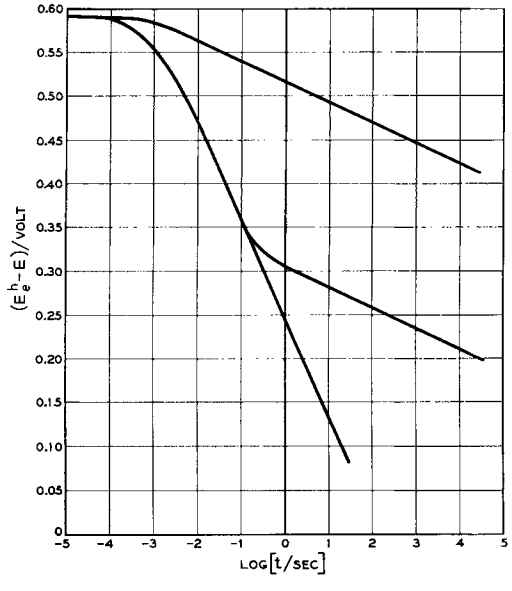

Fig. 2. Decay of hydrogen overpotential at a 1 cm² electrode of a metal whose ions are divalent (z = 2). $i_0 = 10^{-8}$ amp, $\alpha = ½$, $C_{dl} = 20$ μf, V = 10^{-3} liter, E_e^h-E_0 = 0.592 v. Lower curve, E°-E_e^h = 0.183 v; middle curve, E°-E_e^h = −0.080 v; upper curve, E°-E_e^h = −0.344 v.

The most rapid decay corresponds to $E^\circ - E_e^h = 0.183$ v, in which case Eq. [15] is applicable, since the second term of Eq. [14] is no more than about 1% of the first term and may be neglected. The least rapid decay corresponds to $E^\circ - E_e^h = -0.344$ v, and in this case the relative magnitudes of the terms are reversed. The middle curve is for $E^\circ - E_e^h = -0.080$ v, an intermediate case, and is of particular interest because of the relatively sharp transition it exhibits. In the initial portion essentially all the current from the hydrogen evolution reaction goes to change the charge in the electrical double layer and the decay coincides with the decay curve for $E^\circ - E_e^h = 0.183$ v. The later part of the decay is parallel to the decay for $E^\circ - E_e^h = -0.344$ v and like it, results from the capacitative effect shown by the metal-metal ion couple. It is apparent that in this intermediate case, observations of the potential at times greater than 1 sec or of decays from values of $E_e^h - E_0$ of less than about 0.31 v will not include any capacitative effects due to the electrical double layer.

While it is doubtful that experimental conditions corresponding exactly to the approximations introduced in the derivation of Eq. [14] are ever attained in practice, it may be noted that Salkind (22) and Conway and Bourgault (23) have observed two-stage decays of potential analogous to that illustrated in Fig. 2 in studies of the decay of oxygen overpotential on nickel oxide electrodes. Similar considerations may well account for some of the anomalously large slopes observed during open-circuit decay measurements on oxygen-evolving platinum electrodes (8).

Analysis of Decay Measurements in the Tafel Region

From the discussion of the previous section and a comparison of Eq. [15] and [16], it is clear that any decay from a steady-state condition can be represented at least approximately by an equation of the form

$$E = E_0 - b_t \ln(1 + t/t_0) \quad [17]$$

where b_t and t_0 are parameters characteristic of the decay. Where a transition occurs, as illustrated in Fig. 2, values of b_t and t_0 may be associated with each portion of the curve. In the simple case of the discharge of the electrical double layer illustrated in Eq. [15], t_0 may be identified with the quantity $b_t C_{dl}/i_t$, and similar identifications may be made in more complex cases. Although numerical values of b_t and t_0 can be determined by the analysis of measured decay curves, further information is necessary before physical meanings can be assigned to these parameters.

Where t_0 can be identified with $b_t C_{dl}/i_t$, the determinations of the ratio b_t/t_0 is sufficient to determine C_{dl}, and from Eq. [17] this is given by the negative of the initial slope. A similar situation obtains when a faradaic process exhibits a capacitative effect. An

expansion of the logarithmic term of Eq. [17] shows that for small values of t the potential is a linear function of t, but in practice this linear region is sufficiently small that measurements of considerable sensitivity are required if the ratio b_t/t_0 is to be found with any degree of accuracy.

This becomes apparent if the initial slope is considered to be approximated by a line drawn between E_0 and a later value of E. It can be shown that this will differ from the true value $-b_t/t_0$ by more than 10% if the later value of E is more than $0.2b_t$ away. Since values of b_t of greater than ± 0.051 v are seldom observed, it is apparent that precise measurements of the decay must be made within about 0.010 v of E_0 to give b_t/t_0 to 10%.

It is worth noting that in the interrupter method developed by Hickling (24) and others for measuring overpotential when ohmic potential drops exist in the solution between the electrode and the reference electrode, use is made of this linear potential-time region to extrapolate open-circuit measurements of potential to $t = 0$ and thus to determine E_0. Although the values of E_0 are less sensitive than the values of b_t/t_0 to an erroneous assumption as to the range over which the linear region extends, it is clear that care must be exercised when such a linear extrapolation is made.

There are several methods by which b_t and t_0 may be separately determined from experimental data. Most obviously, an empirical choice of t_0 can be made such that E is a linear function of $\ln (1 + t/t_0)$. The slope of such a line is $-b_t$. This procedure is, however, likely to be somewhat more tedious and less accurate than a method not involving trial and error.

When t is much larger than t_0, the potential becomes a linear function of $\ln t$ with a slope of $-b_t$ as shown in Fig. 2. The equation of this linear function is

$$E = E_0 - b_t \ln (t/t_0) \qquad [18]$$

from which it is apparent that the function passes through the value $E = E_0$ at $t = t_0$. Thus a linear extrapolation of the latter part of the E vs. $\log t$ plot to E_0 gives t_0 directly. Since it has been noted that all decay curves for a given electrode coincide at large values of t regardless of the value of E_0, the quantity $E_0 + b_t \ln t_0$ is constant and t_0 has therefore been termed the time required for the potential to decay to E_0 from infinite potential (11).

Two considerations make this method of determining t_0 and b_t less attractive than it at first appears. If it is assumed possible to take an exact tangent to the E vs. $\ln t$ curve at any point and to use this tangent for the determination of b_t and t_0, it can be shown that the value of t_0 obtained will be in error by more than 10% unless the tangent is taken at a time greater than 46 t_0, which corresponds to a potential decay of more than 3.8 b_t. Consequently, the method cannot be used with accuracy unless the potential decay is observed over a sizable range. This requirement eliminates its use in that part of the Tafel region nearest the equilibrium potential because the decay must then be followed into a potential region in which Eq. [17] is no longer applicable.

A second important consideration in the application of this method arises from the assumptions made during the derivations leading to Eq. [17]. For small changes in potential, b_t and t_0 may be taken as constants to a good approximation; but over larger ranges such constancy may be seriously questioned, throwing doubt on the extrapolation to E_0.

The following method of analysis overcomes to a considerable extent the objections raised to the procedures described above. The inverse of dE/dt is, from Eq. [17],

$$\left(\frac{dE}{dt}\right)^{-1} = -\frac{t_0 + t}{b_t} \qquad [19]$$

so that dt/dE is a linear function of t with a zero intercept of $-t_0/b_t$ and a slope of $-1/b_t$. In practice, dt/dE may be approximated by $(t_{n+1} - t_n)/(E_{n+1} - E_n)$ and plotted against $(t_n + t_{n+1})/2$ without introducing significant errors, for it can be shown that the computed derivative is within 5% of the true value as long as $t_{n+1} - t_n$ is less than $1.2(t_n + t_0)$. This procedure is particularly attractive in that it can be used to determine t_0 and b_t from measurements over any small range in potential and is limited only by the accuracy with which E and t can be measured.

Glossary of Symbols

C_{dl} — Capacitance of the electrical double layer, dq_{dl}/dE, farads.
E — Potential measured with respect to an unpolarized reference electrode, v (Gibbs-Stockholm sign convention).
E_e — Equilibrium potential of a faradaic process, e.g., a metal-metal ion process ($i_f = 0$), v.
E_e^h — Equilibrium potential of the hydrogen gas electrode, v.
E° — Standard potential of the faradaic process, v.
E_0 — Potential at beginning of decay ($t = 0$), v.
dq_f — Amount of positive charge entering electrolyte from electrode by means of the faradaic process, coulombs.
q_{dl} — Amount of positive charge on electrode side of the electrical double layer, coulombs.
i_{ext} — Current intensity in external circuit, amp.
i_f — Current intensity corresponding to the faradaic process, dq_f/dt, amp.
i_i — Steady-state current intensity in external circuit at the moment of opening the circuit, amp.
i_0 — Exchange current intensity for an activation-controlled electrode reaction, amp.
t — Time, also time on open circuit, sec.
t_0 — Parameter of decay, sec.
n — Number of electrons passed in an activation-controlled reaction when the rate-determining step occurs once.
α — Transfer coefficient for an activation-controlled reaction.
z — Number of electrons passed by the faradaic process in one occurrence of the over-all reaction.
b_t — Parameter of decay, change in potential for an e-fold change in time when $t >> t_0$, v.
a — Activity.
a_o — Activity of oxidized species.
a_r — Activity of reduced species.
c_o — Molarity of oxidized species.
c_r — Molarity of reduced species.
V — Liters of electrolyte in equilibrium with the electrode.

Arsine Evolution and Water Reduction at an Arsenic Cathode

H. W. Salzberg and Bernard Goldschmidt[1]

Chemistry Department, City College, New York, New York

ABSTRACT

The effects of current density, temperature, acidity, and salt concentration on the evolution of arsine have been studied at arsenic and lead-arsenic cathodes. Analysis of the data indicates that the surface of the electrode is largely covered with chemisorbed hydrogen at current densities as low as 5-10 ma/cm^2, that arsine is formed by reduction of water molecules on the chemisorbed layer of hydrogen, that the rate-determining step is the disproportionation between adjacent surface hydrides, and that water molecule reduction takes place at the electrode even in 1M sulfuric acid at current densities at least as low as 1 ma/cm^2.

Previous work (1-4) on tin, lead, and antimony cathodes has shown that on these cathodes, when cathodic disintegration or hydride formation occurs, the water molecule, rather than the hydronium ion, is the immediate source of the hydrogen present in the hydride molecule. This water molecule reduction is observed at current densities at least as low as 20-30 ma/cm^2 in solutions of pH 2.5 or higher. To see if water molecules are reduced at lower current densities and in more acid solution, it was decided to investigate the arsenic-arsine system, since arsine is known to form at low current densities and because micro methods for its determination are known.

Apparatus, Method, and Materials

The apparatus was that of the previous work, with only minor changes (1). The arsine was absorbed in $HgCl_2$-$KMnO_4$-H_2SO_4 solution and determined colorimetrically by the standard molybdenum blue method (5).

The electrolytic solutions were made of C. P. materials dissolved in distilled water and usually pre-electrolyzed at c.d.'s between 10 and 500 ma/cm^2 for periods up to 24 hr. Check runs using different batches of solution made from different lots of material were in good agreement with each other.

Arsenic cathodes were prepared by plating arsenic out of concentrated solutions of $AsCl_3$ in glacial acetic acid, using the method of Audrieth (6). It is felt that the surfaces were pure arsenic since any zinc that leached out of the brass before plating started would not replate, due to the large differences in both potential and concentration between the zinc and the arsenic. In any event, each cathode immediately before use was cleaned in fresh concentrated HCl and then replated from fresh plating solution for about 10 min at about 3-6 ma/cm^2 to remove impurities and/or oxide film. The lead-arsenic surface was prepared simply by dipping a lead washer of appropriate size into an arsenic plating solution. No conclusions can be drawn concerning this surface except that it was a mixture of arsenic and lead.

Current densities were calculated on the basis of geometric area, which means that real current densities and real rates of arsine formation were lower than the figures given here. Also, due to different

[1] Present address: Department of Chemistry, University of Wisconsin, Madison, Wis.

histories, each cathode must have had a roughness factor at least slightly different from the others.

40°C runs were controlled to within 0.2°C, 25°C runs were controlled to within 1°C.

Potentials were not measured while arsine formation was being determined. Separate cells with a calomel reference were used. First the potential was measured directly at the desired apparent current density. Then the *IR* drop was measured, using a current interrupter technique, and subtracted from the total reading to give the potential of the cathode vs. the calomel. The interrupter was a mercury capillary relay activated by 60-cycle half-wave rectified house current. The make-break times were of the order of microseconds. The *IR* drop was obtained from the calibrated oscilloscopic trace of the potential.

The temperature coefficient was obtained by averaging temperature coefficients for several different cathodes. This procedure was followed because differences in roughness caused different apparent rates at each temperature for the various cathodes whose temperature coefficients, however, were in agreement.

In order to guard against false rates due to changes in surface, each cathode was run first at 25°C, then at 40°C, at 25°C again, at 40°C again, etc, and the temperature coefficients were calculated from values in agreement with each other. Results were then averaged among all other cathodes used in the temperature coefficient experiments. Also, different batches of solution were used with the same cathodes, and the same solutions were used with different cathodes. Whenever results were not self-consistent they were discarded.

As an additional check, after 2 years had elapsed, temperature coefficients were re-run with different materials, different cells, and a different cathode system. The cathode was a 10 cm^2 cone of silver-plated brass which had been plated with arsenic to a thickness of several millimeters. Solutions were made with conductivity water. Solids were CP materials recrystallized from conductance water. The scouring gas was electrolytic hydrogen passed over a palladium catalyst to remove oxygen and then passed over activated carbon at solid CO_2-acetone temperature. Pre-electrolysis was carried out for periods of time up to 5 days. Although apparent c.d. and rates differed from those of the original work, temperature coefficients were in substantial agreement with the original.

In spite of the elaborate precautions discussed above, the results were often dishearteningly irreproducible. To a great extent this was due to differences in surface. Each cathode had a slightly different shape, area, position in the cell, arsenic thickness, arsenic roughness, a different time lapse between the original plating and use, and a different plating current. Results therefore varied from cathode to cathode. Curves obtained with different cathodes were shifted slightly along the axis, although the shapes of the curves were the same. However, differences between curves for different cathodes were minor compared to differences resulting from changes in *p*H. Also, by the nature of the reaction,

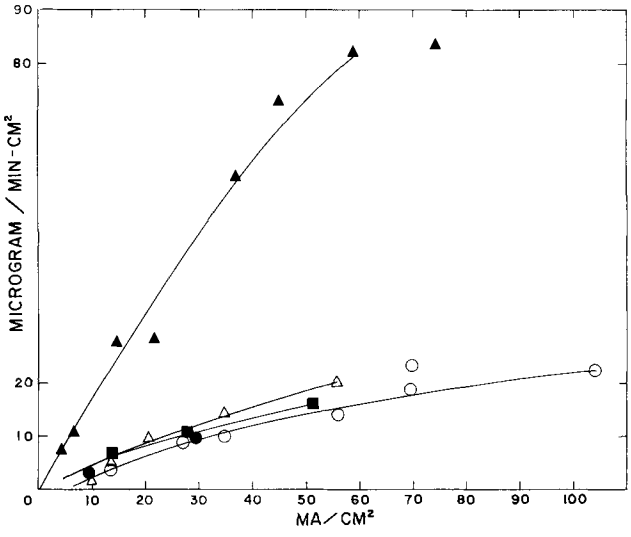

Fig. 1. Rate of arsine evolution vs. current density, ▲, 1M Na_2SO_4, △, 0.1M H_2SO_4; ○, 1M H_2SO_4; •, 1M H_2SO_4-Grube's data; ■, 1M H_2SO_4 on Pb-As cathode.

the surface of any cathode must have changed during each run, thus giving rise to further irreproducibility.

Nevertheless by discarding the results of those cathodes that gave erratic results and by purifying and re-purifying solutions, results were finally obtained that were self-consistent and valid.

Experimental Results

Figure 1 shows the rate of arsine production plotted against apparent current density. The efficiency of arsine formation is low, only about 10% of the current going into arsine in neutral solution and about 1-2% in acid. Increased acidity lowers the rate of arsine formation. Arsine is formed at current densities less than 1 ma/cm^2. At high current densities, the rate falls off, probably due to a high *p*H around the cathode. The rate of arsine production at an arsenic-lead surface in molar acid is definitely higher than at an arsenic surface in the same solution. The fact that the two points taken from Grube's work (7) fit so well is fortuitous, since there would have been a slightly different curve using another cathode. Nevertheless, the agreement is good. Curves obtained, but not plotted here, for mixtures of acid and salt, would fall between those for pure acid and pure salt solutions. Curves obtained, but not plotted here, using cathodes that had accumulated a layer of surface oxide by standing in the laboratory for varying periods of time, gave results that were both higher and more erratic. Results using cathodes that had been deliberately given an oxide coating were also higher.

Figure 2 shows the overvoltage curves for arsenic and arsenic-lead surfaces in acid solution and the *voltage* curve for arsenic in neutral solution. Potentials are higher in neutral solution. Lead-arsenic potentials in acid are more than with arsenic in acid but less than for arsenic in neutral solution. The 25° and 40°C curves in neutral solution correspond at low current densities but diverge above current densities of about 30 ma/cm^2, with the 25°C curve being slightly higher. Each curve has two regions

corresponding to a build-up of potential at low current densities and a leveling off at higher current densities. The slopes observed at higher current densities are about those values generally observed at high hydrogen overvoltage, but in view of the crudeness of the apparatus, with a rather large experimental error. The leveling off at high current densities is in agreement with the results reported by Lloyd (8) and the general shape of the curve is that reported by Grube (7) as shown in Fig. 3. This graph shows that Grube's values differ from ours but that his curve has the same shape. Noteworthy also is the fact that at very low current densities his slope is about 0.03.

Table I gives some temperature coefficients. Within experimental error, they are all the same.

Discussion

Coverage of the surface by hydrogen.—The overall mechanism must proceed by way of a disproportionation between two adjacent arsenic-hydrogen groups. The probability of a simultaneous reaction between three adjacent As-H groups and of three consecutive electrochemical reductions at one site for each arsine molecule is negligible. This disproportionation would then occur between an arsenic-monohydrogen and an arsenic-dihydrogen group.

Table I. Temperature coefficients at constant current

Solution	Cathode	Rate at 40°C/ rate at 25°C
1M H_2SO_4	As	1.3 ± 0.2
1M H_2SO_4	As-Pb	1.2 ± 0.3
1M Na_2SO_4	As	1.2 ± 0.2

Since, in neutral solution, about 10% of the current goes into arsine production via adjacent arsenic hydrogen groups, at least 20% of the surface is covered by hydrogen atoms, even at 1 ma/cm² (Fig. 1). Yet the combination of surface hydrogen atoms in the unadsorbed or physically adsorbed state is extremely rapid (9). For such a large fraction of the surface as 20% to be covered by hydrogen, the heat of adsorption would be at least 23 kcal/mole, using the calculations of Salzberg and Schuldiner (9). This means that the hydrogen would be chemisorbed in the form of a surface hydride. Actually, arsenic and hydrogen do form a strong covalent bond whose energy is estimated by Pauling (10) to be 47 kcal/mole.

The arsenic-dihydrogen group mentioned above is either an adsorbed molecule or a surface dihydride. The latter would have to be extremely unstable since no such substance has been reported. On the other hand, since the bond energy of the hydrogen molecule is about 104 kcal/mole and that of two As-H bonds would be about 94 kcal/mole, an adsorbed hydrogen molecule would not be likely to break down into two hydrogen atoms which then form covalent bonds with an arsenic atom, i.e., disproportionate into an arsine molecule. Rather, the process would go the other way. Two hydrogen atoms held by covalent bonds to the same arsenic atom would combine to form a molecule of hydrogen. Since the radius of an arsenic atom is 1.25Å and that of the hydrogen atom is 0.37Å there would be plenty of room for two hydrogen atoms to be bound to one surface arsenic atom. The dihydrogen group would therefore be AsH_2, a surface hydride, formed either by a second hydrogen atom being produced at a site which already has a hydrogen atom [(a) in Fig. 4] or by a disproportionation between two adjacent AsH groups [(b) in Fig. 4]

In Fig. 4, the large circles represent arsenic atoms, the small ones hydrogen atoms. Step (a) is an electrochemical reaction; step (b) is also an electrochemical reaction; step (c) is a disproportiona-

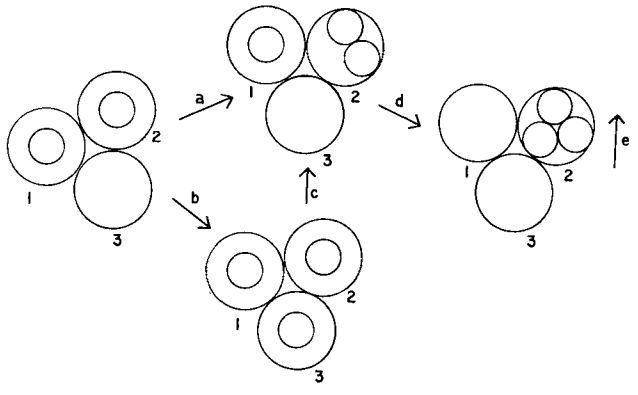

Fig. 4. Diagram of possible reaction paths. Large circles are arsenic atoms, small circles are hydrogen atoms.

tion between two adjacent monohydride molecules forming a dihydrogen molecule; step (d) is a disproportionation forming an arsine molecule; and step (e) is the desorption of the arsine from the surface.

In either event, whether the dihydride is formed electrochemically as in (a) or by disproportionation as in (c) arsine formation must be preceded by the formation of adjacent As-H groups. Since the dihydrogen molecule must be unstable, breaking down rapidly into molecular hydrogen and arsenic, most of the dihydride formed would go directly into molecular hydrogen. An over-all 10% yield of arsine implies that much more than 10% of the current goes into the formation of the unstable dihydrogen hydride and therefore that the surface would be largely saturated with monohydrogen hydride.

The rate-determining process.—The rate-determining step in arsine formation in both neutral and acid solution is (d) in Fig. 4, the disproportionation between As-H and AsH_2. Also, the water molecule, rather than the hydronium ion is the immediate source of the hydrogen found in arsine. These ideas follow from the facts that : (*a*) arsine production falls off as acidity is increased and in acid solution increases as sodium sulfate is added; (*b*) even in acid solutions, the potential at current densities where arsine is produced is high enough to reduce water molecules; (*c*) the temperature coefficient of arsine production at constant current is positive and the same in both acid and neutral solution. The import of this last statement may not be immediately obvious and so some elaboration is required.

The rate of a reaction is directly proportional to the number of reactant particles which possess a total energy equal to that of an activated complex. The energy of the activated complex is relatively independent of temperature. (For example, if the activated complex in this case is a molecule consisting of a surface arsenic atom and two adsorbed hydrogen atoms, there are no degrees of translational freedom, one degree of rotational freedom, and one degree of vibrational freedom less than the normal $3N$-6. The heat capacity at constant volume, according to classical theory, is at most 10 cal/mole-degree. Over a 15 degree range at constant pressure, the energy of the activated complex would change by about 170 cal at most.) Consequently, the reaction products at the moment of formation all have about the same energy regardless of the temperature at which the reaction occurs. After formation, inelastic collisions result in thermal equilibrium and so at higher temperatures the reaction products will have a greater energy. Nevertheless, at the moment of formation, the products have an energy independent of temperature.

One exception to this, however, is the case of electrochemical reactions involving an overvoltage. To speed up these reactions, electrical energy is supplied to the reacting particles, thus increasing the number that have the required energy. If the overvoltage is α, the electrical energy added per equivalent is $\alpha n\mathbf{F}$, where α is a fraction whose value is usually about ½ and **F** is the faraday. The rest of the electrical energy supplied to the system $(1-\alpha)n\mathbf{F}$ goes to the products of the rate-determining step. (This is obvious since this fraction of the expended energy does not influence the rate of reaction.) So, for these reactions, the energy of the reaction products is greater than that of the activated complex by $(1-\alpha)n\mathbf{F}$ until thermal equilibrium is reached. This means that the higher the overvoltage, the greater the energy of the products, since more electrical energy must be supplied. The products of water molecule reduction, which occurs at a higher voltage, will have a greater energy than the products of hydronium ion reduction. The higher the current, the greater the energy of the products, since the voltage is greater. Finally, the higher the temperature, the lower the overvoltage of the reaction and the less the energy of the reaction products at the moment of formation. With this in mind we can get down to cases.

The positive temperature coefficient, at constant current, eliminates an electrochemical, rate-determining step (RDS) since at constant current an electrochemically formed activated complex would be produced at a rate independent of temperature. The RDS then involves neutral products of electrochemical steps, i.e., the RDS is either (c), or (d) or (e) in Fig. 4.

The positive temperature coefficient also eliminates an RDS between electrochemical reaction products that react immediately, before they undergo collisions with solvent molecules and reach thermal equilibrium. The energy of newly formed products of an electrochemical step would decrease, if anything, with increased temperature and decreased overvoltage and hence the temperature coefficient of an RDS involving newly formed reactants would not be positive.

On the other hand, if all of the participants in the RDS had reached equilibrium, there would be no difference in the rates in neutral and in acid solution, since the energies of the reactants would depend only on temperature and not on *p*H. This eliminates the desorption of arsine [reaction (e)] as the RDS.

The only possibilities left are the two disproportionation reactions which could occur between one newly formed hydrogen atom and either one or two previously formed atoms that had already reached thermal equilibrium, that is either (c) or (d) in Fig. 4. Of these the formation of dihydrogen hydride (c) can be dismissed as the RDS. If the movement of the newly formed high-energy hydrogen atom from position 3 to position 2 is slow, the movement of the previously formed, and therefore lower energy, hydrogen atom from position 1 to position 2 should be even slower. But this would make (d) slower than (c) and so (c) could not be the RDS.

By elimination, therefore, the RDS is the disproportionation between the AsH and a newly formed electrochemically produced AsH_2 group, step (d).

The rate of this reaction obviously depends on the energy of the AsH_2. If this is formed by reduction of a water molecule at a high overvoltage, its energy would be higher than if it were formed from a hydronium ion at a lower overvoltage. But, since

the temperature coefficient is the same in both acid and neutral solution, the dihydrogen hydride must be formed with the same energy in both cases. This means that the hydride would be formed by reduction of water molecules, since presumably neutral solutions would not have sufficient hydronium ion present at the surface to maintain the reaction. The difference in rates between the acid and neutral solutions is the result of fewer water molecules being reduced in acid solutions.

The dihydrogen hydride formed from hydronium ion reduction would not have enough energy to form arsine but would break down to molecular hydrogen. Since the ion is more easily reduced than the water molecule, in acid before water molecule reduction can start, a critical current density must be reached at which the surface hydronium ion concentration is too small to support the current. The shape of the curve supports this idea. The greater the acidity, the more hydronium ion initially present, and the higher the neutral salt concentration the fewer hydronium ions initially present at the surface. The data show that increased acidity and decreased neutral salt concentration lowers the rate of arsine formation.

The production of arsine at a lead-arsenic cathode would follow the same mechanism as at an arsenic cathode, since in acid solution the temperature coefficient is the same, the shape of the overvoltage curve is the same, the shape of the rate curve is the same, and the rates and potentials both fall between those of arsenic in neutral solution and in acid solution.

The evolution of hydrogen, as distinct from the formation of arsine, has several different rate-determining steps, depending on the current density. At very low current densities, the surface is not saturated with hydrogen and the RDS is the combination of atoms to form molecules. The initial slope of Fig. 3 is about 0.03, within experimental error, and the overvoltage is less than about 40 mv.

Above about 10^{-5} ma/cm^2, Grube's results indicate that the surface starts to become saturated and the potential increases to that required for production of hydrogen on an arsenic hydride surface. This steep rise also shows up in the first portion of the curves in Fig. 2.

At about 5-10 ma/cm^2, the surface is saturated with monohydrogen hydride and the slope of the overvoltage curve levels off to about the 0.12 value expected for the reduction of a water molecule or the slow or retarded discharge of a hydronium ion. The fluctuations at higher values, especially in neutral solution, are either due to changes in the surface produced by arsine formation or to increase in *p*H.

The same mechanism of hydrogen production applies to the case of the lead-arsenic cathode except that here water reduction probably occurs at a lower current density than on pure arsenic.

Conclusions

It must be re-emphasized that uncertainty as to the true surface area makes the rate and current density data valid only as an upper limit. Also, use of tank hydrogen and ordinary distilled water in the earlier work could have lead to serious errors. However, the checks run with conductance water and a hydrogen purification train were in good enough agreement to indicate that the results were valid.

These conclusions stem from an analysis of the present work and from consideration of the data of Grube (Fig. 3).

1. Arsine is formed by reduction of water molecules on an arsenic surface covered with chemisorbed hydrogen in the form of a covalent hydride.
2. The rate-determining step in arsine formation is the disproportionation between an AsH and an adjacent AsH_2 group or molecule.
3. Water reduction takes place even in lM acid at current densities at least as low a 1 ma/cm^2.
4. The reactions at a lead-arsenic surface are the same as at an arsenic surface except that in acid solution water reduction starts at lower current densities on the arsenic-lead cathode. Consequently, at a given current density, the voltage and therefore the amount of arsine formed is greater at the lead-arsenic surface.
5. At current densities below 1-2 x 10^{-5} amp/cm^2 in acid solution, the formation of hydrogen atoms is reversible. The rate-determining step in hydrogen evolution at this low current density is the combination of hydrogen atoms. The heat of activation is at least about 23 kcal/mole.
6. The saturation of the surface with chemisorbed hydrogen is virtually complete at current densities of about 10^{-2} amp/cm^2.

This work has implications for the general problem of hydrogen overvoltage. It shows, we believe, that water molecules are reduced at cathodes in acid solution at current densities well below those required for cathode disintegration. This is in agreement with the work of Schuldiner (11) and Schuldiner and Hoare (12) who showed that on palladium and platinum water molecules are reduced at low current densities at *p*H 0.8 and 1.4, respectively. In both cases the voltage required for water reduction was less than that which is commonly observed at high overvoltage cathodes, such as mercury and lead.

Perhaps the best summary of the position is that concentration polarization at the surface occurs at current densities much lower than that previously expected and that therefore water molecule reduction occurs.

Technical Notes

Creeping Silver Sulfide

T. F. Egan and A. Mendizza

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

An effect was observed when a silver specimen coated with a porous gold electroplate was exposed to sulfur vapor. Silver sulfide formed at the pore sites as would be expected, but in addition it spread radially and rapidly on the gold surface, to which it was strongly adherent.

For a preliminary investigation of this effect, a silver panel was prepared, one half of which was heavily gold plated to produce a silver-gold junction. The cleaned specimen was suspended in air saturated with sulfur vapor at 60°C at which temperature the vapor pressure of sulfur is 0.0001 mm (1). After an overnight exposure (17 hr) silver sulfide had crept over the gold surface along the entire bimetallic boundary.

Figure 1 depicts the appearance of the sulfided surfaces at the conclusion of the test (165 hr). Periodic measurements were made at a point of maximum creepage and are shown in Fig. 2. A cross section of the specimen at the gold-silver junction is shown in Fig. 3. It is apparent that the cavity was produced by migration of silver ions needed for the formation of the sulfide on the gold. It is also evident that the sulfide coating on the gold is of the same order of thickness as that on the silver. However, it tapers rather abruptly to a thin film which at the leading edge exhibits interference colors (Fig. 1).

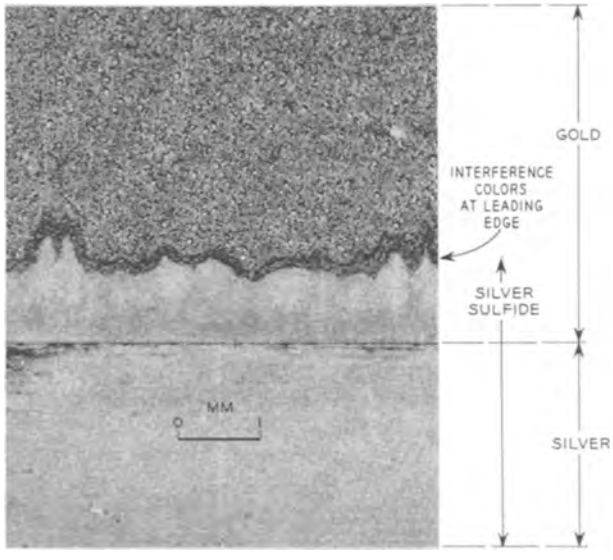

Fig. 1. Advance of silver sulfide on gold after 165 hr in sulfur vapor at 60°C. Leading edge very thin, exhibits interference colors.

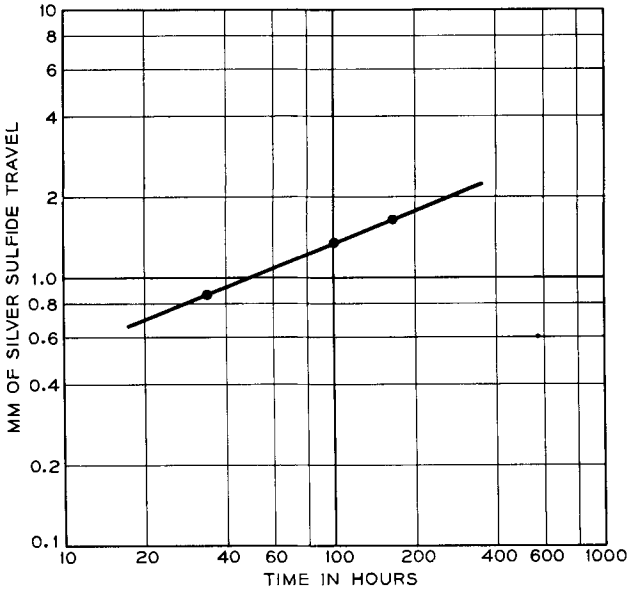

Fig. 2. Creepage silver sulfide on gold-sulfur vapor at 60°C.

The same experiment was performed using rhodium and silver. Direct microscopic examination revealed needles of silver sulfide at the bimetallic juncture but no creepage of silver sulfide on the rhodium surface. Figure 4 is a photomicrograph of a

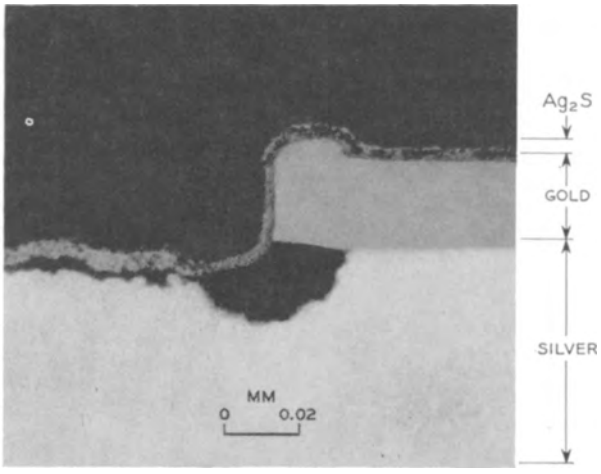

Fig. 3. Cross section of specimen showing cavity in silver and sulfide film on silver and on gold plate.

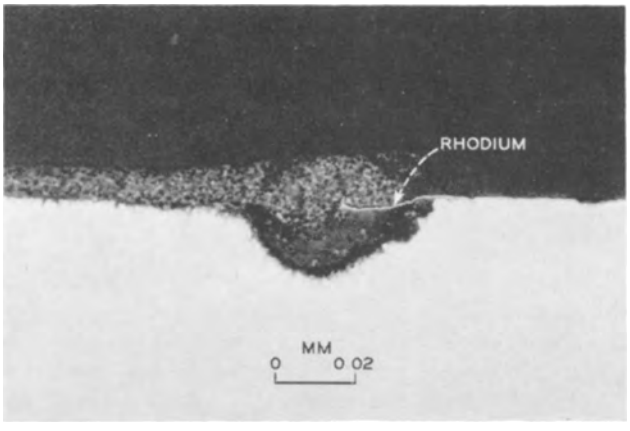

Fig. 4. Cross section of rhodium plated silver showing cavity resulting from silver sulfide needle growth.

cross section of this specimen. It shows what might appear to be a slight amount of creeping of the silver sulfide on the rhodium. This, however, is unlikely since the relatively thick sulfide coating ends abruptly. If creeping had occurred, one would expect the sulfide on the rhodium to taper out to an extremely thin film as had occurred in the case of the gold. The silver sulfide on the rhodium probably resulted from a collapse of the needles during the molding operation. The cavity, which undercuts the rhodium, indicates the quantity of silver required to form the silver sulfide needles. A similar experiment with silver and palladium also failed to produce spreading of silver sulfide.

At the present time there is no completely adequate explanation for the behavior of silver sulfide on the metals studied.

A recent (2) paper discusses a similar effect involving tantalum partly coated with silver and exposed to iodine vapors at 174°C. Silver iodide formed not only on the silver but spread rapidly over the uncoated tantalum surface. The spreading mechanism postulated for this effect assumes local cell action, enhanced by relative ease of flow of ions and electrons in different phases. In this instance spreading of the corrosion product is favored by the ease of flow of silver ions in the iodide and the ease of flow of electrons in tantalum. The same effect was obtained with silver on platinum and on graphite. While this theory appears to be operative in the case of the spreading of silver sulfide on the gold, it is not clear why the same phenomenon does not occur when rhodium or palladium is substituted for the gold, at least at the temperature employed (60°C).

From the practical point of view this phenomenon is of considerable importance. Silver-gold combinations are fairly common in electrical contact design. Some of the usual fabrication methods are electroplating, overlays, and inlays. Silver solder is also used to attach gold to other metals. In all cases, it should be realized that whenever a junction of silver and gold exists in a sulfiding atmosphere, the gold surface will be contaminated with silver sulfide. In these experiments, silver sulfide was more adherent to gold than to silver (Fig. 3) which would indicate that it would be more difficult to remove by contact wipe. Therefore, while silver sulfide is always undesirable on electrical contacts, it may be even more detrimental on gold.

A New Method for Preparing Hydroxide-Free Alkali Chloride Melts

Donald L. Maricle[1] and David N. Hume

Department of Chemistry and Laboratory for Nuclear Science, Massachusetts Institute of Technology, Cambridge, Massachusetts

Molten salts have been used extensively in recent years as solvents for electrochemical processes and investigations. Alkali metal chlorides in particular offer excellent thermal stability, good solvent properties, and a wide potential span between anodic and cathodic decomposition limits. However, the difficulty of removing the last traces of residual moisture from the salts has often necessitated rather arduous drying procedures (1-3). If the moisture is not removed, hydrolysis occurs upon fusion as indicated by Eq. [1]

[1] American Cyanamid Co. Fellow 1958-1959. Present address: American Cyanamid Co., Stamford, Conn.

$$Cl^- + H_2O \rightarrow HCl\uparrow + OH^- \quad [1]$$

The hydroxide ion thus produced precipitates metal ions, attacks glass, and is reduced more easily than the alkali metals, thus diminishing the usable potential range of the solvent.

Laitinen, *et al.* (4) have studied the preparation of a hydroxide-free, 59-41 mole % lithium chloride-potassium chloride eutectic by measuring the hydroxide ion concentration polarographically in the melt. Lithium salts are particularly difficult to dry, and polarography is sensitive to low concentrations of hydroxide ions. As a result they found it necessary to use a procedure involving vacuum treatments and fusion under hydrogen chloride which, until it was developed into a routine operation, required several days to complete. By such means they were able to obtain melts with low polarographic residual currents and with little tendency to etch glass apparatus.

The authors have made a polarographic study of drying procedures for the equimolar sodium chloride-potassium chloride melt 740°C, using a tungsten micro-electrode 0.8 mm in diameter and 5 mm long and a platinum-platinum (II) reference electrode. It was found that if the ordinary dry salts were fused and flushed with pure argon for 20 min to remove dissolved oxygen, only a small hydroxide reduction wave was found. Using a standard addition method for calibration, the hydroxide concentration of such a melt was estimated to be 0.17 millimolal, or 3 x 10^{-4}% expressed as water. If rigorously dried hydrogen chloride is bubbled through the melt for 20 min before the argon flush, even this small hydroxide ion impurity is removed. Typical polarograms with and without hydrogen chloride treatment are shown in Fig. 1. This is in considerable contrast to the lithium chloride-potassium chloride eutectic which will contain gross amounts of hydroxide ions if fused without special drying procedures and in which dry hydrogen chloride is not effective for removing hydroxide ions.

A new and better method of removing hydroxide impurities from both melts has been developed in

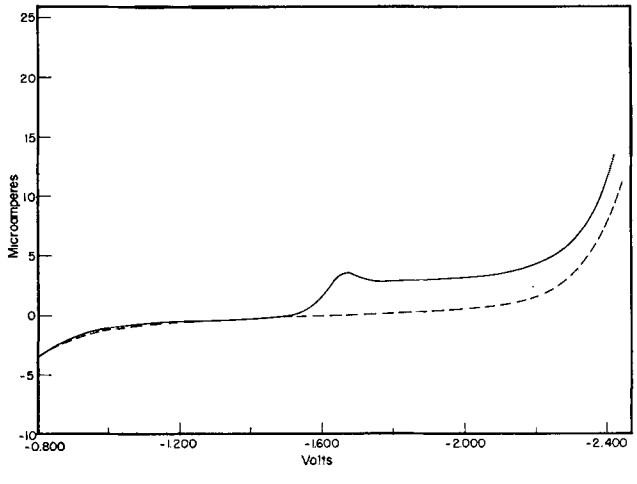

Figure 1. Residual polarographic currents in the NaCl-KCl melt before (solid line) and after (dotted line) removal of hydroxide ion impurity.

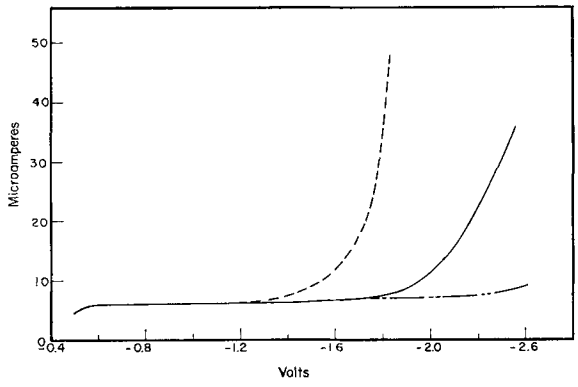

Figure 2. Residual polarographic currents during the purification of the LiCl-KCl eutectic. - - - - - Before treatment; ——— after 20 min chlorine and 20 min argon; ——— - - ——— after 40 min chlorine and 20 min argon.

the present investigation. This method eliminates the need for pre-drying any salts and can be carried out easily and rapidly. It consists simply of passing chlorine through the melt immediately after fusion of the undried salts. The reaction, presumably, is that of Eq. [2].

$$2OH^- + 2Cl_2 \rightarrow O_2\uparrow + 2HCl\uparrow + 2Cl^- \quad [2]$$

The hydroxide ion is thus removed without contamination of the melt with any extraneous nonvolatile species. The oxygen and hydrogen chloride gases are swept out by the chlorine, and the chlorine is easily removed by flushing argon through the melt. After 20 min of treatment with chlorine followed by a 20 min argon flush, the hydroxide ion concentration in a sodium chloride-potassium chloride melt was reduced below the level detectable polarographically. Polarograms recorded before and after the chlorine treatment are shown in Fig. 1. For treating this melt, chlorine has the advantage of being much easier to dry than hydrogen chloride. An additional drawback to the use of hydrogen chloride is its characteristic of altering the fluid characteristics of the melt in such a way that splashing and spattering occurs with consequent deposition of melt at unwanted places in the apparatus.

The use of chlorine is extremely advantageous for drying lithium-ion-containing melts. Figure 2 shows polarograms obtained before and after chlorine treatments in the 59-41 mole % lithium chloride-potassium chloride eutectic at 450°C with a tungsten micro-electrode and a platinum foil used as an anode and reference electrode. It is apparent that after 40 min of chlorine treatment, the hydroxide ion concentration has been reduced below the level detectable polarographically. This was found to be true even if the salts were taken directly out of the bottle, with no pre-drying. A 20-min flush with argon was sufficient to remove the chlorine from this melt also. Therefore, if chlorine is used to purify the melt, the procedure takes only about 1 hr, in contrast with previously used procedures requiring up to several days.

While this method has been used by the authors to purify only the two melts mentioned above, it is

presumed that chlorine could be used to remove hydroxide impurities from other alkali metal and alkaline earth chlorides. However, it is interesting to note that if the temperature of the lithium-chloride-potassium chloride eutectic was raised from 450° to 740°C, reaction [2] did not occur to any appreciable extent, and the color of the chlorine solution changed from nearly colorless to red-brown. The sodium chloride potassium chloride melt exhibits a deep red-brown color when saturated with chlorine at 740°C. It appears as if higher temperatures favor the formation of a chlorine species which has a sufficiently diminished oxidizing power that it cannot oxidize the hydroxide ion in lithium-ion-containing melts.

Brief Communications

Location of Diffused pn-Junctions on Germanium by Electrodeposition of Copper

Reinhard Glang

Diamond Ordnance Fuze Laboratories, Washington, D. C.

The delineation of diffused junctions on silicon by chemical deposition or electroplating of metals has been described frequently in recent publications and can be achieved in various ways. Germanium, however, offers difficulties. It seems to be impossible to sharply define a junction on germanium by chemical displacement reactions (1). Electroplating methods of locating grown junctions on germanium crystals have been reported occasionally (2, 3), but apparently no procedure has been published for defining *diffused* junctions on germanium with metals. The technique described below makes it possible to delineate the junction between p-type germanium and thin diffused n-type layers.

A small piece of a diffused germanium wafer is angle lapped (4) as shown in Fig. 1 in order to expose the junction. The lapping is done against a glass plate, using an alumina abrasive 0.3μ in particle size, in order to avoid deep scratches on the beveled region. The surface is cleaned carefully with organic solvents and distilled water.

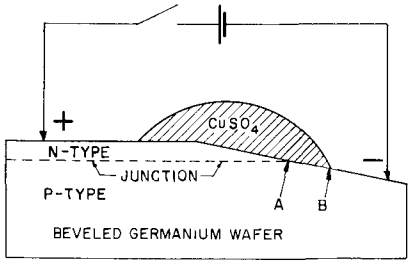

Fig. 1. Copper plating of diffused germanium wafer for delineation of junction.

The plating solution is prepared by dissolving approximately 20 g of $CuSO_4 \cdot 5H_2O$ in 80 ml of water and adding about 1 ml of concentrated (49%)HF. The hydrofluoric acid is intended to keep the germanium surface free from oxide. A small drop of this solution is placed on that part of the beveled surface where the junction is believed to be located. This is done carefully with a capillary pipette, so that the droplet does not flow over the edges of the germanium sample. Two adjustable metal probes are then brought into contact with the surface, one on the beveled p-region and the other on the non-beveled n-region. A small d-c voltage is applied between the probes, and the p-type region serves as the cathode. During these operations, the surface of the sample must be protected from strong light in order to avoid a photovoltage across the junction and consequent deposition of a thin film of copper on the n-region of the wafer. The circuit supplying the voltage is closed at 20-sec intervals for periods of only about 1 sec. After the first pulse, a deposit of copper is usually visible over the whole area between point A and point B in Fig. 1. This layer of copper adheres firmly to the germanium surface.

As indicated above, the voltage is applied continuously for only about 1 sec. Longer applications yield anode reactions which result in an electrolytic etch of the n-region, dulling its surface, and thus interfering with subsequent junction depth meas-

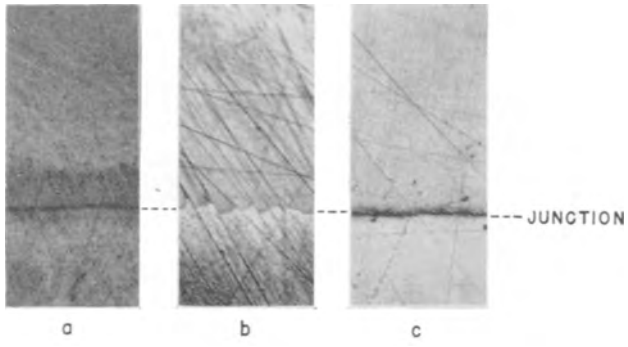

Fig. 2. Diffused pn-junctions in germanium. The lower thirds of the photographs show the copper-plated p-type region of the bevel. Lapping angles and junction depths: (a) 2°, 2μ; (b) ¾°, 2μ; (c) ¾°, 6.5μ. Magnification 300X before reduction for publication.

urements made with an interference microscope (4). The value of the voltage is critical and depends on the dimensions of the sample as well as on the sheet resistivity. On rectangular samples of width 2 mm, length 5-10 mm, junction depth 1-2μ, and sheet resistivity about 150 ohm, a voltage of 15 to 20 v and a current of about 30 to 50 ma adequately define the junction. Too high a voltage causes the copper to begin to spread over the n- as well as the p-region. A more common failure results from a voltage which is too low. In this case, copper tends to deposit from the edge of the drop nearest to the negative probe (i.e., point B, Fig. 1) while the region near the junction (i.e., point A Fig. 1) remains uncovered.

On samples having the previously specified dimensions, but sheet resistivities of 30 ohm or less and junction depths of 8 to 10μ, conditions are less critical; voltages as low a 5 v and currents of about 20 ma have proved effective.

Figure 2 shows samples of diffused germanium the lower thirds of which are the copper-plated p-type regions and the upper two thirds of which are the n-type regions. In Fig. 2a, the upper portion of the sample is not beveled, while in Fig. 2b and 2c the beveled n-region extends all the way to the upper edges of the photographs. Lapping angles and junction depths for these samples are as follows: (a) 2°, 2μ; (b) ¾°, 2μ; (c) ¾°, 6.5μ. As a consequence of the angle lapping procedure, the beveled surface areas are scratched. The surface damage accounts for minor irregularities in the junction delineation as clearly shown in Fig. 2b. On samples having a junction depth of only 1 or 2μ, irregularities in the copper-plated edge larger than those shown in Fig. 2b are occasionally observed, and these irregularities follow the surface profile. For example, when a scratch 1μ in depth was present on the sample's surface prior to diffusion, the junction depth was increased in this particular region.

For junction depths in the order of only 1μ it is advisable to use a lapping angle of 1° or smaller. A steeper bevel tends to permit extension of the copper plated area beyond the junction line, as occurred in Fig. 2a where the lapping angle was 2°. The surface damage which is done in the angle lapping procedure undoubtedly distorts the junction region and causes an apparent inaccuracy in its delineation. The larger the lapping angle the more serious this effect will be.

Considering the fact that the plating voltage biases the junction in the reverse direction, the currents between the probes are surprisingly high. Even in the absence of copper sulfate solution, these currents are of the same order of magnitude. Consequently, there must be a high leakage current, either through or by-passing the junction, but not through the drop. By etching 1 to 2μ deep into the beveled part of the surface, the leakage current can be reduced greatly. This is another indication of the disturbing influence of a damaged surface layer and explains why the voltage is so critical for effective plating. The voltage has to be sufficiently high to force through the droplet and into the diffused n-layer that fraction of the total current which is required to produce a visible deposit of copper. The main fraction of the current, however, will go from the p-type to the n-type region through the damaged surface layer, which offers a path of lower resistance across the junction.

Magnetic Gradient at the Surface of Ferromagnetic Substances

S. Yamaguchi

The Institute of Physical & Chemical Research, Tokyo, Japan

The gradient of the magnetic field found at the surface of a magnet body has been measured by means of electron diffraction. This magnetic gradient was taken into consideration for elucidation of the Hedvall effect in catalysis and corrosion (1).

Experimental.— A flux of electrons spreads in passing through a magnetic field with a gradient. This phenomenon is observable in a diffraction pattern obtained from a ferromagnetic substance (Fig. 1).

A reduced iron catalyst[1] for practical ammonia synthesis and the sharp edge of a razor blade of

[1] This catalyst was produced by reducing blocks of iron oxide (Fe_3O_4) with hydrogen. The iron catalyst thus prepared kept the initial form of the oxide block.

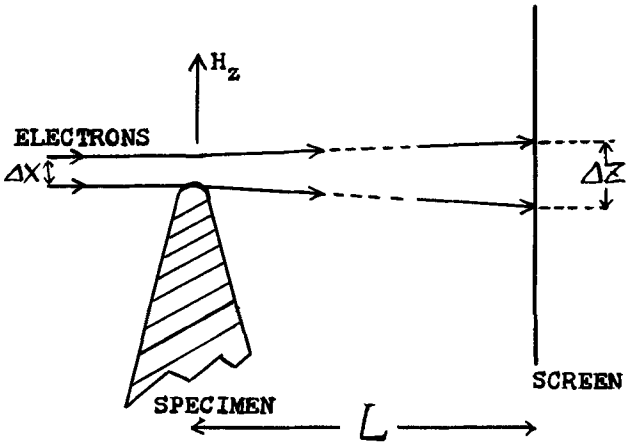

Fig. 1. Experimental arrangement

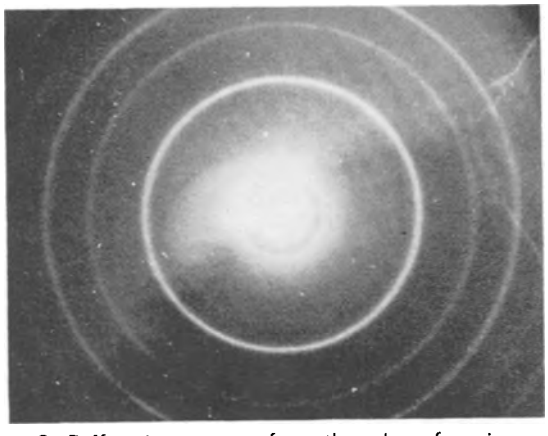

Fig. 2. Diffraction pattern from the edge of an iron catalyst. Wave length: 0.0308Å; camera length: 495 mm; positive enlarged 2.3 times.

hard steel were employed as objects for the experiment. The remanence of the former specimen was about 5000 gausses and that of the latter was about 10000 gausses. The surface (area: about 5 mm^2) of the catalyst was scanned with the electron beam (diameter: about 0.05 mm) in order to locate the maximum gradient of the magnetic field found at the catalyst surface. The electron beam grazed the sharp edge of the razor blade. Diffraction patterns obtained from the iron catalyst (size: 5 x 5 x 1 mm) and that from the razor edge (5 x 5 mm) are shown in Fig. 2 and 3. In these figures it is noticeable that the diffraction rings show a preferred orientation regarding the diffraction width, being diffuse in the direction of the magnetic field, but sharp in the direction perpendicular to the field. The relation between the field (H_z)and the spreading of the diffraction width of the (110) ring is illustrated in Fig. 4.

The central spot found in the diffraction pattern of Fig. 2 is enlarged 35 times in Fig. 5(a). It is noticeable here that the incident beam spreads along the direction of the magnetic field of the specimen. The cross section of the undistorted incident beam is shown in Fig. 5(b) with the same magnification as in Fig. 5(a). The amount of the magnetic spreading of the incident beam is measurable at the diffraction ring as well as at the central spot.

Measurement of the magnetic gradient.—The spreading ΔZ of the incident beam resulting from

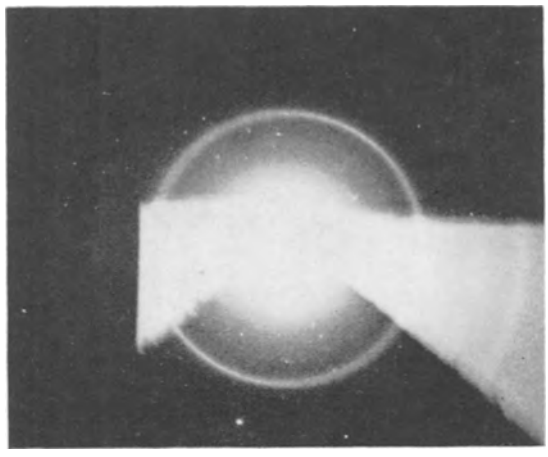

Fig. 3. Diffraction pattern from sharp edge of a razor blade. Wove length: 0.0309Å.

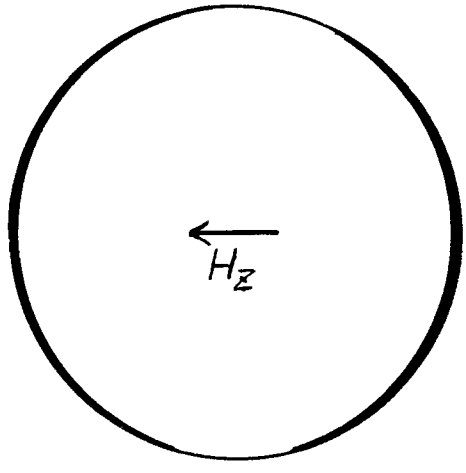

Fig. 4. Oriented spreading of the (110) ring in Fig. 2 and 3. H_z: the direction of the field.

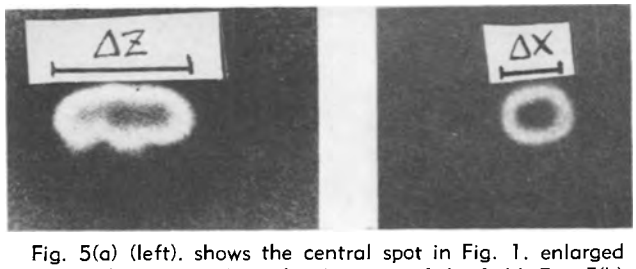

Fig. 5(a) (left). shows the central spot in Fig. 1. enlarged 35 times. It spreads along the direction of the field. Fig. 5(b) (right). shows the cross section of the undistorted incident beam; it is nearly circular.

the action of the magnetic gradient ($\partial H_z/\partial Z$) in the present conditions (Fig. 1) is given by

$$\frac{\Delta Z}{\Delta X} = e \left|\frac{\partial H_z}{\partial Z}\right| \cdot \frac{\lambda L l}{h} \qquad [1]$$

where e is the electron charge (1.6 x 10^{-20} emu), ΔX is the diameter of the flux of the undistorted incident beam, λ is the wave length of the electrons, h is Planck's constant (6.6 x 10^{-27} erg sec), L is the camera length (495 mm), and l is the magnetic path traveled by the electrons. In Fig. 2 or in Fig. 5(a) and (b) we measure $\Delta Z/\Delta X \cong 2.3$, and $\lambda = 0.0308$Å. If the magnetic path l is assumed tentatively to be 1μ we obtain

$$\frac{\partial H_z}{\partial Z} \cong 6 \times 10^5 \text{ gauss/cm}$$

as the maximum gradient according to Eq. [1]. This value of the magnetic gradient is not absolute because of the uncertainty in l.

In Fig. 3 we measure $\Delta Z/\Delta X \cong 3{,}4$, and $\lambda = 0.0309$Å. Therefore, we obtain

$$\frac{\partial H_z}{\partial Z} \cong 9 \times 10^5 \text{ gauss/cm}$$

as the maximum gradient on the razor edge. This value is rather absolute, because the l-value here assumed is approximately equal to the minimum thickness of the truncated wedge of the razor blade (1μ).

Conclusion.—The maximum magnetic gradient is related to the lattice distortion or the magnetostriction found at the surface of the specimen. It is known that catalysis and corrosion of metals depend frequently on this lattice distortion. The magnetic Hedvall effect in catalysis and corrosion should be studied by scanning the magnet surface with a fine electron beam according to the present process.

Overtemperature in Metal Scaling

D. Caplan

National Research Council, Ottawa, Canada

Overtemperature resulting from the heat of reaction can affect the reaction kinetics of gases with metal surfaces. This has been discussed recently in the high-temperature oxidation of iron (1), iron-nickel (2), uranium (3), and molybdenum (4), and by the writer as a possible explanation for large differences in scaling rates of iron-chromium alloys with different surface preparations (5). To investigate the latter and because other measurements of overheating had been indirect, it was decided to determine the overtemperature directly with a thermocouple welded to the surface of the specimen.

The metals tested were high-purity vacuum melted iron, a pure Fe-26 Cr alloy, and a commercial Fe-30 Ni alloy (kindly supplied by R. T. Foley from material used in reference 2). Specimens in sheet form were used to provide an adequate surface/mass ratio. A chromel/alumel thermocouple was spot welded to the prepared metal surface. The assembly was lowered into the open top of a vertical tube furnace (on-off control) and the thermocouple output recorded on a strip chart potentiometer (L&N Speedomax G, full scale 50 mv pen travel in one second). Relevant details of six runs are listed in Table I.

The temperature/time curves are reproduced in Fig. 1. Runs 1 and 2 demonstrate that large overtemperatures can develop when iron is oxidized. A similar conclusion was reached by Schmahl, *et al.* (1), but quantitative comparison of the results is not possible because of the more positive attachment of the thermocouple and differences in the experimental conditions: overheating will be less if these conditions are such as to decrease the reaction

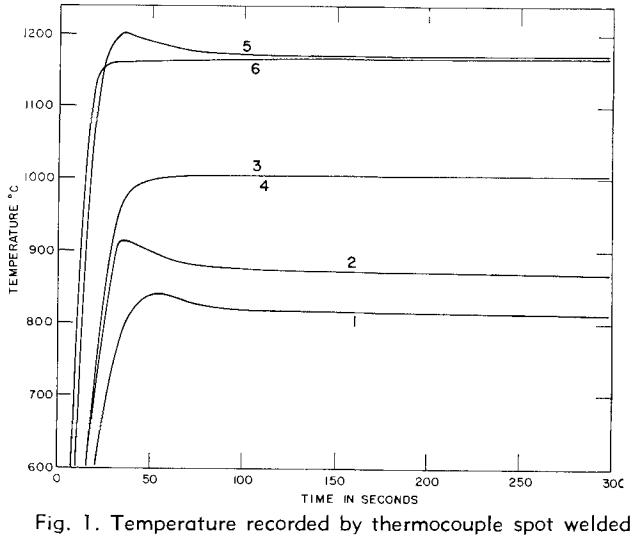

Fig. 1. Temperature recorded by thermocouple spot welded to surface of specimen.

Overtemperature in Metal Scaling

D. Caplan

National Research Council, Ottawa, Canada

Overtemperature resulting from the heat of reaction can affect the reaction kinetics of gases with metal surfaces. This has been discussed recently in the high-temperature oxidation of iron (1), iron-nickel (2), uranium (3), and molybdenum (4), and by the writer as a possible explanation for large differences in scaling rates of iron-chromium alloys with different surface preparations (5). To investigate the latter and because other measurements of overheating had been indirect, it was decided to determine the overtemperature directly with a thermocouple welded to the surface of the specimen.

The metals tested were high-purity vacuum melted iron, a pure Fe-26 Cr alloy, and a commercial Fe-30 Ni alloy (kindly supplied by R. T. Foley from material used in reference 2). Specimens in sheet form were used to provide an adequate surface/mass ratio. A chromel/alumel thermocouple was spot welded to the prepared metal surface. The assembly was lowered into the open top of a vertical tube furnace (on-off control) and the thermocouple output recorded on a strip chart potentiometer (L&N Speedomax G, full scale 50 mv pen travel in one second). Relevant details of six runs are listed in Table I.

The temperature/time curves are reproduced in Fig. 1. Runs 1 and 2 demonstrate that large overtemperatures can develop when iron is oxidized. A similar conclusion was reached by Schmahl, *et al.* (1), but quantitative comparison of the results is not possible because of the more positive attachment of the thermocouple and differences in the experimental conditions: overheating will be less if these conditions are such as to decrease the reaction

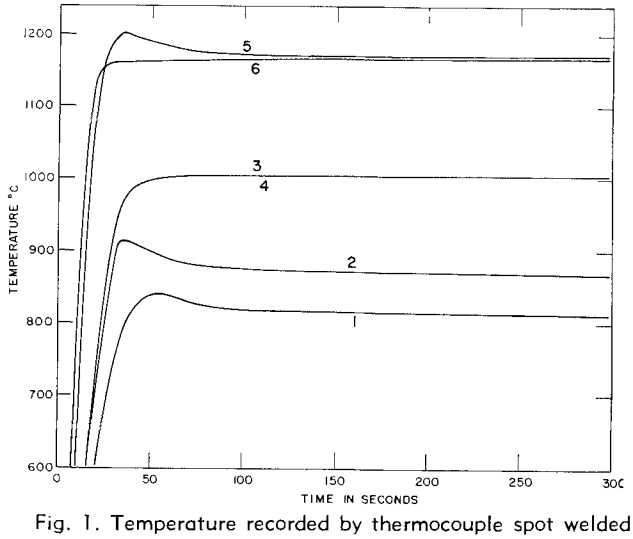

Fig. 1. Temperature recorded by thermocouple spot welded to surface of specimen.

Table I

Run	Alloy	Size, cm	Weight, g	Surface prep.	Temp, °C	Atmosphere	Overtemp, °C
1	Fe	1 × 5 × 0.04	1.3	Electropolished	812	O_2, 200 ml/min	27
2	Fe	1 × 5 × 0.04	1.3	Electropolished	866	O_2, 200 ml/min	47
3	Fe-30 Ni	2 × 3.8 × 0.06	3.4	Etched as in ref. (2)	1005	still air	nil
4	Fe-30 Ni	2 × 3.8 × 0.06	3.4	Etched as in ref. (2)	1005	O_2, 100 ml/min	nil
5	Fe-30 Ni	2 × 3.8 × 0.06	3.4	Etched as in ref. (2)	1170	O_2, 100 ml/min	29
6	Fe-26 Cr	1 × 5 × 0.04	1.3	Electropolished	1165	O_2, 200 ml/min	nil

rate, increase the heat capacity of the specimen, or remove heat more efficiently from it.

The negative result in runs 3 and 4 with Fe-30 Ni at 1000° indicates that the deviation in the Arrhenius plot observed by Foley (2) was not due to overheating but rather to his alternative suggestion, that of a change in scaling mechanism. At 1170° the scaling rate is large enough to give sensible overheating (run 5).

No overtemperature in run 6 demonstrates that the relatively rapid initial scaling obtained with Fe-26 Cr alloys in the electropolished condition (5) is due to some cause other than overheating.

An Investigation of the Discharge Characteristics of Groups VI-VIII Oxides in an Alkaline Electrolyte

C. K. Morehouse and R. Glicksman

Semiconductor and Materials Division, Radio Corporation of America, Somerville, New Jersey

ABSTRACT

Experimental half-cell potential discharge data are given for a number of Groups VI-VIII oxides in strongly alkaline NaOH solution, along with comparisons between these data and their theoretical potentials. In general, the reduction of these oxides at a carbon electrode in alkaline electrolyte is irreversible.

Many of the desirable features of a battery cathode material, such as a high reversible electrode potential and coulombic capacity, stability, and compatibility with other cell components, are found among the metallic oxides. In a previous paper (1) experimental half-cell discharge data were given for a number of Groups Ib-Vb oxides in strongly alkaline NaOH solution along with comparisons between these data and their theoretical potentials. As an extension of this work, half-cell potential discharge data for various Group VI-VIII oxides in NaOH electrolyte are presented in this paper.

Experimental Procedure

Discharge data on the various oxides were obtained by use of a technique previously described by the authors (2). In this technique, a 0.5 g sample of the cathode material mixed with 10% Shawinigan acetylene black was discharged at constant current in a large volume of electrolyte. The change in the cathode potential with time was measured with a L&N Type K potentiometer using a saturated calomel reference electrode. Discharge data were corrected for the *IR* drop associated with the apparatus and electrolyte by means of an oscillographic technique.

The half-cell potentials are all referred to the normal hydrogen electrode and represent the average of two or three measurements. The reproducibility of the data is ±0.01-0.03 v.

In this study, a zinc anode was used with an alkaline electrolyte of 30% by weight NaOH solution which was saturated with ZnO. The solution was 10.7*M* prior to the addition of ZnO. The purpose of the ZnO is to reduce the corrosion of the Zn anode in the strongly alkaline electrolyte. During the discharge, hydroxide ions are formed, but as the solution is strongly alkaline initially, the change in hydroxide ion activity of the solution is negligible.

Potential measurements of the HgO electrode in this electrolyte vs. a S.C.E. give a value of +0.043 v for the HgO half-cell referred to the normal hydrogen electrode. The deviation from the standard potential of the HgO electrode ($E^\circ - E = +0.055$ v) is due to the greater hydroxide ion activity of the electrolyte, as well as to the existence of a liquid junction potential at the alkaline-saturated KCl interface. As these factors are constant for all measurements of the half-cell potentials, +0.055 v can be added to the experimentally determined discharge potentials of the various oxides in order to compare these values with their standard electrode potentials.

Experimental Data and Discussion of Results

Group VIb oxides.—Figure 1 shows half-cell potential discharge curves of CrO_3, Cr_2O_3, MoO_3, and WO_3 obtained when these compounds are discharged at a rate of 0.005 amp/g in the strongly alkaline NaOH electrolyte. As would be expected from standard potential data (3), Cr_2O_3, MoO_3, and WO_3 are reduced with great difficulty and have discharge potentials of −1.10 v or lower. The −1.10 v value is the potential characteristic of the discharge of hydrogen on the carbon electrode in this alkaline solution at that current density. In agreement with these results, Von Stackelberg, *et al.* (4) found that molybdate and tungstate do not produce polarographic waves in neutral or alkaline solution.

Chromic trioxide, which is discharged as a chromate ion in alkaline electrolyte, undergoes a one-step reduction at a potential from −0.35 to −0.40 v in this electrolyte. This value is about 0.2 v more negative than its reversible potential. Hence, the reduction of chromate ion under these conditions of discharge is irreversible. This fact is in general agreement with the polarographic data of Lingane and Kolthoff (5) for the reduction of chromate ion at the dropping mercury electrode. However, their half-wave potential values are from 0.25 to 0.30 v more negative than the cathode potential of CrO_3 given in Fig. 1.

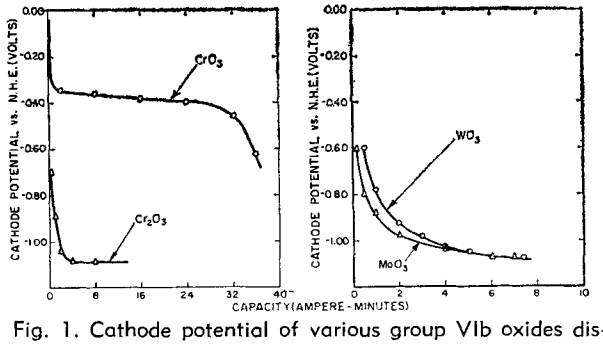

Fig. 1. Cathode potential of various group VIb oxides discharged in 30% NaOH-70% H_2O, saturated with ZnO electrolyte at a rate of 0.005 amp/g.

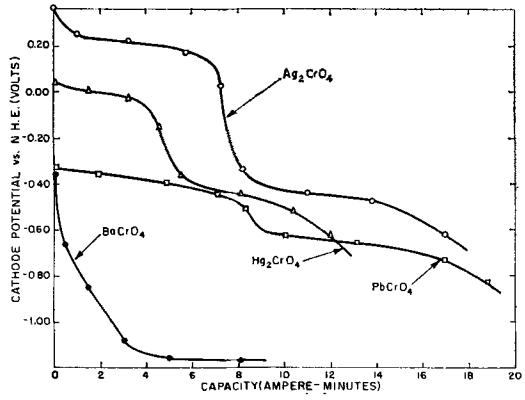

Fig. 2. Cathode potential of various chromates discharged in 30% NaOH-70% H_2O, saturated with ZnO electrolyte at a rate of 0.005 amp/g.

Under the present conditions of discharge, the reduction of $CrO_4^=$ does not proceed farther than the +3 oxidation state because the discharge of hydrogen ions at the carbon cathode takes place at a less negative potential than that required for the reduction of $Cr(OH)_3$ or CrO_2^-. Thus, the reduction of $CrO_4^=$ in alkaline solution can be expressed by the following equation

$$CrO_4^= + 4H_2O + 3e^- = Cr(OH)_3 + 5\ OH^-,\ E^\circ_B = -0.13\ v \quad [1]$$

If a 3 electron change and a −0.60 v end potential are assumed, the CrO_3 electrode operates at an electrode efficiency of 73.5%.

Figure 2 shows half-cell potential discharge curves of $BaCrO_4$ and the metal chromates, Ag_2CrO_4, Hg_2CrO_4, and $PbCrO_4$, all of which contain a reducible cation. The latter three compounds exhibit a two-step potential-time discharge curve with potential steps characteristic of their respective oxides (1), and of the chromate ion. For $PbCrO_4$, the chromate ion is discharged first because its cathode potential is less negative than that of the plumbite ion. With a −0.60 v end potential for Ag_2CrO_4 and Hg_2CrO_4 and an −0.80 v end potential for $PbCrO_4$, and if a 5 electron change is assumed, electrode efficiencies of 69, 74, and 73%, respectively, are obtained from these compounds.

The rapid decrease in cathode potential of the highly insoluble $BaCrO_4$ compound during discharge is believed due to the resultant low concentration of chromate ion available for the electrochemical reaction.

Group VIIb oxides.—Work by Walkley (6-8) on the Mn-Mn^{++} and Mn^{++}-MnO_2 couples has done much to clarify the thermodynamics of the various oxidation states of manganese. According to Latimer (3), it now appears definite that cell measurements on the Mn^{++}-MnO_2 and MnO_2-MnO_4^- couples are reliable and reproducible when the manganese dioxide is in the form of pyrolusite, prepared by heating manganous nitrate. He lists the following alkaline cell reactions which involve manganese dioxide, manganate, and permanganate

$$MnO_4^- + 2H_2O + 3e^- = MnO_2\ (\text{pyrolusite}) + 4\ OH^-,\ E^\circ_B = +0.588\ v \quad [2]$$

$$MnO_4^- + e^- = MnO_4^=,\ E^\circ = +0.564\ v \quad [3]$$

$$MnO_4^= + 2H_2O + 2e^- = MnO_2 + 4\ OH^-,\ E^\circ_B = +0.60\ v \quad [4]$$

The MnO_4^--MnO_2 potential was obtained from direct cell measurements (9), and values for the MnO_4^--$MnO_4^=$ and $MnO_4^=$-MnO_2 couples were obtained by recalculations of the equilibrium measurements of Schlesinger and Siems (10).

The half-cell potential discharge curves presented in Fig. 3 show that $KMnO_4$ initially operates at a potential from 0.06 to 0.08 v lower than the theoretical potentials of the MnO_4^--$MnO_4^=$ and $MnO_4^=$-MnO_2 couples, after corrections are made for the *p*H of the solution and for the liquid junction potential. The two-step potential-time discharge curve of this compound in alkaline electrolyte can be interpreted in terms of a 3 electron reduction to MnO_2, with subsequent reduction to the +3 and +2 oxidation states of manganese. No analytical data, however, are available to confirm this reasoning.

In contrast to $KMnO_4$, $BaMnO_4$ operates at a cathode potential 0.9 v lower than the theoretical potential of the $MnO_4^=$-MnO_2 couple and gives little capacity in the alkaline electrolyte.

$KReO_4$ also operates at a considerably lower cathode potential than $KMnO_4$ in alkaline electrolyte, as would be expected from the following standard potential data given by Latimer (3):

$$ReO_4^- + 2H_2O + 3e^- = ReO_2 + 4\ OH^-,\ E^\circ_B = -0.594\ v \quad [5]$$

$$ReO_4^- + 4H_2O + 7e^- = Re + 8\ OH^-,\ E^\circ_B = -0.584\ v \quad [6]$$

$KReO_4$ operates at a potential of from 0.15 to 0.20 v below its theoretical value, although it is uncertain whether the reduction of $KReO_4$ proceeds by Eq. [5] or [6]. On the basis of a 3 electron reduction step (Eq. [5]), it is calculated that this electrode would operate at an efficiency of 95%, if a −1.0 v end potential is assumed.

It is of interest to discuss the manganese dioxide electrode, which has long been used as a cathode material in primary cells because of its high theoretical electrode potential and coulombic capacity. Although the reduction of manganese dioxide is often represented by a simple equation such as the one calculated by Walkley (11) from thermal data,

$$MnO_2 + H_2O + e^- = MnOOH + OH^-,E^\circ_B = +0.17\ v \quad [7]$$

the half-cell potential discharge curve of this cathode exhibits a sloping characteristic as shown by the data in Fig 3. This suggests a complex reaction mechanism.

Recent studies of the alkaline reduction of manganese dioxide in dry cells by Cahoon and Korver (12) showed both divalent manganese, presumably formed as $Mn(OH)_2$ in the cathode, and an insoluble manganese oxide residue as the reduction products. That divalent manganese is an end product in the alkaline reduction of MnO_2 is evident from the half-cell potential discharge curves in Fig. 3 of electro-

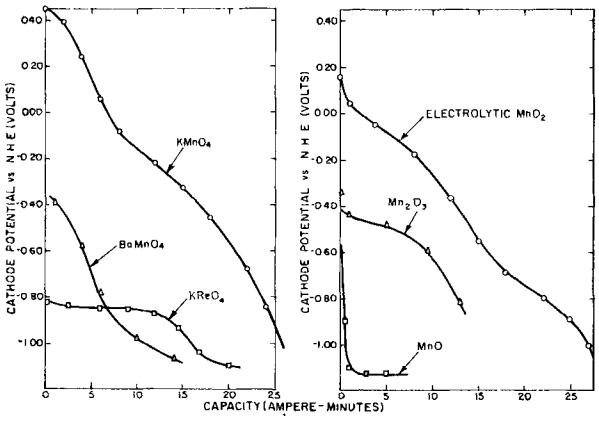

Fig. 3. Cathode potential of various group VIIb oxides discharged in 30% NaOH-70% H_2O, saturated with ZnO electrolyte at a rate of 0.005 amp/g.

lytic MnO_2 (85% MnO_2 content) and Mn_2O_3. For example, if end potentials of −0.40 v and −0.80 v are assumed for a one and two electron reduction, respectively, electrode efficiencies of 80 and 71% are obtained for MnO_2. For Mn_2O_3, an electrode efficiency of 62% is obtained if an 0.80 v end potential and a one electron change are assumed. However, the reduction of Mn_2O_3 may also take place according to the following idealized equations of Walkley (11):

$$3Mn_2O_3 + H_2O + 2e^- = 2Mn_3O_4 + 2\,OH^-, E^\circ_B = -0.18\text{ v} \quad [8]$$

$$2Mn_3O_4 + 2H_2O + 4e^- = 6MnO + 4\,OH^-, E^\circ_B = -0.39\text{ v} \quad [9]$$

Reduction ceases at the divalent manganese state, as evidenced by the discharge data for MnO. This effect is to be expected on the basis of the high negative potential of the $Mn(OH)_2$-Mn couple.

The slightly higher initial cathode potential of electrolytic manganese dioxide as compared to the potential given in Eq. [7] is thought to be due to the difference in the thermodynamic properties of the various oxides which differ chiefly in their E° values (11). These values for γ −MnO_2 are about 150 mv higher than those for pyrolusite.

Measurements conducted in acid solution (6) have shown that the E° values of the following reaction

$$MnO_2 + 4H^+ + 2e^- = Mn^{++} + 2H_2O, E^\circ_A = +1.23\text{ v} \quad [10]$$

depend on both the structural type of oxide and the value of n in the formula MnO_n. The variation in potential of various manganese dioxides in acid solution is illustrated by the half-cell potential discharge data in Fig. 4 for naturally occurring African MnO_2 and a synthetic electrolytic MnO_2. The discharge curves were obtained by discharging these compounds at a rate of 0.005 amp/g in 480 g/l $AlCl_3 \cdot 6H_2O$ electrolyte. A similar relationship between the two dioxides also exists in strongly alkaline solution (13).

The discharge curves for the two manganese dioxides in this acidic electrolyte are considerably flatter than those obtained for these compounds in solutions of higher pH. In addition, if an end potential of zero volt is assumed, both these compounds

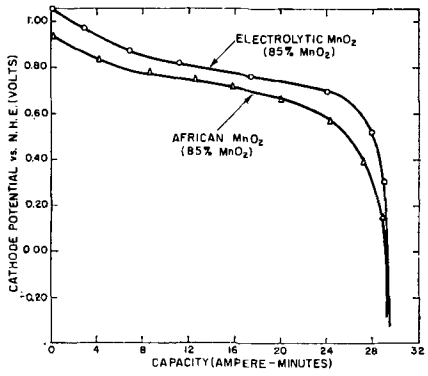

Fig. 4. Cathode potential of synthetic and naturally occurring manganese dioxide discharged in 480 g/l $AlCl_3 \cdot 6H_2O$ electrolyte at a rate of 0.005 amp/g.

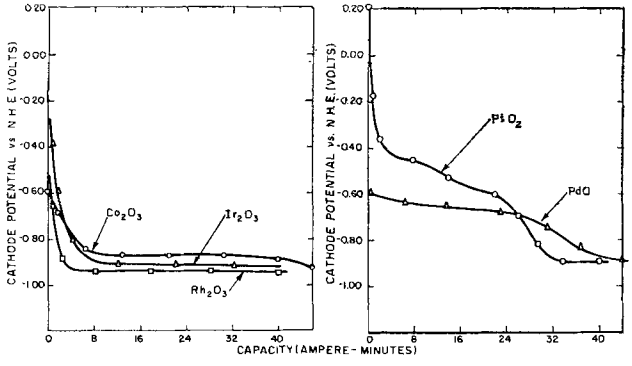

Fig. 5. Cathode potential of various group VIII oxides discharged in 30% NaOH-70% H_2O, saturated with ZnO electrolyte at a rate of 0.005 amp/g.

are reduced to the divalent manganese state with electrode efficiencies of 94%.

Group VIII oxides.—Figure 5 presents a comparison of the half-cell potential discharge curves of the oxides of the +3 valence state of cobalt, rhodium, and iridium, along with the discharge curves of PtO_2 and PdO_2 in alkaline electrolyte. Co_2O_3, Ir_2O_3, and Rh_2O_3 are reduced with difficulty in this electrolyte, and the flat potential-time discharge curve around −0.90 v probably represents the potential at which hydrogen ion is discharged. The discharge of hydrogen ion at the carbon electrode in this electrolyte occurs at a potential approximately 0.2 v less negative than usual (see Fig. 1), probably because of the presence of small amounts of these low hydrogen overpotential metals in the carbon mix. The low cathode potentials of these oxides would not be expected on the basis of Latimer's standard potential data.

Similarly, PtO_2 and PdO operate at potentials considerably below the theoretical values given by Latimer

$$Pt(OH)_6^= + 2e^- = Pt(OH)_2 + 4\,OH^-, E^\circ_B = +0.1 \text{ to } +0.4\text{ v} \quad [11]$$

$$Pt(OH)_2 + 2e^- = Pt + 2\,OH^-, E^\circ_B = +0.15\text{ v} \quad [12]$$

$$Pd(OH)_2 + 2e^- = Pd + 2\,OH^-, E^\circ_B = +0.07\text{ v} \quad [13]$$

Figure 5 indicates that the reduction of PtO_2 to Pt appears to take place in two steps, whereas PdO exhibits a flat potential-time discharge curve in the alkaline electrolyte. For these oxides, electrode effi-

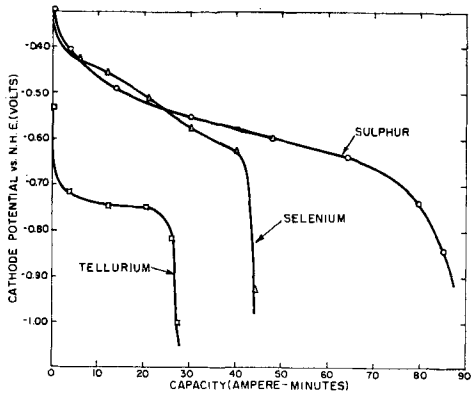

Fig. 6. Cathode potential of various group VIo elements discharged in 30% NaOH-70% H_2O, saturated with ZnO electrolyte at a rate of 0.005 amp/g.

ciencies of 100% are obtained to a −0.90 v end potential.

Group VIa oxides.—One of the most striking characteristics of the Group VIa potentials is the decrease in oxidizing power of the free elements with increasing atomic weight, as indicated by the following standard potential data (3)

$$S + 2e^- = S^=, E^\circ = -0.48 \text{ v} \quad [14]$$

$$Se + 2e^- = Se^=, E^\circ = -0.92 \text{ v} \quad [15]$$

$$Te + 2e^- = Te^=, E^\circ = -1.14 \text{ v} \quad [16]$$

The half-cell potential discharge data of Fig. 6 show that Se and Te in an alkaline electrolyte operate at cathode potentials considerably more positive than the values given by Latimer. The latter values are in doubt, however, because of the difficulty encountered in obtaining accurate thermodynamic data with which to calculate these potentials. S and Se, which have comparable sloping half-cell potential-time discharge curves, operate at approximately the same cathode potentials during the course of the discharge. This is in disagreement with the expected results based on the chemical reactivity of S and Se. If an −0.80 v end potential is assumed, electrode efficiencies of 82,100 and 100% are obtained from S, Se, and Te, respectively.

Figure 7 gives half-cell potential discharge data for various oxides of the +4 and +6 states of these elements. The oxides of Se and Te operate at cathode potentials of from −0.50 to −0.60 v in this alkaline electrolyte, although the corresponding sulfur compounds, Na_2SO_3 and Na_2SO_4, cannot be reduced under the present conditions of discharge.

It is apparent from the data that both the selenate and tellurate compounds are reduced with a corresponding eight electron change to the selenide and telluride ion, respectively. With an −0.80 v end-potential, electrode efficiencies of 93% and 80% are obtained for $NaTeO_4$ and $NaSeO_4 \cdot 10\,H_2O$. Recent work (14) on the controlled potential electrolysis of telluric acid at a mercury cathode further indicates that the reduction of +6 tellurium proceeds to −2 tellurium.

Similarly Lingane and Niedrach (15) showed by a coulometric technique that the reduction of +4 tellurium in alkaline medium proceeds to −2 tellurium according to the following equation:

$$TeO_3^= + 3H_2O + 6e^- = Te^= + 6\,OH^- \quad [17]$$

On the basis of a six electron change, electrode efficiencies of 57% and 65% have been calculated from the data in Fig. 7 for SeO_2 and TeO_2.

Group VIIa oxides.—The free halogens as well as the oxygen acids and their salts are powerful oxidizing agents with respect to their reduction to the halide. Oxides of the +5 and +7 oxidation states, because of their high theoretical capacity, are of principal interest for use as cathode materials in primary cells.

Figure 8 presents half-cell potential discharge curves of $KClO_3$, $KBrO_3$, and KIO_3 obtained when these compounds are discharged at a rate of 0.005 amp/g in strongly alkaline NaOH solution. In agreement with polarographic data (16), the reduction of bromate and iodate ions to the corresponding halide ions takes place in a single step. If an −0.80 v end potential and a 6 electron change are assumed for the reduction of $KBrO_3$ and KIO_3, these compounds operate at efficiencies of 92 and 91%, respectively.

The data in Fig. 8 and Latimer's standard potential data

$$IO_3^- + 3H_2O + 6e^- = I^- + 6\,OH^-, E^\circ_B = +0.274 \text{ v} \quad [18]$$

$$BrO_3^- + 3H_2O + 6e^- = Br^- + 6\,OH^-, E^\circ_B = +0.61 \text{ v} \quad [19]$$

show clearly that the reduction of both ions is irreversible. Despite the more positive standard potential of BrO_3^- as compared with IO_3^-, KIO_3, and $KBrO_3$

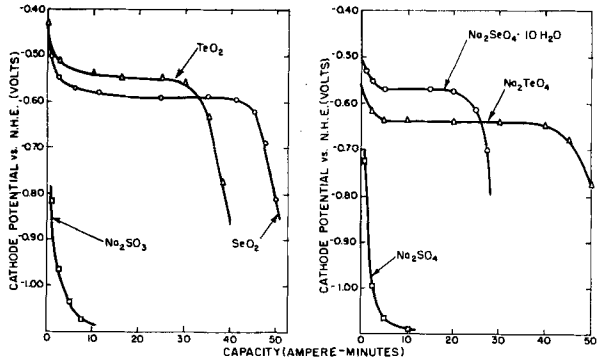

Fig. 7. Cathode potential of various group VIa oxides discharged in 30% NaOH-70% H_2O, saturated with ZnO electrolyte at a rate of 0.005 amp/g.

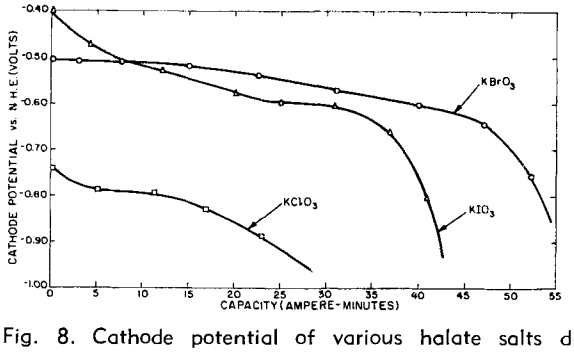

Fig. 8. Cathode potential of various halate salts discharged in 30% NaOH-70% H_2O, saturated with ZnO electrolyte at a rate of 0.005 amp/g.

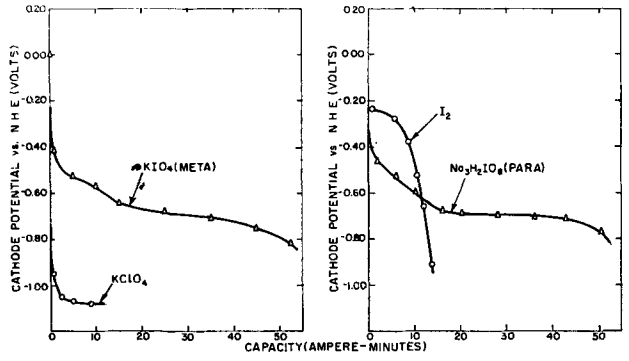

Fig. 9. Cathode potential of various perhalote compounds discharged in 30% NaOH-70% H_2O, saturated with ZnO electrolyte at a rate of 0.005 amp/g.

operate at comparable cathode potentials in the alkaline electrolyte. This is attributed to a higher overpotential for the reduction of BrO_3^- as compared with the reduction of IO_3^-. For example, at the dropping mercury electrode in acid medium, it has been found that the overpotential amounts to about 0.7 v for iodate and about 1.3 v for bromate (16).

The low cathode potential of $KClO_3$, as compared with $KBrO_3$ and KIO_3, is in agreement with observations that chlorate is not readily reduced at a cathode on electrolysis of a chlorate solution, nor is chlorate ion reduced at a dropping mercury electrode.

Figure 9 compares the half-cell potential discharge curves of sodium paraperiodate ($Na_3H_2IO_6$) and potassium metaperiodate (KIO_4) with that of potassium perchlorate. As expected from the highly negative cathode potential of $KClO_3$ given in Fig. 8 and from the fact that the oxidizing power of the oxy acids of chlorine (and their salts) decreases with increase in oxidation number of chlorine, $KClO_4$ cannot be reduced under the present conditions of discharge. The reduction of periodate, however, appears to take place with a two electron change to iodate, as follows:

$$H_3IO_6^{=} + 2e^- = IO_3^- + 3\ OH^-,\ E^\circ_B = \text{ca.} + 0.7\ \text{v} \quad [20]$$

The iodate ion subsequently is reduced to the iodide in accordance with Eq. [18]. If a −0.60 v end potential and a 2 electron change are assumed, both KIO_4 and $Na_3H_2IO_6$ are reduced to the iodate with electrode efficiencies of 86%. For reduction to the halides, KIO_4 and $Na_3H_2IO_6$ give electrode efficiencies of 90 and 100%, respectively, if an 8 electron change and an end potential of −0.80 v are assumed. Similarly, the electroreduction of periodate at the dropping mercury electrode in acid solution (17) shows two general waves corresponding to a reduction to the iodate and then to the iodide.

The high cathode potential of iodine shown in Fig. 9 further indicates that reduction of the iodate proceeds directly to the halide rather than through the halogen stage.

Kinetics of the Dissolution of Copper in Aqueous Solutions of Aliphatic Diamines

S. C. Sircar[1] and D. R. Wiles[2]

Department of Mining and Metallurgy, University of British Columbia, Vancouver, Canada

ABSTRACT

The recent work on the mechanisms of the dissolution of copper in aqueous solutions of amines has been extended to the diamines. The chelating agents used were ethylenediamine, 1,3 propanediamine, and 1,4 butanediamine. The dissolution reaction is shown to involve two distinct steps. The first step is found to be an adsorption pre-equilibrium. In the second step, two types of reaction compete: chelation and attack by a second ligand. Desorption of the complex follows these steps. In 1,4 butanediamine, the chelation step is not observable, while in ethylenediamine the chelation appears to be so fast as to obscure the bimolecular reaction. In propanediamine, both are evident. The reactions of the singly protonated species have been found to be solely by bimolecular attack.

Recent studies (1-4) have done much to elucidate the mechanism of the dissolution of metallic copper in oxygen-containing solutions of various complexing agents. The work of Halpern (1) demonstrated that it is necessary to define two kinetic regions: the "low oxygen pressure" region, in which diffusion of reactants limits the rate, and the "high pressure region," in which the reaction rate is chemically controlled at the surface. Halpern also showed that the rates of dissolution by ammonia molecules and by ammonium ions were essentially independent, although some free ammonia must be present for any dissolution to occur.

Our recent study (4), involving dissolution of copper in solutions of ammonia, and methyl-, ethyl-, and n-butylamines, and their conjugate acids, led to a fairly clear picture of the reactions involved. It was concluded that the reactions take place in the following stages (where A represents the amine, and the subscript s designates species residing in the surface).

$$Cu_s + \tfrac{1}{2}\,O_2 \rightleftharpoons Cu_s{-}O \qquad \text{fast, } K \text{ large}$$

$$Cu_s{-}O + A \rightleftharpoons Cu_s{-}O(A) \qquad \text{fast, } K_1$$

$$Cu_s{-}O(A) + A \rightarrow Cu_s{-}O(A)_2 \qquad \text{slow, } k_2$$

$$Cu_s{-}O(A)_2 + H_2O \rightarrow Cu(A_2)^{++} + 2\,OH^- \qquad \text{fast}$$

Competitive with the attack by the second amine molecule is attack by a molecule of the conjugate acid, or "aminium" ion. Thus, the last two steps could occur in the following way:

$$Cu_s{-}O(A) + AH^+ \rightarrow Cu_s{-}O(A)(A\text{-}H^+) \qquad \text{slow, } k_3$$

$$Cu_s{-}O(A)(A\text{-}H^+) \rightarrow Cu(A)_2^{++} + OH^- \qquad \text{fast}$$

The pre-equilibrium appeared not to involve the aminium ion, a fact which accounts, at least in part, for the observed passivity of copper in ammonia-free solutions of ammonium salts (2, 4).

The rate of a reaction which proceeds according to the above mechanism can be expressed by the following equation:

$$\text{Rate} = \frac{d[Cu^{++}]}{dt} = \frac{K_1[A]S}{1 + K_1[A]} \cdot \{k_2[A] + k_3[AH^+]\} \qquad [1]$$

This equation was found to describe the observed rates very well for ammonia and the aliphatic amines studied. S represents the total surface area.

The observation of the bimolecular nature of the dissolution reaction led to the speculation that ethylenediamine may behave similarly. In this last case, however, the reaction would be monomolecular, because both attacking groups are attached to the same molecule. It seemed to be of interest, in view of this, to study the dissolution kinetics in solutions of longer chained diamines. In such case, one would expect the chelation step to become slower as the number of atoms in the chain increases.

It was with this in view that the present work was undertaken. The reagents used were ethylenediamine (en), 1,3 propanediamine (pn), and 1,4 butanediamine (bn), which form, on chelation, rings with five, six, and seven atoms, respectively. Data on the acid-base equilibria and the copper complexing equilibrium for these diamines are shown in Table I.

Experimental

The experimental methods used were the same as those of the previous work (3, 4). The experiments were performed in a 1-gal stainless steel autoclave fitted with a titanium liner. The oxygen pressure and stirring rate were maintained high enough to in-

sure that the transport of reactants to the surface was not a factor in rate control. Samples withdrawn periodically from the autoclave were analyzed spectrophotometrically for copper by the carbamate method (9). As in our previous work, solutions were maintained at an ionic strength of 0.1 by adjustment with $NaClO_4$. All experiments were done at a temperature of 25.0° ± 0.1°C and at an oxygen pressure of 7.8 atm.

The 1,3 propanediamine and 1,4 butanediamine were obtained from K and K Chemicals Inc., and were used without further purification. On long standing the stock solutions of these reagents tended to become yellowish and were replaced. The ethylenediamine was obtained as 99% pure material from Carbide and Carbon Chemicals Corporation and was used without further purification. It had been found earlier (3) that fractional distillation of the ethylenediamine had no effect on the rate of dissolution.

Acid effects were studied after addition of measured amounts of reagent grade perchloric acid to the diamine solution.

Reproducibility of analyses and of rate measurements was very good, generally to within ±2%. At very high rates, there seemed to be greater scatter in the results. It is not understood why this is so, but it may be that transport control is becoming important.

Results

The experimental measurements made were on the systems under three different sets of conditions involving, respectively, the free diamines, the monoprotonated species (the first conjugate acids), and the free diamines with excess acid added.

Free diamines.—The results of rate measurements on the free diamines are summarized in Table II and shown graphically in Fig. 1, 2, and 3.

The forms of the curves for the three diamines are very different from each other, but can nevertheless be described quantitatively in terms of a single set of competing mechanisms, based on our earlier conclusion (4) that two amine groups coordinate with a copper atom before it enters the solution. If one suppose a surface, covered with adsorbed oxygen atoms, to engage in a fast equilibrium adsorption (K_1) of the diamine molecule, then the desorption of the complexed copper atom may follow after either chelation (k_1) by the diamine molecule al-

ready attached, or attack (k_3) by a second molecule, such that each is coordinated at only one position. The over-all rate of dissolution is then given by Eq. [2]

$$\text{Rate} = \frac{d[Cu^{++}]}{dt} = \frac{K_1[X]S}{1 + K_1[X]}(k_1 + k_3[X]) \quad [2]$$

It is seen that where k_1 is very small, i.e., when chelation does not occur measurably, Eq. [2] reduces to:

$$\text{Rate} = \frac{K_1[X]S}{1 + K_1[X]} \cdot k_3[X] \quad [3]$$

Equation [3] is analogous to that used (4) to describe the bimolecular attack of the mono-amines on copper. It is found (Fig. 3) that this equation very well describes the observed effect of 1,4 butanediamine concentration on the dissolution rate.

If, on the other hand, k_1 is very large, (i.e., much larger than $k_3[X]$) for low values of $K_1[X]$, Eq. [2] reduces to

$$\text{Rate} = K_1k_1[X]S \quad [4]$$

This is equivalent to the expression used in earlier work (3) to describe the effect of ethylenediamine concentration on the rate of dissolution.

In the event that neither the chelation reaction nor the bimolecular attack can be ignored, then Eq. [2] must be used in full. This equation is seen in Fig. 2 to describe rather well the observed rates of dissolution of copper in 1,3 propanediamine.

The values found for the constants are given in Table III. The limits of error quoted are estimated by varying the constant enough to give a clearly bad fit of the data. It is these values for the constants which give the curves drawn in Fig. 1, 2, and 3.

Pure acid species.—Dissolution rates obtained in solutions of the mono-protonated species, ethylenediaminium and 1,3 propanediaminium, are given in Table IV.

The results can be interpreted satisfactorily by Eq. [5]

$$\text{Rate} = \frac{K_2[X]S}{1 + K_2[X]}(k_2 + k_4[X]) \quad [5]$$

where k_2 is found to be zero. It is evident from the form of Eq. [5] that dissolution in these solutions

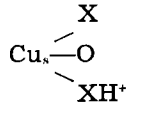
occurs by bimolecular attack. The chelation step, corresponding to the constant k_2, evidently does not occur in the pure acid systems. The mechanism proposed for this dissolution is closely analogous to that described for the free amines.

The values for the constants for the above reactions are given in Table V. The curves shown in Fig. 4 were calculated using these values.

Mixed acid and basic species.—The "acid effect"–the change in rate on addition of acid to an excess of the free diamine–was studied only for 1,3 propanediamine. The results are given in Table VI.

It seems likely that the nature of the processes occurring in this mixed system are the same as those occurring in the pure systems, with two additional "cross-reactions" leading to the same reacting species



Since it is not possible kinetically to distinguish between the two paths by which this species can be formed, the observed cross-reaction rate will be best considered as the linear sum of the two independent

rates. Values were determined for the apparent rate constants by considering each reaction, in turn, to account for the whole of the cross reaction. Values are given in Table VII. This procedure necessarily will involve several sources of error. It is not surprising, then, that the values of the constants computed from the results of individual experiments showed a trend rather than a random scatter. The total range of the trend was only 40%, for reaction rates varying by as much as a factor of six, so it seems justifiable to give a 20% "confidence limit" on the mean values. The total experimental rates and computed rates are compared in Fig. 5.

Summary and Discussion

The dissolution of metallic copper in aqueous solutions of aliphatic diamines has been found to occur as the sum of a complex array of competing processes. These processes all give the same final product, that is, dissolved cupric ion, appropriately complexed, and the competing steps can be isolated only by studying extremes of pH, such that a small number of reactions are overwhelmingly predominant.

The reaction involves an oxygen-adsorption pre-equilibrium step

$$Cu_s + \tfrac{1}{2} O_2 \overset{fast}{\rightleftharpoons} Cu_s{-}O$$

followed by one of two competing pre-equilibria:

$$Cu_s{-}O + X \overset{fast}{\rightleftharpoons} Cu_s{-}O{-}X \qquad K_1$$

$$Cu_s{-}O + XH^+ \overset{fast}{\rightleftharpoons} Cu_s{-}O{-}XH^+ \qquad K_2$$

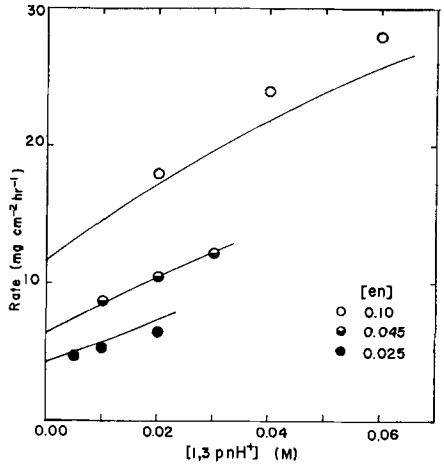

Fig. 5. Rate of dissolution of copper in mixed solutions of ethylenediamine (en) and ethylenediaminium (enH+) perchlorate: Comparison of experimental and calculated values.

The first of these two adsorbed species can form a chelate complex and desorb:

$$Cu_s{-}O{-}X \overset{slow}{\rightarrow} Cu_s{-}O{=}X \rightarrow \qquad k_1$$

$$Cu_s{-}O{=}X + H_2O \overset{fast}{\rightarrow} CuX^{++} + 2\,OH^-$$

The competing step involving the acid species:

$$Cu_s{-}O{-}XH^+ \rightarrow Cu_s{-}O{=}XH^+ \qquad k_2$$

$$Cu_s{-}O{=}XH^+ \rightarrow CuX^{++} + OH^-$$

appears not to occur to a detectable extent. There is also a bimolecular attack, very much the same as that occurring with the mono-amines (4):

$$Cu_s{-}O{-}X + X \overset{slow}{\rightarrow} Cu_s{-}O{-}X \qquad k_3$$

$$Cu_s{-}O{-}XH^+ + XH^+ \overset{slow}{\rightarrow} Cu_s{-}O{-}XH^+ \qquad k_4$$

and the corresponding cross reactions:

$$Cu_s{-}O{-}X + XH^+ \overset{slow}{\rightarrow} Cu_s{-}O{-}XH^+ \qquad k_5$$

$$Cu_s{-}O^+ + X \overset{slow}{\rightarrow} Cu_s{-}O{-}XH^+ \qquad k_6$$

Table VII. Summary of the equilibrium and rate constants

	K_1	K_2	k_1	k_2	k_3	k_4	k_5	k_6
en (K_1k_1 = 240 ± 10)	60 ± 5	120 ± 20	—	0	$<<k_1$	310 ± 10	—	—
pn	22 ± 2	275 ± 25	5.0 ± 0.5	0	85 ± 2	175 ± 10	975 ± 200	210 ± 40
bn		—	<0.1	—	21 ± 0.5	—	—	—

Each of these last steps is, of course, followed by hydration and desorption. The general equation to describe the rate gives the sum of all the six competing reactions.

$$\text{Rate} = \frac{d[Cu^{++}]}{dt} = \frac{S}{1 + K_1[X] + K_2[XH^+]}$$

$$\{K_1[X](k_1 + k_3[X] + ck_5[XH^+])$$

$$+ K_2[XH^+](k_2 + k_4[XH^+] + (1 - c)k_6[X])\} \quad [6]$$

where c and $(1 - c)$ are normalizing constants. The values of the constants in Eq. [6] are summarized in Table VII.

A comparison of constants is very instructive in some respects, although it must be emphasized that because of the complex nature of the system, quantitative comparison of the constants may not be justified.

Of foremost importance is the relation between the competitive reactions of chelation and bimolecular attack, as shown by the constants k_1 and k_3 for the free diamines and by k_2 and k_4 for the first conjugate acids. It is found that ethylenediamine dissolves copper almost wholly by chelation, 1,4 butanediamine almost wholly by means of bimolecular attack, and 1,3 propanediamine by a combination of both. This trend is in agreement with what one would expect from a consideration of the length of the carbon chains involved.

The value 240 obtained for the product K_1k_1 for ethylenediamine is much smaller than one would expect from an extrapolation of the values of K_1 and k_1 obtained for 1,3 propanediamine and 1,4 butanediamine. It seems possible that the chelation may occur so rapidly that the preliminary adsorption cannot attain equilibrium, that is, the term $K_1[X]/(1 + K_1[X])$ of Eq. [2] and [6] does not give the true concentration of the species $Cu_s\overset{en}{\diagup}O$. If this is so, then this system should properly be studied by use of a steady-state treatment. Unfortunately not sufficient data are available to make this distinction meaningful.

In the acid system, it is found that neither ethylenediamine nor 1,3 propanediamine dissolves by the chelation mechanism. This is perhaps surprising in view of the effect of acid on promoting the bimolecular dissolution of copper in the aliphatic monoamines.

It seems significant that in all cases the attack of the surface by a protonated species is more rapid than by the free amine. This is true in the pre-equilibria, in the bimolecular attack and in the cross reactions. This generalization does not, however, hold for the chelation reaction, which does not occur in the acid system.

Keelen and Anderson (10), studying the dissolution of nickel in diamines, suggested that there is competitive adsorption involving the diamine and the solvent where both are necessary in the dissolving species. Thus, they concluded, the chelation can have an interfering effect. This situation is clearly different from the present one, in which contact at two points seems to be required for dissolution.

Brief Communications

The JOURNAL accepts short technical reports having unusual importance or timely interest, where speed of publication is a consideration. The communication may summarize results of important research justifying announcement before such time as a more detailed manuscript can be published. Consideration also will be given to reports of significant unfinished research which the author cannot pursue further, but the results of which are of potential use to others. Comments on papers already published in the JOURNAL should be reserved for the Discussion Section published biannually.

Submit communications in triplicate, typewritten double-spaced, to the Editor, Journal of The Electrochemical Society, 1860 Broadway, New York 23, N. Y.

Dissolution of Single Crystals of Copper in Aqueous Ethylenediamine

Leslie H. Jenkins

Solid State Division, Oak Ridge National Laboratory,[1] Oak Ridge, Tennessee

ABSTRACT

The kinetics of the dissolution of preferentially oriented single crystal plates of 99.999% copper in stirred aqueous solutions of 10^{-2}M ethylenediamine containing oxygen have been studied. The dissolution rates, which were controlled by a transport process in solution, were a function of the temperature and stirring rate of the solution, but were independent of the crystallographic orientation of the exposed metal surface. From the examination of the facets developed during the course of the reaction on crystals with low index faces, it was concluded that the order of stability of the crystal faces was (100) > (110) > (111) in this particular system. Other than anomalous faceting observed in regions thought to correspond to grain boundaries, no correlation between chemical reactivity and crystal imperfections was observed.

The kinetics of the dissolution of polycrystalline copper in aqueous solutions which contain oxygen and a reagent capable of dissolving copper oxides have been studied extensively (1-3). These and other data show that by suitably varying the conditions under which the reaction is carried out, the type of kinetic control operative in any given system may be altered.

Halpern (1) rigorously defined such conditions for the oxidation of copper in aqueous ammonia solutions containing oxygen. More recently data have been obtained on the dissolution of copper in oxygen-containing solutions by several complexing agents, including ethylenediamine (3); however, the kinetic data reported is restricted to regions of high oxygen pressures where the rate is zero-order in oxygen and first-order in the complexing agent.

If single crystals of copper are exposed to environments such as these, facets and/or pits are developed on the surface of the metal. The geometrical symmetry of these facets or pits is a function of, among other things, the crystallographic orientation of the exposed face of the metal crystals. Also, it is generally believed that some of the pits and facets on the surface should bear a relationship to points where dislocations in the single crystals intersect the surface, since these are points at which the chemical potential is greater than that of an idealized atomically smooth surface. Kinks, steps, and other points of departure from the theoretically ideal surface should also be more favorable energetically as sites where reactions are initiated (4). Therefore, it appeared worthwhile to observe the changes in surfaces of single crystals of copper of various crystallographic orientations undergoing dissolution while gathering kinetic data on the system. The reaction of copper with oxygen in dilute aqueous ethylenediamine which is described by the following equation, was chosen for investigation:

$$Cu + 1/2\,O_2 + H_2O + 2\,en \rightarrow Cu(en)_2^{++} + 2\,OH^- \quad [1]$$

[1] Oak Ridge National Laboratory is operated by Union Carbide Corporation for the U. S. Atomic Energy Commission.

Conditions were such that a transport process in solution was rate-controlling. Future work will include observations on this and other aqueous systems under various types of kinetic control.

Experimental

Material.—American Smelting and Refining Company 99.999% material was used to grow copper single crystals of specific orientation by seeding from the melt in graphite crucibles. Specimens produced were parallelepipeds approximately 0.1 x 1 x 7 cm having the desired surface orientation on the 7 x 1 cm area. From these slugs three samples 0.1 x 1 x 2 cm were cut carefully with a jeweler's saw. Each crystal used was within three degrees of the desired surface orientation, and all data reported here were gathered on single crystalline material. A 1/16 in. diameter hole was drilled at one end of the crystal so that it could be suspended in the reaction vessel. The large sides of the crystal were lightly polished on a polishing wheel with 10μ Al_2O_3 to remove gross surface roughness. The sample was then cleaned by washing first in acetone, then in 2:1 HNO_3. A smooth, mirror-like surface was produced on the crystal by electropolishing, washing, and drying in the manner recommended by Young and Gwathmey (5). It was possible to use samples for more than one kinetic determination, if the surface was electropolished before each use; specimens whose surfaces were replicated for electron-micrograph studies were discarded after replication. It was felt that the process of stripping the replica film could introduce defects in the crystals by unknowingly bending or damaging in some other way.

Other than the exceptions noted below, all solutions were made from either CP or reagent grade chemicals and water which had been demineralized, distilled through a tin lined still, and stored in a seasoned polyethylene reservoir. Copper sulfate solutions were made by dissolving a weighed sample of AS&R 99.999% copper in excess, reagent grade

nitric acid. A 10% excess of standard sulfuric acid solution was added, and the mixture evaporated to dryness but not to SO_3 fumes. The residue was dissolved and diluted to volume in a volumetric flask. Portions of this solution were mixed with 10% excess ethylenediamine to prepare solutions of bis-ethylenediamine copper (II) sulfate. Hydrazine solutions were prepared from technical grade 85% hydrazine hydrate in water supplied by The Mathison Company. Since preliminary studies showed that identical results were obtained, both from the standpoint of kinetics and metal surface changes, whether solutions were prepared from triply distilled ethylenediamine or the 95-100% material supplied by Eastman Kodak Company, the latter material was used.

Hydrogen was purified by passing commercial grade tank gas first over hot copper and then through drying towers packed with magnesium perchlorate.

Oxygen-free solutions were prepared by bubbling about 100 ft^3 of purified hydrogen saturated with water vapor through a fine fritted disk in the solution reservoir shown in Fig. 1 at a rate of 10 ft^3 per day.

Apparatus.—The glass reaction vessel shown in Fig. 1 was designed to be used with solutions either free of oxygen or saturated with air. After placing a magnetic stirring bar sealed in glass in the bottom of the chamber, the polished copper crystal was suspended from the glass hook in the barrel of the vessel. The standard taper joint with bright platinum electrodes was placed in position and the entire apparatus attached to the filling rack.

If solutions free of oxygen were to be used, the system, exclusive of the solution reservoir, was alternately evacuated and filled with hydrogen. Twenty cycles were sufficient to remove all detectable traces of oxygen from the system. The volumetric bulb was then filled with about 82 ml

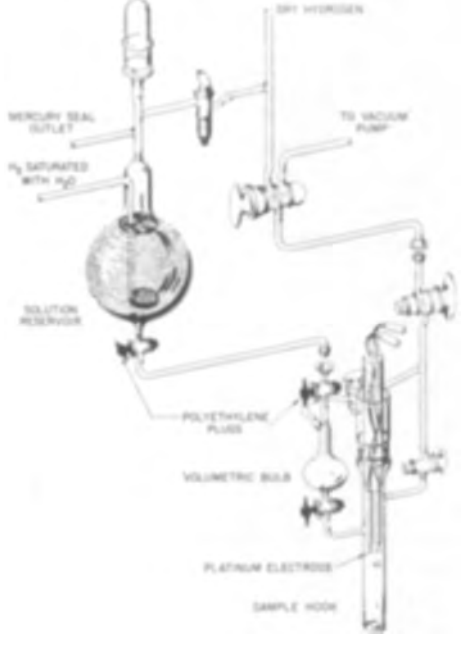

Fig. 1. Portion of filling rack with reaction chamber

of oxygen-free solution under its atmosphere of hydrogen from the storage reservoir, and the stopcocks sealing the bulb from the remainder of the system were closed. The system was again alternately evacuated and filled with hydrogen for a total of ten cycles. At the completion of these operations the solution and the sample were both at atmospheric pressure under hydrogen. A clamshell heater was placed about the reaction chamber, and the copper sample annealed at 450°C for 16 hr. The heater was then removed and the apparatus cooled to room temperature, removed from the rack, and placed in a water bath controlled to ± 0.02°C. After allowing 1 hr for temperature equilibrium to be established, the magnetic stirrer was engaged and all the solution allowed to flow from the volumetric bulb into the reaction chamber. The stopcocks isolating the reaction chamber were then closed.

When solutions saturated with air were desired the volumetric bulb was filled with 82 ml of solution and isolated from the rest of the system. The apparatus was attached to the rack and flushed with hydrogen for 20 cycles. The remainder of the procedure was repeated as on solutions containing no oxygen. By this method the copper sample did not have access to oxygen until contacted by the solution.

Progress of reactions was followed by observing conductivity changes in the solutions with time. Conductivity values were obtained with a Wheatstone bridge arrangement using an oscilloscope as a null detector. Maximum sensitivity of the system was such that the change in resistance produced by the dissolution of one atom layer of copper could be observed; however, in most cases the data were gathered under conditions in which the dissolution of 3-5 atom layers were required to produce an observable change in conductivity. Measurements were taken with the slide wire position held constant during the reaction. The null point was determined by adjusting a five decade standard resistance box.

Surface replicas.—Samples whose surfaces were to be replicated for observation with the electron microscope were removed from the reaction vessel after the desired amount of copper had been removed. They were washed quickly in a stream of distilled water for 1 min, then dried in a jet of oxygen. Surfaces were preshadowed with platinum at a 4:1 shadow angle and replicated with carbon.

Treatment of data.—At time t, the relative concentration of a component which determines the extent of a reaction may be expressed as a function of the observed conductivity values of the solution:

$$\% \text{ material unreacted} = \left(1 - \frac{\Delta\sigma_t}{\Delta\sigma_f}\right) 100 \quad [2]$$

where $\Delta\sigma_t$ is conductivity change from time zero to time t and $\Delta\sigma_f$ is conductivity change from time zero to time reaction completed.

The first-order rate equation expressed in terms of conductivity is:

$$\log \frac{C_i}{C_i - C_i\left(\frac{\sigma_i - \sigma_t}{\sigma_i - \sigma_f}\right)} = kt/2.303 \qquad [3]$$

where C_i is initial concentration of reactant which controls extent of reaction, σ is the conductivity of the solution. The subscripts i, t, and f refer to the initial value before reaction has commenced, the value at time t, and the final value at completion of the reaction, respectively. If resistance values are substituted for conductivity terms, the equation becomes

$$\log \frac{R_f - R_i}{R_i} + \log \frac{R_t}{R_f - R_t} = kt/2.303 \qquad [4]$$

where R is the resistance of the solutions. Subscripts indicate values at times as above.

A plot of log $R_t/R_f - R_t$ vs. time should give a straight line, the slope of which is equal to $k/2.303$, if first-order kinetics are obeyed by the reactant controlling the extent of the reaction. It must be emphasized that Eq. [3] and [4] apply only to the component which governs the extent of the reaction. The denominator of the logarithmic term in Eq. [3] expresses the concentration of such a component at time t. Obviously, the expression is incorrect for a reactant present in excess of that demanded by the stoichiometry of the chemical reaction involved.

Experimental Results

Analytical data.—It is not necessary that the concentrations of the components be known for a kinetic treatment based on conductivity data, but at the completion of the reactions the solutions were analyzed for copper with a Beckman Model DU spectrophotometer using both the ethylenediamine method of Jonassen and Dexter (6) and the neocuproine method of Smith and McCurdy (7). The latter method is two orders of magnitude more sensitive. Data on the solubility of air in water (8) agreed with the copper analysis and showed that the extent of the reaction was limited by the amount of oxygen dissolved in the solutions when an excess of reagent capable of dissolving copper oxide was present.

These two methods of analysis offer sensitive means for determining the concentration of mono- and divalent copper in solutions of ethylenediamine. Tests proved that the cuprous complex of ethylenediamine does not adsorb light of 540 mμ, the wave length for maximum adsorption by the cupric complex (6). Any significant difference in copper concentration detected by the two methods can be attributed to the presence of monovalent copper in the ethylenediamine solution. No such differences were found.

Oxygen-Free Solutions

At 25°C the following solutions, each 10^{-2}M in the reagent listed, which had been deaerated in the manner described, were exposed to copper single crystals which had been annealed and maintained in an atmosphere of hydrogen: ethylenediamine; hydrazine sulfate; hydroxylamine sulfate; hydroxylamine; potassium cyanide (adjusted to pH 9 with KOH); HCl; H_2SO_4. Although it has been reported that in concentrated solutions KCN (9) will react with copper and water to liberate hydrogen, no copper was found in any of the solutions (limit of detection was 0.2 μg total Cu), and examination of the metal surface also showed no detectable changes.

The chemical reaction of major interest in this study was that shown in Eq. [1]. However, when all dissolved oxygen in the system had reacted, the solution contained copper ions in contact with copper metal. Since it represented a potential source of further reaction, the following equilibrium was investigated

$$2Cu^+ \leftrightharpoons Cu^{++} + Cu^0 \qquad [5]$$

To study this reaction, two solutions which had been freed of dissolved O_2 in the manner previously described were prepared; one 10^{-4}M $CuSO_4$ in 10^{-3}M H_2SO_4, the other 10^{-4}M $CuCl_2$ in 10^{-3}M HCl. Each solution, under a H_2 atmosphere in the solution reservoir, was introduced into the reaction vessel shown in Fig. 1 and exposed to a copper single crystal which had been annealed and maintained in a H_2 atmosphere. The apparatus was placed in a constant temperature bath at 25.00° ± 0.02°C. While in the bath the solutions were stirred continuously at a stirring speed of 500 rpm. After four days the solutions were analyzed for total copper by the method of Smith and McCurdy (7), and no change in copper concentration could be detected. In order to observe effects of complex species, an oxygen-free 10^{-4}M solution of a $Cu(en)_2SO_4$ in 10^{-3}M ethylenediamine was also exposed to a copper crystal under the conditions described above. Again, after four days no change in copper concentration could be detected. If the value of 10^6 (see below) for the equilibrium constant of reaction [5] is correct, a change ~ 5 x 10^{-6}M in copper would be expected in the sulfate and chloride solutions. Such a concentration change would be detected easily by the analytical method used.

Bodlander and Storbeck (10) derived a value of 10^4 for the equilibrium constant for reaction [5] from data on the solubility of copper (I) halides in solutions of alkali halides. Although they attempted to interpret the data to account for complex ion formation, it can be shown that in a 0.2M alkali halide solution containing 10^{-4}M copper (II) halide (these concentrations are typical of those studied by Bodlander and Storbeck), the equilibrium constant cannot be less than about 10^6, if no complex ions are formed and the solubility requirements of copper (I) halides are satisfied. Therefore, their interpretation of the data must not correct completely for copper (I) present as a complex ion.

Fenwick (11) avoided the problem of complex ions by determining the copper (I) present in solutions of $Cu(ClO_4)_2$ and $HClO_4$ exposed to metallic copper. The equilibrium constant was determined to be about 10^6. This value agreed, within the limits of experimental error, with that of Luther (12) which had been determined from solutions of $CuSO_4$ and H_2SO_4 exposed to metallic copper. It should be

pointed out, however, that sources of copper (I) other than that shown by Eq. [5] were available in these systems. Air-saturated solutions such as were used in both experiments contain dissolved oxygen capable of reacting with metallic copper to form Cu_2O which would dissolve in the concomitant acids. Also, a film of Cu_2O was surely present on the metallic samples before exposure to the solutions. And finally, the work of Kruger (13) and Miller and Lawless (14) on oxide films formed on copper in various solutions raises the question whether the solutions of Fenwick and Luther were at equilibrium with the metal or an oxide covered metal.

Although there is no proof that the results reported by the authors were obtained on systems at equilibrium, the four days allowed for equilibrium to be established was the same as that allowed by Fenwick. Also, it would appear that some doubt of the validity of previously reported equilibrium constants for the reaction in question is justifiable. It is clear that at the concentrations studied either equilibrium is established so slowly or the extent of reaction is so small that reaction [5] can be disregarded as a means of removing copper from the metal surface in a reasonable time.

Solution Saturated with Air

When saturated with air all the solutions previously mentioned did react with copper. Since it afforded an easy means of analysis for copper the ethylenediamine system was studied extensively. All data were gathered on solutions initially air-saturated which were 10^{-2}M in ethylenediamine. This concentration of complexing agent represents a tenfold excess over that necessary to react with all the copper oxide which could be formed by dissolved oxygen at 25°C.

Rate data were gathered at three different stirring speeds—200, 500, and 650 rpm, at temperatures of 7.50°, 25.00°, 34.47°, 47.04°, and 56.57° all ± 0.02°C. Since the sample was suspended about 2 in. above the impeller and due to the small cross section of the reaction chamber, the stirring efficiency was much less than that in the system described by Halpern (1). Dissolution rates were determined for crystals with surface orientations of (111), (100), (110), (611), and (210). The high index faces gave kinetic results identical to those obtained from the three close-packed faces; therefore, only results from the latter are reported here.

Figure 2 shows the percentage of the original oxygen remaining in solution as a function of time at a stirring speed of 500 rpm at various temperatures. It is obvious that the reaction rate was not affected by the different crystal faces exposed. This was true at all the temperatures which were investigated. Figure 3 demonstrates that an increased stirring rate increased the rate of dissolution but that the rate was not affected by crystal orientation. Again, this was true for the three stirring rates at all temperatures. Typical rate data from conductivity values are shown in Fig. 4. As previously stated, analysis for copper content at the completion of the reactions showed that the extent of the reaction was

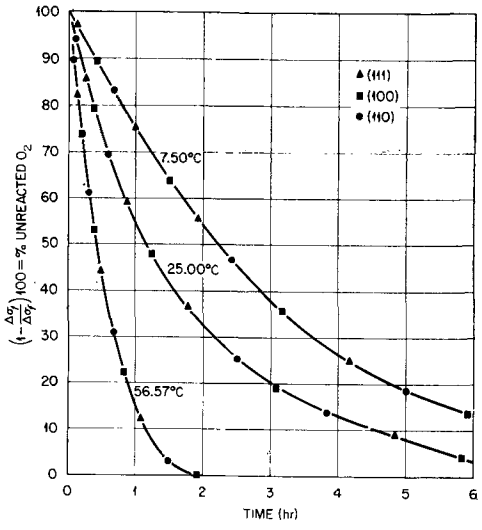

Fig. 2. Effect of temperature and crystallographic orientation on dissolution rate in 10^{-2} M ethylenediamine at a stirring velocity of 500 rpm.

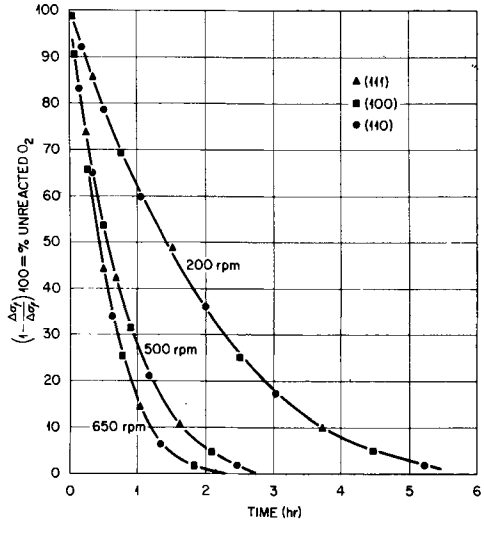

Fig. 3. Effect of crystallographic orientation and stirring velocity on dissolution rate in 10^{-2} M ethylenediamine at 47.04°C.

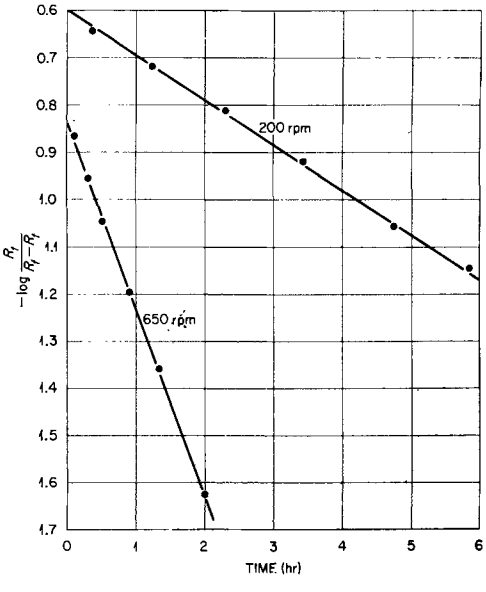

Fig. 4. Effect of stirring velocity on specific reaction rate at 25°C in 10^{-2} M ethylenediamine.

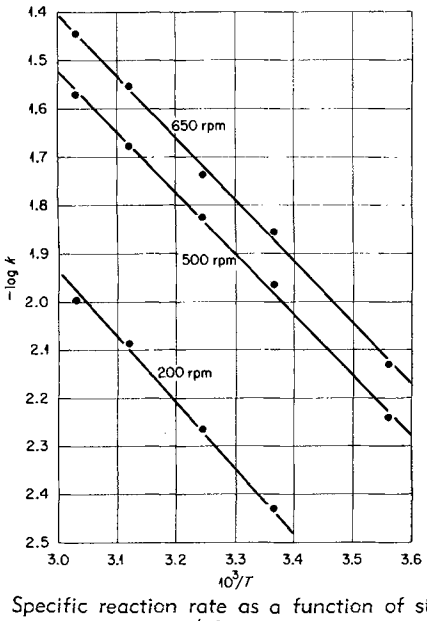

Fig. 5. Specific reaction rate as a function of stirring velocity and temperature in 10^{-2} M ethylenediamine.

determined by the amount of oxygen dissolved in the solutions. Therefore, the applicability of conductivity data to Eq. [2] and [4] demonstrates that the process was kinetically first-order with respect to oxygen and independent of the ethylenediamine concentration in these systems. A plot of log rate constants for the three stirring speeds is shown in Fig. 5 as a function of temperature. From the slopes of the lines, which are identical for the three stirring speeds, the apparent activation energy for the process was determined to be about 5800 cal $mole^{-1}$.

If air-saturated solutions were not stirred and thermal fluctuations in the temperature bath were very small, no reaction occurred at 25° and 35°C. Apparently a protective layer which prevents further reaction is formed over the reacting surface. Not only was no copper detected in the solution after 24 hr, but also there was no evidence of growth of a visible oxide film on the sample. The protective film is very unstable, for normal thermal agitation of unstirred solutions on the laboratory bench at room temperature is sufficient to cause reaction at a reasonable rate.

Experiments in which the stirred solutions were open to the atmosphere were also conducted. Under these conditions, conductivities of the solutions initially changed linearly with time. This is not unexpected if the rate of adsorption of oxygen from the air by the solution was at least as great as the rate at which oxygen reacted with copper. After a period of a few hours, depending on the temperature and the stirring rate, the reaction rate decreased, probably due to the decrease in concentration of free ethylenediamine. This point was not investigated further.

Oxide Film

In systems such as these the presence and possible role of oxide films is always open to question. In order to compare the behavior of these systems with one containing a film, a (110) crystal was oxidized in pure oxygen at 250°C until the sample was covered with a single-crystalline film of Cu_2O 700Å thick. The crystal was placed in the reaction chamber and the system flushed repeatedly with hydrogen. Obviously, it was impossible to anneal the specimen. The dissolution rate of the film in oxygen-free 10^{-2}M ethylenediamine, at a stirring speed of 500 rpm at 25°C, was determined from conductivity changes in the solution. Initially, there was an induction period of 30 min in which no conductivity change could be observed. (The reasons for the existence of an induction period in the dissolution of oxide films are not well understood, but such an observation is not unusual.) Dissolution then started and the conductivity changes were a linear function of time for a 2-hr period, at which time the rate decreased rapidly. About 80 min later the reaction was complete, and no further change with time was observed. The solution was analyzed for copper and the result was in excellent agreement with the amount of copper in an oxide film of this thickness. The decrease in rate at the end of the reaction could possibly be due to a slower dissolution rate of thinner oxide films which lie near the metal substrate; however, it seems more reasonable to assume that other factors, which are not understood at this time, caused the decreased rate.

Conductivity data indicated that at the completion of the 2-hr reaction period, the time at which the reaction rate started to decrease, about 630Å had been dissolved from the film. The copper required to form an oxide film of this thickness is equivalent to a dissolution of 375Å of metal. Air-saturated solutions of ethylenediamine under identical stirring and temperature conditions remove a corresponding amount of copper in about 15 min. While it is certain that the final reaction product in the air-saturated solutions studied is divalent copper, it is problematical whether the reaction proceeds through a Cu_2O or CuO mechanism. Although it is perhaps not permissible to compare the dissolution of Cu_2O films in oxygen-free solutions with other dissolution rates, it would appear that, if an oxide film is present on the crystals studied in air-saturated solutions, it must be an extremely thin one lacking the characteristics usually associated with a thick film.

Surface Effects

The (110) surface showed no substructural effects. At the very earliest point observed in the reaction no etch pits or subgrain boundaries could be seen; only faceting was observed. Figure 6 demonstrates the orderly progression of facet development on this surface. After an amount of copper corresponding to an average of 3000 atomic layers had been removed, the surface was no longer (110) but rather a series of facets thought to be (100) composed of long sharp-topped ridges separated by relatively deep valleys. It is difficult to obtain precise data about the depth of the valleys or the angle at which their sides intersect the base (110) surface from electron micrograph studies; however, it is certain that the facets lie in the (110)-(100) zone, and it is highly probable that the surfaces of the facets are (100) since the "subfaceting" on the

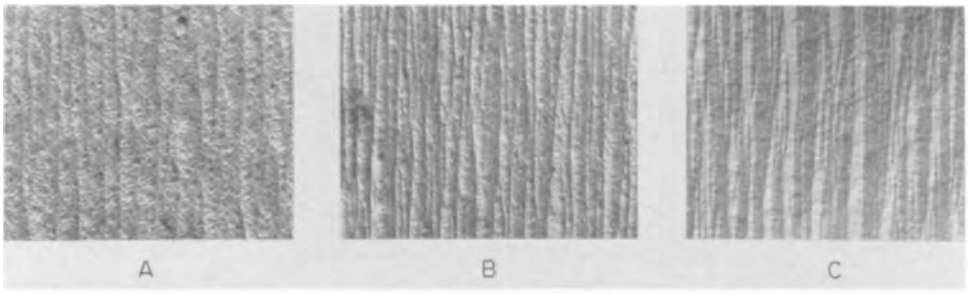

Fig. 6. Facet development on (110) surface. Average atomic layers of copper removed: A, 900; B, 1800; C, 3000. Magnification before reduction for publication: A, 50000X; B, 25000X; C, 8500X.

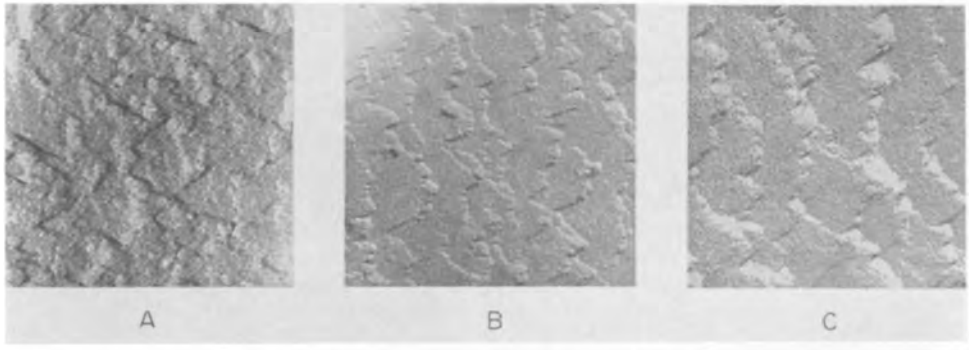

Fig. 7. Facet development on (111) surface. Average atomic layers of copper removed: A, 900; B, 1800; C, 3000. Magnification of A, B, C 17000X before reduction for publication.

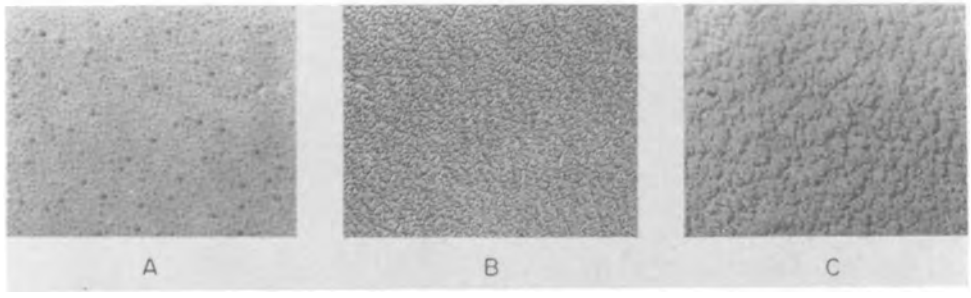

Fig. 8. Hillocks formed on (100) surface. Average atomic layers of copper removed: A, 900; B, 1800; C, 3000. Magnification before reduction for publication: A, 25000X; B, 12500X; C, 17000X.

sides of the valleys is identical with that of a (100) surface. If the fully developed facets are assumed to be (100), calculations of the amount of copper removed prove that the tops of the ridges certainly lie below the original (110) surface; however, the faceting process does start very early, and most of the material removed came from the valley areas.

Pitting is seen on the (111) surface at the earliest observable stages. Figure 7 illustrates how these pits grow and coalesce as the reaction proceeds to produce stepped facets which are oriented in two principal directions. From the orientation of the crystal and the shadows produced in the replication process, it is possible to prove that the facets are principally (110) faces. Furthermore, these facets start developing from pits very early in the dissolution process. Again, data on the total copper removed show that, at stages of the reaction where the facets are well developed, even the tops of the facets are well below the original surface. Also, at early stages of the reaction prior to extensive facet development it is possible to see pits which may have some relationship to the substructure of the crystal. A few of the pits are arranged in lines which apparently have some relationship to subgrain boundaries in the crystal.

Neither pitting nor oriented faceting is observed on the (100) surface even after the removal of copper corresponding to an average of 3000 atomic layers. From the beginning of the reaction rounded hillocks are seen on the surface. The development of these hillocks as the reaction proceeds is shown in Fig. 8. Arrangements of some of the hillocks in lines which may have some correspondence to subgrain boundaries are observed throughout the reaction.

Discussion

Kinetic Results

To prevent the formation of oxide films on a specimen before contact with the solutions it was desirable to anneal and maintain the copper crystal in an atmosphere of hydrogen. Therefore, it was not possible to mask the crystal edges of undesirable orientation from the solution. These edges of various orientations constituted 5-10% of the total exposed surface area. Also, electropolishing rounded off the edges of the crystal to produce other departures from the desired orientation. It seems clear then that if conditions had been such that the rate of oxidation at the crystal face was rate-controlling, no rate difference due to crystallographic orientation would have been observed since such differences would not be expected to be very large. However, the kinetic data at different stirring rates and temperatures demonstrate that conditions were such that a transport process in solution was rate-controlling. The activation energy determined for the reaction is of the magnitude anticipated for a process under transport control but certainly lower than expected for a system in which the rate-determining step is chemical in nature.

During the course of the reaction, the concentration of hydroxyl ion was constantly increasing in accordance with the requirements of Eq. [1]. This resulted in a corresponding decrease in the concen-

tration of the protonated form of ethylenediamine due to the equilibrium requirements of the reaction of ethylenediamine with water

$$en + H_2O \leftrightharpoons enH^+ + OH^- \quad [6]$$

Over-all, the concentration of hydroxyl ion increased about 10% while that of the ethylenediaminium ion decreased the same amount. No change in reaction rate due to these concentration changes was observed. Since initially both concentrations were only about 10% of that of the total ethylenediamine present, the changes in concentrations probably were not large enough to produce the effects observed in systems more concentrated in oxygen, ethylenediamine, and ethylenediaminium ion (3).

Experimental observation established that the reaction rate was directly proportional to the gross surface area of the sample, confirming the repeated observations of others; however, it is interesting that as the reaction proceeded there was no departure from first-order kinetics. Figure 6C shows the (110) surface at a time when the reaction was about 75% complete. At this time the surface area was approximately twice that of the original crystal before reaction started due to the troughs formed by removal of copper. As previously stated, the sides of the valleys show substructural developments like the (100) and certainly are not atomically smooth and, therefore, the roughness factors of this and the original surface can reasonably be assumed to be about the same. Since the average distance between crests of the troughs is about 7000Å these features cannot be considered negligible. Logically, it would be reasonable to expect deviations from first-order kinetics on all major faces of the crystals due to the increase in surface area, especially in the latter stages of the reaction when the change in surface area has reached a maximum. The observed structural effects would lead one to expect the greatest difference on the (110) and the least on the (111) in this particular system. These differences were, of course, not observed.

For such a system under kinetic control by a transport process, the critical area must be approximately that area of the solution which is circumscribed by the boundaries of the sample. Only macroscopic topographical deviations from a flat surface can alter this boundary area and, consequently, the reaction rates. Changes in surface area are effective only to the extent to which they contribute to such macroscopic fluctuations. Since the facets developed on the (110) were approximately 3500Å high, this suggests that the transport dependence observed is related to volume diffusion within the solution rather than diffusion across an interfacial barrier, for it seems clear that the area of such a barrier should be proportional to the microscopic surface area of the crystal.

Surface Orientations

In the system studied the (100) surface appears to be the stable orientation. At no time during the normal reaction is oriented faceting observed on surfaces of this type. However, if crystals of this orientation are reacted in systems with larger volumes so that more copper can be removed, faceting is observed as is demonstrated by the surface replica shown in Fig. 9. These facets consist of pits of various sizes, some of which have grown into each other to form large facets of random orientation. Over-all, there is clearly a tendency to maintain the (100) orientation. At higher magnifications the flat areas of this surface were seen to have a structure similar to that shown in Fig. 8A. It should be noted that casual observations would lead to the conclusion that the pits seen in Fig. 9 are associated with sites which are more reactive than the remainder of the surface. This cannot be the case, for Fig. 8 illustrates that the attack is a general one. The occurrence of pits under these conditions must be largely statistical and results from the propensity of the surface to maintain the more stable (100) orientation. The rapid development of (100) facets on the (110) surface supports the argument that the (100) is the stable orientation under these conditions. The development of facets, largely (110), on the (111) surfaces may represent a metastable condition. Since the (100) orientation is about 55° from the (111) and the (110) only 35°, the faceting observed may represent a progression to a surface state of lower energy as quickly as possible. These observations are complicated by the fact that the original surfaces of these specimens were about 2° removed from the (111). It is difficult to understand why original faceting of threefold symmetry illustrated in Fig. 7A should degenerate to twofold symmetry and why so much of the surface should maintain (111) orientation. It is reasonable to assume that if the surface were permitted to react to the point that it was covered with (110) facets, then the development of (100) facets on (110) facets would be observed; however, such arguments are questionable for the relationships between surface energies and surface area vs. total energy in systems of this type are not obvious. If no external forces are applied to the crystal, the relative stability of copper faces is (111)>(100)>(110). Since this relationship was not observed, it is possible that faceting is dependent on both the reagents in solution and their concentration.

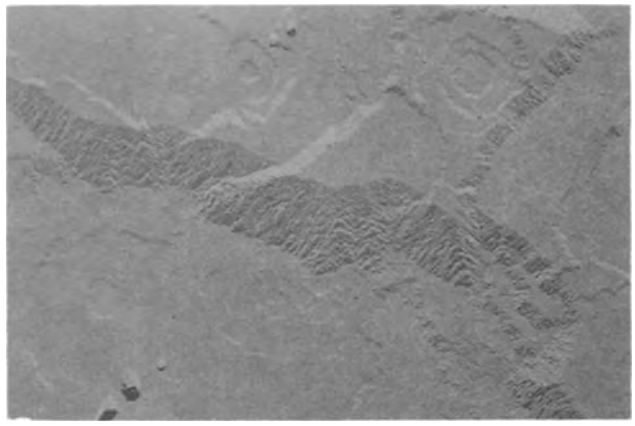

Fig. 9. Facets on (100) surface after dissolution of an average of 30,000 atomic layers. Magnification 6500X before reduction for publication.

Fig. 10. Optical photograph of (100) surface shown in Fig. 8B. Magnification 200X before reduction for publication.

Only from replicas of the (111) surface in the early stages of reaction is it possible to obtain any information about the number of reaction sites. It is seen in Fig. 7A that the initial attack on the surface results in small triangular pits enclosed in larger ones. If each small pit is considered a nucleation point for reaction, then there are about 10^{11} such points per square centimeter of surface area. This number is much too large to be related solely to line defects in the crystal, and it is not certain that the number represents more than a limit to the means of observation.

On all (100) surfaces there are structural details like those shown in Fig. 10 which are thought to be related to subgrain boundaries within the crystal and which persist throughout the normal reaction. Similar patterns are observed on the (111) until faceting becomes so pronounced that they no longer are visible. No substructural effects of this type are observed on the (110). On the (100) these areas are hillocks raised above the rest of the surface indicating a decreased reactivity at these points, while on the (111) the lines are rows of pits which lie below the remainder of the surface, and the reactivity must be greater at such points. Whether or not such areas are representative of subgrain boundaries, their contradictory behavior is difficult to understand.

Conclusions

1. In the dilute, oxygen-free solutions studied, there is no measurable reaction between copper metal and divalent copper in solution. Either values quoted for the equilibrium constants are wrong or equilibrium is extremely slow in being established in these solutions.

2. The rate of dissolution of single crystalline copper in a closed system of air-saturated, 10^{-2}M solutions of ethylenediamine is controlled by a transport process in the solution. The rate is a function of the temperature and rate of stirring of the solution but is independent of the crystallographic orientation of the exposed metal surface. The activation energy determined is of the magnitude expected for a process under transport control.

3. While the dissolution rate appears to be directly proportional to the gross surface area of the sample, it seems likely that this is an oversimplification of a more complex relationship.

4. The dissolution rate of a Cu_2O film of predetermined thickness proved to be much slower than the removal of a corresponding amount of copper under similar conditions. If an oxide film was present on the crystals studied, it was an extremely thin one lacking the usual properties of a true film several angstroms thick.

5. The crystallographic orientation of facets developed on the metal surfaces during dissolution shows that the most stable face is not the close-packed (111). The relative stability of crystal faces in this particular system apparently is (100)>(110)>(111).

6. Nucleation of reaction sites appears to be a random process on all surfaces, and the number of such sites on the (111) face is much larger than would be permitted if reaction sites were limited to points where dislocations intersected the crystal surface.

7. The difference in reactivity of the areas thought to be subgrain boundaries on the (100) and (111) does not support the assumption generally made that these are regions of greater reactivity. At this time, no explanation of the lack of correlation between crystal imperfections and reactivity can be made.

Acknowledgment

J.O. Stiegler prepared all the surface replicas and electron micrographs, and R. M. Wallace is responsible for much of the supporting photographic work in this study. The oxide film on the (110) surface was prepared by the group headed by J. V. Cathcart in the Oak Ridge National Laboratory Metallurgy Division. The author is also indebted to F. W. Young, Jr., for many valuable discussions during the research and in the preparation of this paper. The contributions of all are gratefully acknowledged.

Manuscript received Nov. 4, 1959. This paper was prepared for delivery before the Columbus Meeting, Oct. 18-22, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Studies on Cathodic Protection Using the Hull Cell

I. Action of Corrosion Inhibitors

K. S. Rajagopalan and Y. V. P. Ramachandra Row

Central Electrochemical Research Institute, Karaikudi, India

ABSTRACT

A new method of studying inhibitor action is proposed. It is shown that the action of acid inhibitors is changed profoundly under impressed current conditions. The study also reveals that the potential of the cathodically protected metal is not a fixed value as is usually believed but changes in the presence of inhibitor.

Cathodic protection is used in combination with another well-known method of corrosion prevention, viz., addition of corrosion inhibitor, in electrolytic derusting with acid solutions to prevent basis metal attack. It is, therefore, of considerable interest to know how the two methods function in conjunction with each other, in particular, how the current requirement for cathodic protection is influenced by inhibitor action. This aspect has apparently not received adequate attention so far. Preliminary experiments (1) carried out in this Institute have shown that the current requirement for cathodic protection can be conveniently studied by the Hull Cell technique (2, 3) which is so widely used in the study of electrodeposition and that precise information on inhibitor action under impressed current conditions can be obtained by this method. The application of this technique to the study of inhibitor action in sulfuric acid medium is considered here with reference to four commonly used acid inhibitors.

Experimental

Metal.—Mild steel having the following composition was used: C — 0.1 to 0.2%, Mn — 0.4 to 0.5%, P — 0.07 to 0.08%, S — 0.02 to 0.03%. Specimens of 18 gauge sheet steel cut to the size of Hull cathode and provided with a handle at the center were used in the Hull Cell experiments. Specimens of the same mild steel sheet 3 x 1 in. were used in independent experiments to determine weight loss at protection current. The specimens were initially freed of rust and scale, abraded with 120 emery, and degreased with methanol, hot benzene and hot acetone.

Set-up.—The Hull Cell used here (Fig. 1) is a small box of trapezoidal plan in which the cathode is placed at a fixed angle with respect to the anode (3). Both electrodes occupy the full cross section of the cell and the distribution of current density on the cathode for a 267 ml cell is given by the equation C. D. at any point. Amp/dm^2 = I (2.98-5.24 log L/2.54), where I is cell current in amperes and L is distance in centimeters of the point from the high current density end of the cell. The equation applies between the limits 1.3 and 6.4 cm. The dimensions of the Hull Cell are given in Fig. 1.

The cell was fabricated from ¼ in. thick perspex (trade product made from acrylic resin). To facilitate experimentation at elevated temperatures, the cell was placed inside a lead-lined brass bath of slightly greater height than the Hull Cell and both brass bath and the perspex Hull Cell filled with acid solution till acid level was nearly flush with the top of the cell. A lead anode was used.

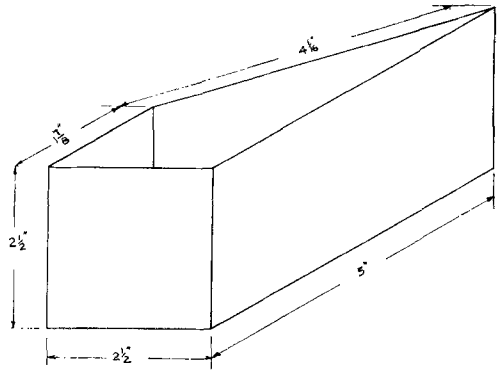

Fig. 1. Hull Cell

Procedure.—Experiments were made at various cell currents. The specimen was introduced into the cell after adjusting the current using a dummy specimen so that current started flowing to the specimen simultaneously with the immersion of the specimen. Immediately after test, the specimen was taken out and quickly reimmersed in a 0.5% NaOH solution followed by rinsing with cold water and drying to prevent attack by the acid after it was disconnected from the cell. The dried specimen was completely etched when the maximum current density obtained on the specimen was insufficient to give protection. An etched as well as a bright, unattacked region was observed when current densities required for complete cathodic protection were obtained in the Hull Cell. The line dividing these two regions were usually quite sharp and reproducible to the extent of less than 3 mm. All the results reported in the paper were obtained under conditions of uniform stirring with a mechanically driven glass stirrer rotating at an approximate speed of 750 rpm.

ature and acid concentration on the current required for cathodic protection in 0.5 mole/l H_2SO_4 solution were studied in the first instance. The results obtained in replicate experiments for a cell current of 1.5 amp are given in Table I.

The metal remained practically unattacked at lower temperatures than 60°C as shown in Table I. As the temperature was increased beyond 50°C, etched and unattacked regions appeared. The dividing line shifted to higher current density values at 70°C as compared to 60°C. Apparently, at temperatures lower than 60°C the rate of corrosion is so low and the effect of even the lowest cathodic current obtainable on the plate are sufficiently marked to make the etching of the metal surface insignificant; while at 60°C and 70°C the corrosion rate is sufficiently high for etching to appear on unprotected regions within the duration of the test (30 min) for a cell current of 1.5 amp. At 2 M acid concentration the metal was practically completely etched

and at 0.5 mole/liter the etched surface was not seen at all. The two regions became visible on the plate only at the intermediate concentrations of 0.5 mole/liter. The values obtained in 0.5 M acid solution at 60°C (see Table I) show that the position of the dividing line between the etched and the unattacked regions is quite reproducible. All the subsequent experiments were carried out at this temperature (60°±2°C).

Applicability of the Hull Cell equation.—The applicability of the equation given earlier, which gives the distribution of current density on the cathode, has been studied in several ways. First, the current densities for cathodic protection when different cell currents are employed have been compared. Results are given in Table II.

It is seen from Table II that a fairly good correspondence is observed between the protection currents obtained at different cell currents.

Losses in weight at the protection currents determined by means of independent experiments at similar current densities are given in Table III. It is seen that the corrosion rate is quite high in the absence of current and becomes negligible at the protection current. The protection currents themselves were calculated on the basis of the Hull Cell

* Inhibition efficiency is calculated by the formula: $\left\{\frac{\text{Wt loss in the absence of inhibitor—Wt loss in the presence of inhibitor}}{\text{Wt loss in the absence of inhibitor}}\right\} \times 100$

equation. The results, therefore, suggest that the protection current can be predicted on the basis of the equation with a fair amount of accuracy. It may, however, be argued that a weight loss of 0.007 to 0.02 g/dm²/30 min cannot be strictly considered as representing complete cathodic protection. It is to be noted, however, that the present work relates to conditions which are connected with processes such as pickling operations which normally do not extend beyond 30 min. For this duration, the rate of loss as obtained should be considered very satisfactory. It may be pointed out in this connection that the maximum inhibition by the most efficient inhibitor used corresponds to a weight loss of 0.05 g/dm²/30 min with an inhibition efficiency of 95%. The combined effect of the two methods is appropriately studied keeping in view the highest order of protection obtainable with either method.

The Hull equation was derived from weight of metal deposited in different regions in various plating baths as well as by the direct determination of current distribution on the Hull plate. Measurement of current distribution on the cathode in Hull Cell under the conditions employed in the present study is of interest. This has been carried out using the strip method described by Hull (2). In this method a ¼ in. steel strip with a perspex back and edges painted with several coats of an acid resistant bituminous paint was used as the auxiliary electrode. It has been observed that current densities obtained by this method show fairly good correspondence with those calculated from the equation mentioned earlier in the region 1.3 to 6.4 cm from the high current density end of the cathode. At greater distances the measured values fall much more slowly than the equation would give. It may be noted in this connection that most of the measurements reported are confined to the region of 6.4 cm.

Protection current in relation to concentration of inhibitor.—The protection current at four concentrations of each of the four inhibitors considered, viz., B-napthol, quinoline, gelatine, and thiourea, are plotted against concentration in Fig. 2. It is seen from the figure that valuable information regarding the behavior of the inhibitors is given by this method. The effect of gelatine increases with concentration and does not reach a maximum value even at 0.1%. As compared to this, quinoline and thiourea make themselves more or less completely felt at the lowest concentration (0.01%), and further changes in concentration do not increase their effectiveness. These are also more effective than gelatine at all concentrations. In the case of B-naphthol, increase in concentration of inhibitor has a profound effect on the requirement of current and it reduces the current requirement more than quinoline and thiourea at 0.1%, although it is less effective than quinoline or thiourea at 0.01%.

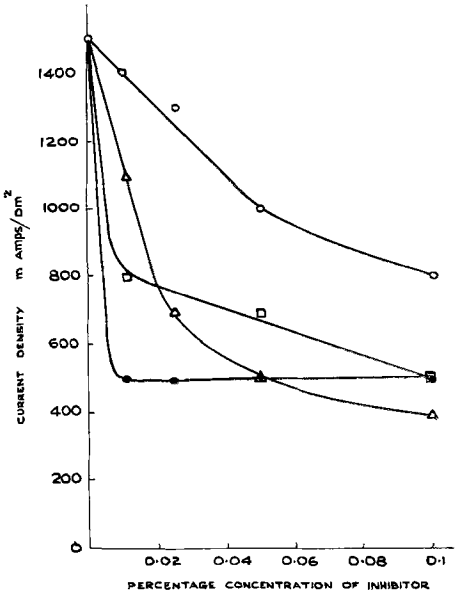

Fig. 2. Protection current vs. concentration of inhibitor. □ quinoline; △ B-napthol; • thiourea; ○ gelatine.

Inhibition efficiences of the 4 inhibitors.—The inhibition efficiency of the four inhibitors are given in Table III in terms of weight loss data with and without inhibitor when no cathodic current is applied. It is seen from Table III that the efficiency of inhibition of the different inhibitors is in the order thiourea > gelatine > B-naphthol, quinoline. The inhibition efficiency of gelatine increases with concentration, and it becomes nearly as efficient as thiourea at 0.1%. Both B-naphthol and quinoline inhibit poorly at all concentrations. As compared to this, the effectiveness of the different inhibitors in reducing the current required for cathodic protection is in the order thiourea > quinoline > B-naphthol > gelatine at 0.01%. It may be mentioned in this connection that, although quinoline and B-naphthol inhibit poorly at 60°C (the temperature at which all the present experiments have been carried out), they inhibit to a greater extent of 25°C.[2] The loss in the inhibitive action of quinoline at elevated temperatures has been noticed by other workers also (4).

Electrode potentials at currents corresponding to protection currents.—The potentials were measured using an electronic millivoltmeter and saturated calomel electrode as the reference electrode. All the potential measurements were made in independent experiments at the protection current densities found by Hull Cell experiments. Potential data are given in Table III. It is seen that the potential corresponding to the protection current is not a constant value and varies with each system, but it remains the same for the same system at all concentrations though the protection current varies. The potentials before current is applied, however, vary with concentration of inhibitor.

The mechanism of cathodic protection as well as inhibitor action has been very satisfactorily interpreted in terms of the Evans diagram (5, 6). In the former case, cathodic protection is believed to have been attained when the metal is cathodically polarized to the open-circuit potential of the local anodes. In the latter case, the inhibitor increases either the anodic or cathodic polarization behavior

[2] It is necessary to draw the reader's attention here to the inhibition efficiency value given in ref. (1). This was obtained in experiment at room temperature as it was not expected that the extent of inhibition would change markedly with temperature. Our main interest at that stage was to bring out the reversal of the order under impressed current conditions.

of the local cells and brings about reduction in the corrosion rate. Both anodic and cathodic polarization behavior can also be influenced simultaneously. The direction in which the over-all potential will shift as a result of inhibitor action has been succinctly dealt with by Mears (7) as well as Hoar (8). In the present case, when no current is applied, the potential shift in all cases is in the nobler direction. Maximum shift is given by gelatine at 0.1% when the metal is 90 mv more positive than in uninhibited solution. This should indicate that all the inhibitors polarize the metal surface anodically and that this effect increases with concentration of inhibitor. On the other hand, the fact that all the inhibitors considered here reduce the current required for cathodic protection suggests that in the presence of inhibitor the metal is more cathodically polarized. It is further noticed that in the case of gelatine and quinoline the potential at which complete cathodic protection is obtained differs from that of uninhibited acid solution. It is reduced by 180 mv in the case of quinoline and 60 mv in the case of gelatine. Thus, it would appear that the action of corrosion inhibitors is a complex phenomenon in which not only increased anodic and cathodic polarization are involved but also a reduction in the potential requirement. Let us now consider the inhibition efficiencies of the different inhibitors given in Table III. Thiourea shows very high inhibition efficiency in the absence of current. This is observed even at the lowest concentration of the inhibitor employed.

The protection current is minimum in this case at 0.01% and there is no change of the protection current with concentration of inhibitor. The potential corresponding to satisfactory cathodic protection is the same as that of acid solution without inhibitor. It would, therefore, appear that thiourea increases the anodic and cathodic polarization characteristics of the metal surface considerably on addition and that this brings about the high inhibition efficiency in the absence of current as well as the lowering of the protection current in the experiments on cathodic protection. In the case of gelatine, the inhibition efficiency increases with concentration; so also the lowering of the protection current increases with concentration. The potential data indicate that the potential at which cathodic protection is obtained is lowered. So gelatine may be said to give cathodic protection and inhibition by lowering the potential requirement and by increasing the anodic and cathodic polarization characteristics of the metal surface and that these are a function of inhibitor concentration. B-naphthol and quinoline cause considerable lowering of the protection current at all concentrations although they give very poor inhibition in the absence of current. This suggests that these inhibitors become effective only in the presence of cathodic current. The conclusions drawn by Mann (9) and others (10) based on over voltage measurements and the theory put forward by Warner (11) that N-type inhibitors which can form quaternary ammonium ions can be adsorbed at cathodic areas when the metal is operating as cathode appears to have some validity in the light of the results obtained with quinoline and B-naphthol. The action of the inhibitors is seen only when cathodic current is applied. This should mean that these two inhibitors are adsorbed on the metal surface only at more negative potentials than the corrosion potential of steel in sulfuric acid [cf. (13)]. Quinoline apparently reduces the current requirement by lowering the potential requirement and B-naphthol by increasing cathodic polarization.

The factors determining the current required for complete cathodic protection have been the subject of a number of important studies. On the basis of practical experience it is believed that, if a steel structure is maintained at a potential of −0.77 v vs. saturated calomel electrode, it will be completely protected. This criterion has been widely used. Our study shows that even in the same electrolyte the presence of small quantities of inhibitors can bring about very substantial changes in the potential at which protection is obtained and that this change takes place to different extents in the case of the different inhibitors. It is, however, a constant value for each system. The theoretical studies of Wagner (12) appear to show that under certain conditions assumed by him the criterion for cathodic protection can be stated without recourse to Evans' diagram and that the current required for cathodic protection can be worked out on the basis of lowering the metal potential to a value 0.2 v more negative than the standard single electrode potential of the metal. The present work indicates that from a practical point of view much greater caution has to be exercised in using particular potential values as criteria for cathodic protection.

Particle Separations by Nonuniform Electric Fields in Liquid Dielectrics, Batch Methods

Herbert A. Pohl and James P. Schwar[1]

Plastics Laboratory, Princeton University, Princeton, New Jersey

ABSTRACT

The motion of suspended solids in nonuniform electric fields in liquid dielectrics is called dielectrophoresis. Some of the quantitative aspects of dielectrophoretic behavior of solids is reported herein. The yield of precipitated solids is seen to rise with applied voltage in cells of cylindrical geometry, until a critical or "sluff-off" voltage is reached. The yield is seen to decrease with increase of volume fraction of suspended solids in the range of 1 to 50% v/v. The yield depends on voltage gradient, applied potential, cell dimensions, and relative dielectric constants of solid and liquid. In particles of given size, yield is observed to be directly dependent on the dielectric constant. Moisture is shown to have a small but demonstrable effect. As expected, the amount and character of dielectrophoretic behavior is observed to be independent of the direction of the field applied.

Current flow during the process was observed to range up to about 20 $\mu\mu$a, and to indicate that a new method of conduction takes place with the particles present. It is suggested that this is due to ionic charging of the particles by usual current flow in the liquid dielectric, with the particles then aiding current flow and energy consumption (dielectric loss) by rotating.

The motion of suspended solids caused by nonuniform electric fields is called "dielectrophoresis" (1-3). The most polar material moves toward the place of greatest field intensity. Unlike electrophoresis, this does not require charged particles. Instead, it depends on the force felt by all polar material when in a nonuniform field. It may be described as arising from the unequal pulls exerted by the forward and backward direction of the electric field on the dipole produced in the particle by the field. Reversal of the field produces no change in the direction of the pull on isotropically polarizable particles.

Prior work on the more quantitative experimental aspects has shown that the field strength, electrode size, cell size, and particle size are important parameters affecting the yield of material held by the central electrode in a cell of cylindrical geometry. Field strength, electrode size, and particle size show criticality. At certain upper limiting voltages, small central electrode diameters, and small particle sizes, all precipitation appears to be prohibited. The work described here is a continued study of other such factors. The effects of varied dielectric constant of the powder, of the dryness of the system, of the polarity, and of the powder concentration are reported.

The apparatus and handling methods used in this study are essentially those as reported earlier.

Effect of Dielectric Constant of the Powder

As shown in the simplified theory (1, 2), the effect should be proportional to the difference in the dielectric constants of the liquid dielectric and the solid.

The following experiment was done in the apparatus previously described (3) with three powdered substances of differing polarizabilities. The dielectric constants of solid ammonium chloride, polyvinyl chloride (PVC), and sulfur are: 7.0, 4.6, and 3.67. The dielectric constant of the liquid dielectric, composed of carbon tetrachloride-benzene mixtures chosen to be equal in density to the solid in use, is approximately 2.26. In agreement with expectation, the amount of ammonium chloride precipitated in a given time at voltages below the critical voltage is found to well exceed that of the polyvinyl chloride or the sulfur. The amount of PVC pulled out in turn exceeds that of the sulfur. Data were obtained on particles of the same average particle size, namely, 163 μ (see Fig. 1 for details).

The critical voltage, i.e., the voltage at which the particles appeared to be no longer held by the central electrode, was observed to increase with increasing dielectric constant of the powder. That for NH_4Cl was 7.6 kv, that for PVC was 7.0 kv, that for sulfur was 5.2 kv under the following experi-

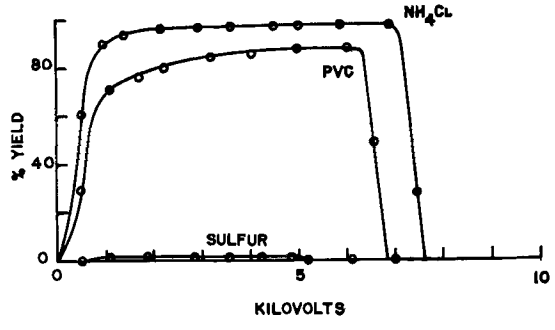

Fig. 1. Effect of varied dielectric constant of the solid powder on the precipitation yield during dielectrophoresis.

[1] Present address: Division of Engineering, Texas College of Arts and Industries, Kingsville, Texas.

mental conditions: powder suspended in CCl_4-benzene mixtures; alternating voltage used, reported as RMS: 60 cps; central wire diameter, 0.794 mm, Teflon coated to a thickness of 5 mils; test duration, 180 sec of flow at 12.5 ml/sec of feed liquid suspension: outer cell electrode diameter, 9.8 mm, ID.

Effect of Electrode Polarity

Data were obtained for the yield of PVC precipitated vs. the applied voltage in static fields, in which the polarity of the electrodes were reversed. The data of Table I show that while the central electrode is positive and the outer electrode negative the precipitation yield is identical to within experimental error with the condition of having the same but inverse voltage on the electrodes. This is in conformity with the view that the phenomenon is not electrophoresis, but is dielectrophoresis. Corona effects about the central electrode are thought to be present, especially at higher applied voltages, for when the field is suddenly reversed at very high voltages, the particles clinging to the central electrode suddenly are rapidly repelled to the cell wall. They will remain there for a time until the charge accumulated on the particles by their imbedment in the "corona region" about the central electrode leaks away. The particles then eventually migrate back toward the central electrode if the reverse voltage is maintained.

Effects of the Presence of Moisture

In an effort to find a factor effective in the behavior of the dielectrophoretic precipitations, the effect of careful drying was studied. The powdered material, in this case, polyvinyl chloride seived to pass 100 mesh, and stop on 140 U.S. mesh screen (nominal 127 μ average particle diameter), was used "as is" after long storage at room humidity, and after drying 24 hr at 105°C. The liquid dielectric, a mixture of CCl_4 and benzene, both of reagent grade, having the same density as the freshly wet powder, was used as received from the supplier, and also after drying over anhydrous $CaCl_2$ for one week. The precipitation yield was observed to be slightly higher (about 2% change in relative values) for the less dry materials. Perhaps this can be attributed to the slight changes in the dielectric constant of the liquid due to the water (see Fig. 2 for details). The critical cut-off voltage for the precipitation was rather higher in the case of the dry materials. This is probably due in part at least to the decreased conductivity of the liquid dielectric. Increased conductivity permits a higher rate of conductive counter-polarization of the particles, thus accelerating sluff-off. Numerically the critical voltages observed were: dry-8.6 kv; wet-7.9 kv.

Table I. Effect of field direction on the yield during dielectrophoresis

Data on particles of polyvinyl chloride of 126μ average particle diameter, suspended in CCl_4:C_6H_6 mixture of closely equivalent density between cylindrical electrodes, outer electrode, inner electrode, liquid velocity and test duration were as in the previous experiment.

Voltage	% Yield (central electrode positive)

6600	83.5
7800	23.9

Effects of Varied Particle Concentration

It is observed that, as the concentration of the solid suspended in the liquid dielectric increased, the yield of solid precipitated in a given time decreases. The experiments showing this were carried out in a cylindrical electrode cell of 9.8 mm ID, using a central wire electrode of 0.794 mm wire that was coated with 5 mil thick layer of Teflon. Polyvinyl chloride powder of spherical shapes, of nominal 127 μ average diameter, as in the above experiment, was used, at various concentrations in mixtures of CCl_4 and benzene adjusted to have similar density. The liquid velocity during the flow period of filling and draining was 12.5 ml/sec; the potential across the cell fixed at 2000 v. The test duration was 180 sec. The yield of powder collected at very low volume fraction (0.047) was 79% and fell smoothly with increase of volume fraction of powder to zero % yield at an extrapolated 51% volume fraction of powder, as the data in Fig. 3 show.

Current Flow during Dielectrophoresis

Preliminary measurements of the current flow taking place during the dielectrophoresis showed that breaks in the current vs. voltage curve occurred at points corresponding to obvious changes in the yield per cent vs. voltage curve. The current flow was observed to be greater with increased concentrations of powder, and to be greater with increase of particle size. Typical results obtained are shown in Table II and in Fig. 4. The data selected

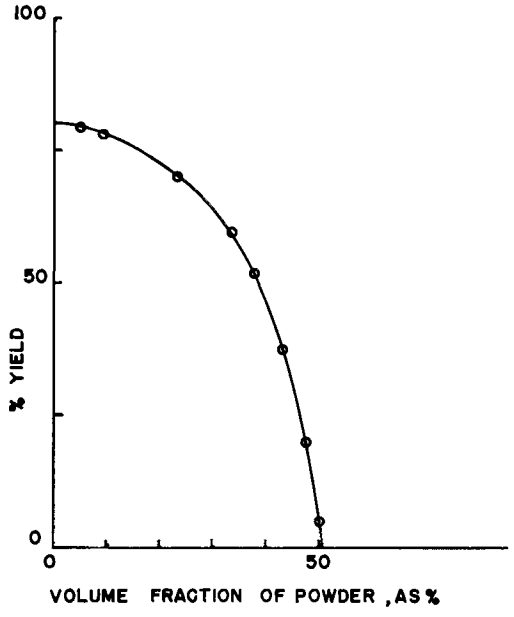

Fig. 3. Effects of powder concentrations on precipitation yield during dielectrophoresis.

Table II. Preliminary data on current flow as affected by concentration and particle size during dielectrophoresis

Particle size Mesh range	Nominal average particle diameter, μ	Current, $\mu\mu$a	Precipitate collected, as % of total	Volume fraction of powder in original suspension
−60, +80	213	2.0	60	0.091
−100, +140	127	1.06	81	0.091
−100, +140	127	2.7	68	0.250

for 2000-v potential across the cell in Table II do not show the break in the current-voltage curves observed but indicate the magnitudes of the currents and the relative changes observed on changing the particle size or concentration.

The data in Table II was obtained using a Kiethley electrometer across a high resistance in series with the cell and voltage supply circuit.

The greater conductivity of powder suspensions of larger particle size coincides with the observed lower critical voltage for sluff-off of the precipitated powder in those cases. The latter phenomenon is believed to be related to the current flow during dielectrophoresis, that current viewed as producing counter-polarization on the particles opposing the dielectrophoretic action. This effect—of current increasing with the particle size—and the observed direct dependence of the current on the

particle concentration lend support to the view that a new method of current carrying is taking place. As suggested in an earlier paper (3), current flow through the liquid dielectric deposits ions on the suspended particles. A rotation of the particles, started, say, by Brownian motion, now acts to carry current across the volume occupied by the particles. This additional current carrying ability of the suspension is believed to be contributing here.

Nonuniform Field Effects in Poorly Conducting Media

Herbert A. Pohl

Plastics Laboratory, School of Engineering, Princeton University, Princeton, New Jersey

ABSTRACT

A simplified theory of the behavior of suspended polymer particles in a real liquid dielectric is presented. It is becoming well known that nonuniform fields exert an attractive force of interesting magnitude on particles of high dielectric constant suspended in a liquid medium of lower dielectric constant. In a real dielectric there is an appreciable effect due to the very small currents (10^{-3} amp at kilovolts applied) which even good liquid insulators support.

It is shown that, in a real dielectric, the initial attraction to the central electrode felt by all particles due to the nonuniform field and its polarizing induction is gradually overcome by the repulsive effects of charge accumulated on the particles due to ionic conduction in the liquid. The "reversal time" for the particle motion is calculated and shown to be reasonable.

The ability of nonuniform electric fields to produce desirable separations of materials of differing dielectric constant is now well recognized. It is the purpose of this paper to help establish some of the more quantitative features of the phenomenon. Mueller (1), Pohl (2-4), and Loesche and Hultschig (5) independently examined the theory of the size and direction of the action of nonuniform fields on mixed dielectrics. Mueller concluded from his excellent analysis that the effects would not be appreciable for particles of molecular size. Loesche and Hultschig also concluded this from their theoretical and experimental study. However, it has been shown (2-4) that the action of nonuniform fields on macroscopic particles is indeed appreciable and can be used for certain separations. Debye (6-9) concluded from theoretical considerations that grading of macromolecules, such as high polymers, should be possible by this technique.

As defined earlier (2) "dielectrophoresis" is the motion of matter caused by polarization effects in a nonuniform electric field. Other effects interfere, such as conduction, thermal convection, diffusion, and the over-all effect of the sequence: charging (whether by electrode, particle, or ion contact) and followed by electrostatic repulsion. As expected, in dielectrophoresis the most polar material moves toward the region of greatest field intensity. However, all materials conduct. In this sense a theory developed on the assumption of no current flow in the electrical system, although helpful, is too simple. As a first step in considering the effects of conduction, the following rather elementary considerations are presented with no guarantee of having more than suggestive merit.

We may assume the particle to be in equilibrium with the various forces on it in a real dielectric

$$F_e + F_j + F_d + F_\eta = 0$$

where F_e is the dielectrophoretic force, F_j the force due to conduction-produced charge, F_d diffusional or osmotic force, and F_η = viscous drag force.

Dielectrophoretic force, F_e.—As shown in a prior paper (3), the dielectrophoretic force on a spherical particle in an electric field with uniform properties (i.e., "corona" effects absent) and cylindrical symmetry is

$$F_e = -4\pi a^3 \epsilon_0 K_1' \cdot \frac{(K_2'-K_1')\ V_1^2}{(K_2'+2K_1')r^3\left(\ln\frac{r_1}{r_2}\right)^2} \cdot r^0$$

$$= -4\pi \frac{a^3 \epsilon_0 K_1' (K_2'-K_1')}{r^3\ (K_2'+2K_1')} \cdot E_1^2 r_1^2 r^0$$

where ϵ_0 is permitivity of free space, r_2 the radius of outer, grounded cylinder, r_1 the radius of inner cylinder at potential V_1, r the distance of particle center from the axis, a the radius of particle, K_1' the relative dielectric constant of liquid medium, K_2' the relative dielectric constant of particles, r^0 the unit radius vector, V, V_1 the potential at r and r_1, respectively, and E, E_1 the field at r and r_1, respectively.

The negative sign indicates that the motion due to this force will be toward the axis. The motion will be strictly radial.

For present purposes we may gather all terms except those of immediate interest into a single constant, k_e,

$$F_e = \frac{-k_e a^3 V_1^2}{r^3\left(\ln\frac{r_1}{r_2}\right)^2} r^0$$

where

$$k_e = 4\pi\epsilon_0 K_1' \frac{(K_2'-K_1')}{K_2' + 2K_1'}$$

Electrostatic force, F_j, on current-induced dipoles.—The force on a particle carrying free electric charges in an electric field, E, is

$$F_j = Q \cdot E$$

where Q is the free charge.

In a field of cylindrical symmetry it may be shown that

$$V = V_1 \ln\left(\frac{r}{r_2}\right) \Big/ \ln\left(\frac{r_1}{r_2}\right)$$

and

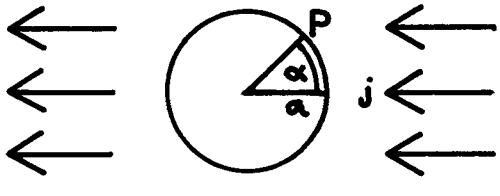
$$E = -\nabla V = -r^0 V_1 \Big/ \ln\left(\frac{r_1}{r_2}\right) \cdot \frac{1}{r} = E_1 \frac{r_1}{r}$$

The charge Q, accumulated by the particles during their life in the liquid and between discharging contacts with the outer electrode will be assumed to be proportional to their cross-sectional area and to the current density. The current in the real dielectric will be assumed due to ionic conduction in the liquid and to charge transfer between particles. It is assumed that voltage gradients sufficient to strip off electrons from the particles by field effects do not act here.

Consider the forces which arise on a particle sitting at rest in a field in which an ionic current flows. Let the particle be an insulator similar (but not necessarily identical) in dielectric constant and conductivity to the liquid medium. The motions of the ions in solution due to thermal motion and electrical forces cause them to diffuse through the liquid and, in particular, to collide with the particles of interest here. These ions generally adhere to the particles because of attractive electrical image forces. These forces arise as soon as the ion comes rather close to the particle. We may expect a high fraction of approaching ions to adhere until such time as the accumulated electric charge on the particle gives rise to a repelling field. The presence of the initial polarization on the particle gives rise to an initially attractive field for the approaching ions. This *induced* "surface" charge will make the surface field on the particle attractive to the ions until neutralized. Only then will the surface charge begin to be repellent to the oncoming ions. Our calculations from this point on largely concern themselves only with the period of ion-carried surface charging of the particle up to the point of neutralizing the induced surface charge, i.e., where no repulsion exists. Hence, we may assume for the present that all oncoming ions are picked up and held by the particle. Ionic current will then deposit equal numbers of positive and negative charge on opposite faces of the particle.

The charge density, q, will be proportional to the current density, j, to the time, t, of deposition; and to the projected area, $d\sigma$, of the area segment dA under consideration at P.

$$q = jt \frac{d\sigma}{dA}$$



Now $\frac{d\sigma}{dA} = \cos\alpha$

therefore

$$q = j_1 t \cos\alpha - j_2 t \cos\alpha$$

where j_1 is the current in the liquid dielectric, j_2 is the current in the particle itself; therefore, $q_{net} = (j_1 - j_2) t \cos\alpha$.

the moment, $d\mu$, of that charge at P is

$$d\mu = 1 \cdot q \cdot dA$$

where $1 = a \cos\alpha$ = lever arm of moment. The total moment of the charged sphere is

$$\mu = \int_A lqdA$$

$$= \int_0^\pi (a\cos\alpha)(jt\cos\alpha)(2\pi a^2 \sin\alpha\, d\alpha)$$

$$= \frac{4\pi}{3} a^3 jt = jt \cdot (\text{volume})$$

Note that the moment turns out to be the volume of the particle times the total positive charge deposited.

This is also true for particles of other shapes. For example, consider a particle of nearly cubic shape, actually a particle of the shape of a sector of a cylindrical annulus sitting at an average distance, r, from the axis of the cylindrical electrode system. Let it have a length of side $2a$ in the radial direction, a length $2a$ in the cylindrical axis direction, and a median arc length also of $2a$ along the circumference of the imaginary cylinder axial to the electrode axis and passing through r. It may be shown that the moment is

$$\mu = 8a^3 jt = jt \cdot (\text{volume})$$

where $8a^3$ is the volume of the nearly cubical particle if $a << r$.

The translational force on a dipole in a nonuniform field is

$$F_j = \mu \cos\theta \cdot \nabla|E|$$

where θ is the angle the dipole makes with the impressed field. Here, $\theta = \pi$ $\cos\theta = -1$.

$$\nabla|E| = \nabla \left| \frac{E_1 r_1}{r} \right|$$

in a field of radial symmetry for

$$E = \frac{E_1 r_1}{r}$$

where E_1 is the field intensity at a distance r_1 hence

$$\nabla|E| = \frac{\partial}{\partial r} \frac{E_1 r_1}{r} = \frac{-E_1 r_1}{r^2}$$

and

$$F_j = \mu \frac{E_1 r_1}{r^2}$$

For a spherical particle laden with charge due to the current flow

$$F_j = \frac{4\pi}{3} a^3 jt \frac{E_1 r_1}{r^2}$$

As the current density, j_0, in an ohmic cylindrically symmetrical field is

$$(j_1 - j_2)_{r=r_0} = j_0 = \frac{E_0}{\rho_1} - \frac{E_0}{\rho_2} = \frac{E_1 r_1}{r_0} \cdot \frac{\rho_2 - \rho_1}{\rho_1 \cdot \rho_2}$$

where ρ_1 and ρ_2 are the specific resistivities of the liquid and the particle, respectively.

At the surface of a spherical particle of dielectric constant K_2' in a medium of dielectric constant K_1' the field E_{1z}, is

$$E_{1z} = \frac{3K_1'}{K_2'+2K_1'} \cdot E_0$$

where E_0 is the field strength in the liquid, far from the particle.

The above relation, strictly speaking, applies only at the onset of current arrival. As the net polarization of the surface drops to zero (the conductance delivered charge equals the field induced polarization charge)

$$E_{1z} = E_0$$

However for $K_2' = 5$, $K_1' = 2$, as for representative pairs of materials,

$$\frac{3K_1'}{K_2'+2K_1'} = \frac{2}{3}$$

hence the variation of field at the surface during charging is not great in such cases. For later mathematical simplicity we choose to set

$$j = \frac{E_{1z}}{\rho} = \frac{3K_1'}{K_2'+2K_1'}\frac{E_0}{\rho}$$

where ρ is the specific resistivity. Hence

$$F_j = 4\pi a^3 t \cdot \frac{E_1^2 r_1^2}{r^3} \cdot \frac{K_1'}{K_2'+2K_1'} \cdot \left(\frac{\rho_2-\rho_1}{\rho_1\rho_2}\right)$$

Diffusional or osmotic force, F_d.—The osmotic pressure, Π, due to a set of suspended particles of concentration, n, per cc is

$\Pi = nkT$ [Van't Hoff equation (10)]

where k is Boltzmann constant and T is absolute temperature.

The pressure gradient along the r direction among the particles of varied concentration is

$\frac{\partial \Pi}{\partial r} = kT\frac{\partial n}{\partial r}$ = force per unit volume of particles.

This pressure gradient or directed force per particle due to concentration gradient is then F_d, where

$$F_d = \frac{1}{n}\frac{\partial \Pi}{\partial r} = \frac{kT}{n} \cdot \frac{\partial n}{\partial r}$$

We may compare the magnitudes of the two forces as follows:

$$F_d = kT\,\Delta n/n \cdot 1/\Delta r$$

Now $\Delta n/n$ is the fractional change in concentration along r for any volume under consideration. The maximum relative change possible is unity (presence vs. absence of particles). The minimum change in radial distance having meaning can be considered to be equal to the diameter, $2a$, of the particle. Then

$$F_{d(max)} = \frac{kT}{2a}$$

For $a = 1\ \mu$, $T = 300°K$, $k = 1.38 \times 10^{-16}$ $\frac{\text{erg}}{(\text{deg.})(\text{molec.})}$

$F_{d(max)} = 2.07 \times 10^{-10}$ dynes per particle

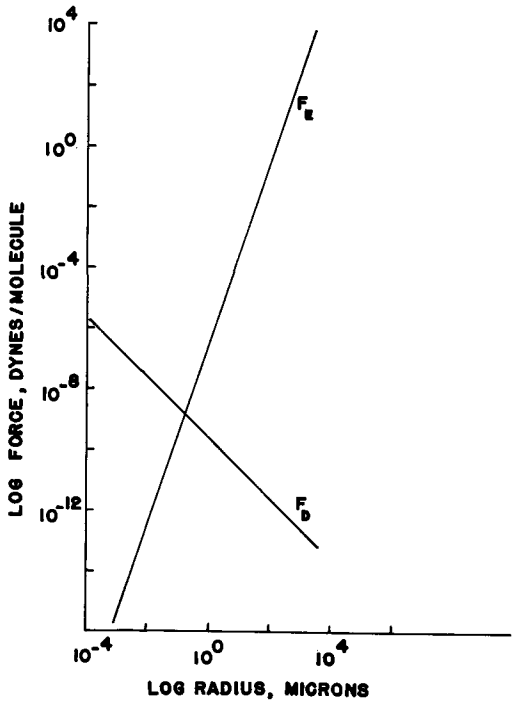


Fig. 1. Comparison of diffusional (osmotic) and dielectrophoretic forces for particles of various radii.

Values for other radii can be ascertained from Fig. 1.

An example of the magnitude of the force on a particle due to a cylindrically symmetrical electric field follows:

$$F_e = \frac{-4\pi a^3 \epsilon_0 K_1'(K_2'-K_1')E_1^2 r_1^2}{r^3(K_2'+2K_1')}$$

For

r = 1 mm = 10^{-3}m = distance from axis

r_1 = 0.5 mm = 5 x 10^{-4}m = radius of central electrode

r_2 = 5 mm = 5 x 10^{-3}m = radius of outer electrode

V_1 = 3000 v (outer electrode grounded)

$|E| = \frac{-V_1}{r\ln(r_1/r_2)}$ = 1.30 x 10^6 v/meter

ϵ_0 = 8.85 x 10^{-12} coul/(volt)(meter) = permittivity of space

a = 1μ = 10^{-6}m

K_2' = 5

K_1' = 2

F_e = 3.15 x $10^{-12}\left[\frac{\text{coulomb volts}}{\text{meter}} = \text{newtons}\right]$

= 3.15 x 10^{-7} dynes

which is much larger than the maximum osmotic force on this particle (2.07 x 10^{-10} dynes).

Values for other particle radii under these electrical conditions can be ascertained from Fig. 1.

For particles of over 1μ diameter this force may be shown to be negligible in comparison with the electrical ones.

Viscous drag.—For spherical particles one may use Stokes' law to find the force, $F\eta$, required to keep spherical particles moving at a velocity, v, in a medium of viscosity, η.

$$F\eta = 6\pi a\eta v = 6\pi a\eta \, dr/dt$$

Particle path in nonuniform fields in real dielectrics.—It is reasonable, as said earlier, to assume that the particle is in effective equilibrium with the various forces on it, i.e.

$$F_e + F_j + F_d + F_\eta = 0$$

Combining equations for these values as given earlier, we find

$$\frac{-k_e a^3 V_1^2 r^0}{r^3\left(\ln\frac{r_1}{r_2}\right)^2}\,\frac{-V_1 r^0 \frac{j_1 a^2 r_1}{r}\int_0^t \frac{dt}{r(t)}}{\ln\left(\frac{r_1}{r_2}\right)}$$

$$+ \frac{kT}{n}\cdot\frac{\partial n}{\partial r} + 6\pi a\eta\frac{dr}{dt} = 0$$

Deposition and dispersion of spherical particles in a cylindrical electrode cell in which ionic current flows.—For purpose of the present simplified calculations we neglect osmotic forces for particles of over 1 μ size. We return then to our assumption of equilibrium among the dielectrophoretic, electrostatic, and viscous drag forces.

$$F_e + F_j = F_\eta = 6\pi a\eta v$$

or

$$6\pi a\eta v = -4\pi\epsilon_0 K_1'\frac{(K_2'-K_1')a^3}{(K_2'+2K_1')r^3}(E_1 r_1)^2 +$$

$$\frac{4\pi a^3 t(E_1 r_1)^2(K_1')}{r^3(K_2'+2K_1')}\cdot\frac{\rho_2-\rho_1}{\rho_1\rho_2}$$

solving for $v = \frac{dr}{dt}$

$$\frac{dr}{dt} = v = \frac{(E_1 r_1)^2 a^2 K_1'\cdot 2}{3\eta(K_2'+2K_1')r^3}$$

$$\left[-\epsilon_0(K_2'-K_1') + \frac{t(\rho_2-\rho_1)}{\rho_1\rho_2}\right]$$

collecting terms in r and t and integrating gives

$$v = \frac{-a^2 A}{r^3} + \frac{a^2 Bt}{r^3}\cdot\frac{\rho_2-\rho_1}{\rho_1\rho_2}$$

$$r^4 - r_0^4 = -4a^2 At + \frac{2a^2 Bt^2}{\rho_1\rho_2}(\rho_2-\rho_1)$$

where r_0 is initial radial distance of particle from axis of cylindrical electrodes, r the "final" radial distance after time, t,

$$A = \frac{2}{3}\frac{(E_1 r_1)^2 K_1'\epsilon_0(K_2'-K_1')}{\eta(K_2'+2K_1')}$$

$$B = \frac{2}{3}\frac{(E_1 r_1)^2 K_1'}{\eta(K_2'+2K_1')}$$

The variation of $r^4 - r_0^4$, a measure of the particle excursion, is seen to be parabolic with time. The furthest inward excursion for a particle is $r_0 - r_1$, which occurs, say, at $t = t_1$.

At $t = t_2 = 2t_1$, the particle originally at r_0 will have drifted out again to r_0. This is because of the eventual overcoming of the attractive dielectrophoretic force, F_e, by the growing repulsive force F_j due to ionic charging of the particle.

After $t = t_2$, the particles will be further out than at the start of the experiment.

At $t = t_1$, the velocity of the particles due to all forces is zero. We may term this "sluff-off time."

$$t_1 = \frac{A}{B}\frac{\rho_1\rho_2}{(\rho_2-\rho_1)} = \epsilon_0\frac{\rho_1\rho_2}{\rho_2-\rho_1}(K_2'-K_1')$$

(therefore the sluff-off time, t_1, is independent of voltage but is directly dependent on the resistance of solution)

$$t_2 = \frac{2A\rho\rho'}{B(\rho'-\rho)}$$

and

$$r_{0\,max}^4 = r_1^4 + \frac{2a^2A^2}{B}\left(\frac{\rho_1\rho_2}{\rho_2-\rho_1}\right)$$

good up to $r_{0max} = r_2$ for conducting particles

In the absence of corona-type effects, the sluff-off time, t_1 is of course expected to be independent of the applied voltage for the dielectrophoretic forces due to initial polarization and current-induced polarization depend in the same way on the voltage.

The maximum "yield" or fraction of the tube contents swept out is

$$y_{max} = \frac{\text{volume swept out}}{\text{total volume available}}$$

$$= \frac{\text{amount of powder deposited}}{\text{total amount of powder available}}$$

$$= \frac{\pi(r_{0\,max}^2 - r_1^2)L}{\pi(r_2^2-r_1^2)L}$$

$$= \frac{\left(r_1^4 + \frac{2a^2A^2\rho_1\rho_2}{B(\rho_2-\rho_1)}\right)^{1/2} - r_1^2}{r_2^2-r_1^2} \text{ for } r_1 \leqq r_0 \leqq r_2$$

and if

$$r_1 << r_2$$

$$y_{max} \cong \left(\frac{2\rho_1\rho_2}{B(\rho_2-\rho_1)}\right)^{1/2}\frac{aA}{r_2^2}$$

At any time,

$$y = \frac{\left(r_{1_r}^4 + 4a^2At - 2a^2Bt^2\frac{\rho_2-\rho_1}{\rho_1\rho_2}\right)^{1/2} - r_1^2}{r_2^2-r_1^2}$$

and for

$$r_1 << r_2$$

$$y \cong \frac{a}{r_2^2}\left(4At - \frac{2Bt^2(\rho_2-\rho_1)}{\rho_2\rho_1}\right)^{1/2}$$

$$\cong \text{const.}\frac{V_1 a}{r_2^2}\left(\text{const. } xt - \text{const. } xt^2\frac{(\rho_2-\rho_1)}{\rho_2\rho_1}\right)^{1/2}$$

The above equations, then, suggest (*a*) that the sluff-off time, t_1, is relatively independent of voltage, (*b*) the sluff-off time, t_1, is directly proportional to the resistivity factor $(\rho_1\rho_2/\rho_1 - \rho_2)$, (c) the deposit will first form, then suddenly unform, (*d*) the amount of deposition should be proportional to (i) particle size, (ii) voltage, (iii) inverse area of cell, (iv) time at short times, and (v) should be of

short life if the system resistivity is low and the resistivities are rather different; or long, if the conductivity of the particles matches or is greater than that of the liquid.

It need hardly be said that the simple theory mentioned can be expected to apply only roughly to systems in which there is superimposed annular fluid flow. Unfortunately, for experimental convenience, the experimental data available are on systems with appreciable annular flow. Only rough analogy may be made with the theory which is for a system with no liquid flow. Experiments designed to test the hypotheses above are under way.

As one check of the theory we can calculate a sluff-off time, t_1, using reasonable values for the indicated constants

$$t_1 = \frac{A}{B}\rho = \epsilon_0\rho\ (K_2'-K_1')$$

Let

$$\rho = 1.3 \times 10^{15} \text{ ohm meter}$$

$$\epsilon_0 = 8.85 \times 10^{-12} \text{ farad/meter}$$

$$K_2' - K_1' = 5 - 2 = 3$$

$$t_1 = 8.85 \times 10^{-12} \frac{\text{coul}}{(\text{volt})\,(\text{m})} \times 1.3 \times 10^{15} \frac{(\text{volt})\,(\text{sec})\,(\text{meter})}{\text{coul}} \times 3$$

$$= 1.15 \times 10^4 \text{ sec, or about 3 hr.}$$

This value of 10^4 sec for an assumed specific resistance of 1.3×10^{15} ohm meters based on that measured for hexane in a similar system (11) turns out to be an entirely reasonable one and lends a measure of confidence to the theoretical results.

Continuous Separations of Suspensions by Nonuniform Electric Fields in Liquid Dielectrics

Herbert A. Pohl and Charles E. Plymale

Plastics Laboratory, Princeton University, Princeton, New Jersey

ABSTRACT

Suspensions of various solids in organic dielectric liquids can be separated continuously into their components by pulsating direct or alternating current electric fields of modest strength. The method and its important variables are described, together with the results observed for several systems. It is found, for example, that there exists a critical lower voltage and a critical upper voltage between which the operation must take place if appreciable separation is to take place. Best results are obtained if the dielectric constant exceeds that of the liquid. Among other separations possible, it is shown that zircon-rutile particle mixtures readily separate under conditions of dielectrophoresis. These materials cannot be separated by density or magnetic methods. A simple theory for the forces exerted on the particles sitting in combined gravitational and nonuniform electric fields is given.

Suspensions of various solids in organic dielectric liquids can be treated continuously by pulsating direct or alternating current nonuniform electric fields of modest strength to clarify or enrich the suspensions. Materials of differing polarizability can be separated. The methods and some of the important variables are described in this paper. It is found, for example, that there exists a critical lower voltage and a critical upper voltage between which operations must take place if appreciable separation is to occur. Best results are obtained if the dielectric constant of the suspended solids exceeds that of the liquid dielectric. An increase in conductivity of both liquid dielectric and of suspension is observed to occur in the voltage range where dielectrophoresis changes. The results are analogous in many respects to those obtained in earlier batch studies (1-4).

Experiments were, speaking broadly, carried out under two types of conditions. In one set, cylindrically symmetrical electrodes were used while close match of densities of powder and liquid was main-

tained. In such an electrode system, the force exerted on the particles depends strongly ($1/r^3$) on the distance from the central electrode axis. In the other set of experiments, an attempt was made to operate between electrodes of such design that the force on the particles did not depend on geometrical position in the channel in which they moved ("isomotive" cell), while the particles fell freely through a liquid of rather lower density than themselves.

Experiments in the Cylindrical Electrode Geometry

As outlined above, particles of various materials were suspended in liquid dielectrics of closely matching density. These suspensions were then subjected to the action of the nonuniform field existing between cylindrically symmetrical electrodes. Flow was continuous and axial in the cell. The feed was at the top. The liquid was withdrawn simultaneously at the bottom from two outlets, one drawing material from the region close to the central electrode and the other drawing material from the periphery (see Fig. 1). The concentration of suspended solids in the two existing streams was compared optically using an electrophotometer. A plot of the observed concentration ratios showed that little effect was to be noted until at least a somewhat critical value of voltage was applied across the electrodes. Beyond this region, a sharp increase in pullout of material was noted at the axial region of the cell as the applied voltage was increased. This increase continued with increase of voltage until a rather sharp maximum was observed, following which a rapid decrease in pullout was displayed until, at a high and rather critical voltage, a return to equality of concentrations of the two exciting streams was observed.

A, high potential (central) electrode; B, feed inlet; C, grounded outer electrode, consisting of bare wire wrapped onto glass tube; D, central takeoff tube; E, insulating (Teflon) central electrode support, perforated to pass suspension of particles; F, peripheral product vent; G, central product vent.

The suspensions examined were (*a*) spherical particles of selected size ranges, e.g., 100-140 U.S. mesh, of polyvinyl chloride suspended in CCl_4-benzene mixture (see Fig. 2), and (*b*) powdered ammonium chloride particles of selected size range suspended in CCl_4-benzene mixture of similar density (see Fig. 3).

Current measurements made on the above systems showed the d-c current to be very small, about

1.0 to 100 $\mu\mu$a or slightly higher. The d-c current was measured using a Kiethley electrometer and appropriate shunts. The current was observed to be ohmic up to about the voltage at which the particles began to respond vigorously to the field. At this point a marked rise in current flow was observed, indicating a second mechanism of conduction had appeared (see Fig. 2-4). The data of Fig. 4 were made for comparison and were obtained on the pure liquid dielectric. The observed slight discontinuity in the current vs. voltage curves in the case of the pure liquid has not been elucidated. The discontinuities for the cases of solids present are rather larger. Alternating current measurements made on the above systems showed, as expected, that the dielectric loss current (10^{-9} amp) was too small to be detected easily in the presence of the relatively large charging current due to capacitance and stray inductances in the system (about 10^{-5}). Figure 5

shows this for 60 cps current vs. voltage for several inner electrode sizes.

Experiments in "Isomotive" Cell Geometry

In these experiments, an attempt was made to have the solid particles pass through the nonuniform field cell in a long narrow tray in between electrodes of such a shape as to produce a force which was constant electrically and directed in opposition to that of gravity. Materials in powder form were then shaken down along this long narrow tray. The tray was given a slight tilt across its narrow dimension and a large inclination along its length (see Fig. 6 and 7). The dielectrophoretic force tended to hold particles up against the slight gravity pull exerted due to the tilt. Those particles most strongly pulled electrically would exit from

the lower end of the tray at one (uppermost) edge of the channel; those pulled least by the electrical force would tend to exit from the lower end of the tray at the other slightly lower edge of the channel. The angle of tilt was roughly estimated as 3° in experiments *A*, *B*, and *C* below. In experiments *D-H*, the tilt angle was more carefully measured by protracting.

The whole tray and electrode system was kept immersed in a low viscosity liquid dielectric (benzene or cyclohexane for experiments *A*, *B*, *C*; carbon tetrachloride for experiments *D-H*). Powders were fed in at the upper end and removed continually by sampling tubes at the lower end. After testing a number of cell designs to at least partially optimize performance, the following results on powders were obtained.

(*A*) Polyvinyl chloride powder was observed to be collectable at will in either of the exits from the cell, depending on the voltage applied. At very low or nil voltages, all of the powder collected in the lower exit. At medium voltages higher and higher fractions of the powder could be collected in the upper exit until, at about 1300 v, about 90% of the existing powder was observed to pass out the upper exit. As the voltage was increased beyond this range, the process was observed to become less selective, the powder behavior more erratic, and the proportion collected in the lower exit increased until the cell acted with very low selectivity (see Fig. 8).

(*B*) A powdered mixture of $Na_2Cr_2O_7 \cdot 2H2O$ and TiO_2, both of mesh size less than 80 was fed into the hopper and cell. At nil voltage very little of either kind of particle was observed to pass into the upper exit. As the voltage was increased a larger and larger fraction of TiO_2 was collected at the upper exit, until at about 300 v a maximum was observed. The proportion of the dichromate passing into the upper exit remained low until about 1000 v. At voltages higher than this (up to 2000 v a.c. rms) a lack of selectivity of the cell was observed, and a mixture of both solids was observed to go into the lower and upper exits (see Fig. 9).

(*C*) A mixture of 60-100 mesh rutile mineral (gray-black form of TiO_2) with 60-80 mesh polyvinyl chloride was passed through the cell. At nil voltage, neither type of particle passed out the upper exit. As the voltage was increased, a greater and greater fraction of the rutile passed into the upper exit, until at a voltage of about 750 v a.c., rms, slight quantities of PVC powder were observed to accompany it out the upper electrode. At higher voltage, as before, less selectivity in the separation was observed (see Fig. 10).

(*D*) The "operating curves" for the pure single components were determined by measuring the volume fraction of feed material which left by the high exit at various applied voltages. Samples of powders passing 100 U. S. mesh and resting on 140 U. S. mesh (nominal 127 μ average particle diameter) were used throughout the following experiments (see Fig. 11-14, e.g.). Following these determinations of the behaviors of the single components, the ability of the isomotive cell to separate 1:1 v/v mixtures of these powders was then determined. Compositions of the materials exiting from the low and high exits were determined by counting under a microscope. The following results (*E-H*) were obtained.

(*E*) *Silicon carbide-aluminum oxide*: Alumina and carborundum obtained from the Bay State Abrasives Company was screened and graded. Separation by dielectrophoresis of the carborundum from the alumina was found to be relatively easy. Figure 15 shows the percentage composition of the streams of powder coming from the high and low exits as a function of applied voltage. It may be seen that the carbide is readily pulled over to the high exit in preference to the alumina. At very

low voltages, neither kind of particle succeeds in reaching the high exit. At low voltage the carbide in pure form succeeds in coming out the high exit. As the voltage increases beyond this point, a larger and larger fraction of it goes out the high exit, until as the lower critical voltage for the alumina is

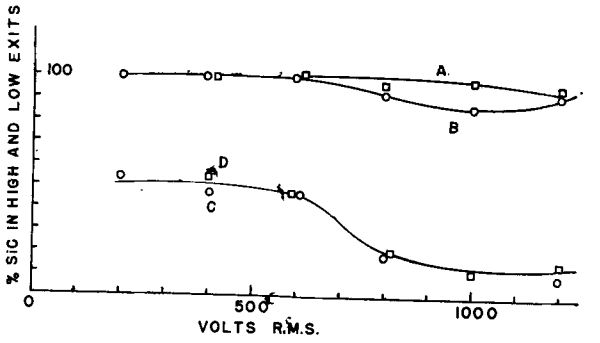

Fig. 15. Behavior of silicon carbide-aluminum oxide particle mixtures in isomotive cell. Composition at (A) high exit, 6° tilt; at (B) high exit, 3° tilt; at (C) low exit, 3° tilt; and at (D) low exit, 6° tilt.

reached, a trace of alumina appears in it. As the voltage applied is increased still further almost all of the carbide and more and more of the alumina goes out the high exit, making the high exit stream steadily richer in alumina. The lower exit now delivers nearly pure alumina.

(*F*) *Silicon carbide-silicon dioxide*: Silicon carbide, as above, and purified "glass grade" sand, "Berkeley Fine Dry Special" from the Pennsylvania Glass Sand Corporation, seived and graded to pass 100 U. S. mesh and rest on 140 mesh (nominal 127 μ average particle diameter) were found to be easily separable by dielectrophoresis. Determination of the "operating curve" for the pure SiO_2 showed that in the present design of isomotive cell it would not come out of the high exit at any voltage applied if the tilt angle was as large as 3°. The curve for pure SiC is shown in Fig. 11. Separation curves are shown in Fig. 16. The behavior over-all resembled that for the Al_2O_3-SiC mixtures except for the nearly complete absence of SiO_2 in the upper exit. Some carry-over was experienced at the higher voltages, however. Experiments showed that SiO_2 particles alone did not move out the higher exit under any conditions of voltage applied at 3° tilt or greater.

(*G*) *Silicon carbide-calcium fluoride*: This mixture was studied because it formed an interesting example of an otherwise difficult separation. The closeness of the densities (SiC) $d_{20} = 3.17$; CaF_2, $d_{20} = 3.18$) and the absence of particularly outstanding magnetic properties precludes density or mag-

netic separations. As can be seen from Fig. 17, these two solids are readily separable by dielectrophoresis in the isomotive cell. CaF_2 like SiO_2 does not move out the high exit if alone at tilts of 3° or more.

(*H*) *Zircon-rutile*: This mixture of minerals which cannot be separated by density or magnetic methods proved readily separable by dielectrophoresis in the isomotive cell. Results are shown on Fig. 18. The separations were done on zircon sand from Yamba Beach, Australia. As received, it contained about 21% rutile from which it was readily separated by a preparatory cleanup run. Rutile, mineral, crushed and graded was used in making 1:1 v/v mixtures for this study. Zircon, like SiO_2, does not move out the high exit if alone in the cell at tilts of 3° or more.

Discussion of Results

It may be considered that forces on the particles in the tray come from at least five causes:

1. Osmotic.
2. Gravitational (corrected for bouyancy).
3. Dielectrophoretic, arising from the effect of the nonuniform electric field on the field polarized neutral particles.
4. Dielectrophoretic, arising from the effect of the nonuniform electric field on the current-induced (or produced) dipoles on the particle surface.
5. Electrophoretic, arising from the effect of the electric field on *excess* charges on the particles. Excess charges, may arise from several possible causes. A charge unbalance may arise from current-induced charging accumulating initially by image force adsorption in equal numbers, followed by local discharge due to "corona" effects at sharp edges on the particle. A charge unbalance may also arise from other causes such as contact or near contact with electrodes or other particles bearing an unbalance of charges. Still other mechanisms are possible. The nature of conduction in these organic liquid dielectrics is not completely clear, although ionic mechanisms appear to be prominent (6). The appearance of a break in the current-voltage curve of the liquid dielectric alone (Fig. 2-4) indicates that there may be some change in type of conduction even in the liquid without large amounts of suspended particles. This opens the question as to the cause of the several breaks observed in the curves for suspensions. It may be that in the present experiments that traces of powder impurity were present in the liquid dielectric studied. It may also be that the effect observed is due entirely to phenomena characteristic of particle-free liquid. Further studies of this intriguing problem are under way.

A simplified theory of the net force at any time after arrival in the field is given below for spherical particles, excluding the more difficult calculable electrophoretic forces arising from more or less random charging, and also excluding osmotic or concentration gradient forces which are generally negligible for particles above about 0.2 μ diameter.

The gravitational force, F_g, effective along the bottom of the tilted tray is

$$F_g = -i\frac{4}{3}(d_2-d_1)a^3 g \sin\alpha \qquad [1]$$

where a is the particle radius, d_2, d_1 the densities of particle and liquid dielectric, respectively, g the gravitational constant, and α the angle of tilt from horizontal.

As shown in earlier work (2) the dielectrophoretic force, F_e, arising from induction in a nonuniform field on neutral particles is

$$F_e = 2\,a^3 K_1'\epsilon_0\left(\frac{K_2'-K_1'}{K_2'+2K_1'}\right)\nabla|E|^2 \qquad [2]$$

where K_1', K_2' are the relative dielectric constants of the liquid and solid, ϵ_0 is the permittivity of free space, and E the electric field at the particle.

In accord with results described elsewhere (5) it can be shown that the dielectrophoretic force, F_j, arising from the effect of a nonuniform field on current-induced dipoles on the surface of spherical particles is

$$F_j = i(\mu\cdot\nabla|E|) \qquad [3]$$

where

$$\mu = 4\pi/3\; a^3 j\, t \qquad [4]$$

μ is electric moment due to current-produced charge accumulation, and j is the net current arriving at surface of particle.

$$j = j_1 - j_2 \qquad [5]$$

j_1, j_2 is the current in medium and particle, respectively, i the unit vector in horizontal direction (unity if $\nabla|E|$ coincides with tray bottom direction), and t the time of flow of current.

By Ohm's law

$$j_1 = E_{1z}/\rho_1 \quad [6]$$

$$j_2 = E_{1z}/\rho_2 \quad [7]$$

where E_{1z} is the electric field at particle-liquid interface

$$E_{1z} \cong E\left(\frac{3K_1'}{K_2'+2K_1'}\right) \quad [8]$$

during most of the charging period and ρ_1, ρ_2 are the specific resistivities of the liquid and particles, respectively.

Combining equations

$$F_j = 2\pi a^3 t\left(\frac{K_1'}{K_2'+2K_1'}\right)\left(\frac{\rho_2-\rho_1}{\rho_1\rho_2}\right)\nabla|E|^2 \quad [9]$$

The net force on the particle in the direction along the tray bottom is then, F_{net}

$$F_{net} = F_e + F_j + F_g \quad [10]$$

$$F_{net} = 2\pi a^2\nabla|E|^2\left(\frac{K_1'}{K_2'+2K_1'}\right)\left[\epsilon_0(K_2'-K_1') + t\frac{(\rho_2-\rho_1)}{\rho_2\rho_1}\right] - i\frac{4\pi}{3}a^3 g(d_2-d_1)\sin\alpha \quad [11]$$

As a test of the above equations, we may examine a comparison of the calculated and observed forces. The electrical and gravitational forces are observed to be in balance, for example, when the voltage is just large enough to cause the particles to begin to go out the upper exit at a given tilt. Table I contains data relevant to this comparison. The voltage values, listed as "V critical" were found from use of data in Fig. 11, 12, 14, and 18, and were chosen at the point where the first particles could be detected in the higher exit during a 3° tilt. The value for the dielectric constant of silicon carbide is estimated from its behavior. The values of $\nabla|E|^2_{max}$ are those[1] calculated for a cylindrical electrode of radius 0.60 cm spaced 0.241 cm from a flat plate. The values of the calculated electrical and gravitational forces, F_e and F_g, were obtained using the given equations.

Table I. Comparison of the calculated electrical (dielectrophoretic) force and gravitional force on particles in a tilted tray (3° tilt) in a nonuniform electrical field due to combined flat and cylindrical plates

Substance	Density, g/cc	Dielectric constant	$V_{critical}$, v(rms)	$\nabla\|E\|^2$, v/m² ×10⁻¹²	F_e, newtons/m³/unit vol.	F_g, newton/m³/unit vol.
SiC	3.17	(10)	500	2.40	(38.2)	810
Al_2O_3	4.0	8.6	800	6.12	87.6	1230
TiO_2	4.26	70	150	0.216	5.8	1370
$ZrSiO_4$	4.7	12.5	600	3.44	61.8	1590

That the calculated values for the electrical force are less than those calculated for the gravitational at balance is believed to be due to what may be termed the "bunching effect." The electrical force is that calculated for lone spherical particles which are so small as to leave the acting electrical field unaffected. The experimental observations of the critical voltages were obtained instead using rather concentrated streams of particles. It is believed that considerable particle-particle and particle-field interactions exist in such circumstances which greatly accentuate the nonuniform field force on the aggregates. This is evidenced, for example, by the bridging effects already noted. This problem is under further study and it is hoped that further light can be shed on this phenomenon.

December 1960 Discussion Section

A Discussion Section, covering papers published in the January-June 1960 JOURNALS, is scheduled for publication in the December 1960 issue. Any discussion which did not reach the Editor in time for the June 1960 Discussion Section will be included in the December 1960 issue.

Those who plan to contribute remarks for this Discussion Section should submit their comments or questions in triplicate to the Managing Editor of the JOURNAL, 1860 Broadway, New York 23, N. Y., *not later than September 1, 1960.* All discussion will be forwarded to the author(s) for reply before being printed in the JOURNAL.

Electrodeposition of High-Purity Chromium from Electrolytes Containing Fluoride or Fluosilicate

N. Ryan

Aeronautical Research Laboratories, Australian Defence Scientific Service, Department of Supply, Melbourne, Australia

ABSTRACT

Investigation of the variables affecting the laboratory scale deposition of chromium from chromic acid electrolytes containing fluoride or fluosilicate has enabled the optimum conditions for the production of high-purity chromium (0.03-0.04 wt % oxygen, 0.0008-0.002 wt % nitrogen) at the highest current efficiency (38-45%) to be determined. This current efficiency is much higher than the 8-10% in the chromic acid-sulfate electrolyte in which chromium of a similar grade can be produced.

Continuous electrodeposition in a larger cell showed that the current efficiency in fluoride-containing electrolytes decreased progressively with time to a steady 25-30%. No explanation has been found for this decrease. After steady conditions have been achieved, the advantages in current efficiency of the fluoride over the sulfate bath remains substantial.

It has been known for several years that fluorides and fluosilicates are effective catalysts in chromium plating solutions. Electrolytes containing these anions have been used commercially, particularly in Germany, but they have not yet been used for the purpose of producing high-purity chromium.

In these laboratories the pure chromium (0.02 wt % O_2, 0.002 wt % N_2, 0.001 wt % max. metallic elements including C, S, Si) required for experimental work on the development of chromium-base alloys is produced from chromic acid electrolytes containing sulfate (1) at current efficiencies of 8-10%. It is known that improved current efficiencies are obtained when using electrolytes containing either fluoride or fluosilicate, and it was therefore decided to investigate solutions containing these anions to determine whether or not they could be used to produce a high-grade chromium deposit.

Work by Bilfinger (2) (reviewed by Hood) (3) on baths containing fluoride and fluosilicate resulted in a series of curves and tables which revealed the optimum deposition conditions necessary to maintain the highest current efficiencies at 55°C. In the present study, an electrolyte temperature of 100°C was chosen for the preliminary investigations, after a consideration of the results of work carried out by Brenner, *et al* (4). These workers showed that the relationship between electrolyte temperature and oxygen content of chromium deposited from chromic acid solutions containing fluoride was similar to that associated with the chromic acid-sulfate electrolytes, i.e., increasing electrolyte temperature resulted in a decrease in the oxygen content of the chromium deposit. The experimental program was therefore designed to yield, for a bath temperature of 100°C, information of a similar character to that previously obtained by Bilfinger at 55°C. This was done by studying independently each variable affecting the efficiency of deposition and purity of the product.

For ease of reading and brevity in this report the expressions "fluoride-containing electrolyte" and "chromium deposited from an electrolyte containing fluoride" will in general be replaced by the terms "fluoride electrolyte" and "fluoride chromium," respectively. The terms "fluosilicate electrolyte," "sulfate electrolyte," "fluosilicate chromium," and "sulfate chromium" have corresponding meanings.

Apparatus

The apparatus, holding 250-300 ml of solution, consisted of a glass vessel with inlet and outlet arms which were used for the electrode connections and for the introduction of the electrolyte. Gases evolved during electrolysis escaped via a reflux condenser, which assisted in maintaining a stable electrolyte concentration by eliminating fume and evaporation losses. Since fresh electrolyte was used for each experiment and deposition runs were limited to 1 hr, no precautions were necessary to counter fluosilicate contamination arising from the glass container. Chemical analysis of the deposited chromium confirmed the absence of silicon. The use of fresh electrolyte also helped to reduce the build-up of trivalent chromium, which would have introduced a further significant variable.

The electrolytes were prepared from high-grade chromic acid containing the following nominal impurities: 0.02% SO_4, 0.004% NO_3, 0.01% Fe, and 0.1% Na. Fluoride was added as hydrofluoric acid and fluosilicate as the potassium salt.

Chromium was deposited on ½ in. diameter copper tubes which were subsequently dissolved by digestion in nitric acid. High-purity lead was first used as the anode material, but this was found to become inactive within a very short period. It was therefore replaced by a 7% tin-lead anode, as used in some commercial fluoride baths. A heavy scale formed on this anode, and in the early test runs this was removed. However this practice was found to

be unnecessary as the scale did not in any way affect the activity of the anode.

For a preliminary study of larger scale production, a plating cell consisting basically of an 8 in. diameter round bottomed "Hysil" glass vessel holding up to 10 l was constructed. A lid of laminated fiber board, coated with a heavy layer of polyvinyl chloride, served as a covering for the cell and held four 12 in. double-surface reflux condensers, the copper cathode (1 in. tube) and electrical connections to the annular anode made from a 7% tin-lead alloy (6 in. diameter, 3/8 in. thick). The volume of electrolyte normally used was 8 l, and as in the case of the small cell no precautions were taken to protect the glass from the action of the fluoride.

Power to this cell was supplied by a 250 amp capacity selenium rectifier. No heating of the electrolyte was necessary, other than bringing up to temperature prior to the commencement of a run, as the power input (200 amp at 5-6 v) was sufficient to maintain a boiling solution. Arrangements for continuous operation were not developed and plating times were limited to 6-7 hr runs.

Analysis

Oxygen analysis of the deposited chromium was carried out by the Adcock method and nitrogen was determined using the semi-micro Kjeldahl method. Fluoride and fluosilicate concentrations in the bath were determined by a modification of the steam distillation process used by Reynolds and Hill (5).

Conditions of Operation

The current efficiency-catalyst acid curves obtained by Bilfinger (2) at 55°C gave strong indications of the sensitivity of current efficiency to

both fluoride and fluosilicate concentration in chromic acid electrolytes. For tests at 100°C, a chromic acid concentration of 300 g/l was selected, this being the standard concentration used in the production of sulfate chromium. Results are recorded in Tables I and II. The efficiency values are plotted against catalyst concentration in Fig. 1. The curve for sulfate electrolytes at 82°C is incorporated in Fig. 1 for comparison.

The results of the above test runs established the catalyst-chromic acid ratio at 1.75% for the fluoride electrolyte and 2% for the fluosilicate electrolyte. Several chromic acid solutions were prepared at concentrations ranging between 100 and 500 g/l CrO_3 each containing the required catalyst addition at the ratio cited above. These solutions were then electrolyzed at current densities of 880-950 amp/ft^2. The electrolyte temperature was maintained at 100°-102°C. The current efficiency data obtained are recorded in Tables I and II and illustrated graphically in Fig. 2.

From a study of the results obtained during this test series, chromic acid solutions of the following composition were prepared: (*a*) 300 g/l CrO_3, 5.25 g/l F; and (*b*) 300 g/l CrO_3, 6 g/l SiF_6. These solutions were electrolyzed at 100°-102°C using current densities ranging from 600 to 1600 amp/ft^2. Results are recorded in Tables I and II and shown in Fig. 3.

All of the above experiments were carried out in boiling electrolytes and the high current efficiencies obtained were particularly interesting. The association of high current efficiency with high temperature differed markedly from the behavior of sulfate electrolytes, i.e., decreasing efficiency with increasing temperature, and warranted further investigation. Hence electrolytes were prepared from 300 g/l solutions of chromic acid containing either 5 g/l fluoride or 6 g/l fluosilicate, and these were electrolyzed at various temperatures using current densities between 850 and 1010 amp/ft^2, as detailed in Tables I and II. The temperatures given in Tables I and II were measured by a thermometer attached to the cathode. It is possible however that the actual temperature at the cathode surface was slightly higher than those registered. The results of these experiments are given in Fig. 4, together with sul-

fate-electrolyte data (6). In the fluosilicate electrolyte, deposits at temperatures below 65°C were powdery, and the calculated current efficiency was thus doubtful. This may have been due to too high a current density which could result in some hydrolysis at the electrode surface.

The information obtained from these tests was both unexpected and interesting in that for both the fluoride and fluosilicate electrolytes current efficiency increased to a maximum value toward 100°C.

Gas Content of Electrodeposits (Oxygen and Nitrogen)

Oxygen.—Analysis of chromium deposited from the fluoride and fluosilicate baths at various temperatures showed that the oxygen content varied with temperature in much the same way as for sulfate chromium, i.e., as the electrolyte temperature was increased the oxygen content decreased rapidly between 50° and 80°C and then more gradually toward 100°C.

Results are recorded in Tables I and II and plotted in Fig. 5 together with the corresponding oxygen-temperature curve for a sulfate electrolyte. From these curves it is seen that while fluoride and fluosilicate chromium can be deposited with low oxygen content (0.03-0.05 wt %) they are unlikely to have as low an oxygen content as sulfate chromium produced under the optimum conditions. Against this, however, are the remarkably high current efficiencies of the fluoride and fluosilicate baths. At 100°C the efficiency of the sulfate electrolyte is 3% as compared with 40-45% for the fluoride and fluosilicate electrolytes.

Nitrogen.—The results suggest that the nitrogen content tends to decrease with increasing electrolyte temperature. However, this effect is doubtful, and other work (7) has shown that when higher nitrate impurity (0.1%) is present in the bath, the nitrogen content of the chromium is unaffected by electrolyte temperature.

Analysis of the chromium deposits from electrolytes of varying catalyst concentrations showed that the oxide impurity was particularly susceptible to changes in fluoride and fluosilicate concentrations. Low oxygen values occurred within the same catalyst concentration ranges which gave highest current efficiency. These values are recorded in Tables I and II and plotted against catalyst-chromic acid ratio in Fig. 6. Similar effects have been noted for the oxygen content of sulfate chromium, as is also indicated in Fig. 6. The nitrogen content was not affected.

Results recorded in Tables I and II show that variation in chromic acid concentration and current density have little or no influence on either the oxygen or nitrogen content in fluoride or fluosilicate chromium.

Electrodeposition from Fluoride Electrolytes in a 10-l Glass Cell

Using the information obtained from the preceding part of this investigation it was decided to carry out some preliminary tests in a larger scale apparatus as a step toward regular chromium production

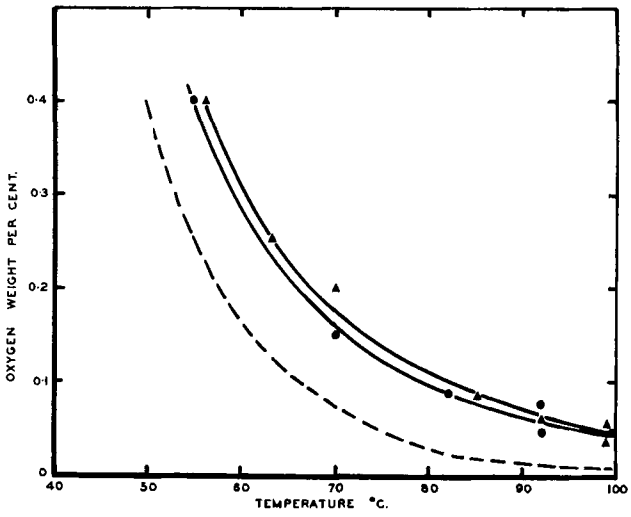

Fig. 5. Decrease in oxygen content with increasing electrolyte temperature. •, Fluoride chromium; ▲, fluosilicate chromium; - - - - -, sulfate chromium.

from fluoride containing electrolytes. Table III which lists details of some of these preliminary runs shows that the current efficiency falls successively as the bath ages.

Factors which could have some influence on this current efficiency decrease are:

1. Trivalent chromium concentration which showed increasing values corresponding to the decreasing current efficiency results (see Table III).
2. The considerable build-up of nodules and the treeing of the deposits which upsets the effective current density by increasing the over-all cathode surface area and which produces a nonuniform distribution of current density over the cathode surface. In addition some loss of chromium results from the detachment of nodules from the cathode.
3. The possible formation of fluosilicate contamination by the chemical action of the fluoride electrolyte on the glass vessel.

Influence of trivalent chromium concentration.—In order to study the effect of this variable on the current efficiency a solution of known trivalent chro-

mium concentration was prepared by adding a known amount of Cr_2O_3. This solution was electrolyzed in the small experimental cell. As indicated in Table IV, a current efficiency of 42% was recorded, which apparently indicated that the trivalent chromium concentration did not influence the current efficiency. However, reconsidering this factor it was thought possible that by introducing trivalent chromium into solution as Cr_2O_3, the trivalent chromium complex formed might not be the same as that which exists in the electrolyte as a result of natural aging. Hence a further solution was prepared in which the trivalent chromium was increased by artificially aging the electrolyte using a large cathode surface area separated from a small anode surface by means of a porous porcelain pot. In this way solutions containing 15 and 27 g/l trivalent Cr were prepared for electrolysis in the small cell. The results, recorded in Table IV again show that trivalent chromium added to the bath does not affect the current efficiency significantly.

Current density and nodule formation.—The above tests suggested the possibility that in the large cell much more chromium was being lost as nodules than had been expected. Work with sulfate electrolytes (1,6) has shown that nodule formation is influenced by current density, lower densities yielding smoother deposits. Tests were therefore carried out with the fluoride electrolyte at lower current densities in the large cell for 6- and 7-hr runs. It was noticed that treeing and nodule formation were reduced. In this way the effective current efficiency was increased to some extent as shown in Table V, but it did not return to the high values obtained (40-45%) in the survey investigation.

Fluosilicate contamination in fluoride electrolyte.—As stated previously no precautions were taken to protect the glassware from etching by the fluoride in the electrolytes used. In the 1-hr experimental runs this factor was considered negligible since the time was short and fresh electrolyte was used for each test. An analysis of the electrolyte which had been in the larger 10 l glass cell for a period of approximately 3 months showed a fluosilicate content of the order 0.6-0.7 g/l SiF_6. This represents a tie-up of 0.5 g/l fluoride which would upset the effective fluoride-chromic acid ratio. This fluosilicate contamination may have contributed to the continual decrease in current efficiency but only to a minor extent, by producing a slight variation in the chromic acid catalyst ratio which could be eliminated by using an inert cell lining.

Table IV. Effect of trivalent chromium concentration

310	5.46	910	34.5
305	5.62	800	33.5
306	5.60	660	34.8

Effects of Impurities in the Electrolyte

Sulfate.—Since high-purity chromic acid would be uneconomical for full-scale chromium production, some tests were carried out using a commercial grade of chromic acid having the following impurity levels: 0.5-0.8% SO_4, 0.003% NO_3, and less than 0.5% metallics. This was found to produce chromium at much lower current efficiencies than those obtained when pure chromic acid was used. It has been reported (2,8) that sulfate additions in fluoride and fluosilicate electrolytes are associated with a decrease in current efficiency. This led to a series of experiments in which sulfate was (*a*) purposely added to a pure chromic acid electrolyte and (*b*) completely removed from a commercial chromic acid electrolyte by precipitation with barium hydroxide, but without introducing excess barium as a further variable. Results are given in Table VI and show that the sulfate impurity in commercial chromic acid appreciably reduces the current efficiency of the fluoride electrolyte.

Tin.—The use of a 7% tin-lead alloy as an anode in the electrodeposition of fluoride chromium introduced the possibility of tin traces being entrapped in the chromium. Using spectrographic and polarographic analysis, 0.005 wt % tin was detected in the chromium. This was not considered of a sufficiently high value to influence the properties of the metal. Further tests were carried out using a pure tin

Table VI. Influence of electrolyte sulfate impurity

Electrolyte	Nominal composition CrO_3, g/l	F, g/l	SO_4, g/l	Current efficiency, %
Commercial CrO_3	300	5	0.65	26
	300	5	0.24	31
Commercial CrO_3 SO_4 pptd. with $Ba(OH)_2$	300	5	Trace	42
Pure CrO_3 with added SO_4	300	5	0.56	29

anode, but even in this extreme case the deposited chromium showed only 0.08% tin. These results are given in Table VII, which also shows that plating ceased during the run with the tin anode. This suggested that while tin might not cause serious contamination of the electrodeposit, it could have a deleterious effect on the performance of the electrolyte. This was confirmed by tests in electrolytes deliberately contaminated with tin, where the current efficiency decreased with increasing tin content, as indicated in Table VII. This factor is discussed further in the following section.

Alternative Anode Materials

As demonstrated above tin contamination of the electrolyte resulted in an efficiency decrease and may arise when using 7% tin-lead anodes continuously. Therefore several alternative anode materials were studied, the primary requirements being an alloy which would remain active and not contaminate either the electrolyte or the deposit. Alloys examined were Pb-7% Sn, -4% Sn, -1% Sn, and 0.5% Sn; Pb-2% Ag; Pb-2% Zn; Pb-2% Ag -2% Zn; Pb-1% Na, and Pb-0.5% Te. The alloys which proved to be most resistant to the fluoride solutions were the Pb-Sn alloys (0.5-4% Sn), Pb-Te, Pb-Ag, Pb-Na. The Pb-Na alloy was particularly brittle and for this reason was not selected. Using the Pb-2% Ag anode, silver was detected in the chromium. It was found that the concentration of tin in the lead anode could be reduced to 0.5% and still maintain an active anode. The probable level of contamination using this anode composition was considered negligible, and it was used in all further tests.

Chromium Deposition in a Polyethylene Lined Plating Cell

Because of the danger of fluosilicate contamination, inert lining materials were investigated. Polyethylene was found to be resistant to the highly active solution but it softened at the high temperatures. However, providing the lining was well supported this was not a major problem.

A polyethylene-lined vessel was designed which consisted essentially of a steel tank (10-12 l capacity) lined first with lead and then with polyethylene. To a lid, which was similarly lined, were attached the electrode inlets and the outlet for waste gases which included a polyethylene-tube spiral condenser. During electrolysis the lid was sealed to the cell with a polyethylene gasket.

The electrolyte, containing 300 g/l CrO_3-5.4 g/l F, was prepared from commercial grade chromic acid, the sulfate impurity being precipitated with barium hydroxide. The results of deposition in this bath are listed in Table VIII; all runs are of 6-7 hr duration. Simultaneous tests, using sample electrolytes from the large bath, were carried out in the small experimental cell and showed higher efficiency values (see Table VIII). These tend to show that the time for deposition or thickness of deposit is the main factor in the low efficiencies recorded in the larger scale cells. The chromium produced in the large cell was of a high order of purity and the current efficiency, although lower than anticipated, remained relatively constant during the tests.

Properties of "Fluoride" Chromium

Chromium deposited from the fluoride electrolyte has been arc-cast, extruded, swaged, and rolled using procedures similar to that already reported (9,10) for chromium deposited from the chromic acid-sulfate electrolyte. Thus it was possible to compare the properties of cold-worked and recrys-

	0.025	0.002	−87	121	219	115

Table X. Room-temperature tensile properties of rolled "sulfate" and "fluoride" chromium

Material	Tensile strength, psi	Elongation on $4\sqrt{\text{area}}$, %	Reduction in area, %
Sulfate Chromium	100,000	40	50
Fluoride Chromium	88,000	57	55

tallized fluoride chromium with those of the sulfate material. The ductile-brittle transition temperatures and tensile properties of these materials in the form rolled strip are listed in Tables IX and X, and show that the fluoride chromium can be fabricated equally as well as chromium deposited from the chromic acid-sulfate electrolyte and has superior ductility values.

Discussion

The most puzzling feature of this investigation is the decrease in current efficiency on changing from the small test cell experiments to the pilot plant stage. At first sight it would appear that this current efficiency decrease was excessive and that some simple explanation might be found in that variables such as trivalent chromium concentration, fluosilicate contamination, or tin impurity could have a deleterious influence. However as has been shown above none of these factors had any appreciable influence on the current efficiency. It was demonstrated that the trivalent ion concentration did not have any influence. The source of the fluosilicate contamination was removed by using a polyethylene lined vessel, and tin contamination was greatly reduced by replacing the 7% tin-lead anode by one containing 0.5% tin.

In view of the above it was considered that the major effect might be due to the nodule growth, treeing, and the general roughness associated with the deposition of thicker coatings than those obtained in the small cell. By comparison with the sulfate bath (1, 6) where efficiencies of the order 14% are obtained for runs of 1 hr but drops to 6-7% for periods up to 72 hr, it may well be anticipated that a current efficiency of 42% in the small fluoride bath for hourly runs could drop to 20% for plating times of say 20 hr giving an equivalent thickness of chromium to that obtained in the sulfate bath. This current efficiency is in fact very close to the one obtained in this investigation which was 25% for 8-hr runs in the pilot plant equipment. By analogy with the operation of the sulfate bath where it is possible, by improved control of the operating variables (10) and also continual purification of the electrolyte by ion exchange, to obtain current efficiencies of 9-10% it should be possible to achieve current efficiencies of 27-30% in the fluoride bath.

It is true that this comparison does not in any way explain why treeing and general surface roughness occurs in aged baths, but it does help to put the drop in efficiency found in the fluoride bath in perspective. An explanation of the phenomenon must wait on a more fundamental attack on the more basic factors operating in the electrodeposition of chromium for considerable periods of time.

In the fluoride electrolyte a minimum current efficiency at electrolyte temperatures between 70° and 80°C was noted. The latter temperature is the maximum at which previous investigators had worked when examining plating conditions for fluoride electrolytes. Because up to this temperature the current efficiency in fluoride electrolytes shows the same downward trend as in sulfate electrolytes it has presumably been concluded that the current efficiency in the former would continue to decrease as the temperature is raised. No explanation for the minimum in the current efficiency-temperature curve can be given on the basis of the present results.

Conclusions

1. The optimum conditions for the deposition of high-purity chromium were (*a*) for the chromic acid-fluoride electrolyte: electrolyte composition, 300 g/l CrO_3, 5.25 g/l F; current density, 1150 amp/ft^2; electrolyte temperature, 100°-102°C; giving a current efficiency of 40-45% in 1-hr runs. (*b*) for the chromic acid-fluosilicate electrolyte: electrolyte composition, 300 g/l CrO_3, 6 g/l SiF_6; current density, 1150 amp/ft^2; electrolyte temperature, 100°-102°C; giving a current efficiency of 38-40% in 1-hr runs. These conditions yielded chromium containing 0.03-0.04 wt % oxygen and 0.0008-0.002 wt % nitrogen.

2. The oxygen content of the chromium was sensitive to changes in catalyst concentration. The catalyst concentration which gave the maximum current efficiency also gave the minimum oxygen concentration. This impurity concentration decreased with increasing electrolyte temperature in the same manner as found in the sulfate electrolytes, but the average minimum value was higher (0.03 wt %) than for the sulfate product (0.01 wt %). This minimum value was not influenced by changes in current density or chromic acid concentration.

3. The nitrogen impurity level was not changed in any consistent manner by any of the variables investigated.

4. Deposition of chromium from the chromic acid-fluoride electrolyte under semi-production conditions was accompanied by a progressive decrease in current efficiency with time to a steady value of 25-30%. The following are the conclusions from the investigation of some of the variables which could effect current efficiency: (*A*) The trivalent chromium concentration did not influence current efficiency. (*B*) A decrease in the current density for large-scale tests produced a slight increase in cur-

rent efficiency due apparently to a decrease in nodule formation (*C*) Tin was detected in both the chromium deposit and the electrolyte, and it was shown that tin contamination could reduce the current efficiency. (*D*) Any sulfate impurity in the chromic acid used must first be removed since sulfate contamination was shown to be associated with a reduction in current efficiency. However, the decrease in current efficiency with time was greater than could be explained by any combination of these factors.

5. "Fluoride" chromium fabricated by arc-casting, extrusion, swaging, and rolling at 700°C possessed mechanical properties which compared favorably with those of "sulfate" chromium prepared by similar means.

Acknowledgments

The author would like to thank Mr. E. J. Lumley for all nitrogen analysis and Messrs. J. B. Dance and A. R. Edwards for continued encouragement and helpful discussion in the preparation of this report. Polarization of Luminescence in ZnS and CdS Single Crystals

A. Lempicki

General Telephone and Electronics Laboratories Inc., Bayside, New York

ABSTRACT

The fluorescent emission from hexagonal ZnS and CdS single crystals is found to be polarized preferentially perpendicular to the c axis for both polarized and unpolarized excitation. Cubic ZnS crystals emit unpolarized radiation. The results are analyzed in terms of a simple dipole theory which is shown to be inadequate for the description of luminescent centers in these materials. Preliminary observations on the polarization of fluorescence of ZnO crystals are reported.

The so-called Weigert effect (1) or polarization of fluorescence has been known for many years. A large amount of work has been done on the properties of organic molecules in various media (1, 2). The method has not been applied extensively to the inorganic luminescent materials. A notable exception is found in the work of Lambe, Compton, West, and Klick (4-7) in this country and Feofilof (3) in Russia. The substances investigated by these authors were mostly halides.

Recent successes in the growth of single crystals of the sulfides (8, 9) made it possible to apply the polarization techniques to the study of the luminescent centers in these materials.

The simplest physical model of a luminescent center can be conceived as an atomic or molecular aggregate giving rise to a classical electric oscillator. If this is the case, the polarization studies should enable us to determine the components of the polarizability tensor and the orientation of the oscillator in the lattice.

Usually the measurement of polarization is made in the longitudinal direction as illustrated on Fig. 1. The fluorescent medium is at the origin of the coordinates O and is excited by an electromagnetic wave propagated along the $-x$ axis. The electric vector E is parallel to z. Observations are made through an analyzer A which can be rotated either parallel or perpendicular to E. One introduces a quantity p:

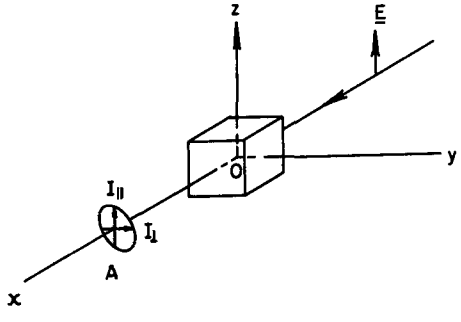

Fig. 1. Measurement of polarization-longitudinal experiments.

$$p = \frac{I_{\parallel} - I_{\perp}}{I_{\parallel} + I_{\perp}} \; ; \; -1 \leq p \leq 1 \qquad [1]$$

where $I_{||}$ and $I_{\perp}$ are the observed intensities of fluorescence for the two directions. The theories of the effect aim at calculating p from a suitable model of the fluorescent center. There are various degrees of sophistication in these theories which are briefly described.

The Rayleigh-Tyndall model.—For monochromatic excitation one assumes that the fluorescence is essentially a scattering process without change of wave length. As in Rayleigh scattering the intensity in any given direction is proportional to the square of the dipole moment μ. This moment is determined by the polarizability tensor α through the equation

$$\mu = \alpha \underline{E}$$

In crystals it is assumed normally that the principal axes of this tensor are oriented along main crystallographic directions. In spite of the usually large Stokes shift ($\lambda_{absorption} < \lambda_{emission}$). This simple model has been used successfully in determining the symmetries of some luminescent centers in halides (4) and in diamond (10).

Separate absorption and emission oscillators.—It has been first pointed out by Perrin (11) in connection with work on fluorescent solutions that sometimes it may be necessary to postulate two different kinds of oscillators. The exciting energy is first absorbed by an absorption oscillator and then transferred to an emission oscillator. This formally allows for a shift in energy between absorption and emission and accounts for negative values of p sometimes observed in solutions. Feofilof has used essentially the same model in determining the symmetry of luminescent centers in CaF_2 and NaF (3). In this case the sign and magnitude of p change with the exciting wave length, and it is necessary to introduce two separate oscillators.

The models (a) and (b) are essentially classical although Jablonski (12) and Lafitte (13) have used quantum mechanical methods in describing the energy transfer between the two sets of oscillators.

Quantum mechanical treatment.—If the symmetry of the crystal and luminescent center are known, it is possible to write down selection rules for dipole transition (14). In a still more refined treatment the matrix elements could be computed, and from these one should be able to estimate p.

Experimental Methods

The experimental arrangement is represented schematically in Fig. 2. A mercury arc source is placed at S. The 3650Å radiation is isolated by means of filter 1 and passes through a Glen-Thompson polarizer which can be rotated about the x axis (θ). The fluorescence generated in specimen C passes through a polaroid analyzer and is detected by a photomultiplier Ph. Filter 2 has a sharp cut-off for the exciting radiation. The optical system of a Zeiss polarizing microscope was adapted for the measurements.

There are several important precautions which must be taken in order to obtain reliable results. Most important is that no polarized excitation reaches the detector. This is achieved by suitable

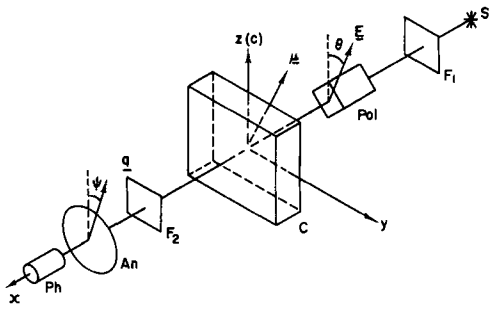

Fig. 2. Experimental arrangement for the measurement of polarization. S, radiation source; F_1, filter; Pol, polarizer; C, crystal; R_2, filter; An, analyzer; Ph, photomultiplier.

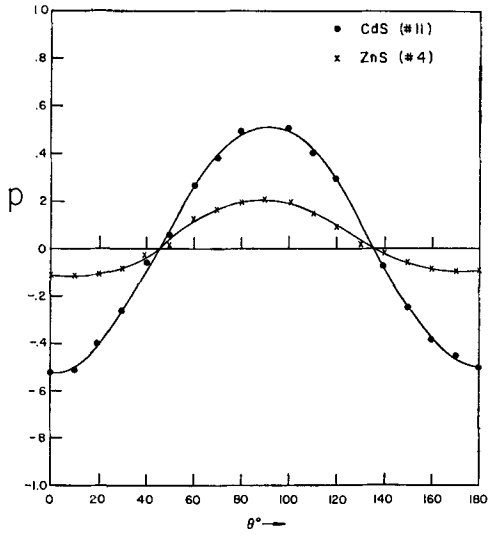

Fig. 3. Polarization factor p vs. the azymuth θ for a CdS and ZnS:Cu crystal. For $\theta = 0$ the exciting electric vector is parallel to the c axis.

combinations of filters 1 and 2. The specimens in form of plates are mounted over a diaphragm. The exciting beam is made nearly parallel by removing the microscope condenser and using suitable stops. It is important that the numerical aperture of the objective gathering the fluorescence be as small as possible. The reason for this is given in the appendix.

Since the angles θ and Ψ can be set independently we can generalize Eq. [1] and define p as

$$p(\theta) = \frac{I(\Psi = \theta) - I\left(\Psi = \theta + \frac{\pi}{2}\right)}{I(\Psi = \theta) + I\left(\Psi = \theta + \frac{\pi}{2}\right)} \qquad [2]$$

In our measurements we have chosen the z axis to coincide with the c axis of the crystals. In case of excitation with natural (unpolarized) light the angle θ is, of course, not specified. We define then for this case

$$p_n = \frac{I(\Psi = 0) - I\left(\Psi = \frac{\pi}{2}\right)}{I(\Psi = 0) + I\left(\Psi = \frac{\pi}{2}\right)} \qquad [3]$$

It should be noted that measurements with natural light are much more sensitive than with polarized light. The reason for this is that, if the filter system

Table I. Polarization data

Type	Impurity, mole %	Fluorescence peak, Å	Structure	$p(0°)$	$p(90°)$	p_n

15. ZnO	Red	5130	Hex.	0.48	—0.48	0.45

(1 and 2) is not ideal and the fluorescence weak, then an appreciable fraction of the excitation can reach the photomultipler. If it is polarized, it will affect the value of p. With natural light this leaking excitation can produce only a constant background independent of the setting of the analyzer.

Results

The ZnS crystals (Table I) used in this investigation were grown by a vapor phase method by Kremheller and Samelson of our Laboratories. Some of them were deliberately activated (by doping the starting powder) with Cu and Mn. Others were used as grown. The impurity concentration is given in the second column of Table I.

Specimens designated by ZnS:Cu and ZnS:Mn were doped intentionally during growth. Those designated by ZnS had only accidental impurities. The concentration of impurities was determined on a random selection of crystals from the same growth batch.

The requirements of bright fluorescence and platelike geometry with the c axis in the plane of the plate seriously limit the number of suitable specimens. A fluorescent spectrum (under 3650Å excitation) was obtained on crystals which were sufficiently bright and the peak is given in the third column. X-ray analysis was obtained for all specimens. Crystals 1 and 2 are essentially free of stacking disorder and birefringence banding. All other ZnS specimens show varying amounts of both. Some, like 5, 6, 9 and 10, show, besides the main structure, diffraction spots due to the other phase. This is indicated in brackets. The remaining three columns of Table I give the values of p for excitation polarized parallel to c, perpendicular to c and natural light.

All the ZnS and CdS crystals, except 7 and 8, which are cubic, show a fluorescence preferentially polarized perpendicular to the c axis. The intensity was too weak for crystals 1 and 2 to measure $p(0°)$ and p (90°), but these crystals have the highest values of p_n observed on any specimen of ZnS. The presence of disorder which is equivalent to the introduction of the cubic phase is seen to decrease the magnitude of p. Table I does not include numerous results obtained on cubic crystals many of which were electroluminescent. No polarization of fluorescence or electroluminescence was found in these. Unfortunately, no hexagonal ZnS:Mn crystals comparable in perfection with specimens 1 and 2 were available. This makes it difficult to distinguish between the property of the luminescent centers (Mn and Cu) and the lattice. It is impossible to compare ZnS:Cu an ZnS:Mn crystals which show different amounts of disorder.

Specimen 11 is a hexagonal CdS crystal with an emission peak near 6800Å.[1] Its fluorescence is also polarized perpendicular to c with a value of $|p| = 0.5$ considerably higher than in ZnS crystals.

Figure 2 gives the variation of p (θ) as a function of the azymuth θ for crystals 4 and 11. The CdS curve is symmetrical about the x axis and can be represented by an equation of the form $p(\theta) = -\frac{1}{2} \cos 2\theta$. If we make measurements with natural light excitation and plot p_n as a function of the angle Ψ we obtain a similar result $p_n = -\frac{1}{2} \cos 2\Psi$. This means that the polarization is quite independent of the mode of excitation. For ZnS the results are somewhat different. As seen from Table I and Fig. 2 we have in general

$$|p| \ (0°) \ | < |p_n| < |p \ (90°)$$

It should be stressed that quantitative measurements of polarization require a rather high degree of external crystal perfection. This is demonstrated by the following observations. One specimen of CdS consisted of a very clear plate joined to a thicker heavily striated part. Measurements of polarization were made in the two regions. In the clear portion p_n was about —0.3, whereas it decreased to almost zero in the less perfect part. To further check the effect of surface we have etched crystal 11 in HNO_3. The previously shiny surface turned rough and the polarization decreased from $p_n = 0.5$ to $p_n = -0.18$.[2] We believe that in specimens 1, 2, and 11 no surface depolarization effects were present.

Miscellaneous Observations

We have observed a polarization of the green electroluminescence in pure (nonphotoluminescent)

[1] The crystal was obtained from Dr. I. Broser of the Fritz Haber Institut der Max Planck Gesellschaft, Berlin. Beyond the presence of silver its exact impurity content is unknown.

[2] That a rough surface produces depolarization can be demonstrated by placing a ground glass plate between the crossed polarizers of a microscope. The field of view will not extinguish.

CdS. The crystals had Ga electrodes which had to be "formed" (15). These measurements were rather difficult because of the instability of emission. Values of p up to -0.3 were observed. The electroluminescence is thus also preferentially polarized perpendicular to c.

Some measurements were also made on ZnO crystals of two distinct types. Clear and transparent crystals (12, 13) obtained from vapor phase reaction show a weak *body* photoluminescence peaking at 5180A. No polarization effects were observed on these. The second category (14, 15) obtained from zinc refineries have a deep red color and an intense fluorescence confined to a *surface* layer. The peak of the fluorescence confined to the surface layer is only slightly lower (5130Å) than that of the clear crystals. However, polarization is quite marked and in this case polarized preferentially parallel to c. A tentative explanation of this effect in terms of surface and volume properties has been proposed by Birman (16).

Discussion

One important question which must be settled before we draw conclusions from our results is the possible effect of dichroism. In ZnS, according to data of Piper, *et al.* (17) and Balkanski and Waldron (18), α ($\|$ c) $<$ α ($\perp$ c), where α ($\|$ c) and α ($\perp$ c) are the absorption constants for light polarized parallel and perpendicular to c. Hence, if fluorescence emission was initially unpolarized, it would become preferentially polarized parallel to c as it travels from the luminescent center to the surface of the crystal. This is contrary to our observations and thus dichroism cannot be responsible for the results. The situation is more complicated in the case of CdS for which α ($\|$ c) becomes larger than α ($\perp$ c) at wave lengths larger than 5350Å (12). Here dichroism could in principle produce the observed polarization at 6800Å. This point was checked directly by illuminating the crystal with unpolarized radiation approximating in wave length the fluorescent emission. The amount of polarization introduced by dichroism in both CdS and ZnS crystals was found to be below the experimental error and thus of no importance for our measurements.

In order to see whether the Rayleigh-Tyndall theory of scattering can account for the observed polarization we shall consider a very general model for the luminescent centers. Let us assume that there are n of them in the volume of the crystal under observation. Each center will be characterized by a certain polarizability tensor α^n_{ij}. The x, y, z coordinate system of Fig. 2 may or may not coincide with the principal axes system of some centers. The polarizability tensors of some centers may be identical.

The exciting radiation produces a dipole moment μ^n in each center. The direction of this moment is determined by the α^n_{ij} — s and the exciting electric field intensity E. Since observations are made along the x axis, only the components μ^n_y and μ^n_z will contribute to the observed intensity. These are given by

$$\mu^n_y = \alpha^n_{yy}\, E \sin\theta + \alpha^n_{yz}\, E \cos\theta$$
$$\mu^n_z = \alpha^n_{yz}\, E \sin\theta + \alpha^n_{zz}\, E \cos\theta \qquad [4]$$

Where θ is the angle between E and the z axis (Fig. 2). Since the polarizability tensor is symmetrical (19) only three components for each center (α^n_{yy}, α^n_{zz}, α^n_{yz}) determine the intensity.

The magnitude of the scattered (photoluminescent) intensity depends on the coherency of scattering from the various dipoles. In the absence of definite information about this we compute the intensity for both complete coherency (I_c) and complete incoherency (I_i). We have

$$I_c(\theta,\Psi) \sim \sum_n (\mu^n_y \sin\Psi + \mu^n_z \cos\Psi)^2$$
$$I_i(\theta,\Psi) \sim [(\sum_n \mu^n_y)\sin\Psi + (\sum_n \mu^n_z)\cos\Psi]^2 \qquad [5]$$

From Eqs. [5], [4], and [2] we can compute the polarization factors for both cases (Eq. [6] and [7]). The corresponding equations for natural light excitation are obtained by averaging Eq. [5] over θ and substituting in Eq. [3] (Eq. [8] and [9]).

$$p_c(\theta) = \frac{[2C\,(B^2\cos^2\theta + A^2\sin^2\theta) + AB\sin 2\theta]\sin 2\theta + [(B^2\cos^2\theta - A^2\sin^2\theta) - \cdots}{(B^2\cos^2\theta + A^2\sin^2\theta) + 2C\,(B\cos^2\theta + A\sin^2\theta)\sin 2\theta + \cdots\cdots}$$
$$\cdots\cdots \frac{-(A-B)\sin 2\theta - C^2\cos 2\theta]\cos 2\theta}{+[(A-B)\sin 2\theta + C^2\cos 2\theta]} \qquad [6]$$

and

$$p_i(\theta) = \frac{(A'\cos^2\theta - B'\sin^2\theta)\cos 2\theta - C' + (2C' + F')\sin^2 2\theta + 2(D'\sin^2\theta + \cdots}{(A'\cos^2\theta + B'\sin^2\theta) + C' + 2(D'\sin^2\theta + E'\cos^2\theta)\sin 2\theta + \cdots\cdots}$$
$$\cdots\cdots \frac{+E'\cos^2\theta)\sin 2\theta + \frac{1}{2}(E' - D')\sin 4\theta}{+\frac{1}{2}(D' - E')\sin 4\theta} \qquad [7]$$

$$p_{rc}(\Psi) = \frac{B^2 - A^2}{A^2 + B^2 + 2C^2}\cos 2\Psi + \frac{2(A+B)C}{A^2 + B^2 + 2C^2}\sin 2\Psi \qquad [8]$$

$$p_{ri}(\Psi) = \frac{B' - A'}{A' + B + 2C'}\cos 2\Psi + \frac{2(D' + E')}{A' + B' + 2'C}\sin 2\Psi \qquad [9]$$

The constants are

$$A = \sum_n \alpha^n_{yy} \qquad A' = \sum_n (\alpha^n_{yy})^2$$
$$B = \sum_n \alpha^n_{zz} \qquad B' = \sum_n (\alpha^n_{zz})^2$$
$$C = \sum_n \alpha^n_{yz} \qquad C' = \sum_n (\alpha^n_{yz})^2$$
$$D' = \sum_n \alpha^n_{yy}\alpha^n_{yz}$$
$$E' = \sum_n \alpha^n_{zz}\alpha^n_{yz}$$
$$F' = \sum_n \alpha^n_{yy}\alpha^n_{zz} \qquad [10]$$

Although the formulas are rather complicated, we can draw from them certain general conclusions, at least in the case of CdS. First, let us remark that for natural light excitation the polarization factors have the form $p_n \sim R \cos(2\theta + \phi)$, where R is an amplitude and ϕ a phase. Any partially polarized radiation must give rise to such a dependence. The important fact is that experimentally we find $R = -\frac{1}{2}$ and $\phi = 0$ (for CdS). This eliminates the sin 2Ψ term in Eq. [8] or [9]. Thus we must have $C = D' = E' = 0$. We now have to consider the coherent and incoherent case separately.

For the coherent case, the requirement $R = -\frac{1}{2}$ yields $A^2 = 3B^2$. If we substitute this into Eq. [6] we see that there is no way of reducing it to $-\frac{1}{2} \cos 2\theta$, which the experiment indicates.

For the incoherent case. we have from Eq. [9]:

$$\frac{B' - A'}{A' + B' + 2C'} = -\frac{1}{2}$$

Again, Eq. [7] cannot be reduced to the form $-\frac{1}{2} \cos 2\theta$ with the three arbitrary constants A', B', C' and the condition $A' \neq B'$.

Before we form our conclusions, let us dispose of a certain approximation which we have not mentioned explicitly. We have assumed that the exciting electric field components are $E \sin\theta$ and $E \cos\theta$ (see Eq. [4]). In fact, for ZnS at the excitation wave length of 3650Å the absorption constant α ($\perp$c) is larger than α (||c). For CdS no measurements are available. If the same is true for CdS as for ZnS, we should use for the y component $E\sigma \sin\theta$ where σ represents an attenuation factor ($\sigma < 1$) as compared with the z component. If we recalculate the polarization factors Eqs. [6], [7], [8], and [9] in terms of σ we still cannot reduce simultaneously [6] and [8] or [7] and [9] to the experimentally observed form of $-\frac{1}{2} \cos 2$ (angle).

Thus, in the case of CdS, and in contrast to diamond and the halides, a model involving arbitrarily oriented anisotropic dipoles cannot account for the results.

The case of ZnS is more complicated because the $p(\theta)$ curves show an asymmetry (Fig. 2) and, therefore, a dependence of polarization of emission on the mode of excitation. It should be stressed that it is very important to obtain measurements of p as a function of θ over a whole period and not only at isolated points. Only then can one draw meaningful conclusions as to the adequacy of the dipole model of a luminescent center.

Finally, even in the case of CdS, it may be possible to construct a model involving two oscillators per center and account for the observations. In such a center an energy transfer would take place. This possibility has been discussed by Dexter (22) and lately by Malemed (23). On the other hand, it is possible to account for the polarization measurements qualitatively in terms of the symmetry of the valence bands in these materials rather than the center itself. A fuller discussion of the various possibilities is given in the accompanying paper by Birman (16).

Acknowledgments

The author is indebted to Drs. A. Kremheller and H. Samelson for the ZnS crystals, to I. Broser for the CdS crystal, to Dr. R. W. Smith, of RCA, for the electroluminescent CdS crystals and to Dr. A. R. Hutson, of B.T.L., for the ZnO crystals. Mr. V. A. Brophy and S. Kellner performed the x-ray analysis and Dr. J. L. Birman has contributed by his discussions and criticism.

Manuscript received Nov. 9, 1959. This paper was prepared for delivery before the Philadelphia Meeting, May 3-7, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

APPENDIX

Imagine the dipole moment μ (Fig. 2) of an oscillator to be decomposed into three components μ_x, μ_y, μ_z. By making $\psi = 0°$ or $90°$ we would like to obtain a signal due only to the components μ_z or μ_y, respectively. The intensity of radiation is zero along the axis of a dipole but increases as the square of the sine of the colatitude angle away from the axis. Thus, if the aperture is large, part of the radiation due to μ_x will also be intercepted by the objective. The ratio of the intensities due to the components μ_x, μ_y, μ_z is given by

$$\frac{I(\mu_z)}{I(\mu_x)} = f(\gamma)\frac{\mu_z^2}{\mu_x}; \frac{I(\mu_y)}{I(\mu_x)} = f(\gamma)\frac{\mu_y^2}{\mu_x}$$

where sin γ is the numerical aperture of the objective. f (γ) can be obtained by computing the ratio of the fluxes through the objective from the dipole radiation intensity formula $I \sim \sin^2\theta\mu^2/r^2$. In Table II we give a few values of f (γ) for different objectives. If all the components of μ are equal the last column gives the percentage admixture of the unwanted $I(\mu_x)$ component. In most of our work we used the first objective.

Polarization of Fluorescence in CdS and ZnS Single Crystals

Joseph L. Birman

General Telephone and Electronics Research Laboratories Inc., Bayside, New York

ABSTRACT

The polarization of fluorescence in hexagonal (wurtzite) crystals of CdS and ZnS gives a clue to the symmetry of the states between which the luminescent transition occurred. Unfortunately this clue is at present equivocal; there are many models for the center which would be consistent with the observed polarization.

Various symmetry properties of the wurtzite structure are discussed; the band structure of CdS and ZnS at k = 000 is discussed. These symmetry and band structure considerations are used to set up and consider various models, Lambe-Klick, Schoen-Klasens, etc., which would be in accord with observation of polarization. It is concluded that the Lambe-Klick model is the simplest which is in accord with the presently available observations. Some experimental tests are proposed which should help the descision among the various models. In conjunction with other single crystal optical, electrical, and magnetic measurements, polarization studies may prove decisive in obtaining quantitative knowledge about the centers in sulfides.

Although the sulfide phosphors have been studied for many years and a great deal of progress has been made in rationalizing their luminescent, photoconductive, and electroluminescent properties by means of particular theoretical models, basic uncertainty remains concerning the chemical nature and energy level structure of the luminescent center in these materials. It was with the hope of contributing to the clarification of the energy level structure of certain important phosphors that the work reported by Lempicki (1) was undertaken. The problem of the chemical nature of the center (the local atomic constituents and configurations) is not discussed in this paper: rather we shall focus on the energy level structure of centers, in the simplest phosphors, which would be consistent with the polarization observations. Because of its simplicity we shall emphasize the Lambe-Klick model, without losing sight of the fact that at the present time no definitive choice of model can be made. Certain experiments will be suggested on the basis of which a decision may be made between the different models.

In Table I a summary is given of the major aspects of the experimental situation presented in Lempicki's paper. We note that the polarization of luminescence at room temperature (3650Å excited) in hexagonal CdS:Ag and ZnS:Cu is considerable but not complete. For CdS:Ag the degree of polarization of fluorescence is constant and independent of polarization of the exciting radiation. For ZnS:Cu we note structure sensitivity, as well as a slight dependence on the polarization of the exciting radiation (1). Some problems which the model should answer are: (*a*) origin of polarization; (*b*) the fact that polarization is not 100% at room temperature; (*c*) polarization of fluorescence is (in CdS:Ag) independent of polarization of exciting radiation; and (*d*) the sensitivity of the ZnS polarization results on the underlying crystal structure.

Table I. Summary of polarization experiments

Material	Radiation	Temp	$I_\perp/I_\parallel$

Band Models for the Sulfide Centers

One common model which was introduced for the centers in the sulfides was the so-called Schoen-

$$\frac{I(\mu_z)}{I(\mu_x)} = f(\gamma)\frac{\mu_z^2}{\mu_x}; \frac{I(\mu_y)}{I(\mu_x)} = f(\gamma)\frac{\mu_y^2}{\mu_x}$$

where sin γ is the numerical aperture of the objective. f (γ) can be obtained by computing the ratio of the fluxes through the objective from the dipole radiation intensity formula $I \sim \sin^2\theta\mu^2/r^2$. In Table II we give a few values of f (γ) for different objectives. If all the components of μ are equal the last column gives the percentage admixture of the unwanted $I(\mu_x)$ component. In most of our work we used the first objective.

Polarization of Fluorescence in CdS and ZnS Single Crystals

Joseph L. Birman

General Telephone and Electronics Research Laboratories Inc., Bayside, New York

ABSTRACT

The polarization of fluorescence in hexagonal (wurtzite) crystals of CdS and ZnS gives a clue to the symmetry of the states between which the luminescent transition occurred. Unfortunately this clue is at present equivocal; there are many models for the center which would be consistent with the observed polarization.

Various symmetry properties of the wurtzite structure are discussed; the band structure of CdS and ZnS at k = 000 is discussed. These symmetry and band structure considerations are used to set up and consider various models, Lambe-Klick, Schoen-Klasens, etc., which would be in accord with observation of polarization. It is concluded that the Lambe-Klick model is the simplest which is in accord with the presently available observations. Some experimental tests are proposed which should help the descision among the various models. In conjunction with other single crystal optical, electrical, and magnetic measurements, polarization studies may prove decisive in obtaining quantitative knowledge about the centers in sulfides.

Although the sulfide phosphors have been studied for many years and a great deal of progress has been made in rationalizing their luminescent, photoconductive, and electroluminescent properties by means of particular theoretical models, basic uncertainty remains concerning the chemical nature and energy level structure of the luminescent center in these materials. It was with the hope of contributing to the clarification of the energy level structure of certain important phosphors that the work reported by Lempicki (1) was undertaken. The problem of the chemical nature of the center (the local atomic constituents and configurations) is not discussed in this paper: rather we shall focus on the energy level structure of centers, in the simplest phosphors, which would be consistent with the polarization observations. Because of its simplicity we shall emphasize the Lambe-Klick model, without losing sight of the fact that at the present time no definitive choice of model can be made. Certain experiments will be suggested on the basis of which a decision may be made between the different models.

In Table I a summary is given of the major aspects of the experimental situation presented in Lempicki's paper. We note that the polarization of luminescence at room temperature (3650Å excited) in hexagonal CdS:Ag and ZnS:Cu is considerable but not complete. For CdS:Ag the degree of polarization of fluorescence is constant and independent of polarization of the exciting radiation. For ZnS:Cu we note structure sensitivity, as well as a slight dependence on the polarization of the exciting radiation (1). Some problems which the model should answer are: (*a*) origin of polarization; (*b*) the fact that polarization is not 100% at room temperature; (*c*) polarization of fluorescence is (in CdS:Ag) independent of polarization of exciting radiation; and (*d*) the sensitivity of the ZnS polarization results on the underlying crystal structure.

No discussion of the ZnS:Mn results is given. Some possible models for the ZnO results are put forward in the Appendix.

Band Models for the Sulfide Centers

One common model which was introduced for the centers in the sulfides was the so-called Schoen-

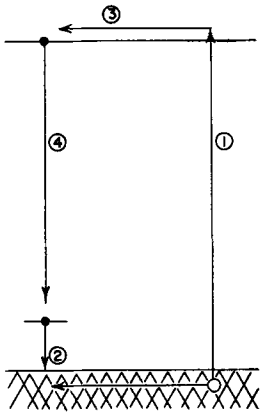

Fig. 1. Schoen-Klasens model for luminescent cycle in the sulfides.

Klasens band model (2). This model is illustrated in Fig. 1. According to the Schoen-Klasens model, the process of luminescence occurs as follows: If an incident photon is absorbed, with energy within the fundamental absorption edge, a free electron and a hole are created. The hole is captured by the center, which thus loses its electron. Since the energy level of the ground state of the center is assumed close to the valence band of the crystal, little energy is released when the hole is captured. (This energy is degraded in the form of infrared emission or thermal energy given up to the lattice.) The center, with a hole localized in it, at an energy level close to the valence band, is now in position to participate in the process of luminescence. Luminescence occurs when a free electron, which has been created by an incident photon, is captured by the hole localized at the center.

More recently, Lambe and Klick (3) have proposed an alternate model, which is shown in Fig. 2. In this model, the ground state of the center consists of an electron bound in an energy level close to the conduction band. As before, the process of luminescence may occur when an incident photon creates an electron and a hole in the crystal. However, if the center is filled initially, the first step, i.e., capture of a hole by the center, is the luminescent process. Subsequent capture of an electron by the empty center serves only to prepare the center again for later participation in further luminescent cycles. In this model, we see that in a certain sense it is the free hole which dominates the process of luminescence.

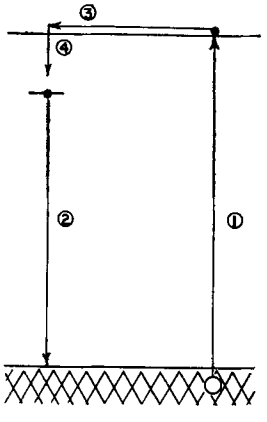

Fig. 2. Lambe-Klick model for luminescent cycle in the sulfides.

In both the Schoen-Klasens and Lambe-Klick models, luminescence and photoconductivity are intimately connected by means of the energy bands in the phosphor—the luminescent process involving the transition of a "free" carrier in an energy band to a bound state (4). If this type of model is correct, it is understandable that the polarization results (1) could not fit into a simple classical oscillator picture: the band scheme is quantum mechanical, with no strict classical analogue. However, without further modification neither Schoen-Klasens nor Lambe-Klick models indicate how polarization may arise. While the weight of experimental evidence in the sulfides seems to favor either Schoen-Klasens or Lambe-Klick "band" models for the centers (5), other possible models cannot be ruled out. In particular, a "two oscillator" model—separate absorption and emission oscillators—may be at least mentioned. For example, in ZnS the absorbed 3650Å radiation may create excitons which then decompose at the center, emitting the characteristic fluorescence. (Even more general kinds of mechanisms might be envisioned for separate absorption and emission processes.) Such processes, within the two oscillator framework, would focus attention on the details of the recombination processes within a more or less isolated center, rather than upon band-center processes (within the context of such models the apparent connection between photoconductivity and luminescence would be more complex to explain than for the band models).

In any event to know how to get the necessary anisotropy to yield polarization requires study of the symmetry of the wurtzite lattice, both for examination of band-center processes and recombination processes within a center located at a particular site. In the next section, certain results pertaining to the effect of the symmetry of hexagonal (wurtzite) lattice on optical selection rules are summarized. An understanding of the effects associated with the symmetry of the hexagonal structure is necessary for us to proceed with further consideration of models.

Symmetry of Wurtzite and Zinc Blende Structures

All of the descriptive information about wurtzite or zinc blende structures is contained in their space group designations: C^4_{6v} for wurtzite, T^2_d for zinc blende (6). Actual experimental CdS crystals seem almost invariably to be of pure wurtzite structure; the ZnS crystals almost invariably are mixed structures, whether or not predominantly wurtzite or zinc blende. The symmetry groups of interest to us in each structure are: the point group of the space group, various site groups.

For zinc blende, the point group of the space group is T_d, for wurtzite it is C_{6v}. Now, in zinc blende there are sites with full symmetry T_d, while in wurtzite no site (occupied) has symmetry C_{6v}. Major interest in these particular symmetry groups arises from the energy band picture, since at k = 000 in the zone, the wave functions of the crystal must belong to

an irreducible representation of the point group of the space group (7). (If a function belongs to a particular irreducible representation of a group, its symmetry properties are specified when the operations [rotations, reflections, etc.] of the group are applied to it. Conversely, knowing the irreducible representations of a group it is possible to indicate the type of functions which may belong to it, that is 's', 'p_x', 'p_y', 'p_z', etc. In what follows we find both approaches helpful.) We also need to consider the spin orbit effect, particularly in sulfides, since this introduces certain effects of interest in the analysis. Formally, the procedure involved is a consideration of the irreducible representations of the "double group" of the particular group (7). The relationship between single and double group representations is easily obtained from the theory and physically corresponds to "turning on" (consideration of) the spin-orbit effect. After wave functions have been classified into symmetry types, the analysis may be carried one step further to a discussion of the allowed optical (electric dipole) selection rules. These rules tell us the states which may be connected by an allowed optical transition, and we shall indicate that a transition between states Γ_i and Γ_j is allowed optically by writing $\Gamma_i \leftrightarrow \Gamma_j$. If a limitation occurs, insofar as the optical transition is only allowed for particular polarization of the electric vector of the exciting radiation with respect to a crystal axis (e.g., the unique [c] or [00.1] of the wurtzite structure) it will be so indicated in the tables. If wave functions and selection rules were known, matrix elements and oscillator strengths of various optically allowed transitions could be computed. This degree of refinement does not seem warranted at the moment.

Since the cubic zinc blende does not possess a unique axis, no polarization effects arise; those states between which optical transitions can occur for point group T_d are so connected without any regard to polarization of excitation or emission. Results are given in Table II. For wurtzite, there exists a unique axis so that polarization effects may arise in addition to straightforward selection rules. Results are given in Table III for group C_{6v}. While at this time we present only the formal results of the group theory analysis, restricting ourselves to labeling the states by means of their symmetry designations, we shall later give a more physical picture of the states (in the band structure section). In any event, if we are given the information that radiation (absorbed or emitted) is, or is not, polarized, and that the "center" which (absorbs/emits) has effective net symmetry T_d, or C_{6v} in zinc blende or wurtzite, respectively, we may, by using Tables II and III, determine all the possible states for these symmetries between which optical transitions are allowed, and then further which states can give rise to polarization effects.

In Table IV similar information is given for the group C_{2v}, a subgroup of both T_d and C_{6v}. No point in crystal space in a wurtzite structure has this symmetry. In zinc blende, this group is a site group (see below).

The site symmetries (8) in zinc blende or wurtzite (that is, the point symmetry of the particular substitutional or interstitial site) are the following: in zinc blende, T_d, C_{3v}, C_{2v}, C_s; in wurtzite, C_{3v}, C_s. The main interest from the point of view of polarization effects would be in the site group C_{3v} in wurtzite structure, as this is the site for both substitutional and interstitial impurities. In addition, C_{3v} is the effective site symmetry in faulted zinc blende structures. In Table V selection rules are given.

Clearly, we are faced with formidable difficulties in attempting to interpret the observed polarization results in terms of the states between which optical transitions have occurred. There is a many-to-one correspondence between the observation of polarization and the pairs of states which might be involved, if these are the states of various "natural" groups in wurtzite. In zinc blende we expect no polarization, except perhaps in the case of faulted

zinc blende crystal structure when the net site symmetry is reduced from T_d to effectively C_{3v}, and a unique axis has been introduced into the crystal structure. While polarization may arise in either wurtzite or faulted zinc blende structures, the values of the polarization must depend on the detailed energy level scheme. For example, it may be not observable if a cluster of closely lying states with different selection rules is optically accessible from a given initial state. In particular, while faulting formally reduces the site symmetry of a zinc blende structure to that of the wurtzite structure: e.g., from T_d to C_{3v}, the states split off by the lower symmetry may remain sufficiently close (if the perturbation is small) to be optically accessible, so that no observable polarization may result.

Conversely even though a particular optical transition may be allowed for both polarizations ($\perp$ and $\|$), the matrix elements whose values relate to the oscillator strength of the transitions for the two polarizations may be sufficiently different in magnitude so as to give an apparent polarization effect. These remarks are intended to emphasize the lack of uniqueness which obtains in assigning particular transitions as those involved in an observation of polarization.

We next discuss band structure of CdS and ZnS.

Energy Bands in the Sulfides

The complexity of the energy bands in some monatomic semiconductors (9) is indicative of what may be true also in the sulfides. On the other hand, we have not yet been driven by the weight of experimental evidence in the sulfides into the need for consideration of comparable complexity. In fact the simplest picture: tight binding (LCAO), extrema at k = 000, seems for the moment adequate, as well as simple, and we restrict our attention to this picture.

Since the outer valence electrons of both Zn (or Cd) and S are 's' and 'p' the states in the crystal are considered at k = 000 which can arise from these atomic orbitals. This means that we need to determine the crystal states (irreducible representations of T_d in zinc blende or C_{6v} in wurtzite) at k = 000 which can be obtained by combining 's' and 'p' orbitals. The states which are important from this point of view are illustrated in Fig. 3. The left side of the figure refers to zinc blende, the right to wurtzite. In Table VI the wave functions which are appropriate to the differently labeled states are indicated. From the figure we see a correlation between zinc blende states and the corresponding wurtzite states. In particular, we note the effect of the different wurtzite crystal symmetry, in causing a splitting of previously degenerate zinc blende states. The additional splitting due to spin orbit effect is also indicated for wurtzite.

Table VI. Wave function at a site

Basic set of s and p functions

$$\phi_{01} = s|\alpha\rangle \qquad \phi_{13} = y|\alpha\rangle$$
$$\phi_{02} = s|\beta\rangle \qquad \phi_{14} = y|\beta\rangle$$
$$\phi_{11} = x|\alpha\rangle \qquad \phi_{15} = z|\alpha\rangle$$
$$\phi_{12} = x|\beta\rangle \qquad \phi_{16} = z|\beta\rangle$$

Group T_d*:

Γ_1: ϕ_{01}; ϕ_{02}.

Γ'_4: ϕ_{11}; ϕ_{12}; ϕ_{13}; ϕ_{14}; ϕ_{15}; ϕ_{16}.

Γ_6: ϕ_{01}; ϕ_{02}.

Γ_7: $\left\{ \begin{array}{l} (1/\sqrt{3})\,[-i\phi_{11} - \phi_{13} + \phi_{16}]: \\ (1/\sqrt{3})\,[i\phi_{12} - \phi_{14} - \phi_{15}]. \end{array} \right\}$

Γ_8: $\left\{ \begin{array}{l} (i/\sqrt{2})\,[\phi_{12} - i\phi_{14}]; \\ (i/\sqrt{6})\,[i(\phi_{11} - i\phi_{13}) + 2\phi_{16}]; \\ (i/\sqrt{6})\,[i(\phi_{12} + i\phi_{14}) + 2\phi_{15}]; \\ (i/\sqrt{2})\,[\phi_{11} + i\phi_{13}]. \end{array} \right\}$

Group C_{6v}†:

Γ_1: $\left\{ \begin{array}{l} a\phi_{01} + b\phi_{15}; \\ a\phi_{02} + b\phi_{16}. \end{array} \right\}$

Γ_5: ϕ_{11}; ϕ_{12}; ϕ_{13}; ϕ_{14}.

Γ_7: $\left\{ \begin{array}{l} a\phi_{01} + b\phi_{15} + c/2(\phi_{11} + i\phi_{13}); \\ a\phi_{02} + b\phi_{16} + c/2(-\phi_{12} + i\phi_{14}). \end{array} \right\}$

Γ_9: $\left\{ \begin{array}{l} (1\sqrt{2})\,(\phi_{11} - i\phi_{13}); \\ (-1\sqrt{2})\,(\phi_{12} + i\phi_{14}). \end{array} \right\}$

* For T_d, x, y, z are along the usual cartesian coordinate axes.

† For C_{6v}, x, y are perpendicular to z, and z is taken parallel to "C", the unique axis.

Table VII. Crystal wave functions

Zinc blende states at $\Gamma(k = 000)$; group T_d:

States with symmetry properties $\Gamma_1 - \Gamma_8$ may be formed (see Tables II and VI) by adding a function centered on one base site to that centered on the other, for example, for Γ_1 crystal function:

$$\Gamma_1: \left\{ \begin{array}{l} a\phi_{01}(Zn) + b\phi_{01}(S) \\ a\phi_{02}(Zn) + b\phi_{02}(S) \end{array} \right\}$$

see Table VI for definition of ϕ.

Wurtzite states at $\Gamma(k = 000)$ — group C_{6v}:

States with symmetry Γ_1, Γ_5, Γ_7, Γ_9 may be simply formed by adding functions centered at the site: Zn1, Zn2, S1, S2, where Zn1, etc., indicates the type of, and number of, the particular site. For a Γ_1 function

$$\Gamma_1: [a\phi_{01}(Zn1) + b\phi_{15}(Zn1)] + [a\phi_{01}(Zn2) + b\phi_{15}(Zn2)] + [a'\phi_{01}(S1) + b'\phi_{15}(S1)] + [a'\phi_{01}(S2) + b'\phi_{15}(S2)]$$

Wurtzite states at $\Gamma'(k = 0, 0, (2\pi)/c)$ — group C_{6v}:

Although $\Gamma' = \Gamma$ in the reduced zone, it is helpful to consider it as distinct in the Jones or Energy zone. States Γ_2, Γ_6, Γ_8, at k = 0, $0(2\pi)/c$ are simply related to Γ_1, Γ_5, Γ_7, at k = 0, 0, 0 respectively. For example:

$$\Gamma_2: [a\phi_{01}(Zn1) + b\phi_{15}(Zn1)] - [a\phi_{01}(Zn2) + b\phi_{15}(Zn2)] + [a'\phi_{01}(S1) + b'\phi_{15}(S1)] - [a'\phi_{01}(S2) + b'\phi_{15}(S2)]$$

(cf. Γ_1 preceding.)

a, b, c, d are constants.

Physically, as earlier writers have indicated, the valence band consists mainly of electronic states localized about S while the conduction band has the states about Zn; this is, of course, an oversimplified picture. Table VI may be helpful in obtaining a physical picture of different wave functions associated with various states. In particular, we note that the zinc blende p-like (x, y, z) valence state Γ'_4 is split by the lower wurtzite potential into $\Gamma_5 + \Gamma_1$ which are, respectively, (x,y) and (s + z) orbital types. The spin-orbit effect in wurtzite causes $\Gamma_5 \rightarrow \Gamma_9 + \Gamma_7$ and it can be seen that Γ_9 remains (x,y) in orbital character, while Γ_7 contains a mixture of (x, y, s + z) states. Other changes caused by symmetry and spin-orbit effects can be easily obtained from Fig. 3 and Table VI.

The order of states, and separations, shown in Fig. 4 seem to be in accord with a variety of experiments in hexagonal CdS, including, absorption and reflection spectra, excitation spectrum of edge emission and of photoconductivity, and the exciton absorption spectrum (10). (On the other hand, preliminary cyclotron resonance results seems to indicate a more complex band structure for CdS, without agreeing or disagreeing with the separations shown in Fig. 4.) Again, the many-one correspondence between these experiments and band models needs emphasis, as some other band level schemes also consistent with the data could be proposed.

Figure 3 also reviews the polarization selection rules between certain states, which were already given in the various tables, and are now to be understood as restricting band-band optical transitions.

The band structure and order of states shown in Fig. 3 may be assumed also to apply to ZnS although there is at this time no comparably complete experimental evidence for ZnS. Numerical calculation, by the cellular method, of the band structure of ZnS in zinc blende and wurtzite structures (neglecting spin-orbit effect) gives an order of states in agreement with that illustrated in Fig. 3. In addition, the problem of crystal faulting is very significant in actual ZnS crystals, the faults causing barriers (11), changes in effective band gap (11) and, perhaps, changes in the order of states in the barrier (this seems unlikely although possible!). Hence, our major concern is with CdS center energy levels, even though actual major interest is in the ZnS luminescent systems.

It is now evident that the band models of Fig. 1 and Fig. 2 must be modified to take account of the actual band structures in the sulfides and that, in addition, if a symmetry designation is applied to the luminescent center state, polarization effects may be expected. While we work within the framework of the band scheme of Fig. 3 and 4 for the sulfides it is necessary to emphasize that the order of states and separations which have been assigned are provisional (although supported by the present weight of evidence).

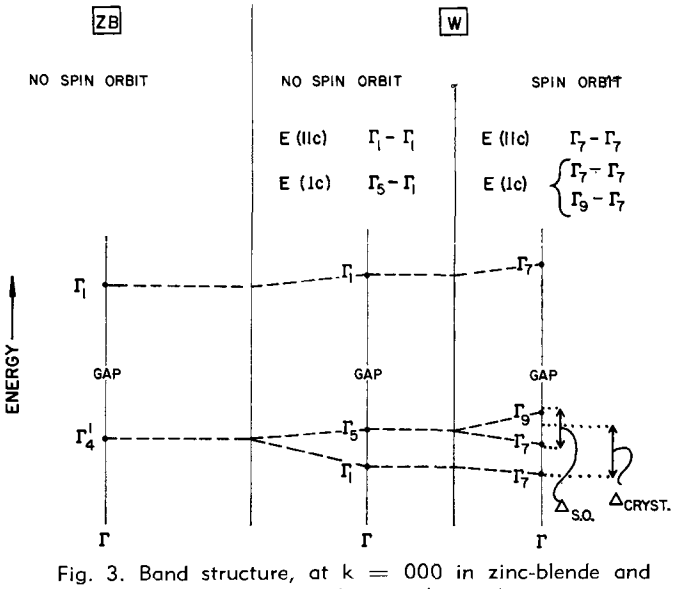

Fig. 3. Band structure, at k = 000 in zinc-blende and wurtzite structures showing the correlation between corresponding states. (This applies to the sulfides.)

Modified Band Models for Sulfide Centers

With the preceding development in mind, we are now in a position to formulate band models which, although still quasi-descriptive, are more refined than the simple S-K and L-K models. It will be possible then to evaluate alternate models and formulate (albeit tentatively) some opinion as to which model more simply accounts for polarization data.

It is evident from Fig. 4 that the valence and conduction band energy levels for a sulfide (particularly CdS) in hexagonal crystal structure, have particular symmetry properties (belong to particular irreducible representations). Similarly, the "center" state wave function must belong to some symmetry type. The simplest assumption one may make would seem to be: *the center has the maximum symmetry allowed for the crystal.* This would call for a center with Γ_7 symmetry, if we include the spin-orbit effect. Since the symmetry of the bands has been fixed (tentatively) by previous arguments we may rule out an S-K model for the moment, as the $\Gamma_7 - \Gamma_7$ transition is allowed for both $\perp$ and $\parallel$ polarizations. (S-K models are discussed below.) We are thus led to the L-K model modified for complex band structure: Fig. 5 in which a center with Γ_7 symmetry is placed near the conduction band. The process of luminescence then involves: (*a*) creation of free electrons and holes, by absorption of radiation whose energy is within the fundamental absorption edge, (b) attainment of thermal equilibrium by the holes, which populate the several

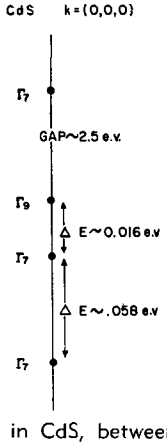

Fig. 4. Separations, in CdS, between states at k = 000. (Not to scale.)

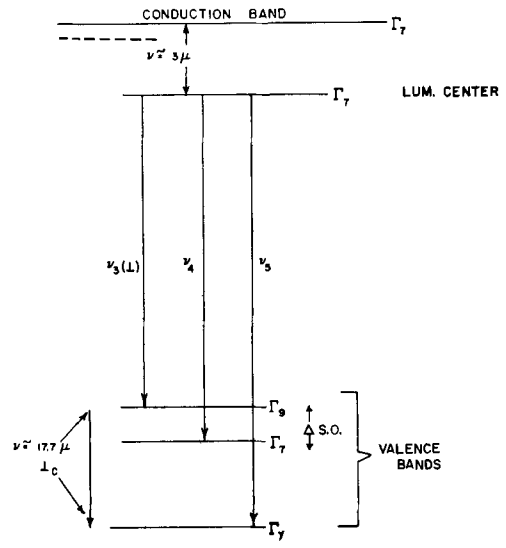

Fig. 5. Modified Lambe-Klick model for luminescent center and cycle. The 3 μ infrared luminescence quench, as well as the 17.7 μ absorption which should quench polarization are shown. Polarization of transitions can be obtained from Table III. The dotted line near the conduction band indicates the level from which edge emission is believed to occur.

valence bands as given by a Boltzmann factor, (c) recombination of the electron in Γ_7 center with a hole, and emission of characteristic radiation ($\nu_3 + \nu_4 + \nu_5$) depending on the state of the hole at the moment of recombination, and finally, (*d*) capture of another electron by the center which is then returned to its initial state. If these are the steps involved in the production of preferentially polarized luminescence, then the L-K model leads to the following predictions for the luminescence (neglecting the lowest Γ_7 valence band):

(I) Both CdS edge emission (from a state closer to the band) and the 6200Å (CdS) emission should be polarized, and both should obey the law for the temperature dependence of polarization

$$I_{\perp}/I_{||} = a \exp(\Delta_{s.o.}/kT) + b \qquad [1]$$

where $\Delta_{s.o.} = 0.016$ ev for CdS if the previous assignments are correct. Note that the significant feature is not that a and b (or $I_{\perp}/I_{||}$) be identical for the edge and 6200Å emission, but that $\Delta_{s.o.}$ be the same. Constants a and b depend on details of edge-center (trap) and luminescent center wave functions and would be only accidentally the same for the different emissions, as would the actual numerical values of polarization at any temperature. However, Δ which arises from the hole distribution between valence bands, must be the same if the L-K model of luminescence as we have presented it, and the accepted model of edge emission (12) are both correct in the approximation used.

(II) The excitation spectrum of luminescence and edge emission should be identical, since all that is involved in excitation is the creation of free electrons and holes (the latter being thermally distributed among the valence bands) and this is an intrinsic (host) property.

(III) The luminescence should be resolvable into several bands (centered on ν_3, ν_4, ν_5) of which ν_3 would be totally polarized $\perp$ to c, as given by selection rules.
