Holes injected into the semiconductor by the cathodic reduction of the oxidizing agent supply the holes required for the anodic dissolution part of the chemical etching process. Combining Eq. [2] with two times Eq. [3] (for charge balance) gives the following over-all reaction for chemically etching silicon in HNO_3-HF mixtures:

$$Si + 2HNO_3 + 6HF \rightarrow H_2SiF_6 + 2HNO_2 + 2H_2O + (4-n)e^+ + (4-n)e^- \quad [4]$$

Each atom of Si dissolving uses up to 2 molecules of HNO_3 and six of HF. The activation energy (~ 4 kcal/mole) (2, 22) for the over-all reaction indicates that the kinetics of the process is diffusion-controlled. Therefore, if the rates of diffusion and convection of HNO_3 and HF from the solution bulk to the Si surface are approximately equal, the maximum etching rate should occur when the mole ratio of HNO_3 to HF is 1/3 [solution composition: 42% by wt (70%) HNO_3 + 58% by wt (49%)HF].

Schmid and Spahn (21, 23) found that HNO_3 reduces beyond nitrous acid, HNO_2, to nitric oxide, NO, when copper is chemically etched in HNO_3. For this mechanism, the over-all cathodic reduction of nitric acid is

$$HNO_3 + 3H^+ \rightarrow NO + 2H_2O + 3e^+ \quad [5]$$

Robbins and Schwartz (1, 24) have assumed that HNO_3 reduces to NO as in Eq. [5] when Si is chemically etched in HNO_3-HF mixtures. However, they also propose that the anode reaction product is SiF_4. As a result, their over-all anode-cathode reaction for etching silicon in HNO_3-HF mixtures gives a 1/3 mole ratio as in Eq. [4] which is only fair in agreement with the results shown in Fig. 1. An excellent agreement is obtained, however, if H_2SiF_6 is assumed to be the anode reaction product instead of SiF_4. The over-all etching reaction obtained by combining Eq. [2] and [5] (Eq. [2] is multiplied by 3 and Eq. [5] by 4 for the necessary charge balance) is as follows:

$$3Si + 4HNO_3 + 18HF \rightarrow 3H_2SiF_6 + 4NO + 8H_2O + 3(4-n)e^+ + 3(4-n)e^- \quad [6]$$

The mole ratio of HNO_3 to HF for this reaction is 4/18 or 1/4.5. This agrees very well with the HNO_3-HF composition which gives the maximum rate of etching shown in Fig. 1 [33% by wt (70%)HNO_3 + 67% by wt (49%)HF]. Klein (2) obtained a maximum etching rate on Si at about the same solution composition. Robbins and Schwartz (1) have properly concluded that to the left of the maximum, where the HF concentration is relatively low, the rate of etching is controlled by the diffusion and convection of HF to the Si surface. The arrival of HNO_3 at the Si surface becomes rate determining in solutions with compositions to the right side of the maximum in Fig. 1.

The number of excess holes and electrons produced in chemically etching Si, as shown in Eq. [4] and [6], depends on the rate of etching and the current multiplication factor $\left(\alpha = \frac{4}{n}\right)$ in the anode reaction. If n is 2, then $\alpha = 2$; but if 4 holes are consumed in dissolving 1 Si atom, then $\alpha = 1$ and no excess holes and electrons are produced. Potential measurements on Ge and Si electrodes in chemical etching solutions indicate that $\alpha > 1$, since the potential is a function of the conductivity type and resistivity as shown in Fig. 5 and 6. The measured electrode potential, except for n-type Si, is shown to be a logarithmic function of the equilibrium hole density. At present, the author does not have a satisfactory interpretation of the results obtained with n-type Si. The material lifetime or the total impurity density were found not to be a factor. Dewald (10) has shown that holes are the potential-determining carriers at semiconductor electrodes in etching solutions. The hole density just inside the space-charge layer (p_1) is large on n-type as well as p-type electrodes. For very strongly p-type samples (equilibrium hole densities $p > \sim 10^{16}$ holes cm^{-3}), p_1 is not appreciably different from the equilibrium hole density and the measured electrode potential becomes almost constant. The limiting potential effect should occur at higher p values if the rate of hole generation at the surface increases. This is confirmed by the results shown in Fig. 5 since the etch rate increases with larger amounts of HF.

The potential (E_{III}) at the semiconductor-electrolyte interface can best be illustrated with typical anode and cathode potential-current curves as shown in Fig. 8. In order to simplify the diagram, the IR drops in the local corrosion circuits were not included. In HNO_3-HF mixtures the cathode reaction is the reduction of HNO_3 according to Eq. [5], while the anode reaction is the dissolution of the semiconductor, Eq. [2]. The case illustrated in Fig. 8 is the condition where the etching rate is determined by the mass transfer of HF to the surface. The intersection of the anode and cathode curves determines the etching or corrosion current, and the measured potential of the electrode. In concentrated HNO_3 without HF, the corrosion current is essentially zero and the measured potential is the open-circuit potential of the cathode reaction—the reduction of nitric acid on the semiconductor. When HF is added, the anode reaction proceeds at a much higher rate before polarization sets in, curve A_2. The etching rate on Ge or Si increases markedly and the measured electrode potential changes in the negative direction. When the measured electrode potential is appreciably far from the open-circuit anode or cathode potential it is often called a mixed corrosion potential. The large initial poten-

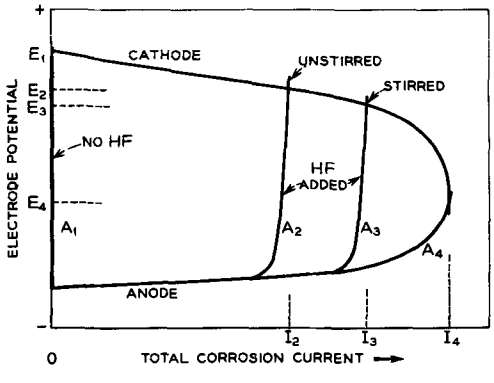

Fig. 8. Typical electrochemical polarization curves for local anodes and cathodes on Ge or Si in HNO_3 with and without HF additions.

tial change in Fig. 3 which occurred when a small amount of HF was added to HNO_3 is attributed to a large change in the mixed interfacial potential. Subsequent changes in the electrode potential at higher etch rates with more HF as shown in Fig. 3 are complicated by changes in E_{II} (inside the semiconductor) due to the excess holes and electrons produced. Stirring increases the supply of the rate-determining material to the surface of the semiconductor. This increases the corrosion current and shifts the electrode potential, as shown in Fig. 8. The potential change with stirring is easily demonstrated by simply jiggling the electrode. When HF is the rate-determining material the potentials of both n- and p-type Ge (or Si) always shift in the negative direction and when HNO_3 is the controlling factor, the potentials become more positive with stirring. Current I_4 and potential E_4 represent the values obtained when the mass transfer of HNO_3 and HF are equally rate determining. As previously mentioned, this occurs on Si at the maximum rate of etching when the HNO_3/HF ratio is about 1-4.5.

Summary and Conclusions

The chemical etching of semiconductors is really an electrochemical process. Semiconductor dissolution takes place at local anode sites while the oxidizing agent is reduced at local cathode areas. The total anodic current always equals the total cathodic current. The average anode and cathode current density calculated from rates of etching data is in the order of amperes per square centimeter. The rate of etching is controlled by the mass transfer of an ionic or molecular species in the electrolyte to the surface of the semiconductor. It is not limited by the supply of holes or electrons in the semiconductor surface. In fact an excess of holes and electrons are produced at the surface. The large number of holes required to maintain the semiconductor dissolution reaction rate at amperes per square centimeter are supplied by hole injection at nearby cathodic areas. Due to a current multiplication effect in the anode reaction, an equal number of excess holes and electrons are produced at the semiconductor surface. These excess holes and electrons modify that part of the measured electrode potential which is just inside the surface of the semiconductor.

Acknowledgments

The author is grateful to Miss A. D. Mills and D. D. Bacon for their help in obtaining the germanium and silicon electrode material used in this work. He is also indebted to U. B. Thomas, J. F. Dewald, and D. L. Klein for their aid in interpreting the data and suggestions as to the best way to present the material.

Preparation of Boron by Fused Salt Electrolysis

Nelson P. Nies

U. S. Borax Research Corporation, Anaheim, California

ABSTRACT

The preparation of elemental boron by fused salt electrolysis was investigated using various electrolytes composed of B_2O_3 dissolved in mixtures of alkali metal and magnesium chlorides, fluorides and oxides, with a graphite crucible anode and a steel cathode at about 850°C. The best product purity, 97.5%, was obtained with a bath containing KCl, KF, and B_2O_3, treated with HCl gas. This electrolyte has the advantage that it is not as volatile as previously used baths containing KBF_4. Lower purities were obtained with baths containing sodium or magnesium salts. An approximate phase equilibrium diagram is given of the liquid system KCl-KF-B_2O_3.

Elemental boron has been prepared by (*a*) thermal reduction of boric oxide with metals (1, 2), (*b*) thermal reduction of boron halides or fluoborates with metals or hydrogen (2-5), (*c*) thermal dissociation of boron halides or hydrides (5-8), and (*d*) fused salt electrolysis. In the first of these methods the highest purity has been obtained by the use of magnesium powder (Moissan process); most commercial boron has been produced by this means. However, the purity of Moissan boron (without further treatment) is usually less than 92%, and this method is limited economically by the cost of the magnesium and the excess B_2O_3 used. Methods (*b*) and (*c*) are capable of producing higher purity boron but also have been limited economically by the cost of raw materials. The electrolytic method is not so limited by raw material costs and was believed worthy of further investigation.

Early work on the electrolysis of alkali borates, reviewed by Andrieux (9), resulted in impure products and low yields. Kahlenberg (10) electrolyzed fused KBF_4 and stated that operation was satisfactory except for contamination of the product with copper from oxidation of the cathode. He also attempted the electrolysis of a KF-B_2O_3 bath but was unsuccessful because of attack on his containers. He reported a product analyzing 100% B from a nonfluoride bath containing KCl, K_2O, and B_2O_3, but, as will be shown, this result could not be confirmed in the present work.

Andrieux (11) reported that in the electrolysis of borates, the product of highest purity, about 85% B, was obtained when the cation present was magnesium. Cooper (12) reported a maximum purity of 96.7% B by electrolysis of a KF-KBF_4-B_2O_3 bath and 99.5% B with KCl-KBF_4 and KCl-KBF_4-B_2O_3 baths. Cooper's electrolytes containing B_2O_3 are analogous to those used in aluminum production. Andrieux and Deiss (13), Ellis (14), Miller (15), Murphy, Tinsley, and Meenaghan (16), Fullam (17), and Stern and McKenna (18) have also electrolyzed baths containing KBF_4. These investigators also obtained their maximum purity by using KBF_4. In most cases they did not reach the maximum purity reported by Cooper.

The use of KBF_4 leads to appreciable loss of boron and fluoride by volatilization, because of its tendency to decompose on heating [v.p. 182 mm at 800°C(19)]. The purpose of the present work was to find, if possible, a bath which would be more stable than those containing fluoborates and which would produce a comparable product.

Experimental

A graphite crucible, of inside diameter 254 mm, inside depth 380 mm, with walls 76 mm thick and with a close-fitting shell of 6.4 mm (¼ in.) Inconel was used as a bath container and as the anode. This was enclosed in a brick furnace heated with a gas burner. The cathodes used were either cylindrical or flat. The flat cathodes were made by welding 5 mm x 127 mm or 152 mm Armco iron plates together with ⅜ in. spacers between them, to form a hollow cathode which could be cooled by blowing compressed air into it. The cylindrical cathodes were made from mild steel pipe closed at the bottom, with a tube inside the cathode extending almost to the bottom for cooling with compressed air at the end of a run. It was found helpful in preventing attack on the cathodes to have tubes for air cooling welded to the cathode above the bath level. A layer of frozen electrolyte was put on the upper part of the cathode, above the bath level, by momentarily dipping the cathode in the bath before bolting it in place for the electrolysis, and this layer was maintained during electrolysis by passing a current of air through these tubes. To start a run, the crucible was filled with about 35 kg of the mixed ingredients (technical grade) and heated until fused and the desired temperature was reached. The cathode was then bolted to a water-cooled copper cathode holder and lowered into the bath. The bath was not covered and no protective atmosphere was used. The current was supplied by Edison batteries. In some experiments the potential was applied to the cathode before placing it in the

bath; this procedure usually resulted in a layer of electrolyte between the black deposit and the cathode. In most experiments, therefore, the current was not turned on until a few minutes after lowering the cathode into the bath, in order to permit melting of the layer of frozen salt which formed at first on the surface of the cathode. Any black scum on the surface of the bath was removed by skimming at frequent intervals. It was found desirable at the end of a run to decrease the current to about 25-40 amp and cool the cathode by passing compressed air through it for a few minutes before raising the cathode from the bath, in order to increase adherence of the deposit to the cathode. The product generally formed on the surface of the cathode as a smooth black deposit (occasionally rough in places) containing about 25% elemental boron and 75% electrolyte. The deposit often showed a tendency to ignite in spots just after removal of the cathode from the bath. If this occurred it was quickly extinguished by covering with granular sodium chloride. On soaking the cathode in water the deposit disintegrated and was easily removed from the cathode. In some cases, the deposit was removed by hammer and chisel, in order to separate the smooth parts of the deposit from the rough. Any parts which appeared different, such as the deposits on the edges and sides of a flat cathode, were separated also. These portions of the crude deposit were extracted with boiling water, digested overnight with hot concentrated HCl, washed and dried at 110°C. The products were practically amorphous to x-rays.

For analysis, a freshly dried 0.2-g sample, was either fused with 10 g of sodium carbonate (20) or dissolved in mixed acids (21); B_2O_3 was determined by titration by the usual method, using mannite.

Data on selected runs with various electrolytes are given in Table I.

Discussion

One of the first bath compositions investigated (Run 1) was the KCl-K_2O-B_2O_3 bath, which had been stated by Kahlenberg (10) to give pure boron. In this nonfluoride bath some alkalinity is necessary to dissolve the B_2O_3. Only a very low yield of 65% boron could be obtained with this bath.

Replacement of KCl partially (Run 2) or completely (Run 3) by KF in these alkaline baths gave a somewhat better but still unsatisfactory purity, 78-79% B. If the alkalinity was increased to 32.5% (Run 4), no deposit at all was obtained. These poor results with alkaline baths may have been due to oxidation of the deposit by carbonate, which was present in alkaline baths in higher concentrations than in nonalkaline baths (Runs 3, 4, 6).

Better results were obtained with electrolytes not containing added alkalinity. Electrolytes com-

[f] Run 10: HCl was passed into this bath for 2½ hr, causing a second liquid of composition 21% KCl, 31% KF and 48% B_2O_3 to form at the bottom of the crucible.
[g] Run 15: Gaseous HF passed into bath before electrolysis.
[h] Run 16: Cooper (12) electrolyte.
[i] Run 19: Product contained 2.3% Mg.
Note: Cathode dimensions: Runs 1-4, 6, 7, 13, 14, 19: flat, 12 × 2 cm, immersed 23 cm; Run 5: cylindrical, 9 cm diameter, immersed 12 cm; Runs 8-12, 15-18: cylindrical, 6 cm diameter, immersed 23-24 cm.

posed of KCl, KF, and B_2O_3 (runs 5-8) gave products ranging up to a maximum of 91.6% boron in the coarser fraction of Run 8. In these experiments the + 100 mesh fraction of the product was usually of higher purity than the finer fractions. When a flat cathode was used, the deposit at the edges, where the current density was greater, generally gave a somewhat higher purity than that on the flat sides. This bath composition gave poor results under some conditions such as low temperatures and low KF or B_2O_3 concentrations. A KF/KCl ratio equal to that of the eutectic in the system KF-KCl also gave poor results (Run 5).

It is known that fused halides exposed to the atmosphere will gradually become alkaline. Since the above experiments indicated that an increase in electrolyte alkalinity gave a poorer quality product, neutralization with HCl was attempted. It was found that the alkalinity could be eliminated by bubbling HCl gas into the fused salt bath through a graphite tube. A convenient means of controlling the addition of the gas was to determine the *p*H of a 0.33% solution of the electrolyte. By electrolysis of these acid-treated baths (Runs 9-12) it was possible to produce boron of markedly increased purity. The highest over-all product purity reached was 96% B in Run 11. Coarser fractions of the products were again of higher purity than the finer fractions and reached 97.3-97.5% B in several runs. Boron of good purity was obtained with electrolytes of which the *p*H of the 0.33% solution ranged from 4.8 to 7.2, and the KCl:KF:B_2O_3 proportions by weight were 47:30:23, 57:30:13, 42:38:20, and 45:40:15.

Figure 1 is a phase equilibrium diagram of the liquid system KCl-KF-B_2O_3. The numbers shown are examples of the product purity obtained with acid-treated baths of various proportions of these components. In Run 10, the HCl was passed into the fused bath for 2½ hr, which apparently caused a loss of HF from the bath and resulted in separation of the bath into two liquids, represented by the ends of the tie line in Fig. 1.

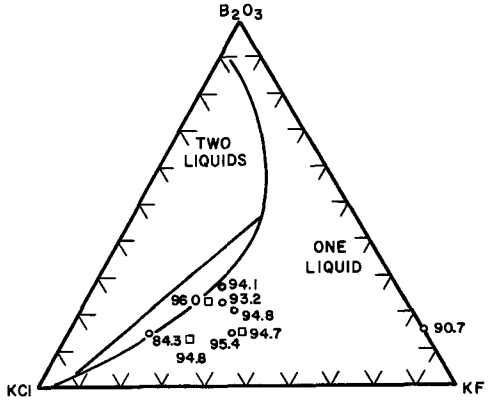

Fig. 1. Phase diagram for the liquid system KCl-KF-B_2O_3 at approximately 800°-900°C (wt %), showing the per cent boron in the product obtained by HCl treatment and electrolysis of various electrolyte compositions. Squares represent products in which the +100 mesh fraction consisted of 97.3-97.5% boron.

For reasons not fully understood, lower purities and "blistering" of the deposits were sometimes observed. A cause of this may be the partial burning of the deposit which sometimes occurred in spots just after removal of the cathode from the bath.

Other electrolyte compositions were investigated. Electrolytes of B_2O_3 dissolved in KF were tried over a range of B_2O_3 concentration up to the composition B_2O_3:2KF suggested by Kahlenberg (10). An attempt was made to acidify these baths by passing in gaseous HF. The HF was absorbed, but less readily than HCl. The maximum product purity obtained with this acidified bath was 90.7% (Run 15) compared with 86.5% without addition of acid (Run 14).

Cooper's (12) electrolyte KCl-KBF_4-B_2O_3 gave typically 93.5-95.5% purity under our conditions. An example is Run 16.

Electrolytes containing sodium salts were tried, HCl being passed in as before (Runs 17, 18). Sodium salts did not absorb either HCl or HF well enough to become acidic. These experiments gave lower product purities than the potassium salts and thus confirm Cooper's (12) statement that sodium salts are detrimental. Metallic sodium was observed in the deposit and on the surface of the bath in some cases, especially where the operating temperature was below the boiling point of sodium, 880°C.

Also, electrolytes composed of KF, MgF_2, and B_2O_3 were tried (Run 19) but the purities were only 82-84% B and the products contained appreciable amounts of magnesium.

Acknowledgment

The author wishes to thank Dr. E. W. Fajans for helpful discussions, and Vincent Morgan, L. E. Hiebert, L. L. Thomas, and S. A. Sorenson for their contributions to the experimental work.

Catalytic Activity and Electronic Structure of Rhodium-Palladium-Hydrogen Cathodes in Acid Solution

James P. Hoare[1]

Scientific Laboratory, Ford Motor Company, Dearborn, Michigan

ABSTRACT

Hydrogen overvoltage measurements were made on a series of rhodium-palladium alloy cathode beads. Two phases, α and β similar to those in the Pd-H system, are considered in the Rh-Pd-H system. Mechanisms for the hydrogen producing reactions on rhodium, palladium, and rhodium-palladium alloy cathodes are discussed. From low current density measurements the catalytic activity of the cathode surface for the hydrogen reaction was determined. It appears that vacancies in the *d*-band of the catalyst metal are necessary for strong bonds between the absorbed hydrogen and the surface but it is the density of states at the Fermi level that determines how strong the chemisorbed bonds are. The catalytic activity is directly related to the heat of absorption and so to the *d*-band structure.

In recent years much interest has been generated in establishing relationships between the surface properties of metallic catalysts and the electronic structure of the bulk metal (1). It has been suggested that on a metal such as palladium, containing vacancies in the *d*-band, hydrogen is adsorbed with a greater heat of adsorption than on an alloy of palladium and gold in which the number of *d*-band vacancies has been reduced (2).

Hydrogen overvoltage measurements were carried out on a series of Pd-Au (3) and Pd-Ni (4) alloys. The results of these investigations indicated that the surface catalytic activity of the electrode is directly associated with the number of vacancies in the *d*-band of the bulk metal through the heat of adsorption of hydrogen on the metal as pointed out by Conway and Bockris (5). It was, therefore, indicated (2, 3, 5, 6) that for metals on which the slow discharge step or Volmer mechanism (7) is rate determining the catalytic activity should increase (2, 3) as the number of holes is increased. However, for those metals on which an H-atom desorption step is rate controlling, such as the slow combination or Tafel mechanism (8) and the so-called electrochemical or Horiuti mechanism (9), the reverse should be true.

In order to test this theory further and possibly to determine whether the catalytic activity is related to the number of holes or to the density of states in the *d*-band it was desired to find a series of alloys in which the number of holes could be increased. An obvious system is that of Rh-Pd. Although the phase diagram of this system is not available, still the two metals have very similar atomic dimensions and both form face-centered cubic crystals (10). Therefore, it is not unlikely that they are completely miscible in one another. Since Rh has one less electron than Pd, additions of Rh to Pd should form a series of alloys with an increasing number of vacancies in the alloy *d*-band. It is with this system that the present investigation is concerned.

Experimental Methods

A series of Rh-Pd alloys of the following compositions were made by melting the required amount of Pd, 99.7% pure, with that of Rh, 99.8% pure, in an induction furnace under a hydrogen atmosphere. These compositions are: 1, 2, 5, 10, 15, 20, 50, and 90 atomic per cent (a/o) rhodium. A portion of the alloy, welded to a Pt wire which served as the electrical contact, was melted to form a small bead. The alloy bead and the Pt lead were imbedded in polyethylene in such a manner that only a hemisphere of the alloy bead was exposed. The exposed apparent surface area of the beads, measured geometrically, ranged between 0.09 and 0.04 cm^2.

The cylindrical cell, shown in Fig. 1, was made of Teflon and was designed to hold about 25 ml of solution. A large piece of Pt gauze lined three quarters of the inner wall and served as the anode, while a rather small piece of Pt gauze served as the reference electrode. The cell top was fitted with a Teflon tube which provided the hydrogen inlet, a

[1] Present address: Research Labs., General Motors Corp., Warren, Mich.

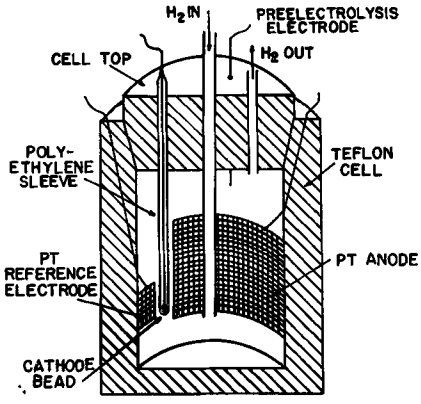

Fig. 1. Teflon cell

short tube for the hydrogen outlet, the polyethylene covered cathode bead and platinum lead, and a hole through which the pre-electrolysis electrode (a Pt wire) could be placed.

The water was triply distilled from an all-quartz still, and all purification techniques were the same as those described before (11, 4). Overvoltage measurements on the alloy beads were carried out with an electronic current interrupter in electrolytically purified 2*N* sulfuric acid solution vigorously stirred with purified hydrogen in the same way as was done in the case of the bright Pd bead (11). Potential measurements were recorded only when the pulse from the current interrupter indicated clean surface (12) conditions (high pseudo-capacitance) (13). The temperature was 25° ± 1°C, and individual points could be reproduced within ± 2.5 mv. The potential η (positive in the direction of anodic polarization) is an electrode potential or overpotential measured by reference to a reversible Pt/H_2 electrode in the same solution.

Results and Discussion

Two series of experiments were carried out on the Rh-Pd alloy beads.

The α-Rh-Pd-H *System.*—In the first series of experiments, the Rh-Pd alloy cathode was anodized at a relatively high current density (0.3 amp/cm^2) for about 30 min. The circuit was broken and the open-circuit potential of the bead vs. a Pt/H_2 electrode in the same solution was followed as a function of time. When the ternary system, Rh-Pd-H, had reached a steady state and the potential had been constant for at least 12 hr, this steady-state value was recorded. Then by means of a constant current source and a high-value series resistor (20 to 60 megohm), the alloy bead was first slightly cathodized stepwise and the time independent (constant for at least 10 min) values of the potential η were recorded for each step. Afterwards, the cathodic current was reduced stepwise to zero and was continued in like manner in the anodic direction. The points on the curves in Fig. 2 are the average values for at least three cycles of increasing and then decreasing the current over the complete current range shown in Fig. 2. These points were reproducible within ± 0.5 mv.

The potential η observed at zero current may be interpreted as a mixed potential derived from two

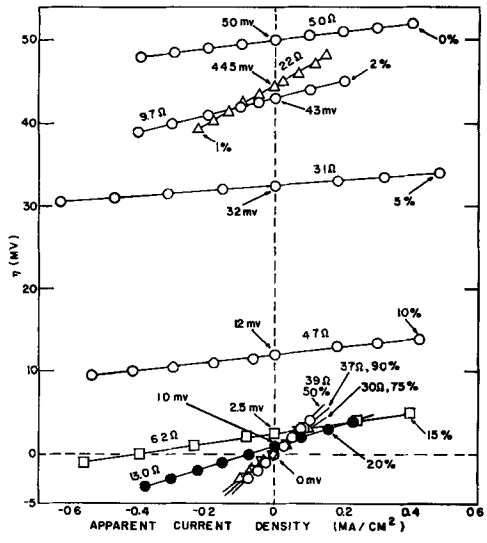

Fig. 2. Apparent current density i vs. electrode potential or overpotential η referred to a Pt/H_2 electrode in the same solution (2N H_2SO_4). phases existing in the Rh-Pd-H system analogous to the α and β phases found in the Pd-H system (14). If, in this region, the mixed potential is determined by the α-phase analogue of the Rh-Pd-H system (hereafter designated as α-Rh-Pd-H), then this steady-state potential is, for practical purposes, identical to the equilibrium potential (15) for the saturated α-phase. Since it has been shown (16) that in the Pd-H system a bead-type of electrode similar to that used in this investigation exhibits the potential of a Pd cathode in the α-phase of maximum composition for periods of time greater than a week, these electrodes are good approximations to a pure α-phase electrode. There may or may not be small amounts of the β-phase also present, but the electrochemical properties are determined by the dominant α-phase.

In the low current density region where a linear relationship between the current density i and electrode potential or overpotential η exists, the slope of the i vs. η curve may be taken as a measure of the rate of the hydrogen reaction k occurring at the electrode (17), i.e., k will be defined as equal to $di/d\eta$. A plot of the rates of reaction obtained from the reciprocal of the slopes of the curves in Fig. 2 for the hydrogen reaction proceeding on the α-Rh-Pd-H cathodes is shown by the triangles in Fig. 3. These experiments were also repeated for a pure Pd bead on which k was observed to be 0.20 mho cm^{-2} in agreement with the value of 0.13 mho cm^{-2} found earlier for α-Pd (18).

The β-Rh-Pd-H *System.*—In the second series of experiments, the Rh-Pd beads, after strong anodization, were cathodized at current densities of the order of 300 ma cm^{-2} for about 90 min. This treatment converted the cathodes completely to the β-Rh-Pd-H phase. Cathodic overvoltage measurements were taken as before (11). Results are shown in Fig. 4. Overvoltage measurements were also

made on a pure Pd and pure Rh bead; these results are included in Fig. 4 and are similar to those found in the literature (11, 19).

In general, it is seen that these data may be placed in two groups. In the first group are the data for high Pd-content cathodes up to 15 a/o Rh. The curves are composed of three sections: the low current or non-Tafel region, a Tafel region in which b is about 0.04 v, and a second Tafel region in which b is about 0.12 v. The high Rh content alloys, from 50 to 100 a/o Rh, form the second group. These curves have only one Tafel region whose b-slope is 0.12 v in addition to the non-Tafel region. Parsons (20) has discussed the mechanisms of electrochemical kinetics in terms of Tafel b-slopes. A slope of 0.04 v found on the high Pd-content alloys as well as on pure Pd (11) is consistent with the electrochemical mechanism on a sparsely covered surface. Although a unique mechanism for a slope of 0.12 v is not available (20), it is felt that the data for high Rh-content cathodes are more easily interpreted in terms of the slow discharge mechanism for the same reasons offered in the case of Pd-Ni alloys (4).

A mixed mechanism is exhibited by the data taken on the 20 a/o Rh cathode shown in Fig. 4. These data seem to correspond to a transition state between the high Rh-content and high Pd-content cathodes. Here a Tafel region with a b-value of 0.075 v is observed which could be explained by a mechanism in which both the slow discharge and the electrochemical steps are equally slow and are equally rate determining.

From a plot of η vs. i at low current densities, the rate k for the hydrogen reaction proceeding on a β-Rh-Pd-H cathode was determined in the same way as for the α-Rh-Pd-H cathode electrodes above. These linear plots did not pass through zero potential for the high-Pd content cathodes at zero current density. This same behavior was noted in the Pd-H (11), Au-Pd (3), and Ni-Pd-H (4) systems and may be interpreted similarly (11) as due to the partial pressure of the dissolved hydrogen. The

curves for the high Rh-content alloys all pass through zero at zero current density. These curves are not shown, but the values for k and for the zero current intercepts η_0 are given in Table I along with the Tafel b-slopes of the high current density regions (Fig. 4).

A plot of k for β-Rh-Pd-H as a function of atomic % Rh is shown by the circles in Fig. 3. In the case of the high Pd-content cathodes, the rate is considerably higher for the β than for the α-analogue. However, the rate is approximately the same in the two cases for the high Rh-content cathodes which is to be expected if these alloys dissolve negligible quantities of hydrogen. The smooth curve drawn through these points would indicate, then, that the hydrogen solubility limit occurs at about 30 a/o Rh. Both curves exhibit a pronounced maximum at about 5 a/o Rh.

Catalytic activity and electronic structure.—The magnetic susceptibility and the low-temperature specific heat of Pd-Rh alloys have been measured (21). A maximum is found in the susceptibility-composition curve at about 5 a/o Rh. This is interesting since one obtains an alloy with a magnetic susceptibility greater than that of either pure substance. From the specific heat data, the electronic heat coefficient γ was determined, and a plot of γ as a function of the alloy composition also exhibits a maximum at about 5 a/o Rh. The fact that both quantities have a maximum value for the same

alloy composition suggests that the density of states at the Fermi level for the alloy is at a maximum value.

It has been assumed that the electrode mechanism on the high Pd-content cathodes is electrochemically controlled and, therefore, that a H-atom desorption step is rate determining. As the number of holes in the d-band is increased by additions of Rh to Pd, the heat of adsorption of hydrogen should increase and the rate of reaction k should decrease (2). This is observed. The reaction rates are higher for all β-Rh-Pd-H cathodes where all holes in the d-band have been filled with electrons from dissolved hydrogen than for the corresponding α-Rh-Pd-H cathodes where all the holes have not been filled as shown in Fig. 3. Apparently this is not the complete picture since each curve in Fig. 3 shows a maximum at an alloy concentration of 5 a/o Rh, suggesting that the rate of the hydrogen reaction on Rh-Pd-H alloy cathodes is also a function of the density of states at the Fermi-level energy of the hydrogen-free Rh-Pd alloys.

Such an interpretation of the data requires that a direct relationship exist between the activation energy and the heat of adsorption of hydrogen, which is not self-evident. By a theoretical analysis of the shape of the energy surfaces involved and by an inspection of the pertinent experimental data, Rüetschi and Delahay (22) were able to show a linear relationship between the hydrogen reaction occurring at Ni, Ag, and Hg cathodes and the heat of adsorption on these metals. However, this gives an expression opposite in sign to that found for Pd-H alloys (2). The rate-determining step on Ni, Ag, and Hg is found to be the slow discharge of a hydrogen ion from the double layer (23). In this case, as the number of holes in the d-band are decreased and, consequently, the heat of adsorption of hydrogen decreased, the rate of reaction should decrease (2) as found by Oikawa (24) for a series of Ni-Cu alloy cathodes. This was observed by Rüetschi and Delahay as shown in Fig. 2 of ref. (22).

Recently, from theoretical considerations, Parsons (25) and Gerischer (26) have come to the similar conclusions that the plot of the logarithm of the rate of the hydrogen reaction at equilibrium conditions, (when the overvoltage η is zero) i.e., the exchange current density i_o, as a function of the energy of adsorption of hydrogen, gives a similar type of curve no matter which step is rate determining. This indicates that the reaction mechanism cannot be determined alone by the sign of the relationship between changes in the rate with changes in the energy of adsorption. This is not held by Conway and Bockris (5). It is to be remembered, though, that Parsons considers a noble metal cathode surface to be highly covered with atomic hydrogen and assumes that the shape of the Morse curve is rigid and does not change as the energy of adsorption changes. Shuldiner and Hoare (3, 4, 11, 27) consider such surfaces to be sparsely covered with atomic hydrogen.

It should also be noted that Parsons, Bockris, and Delahay consider the changes in reaction rate with changes in heat of adsorption obtained from studies of overvoltage on a series of different metal cathodes, while Schuldiner and Hoare (2) observe these changes on continuous series of alloy cathodes. In these latter cases, abrupt changes or even discontinuities in the properties of the cathode surface are less likely.

It is interesting to note that the influence of the density of states on the rate of reaction is such that the activation energy decreases as the density of states in the hydrogen-free Rh-Pd alloys increases. It is not unreasonable to consider that changes in the density of states in the bulk material would change the energy of the surface states which in turn would cause changes in the activation energy of the reaction occurring at the surface.

It is suggested, then, that the presence of holes in the d-band of the Rh-Pd alloy cathodes makes possible the formation of strong chemical bonds between the chemisorbed hydrogen atoms and the metallic atoms of the cathode surface (5); that there is a direct correspondence between the heat of adsorption of hydrogen and the activation energy of the hydrogen reaction; and that, once a strong bond is formed, how strong the bond is or how much energy resides in the bond is a function of density of states at the Fermi-level energy in the bulk hydrogen-free alloy in such a manner that, as the density of states increases, the bond becomes less strong.

For the alloys above about 30 a/o Rh there is not any essential difference between the two curves since these alloys do not dissolve significant quantities of hydrogen and, hence, do not form α- and β-type phases but only one single solid Rh-Pd phase. As suggested above, the slow discharge mechanism is rate controlling on these cathodes. As Rh is added and the number of holes increases, the rate on the high Rh-content cathodes should increase since now the slow discharge mechanism is rate determining. The data in column 2 of Table I does show a trend in that direction. Even though this slight increase may be within the limits of experimental error, the amount of the increase for the high-Rh-content cathodes may actually be very small and difficult to detect because of experimental difficulties. This is true since Rh with about two holes in the d-band per atom is in such great excess in this range of alloy composition (50 a/o Rh) that the percentage of change in the number of holes in the alloy d-band with additions and subtractions of Pd having only 0.6 hole per atom would be very small.

Finally, the initial drop in the rate curves in Fig. 3 from the value for pure Pd is surprising and unexpected. The rate for the 1% Rh cathode was checked twice with new beads, and the value shown was reproduced each time. Although a quantitative explanation for this is not available at this time, a qualitative one may be found in Parsons' work (25). He shows on theoretical grounds that i_o is proportional to $1/p^n$, where p is the partial pressure of molecular hydrogen and n has a value between 0 and 1. If the magnitude of the intercept η_o (Table I) is proportional to the excess partial pressure of

dissolved hydrogen above the equilibrium partial pressure, then it is seen that this partial pressure increases in going from pure Pd to 1 a/o Rh in Pd. Therefore, the rate should drop, since $p > 1$. For higher Rh-content alloys there is little or no change in η_o, and this effect is not observed.

Acknowledgments

The author wishes to express his gratitude to Dr. A. Arrott and Dr. A. W. Overhauser of the Physics Department for most helpful and interesting discussions and to Dr. J. E. Goldman, Manager of the Chemistry and Physics Departments, for his many well-taken comments and faithful support during the course of this work. The author is also indebted to Dr. F. E. Hoare of Leeds University for his fruitful suggestions, to Dr. G. Parravano of the University of Michigan for his most interesting criticism, to the Metallurgy Department of the Ford Scientific Laboratory for the preparation of the alloys, and to the Analytical Section of the Physics Department for the analysis of the alloys.

Fused Salt Polarography Using a Dropping Bismuth Cathode

Raymond J. Heus and James J. Egan

Brookhaven National Laboratory, Upton, New York

ABSTRACT

An apparatus is described which is suitable to study fused chlorides by the polarographic technique. Dropping bismuth is used in a way analogous to dropping mercury. Polarographic waves are shown for $PbCl_2$, $ZnCl_2$, and $CdCl_2$ in a LiCl-KCl eutectic melt at 450°C. The method serves as an analytical tool at high temperatures, besides yielding physicochemical information such as diffusion coefficients by application of the Ilkovic equation.

Many studies have been made on fused salts using the polarographic technique (1-8). In general solid wire microelectrodes have been used to measure concentrations which were found to be proportional to the limiting current. The dipping platinum microelectrode has been used by Flengas (9), and Chovnyk used derivative polarography at wire microelectrodes (10). Nachtrieb and Steinberg used a dropping mercury electrode to study low melting nitrate melts (11).

The dropping mercury electrode has not been employed at temperatures greater than 220°C, due to the high vapor pressure of mercury. Aside from gallium (12), no metal other than mercury has been employed as a dropping electrode, but dropping electrodes should prove useful since they have been so successful in lower temperature studies.

In order to expand the range of temperatures at which dropping electrodes can be used, the following work was undertaken using molten bismuth at 450°C as the electrode material. Bismuth is an adequate metal for this purpose since its chloride is not too stable, the element is liquid over a large temperature range with a low vapor pressure, and it

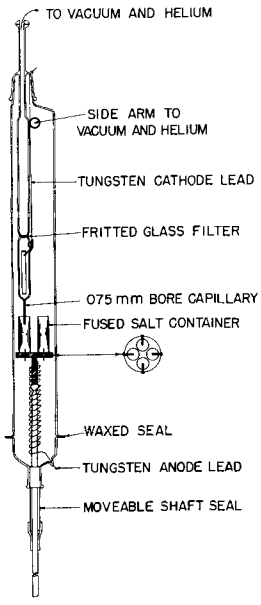

Fig. 1. Dropping bismuth polarographic cell with four fused salt cups.

has a melting point of 271°C. Other metals however can probably be used instead of bismuth depending on the experimental conditions.

Finally, the advantages of the dropping electrode include a constantly renewed surface which is important when ions are being reduced to metals at the electrode, and a shape which enables a mathematical treatment of the mass transport at this electrode (Ilkovic equation). When proper care is taken, the dropping electrode seems to obey these equations better than other electrodes, probably because of the thin diffusion layer which exists at dropping electrodes (13a).

Experimental Details

The apparatus used for obtaining polarograms is shown in Fig. 1. Since it was imperative to exclude oxygen from both the bismuth (the formation of an oxide causes plugging of the capillary) and the fused salt, the capillary and salt cup were contained in a vacuum-tight Vycor tube 70 cm long and 64 mm in diameter. Ground glass ball joints connected the container and the space above the capillary to separate sources of both helium and high vacuum. This arrangement allows one to regulate the pressure difference across the capillary to any value between 0 and 1 atmosphere.

The capillaries were made by drawing Pyrex tubing to a small bore, care being taken to obtain a thick wall so the end could be cut off at 90° to the bore. The particular capillary to be used was then selected by examination using a microscope. Capillaries with a 0.075-mm bore and a 10-cm length were found best suited for experiments. One could produce a slow drop time with this size, and the bore was large enough not to plug easily. Before the bismuth entered the capillary it was filtered through a coarse Pyrex frit located above the capillary.

The fused salt was held in four Pyrex cups which also contained bismuth pool anodes. A tungsten wire was sealed into the bottom of each cup and cleaned electrolytically to insure good electrical contact. The tungsten wires also served to hold the salt cups on a stand which could be raised and lowered to the desired height by a moveable shaft seal. This shaft seal was constructed from "trubore tubing" which was lubricated with a high vacuum grease to keep the container tight to a vacuum better than 10^{-5} mm Hg. Electrical contact to the dropping bismuth cathode was made by sealing a tungsten wire through the inner Pyrex tube as shown. To assure a good electrical contact with the bismuth pool, a tantalum ribbon was spot welded to the tungsten wire.

In an attempt to make the capillary section of use in more than one experiment, a tantalum foil "pillow" was added to this compartment. When the bismuth solidified upon cooling, the pillow would collapse and the glass would not break. Unfortunately, bismuth remaining in the capillary itself would more often than not break the capillary upon expansion.

A wire wound nichrome resistance furnace surrounding the outer Vycor container was used to heat the contents to approximately 450°C. The temperature was measured with a chromel-alumel thermocouple attached to the outside of the Vycor container and was controlled with a recording potentiometer. A sight port through the cylindrical furnace enabled one to view the dropping electrode and the salt cups for manipulation at high temperature.

The current through the cell was measured by recording the voltage drop across a standard resistor (200 or 250 ohm) in series with the cell. A Brown automatic recorder with 25 mv full scale and a pen speed of 3.5 sec full scale was used. The potential applied across the cell varied linearly with time at the rate of 0.3 v/min. This was accomplished by driving a Helipot with a synchronous motor and a Graham variable speed transmission, the source of voltage being a 2-v storage battery.

After each run the entire salt content of the cell was weighed, dissolved, and analyzed for Pb, Cd, or Zn using aqueous polarographic techniques.

The LiCl-KCl eutectic (41 mole % KCl) used as solvent was prepared as follows. The powdered materials, in a weight ratio to form the eutectic mixture, were put above a fine Pyrex frit and attached to a source of high vacuum and purified helium. The contents were heated under vacuum just below the melting point for approximately 24 hr then melted under vacuum for another hour and forced through the frit into capsules by applying an atmosphere of helium pressure over the molten salt. The capsules were then evacuated and sealed off for later use in experiments.

The solute salts were prepared independently. The $PbCl_2$ was used as obtained from the manufacturer. The $CdCl_2$ powder was desiccated for one day under vacuum. The $ZnCl_2$ powder was heated under dry HCl, then melted, and finally evacuated and sealed off in a capsule until used. The bismuth metal was also pretreated before it was loaded into

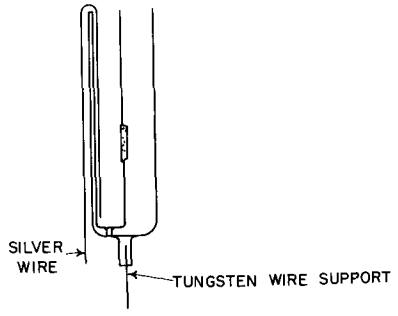

Fig. 2. Fused salt cup using a Ag|AgCl reference electrode

the apparatus by melting and filtering it through a coarse glass frit.

In order to use the half cell Ag|AgCl in LiCl-KCl (eutectic), as a working anode instead of the bismuth pool, the cup shown in Fig. 2 was constructed and replaced the cups shown in Fig. 1. Here a small tube containing a fine Pyrex frit was sealed into one of the ordinary salt cups. A 2 wt % solution of AgCl in KCl-LiCl (eutectic) was added to this tube along with a Ag wire. The remainder of the cup was filled with the solution to be examined. The tungsten wire merely served to hold the cup on its platform and the Ag wire was the anode. Unfortunately, the fine frit would sometimes allow appreciable amounts of AgCl to diffuse through it. The silver chloride would then react with the bismuth pool collected at the bottom of the larger compartment to produce bismuth trichloride. This bismuth trichloride would then be reduced at the dropping electrode and interfere with the shape of the polarograms under investigation. For this reason the bismuth pool anode was used in most experiments.

Experimental Results

Polarograms obtained with the apparatus are shown in Fig. 3, 4, and 5 and Fig. 8. Figure 3 is a polarogram taken on the solvent salt alone giving a background current of 9 μa. This current decreases slightly at larger drop times. An estimate of the reducible impurity content of this salt from the polarogram puts it at about 0.5 millimoles/liter. Figure 4 is a polarogram of $PbCl_2$, whereas Fig. 5 shows a polarogram of $CdCl_2$ in the eutectic mixture. In all of these curves it can be seen that the solvent salt starts to be reduced at around −0.8 v with respect to the bismuth pool.

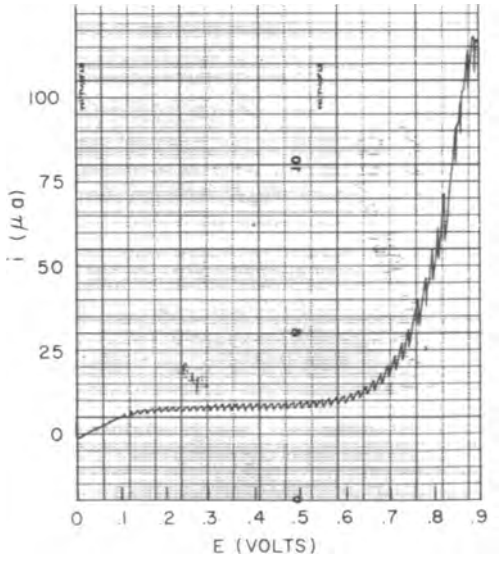

Fig. 3. Polarogram of LiCl-KCl eutectic (blank) using a drop time of 2.7 sec. Potential negative to bismuth pool anode here and in Figs. 4, 5, 8.

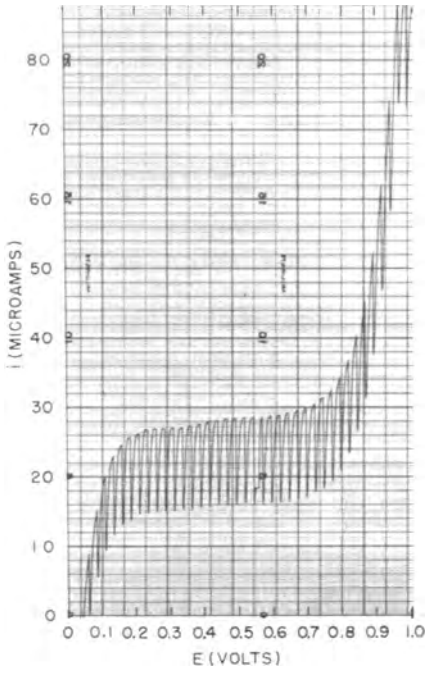

Fig. 4. Polarogram of a 1.8 millimole/liter $PbCl_2$ solution in LiCl-KCl eutectic at a drop time of 4 sec.

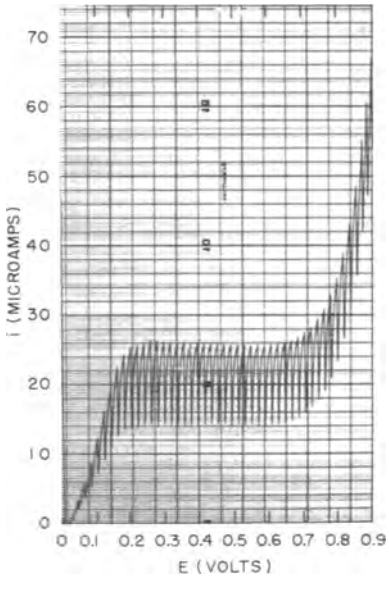

Fig. 5. Polarogram of a 3.4 millimole/liter $CdCl_2$ solution in LiCl-KCl eutectic at a drop time of 3.1 sec.

In the polarogram of $PbCl_2$ there is a small negative current which arises before a voltage is applied to the cell. This is probably due to a mixed potential arising from the reaction

$$2Bi(\text{dropping electrode}) + 3PbCl_2(\text{LiCl-KCl}) = 2BiCl_3(\text{LiCl-KCl}) + 3Pb(Bi)$$

which takes place to a small extent when the fresh bismuth solution comes in contact with the salt

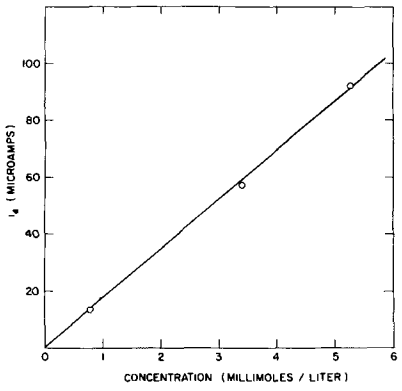

Fig. 6. Concentration dependence of the diffusion current for $PbCl_2$ at a drop time of 4 sec.

solution. Since $CdCl_2$ is more stable than $PbCl_2$ (14), this effect is negligible in the $CdCl_2$ polarogram.

The concentration dependence of the diffusion current is shown in Fig. 6 and 7 for $PbCl_2$ and $CdCl_2$ where a correction has been made for the current from the solvent alone. The diffusion current was taken at the maximum current of each drop. Concentrations were calculated using the density data of Van Artsdalen and Yaffe (15). A straight line is obtained within 5% for concentrations from 0.5 to 5 millimolar. This precision can probably be improved by further purification of the solvent salt and the use of more advanced electrical circuitry techniques.

Figure 8 shows a polarogram of $PbCl_2$ and $ZnCl_2$ in the eutectic mixture with a very fast drop time. Here the limiting current is not diffusion controlled (note the large currents obtained in comparison to those using large drop times), the Ilkovic equation fails and one readily obtains maxima as evidence with the Zn^{++} wave. It was found however that the limiting current was proportional to the concentration even at these fast drop times.

Discussion

The Ilkovic equation for bismuth drops at 450°C is

$$i_d = 880\, n\, D^{1/2} C\, m^{2/3} t^{1/6}$$

where i_d is the diffusion current in microamperes, measured at the maximum current of each drop, t the drop time in seconds, m the mass of the flowing bismuth in mg/sec, D the diffusion coefficient in cm^2/sec, and C the concentration in millimoles/liter. This equation is derived using the density of liquid bismuth at 450°C which is 9.8 g/cm^3 (16). Since the diffusion current i_d is inversely proportional to the two-thirds power of the density of the flowing metal (13b), the above equation is obtained from the corresponding equation for mercury by multiplication of the mercury constant 706 by the two-thirds power of the density ratio of mercury to bismuth $(13.69/9.8)^{2/3}$.

Diffusion coefficients were calculated from this equation by measuring m and t. Knowing the values of i_d and C as shown in Fig. 6 and 7, the values of D were found to be 1.7×10^{-5} cm^2/sec and 1.8×10^{-5} cm^2/sec for $PbCl_2$ and $CdCl_2$, respectively, at 450°C.

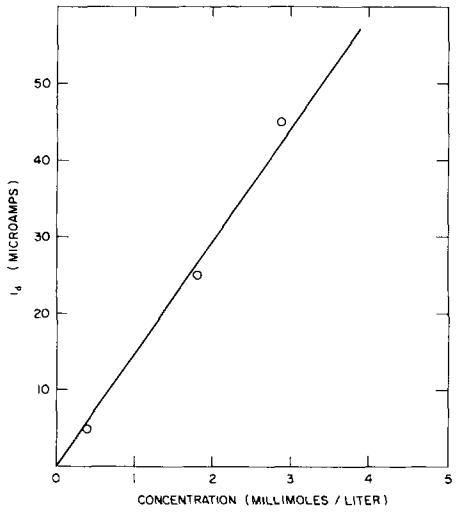

Fig. 7. Concentration dependence of the diffusion current for $CdCl_2$ at a drop time of 3.1 sec.

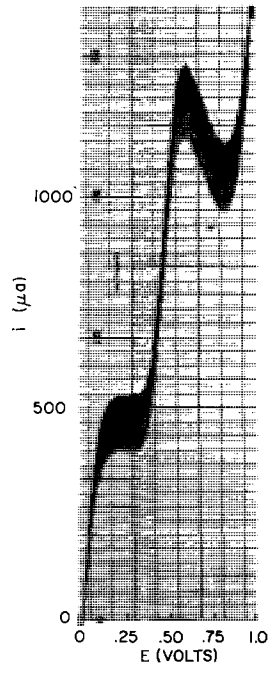

Fig. 8. Polarogram of a solution containing 3.6 millimoles/liter $PbCl_2$ and 8.5 millimoles/liter $ZnCl_2$ in the eutectic mixture at a drop time of 0.8 sec.

Since Laitinen and co-workers (17, 18) have obtained the diffusion coefficients for $PbCl_2$ and $CdCl_2$ in this eutectic mixture from chronopotentiometric measurements, a check was available to see that the Ilkovic equation was applicable. These workers obtain values for D of 2.0×10^{-5} cm^2/sec and 1.7×10^{-5} cm^2/sec for $PbCl_2$ and $CdCl_2$, respectively. The agreement is considered satisfactory and within the limits expected in light of the assumptions made in obtaining the Ilkovic equation and the experimental accuracy of the measurements reported here.

Other elements may also be examined using dropping bismuth electrodes. Although the LiCl starts to be reduced at −0.8 v with respect to the bismuth pool due to its low activity coefficient in bismuth (19) and its high concentration in the salt

mixture, it is estimated that all chlorides less stable than manganese and more stable than gallium (14) can be investigated with pure dropping bismuth electrodes. Use of alloy electrodes might extend the range of elements which can be studied.

In these experiments it was found that when the concentration of reducible ion exceeds 7 or 8 millimoles/liter, polarographic maxima would interfere with the measurements. As expected the maxima occurred more readily at faster drop times. No attempt was made to find a maximum suppressor for these systems.

Acknowledgments

The authors would like to thank Mr. L. Bowditch, Dr. K. Rowley, Miss Elinor Norton, and Dr. F. T. Miles, for their help during the course of this work, and especially Dr. R. H. Wiswall, Jr., who originally suggested this problem. They also thank Dr. R. A. Osteryoung for helpful suggestions concerning the importance of drop time in obtaining a diffusion controlled process.

Manuscript received March 31, 1960. Work on this paper was done under the auspices of the U.S.A.E.C.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

Irreversible Thermodynamics in Electrochemistry

Andre J. deBethune

Chemistry Department, Boston College, Chestnut Hill, Massachusetts

ABSTRACT

The Onsager thermodynamics of irreversible processes provides a unified approach to the study of electrolytic systems out of equilibrium, such as concentration cells with transference, the initial and final emf's of thermal cells, and thermal diffusion (Soret effect) of ions. For concentration cells, the method justifies the classical results obtained by Nernst from equilibrium considerations. For nonisothermal systems, the product S^*dT is the thermodynamic driving force of a process, where S^* is the entropy transported reversibly from the "hot" to the "cold" heat reservoir (in the limiting case of equal temperatures) by the occurrence of a reversible process in the system. The emf of a concentration cell, the initial emf of a thermal cell, and the Soret coefficient, all properties of systems out of equilibrium, are determined, according to the Onsager relations, by the ratios of the reversible fluxes of matter to electricity, of entropy to electricity, and of entropy to matter, respectively, as they occur in systems completely at equilibrium.

The transport entropy S^* can become, according to circumstances, the entropy S^*_I of electrical transport, or the entropy S^*_D of diffusion transport. S^*_I in turn involves the entropies S^*_E of electrochemical transport (for the electrode reactions) and S^*_M of migration transport (for the thermal liquid junction). The contribution of an ion (or electron) to S^*_E and to S^*_M gives rise to the ionic entropies of electrochemical transport S^*_{Ei} and of migration transport S^*_{Mi}, respectively. The latter contributes also to S^*_D. The sum $\overline{S}_i = S^*_{Ei} + S^*_{Mi}$ is known as the entropy of the moving ion and is measurable for a single ionic species. The initial thermal emf involves the transport entropy S^*_I, the Soret coefficient involves S^*_D, while the final thermal emf involves $S^*_I \pm t_g S^*_D$ where t_g is the transference number of the ion to which the electrodes are not reversible.

For the hydrogen ion, $S^{*\circ}_E(H^+) = -4.48$ cal/deg, if S^*_M is taken as zero in a saturated potassium chloride salt bridge. For other ions, $S^{*\circ}_{Ei} = S^\circ_i - z_i\ 4.48$, and the mass action dependence is normal. For most ions, S^*_{Mi} appears to be small, i.e., about 0-3 cal/deg, and the mass action dependence is abnormal and low. In dilute solutions, S^*_{Mi} shows a Debye dependence on concentration. These facts are consistent with the electrostatic interpretation of S^*_{Mi} as the entropy of depolarization of the solvent dielectric when the ion moves away. For ions transferred by a chain mechanism (H^+ and OH^-), S^*_{Mi} is significantly larger. The transport of ions across biological membranes plays an important role in life processes. Since living systems are not necessarily uniform in temperature, ionic transport entropies may have a role to play in the function of the biological cell.

The classic application of thermodynamics to a cell out of equilibrium is Nernst's (1) well-known law for the emf of an isothermal concentration cell with transference, derivable from chemical potentials (free energies), and expressible in terms of ionic transference numbers t_i and ionic concentrations c_i (in ideal solutions) or ionic activities a_i.

Another example of a cell out of equilibrium is a thermal cell (electrochemical thermocouple) consisting of two identical electrode-electrolyte systems maintained at two different temperatures. A thermal cell develops a measurable emf, usually several tenths of a millivolt per degree, directly proportional to the applied temperature differential over not too wide temperature ranges. Thermal cells have been investigated experimentally, since the pioneering work of Bouty (2), by Richards (3), Kolthoff (4), Sorensen (5), and Lange (6), among others. The subject has been reviewed by Lange (7) and by deBethune, Licht, and Swendeman (8, hereinafter referred to as deBLS). Under usual experimental conditions, the emf developed, known as the *initial thermal emf,* has been found stable whenever free convection maintains constancy of the electrolyte concentration across the temperature gradient.

Thermal cells may be subject to thermal diffusion in the electrolyte (Soret effect) (9). This tends to concentrate strong electrolytes, usually in the cold region (10), by several tenths of one per cent per degree (11). The development of these concentration gradients, if not prevented by convection, further affects the emf, which gradually shifts to a new stationary value, the *final thermal emf.* Such

emf shifts were demonstrated experimentally by Agar and Breck (12) in a cell whose electrolyte was wholly contained within the pores of a sintered Pyrex disk, to prevent convective remixing of the thermally diffused solute. The emf shift, of the order of hundredths of a millivolt per degree, followed a first order law with a half-life of about 10 min in their cell, and was essentially complete in 1-2 hr.

The thermodynamic theory of the *initial emf* of a thermal cell has been given by Eastman (13a) and by Wagner (13b) from Carnot's theorem, in terms of certain transport entropies designated by deBLS (8) as the *ionic entropy of electrochemical transport* S^*_{Ei} and the *ionic entropy of migration transport* S^*_{Mi}.[1] These ionic entropies are not separately determinable (without assumptions) for a single ionic species.

Temkin and Khoroshin (14) combined Eastman's theory (13a) of the Soret effect with Nernst's concentration cell equation to obtain an expression for the *final emf* of a thermal cell. While the *initial thermal emf* depends not only on the ion r to which the electrodes are reversible, but also on the gegenion g, Temkin and Khoroshin proved that the *final thermal emf* is independent of the gegenion, [a fact which was experimentally verified by Agar and Breck (12)]. They further proved that the sum $S^*_{Ei} + S^*_{Mi}$, which they denote as the entropy of the moving ion (Entropiya dvizhushchikhsya Iona) $\overline{\overline{S}}_i$, is an experimentally determinable quantity for a single ionic species, provided a value can be assigned to $\overline{\overline{S}}$ for the electrons.

The thermodynamic relations governing electrolytic systems out of equilibrium, such as concentration cells, thermal cells, and thermal diffusion, can be derived in an elegant manner by the methods of irreversible thermodynamics and the Onsager reciprocal relations (15). Treatments along such lines have already been given by Prigogine (16), deGroot (17a), Holtan (17b), Kirkwood (18), van Rysselberghe (19a), Haase (19b), Harned and Owen (20), and Agar (21).

In the present paper, we shall apply the Onsager thermodynamics from a particularly simple point of view, namely, from a consideration of those fluxes that are macroscopically measurable, the flux I of electricity, J of entropy, and K of solute. These fluxes are measurable, I by an ammeter, J by a calorimeter, and K by chemical analysis. The conjugate driving forces are also measurable, so that the method is a powerful one for expressing theoretical relationships between measurable entities under certain nonequilibrium conditions.

General Description of Thermodynamic System

Consider an electrolyte containing a single binary solute, one molecule of which dissociates into $\nu = \nu_+ + \nu_-$ ions of valence z_+ and z_- (with sign). Electroneutrality demands that $\nu_+ z_+ + \nu_- z_- = 0$, while the magnitude of the $\nu_i z_i$ product for either ion will be denoted by β. The molality of the solute is m, its thermodynamic mean ion activity $a_\pm$, and its chemical potential $\mu(\text{salt}) = \nu_+\mu_+ + \nu_-\mu_- = \mu^\circ + \nu RT \ln a_\pm = \mu^\circ + \nu RT \ln \nu_\pm m\gamma_\pm$.

The cell can be represented schematically by

$$\begin{gathered}\text{Cu}(T_1, V)/\text{Electrode } (T_1)/\text{Electrolyte } (T_1, a)/\\ \text{Electrolyte } (T_2, a + da)/\text{Electrode } (T_2)/\\ (\text{Cu}(T_2)/\text{Cu}(T_1, V + dV)\end{gathered} \quad [1]$$

where T_1 and T_2 denote the temperatures of two large separate heat reservoirs No. 1 and 2 in contact with different portions of the system, and $T_2 = T_1 + dT$ and $dT \geqq 0$. The electrical potentials are V and $V + dV$ in the left and right terminals, respectively. The two ionic species will be denoted by the indeces i and j in general, the ion to which the electrodes are reversible by r, the gegenion of r by g. Let the current I be positive when it flows through the cell from left to right. The entropy flux J (in calories·deg^{-1}·sec^{-1}) will be taken positive from the hot (T_2) to the cold (T_1) heat reservoir. The ionic fluxes K_i (in gram ions·sec^{-1}), and the solute flux K (in moles·sec^{-1}), defined as $\Sigma K_i/\nu$, will be taken positive through the liquid junction from right to left. The current I at the liquid junction can be expressed by $\mathbf{F}(K_- - K_+)$ for 1,1-salts and by $-\mathbf{F}\Sigma z_i K_i$ in general.

The irreversible rate of production of Clausius' uncompensated entropy (22, 23) from all these fluxes can be expressed by

$$\dot{S} = IX_I + JX_J + \Sigma K_i X_i \geqq 0 \quad [2]$$

where the driving forces are $X_I = -dV/T$, $X_J = dT/T$, $X_i = d\mu_i/T = R\,d \ln a_i$. The two ionic terms are conveniently coalesced to

$$K_+X_+ + K_-X_- = (K_+ + K_-)\,R\,d \ln a_\pm = KX_K \quad [3]$$

where $X_K = d\mu(\text{salt})/T = \nu R\,d \ln a_\pm$. Equation [2] then becomes

$$\dot{S} = IX_I + JX_J + KX_K \geqq 0 \quad [4]$$

The three fluxes may be expressed by phenomenological equations

$$I = L_{II}X_I + L_{IJ}X_J + L_{IK}X_K \quad [5]$$

$$J = L_{JI}X_I + L_{JJ}X_J + L_{JK}X_K \quad [6]$$

$$K = L_{KI}X_I + L_{KJ}X_J + L_{KK}X_K \quad [7]$$

where the L's are generalized admittances (reciprocal resistances). By the Onsager reciprocal relations, the conjugate cross-admittances are equal, i.e., $L_{IJ} = L_{JI}$, $L_{IK} = L_{KI}$ and $L_{JK} = L_{KJ}$.

Apply Eq. [5] to the cell when the temperature and concentration are both uniform (X_J and $X_K = 0$). A current I flowing is then the resultant only of an externally applied emf $-dV = TX_I$, and Ohm's law shows that $L_{II} = T/r$ where r is the total resistance of the circuit, including any "polarization resistances" of the electrodes. In general, however, Eq. [5] shows the current I as the resultant of three emf's: an externally applied emf $dE_{\text{ext}} = -dV = L_{II}X_I r = TX_I$; a thermally induced emf $dE_{\text{th}} = L_{IJ}X_J r = TL_{IJ}X_J/L_{II}$; and a concentration emf $dE_{\text{conc}} = L_{IK}X_K r = TL_{IK}X_K/L_{II}$.

[1] In Eastman's terminology, the absolute ionic entropy, and the entropy of transfer, respectively. See Appendices I and II for nomenclature of transport entropies.

At the potentiometric balance point, $I = 0$, and

$$-TX_I = TL_{IJ}X_J/L_{II} + TL_{IK}X_K/L_{II} \quad [8a]$$

or

$$-dE_{ext} = dV = dE_{th} + dE_{conc} \quad [8b]$$

i.e., we have the ordinary condition for potentiometric balance, in which the observed potential difference dV between the two terminals is a measure of the combined electromotive forces intrinsic to the system. These emf's are to be considered positive, following the Lewis-Stockholm convention (24), whenever they tend to drive positive electricity through the cell from left to right.

Isothermal Concentration Cells

Take cell [1] at uniform temperature ($X_J = 0$). From Eq. [8],

$$-TX_I = dV = dE_{conc} = TL_{IK}X_K/L_{II} \quad [9]$$

By the Onsager relations, this becomes,

$$dE_{conc} = (L_{KI}/L_{II})\nu RT\, d\ln a_{\pm}. \quad [10]$$

Suppose now that the cell is brought to a state of uniform concentration ($X_K = 0$), and a small external emf applied (dV negative). The current flowing is $I = L_{II}X_I = \beta\mathbf{F}/\tau$ if τ is the time required for the passage of β faradays of positive electricity through the cell from left to right. The simultaneous flux of solute through the cell from right to left is $K = L_{KI}X_I = (K_r + K_g)/\nu$. The ionic fluxes from right to left are $K_r = \beta(1 - t_r)/z_r\tau$ for the ion to which the electrodes are reversible, and $K_g = -\beta t_g/z_g\tau$ for the gegenion, where the t_i's are Hittorf transference numbers. Since $t_r + t_g = 1$, the solute flux becomes

$$K = (\beta t_g/\tau\nu)(1/z_r - 1/z_g) \quad [11]$$

Since $\nu_i z_i = \pm\beta$ (for $z_i = \pm$), $1/z_r - 1/z_g$ is equal to $\pm(\nu_r + \nu_g)/\beta$ for $z_r = \pm$, so that

$$K = \pm t_g/\tau \quad (\text{if } z_r = \pm) \quad [12]$$

The ratio $L_{KI}/L_{II} = (K/I)_{X_J = X_K = 0} = \pm t_g/\beta\mathbf{F}$. Equation [10] then yields Nernst's expression for the emf of a concentration cell with transference

$$dE_{conc} = \pm t_g(\nu RT/\beta\mathbf{F})\, d\ln a_{\pm} \quad (\text{if } z_r = \pm) \quad [13]$$

This equation is derived here as a consequence of the Onsager relations. The emf of an isothermal concentration cell is expressible in terms of the measurable quantities t_g and $a_{\pm}$ and is a fully significant thermodynamic quantity, as discussed by Guggenheim (25).

It is of theoretical interest to decompose the concentration emf [13] into the sum of (a) the difference of the electrode potentials dE_{el}; plus (b) the liquid junction potential dE_{lj}. Neither of these two terms is exactly measurable, and neither is unambiguously calculable from fully significant quantities. Yet both are approximately measurable, e.g., by the use of two saturated potassium chloride calomel electrodes (SCE) immersed in the two electrolyte compartments of the cell, and both can be calculated from any arbitrarily selected definition of single ion activities, such as that implicit in the Debye theory (26).

To clarify the point at issue, postulate an *ideal reference electrode* (IRE), *which can be defined conceptually as an unpolarizable electrode having zero thermal temperature coefficient* (8) *and zero liquid potential at the junction of its salt bridge with any electrolyte.* Two such IRE's are immersed in the two electrolyte compartments of cell [1], and connected by two leads of the same kind of metal to the isothermal potentiometric slide wire to which the two terminals of cell [1] are already connected. The potentials in the two IRE leads are V' and $V' + dV'$, respectively. Then at potentiometric balance for all four electrodes, $dE_{lj} = dV'$, while $dE_{el} = [(V + dV) - (V' + dV')] - [V - V'] = dV - dV'$.

It is convenient to consider the current I and the two ionic fluxes K_r and K_g

$$I = L_{II}X_I + L_{Ir}X_r + L_{Ig}X_g \quad [14]$$

$$K_r = L_{rI}X_I + L_{rr}X_r + L_{rg}X_g \quad [15]$$

$$K_g = L_{gI}X_I + L_{gr}X_r + L_{gg}X_g \quad [16]$$

At the balance point, $I = 0$, and

$$-TX_I = dV = dE = TX_r(L_{Ir}/L_{II}) + TX_g(L_{Ig}/L_{II}) \quad [17]$$

By the Onsager relations, this becomes

$$dE = TX_r(L_{rI}/L_{II}) + TX_g(L_{gI}/L_{II}) =$$

$$TX_r\,(K_r/I)_{X_r = X_g = 0} + TX_g\,(K_g/I)_{X_r = X_g = 0} \quad [18]$$

Consider now a cell at uniform concentration ($X_r = X_g = 0$). The current I is $\beta\mathbf{F}/\tau$, as before. The two electrode reactions together yield the ionic fluxes $K_r = \beta/z_r\tau$ and $K_g = 0$. This gives for the difference of the electrode potentials

$$dE_{el} = TX_r/z_r\mathbf{F} = (RT/z_r\mathbf{F})\, d\ln a_r \quad [19]$$

At the liquid junction, the two ionic fluxes are $K_i = -t_i\beta/z_i\tau$ so that the junction potential becomes

$$dE_{lj} = T\,\Sigma(-t_i/z_i\mathbf{F})X_i = (-RT/\mathbf{F}).$$

$$\Sigma\,(t_i/z_i)\, d\ln a_i \quad [20]$$

In contrast to Eq. [13], neither [19] nor [20] are fully thermodynamically significant since they involve nonfully significant single ion activities. They can be made approximately significant by adopting a rule for the definition of single ion activities, either (a) Scatchard's practical rule (27) "We will define single ion activities as those measured with the use of a saturated potassium chloride bridge" as in pH or pCl measurements (28, 29) or (b) a theoretical rule, consistent with the Debye theory whereby $a_i = \nu_i m\gamma_i$ and $\gamma_i = \gamma_{\pm}^{-z_i/z_j} = \gamma_{\pm}^{\nu_j/\nu_i}$. Where this latter rule is adopted, [19] becomes

$$dE_{el} = (RT/z_r\mathbf{F})\, d\ln m[1 + (\nu_g/\nu_r)\,.$$

$$(d\ln\gamma_{\pm}/d\ln m)] \quad [19']$$

and [20] becomes

$$dE_{ij} = (-RT/\mathbf{F})\Sigma(t_i/z_i)\, d\ln m\,.$$
$$[1 + (\nu_j/\nu_i)(d\ln\gamma\ /d\ln m)] \qquad [20']$$

where $j = g, r$ when $i = r, g$. The right hand sides of both [19'] and [20'] now involve only fully significant quantities.

Equations [13], [19], and [20] are identical with the classical expressions derived from chemical potentials by the application of the reversible thermodynamics of isothermal processes to concentration cells with transference, in spite of the fact that these cells are not at equilibrium. The Onsager relations show why the application of reversible relations to a nonequilibrium situation nevertheless yields correct results. The coefficients of the chemical potential gradients TX_K, or TX_r and TX_g, in the emf equations [10], [17] and [18], become, by the Onsager relations, flux ratios of matter to electricity of the form K/I. However, these flux ratios are to be taken, in each case, in a cell that is completely at equilibrium (X_J and X_K's all equal to zero). The flux I is therefore a reversible flux of electricity in the strict thermodynamic sense, and the K's are the conjugate reversible fluxes of matter. It is the ratio of the reversible fluxes K/I in an equilibrium cell (whose emf is zero) which determines, together with the actual chemical potential gradients, the observable emf of the actual nonequilibrium concentration cell.

Initial EMF of Thermal Cells

Take cell [1] at uniform concentration ($X_K = 0$). From Eq. [8],

$$-TX_I = dV = dE_{th} = TL_{IJ}X_J/L_{II} \qquad [21]$$

By the Onsager relations, this becomes

$$dE_{th} = (L_{JI}/L_{II})\ dT \qquad [22]$$

Suppose now that the cell is brought to uniform temperature ($dT = 0$) and a small external emf applied (dV negative). The current flowing is $I = L_{II}X_I = \beta\mathbf{F}/\tau$, as before. At the same time, the entropy flux is $J = L_{JI}X_I = S^*_I/\tau$ if S^*_I is the entropy transported from the right heat reservoir (No. 2) to the left heat reservoir (No. 1), when β faradays of positive electricity are transferred through the cell from left to right. S^*_I may be termed the entropy of electrical transport. The ratio $L_{JI}/L_{II} = (J/I)_{X_J=X_K=0} = S^*_I/\beta\mathbf{F}$. From [22], one obtains therefore for the initial thermal emf

$$dE_{th} = (S^*_I/\beta\mathbf{F})\ dT \qquad [23]$$

The ratio J/I is, once again, the ratio of two reversible fluxes occurring in an equilibrium cell (whose emf is zero). This ratio determines, together with the actual temperature gradient, the observable emf of the actual nonequilibrium thermal cell. As defined here, the thermal emf is positive whenever the hot electrode is the (+) terminal of cell [1].

The entropy S^*_I is the entropy transported isothermally and reversibly from one heat reservoir to the other by a reversible flow of electricity, in the absence of a temperature gradient. The transport of entropy occurs by a threefold mechanism. (i) The reaction at the right electrode absorbs a quantity of heat Q^*_E from its heat reservoir (No. 2) while the equal and opposite reaction at the left electrode evolves an equal quantity of heat to its heat reservoir (No. 1). The entropy transported is $S^*_E = Q^*_E/T$ and is denoted as the *entropy of electrochemical transport.* (ii) The migration of ions through the electrolyte is accompanied by the absorption of a quantity of heat Q^*_M (Eastman's "heat of transfer") from the electrolyte in the right compartment, and the evolution of an equal quantity of heat to the electrolyte in the left compartment. An equal amount of heat then enters the right electrolyte from the right heat reservoir (No. 2) and leaves the left electrolyte to the left heat reservoir (No. 1), to keep the temperature constant. The entropy transported is $S^*_M = Q^*_M/T$ and is denoted as the *entropy of migration transport.* (iii) The migration of β moles of electrons from the T_1 zone to the T_2 zone of the right-hand Cu terminal of cell [1] transfers heat from the No. 1 to the No. 2 heat reservoir. Dividing this heat by T, one obtains the entropy transported from No. 2 to No. 1 as $-\beta S^*_M$ (E^- in Cu). Thus

$$S^*_I = S^*_E + S^*_M - \beta S^*_M(E^- \text{ in Cu}) \qquad [23a]$$

For the passage of β faradays of positive electricity through the cell from left to right, the reaction at the right electrode may be written as β times

$$\Sigma\omega_k A_k + (1/z_r)A_r + E^-(\text{Cu}, T_2) = 0 \qquad [24]$$

where A_r is the ion to which the electrode is reversible, and the A_k denote neutral substances whose stoichiometric coefficients ω_k may be positive or negative. Thus for Ag/Ag^+ electrodes, reaction [24] is: $Ag^+ - Ag + E^- = 0$; for $Pb/PbSO_4$ electrodes: $\frac{1}{2}PbSO_4 - \frac{1}{2}Pb - \frac{1}{2}SO_4^= + E^- = 0$. The corresponding *entropy of electrochemical transport* S^*_E is, for β faradays,

$$S^*_E = \beta\{-\Sigma\omega_k S_k - (1/z_r)S^*_{Er} - S^*_E(E^- \text{ in Cu})\} \qquad [25]$$

where S_k is the partial molal third law of entropy of the neutral species A_k, and S^*_{Er} is the partial molal entropy of electrochemical transport of the ion r. $S^*_E(E^-$ in Cu) is the electrochemical transport entropy of the electrons in Cu, or in general, in the nonisothermal metallic terminal arm of the cell.

The *entropy of migration transport* can be expressed by

$$S^*_M = \Sigma(-t_i\beta/z_i)S^*_{Mi} \qquad [26]$$

where S^*_{Mi} is the entropy of migration transport of the ion i (also known as its "entropy of transfer," see Appendix II). The total entropy transported by the current becomes

$$S^*_I = -\beta\Sigma\omega_k S_k - (\beta/z_r)S^*_{Er} - \Sigma(t_i\beta/z_i)S^*_{Mi} - \beta\bar{\bar{S}}(E^- \text{ in Cu}) \qquad [27]$$

where $\bar{\bar{S}}$, the entropy of the moving electrons (14), has been written for the sum $S^*_E + S^*_M$ for the electrons in Cu. The only electronic term appearing in the thermal emf is the entropy $\bar{\bar{S}}$ of the moving electrons in the nonisothermal metallic terminal arm of the cell. In Richard's (3) study of the calomel electrode, this was Hg; in Agar and Breck's (12) work, Pt; in the bulk of thermal cell studies, it has been Cu.

Now remove the two electrolyte compartments from cell [1], and allow the two electrodes to touch. Cell [1] becomes the thermocouple: Cu-Electrode. The equivalent value of S^*_E becomes $S^*_E(E^-$ in Electrode$) - S^*_E(E^-$ in Cu) for 1 Faraday. The equivalent of S^*_M becomes $S^*_M(E^-$ in Electrode). Therefore, for the whole thermocouple, Eq.[23] and [23a] yield[2]

$$\mathbf{F}(dE/dT)_{\text{couple}} = \mathbf{F}(dV/dT) = S^*_I = \bar{\bar{S}}(E^- \text{ in Electrode}) - \bar{\bar{S}}(E^- \text{ in Cu}) \qquad [28]$$

A comparison of Eq. [27] and [28] shows that the emf of a thermal cell does not contain a thermocouple emf as such, contrary to earlier statements (3, 8) that it does. But it does contain the entropy $\bar{\bar{S}}$ of the moving electrons in the nonisothermal metallic arm of the cell. No electronic term of the electrode metal itself appears, and the thermoelectric power of the terminal metal relative to the electrode metal makes no direct contribution to the thermal cell emf.

When thermal cells are measured with Cu terminals, and a "thermocouple correction" applied to the data [as in Carr and Bonilla's (30a) study of the Ni electrode], the net effect of the correction, by Eq. [28], is to transform the electronic term in [27] from that of Cu to that of the electrode metal itself. There seems to be no particular advantage to such a procedure, however. The better practice, experimentally and theoretically, would seem to be to *standardize on one metal for the nonisothermal metallic arm of all thermal cells.* In practice, this metal might as well be chosen as Cu.

Equation [28] gives a method for evaluating the entropy $\bar{\bar{S}}$ of moving electrons in different metals, relative to that in a standard metal, usually chosen to be Pb. From the magnitude of thermocouple emf's (microvolts per degree), such entropies amount to microvolt-faradays per degree, i.e., hundredths or tenths of a calorie per degree. Temkin and Khoroshin (14) evaluated the "absolute" value of $\bar{\bar{S}}(E^-)$ in Cu and Pt from the third-law integral

$$\bar{\bar{S}}(E^-) = -\mathbf{F}\int_0^T \sigma dT/T \qquad [29]$$

where σ is the "absolute" Thomson coefficient of the metal, i.e., the heat capacity of the *unit of* positive electricity in the metal (30b). Their results are, in microvolt-faradays per degree,

$$\bar{\bar{S}}(E^- \text{ in Cu}) = -1.95 - 0.005\,(T - 300) \quad (T > 240°\text{K})$$

$$\bar{\bar{S}}(E^- \text{ in Pt}) = 4.54 + 0.044(T - 300) \quad (T > 220°\text{K})$$

Thus, at 298°K, $\bar{\bar{S}}(E^-$ in Cu$) = -1.94\ \mu\text{v}\mathbf{F}$/deg $= -0.045$ cal/deg. The electronic term could then be eliminated completely in [27] by adopting for the nonisothermal terminal arm a metal whose Thomson coefficient is virtually zero, e.g., Pb(30c). In practice, it is more convenient to use copper experimentally. The third-law value for the electrons in Cu is so small that it could, without significant error, be set equal to zero. This we shall do, and we shall thereby adopt a slightly different electronic standard from that of Temkin and Khoroshin. We shall arbitrarily set $\bar{\bar{S}}(E^-$ in Cu) equal to zero at all temperatures. The electronic term in [27] may then be omitted, provided the thermal cell is measured with nonisothermal terminal arms of copper.

Thus for a thermal $Ag/AgNO_3$ cell ($\beta = 1$)

$$\mathbf{F}(dE_{\text{th}}/dT) = S^*_I = S(\text{Ag}) - S^*_E(\text{Ag}^+) + t_-\,S^*_M(\text{NO}_3^-) - t_+\,S^*_M(\text{Ag}^+) \qquad [30]$$

and for a thermal $Al/Al_2(SO_4)_3$ cell ($\beta = 6$)

$$6\mathbf{F}(dE_{\text{th}}/dT) = S^*_I = 2S(\text{Al}) - 2S^*_E(\text{Al}^{+3}) + 3t_-\,S^*_M(\text{SO}_4^{=}) - 2t_+\,S^*_M(\text{Al}^{+3}) \qquad [31]$$

The initial thermal emf depends on the ion to which the electrodes are reversible, and also on the gegenion. The migration terms in [30] and [31] determine the thermal liquid junction potential (tljp), the other terms the effect of temperature on the electrode potentials. Neither of these quantities is separately measurable, without assumptions. Both are conceptually measurable by the use of two IRE's, as defined above.

The two transport entropies S^*_{Ei} and S^*_{Mi} for an ion do not coincide with one another, and neither do they coincide with its conventional partial molal ionic entropy S_i (based on the standard $S°(H^+) = 0$ at all temperatures). S^*_{Ei} is the entropy transported between heat reservoirs by an ion when it sheds its hydration sheath in being consumed at one electrode and picks up a new hydration sheath in being produced at the other electrode. S^*_{Mi} is the entropy transported by the ion when it drags its hydration sheath with it across the cell. Neither of these entropies is separately determinable for a single ionic species (without assumptions). Neutral combinations are determinable, and also the sum $\bar{\bar{S}}_i = S^*_{Ei} + S^*_{Mi}$ for a single ion (see below).

The standard entropy of electrochemical transport of the hydrogen ion was shown by deBLS (8) to be $S^{*\,\circ}_E(\text{H}^+) = -4.48 \pm 0.5$ cal/deg at 25°C, from the thermal temperature coefficient of the

[2] Comparison of [28] with classical expressions for the thermoelectric power shows that $S^*_I = \mathbf{F}\pi/T$, where π is the Peltier heat, i.e., the heat absorbed by the thermocouple when the unit of positive electricity crosses the junction from "Electrode" to Cu. The temperature derivative of the thermoelectric power yields $d^2V/dT^2 = dS^*_I/\mathbf{F}dT = C^*_I/\mathbf{F}T = [\bar{\bar{C}}(E^-$ in Electrode$) - \bar{\bar{C}}(E^-$ in Cu$)]/\mathbf{F}T = -[\sigma(\text{Electrode}) - \sigma(\text{Cu})]/T$, where C^*_I is the heat capacity of electrical transport, $\bar{\bar{C}}$ the heat capacity of the moving electrons, and σ the Thomson coefficient. Thus $\bar{\bar{C}}(E^-$ in Cu$) = -\mathbf{F}\sigma(\text{Cu})$. Over wide ranges of temperature, thermocouple emf's satisfy the empirical equation $V = at + \frac{1}{2}bt^2$. S^*_I is then equal to $\mathbf{F}(a + bt)$ and $C^*_I = \mathbf{F}Tb$. Constancy of b implies that $\bar{\bar{C}}/T$ is a constant.

standard hydrogen electrode which is + 0.871 millivolts per degree when measured with a saturated potassium chloride bridge (8, 31). This result is based on the assumption that S^*_M can be set equal to zero in such a bridge ("saturated KCl bridge rule").

The standard entropy of electrochemical transport $S^{*\circ}_{Ei}$ of any other ion should then be

$$S^{*\circ}_{Ei} = S^\circ_i + z_i \ (-4.48 \text{ cal/deg}) \quad [32]$$

Concentration effects on thermal emf's (8) indicate that the ionic entropy S^*_{Ei} has substantially the same mass-action dependence as the ordinary entropy S_i, i.e.,

$$S^*_{Ei} = S^{*\circ}_{Ei} - R \ln a_i - RT(d \ln a_i/dT) \quad [33]$$

Ionic entropies of migration transport S^*_{Mi} are discussed in greater detail below. For many ions, the values appear to be quite small, about 0-3 cal/deg. For H^+ and OH^-, they are significantly larger, about 10 cal/deg. For many salts, the tljp's should not exceed a few hundredths of a millivolt per degree and should make only small contributions to total cell emf's of several tenths of a millivolt per degree (see below). In strong acids and bases, the tljp's appear to be large, about − 0.35 and + 0.5 mv/deg, respectively, referred to KCl as zero (8). These two values are qualitatively consistent with the Soret effect (below) in that the cold end of the thermal liquid junction dipole takes on the charge of the faster ion (H^+ or OH^-).

Thermal Diffusion (Soret Effect)

Take cell [1] and remove both electrodes. This effectively makes $X_I = 0$. In the steady state of thermal diffusion, $K = 0$, and

$$X_K = -(L_{KJ}/L_{KK})X_J \quad [34]$$

By the Onsager relations, this becomes

$$X_K/X_J = -L_{JK}/L_{KK} = -(J/K)_{X_I=X_J=0} \quad [35]$$

Now bring the cell to uniform temperature ($X_J = 0$), and let there be a small chemical potential gradient (X_K positive), such that the solute flux $K = 1/\tau$, if τ is the time required for 1 mole of solute to diffuse across the liquid boundary from right to left, under the impulsion of X_K, in a cell (without convection) so large that this amount of diffusion does not significantly alter the chemical potential gradient. The concurrent flux of entropy is $J = S^*_D/\tau = (\nu_+ S^*_{M+} + \nu_- S^*_{M-})/\tau$, where S^*_D, the *entropy of diffusion transport,* is the entropy transported from the right heat reservoir No. 2 to the left heat reservoir No. 1 by the passage of 1 mole of solute through the liquid boundary from right to left. Equation [35] then transforms to

$$X_K/X_J = \nu RT(d \ln a_\pm/dT) = -(J/K)_{X_I=X_J=0} = -S^*_D/1 \text{ mole}. \quad [36]$$

The Soret coefficient can be defined as the relative change in solute activity (or concentration) per degree change in temperature, i.e., either

$$d \ln a_\pm/dT = -S^*_D/\nu RT \quad [37a]$$

or

$$d \ln m/dT = -S^*_D/\{\nu RT[1 + (d \ln \gamma / d \ln m)_T]\} \quad [37b]$$

If the entropy of diffusion transport S^*_D is positive, the Soret coefficient is negative, i.e., strong electrolytes concentrate in the cold region. This is the situation normally observed. Soret coefficients usually amount to minus a few tenths of one per cent per degree, the corresponding values of S^*_D are then a few calories per degree per mole. Values for S^*_D for a number of salts are listed in Table I.

Consider two thermal cells identical in every respect, except in the nature of the gegenion g. Then from Eq. [23] and [27], it can be shown that the difference between the initial thermal emf's of the two cells, containing the two electrolytes 1 and 2, is

$$F(dE/dT)_{\text{th},1} - F(dE/dT)_{\text{th},2} = t_{r2} S^*_{Mr}/z_r + t_{g2} S^*_{Mg2}/z_{g2} - t_{r1} S^*_{Mr}/z_r - t_{g1} S^*_{Mg1}/z_{g1} = \pm t_{g1} S^*_{D1}/\beta_1 \mp t_{g2} S^*_{D2}/\beta_2 \quad (\text{if } z_r = \pm) \quad [38]$$

Equation [38] provides a convenient method of evaluating the entropy S^*_D of one salt relative to that of another salt with which it has a common ion, from observations of initial thermal emf's. The vanishing of electrode terms from Eq. [38] implies

that the activity of the ion *r* is the same in the two electrolytes. Clearly, this assumption is valid only for dilute solutions of the two salts, at the same concentration of the ion *r*, and at the same ionic strength. Under this assumption, the difference of the initial thermal emf's given by [38] is simply the difference of the thermal liquid junction potentials (tljp's) of the two salts.

In Table II are listed such differences of tljp's between the electrolytes listed and certain reference electrolytes chosen to be KCl, KBr, KI, and KOH, as determined from observed values of initial thermal emf's (except for values in parentheses which are computed from the reference S^*_D values via Eq. [38]). A positive sign means that the hot end of the thermal liquid junction dipole is more positively charged than that of the reference electrolyte.

The transference numbers utilized in Eq. [38] have been taken, or estimated, from MacInnes (48), Harned and Owen (20), or from the sources of the thermal emf data. The S^*_D values listed in Table II have then been computed from observed Δtljp's and from certain reference S^*_D values (in parentheses) taken from Tables I and III(b).

While the accuracy of the method is limited, as discussed by Tyrrell, *et al.* (49), *e.g.*, an uncertainty of ± 0.01 mv/deg in the Δtljp yields uncertainties in S^*_D ranging from ± 0.5 cal/deg when the relevant transference number is ½, up to ± 2 cal/deg when the transference number drops to 1/10th, nevertheless, the results are in fair agreement with those of other methods [Tables I and III(a)(b)], and are of interest since they yield a number of new values of S^*_D for electrolytes not previously determined.

In dilute solutions, the entropy S^*_D of diffusion transport behaves as an additive ionic property (21). This permits the evaluation of the entropy of migration transport of an ion, relative to that of some standard ion. Such conventional single ion values of $S^*_{M_i}$ are given in Table III, relative to $S^*_M(Cl^-) = 0$ at all concentrations. Column (a) gives Eastman's estimates of 1928, intended by him as absolute values. Column (b) is taken from Agar's work. Columns (c) and (d) are based on the values of S^*_D deduced from the Δtljp's in Table II, except for the reference values in parentheses, and for certain values based on Table IV as noted.

The concentration dependence of S^*_D has been

Table III. Conventional single ion entropies of migration transport $S^*_{M_i}$ (cal/deg) at 25°C based on $S^*_M(Cl^-) = 0$.

discussed by Agar (21). It decreases with increasing concentration (Table I) in dilute solutions, but much less rapidly than a normal mass-action dependent entropy would, and it seems to attain a finite limiting value at infinite dilution. In concentrated solutions of KCl and $AgNO_3$, S^*_D increases with increasing concentration! The derivative $dS^*_D/d \ln a_\pm$ is very close to $-R$ in $CdSO_4$ and to $-\frac{1}{2}R$ in $TlClO_4$, instead of the mass-action value $-2R$ for salts with $\nu = 2$.

In very dilute solutions ($m < 0.02$), S^*_D decreases as a linear function of the square root of the molality. The derivative $dS^*_D/d\sqrt{m}$ has values, in cal/deg. (unit of molality)$^{1/2}$, of −6.0 to −6.5 in dilute KCl, NaCl, KBr, NaBr, and KI; and of −26 in $CdSO_4$. These values are discussed again below in connection with the electrostatic interpretation of the ionic entropy of migration.

Final EMF of Thermal Cells

Restore the two electrodes to cell [1], and allow a Soret steady state to be established. This makes $K = 0$ while $X_K \neq 0$. At potentiometric balance, $I = 0$. Equations [5], [6], and [7] can then be solved, with elimination of X_K, to yield

$$(-X_I/X_J)_{\text{final}} = dV/dT = dE_{\text{fin}}/dT$$
$$= [L_{IJ}/L_{II} - (L_{IK}/L_{II})(L_{KJ}/L_{KK})]/$$
$$[1 - (L_{IK}/L_{II})(L_{KI}/L_{KK})] \quad [39]$$

This expression involves four distinct admittance ratios, three of which have already been evaluated. The fourth admittance ratio is L_{KI}/L_{KK}. This can be equated to $L_{IK}/L_{KK} = (I/K)_{X_I = X_J = 0}$, i.e., it is equal to the ratio of the flux of electricity to the flux of matter in the liquid boundary, in the absence of any applied emf (no electrodes) and of a temperature gradient. However, the flux of matter under such conditions occurs by diffusion of electroneutral groups of ions and does not give rise to an electric current at all. Therefore $I/K = 0$ in the boundary, and this fourth admittance ratio is zero. Equation [39] simplifies to

$$(-X_I/X_J)_{\text{fin}} = L_{IJ}/L_{II} - (L_{IK}/L_{II})(L_{KJ}/L_{KK}). \quad [40]$$

The validity of Eq. [40] can be confirmed by noting that the admittance ratios can be replaced by driving force ratios, e.g., $L_{ab}/L_{aa} = -(X_a/X_b)_{a = X_c = 0}$, so that

$$(-X_I/X_J)_{\text{fin}} = (-X_I/X_J)_{I = X_K = 0} + (-X_I/X_K)_{I = X_J = 0} \cdot (X_K/X_J)_{K = X_I = 0} \quad [41]$$

The latter expression is obviously equivalent to

$$(dV/dT)_{\text{fin}} = (\partial V/\partial T)_{d \ln a = 0} + (\partial V/RT\, \partial \ln a)_{dT = 0} \cdot (RT\, \partial \ln a/\partial T)_{dV = 0} \quad [42]$$

i.e., the final thermal emf is equal to the initial thermal emf L_{IJ}/L_{II} plus a term which is exactly the isothermal emf of the concentration cell that the Soret effect has created.

We have already established that $L_{IJ}/L_{II} = S^*_I/\beta\mathbf{F}$; $L_{IK}/L_{II} = \pm\, t_g/\beta\mathbf{F}$ (if $z_r = \pm$); and $L_{KJ}/L_{KK} = S^*_D/1$ mole. Therefore Eq. [40] transforms to

$$dE_{\text{fin}}/dT = S^*_I/\beta\mathbf{F} \mp t_g S^*_D/\beta\mathbf{F} \quad (\text{if } z_r = \pm) \quad [43]$$

By introducing values for S^*_I (Eq. [27]) and S^*_D, Eq. [43] further transforms to

$$dE_{\text{fin}}/dT = (1/\beta\mathbf{F})\{-\beta\Sigma\omega_k S_k - (\beta/z_r)S^*_{Er} - \beta\bar{\bar{S}}(E^- \text{ in Cu}) - t_r(\beta/z_r)S^*_{M_r} - t_g(\beta/z_g)S^*_{M_g} \mp t_g \nu_r S^*_{M_r} \mp t_g \nu_g S^*_{M_g}\} \quad (\text{if } z_r = \pm). \quad [44]$$

Since $\mp\, \nu_r = -\beta/z_r$ and $\mp\, \nu_g = +\beta/z_g$ for $z_r = \pm$, the terms involving the migration transport

entropy of the gegenion g vanish, while the two corresponding terms for the ion r coalesce to $-(\beta/z_r)S^*_{Mr}$. The final emf therefore reduces to

$$dE_{\text{fin}}/dT = (1/\beta\mathbf{F})\{-\beta\Sigma\omega_k S_k - \beta\bar{\bar{S}}(E^- \text{ in Cu}) - (\beta/z_r)\bar{\bar{S}}_r\} \quad [45]$$

All properties of the gegenion have vanished from Eq. [44] and [45], while the ion r contributes the sum $S^*_{Er} + S^*_{Mr} = \bar{\bar{S}}_r$, denoted by Temkin and Khoroshin (14) as the "entropy of the moving ion." This sum thus becomes a measurable thermodynamic property of a single ion, provided a value can be assigned to the electronic term, as discussed above.

For example, for a thermal Ag/Ag^+ cell, the final emf, with the electronic term neglected is given by $dE_{\text{fin}}/dT = (1/\mathbf{F})\,[S(\text{Ag}) - \bar{\bar{S}}\,(\text{Ag}^+)]$. For a thermal $Hg/Hg_2SO_4/Al_2(SO_4)_3$ cell, it is $dE_{\text{fin}}/dT = (1/6\mathbf{F})[6S(\text{Hg}) - 3S(Hg_2SO_4) + 3\bar{\bar{S}}(SO_4^=)]$.

A comparison of Eq. [43] and [23] show that the *final* minus the *initial* thermal emf of a cell is equal to $\mp\ t_p S^*_D/\beta\mathbf{F}$ (if $z_r = \pm$). This provides an electrochemical method of measuring the entropy S^*_D of diffusion transport, and the associated Soret coefficient (12).

It is of theoretical interest to decompose the measurable final thermal cell emf [45] into formal expressions for the electrode potential difference and the liquid junction potential, since these two quantities are at least conceptually measurable by the use of two IRE's, as defined above. The liquid junction potential in the final state of the thermal cell can be formally expressed by evaluating Eq. [40] for the liquid boundary processes only. In the boundary $L_{IJ}/L_{II} = L_{JI}/L_{II} = (J/I)_{x_J=x_{K=0}} = -\Sigma t_i (\beta/z_i)S^*_{Mi}/\beta\mathbf{F} = (t_-\nu_- S^*_{M-} - t_+\nu_+ S^*_{M+})/\beta\mathbf{F}$; and $L_{IK}/L_{II} = L_{KI}/L_{II} = (K/I)_{x_J=x_{K=0}} = -t_i(\beta/z_i)/\nu\beta\mathbf{F} = (t_-\nu_- - t_+\nu_+)/\nu\beta\mathbf{F}$, provided K is taken as $(K_+ + K_-)/\nu$; while L_{KJ}/L_{KK} as evaluated above is already a boundary quantity equal to $S^*_D/1$ mole $= (\nu_+ S^*_{M+} + \nu_- S^*_{M-})/1$ mole. The substitution of these expressions into Eq. [40] gives, for the final thermal liquid junction potential,

$$dE_{lj,\,\text{fin}}/dT = \nu_+\nu_-(S^*_{M-} - S^*_{M+})/\nu\beta\mathbf{F} \quad [46a]$$

For example, in sodium chloride electrolyte, this becomes $(1/2\mathbf{F})[S^*_M(\text{Cl}^-) - S^*_M(\text{Na}^+)]$, and in aluminum sulfate $(3\cdot 2/5\cdot 6\mathbf{F})[S^*_M(SO_4^=) - S^*_M(\text{Al}^{+3})]$.

By subtracting [46a] from [45], neglecting the electronic term, one obtains the difference of the electrode potentials for the final state of the thermal cell in the form

$$dE_{el,\,\text{fin}}/dT = S^*_E/\beta\mathbf{F} - S^*_D/\nu z_r\mathbf{F} \quad [46b]$$

The first term in [46b] gives the effect of temperature on the electrode potentials, without liquid junction potential and without thermal diffusion. The second term gives the further effect of the thermal diffusion concentration gradient on the electrode potentials. This second term takes the form, in a thermal Ag/AgCl/NaCl cell, $(1/2\mathbf{F})[S^*_M(\text{Na}^+) + S^*_M(\text{Cl}^-)]$; in a thermal $Al/Al_2(SO_4)_3$ cell, $-(1/5\cdot 3\mathbf{F})[2S^*_M(\text{Al}^{+3}) + 3S^*_M(SO_4^=)]$.

Values of the Ionic Transport Entropies

Values of the entropy $\bar{\bar{S}}_i$ of the moving ion have been obtained for Cd^{++} and Tl^+ by Agar and Breck (12) from measured final thermal emf's, and are listed in Table IV. The corresponding entropies S^*_D of diffusion transport, from the difference of final and initial thermal emf's, are given in Table I. In Table IV, $pa_+ = -\log a_+$ where $a_+ = \nu_+ m\gamma_+$, γ_+ is calculated by the rule $\gamma_+ = \gamma_\pm^{-z_+/z_-}$, and $\gamma_\pm$ is interpolated from Latimer (33). The entropy of electrochemical transport S^*_{E+} is computed from entropy data (33) via the "saturated KCl bridge rule" of deBLS (8), Eq. [32] and [33], neglecting the third term in $d\ln a_i/dT$. The entropies of migration transport for the two ions are then computed from $\bar{\bar{S}}_+$ and S^*_{E+} (Table IV), and S^*_D (Table I).

For both Cd^{++} and Tl^+ ions, the mass-action dependence of $\bar{\bar{S}}_+$ parallels that of S^*_{E+}, so that S^*_{M+} is apparently independent of concentration: $S^*_M(\text{Tl}^+) = 3.1 \pm 0.3$ cal/deg; $S^*_M(\text{Cd}^{++}) = 2.5 \pm 0.4$ cal/deg. The migration transport entropies of the anions do vary with concentration, and can be expressed within the range of concentrations studied by the approximate relations: $S^*_M(ClO_4^-) = -3.7 + (\frac{1}{2}R')pa(ClO_4^-)$; $S^*_M(SO_4^=) = -6.6 + R'pa(SO_4^=)$, where $R' = 2.303\,R$ and $pa_i = -\log a_i$. The mass-action dependence for sulfate is normal, while that for perchlorate contains the surprising coefficient $\frac{1}{2}R'$ instead of R'. Thus the concentration effect on S^*_{Mi} ranges from apparently no dependence for Tl^+ and Cd^{++}, to half mass-action dependence for ClO_4^-, to full mass-action dependence for $SO_4^=$. Values of S^*_{M-} for other anions are as follows: 0.1 m NO_3^-, —1.1, —0.9; 0.1 m CH_3COO^-, 3.3; 0.05 m $CO_3^=$, 3.0; 0.1 m Cl^- (in $CdCl_2$), —0.5. The several anion values, calculated above from the KCl bridge rule, show reasonable agreement between the Tl^+ and

Table V. Transport entropies of various ions (cal/deg) from the data of Khoroshin and Temkin (14)

the Cd^{++} series and are not inconsistent with the conventional values of Table III (referred to chloride as zero).

Values of the moving ion entropies $\bar{\bar{S}}_i$ have also been deduced by Khoroshin and Temkin (14) from the ingenious suggestion that initial thermal emf's measured in aqueous LiCl should be virtually the same as final thermal emf's, since S^*_D for dilute LiCl is virtually zero (Table III). This led them to a value of 19.5 cal/deg for $\bar{\bar{S}}^\circ(Cl^-)$. From this, they deduced values for other ions from the relation

$$\Sigma\nu_i\bar{\bar{S}}_i = \Sigma\nu_i S_i + \Sigma\nu_i S^*_{Mi} \qquad [47]$$

where S_i is the conventional ionic entropy. Equation [47] is valid for any neutral ion combination for which $\Sigma\nu_i S_i = \Sigma\nu_i S^*_{Ei}$. The final summation in [47] is, of course, S^*_D for a neutral electrolyte. By taking S_i and S^*_D data from various sources, Khoroshin and Temkin obtained the values of $\bar{\bar{S}}^\circ_i$ given in Table V. Standard entropies of electrochemical transport $S^{*\circ}_{Ei}$ have been computed from conventional entropy data (33) by means of the "saturated KCl bridge rule," Eq. [32]. The migration transport entropy $S^{*\circ}_{Mi}$ is then obtained by difference. The values given in Table V are only approximate, but, on the whole, they are fairly consistent with data given in Tables I through IV.

Ionic Transport Entropies

To distinguish between the ionic entropies of electrochemical transport S^*_{Ei} and of migration transport S^*_{Mi}, it is necessary to consider the interaction between an ion and its environment. Eastman (34) divides the vicinity of an ion "into three concentric regions of gradually differing properties. First, there is the 'ion-cavity,' within which there are no solvent molecules." The thickness of the ion-cavity has been estimated (35) as 0.10Å for anions and 0.85Å for cations, in addition to the crystallographic ionic radius. Next comes the hydration (solvation) layer, described by Eastman in these words: "immediately outside of the ion cavity the (polar) molecules of solvent are strongly attracted and oriented. The inner layers of solvent molecules in this second region, and those extending out from it to varying distances in different cases, are held so strongly by the central ion as to form a complex with it, acting in processes of diffusion, as a single molecule. The third region comprises all the rest of the outer space. In this [third] sphere the solvent molecules are still subject to forces of compression and orientation, diminishing with distance from the center of the complex, and not sufficiently strong to bind these molecules to the ion."

Let one mole of the ion i be associated with n_2 moles of bound solvent (in Eastman's second region) and n_3 moles comprising the remainder of the (unbound) solvent (Eastman's third region). Let S_2 and S_3 be the partial molal entropies of the solvent in these second and third regions, and S_1 the molal entropy of the solvent in the absence of any ions. The compression and orientation of solvent molecules by electrostatic attraction between the ion and the dipoles of the solvent result in S_2 being significantly less, and S_3 somewhat less, than S_1.

When one mole of an ion is transferred from the right to the left electrolyte compartment by the agency of the two electrode reactions, the entropy transported from the right (No. 2) to the left (No. 1) heat reservoir includes the quantity $(n_2 + n_3)S_1 - n_2S_2 - n_3S_3$, *i.e.*, the gain in entropy of the solvent upon its release from the ordering influence of the electric field of the ion, corresponding to the absorption of heat in the breaking of ion-solvent bonds in the second region and in the relaxation of compression and orientation forces in the third region. The entropy of transport for one molal unit of the electrode reaction might therefore be expressed as $S^*_E = S(M) - S_{ic}(M^+) + (n_2 + n_3)S_1 - n_2S_2 - n_3S_3$, where $S_{ic}(M^+)$ is the partial molal entropy of the ion-cavities of M^+. The entropy of electrochemical transport of the ion M^+ becomes $S^*_E(M^+) = S_{ic}(M^+) + n_2(S_2 - S_1) + n_3(S_3 - S_1)$, *i.e.*, it includes entropy terms pertaining to the binding of solvent molecules in the second region and to the orientation and compression of the solvent in the third region.

When one mole of an ion is transferred from the right to the left electrolyte compartment by migration, "the aggregate comprising the first and second regions above remains mostly intact and takes part in no . . . entropy changes. But as the ion moves it leaves behind material which had been under its influence in the third sphere, and brings under its influence solvent molecules not previously so strongly affected. A relaxation occurs, therefore, in the region from which it goes, with an attendant increase of entropy and absorption of heat. The reverse effects appear in the region into which it moves. It is, therefore, these changes in the third sphere that give rise" (Eastman, 34) to the ionic entropy of migration transport $S^*_M(M^+)$ which may be equated to $n_3S_1 - n_3S_3$, i.e., to the gain in entropy of the solvent in the third region upon its release from the electric field of the ion. On this model, the entropy of the moving ion $\bar{\bar{S}}(M^+)$ becomes

$S_{ic}(M^+) + n_2(S_2 - S_1)$, *i.e.*, it includes the solvent entropy terms of the second region only, the region that moves with the ion.

The total entropy of the solvent n_3S_3 in the third region in the presence of the ion, relative to its entropy n_3S_1 in the absence of the ion, can be calculated at infinite dilution from a simple electrostatic model, on the assumption that the solvent in the third region can be treated as a continuous medium of dielectric constant ϵ. Consider a charge q located in a dielectric ϵ and a concentric sphere of radius r so chosen that the surface of the sphere lies well into the dielectric region. The total electrostatic potential energy of the electric field outside the sphere is $q^2/2\epsilon\, k_o r$ where k_o is a constant equal to 1 esu or $10^{-9}/8.988$ amp.sec.volt^{-1}.m^{-1} (36). This energy may be equated to the electrostatic free enthalpy G of the polarized dielectric outside the sphere, whose entropy therefore becomes $-dG/dT = -(q^2/2k_o r)d(1/\epsilon)/dT$. The latter may be taken equal to $n_3(S_3 - S_1)$ and therefore to $-S^*_{Mi}$. Gurney (37) suggests that the dielectric constant may be represented by the empirical formula $\epsilon = \epsilon_0 \exp(-T/\theta)$ where $\epsilon_0 = 305.7$ and $\theta = 219°K$ for water. The derivative $d(1/\epsilon)/dT = 1/\epsilon\theta = 5.83 \times 10^{-5}$ deg^{-1} for water at 25°C. Upon substitution of appropriate numerical values, the ionic entropy of migration is calculated as

$$S^*_{Mi} = +(9.68\ z_i^2/r_A) \text{ cal/deg.mole} \quad [48]$$

at infinite dilution. Taking the crystal radius (38) of K^+ at 1.33Å, plus 0.85Å for the ion cavity, plus 2.80Å as the approximate diameter of one water molecule, a total radius of 5.0Å is estimated for the sphere "bounding" the second from the third regions. S^*_{Mi} can then be calculated as 1.94 cal/deg for K^+ ion at infinite dilution, a value which is of the right order as compared with the conventional single ion value of Table III. However, Eq. [48] cannot be used for any accurate calculation of S^*_{Mi} since the appropriate third region radius, and the short range dielectric constant, are uncertain. Agar (21) has shown that little correlation exists between conventional values of S^*_{Mi} and ionic crystal radii.

At finite concentration, the potential surrounding an ion is reduced by multiplication by the Debye-Hückel factor, $\exp(-\kappa r)$, and Eq. [48] should be multiplied by the same factor. The derivative $dS^*_{Mi}/d\kappa$ becomes $-9.68\ z_i^2\exp(-\kappa r)$ cal.Å/deg. For 1, 1-salts in water at 25°C, and very dilute solutions where $\exp(-\kappa r) \approx 1$, the derivative $dS^*_{Mi}/d\sqrt{m}$, in cal/deg. (unit of molality)$^{1/2}$, $= -3.18$. For both ions of the salt, $dS^*_D/d\sqrt{m}$ is twice this or -6.36 in satisfactory agreement with observed values of -6.0 to -6.5 reported above for several 1, 1-salts. For $CdSO_4$, the limiting slope should be $2^2 \cdot 2$ or 8 times this, about -51. The observed slope in the most dilute solutions for which there are data, -26, appears to be rapidly approaching this limiting value.

Thus Eastman's interpretation of the entropy of migration S^*_{Mi} as being primarily the entropy of relaxation of the polarized dielectric of the solvent in the third region, when the ion departs, appears to be well founded. On this basis, the migration transport entropy of an ion should always be positive, and, according to Eq. [48], multiplied if necessary by the Debye-Hückel factor to take care of interionic attractions, it should always be small, around 1 to 3 cal/deg for univalent ions.

However, electrostatics does not tell the whole story. Agar (21) points out that where an ion breaks up the structure of the water, its presence may actually increase the entropy of the solvent in the third region, and this would lead to negative migration entropies as reported above for several ions (Tables III to V).

To quote Eastman once more: "The conception of solvated ions . . . takes into account only the electrical effects . . . . Several factors . . . neglected . . . may be of importance in certain cases. Any sort of chemical bonding in the ion aggregate may greatly affect the spheres of influence about the central charge, and so alter the heat [entropy] effects attending its diffusion. This kind of thing may differentiate, for example, between positive and negative ions in their orienting and bonding effects on water molecules. The hydrogen nuclei of the solvent may form a sort of hydrogen bond (39) with electrons of the outer shell of negative ions, a type which is not possible between oxygen atoms and most positive ions. The effect of such bonds, if extensively formed, would be to increase region two at the expense of three, with consequent lessening of the heat of transfer [and of the entropy of migration]. The possibility that either ion of the solvent [H^+ or OH^-] may be transferred, in effect, by a chain mechanism, must also be considered in solutions of acids and bases. For if this occurs, not only the energy represented in the third sphere above, but that of the second as well, a very much larger quantity, would be involved in the heat of transfer." There is evidence that S^*_{Mi} for H^+ and OH^- is considerably larger (about 10 cal/deg) than for other ions, as discussed above.

The large values obtained for the conventional entropy of migration S^*_{Mi} of the tetraalkylammonium ions (Table III) appear surprising at first, since Eastman's students (44) had speculatively expected values close to zero, and had even used this hypothesis as a basis for evaluating a set of S^*_{Mi} values, which proved inconsistent with known values of S^*_D from the Soret effect (Table I). The large values actually obtained point to another mechanism than just the electrostatic one discussed above. The hydrocarbon chains must exert some ordering influence on the neighboring water structure, perhaps by the formation of "icebergs" (44). The removal of the alkyl chains by migration of the ions then allows a disordering of the water structure left behind, i.e., a "melting of the icebergs" (44), with a consequent absorption of heat and a positive entropy of migration. The increment in S^*_{Mi} for every

four CH_2 groups added to the ion appears to be around 4 cal/deg, in going from methyl to amyl, i.e., about 1 cal/deg/CH_2 group added. This entropy effect is still small as compared with the intrinsic molal entropies of the materials involved, i.e., about 8.1 cal/deg for CH_2 (from the entropy difference between ethanol and methanol) and 16.7 cal/deg for H_2O. Thus Eastman's students speculations regarding the smallness of the entropy of migration of the tetraalkylammonium ions may still be justified as regards an individual linkage within the ion, even though it is not justified for the huge ion as a whole.

If one attributes the same value of 1 cal/deg to the migration of the methyl (CH_3) group, as well as to CH_2, a residual conventional value of about 3 cal/deg is obtained for the migration entropy of the N^+ core of the R_4N^+ ions, i.e., a value which is quite consistent with that of other simple ions such as Na^+, K^+, Rb^+, and with the electrostatic values, Eq. [48], as well.

The values for divalent ions (Tables III to V) are considerably smaller than what one would expect from the electrostatic relation [48] alone. Undoubtedly, the Debye-Hückel drop-off at finite concentration is already much more significant in this case, as may be the structure-breaking properties of the ion on the solvent, which would tend to lead to negative values of the migration transport entropy.

Summary

The application of the Onsager thermodynamics to electrochemical systems out of equilibrium permits a unified approach to the problems of concentration cells with transference, thermal diffusion in electrolytes, initial and final emf's of thermal cells. For isothermal concentration cells, the method confirms the classical results of Nernst derived from equilibrium considerations of free energy. For non-isothermal systems, the method brings out the entropy S^* transported from hot to cold heat reservoirs (in the limit of equal temperatures), multiplied by the applied temperature differential dT, as the characteristic thermodynamic driving force of a process. For an ion, the entropy transported is different when the ion is transported by electrode reactions and when it is transported by migration. This gives rise to the ionic entropies of electrochemical transport S^*_{Ei} and of migration transport S^*_{Mi}, respectively. Values of the ionic transport entropies can be estimated from data on initial and final thermal emf's and Soret coefficients. For an ion, the standard value of $S^{*\circ}_{Ei} = S^\circ_i - z_i(4.48$ cal/deg) while the nonstandard values of S^*_{Ei} show a normal mass action dependence on concentration. For many ions, except H^+ and OH^-, S^*_{Mi} appears to be small and positive, *i.e.*, about 0-3 cal/deg. Such values are in semi-quantitative agreement with calculations based on Eastman's model of the ionic entropy of migration as the electrostatic entropy of depolarization of the solvent dielectric when the ion moves out. The concentration dependence of S^*_{Mi} does not follow the law of mass action, but it appears to follow the Debye-Hückel relations in dilute solutions. The establishment of better values for the ionic transport entropies remains a challenging task.

Ionic transport across biological membranes is an important process in the release of energy by living systems (18, 40). Holtan (17b) has shown by qualitative experiments that large thermal emf's (of the order of 10^{-2} volts per degree) can be developed in colloidal mixtures and in nerve fibers. He has suggested that such thermal emf's may contribute to the initiation of nerve impulses. The role of ionic transports arising from possible local thermal gradients resulting from metabolic energy release in living systems, needs to be explored, and may be hoped to shed some light on the mechanism of the living cell as a thermodynamic engine. "Where is the way to the dwelling of light?" (Job 38: 19).

Acknowledgment

The author wishes to express his gratitude to the International Nickel Company, Inc., of New York, for a Grant-in-Aid in support of this work.

Manuscript received Dec. 28, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

APPENDIX I

Glossary of Transport Entropies Used in This Paper

S^*: the entropy of transport, the entropy transported reversibly from the right heat reservoir No. 2 (normally the hot one) to the left heat reservoir No. 1 (normally the cold one) by the occurrence of some reversible process in the cell (system), in the limiting case of a vanishing temperature difference between the heat reservoirs.

S^*_I: the entropy of electrical transport, i.e., the entropy transported between heat reservoirs, as above, by the flow of a positive current through the cell from left to right.

S^*_E: the entropy of electrochemical transport, i.e., the contribution to S^*_I of the two equal and opposite electrode reactions.

S^*_M: the entropy of migration transport, i.e., the contribution to S^*_I of the current transported by ionic migration through the solution.

S^*_D: the entropy of diffusion transport, i.e., the entropy transported between heat reservoirs, as above, by the flow of solute across the liquid junction from right to left.

S^*_{Ei}: the ionic entropy of electrochemical transport, i.e., the contribution of an ion (or electron) to S^*_E.

S^*_{Mi}: the ionic entropy of migration transport, i.e., the contribution of migration (or diffusion) of an ion (or electron) to S^*_M or to S^*_D.

$\overline{\overline{S}}_i$: the entropy of the moving ion, i.e., the sum $S^*_{Ei} + S^*_{Mi}$.

Ionic index $_r$: the ion to which the electrodes are reversible; $_g$: the gegenion of $_r$.

APPENDIX II

Comparative Nomenclature for the Three Ionic Transport Entropies Appearing in the Equation $\bar{\bar{S}}_i = S^*_{Ei} + S^*_{Mi}$

Author	$\bar{\bar{S}}_i$	S^*_{Ei},[1]	S^*_{Mi}

Entropy of the Moving Cuprous Ion in Molten Cuprous Chloride from Thermogalvanic Potentials

Ambrose R. Nichols, Jr.[1] **and Cecil T. Langford**

Scientific Research Laboratory, Convair Division of General Dynamics Corporation, San Diego, California

ABSTRACT

Potentiometric measurements have been made on a thermogalvanic cell consisting of copper electrodes immersed in molten cuprous chloride in which there was a temperature gradient. The difference in temperature ΔT between the electrodes was varied from 30° to 70°C and the average temperature of the cell T_{avg} was varied from 462° to 588°C. Over these ranges the emf was proportional to ΔT, and $\Delta E/\Delta T = -0.436$ mv/°C, the hot electrode being the (—) terminal of the cell. From this value, the entropy of the moving cuprous ion in the melt was calculated for three different temperatures.

Thermogalvanic potentials in aqueous solutions have been studied rather extensively beginning with the work of Richards (1) who measured the temperature coefficient of the calomel electrode. It was not until about 1930 that studies were initiated in the electrochemistry of fused salts, but very little work was done in the field for the next twenty years. In the early 1950's there was a resurgence of interest, and as is evident from a recent bibliography compiled by Janz (2), an enormous amount of work has been done during the past eight years on the electrochemistry of fused salts. As is also evident from this same bibliography, practically all of the investigations in this field have been made with systems at uniform temperature throughout.

Much of the recent work with fused salts has been concerned with the development of reference electrodes constructed in such a manner that liquid junction potentials are practically eliminated. Senderoff and Brenner (3) used a coarse asbestos plug in the tube connecting the two half-cells, but apparently sufficient diffusion took place to introduce an unknown boundary potential into their measurements. Others, including Delimarskii (4), and Bockris, *et al.* (5), have used thin diaphragms of soda glass or Pyrex, but these are not suitable for use at high temperatures and, except in the case of concentration cells, do not lend themselves to exact thermodynamic analysis. Some very precise recent work in this field is described in a series of papers by Flengas and Ingraham (6) who developed a reversible silver-silver chloride reference electrode for use at high temperatures. The side-arm tube of the silica half-cell contains a single asbestos fiber (as opposed to a coarse plug) carefully sealed into the tube in a specified manner (6a). By using the same solvent (an equimolar mixture of NaCl-KCl) in the two half-cells with very low concentrations of the solutes (AgCl in the standard, and MCl_n in the other half-cell) the measured emf is, for all practical purposes, free from any liquid junction potential. In their most recent paper (6f) these authors give an emf series for several metals with corresponding standard electrode potentials referred to their standard Ag-AgCl electrode. Throughout their work they have determined the effect of temperature on the emf of each cell studied. The emf measurements, however, are made under isothermal conditions. It would be possible to calculate reaction entropies from their results but impossible to determine entropies of transport.

Many investigators have studied thermogalvanic potentials in aqueous solutions, but the most comprehensive treatment of the subject is given in a

[1] Professor of Chemistry, San Diego State College, San Diego, California.

recent paper by deBethune, Licht, and Swendeman (7) who give references to 28 earlier contributions, clarify the concepts of isothermal and thermal temperature coefficients of standard electrode potentials, and compute values for both of these, at 25°C, for nearly 300 electrodes. Their treatment of the thermodynamics of thermocells is applicable to fused electrolytes and we shall utilize their notations later in discussing our own results.

Reinhold (8) has measured the emf of a large number of thermocells with solid electrolytes. Among them was a cell analogous to ours and we shall compare his results with those obtained in this study. He also found (8c) that the temperature coefficient of the emf of an isothermal cell could be calculated from the thermal coefficients of related thermocells. Holtan (9), who reinvestigated and extended some of Reinhold's work, found a theoretical basis for the correspondence between thermocells and isothermal cells observed by Reinhold.

The present investigation involved measurements of the emf of a thermogalvanic cell consisting of copper electrodes immersed in molten cuprous chloride in which there was a temperature gradient. It was observed experimentally that the *hotter electrode* was the *negative* (−) *terminal*. The cell may be represented diagramatically as

$$(+)\mathrm{Cu(s)} \;|\; \underset{T_1}{\mathrm{CuCl(l)}} \;|\; \underset{T_2}{\mathrm{Cu(s)}}\,(-) \qquad [1]$$

where $T_2 > T_1$. Following the customary convention in thermocells, where a positive emf means that the hot electrode is the (+) terminal (7-9, 12, 14, 15), the sign of the emf of cell [1] is negative. It will be noted that this sign convention agrees with that of the I.U.P.A.C. (10) when the thermocell is diagrammed with the hot electrode on the right. When the outside circuit is closed and the cell operates spontaneously, the electrode reactions are

$$\text{at the hot electrode:} \quad \mathrm{Cu(s,}T_2\mathrm{)} = \mathrm{Cu^+}(T_2) + e^-(T_2), \qquad [2]$$

$$\text{at the cold electrode:} \quad e^-(T_1) + \mathrm{Cu^+}(T_1) = \mathrm{Cu(s,}T_1\mathrm{)}. \qquad [3]$$

If the temperature difference is neglected there is no net over-all chemical reaction but, physically, cuprous ions are transported from the hot electrode to the cooler one inside the cell, and electrons are transported from the hot to the cooler electrode in the outside circuit. Such a cell is analogous to a metallic thermocouple in that the molten electrolyte may be regarded as having replaced one of the dissimilar metals. For this reason some investigators have referred to cells of this type as galvanic thermocouples.

Experimental

A cell, made of Vycor glass, was placed inside a stainless steel container that fitted snugly in an electrically heated muffle furnace from which the door had been removed. The arrangement is shown in Fig. 1; Fig 2 is a sketch of the thermogalvanic cell. The container protruded 12.7 cm beyond the front of the furnace, and a temperature gradient

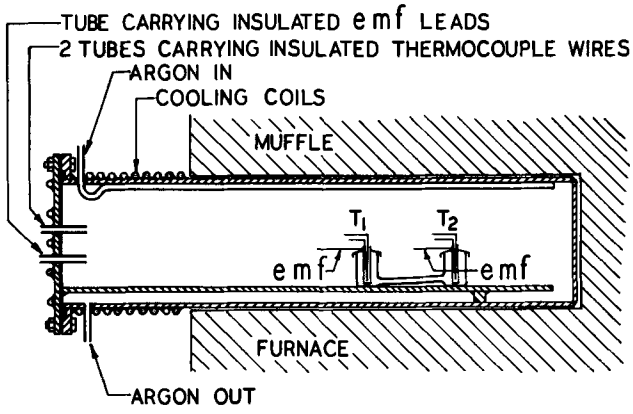

Fig. 1. Thermogalvanic cell assembly

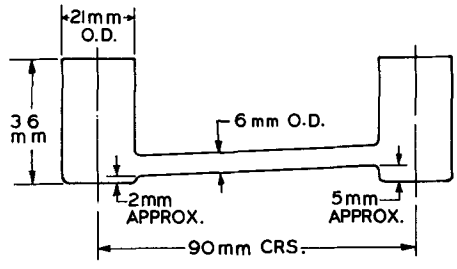

Fig. 2. Thermogalvanic cell made of Vycor glass. Hotter compartment on the right.

was maintained inside it by passing cooling water through coils that surrounded the front parts of the vessel. The tube connecting the two cell compartments was placed at a slight angle to the horizontal to minimize convection currents in the molten salt when the right hand compartment was made the hotter one by placing it toward the rear of the furnace. Powdered cuprous chloride was added to the cell until the connecting tube was full and each of the electrode compartments was about half full. The cuprous chloride was Baker and Adamson's Reagent, A.C.S. grade, dried to constant weight at 110°C without further purification. Preliminary experiments in which vacuum dried, freshly precipitated, cuprous chloride was used gave identical results with those reported here.[2] Electrodes were made from 5-cm lengths of 0.635-cm copper rod. A 0.318-cm hole was drilled from one end of the rod to within 0.16-cm of the other end, giving an open cylinder into which an insulated Pt-Pt + 10% Rh thermocouple was inserted. The junction rested on a single "fish-spine" insulator at the bottom of the cylinder. The cell compartments were covered with crucible lids. A copper electrode for each compartment was inserted through a hole in the center of the lid. When the bottom of the electrode rested on the bottom of the cell compartment the electrode protruded above the lid about 1.3 cm.

The thermocouple wires passed from the electrode through the face-plate of the container and protruded for a distance of 5 cm beyond it. Platinum and platinum + 10% rhodium lead wires ex-

[2] Apparently any Cu^{++} present in the Reagent grade CuCl is reduced by the metallic Cu electrodes, as reported by Flengas and Ingraham (6f).

tended from the front of the face-plate to a near-by Dewar flask where junctions between them and copper lead wires were maintained at the temperature of melting ice. The noble metal lead wires were connected to the corresponding thermocouple wires by means of a compression connector fabricated from a block of micarta that was attached to the outside of the face-plate. Insulated external copper leads passed from the potentiometer through the face-plate for a distance of about 5 cm. These were joined with copper connectors to short lengths of copper wire that were attached to the electrodes. Because of the continuous copper leads from the copper electrodes to the binding posts of the potentiometer, the observed emf was free from any metallic thermocouple voltage. Three double-pole, double-throw switches permitted the three circuits from inside the furnace to be passed either to a 6-point Brown recording potentiometer or to a L & N Type K-2 potentiometer. During a run, air was excluded from the heated cell by passing a stream of oxygen-free argon continuously through the stainless steel container. Argon from a commercial cylinder was passed over copper turnings heated to 350°C in a combustion tube furnace, before it was admitted to the furnace.

At the start of a run, a temperature controller in the heating circuit of the muffle furnace was set to bring the cell to a temperature considerably above the melting point of cuprous chloride. When the first "temperature plateau" was reached, two or three sets of voltages were measured at 10-min intervals, by means of the L & N Type K-2 potentiometer. The Type K-2 readings to the nearest microvolt were recorded and used in the calculations. The controller was then set for the next desired temperature plateau which would be attained in about 30 min. A particular set of voltages was obtained quite rapidly by manipulating the three double-pole, double-throw switches so that the circuit from the thermocouple in the hotter electrode, that from the cooler electrode, and the circuit from the thermogalvanic cell were switched, in turn, from the recording potentiometer to the Type K-2 instrument. Prior to the switching operation each of the three voltages was being printed on the strip chart at intervals of 27 sec and the values could be estimated to 0.01 mv. It was possible, therefore, to preset the Type K-2 potentiometer to a value quite near the actual voltage so that the final balancing required only a few seconds. Indeed, the three voltages could be determined on the Type K-2 in less than 2 min.

It will be observed from Table 1 that the temperature of the electrodes did not remain entirely constant during the two or three sets of readings that were taken at each so-called temperature plateau. During the ascending part of the temperature cycle the furnace cooled slightly at a plateau, while the reverse was true during the descending part of the cycle. It was not deemed necessary to obtain closer temperature control since, for a given set of readings, the actual temperatures of the electrodes and the corresponding emf of the thermogalvanic cell were measured essentially simultaneously.

Results and Discussion

If an aqueous solution of a substance is placed in a temperature gradient, a gradual change in concentration will, in general, take place because of thermal diffusion of the solute. This phenomenon is known as the Soret (11) effect, and the steady state finally attained is the so-called Soret equilibrium. When a solution of an ionic material constitutes the electrolyte of a thermogalvanic cell the emf will, in general, vary from an initial value E_i before the composition of the solution has had time to alter appreciably, to a final value E_s corresponding to the Soret equilibrium or steady state, as shown experimentally by Agar and Breck (12). In a series of papers, Eastman (13) suggested that the emf of such a cell is related to certain entropy changes that occur when it operates, and he introduced the concepts of entropy of transfer S^* and heat of transfer Q^* for those species that move between the electrodes. He proposed the following equation (13c) for the initial emf,

$$-\mathbf{F}(dE_i/dT) = \Delta S_R + \Delta S^*, \qquad [4]$$

where ΔS_R is the entropy gained by the electrode system at the higher temperature in the electrode reaction caused by one Faraday of positive electricity passing reversibly from the electrode to the electrolyte, and ΔS^* is the net entropy of transfer of the ions. $\Delta S^* = t_c S^*_c - t_a S^*_a$, where t_c and t_a are the transport numbers for the cation and anion, respectively.

More recently Temkin and Khoroshin (14), in a theoretical study of thermogalvanic cells, have developed an equation for the steady-state emf E_s. They show that, in so far as the ions are concerned, the heat of transfer of the potential-determining ion only is involved and the effects of the other ions

contained in the solution may be neglected. Their equation [24], with minor changes in symbols, is, for electrodes reversible to positive ions of valence n

$$-n\mathbf{F}(dE_s/dT) = \Delta S_R + Q^*_t/T + nQ^*_{e^-}/T \quad [5]$$

Q^*_t is the heat of transfer of 1 mole of the positive ion with respect to which the electrode is reversible, and $Q^*_{e^-}$ is the heat of transfer of one equivalent of electrons from the electrode. ΔS_R is the change in entropy during the transfer of the ion from the electrode into the solution and is identical with Eastman's ΔS_R in Eq. [4], *i.e.*, it is the increase in entropy for the chemical reaction that occurs reversibly at the hotter electrode when n Faradays of positive electricity pass from electrode to electrolyte. Thus, for reaction [2], the above authors would write

$$\Delta S_R = \bar{S}(\mathrm{Cu^+}) - S(\mathrm{Cu}) \quad [6]$$

where, in the general case, $\bar{S}$ is the partial molal entropy of the positive ion in the solution to which the electrode is reversible. As pointed out by deBethune, *et al.* (7) the ionic entropy involved in this reaction is also an entropy of transport, and is not equal to the conventional $\bar{S}$ for a single ion. They suggest that it be called the ionic entropy of electrochemical transport and be designated by the symbol $S^*_{E_t}$. Also, they suggest that the entropy ΔS_R absorbed by the reaction at the hot electrode be referred to as the entropy of electrochemical transport and designated S^*_E. For the entropy transported through the cell by electrolytic migration, *i.e.*, the net entropy of transfer ΔS^*, they propose the term entropy of migration transport represented by S^*_M.

In terms of the latter concepts, we write for reaction [2]

$$S^*_E = S^*_E(\mathrm{Cu^+}) - S(\mathrm{Cu}) \quad [7]$$

an expression which is equivalent to ΔS_R in Eq. [4] and [5]. Also, S^*_M is identical with Eastman's ΔS^* in Eq. [4] and $S^*_{M_t}$ is the same as Temkin and Khoroshin's Q^*_t/T in Eq. [5].

Temkin and Khoroshin (14) introduced a quantity $\bar{\bar{S}}$, which they called the entropy of the moving ion, and defined it by the equation

$$\bar{\bar{S}} = \bar{S} + S^* \quad [8]$$

where $S^* = Q^*/T$. In terms of the newer concepts and nomenclature discussed above, $\bar{S}$ should be replaced by $S^*_{E_t}$, and S^* by $S^*_{M_t}$, hence for the ionic processes occurring in cell [1] (electrochemical transport and migration transport) Eq. [8] should be written,

$$\bar{\bar{S}}(\mathrm{Cu^+}) = S^*_E(\mathrm{Cu^+}) + S^*_M(\mathrm{Cu^+}) \quad [9]$$

According to Khoroshin and Temkin (15), when the Soret effect is zero $E_t = E_s$. In cell [1] the molten electrolyte consists of only one component, hence no concentration gradient can develop. The measured thermal emf, therefore, is an initial one which is also indefinitely stable, and should be given by both the Eastman Eq. [4], and by the Temkin-Khoroshin Eq. [5]. If we rewrite Eq. [4] in terms of the newer concepts as discussed above, and add a term for the entropy of the moving electron, which Eastman (13c) neglected, we have,

$$-\mathbf{F}(dE_t/dT) = S^*_E + S^*_M + \bar{\bar{S}}_{e^-(\mathrm{Cu})} \quad [10]$$

or

$$-\mathbf{F}(dE_t/dT) = S^*_E(\mathrm{Cu^+}) - \bar{\bar{S}}(\mathrm{Cu}) + t_c S^*_M(\mathrm{Cu^+}) - t_a S^*_M(\mathrm{Cl^-}) + \bar{\bar{S}}_{e^-(\mathrm{Cu})} \quad [11]$$

Similarly, for Temkin and Khoroshin's Eq. [5], for the passage of one faraday, we have

$$-\mathbf{F}(dE_s/dT) = S^*_E(\mathrm{Cu^+}) - S(\mathrm{Cu}) + S^*_M(\mathrm{Cu^+}) + \bar{\bar{S}}_{e^-(\mathrm{Cu})} \quad [12]$$

For copper electrodes in molten cuprous chloride $t_a = 0$ and $t_c = 1$, hence Eq. [11] reduces to Eq. [12] and either may be used with the temperature coefficient of the thermopotential of cell [1]. Upon combining Eq. [9] with Eq. [12] and rearranging, the following equation for the entropy of the moving cuprous ion is obtained

$$\bar{\bar{S}}(\mathrm{Cu^+}) = -\mathbf{F}(dE_s/dT) + S(\mathrm{Cu}) - \bar{\bar{S}}_{e^-(\mathrm{Cu})} \quad [13]$$

Table I gives detailed results for run number 1, and Table II summarizes the results of three separate runs comprising 56 measurements of electrode temperatures and corresponding cell potentials. It was thought the $\Delta E/\Delta T$ might vary with the average temperature of the cell or with the magnitude of ΔT, or with both, but no such variations were observed. In a particular run, ΔT was changed only slightly but the temperature of the furnace was raised through 40°-80°C and then lowered through 80°-120°C during which cycle the values for $\Delta E/\Delta T$ fluctuated around the average shown in the last column with no detectable trend. In run No. 3 the temperature difference between the electrodes was deliberately increased by placing the cell farther toward the front of the furnace where the temperature gradient was greater. Although ΔT was about doubled, $\Delta E/\Delta T$ remained constant over the temperature cycle shown. The average value for $\Delta E/\Delta T$, for all 56 measurements, is -0.436 mv/deg C and may be used for dE_s/dT giving a value of 10.05 cal/deg for the first term on the right of Eq. [13].

The average temperature of the melt varied from about 462° to 588°C (15° below 477° in run No. 2,

Standard deviation of the set = 0.006 mv/°C

Table III. Effect of temperature on the entropy of the moving cuprous ion as calculated by Eq. [13]

Avg. temp of cell, °K	$F(dE/dT)_{th}$, cal/deg mole Cu^+	$S(Cu)$, cal/deg g-atom	$\bar{\bar{S}}_{e^-(Cu)}$, cal/deg equiv	$\bar{\bar{S}}(Cu^+)$, cal/deg mole Cu^+
735	—10.05	13.50	—0.095	23.65
798	—10.05	14.04	—0.102	24.19
861	—10.05	14.55	—0.109	24.71

to 30° below 618° in run No. 3) and the average of these values is 525°C. The last two terms on the right of Eq. [13] are evaluated from the literature for a temperature of the melt of 525°C. Temkin and Khoroshin (14) give the following equation for the entropy of the moving electrons in copper:

$$\bar{\bar{S}}_{e^-(Cu)} = -[1.95 + 0.005\,(T\text{-}300)]\ \text{microvolt-faradays/degree-equiv},\ T \geqq 240°K. \quad [14]$$

This yields $\bar{\bar{S}}_{e^-(Cu)} = -0.102$ cal/deg at 798°K. Giauque and Meads (16) have determined the molal entropy of copper and give the value $S(Cu, 298.1°) = 7.961$ cal/deg. Kelley (17) gives the following equation for the molal heat capacity of copper from 298° to 1357°K,

$$C_p = 5.41 + 1.50 \times 10^{-3}\,T \text{ cal/deg} \quad [15]$$

from which we calculate $S(Cu, 798) - S(Cu, 298) = 6.08$ cal/deg. This gives $S(Cu, 798) = 14.04$ cal/deg.

If the above values are substituted in Eq. [13] we have, at 525°C,

$$\bar{\bar{S}}(Cu^+, 798°K) = 10.05 + 14.04 + 0.10 = 24.19 \text{ cal/deg} \quad [16]$$

Similar calculations for the lowest (462°C) and the highest (588°C) average temperatures of the melt have been made. These results and the above are summarized in Table III.

The following thermocell with solid electrolyte was studied by Reinhold (8c):

$$(+)Cu(s) \,|\, \underset{T_1}{} \, CuCl(s) \,|\, \underset{T_2}{} \, Cu(s)(-) \quad [17]$$

T_2 was kept constant at 400°C and T_1 was varied from 113° to 400°C. From his equation for dE/dT as a function of ΔT we calculate, for $\Delta T = 30°C$, $dE/dT = -0.846$ mv/deg. From theoretical considerations applicable only to solid electrolytes, Holtan (9) calculates, for the same cell with T_1 between 300° and 400°C, $\Delta E/\Delta T = -0.82$ mv/deg. These values are about double our value of — 0.436 mv/deg obtained for cell [1] with molten CuCl. In this connection it is interesting to note that Holtan (9) obtained similar results for the cell,

$$(+)Ag \,|\, \underset{T_1}{} \, AgCl \,|\, \underset{T_2}{} \, Ag(-) \quad [18]$$

thermopotentials for which he measured with both solid and molten AgCl. His observed temperature coefficient of the thermopotential for molten AgCl was approximately half that for the solid electrolyte.

It is possible, by the relationship observed by Reinhold (8c) and confirmed theoretically by Holtan (9), to calculate the temperature coefficient of the thermopotential of the cell,

$$(+)Cl_2(g) \,|\, \underset{T_1}{} \, CuCl(l) \,|\, \underset{T_2}{} \, Cl_2(g)(-) \quad [19]$$

which we may designate as $(\Delta E_{19}/\Delta T)_{th}$. The measured coefficient of cell [1], $(\Delta E_1/\Delta T)_{th} = -0.436$ mv/deg, and the temperature coefficient of the emf of the isothermal cell

$$(-)Cu(s)\,|\,CuCl(l)\,|\,Cl_2(g)(+) \quad [20]$$

can be derived from results of Hamer, Malmberg, and Rubin (18), who calculated the emf of cell [20] at several temperatures up to 1500°C. From a plot of their values of E vs. T we have obtained, by graphical methods, the slope of the curve at $T = 525°C$ and find $(\Delta E_{20}/\Delta T)_{isoth} = -0.220$ mv/deg at 525°C. By Reinhold's rule, which has been demonstrated by deBethune, *et al.* (7) and by Holtan and Krogh-Moe (19), these coefficients are related as follows

$$(\Delta E_{20}/\Delta T)_{isoth} = (\Delta E_{19}/\Delta T)_{th} - (\Delta E_1/\Delta T)_{th} \quad [21]$$

Upon substituting in Eq. [21] the measured value for cell [1] and the derived value for cell [20] we find,

$$(\Delta E_{19}/\Delta T)_{th} = -0.656 \text{ mv/deg at } 525°C \quad [22]$$

The result obtained in Eq. [22] is probably only approximate since it depends not only on the accuracy of our measurements for cell [1], and the reliability of the thermodynamic data used by Hamer, *et al.* in calculating emf's for cell [20], but also on the errors inherent in the graphical differentiation of their results.

Manuscript received Dec. 15, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

Cathodic Processes on Passive Zirconium

Robert E. Meyer

Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee[1]

ABSTRACT

Measurements were made of the rates of reduction of various oxidizing agents on passive zirconium in acid solutions of sodium sulfate at temperatures ranging from 25° to 85°C. The oxidizing agents included in these experiments were oxygen, hydrogen ion, and cupric ion and hydrogen peroxide in the presence of oxygen. The kinetic orders of reduction were determined from potentiostatic experiments in which the current was determined as a function of concentration. Unit and fractional orders were observed with oxygen reduction, and fractional orders from about 0.5 to 0.65 were observed for Cu^{++} and H_2O_2. Possible mechanisms are suggested in which charge transfer through the film is assumed to play a predominant role.

The study of electrochemical reduction on the surface of film-covered electrodes has received comparatively little attention. The usual goal in studies of reduction processes is to measure rates on bare metals, and therefore care is taken to remove any films that may be present. It is clear, however, that the presence of a film can markedly influence the reduction processes at the surface by affecting the energetics of the reaction at the double layer, or by imposing a barrier to charge transfer through the film, or both. The study of reduction processes on film-covered electrodes is important to the field of corrosion for the corrosion of metals that form surface films over the entire surface of the metal must necessarily involve the reduction of the oxidizing agent on the surface of the film.

Zirconium is known to form a film, presumably of ZrO_2, when in contact with O_2 in aqueous solution. The standard potential (1) for the half-reaction $Zr + 2H_2O = ZrO_2 + 4H^+ + 4e^-$ is −1.43 v. It is evident from this potential that ZrO_2 is thermodynamically stable under potentials at which such oxidizing agents as O_2, H_2O_2, and H^+ are easily reduced. Furthermore, measurements made in O_2-saturated 0.1*M* Na_2SO_4 (pH ~ 4) showed that the rate of formation of ZrO_2 at potentials in the vicinity of SCE falls off to values on the order of 10^{-8} to 10^{-9} amp/cm^2 after a few days (2). Therefore it should be possible to study reduction processes on film-covered zirconium without significant interference from the film-forming reactions. It is found, in practice, that determinations of reduction rates are reasonably reproducible on a given sample, and therefore it is safe to conclude that the effect of reduction experiments on the surface of the electrode is slight.

[1] Operated by Union Carbide Corporation for the U. S. Atomic Energy Commission.

In the experiments described here, attention was centered on the reduction of H^+, O_2, and Cu^{++} and H_2O_2 in the presence of O_2. It was found that reasonable steady states could not be achieved with Cu^{++} and H_2O_2 if attempts were made to remove O_2. All measurements were made on electrodes after the corrosion reaction had decayed to a negligible rate.

Theory

For the present purposes the following equation will be assumed as representing the reduction current at an electrode:

$$i_c = K \pi_i (a_i^{p_i}) \exp \frac{-\alpha_c z_c E F}{RT} \qquad [1]$$

where i_c is the reduction current density, $\pi (a_i^{p_i})$ is the product of the activities of the reactants raised to the appropriate orders p_i, $\alpha_c z_c$ is the product of the transfer coefficient and the charge number, and E is the potential of the electrode measured with respect to the reference electrode. The value of K will depend on the particular reference electrode chosen. From experimental data, one can determine K, the orders, and the product $\alpha_c z_c$, and therefore determine information of mechanistic significance.

The product $\alpha_c z_c$ is determined from the slope of the log-current density vs. potential plot and is calculated from the derivative:

$$\frac{\partial \log i_c}{\partial E} = \frac{-\alpha_c z_c F}{2.303\, RT} \qquad [2]$$

The orders are determined in experiments in which the electrode is held at constant potential and the activity of a reactant is increased by progressive additions of concentrated solutions. The orders are calculated from the derivative (3):

$$\frac{\partial \log (i_c - i_{c,o})}{\partial \log a_i} = p_i \qquad [3]$$

where $i_{c,o}$ is the initial current density before additions of the reactant. Actually all of the desired information can be obtained either from a series of galvanostatic (constant i) experiments at various activities or by a series of potentiostatic experiments at various potentials. However, if the electrodes vary somewhat in their properties from day to day, it is better to do both types of experiments since αz factors can be obtained more accurately from galvanostatic experiments and orders can be determined more precisely from potentiostatic experiments.

Experimental

Preliminary experiments showed that great precautions had to be taken in order to obtain reproducible data. In particular, the electrodes had to be prepared carefully and the solution and cells thoroughly freed from impurities.

The electrodes were cylinders machined from ¼ in. crystal-bar zirconium and had an area of 2.2 cm². Before use they were cleaned, chemically polished in H_2O-HNO_3-HF solution, rinsed in boiling triply distilled water, and vacuum annealed for several hours at 750°-800°C. Immediately before use they were removed from vacuum, mounted on Teflon holders, and placed in the cell. Such a procedure involved a few minutes' exposure to air, and therefore the electrodes undoubtedly had a thin oxide film on their surface before being introduced into the cell.

All solutions were made from triply distilled water, one distillation of which was made from alkaline permanganate. The sodium sulfate used was doubly recrystallized and the sulfuric acid was prepared by dilution of the C.P. grade. Solutions were pre-electrolyzed for at least 24 hr before use between platinum electrodes with a current of 5-10 ma. The potential of the platinum cathode was well below the lowest potential used on the zirconium electrodes.

The cells were made from Pyrex and Teflon and no greases, waxes, or other sources of surface-active impurities were used in the cell. The cells were thoroughly cleaned before use, and in most of the experiments the final rinse water and the water used for the solutions was distilled directly into the cell.

Potentials were measured by a L&N model 7664 pH and emf meter coupled to a 10-mv Brown recorder. This apparatus was calibrated periodically with a potentiometer and had an accuracy of ± 1 mv on a 1000-mv scale and ± 0.5 mv on a 100-mv scale. Currents were measured by this same unit by measuring the potential drop across precision resistors. In the constant-potential determinations of the orders, an electronic potentiostat developed at this laboratory was used.

Results

Oxygen reduction.—All measurements of oxygen reduction were made in 0.1*M* Na_2SO_4 of varying pH at temperatures in the interval 25°-88°C. Measure-

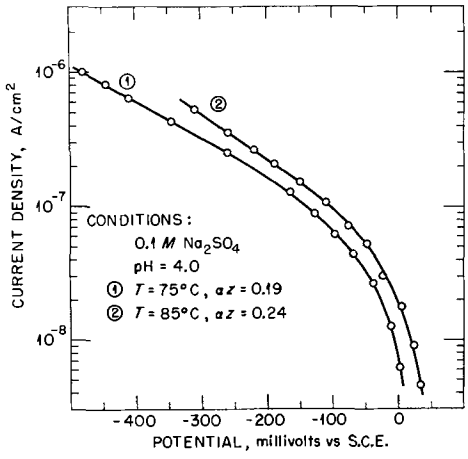

Fig. 1. Oxygen reduction on passive zirconium

ments at the lower temperatures were sluggish, and therefore most of the galvanostatic work was done at 75° and 85°C (Fig. 1). In all cases steady-state values only were used in calculating Tafel slopes. In general, points were taken after the potential showed no drift (< 1 mv) in a period of 5-20 min, depending on the current densities. Slow drifting occurred occasionally but was usually eliminated if the solution were changed and freshly pre-electrolyzed solution admitted. In preliminary experiments, almost all of the samples gave values of αz between 0.18 and 0.35 with 0.25 being an approximate average. In order to obtain a better estimate of $\alpha_c z_c$, three electrodes were prepared under carefully reproduced conditions. These samples showed $\alpha_c z_c$ values of 0.28, 0.32, and 0.33 one day after initial immersion at 75°. There was evidence that at very low current densities, i.e., below ~ 10^{-7} amp/cm², the Tafel slope changed to give a somewhat higher $\alpha_c z_c$. The exact value could not be determined precisely because the potentials at these current densities were too close to the rest potential.

The determination of the reaction order at high concentration of O_2 was carried out potentiostatically by passing pure He, mixtures of He and O_2, and pure O_2 through the cell. At low concentrations of O_2, varying quantities of O_2 were introduced into the cell by anodic evolution on Pt with a closed cell (using an external cathode). Constant current density was used so that the total amount of oxygen present was proportional to the total charge passed. Some of the results are shown in Fig. 2 and 3. In

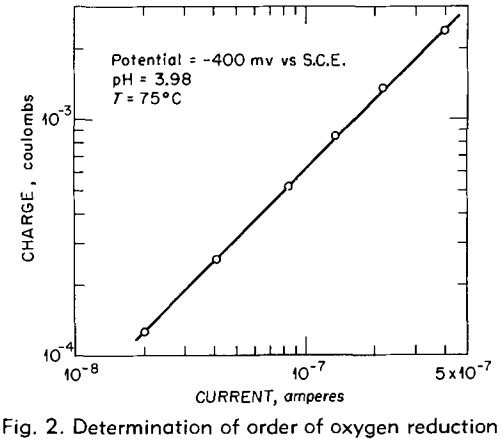

Fig. 2. Determination of order of oxygen reduction

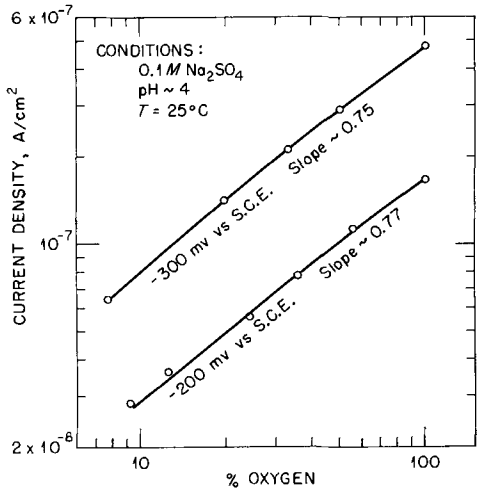

Fig. 3. Determination of order of reduction of oxygen

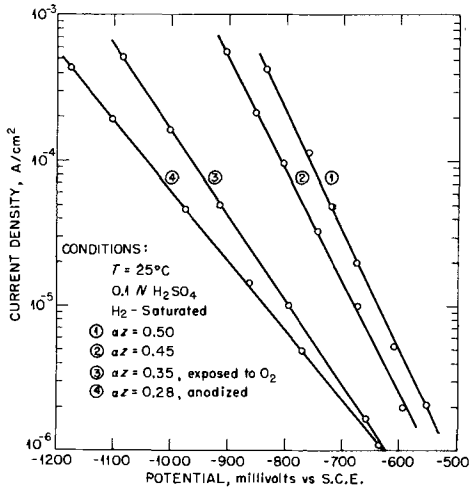

Fig. 4. H^+ reduction on zirconium

Fig. 2, current density is obtained by dividing by 2.2 cm^2, the electrode area. All of the results taken together showed that, for a given electrode under constant conditions, fractional orders of from 0.7 to 0.8 were obtained at high current densities and unit orders were observed at low current densities. For an electrode at 75°, the order slopes changed from unity to fractional in the region 2-5 x 10^{-7} amp/cm^2.

The effect of changing the *p*H at low current densities was to increase the potential by approximately *RT/F* for every *p*H unit decrease in the pH range 2-5. At higher current densities the change was complicated by drifting but the change seemed to be less than *RT/F*. The application of Eq. [3] did not give reproducible orders.

An attempt was made to determine the limiting current due to diffusion with a sample that was unusually stable. By limiting polarization at high current densities to a few minutes, it was possible to estimate roughly the limiting current density as 150 μa/cm^2 for O_2 saturated solutions at 75° (concentration $\approx$ 5 x $10^{-4}M$ and *p*H = 2.75).

In order to check for any possible *IR* drop during polarization, current decay measurements were made with an oscilloscope (Tektronix 536). Using a sensitivity of 1 mv/cm and a current density of about 5 x 10^{-7} amp/cm, no detectable *IR* drop was observed when the current was interrupted.

Hydrogen ion reduction.—The reduction of hydrogen ions was carried out in hydrogen-saturated solutions on electrodes treated in various ways as described below. Unless otherwise mentioned all experiments were carried out at 25°C in H_2-saturated 0.1*N* H_2SO_4. Most of the electrodes were introduced directly into H_2-filled solution-free cells and solution was added only after H_2 was passed through the cell for several hours.[2] When H_2-saturated solution was admitted to the cell, the initial potentials of the zirconium electrode were well below the reversible H_2 potential because of the corrosion reaction $Zr + 2H_2O \rightarrow ZrO_2 + 2H_2$. However, the rate of this reaction decreased rapidly with time and, after an hour, polarization measurements were began. Usually linear Tafel plots were obtainable with electrodes treated this way and two examples are shown as curve No. 1 and 2 in Fig. 4. In general, the slopes were such as to give αz factors of 0.4-0.5, which is frequently observed in hydrogen-evolution experiments on other metals.

If oxygen were admitted to the cell, the potential would rise rapidly before leveling off. After several days the O_2 was removed and Tafel plots such as is shown as No. 3 of Fig. 4 were obtained. A similar effect was produced by anodizing in the absence of O_2 as shown by curve No. 4. Both of these curves show linear Tafel plots but low $\alpha_c z_c$ factors (0.35 and 0.28, respectively).

The effect of *p*H was investigated by preparing an alkaline 0.1*M* Na_2SO_4 solution and decreasing the *p*H by the progressive addition of small quantities of H_2-saturated 2*N* H_2SO_4. The temperature was 25°C and the electrodes were exposed only to H_2-saturated solution before the effect of *p*H was investigated. The electrode therefore had only that small amount of film that would be formed by reaction with hydrogen ions. Results are shown in Fig. 5. In alkaline solution there was no change in current at constant potential with change in *p*H and in acid solution a change of about 60 mv/*p*H unit was observed at constant current. The pH was measured by forcing out several milliliters of solu-

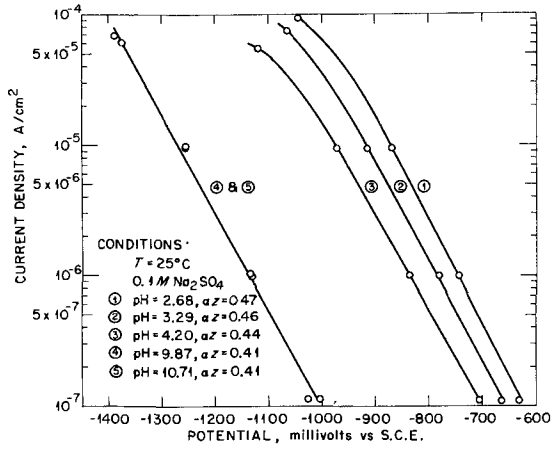

Fig. 5. pH Dependence of H^+ reduction on zirconium

[2] The H_2 was purified with an all Pyrex train containing Drierite, Hopcalite (for CO removal), Ascarite, liquid nitrogen traps, and hot catalyst (either Pd or Cu).

tion through a Teflon valve into an O_2-free container and using a glass electrode with a Beckman Model G pH meter. Results are consistent with discharge from H_2O in basic solution and discharge from hydrogen ions in acid solution.

Reduction of Copper II and H_2O_2.—As mentioned above, the Cu^{++} and H_2O_2 reduction experiments were carried out in the presence of O_2. Because of the decomposition of H_2O_2 at 66°C, the oxygen could not be removed completely in the H_2O_2 experiments. Temperatures had to be maintained at 66°C or higher because at lower temperatures the rates were too slow to measure accurately. The concentrations were changed by precisely measuring out small quantities of concentrated stock solutions of known concentration. Electrodes were prepared in the manner described above, and the corrosion reaction was allowed to decay for several days before measurements were made. All experiments were carried out at constant ionic strength (0.1*M* Na_2SO_4).

Results are shown in Fig. 6 and 7. The order of reduction of Cu^{++} as determined from the slope $\partial \log (i—i_o)/\partial \log a$ varied from 0.66 to 0.61. The orders with respect to H_2O_2 reduction were also fractional, but the slopes varied from about 0.40 to 0.66 as shown in Fig. 7. A possible explanation for these unusual orders is presented below. Tafel slopes could not be measured directly in this case since reasonable steady states were not attained in the absence of oxygen. Potential-current curves taken in the presence of oxygen represent the reduction of both O_2 and Cu^{++} (or H_2O_2) and there may be interaction between them. The Tafel slope can be estimated roughly by taking current-potential points from lines of constant concentration in Fig. 6 and 7. Using this method the slope for copper reduction varied from somewhat greater than RT/F ($\alpha_c z_c \approx 1$) at low current densities to almost $3RT/F$ ($\alpha_c z_c \approx 1/3$) at high current densities and for H_2O_2 the slope was about $4RT/F$.

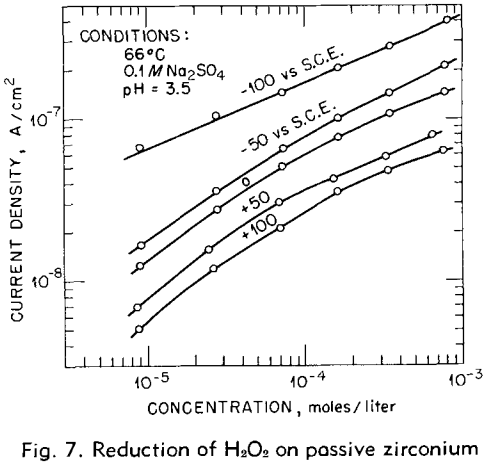

Fig. 7. Reduction of H_2O_2 on passive zirconium

Discussion

In the discussion of these results, it is important to keep in mind that the results described here may be valid only for films prepared as described above. Films which are prepared by higher temperature gaseous oxidation or by anodizing to high voltages are not necessarily similar in kinetic properties to those described here.

The films formed in these experiments are not assumed to be uniform, since the various inhomogeneities at the surface should cause local variations in the nature and amount of the film. This lack of uniformity may cause large variations in current density across the surface of the electrode[3] but it does not invalidate the use of Eq. [1]. This point has been discussed in detail by Posey (3).

Pores or cracks are sometimes suggested as being present in films of this sort. However, at the potentials of these experiments any exposure of bare metal through defects of this type is unlikely. It must be remembered that these potentials are almost 2 v above the equilibrium potential of the reaction $Zr + 2H_2O \rightarrow ZrO_2 + 4H^+ + 4e^-$ and that zirconium is an extremely reactive metal. The arguments against the existence of pores in passive films on iron have been given by Vetter (4) and similar arguments apply to zirconium. Further, the limiting current measurements show that the effective area of the electrode is not significantly smaller than the apparent area. Thus, the experimental figure of 150 $\mu a/cm^2$ should be compared to values of from 80 $\mu a/cm^2$ to 4×10^3 $\mu a/cm^2$ calculated from the well-known equation, $i_l = zFDC/l$ where D is the diffusion coefficient, C is the concentration in moles/cm³, and l is the thickness of the diffusion layer. Values of $D = 2 \times 10^{-5}$ cm²/sec, $z = 4$, $C = 5 \times 10^{-7}$ moles/cm³, and l varying from 0.05 to 10^{-3} cm were taken. Since the experimental measurement was taken under conditions of slight stirring (a slow stream of gas bubbles at the side of the cell), it is clear that the effective area is of the same order of magnitude as the apparent area. This observation is difficult to reconcile with any hypothesis which suggests that only a few pores or singularities are responsible for charge transfer through the film.

Any mechanism of reduction must however take into account the fact that the presence of this film may cause charge transfer through the film to affect

[3] This may also be a cause of the difference observed in different specimens since it is clearly impossible to duplicate the surface of a given specimen.

the over-all kinetics. For very thick films of high resistivity, the film barrier can simply be regarded as *IR* drop, but for the thin films considered here (20-100Å) such an explanation cannot be used. For the reasons described below, it seems better to interpret the data given here on the basis of a potential barrier within the film such that the current, which is assumed to be electron current, is given by the exponential expression, $I \sim \exp -\alpha V/kT$.

According to the original Mott-Cabrera (5) theory of thin film formation on metals, an electric field is formed across the film by electrons which leave the metal surface and find their way to O_2 adsorbed on the surface. The rate-determining step is assumed to be the movement of metal ions through the metal-oxide interface under the influence of the field. However, as Cabrera points out later (6) the transport of electrons through film will also be under the influence of this field, and for all but the thinnest films, the transport of the electrons should also affect the rate.

In the case of zirconium it was shown by the author (2) that a rate law in reasonable agreement with experiment can be derived under the assumption that both ion transport (an anodic process) and the reduction of oxygen were rate-determining. The assumption was made that the reduction current was proportional to $\exp(-\alpha_c z_c V_f/kT)$ where V_f is the potential across the film. The resulting rate-time expression is roughly hyperbolic in rate and time but does not permit a simple exact analytical expression. The important point here is that a fit of the data is obtained if the reduction process is considered a function of the potential across the film and that it too is rate-determining.

Because of the above considerations it is felt that a reduction process on these zirconium electrodes involves charge transfer through the film as well as the usual charge transfer process at the interface. Furthermore, the fractional orders and the unusually low αz factors obtained from the reduction experiments can be best explained from the above assumptions. Before this can be explained the formal mathematics must be stated.

For the purpose of describing these kinetics two cases of a dual-barrier model are used. Case I assumes that, if a reduction process is occurring at a steady-state, two potential-dependent reactions occur at equal rates, the one corresponding to the film reaction and the other to the surface double layer reaction. The rates of the individual reactions can be represented by the two equations:[4]

$$i = K_f \pi_i (a_{i,f}^{p_{i,f}}) \exp(-\alpha_f z_f V_f/kT) \qquad [4]$$

$$i = K_s \pi_j (a_{j,s}^{p_{j,s}}) \exp(-\alpha_s z_s V_s/kT) \qquad [5]$$

where V_f and V_s are the separate potential drops affecting the two different barriers. The activities for the solution reaction are to be taken as the ordinary solution activities. Depending on the nature of the film reaction, the activities in Eq. [4] may represent the effective concentration of electrons, holes, etc., or in some cases may represent the concentration of adsorbed species on the surface of the electrode. Thus, if the film reaction were the transfer of an electron over the potential barrier to adsorbed oxygen, the reaction rate would depend on the number of electrons striking the barrier, the number of O_2 molecules adsorbed, and the probability of electron transport across the barrier.

The over-all measured potential E will be equal to $V_f + V_s + V_k$ where V_k is the constant sum of all of the other potential drops occurring in the measuring circuit. Combining this relation with Eq. [4] and [5] by eliminating V_f and V_s one obtains:

$$i = K_t [\pi_{i,f}(a_{i,f}^{p_{i,f}})^{\frac{\alpha_s z_s}{\alpha_f z_f + \alpha_s z_s}}] [\pi_{j,s}(a_{j,s}^{p_{j,s}})^{\frac{\alpha_f z_f}{\alpha_f z_f + \alpha_s z_s}}] \exp\frac{-\alpha_t z_t E}{kT} \qquad [6]$$

where

$$\alpha_t z_t = \frac{\alpha_f z_f \alpha_s z_s}{\alpha_f z_f + \alpha_s z_s}$$

and

$$K_t = \left(\exp\frac{\alpha_f z_f \alpha_s z_s V_k}{(\alpha_f z_f + \alpha_s z_s) kT}\right) K_f^{\frac{\alpha_s z_s}{\alpha_s z_s + \alpha_f z_f}} K_s^{\frac{\alpha_f z_f}{\alpha_s z_s + \alpha_f z_f}}$$

Therefore

$$\frac{\partial \ln i}{\partial E} = \left(\frac{-\alpha_f z_f \alpha_s z_s}{\alpha_f z_f + \alpha_s z_s}\right) \times \frac{1}{kT} \qquad [7]$$

and

$$\frac{\partial \log i}{\partial \log a_{i,f}} = \frac{p_{i,f}\alpha_s z_s}{\alpha_f z_f + \alpha_s z_s} \qquad [8]$$

and

$$\frac{\partial \log i}{\partial \log a_{j,s}} = \frac{p_{j,s}\alpha_f z_f}{\alpha_f z_f + \alpha_s z_s} \qquad [8a]$$

Equation [6] predicts that the apparent orders as measured by $\partial \log i/\partial \log a$ will be the true order p multiplied by a fraction. This will be true only if all activities are completely independent of each other so that the activity in question can be varied without affecting the values of the activities at either of the barriers. If an activity affecting one barrier is a function of the activity of a reactant of the other, i.e., if $a_s = f(a_f)$, then

$$\left(\frac{\partial \log i}{\partial \log a_f}\right)_E = \frac{p_i \alpha_s z_s}{\alpha_f z_f + \alpha_s z_s} + \frac{p_j \alpha_f z_f}{\alpha_f z_f + \alpha_s z_s}\left(\frac{\partial \log a_s}{\partial \log a_f}\right)_E \qquad [9]$$

If a_s is proportional to a_f, the derivative $\partial \log a_s/\partial \log a_f$ will be unity and, if both p's are unity, the over-all order will be unity.

Although the order determinations were carried out at constant over-all potential, it is still possible that V_f and V_s may have varied, subject to the condition that their sum is constant. If the solution concentration of the oxidizing agent is increased,

[4] One might justifiably object to the use of this rate equation for the film reaction. In this derivation, it is to be regarded purely as a formal equation giving the current as a function of the activities and the potential for a film at constant thickness. The constants K_f and α_f are not necessarily analogous in their theoretical interpretation to K_s and α_s in the rate equation representing the surface reaction.

this will cause an increase in current at the double layer (or through the film if it is adsorbed and affects the film barrier). In order that a steady state be maintained, the potentials V_f and V_s must readjust. The effect of this is described mathematically by Eq. [8], in which it is shown that the apparent order will be p multiplied by a fraction.

Using Eq. [8a], it is possible to predict that lowering $\alpha_f z_f$ will lower the apparent order. Since it was observed experimentally that the thicker the film the lower the $\alpha_t z_t$ coefficient for H^+ and O_2 reduction, it was assumed that this was due to a decrease of $\alpha_f z_f$. Therefore a specimen was anodized to a light blue color (16 v) and reduction of Cu^{++} was carried out with this electrode. The log a vs. log $(i—i_o)$ slope was not linear, but in no portion of the curve was the slope greater than 0.3, as would be predicted qualitatively from Eq. [8a].

Alternatively the fractional orders may be explained by the assumption of an adsorption isotherm such that the activity at the surface is not directly proportional to the activity in the bulk of the solution. This however seems somewhat more arbitrary than the explanation involving the dual barrier. Also, one would have to assume that the same adsorption isotherm holds for H_2O_2 and Cu^{++} since they both give about the same order.

Equation [7] also predicts that the observed $\alpha_t z_t$ will generally be smaller than either $\alpha_s z_s$ or $\alpha_f z_f$. The unusually low transfer coefficients observed in these experiments may be explained on this basis. Thus, if $\alpha_f z_f = \alpha_s z_s = 0.5$, $\alpha_t z_t$ will be 0.25. For O_2 reduction, it is possible to calculate that $\alpha_s z_s = 1.2$ and $\alpha_f z_f = 0.4$, using the fact that the observed order, 0.75, $= \alpha_s z_s/(\alpha_s z_s+\alpha_f z_f)$ and the observed $\alpha_t z_t$, 0.31, $= (\alpha_s z_s \alpha_f z_f)/(\alpha_f z_f+\alpha_s z_s)$. Here it is arbitrarily assumed that oxygen affects the film barrier. The experimental determinations of the apparent order and the apparent Tafel slope are, however, not considered precise enough to warrant accurate calculations of $\alpha_f z_f$ and $\alpha_s z_s$.

The second case that might occur in this system is that which occurs when one of the reactions is essentially at equilibrium. In this case a Nernst-like expression may be used for the potential of the barrier at equilibrium and the normal rate equation for the other. A steady potential across the barrier at equilibrium will be achieved if the activities affecting this barrier remain constant. For the barrier at equilibrium, we may write

$$V_1 = V_{1,0} + \frac{RT}{nF} \ln \frac{\pi a^r_{1,ox}}{\pi a^s_{1,red}} \qquad [10]$$

The standard rate equation, e.g., Eq. [4] or [5], along with the relation $V_1 + V_2 = V_t$ gives:

$$i = K_2(\pi_3 a_2^{p_2}) \left(\frac{\pi a^r_{1,ox}}{\pi a^s_{1,red}} \right)^{\frac{\alpha}{n}} \exp \frac{+\alpha z V_{1,0}}{kT} \exp \frac{-\alpha z V_t}{kT} \qquad [11]$$

The following derivatives are obtained from Eq. [11]:

$$\frac{\partial \log i}{\partial \log a_2} = p_2 \qquad [12]$$

$$\frac{\partial \log i}{\partial \log a_{1,ox}} = r \frac{\alpha}{n} \qquad [13]$$

and

$$\frac{\partial \ln i}{\partial V_t} = -\frac{\alpha z}{kT} \qquad [14]$$

Thus it is possible to obtain either unit or fractional orders in this case depending on whether the added constituent affects the barrier at equilibrium or not. It must be emphasized that the added constituent cannot affect any of the other activities; otherwise Eq. [12] and [13] are not valid.

It is therefore possible for the models proposed here to account for the fractional orders and low values of αz without resorting to unusual adsorption isotherms. Furthermore, the postulate of two barriers seems quite reasonable on film-covered electrodes of this type. There is not enough experimental evidence, however, to say fairly conclusively that these models are valid, or further to give explicit mechanisms for the reduction of the various oxidizing agents. The primary purpose of the presentation was to show that it is possible to obtain these effects from the two-barrier model.

It should be pointed out that two of the effects that do not seem to conform to Case I can be explained by assuming that Case II applies at low current densities. Thus, the fact that unit order is observed with oxygen reduction at low current densities can be explained by assuming that oxygen is adsorbed at the interface and that the rate-determining step is the transfer of electrons through the film barrier to the O_2 at the surface with the ultimate formation of a negatively charged oxygen-containing species, perhaps OH^-. Charge transfer through the surface is effected by a slight perturbation of the equilibrium OH^- (ads.) + $H_3O^+ \rightleftarrows 2H_2O$. The amount of OH^- adsorbed would probably be relatively constant since most of the oxide ions exposed to solution would probably react to form OH^-. At high current densities this equilibrium would be polarized and Case I would apply. This equilibrium also agrees with the observed pH dependence.

Similarly the change of the Tafel slope of Cu^{++} reduction may indicate a change from Case I to Case II with the difference that Cu^{++} (aq.) may not be adsorbed but may affect only the outer barrier. In both of these cases there is not enough experimental evidence to propose specific mechanisms.

The precise mechanism of charge transfer through the film is open to speculation since little is known concerning the structure and semiconducting properties of these films. For the reasons described above, cracks or pores were rejected as a mechanism for charge transfer. Tunnel effect should be extremely dependent on thickness and its effects are probably slight for the stable films present after a day's exposure to O_2. The data on H_2 evolution, however, show large changes in current at constant potential. It is suggested, therefore, that the initial

film present on the samples used in the H_2 overvoltage work is relatively transparent to electrons because of the tunnel effect. The growth of the oxide on the surface then causes a sharp reduction in the rate of tunneling.

In order for electrons to be transferred through the stable films formed by anodizing or exposure to O_2, electrons must *surmount* the barrier imposed by the field in the film. This of course results in very low rates at room temperature and even at 88°C the electrodes will reach rates of about 10^{-9} amp/cm^2 at open circuit after several days. The important parameter here is therefore the height of the potential energy barrier and the rate of transfer should therefore not be so sensitive to changes in thickness. To a good approximation therefore, the rate of transfer will be given by $i = K \exp - eV/kT$ where eV represents the height of the potential energy barrier.

Crystallographic Data on Beta-$Sr_2P_2O_7$

C. W. W. Hoffman and R. W. Mooney

Chemical and Metallurgical Division, Sylvania Electric Products Inc., Towanda, Pennsylvania

The tin-activated alkaline-earth pyrophosphates have been studied by three groups of workers (1-3) with the discovery of several phosphors. Calcium, strontium, and barium pyrophosphate occur in polymorphic modifications and Ranby and co-workers (1) showed that α-modifications were orthorhombic and probably isomorphous. It was also suggested that β-$Ca_2P_2O_7$ and β-$Sr_2P_2O_7$ were probably isomorphous although no crystallographic data were given. Recent work (3) has shown that there is a relationship between the emission and perhaps the excitation spectra of the three tin-activated α-modifications as well as a marked similarity between the excitation and emission spectra of β-$Ca_2P_2O_7$:Sn and β-$Sr_2P_2O_7$:Sn.

In a recent publication, Corbridge (4) working with single crystals of β-$Ca_2P_2O_7$ showed that it was tetrahedral with space group $P4_1$, and cell dimensions: a = 6.66Å and c = 23.86Å. Assuming a similar tetrahedral unit cell for β-$Sr_2P_2O_7$, it turned out to be a straightforward task to index its Debye-Scherrer pattern resulting in a = 6.920Å and c = 24.79Å. Table I lists the observed intensities and the slightly refined d-spacings, (omitting a very weak line at d = 3.30 which has been found to be in error), from a recent publication (5). It is evident that the calculated d-spacings based on the proposed unit cell account very well for the pattern.

The sample of β-$Sr_2P_2O_7$ had been prepared by heating $SrHPO_4$ for several hours at 650°C giving a material whose analysis agreed generally with the theoretical composition of $Sr_2P_2O_7$ (5). Assuming, as

with β-$Ca_2P_2O_7$, 8 $Sr_2P_2O_7$ groups per unit cell a theoretical density of 3.91 g/cm^3 results, in good agreement with the experimental value of 3.86 g/cm^3 (5). In view of the marked similarities between the β-$Ca_2P_2O_7$ and β-$Sr_2P_2O_7$ powder patterns, it is likely that the compounds have the same space group, namely $P4_1$, although single crystal work would be required to definitely establish the space group of β-$Sr_2P_2O_7$.

Acknowledgment

The authors are indebted to Mr. R. C. Ropp for the preparations of several β-$Sr_2P_2O_7$ samples.

Manuscript received May 18, 1960.

Technical Review

The Structure and Relaxation of Dielectrics

Charles P. Smyth

Frick Chemical Laboratory, Princeton University, Princeton, New Jersey

It is the aim of this paper to examine the reasons for the behavior of simple dielectric materials at high frequencies, in particular, in relation to their structures. It is a well-known fact that the dielectric constant and loss of a simple dielectric material depends on its polarizability. For molecular materials, nonpolar molecules give low dielectric constant and zero loss, and molecules with permanent dipole moments give dielectric constants to liquids which are larger, the larger their moments, and the greater their number per unit volume. The loss, which normally occurs only in a certain frequency region, depends on the same quantities, as well as on the frequency. In the region of loss, the dielectric constant falls off rapidly with increasing frequency. This behavior has been described and explained by the familiar Debye theory (1).

In order that these simple relationships may hold, the molecules must have freedom to orient in the alternating electric field used to measure the dielectric constant and loss. It is for this reason that most molecular solids have low dielectric constants and zero losses. However, many crystalline solids composed of symmetrical molecules have been found (2) to behave much like liquids for some distance below the melting point in a so-called "rotator state," and the orientational freedom of the polar segments of large molecules and polymers may result in similar behavior.

The static or low-frequency dielectric constant is observed when the dielectric material is in equilibrium with the applied field. Under the influence of the field, the polar molecules or segments rotate toward an equilibrium distribution of molecular orientation with a resultant polarization of the dielectric. When the polar molecules are very large, or the viscosity of the material is very great, or the frequency of the alternating field is very high, the rotary motion of the molecules is not sufficiently rapid for the attainment of equilibrium with the field. The displacement current then acquires a conductance component in phase with the field, and dielectric loss occurs. The lag in the attainment of the equilibrium is termed dielectric relaxation, which may be defined as the exponential decay with time of the polarization when the applied field is removed. The phenomenon may be treated in terms of a relaxation time, defined as the time in which polarization is reduced to $1/e$ times its value at the instant the field was removed, e being the natural logarithmic base. This definition leads to the relationship that the relaxation time is the reciprocal of the critical angular frequency at which the loss is a maximum. The lag of the molecular dipoles behind the field increases with increasing frequency until the dielectric constant has decreased to a value which receives no contribution from dipole orientation.

The formal relationships between dielectric constant, loss, relaxation time, and frequency of field are largely independent of the mechanism of relaxation. The dielectric relaxation time is obtained by various methods from the measured values of dielectric constant and loss (1). If the dielectric is a dilute solution of polar molecules in a nonpolar solvent, the macroscopic relaxation time thus obtained may be regarded as the molecular relaxation time. If, however, each polar molecule is surrounded immediately by other polar molecules, the change in local internal field caused by the turning of one molecule requires the neighboring molecules to assume new orientations, with consequent longer relaxation time for the dielectric as a whole, the

macroscopic relaxation time. No generally satisfactory relationship between the two relaxation times has as yet been obtained, but an approximate relationship derived independently by O'Dwyer and Sack (3) and by Powles (4) requires the ratio of the macroscopic to the molecular relaxation time to lie between 1 and 1.5. Experiment has shown (5) that the ratio lies within this range for a large number of molecules, while an extension of the range to 0.9-2.0 would include most of the molecules which have been examined. For approximate consideration of the magnitudes of the relaxation times, the difference between the macroscopic and the molecular values can evidently be neglected in most cases, but, in detailed consideration of structural effects, account should be taken as far as possible of the difference. In his early treatment (1) Debye derived a much used and abused equation for the relaxation time τ on the assumption that the orienting dipole was in a spherical molecule of radius a moving in a continuous viscous fluid of internal friction coefficient η:

$$\tau = \frac{4\pi\eta a^3}{kT}$$

where k is the gas constant per molecule and T is the absolute temperature.

When, in early work, several observed values of the relaxation time and the macroscopic viscosity were substituted in this equation, molecular radius values of the right order of magnitude were obtained, the apparent agreement being facilitated by the cube root relationship involved. The development of the equation by Perrin (6) and others in more elaborate form to make it applicable to ellipsoidal molecules gave good agreement with measurements on aqueous solutions of proteins (7). It is to be noted that, in these solutions, the solvent molecules are so small in comparison with the solute as to give an approximation to the continuous viscous fluid assumed by Debye. The full significance of these results for protein solutions is, however, uncertain because it has been shown (8) that proton fluctuations, rather than molecular orientation may be at least partially responsible for the observed behavior (7). When the relaxation times of small, nearly spherical molecules of known radius were measured and used to calculate the coefficient of internal friction or microscopic viscosity, the values found for the latter were only 0.008-0.06 of the macroscopic viscosity, and little parallelism was observed between the internal friction coefficient and the macroscopic viscosity (9). The extreme departure from predicted behavior was observed for t-butyl chloride and dibromodichloroethane in the "rotator" crystalline state, in which the apparent coefficient of internal friction was lower than that of the substance in the liquid state (10). In these cases, the orienting polar molecules are surrounded by molecules of the same or nearly the same size and not by the continuous fluid postulated by Debye.

This behavior may be further illustrated by some recent measurements and calculations (11) on solutions of several polar molecules, which, for the present purpose, may be regarded as rigid. The relaxation times were calculated from the molecular dimensions and the macroscopic viscosity by Fischer's (12) modification of the Perrin equation (6). The calculated value for t-butyl chloride in heptane solution is 25 times the observed at 20°, while, for the solution in Nujol, which has a macroscopic viscosity 257 times that of heptane, the calculated value is 3870 times the observed. For the slightly larger camphor molecule, the ratio is 10.5 in heptane and 2110 in Nujol solution while, for the large and somewhat flat molecule of 1-chloronaphthalene the ratio is 4.4 in heptane and 188 in Nujol solution. The macroscopic viscosity is almost without significance when the polar molecule is spherical and can rotate without displacement of its neighbors, but increase in molecular asymmetry and size increases the extent to which the polar molecule must displace its neighbors in order to rotate and so increases the dependence on viscosity. The long molecule of 4-bromobiphenyl, which has the dipole in its long axis, has a relaxation time in Nujol solution so long that, when measured at a wave length of 1.2 cm, the loss is very small and the dielectric constant is close to the optical dielectric constant, which receives no contributions from the permanent molecular moment. For the Nujol solutions of this molecule, the calculated relaxation time is 19.5 times the observed while, for those in heptane, the ratio is down to 2.1. For all these solutions, the departure of the calculated from the observed relaxation times is less wide, the lower the viscosity and the higher the temperature, which causes the viscosity to be lower. These results indicate that the larger the solute molecules and the smaller the solvent, the better the agreement between the calculated and the observed relaxation times.

Meakins (13) has recently concluded from a number of measurements that, when the polar solute molecule is at least three times as large as the solvent molecule, the solutions give good agreement with the unmodified Debye theory. Measurements (14) on benzene solutions of a large disk-shaped porphyrazine molecule having about 10 times the volume of the solute molecule give fair agreement with the unmodified Debye theory, but a shift of the molecular dipole from the plane of the disk to a direction perpendicular to it increases the relaxation time to 2.5 times the value, an increase not predicted by the unmodified Debye relation. It appears, therefore, that the relaxation times of molecules at least three times as large as the molecules surrounding them may be roughly proportional to the macroscopic viscosity, but dipole direction within the molecule and molecular shape must be taken into account (5, 14). The use of mutual viscosity instead of macroscopic viscosity gives much worse agreement for these solutions of large molecules, although it has been found to lessen the discrepancies between theoretical and observed behavior for some solutions of smaller molecules (15).

Although dielectric loss is proportional to the square of the permanent dipole moment of the

molecule (1), the dipole moment does not occur in the simple Debye equation for the relaxation time. However, the dipole moment affects the relaxation time indirectly through its effect on the intermolecular forces which influence the viscosity. Atomic and molecular polarizability exert somewhat similar effects upon the viscosity and, hence, upon the relaxation time. The Debye equation requires proportionality of the relaxation time to the molecular volume, and a very rough proportionality has been observed (16). The actual effect of change in molecular volume may be large because of its effect on viscosity, in addition to its direct effect on the relaxation time. In spite of the extreme departures of relaxation times of solutions from proportionality to viscosity which have been pointed out, a very definite tendency of the relaxation times of pure liquids to increase with viscosity has been observed (17, 18), so much so that it is frequent practice in comparing relaxation times to use a so-called reduced relaxation time, τ/η, the ratio of the relaxation time to the viscosity.

The specific effects of molecular structure and shape may be illustrated by examples (18). As shown by the Stuart-Briegleb atomic models, fluorobenzene and pyridine depart only a little from the form of the symmetrical benzene molecule, fluorobenzene showing a slight protusion at the fluorine atom and pyridine a slight indentation at the nitrogen atom. The relaxation times of these molecules are nearly the same, although the measured viscosity of pyridine is 47% larger than that of fluorobenzene. Attachment of a methyl group to benzene lowers the viscosity slightly from 0.65 to 0.59 centipoise, while a similar substitution in the 4-position of pyridine lowers the viscosity still less. The protrusion of the methyl group raises the molecular relaxation time of 4-methylpyridine 83% above that of pyridine. It is higher than that of the similarly shaped toluene molecule by 56%, as compared to a difference of 59% in the viscosities. The substitution of methyl groups on the pyridine molecule in the 2- and 6- and in the 2-, 4-, and 6-positions alters the viscosity only slightly but raises the relaxation time greatly, so that 2,4,6-trimethylpyridine has a molecular relaxation time about 6 times that of pyridine. Substitution on the side chain of the toluene molecule raises the viscosity by 15% and doubles the relaxation time, but substitution of a second methyl group in the ortho position of toluene raises the viscosity by 37% and the relaxation time by 59%. The viscosity of *i*-propylbenzene is 16% higher than that of ethylbenzene, while the relaxation time is 42% higher.

In the monohalogenated benzenes, increasing size of the halogen and consequent increase in its polarizability and in the intermolecular forces increase both the viscosity and the molecular relaxation time. Benzonitrile and nitrobenzene, when compared to the monohalogenated benzenes, show somewhat longer relaxation times than would be expected on the basis of their viscosities and molecular volumes. Their larger dipole moments, 4.39 x 10^{-18} for benzonitrile and 4.21 x 10^{-18} for nitrobenzene, may account for this through increased intermolecular action not adequately taken into account in the calculation of the molecular relaxation time. In dilute solution in benzene, relaxation times (10^{-11} sec.) have been found as follows: chlorobenzene, 0.75; bromobenzene, 1.02; nitrobenzene, 1.15. The comparatively small differences between these values and between them and the value for toluene show the importance of the liquid viscosities and the dipole-dipole interactions in causing the much larger differences between the pure liquids which are observed (19).

It is natural to expect that a nonspherical molecule should have different relaxation times around different axes of rotation. Perrin (6) has calculated that, for an ellipsoidal molecule with its permanent moment along one axis, the dispersion is the same as if the molecule were spherical, although the value of the relaxation time is different, while, for an elongated ellipsoid of revolution having a moment perpendicular to the axis of revolution, the single relaxation time is almost the same as that for a sphere of the same volume. If, however, the permanent moment does not lie in an axis of symmetry, more than one relaxation time results. The loss peaks associated with the different relaxation times are normally so close together that a single somewhat broadened and flattened loss maximum is observed. It has been common practice to represent the dependence of the dielectric loss on the frequency by an equation giving a distribution of relaxation times around a most probable value (1). In the equation of Cole (20) and Cole the extent of the distribution is represented by an empirical constant, which is 0 when there is but a single relaxation time and 1 when the number of different relaxation times approaches infinity. For nearly spherical molecules, the constant is zero or close to it. Variation in the environment of the polar molecules may result in some distribution of relaxation times. However, in the mixed solvent, Nujol, the roughly ellipsoidal molecule of 4-bromobiphenyl shows (11) but one relaxation time, in conformity with the Perrin theory, which is frequently not obeyed so well.

It is usually impossible to distinguish experimentally between the different distribution functions. The dielectric losses of the pure alkyl bromides were satisfactorily analyzed in terms of a Cole-Cole distribution (20) of relaxation times around a most probable value for each liquid (21). Recently, however, Professor K. Higasi in the writer's laboratory has carried out an analysis in terms of a distribution of relaxation times between two limiting values (22), one corresponding to the rotation of the terminal CH_2Br group around its C-C bond and the other to the end-over-end rotation of the entire molecule in its extended form. The intermediate relaxation times correspond to orientation by twisting of segments around the other C-C bonds of the molecular chain. This method of analysis is an equally good representation of the experimental results and, for these molecules, is much more logical from the point of view of struc-

ture than the Cole-Cole distribution. Dipole orientation in polymers may occur by mechanisms resembling those just discussed for the alkyl bromides, but the much greater sizes of the molecules provide a greater variety of possible segmental orientation with consequent distribution of relaxation times, so that the loss-frequency curves commonly extend over very wide frequency ranges and have extremely flat maxima.

The presence of movable polar groups, such as CH_3O, CH_2Cl, and NH_2 in otherwise rigid molecules provides a possibility of dipole orientation by a single intramolecular rotation as well as by molecular rotation. The relaxation times observed for such substances are normally the result of two overlapping absorption regions, which can be clearly distinguished only by measurements at several frequencies extending into the region of millimeter waves. Measurements at 3 mm have been combined with those at longer wave lengths to show the existence of only one dielectric absorption region for rigid polar molecules, such as methylquinolines, while alcohols show additional absorption regions (23). Water shows but a single value of the relaxation time in this region with no distribution, but the high value, 6.0, of the apparent optical dielectric constant proves the presence of further considerable absorption at shorter wave-lengths, a conclusion at least qualitatively consistent with the infrared absorption spectrum.

From the practical point of view, it is evident that the dielectric loss of a material, like the dielectric constant, is greater, the greater the number of polar molecules per unit volume and the larger their polarities, provided that the molecules are free to orient in an applied electric field. The frequency region within which the loss is considerable lies within a hundredfold range of frequency or two logarithmic decades when the material has a single relaxation time. When there is a distribution of relaxation times, the frequency region of loss is extended and the maximum loss is lowered. The location of the region of loss is moved to higher frequency, the higher the temperature, the smaller the molecules, and the lower the resistance to molecular or polar group rotation. For large molecules surrounded by small, the measured macroscopic viscosity may give a fair measure of this resistance to orientation, but, for small molecules, the resistance is much lower than indicated by the viscosity, which, in such cases, frequently has little significance. Loss then occurs at higher frequencies than those predicted from the viscosity.

June 1961 Discussion Section

A Discussion Section, covering papers published in the July–December 1960 JOURNALS, is scheduled for publication in the June 1961 issue. Any discussion which did not reach the Editor in time for inclusion in the December 1960 Discussion Section will be included in the June 1961 issue.

Those who plan to contribute remarks for this Discussion Section should submit their comments or questions in triplicate to the Managing Editor of the JOURNAL, 1860 Broadway, New York 23, N. Y., *not later than March 1, 1960.* All discussion will be forwarded to the author(s) for reply before being printed in the JOURNAL.

The Cathodic Behavior of AgO in Alkaline Solutions

Thedford P. Dirkse

Calvin College, Grand Rapids, Michigan

ABSTRACT

A study has been made of the discharge of AgO to determine why only a part of the discharge capacity of AgO is delivered at the potential of the AgO-Ag_2O couple and to determine the role of oxygen in this process. The difference in discharge capacity of electrodes produced by constant-current and by constant-potential anodization also has been studied. A mechanism involving the transport of $O^=$ ions through the electrode material and the reaction of these ions with the electrolyte is presented.

When a fully charged silver-zinc battery is discharged, the voltage-time curve usually has two levels (Fig. 1). The higher of these is generally attributed to the presence of AgO in the silver electrode. However, the processes occurring when AgO is discharged are not well understood. The capacity delivered at this higher level on discharge is usually but a fraction of that theoretically available. Furthermore, this capacity appears to depend on a variety of circumstances, some of which are unknown. In recent years several facts have been brought to light in connection with this capacity. A good deal of the capacity available as AgO on the electrode is delivered at a voltage level corresponding to that of Ag_2O (1, 2). The exact amount delivered at this lower voltage level depends on the current density. It also has been shown that the capacity of AgO delivered at this higher voltage level decreases on stand with no loss in total capacity (3). Recently, Wales and Burbank (4) have shown that during certain periods of discharge the reduction of AgO to Ag_2O and that of Ag_2O to Ag likely proceed simultaneously. Their results fail to give any evidence for the presence of solid solutions of AgO in Ag_2O on discharge.

A second problem associated with the cathodic behavior of AgO arises from the fact that oxygen can be added to AgO without changing the emf of the substance (5). This added oxygen does not alter the x-ray diffraction pattern of AgO except to make it more diffuse.

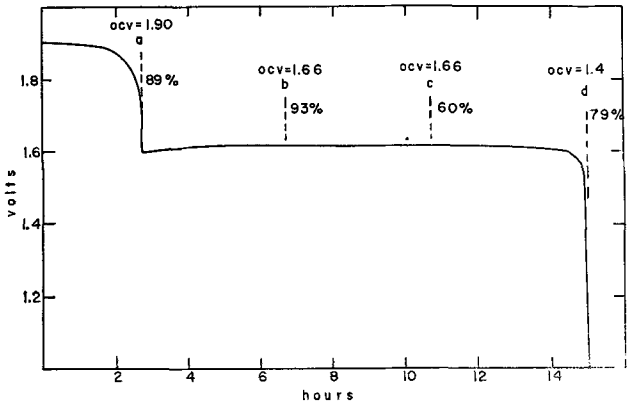

Fig. 1. Voltage-time curve for the discharge of an AgO-Zn-40% KOH cell at room temperature. Percentages are discharge efficiencies.

The present work was carried out to obtain more information on the cathodic behavior of AgO and to investigate more thoroughly the role of oxygen in this process.

Experimental and Discussion

The experimental techniques used in this work were the same as those described earlier (5). When electrodes were to be weighed they were first soaked in distilled water for at least 8 hr, then dried in a stream of purified nitrogen at room temperature, and finally placed in a desiccator for at least 24 hr. All these operations were carried out in the absence of light. After this, the electrodes were weighed and the change in weight was considered to be due to changes in oxygen content. Where possible the electrode was finally reduced to Ag and weighed. The weight of Ag at this time agreed, within experimental error, with the weight at the beginning of the charging process.

Oxygen content.—In the work reported earlier (5) it was shown that when silver is treated anodically in KOH solutions the addition of oxygen to form Ag_2O and AgO follows Faraday's laws. When the gassing potential is reached some oxygen is still added to the electrode. This was determined by weighing the electrode before and after such gassing treatment. At constant-current charging the oxygen added during gassing often corresponded to about 10% of the current passed. Apparent current densities of 0.25 to 2.5 ma/cm^2 were used, yet there was no stoichiometric evidence for complete transformation of all the Ag to AgO even though these electrodes were allowed to remain at the gassing potential for periods of up to 10 hr.

With constant-potential charging, oxygen also can be added to the silver electrode even when the potential is kept below that needed for gassing. Products having oxygen contents corresponding to $AgO_{1.5}$ have been prepared in this manner.

The question then arises whether the oxygen added to the electrode during gassing on constant-current charging or during prolonged constant-potential charging at a potential about 100 mv

below the gassing potential contributes to the discharge capacity of the electrode.

To check this, a commercially prepared sintered Ag electrode, 1.5 x 3.8 cm, weighing 2.4 g, was charged at 0.1 amp in 40% KOH. Its capacity was determined by charging up to the gassing potential and then allowing it to stand 20 hr before being discharged. The discharge capacity exactly equaled the charge input (0.68 amp-hr). The electrode then was given a series of cycles in which it was charged at the same rate and allowed to remain at the gassing potential for 8 to 15 hr. It was discharged immediately after each of these charges, and the discharge capacity was only 3% larger than the previous charge input up to the gassing potential. Thus while prolonged gassing on constant-current charge does add oxygen to the electrode as noted above, this oxygen contributes very little to the discharge capacity. In all these instances, however, there was no complete conversion to AgO. Since this electrode accepted 0.68 amp-hr of charge, its composition when charged corresponded to about $AgO_{0.5}$. Since there definitely was AgO present, as determined by x-ray diffraction and by observation of the discharge voltage-time curve, free silver also was present.

Wales and Burbank (4) observed that prolonged gassing on constant-current charge appeared to produce more perfectly crystalline AgO. This suggests that when the electrode reaches the gassing potential on charge the surface has not been completely converted to crystalline AgO. During gassing more oxygen is added to the surface, forming more completely crystalline AgO. Perhaps it is this oxygen that gives the small increase in discharge capacity which is obtained on prolonged gassing.

This oxygen, however, is not the only oxygen added during the gassing period. The weight gained during gassing is larger than that corresponding to the extra discharge capacity. Earlier work (6) has shown that, when an electrode is charged at constant-current and is allowed to charge at the gassing potential for several hours or more, appreciable amounts of oxygen can be added. This oxygen is held firmly by the electrode material, but it does not add correspondingly to the discharge capacity. Moreover, this oxygen is released on discharge. For example, a sintered Ag electrode, 3.8 cm square and weighing 6.2 g, was charged at a constant-current of 0.04 amp in 15% KOH for 3 days. It was then soaked in distilled water and dried overnight in an oven at 60°C. The weight gain corresponded to a product having the composition $AgO_{0.8}$. This electrode was stored dry in the dark for 2 years and then charged again, this time at 0.7 amp in 40% KOH for 24 hr. It was gassing profusely during the latter part of the charge. When it was soaked in distilled water much gas was evolved. It was then dried for 24 hr at 60°C. There was a slight gain in weight, corresponding to less than 1% of the charge applied. After 3½ weeks the electrode was discharged at 0.1 amp in 42% KOH. After 10 hr the voltage *vs.* Zn fell below 1 v and the discharge was terminated even though there was still visible evidence of oxides on the plate. The electrode again was soaked in distilled water and dried for a day at 60°C. The loss in weight was 0.57 g. Assuming that this loss was due to oxygen, this corresponds to 1.9 amp-hr. Yet only 1 amp-hr had been removed during the discharge. Apparently, about 0.27 g oxygen escaped as bubbles during the discharging process, but no attempt was made to observe this.

Changes do occur if the electrode is stored for some time. Several electrodes similar to the one just described were charged at constant-current and were stored dry for 1 to 2 years. None of them was completely converted to AgO, and none lost weight during this storage. With some, the open-circuit voltage (ocv) after storage was that associated with Ag_2O. Others, however, gave an ocv associated with AgO. Thus, this dry storage does not necessarily lead to complete conversion of AgO to Ag_2O (reaction [1]).

$$AgO + Ag \rightarrow Ag_2O \qquad [1]$$

This reaction does take place when electrodes are stored in electrolyte or even in water. Figure 2 is a picture of electrodes which had been partially discharged. The white portions are Ag whereas the darker portions are oxides of silver. One such electrode was placed in electrolyte, and after about 3 weeks all the Ag had been oxidized to Ag_2O. In such a situation, Eq. [1] represents the net effect of a local cell reaction consisting of a AgO cathode and a Ag anode. This reaction may take place rapidly at first, but as Ag_2O is produced the internal resistance of the local cell is increased and the reaction slows down.

These electrodes did not deliver their total available capacity after storage. After discharge, such

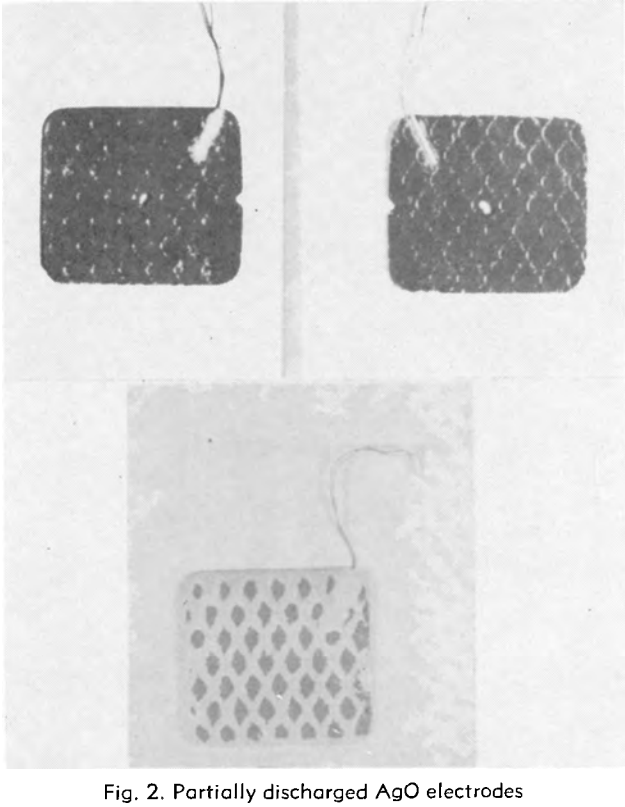

Fig. 2. Partially discharged AgO electrodes

an electrode was heavier than it was before being charged, indicating that discharge had not removed all the oxygen from the electrode material. With one charged electrode, 25% of the theoretical discharge capacity (calculated from oxygen content) was unavailable after storage. This phenomenon has been noted with other electrodes also.

An attempt was made to follow this change during storage by x-ray analysis. Freshly charged electrodes gave good sharp patterns for AgO. In some electrodes there were also areas giving good Ag_2O patterns. After dry storage for 1.5 years the electrodes still gave the AgO pattern, but it was weak and the lines were broader. This indicates a deterioration of the crystallinity of the oxide structure and is likely due to diffusion of oxygen ions to areas of lower oxygen content. There was no loss of oxygen. This diffusion during storage apparently also affects the current path through the electrode, and this may be responsible for the reduction in capacity. The current path is altered, as will be noted later, so that some of the oxygen in the interior of the electrode cannot escape from the silver lattice.

With constant-potential charging (at potentials slightly below the gassing potential) large amounts of oxygen can be introduced into the silver lattice. This oxygen may exceed the stoichiometric ratio of AgO, and yet many of the physical properties are the same as those of AgO (5). It has been suggested that at least part of this oxygen is physically adsorbed rather than chemically bound. This idea is consistent with the following results.

A small electrode was charged in 30% KOH at a constant potential of 350-400 mv above the reversible potential of Ag-Ag_2O. After charge its composition was $AgO_{0.47}$. After standing one week it was discharged in 42% KOH at about 1 ma/cm^2. At intervals the discharge was interrupted, the electrode was dried, weighed, and x-rayed. Then it was inserted in the cell and the discharge continued. The x-ray patterns showed the same variations as have been reported earlier (4). Discharge results are given on Fig. 1. The electrode was weighed at points a, b, c, and d. The loss in weight was considered to be due to a loss of oxygen. This was justifiable since the weight of the silver on the electrode at the end of the discharge was within 0.3% of that on the electrode at the beginning of the experiment. The theoretical weight loss was calculated from the ampere-hours of discharge. This value divided by the actual weight loss was called the discharge efficiency. The discharge efficiency at point a on Fig. 1 refers to the interval from the beginning of discharge to point a, that at point b refers to the interval between a and b, etc. Perhaps as the electrode discharges, adsorbed oxygen escapes in a mechanical fashion from the lattice. On the basis of the efficiencies, this is more easily accomplished toward the end of the discharge.

Three other electrodes were prepared on platinum grids. They were made by pasting the grid with moist Ag_2O, air drying, and thermally reducing them at 550°C to Ag. Then they were subjected to constant-potential charging until they had an oxygen content greater than AgO. Two of them (A and B) were stored dry for 3 months at room temperature and the third was stored dry for 1.5 years after 4 months' storage in the dark in 30% KOH. None of these electrodes lost any appreciable weight over this period of time. This shows that the extra oxygen is bound rather firmly to the silver. Their emf values and x-ray diffraction patterns were those of AgO. There was nothing to indicate a new type of oxide, *e.g.*, Ag_2O_3.

Electrodes A and B were discharged at a very low current density in 28% KOH. Typical discharge curves were obtained, although relatively little discharge capacity (2% and 15% of the total) was obtained at the higher voltage level. Electrode C was discharged in 40% KOH at an 11 hr rate. No discharge capacity was obtained at the voltage level corresponding to AgO. The ocv, however, was 1.9 v *vs.* Zn.

The fact that so little discharge capacity was obtained at the higher level in each case may at first seem to be normal. These electrodes stood for some time before being discharged, and it has been shown that standing reduces the amount of capacity delivered at the high voltage level but does not reduce the total discharge capacity (3). This has been attributed to the fact that on stand reaction [1] takes place (4). If this is the case, there must have been more than a trace of unoxidized silver present in the charged electrodes. It follows then that constant-potential charging does not bring about complete conversion to AgO even though the composition of the material can be represented by $AgO_{1.5}$. It can be argued that reaction [2] takes place at the platinum

$$2AgO \rightarrow Ag_2O + 1/2\ O_2 \qquad [2]$$

grid and that the formation of the Ag_2O increases the internal resistance of the electrode so that the discharge voltage is polarized to the Ag_2O-Ag level. This reaction then would take place in the dry state since these electrodes were stored dry. Ohse (7) noted a lack of evidence for this reaction in 1N KOH.

A comparison was made of the capacity obtained to that theoretically available. The theoretical capacity was calculated on the basis of both silver and oxygen content. Results are given in Table I.

It is obvious that all the oxygen present in these electrodes was not useful for discharge purposes. This also follows from the fact that with electrode C, *e.g.*, the loss in weight of oxygen during discharge was 130% of that corresponding to the actual capacity obtained. Some of this oxygen was apparently released from the electrode during dis-

Table I. Capacity of "AgO" electrodes

Electrode	Composition	% Theoretical capacity on basis of		
		O_2	Ag^{++}	Ag^{+++}
A	$AgO_{1.6}$	56	91	60
B	$AgO_{1.5}$	55	85	57
C	$AgO_{1.2}$	23	27	18

charge without entering into the discharge reaction. The small value for per cent theoretical capacity is due to the prolonged storage of this electrode, as noted earlier in this paper. Since electrode C had a 4 month wet stand it is very possible that reaction [1] proceeded to a significant extent. This could build up sufficient Ag_2O to increase the internal resistance of the electrode, alter the current path within it, and thus bypass some of the oxide during the discharge reaction.

If one assumes that the silver present in the electrode was all in the divalent state, then the actual discharge capacity still is less than theoretical. At the current densities used one would expect practically 100% discharge/charge efficiency. The fact that the actual discharge capacity is less than theoretical supports the idea that some unoxidized silver was present in the charged electrodes. It also makes unnecessary the suggestion that trivalent silver is present in the electrodes. These results support the idea that divalent silver is the highest oxidation state of silver in the charged electrodes. Furthermore, even prolonged constant-potential charging fails to convert all the silver to the divalent state.

It follows from these results that the oxygen content of the electrodes charged by the constant-potential method is no measure of the oxidation state of the silver. This method of charging may be rather inefficient. Although the weight of oxygen added to the electrode follows Faraday's laws (5), the discharge of such an electrode does not necessarily give a capacity equal to the oxygen content. This oxygen is strongly held and not readily released from the dry solid at room temperature. On discharge it appears to be released as the positive charge on the silver atoms (ions) is decreased. It may be forced out of the electrode as the lattice changes from AgO to Ag_2O. As this reduction takes place the silver ions move closer together leaving less room for occluded oxygen. Furthermore, the reduced charge on silver ions decreases the power to attract or adsorb oxygen atoms.

With constant-current cycling the discharge capacity generally equals the charge input up to the gassing potential (8). The weight of oxygen added during charge at moderate rates follows Faraday's laws (5). Prolonged gassing does result in the addition of oxygen and a small increase in discharge capacity. This indicates that the oxygen added during normal charging is a good measure of the state of oxidation of silver. With prolonged gassing, however, much of the oxygen added appears to be merely physically adsorbed.

Polarization.—One of the questions in connection with the discharge of AgO is the extent of polarization. Less than half the discharge capacity of an electrode usually is delivered at the higher voltage level. This raises the possibility that the AgO→Ag_2O process is polarized to such an extent that it operates at the lower potential of Ag_2O→Ag.

The extent of this polarization was studied by an interrupter method (9). Electrodes in which the surface is almost completely AgO showed very little polarization in the initial stages of discharge. A rapid increase in polarization was noted as the AgO was converted to Ag_2O and this polarization at times was so great that it caused the discharge of AgO to take place at a potential below that of Ag_2O (9). After this the potential rose to that of the Ag_2O→Ag process. The point at which the voltage drops to that of the Ag_2O→Ag level seems then to be determined by the current density on the surface layer of AgO. When this exceeds a certain value the potential drops. This drop in potential also is influenced by the formation of increasing amounts of Ag_2O. This highly resistive material may bring about an *IR* drop in the electrode itself.

With small wire electrodes on which but thin films of oxide were produced, about 40% of the discharge was obtained at the higher voltage level over a modest range of current densities. Conceivably this fact can be used to indicate that the fall of potential from the higher to the lower level is determined more by the resistance of the Ag_2O formed than by the increase of current density on the AgO. Since only thin films of oxide are produced, the resistance of the Ag_2O is not as great as with thicker films. Under these conditions the fall in potential occurs at a later stage in the discharge. It also may be that a greater fraction of the AgO present is on the surface and therefore the higher voltage level on discharge lasts relatively longer.

In Fig. 2 the pattern of the silver spots is the same as that of the grid of the electrode, indicating the importance of the current path in the discharge process. Furthermore, this suggests that the electrical resistance is an important factor in this process.

This polarization also is due in part to the electrolyte. This was shown by varying the KOH concentrations. At an apparent current density of about 1 ma/cm^2 the polarization amounted to 3, 6, and 32 mv in 1*N*, 0.5*N*, and 1.0*N* KOH, respectively. These values are corrected for the *IR* drop in the solution.

Mechanisms.—In discussing possible mechanisms for the cathodic behavior of AgO one should know whether the discharge reaction proceeds from the grid to the electrode-electrolyte interface or in the opposite direction. The discharge reaction is the removal of $O^=$ ions from the electrode material. To determine where in the electrode this process begins, the silver oxides were pressed into pellets about 1.25 cm diameter and 0.65 cm thick. They were discharged in a cell shown on Fig. 3. Only a small

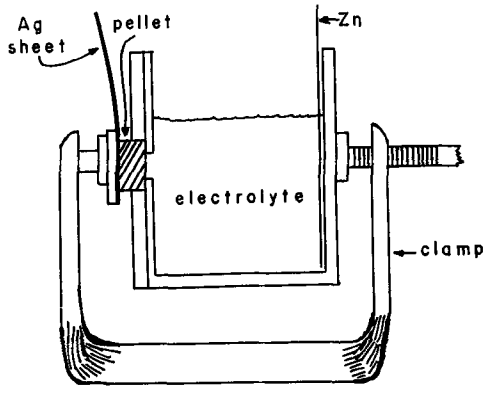

Fig. 3. Cell for use with pelletized electrodes

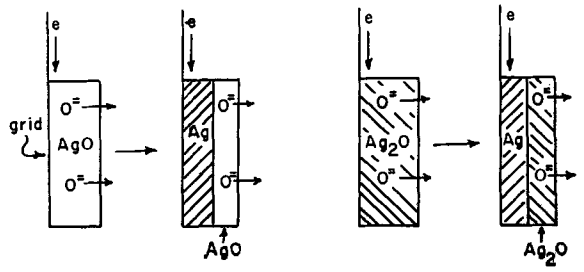

Fig. 4. Mechanism for the reduction of AgO

surface area was exposed to the electrolyte, and the grid (the Ag sheet) was completely outside the cell case. The electrolyte did seep into and penetrate the pellet.

Pellets of both Ag_2O and AgO were prepared and discharged at 35 ma/cm², considering only the surface area exposed to the bulk electrolyte. In either case the material was reduced to Ag during discharge and gave the capacity calculated from its weight, i.e., 231 ma-hr/g of Ag_2O and 432 ma-hr/g of AgO. When the material was discharged only long enough to deliver about half the discharge capacity of the material, it was found that with the Ag_2O pellet the reduced Ag was at the grid and not at the electrolyte. With the AgO pellet the same thing occurred. In fact, there was almost a plane surface that separated the Ag from the unreduced oxide. This plane was practically at the mid-point of the pellet. Furthermore, the unreduced oxide was AgO and not Ag_2O. This was determined by x-ray analysis, and it is possible that small amounts of Ag_2O were present. However, the bulk of the material was AgO. This suggests that on discharge the removal of $O^=$ ions proceeds from the grid toward the electrode-electrolyte interface (Fig. 4). Moreover, no large amounts of Ag_2O need be produced during the discharge of the AgO.

During the discharge of AgO small amounts of Ag_2O may be formed at the electrode-electrolyte interface as the $O^=$ ions are removed from the electrode by the electrolyte. X-ray evidence (4) indicates that this occurs, and the extent of this Ag_2O formation would depend on the current rate. This Ag_2O will be formed then because $O^=$ ions are removed from the surface at a faster rate than they are transported through the electrode material. The current path available is a significant factor since the $O^=$ ions begin to migrate from the areas where the current enters the electrode (Fig. 2).

Because the polarization of AgO is determined to some extent by the concentration of the KOH, it is apparent that some solvent or solute species are involved in this cathodic process. The species available are OH^-, K^+, and H_2O.

The cathodic process involves the removal of $O^=$ ions from the oxide. As the silver is reduced these ions are ejected from the electrode material. It is unlikely that the negatively charged OH^- ions would be responsible for this removal of the negatively charged oxygens. They would, no doubt, be repelled from the electrode.

It is possible that the free H_2O molecules are involved in this process. During discharge the H part of the molecule would be oriented toward the electrode and then the following process could occur

$$\begin{matrix} Ag = O & H \\ & \diagdown \\ & \quad O \\ & \diagup \\ Ag = O & H \end{matrix} + 2\,e \rightarrow Ag_2O + 2\,OH^- \qquad [3]$$

If this explanation is correct, then the cathodic polarization should increase with increase in KOH concentration. In a dilute solution more H_2O molecules would be available for reaction. However, as noted above, no such effect was observed.

Since, as indicated earlier, it is unlikely that the OH^- ions are involved, one is left with the K^+ ions as the reacting species. These ions are hydrated in solution, probably $K(H_2O)_4^+$ (10). Conceivably, these ions are drawn to the electrode with the H atoms oriented toward the electrode surface and then reaction [3] takes place. The charge on the K^+ ion aids in attracting the $O^=$ ions of the solid. It also weakens the O — H bonds in the H_2O. Thus the H_2O molecules bound to the K^+ ions are more reactive than the uncombined H_2O molecules. Attempts were made to determine the effect of substituting Na^+ ions for K^+ ions by using 0.1*N* NaOH solutions and also 7M solutions of $NaC_2H_3O_2$ and $KC_2H_3O_2$. However, any differences observed were within the limits of experimental error.

In summary, the cathodic reaction of AgO involves the removal of $O^=$ ions from the lattice by the H_2O molecules that are bound to the K^+ ions. This reaction occurs at the electrode-electrolyte interface. The amount of interfacial area is extensive because the KOH solution permeates the bulk AgO so thoroughly. As reaction proceeds, $O^=$ ions from the interior of the lattice migrate to this interface. Thus there are two factors responsible for the polarization of the AgO: (*a*) the reaction of $O^=$ ions with hydrated K^+ ions; and (*b*) the transport of $O^=$ ions through the electrode material. If the second process is not as fast as the first one, then the $O^=$ ion concentration at the electrode-electrolyte interface is reduced and the emf of the electrode decreases.

Relation of Electron Configuration to Passivity in Cr-Ni-Fe Alloys

H. G. Feller and H. H. Uhlig

Corrosion Laboratory, Department of Metallurgy

Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

Critical current densities for passivity were measured for single phase Cr-Ni-Fe alloys as a function of Cr content for 20%, 40%, 50% and 60% Ni compositions. Major discontinuities in slope approximate the ratio 12/88 for Cr to Fe in the 20 and 40% Ni alloy series, and 14/86 for Cr to Ni in the 50 and 60% Ni alloy series. These ratios correspond to observed critical compositions for passivity in the Cr-Fe and Cr-Ni binary systems. Additional discontinuities occur at the critical binary Cr to Fe ratio in the 50 and 60% Ni series. This behavior is interpreted in terms of separate electron interaction in the ternary system between Cr and Fe distinct from interaction between Cr and Ni. Flade or activation potentials become more active with increasing Cr content, corresponding to increased stability of passivity. In accord with greater stability, average time for breakdown of passivity increased exponentially with Cr content.

The austenitic Cr-Ni-Fe stainless steels are passive alloys of which the 18% Cr, 8% Ni, balance Fe alloy (18-8) is an important example. These alloys, including the ferritic and martensitic Cr-Fe stainless steels, must contain a minimum of 12% Cr in order to exhibit optimum passivity or corrosion resistance. This critical concentration of Cr has been related to the tendency of an "unfilled" *d* band (or uncoupled *d* orbitals) of Cr to fill (or become coupled) with electrons donated by Fe, a process which is assumed to be just complete at 12%. Larger amounts of alloyed Cr correspond to residual uncoupled electrons or vacancies in surface atoms of Cr accounting for an alloy best able to chemisorb its environment, e.g., $O_2 + H_2O$, and become passive in a manner similar to pure chromium. Below 12% Cr, the *d* orbitals of Cr are coupled and the alloy has chemical properties more nearly resembling Fe, i.e., it is not passive. Similar electron interaction occurs in other binary transition metal alloys, a summary of known relations having been presented recently by one of us (1).

Electron interaction in relation to passivity has also been described for the ternary Mo-Ni-Fe and quaternary Cr-Fe-Ni-Mo passive alloys (2). It was in the interest of exploring this matter further using relatively pure ternary alloys instead of commercial compositions that this investigation was initiated. The Cr-Fe-Ni system is ideally suited to such a study because the phase diagram shows (3) that the alloys at low temperatures (650°C), are solid solution, face-centered cubic, over a wide range of composition. Metallographic examination of several alloys prepared for the present investigation confirmed that they were single-phase.

Measurement of Passivity

Passive behavior of the alloys was evaluated by measuring critical anodic current densities to produce passivity. Data of this kind provide a better criterion of the relation between alloy composition and passivity than do corrosion rates, as was discussed previously by Bond and Uhlig (4). A discontinuity in slope of critical current density plotted with composition, or minima in values of current density are observed at a relatively specific alloy composition. This critical composition has been found to be insensitive to *p*H or temperature of environment in the case of the Cr-Fe alloys (5), or to *p*H in the case of the Cr-Ni alloys (4), whereas similar alloy compositions corresponding to discontinuities in slope or to minima in corrosion rates tend to shift with environment. The discontinuity in slope of critical current densities for the Cr-Fe alloys, for example, comes at 10-12% Cr. This is also the critical composition derived from corrosion rate measurements of these alloys in water or in the atmosphere, but in acids or alkalis, passivity occurs at lower or higher Cr percentages.

The electrochemical mechanism of passivation (6-8) makes it clear why this is so. It has been shown, for example, that stainless steels achieve passivity whenever the anodic current density accompanying corrosion reaches or exceeds the critical current density. The same relation is expected to hold for other passive alloys. But the cathodic

reaction rate varies with environment and shifts the corrosion rate accordingly, thereby inducing passivity at higher or lower alloy compositions depending on the actual rate and the value of the critical current density in a particular environment. The influence of the cathodic reaction is eliminated by relying instead on critical current densities as a measure of the ease or difficulty with which an alloy becomes passive. In addition, constant renewal of the alloy surface by anodic dissolution during measurements avoids compositional changes caused for example by redeposition of ions in solution.

The important consideration from the present standpoint is that discontinuities in the critical current density for passivity are observed as a function of Cr content in the Cr-Ni-Fe alloy system as for the Cr-Fe system. These discontinuities can be interpreted in terms of electronic interaction between components of the alloy, similar to interactions hypothesized previously for the binary Cr-Fe, Cr-Ni, and other alloy systems (1).

Preparation of Alloys, Experimental Procedure

Alloys were prepared from electrolytic Fe and Cr, and from carbonyl Ni, melted in vacuum (10^{-5} mm Hg) by induction in high-purity alumina crucibles. No deoxidizers were added. Casting was carried out in a helium atmosphere by drawing the melts into 7 mm Vycor tubes and quenching in water. The helium was purified by passage over titanium sponge at 800°C, then through a liquid N_2 cold trap. In general, a single series of alloys was prepared by withdrawing a portion of the initial composition melt and quenching, then adding additional calculated amounts of Ni and Fe for the next composition, melting, withdrawing a portion, etc. This procedure was repeated several times. Ingots were homogenized in silica tubes in a helium atmosphere at 1050°C for 20 to 50 hr. Chips were then machined for chemical analysis of Ni and Cr and the remaining alloy was lightly cold-swaged to approximately 5 mm diameter rods. The swaged rods were annealed at 1050°C for 30 min and air-cooled. Representative analyses of 16 alloys showed a carbon content of 0.01-0.02%, and 5 representative samples showed a nitrogen content of 0.007-0.008%.

Electrodes measuring 1 to 2 cm long by 3.4 mm diameter were machined from the annealed rods with a small diameter stem at one end to which a nickel wire was silver-soldered. The wire was enclosed by a Pyrex tube, with a Teflon gasket insuring that only the alloy specimen came into contact with the electrolyte. The surfaces were abraded, using successively finer emery paper to 3/0 grit. After degreasing with benzene, the electrode was inserted into the cell, the latter being arranged so that pickling and washing, and final introduction of electrolyte could be carried out without exposing the electrode surface to air. The pickle was either dilute HNO_3 in the case of low Cr alloys, or dilute H_2SO_4 in the case of high Cr alloys. Deaerated electrolyte and deaerated distilled water for washing were contained in 5-gal carboys connected to the cell by glass tubing. Deaeration was accomplished by bubbling through nitrogen, first purified by passing over copper turnings at 450°C. After pickling of the electrode, the cell was filled and emptied 3 times with water and twice with electrolyte. The electrode was finally pickled anodically for 10 min with electrolyte in the cell using about 1/20th to 1/10th the current density required for passivation. Measurement of critical current density followed immediately.

The cell was all-glass with sealed-in glass electrical connections, separated into two halves by a ground glass joint. It contained two Pt cathodes spaced equally on either side of the test electrode to insure uniform current density. The test electrode fitted into the cell by means of a ground-glass joint. The reference cell was Ag-AgCl in 0.1*N* KCl, connected to a salt bridge filled with H_2SO_4 the tip of which (asbestos fiber sealed in glass) was located near the electrode surface.

The electrolyte for all measurements was deaerated 1.28*N* H_2SO_4 whose *p*H was about 0.4. Measurements were carried out in a constant temperature room maintained at 25° ± 0.5°C.

Critical current densities were determined by measuring times to reach a steady passive potential for a series of current densities, each above the critical value. The reciprocal of these times $1/t$ were then plotted with current densities i in accord with the relation:

$$i - i\ (\text{Crit.}) = K/t$$

where K is a constant equal to the coulombs required for passivation and i (Crit.) is the critical current density for passivity below which passivity is not achieved no matter how long the time. Applied current was obtained from 30 dry cells operating through a high resistance so as to maintain a constant value. The current densities chosen were within a factor of 2 or 3 times the critical current density, over which range the above equation is known to hold.

Potentials were also measured in 1.28*N* H_2SO_4 at which passivity decays spontaneously to an active potential on shutting off the anodic current. These are called "activation" or Flade potentials. A typical decay curve for the 4.8% Cr, 20% Ni, balance Fe alloy, as recorded by a high-input-resistance recorder, is shown in Fig. 1. In general, decay curves were obtained by first polarizing the electrodes to the passive region and holding for ½ to 1 min in order to allow the passive film to form. If insufficient time was allowed, no Flade potential was observed. Based on many measurements, it was found that the Flade potential was independent of time held at the passive potential; however, time to reach the Flade potential after shutting off the current increased the longer the electrode was maintained in the passive state. Flade (9) also observed much earlier that, when iron was held in the passive state for a long period, the time observed for decay tended to be longer.

Results

Critical current densities for 15 alloys all containing 20% Ni (average = 20.1% with a maximum

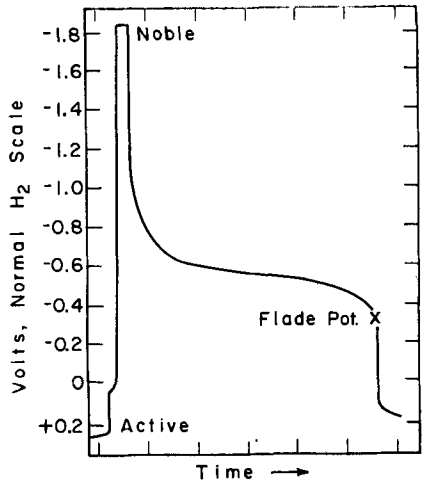

Fig. 1. Recorded potential decay of passivated 4.8% Cr, 20% Ni, balance Fe alloy in deaerated 1.28N H_2SO_4, 25°C.

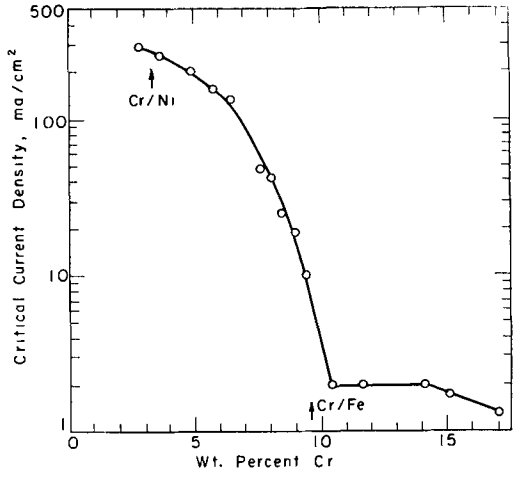

Fig. 2. Critical current densities for passivity of 20% Ni alloys in 1.28N deaerated H_2SO_4, 25°C.

deviation of 0.6%) and variable Cr and Fe are shown in Fig. 2. It is noted that alloys within the low Cr range require current densities in the order of 100-300 ma/cm² for passivation, whereas for alloys of greater than 10.5% Cr, current densities only about 1/100th as large are required. Optimum conditions for passivity can be said to initiate, therefore, at a minimum of 10.5% Cr. Although the corrosion rate corresponding to a critical current density of 2 ma/cm² is approximately 5,000 mdd, which is a high rate, in more dilute acids, of course, the critical current density and corresponding corrosion rate would be much lower. It should also be noted that the current density required to maintain passivity, corresponding to the steady-state corrosion rate of passive alloys, is much less than the critical current density. The important consideration is that as Cr content increases, the critical current density falls markedly and, at 10.5% Cr, achieves relatively low values which remain low for higher Cr compositions. This is typical of the behavior of Cr-Fe and other alloys as they progress from the active to the passive range of composition. The value 10.5% Cr, therefore, is a unique or critical composition.

Similar data for 40% (av. = 40.1%, max. deviation of 0.5%), 50% (av. = 50.0%, max. deviation of 0.6%) and 60% (av. = 60.0%, max. deviation of 0.7%) Ni alloys are shown in Fig. 3, 4 and 5. Major changes in slope occur as for 20% Ni alloys, but with some additional smaller changes in slope also apparent. A possible cause for these smaller changes will be discussed later.

Flade potentials for 20 and 60% Ni alloys are summarized in Fig. 6, each point representing an average of several determinations. Values for 40 and 50% Ni show a similar scatter, with all values for low Cr alloys starting at about −0.45 v to the normal H_2 electrode and ending at about 0 to −0.15 v for 15-20% Cr alloys. The value for the Flade potential E_F of Fe in H_2SO_4 of pH 0.4, as calculated from the relation (5) $E_F = -0.63 + 0.059\ pH$, is

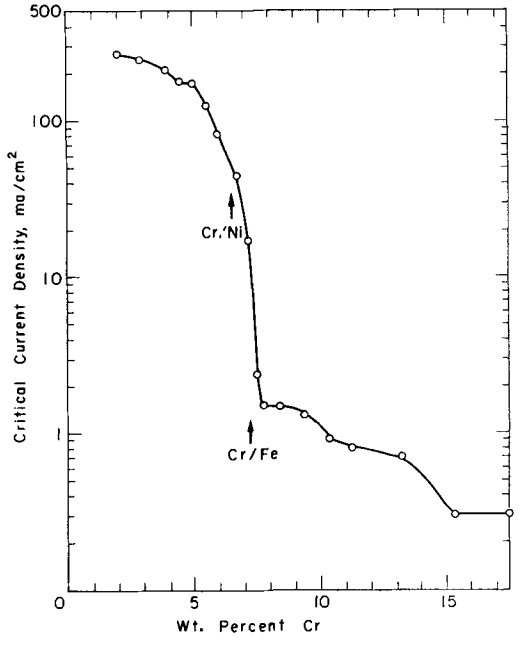

Fig. 3. Critical current densities for passivity of 40% Ni alloys in 1.28N deaerated H_2SO_4, 25°C.

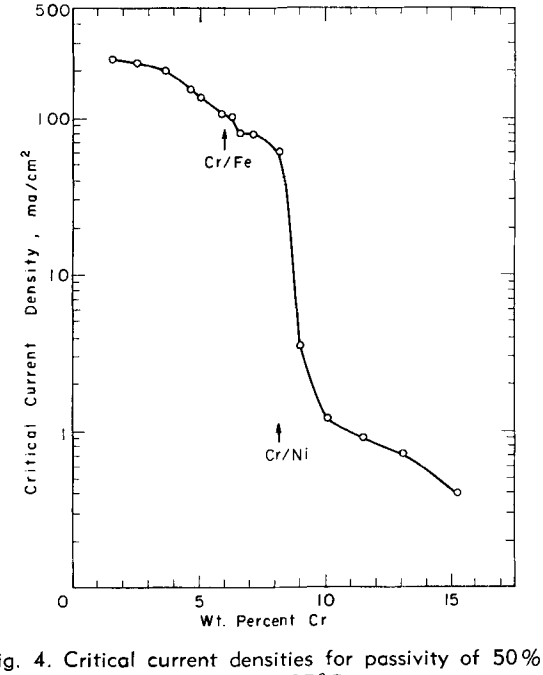

Fig. 4. Critical current densities for passivity of 50% Ni alloys in 1.28N deaerated H_2SO_4, 25°C.

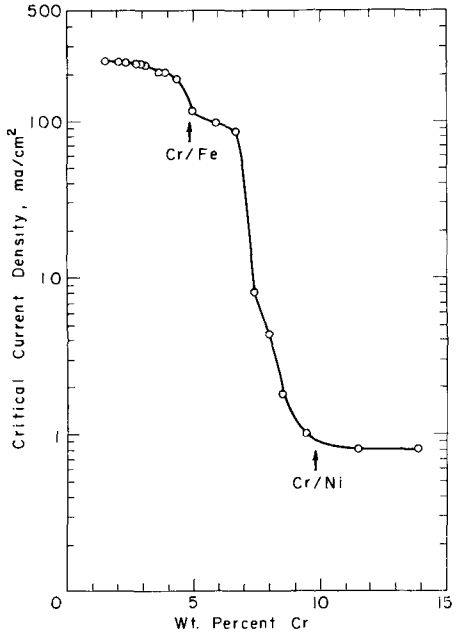

Fig. 5. Critical current densities for passivity of 60% Ni alloys in 1.28N deaerated H_2SO_4, 25°C.

equal to −0.61 v. The less noble values for the alloys indicate that their passivity is more stable than that of iron. The standard Flade potential (pH = 0) for Cr, by way of example, is +0.2 v. Some potentials of Fig. 6 fall off the best curve through all the points. It may not be coincidence that these marked deviations occur mostly at alloy compositions corresponding to discontinuities in slope of critical current density as observed in Fig. 2 and 5. The extent to which the two sets of data can be correlated is not entirely clear, however, and any attempt in this direction would probably require additional measurements on alloys of composition falling in between present compositions.

The over-all shape of the Flade potential curves in Fig. 6, allowing for deviations mentioned above, are similar to those reported for the Cr-Fe alloys in H_2SO_4 by Rocha and Lennartz (10). There is a

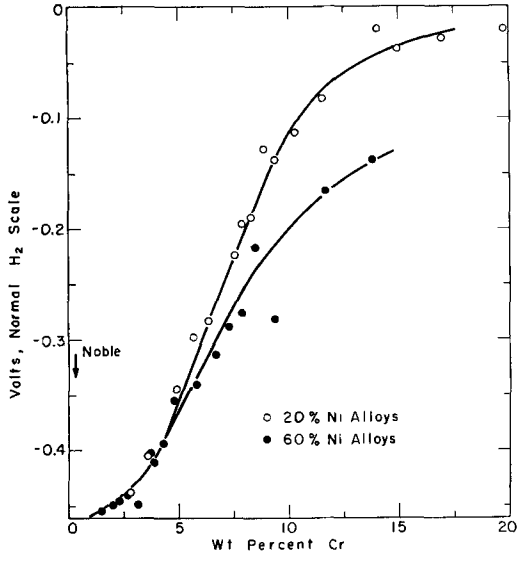

Fig. 6. Activation or Flade potentials of Cr-Ni-Fe alloys in 1.28N deaerated H_2SO_4, 25°C.

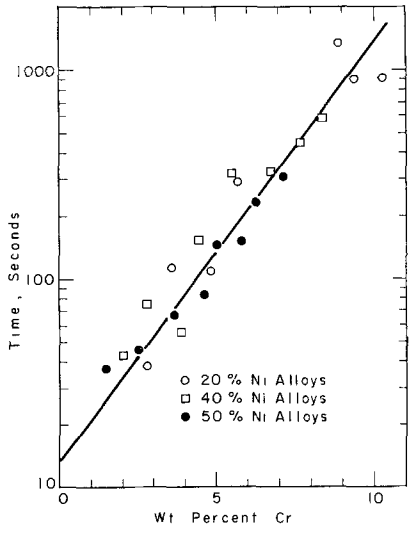

Fig. 7. Relation of Cr content of Cr-Fe-Ni alloys to time for breakdown of passivity in 1.28N deaerated H_2SO_4, 25°C.

bending of the curve both at low and high Cr compositions with relatively steep rise in the region of the critical Cr composition.

Time t_0 in seconds required for passivity to break down increases with Cr content, as Fig. 7 shows, in accord with the approximate relation $\log t_0 = 0.2$ (% Cr) + 1.15. The recorded data are for the 20, 40, and 50% Ni alloy series where the time held at the passive potential in each instance was 15-20 sec. Values for the 60% Ni series also fall on the best straight line through all the points but with greater scatter in the 1 to 3% Cr range. It is concluded that without any Cr, the median life of the passive film in 1.28*N* H_2SO_4 is about 14 sec, which is consistent with the observed behavior of passive iron, including probably also the Fe-Ni alloys. The prolonged life of the passive film as Cr content increases is consistent with the more active values of the Flade potential for higher Cr alloys, which, as mentioned before, parallel increased stability of passivity.

Discussion

Major changes in the slope of critical current densities plotted with respect to per cent Cr presumably can be interpreted in terms of a more protective oxide film initiating at the critical Cr compositions, or alternatively in terms of a stronger bond between discharged OH^- (or O_2) and the base metal, leading in either case to a passive film. A stronger bond between adsorbate and adsorbent would be expected to occur for compositions in which the *d* orbitals of Cr are uncoupled. Under such conditions, corresponding to Cr compositions above the critical value, the observed critical current density is low and tends to change only slightly with increasing % Cr, as shown in Fig. 2 through 5. For compositions corresponding to coupled *d* orbitals of Cr, critical current densities are much higher and the change with alloy composition is greater.

Although a passive film hypothesized to consist of metal oxide may meet the immediate *qualitative* requirements for an explanation of critical Cr compositions in the stainless steels, no quantitative evaluation has been offered by proponents of this

Table I. Calculated values for critical % Cr for passivity in Cr-Ni-Fe alloys

% Ni	Donor electrons from Fe only	Ni only	Fe and Ni
20	9.6%	3.3%	12.5
40	7.2	6.5	12.9
50	6.0	8.2	13.2
60	4.8	9.8	13.4

viewpoint. On the other hand, an evaluation is possible in terms of the electron configuration theory which proposes that the vacant surface *d* orbitals of Cr should be completely coupled by electrons from Fe at 12 wt % Cr or less in the Cr-Fe alloys, or when the weight ratio of Cr/Fe equals 12/88. Assuming that this ratio is maintained in the Cr-Ni-Fe alloys, the following expression is derived for critical per cent Cr for passivity assuming electrons donated only by Fe: Crit. % Cr = 12/88 (100 − Crit. % Cr − % Ni) or Crit. % Cr = 0.120 (100 − % Ni).

On the other hand, if the surface *d* orbitals of Cr are coupled by electrons donated from Ni only, the corresponding value is: Crit. % Cr = 14/86 (% Ni), where 14/86 is the empirical ratio for passivity observed for the Cr-Ni alloys based on observed critical current densities (4). A third case can be considered for which electrons are donated both from Fe and Ni. Using the same empirical ratios for Cr/Fe and Cr/Ni, this leads to: Crit. % Cr = 14/86 (% Ni) + 12/88 (100 − Crit. % Cr − % Ni) = 0.023 (% Ni) + 12.0.

The calculated values for critical Cr compositions are summarized in Table I, and are also indicated for the first 2 cases cited above on Fig. 2 through 5.

For 20% Ni alloys, it is seen in Fig. 2 that the major predicted change of slope at 9.6% Cr for the case of donor electrons from iron comes close to the observed change in slope at about 10.5% Cr. There is no observed change in slope at 3.3% Cr for the case of donor electrons from Ni. For 40% Ni, the predicted change of slope at 7.2% Cr for donor electrons from Fe again comes close to the observed value at 7.6% Cr. Because of the rapidly changing slope in this region, it is not possible to observe whether a change in slope also results from donor electrons from Ni predicted to occur at 6.5% Cr. Furthermore, it is not certain that the slight discontinuity in slope observed at 5% Cr is real.

For 50% Ni alloys, the observed change in slope at about 10% Ni lies to the right of the predicted values based on donor electrons from either Fe or Ni. The observed value, however, comes closer to the predicted value based on donor electrons from Ni equal to 8.2% Cr than it does to the value based on electrons from Fe. In this connection, some significance may attach to the fact that alloys at 50% Ni contain more Ni than Fe. It should be noted in Fig. 4 that a slight change in slope also occurs close to the value of 6% Cr predicted for donor electrons from Fe. This slight change of slope becomes more pronounced in the 60% Ni alloy series in Fig. 5 where the change can no longer be ascribed to possible variations of measurement. The predicted change based on donor electrons from Fe is at 4.8% Cr compared to an observed value of 4.5 to 5% Cr. The major change of slope at about 9.5% Cr now comes close to the predicted value of 9.8% Cr based on donor electrons from Ni. It appears, therefore, that in alloys containing less than 50% Ni, the major critical composition corresponds to electrons donated to Cr from Fe, whereas above 50% Ni, the critical composition corresponds to electrons donated by Ni.

There is no strong evidence that donor electrons come from both Fe and Ni, even though this might be expected on fundamental grounds. The predicted values of critical per cent Cr for donor electrons from both metals lie definitely to the right of the observed major changes in slope. It should be noted that any small changes in slope of critical current density as a function of composition in this higher chromium range fall within the experimental errors of measurement since the maximum change on the logarithmic scale as plotted amounts to only a few ma/cm^2. The same situation does not apply to changes of slope in the lower chromium composition range where deviations from a smooth curve through the observed points amount to tens or hundreds of ma/cm^2.

The primary features of the critical current density curves are described reasonably well, therefore, by the separate electron interaction between Cr and Fe distinct from interaction between Cr and Ni. Furthermore, the critical compositions in the ternary system approximate in each case the critical composition typical of the corresponding binary system. Further experiments are needed to establish whether similar relations can be expected in other passive alloy systems.

Dissolution of Iron in Sulfuric Acid and Ferric Sulfate Solutions

A. C. Makrides[1a]

Metals Research Laboratories, Union Carbide Metals Company,
Division of Union Carbide Corporation, Niagara Falls, New York

ABSTRACT

Dissolution of iron in sulfuric acid solutions containing ferric sulfate is described by the superposition (without distortion) of the partial processes of hydrogen evolution, reduction of ferric ion, and anodic dissolution of iron. Reduction of ferric ion occurs at a diffusion-limited rate. Derived relations between electrode potential and the concentration of ferric sulfate, the linear flow velocity, and time are verified. A comparison of potential-current density curves obtained by polarization and from addition of ferric sulfate suggests that adsorption of ferric ion, if any, has no appreciable effect on iron dissolution

Corrosion or dissolution of metals in environments found in practice often involves a reaction proceeding at a rate limited by diffusion. For example, the corrosion rate of iron in nearly neutral aerated salt solutions is determined, to a large extent, by the rate of diffusion of oxygen to the iron-solution interface. Similarly, dissolution of nickel in acid solution is accelerated by oxygen which apparently is reduced as fast as it diffuses to the interface. A study of such systems is of interest therefore not only in general electrochemical theory but also in developing methods for minimizing corrosion in industrial processes.

It is essential in a study of a heterogeneous reaction proceeding at a diffusion-limited rate to control mass transport to the interface precisely and reproducibly. The rotating cylinder electrode (1-3) meets these requirements and possesses the advantage of a uniform mass transport rate over the whole of its lateral surface. An application of the rotating electrode to dissolution of iron in ferric sulfate solutions is presented here. The results are discussed on the basis of the Wagner-Traud postulate of superposition of partial processes together with elementary hydrodynamic considerations.

Electrochemistry of Iron Dissolution

Iron dissolves in aqueous acid solutions through an electrochemical mechanism (4-6). In moderately concentrated acid solutions and in the absence of reducible substances other than hydrogen ions, the partial processes are described by

$$\eta_c = -\, b_c \log \frac{i_c}{i_{oc}} \quad \text{for } 2H^+ + 2e^- \rightarrow H_2 \qquad [1]$$

and

$$\eta_a = b_a \log \frac{i_a}{i_{oa}} \quad \text{for } Fe \rightarrow Fe^{++} + 2e^- \qquad [2]$$

where the η's are overpotentials associated with current densities i_a and i_c and the i_o's are exchange current densities. At the steady state,

$$i_a = i_c = i_{corr} \qquad [3]$$

at a common electrode potential. The corresponding overpotentials are

$$\eta_c = E_{corr} - E_c^{rev} \qquad [4]$$

$$\eta_a = E_{corr} - E_a^{rev} \qquad [5]$$

where E_{corr} is the corrosion or dissolution potential and E^{rev} the reversible potential for each partial process.

If another reducible substance is introduced in the solution, the partial cathodic current is the sum

$$i_c = i_H + i_r \qquad [6]$$

where i_H is the partial current of hydrogen evolution and i_r the reduction current of the added oxidant. Only the case where i_r is equal to the limiting diffusion current, i_d, is considered here.

Equation [6] expresses the basic assumption of this development, viz., that the partial processes taking place during dissolution can be superimposed without interference. The only restriction imposed is that at the common electrode potential the sum of all cathodic processes equals the sum of all anodic processes. An electrochemical description of dissolution based on this assumption was given first by Masing (7) and in detail by Wagner and Traud (8).

Dependence of the dissolution potential on i_d.—The diffusion current depends on the concentration of oxidant and its diffusion coefficient, and on the flow rate. It is similar to an anodic current applied externally since it is independent of the electrode potential. This analogy is developed below.

If $i_d >> i_H$, then

$$i_c \cong i_d \qquad [7]$$

and the corrosion current for an electrode dissolving under these conditions is given by the diffusion current, while the potential is determined by the anodic polarization curve (Eq. [2]). Formally,

$$i_d = i_{corr} = i_a$$

and

$$\eta_a = E - E_a^{rev} = b_a \log \frac{i_d}{i_{oa}}$$

[1a] Present address: Research Department, Socony Mobil Oil Company, Inc., Dallas, Texas.

or

$$E = b_a \log \frac{i_d}{i_{oa}} + E_a^{rev} \qquad [8]$$

Therefore, it is possible to obtain the anodic polarization curve for the electrode by determining E as a function of i_d.

If $i_d \sim i_H$, both hydrogen discharge and oxidant reduction must be considered. Proceeding similarly to the above

$$E = b_a \log \frac{(i_d + i_H)}{i_{oa}} + E_a^{rev} \qquad [9]$$

with i_H a function of potential. Equation [9] reduces to [8] at sufficiently positive potentials where i_H becomes negligible.

Dependence of potential on concentration.—If the dependence of i_d on the concentration of oxidant, C_{ox} (moles cc^{-1}), is known, we can immediately write down E as a function of C_{ox}. Since under most conditions $i_d >> i_H$, Eq. [8] rather than [9] is used in what follows.

The diffusion-limited current is

$$i_d = n\mathbf{F}\frac{dj}{dt} = n\mathbf{F}kC_{ox} \qquad [10]$$

Here, j is the number of moles of oxidant transported across a unit area of metal-solution interface, t the time in seconds, n the number of equivalents per mole of oxidant, $\mathbf{F}$ Faraday's constant, and k the rate constant in cm/sec. For turbulent flow, and in excess of an indifferent electrolyte (constant ionic strength), k may be assumed independent of C_{ox} (9). From Eq. [8] and [10]

$$E = b_a \log C_{ox} + b_a \log \frac{n\mathbf{F}k}{i_{oa}} + E_a^{rev} \qquad [11]$$

Therefore, at constant k and i_{oa}, the potential is a linear function of the logarithm of the concentration of depolarizer with a slope equal to the Tafel slope of the anodic polarization curve.

Time dependence of the dissolution potential.—The change of E with time can be calculated from Eq. [8] and [10]. The potential of an electrode immersed in a solution originally C_{ox} in oxidant moves in a cathodic (active) direction as oxidant is depleted by reaction. The rate at which oxidant is used is given by Eq. [10]. From Eq. [8]

$$\frac{dE}{dt} = \frac{b_a}{2.30(i_d)}\frac{d(i_d)}{dt}$$

with i_{oa} independent of time. Noting that

$$dj = -\frac{V_s d(C_{ox})}{A}$$

where V_s is the solution volume and A the surface area of the electrode, we have from Eq. [10] for constant k (fixed flow),

$$\frac{d(i_d)}{dt} = n\mathbf{F}k\frac{d(C_{ox})}{dt} = -n\mathbf{F}k^2\frac{A}{V_s}C_{ox}$$

Substituting above and using Eq. [10]

$$\frac{dE}{dt} = \frac{-A}{2.30V_s}k\,b_a \qquad [12]$$

The potential is therefore a linear function of time with a slope given by Eq. [12]. If dE/dt and b_a are known, k can be obtained from Eq. [12].

Dependence of potential on hydrodynamic flow conditions.—Equations [8] and [10] yield a relation between E and k from which we may derive the dependence of the potential on various hydrodynamic parameters. Some useful relations are given below.

The rate constant of a diffusion-controlled reaction occurring at a cylindrical electrode in turbulent flow is

$$k = \frac{D}{\delta} = (C_1)\,V\,(R_d)^{-\beta}\,(Pr)^{-\gamma} \qquad [13]$$

where D (cm^2/sec) is the diffusion coefficient of the oxidant, δ (cm) the effective thickness of the boundary layer, and V (cm/sec) the linear velocity. R_d is Reynolds number, $d_i V/\nu$ with d_i (cm) the diameter of the electrode and ν (cm^2/sec) the kinematic viscosity, and Pr is Prandtl's number, ν/D. Equation [13] is based on an extended Reynolds momentum-mass transfer analogy (the Chilton-Colburn analogy) and is in good agreement with experiments [2] with $C_1 = 0.079$, $\gamma = 0.644$, and $\beta = 0.2$ to 0.3. As noted previously (3), β depends on the range of Reynolds numbers and on the roughness of the electrode. For hydrodynamically rough surfaces β approaches zero, while for smooth electrodes $\beta \cong 0.3$ at small Reynolds number ($\sim 10^3$) and $\cong 0.2$ at large Reynolds numbers ($\sim 10^5$).

Two useful relations can be derived from Eq. [13]. At constant C_{ox}, from Eq. [8] and [10]

$$E = b_a \log k + b_a \log \frac{n\mathbf{F}\,C_{ox}}{i_{oa}} + E_a^{rev}$$

And from Eq. [13]

$$E = b_a \log V^{(1-\beta)} + (\text{Constant}) \qquad [14]$$

Therefore, the potential varies linearly as the logarithm of the velocity at any constant C_{ox} with a slope of $b_a(1-\beta)$.

At constant potential, from Eq. [8],

$$i_a = i_d = \text{const}$$

And from Eq. [10] and [13]

$$(\text{Constant})_1 = n\mathbf{F}k\,C_{ox} = n\mathbf{F}\,(\text{Constant})_2\,V^{(1-\beta)}\,C_{ox}$$

Rearranging,

$$-\log C_{ox} = (1-\beta)\log V + (\text{Constant}) \qquad [15]$$

The value of β for a particular experimental arrangement can be obtained from a log-log plot of the oxidant concentration against the linear velocity at constant potential.

Relations [1], [2], [8], [10], [11], [12], [14], and [15] have been verified for iron electrodes in ferric sulfate solutions 0.5N in sulfuric acid.

Experimental

The experimental arrangement reported previously (3) was modified to reduce the concentration

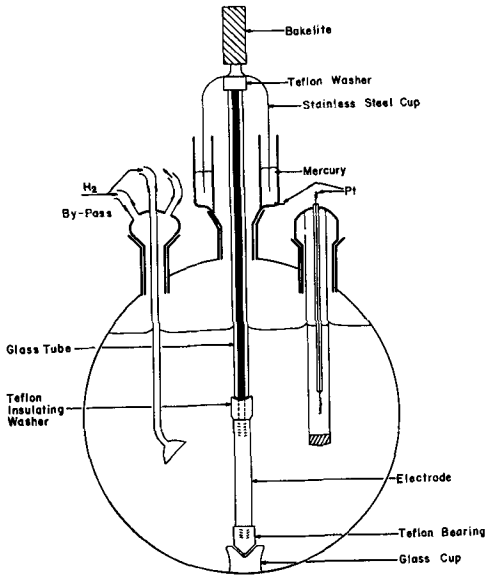

Fig. 1. Reaction cell

of oxygen in solution and to make it easier to vary the rotational speed.

The cell is shown in Fig. 1. The electrode, generally a cylinder 1 cm in diameter and about 4 cm long, was attached to a stainless steel shaft isolated from the solution with a glass tube. A Teflon washer gave a water-tight seal at the point of attachment of specimen to shaft and also isolated the top surface of the cylinder from solution. At the other end of the cylinder, a Teflon bearing riding in a glass cup fused to the cell minimized eccentric motion and at the same time isolated the lower surface of the cylinder from solution. Smaller electrodes, about 1 cm^2 in surface area, were used in polarization studies. In these cases, the Teflon washer at the top was extended to leave only about 0.3 cm of the electrode exposed to the solution.

The steel shaft ended in an inverted steel cup which rotated in mercury and sealed the system from the atmosphere. Electrical contact to the electrode was made through the mercury pool.

Hydrogen, purified over copper at 500°C and through sodium plumbate, concentrated sulfuric acid, triply distilled water, a drying tower, and a cold trap, was passed through the solution prior to a run and over the solution during a run.

Potentials were measured against S.C.E. and platinized platinum with a high impedance L&N pH meter connected to a multiple range, adjustable zero, Dynamaster Bristol recorder. Alternatively, a Rubicon potentiometer was used together with a galvanometer of 0.007 μa/mm sensitivity. A capillary probe with a bridge filled with solution of the same acid concentration was used in polarization measurements. The bridge led to an external S.C.E. A greaseless, closed, stopcock prevented mixing of (air-saturated) solution outside the cell with solution in the cell, but had sufficient conductivity when wetted with solution to maintain electrical contact. Constant current was obtained through appropriate resistances from two banks of three 45-v batteries arranged in series to give 135 v.

Greaseless ground glass joints were used to avoid possible contamination from lubricant. Although some air probably diffused into the cell, any contribution from dissolved oxygen to the cathodic current was negligible (see below).

Electrodes were rotated with a Bodine motor at speeds continuously variable up to 4000 rpm. The motor was electrically insulated from the electrode by a short Bakelite sleeve, friction-fitted on the upper part of the shaft (Fig. 1). Rotational velocities were measured to 0.2% with both a Jaquet tachometer (via an auxiliary shaft driven through an 18:1 reduction gear) and a stroboscope.

Through a ground glass joint (not shown in Fig. 1) small amounts of a concentrated solution of $Fe_2(SO_4)_3$ were added to the solution from a precision ($\pm$0.01 ml) buret equipped with a greaseless Teflon stopcock.

Analytical reagent-grade ferrous sulfate was recrystallized twice, washed with absolute alcohol and anhydrous spectroscopic-grade ether, and dried. Ferric sulfate was prepared from ferrous sulfate by oxidation with hot, concentrated sulfuric acid. Ferric sulfate solutions also were prepared from recrystallized C.P. ferric sulfate. Water was triply distilled, one distillation being carried out of dilute, alkaline potassium permanganate. The reaction vessel and all glass parts were cleaned with a saturated solution of potassium dichromate in concentrated sulfuric acid (cleaning solution) and rinsed with triply distilled water prior to use. Water drained uniformly and with zero contact angle from glass surfaces cleaned in this way.

Electrodes were prepared from Ferrovac E iron (99.92+ iron). They were abraded with 2/0 emery paper, washed with reagent-grade carbon tetrachloride, left to dry, etched in 1:3 HNO_3, washed with distilled water, etched in 1:3 H_2SO_4, and washed again.

Concentrations of various solutions were determined by analysis. The cell was thermostated at 30.0 $\pm$ 1°C.

Results and Discussion

Dissolution in Sulfuric Acid

In 0.52*N* H_2SO_4 the steady-state dissolution potential changed by less than 0.2 mv on varying the speed from zero to 4000 rpm (200 cm/sec). Concentration overpotentials therefore were negligible for both partial processes. Also it may be inferred that the partial current for reduction of any trace of oxygen present in solution was negligible in comparison with the corrosion current.[1]

Metal dissolution in acid alone is described by Eq. [1]-[5], i.e., by specifying the exchange current and Tafel slope for hydrogen evolution and for metal oxidation. These parameters were not always reproducible with iron. In general, electrodes belonged to one of two sets: (i) the steady-state corrosion potential was about —0.510 to —0.520 v vs.

[1] It was suggested (3) that an observed dependence of potential on rotational speed in solutions which were thought to be air-free was attributable to an electrokinetic effect. It is apparent that some dissolved oxygen must have been present in these solutions. As with other oxidants, the partial current for oxygen reduction increases and the dissolution potential becomes more positive when the flow velocity is increased.

S.C.E., the corrosion current about 400 μa/cm^2, b_a = 0.050 to 0.060 v, and b_c = 0.095 to 0.105 v; (ii) the corrosion potential was —0.495 to —0.505 v vs. S.C.E., the corrosion current about 2200 μa/cm^2, b_a = 0.030 to 0.040 v and b_c = 0.095 v. The hydrogen exchange current was considerably larger than in (i) (see below).

The time dependence of the corrosion potential differed for (i) and (ii). For set (i), E_{corr} increased from about —0.550 to —0.515 in about 3-4 hr and remained essentially constant at about this value. For set (ii), the drift continued, although at a smaller rate, for at least 24 hr. The corrosion current increased during this time to the value given above.

The cause of these differences is obscure. The rather wide variation in results obtained in electrochemical studies (4-6, 9-12) with iron and other metals of Group VIII, notably nickel, has been ascribed variously to impurities in solution, impurities in the metal, or to solution of hydrogen in the metal (10, 11). It is possible that some impurities, e.g., carbon and sulfur, have a pronounced effect on the kinetics of dissolution even if present in very small quantities. Since the system was designed primarily for the study of dissolution in solutions with oxidants, results for dissolution in acid alone are limited. The work reported for acid solutions is considered preliminary to a more extensive study with a more suitable experimental arrangement.

The variability of b_a made it necessary in most cases to obtain polarization curves prior to a run in order to compare anodic slopes observed directly and by addition of ferric sulfate. In other cases, the corrosion rate and corrosion potential were used to characterize the electrode.

Figure 2 gives anodic and cathodic polarization curves typical of electrodes belonging to set (i). The reversible H^+/H_2 potential was —0.275 v vs. S.C.E. Hydrogen overpotentials were

$$\eta_c = -(0.105) \log \frac{i_c}{2.2 \times 10^{-6}} \qquad [16]$$

with i_c in amp/cm^2. From $b_c = 2.30\ RT/\alpha_c F$, the transfer coefficient α_c, is 0.57. For the anodic polarization curve

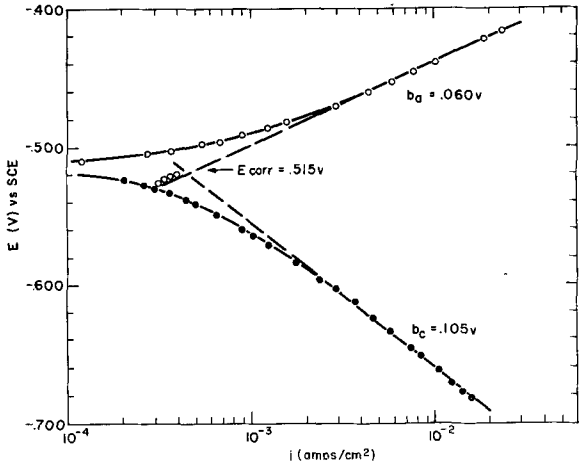

Fig. 2. Polarization diagram for iron in 0.52N H_2SO_4 at 30°C. The diagram is typical of set (i). The electrode was in solution for 10 hr E_{corr} = —0.515 v.

$$E = -0.320 + 0.060 \log i \text{ vs. S.C.E.} \qquad [17]$$

The reversible potential for Fe/Fe^{++} was not known, since activity coefficients for ferrous sulfate were not available. The standard potential for Fe/Fe^{++} is $E' = -0.68$ vs. S.C.E. With an estimate of $E_a^{rev} \cong -0.80$ ($a_{FeSO_4} \cong 10^{-4}$), $i_{oa} \cong 10^{-8}$ amp/cm^2 at this $FeSO_4$ concentration.

The dissolution rate may be obtained by extrapolation of either the anodic or cathodic polarization curves to the dissolution potential (6). At E = —0.515 v, η_c = —0.240 v and from Eq. [16]

$$i_c = i_{corr} = 4.1 \times 10^{-4} \text{ amp/cm}^2$$

A similar extrapolation of the anodic curve to E = —0.515 v yields $i_a = i_{corr} = 5.6 \times 10^{-4}$ amp/cm^2. Alternatively, following Wagner and Traud (8) and Stern (12), i_{corr} may be determined from the slope of the E vs. i_{appl} curve at small values of i_{appl}. If, for example, the electrode is polarized cathodically

$$i_{appl} = i_c - i_a \qquad [18]$$

For convenience, the steady-state dissolution potential (instead of the reversible potential) may be taken as the reference potential so that

$$i_c = i_{corr} \exp(-2.30\ \epsilon/b_c)$$
$$i_a = i_{corr} \exp(+2.30\ \epsilon/b_a) \qquad [19]$$

where $\epsilon = E - E_{corr}$. Substituting [19] in [18]

$$i_{appl} = i_{corr}\left[\exp\left(\frac{-2.30\epsilon}{b_c}\right) - \exp\left(\frac{2.30\epsilon}{b_a}\right)\right] \qquad [20]$$

Expanding around ϵ = 0, neglecting higher terms for small ϵ, and rearranging we obtain the equation given by Stern (12)

$$i_{corr} = \frac{b_a b_c}{2.30\ (b_a + b_c)\ (\epsilon/i_{appl})} \qquad [21]$$

Figure 3 shows a plot of ϵ vs. i_{appl} at small ϵ, from which $i_{corr} = 4.1 \times 10^{-4}$ amp/cm^2.

Figure 4 gives results typical of electrodes belonging to set (ii). The curves drawn through the open triangles were obtained 4 hr after immersion of the electrode in the solution, while the curves through the full triangles were obtained 24 hr after

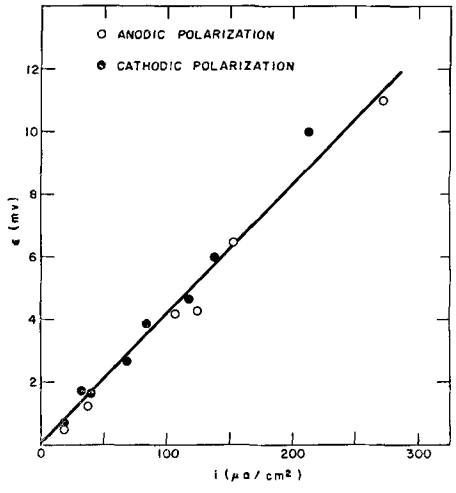

Fig. 3. Polarization data at small applied current densities in 0.52N H_2SO_4 at 30°C.

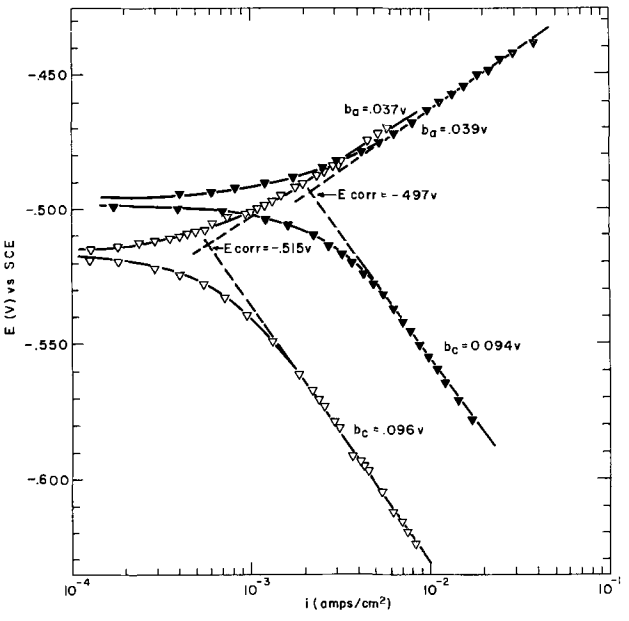

Fig. 4. Polarization diagram for iron in 0.52N H_2SO_4 at 30°C. The diagram is typical of set (ii). Curves through open points were obtained 4 hr after the electrode was in solution, and those through the full points after 20 hr in solution.

immersion. Hydrogen overpotentials for the two cases are

$$\eta_c = -0.096 \log \frac{i}{2 \times 10^{-6}}$$

and

$$\eta_c = -0.094 \log \frac{i}{1 \times 10^{-5}}$$

The anodic polarization curve was essentially unaltered during this time. The two sets of results are described by

$$E = -0.385 + 0.038 \log i \text{ vs. S.C.E.}$$

which yields on assumptions similar to those made above, $i_{on} \cong 10^{-11}$ amp/cm². Therefore, the shift of the corrosion potential to more noble values and the increased corrosion rate result essentially from the increase of the hydrogen exchange current.

Dissolution in Ferric Sulfate Solutions

The behavior of iron electrodes in ferric sulfate solutions paralleled that on anodic polarization. Data with electrodes belonging to set (i) are presented in Fig. 5 which shows the dependence of potential on the concentration of ferric sulfate over the range of velocities 50 to 200 cm/sec. The potential is a linear function of the logarithm of ferric ion concentration at potentials sufficiently removed from the corrosion potential. According to Eq. [11], the slope of the linear sections of these plots should be equal to b_a. Values of b_a determined in this way range from 0.057 to 0.066 v while 0.060 v was measured directly (see Fig. 2).

Rate constants at various velocities are required for comparison of results from anodic polarization and from addition of ferric sulfate. Rate constants were determined by withdrawing 5 ml portions of the solutions at various times and analyzing for iron. Equation [10] was used in the integrated form

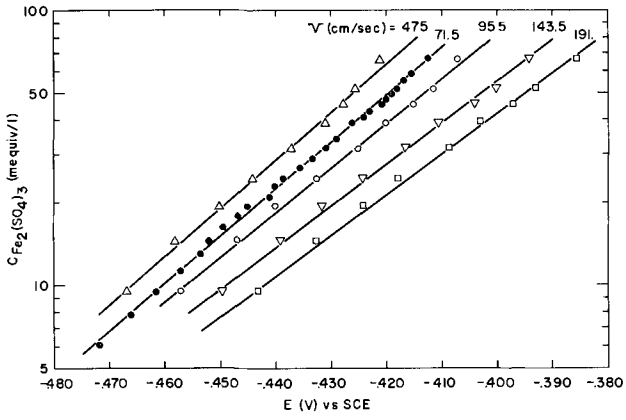

Fig. 5. Electrode potential as a function of ferric sulfate concentration at various linear velocities. The slopes are, from left to right, 0.057, 0.058, 0.062, 0.066, and 0.066 v.

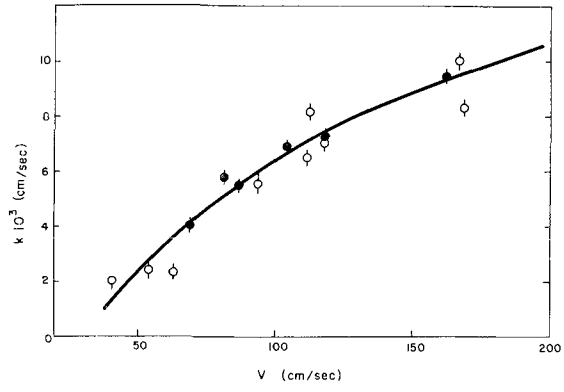

Fig. 6. First order rate constants as a function of velocity in 0.52N H_2SO_4 at 30°C. Values shown by open circles were calculated from the change (determined by analysis) of ferric ion concentration with time using Eq. [22]; solid circles were obtained from the time dependence of the dissolution potential and from the anodic Tafel slope (b_a = 0.060 v) using Eq. [12].

$$k = \frac{2.30\ V_s}{A\ t} \log (C°/C) \qquad [22]$$

Results are shown in Fig. 6. Rate constants cannot be computed from Eq. [13] since the diffusion constant of ferric ion in 0.5*N* H_2SO_4 solution is not known. From experimental values of k, with β = 0.20 (see below), and $\nu = 0.87 \times 10^{-2}$ cm²/sec, we find from Eq. [13] $D \cong 3 \times 10^{-6}$ cm²/sec. The estimated equivalent thickness of the boundary layer is then $\delta = D/k \cong 0.5 \times 10^{-3}$ cm at V = 100 cm/sec.

Potential-current density curves obtained by anodic polarization and from addition of ferric sulfate are compared in Fig. 7. Points obtained by the two methods differ by less than 10 mv at any current density.

Dependence of Dissolution Rate and Potential on Flow Velocity

According to [15], a plot of log C vs. log V at constant potential is linear with a slope of $(1-\beta)$. Data from Fig. 7 are plotted in Fig. 8 at E = const = — 0.420 v vs. S.C.E. Over the limited range of velocities used (50-200 cm/sec), $(1-\beta)$ = 0.80 or β = 0.20. Using this value for β, it is expected from Eq. [14] that a plot of log V vs. E at constant C is linear with a slope of 0.80 b_a. Figure 9 gives such

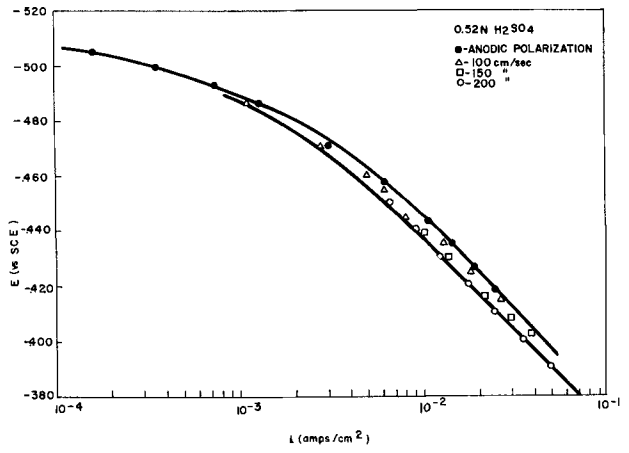

Fig. 7. Comparison of anodic curves obtained directly and by addition of $Fe_2(SO_4)_3$ for electrodes of set (i).

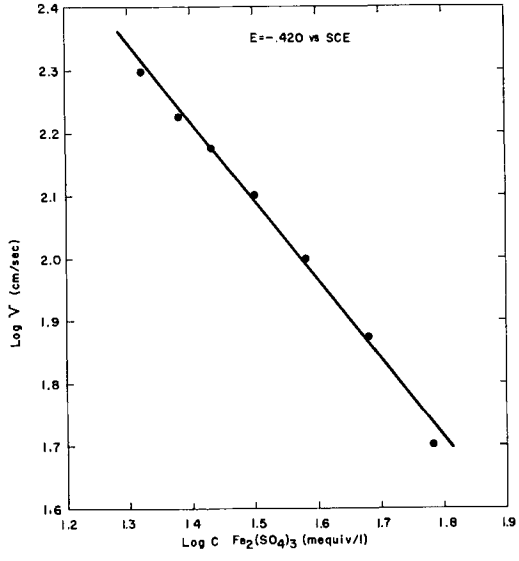

Fig. 8. Plot from data given in Fig. 5 at constant potential

plots for an electrode having a mean value of b_a = 0.060 v ($E_{corr} = -0.521$) at 34.6, 46.1, and 67.5 mequiv/l of $Fe_2(SO_4)_3$. The observed mean slope of 0.044 is in good agreement with a calculated value of 0.048 v.

Time Variation of Potential

The change of potential with time at various flow velocities is given in Fig. 10. From the slope, dE/dt, and with b_a = 0.060 v, rate constants were obtained from Eq. [12]. These are shown as solid circles in Fig. 6. The good agreement with k's found by analysis confirms the validity of Eq. [12].

Electrodes of set (ii).—Figure 11 shows the dependence of potential on ferric ion concentration for electrodes belonging to set (ii). The slope of the linear section of the curve is 0.040 v. Results were similar to those described above. The smaller Tafel slope of the anodic curve led however to relatively smaller changes of potential.

General Discussion

Although the anodic reaction for dissolution of iron in sulfuric acid solution followed a Tafel relation, both the slope and the exchange current varied

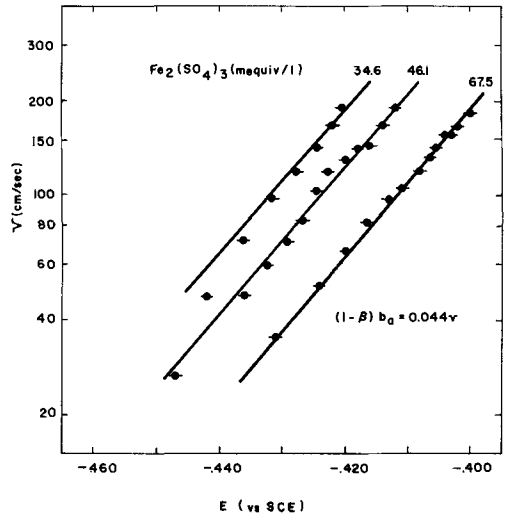

Fig. 9. Dependence of electrode potential on velocity at constant $Fe_2(SO_4)_3$ concentration in 0.52N H_2SO_4 at 30°C.

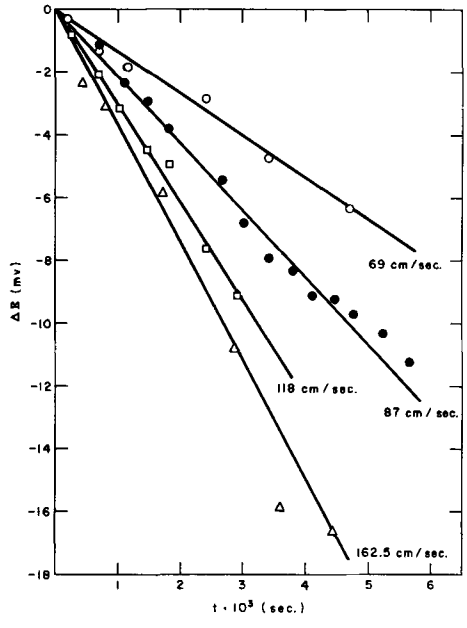

Fig. 10. Change of potential with time at various flow velocities.

within rather wide limits. As noted above, Tafel slopes were generally either about 0.035 or 0.060 v; exchange currents were smaller by 10^3 for electrodes having the former slope.

Reported Tafel slopes for the Fe/Fe^{++} couple also vary widely. Roitar, Jura, and Polujan (13) found for "electrolytic iron" in 1.25M $FeSO_4$, b_a = 0.060 or 0.075 v, depending on the history of the electrode, with $i_o \cong 3 \times 10^{-6}$ amp/cm². Stern and Roth (14) reported b_a = 0.068 v in 4% NaCl at pH of 1.5. Okamoto, Nagayama, and Sato (11) found b_a = 0.10 with Armco iron in 0.3N H_2SO_4. Hoar and Hurlen (15) determined b_a = 0.030 and $i_o \cong 3 \times 10^{-11}$ amp/cm² in 0.5M $FeSO_4$ + 0.1M $NaHSO_4$. Bonhoeffer and Heusler (16) obtained b_a = 0.030 in perchlorate solutions, a value also reported by Kaesche (17) in similar solutions.

Pronounced time dependence of the anodic polarization curve is also generally observed and is frequently associated with an open hysteresis loop

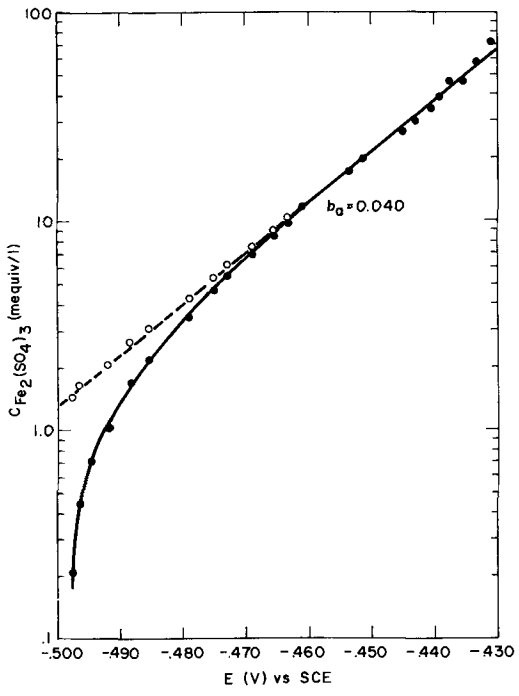

Fig. 11. Electrode potentials as a function of $Fe_2(SO_4)_3$ concentration at V = 58 cm/sec. Data are typical of electrodes of set (ii). Open circles were calculated from Eq. [27] as explained in text.

(6, 11). The curve traced on decreasing the current density falls below the curve obtained on increasing the current, the corrosion potential being displaced after a cycle to a more negative value. A similar drift toward lower overpotentials, particularly at high current densities, was observed here. In obtaining anodic polarization curves, each current setting was held for about 1 min during which time the potential decreased by about 1 mv. The electrode returned to a potential 10-15 mv more negative than E_{corr} after anodic polarization and drifted to within a few millivolts of E_{corr} in about 15 min.

A number of hypotheses have been advanced to account for the anodic behavior of iron. It has been suggested repeatedly (4, 11, 18) that the extent of adsorption of atomic hydrogen on the surface of an iron electrode decreases with increasing (more noble) potential. It is possible to account for some of these effects on the assumption that an adsorbed film of hydrogen interferes with the rate of the $Fe \rightarrow Fe^{++}$ reaction. Alternatively, adsorption of hydroxyl ion and its variation with potential (19) have been postulated.

Anodic overpotentials for iron are relatively large, the exchange current being of the order of 10^{-8} -10^{-11} amp/cm^2. It is probable that small amounts of impurities have a pronounced effect on dissolution kinetics. One expects dissolution to proceed mainly at sites where metal cations are in states of higher energy than at the rest of the surface (20). These may be at subgrain boundaries, dislocations, edges of incomplete layers, etc. As ions from such sites dissolve, near neighbors are placed in positions energetically favored for dissolution. However, these sites are probably also preferred for adsorption of impurities. It is thus probable that impurities in quantity far less than a monolayer may have a large effect on the anodic partial reaction. Some impurities may be introduced from the dissolving electrode. Okamoto, Nagayama, and Sato (11), for example, suggest that sulfide ions produced from sulfur inclusions in Armco iron may be responsible for the anodic hysteresis loop. It is probable that the divergent results quoted above are a consequence of extraneous impurities and are not characteristic of clean iron electrodes. It should be noted, however, that impurities present in quantities sufficient to affect the anodic partial reaction may have a relatively small or even negligible effect on processes, such as reduction of ferric ion, which proceed over essentially the whole of the electrode surface.

Dissolution in Ferric Sulfate Solutions

Previous work (1, 3) has shown that reduction of ferric ion on iron and mild steel in acid solution proceeds at a diffusion-limited rate. The first order kinetics, the dependence of the rate on flow velocity, and the absolute magnitude of the rate constants ($\sim 10^{-3} - 10^{-2}$ cm/sec) are all in accord with the assumption that dissolution is limited only by the rate of diffusion of ferric ion to the interface.

It is in general possible to determine the anodic partial curve from the dependence of potential on the concentration of oxidant when the oxidant is reduced at a diffusion-limited rate (Eq. [11]). The question to be answered experimentally is whether the oxidant, ferric ion in this case, modifies the anodic partial curve or the reduction kinetics for hydrogen evolution.

The anodic partial curve is not changed by ferric ion. Although the anodic slope was variable, values obtained with the same electrode by anodic polarization and from the dependence of potential on the ferric ion concentration coincided closely. It may be concluded that ferric ion has no specific effect on the anodic partial curve.

The absence of specific effects is not surprising. If reduction occurs at a rate limited by diffusion, a concentration gradient of an equivalent thickness δ is established in the steady state.[2] If sufficient in-

[2] The equivalent thickness of the boundary layer is obtained by assuming that the concentration of the diffusing species changes linearly with distance from a value of zero at the interface to its bulk concentration at δ. The physical thickness of the boundary layer may be approximated with sufficient accuracy for the purpose of this discussion by δ.

different electrolyte is present, changes of ionic strength caused by ferric ion may be neglected. Ferric ion could then influence the kinetics of metal dissolution or of hydrogen reduction either by adsorption in the fixed part of the electrical double layer or through reaction with some intermediate formed in either process.

There is no apparent intermediate in the anodic process with which ferric ion could interact. At the same time, adsorption of ferric ion is unlikely since it is precisely in the region of the Helmoltz layer that its concentration approaches zero ($C \cong (10^{-5} C_{bulk}) \cong 10^{-6}$ to 10^{-7} equiv/l). The concentration gradient for ferrous ion is, of course, opposite to that for ferric ion. However, the results show that the local excess of ferrous ion had little effect on the anodic curve.

Ferric ion could modify the hydrogen evolution reaction (h.e.r.) by reacting with adsorbed hydrogen atoms formed when hydrogen is discharged. Interference effects, if any, will be significant in the neighborhood of the corrosion potential. At more positive potentials the h.e.r. reaction becomes negligible.

The two most likely mechanisms for the h.e.r. on iron are slow discharge and the adsorbed hydrogen-hydrogen ion reaction.[3] These may be written as

$$H_3O^+ + e \rightarrow H_{ads} + H_2O \qquad [23]$$

and

$$H_3O^+ + H_{ads} + e \rightarrow H_2 + H_2O \qquad [24]$$

with

$$H_2O + H_{ads} + Fe^{+++} \rightarrow H_3O^+ + Fe^{++} \qquad [25]$$

possible in the presence of ferric ion.

If we denote the rate by v, and if [23] is rate controlling, i.e., $v_2 > 10\ v_1$, the over-all rate of h.e.r. is unaffected by [25] in the range $i_d \sim V_3 \sim V_{h.e.r.}$. Similarly, if [24] is slow and [23] fast, again [25] is negligible for $V_{h.e.r.} \sim V_3$. In either case, the stationary concentration of H_{ads} is not changed to any appreciable extent by reaction [25]. Only if [23] and [24] are comparable in rate will reaction [25] have an appreciable effect on the h.e.r. It is shown below that no effect was detected.

It must be emphasized that the possible effects on the h.e.r. discussed above are in addition to the expected decrease in rate at the more positive potentials in ferric sulfate solutions. This decrease is, of course, allowed for in superposing partial processes.

It has been proposed (21) that ferric ion reduction and hydrogen evolution are competitive not because of indirect reduction (process [25] above) but through competition between ferric and hydrogen ions for available adsorption sites. The suggestion was based on an interpretation of the dissolution rate of mild steel in stagnant ferric sulfate solutions (21).

Let us examine the dependence of the dissolution rate of ferric ion concentration, particularly in the range $i_d \sim i_H$. The dissolution rate (equiv/cm²/sec) is

$$\text{(dissolution rate)}\ F = i_a = i_d + i_H$$

If we choose the dissolution potential in the absence of ferric ion as the reference potential, then

$$i_a = i_{corr} \exp\ (2.30\ \epsilon/b_a) \qquad [26]$$

or

$$\epsilon = b_a \log\ (i_a/i_{corr})$$

where i_{corr} is the dissolution rate in acid alone. But from $i_a = i_d + i_H$,

$$i_a = i_d + i_{corr} \exp\ (-2.30\ \epsilon/b_c) \qquad [27]$$

and substituting [26] into [27]

$$i_a = i_d + i_{corr}\ (i_{corr}/i_a)^{b_a/b_c}$$

from which

$$i_a - i_{corr}\ (i_{corr}/i_a)^{b_a/b_c} = i_d = nFk\ C_{Fe^{+++}} \qquad [28]$$

Possible interference effects may then be looked for (a) in the rate of reduction of ferric ion as a function of $C_{Fe^{+++}}$ and (b) in the rate of hydrogen evolution as a function of $C_{Fe^{+++}}$. We have already shown (22) that within the range 0.01 to 0.467 equiv/l for which data are given in (21), the rate of ferric ion reduction is proportional to the ferric ion concentration with an average rate constant of 1.75×10^{-4} cm/sec.[4]

The rate of hydrogen evolution is given in Eq. [28] by the second term on the left-hand side. From (21), $i_{corr} = 0.39$ ma/cm² and $b_a = 0.060$ v. The curve given in Fig. 12 was calculated using the value of k given above and assuming $b_c = 0.100$ v. The points shown are experimental values given in Table II of ref. (21). The curve lies somewhat above a "least squares" line but is in fairly good agreement with the average rates of hydrogen evolution found in (21).[5]

Equation [27] can be used to determine whether the cathodic partial reactions are additive. At any given concentration of ferric ion, the rate of hydrogen evolution can be calculated if it is assumed, as above, that the two processes are independent. Figure 11 shows the results of this calculation. Here, $i_{corr} = 390\ \mu$a/cm² at $E_{corr} = -0.500$ vs. S.C.E., and $b_c = 0.100$ v. For each concentration i_d was calculated from the rate constant ($k = 3.1 \times 10^{-3}$ cm/sec) and i_H was obtained from the second term on the r.h.s. of Eq. [27]. Anodic currents obtained in this way were converted to equivalent concentrations of ferric ion and are shown as open circles on the same figure. They fall, within experimental error, on the line extrapolated from high concentrations of ferric ion ($i_d >> i_H$). It may be concluded that hydrogen evolution and ferric ion reduction do not interfere with each other.

Conclusions

An analysis of changes of electrode potential with concentration and flow velocity shows that the Tafel line for the Fe/Fe^{++} couple is unaffected by ferric ion. Specific effects expected if adsorption of ferric ion took place are not found. The overpotential curve

[3] It is not likely that a combination of absorbed hydrogen atoms is the slow step for the h.e.r. on iron since the Tafel slope is about 0.1 v.

[4] For the experimental conditions employed in (21), a dependence of the reduction rate on $(C_{Fe^{+++}})^{5/4}$ is expected (23). However, experimental scatter made it impossible to distinguish between a 5/4 power and linear dependence (see (22)).

[5] A decrease of the rate of hydrogen evolution with time was observed in (21). The experimental points shown are, therefore, average rates over 5 hr.

for hydrogen evolution is also apparently unaffected but the experimental evidence is less extensive in this case. These conclusions may be extended to other systems where reduction occurs at a rate limited by diffusion. In general, it is unlikely that the oxidant will have a specific effect, either on the anodic reaction or on hydrogen evolution, since its concentration approaches zero at the interface. Specific effects may appear however if the reduction products adsorb on the electrode.

Acknowledgment

The author thanks Mr. R. Aikin who skillfully assisted in the experimental part of this work. Helpful discussions with Dr. M. Stern are gratefully acknowledged.

Manuscript received March 23, 1960.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

Inhibition of Metal Dissolution by Ferric Sulfate

A. C. Makrides and Milton Stern

Metals Research Laboratories, Union Carbide Metals Company,

Division of Union Carbide Corporation, Niagara Falls, New York

ABSTRACT

Iron-chromium alloys are passivated in acid solution at a critical ferric sulfate concentration which depends on acid normality and flow velocity. Smaller concentrations of ferric ion increase the dissolution rate of active electrodes by providing a cathodic partial process occurring at a diffusion-limited rate. Once passivity is achieved, however, considerably less than the critical ferric ion concentration is required to maintain the electrode passive. The dependence of the electrode potential on the concentration of ferric ion is quantitatively related to the anodic polarization curve of the electrode. Polarization curves obtained in the active region coincide with curves derived from studies with ferric ion. The inhibitor concentration required to produce passivity is directly proportional to the anodic critical current density, while the primary passive potential is not changed by ferric ion. These results suggest that adsorption of ferric ion is not responsible for inhibition by this ion.

A number of oxidizing substances inhibit metal dissolution by inducing a transition from the active to the passive state (1). A characteristic electrochemical difference between the action of these substances and that of nonoxidizing inhibitors is the change of electrode potential which they produce. Oxidizing inhibitors displace the mixed potential in the positive (noble) direction by about 1 v, while nonoxidizing inhibitors produce changes which may be of either sign and which rarely exceed 0.1 v.

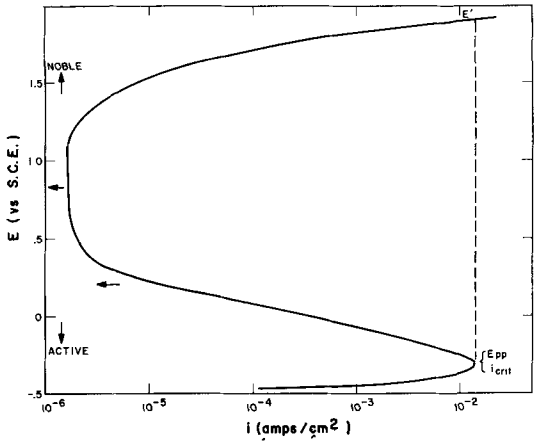

Fig. 1. Schematic polarization curve typical of iron-chromium alloys (series 400 stainless steels). Dashed curve shows transition to oxygen evolution with constant current source. Full curve is obtained in a potentiostatic experiment. E_{pp} is the primary passive potential and i_{crit} the critical current density. Arrows at left indicate decreasing current with time in this potential region.

It is generally agreed that nonoxidizing inhibitors reduce the dissolution rate by forming an adsorbed film at the metal-solution interface (2). Conflicting mechanisms have been proposed for inhibition by oxidizing substances. It has been suggested (3) that oxidizing inhibitors induce passivity by adsorption. It is possible however to give an account of inhibition in which specific effects, such as expected from a model postulating adsorption, are not assumed (1). A study of inhibition by ferric ion was carried out to determine whether specific effects are, in fact, present. As shown below, the results are consistent with the generalized description given in (1). It may therefore be concluded that inhibition is not related to adsorption of ferric ion.

Passivating inhibitors.—The anodic polarization curve of a number of common metals and alloys (1, 4, 5) is of the general type shown in Fig. 1. The full curve is the result of a potentiostatic and the dashed curve of a galvanostatic experiment.

With no applied current, the electrode dissolves at some rate i_{corr} corresponding to a mixed potential E_{corr}. If the electrode is polarized anodically with a constant current source, the rate of the anodic partial reaction increases smoothly with potential until at some current i_p a large, discontinuous potential jump occurs (from E_{pp} to E' on the diagram). Oxygen evolution takes place at E'. However, if a polarization curve is obtained by controlling the potential and allowing the current to vary, potentials intermediate between E_{pp}, the primary passive potential (6), and E' are attainable. At first, the steady-state current decreases in this potential region. After some low value is reached, it becomes more or less independent of potential over an interval of several tenths of a volt. Oxygen is again evolved at sufficiently positive potentials.

In general, several hours are required to achieve a steady state at potentials more positive than E_{pp}. In some cases time dependent results are also observed at potentials somewhat more negative than E_{pp}.

The reversible potential of a redox couple whose oxidized form is an inhibitor lies in the passive potential region. Since a mixed potential in the passive region can be maintained with such redox couples, stable inhibition (small dissolution rate) is observed when the metal is passivated either externally or by the added redox couple. The redox couple may displace the potential to the passive region when its reduction rate exceeds some current equivalent i_p'.

A specific effect by an inhibitor can be detected experimentally by comparing anodic polarization curves with and without inhibitor. If the inhibitor alters the anodic reaction in some specific way, then at any given potential the anodic partial current will be less than that indicated by the anodic curve determined in the absence of inhibitor. If this is the case, one expects i_p to differ from i_p'. Further, the potential, say E_{pp}', at which the inhibitor induces a transition to a passive state should also differ from E_{pp}. If, on the contrary, the inhibitor has no specific effect, the anodic partial current will depend only on the potential. Therefore, $i_p' = i_p$ as well as $E_{pp}' = E_{pp}$. This study was directed toward determining these quantities with and without ferric sulfate.

Experimental

Previous work (7, 8) established that ferric ion is reduced on iron and mild steel at a rate limited only by diffusion. Since it appeared probable that this would also be true for the iron-chromium alloy used here, it was essential to control the rate of mass transport to the interface precisely and reproducibly. A rotating, cylindrical electrode was chosen since it satisfied these requirements and possessed the advantage of a uniform mass-transport rate over the whole of its lateral surface.

The experimental arrangement was described in detail previously (8). Briefly, electrodes of various projected surface areas were rotated at equivalent linear velocities up to 200 cm/sec in hydrogen- or argon-saturated sulfuric acid solutions. Small amounts of a concentrated solution of ferric sulfate were added from a precision buret.

Only glass and Teflon were in contact with solution. Greaseless ground glass joints were used to avoid possible contamination from lubricant.

Ferric sulfate was prepared from ferrous sulfate by oxidation with hot, concentrated sulfuric acid. Solutions were also prepared from recrystallized C. P. ferric sulfate. Water was triply distilled, one distillation being from dilute, alkaline potassium permanganate. The reaction vessel and all glass parts were cleaned with a saturated solution of potassium dichromate in concentrated sulfuric acid (cleaning solution) and rinsed with triply distilled water prior to use. Water drained uniformly and with zero contact angle from glass surfaces cleaned in this way.

Potentials were measured against S.C.E. and platinized through a high impedance L&N pH meter connected to a multiple-range, adjustable-zero, Dynamaster Bristol recorder. Alternatively, a Rubicon potentiometer was used together with a galvanometer of 0.007 μa/mm sensitivity. A capillary probe

with a bridge filled with solution of the same acid concentration was used in polarization measurements. The bridge led to an external S.C.E. A greaseless, closed stopcock prevented mixing of (air-saturated) solution outside the cell with solution in the cell, but had sufficient conductivity when wetted with solution to maintain electrical contact. Constant current was obtained through appropriate resistances from two banks of batteries, each consisting of three 45 v cells arranged in series to give 135 v.

Potentiostatic measurements were conducted with an Analytical Instruments Company potentiostat, an electromechanical device. It was necessary to use the same material for the test electrode and for a potentiostat reference electrode and to place the two electrodes in the same solution, since this potentiostat does not operate properly if a high impedance exists between the electrodes. Auxiliary electrodes of the same material as the test electrode were placed directly in the cell. Electrodes were cut from a bar of an iron-chromium alloy (stainless steel 410) of the following per cent composition: 12.39 chromium, 0.09 carbon, 0.44 manganese, 0.024 phosphorus, 0.022 sulfur, 0.27 silicon, 0.24 nickel, 0.07 molybdenum, and 0.12 copper. They were abraded with 2/0 emery paper, washed with reagent-grade carbon tetrachloride, left to dry, etched in 1:3 HNO_3, washed with conductivity water, etched in 1:3 H_2SO_4, and washed again.

Concentrations of various solutions were determined by analysis. The cell was thermostated at 30° ± 1°C.

Results and Discussion

General observations.—Electrodes were active in hydrogen-saturated sulfuric acid solutions with potentials in the neighborhood of −0.490 v *vs.* S.C.E. The corrosion potential increased with time at first, but drift became negligible (< 2 mv/hr) after about 3 hr of immersion. Electrodes were aged therefore for at least 3 hr before a run.

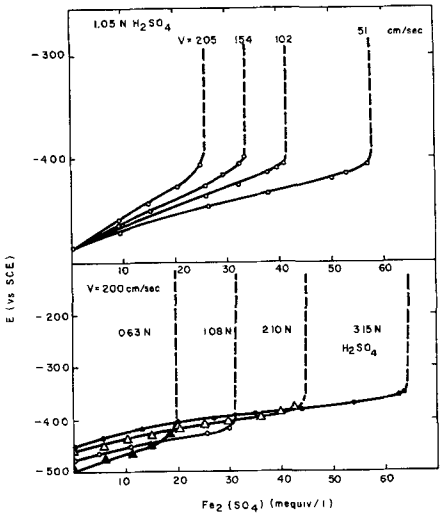

Fig. 2. Electrode potentiol as a function of ferric sulfate concentration at (top figure) various velocities in solutions of constant acidity and (bottom figure) in solutions of varying acidity at constant velocity. Dashed lines indicate discontinuous transition to potentials about +0.4 v vs. S.C.E. Tronsitions to passive potentials were irreversible (see text).

The potential moved in the anodic direction when ferric sulfate was added (Fig. 2). About a minute was required to establish a steady state after each increment in ferric ion concentration. A discontinuous transition from active to noble potentials occurred at a critical ferric ion concentration. The increase of potential was about 0.8 v. The critical concentration varied with flow velocity and acid normality as shown in Fig. 2.

Once passivity (noble potential) was produced, the electrode remained passive when the flow velocity was decreased. In the cases studied here, the electrode remained passive even when the rotational velocity was reduced to zero.

Passive specimens could be activated by cathodic polarization. The current required for activation increased with the amount of ferric ion in solution and with rotational velocity.

Detailed studies of the active region, of the transition to a passive potential, and of the passive potential region are presented below.

Active potential region.—Anodic polarization curves were obtained with a constant current source, with a potentiostat, and by following the potential as a function of ferric ion concentration.

For an electrode dissolving at a rate i_{corr} in a hydrogen-saturated acid solution

$$i_a = i_H = i_{corr} \qquad [1]$$

Here i_a is the partial anodic current corresponding to metal dissolution and i_H the partial cathodic current corresponding to hydrogen evolution. Both i_a and i_H are functions of potential.

If the electrode is polarized anodically by a constant current source, then

$$i_a = i_{appl} + i_H \qquad [2]$$

at a potential E more positive than the corrosion potential, E_{corr}. Since i_H decreases exponentially with potential, at sufficiently positive potentials

$$i_a \simeq i_{appl} \qquad [3]$$

where i_{appl} is the externally applied current. At sufficiently positive potentials, therefore, an anodic polarization curve obtained with a constant current source coincides with the anodic partial curve for the metal.

The same remarks apply to a polarization curve obtained with a potentiostatic device in this potential region.

If another reducible substance is introduced in the solution, the cathodic partial current, i_c, is the sum of the hydrogen evolution current and of the reduction current of the added oxidant. If reduction of oxidant occurs at a diffusion-limited rate, then

$$i_a = i_c = i_H + i_d \qquad [4]$$

where i_d is the limiting diffusion current and is independent of potential. At large flow velocities and large concentrations of oxidant, $i_d >> i_H$ and

$$i_a = i_c \simeq i_d \qquad [5]$$

A plot of potential against i_d under these conditions yields the anodic partial curve for the metal. Specific effects attributable to the oxidant (or to its reduction product) may be detected by comparing anodic partial curves obtained in this way with curves measured directly (Eq. [3]).

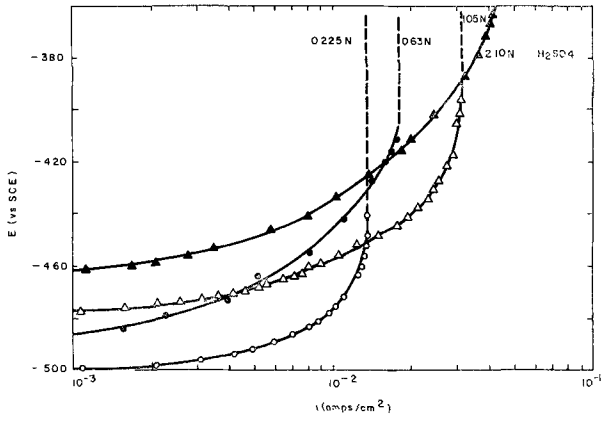

Fig. 3. Polarization curves with a constant current source in solutions of varying acidity. Dashed lines indicate transitions to potentials where oxygen is evolved ($> +1.0$ vs. S.C.E.).

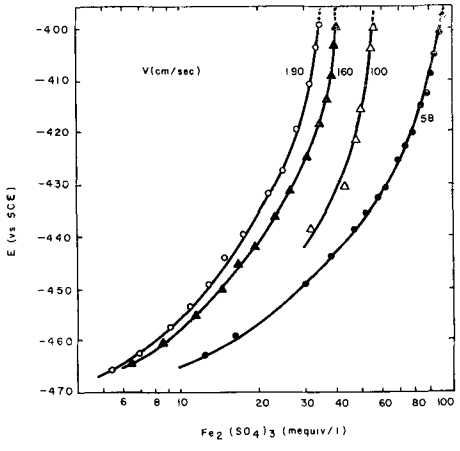

Fig. 4. Potential as a function of ferric sulfate concentration in N H_2SO_4 at various velocities.

Polarization curves obtained with a constant current source are shown in Fig. 3. Results were not time dependent in the active region, even at potentials close to the primary passive potential. Electrodes polarized for long periods (30 min) at a current density only 0.2 ma/cm^2 less than the critical did not show any tendency to become passive and the potential did not drift. In general, each current setting was held for 3 min, the same time interval used in runs with the potentiostat.

Figure 4 shows the dependence of the potential on concentration of ferric ion in the active region. The curves are similar to the polarization curves of Fig. 3. The primary passive potential, taken as the most positive potential observed before a transition to a passive state occurred, was essentially that found with a constant current source.

The reduction current for ferric ion must be known as a function of concentration and flow velocity in order to compare results of Fig. 4 with those of Fig. 3. If ferric ion is reduced at a diffusion-limited rate (see below)

$$i_d = \frac{n\mathbf{F}V_s}{A}\frac{dc}{dt} = n\mathbf{F}kC_{ox} \qquad [6]$$

Here n is the number of equivalents per mole of oxidant, $\mathbf{F}$ Faraday's constant, C_{ox} the concentration of oxidant, A the (projected) surface area, V_s the volume of solution, t the time, and k a rate constant. The rate constant depends on various hydrodynamic parameters but is independent of the nature of the electrode since the diffusion gradient is entirely within the liquid phase. Reaction rate constants used here were determined for the same experimental conditions from the dissolution rate of iron electrodes in ferric sulfate solutions (see ref. 8).

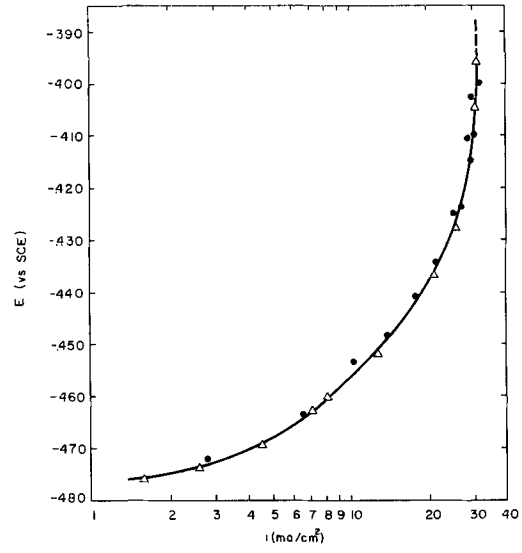

Fig. 5. Comparison of polarization curves obtained with a constant current source (triangles) and indirectly from the dependence of potential on $Fe_2(SO_4)_3$ concentration (circles). In the latter case, current densities were calculated from Eq. [6].

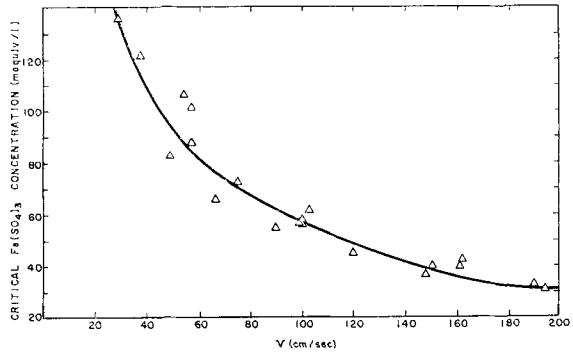

Fig. 6. Critical $Fe_2(SO_4)_3$ concentration required for passivity in N H_2SO_4 as a function of velocity. Points shown were obtained with six different electrodes.

Anodic polarization curves in N H_2SO_4 obtained with a constant current source and from Eq. [5] and [6], using constants given in ref. (8), are compared in Fig. 5. Essentially the same curve is obtained by either method.

Transition to a passive potential.—A discontinuous transition to a potential in the passive region occurs at a ferric ion concentration which depends on acid normality and flow velocity. The critical ferric ion concentration in N H_2SO_4 is plotted as a function of flow velocity in Fig. 6.

If the critical current density required for passivating the electrode is independent of the ferric ion concentration, then from Eq. [6]

$$i_p' = n\mathbf{F}kC_{crit} = \text{(constant)} \qquad [6a]$$

where C_{crit} is the concentration of ferric ion required to produce passivity.

For turbulent flow, the rate constant is given by [see ref. (8)]

$$k = (\text{Constant})\ V\ (R_d)^{-\beta}\ (Pr)^{-\gamma} \qquad [7]$$

Here V is the linear flow velocity, R_d is Reynolds number, $\frac{Vd_i}{\nu}$, with d_i the diameter of the electrode and ν the kinematic viscosity, and Pr is Prandtl's number, ν/D, with D the diffusion coefficient of ferric ion. For the conditions employed here [see ref. (7)]

$$k = (\text{constant})\ V^{0.80}$$

Substituting in Eq. [6a]

$$C_{crit} = (\text{Const.})\ V^{-0.80} \qquad [8]$$

A log-log plot of C_{crit} against the velocity (Fig. 7) has a slope of −0.79 in good agreement with Eq. [8]. Equivalent current densities required for passivity were calculated from Eq. [6a] and are given in Table I. The equivalent current density for passivity is independent of the concentration of ferric ion and differs by less than 10% from the critical current density found by anodic polarization. The rate constants used in calculating i_p' were determined in 0.5N H_2SO_4. Rate constants in N H_2SO_4 are probably smaller, mainly because of a decrease of the activity coefficient of ferric ion. The higher mean value of i_p' is probably due to somewhat larger rate constants in 0.5 than in N H_2SO_4.

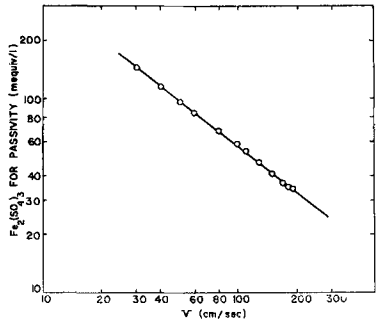

Fig. 7. Critical $Fe_2(SO_4)_3$ concentration for passivity as a function of velocity plotted according to Eq. [8]. The slope of the log-log plot is −0.79.

The conclusions drawn from Table I were confirmed by anodically passivating electrodes in solutions containing less than the critical ferric ion concentration. If ferric ion has no specific effect, the sum of the equivalent reduction current for ferric ion and of the applied current should be constant and equal to the critical current. Table II shows this to be true and also shows that the primary passive potential is not changed by ferric ion (see also Table I).

Table III compares equivalent current densities for passivity with ferric sulfate to critical current densities determined by anodic polarization for various acid normalities. Primary passive potentials are also given.

Passive potential region.—When the critical ferric ion concentration is exceeded, the electrode becomes passive with a mixed potential positive with respect to S.C.E. The potential depends on the ferric ion concentration and to a small extent on the normality of H_2SO_4, but is independent of flow velocity. It drifts slowly to more positive values, reaching a steady state after about 100 hr. At concentrations of the order of 0.010 equiv/1, the mixed potential is negative to the reversible Fe^{+++}/Fe^{++} potential, but it essentially coincides with the reversible potential at larger ferric ion concentrations (0.10 equiv/1).

The time dependence of the mixed potential in the passive region is probably caused by a decrease

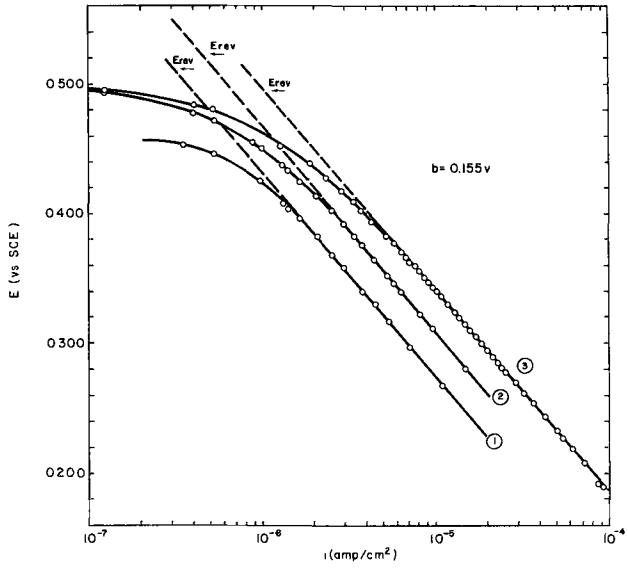

Fig. 8. Cathodic polarization curves of ferric sulfate on passive electrodes. Arrows indicate the reversible potential for the Fe^{+++}/Fe^{++} couple measured with a platinized platinum electrode. Curves 1 and 2 were obtained with solutions 0.0011M in ferrous ion and respectively 0.0138M and 0.0288M in ferric ion. For curve 3, $[Fe^{++}] = 0.005M$ and $[Fe^{+++}] = 0.066M$. Exchange currents are (from 1 to 3) 3.3, 4.3, and 8.1 × 10^{-7} amp/cm² while the Tafel slope is for all cases 0.155 v. The solution was N in H_2SO_4.

in the rate of oxidation of the passive electrode. In similar studies with type 304 stainless steel it was found (9) that the oxidation rate at constant potential was inversely proportional to time. This observation suggested a logarithmic oxidation law for the increase in thickness of the passive film. It is believed that type 410 stainless steel behaves similarly, although no detailed observations were made.

Cathodic polarization curves for reduction of ferric ion on passive electrodes were determined after the electrode had reached a steady state. Curves for various ferric ion concentrations are given in Fig. 8. At any given potential the current increases with ferric ion concentration. The Tafel slope is 0.155 v and is independent of ferric ion concentration. The Tafel curves measured here are similar to the ones reported by Stern (10) for 304 stainless steel.

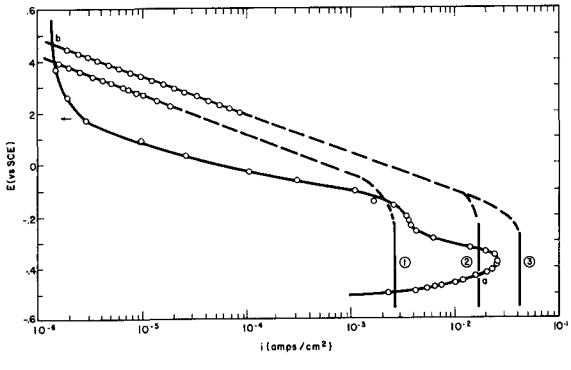

Fig. 9. Superposition of reduction curves for ferric ion and of the anodic polarization curve of Type 410 stainless steel in N H_2SO_4. Reading from curve 1 to 3, 0.010M Fe^{+++} at 55 cm/sec, 0.066M Fe^{+++} at 55 cm/sec, and 0.066M Fe^{+++} at 100 cm/sec. The upper sections of the reduction curves were determined by cathodic polarization on passive electrodes, while the solid lines at lower right are limiting diffusion currents obtained from Eq. [6] (see text). The dashed lines connecting the two are extrapolated from the passive region.

Potentiostatic curves.—Figure 9 gives a potentiostatic anodic polarization curve for type 410 stainless steel in N H_2SO_4. The primary passive potential is —0.380 v; the critical current density 28 ma/cm². These are to be compared with —0.395 v and 30 ma/cm² determined by polarization with a constant current source (see Table I). At each potential setting positive to E_{pp}, the current decreased rapidly at first and then changed slowly with time. The points shown were taken at 3-min intervals at which time the initial rapid change had come to an end.

Polarization curves for reduction of ferric ion are also shown in Fig. 9. The experimentally measured curves are connected with dashed lines calculated from the Tafel constants (slope and exchange current) and from the measured limiting diffusion current. It should be noted that the diffusion current is independent of the nature of the electrode and is a function only of the concentration and flow conditions.

General Discussion

Results shown in Figure 9 account completely for both the accelerating and the inhibitive effect of

ferric ion. Starting with a specimen freely corroding in acid solution, the figure indicates that ferric ion in concentration less than the critical increases the dissolution rate by providing an additional cathodic reaction which occurs at a rate limited by diffusion. The dissolution rate increases with increasing concentration and flow velocity until some critical current, i_p', is exceeded. This current is the same as the critical current found by anodic polarization (either potentiostatically or from a constant current source). When this critical current is exceeded, the electrode becomes passive with a dissolution rate of about 10^{-4} to 10^{-7} amp/cm^2.

At small concentrations and flow velocities two mixed potentials, indicated by points a and b on Fig. 9, are stable. The potential assumed by the system on addition of ferric ion depends on its previous state. Thus, if the electrode is originally active, ferric ion displaces the potential to (a), while if the specimen is already passive, potential (b) is stable. These observations account for the widely different concentrations required to produce and to maintain passivity. Thus, ferric ion causes a transition to a passive state only if its reduction rate exceeds i_p, which is in this case about 3 x 10^{-2} amp/cm^2. However, the reduction current necessary to maintain the electrode passive is only about 10^{-6} amp/cm^2, and decreases with time to probably less than 10^{-7} amp/cm^2.

An electrode in state (a) may be displaced to state (b) by polarization with an external source. When the sum of the applied anodic current and the equivalent reduction current exceed i_p (see Table II), the electrode undergoes a transition to a passive state which is maintained, since it is stable, even when the applied current is reduced to zero. Similarly, if the electrode is at potential (b), it may be activated by a cathodic current and remains active at (a) even after the applied current is reduced to zero. However, when the reduction rate of ferric ion exceeds the critical current density, the system is no longer bistable. In this case, the only stable mixed potential is in the passive region.

Figure 9 describes adequately the stainless steel-ferric sulfate system both at potentials more active than E_{pp} and in the neighborhood of the reversible Fe^{+++}/Fe^{++} potential. No experimental information is available, however, for ferric ion reduction at potentials between E_{pp} and about +0.1 v *vs.* S.C.E. An extrapolated curve is shown in this potential region in Fig. 9. This extrapolation is only approximate since the Tafel parameters for reduction are probably not the same on passive and active surfaces. It is likely that on active surfaces the exchange current is several powers of ten larger than on passive electrodes. An increase in exchange current shifts the reduction curve for ferric ion to the right, *i.e.* to lower overpotentials at any given current density. The dashed line must therefore be considered as giving a lower limit for the current at any given potential. The limiting current densities indicated by vertical solid lines in Fig. 9 are, of course, independent of the surface state of the electrode; their magnitudes were determined in separate experiments.

The starting point of this investigation was the attempt to determine whether adsorption of an oxidizing inhibitor, such as ferric ion, played a significant role in inhibition. If inhibitor ions are specifically adsorbed, changes in the composition of the surface state of the metal brought about by adsorption will be manifest in the anodic polarization curve of the metal. The results above clearly show that ferric ion produces no detectable change in the anodic behavior of stainless steel 410. It may be concluded that adsorption of ferric ion is unrelated to inhibition by this ion.

The Influence on the Oil Dielectric Strength of the Gas Pressure in Equilibrium with the Oil

Paolo Gazzana-Priaroggia and Giuseppe Palandri

Research Laboratories, Società Italiana Pirelli, Milan, Italy

ABSTRACT

A laboratory investigation of the influence of gas pressure on the electrical breakdown of thin oil, as used in oil-filled cables, was carried out at gas pressure between about 5 x 10^{-6} mm Hg and 1000 mm Hg. The test cell consisted of a glass container enclosing a platinum sphere gap (0.5 mm). Tests were carried out at ambient temperature. The results of this investigation showed that the dielectric strength of the oil is absolutely independent of the gas pressure, provided a perfect equilibrium is reached between the gas dissolved in the oil and the free gas remaining in the cell above the oil surface.

The influence of dissolved gas on the dielectric strength of oil has been discussed often and some data have been published giving the relation between oil dielectric strength and gas pressure (1, 2). These experimental results, of course, refer only to gas dissolved in the oil and not to gas in the form of bubbles or films.

This matter is not only of scientific but also of practical interest with regard to the problem of degassing oils used as impregnants of high-voltage electrical equipment. Published data, however, were not obtained under conditions of most interest to the present authors and they therefore undertook this study. For practical reasons it was decided to study the behavior of thin mineral oil as used in oil-filled cables under 50-cycles stress and to use dry air in the range of 5 x 10^{-6} mm Hg to about 1000 mm Hg.

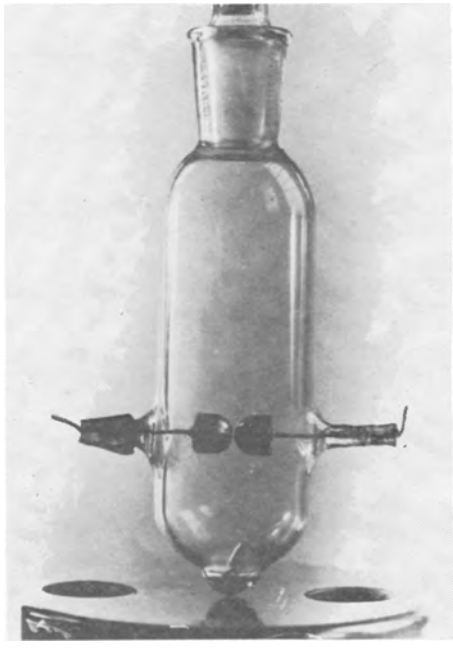

Fig. 2. Sphere gap cell

The apparatus is shown schematically in Fig. 1. Detail of the sphere gap cell S is given in Fig. 2.

Preparation of Tests

From the first test it appeared evident that to obtain sufficiently consistent results a certain cleanliness of the oil was necessary. To this end 55 cm^3 of clean, dry oil were introduced into the sphere gap cell. This oil had been filtered previously under vacuum through a glass filter. The sphere gap cell then was connected to the remainder of the testing apparatus. The oil was degassed by heating and stirring under vacuum at 110°C. To avoid fractionation of the oil while it was being degassed, the condenser R and the reflux condenser r were introduced into the vacuum circuit between the sphere gap cell S and the vacuum traps T.

The evacuation of the sphere gap cell was carried out by means of a diffusion pump for pressures below 10^{-3} mm Hg and with a mechanical pump, for

higher pressures. The absolute pressure was measured by means of a MacLeod gauge directly connected to the apparatus through a cold trap. To make sure that no moisture was present in the oil, the oil was degassed thoroughly and then saturated with dry air before reaching the desired pressure by pumping.

Each pressure was obtained and kept constant during the test by means of a vacuum limiter inserted in the vacuum circuit.

Test Results

The oil subjected to the investigation was the NJ 2 thin oil produced by Italian Standard Oil, having a viscosity of 25 centistokes at 20°C. 50-cycle a-c dielectric strength measurements were made as a function of the absolute pressure starting from 6 x 10^{-6} mm Hg, which was the highest vacuum obtainable with the present equipment, up to atmospheric pressure. The voltage was applied starting from 10 kv and then increasing it in steps of 10 kv/min.

From the first test it became evident that a considerable spread of results was obtained unless the greatest care was taken to make sure that the gas dissolved in the oil was in complete equilibrium with the free gas present in the sphere gap cell above the oil surface. If the saturation pressure of the oil was higher than the pressure of the free gas, the dielectric strength results obtained were considerably lower than the results obtained when a perfect equilibrium was reached. To overcome this difficulty, after the desired absolute pressure value was reached, the oil was left to cool down to the ambient temperature and kept under the desired pressure value with continuous stirring for about 24 hr before making any dielectric strength test.

To limit to as much as possible the influence of the static head of the oil, the oil level was kept at the minimum value necessary to obtain complete covering of the platinum spheres. This requirement determined the amount of 55 cm^3 of the oil which was mentioned before. The static head above the center point of the gap was 30 mm.

The results obtained are shown in the diagram of Fig. 3, in which average values and spread of results are indicated. For each pressure 10 different tests were made. No subsequent tests were made on an oil sample after the first discharge. This was done to avoid trouble due to gas evolution from the oil following breakdown since this could alter the pressure equilibrium. As can be seen, the average dielectric strengths lie on a straight line parallel to the abscissa, having on ordinate value of 400 kv/cm rms. All tests were carried out at ambient temperature (18°+25°C).

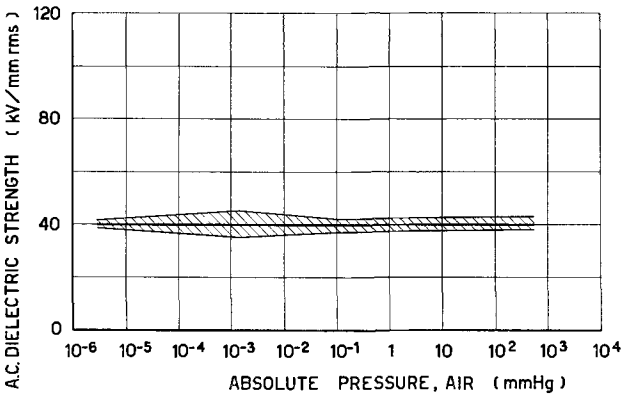

Fig. 3. A-C dielectric strength of thin cable oil vs. absolute air pressure.

Interpretation of Results

The values obtained for the average dielectric strength of about 400 kv/cm rms are lower than the results obtained by other investigators on pure liquid hydrocarbons under controlled physical conditions (3, 4). However, the consistency of the results obtained in the tests described in the present paper indicates that the tests were certainly governed by a well-determined breakdown mechanism. The conclusion could be that this mechanism differs from the breakdown mechanism ruling the tests described by the above-mentioned investigators.

It seems to the authors that an explanation may be found in the fact that the breakdown mechanism of absolutely pure dielectric liquids probably is ruled only by the movement of electrons, accelerated by the electrical field, which ionize the oil molecules; on the other hand the breakdown mechanism with which the tests described above are concerned probably is ruled by particles much bigger than electrons such as molecular aggregates or submicroscopic impurities, still accelerated by the electrical field but unable to ionize the oil molecules.

Two facts are of great importance in understanding these tests: (*a*) the breakdown is practically independent of the saturation pressure of the oil provided a perfect equilibrium is reached between the gas dissolved in the oil and the free gas above the oil surface; and (*b*) the breakdown strength is lowered when the saturation pressure is higher than the pressure of the free gas.

These two facts, combined with the assumption made above that particles much bigger than electrons are responsible for the breakdown of oils as used in industrial apparatus, have suggested the following theory:

A charged particle in suspension in the oil is accelerated by the electrical field and tends to cavitate the liquid in its wake; if the saturation pressure of the gas dissolved in the oil is equal to the pressure of the free gas acting on the oil surface, this tendency is very much reduced. Breakdown occurs when the movement of the particle becomes quick enough to create a cavitation in which gaseous ionization may take place.

Within the conditions of the present investigation it can be concluded that, when this particular state is reached, ionization occurs whatever the pressure of the gas dissolved in the oil, provided this is not higher than a pressure approximately equal to the atmospheric pressure.

Tests not reported in this paper indicate that when the gas pressure is higher than atmospheric the breakdown strength does not remain constant but tends to rise above 400 kv/cm rms. This suggests that in this condition gaseous ionization does not follow immediately when the cavitation onset level is attained but that a higher field is required to pro-

duce bubbles of such a dimension to cause ionization of the gas evolved in the cavity.

Electropolishing in Cyanide Electrolytes

F. Sullivan and E. H. Newton

Arthur D. Little, Inc., Cambridge, Massachusetts

ABSTRACT

Mirrorlike polished surfaces can be obtained on silver, sterling silver, gold alloys, copper, and brass by electropolishing in cyanide electrolytes. The optimum current density and agitation rate to obtain a brilliant polish varies widely with the metal being polished. For silver and silver plate a current density range of 1.1-2.8 ASD at 45 cm/min is necessary; for copper and brass the range is 2-8 ASD at 1300-2600 cm/min. Agitation is not critical in gold alloy electropolishing because the very high current density (>250 ASD) induces copious gassing. Rapid periodic movement of sterling silver into and out of the polishing bath within a current density range of 10-16 ASD is required to mirror polish this alloy.

Anyone who has observed the anodes in a copper or silver cyanide plating bath may have noted the different appearance they assume at various times, dull and etched, bright or filmed. These surface changes represent the three conditions important in characterizing the events taking place at the anode during electropolishing, that is, the etching region, the polishing region, and the permanent film region of the voltage-current density relationship.

This paper covers details of the commercial electropolishing of silver plate and pilot plant studies on the electropolishing of sterling. Laboratory electropolishing of gold alloys, copper, and brass is also discussed. All of the studies were carried out in cyanide electrolytes.

The relationship between most of the operating variables encountered in polishing cyanide soluble metals in cyanide electrolytes is most conveniently expressed in the form of voltage-current density or polishing curves. The information necessary to construct a polishing curve is obtained by noting the current passing through the cell and the appearance of the anode while increasing the voltage at 0.2 v increments. In order to start with a uniform surface, a light etch is first produced on the anode. The anode is removed at each voltage step and the degree of etch or polish determined.

Electropolishing of Silver Plate

One series of experiments designed to determine the effect of agitation rate on the shape of the polishing curve was carried out in a bath which was 0.3M with respect to silver cyanide, free potassium cyanide, and potassium carbonate (1). The anode was a silver-plated copper panel rotated at various speeds.

Figure 1 shows typical polishing curves for silver plate at three agitation rates. The polishing zone is indicated by the dotted lines at the letter P. In this area the anode was mirror bright all over. Below the polishing zone the silver surface was dull and etched. Above the polishing zone, the anode assumed a cloudy blue appearance. The broadest polishing range occurred at the intermediate agitation rate. With no agitation the polishing range was very

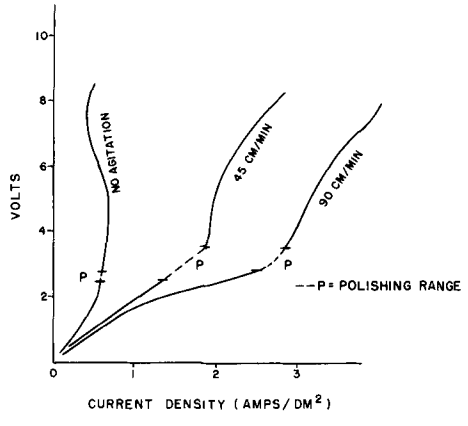

Fig. 1. Typical polishing curves for silver plate at various agitation rates. Bath composition: silver (as metal), 32.4 g/l; KCN (free), 19.5 g/l; K_2CO_3, 42 g/l.

narrow and operating in this range was impractical. At the higher agitation rate the polishing range also narrowed.

Temperatures ranging from 10°-50°C had only minor effects on the polishing results obtained. In general, the higher the temperature the higher the current density at a given voltage. This would be expected from the increased conductivity. While good polishes could be obtained at higher temperatures, the results showed no improvement over those obtained at room temperature. At the higher temperatures, polishing was more difficult to control because of slight etching action after the current had been cut off. Cyanide breakdown was more rapid at higher temperatures. At low temperatures, throwing power appeared somewhat improved.

Commercial electropolishing of silver plate.—Silver plate has been electropolished commercially by several large silver companies on both continuous and batch installations (2). Electropolished surfaces of high quality have been produced on such materials as costume jewelry, novelties, holloware, and flatware. The electropolishing solution most generally used commercially is shown in Table I (3). The cathodes may be either silver or stainless steel with an area at least twice than of the anodes. The work should pass through the bath by either straight line or reciprocal motion at a rate of approximately 45 cm/min. The voltage is generally between 2.5 and 3.5, but these limits may be extended in either direction where conditions demand. The current density is in the range of 1.1-2.8 amp/dm^2 (4).

When the correct polishing conditions exist, a uniform brown film forms on the anode remaining there throughout the polishing cycle. The agitation must be smooth to protect this anodic film which is essential for optimum leveling and brightness. It is believed that this polishing film permits the selective dissolution of the projections or irregularities in the plate thus producing leveling and brightening.

In the continuous flatware process used by a large silver company, spoons, forks, and other articles are mounted in racks and conveyed through a typical cleaning and plating cycle (5). After the plating rinse and pre-dip operations, they pass through an electropolishing bath of the composition previously described. The work moves through the bath at approximately 45 cm/min and remains in the solution about 20 sec. Rinse and pre-dip cycles are advisable, because without these, the drag-in of silver plating solution will rapidly change the composition of the polishing bath and necessitate frequent analysis and adjustment.

Table I. Bath composition and conditions for electropolishing silver plate

Composition	Grams/liter
Silver (as metal)	32.8
Free potassium cyanide	19.5
Potassium carbonate	41.5
Polishing conditions	
Voltage	2.5-3.5
Current density	1.1-2.8 amp/dm^2
Agitation rate	45 cm/min
Temperature	ambient

Holloware.—Silver-plated holloware has also been successfully electropolished by several large silver companies. Articles such as trays, coffee pots, creamers, Paul Revere bowls, baby cups, and many other items have been polished commercially with excellent results. In general, polishing conditions are essentially the same as those for polishing flatware, except the polishing time usually ranges from 1 to 1½ min and the agitation should be reciprocal. Articles to be electropolished should be racked so as to allow the least resistance or turbulence as they pass through the bath.

In articles such as deep bowls, it may be necessary to adjust the distance between the cathodes and anode to obtain maximum throwing power. In some instances internal anodes are necessary for polishing deeply recessed surfaces.

In a few cases, "thieves" have been used to protect certain areas from receiving too much current. These points of high current density, unless shielded, will have a smoky blue appearance.

Advantages and Limitations.—Let us consider a few of the advantages of electropolishing silver. Hand buffing is a slow, expensive, dirty operation. By electropolishing, wheel finishing costs can be reduced from 20 to 100% depending on the class of the article. The 100% figure may sound a bit strange but in costume jewelry and some special lines wheel finishing has been eliminated completely. Electropolishing is ideal for intricate shapes or filagree work where buffing is extremely difficult or impossible. The saving in refining costs compared to the savings realized by refining of buffing dust is appreciable. The silver removed from the work plates out on the cathodes and is recovered in pure metallic form.

Electropolishing in cyanide is a short operation, and many pieces can be processed at one time. Finished articles have more silver more uniformly distributed on them than their buffed counterparts. If properly carried out, it is possible to obtain as high a luster by the removal of 2% of the silver deposit as would be possible by removing 5-10% by hand buffing.

One of the outstanding advantages in electropolishing holloware is the excellent brightness which results in difficult to buff areas such as the inside of handles. The saving in finishing costs and the other advantages previously mentioned in the electropolishing of flatware also apply to holloware.

Although in certain applications a saleable finish can be produced directly from the tank, electropolishing does not necessarily eliminate all finishing operations. Electropolishing cannot exactly duplicate a finished buffed surface. In the field of flatware, for instance, esthetic requirements often demand that the brilliant electropolished glitter be toned down or softened. This would necessitate a wheel operation.

The quality of the plate and the conditions of the basis metal have a marked influence on the resulting polish. The amount of silver removed is generally so small that imperfections in the base

are not eliminated. In fact, the high luster tends to accentuate flaws. Good pre-plate finishing and a smooth electrodeposit are prerequisites for good electropolishing.

There was considerably more interest in electropolishing silver plate ten years ago than at the present time. The popularity of electropolishing now appears to have diminished appreciably due to the advent of several of the modern proprietary bright silver plating baths. Electropolishing does, however, have its place in certain applications such as the continuous production of silver flatware where control of the polishing bath is not as critical as the control of the bright plating bath.

Sterling Silver

In the laboratory sterling silver has been electrolytically polished to a specular brightness in a cyanide bath. Mirror bright polishes have been obtained on flatware, holloware, costume jewelry, and other commercially produced sterling articles (6). Because of certain difficulties which will be discussed later, the electropolishing of sterling has not yet progressed beyond the pilot plant stage.

The bath composition was only slightly different from that used for electropolishing silver plate, but the form and speed of agitation differ greatly. The recommended bath is shown in Table II and was operated at room temperature. The anode, or work, was agitated by repeated immersions and withdrawals from the solution. The cycle of anode movement may be termed a stroke, and the work was lifted clear of the solution with each stroke. This had the effect of cutting the current on and off. The best polishing occurred at current densities between 10 and 16 amp/dm^2 at a potential of from 2.5 to 12 v. The agitation was at least 20 strokes/min and the polishing time approximately 1½ min. Articles were positioned on the racks so as to produce the least turbulence.

The exact reason for the marked improvement in the polishing of sterling silver when repeatedly removed from the solution is not known. Exposure of the film to air may allow the cupric ion formed by evolution of oxygen during the anodic process to be reduced by the cyanide to the more stable cuprous state. Removal of the work from the bath and the consequent draining of excess cyanide could assist in reestablishing the polishing film. The film formed on copper during polishing in cyanide solutions is not as readily dissolved as the film formed on silver. Consequently, the rate of agitation during the polishing of alloys containing copper

Table II. Bath composition and conditions for electropolishing sterling silver

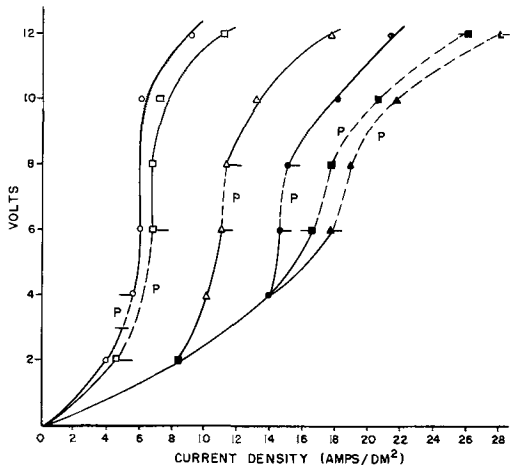

Fig. 2. Polishing curves for sterling silver at various agitation rates. - - P = polishing range; length of stroke = 26 cm. Agitation rate: ○, 10 strokes/min; □, 20 strokes/min; △, 40 strokes/min; ●, 60 strokes/min; ■ 80 strokes/min; ▲, 100 strokes/min.

must be considerably higher than during the polishing of pure silver to increase the cyanide ion concentration of the anodic film. Agitation in the solution without the dunking action is not sufficient to polish sterling. Figure 2 shows typical polishing curves for sterling silver at various agitation rates. Good polishing was noted only in the dotted areas designated by the letter P. Below this area is the etch region and above is the permanent film zone. At the higher agitation rates, the polishing range is extremely broad.

Interrupting the current without withdrawal of the anode from the solution will result in semi-bright etched surfaces. For example, a piece of sterling with an area of 24 cm^2 was immersed in a bath at 5 v, and the current was turned on and off at a rate of 30 times/min. A brown film appeared and disappeared with the current. At the end of 2 min the sample was semi-bright and etched. Turning the current on and off 60 times/min did not improve the brightness.

A series of experiments was carried out to determine the behavior of sodium and potassium salts in sterling silver polishing baths. Three compositions were investigated: (*a*) containing mixed sodium and potassium salts, (*b*) containing all sodium salts, and (c) containing all potassium salts. Figure 3 shows the effect of these cations on the shape and position of the polishing curve. The potassium bath (No. 3) polished at a lower voltage but higher current density than the other two solutions. The composition containing all sodium ions produced the poorest polish. The best polish was noted in the straight potassium bath.

An interesting application is in controlling the weight of sterling while polishing takes place. In the laboratory seven sterling silver soup spoons were suspended from a rack and repeatedly immersed and withdrawn from the polishing bath at a rate of 30 times/min. Five volts was applied at a current density of 15 amp/dm^2. The original weight of the spoons was 304.3 g, but after several minutes of operation the weight was reduced to 278.3 g. The

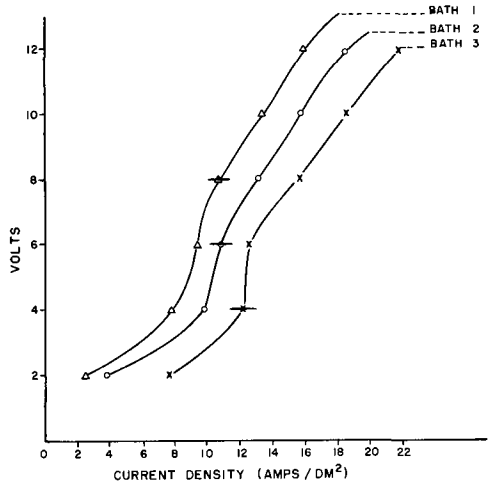

Fig. 3. Polishing curves for sterling silver in various bath compositions; polishing above line, etch region below line; agitation, 60 strokes/min. Composition (g/l): bath 1, 2, 3, AgCN, 40.2; bath 3, KCN, 26; bath 1,2, NaCN, 19.6; bath 1,3, K_2CO_3, 41.5; bath 2, Na_2CO_3, 31.8.

spoons were all very bright and required no mechanical buffing to attain further brilliance.

The sterling silver polishing bath will remove fire scale. This method has many obvious advantages over the nitric acid solution commonly used for this purpose.

Pilot plant studies.—In a 100-gal sterling polishing bath installed at one of the large sterling silver companies, thousands of pieces of flatware and holloware were electropolished to determine the utility of the bath. The brightest polishes were obtained on flatware, and more than 5000 pieces were processed. Although bright polishes could be obtained, difficulty was encountered in pit removal. For example, in manufacturing flatware from heavy wrought material the forming hammer closes up many defects present in the stock. Electropolishing tends to open up these defects. In polishing holloware, the immersing and withdrawing operation sometimes created drainage and racking problems. However, after a 6-month operating period, the bath was still performing well, a fact which indicates that there was no stability problem.

As a result of this study and subsequent laboratory work, it is felt that the process is most suitable for polishing specialty items such as trays or coffee pots and small articles such as costume jewelry. Approximately 1 hr of finishing time could be saved by electropolishing large sterling trays, and 20 min could be saved by electropolishing coffee pots. Since only a few hundred of these items were made per year, the savings from electropolishing these articles did not justify installing the process. Other applications which appear more promising are weight reduction and the removal of fire scale.

Other Metals

Electropolishing of gold alloys.—The investigation into the electropolishing of gold alloys was carried out as part of a general program for determining the anodic behavior of metals in cyanide solutions. Most of the work was done in 3*N* potassium cyanide solutions to avoid complicating reactions. No attempt was made to develop a practical polishing bath.

All the tests were run in 2-l beakers containing 1 l of solution; a new solution was used for each experiment. Four sheet copper cathodes 8.3 cm x 6.4 cm were hung symmetrically around the sides of the beaker. The samples used were silver-gold and copper-gold binary alloys, (18, 16, 12, and 10 karat). All of the copper-gold alloys looked like copper. The silver alloys varied in color from the bright yellow brass of the 18 karat to the silvery color of the 10 karat. Anodes were 2.54 x 5.08 x 0.16 cm. The cathode to anode ratio was approximately 8:1. The cathode to anode distance was 4.3 cm.

For most of the tests the sample was rotated at 22 rpm in a circle of 4.45 cm diameter which corresponds to a linear speed of approximately 310 cm/min.

The potential was increased stepwise from 0 to 20 v. Each voltage was applied for 30 sec, and readings were taken on the ammeter at the start and after equilibrium had been reached. After every few points the voltage was dropped to the etching region and a very light etch given to the surface so that the previous condition of the surface would not influence the results. In the very high current density regions (220-330 amp/dm^2) the time at each point was shortened to 20 sec so the sample would not be dissolved too rapidly. A small microscope lamp was used to illuminate the specimen while in the bath. The sample was removed from the bath, washed, and dried at each point when any change was observed.

Complete polishing over the whole surface of the samples was obtained only at the higher voltages and current densities. (16-20 v, 240-350 amp/dm^2). All the alloys polished like pure gold in 3N potassium cyanide. No good polishing was observed in the voltage range where copper or silver are ordinarily polished.

Voltage-current density curves on these alloys showed only slight differences. With the copper alloys at a given voltage, slightly higher current densities were obtained with decreasing gold content. With the silver alloys the curves showed no correlation with gold content. Figure 4 shows a typical polishing curve for a binary gold alloy.

Individual cases varied somewhat, but to reach the polishing range the general pattern as the voltage was increased was as follows: 1, Linear rise of the current with voltage. No films are present in this region and the surface of the anode is etched; 2, polarization point at which film formation begins; 3, polarizing region in which soluble or loosely adherent films are present. In this region the anode has an etched surface with or without edge polishing; 4, more sloping, less polarized region usually accompanied by soluble films with the surface of the anode partly polished; 5, second etch region with no films and a linear rise of current with voltage; 6, partly polished region with no films and a linear rise of current with voltage; 7, polishing region. Surface of the anode is completely polished. Vigorous gassing is present in this region at both the cathode and anode.

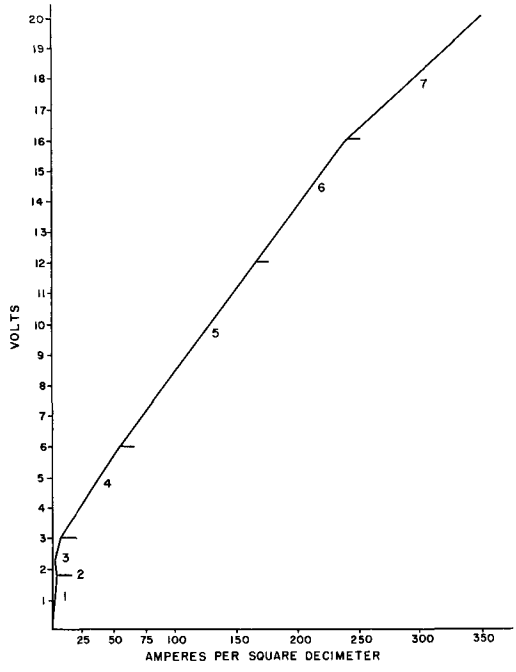

Fig. 4. Typical polishing curves for binary gold alloys; bath composition, 3N KCN; agitation rate, 310 cm/min. Appearance of gold surface: 1, etch; 2, start of film formation; 3, etch and/or edge polishing; 4, part polish, part etch; 5, etch; 6, part polish, part etch; 7, polish.

Agitation of the work was not critical. Comparisons of data obtained in experiments in which the work was not agitated with experiments in which the work was rotated in one direction at 310 cm/min showed only slight differences.

Although all the tests were started at room temperature, no attempt was made to control temperature so by the time a complete curve was plotted, the solution had been warmed up to about 45°C. One experiment was carried out in the reverse order starting with 20 v at room temperature and ending at the low voltage and higher temperature. No significant difference was noted between the curve prepared from this data and the previously described curve. This indicates that temperatures from 20° to 45°C have little or no effect on the polishing curve.

Although most of the work was carried out in 3*N* potassium cyanide solutions, concentrations of 0.3*N*, 1*N*, and 7*N* were also studied. None of these polished as well as the 3*N* solution.

Experiments were also performed with 3*N* sodium cyanide and 3*N* barium cyanide instead of potassium cyanide. The sodium cyanide gave a slightly improved polish at high current densities and voltage. The barium cyanide solution polished similar to the potassium cyanide bath. Current density-voltage curves for these cyanides closely resembled the 3*N* potassium cyanide curve.

Very little change in the quality of polish or current density-voltage curves was obtained by adding the following materials to the 3*N* potassium cyanide bath: additional potassium gold cyanide, copper cyanide, potassium ferrocyanide, potassium ferricyanide. However, the addition of 30 g/l potassium tartrate shifted the polishing range to a lower

Table III. Bath composition and conditions for electropolishing copper and brass

voltage. Between 5 and 10 v and at 55-110 amp/dm^2, a good polish was obtained over the whole surface. With the 3*N* potassium cyanide bath alone, no polish or only part polish-part etch was obtained in this range. At higher voltages and current densities, the tartrate-potassium cyanide bath acted the same as plain potassium cyanide.

Brass and copper polishing.—In the laboratory copper and brass have been electropolished to mirror brightness in cyanide polishing baths. The most brilliant finishes were produced on brasses containing 70% or more copper. Leaded brass could not be polished satisfactorily.

The electropolishing solution which we have found most effective is shown in Table III. Polishing was carried out at a current density of 2-8 amp/dm^2 at agitation rates ranging from 1300-2600 cm/min. The extremely high rate of agitation was a major problem. On a curved surface where there is streamlined flow, mechanical agitation was possible. However, with flat surfaces and odd shaped items, very fast hand agitation was necessary to produce good polishing. We were unsuccessful in our attempts to duplicate the hand agitation by mechanical means.

Figure 5 shows the effect of three agitation rates on the polishing curves obtained by electropolishing short lengths of red brass pipe in the above bath. The initial "free cyanide" was about 50 g/l and the *p*H was 12. The pipe was agitated by rotating it in a circular path 7.6 cm in diameter. No polishing occurred at the lowest agitation rate. The best mirrorlike polish was obtained at 2600 cm/min at the knee of the curve, that is, between 2.3 and

Agitation rate	very fast hand
Temperature	50°-60°C
Time	3-5 min

2.5 v at about 4 amp/dm^2. Under these conditions 68% of the metal lost from the polished anode plated out on the copper cathodes.

Pure copper may also be polished in the above bath. An additional stability problem was encountered because the copper tended to build up in the solution while the zinc was being depleted. The addition of a zinc anode remedied this, permitting brass to plate out during the electropolishing operation, thus maintaining the desired solution balance. Occasional readjustments of the copper and zinc concentration and close control of "free cyanide" were necessary for continued operation of the bath.

The quality of an electropolished surface depended to a great extent on the grain size of the metal. The effect of grain size of 70/30 brass on the resulting polish was noted in a series of experiments carried out in the polishing bath shown in Table IV. The composition of this solution departed considerably from that used in previous research and was similar to the type of bath used in brightening or stripping solid gold rings (7). The bath was operated at a higher temperature and current density than the bath described previously. Brass did not plate out at the cathode so periodic analysis of the bath was necessary for continued operation.

Five panels of 70/30 brass with grain sizes varying from 0.010 to 0.075 mm and hardnesses ranging from ½ hard, ¼ hard, and soft were polished for 3 to 5 min using very fast hand agitation. A uniform polish could be produced only on panels that were bent into a semicircle. Although all panels were polished to some degree, rolling marks were not completely removed in any case. The panels with the smallest grain sizes were polished to a mirror bright state. The polish on the larger grain size brass samples was decidedly inferior. The hardness of the panels had no effect on the quality of the polish.

Particle Growth during Zinc Sulfide Phosphor Preparation

A. Kremheller[1] and S. Faria

General Telephone and Electronics Laboratories, Incorporated, Bayside, New York

ABSTRACT

The influence of processing conditions, such as time and temperature, and the effect of fluxing agents on the particle size and concomitant properties observed during zinc sulfide phosphor preparation are reported. The particle size increases exponentially with the reciprocal firing temperature and as the square root of the firing time when phosphors are prepared in open boats; the activation energy and frequency constant depend on the flux employed. A particle size anomaly is observed when zinc sulfide powder containing zinc chloride is processed near 1000°C in sealed quartz vials. This anomaly, which can be ascribed to the Hedvall effect, is accompanied by anomalies in chloride retention and crystal structure.

Commercial zinc sulfide phosphors are usually prepared by heat treatment of the host material in the presence of an activator and a coactivator (1). The average particle size of the zinc sulfide crystallites increases during this treatment, and the final particle size depends on the processing conditions and the additives. Tiede and Schleede (2) observed that the fluxing agent promotes crystal growth at low temperatures by lowering the melting point of the base material. A few years later Schleede and Gantzckow (3) proposed that a thin film of the fluxing agent dissolves small particles of the base material, and that subsequent precipitation takes

[1] Present address: Republic Aviation Corp., Farmingdale, N. Y.

place on large particles with concomitant increase of the average particle diameter.

Work and Odell (4) discussed particle size and the growth mechanism during heat treatment of zinc sulfide powder and observed that the development of pigment properties of zinc sulfide is closely related to changes in particle size. The authors indicated that their experimental data agree quite well with the theory of growth by vaporization; they also pointed out that the theoretical considerations are quite similar for particle growth by dissolution and subsequent reprecipitation. They found that the particle size is primarily a function of the processing temperature, and only secondarily of time. Leverenz (5) established that zinc sulfide crystals grow in approximate proportion to exp $(-E/kT)$, where E is the activation energy connected with the growth process. The growth rate decreases with increasing time because the crystals approach a size distribution that is determined largely by the temperature and by the nature and sizes of the initial particles. Bube (6) confirms that the particle size varies exponentially with the reciprocal of the processing temperature and finds an activation energy of 1.3 ev for the host material without additives. Shionoya and Amano (7) showed that the change of the particle volume with processing time is proportional to the reciprocal processing temperature. The proportionality constant is considered to contain the activation energy, which is nearly three times as high without as with the fluxing agent. They found that the increase of the particle volume with time t is constant at constant temperature, which is not in agreement with our results (8) which lead to a $t^{3/2}$ dependence, as explained in the discussion section.

The present paper deals with the influence of time and temperature of heat treatment and the effects of various additives on particle size, crystal structure, and luminescence of zinc sulfide powder. This includes processing in open boats and sealed quartz vials, study of the final product, and elucidation of the growth mechanism as a function of experimental conditions. The implications of the experimental data as to the influence of the various processing parameters on particle growth and related properties are discussed.

Experimental

The zinc sulfide powder and the additives used in these experiments were essentially free of heavy metals to the limit of spectrographic detectability. The zinc sulfide powder contained about 0.45% by weight of sulfate and less than 0.002% of chloride.

The samples are kept in transparent quartz boats and heated in transparent quartz combustion tubes in an atmosphere of helium during open-boat processing; the linear flow rate was about 1 cm/min. Another series of experiments was conducted with sealed evacuated quartz vials containing the base material and the source of the coactivator. The purpose of using sealed vials was to keep the flux concentration constant during the heat treatment.

A simplified gas adsorption method, microscopic counting, x-ray analysis, and electron photomicrography were employed in determining the particle size and the crystal structure, as discussed previously (9). The same publication (9) also describes a semi-quantitative method which was employed in the present investigation to obtain a measure of photoluminescence intensity. The determination of chloride has been discussed in some detail in a previous publication (10). This method permits one to determine quantitatively amounts of 0.001% by weight of chloride in 1 g of zinc sulfide; results have been found to be reproducible and accurate.

Results

Particle growth studies are of interest by themselves and are a first step in controlling the particle size so that phosphors of a given particle size can be prepared. For instance, a given particle size can be attained by processing the powder at low temperature for a long time or at high temperature for a short time; proper selection of processing conditions will depend on other requirements on the final product.

While the processing conditions are important with respect to particle growth, it is well understood that the initial particle size and the size distribution also have to be considered, especially, when zinc sulfide powder is processed at low temperature and/or for very short times. For this reason, our experimental conditions have been selected in such a manner that the initial particle size can essentially be neglected with respect to the final size. In the present study the average initial particle diameter was 0.02 μ, and the final diameter was at least ten times as large.

In order to study the influence of the flux and processing conditions without additional complications, activators were not added. The experiments and results are arranged in two sections. The first part presents phosphor processing in open boats, while the second part deals with the study of material preparation in sealed quartz vials.

Phosphor Preparation in Open Quartz Boats

Zinc sulfide powder without flux addition was processed at temperatures from 200° to 1250°C for up to 40 hr in open boats. It was found that the average particle size increases exponentially with the reciprocal of the processing temperature, as is implicit for a typical case in Fig. 1. In another series of experiments, the processing temperature was

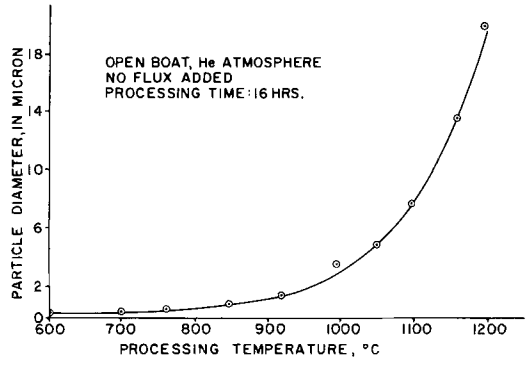

Fig. 1. Average particle diameter as a function of processing temperature.

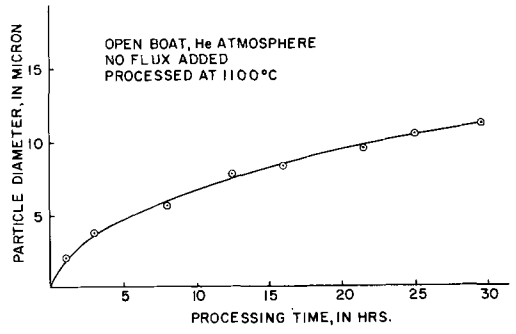

Fig. 2. Increase of average particle diameter with processing time.

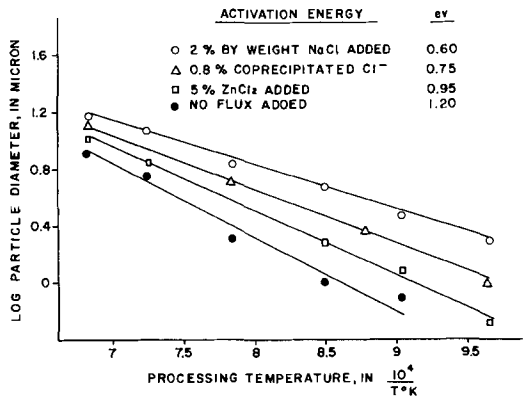

Fig. 3. Dependence of average particle diameter on reciprocal processing temperature; fluxing agent as the parameter.

kept constant and the processing time was varied. A typical result of this study is presented in Fig. 2. The curve corresponds to the hypothesis that the particle size increases with the square root of the processing time. Accordingly, the average particle diameter X can be expressed[2] as a function of processing temperature T and time t by the equation:

$$X \cong At^{1/2} \exp(-a/T) \qquad [1]$$

Equation [1] contains the constants A and a, which are found to be $A = 3.15 \times 10^4$ micron hr $^{-1/2}$ and $a = 1.25 \times 10^4$ °K, when no coactivator is added.

X-ray diffraction analysis indicates that the originally cubic zinc sulfide powder is transformed into the hexagonal form when processed above 1100°C. At processing temperatures below 900°C the processed material is cubic, while amounts of hexagonal phase that increase with the temperature are found in the intermediate interval. The samples exhibit some luminescence if they are processed above 1000°C.

In another series of experiments, various amounts and kinds of fluxes were added. It was found that the fluxing agent changes the constants A and a in Eq. [1]. Effective fluxing agents lower the value of a, which may be interpreted as a decrease in the activation energy needed for the growth process. Figure 3 represents data that are in good agreement with Eq. [1]; the experimental points are plotted for zinc sulfide without flux and with 2% by weight of NaCl processed for 2 hr at various temperatures. The constants in Eq. [1] are $A = 2 \times 10^3$ micron hr$^{-1/2}$ and $a = 7.5 \times 10^3$ °K when 2% NaCl is used as the additive. The same Eq. [1] is obeyed when 5% by weight of zinc chloride or 0.8% of coprecipitated chloride are present (see also Fig. 3).

Phosphor Preparation in Sealed Quartz Vials

In order to keep the concentration of the fluxing agent constant, zinc sulfide powders with flux addition were heat-treated in sealed quartz vials. In one series of experiments a constant amount of various halides was added before processing for 3 hr at 850°C. The purpose of this study was to compare qualitatively the influence of various halide anions and of the cations zinc and sodium on particle growth and attendant properties. Figure 4 shows photomicrographs of zinc sulfide processed with 0.007 gram atom of halide per mole zinc sulfide. Zinc sulfide with sodium halide leads to a growth habit in the form of triangular plates, while zinc halides lead to spherical polyhedra, similar to those observed without coactivator. Table I presents data on these samples. It is seen that the average particle diameters of samples with sodium halide addition are larger than those with zinc halide addition. The sodium halides favor the formation of cubic structure; however, one also observes that the cubic samples are larger in particle size than the partially hexagonal samples. It appears that flux action leading to large particles requires that the sodium halide be liquid. While there are considerable variations from sample to sample in various properties, the zinc halides are essentially as effective as the sodium halides with respect to the photoluminescence intensity.

Another series of experiments yielded quite unexpected results, when 0.25% by weight of zinc chloride was physically admixed to zinc sulfide in sealed vials which were subsequently heat-treated for various times and temperatures. Equation [1] is not valid in this case, because one observes a peak in particle size as a function of processing temperature near 1000°C, as shown in Fig. 5. The curve in Fig. 5 shows the dependence of the particle size on the temperature of processing from 800° to 1200°C for a processing time of 4 hr; the curves for 2, 8, and 16 hr, which are not shown, vary in absolute particle size while their general shape is the same. The anomalous peak near 1000°C is accompanied by anomalous behavior with respect to the crystal structure and the amount of retained volume chloride,[3] as shown in Fig. 5. It was found that these

[2] The left side of Eq. [1] is equal to $(X^2 - X_0^2)^{1/2}$ which has been approximated by X since $X > X_0$.

[3] See definition of "volume chloride" in ref. (10).

zinc sulfide phosphors contain some hexagonal structure even at processing temperatures below 950°C, while the pure hexagonal structure occurs above 1050°C and pure cubic structure is found in the intermediate range. The amount of retained volume chloride is lowest in the region of the anomalous peak. It appears that the anomaly near 1000°C can be explained as being due to the Hedvall[4] effect (11), since one observes a considerable amount of randomness in the crystal structure of zinc sulfide crystals (especially for those of cubic structure) that are annealed at this temperature (12). The degree of randomness was found to be enhanced considerably during annealing in the presence of halide when compared with samples containing no additives. A series of samples without additives was used as a blank; in this case the anomalous growth peak was absent.

It appears that the randomness in the crystal structure seems to facilitate crystal growth near 1000°C while the degree of incorporation of chloride is actually decreased. One may also conclude that the low concentration of volume chloride in particles processed near 1000°C can be interpreted by assuming that the growth rate is increased by randomness while the diffusion or incorporation of chloride is lowered. It is also possible that chloride is incorporated by diffusion alone and that the diffusion rates in hexagonal and cubic zinc sulfide may differ. In that case one would expect to find the largest amount in the smallest particles because of their large surface area and in those of hexagonal structure because of their open structure. These observations appear to be closely connected with the fact that chloride influences the cubic-hexagonal structure equilibrium (12).

[4] The Hedvall effect ascribes similar anomalies to the increased chemical reactivity near a transition point.

Summary and Discussion

As part of commercial phosphor preparation zinc sulfide powder is submitted to a heat treatment process during which the particle size increases. The average particle diameter is found to increase with the square root of the processing time and exponentially with the reciprocal of the temperature during phosphor preparation in open boats. The growth process is related to the tarnishing reaction, corrosion processes, and similar diffusion-limited growth phenomena (13). For instance, the same exponential dependence of the growth rate on the temperature has been found by Keck (14) for the growth of selenium films in vacuum. The time dependence of particle growth with $t^{1/2}$ has been found, for instance, for $Ba(OH)_2$ on BaO by Jahoda (15) and for germanium oxide films by Lukes (16).

The growth Eq. [1] can be derived theoretically if one considers the particle growth as a quasi-chemical reaction (17). The derivation, which is not discussed here, leads to an expression for a diffusion-limited process. Constant a in Eq. [1] can be interpreted as being equal to the activation energy E for the growth process divided by the Boltzmann constant k. The constant A is then found to be proportional to the concentration of molecules, ions, or atoms in the gaseous phase and inversely proportional to the concentration of mobile molecules in the solid substance. These concentrations and the activation energy may be modified by the presence of additives, so that one would expect, in agreement with our experiments, a variation in a and A with the kind of additive employed. Since additives that are solids at the processing temperature do not affect the particle growth significantly (see NaF-addition in Table I), one may assume that the vapor pressure of the additive must be fairly high in order to be effective in stimulating particle growth. The concentration of the additive appears not to be critical, because in open boats a considerable amount of the additive is lost (10) with processing time and temperature, and the values of a and A in the growth Eq. [1] do not change, as can be seen in Fig. 3.

It is interesting to find that Shionoya and Amano (7) obtained activation energies without an additive and with 2% NaCl added, which are about 2 to 3 times larger than our values. The explanation of this discrepancy is quite simple, since one finds that they consider the particle volume rather than the diameter. In this case the growth Eq. [1] is essentially raised to the third power, so that the activation energy for volume growth should be three times

that for linear growth. According to Eq. [1] the volume should be proportional to $t^{3/2}$, while Shionoya and Amano (7) found a linear dependence between particle volume and the processing time t. It appears that the difference in time dependence can be ascribed to the limited range of experimental conditions that Shionoya and Amano (7) considered.

The other series of experiments in sealed quartz vials which led to the observations of the anomalous behavior near 1000°C has been discussed in the result section. The Hedvall effect (11) offers a possible explanation for the growth anomaly; however, there has to be some additional influence and/or interaction to account for the anomalies in crystal structure and chloride incorporation in the case of sealed vials, because none of the above three anomalies has been observed when processing was conducted in open boats.

It is quite apparent that many problems in this field require further study. The present experimental investigation has led to a growth equation which explains certain results. On the other hand, it is also clear that the growth Eq. [1] can only be considered to be an approximation which does not apply in certain cases. It is expected that future investigations will lead to a better understanding of the anomalous behavior, the growth process and phosphor preparation which may finally contribute to the synthesis of novel or improved phosphor materials.

Electroluminescence Maintenance

W. A. Thornton

Lamp Division, Westinghouse Electric Corporation, Bloomfield, New Jersey

ABSTRACT

The maintenance of several electroluminescent phosphors, mainly of the ZnS:Cu,Cl type, has been investigated. Data are given illustrating its dependence on phosphor properties, such as copper and chlorine additions, firing temperature and particle size, on conditions of operation, and on lamp construction. Changes in properties other than light emission and recent maintenance improvements are described.

Electroluminescence (1, 2) shows a characteristic slow decrease in light emission, in common with all other practical light sources, over long periods of operation of the lamp. Improvements in the maintenance of electroluminescence have kept pace with increases in brightness and efficiency and have required knowledge of the dependence of electroluminescence maintenance on phosphor properties, conditions of operation, and lamp construction. It is the purpose of this paper to describe the influence of these factors on electroluminescence maintenance. Electroluminescent phosphors have not changed basically from the type discovered by Destriau (3, 4) in 1936, and consist typically of zinc sulfide activated by copper and chlorine. The ZnS:Cu,Cl and ZnS:Cu,Mn,Cl phosphors are in most general use, and it is to these that the data to follow primarily refer.

Electroluminescence maintenance has been the subject of three previous papers. Observations on photoluminescence, dark capacitance and conductance, photoconduction, wave form, and low-temperature deterioration of light emission were related by Thornton (5) (Paper I) to the typical maintenance (brightness-time) curve by assuming field-diffusion of traps or donors within the phosphor

crystal. Roberts published a paper (6) (Paper II) based in part on results obtained much earlier (7), in which he gives an empirical relation accurately describing typical brightness-time behavior, gives some data on voltage and frequency dependence of maintenance, and also concludes that deterioration is due to physical processes within the phosphor grain. Deep traps appearing in the phosphor crystal during deterioration are ascribed by Thornton (8) (Paper III) to incoming oxygen ions; the presence of the deep traps was indicated by thermoluminescence measurements and by the fact that brightness-voltage changes with deterioration could be reproduced by firing into the phosphor deep-trap-producing impurities such as In, Cd, and Ga, and could be removed temporarily simply by heating the deteriorated lamps. That oxygen is involved was indicated by similar thermoluminescence behavior of oxygen (9) in ZnS, by the fact that the brightness-voltage changes with deterioration could also be reproduced by firing small amounts of ZnO into the ZnS phosphor, and by the appearance of free zinc (10) on the phosphor crystals during electroluminescence deterioration.

Most of the data presented in this paper were obtained from conventional electroluminescent lamps which consist of phosphor powder dispersed in a plastic dielectric material (polyvinyl chloride acetate) at room temperature. When organic materials are used as the dielectric, the lamp is subjected to temperatures no greater than 50° to 100°C. Therefore, all the data presented here are characteristic of electroluminescent phosphor powders as prepared. In the case of ceramic lamps, which are subjected to processing temperatures in the neighborhood of 600°-700°C, profound changes occur in the phosphor during this processing and its electroluminescence properties are altered; no consideration is given here to the ceramic type of electroluminescent lamp.

II. Results

A. Dependence of Maintenance on Phosphor Properties

1. Copper and chlorine additions.—ZnS:Cu,Cl phosphors showing blue electroluminescence are known to have much poorer maintenance characteristics than similar phosphors of the same type which show green emission. It is of interest, practically, to determine the dependence of electroluminescence maintenance on the proportions of added copper and chlorine in phosphors[1] made at constant firing temperature and covering a wide range of copper and chlorine additions. The phosphor samples, about forty in all, were sprayed on conducting glass. The phosphor/plastic (Ucilon[2]) weight ratio was unity, gross thickness of the finished lamps was about two mils, and they were coated with evaporated aluminum to form the rear electrode. The lamps were mounted in good thermal contact with a massive metal base and operated together, from a single power supply and simultaneously, in an air-conditioned room (temperature about 70°F., R.H. about 30%). The temperature of the lamps did not rise significantly above room temperature. The deterioration to be described is the "intrinsic" deterioration characteristic of the phosphor rather than that due to its environment. Light output measurements during deterioration were made with an RCA 931-A photomultiplier and battery box for long-time stability. No spectral shift with deterioration was detected (see Section D-3). Initial brightness measurements were made in a castor-oil cell, 60 μ thick, using the Ultrasensitive Spectra Brightness Meter.[3] Cell thickness reproducibility is better in the oil cells than in the sprayed lamps, although brightness readings among the sprayed lamps agreed well with those obtained with the oil cell. All of these measurements were made at 4000 cps, the frequency at which electroluminescent maintenance was determined.

The percentages of added impurities are plotted as ordinate and abscissa, respectively, on logarithmic scales in Fig. 1. In this figure are plotted contours of equal maintenance, in per cent of initial brightness, after operation at 150 v, 4000 cps. Contours plotted for short and long periods of operation show the same configuration. Electroluminescence maintenance improves rapidly with increase of both copper and chlorine additions. The contours are roughly symmetrical about the line of equal copper and chlorine additions; this is the line of unity slope in Fig. 1. Furthermore, again roughly, a schematic representation of these contours may be given as in the inset of Fig. 1. This implies that, for a given maintenance characteristic, certain equal additions of copper and chlorine are required. For example, for 10% maintenance, an addition of 0.5 mole % of copper and 0.5 mole % of chlorine is required. Further additions of chlorine (at constant copper) or of copper (at constant chlorine) will not improve the maintenance; instead a greater addition of both is required. Since the contours show no sign of closing, it may be assumed that further maintenance improvement may be realized by greater impurity addition. This is of interest practically only if maintenance is the only requirement. To a marked degree, there is a correlation between better main-

tenance and longer wave-length emission, as shown in Fig. 1. Here are plotted the maintenance contours and also visual color contours which, although subjective, are correct in their gradation from apparent shorter to longer wave lengths. The maintenance and color contours are not coincident. This means, for example, that there is a definite procedure for obtaining a green-emitting phosphor of optimum maintenance (in this case, by extrapolation to 10 mole % copper and 2 mole % chlorine added). While the blue-emitters are always poorer in maintenance, Fig. 1 demonstrates simple matching of a required color to optimum maintenance and hence the best blue emitter is chosen easily. Note that the color contours of Fig. 1 follow the simple schematic diagram even more closely, and hence the same discussion applies.

The third important characteristic is brightness. Contours of equal brightness (in arbitrary units proportional to ft-L) are given in Fig. 2. Initial brightness contours (not shown) for the sprayed cells which were deteriorated had the same configuration; the plotted brightness data were obtained from oil cells. Figure 2 includes the maintenance contours already described. In the blue region, the brightness and maintenance contours are approximately coincident; that is, maximum brightness and maximum maintenance for a certain color occur at about the same point. In the green and yellow-green regions the contours are not at all coincident, but at least the high brightness contours are elongated in the direction of best maintenance so that not much brightness is sacrificed in realizing good maintenance. Brightness and maintenance are often equally important, and the total light emitted throughout the operating life of the lamp (lumen-hours) is the criterion. Peak "lumen-hours" is obtained in the green and falls off by a factor of twenty toward the yellow; hence, the effect is due neither to decreasing luminosity (since luminosity rises slightly in this range, 5200-5650Å) nor to poorer maintenance but is a marked physical effect. In the blue regions, fortunately, a ridge occurs at about 1 mole % copper along which maximum lumen-hours can be chosen for a given color.

As discussed in Section III, density of trapping sites is thought to be related to the maintenance of a phosphor. For this reason, the thermoluminescence of each phosphor in this series was measured by integrating the thermal glow, between —195°C and room temperature, following equal irradiation at 365 mμ at the lower temperature. In Fig. 3 the total light output due to thermoluminescence (release of trapped electrons followed by recombination) is plotted in arbitrary units.

As a matter of interest, the yellow-emitting ZnS:Mn,Cu,Cl phosphors show similar contours and as wide a maintenance variation as the ZnS:Cu,Cl type described above, depending also on copper and chlorine additions. For samples of yellow phosphors of this type with various copper and chlorine additions, the time to half brightness at 4000 cps ranged from 4 to 350 hr. The initial brightness of the best maintenance phosphor was about 60% of that of the brightest yellow phosphor.

2. Firing temperature.—A series of blue-white ZnS:Cu,Cl phosphors[4] was fired at various temperatures. The experimental procedure was identical to that described in the previous section. The maintenance of those phosphors fired at higher temperatures was much better than the maintenance of those fired at 950°C and below (Table I). The brightness units are proportional to foot-lamberts; maintenance is given in per cent of initial brightness after 24 hr at 150 v, 4000 cps. Comparing the variations with firing temperature with the corresponding contours of Fig. 1, the increasing firing temperature appears to have the effect of causing increased retention of copper. The practical result is a blue-white phosphor of much improved maintenance.

Part but not all of the maintenance improvement with increasing firing temperature is undoubtedly due to the increase in particle size with increasing temperature, as shown in Table I. The dependence of maintenance characteristics on particle size is described in the next section.

3. Particle size.—Any alteration of the phosphor (impurity addition, firing temperature, etc.) re-

[4] Supplied by A. Wachtel.

Y (2)	Yellow	ZnS: Cu, Mn, Cl

sults, in general, in a change in mean particle size also. Efficiency (11) and brightness (11, 12) have been shown to depend on mean particle size. The maintenance of output also depends on particle size. Therefore an observed variation in maintenance, for instance, cannot be attributed entirely to a certain alteration of the phosphor if a particle size change also is induced by the alteration. This section describes a determination of the dependence of maintenance on particle size alone, in order that this effect of particle size may be allowed for in determining true maintenance variation due to phosphor alteration.

From each of the six phosphors listed in Table II five or six fractions were separated out by water settling. Several particle size determinations were made by microscope and the apparent mean particle size averaged to obtain the nominal particle diameter used in plotting the data. These nominal particle sizes are very approximate, and only the large differences in the mean diameter of the fractions make the determination meaningful. Although the number of particles considerably coarser than the nominal size was negligible, there were small numbers of fines present in the coarser fractions. The nominal average particle sizes designated are estimated to be within about 15% of the true average in the case of most of the 30 fractions; one or two fractions, however, consisted of particles of approximately two different diameters, and these were discarded. Each fraction apparently consists of a bell-shaped distribution similar in shape to the original phosphor. Such a distribution is well suited to this maintenance study, since any actual electroluminescent phosphor of interest practically will have such a distribution.

The dependence of maintenance of the phosphors on particle size is shown in Fig. 4. All of the curves are seen to extrapolate approximately through the origin. The dependence of the blue phosphor is nearly linear to 12 μ; it is characteristic of the blue phosphors, having relatively low copper and chlorine additions, that the range of particle size is limited. The dependence of the other phosphors is also quite linear to about 12 μ, and then the maintenance becomes fairly constant at larger particle size. The slight apparent decrease in maintenance of the largest particles in some cases may not be real, but may be due to the presence of a few fine particles as already noted.

Thus, the particle size effect is considerable. On the other hand, particle size is by no means the major consideration in electroluminescence maintenance. Modified firing procedures have been shown to lead to maintenance improvement factors of as much as twenty; no difference in average particle diameter of the original and such modified phosphors is apparent by microscope. Maintenance also has been shown to depend very strongly on copper and chlorine additions during phosphor preparation (Section A-1.); in the array of samples studied, the maintenance of electroluminescence brightness varied by a factor of 50 while the particle size ranged over a factor of 2 or 3. In a method of maintenance improvement over conventional blue phosphors by use of other coactivators (13) the maintenance differs by a factor of 18 while the particle diameter ratio is roughly 2. Higher firing temperatures improve the maintenance of a blue phosphor by a factor of ten while the particle size is increased by a factor of three (Section A-2). Hence, in the last four examples, the particle size effect on maintenance is a minor one, compared to the over-all maintenance variations cited.

4. Emission color variation with particle diameter. —In certain phosphors of the ZnS:Cu,Cl type a definite shift occurs in emission color with variation of particle size from the same phosphor batch. The emission spectra of the five particle size fractions of the blue-green phosphor of Table II are given in Fig. 5 together with mean particle diameter as determined by microscope. The shift of emission toward the blue with increasing particle size is not consistent with the general improvement in maintenance of phosphors the longer wave length their emission color. Small and large particles from the same batch are apparently activated differently, and emission color indicates that the smaller particles are more highly activated. Maintenance has been shown to depend very strongly on activation (per cent addition of copper and chlorine) and also to

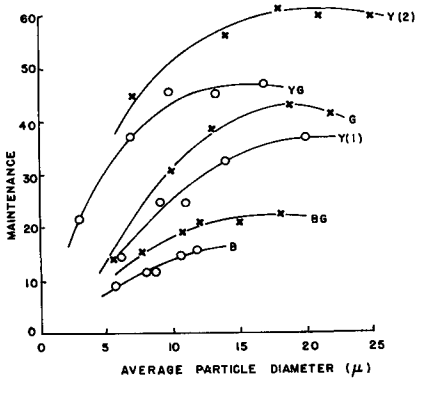

Fig. 4. Dependence of maintenance (per cent of initial brightness, 120 v, 4000 cps) on particle diameter.

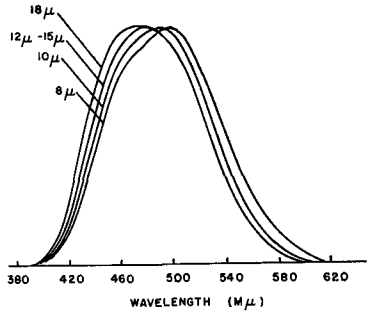

Fig. 5. Variation of emission color with particle size from the same lot of phosphor. Blue-green ZnS:Cu, Cl.

depend somewhat on particle size. These dependences, as determined, are slightly inaccurate due to the interrelation of activation and particle size.

The emission color of the blue and deep yellow-green phosphors (near the extremes of the color range of ZnS:Cu,Cl class) does not vary with particle size, very likely because (*a*) the blue fine particles contain only active blue luminescence centers and so the coarse particles can emit no bluer light, and (*b*) the coarse yellow-green particles contain only active yellow-green luminescence centers so the finer particles can emit no yellower light. The possibility that the yellower emission from smaller particles might be due to their stronger absorption of blue emission, was eliminated by the following experiment. A large-particle fraction (20-30 μ diameter, blue-green emission) was crushed to an average diameter of 1 or 2 μ. No change in the electroluminescence emission spectrum occurred within experimental error due to this mechanical reduction in particle size, and it differed significantly from the spectrum of the original small-particle fraction (4-6 μ diameter, green emission) of the same phosphor batch.

B. Dependence of Maintenance on Conditions of Operation

1. Frequency.—It is well known that electroluminescent phosphors deteriorate more rapidly at higher frequencies (5, 6). This behavior is true generally, with no known exceptions. It was suggested[5] that, at least approximately, a universal deterioration curve results from plotting the per cent of initial brightness against the total number of cycles of operation, rather than the hours of operation. The validity of such a universal deterioration curve was determined for the phosphors in Table II. Figure 6 shows the data plotted in terms of cycles of operation. A universal curve can be drawn approximately for frequencies higher than 1000 cps, but at lower frequencies significant deviations from the universal curve occur. On the basis of these curves, a parameter useful for describing the maintenance properties of an electroluminescent phosphor is the high-frequency half-life under dry conditions, defined as the number of cycles of operation at frequencies greater than 1000 cps after which light emission has been reduced to half the initial value.

[5] By E. A. Sack, Westinghouse Research Laboratories, Pittsburgh, Pa.

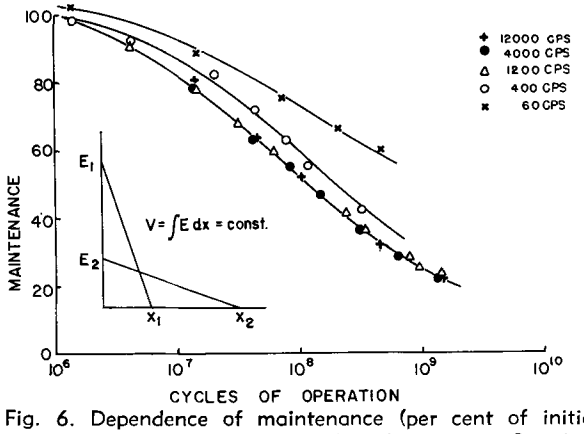

Fig. 6. Dependence of maintenance (per cent of initial brightness) on total number of cycles of operation. Standard green phosphor, 200 v. Inset: Field distribution at (1) high and (2) low frequency.

All the phosphors showed low-frequency deviations from the universal curve which satisfactorily described deterioration above 1000 cps. These deviations ranged from a factor of two in half-life for the phosphor with blue emission to a factor of ten with the yellow-green. Generally, these deviations are in the direction of longer half-life (in cycles) at lower frequency; the blue phosphor, however, showed a shorter half-life in cycles at low frequency. The yellow-emitters showed low-frequency deviations which were intermediate between the blue and yellow-green.

The frequency dependence of maintenance is therefore very strong, covering a range in half-life even greater than the range of frequencies of operation.

It might be expected that if two identical lamps are operated, one at a high frequency and one at a low frequency and at the same applied voltage, that the brightness of the high-frequency lamp would initially be much greater than that of the low-frequency lamp but would eventually fall below; this would follow if the lumen-hour capabilities of the two lamps were about equivalent. It is observed, however, that of two identical lamps operated at the same voltage and different frequencies, the brightness of the lamp operated at the higher frequency never falls below that of the lamp operated at lower frequency. Lamps operated at high frequency, although they have deteriorated to a small percentage of initial brightness, are still brighter than identical low-frequency lamps. The brightness-time curves of these lamps approach each other more and more closely after a period of operation but apparently do not cross even after very long times. Such behavior suggests fast-deterioration and slow-deteriorating components of light emission, the latter being relatively independent of frequency. The presence of two components is particularly marked in the case of an improved-maintenance yellow phosphor described in Section E and in Fig. 14.

2. Voltage (field strength).—It is not unreasonable to expect that an increase in voltage and field strength will lead to more rapid deterioration of the phosphor since the light output is higher. Roberts (6) reported, however, that the maintenance of certain lamps improved slightly with increase in field strength. A determination of the voltage dependence of maintenance was made for blue and green ZnS:Cu,Cl phosphors and a yellow-emitting ZnS:Mn,Cu,Cl phosphor. Some of the results are given in Table III. At low frequency (60 cps) the maintenance of the blue phosphor improves with increasing field strength. At intermediate frequency (400-4000 cps) the blue and green phosphors deteriorate slightly more rapidly at higher field strengths, and the yellow phosphor shows no voltage dependence within experimental error. Thus, electroluminescence maintenance does not depend appreciably on the field strength experienced by the phosphor. The greatest observed variation in half-life over the range of useful voltage is no more than a factor of two or three; this is to be compared

Table III. Dependence of maintenance (half-life) on applied voltage for various phosphors and frequencies

	Initial brightness, arb. units	Voltage	Half-life, hr
	1300	400	380
	700	310	290
Blue	400	230	210
60 cps	50	150	150
	8	75	180
	1600	370	1.0
	1300	340	1.3

	770	370	2.2
	580	340	3.5
Green	320	300	2.6
4000 cps	100	200	3.5
	6	92	5.0
	600	400	14
	380	360	14
Yellow	250	317	14
4000 cps	60	212	16
	2	97	12

to the variation of 1000 to 1 due to frequency. There is little disadvantage, therefore, in operating a lamp close to breakdown in order to obtain maximum brightness, since the maintenance is about that observed at much lower voltages. Conversely, maintenance cannot apparently be improved significantly by reducing the field strength on the phosphor.

3. Temperature.—Electroluminescence deterioration proceeds (5) at a rate too slow to measure if the phosphor is maintained at liquid nitrogen temperature (−195°C). On the other hand, the maintenance is poorer at temperatures higher than room temperature than it is at room temperature. This behavior is illustrated by Fig. 7.

4. Humidity.—It is well known generally in electroluminescence work that moisture has a strong deleterious effect on the maintenance of output. Atmospheric water vapor is perhaps the most important adverse influence on electroluminescence maintenance from the point of view of practical

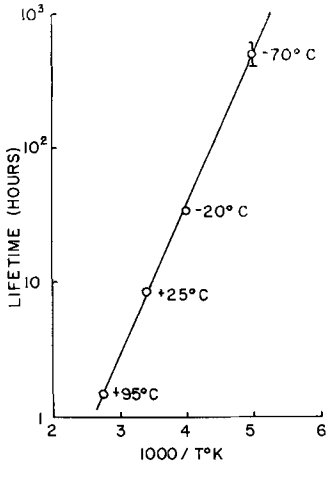

Fig. 7. Dependence of lifetime (time to half of initial brightness) on temperature. Standard green phosphor, 150 v, 4000 cps.

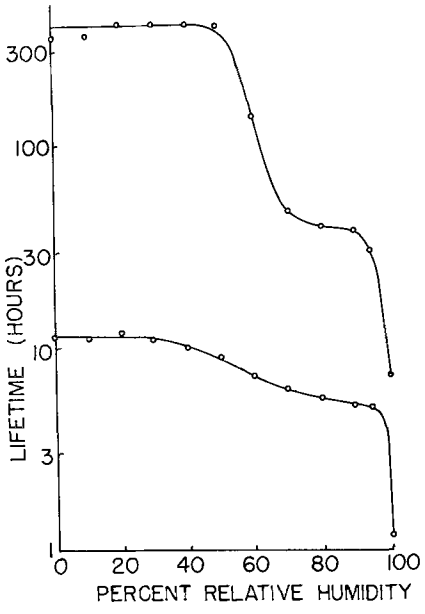

Fig. 8. Dependence of lifetime (hours to half of initial brightness) for two green ZnS:Cu, Cl, phosphors as a function of per cent relative humidity. 4000 cps, PVCA dielectric, 23°C.

application. Operation at zero humidity is certainly the ideal condition for obtaining information on the intrinsic maintenance behavior of a phosphor, and this has been done for much of the testing reported in this paper. For experimental unprotected lamps, when the relative humidity of the air-conditioned laboratory rose above 30% the lamps were always operated in a closed vessel of the desiccator type at zero humidity. The dependence of lifetime on per cent relative humidity is shown in Fig. 8 for a standard and an improved green ZnS:Cu,Cl phosphor. The curves shown were obtained with sulfuric acid solutions, and similar results were obtained with saturated solutions of solid materials. The reduction in lifetime from low to high humidity (excluding 100%) is by a factor varying from 2 to 10. The deterioration observed when a phosphor is operated in a vacuum (10^{-5} mm Hg) either with or without plastic dielectric[6] is similar to what is observed if a lamp is operated in air at zero humidity or in 100% humidity so long as perfect protection from moisture is achieved; the plastic dielectric apparently serves only to slow the ingress of moisture somewhat. Moisture has apparently no detectable adverse effect on the phosphor so long as voltage is not applied; if the phosphor layer is thoroughly dried before operation, the maintenance is unaffected. Storage of an already aged phosphor under humid conditions, or even wetting it, will show no adverse effects so long as the phosphor is dried before the field is applied.

Zinc selenide electroluminescent phosphors which emit in the red have been found to show far better

[6] As long as no moisture is present, the nature of the dielectric material seems to have no effect whatsoever on the maintenance characteristics of a given phosphor. Various waxes, epoxy resin, nitrocellulose, Lucite, polyvinyl chloride acetate (PVCA) which was generally used in the lamps described in this report, castor oil, air, and vacuum led to very similar rates of deterioration so long as the humidity was low or zero. This conclusion does not apply (a) to solid dielectric materials which are not stable with time, such as plastics containing volatile plasticizers, or (b) to glass dielectrics during the firing of which the phosphor is altered because of the higher temperatures necessary.

maintenance than zinc sulfides. It has been found also that the electroluminescence of a selenide phosphor is remarkably maintained in the presence of moisture.

5. *Two lifetimes from electroluminescent lamps.* —An electroluminescent lamp deteriorated at high frequency and low voltage to a fraction of its initial brightness may show no evidence of deterioration under low frequency and high voltage excitation. In other words, a lamp excited to brightness L_0 at high frequency and low voltage (HFLV) can be quite completely deteriorated and then can be excited to L_0 again by the same LFHV conditions which produced an equivalent brightness L_0 initially. When excited by the low frequency and high voltage, the phosphor is as fresh as initially and an entirely new "lifetime" is begun. The first deterioration has little or no effect on the rate of the second deterioration. Coarse (15 μ) particles and fine (3 μ) particles show the same behavior; namely, deterioration at a high frequency is not seen at a much lower frequency as long as the operating voltage is higher than that at which the deterioration took place; this will usually be the case in practice since higher voltage is required to reproduce a given brightness at lower frequency. A typical pair of frequencies at which the two "lifetimes" may be obtained is 60 and 4000 cps. Since newer coarse phosphor powders show very reasonable maintenance at frequencies as high as 10,000 cps, the first high-frequency "lifetime" can be long enough to be practically valuable. The purpose of this section is to illustrate this behavior by means of the maintenance contours to be described, and to show that the sequence HFLV followed by LFHV operation is the correct one to obtain the two "lifetimes" from an electroluminescent lamp.

One lamp made with standard green phosphor was deteriorated for 400 hr at high frequency (20 kcps) and low voltage (60 v rms) to 20% of initial brightness. This operating point is indicated by the cross in Fig. 9, which is a maintenance contour in frequency and voltage of the deteriorated lamp. The heavy lines and plotted points are apparent maintenance, in per cent of initial light output, as measured under frequency and voltage conditions other than those at which deterioration took place; that is, brightness was measured, before and after deterioration, at each combination of voltage and frequency. Note, for example, that this lamp shows no sign of deterioration at 160 v, 60 cps and that its light output under these conditions is equal to the initial light ouput before the original deterioration at HFLV.

The dashed lines of equal light emission illustrate the well-known observations (*a*) that the frequency dependence of electroluminescence becomes negligible at low voltage, where the voltage dependence of emission is strong, and (*b*) that the frequency dependence is strong at high voltage, where the voltage dependence is weak.[7] A change in operating conditions from HFLV to LFHV operation is more or less parallel to the equal-brightness lines; hence, light output under the latter conditions can be equal

[7] An explanation of these interdependences is given in ref. (14).

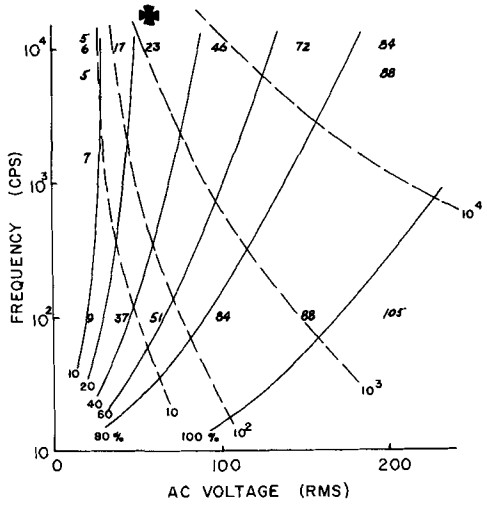

Fig. 9. Apparent maintenance (solid lines, per cent of initial brightness) at voltage and frequency other than that at which deterioration took place. Cross indicates conditions of deterioration (see text for time of deterioration). Dashed lines are initial brightness in arbitrary units. Standard green phosphor.

to or greater than the initial light output at the conditions under which deterioration took place.

Another lamp was deteriorated at a lower frequency (60 cps) and a higher voltage (150 v rms). For this case of initial LFHV operation, which resulted in deterioration of electroluminescence to 12% of initial, subsequent operation under the opposite HFLV conditions makes little difference in the observed state of deterioration, and no advantage is gained. Improvement results only by moving to lower frequency or higher voltage or both as in the previous case, but even then the recovery is not large (from 12% to about 30%).

Reasons based only on the mechanism of electroluminescence have led to the view (8) that an increase in frequency of excitation leads to more marked localization of the light-emitting and deterioration processes of electroluminescence. In a study of the field quenching of alpha particle scintillations, Alfrey and his associates (15) have obtained further and independent evidence that localization of the electric field is greater at high frequency. It is generally accepted that low voltages lead to greater localization of the high-field region or, put in another way, that with increase in voltage the high-field region extends farther and farther into the crystal (6). Such behavior will lead to maximum localization of deterioration effects if excitation is at high frequency-low voltage (HFLV), to the upper left in Fig. 9. Following deterioration under such conditions, marked recovery takes place if frequency is reduced or voltage increased or both. This is because in either case the light-emitting high-field region is extended into fresh regions of the phosphor crystal and the deterioration becomes proportionally less evident. In fact, in the voltage and frequency region below and to the right of the 100% line in Fig. 9, the active region extends so far into fresh parts of the crystal that the reduced emission from the original small region of excitation

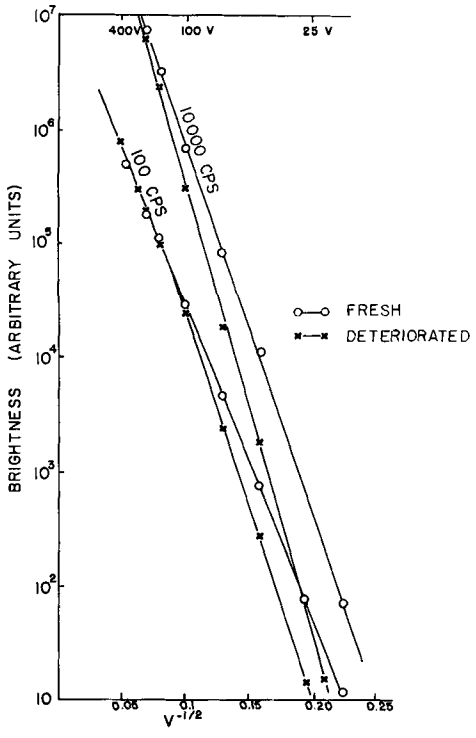

Fig. 10. Change in brightness-voltage dependence with deterioration (at 20,000 cps, 60 v, 15 hr). Standard green phosphor.

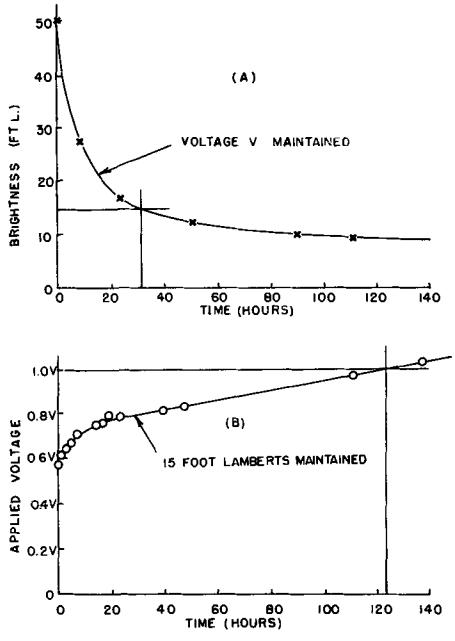

Fig. 11(A). Maintenance characteristic for constant voltage operation (4000 cps). Standard green phosphor.

Fig. 11(B). Maintenance characteristic for constant brightness operation (4000 cps). Standard green phosphor.

is masked, and deterioration effects are no longer seen. That the deterioration in the original active region is nonuniform is suggested by the observation that further localization of the active region by increasing the frequency or reducing the voltage from the conditions under which the deterioration took place, leads to even poorer apparent maintenance.

6. Localization of the electric field.—Further evidence that the excitation region in the phosphor is contracted by decrease in voltage or an increase in the frequency and expanded by an increase in voltage or a decrease in frequency appears in Fig. 10. The lamp from which the data for this figure were obtained was deteriorated at 20,000 cps and 60 v for 15 hr. Following this, the voltage-brightness characteristics were compared at 10,000 cps and at 100 cps with those for the fresh lamp. At 10,000 cps the effect of the deterioration is seen up to 400 v, but at 100 cps the effect is observed only up to 100 v. Apparently the "extent" of the high-field (excitation) region coincides with the volume of the phosphor crystal which was deteriorated at 100 v, 100 cps and at 400 v, 10,000 cps.

7. Constant brightness operation.—In lamp applications where there is a brightness control and where the desired brightness is less than the maximum brightness obtainable, operation is expected to be at constant brightness. Deterioration with operation is corrected for implicitly by resetting the brightness control (voltage) to a different setting as deterioration proceeds. The question was raised[8] whether a lamp operated at constant brightness would have a longer useful life than an identical lamp operated, as usual, at constant voltage. The question is made meaningful only if some restriction is made, such as that the rated voltage of the lamp should not be exceeded. Increasing the voltage during life should, by extending the excitation region into fresh parts of the phosphor crystal, result in longer life (see Section B-5 and B-6). This was confirmed by the results shown in Fig. 11. Operation was at 4000 cps. Two similar lamps were used, in each case V being the rated voltage at which the lamp brightness was initially 50 ft-L. The "desired" brightness was chosen at 15 ft-L. Figure 11 (A) represents a lamp operated at constant rated voltage V. This lamp deteriorated to 15 ft-L after about 30 hr of operation at 4000 cps, a typical maintenance figure for an early green-emitting ZnS:Cu,Cl phosphor. Figure 11 (B) represents the other lamp operated at the constant "desired" brightness of 15 ft-L. The applied voltage was about 0.6 v initially and rose to a value of V in about 120 hr. The useful life of the constant brightness lamp was therefore about four times that of the lamp operated at constant voltage. At the end of its "life" each lamp was operating at voltage V and a brightness of 15 ft-L. In one case the useful life is terminated by too low a brightness at rated voltage, and in the other case by too high a voltage to maintain rated brightness.

This increase in lifetime by constant brightness operation was confirmed[9] also at 400 cps. Different dielectric materials and lamp thicknesses were tested. The dielectric material had no effect. Lamp thickness does, however, have a strong effect; the thicker the lamp and the higher the breakdown voltage, the smaller the advantage in constant brightness operation. The reason is as follows: At a

[8] By S. Goldfarb, Wright Air Development Center, Dayton, Ohio.

[9] Data from R. W. Wollentin.

given required brightness the brightness-voltage dependence is stronger for the thicker lamp since the required field strength is lower. Therefore the initial voltage is a larger fraction of the final voltage, the voltage increase during life is smaller, and the utilization of fresh phosphor regions due to the voltage increase is less marked. The effect on lifetime is large indeed, since the thick lamps last only twice as long as with standard (constant-voltage) operation, while the lifetime of the thinner lamps is four times as long. This effect is beneficial, since lamps normally will be operated as near breakdown as possible to realize maximum brightness at minimum voltage (thin lamps), and such operation will lead to maximum improvement in lifetime due to constant brightness operation. In such a case, the maximum voltage obviously must not exceed the breakdown voltage of the lamp.

8. External series impedance.—The impedance of electroluminescent lamps is dependent on frequency and voltage of excitation (11, 16). The impedance of these lamps increases during life (see Section D below), and this effect is greatest with low frequency and high voltage operation. The impedance increase occurs in the phosphor powder itself; the dielectric material does not change its electrical properties with life if the lamp is properly finished and cured. Therefore, an added fixed impedance in series with the lamp will divide the voltage in such a way that the effective voltage on the lamp will automatically increase during life as the impedance of the lamp (phosphor) increases. This increase in effective voltage will tend to compensate for the normal decrease in brightness with life. Lamps were made with a poor maintenance blue phosphor in order to obtain the results in a short time, and were operated at 400 cps. Table IV identifies the series element, the total voltage applied to the lamp and series impedance combination, and the time in hours for the brightness to decay to half the initial brightness. Similar experiments have been conducted at 60 cps and increases in half-life of about five times have resulted from the addition of a series resistor equal to the initial impedance of the lamps.

It is interesting to note that operation of a lamp with a series impedance is inherently stable. The impedance of the lamp (phosphor) decreases with increasing field strength. Therefore, as the lamp impedance increases due to operation and the effective voltage across the lamp increases, this increase leads in turn to a reduction in lamp (phosphor) impedance at the new higher field strength. The effect is a type of negative feedback ensuring stability of operation. It should be borne in mind that the dielectric embedding material itself acts as an impedance in series with the phosphor crystals. At low phosphor concentrations where, on the average, each phosphor crystal is isolated in the dielectric, the maintenance is better than at high concentrations where each crystal is effectively in contact with one or more others and the series impedance effect is absent. Under certain conditions the maintenance is expected to improve upon addition of a clear coat, for the same reason. These effects are described in later sections.

9. Pre-aging effects.—Pre-aging at rated voltage and frequency leads to apparent improvements in maintenance since early deterioration is more rapid than later, and the "initial" brightness is then defined as that after some deterioration (the pre-aging) has taken place. Pre-aging is feasible so long as excess brightness is available. Pre-aging, at voltages and frequencies other than those under which the lamp is to be run, can lead to the same maintenance improvement in a much shorter time.

An improvement in 400 cps maintenance is associated with a certain cost in initial 400 cps brightness. This relation is given roughly in Table V, where L_o is the initial brightness and L_a is the brightness after aging, both measured under operating conditions rather than pre-aging conditions, and holds approximately regardless of the conditions of pre-aging. Various pre-aging conditions necessary to achieve the maintenance improvement in 1 and 2 of Table V are given in Table VI. Hence, for example, the 400 cps half-life of a lamp can be

Table IV. Effect of series impedance on maintenance

Lamp	Element	Total voltage	Half-life, hr

improved by a factor of five at a reduction of 40% in initial brightness and this pre-aging can be accomplished in times varying from 3 to 130 hr depending on the frequency and voltage used for pre-aging.

C. Dependence of Maintenance on Lamp Construction

1. Phosphor concentration.—It has been customary to use a phosphor/plastic-dielectric weight ratio which yields maximum initial brightness within breakdown voltage requirements. It was found that this weight ratio also has an effect on maintenance and so this factor must be considered when arriving at an optimum ratio.

A set of lamps made with standard green phosphor and PVCA dielectric and utilizing a wide range of phosphor/plastic weight ratios (while maintaining constant lamp thickness) was subjected to accelerated life test at 4000 cps. At low phosphor concentrations or weight ratios, the maintenance is constant, independent of concentration. At a certain higher concentration the maintenance worsens rather abruptly and then remains constant at the poorer value for still higher phosphor concentrations. The corresponding half-life is reduced by a factor of two or three at high phosphor concentrations. Because of this peculiar result, these experiments were repeated by spraying an entirely new series of lamps. The results were essentially the same. The experiments were repeated for the third time to obtain more data in the transition region. These results are given in Fig. 12. The curve marked $t_{1/2}$ is the half-life in hours taken from the actual maintenance curve for operation at 120 v, 4000 cps. The transition is continuous as the phosphor/plastic weight ratio changes. The curve marked L_o is the initial brightness in ft-L at 120 v, 400 cps. Above a ratio of 5.0 some arcing occurs. The curve marked $L_o t_{1/2}$ is the product of L_o and $t_{1/2}$ and is indicative of the total light output during the life of the lamp.

2. Phosphor layer thickness.—It is intended only to re-emphasize here that the maintenance variation due to different applied voltages on lamps of constant thickness is also to be expected when lamps of various thicknesses are to be operated at a certain predetermined voltage. As shown in the preceding and following sections, phosphor concentration and

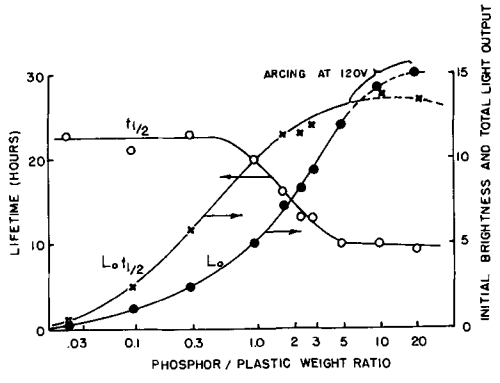

Fig. 12. Dependence of maintenance (hours to half of initial brightness at 120 v, 4000 cps), initial brightness (ft-L at 120 v, 4000 cps) and the product of these, in arbitrary units, on phosphor/plastic weight ratio. Standard green phosphor, constant thickness lamps.

Table VII. Dependence of maintenance on number of clear coats

No. clear coats	Half-life, cycles	Half-life, hr at 400 cps	Breakdown brightness, arb. units	Breakdown voltage, v
0	0.4×10^8	60	11	200
1	0.41	60	16	240
3	0.51	70	23	350
10	0.7	100	22	500
30	1.4	200	17	700
100	2.4	330	—	—

clear coat thickness must be identical among lamps in which this phosphor layer thickness or field strength effect is to be utilized or studied.

3. Clear coat thickness.—A clear coat is a layer of clear dielectric material containing no phosphor and is often applied to a lamp before or after the phosphor/plastic layer has been laid down. The half-life of conventional sprayed lamps has been observed to increase with the number of clear coats up to a factor of six times the half-life of an identical phosphor layer with no clear coat. Identical lamps consisting only of a thin phosphor/plastic layer were sprayed. Some were reserved as controls and the others were sprayed with from 1 to 100 very thin clear coats of PVCA lacquer-thinner solution. All lamps were operated at 150 v, 4000 cps. Table VII gives the half-life in number of cycles to half-brightness, the breakdown brightness, and the breakdown voltage as a function of the number of clear coats applied over the identical phosphor-plastic base layer. This indicates that in the particular case where a certain brightness is desired and excess voltage is available, maximum maintenance is obtained by utilizing as high a voltage as possible and increasing the clear coat to phosphor-layer ratio until the desired brightness is obtained. Previous indications that clear coats improve maintenance have sometimes been attributed to better moisture protection. The above experiments were carried out in an air-conditioned laboratory in about 30% relative humidity. The effect of clear coats on maintenance may also be that the clear coat behaves as a series impedance (primarily a capacitance) and the maintenance improvement may be the same as that observed when a series capacitor is connected to the lamp (see Section B-8).

D. Changes in Other Properties with Deterioration

1. Electrical properties.—In the fresh electroluminescent phosphor layer, both the capacitance and the conductance increase with increasing voltage (16). This behavior changes, however, with deterioration of the lamp (Fig. 13). The voltage dependence of both capacitance and conductance in the fresh lamp has largely disappeared in the deteriorated lamp, and this is observed over a wide range of frequencies of measurement and of deterioration. The reduction at high voltage of conductance leads to a reduction in power dissipation at high voltage; little change in either is observed at low voltage. The changes in power absorption and light emission during deterioration lead to drastically reduced efficiencies at low voltage. At high

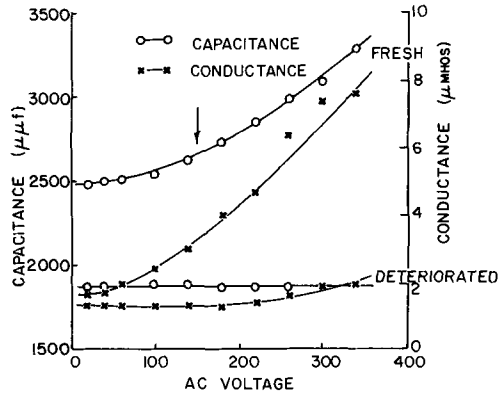

Fig. 13. Variation in capacitance and conductance for fresh and deteriorated lamps. Arrow indicates voltage at which deterioration took place. Standard green phosphor. 4000 cps, 150 v, 1000 hr.

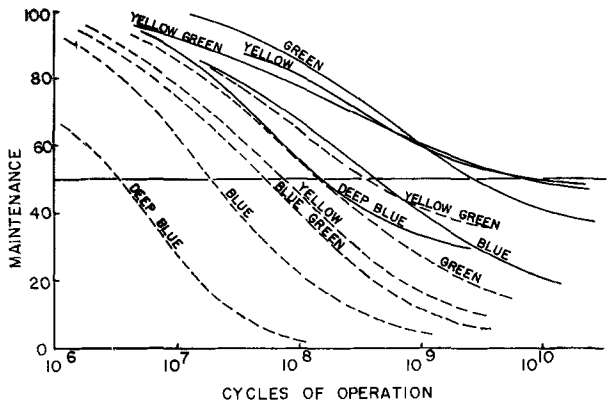

Fig. 14. Comparison of maintenance (per cent of initial brightness) characteristics of standard phosphors (dashed curves) and improved phosphors (solid curves), 150 v, 4000 cps.

voltage the efficiency can remain quite unchanged or can increase appreciably; this effect is a shift of peak efficiency toward higher voltage due to deterioration, and is another manifestation of the localization of deterioration effects in the phosphor crystal.

The gradual decrease with operation of the capacitance (5, 6) and conductance of a phosphor layer may be related directly to the electroluminescence process. Three cells were operated singly while in a bridge circuit for 120 hr at 150 v, 4000 cps. Cell A was a conventional sprayed phosphor-plastic layer of green-emitting ZnS:Cu, Cl phosphor. Cell B was similar except that no plastic dielectric was present. Cell C consisted of clear plastic dielectric with no phosphor, and the electrical characteristics of this cell did not change with operation. Components of the capacitance and of the conductance decrease roughly in proportion to the decrease in light output for both the conventional phosphor-plastic sprayed layer and the water-settled layer of phosphor powder alone.

2. Frequency response.—High-frequency deterioration depresses the light output more strongly in the frequency region where deterioration took place than at lower frequencies. Low-frequency deterioration depresses the brightness about equally at all frequencies. This observation also is related to the localization of electric field with increasing frequency discussed in Sections B-5 and B-6.

3. Emission spectrum.—No change in emission spectrum of ZnS:Cu, Cl phosphors with deterioration has ever been observed. In the case of conventional green-emitting phosphors, a quantitative search for such a spectral change was made and none found beyond slight discrepancies which could be attributed to darkening of the plastic dielectric material. The emission spectra of twelve phosphors (including ZnS:Cu, Cl emitting from the deep blue to yellow-green, ZnSSe:Cu,Cl emitting in the yellow, red ZnSe:Cu, Cl, blue-green ZnS:Cu, Pb, Cl, and yellow ZnS:Cu, Mn, Cl) were compared when fresh and after long deterioration to a few per cent of initial brightness. Only the ZnSe:Cu, Cl phosphor appeared to shift slightly, toward longer wave lengths. The other phosphors showed no detectable change in emission spectrum.

D. Recent Maintenance Improvements

The phosphors described in this paper are predominantly conventional ZnS:Cu, Cl phosphors in which emission color shifts from the deep blue to the yellow-green as copper and chlorine additions are increased. The yellow-emitting manganese-activated ZnS:Cu, Mn, Cl phosphors behave much like those without manganese in their maintenance behavior, the manganese serving primarily to shift the blue or green "normal" emission to a relatively invariant yellow (17). The maintenance characteristics of earlier standard phosphors (dashed curves) are summarized in Fig. 14, where per cent of initial brightness is plotted against cycles of operation; the data were obtained at 150 v, 4000 cps, low humidity, and the resulting "universal curves" describe the maintenance behavior at frequencies of about 1000 cps or higher (Section B-1). Recent improvements in maintenance of the same basic phosphors have been made possible by alterations in activation and by modified firing procedures. These improved phosphors, covering the same range of emission color, are represented by the solid curves in Fig. 14; the same operating conditions as above were used in obtaining the data. These maintenance improvements do not usually sacrifice initial brightness. The old and new deep blue and greenish blue phosphors are about equivalent in brightness, the improved-maintenance green phosphors are often brighter than the original, and the improved maintenance yellow in Fig. 14, for example, has half the initial brightness of the original yellow shown, while its half-life is 100 times longer. This particular phosphor involves only an increase in Cu-Cl addition in accordance with Section A-1. The small losses in initial brightness as maintenance improves, as in the case of the yellow phosphor, are gradual and a compromise can be made at any point; however, integrated light output over the life of the lamp (lumen-hours) improves very rapidly indeed as maintenance improves. In fact, it is a property of some of the recent phosphors that a relatively high plateau of light emission is reached after long oper-

ation, as in the case of the improved yellow of Fig. 14. Obviously if the point of leveling off is near 50%, as in this example, the half-life, or time to half of initial brightness, is not a useful parameter for measuring maintenance since (a) minor differences in phosphors would lead to large variations in this quantity, and (b) defining the useful life to include deterioration to levels somewhat less than 50% of initial would increase it by a large factor.

Taking the improved green phosphor as an example, 1000 cps operation leads to a half-life of 750 hr. Because the high-frequency half-life in cycles is about doubled for 400 cps operation and roughly ten times greater for 60 cps operation of this type of phosphor (Section B-1), the corresponding extrapolated half-lives are 3750 hr at 400 cps, and 12,000 hr at 60 cps; such behavior requires good moisture protection and great patience to measure.

III. Discussion

The improvement in maintenance with increasing equal copper and chlorine additions can be explained as follows. The normal trapping or donor sites are associated with Cu-Cl centers in strongly electroluminescent ZnS:Cu, Cl phosphors. Excess chlorine (lower right hand region in Fig. 1-3) leads to phosphorescence and deeper traps which are detrimental to electroluminescence. The greater the copper-chlorine addition to the phosphor, the higher the expected concentration of normal traps or Cu-Cl centers, and the less rapid the quenching of electroluminescence either by a given rate of incoming deeper traps (8) or depletion of normal traps by outward diffusion (5). That the density of normal traps and good maintenance are strongly correlated is shown by Fig. 3, even though the deep traps, contributing to phosphorescence and not to electroluminescence, confuse interpretation in the low-copper high-chlorine region (lower right) of the figure. As the concentration of Cu-Cl centers increases, the electroluminescence brightness reaches a peak and then drops off (Fig. 2), perhaps due to self-quenching by the centers (concentration quenching), but maintenance apparently continues to improve. The degree of deterioration of electroluminescence after a period of operation is very likely related to the ratio of the concentration of deep traps which have appeared to the concentration of normal traps.

Maintenance improves with increasing particle diameter. If deterioration is due to the introduction of a foreign substance from the surface into the crystal volume, or to the escape from the volume to the surface of some entity necessary to electroluminescence, then an increase in the rate of deterioration with increase in surface to volume ratio is to be expected; experimentally the rate of deterioration is proportional to this ratio for all but the largest particle sizes.

Maintenance depends strongly on frequency and very little on voltage. An increase in frequency reduces the crystal volume experiencing the field and increases the maximum electric field in the crystal; therefore the rate of field-diffusion is increased and the volume affected by it is reduced and deterioration becomes more rapid. In the schematic inset of Fig. 6, E_1 and X_1 refer to the maximum field and extent at high frequency. As the active charge density decreases with deterioration, the slope dE/dX decreases and the field configuration approaches that of the low frequency case (E_2, X_2). Hence the light output also decreases toward that characteristic of low frequency excitation but never drops below since E_2 will always be less than E_1. An increase in voltage increases the maximum field but also increases the extent of the field so, although the rate of diffusion is greater, the volume into or out of which the diffusion takes place is also increased and the net effect on maintenance may be small. In the case of the blue phosphor (Section B-2) the copper-chlorine addition is relatively small so the volume concentration n of trapping or donor sites is expected to be small. It follows from Poisson's relation that the extent of the field will increase more rapidly with voltage if n is small. This blue phosphor (Table III) actually maintains output better at high voltages than at low voltages (at low frequency) as if in fact the excited crystal volume increased more rapidly with voltage than the rate of field-diffusion causing deterioration.

The temperature dependence of deterioration is very strong. If the diffusion of ions is involved, the electroluminescence half-life should be related to the ionic mobility (5) and should show an exponential temperature dependence. This dependence of half-life on temperature is shown experimentally in Fig. 7 and corresponds to an activation energy of about 0.1 ev.

In Section B-5 it was shown experimentally that electroluminescence deterioration is at least somewhat nonuniform, since contraction of the excitation region by reducing the voltage or increasing the frequency leads to a progressively smaller fraction of the light emission originally observed under the same conditions. This is to be expected. Any decrease of the positive charge density (the ionized donor or trapping sites active in the electroluminescence process) due either to incoming deeper traps or depletion of the normal traps by field-migration outward will reduce the field gradient gradually during deterioration and, at constant voltage, expand the high-field region into fresh parts of the phosphor crystal. Hence contraction of this region, as above, confines the excitation to phosphor parts which have been deteriorated the longest.

Evidence for the localization (8) of the electric field with increase in frequency was given in Sections B-5, B-6, and D-2. The pre-aging data of Section B-9 also indicate this effect. To pre-age a lamp to a given fraction of its initial brightness (measured at an arbitrary voltage and frequency) the voltage also must be increased if the frequency is increased; the contraction of the excitation region at the higher frequency must be counteracted by its expansion at higher voltage. Further evidence for this effect is implicit in the data of Sections B-1 and B-2. The blue phosphor, the only one showing better maintenance at high voltage (high fields),

also shows better maintenance as a longer half-life in terms of cycles of operation at high frequency (high fields). The other phosphors have longer half-lives in cycles at low frequency (low fields) and at low voltage (low fields). Incidentally, it was noticed recently that in his major 1947 paper (4) on electroluminescence, Destriau developed an analytical expression predicting higher active fields at higher frequencies of excitation.

The absence of even a slight shift in emission color, as deterioration proceeds to a point where brightness is only a few per cent of initial, suggests that the luminescence centers are not destroyed during electroluminescence deterioration for the following reason. All of the ZnS:Cu, Cl phosphors emit in both of the well-known blue and yellow-green emission bands of this type of phosphor; the blue-green and green emitters of this class, in particular, show substantial components of emission in both of these bands. If the blue and green centers differ significantly in their physical or electrical configuration, and if the motion of one constituent of the centers is involved in electroluminescence deterioration, then one of the centers is likely to be more vulnerable to destruction than the other by the deterioration process. No such effect seems to exist within the experimental error of a few per cent. On the other hand, the trapping and release of electrons is now considered to be an indispensable part of the electroluminescence process (14, 18-21). One theory (14) of electroluminescence in zinc sulfide explains the bulk of typical experimental data by considering only the trapping and release process without dealing explicitly with either recombination at the centers or the ionization process. If this trapping process is quenched by either or both the mechanisms described in Papers I or III, the electroluminescence brightness will deteriorate without destruction of the centers; as already pointed out, the maintenance of photoluminescence suggests that the luminescence centers remain intact.

In Section B-1 it was pointed out that some phosphors show a very definite slowly deteriorating component of light emission after long operation, and that probably all phosphors show this to some degree. In Fig. 15 the brightness-time data of a typical phosphor have been fitted by assuming

$$L = \frac{L_1}{1 + t/t_1} + \frac{L_2}{1 + t/t_2}$$

where $L_1 + L_2 = L_0$ and t_1 and t_2 are the widely different half-lives of the two components; here, $L_1 = L_2 = L/2$, $t_1 = 6$ hr and $t_2 = 97$ hr. In some cases according to such an analysis, the long-lived component deteriorates extremely slowly and is also a major fraction of the initial brightness; an example is the improved maintenance yellow phosphor of Fig. 14.

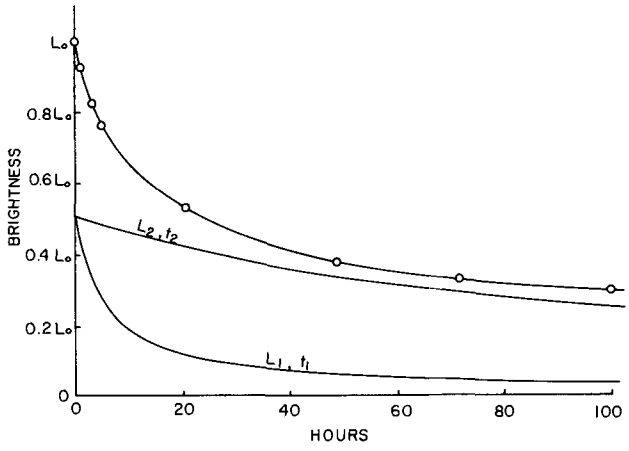

Fig. 15. Resolution of normal maintenance characteristic into short-lived and long-lived components. Standard green phosphor, 150 v, 4000 cps.

Acknowledgment

It is a pleasure to acknowledge the cooperation and valuable assistance of the author's associates. He wishes to thank particularly J. VanBroekhoven, W. Lehmann, and A. Wachtel for kindly supplying many of the phosphors, R. L. Fitzmaurice for making the countless lamps and for help in obtaining the data, J. M. Grasso and R. M. Potemski for their assistance, and H. F. Ivey for continued encouragement and helpful discussion.

Manuscript received March 24, 1960. This paper was prepared for delivery before the Chicago Meeting, May 1-5, 1960. Much of the work described in this paper was carried out under Contract AF33(616)5811 from the Wright Air Development Center.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

Determination and Identification of Impurities in Silicon from Low-Temperature Hall Data

R. T. Bate

Battelle Memorial Institute, Columbus, Ohio

and L. R. Weingarten and D. J. Shombert

Research Laboratory, Merck, Sharp and Dohme, Rahway, New Jersey

ABSTRACT

Low-temperature measurements of the Hall effect have been used to determine donor and acceptor concentrations and in some cases to identify the major impurity in silicon. A simple apparatus for making these measurements with liquid helium is described. Typical results are presented and correlated with lifetime data at room temperature. Interpretation of the Hall coefficient measurements is discussed, and a simplified analysis of the case of the two types of donor impurity is suggested.

Experimental Apparatus

Low-temperature Hall measurements have been used by many workers to study impurity levels in silicon.[1, 2] This paper describes the use of such measurements to evaluate high-purity Merck silicon.

Figure 1 shows the Dewar used for these measurements, which is relatively simple in design. The liquid nitrogen Dewar which serves as a radiation shield has been omitted for clarity. The Dewar, made of Pyrex, is arranged so that four samples can be run at one time, and these are fastened to a relatively massive brass block which is surrounded by a tube containing helium gas at 1 atm. Outside this is a reflux column, in which the helium pressure can be varied to control the transfer of heat from the samples to the liquid helium bath above. The gasket seal at the top of this column is arranged so that the pressure cannot cause an explosion as the Dewar warms. Under proper conditions, the samples will warm from 20° to 80°K in 5-6 hr. Measurements are made by d-c potentiometry, and the magnetic field is monitored by NMR.

Theory of Hall Effect

In extrinsic silicon, the Hall coefficient in a homogeneous rectangular sample is given by Eq. [1], [2], and [3], shown below

$$R = 10^8 \frac{V_H T}{IH} \frac{\text{cm}^3}{\text{coulomb}} \qquad [1]$$

$$R_n = \frac{r_c}{ne}, \frac{1}{e} = 6.25 \times 10^{18} \text{ coulomb}^{-1} \qquad [2]$$

$$R_p = \frac{r_v}{pe} \qquad [3]$$

V_H is the Hall voltage, I is the current in amperes, T is the thickness in cm, and H is the magnetic flux density in gauss; p and n are the hole and electron concentrations, respectively, and r_v and r_c are the respective Hall coefficient factors. These factors depend in general on crystal orientation, impurity

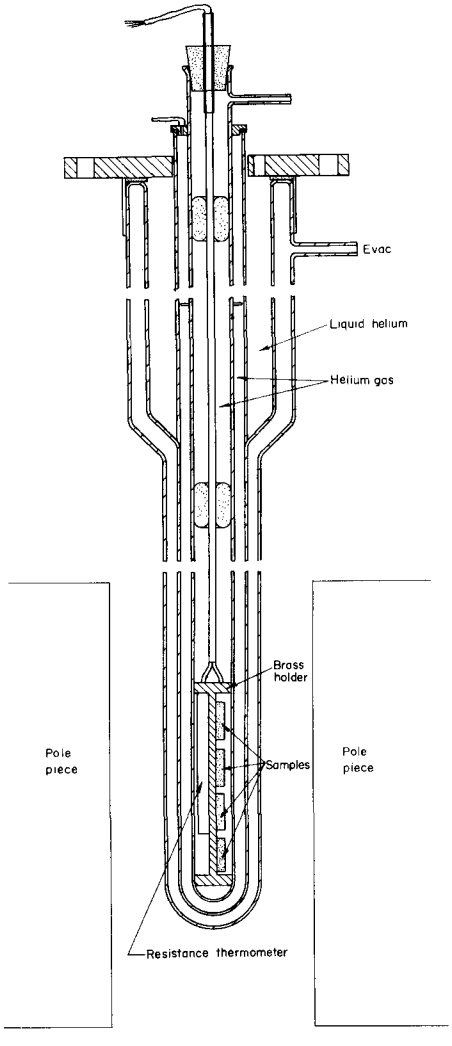

Fig. 1. Dewar for Hall measurements

[1] A method of determining the degree of compensation of p-type silicon from magnetoresistance measurements of liquid nitrogen temperature has been proposed also (1).

[2] References to much of this work are given in the review articles by Burton (2) and Kohn (3).

concentration, temperature, and magnetic field. If they can be determined, then the hole or electron concentration can be deduced directly from Hall measurements.

A discussion of the Hall coefficient factor for p-type silicon has been given by Beer and Willardson (4), and Gold and Roth (5) have studied n-type silicon. In p-type material, this factor is quite sensitive to ionized impurity scattering; however, the effect of impurity scattering in n-type material has not been calculated in terms of the exact conduction band structure. In high-purity silicon, the Hall coefficient factors are probably near unity below 40°K for reasonably strong magnetic fields. This assumption has been justified for p-type silicon by the careful work of Klein and Straub (6). Since our analysis of the Hall data required consideration only of the region below 40°K and the exhaustion region, correction for the Hall coefficient factor was necessary only in the determination of the exhaustion carrier concentration. The effect of impurity scattering in the exhaustion region in p-type material can be included by assuming initially that $r_v = 1$ at all temperatures and by calculating an approximate impurity concentration. This concentration is used then to calculate an impurity mobility from which the Hall coefficient factor can be evaluated by the method of Beer and Willardson. The Hall coefficient factor so determined then is used to correct the exhaustion carrier concentration.

The electron or hole concentration in extrinsic material is given by Eq. [4] or [5] below:

$$\frac{n(n+N_a)}{N_d-N_a-n} = A_c T^{3/2} \frac{\Sigma_i N_d^i f_d^i \exp(-\epsilon_d^i)/KT}{\Sigma_i N_d^i f_d^i}, \qquad A_c = 2.78 \times 10^{15} \frac{\text{deg}^{-3/2}}{\text{cm}^3} \quad [4]$$

$$\frac{p(p+N_d)}{N_a-N_d-p} = A_v T^{3/2} \frac{\Sigma_i N_a^i f_a^i \exp(-\epsilon_a^i)/KT}{\Sigma_i N_a^i f_a^i}, \qquad A_v = 5.62 \times 10^{14} \frac{\text{deg}^{-3/2}}{\text{cm}^3} \quad [5]$$

where N_a and N_d are the total acceptor and donor concentrations and N_a^i, f_a^i, and ϵ_a^i are the concentration, Fermi factor, and activation energy for a particular species of acceptor, N_d^i, f_d^i, and ϵ_d^i are the corresponding quantities for a particular donor. The Fermi factor for an impurity is just the probability that it is not ionized and for an acceptor is given by

$$f_d^i = \{1 + \tfrac{1}{4} \exp[(\epsilon_F - \epsilon_a^i)/KT]\}^{-1}$$

and for a donor by

$$f_d^i = \{1 + \tfrac{1}{2} \exp[(\epsilon_F - \epsilon_d^i)/KT]\}^{-1}$$

where ϵ_F is the Fermi energy. These equations are derived under the following assumptions: (*a*) only singly ionized (*i.e.*, groups III and V) impurities are present; (*b*) classical statistics hold; (*c*) no local interaction between impurities occurs; (*d*) excited bound states of carriers on impurities can be ignored (7); (*e*) the spin-orbit splitting of the degenerate ground state of the electron at the impurity site and perturbations of the band structure by the impurity can be assumed negligible (7); (*f*) the ground state of a donor is assumed doubly degenerate and that of an acceptor fourfold degenerate; and (*g*) impurity band conduction is not important. Under these assumptions, a unique activation energy can be defined which is just equal to the energy necessary to excite an electron from the valence band into the ground state of an acceptor or from the ground state of a donor into the conduction band.

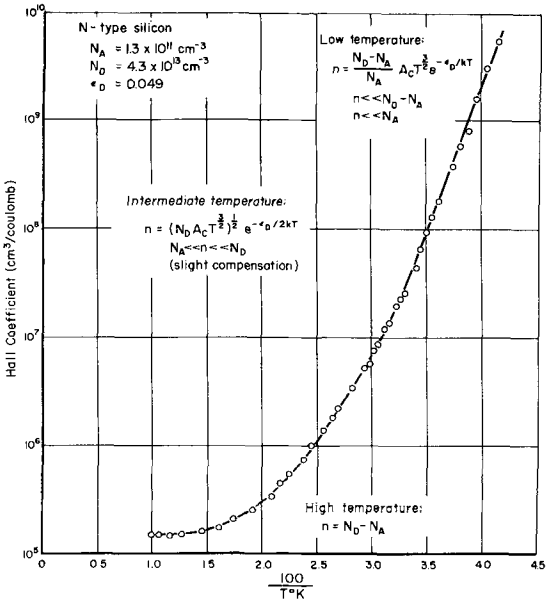

Fig. 2. Temperature dependence of Hall coefficient of n-type silicon.

Results and Discussion

Since the activation energies are known (8) for most singly ionized impurities in silicon, it is theoretically possible to identify those impurities and to determine the total donor and acceptor concentrations by fitting Hall data to these equations.

Figure 2 shows a temperature plot of the Hall coefficient for an n-type sample in which one donor (arsenic) seems to be predominant. This leads to the familiar situation in which three approximately linear regions appear on a semilog plot of the Hall coefficient *vs.* reciprocal temperature. The equations for the carrier concentration in each of these regions are given in the figure. The intermediate linear region occurs only in relatively uncompensated samples. The slope in this region is just half that in the low temperature region (neglecting the $T^{3/2}$ factor). The transition between these two regions occurs when the carrier concentration is approximately equal to the minority impurity concentration.

The fact that the intermediate linear region is observed in an n-type sample of this purity is rather surprising, since it suggests a very low boron concentration. Note from Fig. 2 that the analysis yields an acceptor concentration of the order of 10^{11} cm^{-3}. It is not clear whether this figure indicates the true boron content or whether some of the boron has become electrically inactive, possibly because of local interaction with some other impurity or defect.

The Hall plots for many undoped n-type samples show approximately linear regions between 20° and 40°K which correspond to activation energies in the

Table I. Activation Energies for Group III and Group V Impurities in Silicon

Group III acceptors	ev	Group V donors	ev
B	0.046	P	0.044
Al	0.057	As	0.049
Ga	0.065	Sb	0.039
In	0.16	Bi	0.067

For two donors whose activation energies differ by $\Delta\epsilon_1$ plot ln $(T^{3/2}R)$ *vs.* $1/T$ at low temperature:

$$\text{Slope} = 1/k\left[\epsilon_1 + kT\ln\left(\frac{N_1}{N_d} + \frac{N_2}{N_d}e^{\Delta\epsilon/kT}\right)\right]$$

range 0.039-0.049 ev. As can be seen from Table I, this range includes three relatively closely spaced levels associated with antimony, phosphorus, and arsenic. The behavior of the Hall coefficient in relatively uncompensated samples can be explained if it is assumed that two or three of these impurities are present. If $N_a << N_d$, the low-temperature slope of a plot of $T^{3/2}$ x the Hall coefficient *vs.* reciprocal temperature for the case of two donors in an n-type sample is $1/k[\epsilon_1 + kTln(N_1/N_d + N_2/N_d \exp^{\Delta\epsilon/KT})]$ where N_1 is the concentration of the donors with the lower activation energy, N_2 is the concentration of those with the higher activation energy, and $\Delta\epsilon$ is the difference of their activation energies. This slope is somewhat temperature dependent, but it always lies between the slopes expected for donor one alone and donor two alone. Assuming that the average experimental slope is given approximately by its value at 25°K, we can define an effective activation energy for a pair, and the carrier concentration at 25°K then is given by an equation which is of the same form as the relation for a single donor. Thus the total donor and acceptor concentrations for the case of two donors can be determined from the Hall coefficient at 25°K, the slope of the $T^{3/2}R$ plot at 25°K, and the exhaustion Hall coefficient in the same way they are found in the case of a single donor. This procedure is valid only provided $n(25°K) << N_a << N_d$ because the relative populations of the two levels are influenced by compensation.

For the case of two donors, the effective activation energy is easy to compute, and Fig. 3 shows a plot for the pairs, Sb-P, P-As, and Sb-As as a function of relative concentration. If measurements are made carefully, these plots can be used to estimate the relative concentrations for different pairs which might be present.

Figure 4 shows a Hall plot for two p-type samples. The low-temperature slopes are both characteristic of boron, but number two, which is from a zone refined crystal, still exhibits the intermediate temperature characteristic at the lowest temperatures. This is indicative of extremely low compensation.

Table II gives a summary of the results of Hall and room temperature lifetime measurements on some single crystal silicon samples.

Conclusions

The activation energies of the p-type samples investigated were all characteristic of boron, and the

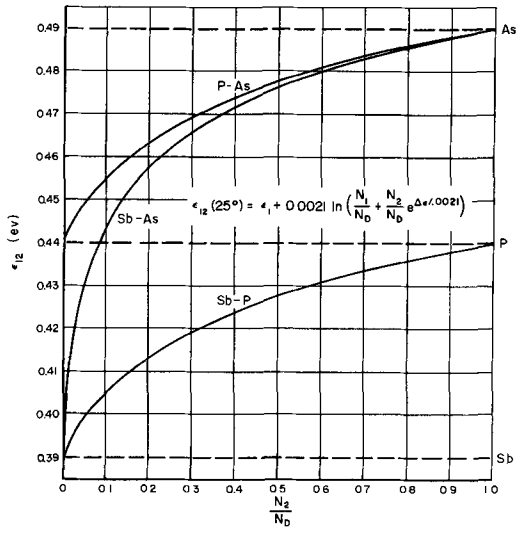

Fig. 3. "Effective" activation energy for pairs of donors in silicon at 25°K.

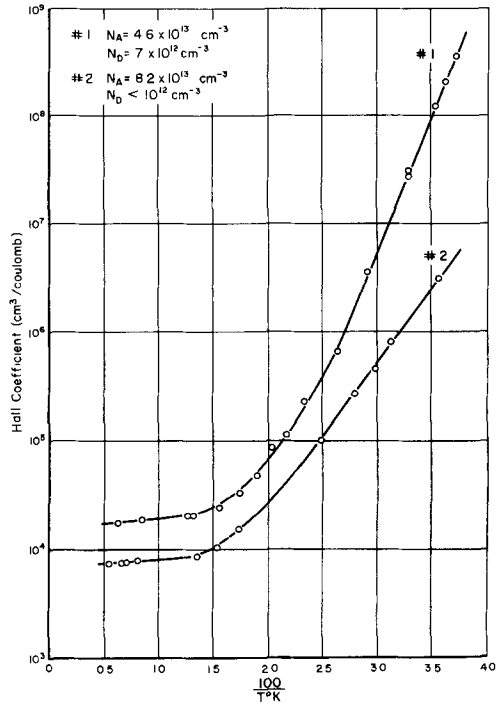

Fig. 4. Temperature dependence of Hall coefficient for two p-type silicon samples.

"effective" activation energies of the n-type samples were in the range 0.039-0.049 ev. It is concluded from this that the major acceptor impurity in all the samples investigated is boron and that it is present in concentrations of about 10^{13} cm^{-3}. The major

Table II. Lifetime Data on Some Single Crystal Silicon Samples

Sample	N_a, cm^{-3}	N_d, cm^{-3}	$N_a + N_d$, cm^{-3}	Lifetime, μ sec

A Modified Closed Box System for the Diffusion of Boron in Silicon

R. S. Yatsko and J. S. Kesperis

U. S. Army Signal Research and Development Laboratory, Fort Monmouth, New Jersey

ABSTRACT

A modified closed box diffusion system has been investigated over a wide range of conditions. Boron layers have been diffused in silicon from B_2O_3-SiO_2 sources ranging from concentrations of 0.2% B by weight to pure B_2O_3. Nonmelting source conditions have been varied to melting source conditions yielding surface concentrations ranging from 10^{18} to 10^{21} carriers/cc. Some effects of environmental atmospheres and materials are discussed. Applications to photovoltaic devices and double diffused transistors are described.

Boron diffusion is by far the most common approach today in the achievement of precision controlled p-type areas in silicon semiconductor devices. Yet methods currently in use for obtaining desirable surface concentrations of boron utilize widely varying diffusion techniques. Even techniques for the production of diffused areas of similar doping content and depth vary widely from one user to the other.

It is the objective of this paper to discuss the investigation of a general diffusion system for boron, capable of reproducibly attaining particular surface concentrations in the range 10^{18} to 10^{21} atoms/cc by using only simple variations of source concentration, temperature, and time. Experimental data, the capabilities, and limitations of this process are discussed, and although a complete investigation of the system is not presented, the results obtained have already been successfully applied to various semiconductor devices at these laboratories and should serve as useful information to those concerned with the design and fabrication of silicon devices.

Experimental

Figure 1 shows a typical diffusion boat consisting of quartz with provisions for holding a small platinum box in the center which carries the source material. Two center posts contain the box and separate it from two end compartments which carry the silicon wafers. The boat is constructed by sealing off tubular quartz and cutting a longitudinal section off, such that approximately ¾ of the cross-section area remains on the boat. The cut edges of the boat are carefully lapped flat with a 600 grit. A quartz flat plate acts as a cover plate. A 0.003 in. platinum sheet, equal in area to the quartz flat, acts as a gasket between the lapped edges and the cover plate. It is this gasket which forms a partial seal for the diffusion process. A single annealing process at 1100°C was sufficient to allow the platinum gasket to form on the contours of the quartz boat. The gasket could then be used many times with the same boat during subsequent diffusion runs with no further forming treatment. During the actual diffusion run, platinum wire was wrapped tightly about the entire assembly to prevent any movement of the parts during insertion and removal from the furnace.

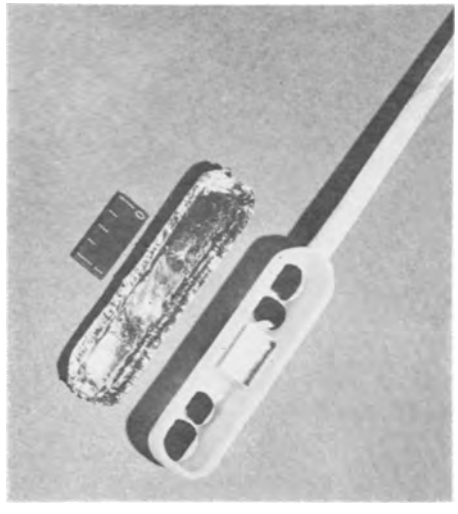

Fig. 1. Modified closed box showing quartz boat containing Pt source box and polished Si wafers. Formed Pt gasket is shown at left.

The boat thus constructed has only a partial seal and differs from a sealed capsule in this respect. However, the disadvantage of a finite leak rate was

not found to be significant as far as achievement of desired surface concentrations was concerned; the obvious advantages of ease in loading and re-use made it quite preferable to a sealed capsule technique.

Silicon wafers were polished carefully to a mirror finish using Linde A abrasive in an automatic bowl feed polisher. Diffusion was carried out in a Kanthal wound furnace using alundum tubes sealed off carefully at each end, with provisions for the insertion of the boat and dry argon gas.

Junction depths were measured by standard angle lapping and staining techniques (1). Evaluation of surface concentrations were made with four-point probe resistance measurements and the published data of Backenstoss (2).

Effects of system materials and environmental atmospheres.—The $B_2O_3SiO_2$ source is reactive with quartz and must be isolated from the quartz in the system. Initial attempts to use a high purity graphite modified closed box resulted in very nonuniform silicon surface layers that could not be removed by HF, dilute NaOH, or boiling HNO_3 followed by HF rinses. Furthermore, a significant erosion of the actual silicon surface was observed. These difficulties are eliminated by the use of either an all-platinum system (with provisions for holding the silicon on quartz flats) or an all-quartz system with a platinum container for the source as was adopted for these experiments.

The nature of the surrounding atmosphere and particularly the presence of the water vapor is of major importance in a closed box system which is not sealed totally against leaks. Early attempts to use the modified closed box with a surrounding air ambient consistently produced diodes with very low forward inflection voltages. Solar converters produced in this manner gave corresponding open-circuit voltages in the 0.3-0.4 v range. It became necessary to make the diffusion tube air tight and to flush the system carefully with argon which was passed through two liquid nitrogen traps to insure an acceptable level of dryness. The incorporation of these methods improved the reproducibility of electrical characteristics and resulted in normal inflection voltages.

Preparation of the diffusion source.—Four selected sources were prepared for diffusion from boric and silicic acids. Compositions ranged from the equivalent of pure boron oxide to 0.2% boron in the following manner: pure B_2O_3, $4B_2O_3$-$1SiO_2$, $1B_2O_3$-$1SiO_2$, and 0.2% B. The composite sources were prepared by mixing boric and silicic acid powders together, adding distilled, deionized water, drying over low heat with constant stirring. The source was then placed in a platinum source box and sintered at the diffusion temperatures under a dry argon atmosphere.

Diffusion from composite oxide sources must be preceded by a suitable sintering at either the diffusion temperature or at temperatures slightly higher in order to obtain consistent diffusion results. The sintering or "bake out" process is used to dry and homogenize the source and at the same time probably acts to saturate the quartz box with boron. As can be expected, nonmelting oxide sources are much more difficult to homogenize than melting sources. Consistent diffusion results have been obtained with melting sources after 1.5-2 hr of bake out, depending on the diffusion temperature and SiO_2 concentration in the source, while bake out times of 6 to 7 hr were necessary with nonmelting oxide sources. Thurston (3) and co-workers have studied the bake out time required for 0.1% B sources by experimentally comparing the diffusivities of phosphorus and boron in silicon dioxide. Although boron showed five times the diffusivity of phosphorus in silicon dioxide, bake out of nonmelting boron-silicon dioxides required 7 hr while nonmelting phosphorus-silicon dioxide sources required only 3 hr. It was also found that when fresh sources of B_2O_3-SiO_2 were used in an already used quartz capsule, an additional 7 hr bake out was necessary. On the basis of these experiments, the saturation of the source and quartz capsule could not explain effectively the unusually long bake out time required for nonmelting B_2O_3-SiO_2 sources.

Results and Discussion

Runs 1 and 2 in Table I show the range of results obtained for diffusions at 1129°C with a 0.2% B nonmelting source. Runs 3 to 5 show the results at 1218°C. Surface concentrations varied only by one-half order of magnitude between these temperature extremes. Reproducibility of penetration and doping at a given temperature was very good. These diffusions were characterized by very uniform post diffusion oxides with a maximum oxide thickness of 2800Å at 1218°C for 30-min diffusion time. Excellent uniformity of surface concentration was found over the entire area of the diffused wafers.

In order to obtain high surface concentrations at temperatures practicable for device manufacture, it was found necessary to increase the B_2O_3 in the source. It was determined that the order of 0.2% B represented the maximum concentration for nonmelting conditions in the source at 1200°C. An order of magnitude increase in boron concentration produced partial melting at temperatures as low as 1125°C. Progressive increases in the B_2O_3 concentration changed the appearance of the baked out source from a white powder (0.2% B) to an agglomeration of small hemispherical globules (2% B), through a series of uniformly white translucent glasses to 50% B_2O_3, followed by an increase in the transparency of the melt as the pure B_2O_3 glass was approached. The change in source appearance from nonmelting to melting conditions was accompanied by a sharp departure in appearance of the post diffusion oxides. It was found impossible to maintain uniformity in the grown oxide with melting sources. These variations in oxide thickness were accompanied at certain temperatures with nonuniformity in sheet resistance over the area of the diffused wafer, but in most cases, very uniform results were obtained.

Diffusion from 50% B_2O_3 sources had to be carried out at 1125°C or higher in order to obtain uniform sheet resistances over the entire wafer area. Runs 6 and 7 (Table I) show the variation in sheet resistance obtained on two wafers at 1100°C. Variations

of one order of magnitude in surface concentration were observed from wafer to wafer at 1100°C. Uniform sheet resistances were obtained at 1125°C and higher, with a much greater reproducibility in surface concentration. Runs 8 to 11 show the range of diffusion results for 25 min and 20 min diffusion time at 1125°C. Higher surface concentrations were obtained at 1200°C with the 50% B_2O_3 source. Runs 12 to 16 list the data obtained from the five wafers diffused at 1200°C.

In order to determine whether an increase in boron concentration would result in higher surface concentrations at 1125°C, five runs were made with an 80% B_2O_3 source (Runs 17-21). No significant difference was observed in surface concentration between the two sources at 1125°C. At 1200°C the difficulty encountered in removing postdiffusion oxide layers from the 80% source made a comparison with the 50% source impossible.

It was found that the postdiffusion oxides became more difficult to remove with longer diffusion times. Although no difficulties were encountered with the 50% and 80% source at 1125°C for diffusion times of 15 min to ½ hr, deep diffusions of 4 hr duration produced surface layers very difficult to remove. Diffusions for 4 hr at 1200°C produced surface layers which were impossible to remove. Diffusions from pure B_2O_3 sources had to be performed at temperatures below 1025°C to prevent pitting and erosion of the silicon surface. However at 1000°C, no difficulties were encountered for diffusion times as long as 2.5 hr.

Runs 22-28 list the data from 7 control runs made at 1000°C for 2.5 hr with pure B_2O_3 as the source. Excellent control of sheet resistance and penetration was obtained.

Fabrication of solar cells.—Five solar cells were fabricated utilizing the pure B_2O_3, 1000°C process. Since doping levels of 2×10^{20} were obtainable by this process, it was thought that the relatively low temperature required would be the least deleterious to the lifetime in the device, and this was the basis for choosing this as the beginning process in determining the optimum modified closed box process for solar cell fabrication. The diffused cells were given electroless nickel contacts to both p- and n-sides, followed with a solder dip. A polystyrene coating was placed over the active area to reduce reflection. Evaluation was conducted with a tungsten filament light source, filtered through a water bath to reduce the infrared. The illumination was calibrated to a radiation rate of 84.4 mw/cm^2. The total dark current series resistance amounted to 0.2 ohm. Surface concentrations and junction depths were as shown in Table I for the pure B_2O_3 runs. Results are indicated in Table II. Figure 2 shows the comparative light output current-voltage characteristics for cells 1 and 5 which represent the performance extremes from this group.

Application to Transistor Fabrication

The technique was applied to the fabrication of the emitter region of a p-n-p transistor. Table III

shows results obtained for a number of emitter diffusion runs. The base region into which the boron emitters were diffused was diffused previously with antimony. The antimony depth of diffusion was approximately 2.5 μ and the surface concentration ranged from 1×10^{19} atoms/cc to 2×10^{19} atoms/cc. It was necessary to diffuse the boron emitters to shallow depths in order to maintain a thin base region. The aim was to diffuse the boron emitters to depths varying from 1.0 to 1.5 μ, attain a surface concentration greater than 10^{20} atoms/cc, and obtain masking in regions where the boron was not desired. Examination of Table III reveals that the sheet resistance of the group of wafers diffused with the 80% source ranged from 4 to 6 ohms/square. Diffusion depths varied from 1.3 to 1.4 μ for the temperature and time used, and the surface concentration achieved ranged from 3×10^{20} to 4×10^{20} atoms/cc for the temperature used. Diffusions with the 50% source were performed at two different temperatures, 1125° and 1106°C. At 1125°C the diffusion depths obtained were 1.4 μ and the sheet resistance was 11.2 ohms. At 1106°C the diffusion depths varied from 1.0 to 1.1 μ and the sheet resistances from 14.4 to 15.7 ohms. A surface concentration of 2×10^{20} atoms/cc was obtained at both temperatures at which the diffusions were made. Pure B_2O_3 was used for lower temperature diffusions. A surface concentration of 2×10^{20} atoms/cc was achieved at the temperature used. Sheet resistances varied from 8 to 10 ohms/square and junction depths ranged from 1.2 to 1.3 μ. No difficulty was encountered in removing the oxides from any of the diffused samples. Masking of boron where desired can be obtained by choosing a suitable combination of diffusion conditions and oxide thickness. For the diffusion conditions listed and an oxide thickness of approximately 1800Å complete masking of boron was achieved. The three melting sources have been used for forming emitters in fabricating a high-frequency p-n-p transistor. The nonmelting source is an excellent technique for forming a base region in a n-p-n or n-p-i-n structure.

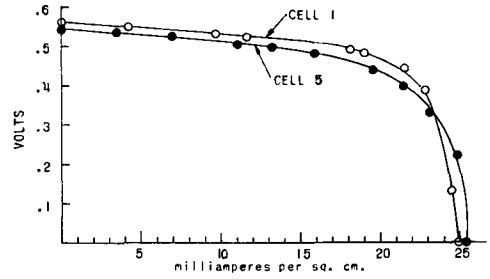

Fig. 2. Output current-voltage characteristics for cells 1 and 5 under 84 mw/cm² illumination.

Summary

The box technique described herein can be utilized with good advantage on many areas of silicon device technology. Specifically, the excellent control and uniformity of nonmelting sources (0.2% B max) is ideally suited for formation of base areas in n-p-n transistor structures where concentrations over 1×10^{19} carriers/cc are not required. Highly doped areas, 5×10^{20}-1×10^{21} can be obtained easily with the 50% B_2O_3 source. Moderate doping in the 1×10^{20}-5×10^{20} range is best obtained with the 50% and 80% B_2O_3 sources. Where low diffusion temperatures are required, pure B_2O_3 sources can consistently yield doping levels of 2×10^{20} at 1000°C. Consistently reproducible high efficiency solar converters in the 11% efficiency range are being made from pure B_2O_3 sources. Higher conversion efficiencies may be possible by increasing the surface concentration by diffusion from a composite source at higher temperatures, but this remains to be seen.

Emitter junctions have been made by three different diffusion sources, 80% B_2O_3, 50% B_2O_3, and pure B_2O_3. All three sources met specific device p n p requirements of doping (2×10^{20} min), successful oxide masking of the base, and ease of emitter oxide removal. The specific process for a particular device will depend of course on the best device yield as well as on meeting the design specifications.

General observations of the process can be summarized as follows: (*a*) long time diffusions (4 hr) with composite sources produced very tenacious surface layers and irregular junctions; (*b*) a minimum SiO_2 concentration of 50% was required for diffusion at 1200°C or above; (*c*) 50% sources required temperatures of 1125°C min for best repro-

ducibility of diffusion results; and (*d*) diffusion from pure B_2O_3 sources must be restricted to a maximum temperature of 1025°C to minimize surface erosion and pitting. At 1000°C, no difficulties are encountered.

Acknowledgment

The authors wish to thank Dr. Howard Loar of Bell Telephone Laboratories, Murray Hill, New Jersey, for the helpful discussions on the effects of environmental atmospheres on boron diffusions, and Messrs. J. Mandelkorn and A. LaRocque, USASRDL, for their helpful comments during the course of this work. Particular indebtedness is due Mr. W. Pharo, USASRDL, whose careful growth and preparation of silicon material made this work possible.

Manuscript received March 21, 1960. This paper was prepared for delivery before the Houston Meeting, Oct. 9-13, 1960.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

Properties of PbSe Prepared by Powder-Metallurgy Techniques

J. F. Miller and R. C. Himes

Battelle Memorial Institute, Columbus, Ohio

ABSTRACT

The application of powder-metallurgy techniques to the preparation of bulk specimens of lead selenide was studied; both the hot-press and the press-and-sinter methods were employed. Compacting pressure, sintering temperature sintering time, and the particle size of the powder were treated as variables. Electrical and thermoelectric properties, densities, and microstructures of the specimens were studied.

Sound specimens of near-theoretical density and with electrical and thermoelectric properties similar to those of the best of cast lead selenide were prepared successfully by the hot-press method. Densities of hot-pressed specimens, which were highest for those prepared at 750°C, 8100 psi, were observed to decrease with sintering temperature in the range 750°-450°C, and with compacting pressure in the range 8100-2000 psi. The pressed-specimen density was not affected appreciably by variations of sintering time (in the range 5 min-5 hr at 750°C) or variations of the particle size of the powder (in the range —60 to —200 mesh). Electrical properties of specimens with densities in the range 90-98% of theoretical, which were prepared by both the hot-press and the press-and-sinter methods, did not change significantly as density varied in this range.

Lead selenide is a potentially useful semiconductor for several types of applications. Among these are applications which make use of (*a*) its thermoelectric properties, and (*b*) the (high) positive temperature coefficient of resistance of doped lead selenide in the extrinsic temperature range. However, when conventional casting techniques are used to prepare lead selenide circuit elements, several difficulties are encountered. Unless temperature and environment are controlled precisely, there is a pronounced tendency for pores or voids to form in the castings. If cooling rate is low enough to induce reasonable crystal growth, doping elements segregate. Both of these phenomena tend to produce electrically heterogeneous castings. In addition, when special shapes are required, they often cannot be cast at all or cannot be cast with the desired degree of precision. Use of powder-metallurgy techniques was seen as one possible means of satisfactorily circumventing these difficulties, providing specimens with acceptable physical and electrical properties could be prepared in this manner.

In this investigation of the application of powder-metallurgy techniques to the preparation of lead selenide, both the hot-press and the press-and-sinter methods were employed. Compacting pressure, sintering temperature, sintering time, and particle size of the powder were treated as variables. Electrical and thermoelectric properties, densities, and microstructures of the specimens were studied to evaluate the processes.

Experimental Procedures

The lead selenide used in this research was prepared initially by reacting high-purity (99.999%) lead and selenium in the molten state in evacuated, sealed, quartz containers. The master batch of n-type material, which was used in the majority of the experiments, was doped with 0.25 at. % excess lead and 0.025% by weight of bismuth. To ensure that this material would be as nearly uniform as possible, it was quenched in room-temperature oil from the molten state. The p-type lead selenide employed was from an ingot which was cast by the Bridgman method and doped with 0.02% by weight of arsenic.

Except as is otherwise noted, the powders were prepared, classified as to particle size, loaded into

the pressing equipment, and were pressed in an atmosphere of dry argon. The powder-metallurgical specimens prepared were cylinders ⅝ in. in diameter by approximately ½ in. long.

Hot pressing was done in inductively heated graphite dies. Design and operation of the hot-pressing apparatus has been described by Bourke, *et al.* (1). Hot pressing was done at three temperatures, 750°, 600°, and 450°C; at three compacting pressures, 8100, 4000, and 2000 psi; and for various sintering times in the range 5 min-5 hr. Powders of three particle-size ranges were used: −200 mesh; −100 + 200 mesh; and −60 + 100 mesh.

Specimens prepared by the press-and-sinter method were first compacted in latex tubes under 100,000-psi hydrostatic pressure. The compacts then were transferred to quartz tubes, which were evacuated and sealed with a minimum of free (vapor) space. The specimens were sintered at temperatures of 450°, 600°, and 750° for a period of 5 hr.

For anneal treatment, cast specimens also were sealed in close-fitting, evacuated quartz tubes. Similar cooling rates were established following the heat-treatment step in all three processes (*i.e.*, hot press, press and sinter, and anneal) so that specimens would be comparable in this respect.

Electrical measurements were made on bridge-type Hall specimens to which Chromel leads were attached by spot welding. Both d-c and a-c Hall measurements were made. In cases where both types of measurements were made on a given specimen, values for resistivity, Hall coefficient, and mobility obtained from the a-c data were generally lower (*e.g.*, mobilities lower by 5-10%) than those from the d-c measurements. A qualitatively similar change was noted in d-c values when procedure was altered from that of making measurements after a steady-state condition had been obtained to that of making measurements as soon as possible after current and magnetic field had been turned on. It is likely that the differences arise because of the relatively large Peltier effect in this high-Z material.[1]

Thermoelectric properties were determined by use of the "Z-meter" (2). This device makes possible reasonably accurate measurements of both the Seebeck coefficient and thermal conductivity of such small (1.5 cm long) specimens as were available for this research.

Densities were determined gravimetrically by the hydrostatic method and were measured with respect to both ethanol and methanol. It was found that water, which was initially tried as a reference fluid, does not "wet" lead selenide perfectly, and as a result yields scattered, low values. With the technique employed, multiple measurements were made yielding mean density values to which probable errors of less than ±0.01 g/cm³ could be ascribed in every case.

In preparing the specimens for metallographic examination, Murakami's electrolytic etch, containing 22 parts $K_3Fe(CN)_6$, 5 parts NaOH, and 945 parts water by weight, was used to bring out grain boundaries.

[1] The thermoelectric figure of merit $Z \equiv \alpha^2/K\rho$, where α is the Seebeck coefficient; K, thermal conductivity; and ρ, electrical resistivity.

Experimental Results and Discussion

Electrical properties.—The preparation, electrical properties, and densities of the powder-metallurgical specimens are summarized in Table I. (In this table, data on several of the specimens are repeated one or more times to facilitate comparisons.) Properties of specimens of the cast material (first group in table) are also given. Measured electron mobilities (Hall) for the cast lead selenide are low, presumably because of high concentrations of grain boundaries and defects in this quenched material. Heat treatment similar to that given the powder-metallurgical specimens in preparation (*i.e.*, anneal at 750°C for 5 hr, see specimen 74B-1) failed to change electrical properties significantly, however.

In general, electrical properties of the powder-metallurgical specimens compare favorably with those of the cast polycrystalline material and with those of polycrystalline and single-crystal lead selenide which are reported by others (3, 4). Resistivities and Hall mobilities for the powder-metallurgical specimens are similar to those for cast polycrystalline and single-crystal lead selenide of like purity that has solidified progressively and slowly from the molten state. Seebeck coefficients and temperature dependencies of Seebeck coefficient and resistivity in the range 300°-575°K, which were studied for a number of the powder-metallurgical specimens, were also similar to those for cast lead selenide.

For the n-type material, electrical properties vary somewhat from specimen to specimen. However, no correlation is apparent between the relatively minor variations in electrical properties observed and changes made in conditions under which the samples were prepared.

For the p-type lead selenide, resistivity and Hall coefficient of the hot-pressed specimen are significantly lower than those of the cast starting material, while on the other hand, mobility in the specimen remained quite good. Since just one experiment with p-type lead selenide was conducted in this exploratory study, it is not possible to say whether the changes noted are inevitably to be expected in hot pressing p-type material or are to be expected only under certain experimental conditions and/or with specific doping agents.

Density.—For a majority of the n-type hot-pressed specimens, determined densities are higher than both the theoretical value calculated from x-ray data and the measured density of sound specimens of similarly doped cast lead selenide. In addition, in a number of cases, measured densities are also higher than can be accounted for, even though consideration is given to concentrations of excess lead and bismuth which are present. The possibility of an effect of pressure on the lattice is suggested.

Density of both the hot-pressed and the pressed-and-sintered specimens varied in a normal manner with respect to sintering temperature and compacting pressure. Density of the 5-hr hot-pressed specimens decreased as sintering temperature was reduced in the range 750°-450°C (with pressure held constant, consider specimens 79-81), and as compacting pressure was reduced in the range 8100-

2000 psi (with temperature held constant, consider specimens 79, 90, 91). For the press-and-sinter method, in which samples were initially compressed to near-theoretical density, density of the sintered specimens decreased as firing temperature was increased through the range 450°-750°C. In the ranges studied, density did not vary appreciably with hot-press time (5 min-5 hr at 750°C, 2.5-5 hr at 600°C) or particle size (−60 to −200 mesh).

The study was not sufficiently comprehensive to permit a full evaluation of combined effects of the variables. However, if the hot-press process variables are considered singly, it may be noted that near-theoretical densities were attained at minimums of 8100 psi compacting pressure, 600°C sintering temperature, and 5 min hot-press time; densities roughly equal to that of cast material were attained at minimums of 4000 psi compacting pressure, and 450°C sintering temperature.

Density of the p-type specimen, which was hot pressed for 5 hr at 750°C, is significantly lower than that of similarly treated n-type material. The excess lead, which was present in the n-type material, apparently has a salutary effect on the sintering process. The sintering of p-type lead selenide, which may proceed by different mechanisms, should be the subject of a separate study.

It is considered significant that, although densities of the sintered specimens ranged down to about 90% of theoretical, electrical properties did not change appreciably, Such low-density powder-metallurgical materials, because of the possible effect of the high concentrations of grain boundaries and voids (*i.e.*, lattice discontinuities) on thermal conductivity, may possess superior over-all thermoelectric properties.

Microstructures.—Microstructures of the hot-pressed lead selenide specimens, Fig. 1, show clearly the effects of variation of sintering temperature and time on average grain size, and of variation of compacting pressure on density.

At 750°C, 8100 psi, (Fig. 1a) considerable growth of crystals was obtained in the course of a 5-hr treatment, but at 450°C under otherwise similar conditions (Fig. 1b) little or no crystal growth occurred. However, some crystal growth is seen to have occurred in only 5 min at the higher temperature (Fig. 1c). In photomicrographs 1a, d, and e, the decrease in average grain size and density (*i.e.*, increase in concentration and size of voids) as compacting pressure is decreased from 8100 to 2000 psi may be seen. Differences between 8100 and 4000 psi are slight, but at 2000 psi both density and average grain size are considerably reduced.

Even though an extremely high compacting pressure (100,000 psi) was used in the press-and-sinter method, crystals present in the specimens were small and densities were relatively low (Fig. 1f).

phase were found in all specimens. However, metallographs showed that concentrations of this phase were considerably higher in specimens which were prepared from powder that was exposed to air in the course of grinding and loading operations.

Thermoelectric properties.—Thermoelectric properties of a typical high-density hot-pressed lead selenide specimen, which are given in Table II, indicate that material with a good thermoelectric figure of merit can be prepared by this method. It should be noted that these favorable indications have been obtained without any effort to optimize the powder-metal product with respect to thermoelectric properties. As has been suggested previously, thermoelectric properties of low-density powder-metallurgical lead selenide may be of special interest and should be the subject of future studies.

Conclusions

Sound specimens of n-type lead selenide with electrical and thermoelectric properties similar to those of cast lead selenide can be prepared by hot pressing.

Near-theoretical densities can be obtained by hot pressing for only 5 min at 750°C, 8100 psi, and for 2.5 hr at 600°C, 8100 psi. Density of the specimens decreases with sintering temperature in the range 750°-450°C, and with compacting pressure in the range 8100-2000 psi. No appreciable effect on density is produced by variation of sintering time (in the range 5 min-5 hr at 750°C, 2.5-5 hr at 600°C). Variation of size of powder particle in the range −200 to −60 mesh likewise produces no noticeable effect.

Electrical properties of hot-pressed p-type lead selenide deviate from those of the cast starting material to a greater degree than do those of the n-type material. Density of the p-type material is significantly lower than that of n-type material which is hot-pressed under similar conditions.

Specimens produced by the hot-press method contain larger crystallites and are of higher density than those prepared by the press-and-sinter method (100,000 psi). Specimens with densities in the range 90-98% of theoretical can be prepared by both methods. Anomalously high densities (above 100% of theoretical) can be attained by hot pressing. Of possible significance is the fact that electrical properties of the lead selenide that is doped suitably for thermoelectric use do not change appreciably as density varies in the range covered in this investigation.

Acknowledgments

The authors wish to express their thanks to J. E. Mock, who prepared the specimens, F. J. Reid and B. Paris, who made the electrical measurements, and J. L. McCall, who prepared the metallographs.

Manuscript received April 29, 1960. This investigation was supported by The Selenium and Tellurium Development Committee.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

Brief Communications

The JOURNAL accepts short technical reports having unusual importance or timely interest, where speed of publication is a consideration. The communication may summarize results of important research justifying announcement before such time as a more detailed manuscript can be published. Consideration also will be given to reports of significant unfinished research which the author cannot pursue further, but the results of which are of potential use to others. Comments on papers already published in the JOURNAL should be reserved for the Discussion Section published biannually.

Kinetics of the Formation of the Iron-Tin Alloy $FeSn_2$

Robert P. Frankenthal[1] and Alexei W. Loginow

Applied Research Laboratory, United States Steel Corporation, Monroeville, Pennsylvania

ABSTRACT

The kinetics of the formation of the iron-tin alloy $FeSn_2$ have been studied at temperatures below and above the melting point of tin (232°C). At all temperatures studied, the growth obeyed the parabolic-rate law. This is indicative of a diffusion mechanism. An Arrhenius plot of the data gives a straight line below the melting point of tin and a straight line above the melting point of tin, with a sharp break at the melting point. The activation energy is the same below and above the melting point of tin and is 29.3 ± 1 kcal/mole. The kinetics of the growth were also studied as a function of various properties associated with the tin plate: tin-coating weight, steel base, and the type of pickle to which the steel base was subjected prior to electroplating of the tin. No effect due to any of these variables was found.

At temperatures up to 496°C, iron and tin react to form the intermetallic compound $FeSn_2$ (1). This compound will form not only above the melting point of tin (232°C) but also below it (2), contrary to the findings of Davies and Hoare (3). Little data have been published on the rate and mechanism of formation of this alloy: Seybolt (4) measured the rate of alloying when steel is immersed in a bath of molten tin at constant temperature and found the parabolic-rate law to be obeyed. This is indicative of a diffusion mechanism. Thwaites (2) has studied the formation of the alloy and its metallography as a function of the rate of change of temperature, at temperatures above the melting point of tin. He also reported a few results on the formation of the alloy at constant temperatures below the melting point of tin. Lambert (5) studied the alloy-growth rate on commercial tin plate at temperatures below the melting point of tin. However, because of the short times investigated and the thin tin coatings on his samples, he was not able to determine whether the alloy grew by a diffusion mechanism; also, his experiments were done with an initial alloy coating present and this unnecessarily complicated the calculations. He also stated that according to the phase diagram, at temperatures below the melting point of tin the alloy FeSn must be formed; however, this was not verified by analysis. Moreover, Stoll and Birch (6) have not been able to observe by electron diffraction any patterns other than that of $FeSn_2$ on alloys formed at temperatures up to 260°C.

The present work represents an analysis of the rate of formation curves at constant temperatures below and above the melting point of tin and the effect of temperature on the rate of formation of the alloy. Since the alloying was performed on steel covered with an electroplated tin coating, the effect of (*a*) variations in the thickness of the tin coating, (*b*) the steel base, and (*c*) surface preparation of the steel prior to electroplating on the rate of formation of the alloy were also examined.

[1] Present address: E. C. Bain Laboratory for Fundamental Research, United States Steel Corporation, Monroeville, Pa.

Experimental

The samples were prepared by electroplating the tin onto Type L (low metalloid; % Fe > 99) steel sheets from a phenolsulfonic acid electrolyte to thickness of 0.29 mg/cm², 0.50 mg/cm², 0.72 mg/cm², and 1.05 mg/cm². The tin plate with a coating of 0.72 mg/cm² was prepared with four different pickling treatments of the steel base prior to electroplating, to determine whether steel preparation had any effect on the rate of alloy formation. All pickling treatments were performed at room temperature (approximately 27°C): (*a*) electrolytic pickle in 5% H_2SO_4, 1.5 sec cathodic, 1.5 sec anodic; (*b*) electrolytic pickle in 5% HNO_3, 1.5 sec cathodic, 1.5 sec anodic; (*c*) 5-sec dip in 5% H_2SO_4; (*d*) 5-sec dip in 5% HNO_3. The steel came from four different coils produced in different steel mills at different times to determine coil to coil variations on the rate of alloy formation.

The alloys were prepared by heating the samples in a constant-temperature oil bath for various times ranging from 2 sec to 6 hr, these times being dependent on the temperature under study, which ranged from 175° to 316°C. The melting point of tin is 232°C. The temperature of the oil bath was controlled to ±0.5°C for temperatures up to 260°C. At the higher temperatures, the control was ±2°C. Upon removal from the oil bath, the samples were quenched immediately to room temperature in water or in an organic liquid. The quantity of alloy formed was determined coulometrically by the method of Kunze and Willey (7), as was the tin coating weight of the material used. In this method, the tin and the alloy are anodically stripped at constant current in 1M HCl. When all the tin has been stripped and again when all the alloy has been stripped, the potential of the sample, as measured with a silver-silver chloride reference electrode, becomes more positive. The potential-time behavior of the sample was followed on a recorder (chart speed of 30 in./min). From the measured time required to strip the tin and the alloy and from the

known current, the quantity of tin and alloy present could be calculated making use of Faraday's Laws of electrolysis. It was possible to determine the alloy to ± 0.002 mg/cm^2 by this means.

Results and Discussion

The rate of alloy growth at all temperatures studied decreased with time, as would be expected if the parabolic-rate law were obeyed; this is typical for alloying reactions and is indicative of a diffusion mechanism. Seybolt (4) found this in his study of the tin-iron system above the melting point of tin. Therefore, the data were plotted (Fig. 1 and 2) according to the parabolic-rate law, w^2 vs. t, where w is the quantity of alloy formed at time t. Linear plots are observed, but they do not go through the origin as would be expected if the parabolic-rate law were obeyed from the beginning of the reaction ($t = 0$). This type of phenomenon is frequently observed in gas-metal reactions, such as oxidation (8) or sulfidization reactions (9), and is attributed to an

interface reaction between the metal and the gas that establishes the initial reaction layer, after which diffusion through the reaction layer becomes rate-controlling. It would be natural to expect the same situation to exist in this study since the conditions are analogous, except that either a solid-solid or a solid-liquid reaction exists at the interface instead of a solid-gas reaction. The mathematics of the metal-gas reaction were treated initially by Fischbeck (10) and by Wagner (11) and more recently by Dravnieks and Samans (9), who assumed first-order kinetics for the interface reaction. This approach was applied to the data obtained in these studies in the hope of determining the rate of the interface reaction. However, the data did not follow this relationship and thereby indicated that the interface reaction did not obey simple first-order kinetics. No further attempt was made to study the interface reaction.

Parabolic-rate constants for the diffusion reaction at the various temperatures, the slopes of the plots in Fig. 1 and 2, are given in Table I. An Arrhenius plot of the log of the parabolic-rate constant vs. the reciprocal of the absolute temperature is shown in Fig. 3. Table I and Fig. 3 include data not shown in previous figures. Two straight lines with a sharp break at the melting point of tin are observed. The

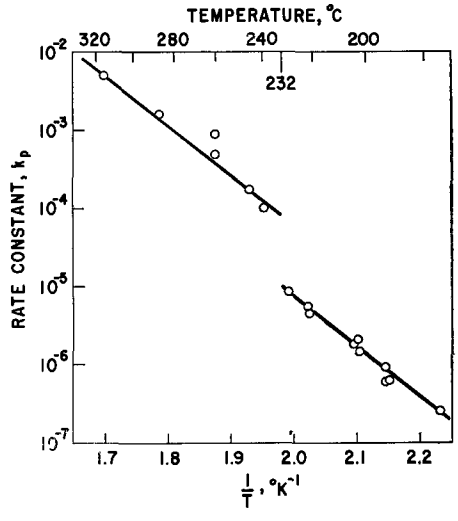

Fig. 3. Rate of formation of $FeSn_2$ with temperature.

calculated activation energy below and above the melting point is the same within experimental error and is 29.3 ± 1 kcal/mole. This value is in good agreement with the value of 28.6 kcal/mole [2] found by Seybolt (4). No similar results for analogous systems have been found in the literature. The sharp increase in the reaction rate above the melting point of tin is believed due to increased contact area at the Sn-Fe interface, compared with solid tin electrodeposited on iron.

The intercepts of the parabolic plots on the ordinate, Fig. 1 and 2, average at approximately 0.006 mg/cm^2. From the density of $FeSn_2$ (12), 7.74 g/cm^3 and the lattice parameters (13) of the alloy, a = 6.53Å and c = 5.33Å, this is calculated to be equivalent to a thickness of 11 unit cells of the alloy, which does not seem to be an unreasonable thickness, at which the interface reaction ceases to be rate-determining and the diffusion reaction commences to be rate-determining.

Tin-coating weight.—In early experiments, it was observed that some of the tin was dissolved from the samples in the oil bath, but it was not known how this affected the results. Hence, the effect of the thickness or weight of the tin coating on the rate of growth of the alloy was studied. Results are shown in Fig. 4 for 204° and 239°C. It is apparent that there is no effect except possibly at the high alloy weight levels for the 0.29 mg/cm^2 plate, in which case the results are low. These are low because there was insufficient tin on the plate (some having dissolved in the oil bath) to form more alloy, as evidenced by the fact that these samples had no free tin left on them when they were removed from the oil bath.

Steel base.—Data in Fig. 3 were obtained using the steel from the four different coils described previously. Alloy-growth studies with each steel were made at temperatures below and above the melting point of tin. Since the data from each of the coils lie on the observed lines, it is concluded that coil to coil variations do not affect the kinetics or mechanism of the growth of the alloy.

Pickle.—Figure 5 shows the effect of the various pickling treatments prior to electroplating on the rate of formation of the alloy layer at 202° and 240°C. No effect is evident, although these different treatments undoubtedly affect the surface of the steel in different manners.

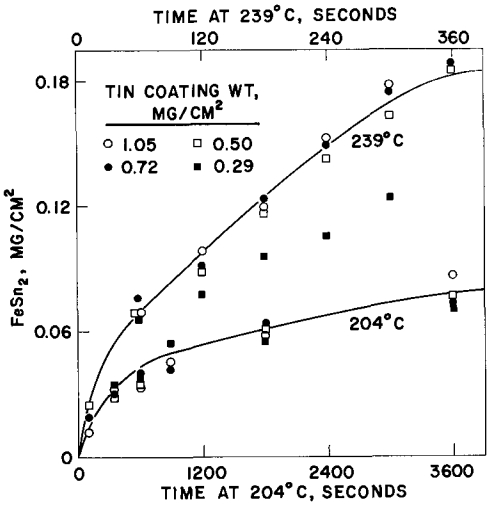

Fig. 4. Formation of $FeSn_2$ as affected by tin-coating weight.

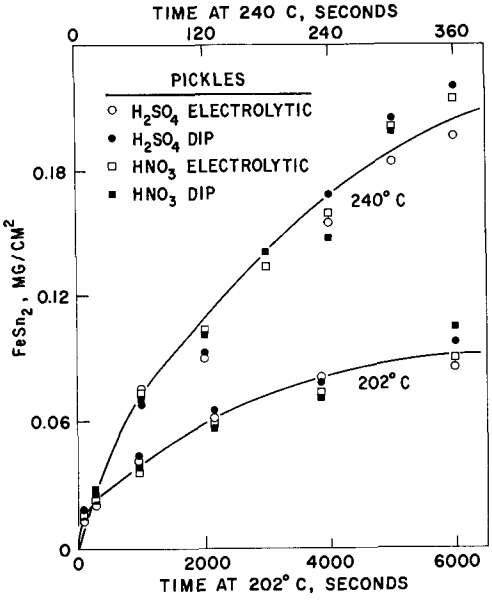

Fig. 5. Formation of $FeSn_2$ as affected by pickling conditions.

Summary

The kinetics of the formation of the iron-tin alloy $FeSn_2$ have been studied at temperatures below and above the melting point of tin (232°C). At all temperatures studied, the growth obeyed the parabolic-rate law. This is indicative of a diffusion mechanism. An Arrhenius plot of the data gives a straight line below the melting point of tin and a straight line above the melting point of tin, with a sharp break at the melting point. The activation energy is the same below and above the melting point of tin and is 29.3 ± 1 kcal/mole. The kinetics of the growth were also studied as a function of various properties associated with the tin plate: tin-coating weight, steel base, and the type of pickle to which the steel base was subjected prior to electroplating of the tin. No effect due to any of these variables was found.

Acknowledgment

The authors wish to thank Drs. R. T. Davis, Jr., and C. Luner for their helpful discussions and Messrs. R. F. Higgs and E. C. Brendlinger for preparing the tin plate used in these studies.

Manuscript received April 22, 1960.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

[2] Seybolt reported an activation energy of 14.3 kcal/mole. However, his rate constants were calculated from the slope of a w vs. $t^{1/2}$ plot and are thus equal to the square root of the rate constants calculated from a w^2 vs. t plot; the activation energy calculated from the former rate constants will be equal to one-half that calculated from the latter rate constants.

Properties of Vanadium-Columbium Alloys

S. T. Wlodek

Metals Research Laboratory, Union Carbide Metals Company,

Division of Union Carbide Corporation, Niagara Falls, New York

ABSTRACT

The development of a series of vanadium-columbium alloys is described. The exploitation of this alloy system allows the design of high-strength, low-density compositions possessing good aqueous corrosion resistance in boiling, oxidizing, or reducing acids and sufficient oxidation resistance to allow their fabrication by conventional hot-working techniques in air. In the warm-worked condition, the spectrum of properties measured under inert atmosphere conditions (strain rate 0.005^{-1} sec) includes ultimate tensile strengths of 120,000 to 35,000 psi over the temperature range of 700°-1000°C and stress-rupture properties at 700°C corresponding to 100-hr life at stresses in excess of 100,000 psi. Tensile strengths as high as 70,000 psi at 1000° and 40,000 psi at 1200°C were observed at higher rates of loading in the warm-worked and stress-relieved conditions.

The high melting point (1900°C) and low density (6.1 g/cc) of vanadium suggest a material of promising mechanical properties at elevated temperature with an advantageous strength-to-weight ratio for applications where such a factor would be of importance. Unfortunately, the high melting point of pure vanadium is not accompanied by the expected degree of high-temperature strength (1). This drawback, common to the other VB periodic group refractory metals, columbium and tantalum, is offset by the excellent room-temperature fabricability and ductility down to liquid nitrogen temperature. Vanadium possesses good liquid metal corrosion resistance, and because all of its short-lived isotopes decay without emitting excessively strong decay products it is often regarded as a promising structural material for nuclear applications. Of all the refractory metals, however, pure vanadium is probably the least resistant to oxidation and aqueous corrosion. The low melting point of V_2O_5 (660°C), the main oxidation product on a vanadium-base material, produces such catastrophic rates of reaction above 660°C, that the hot-working of vanadium is a most uneconomical procedure. The protection of a vanadium-base material against oxidation by means of coatings is also made a most difficult, if not impossible, problem. The poor corrosion resistance of vanadium, in either oxidizing or strongly reducing acids or high chlorine concentrations, limits its application in chemical environments.

Attempts at improving the properties of vanadium by alloying have involved the use of titanium with further additions of a third element, such as: chromium, aluminum, or silicon for strength, and oxidation resistance, as well as carbon for improved fabricability. These studies, performed primarily by Rostoker, Yamamoto, and Riley (2), and recently fully summarized by Rostoker (3), have resulted in an appreciable improvement over the properties of pure vanadium. Ultimate tensile strengths of 130,000-90,000 psi and 100-hr rupture strengths of 100,000-10,000 psi were obtained in the temperature range 500°-700°C. A different system of alloys based on the vanadium-titanium binary and containing additions of tantalum, columbium, molybdenum, or carbon in amounts not exceeding 1 weight per cent (w/o) has been proposed by Smith and Van Thyne (4) for applications requiring medium strength combined with high fabricability and good aqueous or liquid metal corrosion resistance.

It is the purpose of this paper to present some preliminary results on the oxidation resistance, mechanical properties, and aqueous corrosion behavior of a family of alloys based on a vanadium-columbium system in the region of 20-50 w/o columbium.

The vanadium-columbium phase diagram portrays a system of complete solid solution with a minimum in the liquidus at 1810°C, corresponding to a composition of 35 w/o columbium (5). Of all the elements that are completely miscible with vanadium, columbium possesses the largest degree of atomic mismatch combined with complete solid solubility. The high-melting points of this alloy system and the large atomic size difference between vanadium and columbium suggest a system with good high-temperature properties. The complete miscibility of vanadium and columbium suggests a minimum loss in fabricability on alloying with a maximum increase in strength. Although the columbium-vanadium system is of the liquidus minimum type, a

Table I. Analyses of materials

Hydrogen	0.001	—
Nitrogen	0.038	0.030

characteristic often associated with systems that undergo clustering or disproportionation at some lower temperature, no evidence of the formation of a second phase was ever observed in this study. Even in columbium-vanadium alloys containing 20-50 w/o columbium and annealed for up to 100 hr at a temperature range of 700-900°C only single-phase structures were observed. This is in agreement with the work of Wilhelm, *et al.* (6), who similarly failed to find the sigma phase reported by Rostoker and Yamamoto (7).

Turning now to the oxides, the Cb_2O_5-V_2O_5 system may be roughly described as a simple peritectic type with appreciable amounts (about 20 vol %) of Cb_2O_5 being soluble in V_2O_5 at 600°C. The addition of Cb_2O_5 to V_2O_5 raises the melting point of vanadium pentoxide to the point that an equimolar mixture of V_2O_5 and Cb_2O_5 is completely solid at temperatures up to 950°C. The greater affinity of columbium for oxygen and the complete miscibility of columbium and vanadium metal all indicated the possibility that columbium might increase the oxidation resistance of vanadium by promoting the formation of a higher melting point oxide.

These were the reasons for considering this study as being a likely approach to a series of vanadium-base alloys possessing better mechanical properties and superior oxidation resistance.

Preparation of Alloys

Commercial-grade vanadium and columbium as produced by Union Carbide Metals Company with the analyses given in Table I were used throughout this study. The other alloying elements employed were also of commercial purity.

All aqueous corrosion and some oxidation samples were prepared by the nonconsumable arc melting of 70-g, 2-in. diameter buttons. The charge was prepared by compacting the vanadium and columbium as 10-mesh powders with the titanium being added in the same form. Additions of aluminum, silicon, and chromium were made by means of the intermetallic compounds Al_3Cb, $CbCr_2$, or $CbSi_2$, these master alloys having been prepared previously by melting the elemental powders. After compaction, the charge was melted four times, twice on each side, on a water-cooled copper hearth using a tungsten electrode, the melting operation being carried out in an atmosphere of pure argon with currents in the order of 200-500 amp at 24-26 v.

Wrought material for mechanical property and certain oxidation studies was obtained from consumable 1½-in. diameter 800-g ingots. The consumable electrodes were formed by welding together five 4-in. long bars of the alloy composition, the bars having been previously prepared by nonconsumable, tungsten electrode melting using the same technique described above for buttons. Satisfactory ingots with an equiaxed as-cast grain size were prepared by d-c arc melting with currents of 600-1000 amp and in an atmosphere of 120 mm Hg of argon. After dressing, these ingots were extruded in air at temperatures of 1100°-1200°C. To keep the extrusion times as short as possible, induction heating was used to preheat the billets, and the actual extrusion, at a 4-to-1 ratio, was performed in a fast-acting, flywheel activated, impact-extrusion press at speeds of 40-100 ips. Subsequent hot-working to ⅜-in. diameter was performed by swaging in the temperature range of 1000°-1100°C or by cold-working at room temperature. An argon atmosphere was used for preheating the billets prior to the extrusion and swaging operations. All fabricating procedures were performed in air; no canning or in-plant coating techniques were used.

As given in Table II, this technique of wrought sample preparation produced compositions close to the nominal analysis with a slight amount of oxygen pickup from the swaging operation.

The fabrication of most of these alloys, below about 1100°C, is tantamount to warm-working. For 0.5-hr annealing times, the recrystallization temperature of binary vanadium alloys containing 30-40 w/o columbium is about 1150°C. Very little grain growth occurs as the annealing temperature is increased to 1300°C. The recrystallization temperature for the vanadium-columbium-titanium ternary alloys, especially if modified with quaternary aluminum or silicon additions, is somewhat lower, ranging as low as 1100°C for the 50% V-40% Cb-10% Ti alloy to 1050°C for the 45% V-40% Cb-10% Ti-5% Al composition. The microstructures

* Carbon, oxygen, and nitrogen analyses obtained on wrought material after tensile testing. Additional pickup of oxygen probably occurred during creep-rupture testing. The above oxygen levels were the maximum observed. Values as low as 0.15 w/o oxygen were sometimes encountered.

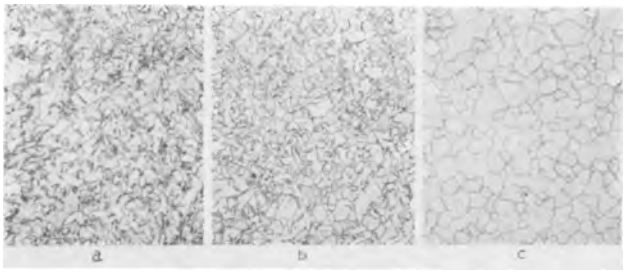

Fig. 1. 60% Vanadium-40% columbium alloy, all etched in 1 HF:1 HNO_3:3 glycerol. Magnification 100X before reduction for publication. (a) Swaged at 1000°C, annealed 0.5 hr at 1000°C, hardness 243 VPH; (b) swaged at 1000°C, annealed 0.5 hr at 1100°C, hardness 242 VPH; (c) swaged at 1000°C, annealed 0.5 hr at 1200°C, hardness 210 VPH.

illustrated in Fig. 1 for the 60% V-40% Cb composition as-swaged at 1000°C and annealed for 0.5 hr at 1000°, 1100°, and 1200°C exemplify the structure of these alloys. All the compositions given in Table II were single phase. The amount and extent of slip bands shown in Fig. 1 were characteristic of the warm-worked state, with deformation twins being readily observed in the compositions cold-worked at room temperature. Both types of deformation markings were less prevalent in titanium-containing alloys.

Corrosion Testing

Corrosion tests were performed on as-cast specimens of columbium-vanadium binary alloys over the range 20-50 w/o columbium with and without ternary titanium additions at the 10-20 w/o level. As shown in Fig. 2, the addition of columbium to vanadium greatly increased the corrosion resistance to boiling 65% HNO_3, boiling 5, 10, and 15% HCl, and boiling 10, 20 and 30% H_2SO_4 solutions. Further improvements, especially in regard to the corrosion resistance in boiling 65% HNO_3, were obtained on the addition of columbium in the presence of 10 and 20% titanium. The addition of titanium to the vanadium-columbium base, however, was found to increase the rate of corrosion in HCl and H_2SO_4 solutions. The addition of 20-50 w/o columbium, with and without further titanium additions, improved the room-temperature resistance to wet chlorine attack at room temperature to the point that corrosion rates of less than 1 mil/year were obtained. All these data were derived from 48-hr duplicate tests with the exception of the chlorine corrosion data which were obtained from 90-hr periods.

With the exception of boiling 65% HNO_3 solutions, where vanadium-columbium-titanium alloys behaved best, the most corrosion-resistant composition studied was the 50% Cb-50% V alloy. Exhibiting a corrosion rate in 65% HNO_3 of 17 mils/year, this composition corroded in boiling 5, 10 and 15% HCl at rates of 8, 50, and 83 mils/year, respectively. In addition, the 50% V-50% Cb alloy was found to corrode in boiling H_2SO_4 solutions of 5, 10, 20, and 30% concentration by weight at rates of 11, 17, 31, and 63 mils/year. By means of a bar diagram of the type first introduced by Stern and Bishop (8) the over-all corrosion resistance of the 50% V-50% Cb alloy is compared with other corrosion-resistant alloys and pure vanadium in Fig. 3. In this type of diagram, the total area below each horizontal bar denotes the range of environments in which that composition resists attack. Although the nature of this diagram is highly qualitative, the over-all degree of corrosion resistance possessed by the 50% V-50% Cb alloy is evident. This ability to withstand oxidizing or reducing acids in the presence or absence of chlorides is an appreciable improvement over pure vanadium, which, as shown in Fig. 3, is only able to withstand relatively dilute reducing solutions and relatively low chloride environments.

Oxidation Testing

The rate of oxidation of vanadium-columbium alloys containing from 20 to 40 w/o columbium with or without further additions of titanium, silicon, chromium, and aluminum in ternary or quaternary combinations was evaluated by means of continuous weight-gain measurements and intermediate exposure tests involving the subsequent measurement of the amount of metal consumed.

Continuous weight-gain measurements were obtained in an atmosphere of pure and dry oxygen at 700°, 800°, and 900°C. Test samples consisted of as-cast parallelepipeds (1.5 x 0.8 x 0.8 cm) abraded

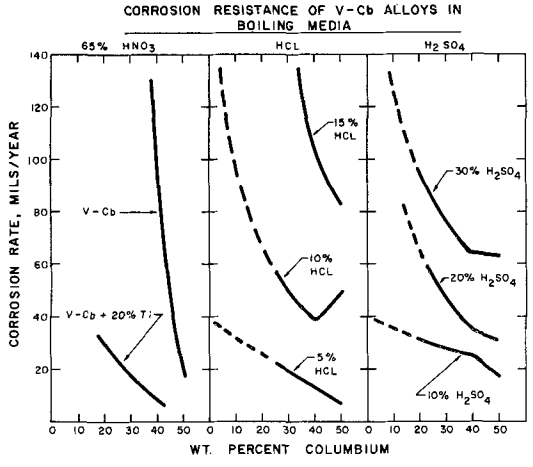

Fig. 2. Effect of columbium additions on the corrosion of vanadium in boiling 65% HNO_3, HCl, and H_2SO_4. Effect of a 20% titanium addition on the behavior of a V-Cb alloy in 65% HNO_3 is also shown.

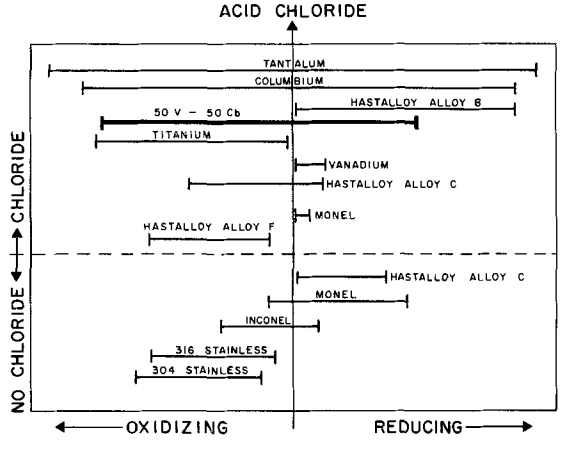

Fig. 3. Comparison of corrosion resistance of 50V-50Cb to other materials (8). Each alloy exhibits adequate corrosion resistance in all environments below its solid line.

under kerosene through 0000 emery paper and then rinsed in benzene before testing. The sample was suspended from one arm of a Mauer (9) automatically recording, gravimetric balance by means of a quartz rod and a platinum sling. Pure dried oxygen at a flow rate of 22.4 l/hr was passed over the specimen, the resulting increase in weight being recorded to the nearest 1.0 mg. The average length of the oxidation test was of the order of 6-8 hr.

The most significant results obtained in the rate measurements are tabulated in Table III in terms of the instantaneous oxidation rate exhibited by the alloy after 5.0 hr exposure, an interval which allowed some semblance of steady-state kinetics to be achieved. This method of comparing oxidation rates had to be adopted in view of the varying kinetic forms of oxidation exhibited by vanadium-base alloys. As shown in the weight gain *vs.* time plots in Fig. 4, various combinations of reaction rates were observed during oxidation even at 700°C.

On the basis of these results, it was possible to conclude that, while the addition of columbium to vanadium does suppress the formation of a liquid oxide, a maximum reduction in oxidation rate can be obtained only by the addition of titanium,

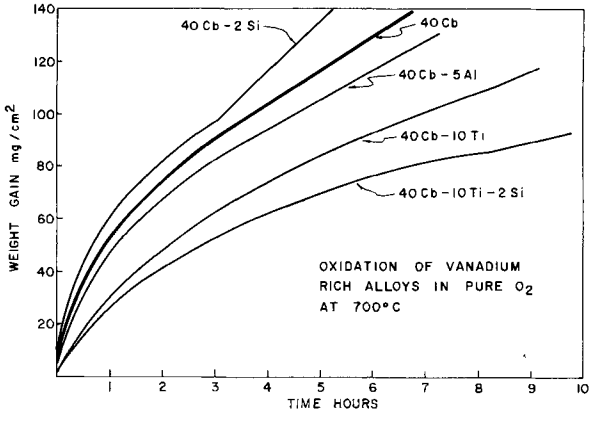

Fig. 4. Oxidation of columbium containing vanadium alloys as characterized by weight-gain values at 700°C.

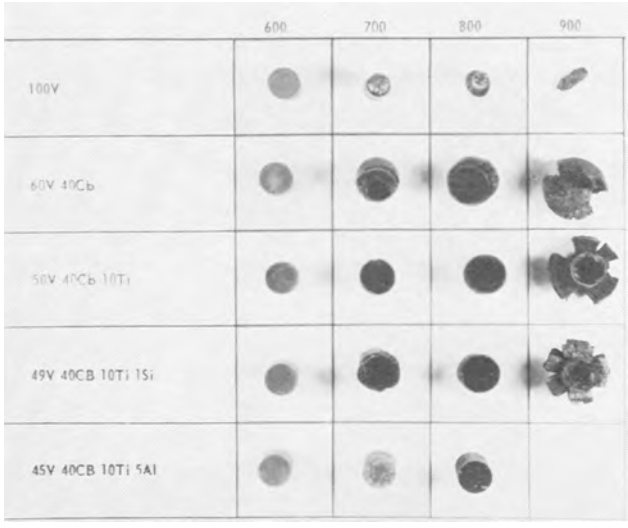

Fig. 5. Appearance of ⅜-in. diameter samples after 5.0 hr exposure in air.

especially in the presence of small amounts of silicon or aluminum.

Oxidation measurements by means of metal loss techniques, wherein the decrease in sample diameter after oxidation is measured, were made on pure vanadium and four alloys. The alloys were:

60% V-40% Cb
50% V-40% Cb-10% Ti
49% V-40% Cb-10% Ti-1% Si
45% V-40% Cb-10% Ti-5% Al

These compositions were selected on the basis of the weight-gain measurements described above to combine the minimum oxidation rate with a single phase structure. Tests were performed on wrought ⅜-in. diameter specimens over a temperature range of 600°-900°C for time periods of up to 10 hr at 900°C and up to 100 hr at lower temperatures. The 45% V-40% Cb-10% Ti-5% Al alloy was also evaluated at 1000°C. The visual appearance of some of the samples after oxidation is portrayed in Fig. 5. Following exposure in undried static air at the proper temperature and time combination, oxidation products were removed by abrasion and etching in a 20% KOH-5% $KMnO_4$ solution, and the amount of metal consumed, the metal loss, was measured with a micrometer to the nearest mil (0.001 in.). The decrease in sample diameter in terms of metal loss expressed in mils per side is plotted for a constant 5-hr period of air exposure against temperature in Fig. 6. Figure 7 presents the rate of oxidation of pure vanadium and a 50% V-40% Cb-10% Ti alloy as well as the 49% V-40% Cb-10% Ti-1% Si and 45% V-40% Cb-10% Ti-5% Al alloys at 700°C.

These measurements indicate a reduction in oxidation rate for the quaternary alloys and for the simple V-Cb-Ti ternary that approaches a five- to sevenfold improvement over pure vanadium. The rate of oxidation of the 45% V-40% Cb-10% Ti-5% Al alloy is particularly outstanding for a vanadium-base composition with no liquid oxide being observed at temperatures up to 1000°C. Liquid vanadium pentoxide was definitely noted on the other compositions tested at 900°C, and in the case of the

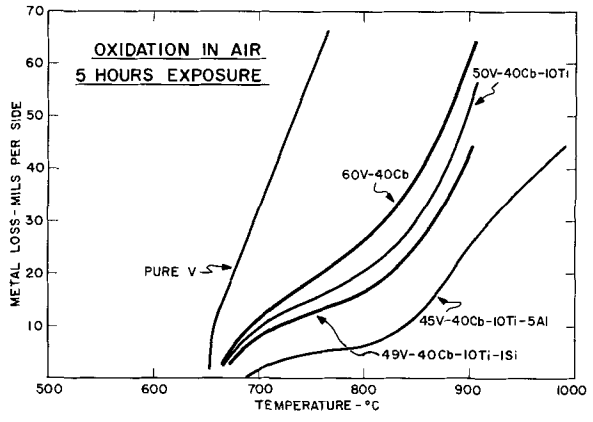

Fig. 6. Effect of temperature on oxidation of vanadium-columbium alloys.

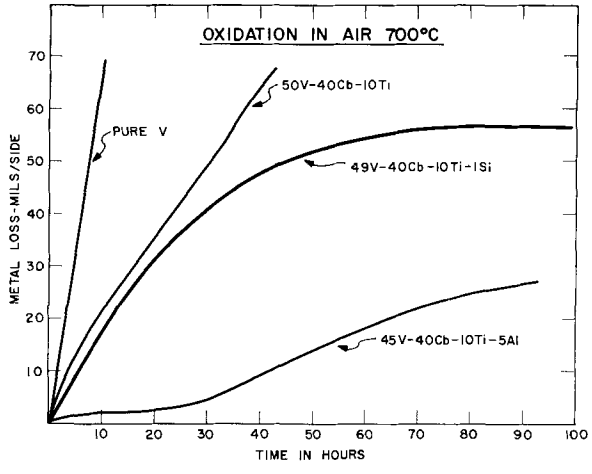

Fig. 7. Oxidation of vanadium-columbium alloys as characterized by a size decrement value at 700°C.

60% V-40% Cb alloy, small amounts of liquid oxide were observed on samples exposed at 800°C. The appearance of liquid vanadium pentoxide during the oxidation of these alloys is to some extent time-dependent, becoming more pronounced as the oxidation process proceeds. In all samples examined, no subscale surface hardening of the type encountered in columbium-base alloys or pure vanadium was noticed.

Mechanical Properties

The determination of the mechanical properties of vanadium-columbium alloys was focused primarily on the compositions of promising oxidation and corrosion resistance.

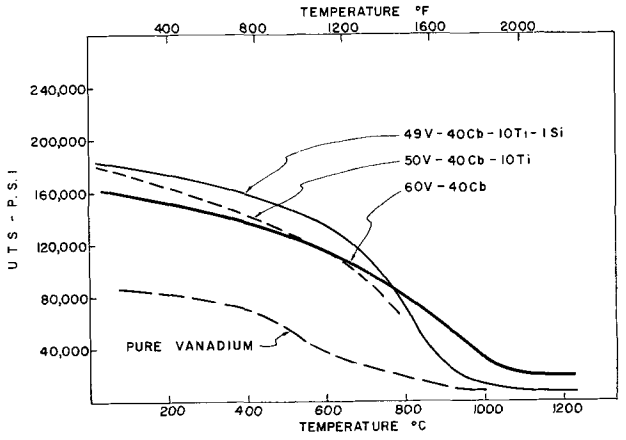

Fig. 8. Effect of temperature on tensile strength of alloys tested at 0.005^{-1} sec.

Tensile tests were performed on wrought materials using a button-head type miniature tensile specimen, with all tests being performed in vacuum. The tensile properties of as-swaged vanadium-columbium alloys with and without further additions of titanium, silicon, and aluminum are presented in Table IV for room temperature, 700° and 1000°C. These data augmented by results obtained at 1200°C are plotted in Fig. 8 for the stronger alloys in the as-swaged condition. The as-swaged condition is equivalent to warm-worked material for all alloys with the possible exception of the 45% V-40% Cb-10% Ti-5% Al composition. The effect of cold-work on the mechanical properties of the 70% V-30% Cb and 50% V-40% Cb-10% Ti alloys is presented in Table V, which also includes data on the effect of heat-treatment on the properties of warm-swaged vanadium-columbium alloys. All alloys studied could be cold-swaged at room temperature after a primary breakdown by extrusion. The high compressive strength of these materials, however, produced very frequent die failures during swaging, and since cold working did not affect the mechanical properties appreciably, the production of cold-swaged material was limited. Cold work decreased the room-temperature ductility of these materials without producing appreciable elevated temperature strengthening, even at temperatures well below the recrystallization temperature. Annealing warm-worked material in the temperature range of 1100°-1300°C tended to produce some reduction in mechanical properties which was more than made up by increased room-temperature duc-

tility. The sparsity of data makes even these comments questionable, but the generalization that the room-temperature ductility of these materials can be increased by the proper heat-treatment is definite. This, of course, is valid only for conditions of tensile loading applied at the strain rate used (0.005-0.02^{-1} sec). Although the tensile properties of the vanadium-columbium type of alloys are not affected appreciably by variations in strain rate within this spectrum of rate of load application, much higher rates of loading will decrease the ductility parameters and markedly increase the ultimate tensile strength. This has been observed even at 1200°C. The ultimate tensile strength of a warm-worked 60% vanadium-40% columbium alloy will vary from some 20,000 psi to 40,000 psi at 1200°C as the strain rate is increased from 0.02^{-1} sec to 0.20^{-1} sec.

The concluding step in these mechanical studies involved creep-rupture tests on as-swaged 60% V-40% Cb, 50% V-40% Cb-10% Ti, and 49% V-40% Cb-10% Ti-1% Si compositions. All tests were performed at 700°C in an atmosphere of pure helium gettered by a titanium collar placed around the creep-rupture specimen. The stress-rupture properties of these alloys at 700°C are shown in Fig. 9. Stress levels for a 100-hr life to rupture of 110,000 psi for the 60% V-40% Cb alloy, 85,000 psi for the 50% V-40% Cb-10% Ti alloy, and 90,000 psi for the 49% V-40% Cb-10% Ti-1% Si, were reflected in a correspondingly high creep resistance. As given in Table VI, the 100,000 psi minimum

* As-swaged at 1000°-1100°C.

creep rate of the vanadium-columbium alloys at 700°C varied from 1.0 to 1.85×10^{-4} in./in./hr.

The high mechanical properties of the 60% V-40% Cb and the 49% V-40% Cb-10% Ti-1% Si alloys are even more attractive when compared with the properties of other materials on the strength-to-density basis. Such a comparison is presented in Fig. 10 where the strength-to-weight ratio of these two compositions is compared to the same ratio for the strongest iron-, titanium-, and molybdenum-base alloys. In this plot, the ultimate tensile strength of the vanadium-columbium alloys refers to the warm-worked condition as evaluated at a strain rate of 0.005^{-1} sec. If data obtained at strain rates of 0.20^{-1} sec had been used, the 60% V-40% Cb composition would approach the strength-to-weight ratio of the molybdenum-0.5 titanium alloy at 1200°C (2192°F).

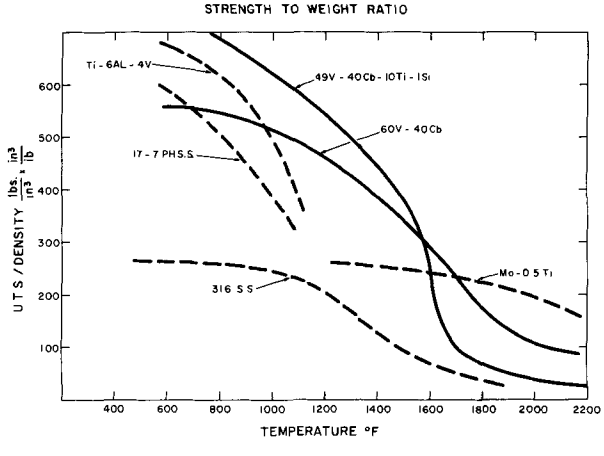

Fig. 10. Comparison of tensile properties of some commercial alloys and the vanadium-columbium compositions on a strength-to-weight basis.

Summary and Discussion

The aqueous corrosion and oxidation resistance as well as the high-temperature strength that can be imparted to vanadium by columbium additions present an appreciable improvement over other vanadium base systems (3, 4). Relatively simple alloys such as the 50% V-50% Cb or 60% V-40% Cb compositions exhibit degrees of corrosion resistance and elevated temperature strength that compare favorably with the best materials in present day commercial use. More complex alloys as exemplified by the 45% V-40% Cb-10% Ti-5% Al begin to show a level of oxidation resistance that would at least assure reliability in a coated structure, while even the simple binary combinations exhibit sufficient resistance to liquid V_2O_5 formation to allow their fabrication at elevated temperatures without cumbersome canning or coating procedures. None of these alloys, of course, is oxidation resistant enough above 660°C to permit prolonged service in air.

The degree to which columbium additions will increase the high-temperature strength of vanadium is an excellent example of the solid solution strengthening that can be imparted by adding a solute of high solubility that produces the maximum amount of lattice strain for a minimum decrease of the solvent's melting point. The small loss in fabricability and the retention of ductility after recrystallization that is made possible by such a strengthening mechanism are also beneficial. Nevertheless, the alloys are highly strain-rate sensitive, a condition that can be improved at the expense of strength by titanium additions.

The solubility of Cb_2O_5 in V_2O_5 and the resultant increase of the melting point of the vanadium pentoxide are partially responsible for the observed improvement in oxidation. Equally significant is the complete intersolubility that exists in the metallic phase and higher affinity of columbium for oxygen. Both of these latter two factors are believed to promote the inclusion of columbium in the oxide phase. A further reduction in reaction rate can be obtained by titanium and aluminum additions.

The observed increase in corrosion resistance is probably a reflection of the passivity inherent to columbium, a property which for this metal is usually associated with the presence of a protective film.

In closing, it may be noted that, although each of these possible mechanisms requires a high level of columbium in terms of weight per cent, the atomic concentration of columbium is roughly one-half of that expressed on a weight basis. The properties exhibited by these vanadium-columbium alloys can, therefore, be correctly ascribed to a vanadium-rich system and regarded as a further development in the alloy systems of this refractory metal.

Correction

Subject to the publication of the paper "Oxidation of Niobium in the Temperature Range 350°-750°C" by D. W. Aylmore, S. J. Gregg, and W. B. Jepson in the June 1960 issue of the Journal, the authors have been informed by Messrs. Murex Ltd. that the figure for the carbon content of the niobium (Batch A) was incorrectly quoted. The correct value is 0.01%.

Technical Notes

NMR Measurements of the Knight Shift in Conducting PbO_2

D. A. Frey and H. E. Weaver[1]

Instrument Division, Varian Associates, Palo Alto, California

According to the quantum mechanical model, nuclei possessing units of angular momenta and a nonzero magnetic moment are allowed only discrete orientations in an applied magnetic field. In the case of the Pb^{207} isotope where the nucleus has a spin of ½ units, there are two separate field-dependent energy levels. The energy of these levels is given by

$$E = \vec{\mu} \cdot \vec{H}$$

or

$$\nu = \gamma H_0 \text{ for the transition frequency,}$$

ν being the frequency, μ the magnetic moment, H the value of the magnetic field, and γ the gyromagnetic ratio for a given nucleus.

By varying the applied magnetic field, H, and simultaneously irradiating the sample containing the isotope under investigation with an oscillating magnetic field of frequency, ν, an NMR (nuclear magnetic resonance) absorption of energy from the rf-field may be detected when the value of the field-frequency satisfies the relation, $\nu = \gamma H_0$. NMR techniques have a wide range of application in the study of the molecular environment and its influence on the resonance character of the nuclei in an external magnetic field.

The effective magnetic field at the nucleus may differ from that of the applied field because of the influence of the external field on the environmental electrons of the nuclei, be they valence or conduction electrons. The magnitude and sign of the "chemical shifts" associated with a particular compound containing the resonating nucleus can easily be measured via the techniques of NMR. In the case of nuclei of high atomic number these relative shifts can amount to several per cent of the applied field (1). For conductors this "chemical shift" has the name Knight shift (1) after its discoverer.

Lead dioxide has long been known to be a conductor of electricity but until recently (2, 3) little quantitative data were available on its physical properties. In an earlier note Piette and Weaver (4) measured the resonance of Pb^{207} in PbO_2 and other lead compounds relative to that in the metal and found that the data were indeed consistent with the concept that PbO_2 does behave as a metal. Thomas (2) measured the conductivity and Hall coefficient for rather dense samples of PbO_2 and found that the carriers were electrons and that the temperature coefficient of conductivity is negative. Rüetschi, *et al.* (3) have measured the electrochemical properties of both α- (orthorhombic) and β- (tetragonal) forms of PbO_2. They have made extensive measurements on the effect of oxygen removal from PbO_2 on the electrical properties of both allotropic forms. It has been established that PbO_2 never has the stoichiometric composition, but rather shows an oxygen deficiency yielding a mixture with a formula more like $PbO_{1.98 \text{ to } 1.98}$. The lack of stoichiometric composition is generally felt to be the origin of the conductivity.

Lead dioxide is generally available in powder form with particle sizes of less than 1 μ. In this form it is ideally suited for NMR at 8 mc/sec and even EPR (electron paramagnetic resonance) at 9000 mc/sec, since the particles are smaller than the skin depth. Nuclear and electron resonance techniques are the "noncontacting" type, thereby requiring essentially no sample preparation and specifically no electroding.

Piette and Weaver (4) have measured the chemical shift of Pb^{207} in several representative lead compounds, in particular commercial PbO_2 (presumably β-form) relative to the resonance in lead metal. Rocard, *et al.* (5) reported later on a similar set of measurements, but with some variation in the Knight shift in PbO_2 compounds depending on the assay. They ascribed these differences to impurity content. Accordingly a series of experiments were designed to investigate the variation of the chemical shift (or Knight shift) of the Pb^{207} resonance in as many different forms of PbO_2 as were available. This note then deals exclusively with NMR and EPR measurements in PbO_2 and Pb metals.

Instrumentation

In those room-temperature measurements involving NMR a standard Varian V4200 wide line spectrometer was employed. A standard probe with the Dewar insert with associated transfer Dewar and heat exchanger were employed for measurements made at other than room temperature. By adjusting the flow rate of dry nitrogen gas, the temperature of the sample could be continuously varied from room temperature down to −185°C. For the EPR measurements a standard V4500 spectrometer plus cryogenic accessories were used. The magnet employed was V4012-3B with 2⅝ in. air gap with associated current stabilization.

[1] Present address: Physik-Institut Der Universität Zurich, Zurich, Switzerland. Dr. Weaver is on leave of absence from Varian Associates.

Table I. Summary of PbO_2 NMR measurements at room temperature

β-PbO_2 N L Co.	$0.62 \pm 0.02\%$	0.55
α-PbO_2 E S B	0.48	—

Measurements

The NMR experiments performed fell into two major classifications: (i) room-temperature measurements as a function of sample preparation and crystal symmetry, (ii) measurement of the Knight shift as a function of temperature, and thermal decomposition of PbO_2 with increased temperature above 200°C. EPR experiments were designed merely to detect a resonance.

Nuclear magnetic resonance.—NMR measurements of the Knight shift relative to Pb metal were made on all available samples. Table I indicates that at least two separate shifts appear to have been observed for the β group and a third for the α sample. Since the Knight shift in the PbO_2 resonance is dependent on the density of conduction electrons near the top of the Fermi distribution, Knight shift values for these samples can be said to correspond qualitatively with their conduction properties. However, the mechanism by which conduction electrons are made available is not completely understood.

Oxygen deficiency rather than impurity content probably is responsible for the conduction electron density, hence the fluctuations among the β group. It is noteworthy that both the 90% and 95% B & A samples have approximately the same Knight shift (relative to the metal), while the ESB and NL Co. samples have considerably higher values.

To obtain further quantitative information, first moments indicative of the relative intensities were calculated from the resonance curves obtained from each of the β samples, normalizing the B & A 95% moment (or intensity) to one. In Fig. 1 (a-e) are shown typical traces of the lead resonance in various available forms of PbO_2. The signal-to-noise of ESB-α-PbO_2 (Fig. 1e) was particularly poor because of a small amount of sample. Microscopic examination of the samples at an optical magnification of 800 gave no conclusive information regarding the relative particle size which would affect the density of the sample and hence the signal-to-noise obtained from a given volume.

Variations in NMR Knight shift measurements were also used as an indication of the change in PbO_2 conductivity with thermal decomposition. Table II clearly shows a decrease in the Knight shift (or an increase in the shift relative to the metal) as the thermal decomposition progresses. This suggests that the compound goes through the transition from conductor to semiconductor before becoming an insulator in the form of PbO. It is interesting to note that further loss of oxygen (prior to an actual crystal phase change) does not improve the conduction properties, which at best is anomalous in light of the model proposed: *viz.*, it is just this initial oxygen deficiency that is responsible for the conductivity.

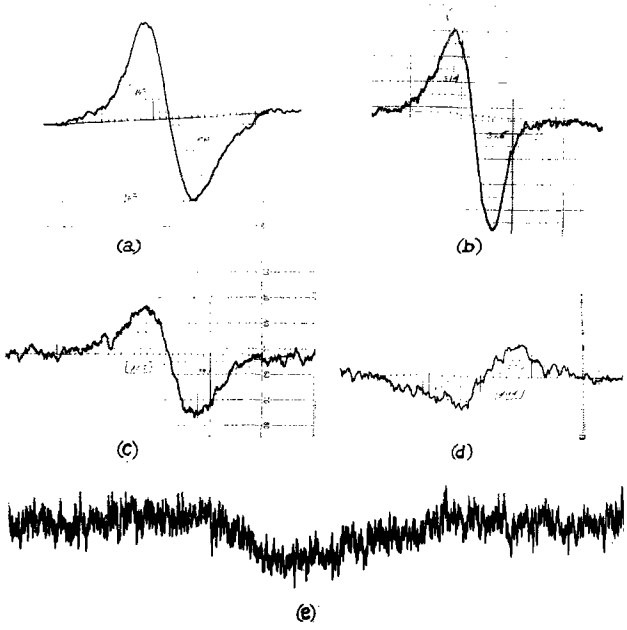

Fig. 1. Representative NMR traces of PbO_2 at 7.5 Mc/s. (a) B & A β—PbO_2 95%; gain x-10-2; (b) ESB β—PbO_2; gain x-10-3; (c) B & A β—PbO_2, 90%; gain x-10-3; (d) NL Co. β— PbO_2; gain x-10-4; (e) ESB α-PbO_2; gain x-10-4.

Electron paramagnetic resonance.—Since the particle size of the PbO_2 samples was less than the skin depth even at microwave frequencies it seemed worthwhile to investigate them for possible electron resonance. The resonance, if detected, could stem then either from paramagnetic impurity, presumably transition elements in a favorable environment, or from the conduction electrons themselves. Accordingly samples were prepared and a series of experiments were made from room temperature down to less than 2.0°K.

To date the results have been inconclusive. Lines which might be ascribed to the β-PbO_2 seem not to follow an expected pattern. Further, because of the excessive width of the observed resonance the amplitude is small and hence the attendant signal-to-noise is poor. The lack of a well-defined conduction electron resonance is not at all surprising in light of the proposed mechanism of oxygen deficiency to account for the conductivity. This model implies that there is a rather large concentration of "free" lead ions interstitially located in the regular PbO_2 lattice,

Table II. Summary of relative NMR shifts for heat-treated samples of β— B & A (95%) PbO_2

Temperature, °C	Shift* relative to untreated samples (gauss)
Room	0.0
200	—2.2
285	—6.5
330	—12.7
360	—15.3

* A negative shift implies a shift in the resonance toward higher fields.

and the presence of these "foreign" atoms could cause severe inhomogeneous temperature-independent broadening of the resonant line thereby making the resonance impossible to detect. Such seems to be the case. No resonance was detected in the lead metal powders.

Conductivity.—An experiment was performed with the low-temperature facilities at the Westinghouse Research Laboratories with β-PbO_2 commercial grade in an attempt to detect a superconducting transition. None was observed down to a temperature of 1°K (6).

Conclusion

From these data it is evident that the chemical shift associated with the resonance of Pb^{207} is indeed a Knight shift characteristic of a conductor. A series of controlled experiments measuring the NMR Knight shift relative to Pb metal as the oxygen-lead ratio is varied might well yield much more conclusive data.

Determination of the Standard Free Energy of Formation of Lead Selenide

Cabell B. Finch[1] and J. Bruce Wagner, Jr.

Department of Metallurgy, Yale University, New Haven, Connecticut

In conjunction with diffusion studies in this laboratory on the semiconducting compounds, PbS, PbSe, and PbTe, measurements have been carried out to determine the standard free energy of formation of lead selenide. Following the suggestions of Wagner (1-5), a galvanic cell involving a solid electrolyte

$$Pb(s) \mid PbCl_2 + 1\%\ KCl(s) \mid PbSe(s), Se(l) \qquad (I)$$

was used. The virtual cell reaction of cell (I) on passing two faradays is

$$Pb(s) + Se(l) = PbSe(s) \qquad [1]$$

The lead selenide was prepared by synthesis from its elements. Lead, 99.999% pure, was reacted with 99.99+% selenium by a method used for the synthesis of cuprous sulfide (4). The synthesized PbSe was mixed with an excess of the pure selenium and pressed into pellets at a pressure of about 350 kg/cm^2. The solid ionic electrolyte, $PbCl_2$ + 1% KCl, was prepared as described elsewhere (6) and pressed into pellets. Crucibles to contain the molten selenium coexisting with PbSe were made by drilling a hole in one side of the electrolyte pellet. The galvanic cell was assembled by placing a 99.999% lead pellet in a graphite crucible. The crucible of electrolyte which contained the PbSe pellet with excess selenium was placed on top of the lead pellet. Glass wool or asbestos was packed between the walls of the graphite and electrolyte crucibles in order to prevent vapor transport of selenium to the pure lead. A graphite electrode was placed in contact with the PbSe pellet and the entire cell was placed in a glass tube under argon as described in ref. (3).

A controller maintained the temperature better than ±1°C and the temperature was measured with a chromel-alumel thermocouple which was calibrated previously against the melting points of lead, zinc, and aluminum. The electromotive force measurements were consistent on increasing and decreasing the temperature between 200° and 300°C, and

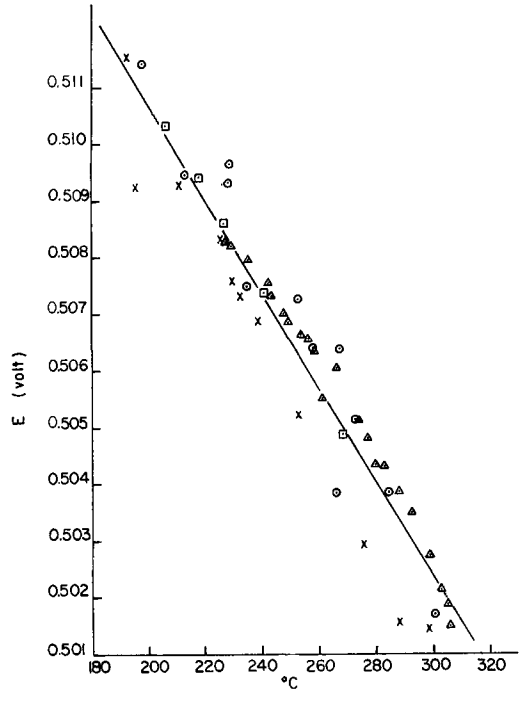

Fig. 1. EMF vs. temperature for the cell, Pb(s) | $PbCl_2$ + 1% KCl | PbSe(s), Se(l)

[1] Present address: Oak Ridge National Laboratory, Oak Ridge, Tenn.

the results of four separate experiments are shown in Fig. 1. Using a least squares analysis of all these data the standard free energy of formation of lead selenide in the range of 200° to 300°C may be expressed by the equation

$$\Delta G^\circ = -nFE = [-23{,}352 + 3.8(t - 250)] \text{ cal} \quad \text{(II)}$$

where **F** is the Faraday constant, E the electromotive force, and t the temperature in °C.

All but two of the emf data, one at the high temperature and one at the low temperature, lie between ±1.5 mv of the least square curve. This corresponds to ±69 cal in ΔG°. Thus with a temperature variation of ±1°C the total estimated accuracy is better than ±80 cal in ΔG°.

Below about 200°C, the attainment of steady values was very sluggish. Above about 300°C, the vapor pressure of selenium was sufficiently high that vapor transport sometimes caused contamination of the lead pellet. At the end of each experiment, the lead was examined for selenium contamination and any results obtained under these conditions were discarded. In addition, the higher temperatures favored plastic deformation of some of the cell components causing short circuits. Therefore the present measurements were restricted to the range of 200° to 300°C. The present value of the standard free energy of formation agrees well with unpublished data of Lorenz and Wagner (5).

Microalloy Junction for Silicon

L. Maissel

Research Division, Philco Corporation, Philadelphia, Pennsylvania

The development of the germanium microalloy junction (1) brought about considerable improvement in the frequency response of transistors made by electrochemical techniques (2); its main features are high injection efficiency and very shallow depth of penetration (approximately 0.001 mil). It consists, basically, of an indium-gallium dot alloyed at as low a temperature as possible.

In searching for a similar contact for silicon it was first necessary to analyze the general requirements for a satisfactory microalloy junction. By definition, the metal used in forming the junction must be such as to dissolve only a small percentage of its own volume of semiconductor when alloying takes place. The metal semiconductor phase diagram should, therefore, be of the general form of Fig. 1.

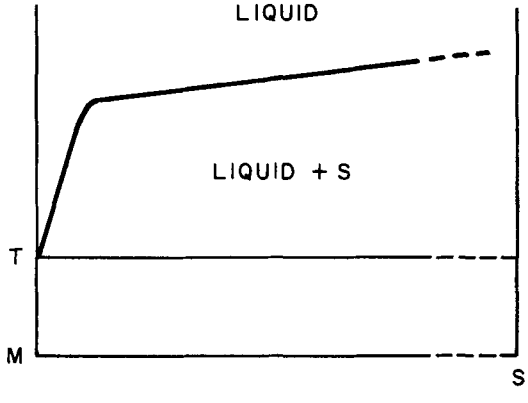

Fig. 1. Metal semiconductor phase diagram

In the case of germanium the metals that have this type of liquidus curve are indium, bismuth, lead, and gallium. Gallium cannot be used in practice because of its low melting point. Any of the other three would be suitable if it were not for the requirement that the microalloy junction must possess high injection efficiency as well as shallow penetration. This means that a small percentage of some suitable dopant must be included with the alloying metal. The only two dopants that are sufficiently soluble in germanium, to give a high injection efficiency junction, are aluminum and gallium. The former is, however, almost completely immiscible at all temperatures with all three of the possible alloying metals. Gallium is immiscible with bismuth and lead but, fortunately, not with indium. The indium-gallium combination is thus the only one suitable for a germanium microalloy[1] if alloying is allowed to proceed to equilibrium.

Similar reasoning applied to silicon indicates that either tin or antimony might be suitable metals for microalloying. The former, however, has shallow penetration only at relatively low temperatures (below 600°C) where dopant solid solubilities are also low. Antimony has shallow penetration below 800°C and has the additional advantage of also being a donor element with reasonable solid solubility in silicon at these temperatures.

Accordingly, an attempt was made to make an

[1] Microalloy junctions also can be formed by using a very rapid heating cycle, so that equilibrium and hence full penetration is not reached. However, it will be shown that nonequilibrium alloying is unsuitable for silicon.

alloyed junction of pure antimony in silicon. Initial attempts failed because of "balling up" of the antimony during alloying. That this was not surprising can be seen from the following considerations

If a given liquid is to wet a solid, it is a necessary (although not sufficient) condition that the surface tension of the solid must exceed that of the liquid. The surface tension of liquid antimony is approximately 350 dynes/cm; the values for solid silicon and solid silicon dioxide are approximately 600 dynes/cm and 300 dynes/cm, respectively (3). Thus the condition for antimony wetting is satisfied by silicon but not by its oxide. In view of the invariable presence of a thin oxide layer on the surface of silicon the net effect is that antimony will not wet silicon.

Since the surface tension of almost all liquid metals is greater than 300 dynes/cm it would seem that very few metals should ever wet silicon. However, the oxide film is generally of a porous nature so that metal and silicon are in fact in direct contact in a limited number of places. If the metal and the silicon have a eutectic reaction then, as long as the temperature is kept below the melting point of the pure metal (but above the eutectic point) fusion can begin in the regions of direct metal-to-silicon contact. The liquid so formed spreads out as it dissolves silicon so that the oxide film is undercut and, eventually, dislodged. In the absence of a eutectic reaction it should still be possible to promote wetting of the silicon by the metal provided the latter can be constrained from "balling up" long enough for the process of oxide film undercutting to become effective.

Direct mechanical constraint of the liquid antimony by suitable jigging was not considered feasible because of the extremely delicate nature of the electrochemically formed base region. Several other ways of achieving the required constraint were explored. Alloying was attempted in an oxidizing atmosphere in the hope that the skin of antimony oxide that formed prior to the melting of the antimony would be tough enough to hold it in position. Some success was obtained but results were not reproducible. A layer of refractory metal was tried in place of the oxide but this invariably broke contact with the silicon and simply floated on the surface of the antimony.

Alloying of antimony to silicon then was attempted by use of the technique of "dip alloying." The principle behind this method is as follows: suppose silicon, with a dot of plated antimony on its surface, is plunged into a fused salt bath. Provided the melting point of the bath is greater than that of antimony, the crust of salt that freezes on the surface of the cold silicon when it first enters the bath will still be solid when the antimony reaches its melting point. During the brief period before the crust remelts the antimony is thus constrained by a tough close-fitting jacket, so that wetting can occur by the mechanism discussed above. A number of salt baths were investigated for use in this connection and successful alloying of antimony to silicon was obtained in both KCl and KBr. Most compounds that were tried had to be rejected because they reacted with either antimony or silicon or both.

In order to establish that a true microalloy junction was being formed during dip-alloying, a number of test transistors were fabricated as follows: blanks of 5 ohm-cm p-type silicon were jet-etched to a thickness of approximately 0.4 mil. Dots of antimony 20 and 40 mils in diameter were then jet-plated onto opposite sides of the etch pit from an ethylene glycol solution containing 10 g SbF_3 and 60 g HF per liter. After dip-alloying in KCl for 30 sec at 800°C, units were rinsed in deionized water (to remove KCl) and were then clean-up etched. Whereas the antimony dots had shown only weak rectification before alloying, the alloyed units exhibited alpha-values of approximately 0.9. To measure the junction thickness, punch-through voltages before and after alloying were compared. These measurements showed the depth of penetration to be approximately 2×10^{-6} in., about twice that of a typical germanium microalloy junction. The feasibility of microalloying silicon was thus demonstrated.

Electrolytic Production of Zirconium in a Fused Salt Voltaic Cell

Meyer L. Freedman

Refractory Metals Laboratory, General Electric Company, Cleveland, Ohio

The production of refractory metal powders by electrolysis of their compounds in molten salt solutions has been investigated intensively because of the valuable properties of high purity and coarsely crystalline form which may be obtained (1). The low oxygen, carbon, and nitrogen contents which can be achieved are particularly valuable for titanium, zirconium, boron, silicon, and beryllium, since these metals cannot be purified readily during processing. Also, because of their particle sizes, the electrolytically produced metal powders are consolidated more readily by conventional metallurgical processing than the metal sponges produced by chemical reduction. These advantages apply in part

Electrolytic Production of Zirconium in a Fused Salt Voltaic Cell

Meyer L. Freedman

Refractory Metals Laboratory, General Electric Company, Cleveland, Ohio

The production of refractory metal powders by electrolysis of their compounds in molten salt solutions has been investigated intensively because of the valuable properties of high purity and coarsely crystalline form which may be obtained (1). The low oxygen, carbon, and nitrogen contents which can be achieved are particularly valuable for titanium, zirconium, boron, silicon, and beryllium, since these metals cannot be purified readily during processing. Also, because of their particle sizes, the electrolytically produced metal powders are consolidated more readily by conventional metallurgical processing than the metal sponges produced by chemical reduction. These advantages apply in part

also to vanadium, columbium, tantalum, chromium, molybdenum, and tungsten.

Electrolytic extraction has not been utilized more widely for the refractory metals because of problems inherent in the anode reactions. The anodic generation of corrosive gas at high temperature may require the use of graphite containers sometimes resulting in high maintenance costs (2). Anodic polarization effects may be troublesome especially with fluoride salts (3). The problems resulting from anode reactions can be largely eliminated by the use of soluble anodes (4). Cell corrosion and anode effects are avoided, but the process then becomes one of electrorefining rather than electrowinning.

Sodium metal can be used for obtaining all of the refractory metals as sponges or fine powder by high-temperature reduction of their appropriate compounds (5). The use of sodium metal as the soluble anode in a fused salt cell should eliminate corrosion problems while generating *in situ* the current required for effecting the cathodic reduction. Refractory metals could thus be produced with the desirable properties of electrolytic powders while avoiding the difficulties of fused salt electrolysis.

Production of metal powder by this voltaic cell action was observed while experimenting with the sodium reduction of K_2TaF_7. A nickel crucible was filled with a bottom layer of K_2TaF_7, a middle layer of NaCl-KCl eutectic, and a top layer of sodium metal. The layers were separated by porous diaphragms made from Monel screen. After melting under argon, large flakes and crystals of tantalum metal were found adhering to the lower diaphragm and to the crucible wall beneath the unreacted tantalum salts. Spectrographic analysis of the washed tantalum showed it to contain less than 0.01% of copper, iron, or nickel as major impurities. The metal flakes were soft, ductile, and easily compacted into mechanically strong pellets.

The voltaic cell metals extraction phenomena was investigated on a larger scale with the apparatus shown in Fig. 1. The 10 cm diameter stainless steel container was placed in a pot furnace. Vacuum drying of the loaded cell before melting was accomplished by the use of a steel cover and rubber gasket which rested on the flange. A charge of 650 g of equimolar C.P. NaCl-KCl provided a 6 cm layer of molten salt at 750°C. Access of air was prevented by a stream of argon. After melting the salt, the cathode was lowered to the cell bottom and 25 to 50 g of sodium metal was added to the cell by melting through a porous stainless steel filter to remove oxides. Five grams of vacuum dried technical grade K_2ZrF_6 was then added to the cathode chamber to give a concentration in the molten salt of about 3% by weight. Additional 5-g portions were added at 30-min intervals during the course of the reaction. At the conclusion of a run the cathode was raised slowly to permit drainage of molten salt and then cooled under argon in the upper chamber. The cathode was then dismantled and the zirconium crystals separated from adhering salts by boiling first with water and then with dilute HCl.

A number of cathode arrangements were tried. With a basket made of 40 mesh Monel screen, the zirconium deposited only on the cell bottom and baffle wall. Thick pads of zirconium crystals formed on both the inside and exterior of a hollow cathode made from perforated nickel foil. The cathode shown in Fig. 1 was constructed from a 5 cm diameter nickel tube which was perforated with two rows of closely spaced 0.6 cm holes. A porous nickel diaphragm covered these holes and was folded over the end of the tube to support a sheet nickel bottom plate. The diaphragm was made by filling the openings of 40 mesh Monel screen with a paste of nickel powder, drying, and sintering in hydrogen at 1100°C.

In one run, 40 g of K_2ZrF_6 was added over a 4-hr period and 11.5 g of washed zirconium crystals were obtained for a yield of 89%. The addition of 50 g of K_2ZrF_6 in 3 hr reduced the cathode yield to 80% of theoretical. The metal was deposited as a thick pad of dendritic crystals over the interior walls and bottom of the cathode. This permitted drainage of

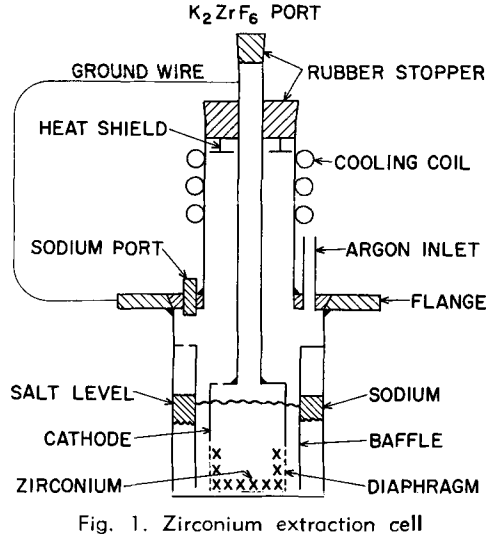

Fig. 1. Zirconium extraction cell

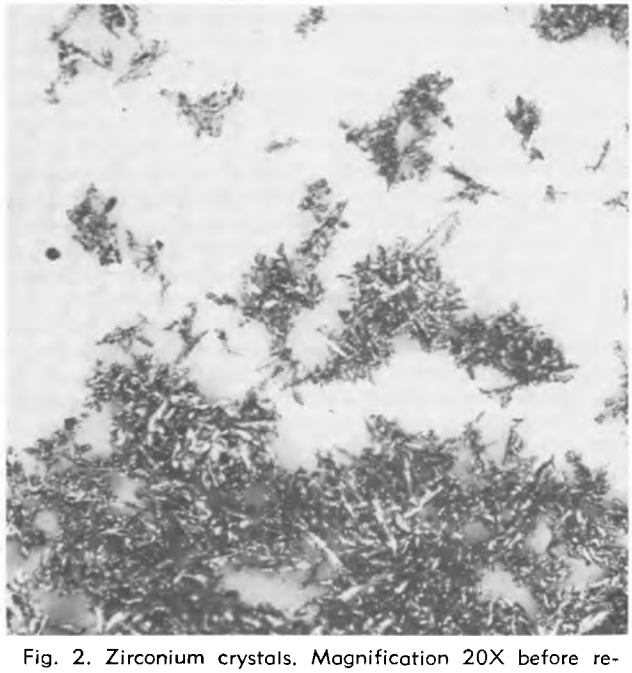

Fig. 2. Zirconium crystals. Magnification 20X before reduction for publication.

molten salts so that a weight of salt equal to only about twice that of the zirconium was retained by the cathode. The recovered metal powder was a silvery gray color with a bulk density of 0.9 g/cc. Figure 2 shows the dendritic form of these zirconium crystals. A 100 mesh screen retained approximately 50% so the average particle size was estimated as 150 μ. A qualitative spectrochemical analysis indicated only traces of iron and nickel impurities. While the particle size is similar to that reported for electrolytic zirconium (6) the dendritic form is more pronounced. Compaction to 80% of theoretical density was obtained on pressing at 50 tons/in.^{2}. The sample thus compares favorably in this respect to hydride zirconium powders (7). A Rockwell B hardness of 90 was determined on a pellet which had been further consolidated by electron beam melting. This value is well within the range for commercially pure zirconium.

The design of this experimental cell did not permit successful reuse of the salt charge. The zirconium obtained in the second run with the same salt bath was a mixture of dendritic crystals and fine black powder similar to the powder obtained by direct reduction of K_2ZrF_6 with sodium. During the time required for the removal of one cathode and the insertion of a second, atomic sodium had apparently diffused into the bulk of the molten salt. This then reacted directly with the K_2ZrF_6 as it was added to the new cathode. For continuous use of the salt bath, provision must thus be made for sealing off the sodium compartment between runs. Otherwise, a second porous diaphragm might be used to restrict the atomic diffusion of sodium while permitting ionic transport.

The anode slit height, fixed by the distance between the bottom of the baffle and the cell bottom, was also found to greatly influence the character of the extracted zirconium. A slit height of approximately 2 mm was generally used. A voltmeter connected in place of the ground wire then registered 0.6 v with the cathode raised slightly above the cell bottom during a run. When the anode slit height was increased to 5 mm the volt meter registered nearly zero. Zirconium was still deposited on the interior surface of the cathode in good yield. However, instead of dendritic crystals, the metal now consisted of irregular gray flakes having rough pebbled surfaces. The zirconium in this form prevented the drainage of molten salt from the cathode at the end of the run and was also difficult to wash free of salt. With the enlarged anode slit the concentration of atomic sodium in the molten salt adjacent to the cathode must have been nearly as high as the concentration within the sodium compartment. Under these conditions, the outer surface of the cathode itself would serve as the anode.

While fluoride salts were used in these experiments, the voltaic cell process should be more advantageous with a chloride feed. In the absence of fluorides, a porous ceramic diaphragm could be used to enclose the cathode volume while a porous metallic diaphragm would confine the sodium. Continuous operation could then be obtained with solid cathodes and molten NaCl.

Other methods have been reported for using molten inert salts in the production of refractory metal powders by sodium reduction. Thus, Vaughan partially submerges a metal grid in a fused salt bath containing a refractory metal halide and sprays sodium metal upon the grid (8). The sodium is claimed to wet the grid and to be carried along the grid surface beneath the melt where it reacts to form crystals of the refractory metal. Dean produces large crystals of refractory metals by reacting very dilute solutions of sodium and refractory metal halides in a molten salt medium (9).

June 1961 Discussion Section

A Discussion Section, covering papers published in the July–December 1960 JOURNALS, is scheduled for publication in the June 1961 issue. Any discussion which did not reach the Editor in time for inclusion in the December 1960 Discussion Section will be included in the June 1961 issue.

Those who plan to contribute remarks for this Discussion Section should submit their comments or questions in triplicate to the Managing Editor of the JOURNAL, 1860 Broadway, New York 23, N. Y., *not later than March 1, 1960.* All discussion will be forwarded to the author(s) for reply before being printed in the JOURNAL.

Technical Feature

Fuel Cell Thermodynamics

Andre J. deBethune

Chemistry Department, Boston College, Chestnut Hill, Massachusetts

ABSTRACT

A simple fuel cell, operated reversibly, puts out, either electrochemically or in osmotic-mechanical form, an amount of useful work equal to the chemical potential (free enthalpy, Gibbs free energy) $-\Delta G$ released isothermally by the fuel plus oxygen upon their combination. This may be larger than the corresponding Carnot output $(-\Delta H)\,(T_h - T_l)/T_h$ of the same amount of fuel used to fire a reversible heat engine.

A coupled (regenerative) fuel cell regenerates the cell reagents by decomposing the reaction products at a high temperature (obtainable from a nuclear reactor). It thus acts as a heat engine in converting heat from the nuclear reactor into useful work. Its reversible work output, given by the summation of $-\Delta G$ for all isothermal steps, is exactly equal to that predicted from the heat inputs by Carnot's theorem in integral or differential form, for any fuel cell reaction, and for zero and finite values of ΔC_p for the cell reaction. The useful work output of an idealized practical irreversible fuel cell cycle is also given.

Simple Fuel Cell

A simple fuel cell (1) puts out directly and isothermally as useful work (2) the chemical potential released by a fuel (reductant) plus oxygen (oxidant) upon their conversion to combustion (reaction) products. If the cell operates electrochemically, the useful work output appears as electrical work, which is, under reversible conditions, equivalent to the charging up of a condenser. If the cell operates through semi-permeable membranes as an osmotic reaction engine, the useful work may appear in mechanical form, equivalent to the lifting up of weights (2, 3). Living systems function through the mechanism of osmotic membranes (4). The biological cell might therefore be described thermodynamically as an osmotic-mechanical fuel cell.

The maximum (reversible) useful work output $W_{u\,max}$ of the reaction

Fuel (reductant) + oxidant
= combustion (reaction) products [1]

conducted isothermally in a fuel cell, operating at a temperature T_f, is equal to the chemical potential (free enthalpy) released $-\Delta G_f$. In contrast, the same amount of fuel, firing a conventional power plant, yields a maximum useful work output equal to the heat (enthalpy) released $-\Delta H_h$ (at a high temperature T_h) multiplied by the Carnot efficiency $(T_h - T_l)/T_h$, where the low temperature T_l cannot ordinarily be less than ambient. The ratio of the first to the second of these work outputs, *i.e.*, the "fuel cell gain ratio," may be expressed in the form

$$\text{"Fuel Cell Gain Ratio"} = \frac{(-\Delta H_l) + T_f \Delta S_l - \int_l^f \Delta C_p\, dT + T_f \int_l^f \Delta C_p\, d\ln T}{(-\Delta H_l) - \int_l^h \Delta C_p\, dT} \cdot \frac{T_h}{T_h - T_l} \quad [2]$$

where h, f, and l refer to the temperatures T_h, T_f, and T_l, respectively, and the integrals contain summations of all enthalpies or entropies of transition that may be involved. In the special case where the reaction entropy ΔS_l and heat capacity ΔC_p are both zero, expression [2] shows that fuel cell operation permits a complete recovery of the reaction enthalpy drop $-\Delta H_l$ as useful work, without Carnot limitation.

Liebhafsky (1) discusses the thermodynamics of the reaction

$$H_2(g) + \tfrac{1}{2}O_2(g) = H_2O(g) \quad [3]$$

From his data and from Latimer (5), one can obtain the figures: $W_{u\,max}$(fuel cell) $= -\Delta G^\circ_{298} = 54{,}635$ cal per molal reaction unit at 298°K. By comparison, $W_{u\,max}$(power plant) $= -\Delta H^\circ_h (T_h - T_l)/T_h$. This has the values (taking $T_l = 298$°K)

T_h (°K)	400	500	1,000	2,000
$W_{u\,max}$ (power plant) (cal)	14,080	23,500	41,600	51,200

Thus the comparative advantage of the fuel cell is marked, especially at low temperatures, but tends to diminish, or even turn to a disadvantage, at

higher temperatures (1). The latter difficulty tends to arise especially for negative values of ΔS and ΔC_p, as shown by Eq. [2]. The simple fuel cell is free from the Carnot-efficiency limitation of the fuel-fired power plant, since it yields its work isothermally. The thermodynamic price paid, in either case, is the permanent conversion of a quantity of fuel to combustion products. The desirable thermodynamic properties for a simple fuel cell reaction are ΔG negative, ΔS zero or positive, ΔC_p zero or positive.

These thermodynamic properties are related to the reversible cell emf E as follows

$$-\Delta G = -\Delta H + T\Delta S = n\mathbf{F}E \qquad [4]$$

$$\Delta S = n\mathbf{F}(dE/dT) \qquad [5]$$

$$\Delta C_p = n\mathbf{F}T(d^2E/dT^2) \qquad [6]$$

These quantities can be evaluated from electrode potentials (5, 6), and from their temperature coefficients (6), and second temperature coefficients (7). An illustrative calculation is given below for reaction [3].

The following numbers give standard Gibbs-Stockholm (8) electrode potentials $V°$, and their first and second isothermal temperature coefficients (6, 7), for hydrogen and oxygen electrodes.

	$V°$, v	$(dV°/dT)_{isoth}$, mv/deg	$(d^2V°/dT^2)_{isoth}$, μv/deg^2
$H_2 = 2H^+ + 2E^-$	0.0000	0.000	0.000
$2H_2O(l) = O_2 + 4H^+ + 4E^-$	+1.229	−0.846	+0.552
$2H_2O(g) = O_2 + 4H^+ + 4E^-$	+1.185	−0.230	−0.173

For cell reaction [3], the above numbers yield $E° = 1.185$ v, $dE°/dT = -0.230$ mv/deg, and $d^2E°/dT^2 = -0.173$ μv/deg^2 at 25°C. The reaction entropy $\Delta S°$ is therefore $2\mathbf{F}(-0.230$ mv/deg$) = -10.6$ cal/deg, while $-\Delta G° = 2\mathbf{F}(1.185$ v$) = 2.370$ v$\mathbf{F} = 54.6$ kcal, and $-\Delta H° = -\Delta G° - T\Delta S° = 57.8$ kcal. The reaction heat capacity $\Delta C_p°$ is $2\mathbf{F}(298°\text{K})(-0.173$ μv/deg$^2) = -2.38$ cal/deg.

For a similar cell reaction with liquid water as the final product, $E° = 1.229$ v, $dE°/dT = -0.846$ mv/deg, and $d^2E°/dT^2 = +0.552$ μv/deg^2. The reaction entropy $\Delta S°$ is now $2\mathbf{F}(-0.846$ mv/deg$) = -39.0$ cal/deg, while $-\Delta G° = 2\mathbf{F}(1.229$ v$) = 56.7$ kcal, and $-\Delta H° = 68.3$ kcal. The reaction heat capacity $\Delta C_p°$ is now $2\mathbf{F}(298°\text{K})(+0.552$ μv/deg$^2) = +7.59$ cal/deg at 25°C.

Coupled (Regenerative) Fuel Cell

An electrochemical (or an osmotic-reaction) cell can be coupled with a high temperature source of heat (*e.g.*, a nuclear reactor) to decompose the combustion (reaction) products and regenerate the reactants of reaction [1]. Such a device is also termed a fuel cell (1), although in this case, cell reaction [1] no longer is the primary source of energy but is merely a step in a cycle that converts heat from the high temperature source into work. Such a coupled fuel cell is not ordinarily a simple Carnot cycle (*i.e.*, a cycle of two isothermals and two adiabatics), but if it is operated reversibly, it has a useful work output determined exactly by Carnot's theorem in either integral or differential form. This was proved to be true for the integral form by Liebhafsky (1) for the case where ΔC_p is zero. He also proved this to be approximately true, by a numerical example, for an idealized practical case in which only the heat exchanges during the warming-cooling portions of the cycle were allowed to be irreversible.[1]

For complete reversibility, the output of a regenerative fuel cell obeys Carnot's theorem in differential form exactly, even when ΔC_p is not zero. This can be proved by considering the following cycle of operations

$$\mathrm{M} + \mathrm{X} = \mathrm{MX} \text{ (at } T_l) \qquad [\mathrm{A}]$$

$$\mathrm{MX}(T_l) = \mathrm{MX}(T_h) \qquad [\mathrm{B}]$$

$$\mathrm{MX} = \mathrm{M} + \mathrm{X} \text{ (at } T_h) \qquad [\mathrm{C}]$$

$$\mathrm{M} + \mathrm{X}(T_h) = \mathrm{M} + \mathrm{X}(T_l) \qquad [\mathrm{D}]$$

All reactants and products are in their arbitrarily chosen standard states. All steps are completely reversible. Reaction A has a useful work output $W_{uA} = -\Delta G_A$. For a reversible reaction, the heat input $Q_A = T_l\Delta S_A$. The enthalpy change (2) is $\Delta H_A = Q_A - W_{uA}$. The thermodynamic properties of step A are summarized in Table I.

[1] Liebhafsky's efficiency of 73.3%, compared with a Carnot efficiency of 75%, should have been reported as 71.8%.

Table I. Thermodynamic properties of the four-step regenerative fuel cell cycle A-B-C-D

Step	ΔG	ΔH	ΔS	W_u	Q
A	ΔG_A	$T_l\Delta S_A + \Delta G_A$	ΔS_A	$-\Delta G_A$	$T_l\Delta S_A$
B and D combined	$\int_l^h \Delta C_p dT$ $-\Delta S_A(T_h - T_l)$ $-T_h\int_l^h \Delta C_p d\ln T$	$\int_l^h \Delta C_p dT$	$\int_l^h \Delta C_p d\ln T$	0	ΔH_{BD}
C	$-\Delta G_A$ $+\Delta S_A(T_h - T_l)$ $-\int_l^h \Delta C_p dT$ $+T_h\int_l^h \Delta C_p d\ln T$	$-\Delta H_A$ $-\int_l^h \Delta C_p dT$	$-\Delta S_A$ $-\int_l^h \Delta C_p d\ln T$	$-\Delta G_C$	$T_h\Delta S_C$
Cycle	0	0	0	$-\Delta G_A - \Delta G_C = -\Delta S_A(T_h - T_l)$ $+\int_l^h \Delta C_p dT - T_h\int_l^h \Delta C_p d\ln T$	

The heating and cooling steps B and D are in general not adiabatics, but they can be conducted as reversible heatings or coolings in the usual fashion, *i.e.*, by the conceptual use of an infinite number of heat reservoirs whose temperatures differ by intervals of dT. The heat absorbed in step B is then $\int_l^h C_p(\mathrm{MX})\,dT$, while the heat released in step D is $\int_h^l C_p(\mathrm{M}+\mathrm{X})\,dT$. Both integrals are understood to contain any heats of transition that may be involved. The net heat absorbed in heating and cooling combined is $\int_l^h \Delta C_p\,dT$ where $\Delta C_p = C_p(\mathrm{MX}) - C_p(\mathrm{M}) - C_p(\mathrm{X})$. At constant pressure, the useful work output is zero (2). The other thermodynamic properties of steps B and D combined are given in Table I, and all integrals are understood to contain summations of all enthalpies or entropies of transition.

At the high temperature T_h, the decomposition of MX, reaction C, has a further useful work output (which may in actual cases be negative, *e.g.*, as for an electrolytic decomposition and separation of M and X) equal to $-\Delta G_C$. The thermodynamic properties of step C are given in Table I.

For the whole cycle, the total useful work output, equal to the net heat input from all sources, is

$$W_u(\text{cycle}) = \oint dQ = -\Delta G_A - \Delta G_C$$
$$= -\Delta S_A(T_h - T_l) + \int_l^h \Delta C_p\,dT - T_h\int_l^h \Delta C_p\,d\ln T \quad [7]$$

According to Carnot's theorem in differential form, the useful work of the cycle should be given by

$$W_u(\text{cycle}) = \int_l^h dQ\,(T - T_l)/T \quad [8]$$

where dQ is an infinitesimal amount of heat received reversibly by the system from a heat reservoir at temperature T. Equation [8] can be expanded to give

$$W_u(\text{cycle}) = Q_C(T_h - T_l)/T_h + \int_l dQ_{B+D}\,(T - T_l)/T \quad [9]$$

where $dQ_{B+D} = \Delta C_p\,dT$. Evaluation of the two terms in Eq. [9] leads to the expression already given in Eq. [7]. Thus the work output of the cycle satisfies Carnot's theorem exactly, for a reversible operation throughout.

In practice, one of the chief sources of irreversibility in a regenerative fuel cell lies in the heat exchanges during heating and cooling (1). These can be minimized by having ΔC_p as close to zero as possible. The desirable thermodynamic properties for a regenerative fuel cell reaction are therefore

ΔG_A negative

ΔS_A negative

ΔC_p as close to zero as possible.

Finally, it is of interest to write expressions for the useful work output of a regenerative fuel cell cycle in which the two isothermal steps are reversible, while the heating and cooling steps are allowed to be irreversible. This is a much closer approximation to the actual situation for ΔC_p different from zero than the completely reversible cycle discussed above. From a consideration of the entropy-temperature diagram (9), it can be shown that this work is $S^*(T_h - T_l)$ where S^* is the quantity of entropy which falls reversibly through the temperature drop from T_h to T_l in driving forward the operation of one cycle. The useful work will therefore be $(-\Delta S_A)(T_h - T_l)$ or $\Delta S_C(T_h - T_l)$, whichever is smaller. For ΔC_p negative, the useful work output is

$$(-\Delta S_A)(T_h - T_l) = -\Delta G_A - \Delta G_C$$
$$-\{\int_l^h \Delta C_p\,dT - T_h\int_l^h \Delta C_p\,d\ln T\} \quad [10]$$

For ΔC_p positive, the useful work output is

$$\Delta S_C(T_h - T_l) = (-\Delta S_A - \int_l^h \Delta C_p\,d\ln T)(T_h - T_l) =$$
$$-\Delta G_A - \Delta G_C - \{\int_l^h \Delta C_p\,dT - T_l\int_l^h \Delta C_p\,d\ln T\} \quad [11]$$

In both Eq. [10] and [11], the expressions in braces represent the dissipated energy of the irreversible cycle, a quantity which is always positive.

Diffusion Theory of Polarization and Recuperation Applied to the Manganese Dioxide Electrode

Allen B. Scott

Union Carbide Consumer Products Company, Parma, Ohio and

Department of Chemistry, Oregon State College, Corvallis, Oregon

ABSTRACT

The behavior of MnO_2 electrodes during and following cathodic discharge is accounted for on the basis of diffusion of the reduction product into the solid electrode. A solution of the diffusion equation predicts the general form of the discharge and recuperation curve satisfactorily. A method for determining the electrode surface area and diffusion coefficient is given and results of some preliminary experiments outlined.

Polarization and recuperation processes in oxide electrodes have received much attention in recent years, particularly those in manganese dioxide primary cell cathodes. Vosburgh (1) recently reviewed current theories of the MnO_2 electrode and has given a comprehensive bibliography. Of the mechanisms proposed, that which appears to have been originally advanced by Coleman (2) seems to have the greatest body of experimental and logical support, at least in the case of discharge at moderate current density in electrolytes having *p*H in the middle range. Coleman proposed that polarization and recuperation resulted from the accumulation of lower (hydrous) oxide on the surface and its subsequent diffusion into the solid MnO_2 and suggested that the diffusing entities were protons and electrons. He applied Fick's law to the process in order to find a relation between drain and capacity of actual electrodes; his development was complicated by allowance for the transport of the lower oxide by the electric field as well as by ordinary diffusion, although he recognized that only the latter might actually occur. Simple calculations given later show that transport by the field is insignificant. Easily available solutions for the diffusion equation, applied to a simplified model of the electrode, lead to equations for both polarization and recuperation well in accord with experiment.

Kozawa (3) reduced MnO_2 with a known amount of Mn^{++} ion and concluded that the lower oxide produced remained primarily on the surface, and that diffusion of the lower oxide into the MnO_2 was not of importance. However, his calculations were based on surface area measured by the BET method with nitrogen, and it is probable, as is shown later, that the surface presented to the electrolyte was smaller than the BET area by 5 to 10 times. In such a circumstance, the lower oxide comprised perhaps as much as the equivalent of 20 layers, and the samples were already in late stages of recuperation when potentials were measured.

The MnO_2 electrode is very nearly reversible to H^+ ion, its potential decreasing by about 0.06 v with a unit increase of *p*H. The primary electrochemical reaction for the electrode operated at moderate current densities is thus

$$MnO_2 + H^+ + e = MnOOH \qquad [1]$$

Mn^{++} is found in the electrolyte (4, 5) during discharge (except during early stages at pH > 7.5) but is undoubtedly produced by secondary chemical reactions. For example ΔF at 25°C for the consecutive reactions

$$MnOOH + H_2O = Mn^{+++} + 3OH^-$$
$$2Mn^{+++} + H_2O = Mn^{++} + MnO_2 + 4H^+$$

is -26.0 kcal at pH $= 7$ and Mn^{++} activity $= 0.01$, according to approximate data given by Latimer (6). Alternatively MnOOH may decompose in the solid state, ΔF° for the reaction

$$2MnOOH = Mn(OH)_2 + MnO_2$$

being estimated (6) at -10 kcal. $Mn(OH)_2$ would dissolve readily at *p*H $= 7$. Thus there appears to be no necessity to assume the reduction to divalent manganese as a primary step except perhaps at high current density or excessively low *p*H.

A complete theory of polarization and recuperation would have to take cognizance of a great variety of secondary reactions[1] as well as the role of carbon; for the present, it seems that more will be gained by restricting consideration to the process [1], polarization and recuperation occurring by the mechanism of Coleman.

Diffusion Theory of Polarization and Recuperation

The bobbin of a dry cell is a complicated electrochemical system, and for our purposes it will be preferable to simplify the arrangement of components to the following:

Carbon/Black/MnO_2/Solution

Conduction is entirely electronic in the carbon and the black, and almost entirely electronic in MnO_2, since MnO_2 has a conductivity between 0.1 and 0.01

[1] A theory of the effect of the removal of Mn^{++} from the electrode during discharge in acid electrolytes on polarization and recuperation has been developed by Yoshizawa and Vosburgh, (7).

ohm^{-1} cm^{-1} at room temperature (8) which certainly cannot arise from ionic migration. The electrochemical reaction, therefore, takes place at the MnO_2-solution interface. The field in the MnO_2 is very low; for example, at a current density of 1 ma cm^{-1}, taking the MnO_2 conductivity to be 0.01 ohm^{-1} cm^{-1}, the field is only 0.1 v cm^{-1}. This result shows that any migration of ions which occurs within the MnO_2 must take place as the result of chemical potential gradients rather than electric potential gradients. By comparison, if we assume unit activity coefficient, a change in mole fraction of MnOOH from 0.5 at the surface to 0.1 at a point 1 μ inside the surface of MnO_2 undergoing cathodic reduction results in a mean chemical potential gradient of 4 x 10^7 joule mole^{-1} cm^{-1}, which would exert the same effect as an electric field of 420 v cm^{-1}.

During discharge the following processes occur. Protons are transferred from solvent molecules to oxide ions on the MnO_2 surface under the influence of the negative potential of the cathode. At the same time, electrons are stably trapped on neighboring Mn^{+4} ions, reducing them to Mn^{+3}. The dilution of MnO_2 with MnOOH in the form of a solid solution reduces the MnO_2 activity and thus the electrode potential decreases as the reaction proceeds. Johnson and Vosburgh (9) studied the potential of electrodes made of mixtures of MnO_2 and MnOOH which were presumably allowed to come to equilibrium, 50 days being allowed for interdiffusion of the two solids, and found that the emf could be represented by

$$E = E^\circ + 0.073 \ln \frac{\text{mole \% } MnO_2}{\text{mole \% MnOOH}} \qquad [2]$$

at 25°C. The difference between the factor 0.073 and the theoretical value 0.059 is ascribed to the use of mole per cents rather than activities. E° varies with pH; the average at pH = 7.5 was found to be 0.416 v with respect to saturated calomel.

Recuperation consists of the diffusion of protons and electrons toward the interior under the driving force of the chemical potential gradient.

A quantitative theory for the polarization and recuperation can be obtained readily by the use of the foregoing model. Consider the MnO_2 to consist of a semi-infinite solid, bounded by the plane $x = 0$. The region $x < 0$ is occupied by solution. During discharge at constant current density, F_0 equivalents of MnOOH are produced per unit area per unit time. The diffusion problem can be solved by analogy to a problem in heat transfer, namely, the case of linear heat flow in a semi-infinite solid, initially at zero temperature, with a constant flux of heat across the boundary surface. Equations of interest in the present application, after throwing into a form suitable for mass transfer, are the following (10).

At $x = 0$, that is, on the surface of the MnO_2, the concentration of MnOOH as a function of time is

$$C = \frac{2F_0}{(D\pi)^{1/2}} \{t^{1/2} - (t-T)^{1/2}\} \qquad [3]$$

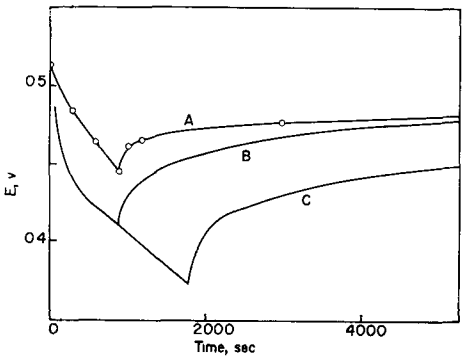

Fig. 1. Discharge and recuperation curves for the MnO_2 electrode. B, C, calculated; A, experimental (Ferrell and Vosburgh).

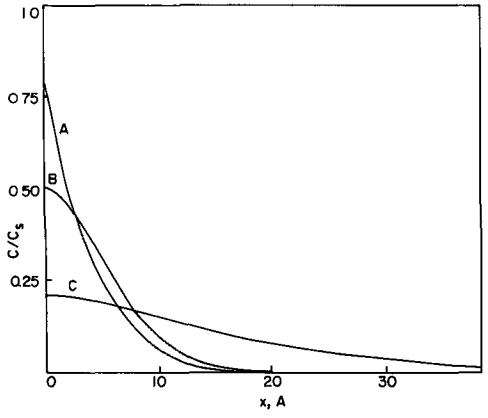

Fig. 2. Variation of MnOOH concentration with distance from surface. A, 1800 sec, discharged stopped; B, 2200 sec; C, 8200 sec.

and within the solid the concentration of MnOOH as a function of x, the distance from the surface, at any time t is

$$C = \frac{2F_0}{D^{1/2}} \left[t^{1/2} \left(\text{ierfc} \frac{x}{2(Dt)^{1/2}} \right) - (t-T)^{1/2} \left(\text{ierfc} \frac{x}{2D^{1/2}(t-T)^{1/2}} \right) \right] \qquad [4]$$

Here D is the diffusion coefficient for protons, accompanied by electrons, in the solid (assumed constant for the present), t is the time following start of the discharge, and T is the time at which the discharge stops and recuperation begins.[2] For $t<T$ the terms involving $t - T$ are to be taken as zero.

Using discharge and recovery curves such as those of Ferrell and Vosburgh (11) as a guide, the following values of the constants were arbitrarily assigned:

$F_0 = 1 \times 10^{-12}$ eq cm^{-2} sec^{-1} ($i = 9.5 \times 10^{-8}$ amp cm^{-2})

$D = 1.2 \times 10^{-18}$ cm^2 sec^{-1}

The concentration of MnOOH when pure, computed from the density, is 5.47 x 10^{-2} eq cm^{-3}. That of MnO_2 is 5.70 x 10^{-2} eq. cm^{-3}. The concentration of MnO_2 is given approximately by

$$C_{MnO_2} = 5.47 \times 10^{-2} - C_{MnOOH} \text{ eq cm}^{-3}$$

With these values and Eq. [2], [3], and [4], the curves of Fig. 1 and 2 were computed for discharge at pH = 7.5.

Figure 1 shows the variation in E with time for a discharge at current density 9.5 x 10^{-8} amp cm^{-2}, the

[2] ierfc (y) is defined by

$$\text{ierfc}(y) = \pi^{-1/2} \exp(-y^2) - 2y \pi^{-1/2} \int_y^\infty \exp(-z^2)\, dz.$$

discharge being discontinued at $T = 900$ sec and at $T = 1800$ sec. Recuperation occurs very rapidly on first stopping the discharge, but the rate of recuperation declines with time. Figure 2 shows the calculated distribution, as a function of the distance from the surface, of the MnOOH produced. Curve A represents the situation at the time of discontinuance of the discharge, curve B, 400 sec later, and curve C, 6400 sec later. It is evident that the surface was nearly saturated at 1800 sec, C_s indicating the concentration corresponding to pure MnOOH. In fact, from [3] it may be calculated that the surface would have been saturated after 2800 sec of continuous discharge.

Curve A of Fig. 2 shows clearly why the initial part of the recuperation is very rapid. The concentration gradient at the surface is extremely high during discharge; after the discharge stops the steep gradient at the surface is rapidly leveled (curve B), after which the potential rises much more slowly.

In Fig. 1 is also shown typical data of Ferrell and Vosburgh (11) for the discharge of an electrolytically deposited MnO_2 electrode at pH near 7.5, to be compared with the form of the calculated curve. The ordinates are not particularly significant, as the initial potential of MnO_2 is quite variable and further the choice of E° in Eq. [2] is somewhat arbitrary. Diffusion in the solid is seen to be adequate to account for the chief aspects of the discharge and recuperation.

It is to be noted that the slope of the calculated curve is greater than that of the observed curve after an extended period of recovery. This is almost certainly the result of assuming the solid to be semi-infinite. In the actual material composed of small, highly irregular particles, there will be many regions where advancing diffusion fronts will overlap, thus retarding diffusion.

There are two additional assumptions in the theory which require comment. First, it has been assumed that D is independent of C. It would appear, however, that D should be proportional to the concentration of unoccupied sites for protons, *i.e.*, proportional to C_{MnO_2}, and thus its variability would make itself felt wherever the concentration of MnOOH becomes large.

Second, the solid is not a continuous medium, and consequently the surface, instead of being a geometrical plane, is a region of finite thickness, namely about half the unit cell edge[3] (there being two MnO_2 formulas per cell). When D = 0 the rate of increase of concentration in the surface layer during discharge is not infinite, as given by Eq. [3], but is $F_0/1$ where 1 is the thickness of the surface layer. As D and t increase, the effects of the discontinuous structure diminish, and the surface concentration, instead of increasing linearly with time, becomes proportional to $t^{1/2}$.

If E is plotted against time for a constant-current discharge, the time required to saturate the surface with MnOOH, indicated by t_s, is located approxi-

[3] There is no unique way to compute the thickness of the surface layer of MnO_2, as this depends on the crystal plane assumed to lie parallel to the surface; further, the value would depend to some extent on the fraction of MnO_2 reduced to MnOOH.

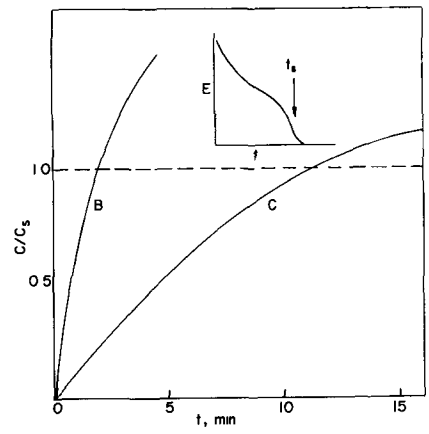

Fig. 3. Growth of MnOOH concentration at surface. A, location of t_s, the saturation time; B, t_s = 1.8 min; C, t_s = 11 min.

mately at the second inflection (inset, Fig. 3). If the discharge is very rapid,

$$C_s = \frac{F_0}{1} t_s \qquad [5]$$

In case the surface area of the oxide is unknown, F_0 may be determined in this manner, and from it, by use of the known current, the surface area may be found. Having the surface area, the oxide may be discharged at a lower rate, for which Eq. [3] may be expected to hold and

$$C_s = \frac{2F_0}{(D\pi)^{1/2}} t_s^{1/2} \qquad [6]$$

This provides a method for the measurement of D.

Experimental

To illustrate the application of the theory, some simple experiments were carried out. Using a modification of the Utilization Test (12) discharge tests were performed on electrolytic MnO_2 of surface area 63.9 m^2/g, determined by the BET method. Figure 4 shows the results of three such experiments. In an even layer against the face of a large graphite electrode, 0.706 g of MnO_2 was pressed. The electrode was made the cathode at a current of 200 ma, with an electrolyte of NH_4Cl and NH_3 at pH = 7.0 and a zinc anode. The potential of the cathode with respect to a saturated calomel electrode was measured by

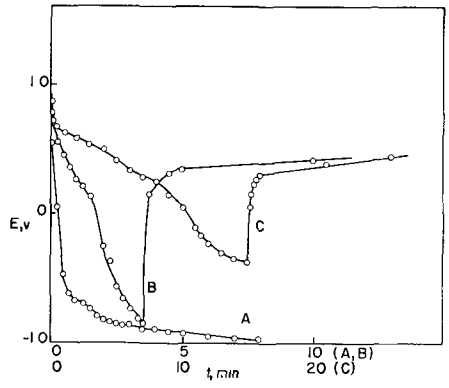

Fig. 4. Discharge of MnO_2. A, virgin sample, 200 ma; B, after recharging, discharged at 50 ma; C, after recharging, discharged at 10 ma.

means of a vacuum-tube voltmeter. An inflection at 1.8 min is barely discernible in curve A.

The oxide was then recharged, by making it the anode at 200 ma for 4 min, at 100 ma for 6 min, and allowing it to stand on open circuit until the voltage was steady. Upon cathodic discharge at 50 ma (curve B), the inflection was again observed at 1.8 min, but it was more pronounced. The polarization in the early part of the discharge was much diminished. At 3.5 min the current was discontinued and the recuperation was observed. Curve C was obtained, after again recharging the oxide, using a current of 10 ma.

Taking the thickness of the surface layer as one-half the mean unit cell edge for $\beta-MnO_2$, or 1.94Å, and assuming [5] to apply to the 50 ma discharge, $F_0 = 9.8 \times 10^{-12}$ eq cm^{-2} sec^{-1}, and the effective surface area is 5.4 m^2 or 7.7 m^2/g. This is only about 12% of the surface area measured by the BET method. As previously mentioned, this result has an important bearing on the experiments of Kozawa. D from [6] is 2.7×10^{-17} cm^2 sec^{-1}. This should be taken as a rough approximation only, on the basis of these preliminary experiments.

The effects of diffusion are apparent at 10 ma, where t_s is greater than 5 times t_s for the 50 ma discharge. A schematic plot of concentration at $x = 0$ *vs.* t is given in Fig. 3 for experiments B and C. It would assist in verifying the diffusion theory if further simple experiments of this kind were carried out to establish if $F_0 t_s^{1/2}$ were constant at higher values of $t_s^{1/2}$. The value of D could then be established.

The potential at t_s is not clearly defined. Equation [2] predicts a sigmoid discharge curve, E going to $-\infty$ at t_s; however, at $t > t_s$, E would be governed by a second relation involving MnOOH and $Mn(OH)_2$. Practically, E at t_s should be about that reported by Kozawa (3) for the Mn_2O_3 electrode, or 0.23 v with respect to the saturated calomel electrode. The observations reported here indicate that a large part of the polarization during the 200 ma discharge of the virgin MnO_2 was activation polarization. At the lower current densities, after recharging the oxide, E at t_s was still about 0.2 v less than that of the Mn_2O_3 electrode. Whether there is activation polarization under these conditions may be decided by means of an oscillographic method; however, previous results (1) make this appear unlikely. In any case, the choice of t_s is probably not much affected by the magnitude of E.

Acknowledgment

It is a pleasure to acknowledge the valuable contributions of G. E. Evans and J. A. Krumhansl who suggested the application of the physics of solids to the electrode process, of N. C. Cahoon and M. P. Korver who made available the utilization test equipment and provided much useful information concerning the theory of discharge and recuperation, and of D. R. Allenson and A. W. Smith with whom beneficial discussions were held.

Manuscript received April 5, 1960.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

Aluminum Reactions with Water Vapor, Dry Oxygen, Moist Oxygen, and Moist Hydrogen between 500° and 625°C

P. E. Blackburn and E. A. Gulbransen

Chemistry Department, Research Laboratory, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

The rate of reaction between water vapor and aluminum is greater than that between the metal and oxygen. Mixtures of water vapor with either oxygen or hydrogen react with the metal at the same rate as does water vapor alone. Hydrogen blisters are formed in the metal in the presence of water vapor, but none is observed when water is absent. Blister formation in water vapor is not detected if the metal is first reacted with HCl solution.

Relatively little study has been given the reaction between water vapor and pure aluminum, although considerable research has been done on aluminum oxidation in air, oxygen, and liquid water. Oxidation of the metal in oxygen within the temperature range 350°-550°C was measured by Gulbransen and

Wysong (1). They found a parabolic rate from 350° to 475°C and a linear oxidation rate above this temperature region. Smeltzer (2) has measured oxygen reaction rates of metallographically polished and annealed aluminum between 400° and 600°C. He fitted his data to two parabolic rate constants which apply to thin and thick films. The oxide film was observed to grow very slowly above a weight gain of 35 to 40 $\mu g/cm^2$.

The barrier oxide thickness of films formed on aluminum in dry and moist atmospheres from room temperature to 600°C has been measured by Hunter and Fowle (3). Their method consisted of measuring the voltage necessary to produce normal leakage through the oxide film. The barrier oxide formed between 25° and 500°C was found to be amorphous, while a thicker crystalline film was discovered above 475°C. The thickness of each type of barrier oxide is a linear function of the temperature. For crystalline forms the thickness reaches 205Å at 600°, and for amorphous films it is 55Å at 500°. The oxide layer in excess of the barrier film is porous.

Plumb (4) has measured the specific surface area of aluminum with various surface preparations. The procedure required determining the thickness of a known amount of oxide deposited anodically on aluminum. The specific area relative to the apparent area decreased with oxide thickness. Surface roughness of 25 for rough abrasion, 6 for metallographic polish, 2 for chemical polish, and 2.5 for as-rolled samples were observed at oxide thicknesses of about 30Å.

Draley and Ruther (5) studied the reactions of both commercial 2 S aluminum and the pure metal with liquid and gaseous water. They have observed the presence of blisters in specimens oxidized in liquid water. Although these blisters usually contained corrosion products, some were found to be gas filled. Samples exposed to liquid water for two weeks at 290°C were completely destroyed. A cycle of decomposition resulted from water filling the blisters succeeded by further attack producing more blisters. Draley and Ruther have postulated a mechanism for blister formation. Briefly, protons from the reacting water diffuse through the oxide film to the metal, balancing the charge of aluminum cations moving to the gas-oxide interface. The protons are then reduced to hydrogen atoms, some of which diffuse into the metal where they combine in rifts and cavities to form hydrogen molecules. The molecular hydrogen pressure expands the soft metal, forming blisters. Vacuum fusion analyses of oxidized samples showed that the gas filling the blisters was hydrogen. It is proposed that impurities with low hydrogen overvoltage potentials catalyze the combination of hydrogen atoms within the metal. Alloys containing additions of such elements were found to resist water attack. It is suggested that these added materials catalyze formation of hydrogen molecules at the oxide metal interface. Hydrogen molecules cannot diffuse into the metal, since only atomic hydrogen is believed to diffuse.

Carlson (6) has found that intergranular attack of aluminum at 100°C is considerably less in hydrochloric acid than in distilled water.

Coriou, *et al.* (7) found that pure aluminum was severely corroded in liquid water above 200°C. Blisters formed in the pure aluminum resulted in an appreciable expansion of the metal. Practically all of the blisters were formed in grain boundaries since there was little change in the volume of aluminum single crystals.

The present research was proposed to study the reaction of aluminum in water vapor and in mixtures of water vapor with hydrogen or oxygen.

Experimental Procedure

Apparatus.—The apparatus used for this study consisted of a vacuum system made of Pyrex tubing and metal Alpert (8, 9) valves. The apparatus was evacuated with two-stage oil diffusion pumps separated from the "clean" system by crackers. A Bayard-Alpert (10) gauge and a mercury manometer, separated from the system by a null manometer, were used to measure pressures within the apparatus. Samples were heated inside a mullite furnace tube, which was sealed directly to the Pyrex system.

A Kanthal resistance furnace which heated the mullite tube was held to within ± 0.5°C by a L & N controller. Bake out ovens enclosed the system, permitting degassing or maintenance of temperature above the condensation point of water wapor.

An all-quartz microbalance was constructed of small rods. Sensitivity was increased by using a girder type beam which weighed less than half a gram. Fine quartz filaments, sealed directly to the beam and quartz frame, were employed in vertical suspension at the fulcrum and at each end of the beam. This balance had a sensitivity of 321 $\mu g/cm$ where the position of the beam could be read with a traveling microscope to ±0.0005 cm.

Gases.—Either spectroscopically pure oxygen obtained from Linde Air or tank hydrogen diffused through a palladium tube was admitted to a mixing bulb from which it could be added to the system as a

single component gas or mixed with water vapor. Water vapor was generated from a bulb of degassed distilled water.

Samples.—Two types of very pure rolled aluminum were kindly furnished by the Kingston Laboratories of Aluminium Limited. Table I compares spectrographic analyses of polished and annealed materials with those of reacted samples.

The effects of three types of surface treatment on oxidation behavior are compared in Fig. 1. The greater apparent oxide thicknesses formed on the "as-received" and on Smeltzer's metallographically polished sample are attributed to greater surface roughness for these samples (see Results and Discussion).

The electrochemical polish was carried out in a solution consisting of one part perchloric acid and 5 parts methanol at 10°C and 25 v. The chemical polishing solution was 6% nitric acid and 94% phosphoric acid, used at a temperature of 95°C. The sample was washed in 55°C distilled water. Oxidation behavior of the two specimens appeared to be similar. All of the remaining experiments were made with chemically polished samples.

Procedure.—The procedure consisted of suspending a polished specimen in the furnace tube from one end of the balance beam. After evacuating and degassing the system, the specimen was degassed and annealed at 600°C for one hour. The pressure in the system varied between 10^{-5} and 10^{-6} during the degassing treatment. The samples lost an average of 1 μg of gas per cm² during the annealing process. The furnace was adjusted to the desired temperature, gases were admitted from the mixing bulb, and the change in weight with time was observed.

Results

Kinetics.—Figure 2 shows the weight gain *vs.* time curves obtained for samples oxidized in 0.1 atm of oxygen at 500, 550, 600, and 640°C. For the latter three temperatures the reaction consists of a relatively fast oxidation rate up to a weight of 5 to 6 μg/cm², where the rate becomes very slow. The 500° measurement was considerably slower than the higher temperature experiments. In these cases, as in the remainder of the kinetic studies, the data failed to conform to any of the theoretical curves, *i.e.*, linear, parabolic, cubic, logarithmic, or inverse logarithmic.

The oxidation of aluminum in 0.1 atm of water vapor for samples reacted at 25° intervals from 500° to 625°C is shown in Fig. 3. Here the extent of rapid oxidation is again between 5 and 6 μg/cm². No significance is attached to the apparently greater oxide thickness on the 575°C measurement. It is believed to be due to a larger surface roughness as a result of pitting during chemical polishing. After 24 hr the 500° measurement reached 6.0 μg/cm² while the 525° measurement was at 7.1 μg/cm². Assuming smooth surface and formation of Al_2O_3, the oxide depth is 53Å for each microgram of oxygen reacting per square centimeter. Film thicknesses based on these assumptions are given in Fig. 3. The slower rate then begins at about 300Å. However, Plumb has shown that chemically polished aluminum has a surface roughness of between 1.5 and 2.0, so the onset of the lower oxidation rate is actually between 170 and 220Å when the room temperature film of 20Å is added. Hunter and Fowle indicate that crystalline barrier films for aluminum oxide vary between 170 and 205Å over this temperature range. It is apparent that rapid oxidation ceases once the barrier oxide layer has formed. The lower rate is thus due to growth of a porous oxide over the barrier oxide. This mechanism applies to both oxygen and water vapor corrosion. The difference between this data and Smeltzer's may be attributed to a difference in surface roughness. According to Plumb the surface roughness of abraded samples may vary between 6 and 25, depending on the method and grit size used. Smeltzer's values for the extent of aluminum oxidation would fall in line

with a barrier oxide thickness of 200Å if average surface roughnesses of 8 to 10 are used for his specimens.

Apart from the extent of oxidation described above, other features of the kinetic curves are less readily explained. Between 575° and 625°C the rapid rate from 1 to 5 $\mu g/cm^2$ appears to be almost linear, whereas between 500° and 550°C there is an upward curvature. The latter effect is characteristically observed in nucleation and growth controlled reactions. The rate over the first 0.5 to 1 $\mu g/cm^2$ is seen to be much more rapid than the subsequent weight gain. In this region the amorphous barrier layer described by Hunter and Fowle may be formed. These authors observed that the amorphous layer grows much faster than the crystalline film.

Samples oxidized in oxygen and water vapor gave identical electron diffraction patterns, indicating that the reaction in water vapor above 500°C results in a nonhydrated oxide film. This is consistent with the thermodynamics of alumina hydrates, compounds which are unstable at these temperatures.

Blister formation.—All of the 10-mil samples oxidized in water vapor developed blisters within the metal large enough to form easily visible mounds on the surface. Blisters were formed either on grain boundaries or along lines parallel to the rolling direction. A photomicrograph of the surface of a sample oxidized in water vapor at 600°C clearly shows swellings on the grain boundaries (Fig. 4).

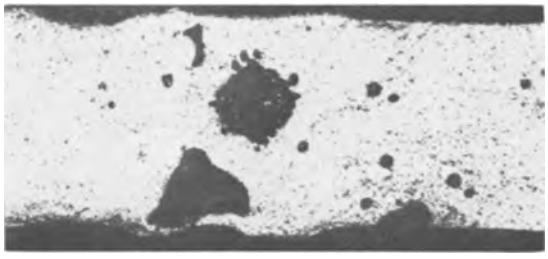

Fig. 6. Aluminum reacted in water vapor at 600°C, etched in 10% HF. Magnification 200X before reduction for publication.

No blisters formed on any of the samples oxidized in oxygen. Cross sections of water vapor samples (Fig. 5) show that, in addition to large blisters which swell the metal, there are many small cavities. Cross sections of as-received British specimens revealed the presence of small cavities and occasionally some large ones. It was observed that large cavities in water vapor reacted samples could be classified into two categories: (*a*) smooth walled blisters which swelled the metal, and (*b*) nondeforming cavities with walls constructed of a series of many small pits (Fig. 6). Since as-received specimens had both small cavities and the second type of large cavity, it was not possible to tell whether blisters appearing in the reacted specimens were already there or were increased by the reaction. The large smooth walled cavities resulted from the water vapor reaction since they were found only after samples had been oxidized in water vapor.

Although small blisters appear in as-received specimens, their presence in reacted samples occurs to a much greater extent. It would seem that small blisters, as well as large cavities, may form during the reaction.

The total hydrogen content of samples after reaction in water vapor (Table II) is less than 0.6% of the total weight gain, while the hydrogen content of water is 11% by weight. Thus, if the presence of hydrogen is due to reaction with water, only a small fraction of the available hydrogen enters the sample. Since the blister formation appears to be limited to impurity sites, either in grain boundaries

or at inclusions, this low yield of hydrogen is not surprising.

The effect of an oxygen formed oxide layer on the water vapor reaction is shown in Fig. 7. Two samples were oxidized in oxygen; sample A for 3 min followed by addition of water vapor, sample B for 9 min followed by removal of oxygen and addition of water vapor. For the first case the reaction rate was sharply accelerated with addition of water vapor. In both cases the extent of oxidation was the same as in either water vapor or oxygen alone. The oxygen formed oxide layer appears to suppress formation of blisters which swell the metal, since there were very few in sample A and only one in sample B. There are two possible explanations for this finding. First, hydrogen may diffuse less readily through an oxygen formed film. Second, hydrogen pickup, which occurs simultaneously with formation of the oxide layer, is decreased in an amount proportional to the thickness of the oxygen formed film. The latter interpretation is derived from the fact that the total oxide thickness is the same whether it is formed in oxygen or in water vapor.

Before water vapor was added to these two specimens, 0.9 μg of oxygen per cm^2 reacted with sample A, and 2.5 μg of oxygen per cm^2 was taken up by sample B. If hydrogen pickup is proportional to the amount of oxide formed during the water vapor reaction, the second explanation implies that blisters would not be formed from hydrogen evolved from a μg/cm^2 oxygen pickup. Another water vapor sample was reacted until the weight gain reached 3.4 μg/cm^2. This specimen was covered with blisters somewhat smaller than those on samples oxidized

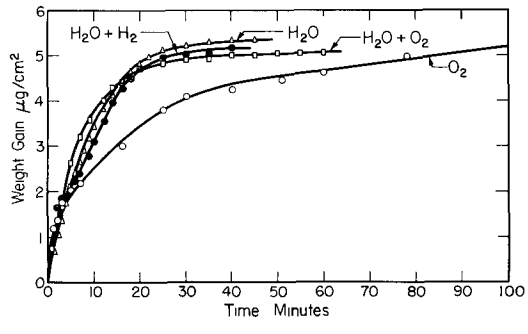

Fig. 8. Effect of corrosive atmosphere on aluminum oxidation rate at 600°C.

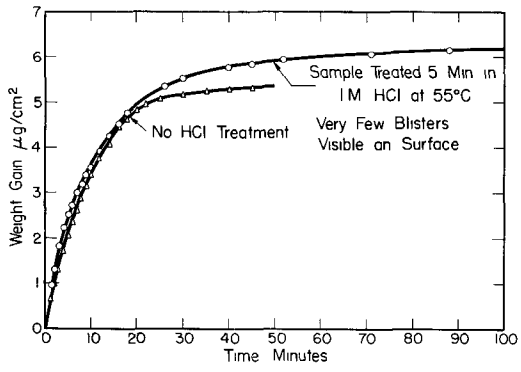

Fig. 9. Effect of treatment in HCl solution on aluminum water vapor reaction at 600°C.

to 5.5-6.0 μg/cm^2. Thus, the chief inhibitor of blister formation appears to be the resistance to hydrogen diffusion offered by oxygen formed oxide films.

The addition of oxygen or hydrogen to water before reacting it with aluminum made no apparent change in either reaction kinetics or blister formation. This is consistent with earlier observations (1) that the aluminum oxidation rate is independent of oxygen pressure. Here the oxygen partial pressure was varied between 10^{-1} and 10^{-24} atm. The rate of reaction in water vapor or in mixtures of water vapor with hydrogen or oxygen was about twice that in oxygen alone. Figure 8 presents reaction rates for samples oxidized at 600°C by the various treatments.

The suppression of intergranular attack by HCl additions to water, observed by Carlsen, was tested here. Samples were treated with HCl solutions at 55°C, washed in distilled water, annealed in vacuum, and reacted with water vapor. The kinetics of the reaction (Fig. 9) were the same as for samples without the HCl treatment, but no blisters were observed.

Table II shows the effect of HCl treatment on hydrogen content of French aluminum oxidized in moist air at 600°C. The hydrogen content of samples treated in HCl before reaction with water vapor is lower than any of the other samples tested. This is further evidence, although of a negative character, that the blisters are filled with hydrogen.

The role played by HCl in the suppression of blisters is not clearly understood from the available information. If impurities in the metal are important

in the mechanism of blister growth, then treatment in HCl solution may result in removal of some of the impurities. This could occur either by solution of their chlorides during preparation or by vaporization of the chlorides during the degassing and annealing at 600°C. Table I gives results of spectroscopic analysis of samples following various reactions. The boiling points of the chlorides at 10^{-4} atm (10) and solubility of the chlorides in water (11) are found in Table III. There appears to be very little difference in the level of impurities in various samples. All the chlorides are water soluble, and iron, silicon, and aluminum chlorides have extremely high vapor pressures at the annealing and reaction temperature. Copper, magnesium, and manganese chlorides evaporate at a lower rate.

It is also possible that HCl suppresses blister formation by reacting with aluminum to form a chemisorbed layer of $AlCl_3$. Such a barrier may inhibit the diffusion of hydrogen.

Discussion

Since the as-received material held a considerable amount of hydrogen, the cause of the blisters is difficult to uncover. From Table II, however, it may be seen that a very low hydrogen content is found in chemically polished and vacuum annealed samples. The amount of hydrogen does not change with reaction in oxygen, whereas water vapor reaction significantly increases the hydrogen content. The rather wide scatter in these values is a function of sample size. Each specimen weighed about 0.3 g, and thus liberated only a few tenths of a microgram of gas for vacuum fusion analysis.

The data from this study are in general agreement with Draley and Ruther's experimental results. It may be noted that these earlier authors did not locate the blister with reference to grain boundaries. It is believed that their specimens came of material of much smaller grain size, making the relationship between grain boundaries and blisters obscure. Although these results appear to substantiate the Draley and Ruther theory, further work is necessary to clearly establish mechanism of blister formation.

Grace and Seybolt (13) studied the selective oxidation of aluminum in an iron-aluminum alloy between 700° and 900°C in hydrogen-water vapor mixtures. Since their study was on an alloy, their results are not applicable to our work on pure aluminum. In spite of this, there are some points which are worth mentioning. First, Grace and Seybolt made no correction for surface roughness, which could have been from 2 to 10. Second, they assume an initial weight gain of 2 to 3 $\mu g/cm^2$ (uncorrected surface area) during the first 15 min. In our work almost all of the oxide formed during the first 15 min at temperatures above 600°, *i.e.*, about 3.5 $\mu g/cm^2$ (area corrected for surface roughness). Third, Grace and Seybolt determined an oxygen pressure dependence by varying the water pressure in a constant pressure of hydrogen. This dependence was near the 1/7 power of water vapor-hydrogen ratio where H_2O/H_2 was varied by three orders of magnitude. In this study the oxygen pressure was varied by a factor of 10^{23} with no apparent change in the rate of aluminum oxidation. The suggestion may be made that the pressure dependence observed by Grace and Seybolt is due to the water vapor pressure and not to the H_2O/H_2 ratio.

The Grace and Seybolt study gives a much lower rate of reaction than that which one would find by extrapolation of this data to their temperature range. They also found parabolic oxidation which was not found here (with the possible exception of the initial 50Å film). In view of these differences it would appear that the selective oxidation of the iron-aluminum alloy cannot be treated as if it were aluminum alone oxidizing at a higher temperature.

Thermodynamic calculations were made for the 600°C reaction,

$$H_2O = H_2 + 1/2\ O_2 \qquad [1]$$

The minimum partial pressure of oxygen in water and hydrogen and the lowest partial pressure of hydrogen in water and oxygen may be computed for reaction [1]. The mixed gases each contained 0.1 atm of water with an equal amount of hydrogen or oxygen.

Although the thermodynamic oxygen pressure was varied from 10^{-1} to $10^{-24.9}$ atm and the thermodynamic hydrogen pressure was varied from $10^{-12.5}$ to 10^{-1} atm, there was no apparent change in either the kinetics of the oxide growth or the formation of hydrogen blisters.

These calculations indicate that the reaction rate is independent of oxygen partial pressure. Vacancy diffusion is therefore excluded as a rate-controlling mechanism both by the failure of the curves to obey the parabolic rate law and by the absence of pressure sensitivity.

Conclusions

Aluminum reacts rapidly with water vapor above 500°C to form a crystalline oxide layer about 200Å thick. The rate of reaction beyond this oxide thickness is extremely low. The mechanism of reaction is rather complex, involving the formation of a thin amorphous barrier layer which crystallizes and thickens. Inasmuch as the kinetic curves fail to fit theoretical curves it is not possible to determine the method of oxide formation. Hydrogen and oxygen additions to the water vapor appeared to have no effect on the kinetics.

Hydrogen-filled blisters formed in the metal along rolling lines and between grain boundaries when water vapor was present in the gas phase. Hydrogen or oxygen added to the water vapor had no effect on blister formation.

Acknowledgment

The authors are grateful to Professor Duval for his helpful suggestions, to W. M. Hickam for developing a microgas fusion analysis for use here, and to J. Senko for the spectroscopic analysis.

Manuscript received Dec. 21, 1959. This paper was prepared for delivery before the Ottawa Meeting, Sept. 28-Oct. 2, 1958. This study was supported by the U.S.A.E.C. under subcontract to Bettis Plant.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

Dissolution of Copper in Sulfuric Acid Solutions

D. P. Gregory[1] and A. C. Riddiford

Department of Chemistry, The University of Southampton, United Kingdom

ABSTRACT

When copper disks rotate in sulfuric acid solutions, the observed rate of dissolution is first order with respect to the concentration of dichromate ion used as a depolarizer. By studying the effect of temperature and stirring speed at high and low acid concentrations, the process is shown to be determined completely by the rate of transport of dichromate ion to the reacting surface. This has been confirmed by studying the effect of different surface preparations, by measuring the rate of reaction of brass and amalgamated copper with these solutions, and by comparing the observed values with the theoretical rates. The effect of blocking off progressively larger areas of the working surface is reported.

From a number of studies of the dissolution of copper in acid solutions containing a suitable depolarizer (1-12), it appears that in some cases the surface process is so slow that the observed rate is a measure of the dissolution process occurring at the interface, whereas in others the observed rate is determined partly or wholly by a transport process. It is difficult to draw any general conclusions concerning the conditions under which one might expect to be able to study the surface process itself inasmuch as some of the investigations were purely qualitative in nature, and most of the others were confined to very narrow ranges of experimental conditions; but the results as a whole do suggest that the extent to which transport processes obscure the surface reaction is governed by the *p*H of the solution and by the concentration and nature of the species used as a depolarizer.

Published results leave little doubt that varying the type of depolarizer used may have a very marked effect on the character of the dissolution process. In the case of molecular oxygen, for example, the recent, detailed study of the dissolution of polycrystalline copper in sulfuric acid solutions (12) has shown that the observed rate is free from any measure of transport control. At the other extreme, the work of King and his co-workers (5, 6, 8) and of Buben and Frank-Kamenetskii (9) makes it fairly certain that the rate of dissolution in acid solutions of ferric salts is controlled entirely by the rate of transport of ferric ion to the interface under the chosen experimental conditions. Intermediate between these extremes are cases where the observed rate is controlled jointly by both the surface process and a transport process, *e.g.*, the dissolution of copper cylinders in an acetate buffer containing *p*-benzoquinone (10).

Much less is known concerning the effect of varying the concentrations of acid and depolarizer. Van Name and Hill (2) studied the dissolution of a number of metals in sulfuric acid solutions containing either ferric alum or the dichromate ion as depolarizer, and in hydrochloric acid solutions containing ferric chloride. In each case, they studied the effect of varying the concentration of acid and concluded that, whereas the observed rate is purely transport controlled at high concentrations, there is a general tendency for the surface process to begin to affect the over-all rate as the concentration of acid is diminished. The work of Lu and Graydon (12) provides the only other study of the effect of *p*H on the rate of dissolution of copper. In this case, as mentioned above, sulfuric acid solutions containing molecular oxygen were used, and the observed rate is a measure of the dissolution process at the copper/solution interface. Varying the concentration of acid has very little effect on the rate as long as the acid is present in excess; above *p*H 1, however, the rate declines rapidly as the concentration

[1] Present address: "Shell" Research Ltd., Thornton Research Centre, Chester, U. K.

is decreased, probably as a result of film formation on the surface of the copper.

This investigation provides the only detailed information available concerning the effects of varying the concentration of the depolarizer and the temperature. The study of these effects demonstrated the absence of any measure of transport control and thus enabled Lu and Graydon to suggest a possible mechanism for the dissolution process when oxygen is used as a depolarizer. For this reason, however, it throws little light on the general problem of deciding the conditions under which one might expect to be able to study the surface process, and it therefore seemed desirable to make a detailed study of the effect of a different depolarizer on the rate of dissolution of copper in sulfuric acid solutions.

The dichromate ion was chosen since it appeared possible that the observed rate might be controlled jointly by the surface process and by one of the transport processes at low acid concentrations. From the results of Van Name and Hill (2), the observed rate is purely transport controlled at sulfuric acid concentrations of 0.25M and above, whereas King and Weidenhammer (5) have indicated that the rate of dissolution of copper in 0.1M acetic acid solutions may be controlled by a slow surface process when the concentration of dichromate ion is less than 0.1M. The present study has been made using the rotating disk system, and particular attention has been paid to experimental conditions for which the rates of the transport processes may be calculated (13, 14).

Experimental

The main features of the apparatus have been described elsewhere (14). Disks were cut from ANALAR grade copper foil (*ca.* 0.15 mm thick) and were fixed to a brass former with black wax as shown in Fig. 1. The brass former fitted closely over the end of the stirring shaft and was held in place by a locking pin. The exposed brass of the former and the upper surface of the disk were protected from attack by a coating of black wax applied in hot benzene solution. This was shown to be impervious to acid dichromate solutions. Mounting the disks in this way was found to be more satisfactory than the previous method whereby disks were cut from thick foil and mounted on metal or perspex studs (14). In addition to minimizing edge effects, a fresh disk could be used for each run, easing the task of securing a reproducible surface for processes which may not be entirely transport controlled.

Experimental solutions were warmed to the thermostat temperature and degassed before being transferred to the reaction vessel. In the vessel, a stream of nitrogen ($O_2 < 0.05\%$) was bubbled through the solution for at least 5 min to maintain it free from atmospheric oxygen. During this period, the disk was mounted on the stirring shaft and, with the motor running, a beaker containing a solution identical with that in the reaction vessel was brought up to immerse the disk. All bubbles were removed from the under surface, and the copper was subjected to a preliminary etch for 5 min ±5 sec in an attempt to secure a reproducible surface. On removal of the beaker, the motion of the disk threw off most of the adhering liquid. The disk then was immersed in the reaction vessel, the underside of the disk was inspected to ensure that no bubbles had been trapped, and the nitrogen delivery tube was raised above the surface of the solution to maintain a slight positive pressure of nitrogen within the vessel.

Samples were withdrawn at 5-min intervals, run into excess ferrous ammonium sulfate solution, and back-titrated with standard dichromate solution. At the end of the run, the disk was removed from the solution, washed, stripped from the former, and its mean diameter measured using vernier calipers. The unit rate constant, k_1, was evaluated graphically from the first order expression (14): $k_1 t = (2.303 \Sigma V. \Delta\log c)/A$, where t is the time in min, A is the apparent area of the underside of the disk, and $\Delta\log c$ denotes the difference in the logarithm of the concentration of dichromate, c, at the beginning and end of an interval during which the volume is V.

The following were chosen as standard conditions: a disk rotating at 146 rpm in a solution 1.0M in sulfuric acid and 3.0 x 10^{-2}M in potassium dichromate, at 25°. In most cases, runs were performed at least in duplicate for each set of experimental conditions, and standard runs were conducted at frequent intervals as a check. In general, the rate constants for any set of conditions seldom differed by more than 3%, and frequently agreed to within 1%. Figure 2 exemplifies the good first order plots obtained.

The diffusion coefficient of dichromate ion under various conditions and the kinematic viscosity of

the solutions were determined by methods described elsewhere (14).

Results and Discussion

Solutions 1.0M in sulfuric acid.—When the ratio of the concentration of sulfuric acid to that of the dichromate ion is high, the rate of dissolution of copper is first order with respect to the concentration of dichromate ion. This is shown both by the linearity of the kinetic plots, examples of which are shown in Fig. 2, and by the fact that variation of the initial concentration of dichromate ion over a wide range is without significant effect upon the observed rate constant (Table I).

The extent to which the observed rate is governed by the transport of a solute species to the surface may be determined by comparing k_1, the observed unit rate constant, with k_T, the unit rate constant computed from the extended Levich theory (14). On this theory,

$$k_T = (0.554 D^{2/3} \nu^{-1/6} \omega^{1/2}) / [0.8934 + 0.316 (D/\nu)^{0.30}] \text{ cm sec}^{-1} \quad [1]$$

where D (cm^2 sec^{-1}) is the diffusion coefficient of the solute species, ν (cm^2 sec^{-1}) is the kinematic viscosity of the solution, and ω (rad. sec^{-1}) is the angular velocity of the disk.

Application of this equation to the experimental results shows that for solutions 1.0M in H_2SO_4 the observed rate is determined by the transport of dichromate to the copper surface. Thus, Fig. 3 shows the effect of varying the rate of stirring over the range 73-292 rpm for a solution 3.0 x 10^{-2}M in dichromate ion at 25°. The full line is the slope computed from Eq. [1] using the directly determined values $D_{25} = 9.07 \times 10^{-6}$ cm^2 sec^{-1} and $\nu_{25} = 1.01 \times 10^{-2}$ cm^2 sec^{-1}. Figure 4 shows the effect of varying the temperature between 15° and 45° for the same dichromate concentration, and a speed of 146 rpm. Again, the full line is the plot computed from the extended theory using the additional data $D_{45} = 1.39 \times 10^{-5}$ cm^2 sec^{-1} and $\nu_{45} = 6.83 \times 10^{-3}$ cm^2 sec^{-1}. In both cases, the theoretical slopes are slightly higher than the best straight lines through the points, but the deviation, which amounts to no more than 2%, lies within the limits of experimental error.

In confirmation of this conclusion that the surface process exerts no influence on the observed rate under these experimental conditions, supplementary experiments under the standard conditions showed that amalgamated copper disks (mean $k_1 = 0.133$ cm min^{-1}) and brass disks (mean $k_1 = 0.130$ cm min^{-1}) dissolve at the same rate as copper (mean $k_1 = 0.131$ cm min^{-1}).

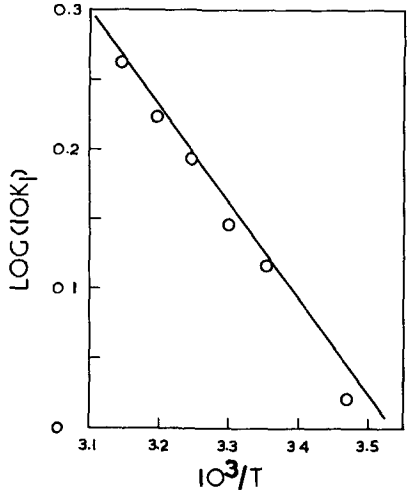

Fig. 4. Temperature coefficient, 1.0M H_2SO_4, 3.0 x 10^{-2}M $K_2Cr_2O_7$, 146 rpm.

Interesting results were obtained when the dependence of the observed rate on the method of preparation of the copper surface was studied. It has been suggested (13, 15) that roughening the surface should be without effect on the rate of transport controlled processes provided that the degree of roughening is not so large that the critical Reynolds number for the onset of turbulence is exceeded, whereas the rate of processes controlled by the surface reaction should increase. To test this suggestion, copper disks were coated cathodically with a spongy copper deposit and others were cut from a sheet of copper which had been ground with 100 grade carborundum powder. Under standard conditions, rather poor reproducibility was obtained for runs using the plated disks, probably because of the difficulty experienced in coating the upper surface and edges of the disk with black wax. The plated surface was so porous that the wax tended to be absorbed and to run over onto the lower working surface. Nevertheless, the observed rate constants ($k_1 = 0.128$, 0.132, 0.136 cm min^{-1}) are in fair agreement with the standard value. In the case of the

ground surfaces, however, the first order plots showed a high initial rate, which decreased with time and finally settled down to the standard rate.

A change from a high initial rate to a lower rate is sometimes due to a shift from transport control toward control by the surface process. In the present case, however, the lower (standard) rate is in excellent agreement with the theoretical value computed from Eq. [1], so that another explanation must be sought. It is possible that the irregularities produced on the surface by the carborundum treatment set up a small degree of local turbulence with a corresponding increase in the initial rate. Bircumshaw and Riddiford (15) reported a marked increase in the rate of dissolution of zinc in iodine solutions when jewellers rouge, used as a polishing agent, was embedded in the metal surface. Again, there was no question of control by the surface process. King (16) has reviewed other studies in which enhanced transport controlled rates have been found for roughened or etched surfaces.

In the present system, a similar effect was noted when small gas bubbles were inadvertently trapped on the underside of the disk. As in the case of bubbles trapped under zinc disks rotating in iodine solutions (14), the observed rates were higher than the standard value. Examination of the disks after withdrawal from the reaction vessel showed markings following the fluid flow lines at the surface of the disk (13) and resembling the tracks made by drops of liquid on a rotating disk (17). Microscopic examination of the marking caused by one such bubble, or surface obstruction, is shown in Fig. 5. It will be seen that a trough has been etched around the protected part of the copper surface, penetrating the 0.15 mm thick disk in one place, and along a "tail" following the flow line. The trough is very much larger than the surface obstruction and, if due to local turbulence, is certain to increase the observed rate.

The initial concentration of acid.—The effect of varying the initial concentration of acid over the range 0.01-1.53M was studied at 146 rpm and 25°

Fig. 5. Enlargement of marking caused by surface obstruction. Magnification 30X before reduction for publication.

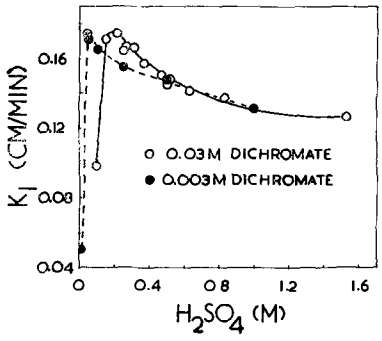

Fig. 6. Dependence on concentration of acid, 25°, 146 rpm

for both low (3×10^{-3}M) and high (3×10^{-2}M) dichromate concentrations. The mean values of k_1 are shown in Fig. 6, and it will be seen that the concentration of dichromate ion is without effect provided that the acid concentration is greater than *ca.* 0.5M.

At very low acid concentrations, there is a marked decrease in the rate. The first order kinetic plots were no longer linear, and the rate constants were estimated from the initial slopes. Acid-soluble films were formed on the disks, suggesting acid "starvation" under these conditions. From the stoichiometry of the over-all reaction, the acid, expressed as moles H_2SO_4, is consumed at a rate seven times faster than the rate at which dichromate ion is reduced. Dissolution in any solution for which the initial acid/dichromate ratio is less than 7 will be hindered eventually by a shortage of acid; on the other hand, if the initial ratio is greater than 7, this trouble will not be experienced. In the present case, an initial ratio of 7 corresponds to 0.2M H_2SO_4 for the high, and 0.02M H_2SO_4 for the low dichromate concentrations. The actual breakdowns occur in these regions (see Fig. 6). No further study of this region was made, since more interest attached to the reason for the divergence of the curves at moderate acid concentrations.

When the initial acid concentration is 0.25M, the divergence is very marked, although there can be no question of a deficiency of acid in the sense dis-

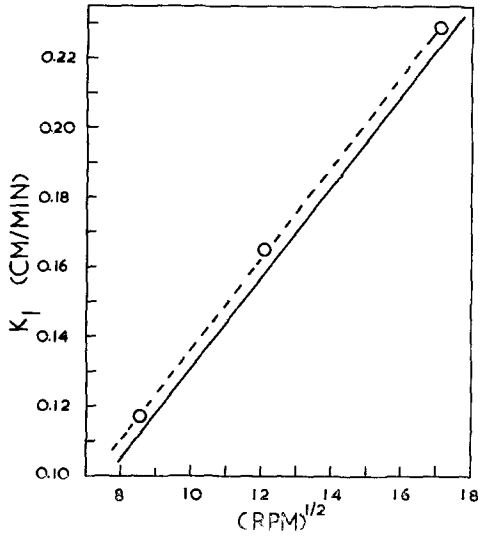

Fig. 7. Effect of stirring, 0.25M H_2SO_4, 3.0×10^{-2}M $K_2Cr_2O_7$, 25°.

cussed above. A brief study of the effect of stirring speed was made for this acid concentration using 3 x 10^{-2}M dichromate, and the results are shown in Fig. 7. The mean value of the observed rate constant is accurately proportional to the square root of the stirring speed, showing that under these conditions the process is also transport controlled. Consideration of Eq. [1] shows, however, that another factor is now influencing the rate. The determined values for the diffusion coefficient of dichromate ion at 3.0 x 10^{-2}M and 3.0 x 10^{-3}M, respectively, are identical within the limits of experimental error (D_{25} = 1.16 x 10^{-5} cm^2 sec^{-1}) for this acid concentration and lead to theoretical values for k_T at 146 rpm of, respectively, 0.158 and 0.157 cm min^{-1}. This is in good agreement with the observed value (0.155 cm min^{-1}) for the lower dichromate concentration. The observed value for the higher dichromate concentration (0.165 cm min^{-1}) is distinctly higher than the theoretical value, as indeed are the observed values at other stirring speeds. The full line in Fig. 7 indicates the theoretical slope computed from Eq. [1].

Since Eq. [1] predicts the maximum rate at which dichromate ions can be transported to the surface by the combined effect of diffusion and convection, it must be assumed that, at 3.0 x 10^{-2}M dichromate concentration, the transport process has been speeded up in some way; a shift toward control by the surface process would be marked by a decrease in the observed rate.

In general, ions may be transported to a surface in three ways, by diffusion, convection, and by migration under the influence of an electrical potential gradient (18). At high acid concentrations, when the relative concentration of dichromate ion is small, ionic migration will be negligible, and Eq. [1] will be applicable. If there is insufficient acid or foreign ions to suppress ionic migration through the electrical double layer, however, the rate of transport of dichromate ion will be increased. To check this explanation and to eliminate the effect, a series of runs were conducted using solutions to which sodium sulfate had been added.

Effect of adding sodium sulfate.—The initial concentration of sulfuric acid was varied over the range 0.1 to 1.0M. For runs in which the initial acid concentration was less than 1.0M, sodium sulfate was added to bring the total concentration of sulfate and bisulfate ions to 1.0M. In each case, the initial concentration of dichromate ion was 3.0 x 10^{-2}M, and the runs were performed at 25° and 146 rpm. The mean values of the observed rate constant are shown in Fig. 8, which may be compared with Fig. 6.

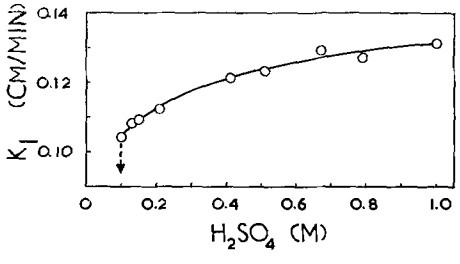

Fig. 8. Dependence of rate on concentration of acid, with added Na_2SO_4, 3.0 10^{-2}M $K_2Cr_2O_7$, 25°, 146 rpm.

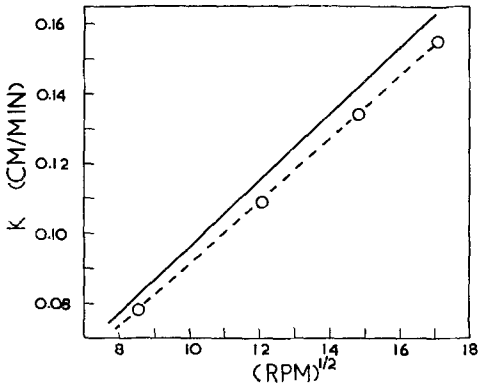

Fig. 9. Effect of stirring, 0.15 H_2SO_4, 0.85M Na_2SO_4, 3.0 x 10^{-2}M $K_2Cr_2O_7$, 25°.

The marked fall-off at very low acid concentrations is still observed, but the general trend now has altered. The observed rate constant now decreases with decreasing acid concentration due to the marked increase in the kinematic viscosity of the solution.

It is of particular interest to note that the value for a solution 0.21M in sulfuric acid and 0.79M in sodium sulfate (k_1 = 0.112 cm min^{-1}) is the same as that found for runs under the same conditions except that the initial concentration of dichromate was 3.0 x 10^{-3}M, *i.e.*, the divergence apparent in Fig. 6 has been eliminated by the added electrolyte. The observed value is, however, distinctly lower than that predicted by Eq. [1].

Since the addition of sodium sulfate increases the viscosity of the solution, the rate of the transport process is retarded, so that a shift toward surface control may be ruled out. The reason for the discrepancy between the observed and computed values may be traced to the fact that Eq. [1] is limited to the case of electrolyte solutions containing not more than three ion species.[2] In the absence of sodium sulfate, and with sufficiently high acid/dichromate ratios, it has been shown that the present system approximates closely to the theory. The presence of a large excess of sodium sulfate, however, introduces another ion species, and the theory is inapplicable.

In order to study the characteristics of this case, tests for transport control were applied to a solution 0.15M in sulfuric acid, 0.85M in sodium sulfate, and 3.0 x 10^{-2}M in dichromate.[3] The effect of varying the stirring speed at 25° is shown in Fig. 9, in which the full line is the slope computed from Eq. [1] using the determined values D_{25} = 7.71 x 10^{-6} cm^2 sec^{-1}, ν_{25} = 1.19 x 10^{-2} cm^2 sec^{-1}. It is seen to be distinctly higher than the experimental slope. The effect of varying the temperature at 146 rpm is shown in Fig. 10. From the slope, the apparent energy of activation is 3.4 kcal mole^{-1}, in good agreement with

[2] For this case, the problem of calculating the concentration profile through the transport boundary layer can be separated from the problem of determining the variation of the electrical potential through the double layer (19). When more than three ion species are present, however, this separation is not possible, and the path to a complete solution of the transport equations is barred by formidable mathematical difficulties. Nevertheless, the dependence of k_T on D, ν and ω is dimensionally of similar form to Eq. (1), but the number of proportionality must be determined by experiment (13).

[3] In the presence of added sodium sulfate, acid starvation is not detected until the acid/dichromate ratio is reduced to 7/2. The sodium sulfate decreases the rate both by increasing the viscosity of the solution and by eliminating ionic migration through the double layer. At this lower rate, for 0.15M H_2SO_4, acid exhaustion is not approached over the time intervals studied.

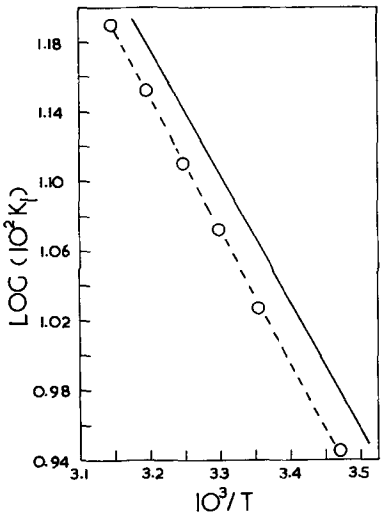

Fig. 10. Temperature coefficient, 0.15M H_2SO_4, 0.85M Na_2SO_4, 3.0 x 10^{-2}M $K_2Cr_2O_7$, 146 rpm.

the value found from Fig. 4. Again, the full line is the plot computed from Eq. [1] using the additional values $D_{45} = 1.20 \times 10^{-5}$ cm^2 sec^{-1}, $\nu_{45} = 7.96 \times 10^{-3}$ cm^2 sec^{-1}.

Figures 9 and 10 suggest that, for these conditions

$$k_T = \text{const. } D^{2/3} \nu^{-1/6} \omega^{1/2} \text{ cm sec}^{-1} \qquad [2]$$

where the constant is less than the value given by Eq. [1]. On dimensional grounds, the only effect of increasing the number of ion species beyond three should be a change in the number of proportionality. In this case, the mean value for the constant in Eq. [2] is found to be 0.562, *ca.* 7% lower than the value 0.605 predicted by Eq. [1].

That the process is indeed transport controlled under these conditions was checked by studying the effect of deliberately roughening the surface. For solutions 3.0 x 10^{-2}M in dichromate at 146 rpm and 25°, grinding the surface with carborundum gave a mean value for k_1 of 0.105 cm min^{-1} compared with the value 0.109 cm min^{-1} obtained with the standard surface. It is of interest to note that these runs with roughened surfaces gave linear first order plots without the initially high rates found in the absence of added sodium sulfate. Presumably, the high viscosity of the sodium sulfate solutions diminishes the local turbulence.

Edge effects.—For the dissolution of zinc disks rotating in aqueous iodine solutions (14), the observed rate constants at low stirring speeds were found to be higher than those predicted by Eq. [1]. It was pointed out that this could be explained equally well either by the assumption that the thickness of the disks gave rise to edge effects, or by assuming a contribution to the observed rate by natural convection.

In the present investigation, this effect is not observed, as will be seen from Fig. 3, 7, and 9, k_1 being accurately proportional to the square root of the stirring speed over the same range as that studied with the zinc disks. The very much thinner disks used in this investigation make it fairly certain that the earlier observations were in fact due to edge effects. Experiments with rotating disk cathodes have confirmed this view.

Blocking off the working surface.—It has been reported that the use of inert Perspex center studs is without effect on the observed rate of dissolution of zinc disks rotating in iodine solutions, although the exposed area of the stud amounted to *ca.* 4% of the working surface of the disk (14). Since the copper/dichromate reaction has been shown to be transport controlled under standard conditions, a similar effect should be found for this system. Progressive enlargement of an inert patch at the center should be without effect on the observed rate up to a certain point. Beyond this point, the exposed copper will be unable to cope with all the dichromate supplied by normal and radial transport, and this will result in a decrease in the observed rate. This decrease will become more marked as the blocked area is increased.

In general, the temperature coefficient of a surface process is larger than the temperature coefficient of the transport process (20). The effect of increasing the temperature will be a relative increase in the rate at which the exposed copper can cope with the dichromate supplied, and the breakdown point should then occur at a larger value of the blocked area.

To test these views, black wax was used to block off circular patches at the center of the copper disks, care being taken to ensure that the blocked off circles were concentric with the disks. Runs were carried out at 25° and 45° under otherwise standard conditions, and the mean values for k_1, computed per unit area of the *total* surface of the underside of the disk, are shown in Fig. 11. It will be seen that at 25° there is no significant effect on k_1 until the area blocked off exceeds *ca.* 10% of the total area; above this value there is a marked decrease. At 45°, the breakdown occurs at a higher value, *ca.* 15%.

Further study of this effect is desirable, but it would be better to use an inert electrode for the purpose since, when the disk is attacked, a step is formed at the edge of the blocked area which may promote a measure of local turbulence.

Microtopography of Oxide Films Formed on Tantalum

R. E. Pawel, J. V. Cathcart, and J. J. Campbell

Metallurgy Division, Oak Ridge National Laboratory,[1] Oak Ridge, Tennessee

ABSTRACT

Optical and electron microscopy were used to characterize the surface of tantalum specimens oxidized at temperatures ranging from 300° to 700°C. At the lower temperatures, the initial stages of oxidation were shown to consist of an aggregation of oxide platelets visible on the surface as crystallographically dependent, acicular structures extending from the grain boundaries. At higher temperatures, nodular growths were observed whose nucleation was not a grain-boundary phenomenon. Continued oxidation at temperatures of 500°C and above produced blistering and cracking of the oxide layer. The oxide platelets were shown to have grown during oxidation and not during cooling from the reaction temperature. At higher temperatures, both platelets and nodules served as preferred sites for blister and crack formation in the oxide and thus played an important role in the transition from the protective to the nonprotective stage of oxidation of tantalum.

Previous work (1, 2) has shown that the gaseous oxidation of tantalum takes place in a nonuniform fashion, characterized at least in the initial stages by the formation in the metal of discrete platelets of oxide resembling a typical Widmanstätten structure. The tendency for tantalum to react in such a heterogeneous manner illustrates the need for consideration of oxide morphology in any interpretation of the oxidation mechanism.

Oxidation rate measurements of Cathcart, *et al.* (1) have shown that the oxide film formed on tantalum in pure oxygen at atmospheric pressure is initially protective but becomes nonprotective as the oxidation proceeds beyond a critical point. The rate of oxidation finally approaches a constant value for longer oxidation periods. This general rate behavior is identical to that observed for niobium (3). Electron optical observations on oxidized specimens of both metals show that the onset of the nonprotective portion of the rate curves may be correlated to the formation of small blister-like cracks on the surface of the oxide. Presumably, these cracks permit easy access of oxygen to the reaction zone, resulting in the marked increase in oxidation rate.

While remarkable similarities exist in the oxidation rate curves for niobium and tantalum and in the physical and chemical properties of the two metals and their oxides, there are significant differences in the morphology of the oxide films formed on these metals, especially in the early stages of oxidation. The oxidation of niobium in the protective region is characterized by the formation of a reasonably uniform oxide film and the development of a normal sequence of interference colors as the oxide thickens. However, the initial stages of tantalum oxidation show the aforementioned platelet struc-

[1] Operated for the U. S. Atomic Energy Commission by the Union Carbide Corporation.

ture, and well-defined interference colors are not observed. It is of interest to observe that other gas-tantalum reactions, notably those with sulfur (4) and nitrogen (5), also produce a platelet structure.

In the present investigation, an effort has been made to characterize the morphology of the early stages of tantalum oxidation.

Specimen Preparation

Tantalum specimens (nominal analysis: 99.71% Ta-0.15% Nb-0.03% Fe-0.03% C-0.05% W) were cut from 0.5 mm sheet in the form of coupons, 1 x 2 cm. In most of the work reported here, the specimens were preannealed in vacuum for 1 hr at 1200°C; some specimens were strain annealed for longer periods at 1200° and 1300°C to produce a larger grain size. The specimens were mechanically polished through 0.3-μ levigated alumina and finally electropolished in a 90% H_2SO_4-10% HF solution. The specimens were then placed in quartz reaction tubes and annealed at a pressure of approximately 2×10^{-6} mm Hg at the reaction temperature for approximately 16 hr prior to oxidation. This method of specimen preparation yielded surfaces which appeared smooth in the light microscope, and which, upon oxidation, gave consistently reproducible results. Except as noted, all oxidations were performed in dry oxygen at atmospheric pressure.

The surface topography of the oxidized tantalum specimens was examined by both optical and electron microscopy. Both direct and indirect carbon replicas were used for electron microscopy, the indirect method (preshadowed carbon replica of a stripped parlodion intermediate) being used exclusively with the heavier oxide films. Each method yielded essentially identical results on a given specimen.

Mode of Platelet Formation

The resemblance of the platelet structure to the patterns observed in many precipitation systems suggested the possibility that the platelets were formed during cooling from the reaction temperature rather than during oxidation. This possibility was investigated using "hot" direct replication and hot-stage optical microscopy.

In a hot replication experiment, the specimen was oxidized in air at 400°C on a small hot plate in the vacuum evaporator. After oxidation, the system was evacuated and, with the specimen still at 400°C, a direct carbon replica, preshadowed rather heavily with gold or palladium, was made of the surface. After cooling, this replica was removed and the specimen re-replicated in the normal fashion. Electron micrography showed that essentially the same structure existed before and after cooling from the reaction temperature. The presence of shadows in the hot replica was regarded as conclusive evidence that the platelets were present at the reaction temperature.

The results of the hot-stage microscope studies served to confirm that the platelets formed during oxidation. Although the magnification and resolution of the microscope were not sufficient to permit observation of fine details, the general progress of the air oxidation at 400°C could be followed. First, a gradual darkening of several grains in the specimen was seen as platelets became visible in other lighter grains. Many platelets were observed to grow after nucleation at grain boundaries. As oxidation continued, the platelets frequently developed small feather-like subplatelets. No detectable changes in topography occurred as the specimens were cooled to room temperature in vacuum.

It should be indicated that the specimens used in this phase of the study were all oxidized in air and that the temperature control was poorer than with the standard apparatus; however, the morphology of these specimens compared favorably with that of the more carefully oxidized samples.

Oxide Morphology

The first stages of tantalum oxidation were studied over the temperature range 300°-700°C. Particular attention was paid to the initial growth behavior and its possible influence on the onset of blistering or rupturing of the oxide film. It has been suggested that the large oxide-metal volume ratios and the predominance of anion diffusion in the oxides lead to the generation of significant stresses in the oxide films formed on niobium and tantalum (1, 3). The phenomenon of highly localized crack formation in the oxide films can then be interpreted as resulting from the severe, localized deformation of the existing oxide by the forces exerted when fresh oxide is formed in a partially restricted region such as a cavity at the oxide-metal interface. The geometry associated with an oxide platelet is such that it is reasonable to expect that directional stresses would develop at such a site and lead ultimately to the formation of a crack or a blister in the oxide film. Thus, the manner in which platelet growth occurs may influence the oxidation kinetics markedly.

Only the very initial stages of oxide formation occurred on specimens oxidized at 300°C for times varying up to 95 hr. In the electron microscope, the oxide appeared as fine needles originating in the grain boundaries and extending into the grains along definite crystallographic directions as shown in Fig.

Fig. 1. Typical grain-boundary platelet growth on tantalum oxidized at low temperature. Note "bubble raft" background texture. Annealed 1 hr at 1200°C; oxidized 95 hr at 300°C; indirect replica. REF: J. V. Cathcart, R. Bakish, and D. R. Norton, This Journal, in press. Magnification 16,800X before reduction for publication.

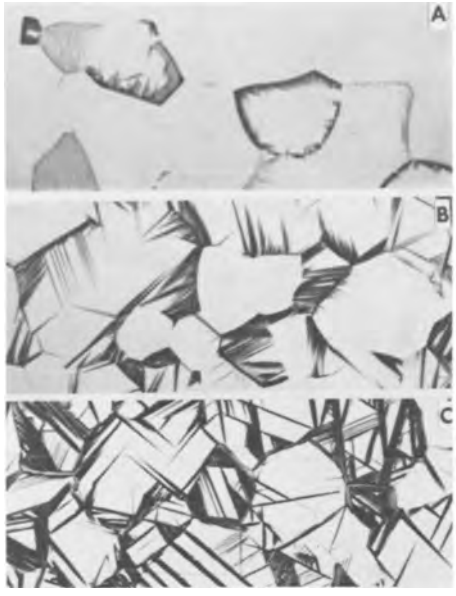

Fig. 2. Early stages of oxidation on coarse grain size tantalum at 500°C. Annealed 16 hr at 1200°C; oxidized (a) 15 min, (b) 30 min, and (c) 1 hr at 500°C. Magnification 500X before reduction for publication.

1. The "bubble-raft" structure discernible in Fig. 1 was found to be present on electropolished surfaces prior to oxidation and occurred as a result of electropolishing. Use of this fine-structure as a marker has been reported by one of us (1). At 400° and 500°C, the growth process was similar although the rate of oxidation was much greater. Prolonged oxidation at 500°C resulted in the formation of blister-like cracks in the oxide. Optical micrographs of tantalum specimens after oxidation at 500°C in the pre-blister range are shown in Fig. 2. The importance of grain-boundary nucleation in the oxidation process and the course of the subsequent growth of the platelets are illustrated.

Glancing-angle x-ray diffraction patterns obtained from specimens oxidized for times up to 8 hr at 500°C indicated that Ta_2O_5 was the major oxide formed under these conditions. After 15 min of oxidation, only a few extremely faint lines, other than the metal lines, were observed. After 1 hr of oxidation, corresponding to the time required to develop the platelet structure shown in Fig. 2c, the pentoxide lines were quite evident. The intensity of these lines increased during growth of the platelets. Very weak lines in the diffraction pattern could not be attributed with certainty to any known lower oxide of tantalum.

Fig. 4. Cross section of oxidized tantalum specimen showing growth of platelets into the metal. Annealed 1 hr at 1200°C; oxidized 6 hr at 500°C; indirect replica. Magnification 6900X before reduction for publication.

As oxidation continued at 500°C, randomly distributed blisters and cracks appeared on the surface, as shown in Fig. 3. Although the platelet structure in this micrograph is rather obscure, the size, shape, and position of the blisters do not seem to coincide with the traces of the platelets on the surface of the specimen. An electron micrograph of a cross section of a tantalum specimen oxidized at 500°C is presented in Fig. 4. The edge of the specimen is distorted; however, the platelets are seen to have grown into the metal to an appreciable depth. The largest platelets extend approximately 5 μ into the metal.

At 600°C a change in the basic oxide morphology was observed. On some grains, nodular oxide growths were interspersed with platelets. In some instances, the nodular growths showed crystallographic character and even the tendency to develop in the manner of a platelet. These characteristics are

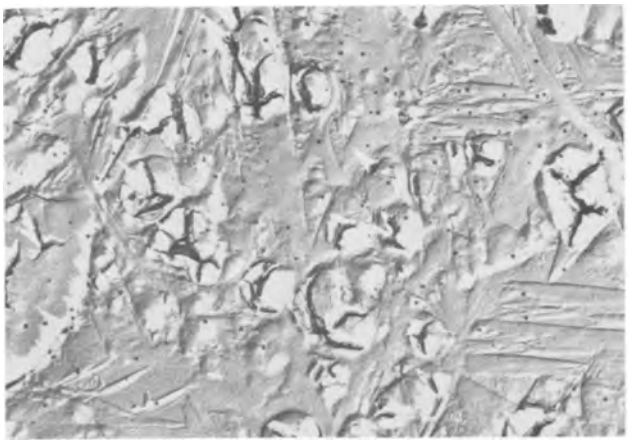

Fig. 3. Blister-like cracks observed on oxidized tantalum surface after prolonged oxidation. Annealed 1 hr at 1200°C; oxidized 7 hr at 500°C; indirect replica. Magnification 9600X before reduction for publication.

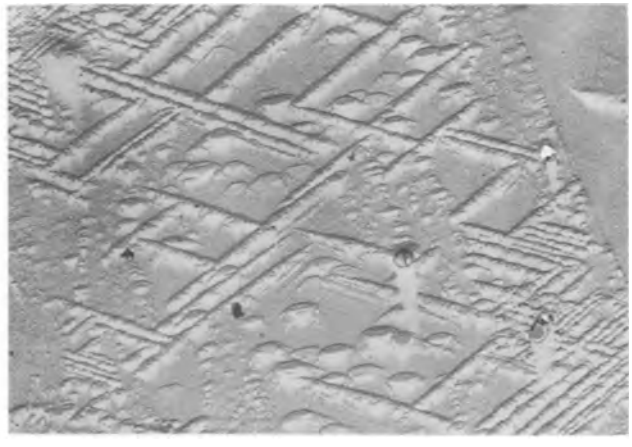

Fig. 5. Platelets and nodules formed on single grain on oxidation at 600°C. Annealed 1 hr at 1200°C; oxidized 1 min at 600°C; direct replica. Magnification 6900X before reduction for publication.

Fig. 6. Blister-like cracks appearing in grain after prolonged oxidation at 600°C. Annealed 1 hr at 1200°C; oxidized 15 min at 600°C; indirect replica. Magnification 6900X before reduction for publication.

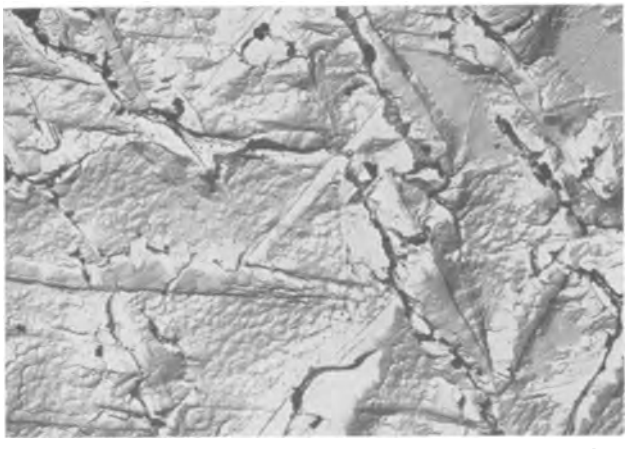

Fig. 7. Elongated cracks appearing along platelets after prolonged oxidation at 600°C. Annealed 1 hr at 1200°C; oxidized 15 min at 600°C; indirect replica. Magnification 6900X before reduction for publication.

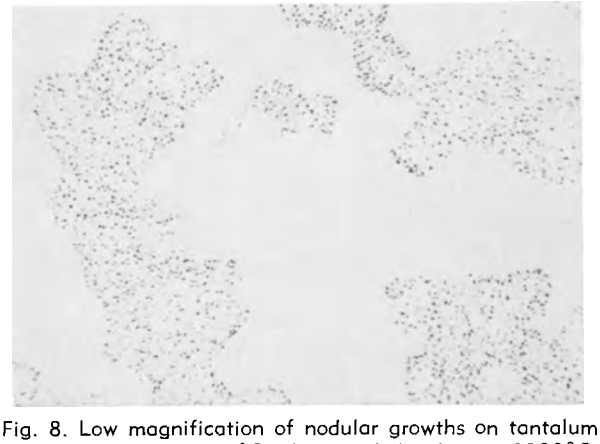

Fig. 8. Low magnification of nodular growths on tantalum surface oxidized at 700°C. Annealed 16 hr at 1200°C; oxidized 6-10 sec at 700°C. Magnification 500X before reduction for publication.

illustrated in Fig. 5. On the basis of longer (15 min) oxidation experiments at 600°C, nodular growths were found to be preferred sites for blister formation. Certain grains, originally exhibiting dense nodular formations, became blistered and oxidized much more heavily than adjacent grains where the oxide was present predominantly in platelet-type structures. Moreover, at this temperature, there appeared to be a more definite relation between the platelet growths and crack formation. In former platelet areas of these specimens, the fissures were elongated and closely followed the traces of the platelets. Even during earlier stages of oxidation at this temperature, blisters tended to form at intersections of platelets. Figures 6 and 7 are examples of crack formation in the two types of areas. Figure 6 also illustrates the extreme difference in oxidation behavior from grain to grain which was observed in these specimens.

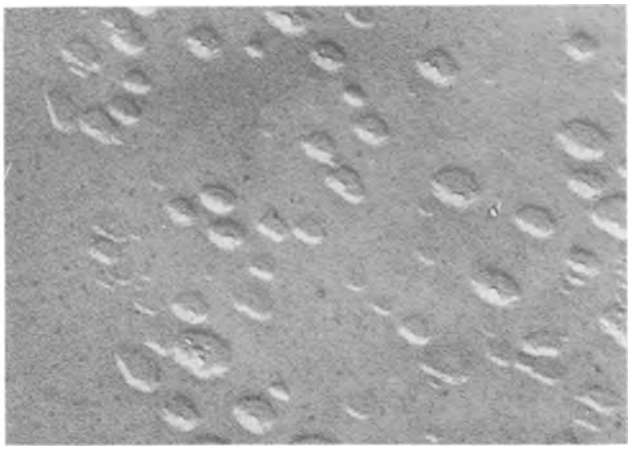

Fig. 9. Nodular growths on tantalum surface oxidized at 700°C. Annealed 16 hr at 1200°C; oxidized 6-10 sec at 700°C; indirect replica. Magnification 9600X before reduction for publication.

At 700°C the nodular growth was even more pronounced, and the first stages of oxidation consisted almost entirely of nodular-type attack. Figures 8 and 9 are typical optical and electron micrographs of these features.

Conclusions

The results of this investigation serve to illustrate the complex behavior of the initial stages of gaseous oxidation on tantalum surfaces. While the mechanism for platelet formation is not yet known, the fact that they contribute importantly to the oxidation process, at least at higher temperatures, has been demonstrated. On the basis of the results obtained, the following conclusions appear justified:

1. Oxide platelet formation on tantalum occurred at the temperature of oxidation and involved a highly directional growth process. At any one time during oxidation a wide spectrum of platelet sizes existed. X-ray data indicated Ta_2O_5 as the predominant oxide.

2. At lower temperature, the nucleation of platelets occurred primarily at grain boundaries, but at 600°C and higher, nodular growths were observed whose nucleation did not involve a grain-boundary process.

3. At lower temperatures, no direct correlation was observed between the platelet structures and blister formation in the oxide. At higher temperatures, both nodules and platelets served as preferred sites for blisters and elongated cracks.

4. Tantalum, especially at the higher temperatures, exhibited a pronounced dependence of first-stage oxidation rate on crystallographic orientation.

The Difference Effect and the Chunk Effect

G. A. Marsh and E. Schaschl

Research Center, The Pure Oil Company, Crystal Lake, Illinois

ABSTRACT

The negative difference effect in the case of steel can be explained in terms of corrosion by removal of blocks or "chunks" of metal containing perhaps only a few atoms. The "chunk effect" also explains the observed fact that, under conditions of high corrosion rate, minimum protective current can be much less than the calculated corrosion current. It is suggested that the chunk effect and anodic polarization occur on the same piece of metal. Either the positive or the negative difference effect may be observed depending on the corrodent.

Positive Difference Effect

The positive difference effect has been considered one of the supporting pillars of the electrochemical theory of aqueous corrosion. This effect was first recognized and named by Thiel and Eckell (1), who worked with aluminum dissolving in sodium hydroxide solution.

Thiel and Eckell reasoned that, when a metal is made an anode in an electrolytic cell, its rate of corrosion should be the sum of (*a*) local action as observed in the absence of external current, and (*b*) the corrosion rate equivalent to the applied current (utilizing the electrochemical equivalent of the metal in question). In actual tests with aluminum, however, they found the observed corrosion rate to be *less* than the sum of the components (*a*) and (*b*). To state their observation quantitatively, let I_o equal the freely corroding rate,[1] I_u equal the observed corrosion rate occurring on application of I_x, and I_x equal the externally applied current.

From Faraday's law I_x, when positive (anodic), results in an equivalent corrosion rate. To rephrase Thiel and Eckell's discovery, they expected to find

$$I_o + I_x - I_u = 0 \qquad [1]$$

Actually, they found

$$I_o + I_x - I_u = \Delta \qquad [2]$$

Δ was a positive number which they called the "difference effect." (Later they found that Δ could be negative in some cases; this discovery led to the use of the terms "positive" and "negative" difference effect.) Furthermore, Δ was linear over a certain range of I_x, so

$$\Delta = KI_x \qquad [3]$$

Since I_u and I_x are expressed as current densities, Eq. [2] and [3] can be combined:

$$I_u = I_o + I_x (1 - K) \qquad [4]$$

K is a slope; if it has a value of +1, the applied current will have no effect on measured corrosion rate. Where the positive difference effect has been observed, K lies between 0 and 1.

For small values of I_x, linearity of the curve I_u *vs.* I_x is often obtained, permitting one to obtain K from easily measured quantities:

$$K = \frac{I_o - I_{u1}}{I_{x1}} + 1 \qquad [5]$$

where the subscript 1 applies to one particular value of applied current.

The constant K was believed by Müller (2) to have fundamental significance regarding the mechanism of the anodic process. As K is independent of applied current, it must depend only on the system of metal/solution being studied.

Straumanis (3, 4) has explained the positive difference effect in terms of anodic polarization. According to his view, the positive difference effect is pronounced if there is interference with the delivery of electrons to the local cathode, or if there is interference with dissipation of ions into the corrosive agent. We believe that the latter effect is the more likely one. So with increasing anodic current, whether originating in local cells or externally applied, there is increasing anodic polarization which

[1] Corrosion rates in this paper are stated in terms of the equivalent current densities. Applied currents are also stated as current densities.

decreases the driving force for local action and gives rise to the observed positive difference effect.

The positive difference effect is *observed* only upon application of anodic current, but the phenomenon responsible for it takes place at zero applied current as well as at applied anodic currents. That anodic polarization occurs in freely corroding metals (*e.g.*, steel) is apparent from the fact that the current required for cathodic protection of a specimen showing the positive difference effect is greater than the corrosion current of the freely corroding metal. If there were no anodic polarization, the protective current would necessarily equal the corrosion current.

Negative Difference Effect

Müller (2) and Kroenig and Uspenskaja (5) found that the difference effect was negative for some metal-corrodent combinations. They and others (4, 6, 7) explained this as the result of disruption of a surface film. According to this theory, application of positive current to a specimen gradually breaks down its shielding film, thus exposing more metallic surface to attack by the corrodent and thus increasing local action. In some cases these investigators observed flaking of films in systems in which the negative difference effect was found.

Relationship between Cathodic Protection and Positive and Negative Difference Effects

In local action, assuming the local anodes do not polarize, the anodic current (*i.e.*, I_o) is equal to the current of the local cathodes. External cathodic current can be substituted for the local cathodic current. The current I_p required for cathodic protection is then identical to I_o. Thus I_p is a measure of the actual electronic current given up in the anodic process.

Anodic polarization, always present to some extent, requires I_p to be greater than I_o. Actual I_p/I_o ratios for numerous cases reported in the literature average about 1.2, indicating that for common cases such as soil corrosion there is almost but not quite complete cathodic control. Since I_p/I_o ratios above unity indicate some degree of anodic polarization, if one applied anodic current to a specimen which displayed an I_p/I_o ratio of 1.2 one should expect the positive difference effect to be evident.

For many cases the I_p/I_o ratio turns out to be far *less* than unity (8). These cases are found (for steel) in highly corrosive solutions, *viz.*, low *p*H or high dissolved oxygen concentration with a high degree of agitation. Under these same conditions of *p*H and dissolved oxygen, the negative difference effect is observed upon application of anodic current.

The low I_p/I_o ratio is not explained readily by the film-breakdown theory of the negative difference effect. The negative difference effect by definition drops to zero as applied anodic current becomes zero; Δ is not defined for negative values of I_a.

To explain the facts observed upon application of negative current, *i.e.*, cathodic protection, it is not enough for the potential of cathodic areas to be changed (in proportion to the current) to the open-circuit potential of the anodes. If such a proportional change occurred, I_p/I_o would remain at or slightly greater than unity. In order for the I_p/I_o data to be explained in terms of films, the potential of cathodic areas must change much faster than the applied current. The area or the efficiency of the cathodes must be affected by negative current. Or, alternatively, the application of negative current must result in the growth of a film over the anodic areas. But the system is under essentially cathodic control; variations in anodic area should have little effect on the cathodic reaction. Also, application of negative current would not be expected to stabilize an anodic film on steel. Indeed, the negative current should cause the reduction of films such as oxides that we normally associate with steel.

Under violently corrosive conditions where films are least likely to be present the negative difference effect is very pronounced. Under conditions of partial aeration, low velocity, neutral *p*H, where such films should be more stable on steel, the negative difference effect is *less* pronounced; under static conditions most favorable to film stability (*e.g.*, soil corrosion), the negative difference effect is absent altogether. Thus, the facts do not support the film breakdown theory of the negative difference effect in the case of steel. (This in no way suggests that the film breakdown theory may be invalid for other metals.)

Dissolution by "Chunks"

External current just sufficient for cathodic protection merely takes the place of local cathodic current, which in turn is essentially equal to the local anodic current. A low I_p/I_o ratio indicates that much more metal is being dissolved under freely corroding conditions than can be accounted for by local anodic current. To explain the low I_p/I_o ratio found when steel corrodes at high rates, the authors suggested that corrosion of steel under these conditions might proceed with the removal of "chunks" of iron containing several atoms (8). Dissolution by chunks would also explain the negative difference effect.

Relatively little work has been done on the difference effect in steel. So far particles of free iron have not been observed, perhaps because they are of only atomic dimensions. But dissolution by chunks has been observed in other metals.

Straumanis (9) points out that Al displays the negative difference effect when dissolving anodically in KCl-HCl solution. He writes: "The self-dissolution of the Al . . . increases with [application of anodic current]. After interruption of the current, H_2 evolution decreases and a cloud of white dust appears . . . . Very small hydrogen-evolving particles can be seen floating in the electrolyte, which evidently were separated from the Al together with the scale." Straumanis does not say what the particles might be, but we believe they are most likely tiny fragments of aluminum released from the parent metal by undermining.

Roald and Streicher (10) actually found "blocks" of aluminum of the order of 0.005 mm in length when certain Al alloys were dissolved in HCl. Similarly, Hoey and Cohen (11) and Higgins (12) found free Mg metal particles in the corrosion products

when Mg was dissolved anodically in NaCl solutions. Hoey and Cohen suggested that "local corrosion and/or undermining of metallic magnesium at the anode are appreciable and may, in fact, account for the observed low anodic current efficiencies of magnesium." Vermilyea (13) dissolved silver anodically and found "anode slime" composed of minute particles of metallic silver. If corrosion rate and applied current data had been taken by these workers, they would necessarily have observed the negative difference effect.

Generalized picture of corrosion rate as a function of applied current.—It has been mentioned above that the film disruption theory is inadequate to explain the low I_p/I_o ratio encountered with steel in high corrosion rate conditions, and that dissolution by chunks explains not only this but also the negative difference effect. If corrosion occurs by chunks in anodic dissolution, would it not occur in the same manner during free corrosion? To explain the low I_p/I_o effect one must assume that it does. Then

$$I_u = I_x + I_a + I_b \qquad [6]$$

where the applied current I_x results in corrosion in strict accordance with the Faraday equivalent, the rate I_a is the true local action rate, and the rate I_b is due to corrosion by chunks, *i.e.*, the "chunk effect" rate. If I_x is zero, $I_u = I_o$; the observed corrosion rate equals the freely corroding rate. Under this condition

$$I_o = I_{oa} + I_{ob} \qquad [7]$$

In this case I_{oa} and I_{ob} are the particular local action and chunk effect rates occurring together which are measured as the freely corroding rate.

For corrosion under cathodic control, the protective current

$$I_p = I_{oa} \qquad [8]$$

because the current consumption of the local cathodes is completely satisfied by the external current, so that no local action is possible. Since I_u is zero when current I_p is applied, (by definition of I_p) it follows from Eq. [7] that I_b must be zero also when I_p is applied. Therefore the chunk effect varies with applied current. The variation is believed to be more or less linear with applied current, inasmuch as I_u *vs.* I_x curves for steel are essentially linear.

Figure 1 depicts theoretical relationships between the observed corrosion rate and applied current for several types of conditions. The 45° line DBM represents the theoretical Faraday equivalence for corrosion under cathodic control. The line AB represents cathodic protection of a common corrosion system under partial anodic control (the ratio of currents AJ/DJ for steel in typical soils appears to be about 1.2). Since anodic polarization is involved, line BL (representing the extension of line AB) depicts the metal corroding with a positive difference effect, namely, the distance ML. The freely corroding rate in each case is I_o.

The line EB represents cathodic protection in cases where the ratio I_p/I_o is much less than unity. (As analyzed above, partial anodic control explains why I_p/I_o can be greater than unity, while the chunk effect explains why this ratio can be less than unity.) Ideally, I_p equals the true local action I_{oa}. The corrosion rate I_{ob} due to chunk effect is

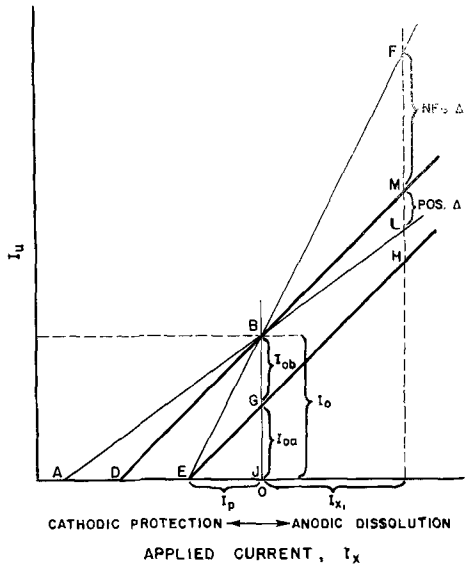

Fig. 1. Generalized corrosion rate—applied current relationships. Point B is the freely corroding rate in each case. Points E, D, and A are minimum protective currents. Points F, M, and L are observed corrosion rates with a given anodic current I_{x1}. The particular curve followed is dependent on the corrodent and the metal.

$$I_{ob} = I_o - I_p \qquad [9]$$

From Eq. [9] the chunk effect rate can be computed from the freely corroding rate and the minimum protective current. However, the freely corroding rate is merely one arbitrary point on the corrosion rate *vs.* applied current curve. If this curve is extended, (EBF on Fig. 1), a region is entered where the measured corrosion rate is greater than the Faraday equivalent rate. The true local action on application of anodic current is represented by point H; the observed corrosion rate is represented by point F. The distance FM is, by Thiel and Eckell's definition, the negative difference effect. The part of the corrosion rate occurring by chunk effect is represented by the distance FH.

Figure 1 illustrates that the chunk effect may be a fundamental property of a corroding system, while the negative difference effect is one of several possible manifestations of this property. If the chunk effect occurs, it does so even at zero applied current; that is, it occurs while the metal is freely corroding. The negative difference effect on the other hand by definition is nonexistent at zero applied current.

In Fig. 1 the curve EBF, corrosion rate *vs.* applied current, is represented as a straight line. It is recognized that none of the curves other than the Faraday equivalent is necessarily an exact straight line over the whole range of I_x. In the case of steel, however, I_u appears to be quite linear both with negative and positive values of I_x, at least up to I_x values equal to I_o. If corrosion rate varies linearly with applied current, the part of the freely corroding rate that is due to local action, I_{oa}, can be readily obtained:

$$I_{oa} = \frac{I_o I_{x1}}{I_{u1} - I_o} \qquad [10]$$

where I_{u1} is the observed corrosion rate when a current I_{x1} is applied to the corroding specimen. I_{oa} is also numerically equal to the current I_p required for cathodic protection.

This leads to a calculation of chunk effect ratio, C, which is the fraction of the freely corroding rate that is due to chunk effect:

$$C = \frac{I_{oh}}{I_o} = 1 - \frac{I_{x1}}{I_{u1} - I_o} \qquad [11]$$

The chunk effect ratio can also be computed by combining Eq. [9] and [11]:

$$C = \frac{I_o - I_p}{I_o} \qquad [12]$$

The difference effect can be determined experimentally as:

$$I_o + I_{x1} - I_{u1} = \Delta \qquad [13]$$

and since I_{u1} is larger than the sum of $I_{x1} + I_o$, the difference effect Δ is negative. From the Thiel and Eckell slope K (Eq. [5]) it is seen that K and the chunk effect ratio C are related:

$$C = \frac{-K I_{x1}}{I_{u1} - I_o} \qquad [14]$$

Up to this point the cases of corrosion with anodic polarization (positive difference effect) and corrosion with chunk effect have been considered as occurring separately. In a general case anodic polarization and the chunk effect occur simultaneously on the same piece of metal. If the decrease in local action rate exactly equals the rate at which the chunks are leaving the metal, there will be no measurable departure from the Faraday equivalence (line DBM of Fig. 1). Ordinarily, the two effects would not be equal: either the positive difference effect or the chunk effect is predominant and is observed depending on the nature of the corrodent.

Experimental

Demonstration of the negative difference effect in the case of steel.—The negative difference effect was observed as an incidental effect in experiments with dissolved oxygen concentration cells. From the standpoint of studying concentration cells the mode of generation of cell current is important; but here we are concerned with cell current merely as an externally applied current, I_x. This applied current could just as well have been obtained by using an external cathode and current source. A suitable apparatus is shown schematically in Fig. 2. The solutions used contained NaCl at various concentrations, with known dissolved oxygen concentrations between 0 and 6.5 ppm. The pH of the solutions was adjusted with NaOH or HCl at frequent intervals. The electrodes were electrical resistance probes (14) of SAE 1010 mild steel, unannealed. They were etched prior to use by immersion for 10 sec in 6*N* HCl containing 1% ferric chloride. Following this, the probes were washed in water and acetone, dried, and stored temporarily in a desiccator until used.

In such a dissolved oxygen concentration cell, the cell current depends mainly on the degree of aeration and agitation in each zone. By suitable choice of conditions the current density on the anode could be made as high as 170 μa/cm^2 (160 ma/ft^2). To compute the difference effect in such experiments one had only to obtain the freely corroding rate I_o of the unconnected probe in the anodic compartment of the cell, add the cell current I_x, and subtract the corrosion rate I_u of the anodic connected probe. Corrosion rates were obtained with the probes *in situ* by means of a corrosion meter (14). The difference effect using this method is measurable in terms of loss of metal rather than in terms of the generation of hydrogen as in most previous experiments.

As a further refinement, one could interrupt the cell current at any point and apply cathodic protection in small increments while continuously measuring the corrosion rate, thereby obtaining the minimum current needed for cathodic protection. Using steel probes initially 25 μ thick (0.001 in.) one could measure thickness changes of the order of 0.05 μ (0.2 μ in.) by means of the changes in electrical resistance.

The results with neutral solutions show a trend in the direction of negative difference effect, the effect becoming quite pronounced at low pH (Fig. 3). It is significant that some of the runs of Fig. 3

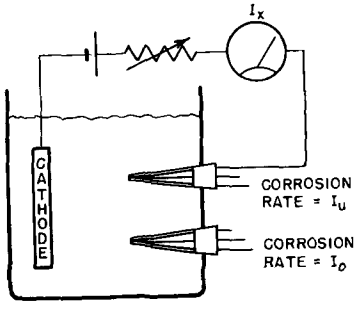

Fig. 2. Apparatus for studying corrosion rate—applied current relationships. Electrical resistance corrosion probes were used to determine the corrosion rates. The polarity of the battery could be reversed to permit study of cathodic protection.

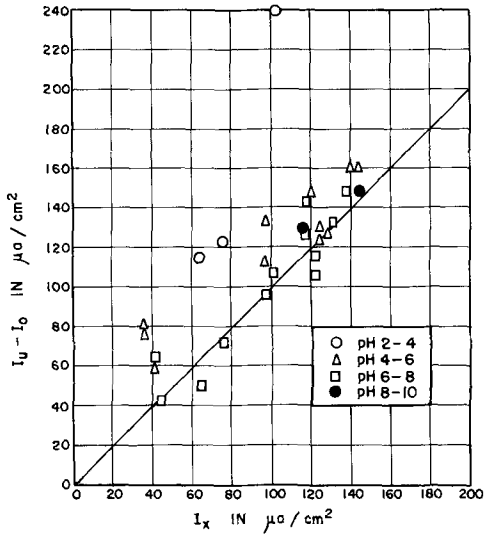

Fig. 3. Effect of pH on difference effect of steel, various NaCl solutions. Each point represents a separate run. By Thiel and Eckell's definition, points lying above the 45° line of equivalence indicate a negative difference effect; points lying below the line indicate a positive difference effect.

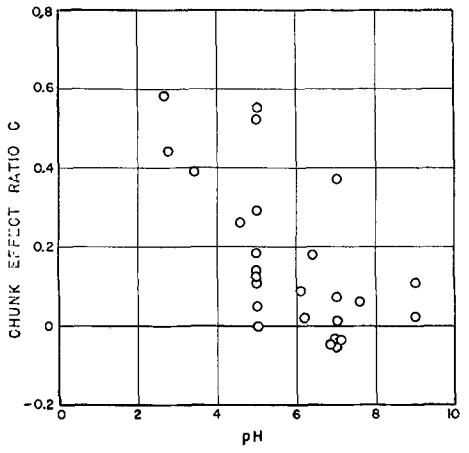

Fig. 4. Variotion of chunk effect with pH. Dato used in plotting Fig. 3 were replotted in terms of chunk effect rotio C calculated from Eq. [11]. Note the pronounced increase in C at low pH.

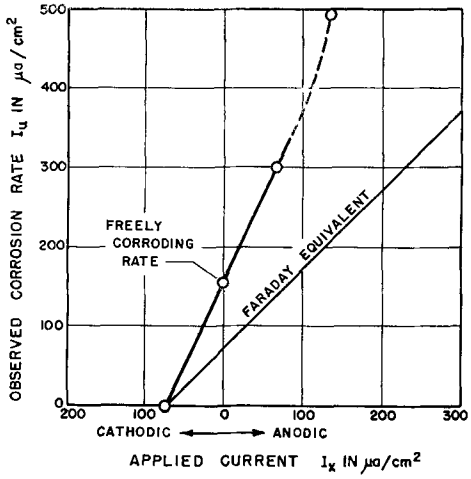

Fig. 5. Chunk effect of steel dissolving in dilute HCl, pH 2. Based on the Faraday equivalent of the cathodic protection current, about half the freely corroding rate is attributable to corrosion by more than one atom at a time.

were made in oxygen-free solutions. Thus while oxygen appears to be necessary in order to obtain the negative difference effect in, say, magnesium (5), there is no such restriction in the case of steel.

In Fig. 4, the data of Fig. 3 were replotted in terms of the fraction of the freely corroding rate due to chunk effect (C) as a function of pH. It is seen that at low pH values C may be greater than 0.5, indicating that over half of the corrosion rate is attributable to the chunk effect mechanism. This result is in general agreement with I_p/I_o data tabulated in ref. (8).

In Figs. 3 and 4 each point represents a single run with a cell of certain composition; I_x is the cell current, and $I_u - I_o$ is the difference in two measured corrosion rates. At low values of I_x, the quantities I_u and I_o are not very different, so that scatter of the data is inevitable. With a given set of conditions the cell currents were reproducible within a few microamperes; the corrosion rates in the low range were reproducible within about 2 $\mu a/cm^2$.

To illustrate the improvement in the quality of data when a single specimen was used to obtain several I_u *vs.* I_x points, an experiment was carried out in which a steel electrical resistance probe was immersed in an aqueous solution of pH 2. The freely corroding rate was determined and was converted into equivalent current; then cathodic current was applied in increments until the protective current was reached. Next the freely corroding rate was again determined and found to be the same as it was at the start of the experiment. Anodic current was again applied and a new corrosion rate was measured. The results are plotted in Fig. 5.

Based on the freely corroding rate (equivalent to 153 $\mu a/cm^2$) and the protective current (75 $\mu a/cm^2$) the chunk effect ratio C for the system of Fig. 5 was about 0.5. The measured corrosion rate was linear with applied current up to a high anodic current.

After the probe of Fig. 5 had been made anodic for a period long enough to obtain the corrosion rate, the anodic current was turned off and the protective current was again determined. This current (82 $\mu a/cm^2$) was still essentially the same as before the anodic treatment, indicating that the local action current had not been affected by the treatment. The freely corroding rate increased slightly when measured before and after the treatment.

This phenomenon occurs consistently when steel is made highly anodic at low pH: I_o increases after each treatment while I_p remains constant. Disruption of a shielding film would explain the increase in I_o but not the constancy of I_p. If more area is exposed for local action, more protective current should be required. These facts indicate that the chunk effect increases as corrosion proceeds, if the corrosion rate is very high.

Table I lists data obtained with a smooth mild steel probe immersed in dilute HCl of pH 2. Both I_o and I_p were obtained at intervals after applying anodic current. The local action current as reflected by I_p remained practically constant. "Blank" probes, not subjected to anodic current, maintained constant values of I_o and I_p over the period of the experiment; the values were reproducible within about 3 μa per cm^2. However the I_o of the anodically treated probe doubled during the experiment. The difference effect

slope K decreased from -0.7 to -4.2, but K could be calculated only for the periods of time in which anodic current was being applied. The chunk effect ratio C, calculated from either Eq. [11] or [12], showed a gradual increase, with a reasonably good fit of values obtained by the two methods.

From this type of experiment, K appears to be of little value in depicting the mechanism of corrosion. If K in the example above is some measure of the disruption of a shielding film, one must ask why I_p does not vary with K. The chunk effect hypothesis on the other hand might aid in the study of mechanism. The gradual increase in C indicates that, as corrosion proceeds under conditions of high corrosion rate, a greater per cent of the freely corroding rate takes place by removal of more than one atom at a time. As I_p is essentially constant, this is not likely due to an increase in cathodic surface area, but rather to the geometric pattern by which the lattice dissolves.

Summary

Theories of film shielding of anodic areas do not explain adequately the negative difference effect and the relationship between minimum protective current and freely corroding rate in the case of steel. These effects can be explained by supposing that under certain conditions corrosion proceeds partly through removal of chunks of metal containing perhaps only a few atoms. This is believed to occur over the whole range of applied currents from cathodic protection to high anodic currents. The chunk effect is most pronounced (in steel) under conditions which yield high corrosion rates. In experiments at pH 2, for example, about 50% of the observed corrosion rate could be attributed to the chunk effect mechanism.

It is suggested that the chunk effect and anodic polarization occur on the same piece of corroding metal. Thus either the positive or the negative difference effect may be observed, depending on the corrodent.

Manuscript received Feb. 5, 1960; revised manuscript received Sept. 9, 1960. This paper was prepared for delivery before the Houston Meeting, Oct. 9-13, 1960.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

Symbols Used

- Δ — Thiel and Eckell's difference effect.
- K — Thiel and Eckell's slope constant.
- I_x — Applied current density.
- I_w — Observed corrosion rate expressed as equivalent current density.
- I_o — Freely corroding rate expressed as equivalent current density.
- I_p — Minimum protective current density.
- I_a — Local action current density.
- I_b — Chunk effect corrosion rate expressed as equivalent current density.
- I_{oa} — Local action current density under the condition of zero applied current.
- I_{ob} — Chunk effect corrosion rate at zero applied current.
- C — Chunk effect ratio.

Correction

In the September 1960 issue of the JOURNAL on page 768 of the paper by K. B. Oldham "Theory of Faradaic Distortion" the term "C +" was omitted from Eq. [6]. Equation [6] should read

$$C(0, t) = C + \sum_{j=0}^{\infty} \mu_j \cos j\omega t + \sum_{j=1}^{\infty} \lambda_j \sin j\omega t \qquad [6]$$

Flash Conductivity in Solution of Triphenylamine in n-Hexane

H. Rüppel, U. Krog, and H. T. Witt

Physikalisch-chemisches Institut der Philipps-Universität, Marburg/Lahn, Germany

ABSTRACT

A method is described for detecting short-lived charged primary products (ions, electrons) produced in photochemical reactions. The photochemical reaction is initiated by a light flash in an electric field of approximately 1000 v/cm. Photochemical changes produced in the solution are measured by a current impulse which occurs between the electrodes. The method is applicable for organic solutions which have a very small conductivity in the dark. Solvents such as hexane, benzene, and toluene may be used. The method was applied to detect light-produced short-lived radical ions of triphenylamine and similar substances in n-hexane. The electrical detection of flash conductivity in the case of triphenylamine was examined optically by measuring the transient absorption band of the photoproduct by flash photometry.

Ultraviolet radiation of a wave length $\lambda > 200$ mμ generally causes no additional conductivity in liquid organic media. That is to say, organic liquids either have no absorption bands in this spectral range (*e.g.*, hexane) or only such absorption bands as lead to excited electron states and not to the splitting off of an electron (*e.g.*, benzene). When there are ionization bands the radical ions produced in the liquid generally have a very short lifetime. Therefore the stationary amount of charge carriers produced by steady light is so small that an additional conductivity cannot be detected readily.

Conditions may be more favorable if, instead of steady light, the light of an electronic flash is used. Flash light is about 1000 times more intense than steady light, and, if ionization bands exist, it may be expected that flash light will give rise to a brief but measurable conductivity in the organic liquid. This conductivity phenomenon has been designated by us as "flash conductivity" (1).

Detection of flash conductivity was first attempted in the system triphenylamine in liquid n-hexane. According to Lewis and Lipkin (2) it is probable that there is an ionization of triphenylamine by u.v. with $\lambda > 200$ mμ. On irradiating a solid solution of triphenylamine at 90°K by u.v. light, Lewis discovered a new absorption band at 660 mμ. Comparing this with the known absorption spectrum of the radical ion of triparatolylamine, he assumed that he had produced a triphenylamine positive ion. Furthermore, according to the electron gas model of Kuhn (3) one could even expect the triphenylamine to have an absorption band in the visible spectral range. There had been, however, no direct electrical proof for the ionization ion in the solid solution. In the *liquid* solution the triphenylamine radical ion had not been detected either electrically or optically.

For the detection of the triphenylamine positive ion in liquid solution it had to be demonstrated that flash excitation of the triphenylamine solution gives rise to: (*a*) a brief additional conductivity, and (*b*) a transient absorption band in the visible red.

Methods of Measurement

A schematic drawing of the arrangement for measuring flash conductivity is shown in the upper part of Fig. 1. The triphenylamine solution was placed between the electrodes of a quartz cell. The electric field was approximately 1000 v/cm. If charge carriers are produced by the flash, they will move in the electric field during their lifetime, inducing a current impulse on the electrodes. The current impulse can be amplified by the pulse amplifier (PA) and indicated on the oscilloscope (CRO).

The current impulse comes about as follows. Every charge carrier produced by the flash moves in the electric field E with a velocity $u = v \cdot E$, where v is the mobility of the charge carrier. During its lifetime τ, the charge carrier travels a distance $s = v \cdot E \cdot \tau$. By this means a definite charge q is induced on the electrodes,

$$q = e \cdot s/d = e \cdot (v \cdot E \cdot \tau)/d \qquad [1]$$

where e is the electrical charge of the particle and d the distance between the electrodes.

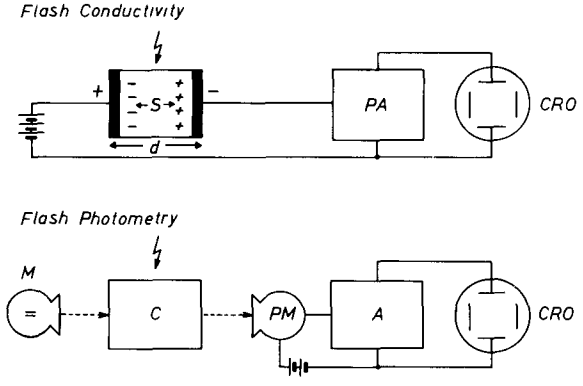

Fig. 1. Upper part: schematic drawing of the electrical arrangement (flash conductivity), d—distance between the electrodes, s—distance the charge carrier travels in the electric field during its lifetime, PA—pulse amplifier, CRO—cathode-ray oscilloscope; lower part: schematic drawing of the optical arrangement (flash photometry); M—measuring light source, C—quartz cell, PM—photomultiplier, A—amplifier.

If the production of ions per flash results in a total charge Q_o, then the current impulse at the amplifier input is given by the expression

$$Q = Q_o \cdot (v_+ + v_-) \cdot E \cdot \tau / d \qquad [2]$$

where v_+ is the mobility of the positive and v_- that of the negative charge carrier. This simple equation is valid if $(v_+ + v_-) \cdot E \cdot \tau << d$ (1).

The lower limit of measurement is fixed by the noise of the preamplifier tube. In the present case the noise level corresponded to a charge of approximately 5000 electrons. Substituting this value for Q and the known values for E, d, and v (4) one obtains a given lower limiting value of the product $Q_o \cdot \tau$, $(Q_o \cdot \tau)_{min} \approx 5 \cdot 10^3$ e·sec, which is just within the limit of measurement. Thus, the flash conductivity method is very sensitive. Assuming an ion lifetime of 10^{-1} sec, a concentration of about 10^{-18} mole/l [1] can be detected, or, in the other extreme, at a given ion concentration of 10^{-7} mole/l, ions with a lifetime of 10^{-12} sec can be detected.

In the lower part of Fig. 1 a schematic drawing of the optical arrangement for flash photometry is shown, the principle of which was reported by Norrish and Porter (5) and by Davidson and co-workers (6). A beam of monochromatic measuring light (M) passes through the quartz cell (C) and falls onto a photomultiplier (PM). If the flash produces photochemical changes in the solution which give rise to a new absorption band, the photomultiplier will detect a change in the intensity of the measuring light. The corresponding current variation in the photomultiplier output can be amplified (A) and indicated on the oscilloscope (CRO). The lower limit of measurement is fixed by the noise of the photomultiplier cathode. The theoretical value of the resolution limit is practically reached by our arrangement (7). At a signal risetime of $\approx 10^{-5}$ sec an absorption change of 0.1% is detectable.

Results

Electrical measurements.—Excitation of the triphenylamine solution in n-hexane with unfiltered flash light produced the expected current impulses. The current impulses rise linearly with the electric stress E, indicating that the lifetime of the ion is small enough to satisfy the condition for Eq. [2], or, in this case, $\tau << 1$ sec. In order to determine which of the absorption bands of the triphenylamine (see Fig. 3, solid curve) gives rise to ionization, the light of the flash was filtered. Measurements indicated that ionization accompanies absorption only in the u.v. absorption with $\lambda < 250$ mμ. Other parameters such as concentration of triphenylamine, oxygen content of the solution, etc., were also varied. The results of these measurements confirmed expectations (1).

Flash conductivity could also be detected in n-hexane solutions of diphenylamine, tetramethyl-paraphenylendiamine, and both types of chlorophyll. (Under equal experimental conditions the electrical signal in the case of chlorophyll is about three times larger than with triphenylamine. The order of magnitude of the current impulse is Q $\approx$ 10^{-13} amp sec.) On the other hand, exciting a solution of benzene in n-hexane with u.v. light of the spectral range $\lambda > 200$ mμ produced, as had been expected, no electrical signal (see above).

[1] The volume of the quartz cell was approximately 0.1 l.

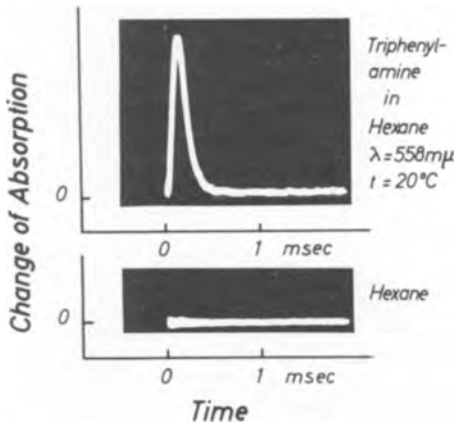

Fig. 2. Change of absorption vs. time as received on the oscilloscope. Upper part: increase of absorption was produced by irradiating triphenylamine in n-hexane with the intensive light of an electronic flash. Concentration of triphenylamine: $3 \cdot 10^{-5}$ mole/l. Wavelength of the measuring light, 558 mμ ($\Delta\lambda$ = 17mμ); temperature, 20°C; electrical energy of the flash discharge, 240 j; length of the quartz cell, 10 cm. The maximum of the absorption change corresponds to a decrease of transmission of approximately 6%. Lifetime of the photoproduct (triphenylamine positive ion) $\tau < 10^{-4}$ sec. Lower part: Response of the optical arrangement on flash light excitation of pure n-hexane.

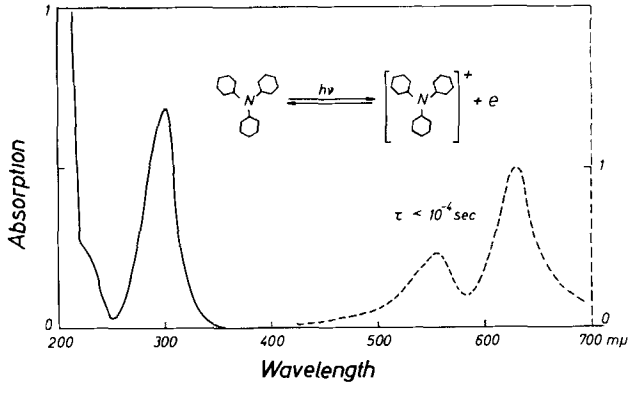

Fig. 3. Absorption vs. wave length. Solid line: normal absorption spectrum of triphenylamine in n-hexane; dashed line: transient absorption spectrum received by flash photometric measurements on illuminating triphenylamine in n-hexane by intensive flash light. (Preliminary measurements; position and relative heights of maxima may be submitted to some change.) Temperature: 20°C. Electrical energy of the flash discharge, 240 j; flash duration, approximately $2 \cdot 10^{-4}$ sec; lifetime of the photoproduct (triphenylamine positive ion) $\tau < 10^{-4}$ sec. (Both absorption spectra are plotted in arbitrary units.)

Optical measurements.—In addition to the electrical detection of charged photoproducts in the triphenylamine solution, there was also a brief appearance of a new absorption band. This may be due to the triphenylamine positive ion. The optical signal measured at a wave length of 558 mμ is shown in the upper part of Fig. 2. It was received on the oscilloscope when the intensive flash light excited the triphenylamine solution. The time course of the optical signal corresponds approximately to that of the flash light emission, indicating that the lifetime of the transient photoproduct is shorter than 10^{-4} sec. The entire transient absorption spectrum could be

traced from measurements taken at various wave lengths. The main peak of the new absorption band lies in the spectral range around 650 mμ[2](Fig. 3, dashed curve). According to the experimental work of Lewis (2) as well as to the calculations of Kuhn (3) based on the electron gas model, there is good evidence for the triphenylamine radical ion to show an absorption band in this spectral range. Thus, the transient absorption band observed on exciting the triphenylamine solution may be ascribed to the triphenylamine positive ion.

Experimental.—The measurements have been described in their essential features without regard to experimental difficulties. Owing to its high sensitivity, the apparatus is very subject to interference, most of which is caused by the intensive flash discharge. Measurements are disturbed by the electromagnetic field and by the sound and any random light of the flash. The latter causes electrode effects in the cell or false light signals on the photomultiplier. Nearly all of these troubles may, however, be handled appropriately.[3]

Conclusions

The method of using flash conductivity may be extended to quantitative measurements, *i.e.*, it may be used to measure ionization potentials, which have, until recently, been little known in the liquid state.

Finally, there is one circumstance which remains to be discussed. In a system such as triphenylamine in liquid or rigid solution it is not clearly known where the separated electron stays during its lifetime.[4] It might, therefore, be desirable to investigate systems with a definite electron acceptor present. There are donor-acceptor systems in which an electron transfer takes place from the photo-excited electron state:

$$A^* + B \rightarrow A^+ + B^- \rightarrow A + B$$

[This scheme has been used to explain the quenching of fluorescence of certain organic compounds (9)]. Owing to the high sensitivity it should be possible to detect such an electron transfer electrically in the apparatus described above. Reactions of this kind are the subject of our current investigation.

[2] Independent of the flash photometric measurements (Fig. 1) the transient absorption curve (Fig. 3, dashed line) was measured recently by us also using the method of flash spectroscopy (5).

[3] More details of the experimental technique are described in ref. (1) and (7).

[4] Tentative ideas are discussed by Lewis (2), Linschitz (8), and especially by LeBlanc (4) (see also paper by O. H. LeBlanc, Jr., presented at the Philadelphia Meeting of the Society, May 6, 1959.

Acknowledgment

The authors wish to thank Miss Rilla Spangler, West Chester, Pa., and Mr. Günter Eckel, Marburg/Lahn, for helpful suggestions regarding the textual revision of this manuscript. Electrodeless Passage of Direct Current through an Electrolyte

Abner Brenner

National Bureau of Standards, Washington, D. C.

ABSTRACT

An experimental setup is described for directly observing the electrical migration of a dye in a conducting system without electrodes. Direct current was produced in a continuous circuit of electrolyte, which included the dye solution, by means of a transformer and a mechanical commutator.

The passage of direct current between electrodes immersed in a conducting solution produces two phenomena: chemical reactions at the electrodes and mass transport of the solute. If one looks at this process phenomenologically, one is tempted to ask naively whether the mass transport would occur if current were passed through the solution in such a way that no electrode reactions occurred. To perform this experiment it would be necessary to produce direct current in an electrolyte without using electrodes.

On the basis of the currently accepted theories of the structure of electrolytes, it seems obvious that electrical migration[1] would occur even in the ab-

[1] Ionic or electrical migration is considered to be the flux of dissolved matter, in accordance with Faraday's law, through an electrolyte as a result of the flow of current.

sence of electrolysis. The ions in solution, being charged particles, would move in the electric field that is applied across the solution. However, the possibility could be envisioned that in the absence of electrolysis the positive and negative ions consort together as dipoles and the current then could be carried by a flow of electrons or holes as in a semiconductor or metal. As an example, the conduction of electricity through the solution of an alkali metal in ammonia is supposed to occur by a flow of electrons.

Even though current theory predicts that electrical migration would occur in the absence of electrolysis, the auther considered that direct observation of the predicted phenomena would make an interesting experiment. An additional element of interest was provided in designing the apparatus for producing direct current in the electrolyte without using electrodes.

In looking into the literature of the electrodeless passage of current through an electrolyte, the author found the subject was a rather old one. It had been the center of lively discussion and controversy 60 years ago and then had been forgotten. The author learned of the early literature somewhat by accident. In the course of preparing the J. W. Richards Memorial Lecture, the author learned that both Richards, the first president of The Electrochemical Society, and Carl Hering, the fourth president of the Society, published papers on the subject. Richards (1, 2) believed that conduction through an electrolyte occurred by the same mechanism as "metallic conduction" and that electrical migration was a secondary phenomenon which resulted from the chemical changes that occurred at the electrodes. According to his view, in the absence of electrolysis there should be no electrical migration.

Richards also attempted to show that current could be passed through an electrolyte without causing chemical changes. His experiment, which involved zinc electrodes immersed in solid zinc chloride, was unsatisfactory, because the current used was so small that evidence of electrolysis could not be detected. It was severely criticized.

Hering was of the opinion that the electrodeless passage of current through a solution would not produce any phenomena radically different from those obtained with the passage of current introduced through electrodes. He did not actually do any experimental work on the problem, but he described (3, 4) various types of unipolar devices that would achieve the electrodeless flow of current.

Marvin (5) constructed a unipolar device which, however, did not yield sufficient current for experimental purposes. By introducing two copper electrodes into the circuit he was able to obtain a deflection of a galvanometer. His other experiments involved the use of alternating current. Both he and others (6) have shown that an alternating magnetic field can induce an alternating current in a continuous tube of electrolyte. The presence of the current in the electrolyte was demonstrated by its magnetic field or by its heat effect. The electrodeless measurement of the conductivity of electrolytes by making a tube of electrolyte one element of a transformer is now in routine use (7). Experiments with induced alternating currents give no direct information on transport of material in the absence of electrodes.

The major part of the effort in this investigation was expended on the construction of apparatus and the development of a method for detecting electrical migration produced by small currents of the order of microamperes. The objective of the investigation was to set up an experiment which would permit one to observe, qualitatively, electrical migration in the absence of electrolysis. However, a comparison between the effects of the induced direct current and a current introduced by electrodes put the experiments on a semiquantitative basis.

Apparatus

Electrical and mechanical.—The apparatus consisted of three parts: a transformer, a commutator, and an electrolyte system. The apparatus is shown diagrammatically in Fig. 1 and 3 and a photograph is shown in Fig. 4.

The transformer core was originally part of the control equipment on an electric furnace and had large secondary windings that carried several hundred amperes. All windings were removed and the core was wound with a primary consisting of several hundred turns of No. 12 copper wire and a secondary consisting of a rubber tube, about 4 cm inside diameter and 8 meters long, filled with a saturated ammonium nitrate solution. This salt solution was chosen because it is a fairly good conductor and is not very corrosive.

The method of producing the direct current in the electrolyte circuit was periodically to reverse a direct current passing through the primary coil of the transformer. This ordinarily would produce an alternating current in the tube of electrolyte, but by breaking the circuit in the latter at the proper time the reversal of current was prevented. The appara-

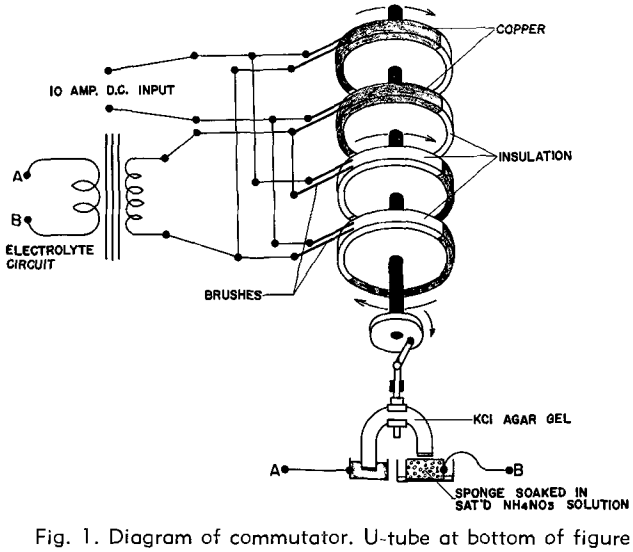

Fig. 1. Diagram of commutator. U-tube at bottom of figure closes electrolyte circuit by being brought into contact with a sponge saturated with ammonium nitrate solution. The U-tube moves vertically up and down in synchronization with the rotation of the commutator wheels. The current through the primary is reversed when the junctions between the copper and insulating parts of the wheels pass under the four pairs of brushes.

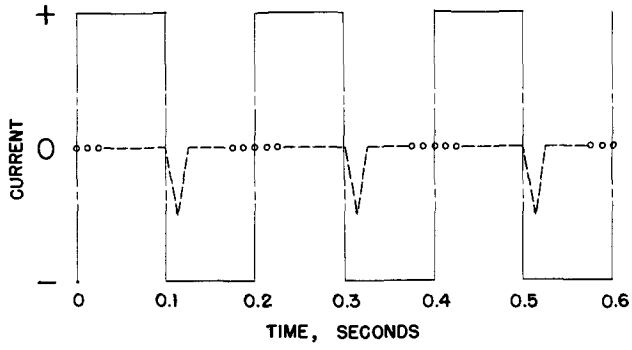

Fig. 2. Schematic representation of the currents in the primary winding of the transformer and in the secondary winding comprising the tube of electrolyte. ————, Current through primory; — — — current through secondary; o o o o, open circuit in secondary.

tus corresponds to a mechanical half-wave rectifier. The principle of operation is made clear with the aid of Fig. 1 and 2. The commutator consisted of four wheels with half of the periphery of each covered with copper and the other half with insulation. Two adjacent copper brushes contacted each wheel. When the junctions between the copper and the insulating segments passed the four pairs of brushes, the current through the primary coil was reversed.

The circuit in the electrolyte was made and broken by a U-tube containing potassium chloride solution in agar-agar gel. The tube was given a vertical reciprocating motion by a crank attached to the same shaft as the commutator wheels. The U-tube (see Fig. 4) was closed at both ends with porous glass diaphragms which served to retain the agar-agar gel during operation of the device. When the U-tube was in its lowest position, it pressed against a sponge saturated with ammonium nitrate solution and thereby completed the electrolyte circuit shown diagrammatically in Fig. 3.

The commutator operated in three steps: Step 1. The electrolyte circuit is closed by the U-tube (connected to the crank) pressing against the sponge. Figure 1 shows the arrangement of components just prior to closing the circuit for step 1. The closing or

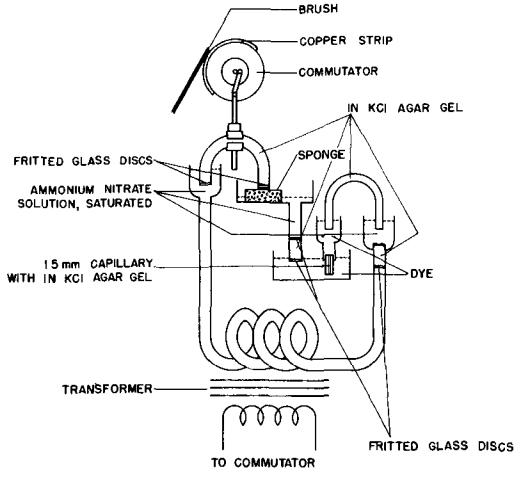

Fig. 3. Diagram of electrolyte circuit. A direct current is produced in the circuit by means of cyclically reversing the current though the primary of the transformer and interrupting the current in the secondary by means of the vertically actuated U-tube.

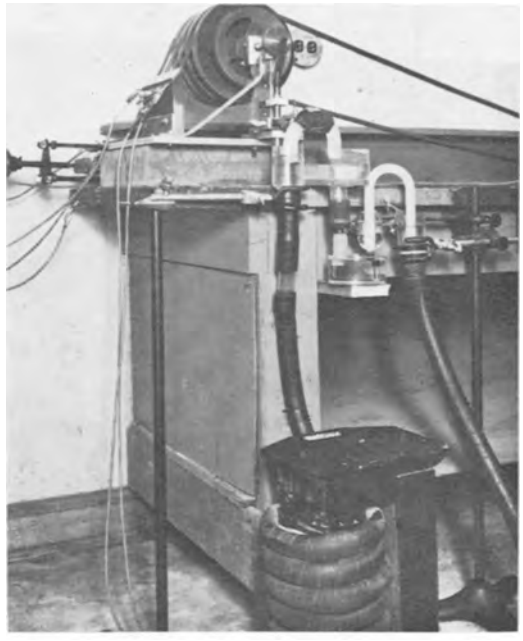

Fig. 4. Photograph of the apparatus

opening of the electrolyte circuit does not produce a flow of current through the electrolyte. Step 2. The junctions on the wheels pass under the brushes and cause the current to reverse through the primary. This change of magnetic flux induces a current in the electrolyte circuit. Step 3. The U-tube is raised from the sponge, which motion breaks the electrolyte circuit. Shortly thereafter the junctions on the wheels again pass under the brushes, causing the current through the primary to reverse to its original direction. Since the electrolyte circuit was broken previously, this produces no current in it. The positions of the brushes and the U-tube are now again as shown in Fig. 1 and the cycle is ready for a repetition.

The commutator was operated at about 300 rpm. The current in the primary was about 10 amp. The current in the electrolyte was measured roughly by intercalculating a microameter and two cadmium electrodes immersed in cadmium chloride solution into the electrolyte circuit. The latter consisted of the tube of ammonium nitrate solution, the dye solutions, and the 1.0M potassium chloride solution in the capillary. The current flowed in pulses having a peak value of 300 μ amp. The voltage was about 0.5 v.

The success of the transformer device depended largely on the use of the U-tube and sponge to break the electrolyte circuit. At first, various types of revolving and reciprocating stopcocks were used to break the circuit. However, they were unsuccessful for two reasons. The film of solution that formed around the plug prevented the circuit from being broken efficiently and the plugs galled and caused the cocks to leak. The use of Teflon plugs did not solve the problem. Another important factor in the operation of the apparatus was the reversing of the current through the primary instead of merely breaking the circuit. Reversing the primary current increased the current in the electrolyte circuit about fivefold.

Apparatus for observing ionic migration.—Since only small currents were generated in the electrolyte, a sensitive method of observing electrical migration was necessary. The moving boundary method was found to be unsuitable. The method adopted was to observe the movement of a dye, erythrosine B, (the di-sodium salt of tetraiodofluorescein) into a capillary containing a gel.

The size of the capillary was important. Preliminary experiments had shown that in a capillary about 0.5 mm in diameter, the migration caused by a current of 25 μamp in 15 min was readily detected. With still smaller capillaries, probably the migration effects of even smaller currents can be detected. However, the minimum size of the capillary that could be used in the experiment was limited by the small voltage that was available, and the gain in sensitivity was offset by the reduction in current due to the high electrical resistance of the solution in the capillary. On the other hand, a large capillary decreased the sensitivity of the experiment because of increased amount of dye diffusing into the capillary. This could be greater than that carried in by electrical migration. The optimum inside diameter of the capillary was 1.5 mm. The capillary was filled with an agar gel containing about 2% agar-agar and 1.0*N* in potassium chloride. A more dilute solution of potassium chloride would have been preferable, since it would carry less current at the junction with the dye solution. However, the resistance of a 0.1*N* solution of potassium chloride in the capillary was too high.

The use of the capillary filled with agar gel also involved a mechanical problem, because the thread of gel readily became detached from the capillary wall and occasionally even slipped out of the tube. To obviate this difficulty the capillary surface was roughened with glass powder in the following manner. A drop of mineral oil was allowed to flow through the capillary and wet the surface. Then glass powder was drawn through the tube by connecting one end to a vacuum line and placing the other end near a small quantity of powder. Finally, the capillary was heated several hours at 600°C to cause the glass powder to fuse to the wall. Capillaries about 20 cm long were prepared and pieces about 2 cm long which were used in the experiments were cut off with a diamond wheel.

The capillary was connected to the funnel shaped piece of glass shown in Fig. 4 by a rubber stopper or tube. The entire current in the electrolyte circuit passed through the capillary.

Procedure

The experiments themselves were simple and required little time. A 0.01M solution of erythrosine was poured into that vessel to which the capillary was attached, and the lower end of the capillary protruding from the end of the vessel was immersed in a beaker of the dye solution. In this manner both ends of the capillary were in contact with the dye. In Fig. 4 the dye solution has been omitted. The circuit between the beaker of dye solution and the solution in the electrolyte coil was completed with another U-tube filled with potassium chloride-agar gel.

Table I. Summary of experiments

Comparison of the electrical migration of erythrosine B with and without conventional electrodes. Dye solution, 0.01M. Solution in capillary was 1.0M potassium chloride and contained about 2% of agar. Diameter of capillary, 1.5 mm. Thirty minute run at about 300 rpm. Peak current, 300 μamp.

	Description of experiment	Migration of dye,* mole × 10^{-8}
1.	Electrodeless	6.0
2.	Electrodeless. Direction of current opposite to that of No. 1	6.7
3.	Current, 150 μamp, from an external source introduced by electrodes	6.0
4.	Current, 90 μamp, from an external source introduced by electrodes	3.4
5.	Induced direct current as in No. 1 and No. 2, except that Cd electrodes were placed in the electrolyte circuit	2.8
6.	Control. Diffusion of dye into capillary without current	1.4

* All electrical migration experiments were corrected by subtracting 1.4 × 10^{-8} moles of dye as determined by control experiment No. 6.

Since during the experiment dye diffused into the capillary tube, it was necessary to make a control experiment to correct for it. This was done by immersing another piece of capillary in the dye solution for the same length of time as the duration of the experiment. No current flowed through the control capillary.

Induced current was passed through the system for 30 min, which time was adequate to produce appreciable migration of dye into the main capillary. Both the main and the control capillaries were removed from the dye solution and rinsed. The ends containing the dye were cut off and placed in small test tubes containing 7 ml of water, and the gel was dissolved by heating. The concentration of dye in the solution was measured with a spectrophotometer, and the content of dye in the capillary was calculated.

Since the color of the dye is due to the anion, during current flow it migrated into one end of the main capillary and away from the other end. However, diffusion caused some dye to enter the latter end, but the amount was only about one-third that in the control capillary. The content of the dye in the control capillaries was reproducible within the limits of the measurement of the dye concentration.

Three types of experiments were made. These are listed in Table I. Experiments 1 and 2 dealt with electrical migration in the absence of electrodes. Experiments 3 and 4 involved the use of electrodes and permitted a comparison with the electrical migration of experiments 1 and 2. Experiment 5 was made with induced direct current, but cadmium electrodes were placed in series with the electrolyte circuit.

Results

The data in the table show that the electrical migration of the dye was roughly about the same in the presence or absence of electrodes. This was of the order of 6 x 10^{-8} moles. The current was not

measured during the electrodeless experiments so that a qualitative comparison with experiments 3 and 4 was not possible. However, the currents in the latter experiments were of about the same order of magnitude, since the peak value of the induced current was about 300 μamp.

Comparison of experiments 3 and 4 shows that the electrical migration into the capillary was approximately proportional to the current, so that the capillary method is valid as a comparative method of studying electrical migration.

To make certain that no geometrical or extraneous effects were involved in the electrodeless experiments, the currents in experiments 1 and 2 were made to flow in opposite directions. In one experiment the dye migrated into the upper end of the capillary and in the other into the lower end.

The amount of migration obtained in experiment 5 with cadmium electrodes in the circuit was less than in experiments 1 and 2. This indicates that the current during this experiment must have been less than that in 1 and 2. This could have been caused by the resistance of the additional electrolyte in the circuit (the cadmium chloride solution) and a microameter or by variations in the performance of the equipment.

The amount of electrical migration of the dye in all of these experiments indicated that it was carrying only about one-thirtieth of the current. This is understandable, since the dye, which was only 0.01M, was migrating into a capillary containing 1M potassium chloride. Hence, at the juncture of the two solutions, the major portion of the current must have been carried by the potassium chloride solution.

Since the induced direct current produced normal electrical migration, it was of interest to determine whether it also produced normal electrolysis. The induced direct current was passed through a copper wire and a platinum wire, serving as anode and cathode, respectively, immersed in a copper sulfate solution. A copper deposit was obtained in an amount roughly corresponding to the current that passed.

Summary

An apparatus was devised for producing a direct current in an electrolyte without the use of electrodes. With this apparatus it was possible to observe the electrical migration[2] of a dye in a capillary.

Acknowledgment

The author acknowledges the patient and skillful assistance of O. V. Hurst in constructing the mechanical and electrical parts of the induced current apparatus and the assistance of J. L. Sligh in performing the experiments involving the passage of current through the gas phase.

Manuscript received June 13, 1960; revised manuscript received Aug. 9, 1960. This paper was prepared for delivery before the Columbus Meeting, October 18-20, 1959.

[2] It has been suggested that the movement of the dye, instead of being due to ionic migration, might be caused by electroosmosis of water through the capillary. This possibility cannot be completely discounted, but it is unlikely, since the movement of water in solutions as strong as the one in the capillary (1.0M) is considered to be due to ion hydration and not to electroosmosis.

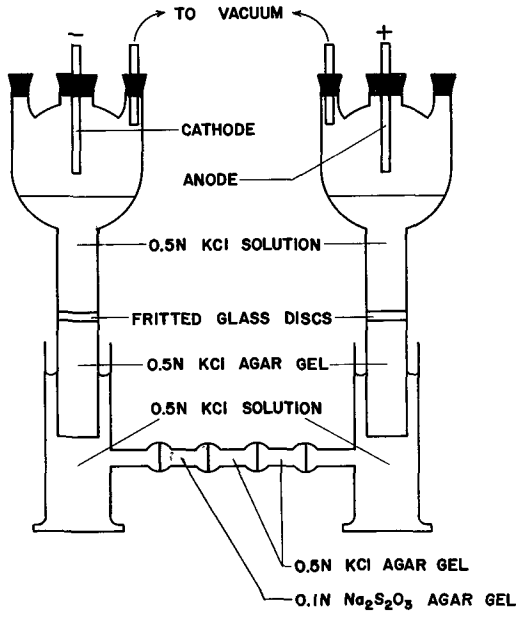

Fig. 5. Diagram of the circuit used for studying the migration of thiosulfate ion in a system provided with a gaseous discharge.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

APPENDIX

Electrical Migration in an Electrolyte in Contact Only with a Gas

Another method of passing current through an electrolyte without immersing electrodes in the liquid is to pass the current through the gaseous space above the liquid. The experimental arrangement for this is shown in Fig. 5. It is well known that the chemical effects at the solution-gas interface are several times greater than the amount predicted by Faraday's law (8). Hence, it was of interest to determine whether the electrical migration in the electrolyte was normal or greater than normal.

Metallic electrodes were suspended several centimeters above the surface of the electrolyte which was contained in a closed vessel, and the system was pumped down to a pressure of about 1 cm. A discharge through the gas phase was obtained with a few hundred volts. The current was set at 0.1 amp, although larger currents could have been obtained. The current passed from the metallic electrodes through the gas and the electrolyte which was contained in tubes. To prevent the electrolyte from being forced into the evacuated chambers, a KCl-agar gel was placed in the circuit in contact with a fritted glass partition.

The migration of ions in the electrolyte was investigated by using a gel containing sodium thiosulfate. The migration of the thiosulfate across a boundary into a KCl-agar gel was determined by titration with a standard iodine solution. The amount of thiosulfate that migrated in the system with the gas discharge was compared with that which migrated in a conventional system provided with metallic electrodes. The amounts were the same within the experimental precision which was about 5%.

Formation of Phosphor Films by Evaporation

L. R. Koller and H. D. Coghill

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

Three processes for making ZnS phosphor films are described. One process for ZnS activated with Cu, Ag, or Mn involves evaporation of powder phosphor onto a room-temperature substrate followed by heat treatment of the film in an H_2S + HCl atmosphere. A process for ZnS:Mn alone involves the single step of evaporating the phosphor onto a substrate held between 250° and 400°C. The third process involves evaporating the phosphor in a single step onto a heated substrate in a uniformly heated enclosure such as the "Hot Wall Bell Jar." A fourth process used for silicate, phosphate, and borate phosphors involves a reaction during the course of evaporation between ZnF_2 and a heated substrate.

Thin continuous films of phosphors a few microns thick are useful for practical applications as well as for investigation of cathodo, photo, and electroluminescent phenomena. One method of preparing such films is by evaporation *in vacuo*. The technology of forming phosphor films by evaporation is relatively new. DeBoer (1) patented a process for evaporating ZnS and $CaWO_4$ x-ray intensifying screens in 1934 although it is questionable whether his films would be considered luminescent by present standards. Williams (2) prepared a number of different kinds of phosphor films by evaporation in 1947. He found that efficient films of manganese-activated zinc fluoride could be evaporated but that zinc sulfide, zinc sulfoselenide, and zinc cadmium sulfide films failed to show appreciable luminescent efficiency. More recently Koller (3), and Feldman (4) described methods for making sulfide and fluoride phosphor films. Feldman also described methods for making oxygen containing phosphors. Rychlewski (5) patented methods for forming films of ZnS as well as some oxygen containing phosphors. All three of these methods involve heat treatment at some stage of the process. Studer and Cusano (6) have formed films of a variety of ZnS:Se phosphors by a different but related procedure, namely, vapor reaction.

Although ZnS and some other host lattice materials may be readily evaporated *in vacuo* and condensed again in the form of thin transparent films, these films are not necessarily luminescent (with the possible exception of ZnF_2). The formation of a phosphor film imposes the additional requirement that the film be crystalline and contain activator and coactivator materials in suitable lattice sites and concentration.

Since the vapor pressures of the various constituents of a phosphor differ widely, the condensate (*i.e.* the film) will not have the same composition as the phosphor material evaporated. Furthermore the composition of the condensate will change during the course of the deposition as the phosphor composition changes due to this fractional distillation. These effects result in a gradation of composition throughout the depth of the film.

The composition of the film is also affected by the difference in accommodation coefficients of the phosphor components. Not every molecule which arrives at the substrate surface remains there. Many are reflected from the surface and condense on the relatively cold wall of the bell jar. The composition of the film will depend on the relative accommodation coefficients of the phosphor constituents which in turn are functions of the temperature of the substrate. Accordingly, the composition of a film will depend in a rather complex way on the nature of the material being evaporated, the length of time during which the evaporation has been in progress and the temperature of the evaporator and the substrate.

From these considerations it can be seen that the optimum conditions for forming films of any given phosphor will depend on the nature of the phosphor and that no one method will be satisfactory for all phosphors.

The procedures for forming phosphor films may be broadly classified as follows.

Two-step processes: (a) simultaneous evaporation of host lattice and activator materials and condensation on room-temperature substrate followed by heat treatment; (b) sequential evaporation of host lattice and activator materials (order immaterial), both condensed on room-temperature substrate followed by heat treatment.

One-step processes: simultaneous evaporation of host lattice and activator onto heated substrate.

Reaction processes: phosphor formed in one step by reaction of a compound with a heated substrate.

Apparatus

All of the two-step processes and some of the one-step processes were carried out in a vacuum system with an 18 in. bell jar exhausted by a 6 in. oil diffusion pump. The system had no cold trap. During the course of an evaporation the pressure maintained was about 10^{-4} mm.

A number of different types of evaporators made of tungsten wires and tungsten foil were used. The most versatile and useful was a foil boat formed by folding a strip of 0.001 in. tungsten foil lengthwise and clamping the ends. A boat ⅜ in. high 1¾ in. long is heated to a temperature of 1673°K by a current of 60 amp with a drop of about 3.2 v. Tungsten was the most satisfactory material for evaporating sulfide phosphors and did not react significantly with them. It also had less copper impurity present than either platinum or molybdenum. Platinum was used for evaporating fluoride phosphors.

The heater for the substrate consisted of a bank of four 500-w tubular quartz infrared lamps mounted on a reflector and placed a few inches above the substrate.

Most of the materials evaporated were in the form of crystalline powders. In order to keep these from jumping out of the boat and sputtering, they were compressed into pellets by means of a small hydraulic press. These compact pellets could be evaporated at the rate of about 0.05 g/min with very little sputtering.

Preparation of Surface

Most of the films were deposited on 2 in. diameter Pyrex disks. The glass was cleaned with a mild abrasive, rinsed in distilled water, and air dried. Other cleaning methods appeared to give equally satisfactory results.

Evaporation

After the preliminary heating of the substrate, films were formed by evaporating the phosphor at rates of about 0.05 g/min with the source 3-6 in. from the substrate. Films were usually deposited to a thickness of about 2μ. The film growth could be monitored by observation of the interference color.

The effect of the vapor pressures of the constituents on the composition is illustrated by the analysis of ZnS:Mn films formed by evaporating a ZnS:Mn phosphor having an Mn content of 0.1%. By means of a slide changer, films were collected during the first, second, and third minutes of evaporation. The Mn/Zn ratios in these films were 0.003, 0.007, 0.011, respectively, compared with 0.001 for the original material. Thus the Mn/Zn ratio in the film was greater than that of the source material and increased progressively during the course of the evaporation. A number of analyses of other ZnS:Mn films showed a Mn/Zn ratio of as much as ten times that of the original film. Thus in addition to a variation in activator concentration with film thickness, ZnS:Mn films tend to have an over-all higher Mn content than the source material.

The effect of the accommodation coefficient on film composition is illustrated by some experiments on evaporation of a ZnCdS phosphor onto substrates at various temperatures. The same evaporation procedure was followed in successive runs. The substrate temperature is given in the first column of Table I. In these experiments the substrate temperature was not constant but increased during the course of the evaporation due to the heating effect of the evaporator. The second column gives the cadmium to zinc ratio. The source material had a cadmium to zinc ratio of 9/1. Table I shows the marked decrease in the Cd/Zn ratio with increasing substrate temperature. The maximum at the low temperature end of the range was not investigated further.

Table I.

Substrate temp, °C	Cadmium to zinc ratio
190-250	6.4/1
250-280	8.1/1
280-330	4.2/1
330-370	2.2/1
430	2.1/1

Two-step process for zinc sulfide phosphors activated with Ag, Cu, *and* Mn.—Evaporation of sulfide phosphors and condensation on a glass substrate at or near room temperature results in clear transparent films. The presence or absence of activator has relatively little effect on film formation. The films formed in this way, however, are not luminescent. Electron diffraction shows them to be amorphous. In order to convert these films to phosphors they must be crystallized by heat treatment. This is accomplished by heating them in an atmosphere of H_2S + 10% HCl at about 650°C for ½ hr. This treatment converts them from the nonluminescent amorphous state to the luminescent crystalline state. Electron diffraction shows that after this heat treatment the films are hexagonal and microcrystalline with the crystal size of the order of 1000Å. After this treatment, the films have a matte surface. They become quite transparent if polished.

The HCl vapor is necessary in order to introduce Cl coactivator into the lattice simultaneously with the recrystallization as it is probable that Cl coactivator is lost during the evaporation process. A higher concentration of HCl than 25% results in excessive attack on the film while less than 2% is not effective. The H_2S flow is regulated at about 2 ft³/hr. The optimum time of heating is about ½ hr. Shorter times result in significantly less efficient films while heating up to several hours does not result in any further improvement. No activation is obtained below 550° or above 750°C. The lower limit is probably determined by the rate of diffusion of activator and coactivator. The upper limit is probably determined by the retention of chlorine by the phosphor which Goldberg and Kremheller (7) found to be a maximum at 650°C.

Attempts to introduce Cl by evaporation of AgCl or $ZnCl_2$ simultaneously with the ZnS were not successful.

Attempts were made to use Al as a coactivator for ZnS:Ag by evaporating Al onto the surface of the film and then heat treating *in vacuo* or dry nitrogen. Amounts of Al less than 1% of the weight of the film were ineffective. Larger amounts resulted in moder-

ate bluish-green luminescence. The films remained clear, transparent, and colorless although similar films without the Al subjected to the same heat treatment developed a matte etched surface.

Indium and gallium coactivators only resulted in weak orange luminescence when added to ZnS:Ag.

The method of introduction of the activator is relatively unimportant. It may be introduced simultaneously with the deposition of the ZnS by evaporating a standard powder phosphor. It may be mixed with the ZnS, or it may be evaporated from a separate boat in the form of a salt or the pure metal either simultaneously with, prior to or after the ZnS evaporation. The over-all activator phosphor ratio must be correct however; hence the evaporation conditions must be determined empirically.

The temperature of the substrate on which the phosphor is deposited is crucial. Films deposited *in vacuo* on a substrate at a temperature above about 100°C are crystalline but they are nonluminescent (with the exception of ZnS:Mn) and do not become luminescent when heat treated (at 650°C) in H_2S + 10% HCl. A possible explanation is that in the crystallized material diffusion of chlorine at this temperature takes place mainly along the grain boundaries, and not through the body of the crystals. Heat treatment (below 650°C) is only effective in activating sulfide films provided they are initially in the amorphous condition corresponding to deposition at substrate temperatures below 100°C.

This two-step procedure has proved to be effective for making photo and cathodoluminescent Zn and Cd sulfide films with Ag, Cu, and Mn activators having brightnesses 1/5 to 1/10 of the corresponding phosphors.

One-step process for Mn *activated* ZnS.—Manganese activated ZnS differs from the Cu and Ag activated Zn sulfides in that it can be formed by a one-step process. This consists of evaporating the phosphor material and depositing it on a substrate in the range from 250° to 400°C. This results, without any further treatment, in a cathodo and weakly photoluminescent film. The reason for this difference in behavior between the Mn and the Ag and Cu activated phosphors is that the luminescence is the result of electron transitions between levels in the Mn center while in the other phosphors the transition is from the conduction band to the center. The latter process requires a higher degree of perfection of the host lattice than is obtained by crystallization at 250°C. At higher substrate temperatures the chlorine coactivator is lost as pointed out in the previous section.

One-step process for ZnS *phosphors—"Hot Wall Bell Jar."*—The ideal condition for forming phosphor films is to deposit them on a substrate at a temperature high enough so that the incident molecules will have sufficient mobility to form an ordered structure. With sulfide phosphors evaporated in an ordinary bell jar the substrate temperature is limited to not much above 300°C. This is because of the re-evaporation or reflection from the heated substrate. At 400°C this is so great that only very thin films are formed while at 600°C no deposition takes place at all. This is in spite of the fact that at 600°C

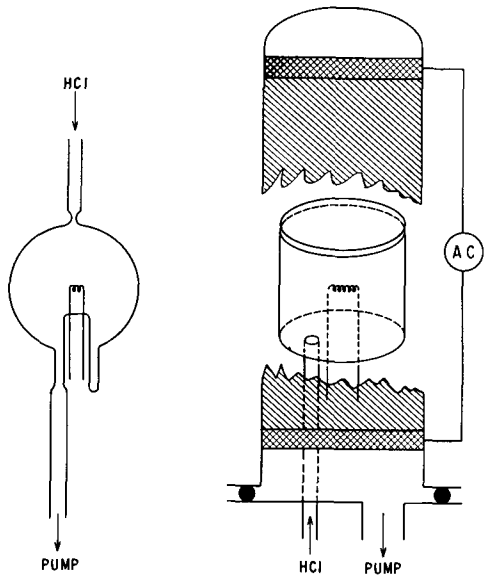

Fig. 1a. Bulb for evaporation on heated wall; Fig. 1b. Hot wall bell jar.

the rate of evaporation of ZnS is only of the order of 10^{-11} g/cm²/sec. In order to form films on surfaces at elevated temperatures it is necessary to carry out the evaporation in a vessel whose walls are uniformly at the substrate temperature. In any ordinary bell jar system the walls and the base are usually at a substantially lower temperature than the substrate and so act as a sink for ZnS.

This difficulty can be avoided by depositing the film on the wall of a uniformly heated spherical bulb with an evaporator at the center. This arrangement is shown in Fig. 1. The evaporator consists of a helical tungsten filament in which is placed a pellet of the phosphor. The bulb is pumped continuously and is in an oven to maintain a uniform wall temperature. A small flow of HCl is maintained through the bulb to make up for the loss of coactivator during the evaporation of the phosphor. The loss of host lattice material or activator through the connection to the pump is negligible, but the chlorine is more volatile and it is necessary to introduce some to make up for the losses. The HCl flow required is about 10,000 μl/g of phosphor evaporated.

To the extent that the bulb walls are at uniform temperature there is no tendency for the different phosphor components other than the coactivator to separate out, and the composition of the deposit will be the same as the material evaporated. The relatively high temperature of the walls during deposition insures diffusion of the activator uniformly throughout the film.

By this procedure Cu, Ag, and Mn activated ZnS phosphor films were made by evaporation of commercial powder phosphors. A number of sulfoselenide phosphor films have also been prepared in the same way. The films show both cathodo and photoluminescence when deposited at 650°C. As the deposition temperature is lowered, both of these decrease in efficiency but the effect on the photoluminescence is more marked. At 500°C the latter is negligible while the cathodoluminescence is still fairly efficient. Below this temperature the cathodoluminescence also falls off rapidly.

The phosphors prepared in this way show approximately the same emission and excitation spectra as the corresponding powder phosphors. Their brightness is 1/5 to 1/10 of that of the powders under the same excitation. The decay rate of the luminescence is usually higher for the films than for the corresponding powders.

While this procedure is very effective in forming films, the samples on curved bulb walls are unsuitable for many applications. Accordingly a system was devised for depositing the films on flat 2 in. diameter Pyrex disks. This system is shown schematically in Fig. 1b. It consists essentially of a small quartz chamber closed at the top and bottom by glass disks which seat against ground shoulders. The upper disk is the sample to be coated, the lower one is perforated for evaporator filament leads and HCl inlet tube. This chamber is essentially a demountable bulb. It is placed in a small quartz bell jar. The bell jar is coated on the outside with a conducting tin oxide coating having a resistance of about 30Ω between the silver paste ring electrodes. By passing a current through this coating the walls may be heated rapidly and uniformly to as much as 700°C. The bell jar is sealed by an "O" ring. The base plate is water cooled and an additional metal ring on top of the bell jar flange is also water cooled to protect the "O" ring.

Various cathodo, photo, and electroluminescent sulfoselenide phosphors have been made with this apparatus.

Reaction process for forming oxygen containing phosphors.—A number of oxygen containing phosphors may be formed by reaction of a vaporized substance with a heated substrate in a single step. One of these is Zn_2SiO_4:Mn. This is formed by reaction of ZnF_2:Mn with a heated substrate consisting of a high silica content glass such as fused quartz, Vycor, Pyrex, or Corning No. 1710. The glass substrate is maintained at a temperature in the 550°-650° range while ZnF_2:Mn is evaporated from a platinum evaporator filament. The ZnF_2 reacts with the SiO_2 of the glass according to the reaction

$$2ZnF_2 + 2SiO_2 \rightarrow Zn_2SiO_4 + SiF_4$$

The SiF_4 is volatile and is pumped out of the system leaving a layer of Zn_2SiO_4 well bonded to the glass. As the evaporation continues, the willemite becomes covered with a layer of ZnF_2. Thus the deposit consists of two layers; the Zn_2SiO_4 next to the glass and on top of this layer of ZnF_2. The ZnF_2 can be readily dissolved in NH_4OH leaving the insoluble film of willemite. The two-layer system of a yellow phosphor on top of green phosphor may also be used as a penetron (8, 9). This reaction method of forming willemite permits the formation on Pyrex or other high silica glasses at temperatures several hundred degrees below those required when the phosphor is formed by the two-step process.

Rottgardt (10) has described a related method of forming silicate phosphors by evaporating a fluoride onto a silicate base and subsequently carrying out the reaction by heat treatment in air.

An analogous process may be used to form a zinc borate phosphor. In this case a borate glass is used as the substrate and ZnF_2 again is evaporated. Since good borate glasses with sufficiently high melting points are not available this process is carried out with a borate glass glaze on the surface of No. 7052 FN glass. The resultant phosphor is a red cathodoluminescent zinc borate with an overlying layer of ZnF_2:Mn. The latter may be dissolved off in NH_4OH without damage to the zinc borate.

An analogous process can also be used with phosphate glasses. These, however, are low melting and unsatisfactory for many purposes. An alternative process is possible here. This is to first evaporate a layer of ZnF_2:Mn onto a Pyrex substrate at, say, 300°C, which is low enough to avoid reaction with the glass but high enough to insure good adhesion. The temperature is then raised to 550°C and a pellet of P_2O_5 is evaporated. This reacts with the ZnF_2 to form $Zn_3(PO_4)_2$:Mn.

Summary

A considerable number of zinc cadmium sulfoselenide phosphor films can be made by vacuum evaporation of commercial powder phosphors. Luminescent films of zinc sulfide activated with Cu, Ag, or Mn may be formed by deposition at room temperature followed by heat treatment in a suitable atmosphere. The same phosphors may be formed in a single step by evaporation onto a heated substrate in the "Hot Wall Bell Jar."

Manganese activated ZnS may also be formed in a single step by deposition on a substrate between 250° and 400°C.

Zinc silicate, phosphate, and borate may be formed in a single step by reaction of zinc fluoride with a heated substrate.

Thermoelectric and Crystallographic Properties of Ag_2Se

J. B. Conn and R. C. Taylor

Research Laboratories, Merck Sharp and Dohme, Rahway, New Jersey

ABSTRACT

Silver selenide has been prepared by fusion techniques and found to be a good thermoelectric material. The Seebeck coefficient, resistivity, and thermal conductivity have been measured as a function of temperature. The effect of doping with 30 different elements and compounds at different doping concentrations has been studied. The inter-relationships between the thermoelectric properties have been examined and are discussed. The crystal lattice of silver selenide has been determined, and the subcell and superstructure are elucidated.

During the past few years, this laboratory has been engaged in a study of thermoelectric materials. In the course of these investigations, the excellent properties of silver selenide were discovered. A thorough examination of the material was made, including crystallographic studies, temperature dependence of its thermoelectric properties, and effect of alloying and doping on these properties.

The semiconducting properties of silver selenide have been put to use in thermopiles by Schwarz (1). His n-type material was a silver sulfide-silver selenide alloy with a figure of merit of 0.9×10^{-3} deg^{-1}. The corresponding p-type material was an alloy of silver, copper, tellurium, and selenium with a figure of merit of 1.0×10^{-3} deg^{-1}. Resistivity and Hall effect of silver selenide have been studied by Mooser and Pearson (2) and by Busch and Junod (3). The energy gap and room-temperature electron mobility were also determined by Busch and Junod to be 0.075 ev and 2000 cm^2/v-sec, respectively. They found the material to show metallic behavior above the transition temperature of 133°C. They observed no measurable ionic conductivity. Miyatani (4) measured the properties of silver selenide via the emf of the galvanic cell $Ag/AgI/Ag_2Se/Pt$ and at 130°C determined the electron mobility to be 810 cm^2/v sec and the effective electron mass to be 0.11 m. Junod (5) recently published an extensive investigation of the crystallographic and semiconducting properties of silver selenide, silver sulfide, and copper selenide, including conductivity, Hall effect, Seebeck coefficient, and other properties.

Materials

Starting materials were sufficiently pure so that further purification was not considered necessary. Selenium was obtained in 99.999+% purity from American Smelting and Refining Company. Silver of 99.99+% purity from American Smelting and Refining and of 99.9999% purity from Consolidated Mining and Smelting Company of Canada, Ltd. was used. Doping materials were of a similar high purity.

Preparation.—All samples were prepared in 12 mm 1D quartz tubes which had been carbon-coated prior to introduction of the materials. Carbon-coating was accomplished by pyrolysis of acetone vapor (using nitrogen as a carrier gas) on the inside surface of the quartz tube at about 900°C. Carbon-coating had the reducing properties which are found so advantageous in graphite crucibles and so prevented reaction of oxides with the quartz. At the same time the undesirable absorption of selenium vapor into graphite was eliminated by substitution of the thin carbon coating. The materials were then introduced into the quartz tube in the desired composition, the tube evacuated to about 10^{-5} mm and sealed. The tube was kept at 1050°-1100°C for 16 hr followed by a 3-hr cooling period in the furnace, or a 24-hr drop time through a temperature gradient. No difference in properties was found between ingots prepared by the two different methods, nor were we able to produce more than slightly oriented ingots because of the phase change at 133°C. Ingots weighed about 40 g. After removal from the quartz tubes, the ingots were machined for measurement. Samples were found to be homogeneous, with clean, but slightly pitted surfaces. Except in the few cases where the quartz tubes cracked in cooling (and this was invariably found to be due to insufficient carbon coating) the ingots were free of surface oxidation. In most cases the ingots were malleable and easily machined. A few of the samples which had been doped with excess sulfur, selenium, tellurium, or silver iodide were found to be brittle; apparently the high vapor pressure of these doping agents produces internal cracks in the ingot. Many of the ingots were annealed at 125°C for 48 hr with no apparent effect.

Measurements

The samples were cut to approximately ¾ in. long and faced off on a lathe. Two rings were machined into the surface of the sample and into these rings platinum wires were tightly wound to act as the probe for a-c resistivity measurements. The sample was then placed between two resistance wire wound graphite heaters, and pressure for thermal and electrical contact was applied to the unit by a vise type jig. A temperature gradient of 5°-15° was maintained across the length of the sample by

power supplied from a d-c source to the resistance heaters. At thermal equilibrium ΔT was determined from two thermocouples placed through the center of each heater and in contact with the sample. The thermal emf was measured from the copper leads of each thermocouple. Measurements were made with a L&N type K-3 potentiometer. The measurement temperature was taken as the average between hot and cold ends of the sample.

Resistivity as a function of temperature was determined by means of current contacts made to the sample through the graphite heaters; the potential drop was measured across the platinum probes.

Thermal conductivity data were obtained by placing the sample between a copper sink in contact with an ice-water reservoir and a resistance heater; ΔT was measured with thermocouples placed in the sink and heater about 1 mm from the sample contact. The heat lost by conduction through the sample to the cold sink was balanced by the input to the heater, the temperature of which was kept within 1°C of ambient. K is calculated from the resistance and the current required to keep the heater at ambient.

Crystallographic Investigations

An extensive study of the structure of low-silver selenide was published by Boettcher, *et al.* (6). The unit cell was described as tetragonal, a = 7.06Å, c = 4.98Å, the axial ratio changing with temperature. The lattice was deduced as essentially selenium packing, with silver atoms occupying random sites in the interstices.

Numerous samples of cast silver selenide have been subjected to x-ray diffraction study during the course of this work, and the patterns were sensibly the same, save for crystal ordering. However, far too many reflections were present to be accounted for on the basis of Boettcher's tetragonal axes. On the other hand, an assignment was arrived at on the basis of a 4-molecule orthorhombic unit cell, a = 4.344Å, b = 7.111Å, c = 7.790Å; this reproduced nearly all of the observed reflections exactly, the exceptions being occasional split lines, one member of which could not be incorporated unless all axes were doubled. This suggested the existence of a superstructure, but its nature remained in doubt until completion of the experiment described below.

It was decided to attempt direct preparation of crystalline low-silver selenide by wet process at room temperature, involving reaction of a water-soluble silver salt with a soluble selenide. Since the silver chalcogenides are soluble in alkali cyanide solutions, it was anticipated that interaction of potassium silver cyanide with potassium selenide would provide a crystallization medium for silver selenide. Accordingly, a concentrated solution of silver(I) oxide in potassium cyanide, having composition $K_3Ag(CN)_4$, was added gradually to a freshly prepared strongly alkaline solution of the stoichiometric amount of potassium selenide under stirring and nitrogen atmosphere. The precipitate produced at first was black and finely divided, but when about half of the silver cyanide reagent had been added, a rapid transformation set in, with conversion to a gray, coarse, and very bulky solid. After completion of the metathesis, the product was collected, washed, and dried *in vacuo*.

Under the microscope the particles were seen to consist of globular rosettes of lustrous minute prisms; the x-ray diffraction pattern was essentially that of all other low-silver selenide samples but was exceptionally bright, and showed a wealth of detail not previously observed. The analytical data were surprising and at first sight very disappointing: the Ag/Se ratio was 2.28, a large divergence from the stoichiometric. It was noticed however, that this ratio is 16/7 within the accuracy of the microanalytical determination.

For $Ag_{16}Se_7$, F. W. 2278.8,	Calc.	Found
Ag	75.75	76.1
Se	24.25	24.4
	100.00	100.5

The x-ray diffraction data were then worked up (Norelco Wide-Range Diffractometer, CuKα radiation). The spacings fit an orthorhombic unit cell, a = 8.630Å, b = 14.13Å, c = 15.50Å, and containing $4Ag_{16}Se_7$. The calculated density is 8.00; observed pyknometrically, 7.96. The subcell contains $4Ag_2Se$; the superstructure is derived from it by a systematic vacancy at every eighth selenium lattice site. The formation of this defect phase is all the more striking when it is recalled, as stated above, that it began to crystallize in the presence of a large excess of selenide ion.

Inspection of the phase diagram for the system Ag-Se, as published by Hansen (7), shows that a homogeneous phase of composition $Ag_{16}Se_7$ cannot be attained from a melt, since a liquid miscibility-gap intervenes. Indeed, when the powder was melted in sealed quartz under vacuum, the resulting ingot was coated with silver. Evidently, when high-silver selenide, which is stoichiometric, is cooled through the transition, it can only approximate the structure of the true low-temperature phase.

The question concerning the tetragonal phase described by Boettcher becomes even more puzzling in view of the recent publication of Junod (5) who states that his x-ray diffraction data were in complete agreement with Boettcher. The present authors have had opportunity to discuss this matter with members of the research staffs of other organizations, who also have studied low-silver selenide; they found as we did, that the system is not tetragonal. In fact, one group arrived independently at an orthorhombic axial assignment in close agreement with our own data for the subcell. It can only be surmised that if the tetragonal phase does exist, it must be a metastable transitional form.

Thermoelectric Properties

Stoichiometric silver selenide.—Silver selenide is a semiconducting material with orthorhombic symmetry at room temperature. At 133°C it undergoes a transition to a cubic lattice. The melting point is 897°C. According to the phase diagram (7), the range of miscibility in the liquid state of excess silver or selenium in silver selenide extends from 32 to 44.5 at. % selenium. Beyond these limits a layered ingot results on cooling from the melt.

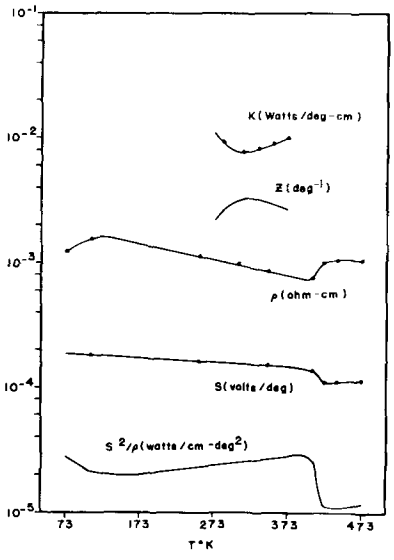

Fig. 1. Variation of thermoelectric properties of stoichiometric silver selenide with temperature.

The variation of the thermoelectric properties of silver selenide with temperature is shown in Fig. 1. The Seebeck coefficient shows a linear decrease from −167° to 120°C, then falls sharply at the transition temperature of 133°C, followed by a slow rise to 220°C. The data of Junod (5) show an increase in Seebeck coefficient to about 0°C followed by a decrease to the transition point, then a sharp break at the transition point. While our studies indicate a decrease in Seebeck coefficient of only about 40 μv/°C through the transition point, those of Junod show a decrease of about 80 μv/°C.

Silver selenide exhibits typical nondegenerate semiconductor behavior in its resistivity, which decreases with increasing temperature from −180°C to the transition point. Here a sudden increase in resistivity occurs followed by a slow rise. Thus the cubic high-temperature form exhibits the behavior of a metal or degenerate semiconductor, as reported by Junod. His data, while being in substantial agreement with ours, show a decrease in resistivity through the transition point, this being followed by a slow increase.

Table I. Room temperature properties of Ag_2Se

R(cm^3/coulomb)	μ(cm^2/v-sec)	n(cm^{-3})
2.2	2050	2.8×10^{18}
S(μv/°C)	ρ(ohm-cm)	k(watts/deg-cm)
−150	10.2×10^{-4}	0.009

The thermal conductivity curve shows a minimum at room temperature. An increase occurs as the temperature increases due to the presence of transport processes other than those associated solely with electrons or phonons, such as ambipolar diffusion. The increase as temperature decreases is a result of reduced phonon-phonon interactions. A maximum figure of merit, in excess of 3.0×10^{-3} deg^{-1} occurs at about 40°C.

A summary of the room temperature properties of stoichiometric silver selenide are shown in Table I. These values are found to be in close agreement with those of Junod.

Effect of doping.—The thermoelectric properties are listed in Table II. With the exception of Cu, AgI, and the group IIB elements, doping agents had very little effect on Ag_2Se. In many cases, the thermoelectric properties are identical for a particular element at the doping levels of both 0.1 and 0.5 mole %, indicating that Ag_2Se is saturated with respect to that element at <0.1 mole %. This low solubility of most foreign materials in Ag_2Se is a prime factor in its insensitivity to doping. It is obviously impossible to p-dope silver selenide, a phenomenon which has been observed in other cases such as ZnSb (8).

The reproducibility of Seebeck coefficient for duplicate ingots, with very few exceptions, has been excellent. Reproducibility of resistivities was not

quite as good, especially in the case of stoichiometric Ag_2Se, where Seebeck coefficient for six samples is within the limit of −146 to −153 μv/°C while ρ covers a range of 7.7 to 13.3 ohm-cm.

The effects of the various doping agents can be considered from the viewpoint of the periodic groups of elements. Only the effect on one parameter need be discussed, since the value of one determines the values of the others, as will be seen in the following sections.

Elements of groups IB and IIB are the only ones to show a large effect on the thermoelectric properties. In group IB, the order of effect is Cu > Ag > Au. In group IIB, the order is reversed, being Hg > Cd > Zn. The order in the group IIB elements parallels the energy gaps of the selenides of these elements, as shown in Table III.

In both cases metallic behavior is approached as one goes from Zn to Cd to Hg. The energy gap of Ag_2Se is 0.075 ev (3). The compound Au_2Se does not form. The energy gap of Cu_2Se is not known but is most likely lower than that of Ag_2Se, since the Seebeck coefficient and resistivity of Cu_2Se are lower than those of Ag_2Se. Thus in the group IB elements, metallic behavior would be approached in the order Au-Ag-Cu, as shown in Table IV. The implication of the reverse trends in the two groups in their doping action on Ag_2Se is that the elements form their normal bond patterns rather than entering in simple isomorphous replacement.

Group VIA has no effect whatsoever, the Seebeck coefficient remaining in the range of −150 μv/°C at both doping levels for S, Se, and Te. If, as mentioned previously, elements form their normal selenide bonds, this would explain the lack of effect of the VIA elements. Groups IIIA (Al, Ga, In, Tl), IVA (Ge,Sn,Pb), and VA (P,As,Sb,Bi) all behave similarly, lowering the Seebeck coefficient to the range of −120 μv/°C at 0.5 mole %. Apparently all but Sn and As saturate Ag_2Se at less than 0.1 mole %, accounting for the leveling of Seebeck coefficient at −120. The transition elements displayed widely divergent effects on the properties, no trends being obvious.

As shown in Fig. 3 and 4, the samples mainly fall into two groups, one with a Seebeck range of 115-125 μv/°C and the second with a range of 145-155 μv/°C. The average figure of merit of 18 materials in the 145-155 range is 2.4 x 10^{-3} deg^{-1}, with six of the samples exceeding 2.5 x 10^{-3} deg^{-1}. The average Z in the 115-125 range, for 19 alloys is 2.2 x 10^{-3} deg^{-1}, with only one exceeding 2.5 x 10^{-3} deg^{-1}.

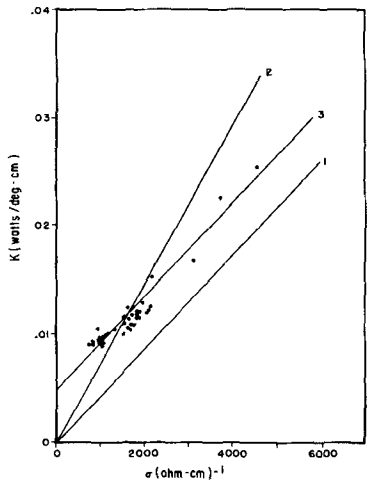

Fig. 2. Electrical conductivity vs. thermal conductivity for stoichiometric and doped samples of silver selenide at room temperature. Curve 1, Wiedeman Franz law, nondegenerate semiconductor, $Kel\rho = 4.35 \times 10^{-6}$ v^2/deg. Curve 2, Wiedeman Franz law, metals, $Kel\rho = 7.35 \times 10^{-6}$ v^2/deg. Curve 3, silver selenide.

Relationship between K and σ.—The relationship between thermal and electrical conductivity at room temperature is shown in Fig. 2. Line 1 represents the Weidemann-Franz ratio for nondegenerate semiconductors (<2.5 x 10^{19} carriers cm^{-3}), where $Kel/\sigma = 4.35 \times 10^{-6}$ V^2/deg. Line 2 is the Wiedemann-Franz ratio for metals (or degenerate semiconductors) where $Kel/\sigma = 7.35 \times 10^{-6}$ V^2/deg. Line 3 is that for the experimentally determined values for Ag_2Se, stoichiometric and doped, where K is the sum Kel + Kph. It is seen that a straight line relationship exists between K and σ for silver selenide which parallels the Wiedemann-Franz law for nondegenerate semiconductors. Since Ag_2Se is then a nondegenerate semiconductor, the ratio $Kel/\sigma = 4.35 \times 10^{-6}$ V^2/deg must hold. Extrapolation of the data to $\sigma = 0$ yields a Kph value of 0.0046 watts/deg-cm. By reducing the thermal conductivity values of the silver selenide samples 0.0046 watt/deg cm, it is found that the line for Ag_2Se and that for nondegenerate semiconductors coincide. The average product $Kel\rho$ for all samples is 4.37 x 10^{-6} V^2/deg, as necessitated by the Wiedemann-Franz law. Any deviation from line 3 for any silver selenide samples can be attributed theoretically to some degree of structure doping, which would then alter the lattice contribution, Kph, from its value of 0.0046 watt/deg-cm. Deviation of the product $Kel\rho$ from 4.35 x 10^{-6} V^2/deg is then a measure of the crystal disorder, except at very high conductivities where the materials become degenerate.

Relationship between S and σ.—The relationship existing between Seebeck coefficient and electrical conductivity is shown in Fig. 3. A large scattering exists at the high conductivity end of the line. As doping agents inject a higher concentration of carriers, electrical conductivity increases and Seebeck coefficient decreases. The values of $S^2\sigma$ remain within the region of 2-3 x 10^{-5} watts/cm-deg^2, for materials with Seebeck coefficients between −90

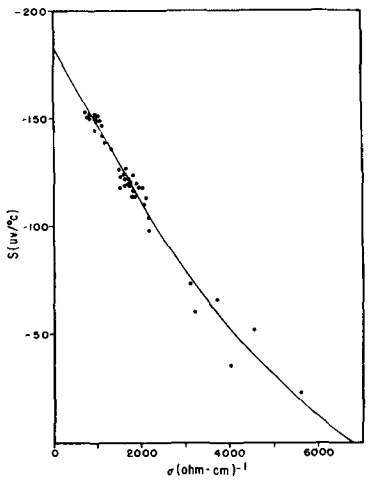

Fig 3. Electrical conductivity vs. Seebeck coefficient for stoichiometric and doped silver selenide at room temperature.

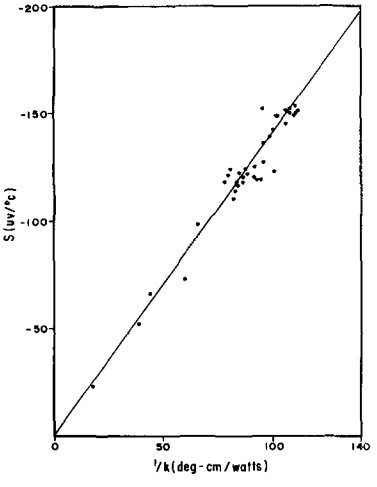

Fig. 4. Thermal resistivity vs. Seebeck coefficient for stoichiometric and doped samples of silver selenide at room temperature.

and −150 μv/°C. The highest values of $S^2\sigma$ are found in the Seebeck coefficient range of −120 μv/°C; however, their Z values are lower than those in the −150 μv/°C range due to higher thermal conductivity.

Relationship between S and K.—The product of Seebeck coefficient and thermal conductivity is remarkably constant at 1.4, resulting in a straight line passing through the origin when Seebeck coefficient is plotted against thermal resistivity, as shown in Fig. 4. The constancy of this product suggests a considerable phonon drag term in the Seebeck coefficient, the product being (Sel + Sph) (Kel + Kph). If no phonon term were present for S, the product would not be expected to be constant any more than it would be for ρ (Kph + Kel), since one term would be entirely electronic, and the other both electronic and phonon. Thus the product Sel σ is probably constant as is Kel ρ. However, the problem of determining Sel presents far more difficulty than does Kel since only a certain proportion of the phonon activity contributing to K will contribute to S. A wavelength requirement for phonons must be met before they will contribute to S. This requirement is that only phonons which have wave lengths not less than the electron wave length will contribute to S.

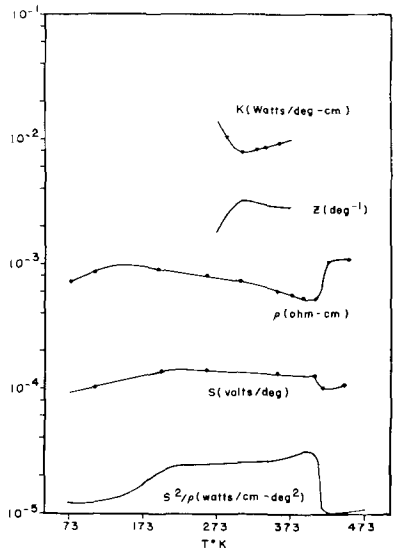

Fig. 5. Variation of thermoelectric properties with temperature of silver selenide doped with 0.1 mole % P.

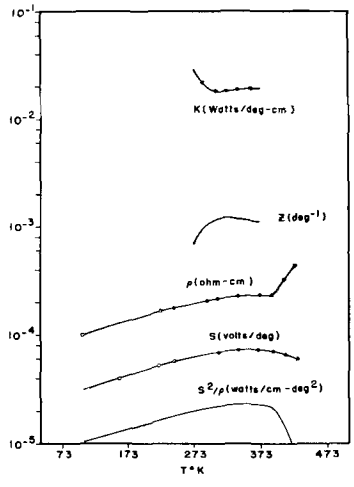

Fig. 6. Variation of thermoelectric properties with temperature of silver selenide doped with 0.1 mole % Hg.

Phonons satisfying this requirement possess a much longer free path length than the bulk of the phonons, and these phonons possess the most marked directional properties along the temperature gradient (9). Therefore the effect of dragging of electrons by such phonons is particularly large. The number of phonons possessing these long wave lengths is probably extremely dependent on crystal perfection. Normally a phonon wave length ranges from one to a few atomic distances, while electronic wave lengths may easily exceed 10 atomic distances.

Effect of temperature on doped Ag_2Se.—The temperature dependence of Seebeck coefficient, resistivity, and thermal conductivity of silver selenide doped with 0.1 mole % phosphorus and 0.1 mole % mercury was investigated. The results are shown in Fig. 5 and 6. The Seebeck coefficient for phosphorus-doped Ag_2Se increases fairly rapidly with temperature to a maximum at about −40°C and then falls slowly to the transition temperature where a sharp drop occurs, followed by a rise to 175°C. In the mercury-doped sample, the Seebeck coefficient increases with temperature to a maximum at 95°C, followed by a decrease at the transition point which is more

gradual than for the stoichiometric or phosphorus-doped samples.

In its resistivity, phosphorus-doped Ag_2Se behaves in a fashion similar to the stoichiometric material except that degenerate conduction exists below −120°C. Mercury-doped Ag_2Se, on the other hand, acts as a degenerate semiconductor throughout the entire temperature range as would be expected from its low resistivity.

The variation of thermal conductivity and figure of merit with temperature is similar to that for Ag_2Se. Thermal conductivity minima in all cases occur at about room temperature. It can be seen that the high-temperature increase in thermal conductivity is much more gradual for the mercury-doped sample. Since this material is degenerate, ambipolar diffusion, if it occurs at all, will have much less effect at higher temperatures due to the larger number of excess carriers present.

Stoichiometric and mercury-doped silver selenide alike display a maximum figure of merit at about 40°C. However, the maximum figure of merit for mercury-doped Ag_2Se is only 1.2×10^{-3} deg^{-1} as against 3.3×10^{-3} deg^{-1} for the undoped compound. Phosphorus doping shifts the maximum to about 30°C and is 3.2×10^{-3} deg^{-1}.

Conclusions

Silver selenide has been found to be a good thermoelectric material. It has a figure of merit of the order of 3×10^{-3} deg^{-1} in the vicinity of room temperature. It has been found impossible to p-dope silver selenide. The stoichiometric material shows the best thermoelectric properties, no improvement being obtained by doping. The compound is nondegenerate from −167°C to the transition point of 133°C, after which its behavior is metallic. Doping was found to occur by formation of normal bond patterns. Kph for silver selenide is 0.0046 watt/°cm, and it is believed that a phonon drag term exists in the Seebeck coefficient. The material becomes degenerate if doped with mercury. The favorable combination of electrical and thermal conductivities characteristic of low-Ag_2Se is ascribed to the existence of a crystal superstructure based on an orthorhombic defect phase having composition $Ag_{16}Se_7$.

Acknowledgments

The authors wish to thank Dr. G. V. Downing and associates for measurements of the thermoelectric parameters.

Separation of Sulfur, Selenium, and Tellurium from Arsenic

J. M. Whelan, J. D. Struthers, and J. A. Ditzenberger

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Three methods have been investigated for separating trace amounts of sulfur present in high-purity arsenic. These are: (*a*) vacuum sublimation, (*b*) sublimation in a hydrogen stream, and (c) distillation of arsenic from an arsenic-lead solution. The last method is somewhat more effective than the second. The first was unsatisfactory. The lead process yielded arsenic containing the following atom fractions of sulfur, selenium, and tellurium; 1×10^{-9}, $\leq 2.7 \times 10^{-8}$, and $\leq 2 \times 10^{-8}$, respectively. Concentrations of these impurities were measured with the aid of radiotracer techniques.

Arsenic of high purity is required for the preparation of the semiconductors InAs and GaAs. The atom fractions of sulfur and selenium in available "semiconductor grade" arsenic are in the range 0.2 to 5×10^{-6}. These impurities are donors in the above semiconductors which cannot be removed readily by zone refining because of their unfavorable distribution coefficients (1-5). The donor concentrations, $\sim 2 \times 10^{16}$ cm^{-3}, in better samples of InAs and GaAs can be attributed to the residual amounts of sulfur and selenium in the arsenic.

A number of methods have been proposed to reduce further the concentration of sulfur in arsenic. These are: (*a*) vacuum sublimation (6), (*b*) sublimation in H_2 (5, 7), (c) condensation into Pb followed by distillation (7), (*d*) repeated oxidation and reduction with carbon (8), and (*e*) H_2 reduction of redistilled $AsCl_3$ (9). These methods have been

evaluated primarily by differences in the carrier concentrations and mobilities of InAs samples made from the initial and purified As. This evaluation is subject to a number of uncertainties such as the purity of the indium and contamination associated with the InAs preparation. However, the Pb condensation-distillation proposed by Harman, Stambaugh, and Goering was somewhat more promising than the others. An atom fraction of sulfur in the arsenic equal to 9×10^{-7} would account for the net donor concentration in their InAs. Compensation or other donor impurities would either raise or lower this estimate.

We re-examined the vacuum sublimation, H_2 sublimation, and Pb condensation-distillation methods for their relative efficiencies for reducing the sulfur content in arsenic. As will be described, we found the Pb condensation-distillation to be more effective than the others. Quantitative results are given later to indicate the residual concentrations of sulfur, selenium, and tellurium in arsenic purified by this method. Concentrations of the above impurities were measured by radiotracer techniques. By the use of radioactive tracers it is possible to determine concentrations of sulfur, selenium, and tellurium which are lower by several orders of magnitude than can be determined by chemical, spectrographic, or spectrophotometric methods. Sulfur[35] was obtained as BaS in $Ba(OH)_2$ solution and converted to As_2S_3 for arsenic doping. Radioactive Se and Te were used directly after irradiation at the Brookhaven reactor in a flux of 8×12^{12} neutrons/cm^2/sec for 31 days. Beta counting was used for the powdered arsenic samples containing sulfur and tellurium. Gamma counting was used for those samples containing selenium.

The three methods used for separating trace amounts of sulfur from arsenic are based on the relative vapor pressures of arsenic and the sulfur species. At low concentrations, ~ 1 ppm, sulfur is probably present in arsenic as a solute, As_2S_2. The relative difference in vapor pressure of this sulfide and arsenic (1.0 and 0.4 atm, respectively, at 565°C) is probably too small for the degree of separation desired under ideal conditions by a single sublimation. Sublimation in hydrogen favors the reduction of the sulfide in the vapor phase to $H_2S(g)$ and $As_4(g)$. Arsenic is condensed in the exhaust hydrogen stream. It is desirable to use a high ratio of H_2 to As_4 partial pressures to shift the equilibrium to the right for the reaction: $As_2S_2(g) + 2H_2(g) = \frac{1}{2} As_4(g) + 2H_2S(g)$. The third method consists of dissolving arsenic in lead followed by distillation from the resulting solution. Many metals form stable sulfides with low vapor pressures. Lead was a particularly good choice because it does not form arsenides. This facilitates the arsenic recovery by distillation.

Experimental

The first series of experiments were intended to determine the relative effectiveness of the three processes for separating small amounts of sulfur from arsenic. Arsenic, containing an estimated sulfur concentration of 1-10 ppm, was mixed with an amount of radioactive sulfur equivalent to 2 ppm of the arsenic. This mixture was sublimed twice to mix the tracer sulfur with that originally present. The arsenic was condensed as a rod during the second sublimation. The end and center sections were analyzed to determine their relative sulfur concentrations. Absolute concentrations were not obtained because of the uncertainty of the sulfur concentration originally present in the arsenic. Intermediate sections of the arsenic rod were used for the separation experiments described below. The initial sulfur concentrations of these sections were taken as averages of the appropriate end and center sections. One section of the above rod was sublimed in a sealed quartz tube 50 cm long which had been previously evacuated. This tube was heated uniformly to 600°C and then one end cooled to 350°C. The resulting temperature gradient was maintained for 58 hr. Arsenic condensed in the cold end to form a rod 22 cm long. The rod was then divided into five approximately equal sections. The first and last section corresponded to the coldest and hottest sections of the rod, respectively. Sulfur concentrations of the five sections are listed in the first column of Table I. The initial sulfur atom fraction is 1.6 α where α is a constant having a value between the limits 10^{-5} to 10^{-6}. As previously mentioned, the uncertainty in the value of α arises from the uncertainty in the sulfur concentration of the arsenic before doping with tracer sulfur. After sublimation, the first and last sections to condense had atom fractions of sulfur equal to 2.7 α and 1.0 α, respectively. The small difference between these concentrations illustrates the limitations of simple vacuum sublimation for separating trace amounts of sulfur from arsenic.

A second arsenic sample in which the sulfur atom fraction was 1.4 α was sublimed in a hydrogen stream at 450°C. The hydrogen at 1 atm was first passed through a charcoal trap at 78°K and then over the arsenic at 450°C at a rate of approximately 400 cc/min. From the time required to sublime the arsenic, we estimated the ratio of H_2 to As_4 pressures to be between 100 and 200 to 1. The atom fraction of sulfur in the arsenic collected in the exhaust stream was 0.004 α, a substantial reduction from 1.4 α in the starting material.

The sulfur atom fraction in the arsenic used for the Pb-condensation-distillation experiment was 2.0 α. This arsenic was condensed into lead at 550°C contained in a sealed tube. The weight ratio of arsenic to lead was 1:2. It was then distilled from the solution at 535° and condensed into a cooler region

Table I. Relative effectiveness of vacuum sublimation, H_2 sublimation, and Pb condensation-distillation for separating trace amounts of sulfur from arsenic

	Vacuum sublimation	Sublimation in H_2	Pb condensation and distillation
Initial atom fraction of S in As	1.6 α	1.4 α	2.0 α
Final atom fraction of S in As	1st fraction 2.7 α 2nd fraction 1.6 α 3rd fraction 1.4 α 4th fraction 1.5 α 5th fraction 1.0 α	0.044 α	<0.001 α
	$10^{-5} > \alpha > 10^{-6}$		

of the tube. The atom fraction of the sulfur in the recovered arsenic was equal to or less than the detection limit, 0.001 α. These results are summarized in Table I.

The lead condensation-distillation was somewhat more effective than sublimation in hydrogen for removing small amounts of sulfur from arsenic. The latter method would not be expected to be as good for separating small amounts of selenium and tellurium from arsenic because of the lower stability of H_2Se and H_2Te. Lead selenide and telluride are stable. They were expected to have low vapor pressures when diluted with a large excess of lead at temperatures in the range of 600°-700°C. The experiments described below illustrate the effectiveness of the lead method for separating trace amounts of sulfur, selenium, and tellurium from arsenic. The example for sulfur differs from the previous one in that isotopic dilution effects were greatly reduced.

The arsenic used in these experiments was supplied by American Smelting and Refining Co. Estimated atom fractions of sulfur, selenium, and tellurium in the arsenic are $\sim 2 \times 10^{-6}$, $\sim 10^{-7}$, and $< 10^{-7}$, respectively. Those for sulfur and selenium were furnished by the supplier and that for tellurium was based on the failure to detect it by mass spectrographic means (10). Dilution errors associated with tracer techniques were minimized by first doping the arsenic with the large amount of the appropriate tracer impurity in comparison to that originally present. An amount of radioactive sulfur as As_2S_3 equivalent to 500 times the sulfur originally present was sealed in an evacuated quartz tube with the first arsenic sample. This was sublimed and condensed six times from one end of the tube to the other at approximately 600°C to insure adequate mixing. The sample was then crushed and resublimed to form a rod. After discarding the ends of this rod, the remainder was divided into five sections. The end and center sections were analyzed for their sulfur content. Averages of these were used to estimate the concentration of the two remaining pieces prior to purification by distillation from lead. The minimum and maximum atom fractions of sulfur were 1.1 and 3.9×10^{-6}. These figures combined with those in Table I show that sublimation is a satisfactory method for reducing the atom fraction of sulfur in impure arsenic to $\sim 10^{-6}$.

Radioactive elemental selenium was mixed with another arsenic sample in the same manner as that described above for mixing arsenic and As_2S_3. The minimum and maximum limits for the atom fraction of selenium in this sample were 1.0 and 1.7×10^{-4}. The large amount of selenium in the final arsenic suggests that simple sublimation is relatively ineffective for separating even moderate amounts of selenium from arsenic.

Tellurium doped arsenic was prepared by subliming twice a mixture equivalent to an atom fraction of radioactive tellurium of 10^{-6}. The tellurium atom fraction in the center portion of the final arsenic prior to the purification was between 1.3 and 2.4×10^{-7}.

Each of the arsenic samples prepared for purification was sealed in an evacuated quartz tube with twice its weight of high-purity lead and placed in a vertical tubular furnace. The bottom of the tube containing the lead was maintained at 600°C and the upper portion between 600° and 650°C. The arsenic dissolved in the lead overnight. Following this, the thermal gradient of the furnace was readjusted to give a uniform temperature of 600°C. Arsenic was distilled from the solution by gradually withdrawing the tube from the furnace and allowing the arsenic to condense in the upper colder section. This section containing the arsenic was sealed off and an additional amount of arsenic was distilled and condensed after increasing the temperature of the lead solution to 700°C. The arsenic fractions distilled from the lead at 600° and 700°C were analyzed for sulfur, selenium, and tellurium. Atom fractions of sulfur, selenium, and tellurium in the arsenic distilled from the lead solution of 600°C were 1.1×10^{-9}, $\leq 2.7 \times 10^{-8}$ and $\leq 2 \times 10^{-8}$, respectively. The major errors in concentrations of sulfur, selenium, and tellurium found in the purified arsenic result from errors in the preparation of the comparison standards and from the statistical fluctuations inherent in counting data. It is estimated that the analytical data are accurate to within ±25%. The average arsenic yield was 65% when distilled from the solution at 600° and 84% at 700°C. However, the atom fractions of sulfur and selenium in the fractions distilled from the solution of 700°C were substantially higher, 6.6×10^{-8} and 7.4×10^{-7}, respectively. No change was observed in the tellurium concentration of the condensate even when the temperature of the lead solution was raised to 760°C. These results are summarized in Table II. The weights of the initial doped arsenic samples varied between 1.5 and 5 g. Increasing the amount of arsenic to 250 g and maintaining the 1:2 weight ratio of arsenic to lead has raised the average yield distilled from the lead solution of 600°C to 85%.

Discussion

Lead has a vapor pressure of $\sim 10^{-3}$ mm at 600°C. Therefore, one expects to find a small concentration

Table II. Effectiveness of Pb condensation and distillation for separating sulfur, selenium, and tellurium from arsenic

	Sulfur	Selenium	Tellurium
Initial atom fraction	1.1 to 3.9×10^{-6}	1.0 to 1.7×10^{-4}	1.3 to 2.4×10^{-7}
Atom fraction in As distilled from Pb bath at 600°C	1.1×10^{-9}	$\leq 2.7 \times 10^{-8}$	$\leq 2 \times 10^{-8}$
Atom fraction in As distilled from Pb at 700°C	6.6×10^{-8}	7.4×10^{-7}	$\leq 2 \times 10^{-8}$

of lead in the arsenic after separation of sulfur, selenium, and tellurium. Before using the arsenic to prepare GaAs, it is resublimed twice. The lead concentration after this is ~ 1 ppm. Concentrations of 1 ppm of lead in arsenic are not nearly as serious as similar concentrations of sulfur and selenium, because the lead can be readily removed from GaAs by zone refining. Its distribution coefficient is < 0.02 (4).

The results in Table II indicate that even lower concentrations of sulfur and selenium in arsenic could be obtained by distilling the arsenic from the lead solution at a lower temperature. The only disadvantage to using a lower temperature is the reduction in arsenic yield due to a lower arsenic vapor pressure. Distillation below 550°C would require a more dilute solution of arsenic in lead in accordance with the As-Pb phase diagram. This would further reduce the arsenic yield.

Assuming arsenic is the only source of sulfur, selenium, and tellurium in GaAs or InAs, the equivalent concentrations in these compounds to those in Table II would be 2×10^{13}, $\leq 6 \times 10^{14}$, and $\leq 4 \times 10^{14}$ atoms cm^{-3}, respectively. Weisberg and Rosi noted a difference in the electrical properties of InAs made from arsenic distilled from lead when the lead arsenic solution was first equilibrated at 600° and 750°C prior to distillation from the solution at 600°C (5). The InAs made from arsenic equilibrated at the higher temperature had a net donor concentration of 1.4×10^{16} whereas arsenic equilibrated at 600°C yielded InAs with a net donor concentration of 2.7×10^{16} cm^{-3}. These differences are not likely to be due to differences in the sulfur and selenium concentrations in the two arsenic samples in light of the data in Table II.

Conclusion

Simple sublimation is not a satisfactory method for separating trace amounts of sulfur from arsenic. Sublimation in hydrogen is somewhat less effective than distillation of arsenic from a lead-arsenic solution. The latter method has been used to reduce the atom fractions of sulfur selenium and tellurium in arsenic to 1×10^{-9}, $\leq 2.7 \times 10^{-8}$, and $\leq 2 \times 10^{-8}$, respectively.

Electrolytic Vanadium and Its Properties

D. H. Baker, Jr.,[1] and J. D. Ramsdell

U. S. Bureau of Mines, Boulder City, Nevada and Reno, Nevada, respectively

ABSTRACT

The fused salt electrorefining technique has been applied successfully to vanadium. The electrolyte was sodium chloride containing 3-6% vanadium as vanadium dichloride. Current efficiency was approximately 91%. Oxygen and nitrogen impurities were reduced by two thirds of the amount contained in the feed material. The hardness of the product was reduced from 97 Rockwell B to 35 R_B. Arc melted ingots could be given a 99% cold reduction by rolling before edge cracking appeared.

Growing interest and the industrial need for purer metals and improved alloys for application under high-temperature and high-speed conditions has demanded the elimination and/or control, as far as possible, of impurities.

As a part of this program of intensified research, the Federal Bureau of Mines Reno Metallurgy Research Center and the Boulder City Metallurgy Research Laboratory have undertaken a joint investigation to produce and evaluate high-purity vanadium.

In the past few years the Bureau of Mines has developed and proved the technical feasibility of fused salt electrorefining of metals such as titanium (1), beryllium (2), hafnium (3), zirconium, to remove impurities, such as O_2 and N_2, as well as certain other elements.

Fused salt refining of vanadium was considered because the gaseous impurities, nitrogen and ox-

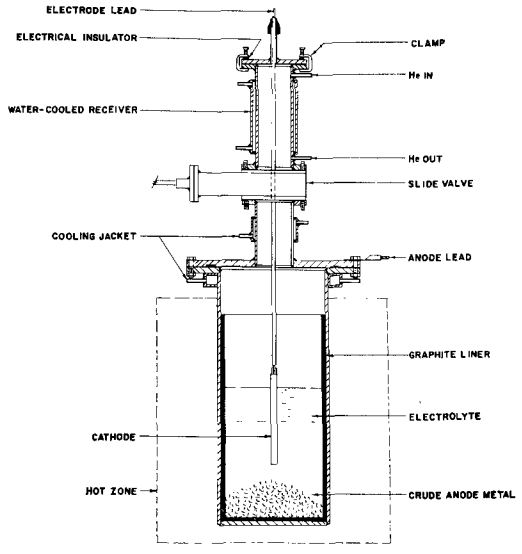

Fig. 1. Schematic drawing of cell

ygen, which can be controlled by this technique, have serious effects on vanadium's physical properties. Commercially, the production of low nitrogen-oxygen vanadium is an expensive, complicated and time-consuming process by any of the standard reduction techniques.

Since the fused salt electrorefining technique has shown the ability to control gaseous impurities in other reactive metals such as titanium and has been scaled up to a 10,000-amp cell, the technique offered a means of improving the quality of technical grade vanadium at something approaching a commercial scale.

This investigation was undertaken to ascertain the feasibility of applying the fused salt electrorefining method to the production of a metal product exceeding the purity of present commercial vanadium metal (99.5 V). The principal specific object was to improve the ductility of the final product by removing oxygen and nitrogen.

Description of Process

Input material.—The anode, or feed material, is commercially produced vanadium metal having a Rockwell B hardness of 97 and containing, according to the producer, 99.5% V, 0.30 Fe, 0.18 O_2, 0.03 N_2, 0.006 H_2, and 0.03 Cr.

Equipment.—Figure 1 is a schematic diagram of the 12-in. diameter electrolytic cell used. This cell was identical to those used for refining titanium metal, except for a graphite liner to minimize iron contamination of the bath. A receiving chamber and valve system permitted the introduction and removal of the cathode without disturbing the inert atmosphere of the cell proper.

External heat was used to maintain the electrolyte at an operation temperature of about 800°C.

Vanadium metal, crushed to $-\frac{1}{2}$ in., was charged to the bottom for the anode. On the basis of experience gained in operating similar cells on other metals, the minimum ratio of the cathode to the anode area was fixed at 1:3. Under higher anode areas, exceeding the minimum, more operative stability was obtained. The cathode used in the 12-in. diameter cell was a $\frac{3}{4}$-in. diameter iron rod.

Vanadium chloride was applied to the 60-lb sodium-chloride bath through the reaction of chlorine gas and a small amount of admixed hydrogen chloride with the granular anode metal contained in the cell bottom. The reaction of hydrogen chloride alone with the vanadium anode material was extremely slow. The hydrogen evolved from the hydrogen chloride passed from the chlorinator and through the bath assisting in the purification of the sodium chloride. The off gas was permitted to escape from the cell through an oil bubbler.

Working procedure.—The cathode, cleaned and burnished, was introduced into the cell through the receiving chamber above the bath compartment. The receiving chamber was evacuated and charged with inert gas (helium), after which the cathode was lowered into the bath through a valve. Prior to use, the cathodes were stored in a drying oven under controlled low-humidity atmosphere.

Upon completing the cathode placement, the appropriate voltage was applied for the particular test, and the refining process was conducted.

On completion of the "run," the cathode, bearing the product metal, was withdrawn into the upper cell chamber, previously evacuated and charged with inert gas, to cool before final removal from the cell.

Deposits were leached with a 2-3% HCl solution to dissolve the entrained salts and subjected to agitation in a high speed mechanical agitator to separate the metal crystals. Salt-free metal crystals were then washed with acetone to assist in the rapid removal of moisture and sized through the appropriate screens.

Testing the product.—The general quality of the product was quickly determined on the basis of hardness tests alone for preliminary "run" evaluation purposes. Individual run products shown to be similar by chemical and hardness evaluation were composited for further study. Compacts of the crystalline vanadium powders weighing 10-70 g were melted into buttons or cigar-shaped ingots in a tungsten electrode arc furnace under helium. Ingots were homogenized by remelting five times, being turned over after each melt. Samples were also taken for complete analysis or for semiquantitative analysis. Hardness was found to correlate reasonably well with the degree of purity. The relation of hardness to oxygen content is shown in Fig. 2.

Investigations

A total of 127 cycles or runs were made in the 12-in. cell before the graphite liner failed terminating the operation. The specific factors contributing to the failure of graphite were primarily the result of stresses arising from thermal cycles of the iron container and graphite liner. No evidence of corrosion or reaction with the graphite were detected as illustrated by the metal analysis of less than 0.01% carbon.

When the cell was placed in operation, the electrolyte contained 2.8% soluble vanadium. The first three cycles were made for the purpose of conditioning the electrolyte, a total of 68 amp-hr at 0.2 v. Very fine, needle-like, crystals of cathode metal were discarded because of iron contamination.

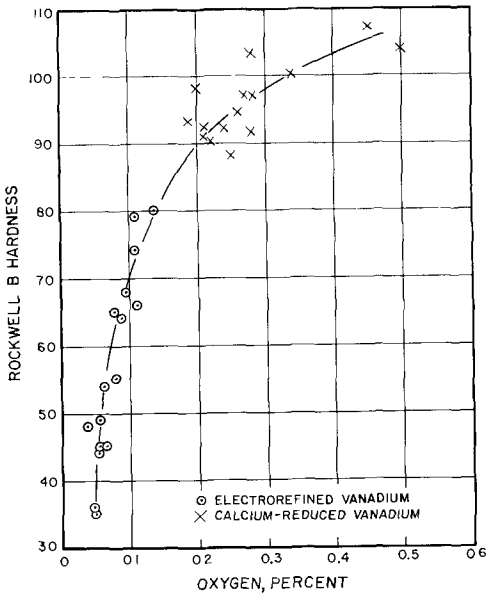

Fig. 2. Effect of oxygen on the hardness of arc-melted vanadium.

The metal product from the fourth run tested 95 R_B in hardness and there was a progressive improvement in succeeding cycles with a hardness as low as 35 on the +35 mesh fraction. Vanadium metal produced in the following 60 cycles of operation was separated into four sieve products as shown in Table I. Approximately 72% of the cathode metal produced was coarser than 80 mesh standard Tyler. The total deposited metal had a weighted average hardness of 52 R_B.

Production of soft, coarsely crystalline, cathode metal is affected by the anode area in addition to other factors. A large anode area with fresh metal surface results in a high quality product; the effect is shown in Table II. Hardness of the metal product decreases very quickly after the addition of anode material.

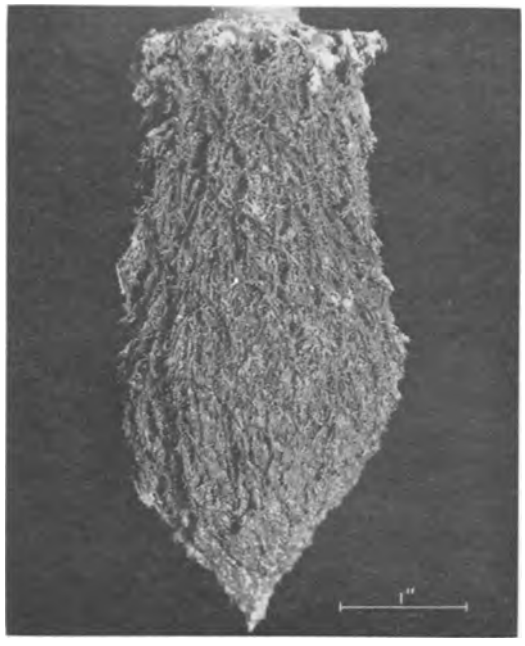

Fig. 3. Vanadium cathode deposit, as removed from the cell, produced 0.45 v.

Coarse crystalline metal was produced at applied voltages between 0.4 and 0.7 v. The bath contained 3.0% vanadium as the dichloride and was at a temperature of at least 800°C. Figure 3 illustrates the coarser deposits obtained at 0.45 v. Deposits produced at very low voltages (less than 0.3 v) or above 1.0 v contain much finer crystals. Voltages above 2.0 v would cause electrowinning from the bath with the evolution of chlorine gas, chemical attack on the iron of the cell, and iron contamination of the bath and the product. A typical range of analyses of the refined metal is C < 0.01%, Fe 0.003-0.05% O_2 0.04-0.10%, N_2 < 0.002%.

Current efficiencies for 100 cycles or runs were nearly all within the range of 88-94% with an average of 91%, based on the assumption that vanadium is transported at a valence of 2. At the average current efficiency, 522 amp-hr will deposit 1 lb of vanadium metal.

The first 100 runs with the 12-in. cell were made at voltages from 0.2 to 1.5 v and with initial current densities from 100 to 3500 amp/ft^2. No major importance can be given to the calculated current density because the cathode area begins to increase the instant metal deposits. The currents are kept within the limits from 2 to 68 amp by choice of immersion depth of the cathodes used.

Vanadium metal can be purified in respect to O_2 and N_2 by the fused salt electrorefining technique. Reduction of these gaseous impurities was in the order of two thirds, hardness was reduced from 97 Rockwell B to a low of 35 R_B.

Primary Fabrication

Arc-melted electrorefined vanadium is characterized by large randomly oriented grains. Within the grains are configurations (revealed by conventional etching techniques) in the form of pits and sub-boundaries similar to structures associated with dislocation sites.

After melting, the 10-g buttons were easily cold rolled to 0.005 in. sheet, a total reduction of 98%, with no intermediate anneals. Electrorefined vanadium shows a hardness increase of approximately 55 V.h.n. greater than its original annealed hardness when cold reduced 65%. Most of the hardening occurs in the 0-15% cold work range, approximately 27 V.h.n. for a reduction of 5% and about 38 V.h.n. for a reduction of 15%. Above 15% reduction range, hardening increases at a reduced rate with increasing amounts of deformation.

The large columnar grains of the larger arc-melted ingots deformed nonuniformly, and whenever annealing was preceded by heavy reductions recrystallization produced a banded structure that persisted during grain growth. After considerable experimental work with various sequences of flat rolling, swaging, square rolling, and cold pressing, a schedule of cold pressing and square rolling followed by annealing was adopted for initial large ingot breakdown of approximately 75% reduction in area. Although some banding was still present, this working sequence produced optimum grain structure and retained enough cross-sectional area for further testing.

Recrystallization

For recrystallization studies, these bars were further cold-rolled from 5 to 65% reduction in area. To protect the specimens from gaseous contamination during annealing, they were sealed in Vycor capsules, and were annealed for 1 hr at temperatures of 200° to 1000°C. The effect of temperature on the Vickers hardness for one lot of electrolytic vanadium is shown in Fig. 4.

For all reductions heated to temperatures in the range of 200° and 400°C, an increase in hardness of 3-15 V.h.n. over that of the cold worked metal is noted. As the temperature is increased above 400°C, hardness decreases rapidly for all reductions until the prior to deformation hardness is reached. The return to pre-deformation hardness occurs for annealing temperatures in the range of 900°-1000°C and corresponds to the temperature range for the beginning of grain growth. In general, for annealing temperatures between 900° and 1000°C, the 65% cold worked metal show an increase in hardness while the 5% cold work specimens show a continuing decrease in hardness. The 35% cold worked specimens exhibit both increasing and decreasing hardness in this annealing range (900°-1000°C). A similar high-temperature hardening effect was noted by Pugh (4) for 80% cold reduced vanadium annealed above 1200°C.

An anomaly occurs in the temperature range of 600° to 800°C, in the hardness *vs.* annealing temperature curve for all reductions in general; it is most pronounced for the low reductions. According to Lacy and Beck (5), this anomaly is attributed to an aging mechanism similar to strain aging in steel and titanium. Rostoker, *et al.* (6) noticed this same anomaly for high percentages of cold work rather than for the low reductions as noted in this investigation. It appears, if this anomaly is due to strain aging, that decreasing the quantity of interstitial impurities in vanadium reduces the amount of deformation necessary to promote strain aging in this temperature range.

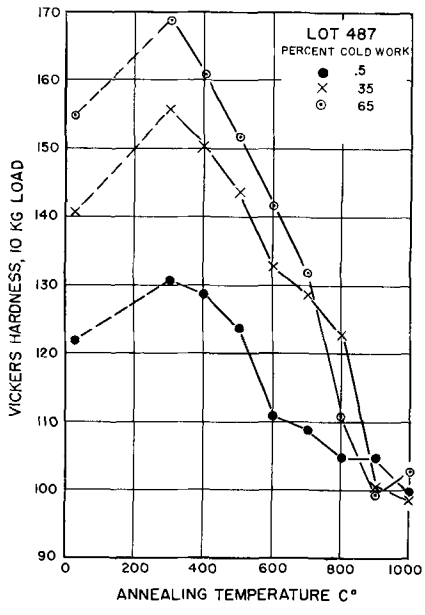

Fig. 4. Effect of temperature on the Vickers hardness of electrorefined vanadium.

The rapid decrease in hardness for the 35, 50, and 65% cold worked metal annealed in the range of 700°-800°C corresponds to the terminus of the mentioned anomaly and also to the initial microscopic evidence of recrystallization for these same reductions.

Microscopic evidence of recrystallization by nucleus growth for vanadium cold-reduced 65% is first observed for the 700°C anneal; recrystallization by nucleus growth for reductions of 35-50% is first observed for the 800°C anneal. Recrystallization is essentially complete for these three reductions after a 900°C anneal. The 35% reduction is near the minimum critical deformation necessary to promote nucleus growth rather than grain coarsening. Grain coarsening was observed for reductions of 5, 15, and 25%. Lacy and Beck (5) report metallographic recrystallization occurring in 60% extruded vanadium for annealing temperatures in excess of 750°C, while Nash, *et al.* (7) noted that metallographic evidence of recrystallization for iodide vanadium cold work 90% was present for annealing temperatures between 650° and 700°C.

Grain growth is evident in all reductions for annealing temperatures in excess of 900°C and is continuous except for the 5% cold-worked metal, which exhibits extreme discontinuous grain growth between 900° and 1000°C.

Mechanical Properties

Tensile data for vanadium cold rolled 50% and annealed at 950°C is plotted as a function of oxygen content in Fig. 5. Oxygen is used as a parameter since the authors observed it to have a greater and more consistent effect on the strength and hardness than other impurities found in high-purity vanadium.

Strength and hardness are plotted as straight line functions of oxygen content. As oxygen content increases from 0.047 to 0.109 w/o, tensile strength

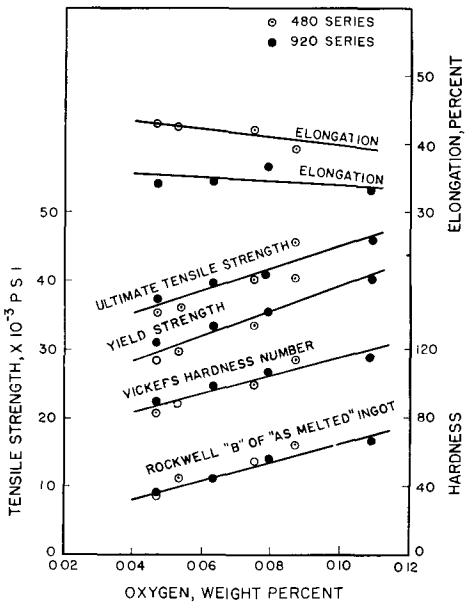

Fig. 5. Comparison of the effect of oxygen content, tensile strength, hardness, and elongation of electrorefined vanadium.

increases from 35,000 to 46,000 psi while hardness increases from 83 to 116 V.h.n. Ductility as measured by tensile elongation (33-43% in 1 in.) is not appreciably influenced by oxygen content.

Approximately 60% of the tensile specimens tested exhibited a yield phenomenon similar to that noted by Lacy and Beck (5) that consists of an upper and lower yield point which differ on an average of 2,000 psi.

An indication of the significance of oxygen rather than nitrogen, which was once thought to be the major hardener and strengthener of vanadium, becomes more apparent by individual comparisons.

Lot	O_2	N_2	Y.S.	U.T.S.
A	0.093	0.016	45,600	53,000
J	0.084	0.014	41,800	48,600
B	0.055	0.014	30,000	37,200

Comparison of the above lots indicates that the tensile and yield strengths decrease progressively with decreasing oxygen content and constant nitrogen content.

Lot	O_2	N_2	Y.S.	U.T.S.
K	0.107	0.004	46,700	53,000
488	0.087	0.003	40,500	45,900
H-I	0.062	0.003	36,000	43,200

Comparison of lots K, 488, and H-I again indicates that the tensile and yield strengths decrease with lower oxygen content and constant nitrogen content of a much lower level than for lots A, J, and B.

Lot	O_2	N_2	Y.S.	U.T.S.
A	0.093	0.016	45,600	53,000
K	0.107	0.004	46,700	53,000

In this comparison, despite the very marked difference in nitrogen content, the tensile and yield strengths remain practically constant.

Lot	O_2	N_2	Y.S.	U.T.S.
486	0.053	<0.001	28,900	36,100
B	0.055	0.014	30,000	37,200
H-I	0.062	0.003	36,000	43,200

A comparison of lots 486, B and H-I shows that the tensile and yield strengths are consistent at very similar oxygen contents and very dissimilar nitrogen contents. In this case, the oxygen level is nearly one-half that of the previous comparisons of lots A and K. These comparisons indicate, within the limits of the compositions investigated, that the influence of oxygen on the mechanical properties is much more pronounced than that of nitrogen.

Further study is required to obtain more direct correlation of properties with oxygen and/or nitrogen content as these elements appear to be most potent in their specific influence.

Physical Properties

Thermal expansion properties were independent of impurity content and the derived value for the coefficient of thermal expansion at 20°C is 8.84 x 10^{-6}/°C.

Resistivity correlated well with other properties measured for the respective lots of electrolytic vanadium. Resistivity decreased with increasing purity and decreasing strength. The values obtained varied from 22.6 to 25.2 microhm-cm at 26°C, which are, in general, lower than those previously reported for vanadium: 24.8-26.0 microhm-cm.

These Bureau of Mines investigations have shown that the fused salt electrorefining technique offers a feasible means of controlling the quantity of gaseous impurities, such as O_2 and N_2, in vanadium metal to low levels consistently. The study also has shown that the properties of electrorefined vanadium are considerably different from those exhibited by commercially available vanadium because of the reduction of impurity content. The oxygen content more than any other single impurity showed the most marked affect on hardness strength and workability.

On the Vacuum Sintering of Tungsten Ingots

J. W. Pugh and L. H. Amra

Refractory Metals Laboratory, General Electric Company, Cleveland, Ohio

ABSTRACT

A furnace for vacuum sintering tungsten is described, and results obtained from tungsten sintering experiments are discussed. The rate of densification at various temperatures is given special emphasis, but microstructure, hardness, fabricability, and purity are also examined. Temperatures from 1800° to 3100°C and times from 0.25 to 8.00 hr were employed. Results indicate that sintered densities at least as high as 82.5% of theoretical density are necessary for successful fabrication, and that densities as high as 97.0 have structures which are readily fabricable. High-temperature vacuum sintering is found to produce very pure tungsten, commensurate in this respect with the best arc cast tungsten.

The sintering of tungsten is not a new process. In the first decade of this century at least seven ingenious techniques were employed to consolidate tungsten so that it could be used for electric lamp filaments (1). The technique devised by Coolidge in 1909 was the most successful (2). His process which involved sintering pressed powder ingots in hydrogen and fabricating them to wire by swaging and drawing at progressively lower temperatures is essentially the one being used today. Little interest in vacuum sintered tungsten has been reported, although several advantages over hydrogen sintered metal might be expected.

Some of the most promising alloying elements for tungsten alloys are Ti, Zr, Hf, Cb, and Ta. These elements are all hydride formers, and their addition to tungsten requires consolidation in an inert atmosphere. High vacuum is perhaps the easiest and most satisfactory answer to this requirement. Moreover, vacuum offers the additional advantage of deoxidation since the vapor pressure of tungsten oxide is quite high at sintering temperatures and the vapor pressure of tungsten is relatively low. The sintering process can take effective advantage of this relatively unique situation because the vapor can be removed readily through the porous network of the compacted ingot. It is also true, of course, that the equilibrium of any purification reaction which results in gas evolution would be shifted favorably in vacuum.

In view of the foregoing, a vacuum sintering furnace was constructed, and some basic data on the vacuum sintering of tungsten were obtained.

Procedure

A schematic diagram of the furnace employed for these experiments is shown in Fig. 1. This furnace provides for heating compressed powder ingots by means of their own electrical resistance. 720 KW of powder is available between a stationary top electrode and a movable lower electrode, both of which are water cooled. Expansion and contraction of ingots during sintering is compensated for by means of a feed back device which involves a strain gauge, amplifier, and electrode drive mechanism. Vacuum of about 10^{-4} mm pressure is maintained by means of a 25 cm, (10 in.) oil diffusion pump and a Kinny 3.12 cubic meter/min, (110 ft^3/min) mechanical pump. An auxiliary 0.42 cubic meter/min (15 ft^3/min) mechanical pump is used for rough pumping the system.

Tungsten powders having a Fisher Sub-sieve size of 4.53 μ were compressed in a double acting hydraulic press at pressures of 1.89 metric tons/cm^2 (12 TSI) to form ingots having the dimensions 0.95 x 0.95 x 61.0 cm (⅜ x ⅜ x 24 in.). The green ingots were presintered 1 hr at 1200°C in hydrogen so that they had a presintered density of 11.5 g/cc. They were then placed in the vacuum sintering furnace and brought to the prescribed sintering temperature at the rate of 20°C/min. After prescribed times at temperature, each ingot was cooled rapidly to room

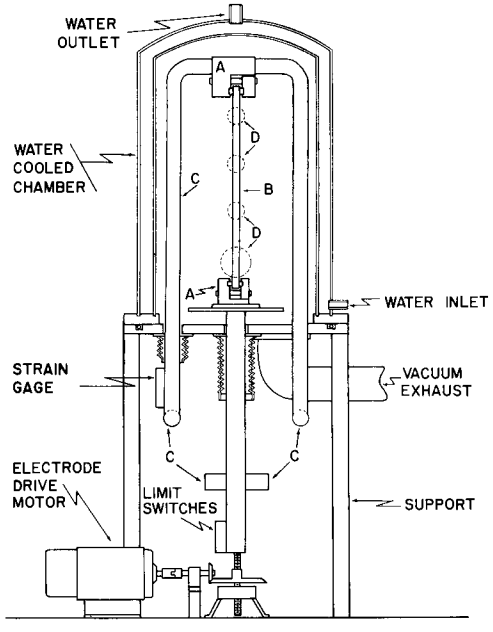

Fig. 1. Schematic representation of vacuum sintering furnace: A, electrodes; B, ingot; C, lead; D, sight port positions.

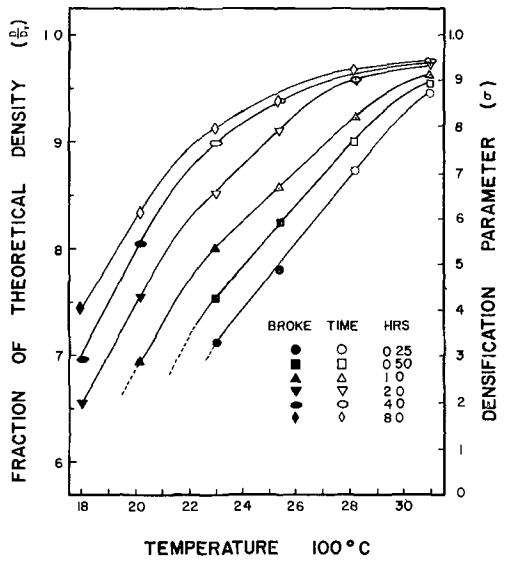

Fig. 2. Effect of temperature on the densification of tungsten ingots

temperature. The initial cooling rate in each case was approximately 500°C/min.

After the ingots were sintered, they were evaluated for density, microstructure, fabricability, and purity. Fabrication testing consisted of attempting to swage each ingot to 40% reduction in area after heating it to 1600°C.

Results and Discussion

Figure 2 indicates the effect of temperature on sintered density for various times at temperatures. The parameter plotted as the ordinate is the one commonly used to describe the degree of densification in sintered ingots: the density of the ingot (D) divided by the density of completely consolidated tungsten D_T. The Densification Parameter (σ) at the right is the densification achieved for the ingot divided by the maximum densification possible.

$$\sigma = \frac{D - Do}{D_T - Do}$$

where Do is the density of the ingot before sintering. The solid data point symbols in Fig. 2 represent ingots which could not be swaged satisfactorily. Apparently an ingot must attain more than 82.5% of its theoretical density before it can be fabricated in this way.

These data are plotted in another way in Fig. 3. Here the densification parameter is plotted as a function of time for each of the five temperatures employed. Figure 3 was used to plot the relationships shown in Fig. 4. Here the logarithm of sintering time is shown as a function of reciprocal absolute temperature for five different states of constant densification. These relationships are apparently straight lines and the empirical Arrhenius equation,

$$t = A \exp\left(\frac{\Delta H}{RT}\right)$$

is suggested. Here t is time, A is a constant, R is the gas constant, T is absolute temperature, and ΔH is the apparent activation energy for sintering. Note

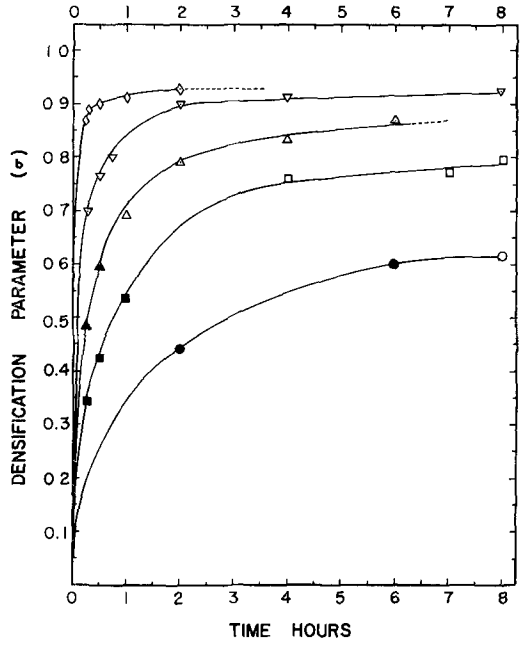

Fig. 3. Effect of time on the densification of tungsten ingots

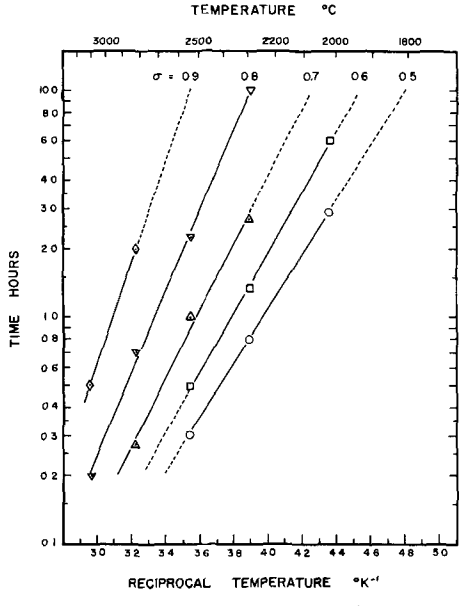

Fig. 4. Time-temperature relationships for vacuum sintered tungsten

that while these relationships are straight, they are not parallel and that the apparent activation energy changes from about 55 kcal/mole for a densification parameter of 0.5-105 kcal/mole for a parameter of 0.9. The precision of these determinations is not great, and the interpretation of these activation energies in terms of rate processes and mechanisms is not within the scope of this investigation. It does seem clear, however, that the effective or apparent activation energy as obtained from Fig. 4 increases with densification. A similar result for pre-reduced copper powder sintered in vacuum has been reported by Jordan and Duwez (3). Figure 5 shows how grain size increases as a function of time for three sintering temperature, and Fig. 6 permits a comparison of three microstructures which resulted from 2-hr treatments at the same three temperatures. The increase in pore size observed with

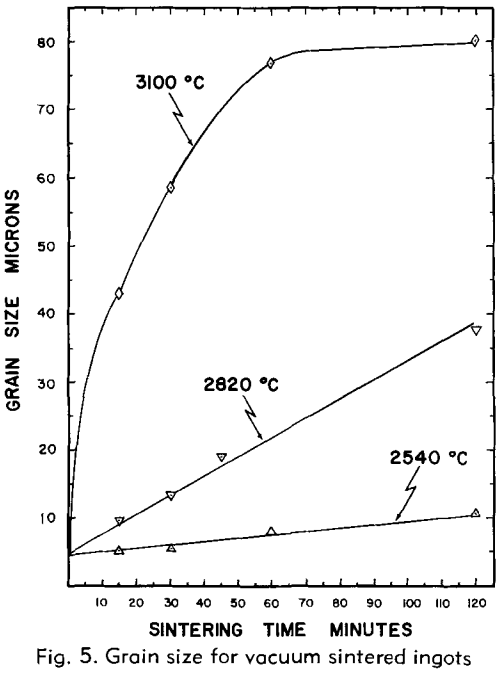

Fig. 5. Grain size for vacuum sintered ingots

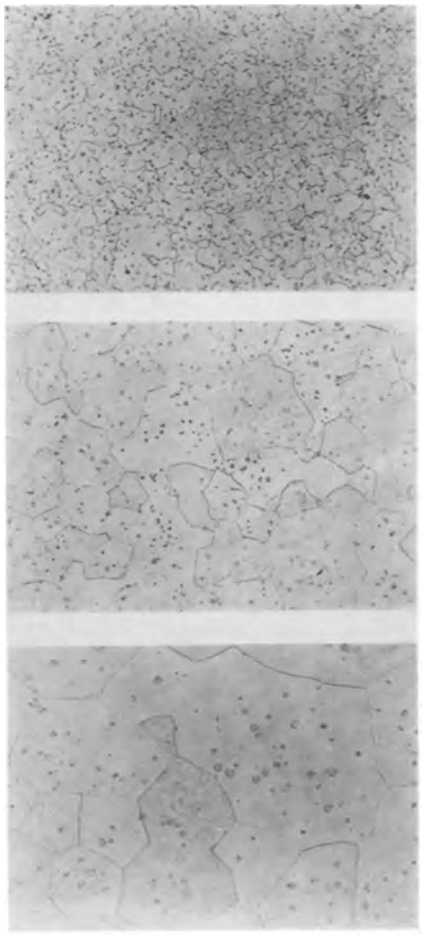

Fig. 6. Microstructures of tungsten ingots vacuum sintered 120 min. (a) (top) 2540°C; (b) (center) 2820°C; (c) (bottom) 3100°C. Magnification 250X before reduction for publication.

increasing density agrees with the findings of Rhines, Birchenall and Hughes (4). Figure 7 shows the effect of density on the hardness of the sintered ingots. Rockwell A measurements were taken first on each ingot. Diamond Pyramid Hardness was made on seven ingots to provide the relationship shown here.

3100	15	18.26	94.5	63.9	540
3100	18	18.42	95.5	63.0	
3100	30	18.44	95.5		
3100	60	18.60	96.4	64.5	
3100	120	18.75	97.0	63.5	334

Of special interest are the vacuum gas analysis results shown in Table I. The improvement in impurity content with time and temperature is remarkable. The oxygen content of the ingot sintered for 2 hr at 3100°C is perhaps comparable to the best arc-cast ingot analysis. This comparison is inexact because both products are so pure that they extend the analysis technique to its limit of resolution.

Conclusion

Table II provides a summary of the data obtained in these experiments. The information available here is sufficient to permit the programming of vacuum sintering treatments for tungsten with confidence. There are a number of unexplored avenues of practical experimentation remaining. For example, it would be most useful to know the effect of particle size and size distribution on sintering kinetics. It would also be of interest to know the effect of a variety of impurities on sintering kinetics and on gas content.

Manuscript received April 20, 1960. This paper was prepared for delivery before the Houston Meeting, Oct. 9-13, 1960.

Liquidus Curves for Aluminum Cell Electrolyte

III. Systems Cryolite and Cryolite-Alumina with Aluminum Fluoride and Calcium Fluoride

Anne Fenerty[1] and E. A. Hollingshead

Aluminium Laboratories Limited, Arvida, Quebec, Canada

ABSTRACT

Liquidus curves have been determined by means of cooling curves and visual examination of the cooling melt. The binary systems of cryolite with aluminum fluoride and calcium fluoride gave, respectively: peritectic point at 30% aluminum fluoride and 739°C, eutectic point at 40% aluminum fluoride and 694°C; eutectic point at 26% calcium fluoride and 945°C. In the system cryolite-alumina-calcium fluoride the ternary eutectic point was at 2.9% alumina, 21% calcium fluoride and 933°C. (Compositions are in weight per cent). Diagrams are given for the cryolite-rich part of the systems cryolite-calcium fluoride, cryolite-alumina-aluminum fluoride, cryolite-alumina-calcium fluoride, and cryolite-alumina-aluminum fluoride-calcium fluoride.

In the two preceding papers (1, 2) liquidus diagrams were reported for cryolite-alumina and for cryolite and cryolite-alumina with sodium fluoride, sodium chloride, and aluminum fluoride. The object of the present paper is to present additional data, a revised liquidus diagram for cryolite-alumina-aluminum fluoride, and liquidus diagrams for the cryolite-rich part of the systems cryolite-calcium fluoride, cryolite-alumina-calcium fluoride, and cryolite-alumina-aluminum fluoride-calcium fluoride.

Foster (3) recently reported the determination of the cryolite-alumina phase diagram by quenching methods. His results, except for pure cryolite, agree within the experimental error with those obtained in this laboratory (1) by cooling curves and visual examination of the cooling melt, the techniques used to obtain the results presented in this paper.

For the melting point of pure cryolite Foster (4) found 1004°C through quenching methods with a thermocouple calibration based in part on 992°C for the melting point of sodium fluoride. Both these are lower than the corresponding values of 1009° and 994°C found in this laboratory (2) by the cooling curve method. For comparison Grjotheim (5) found 1008.5° and 994.5°C, respectively, by the cooling curve method. Dworkin and Bredig (6) found 995°C for sodium fluoride, while Sense and others (7) found 996°C from the intercept of the vapor pressure-temperature curves of the liquid and solid. On the other hand much higher values for both cryolite and sodium fluoride, 1027° and 1012°C, respectively, were found by O'Brien and Kelley (8) from heat content measurements. It has already been noted (9) that too high a melting point was obtained in this way for nickel chloride, 1030°C *vs.* 1009° from cooling curves.

Materials

Hand-picked natural cryolite containing no visible impurities was crushed to −100 mesh or, preferably, to −20 mesh. The principal impurities in the two lots used were 0.01 and 0.02% iron and 0.01 and 0.04%

[1] Present address: Flint, Michigan.

silicon respectively. The alumina, produced experimentally, had a loss on ignition at 1000°C of 0.08% and contained 0.03% Na, 0.03% Ca, 0.03% Fe, 0.03% Si, 0.02% Ti, and 0.14% F. The aluminum fluoride was purified by vacuum distillation of Alcan dry-process aluminum fluoride. It contained 0.23% cryolite, 0.03% aluminum sulfate, 0.02% iron, 0.02% silicon, 0.01% manganese, and 98.4% aluminum fluoride (based on total fluorine content). The calcium fluoride was reagent-grade, from J. T. Baker Chemical Co. It had a loss on ignition at 110°C of 0.3-0.4% and contained 98-99% calcium fluoride (based on total fluoride content).

Method

The apparatus and methods were substantially as described in the first paper (1). The 150-g samples were made up by weight, thoroughly mixed, heated to about 100°C above the melting point, and stirred at about 100 rpm until clear and during the determination of the freezing point.

Primary freezing points were determined by the cooling-curve method when the first appearance of crystals in the melt, as observed through a telescope, corresponded to the primary break in the cooling curve. In general this was so on the cryolite side of the eutectic point. On the alumina side of the eutectic point and on most melts containing 25% or more of calcium fluoride or aluminum fluoride the primary freezing point was obtained by the visual method. In this method the temperature at which crystals first appear in the slowly cooled melt is determined. For final determinations rates of cooling of 0.1-0.15°C/min were used and the melt was observed every 5-15 min. The failure of the cooling-curve method to detect the primary crystallization of alumina is attributed to the steepness of the liquidus curve (low heat of crystallization and small percentage of crystals forming per unit decrease in temperature), and to the sluggishness with which alumina crystallizes.

The platinum, 10% rhodium-platinum thermocouples were all made from the same two spools of wire. One of them was calibrated in pure silver, in copper-silver eutectic alloy (799.0°C), and in standard samples of aluminum and copper certified by the National Bureau of Standards. Each thermocouple was checked periodically at the freezing point of reagent-grade sodium chloride, 801°C.

Accuracy

Two or more determinations were usually made for each composition and the mean or median value selected. With the cooling-curve method this value should not be in error by more than 3°C.

With the visual method duplicate values usually differed by less than 10°C. They would tend to be low because it was not possible to make a proper correction for supercooling. An upper limit for this correction was determined for one composition (cryolite—11% alumina) by cooling slowly until crystals appeared, then heating slowly with continuous stirring to determine the lowest temperature at which they would redissolve. This was found to be 10°-14°C higher than the mean temperature (972°C) at which the crystals appeared. Since some superheating must be required to redissolve, the negative bias of the visual method is probably less than 10°C.

For melts containing 25% or more aluminum fluoride results by the visual method were less reproducible than indicated above. This may be attributed in part to the greater steepness of the liquidus curve on the alumina side of the eutectic point. Changes in melt composition, as indicated by weight loss, were similar to those for cryolite-alumina melts.

Results

The liquidus diagram for cryolite-aluminum fluoride, reported in the preceding paper (2), was redetermined and slightly higher liquidus temperatures obtained. The revised values for the peritectic point are 739°C and 30% aluminum fluoride (weight per cent), for the eutectic point 694°C and 40% aluminum fluoride. It was verified by the visual method that on the aluminum fluoride side of the eutectic point the liquidus temperature rises rapidly to 860°C at 45% aluminum fluoride. This contradicts Grjotheim's finding (5) by the cooling-curve method that there is a maximum of 731°C at 45.2% aluminum fluoride corresponding to the compound $NaAlF_4$.

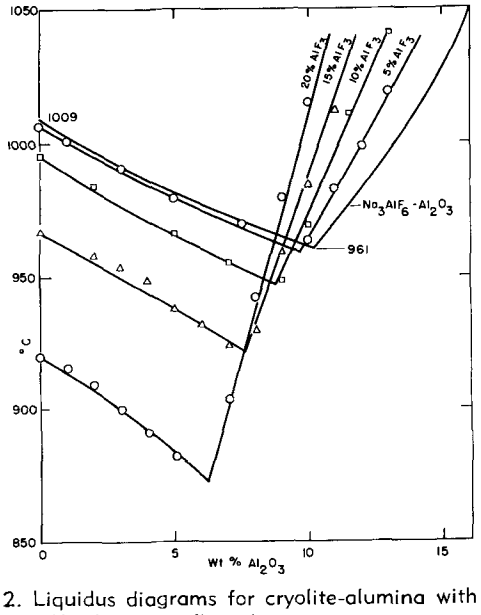

Fig. 2. Liquidus diagrams for cryolite-alumina with 5, 10, 15, and 20% aluminum fluoride.

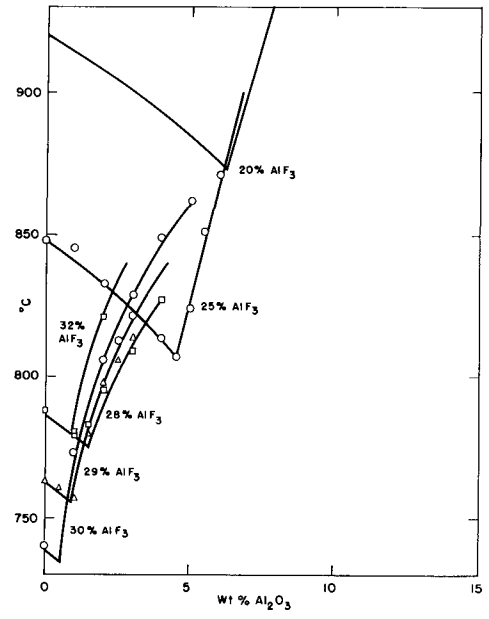

Fig. 3. Liquidus diagrams for cryolite-alumina with 25, 28, 29, 30, and 32% aluminum fluoride.

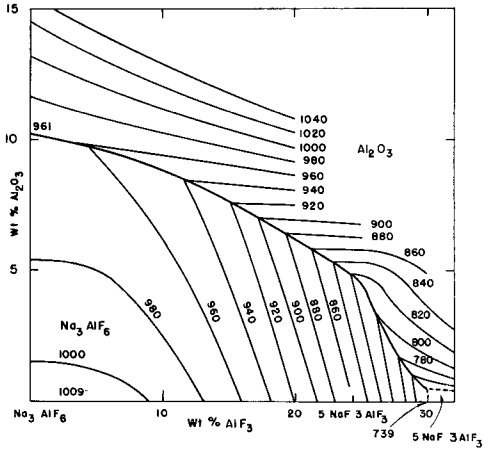

Fig. 4. Liquidus diagram for cryolite-alumina-aluminum fluoride

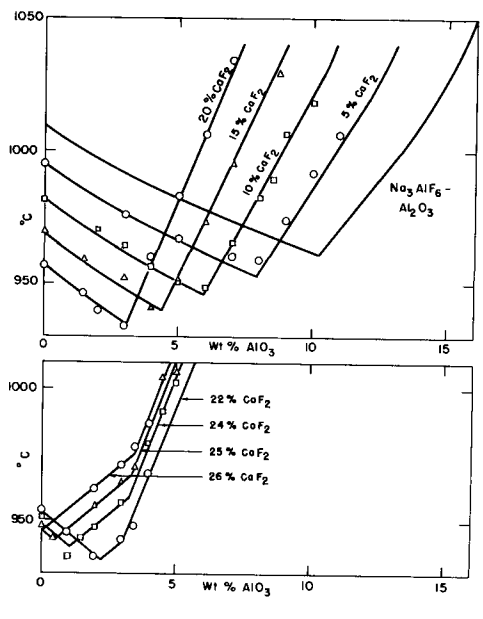

Fig. 5. Liquidus diagrams for cryolite-alumina with 0, 5, 10, 15, 20, 25, and 26% calcium fluoride.

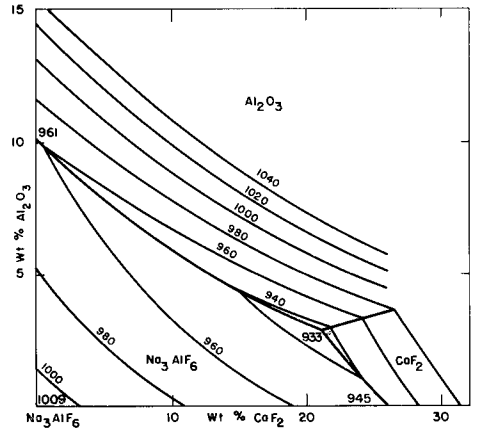

Fig. 6. Liquidus diagram for cryolite-alumina-calcium fluoride.

The liquidus diagram for cryolite-calcium fluoride (Fig. 1) was found to have a eutectic point at 26% calcium fluoride and 945°C This is in good agreement with the 25.5% calcium fluoride and 942°C obtained by Gupalo (10).

In the ternary system cryolite-alumina-aluminum fluoride sections were determined at 5, 10, 15, 20, 25, 28, 29, 30, and 32% aluminum fluoride, and the results are plotted in Fig. 2 and 3. The ternary diagram (Fig. 4) is based on these, on the revised diagram for cryolite-aluminum fluoride (see above), and on the diagram for cryolite-alumina (1) redrawn with the eutectic point at 10.2% alumina and 961°C. This ternary diagram replaces the preliminary diagram presented in the preceding paper (2). The eutectic line separating the fields of crystallization of cryolite and alumina and the isothermal contours indicating the solubility of alumina show a gradual reduction in alumina content with increasing aluminum fluoride content up to 25% of the latter. Beyond this they show a much more rapid decrease in alumina content.

Kostyukov's (11) diagram for this system, based presumably on measurements by the cooling-curve method which does not adequately detect the crystallization of alumina, gives alumina solubilities which are much too high. Thus the peritectic point, at which the melt is saturated with respect to alumina, cryolite, and chiolite, is given as 5.7% alumina, 27.8% aluminum fluoride and 710°C. Also the ternary eutectic point, at which the melt would be saturated with respect to alumina, chiolite, and aluminum fluoride, is given as 3.9% alumina, 36.8% aluminum fluoride and 678°C. The more recent work of Fuseya and Takeda (12), carried out by the cooling-curve method, gave alumina contents higher than those of Kostyukov. For comparison the present work indicates that the alumina content at the ternary peritectic and eutectic points is less than 1%. It may be noted too that the results of both these laboratories for the eutectic point in the system cryolite-alumina (16 and 18% alumina, respectively) are also in error.

For the ternary system cryolite-alumina-calcium fluoride the results for sections taken at 5, 10, 15, 20,

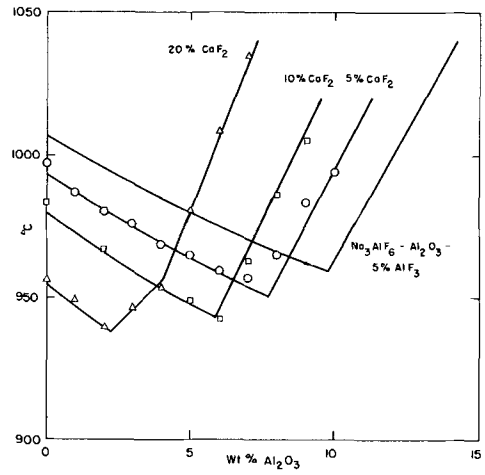

Fig. 7. Liquidus diagrams for cryolite-alumina 5% aluminum fluoride with 5, 10, and 20% calcium fluoride.

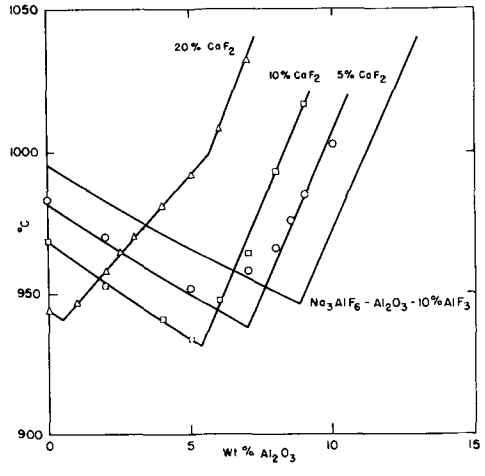

Fig. 8. Liquidus diagrams for cryolite-alumina-10% aluminum fluoride with 5, 10, and 20% calcium fluoride.

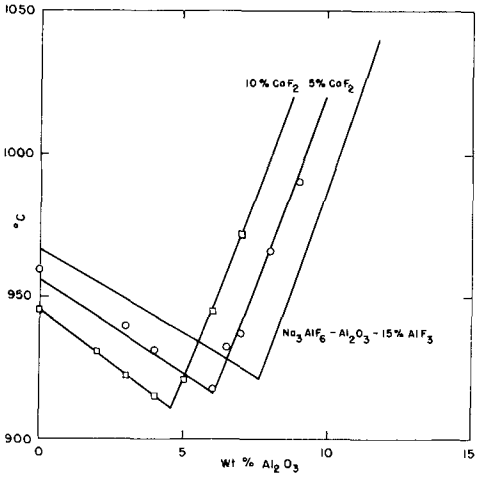

Fig. 9. Liquidus diagrams for cryolite-alumina-15% aluminum fluoride with 5 and 10% calcium fluoride.

22, 24, 25, and 26% calcium fluoride are plotted in Fig. 5. The ternary diagram, based on this and on the diagrams for cryolite-calcium fluoride and cryolite-alumina, is given in Fig. 6. It is a simple eutectic diagram with the ternary eutectic point at 2.9% alumina, 21% calcium fluoride and 933°C.

Henry and Lafky (13) determined the percentage of alumina which would dissolve in cryolite-calcium

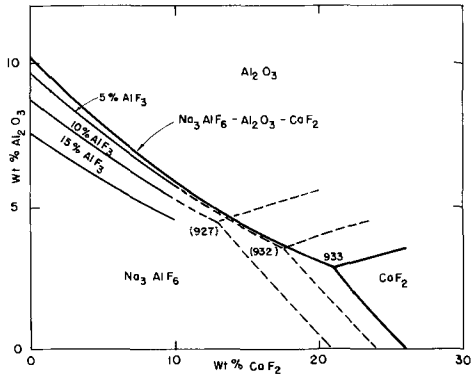

Fig. 10. Eutectic lines for cryolite-alumina-calcium fluoride with 5, 10, and 15% aluminum fluoride.

fluoride melts on prolonged stirring at a given temperature. Values at 1000°C interpolated from their results and from the present work are compared below:

	0% CaF_2	5% CaF_2	10% CaF_2	15% CaF_2
Henry and Lafky	12.0	10.3	8.5	6.8
This work	13.2	10.8	8.9	7.2

Their results are consistently slightly lower than those of the present investigation which is not unexpected in view of the methods used. Gupalo's (10) result for the ternary eutectic, 10.5% alumina, 13.6% calcium fluoride and 923°C, is quite different from that given above. Again the most likely explanation is failure to detect the initial crystallization of alumina.

The effect on the system cryolite-alumina of combined additions of 5, 10, or 15% aluminum fluoride and 5, 10, or 20% calcium fluoride was determined; results are plotted in Fig. 7, 8, and 9. Figure 10, based on these, shows the effect of 5, 10, and 15% aluminum fluoride on the eutectic lines of the system cryolite-alumina-calcium fluoride taken from Fig. 3. The field of crystallization of calcium fluoride is shifted to much lower percentages of calcium fluoride. For example, the addition of 10% aluminum fluoride shifts the ternary eutectic point from 21% calcium fluoride to approximately 13%.

In this quaternary system Abramov, Kostyukov, and Kulakov (14) have examined the pseudoternary section chiolite-alumina-calcium fluoride, which was not done by the present authors. However, in view of the method used (cooling curves and optical identification of the primary crystals) and of the discrepancy between Kostyukov's results and those reported here for the ternary system cryolite-alumina-aluminum fluoride, their alumina solubilities are most likely to be too high.

The Structure of Cryolite-Alumina Melts

Perry A. Foster, Jr. and William B. Frank

Alcoa Research Laboratories, Physical Chemistry Division, Aluminum Company of America, New Kensington, Pennsylvania

ABSTRACT

The integrated cryoscopic equation, Temkin's formulation for ionic melts, and recent findings on the constitution of molten cryolite are employed to evaluate several reaction mechanisms for the solution of alumina in cryolite. The reaction mechanism that emerges as the most probable from a plot of -log a_c *vs.* $1/T$ is $3F^- + Al_2O_3 = 3/2\ AlO_2^- + 1/2\ AlF_6^{3-}$. The deviation from linearity of the plot for this reaction at high alumina contents can be attributed to some dimerization of the AlO_2^- ions to give $Al_2O_4^{2-}$ ions.

There is no method available for the direct structural evaluation of molten salts comparable to x-ray diffraction in the study of solids. A technique frequently used is to employ the integrated cryoscopic equation

$$-\ln\ a_i = (\Delta H_f/R)\,(1/T - 1/T_o) \qquad [1]$$

where a_i is the activity of the solvent, ΔH_f the cryoscopic heat of fusion of the pure solvent, T the liquidus temperature in °K, and T_o the melting point of pure solvent.

The use of this equation presupposes that ΔH_f is independently known, that ΔH_f does not vary with temperature ($\Delta C_p = 0$), that a reliable phase diagram exists from which liquidus temperatures are known over a range of compositions, and that there is no solid solubility.

Various reaction mechanisms are now hypothesized between the solvent and the solute which will permit an evaluation of the solvent activity in the liquid (a_i).For ideally behaving simple salt systems, where the solvent and solute do not dissociate, the activity of the solvent (a_i) may be equated to its weighed-in mole fraction (N_o). This criterion has been used as a test of ideality in certain molten salt systems (1). In a system such as that considered in this report, where the solvent (cryolite) dissociates on melting, knowledge of the products of dissociation and the degree of dissociation as a function of temperature is required. This information is now available for cryolite.

If the solvent activity is calculated from a reaction mechanism which properly describes the constituents present, and the system behaves ideally, a plot of $-\ln a_i$ vs. $1/T$ will be a straight line, the slope of which corresponds to the known ΔH_f.

Properties of Molten Cryolite

Dissociation of cryolite.—It is now known that cryolite dissociates partially to simpler compounds on melting. From calculations based on densities of NaF-AlF_3 melts, Frank and Foster (2) arrived at a scheme of dissociation to sodium fluoride and sodium tetrafluoaluminate, as follows:

$$Na_3AlF_6 \rightleftarrows 2NaF + NaAlF_4 \qquad [2]$$

The equilibrium constant for the reaction can be written:

$$K_D = a^2_{NaF} \cdot a_{NaAlF_4}/a_{Na_3AlF_6} \qquad [3]$$

Grjotheim (3, 4) arrived at the same scheme by an independent method, involving calculations based on a cryoscopic study of the NaF-AlF_3 system. The actual value of the dissociation constant at the melting point obtained by these two methods differs somewhat because of different approximations in the calculations. Nevertheless, this concept of molten cryolite explains so many observations of cryolite behavior that there is little doubt that the mechanism is correct.

Temperature dependence of the cryolite dissociation constant K_D.—In order to carry out the cryoscopic calculations over a range of cryolite-alumina compositions, it was necessary to know the extent of dissociation of molten cryolite as a function of temperature. The dissociation constant was determined

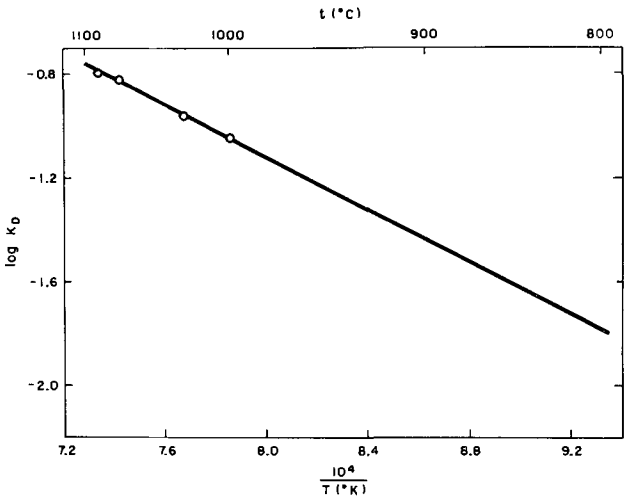

Fig. 1. Dissociation constant of cryolite as a function of temperature.

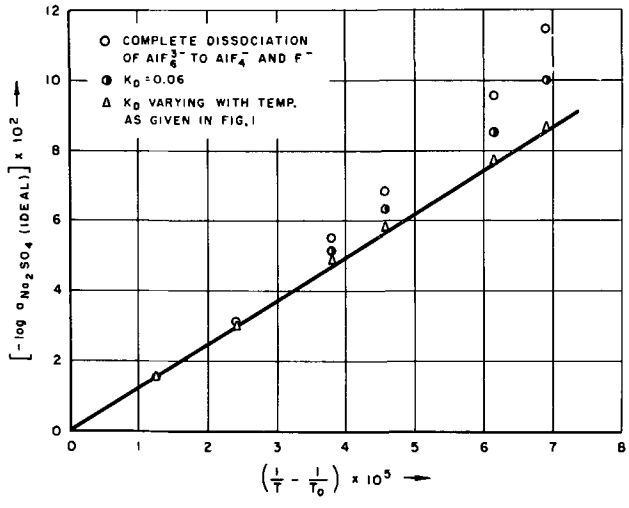

Fig. 2. Sodium sulfate activity as a function of temperature for the system Na_2SO_4-Na_3AlF_6.

by Frank and Foster (2) at four temperatures from 1000° to 1090°C. A plot of log K_D *vs.* $1/T$ was linear and the heat of dissociation was calculated from the slope as 22.5 kcal/mole (Fig. 1).

Since the validity of calculations in the cryolite-alumina system is dependent on accurate knowledge of the cryolite dissociation, it was important to test the values of K_D in another system involving cryolite as one of the binary constituents. Grjotheim (5) reported on a cryoscopic study of the Na_2SO_4-rich side of the Na_2SO_4-Na_3AlF_6 system. The purpose of the work was to substantiate the selection of the dissociation scheme of cryolite to NaF and $NaAlF_4$ and his value of 0.06 for the dissociation constant. Results are shown in Fig. 2, where $-\log a_{Na_2SO_4}$ is plotted against $(1/T - 1/T_0)$.

The solid line represents the known calorimetric heat of fusion of sodium sulfate. The open circles give the conformity to this line when the added cryolite is considered to be completely dissociated at all concentrations. The half-filled circles show the improved conformity when Grjotheim's dissociation constant of 0.06 is used over the range of temperatures of the investigation. The triangles show the almost perfect agreement that is obtained when the variation of K_D with temperature, extrapolated from the values of Frank and Foster (2), determined in the temperature range 1000°-1090°C to the temperature of the Na_2SO_4-Na_3AlF_6 system, 800°-880°C, is used. The agreement gives confidence in the use of this information on the degree of dissociation of cryolite for further calculations in the cryolite-alumina system with liquidus temperature of 962°-1004°C.

Heat of fusion of cryolite.—Two recent calorimetric determinations of the heat of fusion of cryolite gave values of 27.91 (6) and 27.64 (7) kcal/mole. An average of 27.8 kcal is employed here. It is now recognized that this is not only the heat of fusion but also includes a heat effect due to the partial dissociation of cryolite. The true cryoscopic heat of fusion ΔH_f, for undissociated cryolite becomes

$$\Delta H_f = \Delta H_F - \alpha\,\Delta H_D \qquad [4]$$

where ΔH_F is the calorimetric heat of fusion, 27.8 kcal; α the degree of dissociation at the melting point (0.35) (from ref. 2); and ΔH_D the heat of dissociation, 22.5 kcal, for reaction [2] with reactants and products in the liquid state. A value of 19.9 kcal/mole of undissociated cryolite is obtained from Eq. [4]. This value determines the slope of the line that a given reaction scheme of cryolite and alumina must reproduce if it is to be considered valid.

The assumption that the cryoscopic heat of fusion of cryolite is independent of temperature can be shown to be valid by correcting the heat content data (6, 7) for dissociation. The four measurements of the heat content of cryolite above the melting point by O'Brien and Kelley (6) and the three measurements by Albright (7) indicate that the apparent heat capacity of the liquid is greater than the heat capacity of the solid. However, when allowance is made for the temperature dependence of dissociation and the heat of dissociation as determined by Frank and Foster (2), the heat capacities of solid and liquid cryolite are almost identical. Therefore, the assumption of a constant ΔH_f should not lead to significant error.

Activities in Cryolite-Alumina Melts

The liquidus temperatures of the cryolite-alumina system are taken from the recent work of Foster (8). These temperatures range from the melting point of cryolite (1004°) to the eutectic temperature (961°C). Only the quantity a_i, the activity of the undissociated cryolite in the melts, remains to be evaluated in Eq. [1].

Temkin ionic model for molten salts.—Temkin's formulation (9) for the activity of a component in an ionic melt is accepted. According to that model, the activity of a component M_iA_i is given by

$$a_{M_iA_i} = (n_{M_i^+}/\Sigma_i n_{M_i^+}) \cdot (n_{A_i^-}/\Sigma_j n_{A_j^-}) = X_{M_i^+} \cdot X_{A_i^-} \qquad [5]$$

where $n_{M_i^+}$ is the number of cations of species M_i, $\Sigma_i n_{M_i^+}$ the total number of cations, $n_{A_i^-}$ the number of anions of species A_i, $\Sigma_j n_{A_j^-}$ the total number of anions, $X_{M_i^+}$ the cation fraction, and $X_{A_i^-}$ the anion fraction.

The ion fractions are raised to the appropriate power indicated by the number of times a given ion

appears in the formula of the component being considered.

In mixtures of components that have a common monovalent cation, such as Na^+ in most of the cases considered in this report, the cation fraction X_{Na^+} equals unity; and it can be shown from [5] that the activities of the individual components reduce to their anion fractions X_{A_j}.[1]

Method of calculation.—From [5] it follows that the activity of cryolite a_c can be expressed as

$$a_c = X^3_{Na^+} \cdot X_{AlF_6^{3-}} \qquad [6]$$

When sodium is the only cation present in the melt, Eq. [6] can be simplified to

$$a_c = X_{AlF_6^{3-}} \qquad [7]$$

The value of the anion fraction for undissociated cryolite $X_{AlF_6^{3-}}$ is determined by the degree of dissociation α as follows. Consider the equilibrium

$$AlF_6^{3-} \rightleftarrows AlF_4^- + 2F^-$$

$$K_D = (X_{AlF_4^-}) \cdot (X_{F^-})^2/(X_{AlF_6^{3-}}) \qquad [8]$$

This expression is equivalent to Eq. [3] where K_D had been expressed in terms of activities of components rather than anion fractions.

For one mole of cryolite before dissociation, at equilibrium the number of moles of AlF_4^- is α; of F^-, 2α; of AlF_6^{3-}, $1-\alpha$; the total moles of anions, $1+2\alpha$.

The expressions for the anion fractions become:

$$X_{AlF_4^-} = \alpha/(1+2\alpha)$$
$$X_{F^-} = 2\alpha/(1+2\alpha)$$
$$a_c = X_{AlF_6^{3-}} = (1-\alpha)/(1+2\alpha) \qquad [9]$$

These anion fractions are substituted into Eq. [8] to give

$$K_D = 4\alpha^3/(1-\alpha)(1+2\alpha)^2 \qquad [10]$$

Since K_D is known as a function of temperature, α can be calculated, and the cryolite activity can be determined from Eq. [9].

When alumina is added to cryolite, the degree of dissociation α changes to some new value α_i that is different for different possible reaction schemes. The ion fractions, expressed as X_i, are now written in terms of both α_i and N_i, where N_i represents the weighed-in mole fractions of the starting components. The weighed-in mole fractions of cryolite and alumina are N_0 and N_1, respectively ($N_0 + N_1 = 1$).

For any isoplethal composition, values for T and K_D are known. An equation similar to Eq. [10] is utilized to obtain α_i. This quantity is now used in an equation similar to Eq. [9] to calculate a_c (cryolite activity). —Log a_c can now be plotted against $1/T$ for each reaction mechanism. If the chosen mechanism is the proper one and the system behaves ideally, this plot should be a straight line whose slope is $\Delta H_f/(2.303R)$.

[1] The existence of a common monovalent cation permits equating the anion fraction to the simple mole fraction. This was done by Frank and Foster (*loc. cit.*) in the study of the constitution of cryolite.

Table I. Isoplethal compositions with related liquidus temperatures and cryolite dissociation constants

Possible mechanisms for the solution of alumina in cryolite.—Some of the schemes for the reaction of alumina with cryolite that have been proposed in the literature are presented below. In all but the first case, alumina is considered to be completely consumed in the formation of some new oxygen-containing species. In each case, the equilibrium between cryolite, sodium fluoride, and sodium tetrafluoaluminate is maintained. The reaction to form the oxygen-containing constituent influences this equilibrium by consuming and/or forming one of the three species, and by changing the total number of moles present.

List of Schemes

I. Simple solution, without ionization
II. $5/2AlF_6^{3-} + Al_2O_3 = 3/2AlO_2F_2^{3-} + 3AlF_4^-$
III. $AlF_6^{3-} + Al_2O_3 = 3AlOF_2^-$
IV. $AlF_6^{3-} + Al_2O_3 = 3/2Al_2O_2F_4^{2-}$
V. $Al_2O_3 = AlO^+ + AlO_2^-$
VI. $3F^- + Al_2O_3 = 3/2AlO_2^- + 1/2AlF_6^{3-}$
VII. $3F^- + Al_2O_3 = 3/4Al_2O_4^{2-} + 1/2AlF_6^{3-}$

Results

Details of the calculations for the individual schemes are given in the Appendix. The numerical values for the quantities N_0, N_1, and K_D corresponding to each liquidus temperature are listed in Table I. The values for the cryolite activity calculated for each of the seven schemes are given in Table II. The linearity of the plot of log a_c *vs.* $1/T$ and the agreement of its slope to the cryoscopic heat of fusion (19.9 ± 1.0 kcal) provide the criteria by which the schemes are evaluated. Figure 3 presents a graphical comparison of the schemes with the dashed line representing the cryoscopic heat of fusion of cryolite.

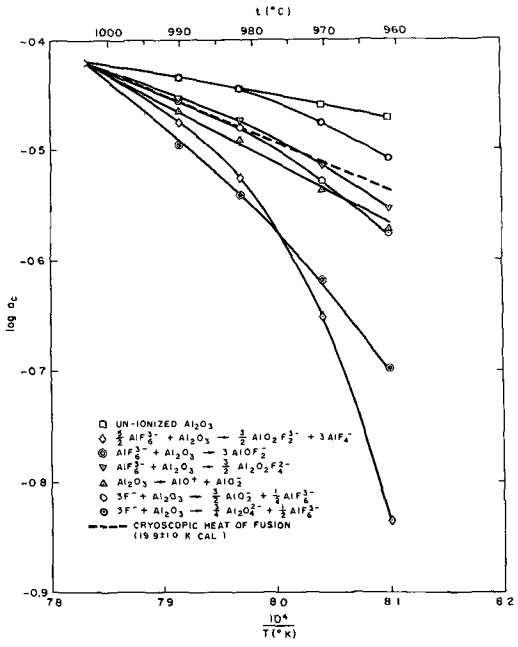

Fig. 3. Cryolite activities as a function of temperature in the system cryolite-alumina.

Scheme I, in which alumina is considered as a molecular solute, produces points falling on a line whose slope gives a low value for ΔH_f of 7.5 kcal. Schemes II, III, and V are rejected because they give high values of ΔH_f of 25 to 40 kcal in the dilute region where the curves are somewhat linear. Scheme IV ($Al_2O_2F_4^{2-}$) approximates the expected slope at low alumina concentrations. However, even the initial slope of 17.5 kcal is outside the expected error in the heat of fusion for cryolite. Scheme VII ($Al_2O_4^{2-}$) gives a low value for ΔH_f of 7.5 kcal in dilute solutions. Scheme VI (AlO_2^-) is the only scheme that reproduces the heat of fusion line in the dilute region. The points up to 5% alumina fall essentially on a line whose slope corresponds to a cryolite heat of fusion of 19.7 kcal. At higher alumina contents there is considerable deviation.

Discussion

Scheme I which produced a line whose slope gave a low value of 7.5 kcal for the heat of fusion can also be ruled out by other experimental evidence. In cryolite-alumina melts, complete exchange occurs rapidly between the aluminum of aluminum oxide and that of cryolite (10). The density of fused cryolite decreases upon the addition of the more dense aluminum oxide (11). A reaction between cryolite and alumina, rather than a physical solution of alumina in cryolite, is indicated.

Scheme VI (AlO_2^-) showed good agreement with the cryoscopic heat of fusion for alumina contents up to 5 wt %. The existence of the anion AlO_2^- in cryolite alumina melts was suggested by transport number determinations (10), viscosity and density measurements (12) in cryolite alumina melts. Sodium aluminate has been identified by x-ray powder diffraction patterns in NaF-Al_2O_3 melts quenched from above the liquidus.

It may not be unreasonable to expect that the observed deviation at higher alumina contents is due to interaction between AlO_2^- ions that gives rise to partial dimerization ($Al_2O_4^{2-}$). In the soda-alumina system, sodium aluminate ($Na_2O \cdot Al_2O_3$) is a well-established compound melting at 1650°C. The nature of its ions in the molten state is not known. Both AlO_2^- and $Al_2O_4^{2-}$ are possible anions; however, calculations of a possible equilibrium between AlO_2^- and $Al_2O_4^{2-}$ over the composition range from pure cryolite to the eutectic temperature led to an unreasonable variation in the equilibrium constant for the monomer-dimer reaction.

Although the evaluation contained in this paper cannot be interpreted as conclusive evidence of the validity of a single reaction mechanism, it is of interest to note that several proposed mechanisms can be ruled out and that the mechanism suggested by this investigation is in agreement with other experimental evidence.

APPENDIX

The documentation for the complex anion product and the mathematical expressions for the cryolite activity and dissociation constant are given here.

Scheme I.—A conceivable but unlikely mechanism for the incorporation of alumina in croylite is the simple solution of un-ionized Al_2O_3 molecules. In treating this case, the Temkin model must be abandoned since there is no meaning to an "ion fraction." The cryolite activity is equated to its mole fraction, considering all components in the molecular form. At equilibrium

$$a_{Na_3AlF_6} = (N_0 - N_0\alpha_i)/(2N_0\alpha_i + 1) \qquad [1]$$

The degree of dissociation α_i is calculated from the following expression for the dissociation constant

$$K_D = \left(\frac{\alpha_i}{1-\alpha}\right)\left(\frac{2N_0\alpha_i}{2N_0\alpha_i + 1}\right)^2$$

Scheme II.—Forland (13) investigated the equilibrium between carbon dioxide and molten mixtures of sodium fluoride, cryolite and aluminum oxide. The results were explained by assuming that alumina dissolves as a complex ion containing two oxygen atoms for each aluminum. Although it was difficult to determine the number of fluorine atoms in the complex, Forland suggested that two was the most probable number. The formation of this anion can be written as

$$(5/2)\,AlF_6^{3-} + Al_2O_3 \rightarrow (3/2)\,AlO_2F_2^{3-} + 3AlF_4^-$$

The anion fraction of cryolite becomes:

$$X_{AlF_6^{3-}} = (N_0 - N_0\alpha_i - (5/2)N_1)/(N_0 + 2N_0\alpha_i + 2N_1) \quad [2]$$

The value of α_i to be employed in Eq. [2] is obtained from the following expression for the dissociation constant

$$K_D = \left(\frac{2N_0\alpha_i - 6N_0 + 6}{7N_0 - 2N_0\alpha_i - 5}\right)\left(\frac{2N_0\alpha_i}{N_0 + 2N_0\alpha_i + 2N_1}\right)^2$$

Scheme III.—Boner (14) interpreted the alumina-cryolite phase diagram and x-ray analysis of the phases in equilibrium as evidence for the existence of $AlOF_2^-$. The formation of this anion can be written as

$$AlF_6^{3-} + Al_2O_3 \rightarrow 3AlOF_2^-$$

The anion fraction for this reaction becomes

$$X_{AlF_6^{3-}} = (N_0 - N_0\alpha_i - N_1)/(N_0 + 2N_0\alpha_i + 2N_1) \quad [3]$$

The values of α_i are obtained from the following expression for the dissociation constant

$$K_D = \left(\frac{N_0\alpha_i}{2N_0 - N_0\alpha_i - 1}\right)\left(\frac{2N_0\alpha_i}{N_0 + 2N_0\alpha_i + 2N_1}\right)^2$$

Scheme IV.—Treadwell (15) proposed the formation of the oxyfluoride ion $Al_2O_2F_4^{2-}$ in cryolite-alumina melts. The formation of this anion can be written as

$$AlF_6^{3-} + Al_2O_3 \rightarrow (3/2)\,Al_2O_2F_4^{2-}$$

The cryolite anion fraction becomes

$$X_{AlF_6^{3-}} = (N_0 - N_0\alpha_i - N_1)/(N_0 + 2N_0\alpha_i + (1/2)N_1) \quad [4]$$

The following expression provides the values of α_i to be employed in Eq. [4].

$$K_D = \left(\frac{N_0\alpha_i}{2N_0 - N_0\alpha_i - 1}\right)\left(\frac{2N_0\alpha_i}{N_0 + 2N_0\alpha_i + (1/2)N_1}\right)^2$$

Scheme V.—Rolin (16) concluded, from the results of a cryoscopic study of the cryolite-alumina system, that the dissociation of alumina can be represented by the equation

$$Al_2O_3 \rightarrow AlO^+ + AlO_2^-$$

The cryolite anion fraction becomes

$$X_{AlF_6^{3-}} = (N_0 - N_0\alpha_i)/(N_0 + 2N_0\alpha_i + N_1) \quad [5]$$

The following equation is solved for α_i,

$$K = \left(\frac{\alpha_i}{1-\alpha_i}\right)\left(\frac{2N_0\alpha_i}{N_0 + 2N_0\alpha_i + N_1}\right)^2$$

and $X_{AlF_6^{3-}}$ is calculated by substituting this value of α_i into Eq. [5]. However, in this case the expression does not represent the activity of the solvent, cryolite, since the cation fraction is not unity and must be evaluated also.

The cation fraction of sodium can be expressed as

$$X_{Na^+} = (3N_0)/(3N_0 + N_1) \quad [6]$$

The cation-anion fraction product becomes

$$a_c = X_{Na^+}{}^3 \cdot X_{AlF_6^{3-}}$$

Substitution of expressions for anion and cation fractions, (Eq. [5] and [6]) yields

$$a_c = \left(\frac{3N_0}{3N_0 + N_1}\right)^3\left(\frac{N_0 - N_0\alpha_i}{N_0 + 2N_0\alpha + N_1}\right)$$

Scheme VI.—Transport number determinations (10) in cryolite-alumina melts and viscosity and density measurements (12) suggest the existence of the aluminate ion. The formation of this anion can be written as

$$3F^- + Al_2O_3 \rightarrow (3/2)\,AlO_2^- + (1/2)\,AlF_6^{3-}$$

The cryolite anion fraction becomes

$$X_{AlF_6^{3-}} = (N_0 - N_0\alpha_i + (1/2)N_1)/(N_0 + 2N_0\alpha_i - N_1) \quad [7]$$

From the following expression for the dissociation constant, values for α_i are obtained

$$K_D = \left(\frac{N_0\alpha_i}{N_0 - N_0\alpha_i + (1/2)N_1}\right)\left(\frac{2N_0\alpha_i - 3N_1}{N_0 + 2N_0\alpha_i - N_1}\right)^2$$

Scheme VII.—Frejacques (17) postulated the existence of the compound $Na_2Al_2O_4$ in cryolite-alumina melts. The formation of the anion of this compound may be written as

$$3F^- + Al_2O_3 \rightarrow (3/4)\,Al_2O_4^{2-} + (1/2)\,AlF_6^{3-}$$

The cryolite anion fraction becomes

$$X_{AlF_6^{3-}} = (N_0 - N_0\alpha_i + (1/2)N_1)/(N_0 + 2N_0\alpha_i - (7/4)N_1) \quad [8]$$

The values of α_i to be used in Eq. [8] are obtained from the following expression of the dissociation constant

$$K_D = \left(\frac{N_0\alpha_i}{N_0 - N_0\alpha_i + (1/2)N_1}\right)\left(\frac{2N_0\alpha_i - 3N_1}{N_0 + 2N_0\alpha_i - (7/4)N_1}\right)^2$$

Technical Notes

On the Role of the Oxygen Concentration Cell in Crevice Corrosion and Pitting

G. J. Schafer, J. R. Gabriel,[1] and P. K. Foster

Department of Scientific and Industrial Research, Dominion Laboratory, Wellington, New Zealand

Uhlig (1) states that contact corrosion of stainless steels ". . . proceeds by a mechanism identical to that described . . . for pit growth." In the case of stainless steel others also have recognized the similarity between crevice corrosion and pitting (2), but it does not appear to have been suggested to date that the two processes are identical for any metal in any electrolyte. Possibly because of the obvious difficulties associated with measurements on pits or crevices, relatively few fundamental investigations appear to have been attempted. However, Ulanovskii and Korovin (3) showed that the solution in stainless steel crevices corroding in sea water reached pH values of about 3 while Rozenfeld and Marshakoff (4) showed that the solution pH in corroding aluminum crevices also falls below that of the bulk of the solution. (They also suggested that this low pH is more important than differential aeration after corrosion has been initiated.)

The acid nature of the solution in pits has been demonstrated for a number of metals (5, 6) and Hoar's acid theory (7-9) is at present probably the most generally accepted explanation of the pitting attack on many metals.

So it can be said that in all cases investigated, the solution pH fell at sites of local corrosion.

No oxygen concentration measurements in corroding pits and crevices have been located by the authors, but Evans and others have postulated that crevice corrosion is initiated by local exhaustion of oxygen (or inhibitor) in a crevice (10-12) while May (13) concluded that the pitting of copper in waters containing chloride was dependent on the interaction of anodically produced cuprous chloride with oxygen diffusing towards the anode, and Streicher (2) attributed stainless steel pitting to the joint action of differential acid and oxygen concentration cells.

Thus, while there is no direct evidence, it is widely held that pitting and particularly crevice corrosion are influenced by the action of differential aeration cells.

Another mechanism known as the metal ion concentration cell is well established in the literature but has been shown to be invalid (14) (see also Appendix I).

[1] Present address: Atomic Energy Research Establishment, Harwell, England.

In the present work it is suggested that pitting and crevice corrosion are identical processes, each depending on the conjoint action of the acid mechanism and differential aeration. To support this hypothesis two arguments are advanced against a differential aeration cell mechanism as the sole agent responsible for any localized corrosion.

1. Unless oxygen is used up at anodes, a self-supporting steady-state system depending solely on differential aeration is impossible. This is shown as follows: The differential aeration cell mechanism assumes that oxygen concentration on a particular anode is smaller than on adjacent cathodes. Oxygen concentration on an anode must therefore either be constant or reach a minimum value.

Consider a steady-state differential aeration system in which oxygen is transported by diffusion only, oxygen is used up only at cathode areas, no oxygen is evolved anywhere, and anodes of finite area exist.

Let C be the oxygen concentration.

At anodes no oxygen is consumed or produced, so $\text{grad}_n C = 0$ on the anode surface. It follows that C cannot be constant on the anode because if so, calculation of C and ∇C at a point close to the anode by Taylor's series would show that C and ∇C had not changed on moving off the surface. The Taylor series calculation then could be repeated for a point a little further away and so on, until it was shown that C = constant everywhere and $\nabla C = 0$ everywhere. This corresponds to the case where no corrosion action takes place and is of no interest.

Since oxygen flow is always toward cathodes, there can be no minimum of C on an anode surface, and any minima of C must be on cathodes. Since oxygen concentration is a continuous function of position, this implies that, for any anode-cathode interface in the type of system considered, there must be points on the cathode side of the interface (perhaps only very close to the interface) where the oxygen concentration is smaller than the concentration at some place on the anode side of the interface (perhaps relatively far from the interface). But this is contrary to hypothesis because it is implicit in the concept of a differential aeration cell that oxygen concentration must always be greater at cathodes than at anodes.

The only way to resolve this difficulty while retaining the requirement of steady state is to assume either that only point anodes exist, or that oxygen is consumed at anodes. The former assumption is untenable because infinite anode current densities would occur, hence oxygen must be consumed at anodes.

However, the oxygen which must be used at anodes in general represents anode corrosion due to local microcell action. Hence local microcell action at anodes is essential for the working of a self-supporting differential aeration cell and must contribute to the dissolution of metal. In other words, if the current flowing between the anodic and cathodic regions were measured, it would not be found to account for all of the observed corrosion.

2. The differential aeration mechanism itself, if considered in detail, leads to differential acid concentrations. For if a differential aeration mechanism causes localized corrosion, the *p*H of the solution at anodic areas must become lower than the *p*H of the solution at cathodic areas due to the preponderance of metal ion production and oxygen depolarization at the two respective surfaces.

It is therefore postulated that after the mechanism which determines the site of corrosion initiation has ceased to operate (*i.e.*, as soon as localized attack has begun), for any particular metal in a certain medium, exactly the same mechanism operates in the case of pitting and crevice corrosion. So in many cases of crevice corrosion it is probably an acid mechanism which chiefly accounts for the localized nature of the attack. The local exhaustion theory accounts mainly for the position at which attack is initiated.

It may be noted that the operation of an acid mechanism corrosion cell *ipso facto* produces a differential aeration effect because the microcell corrosion due to acid conditions uses up oxygen. So if, for example, a pit is initiated on a piece of stainless steel either by oxygen starvation or by acid attack (other things being equal), the final corroding systems should be identical.

Important factors such as active-passive cells (*e.g.*, stainless steels) and oxygen-absorbing anodic corrosion products (*e.g.*, copper) have not been discussed here because, while they may influence the relative importance of the differential aeration and the differential acid concentration cells, the above arguments are basically unaffected.

Conclusion

It is proposed that the crevice corrosion mechanism must, like pitting (2, 15), be divided into two stages. A differential aeration or inhibitor exhaustion mechanism is decisive in determining the locations at which crevice corrosion is initiated. After initiation, however, continued crevice corrosion depends also on the acid mechanism frequently used to explain the autocatalytic nature of pitting.

The presence of oxygen as a depolarizing agent is still essential, but not in the sense of a differential aeration mechanism. The following example illustrates this point. Copper corrodes only very slowly in oxygen-free HCl, but if oxygen is added corrosion occurs rapidly (1). Thus oxygen is necessary as a depolarizing agent for the corrosion of copper in HCl, but differential aeration plays no part.

Pitting is considered to be merely a limiting case of crevice corrosion, the difference being that macroscopic geometrical factors determine the initiation sites of crevice corrosion, while random microscopic factors usually determine the sites of initiation of pitting corrosion. For any particular metal, steady-state pitting and crevice corrosion occur by identical mechanisms involving the conjoint action of differential acid concentrations and differential oxygen (or other depolarizer) concentrations.

APPENDIX I

The experiments of Marshakoff and Rozenfeld on copper crevice corrosion (16) call for some comment. It has been proved that the metal ion concentration cell cannot be a cause of steady-state crevice corrosion (14), (or, for that matter, any other type of localized corrosion), but Marshakoff and Rozenfeld concluded that metal ion concentration cells were in fact operative in their experiments.

We agree with their interpretation, but we consider that the experiments were designed wrongly, and while in the cases of the other metals investigated this has only quantitatively influenced the results, in the case of copper it has lead to wrong conclusions.

Our objection is that the electrolyte used in many of the experiments (and in particular the experiments on copper) was far too aggressive.

Crevice corrosion is not a serious hazard in situations where the electrolyte causes general attack of freely

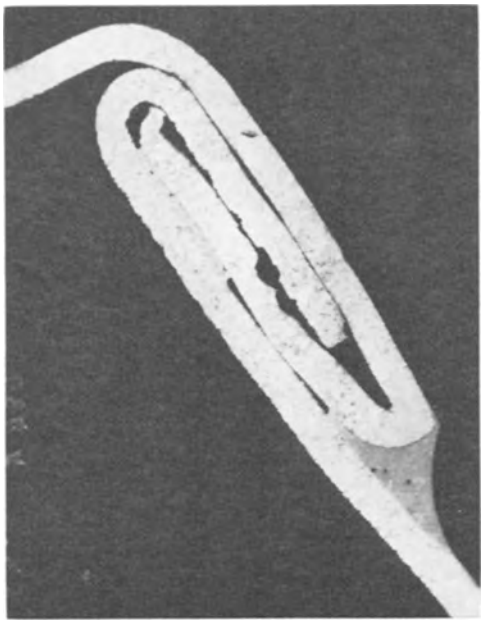

Fig. 1. Section of a brazed seam from a copper water tank. Slight general attack of the copper on the inside surface has occurred. There is no special corrosion at the crevice mouth, but the copper has been attacked locally at a number of places inside the crevice. Specimens of this kind, where crevice corrosion has occurred in the absence of interfering effects are relatively rare in our experience. Magnification 9X before reduction for publication.

exposed metal (*e.g.*, copper in 2*N* NaCl solution). As shown by Marshakoff and Rosenfeld in the cases of iron (17) and copper (16) immersed in 2*N* NaCl solution, corrosion in the crevices is less severe than corrosion of the freely exposed metal surfaces, and the electrical coupling of crevices to freely exposed metal produces only small changes in this state of affairs. Thus the crevice corrosion mechanisms are inevitably masked to a greater or lesser extent by the general corrosion taking place.

Crevice corrosion is most serious and most apparent when the freely exposed metal is relatively immune to attack and metal dissolution occurs predominantly at crevices. Only under such conditions (which usually involve a much less aggressive medium than 2*N* NaCl) is it likely that mechanisms can be successfully investigated, because the interfering general corrosion is absent.

We consider the metal ion concentration effects observed by Marshakoff and Rozenfeld to be a *result* of the general corrosion caused by the aggressive electrolyte, inside and outside the copper crevice and not the *cause* of any corrosion. In the absence of the aggressive electrolyte their experimental results would have been quite different.

A further objection to the metal ion concentration cell mechanism is that it offers no explanation for the local nature of the attack at the crevice mouth referred to by Marshakoff and Rozenfeld. In a high conductivity electrolyte such as 2*N* NaCl or sea water, corrosion would be expected to spread evenly over large areas of freely exposed metal surrounding a crevice. Also crevice corrosion of copper does not always occur at the crevice mouth (Fig. 1).

Electrodeposition of Pure Copper

Sidney Barnartt

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

Electrodeposition is attractive as a method of preparing copper plates having known added impurities. Such copper test plates are useful for oxidation to cuprous oxide semiconductors in the study of rectifiers and photovoltaic cells. As a starting point, however, a method of electrodepositing high-purity copper is necessary. The present report deals with this phase. After sufficient purity is achieved, certain metallic impurities may be incorporated one at a time by addition of an appropriate salt to the electrolyte.

Smart, Smith, and Phillips (1) have described the complex purification method used by the American Smelting and Refining Company (ASR). This involved ferric hydroxide precipitation, sulfide precipitation, electrodeposition from a sulfate solution, oxidation of the molten metal, electrodeposition from a nitrate solution, and finally melting in a high-purity graphite crucible. A much simpler procedure on a smaller scale, involving one electrodeposition step and no subsequent melting, is reported here. Data on the degree of purity attained are presented.

Procedure

The electrolyte used was $CuSO_4$-0.6M, H_2SO_4-0.8M. This was prepared from $CuSO_4 \cdot 5H_2O$ (tested-purity reagent from a single manufacturer's lot number), redistilled water, and distilled H_2SO_4 obtained by fractional distillation in all-Pyrex stills. The copper sulfate was first dissolved in water, and a solution of

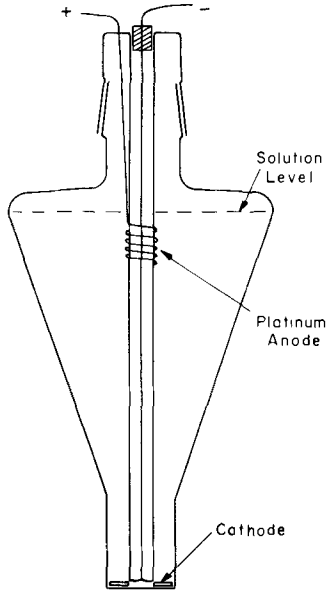

Fig. 1

reagent grade $Na_2S \cdot 9H_2O$ added to a concentration of 6 x 10^{-4}M. After heating to 70°C and cooling overnight, the mixture was decanted and filtered by suction through a fritted Pyrex filter ("ultrafine" porosity). The H_2SO_4 was then added and the volume adjusted.

Electrodeposition was carried out at 30°C and a cathode current density of 50 ma/cm^2. The Pyrex cell used is shown in Fig. 1 and was a modified inverted Erlenmeyer flask having a flat bottom. The cap of the cell held the platinum wire anode which surrounded a central vertical tube, into the bottom of which a platinum lead was sealed and protruded sufficiently to contact the cathode washer at its inner edge. The cathode diameters, 1.3 cm inner x 3.8 cm outer, closely matched the diameters of the central tube and catholyte well. The cylindrical catholyte well was 5.1 cm high and contributed to uniformity of current distribution over the cathode. All deposits were approximately 180μ in average thickness. After being stripped from the base metal and trimmed to 3.6 cm OD x 1.5 cm ID, they had a thickness variation of less than ±5%.

The cathode was a stainless steel washer having rounded edges. It was preplated with copper to a thickness of 2μ in an auxiliary acid copper bath, purified copper was deposited to the desired thickness, and then the edges of the deposit were cut to release the copper disk. The latter was treated anodically in an alkaline cyanide solution to dissolve 2.5μ of copper, thus removing the preplate layer. Final cleaning before analytical or residual resistivity measurements comprised "bright dip" in HNO_3-H_2SO_4-HCl solution followed by 10% HNO_3, redistilled water, and absolute alcohol.

Copper deposition from the acid sulfate electrolyte used resulted in a reduction of the $CuSO_4$ concentration and an increase in H_2SO_4 concentration. The solution was readjusted to the original composition after each washer was plated by removing 50 cc of the electrolyte and adding 50 cc of a purified replenishing solution having the appropriate $CuSO_4$ and H_2SO_4 concentration. By this means the solution composition was maintained constant to within ±2.5%.

Spectroscopic analysis was used for determination of metallic impurities in the copper. Arc-spectra of 50 mg samples were obtained and compared with similar spectra for high-purity copper standards.[1] Oxygen was determined on 0.7-g samples by the vacuum-fusion method, and sulfur on 1.5-g samples by a combination vacuum-fusion and mass-spectrometric procedure as described by Hickam (2, 3). Residual resistivity measurements were made on strips cut from the electrodeposit, which were vacuum annealed at 900°-940°C for 15 hr at a pressure of 10^{-6} mm Hg. On each sample resistivities measured at 4.2° and 1.9°K agreed within ±1%.

Results

The cathodic copper deposits 180 μ thick had very smooth, matte surfaces. Analyses of these deposits are given in parts per million (ppm) in Table I. Over 30 elements not listed in the table were found to be absent in the relatively sensitive arc spectra obtained. The indicated purity is 99.999+%, similar as far as is known to that of the elaborately purified ASR copper. Analytical data reported for the latter (1) are listed in the table for comparison. Actual measurements of oxygen concentration were not reported for the ASR metal, but this certainly would be less than our value of 3 ppm because ASR copper was melted in high-purity graphite as a final step.

Table I. Copper analyses, ppm

Element	Electrodeposited copper (this report)	ASR copper (1)
O	3	
S	<1	<1

Table II. Residual resistivities of polycrystalline copper

Copper used—reference	Vacuum-annealing temperature, °C	$10^3\rho_{4.2°}/\rho_{273.2°}$
Electrodeposited—this report	900-940	1.6-2.0
ASR—MacDonald and Pearson (4)	(as cast in graphite)	9.8
ASR—Kropschot, Garber, and Blatt (5)	950	1.85
ASR—White and Woods (6)	530	1.62
ASR—Powell, Roder, and Hall (7)	400	0.65
ASR—White and Tainsh (8)	530	0.56

Our residual resistivity measurements are compared in Table II with measurements on ASR copper, which has been studied by several authors.[2] The latter values vary over a wide range. It has been shown that the residual resistivity of high-purity copper is markedly dependent on annealing temperature and on slightly oxidizing or reducing conditions during the annealing procedure (4, 9), as well as on impurities unintentionally introduced. For annealing temperatures of 900°-950° the residual resistivities of the two types of copper are in excellent agreement, even though the ASR metal had been melted previously while the electrodeposited was not. This would indicate the same effective impurity concentration, but the agreement is probably fortuitous. Thus one can conclude only that the low value of residual resistivity found for the electrodeposited copper indicates high purity; a reliable purity rating relative to ASR copper is not possible from the data in Table II.

[1] Adam Hilger Ltd. (Johnson Matthey Ltd., England).

[2] It is assumed that the high-purity ASR copper obtained by each of these groups was metal prepared by the method of Smart, Smith, and Phillips (1).

Because of the high purity achieved, the simplified preparation described herein provides an attractive starting point for laboratory studies on copper having controlled added impurities, the impurities being added to the plating bath.

Acknowledgment

The collaboration of M. P. Garfunkel on residual resistivity measurements is gratefully acknowledged. Analytical data were contributed by Miss J. Senko, W. M. Hickam, and W. F. Harris.

Manuscript received July 1, 1960.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

Some Observations on the System ZnS-AlP

Arrigo Addamiano

Lamp Research Laboratory, General Electric Company, Nela Park, Cleveland, Ohio

Zinc sulfide phosphors with phosphorus activator and chlorine coactivator have been described by McKeag and Ranby (1). More recently Apple (2) has shown that, under special conditions (presence of Cu activator), phosphorus and other group V elements can behave as coactivators in zinc sulfide. We have made some observations on the related system ZnS-AlP. Our work is in agreement with the investigations mentioned above and with the theory of charge compensation of Kröger and Dikhoff (3).

Interest in the system ZnS-AlP was motivated by the close similarity in crystal structure of the two substances, accompanied by a large difference in the band gaps (3.7 e.v. for ZnS, and 3.0 e.v. for AlP). The low-temperature modification of zinc sulfide has the cubic zinc-blende structure with a cell edge (4) of 5.4060Å. Aluminum phosphide also crystallizes with the zinc-blende structure and a lattice parameter (5) $a_o = 5.451$Å. The bonds in these compounds are at least partly covalent, and a comparison of the tetrahedral covalent radii of the atoms, as given by Pauling (6), (Zn 1.31Å; Al 1.26Å; P 1.10Å; S 1.04Å) shows relatively small differences.

For the study of the solubility of AlP in ZnS we used luminescent grade zinc sulfide (prefired in H_2S) and aluminum phosphide prepared as described in another paper (5). Intimate mixtures of fine powders of the two substances, with different molar content of AlP (0.5; 1.0; 5.0; 10; 20; 40; 60; 80%) were sealed in fused silica tubes in an argon atmosphere (measuring 200 mm at room temperature) and were fired 24 hr at 900°C. When the furnace was cool the tubes were extracted and the products obtained examined by x-ray diffraction using a GE-XRD3 diffractometer. For comparison x-ray data were collected also for pure ZnS and AlP, and for the unfired mixtures. Emission spectra under 3650Å and other optical data for the fired mixtures were obtained using a grating spectrophotometer.

The analysis of the x-ray diffraction data was delicate because most of the low-θ lines of zinc blende and aluminum phosphide overlap, while the high-θ lines are relatively weak. For a content of aluminum phosphide between 10 and 80 mole % the patterns of β-ZnS and AlP are clearly discernible, the high-θ reflections well resolved, and no other lines are present. For a content of AlP less than 10% the pattern of AlP does not show up either above the background in the fired samples or in the unfired mixtures. Yet, since no shift of the high-θ lines appears in the pattern of zinc sulfide, the conclusion is reached that the solubility of AlP in ZnS is very small, probably about 1 mole % or less. This conclusion is in agreement with the finding of McKeag and Ranby (1) who did not find "any significant deviation in structure" for their phosphorus activated zinc sulfide phosphors as compared to unactivated zinc sulfide.

To further check this point we have reacted a mixture of Zn_3P_2 and Al_2S_3 in a sealed quartz tube in an argon atmosphere at 900° for 24 hr. X-ray analysis of the products so obtained showed that an almost complete reaction had occurred, with disappearance of the patterns of Zn_3P_2 and Al_2S_3 and appearance of the patterns of AlP and ZnS.[1]

As for the emission spectra under u.v. (3650Å) irradiation, a bright yellow emission is present at liquid air temperature in all the fired mixtures for concentrations of AlP up to 80%. At room temperature, however, the yellow band appears only in the samples with small amounts of AlP added(up to about 10%), the brightness being a maximum in the interval 0.5-1.0% AlP. The maximum in the emission curve in the yellow region is at about 5750Å. A typical emission curve is shown in Fig. 1. Except for a shift of the emission peak, which may be due,

[1] A trace of zinc metal was also found. This is believed to be due to reaction between excess aluminum present in the commercial Al_2S_3 used and either Zn_3P_2 or ZnS.

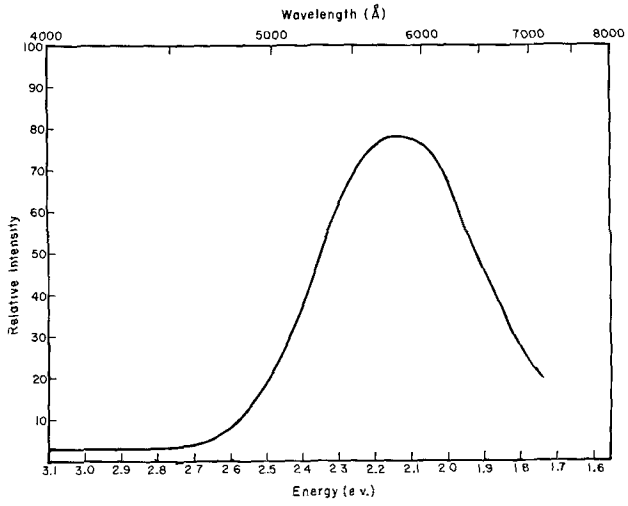

Fig. 1. Emission spectrum for ZnS:P,Al phosphors prepared with 1 mole % AlP added. Excitation by $\lambda = 3650$Å.

at least in part, to differences in experimental conditions, this emission closely resembles that observed by McKeag and Ranby in ZnS:P,Al phosphors prepared at 900°-1000°C. This similarity in the emission spectra of ZnS:P,Cl and ZnS:P,Al lends strong support to the theory of charge compensation (3) according to which a trivalent cation (Al) as coactivator should behave in the same way as a monovalent anion (Cl) coactivator.[2] It can be assumed that in ZnS:P,Al phosphorus substitutes for sulfur and aluminum substitutes for zinc.

[2] Note: It should be noted that, as mentioned by Apple (2), ZnS:P without coactivator is practically nonluminescent when prepared in H_2S at 950°.

We may summarize the results of the present investigation by saying that ZnS:P,Al phosphors with yellow emission can be prepared by diffusion of AlP in ZnS at 900°. In spite of the similarities in crystal structure and covalent atomic radii between ZnS and AlP the solubility of AlP in ZnS is very limited, probably not in excess of 1 mole %. The existence of ZnS:P,Al phosphors with emission similar to that of ZnS:P,Cl phosphors brings further support to the theory of charge compensation and shows that in ZnS:P,Al phosphors, P is the activator and Al the coactivator atom.

Acknowledgments

The author wishes to thank Dr. Eugene Apple for criticism and suggestions, Dr. Ralph M. Potter for his assistance in the measurement of the emission spectra and for critically reading the paper, and Miss Jeanette R. Cooper for the x-ray data.

High-Temperature Base-Tab for Silicon

Leon Maissel[1]

Research Division, Philco Corporation, Philadelphia, Pennsylvania

In the course of recent work in silicon transistor development, the need arose for a base-tab that could be attached to the silicon blank early in the manufacturing process so as to serve as a holder for the silicon during subsequent steps. As temperatures in excess of 800°C occurred during one or more of these steps, it was not possible to use a conventional gold solder which fuses at approximately 360°C.

The following are the general requirements for a satisfactory base-tab solder: (i) It should readily wet the semiconductor when melted in contact with it. The existence of a eutectic reaction between solder and semiconductor guarantees this. (ii) It should be sufficiently ductile so that considerable mismatch between its coefficient of thermal expansion and that of the semiconductor can be accommodated without undue strain being introduced in the joint. Conversely, if it has a coefficient of expansion close to that of the semiconductor, it need not be so ductile. (iii) It should "dope" the region near the tab to the same type (n or p) as the rest of the semiconductor; otherwise a rectifying junction may be formed. Correct doping can be insured in practice by including a trace of suitable impurity in the solder. (iv) It should substantially reduce the minority carrier lifetime in the vicinity of the junction. Without this quality the junction, although nonrectifying, may still not be entirely ohmic. For a sufficiently potent lifetime killer, condition (iii) disappears.

Also the material of the tab itself should match the semiconductor reasonably well with regard to coefficient of expansion but, as is the case for the solder, considerable mismatch can be accommodated if the latter is sufficiently ductile.

Gold satisfies these requirements very well, but in choosing a solder having more favorable high-temperature properties than gold, platinum was considered to have the most promise. It has a eutectic reaction with silicon at 830°C (1) and possesses high ductility (2). Its effect on minority carrier lifetime in silicon was not known, but it is not one of the

[1] Present address: IBM Corp., Product Development Lab., Poughkeepsie, N. Y.

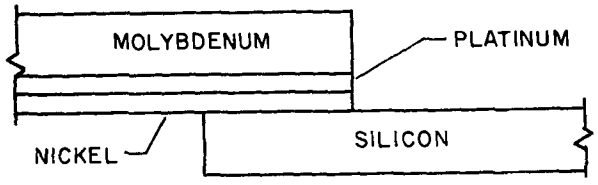

Fig. 1

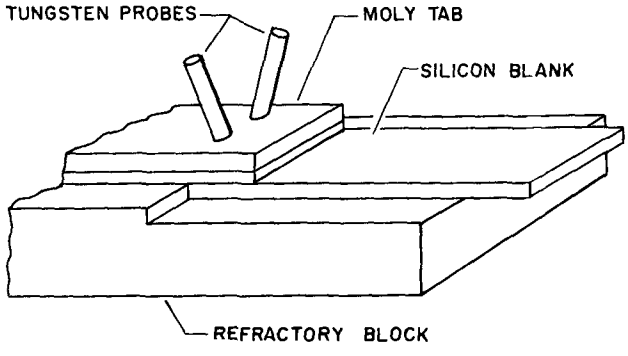

Fig. 2

recognized dopants so that it should be possible to satisfy condition (iii) for both n- and p-type silicon. Molybdenum was selected for the tab itself, having a coefficient of expansion fairly close to silicon (3) over the temperature range concerned as well as a high melting point.

Preliminary experiments showed that molybdenum could be bonded to silicon by means of platinum, but that the resulting joint had unexpectedly poor thermal properties. It was postulated that platinum ductility was being reduced by the formation of intermetallic compounds with silicon. In an attempt to reduce this effect, a number of additives to the platinum were investigated, and it was found that the introduction of a nickel layer about one third the thickness of the platinum produced a joint that was substantially strain-free and capable of temperature cycling over a wide range. This result was also somewhat unexpected since a pure Si-Ni-Mo joint was found to crack immediately on cooling. The fact that the Ni-Pt bond was much more strain-free than that using pure Pt suggested that either the Ni-Pt was more ductile than pure Pt, that the Ni-Pt matched the silicon more closely in expansion coefficient, or that Ni was suppressing the formation of Si-Pt intermetallic compounds as postulated above. Evidence against the first two mechanisms was provided by the fact that a bond formed between elements in the order Si-Pt-Ni-Mo was almost as badly strained as the straightforward Si-Pt-Mo bond, whereas the Si-Ni-Pt-Mo bond was substantially strain-free. Figure 1 shows in cross section the structure that was found best suited for joining a 5-mil molybdenum tab to a 5-mil silicon blank.

In order to prepare the tabs and bond them in a reproducible manner the following scheme was devised.

First, 5-mil Mo sheet was cleaned by scrubbing in detergent. It was then anodized in a mixture of concentrated sulfuric and phosphoric acids, dipped in a strongly alkaline solution (in this case, Lectrite N.F.) and, after rinsing, immediately given a chrome strike coat (100 to 1, CrO_3 to H_2SO_4). This was followed by a Ni strike from a standard Wood's bath after which the Pt (approximately 0.2 mils as in Fig. 1) was deposited from a solution of Platanex III.[2] The Mo was plated on both sides to protect it against oxidation during its subsequent life as a base-tab.

Following the Pt, a layer of Ni (approximately 0.1 mil thick as in Fig. 1) was deposited from a standard Watt's bath (on one side of the Mo only). The Mo sheet was cut into strips 75 mils wide and 200 mils long and bonding to the Si blanks (75 x 150 x 5 mils) was effected as illustrated in Fig. 2.

The Si blank was dipped in HF, rinsed in deionized water, dried in dry filtered air, and then laid on a refractory block, the moly-tab being pressed against it by means of two tungsten rods (or probes) as shown. Heat was produced by passing current between the probes for a pre-set period of time. For consistent results it was necessary to perform the operation in an inert atmosphere. Nitrogen does not qualify as an inert atmosphere in this instance. It was extremely important to be certain that pressure was applied uniformly by the two tungsten probes; otherwise the solder wetted only in the area of highest pressure and, in some cases, even penetrated to the other side of the Si. Optimum results were obtained by heating at approximately 1,000°C for 10-15 sec. A suitable material for the refractory block was difficult to find, the only really satisfactory one being carbon. Because of the mechanical weakness of pure carbon, in practice a block of alundum, having its surface coated with graphite, was used. The graphite coating had to be renewed frequently.

Low resistance ohmic contact could be made to p-type but not to n-type Si by this process. Spectrographic analysis of the Ni deposited from a Watt's bath showed that it contained approximately 0.05% boron. This was not surprising in view of the large quantity of boric acid in the Watt's bath. Because of the high distribution coefficient of boron, this amount was sufficient to insure ohmic contact to p-type Si and rectifying contact to n-type Si. In order to pursue this still further the 0.1-mil Ni layer was deposited from the following bath (4): $NiSO_4 \cdot 6H_2O$, 175 g/liter; $NiCl_2 \cdot 6H_2O$, 50 g/liter; H_3PO_4, 50 g/liter; H_3PO_3, 1.3 g/liter. In addition, 14 g of $NiCO_3$ were neutralized with approximately 50 g of H_3PO_3 and added to this solution.

Nickel deposited from this solution contained about 1% of phosphorus and, as expected, base-tabs prepared in this way gave low resistance contacts to n-type Si and high resistance ones to p-type Si.

Table I gives results obtained with various combinations of base-tab and silicon type. Tabs were attached as described above at opposite ends (but on the same face) of a silicon blank, and the measured resistance was compared with that calculated from the geometry of the system, the resistivity of the silicon being known from four-point probe measurements. Resistance measurements were at 3 v.

Besides satisfying the electrical requirements for base-tabs (as shown in Table I) the units were also

[2] Platinum plating solution marketed under that name by the Sel-Rex Corporation.

Table I

Silicon type	Buffer acid	Measured R ohm	Calculated R ohm	Approximate contact resistance ohm/cm²
Resistivity type				
0.2 ohm-cm p	Boric	1.2	1.1	0.001
1 ohm-cm p	Boric	45	41	0.05
5 ohm-cm p	Boric	200	180	0.25
1 ohm-cm n	Boric	20,000	50	250
1 ohm-cm n	Phosphoric	150	50	1.2
1 ohm-cm p	Phosphoric	1,500	45	18

given thermal and mechanical shock tests similar to those used for testing the conventional gold alloy base-tabs, for example, repeated plunging into liquid nitrogen from room temperature. In all cases, mechanical and thermal strength was found to be at least as good as for the conventional tabs. Silicon blanks could not be separated from their tabs until the temperature exceeded 800°C. If the pulling force was limited to the blanks' own weight they remained attached to the tabs at and above this temperature, presumably because of surface tension.

Acknowledgments

The author wishes to thank Mr. H. A. Cassel for his assistance during several phases of this work and Mr. R. Duva of Sel-Rex Corporation for valuable advice on platinum plating.

Copper Sulfide Creep on Porous Electroplate

M. S. Frant

Research Division, AMP Inc., Harrisburg, Pennsylvania

The spread of silver sulfide from a pore site on a porous gold electroplate after exposure to sulfur vapor has been reported recently by Egan and Mendizza (1). They found that the silver sulfide creep effect was specific for gold electroplate and did not occur on rhodium or palladium plate.

This paper reports that similar creepage phenomenon has been observed on tin electroplate over copper, and that copper sulfide apparently will creep over a variety of other covering metals. Figure 1 shows samples of tin-plated copper returned from field service in a location in which sulfides were known to be present. To the naked eye the pore sites appear as small black spots. However, under magnification (Fig. 1a) the characteristic "flowery" appearance can be seen. In Fig. 1b another feature is shown: the central black area is surrounded by a thinner brown region. The outer brown region often has spots at a periphery which are black also. It has not been established whether the chemical composition of this region is different, whether the color difference can be attributed only to a difference in the film thickness, or whether it represents other pore sites.

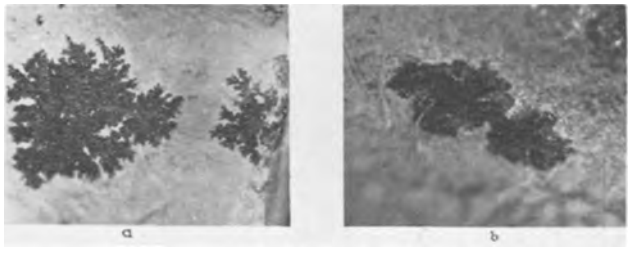

Fig. 1. Copper sulfide spots on tin-plated copper samples returned from field service. Area shown: 7.8 mm².

Figure 2a shows similar black spots surrounded by the brown area on samples which had been in storage for over a year in brown kraft boxes, but which had not otherwise been exposed to an adverse environment.

Microchemical spot tests (2) were positive for copper and sulfides, negative for other likely metals and anions. To confirm, similar tin-plated copper specimens were suspended over powdered sulfur at 60°, a technique which had been used previously for evaluating antitarnish treatments on silver. Exposures of two to three days led to spots identical in appearance to the samples returned from the field, and giving the same chemical tests.

To establish that the black spots occur at pore sites, two experiments were performed. First, tin-plated specimens were deliberately scratched before exposure to sulfur vapor. Figure 2b shows such a

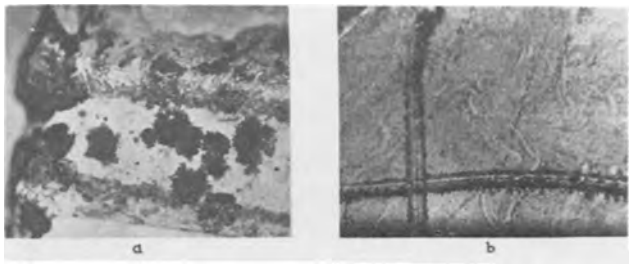

Fig. 2. a. Copper sulfide spots on tin-plated copper which had been stored in brown kraft boxes; Fig. 2b, Copper sulfide growing from scratches in tin-plated copper held 24 hr over sulfur at 60°. Areas shown: 7.8 mm².

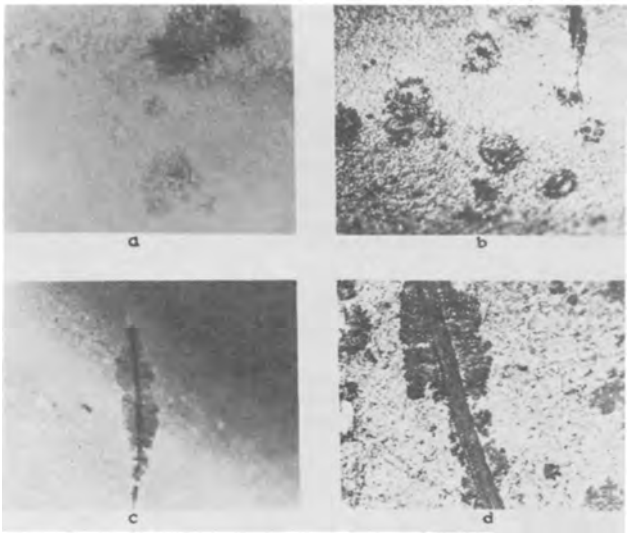

Fig. 3. Copper sulfide spots on (a) nickel-plated copper; (b) nickel-plated brass covered with palladium; (c) tin-plated silver solder; and (d) gold-plated copper. Areas shown: 7.8 mm^2, except for (c) which was 20X before reduction for publication.

Fig. 4. Copper sulfide growth from scratch in nitrocellulose lacquer on copper after 24 hr over sulfur at 60°. Area shown: 7.8 mm.

scratch after exposure. The black film can be seen spreading out from the scratch. Second, tin-plated copper samples were pressed against filter paper pads, soaked in ammonia-ammonium persulfate solution (3) which gives a blue color at pore sites. The samples were then washed, dried, and exposed to sulfur vapor. Good correlation was found.

Similar creepage phenomena have been noted on nickel-plated copper (see Fig. 3a), nickel-plated brass covered with palladium[1] (Fig. 3b), tin-plated silver solder (80% Cu, 20% Ag) (Fig. 3c), and gold-plated copper (Fig. 3d). The samples of nickel and palladium plate do not show as much of the "flowery" appearance or color differences as tin plate and gold plate. Interference colors were widely observed on gold-plated samples; spots would develop overnight on gold plate which was as much as 1 μ (40 millionths of an inch) thick.

[1] The palladium coating was approximately 2.5μ (100μ in.) thick and was applied by an electroless process using tetrammine palladous chloride through the courtesy of R. F. Vines, International Nickel Co.

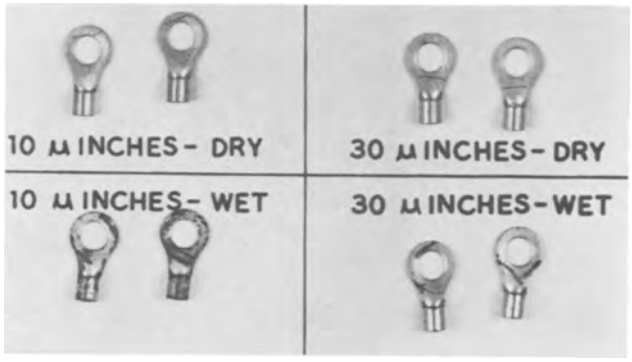

Fig. 5. Effect of moisture and gold thickness on growth on copper sulfide films. Shown are gold-plated specimens having 10 and 30 μ in. average thickness, and the results of 18 hr in a closed container with sulfur which either contained several per cent of water or had been dried overnight over P_2O_5.

To determine whether the outer metallic plating entered into a chemical reaction with the growing film, specimens of O.F.H.C. and electrolytic copper were coated with nitrocellulose or acrylic lacquers, the lacquer scratched, and the sample exposed to sulfur vapor. After several days a growth of copper sulfide (Fig. 4) could be clearly observed spreading out on top of the lacquer.

The effect of moisture on the growth rate is rather striking. After it was observed that sulfur samples and containers seemed to lose their ability to produce spots after a number of cycles, replicate tests were run on sulfur which had been dried and on sulfur containing several per cent of water. The typical result is shown in Fig. 5, in this case for gold-plated copper. The accelerating effect of moisture has been reported for H_2S attack on copper by Shklovsky (4), and for the reaction of sulfur with silver by Smith (5).

The fact that the copper sulfide films will grow on a variety of metals and on a nonmetal suggests that the surface material does not enter into the chemical reaction. Further, the spreading of a sulfide over a presumably nonconducting lacquer film must occur by a different mechanism than that proposed by Gensch and Wagner (6) for the spreading of a silver iodide film along a tantalum surface, since they attributed the spreading to the relatively easy flow of electrons through the substrate on which the spreading occurs. The differences in amount and appearance of the films on the various metals may be attributable to differences in pore size, or to the presence of an adsorbed water layer which would aid in the spread of the film.

The available literature (7) indicates that the formation of copper sulfides occurs by simultaneous diffusion of sulfur inward and copper outward, with the latter effect predominating. Such a mechanism would be consistent with the observations reported here.

The precautionary statement of Egan and Mendizza (1) on the practical importance of this phenomenon should now be extended to a much wider range of metals. Gold, nickel, and tin, on copper or copper alloy substrates are among the most widely used combinations for electrical contacts and terminations. In sulfiding atmospheres, contact failure due to sulfide formation may occur by creepage out

from pores even when "sulfide-resistant" platings are employed.

Brief Communication

Electronic Analysis of the Fe-Ni System

S. Yamaguchi

The Institute of Physical and Chemical Research, Tokyo, Japan

In the present study, an electron beam was applied to the crystallographic and the thermomagnetic analysis of the Fe-Ni system. Invar (Ni: 36% by weight) whose Curie point was known to be 120°C was used for the experiments described below. Invar powder was prepared by filing from an ingot. The particles of Invar were held by magnetic attraction on the sharp edge of a razor blade (5 x 5 mm) of hard steel whose remanence was known to be about 10,000 gauss. In this way the magnetic induction of the Invar particles was kept saturated. To study electron diffraction, an electron beam was allowed to graze these Invar particles as indicated in Fig. 1.

Experimental procedure.—The following process was carried out to investigate the magnetic states of the Invar particles as a function of their temperature. The diffraction pattern was first photographed with the specimen kept cool. Here care was taken not to preheat the specimen with the electron beam. Exposure to the electron beam (wave length 0.0299Å and current 0.1 ma) could be reduced to little more than the time necessary for photographing the diffraction pattern (only 0.5 sec). Second, a diffraction pattern from the specimen preheated with the electron beam for 2 min without interruption was superimposed on the first pattern from the cool specimen. In this process, the position of the photographic plate as well as the wave length and the current of the incident beam were kept constant. A double diagram obtained in this way is shown in Fig. 2.

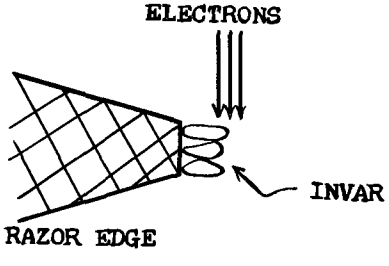

Fig. 1. Arrangement of the Invar specimen relative to the incident beam.

Analysis of the diagram.—In Fig. 2 there is evident an eccentricity between the diffraction rings corresponding to the cold and hot states of the austenitic specimen. This eccentricity means that the Lorentz effect of the cold specimen on the electron beam is distinguishable from that of the hot specimen. It is possible to calculate the difference between the magnetic induction in the two states (ΔB) from the ring eccentricity measurable in Fig. 2 (ΔZ). We have a relation between ΔB and ΔZ:

$$\Delta B = \frac{h}{eL\lambda l} \cdot \Delta Z \qquad [1]$$

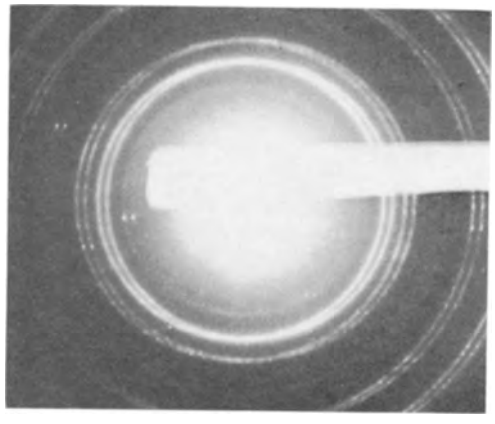

Fig. 2. Double diagram from the cold and from the hot specimen showing the difference of the Lorentz effect; wave length: 0.0299Å; camera length: 495 mm; Positive enlarged 4 times before reduction for publication.

where h is Planck's constant (6.6×10^{-27} erg. sec), e is the electron charge (1.6×10^{-20} emu), L is the camera length (495 mm), λ is the wave length of the electron beam (0.0299Å), and l is the magnetic field region traversed by the electron beam.

In Fig. 2 we measure $\Delta Z = 0.04$ cm. We obtain, therefore,

$$\Delta B \cong 4000 \text{ gauss}$$

according to Eq. [1]. Here $l \cong 3\ \mu$ was assumed.[1]

Discussion of results.—This ΔB-value is understandable as being the difference between the saturation induction of Invar and the remanence of the razor edge. It is plausible that the temperature of the specimen irradiated with the beam for 2 min was above 120°C, *i.e.*, the Curie temperature of Invar. If this is true, then the ΔB-value here measured (4000 gauss) should equal the difference between the saturation induction of Invar at room temperature ($B_s \cong 15000$ gauss) and the remanence of the razor edge ($B_r \cong 10000$ gauss). There is indeed found to be a rough agreement between them ($B_s - B_r \cong \Delta B$).

It was observed during the present experiment that some of the Invar particles fell from the razor edge when they were irradiated with the rather strong beam. As the temperature of these particles here exceeded the Curie temperature (120°C), they followed the normal influence of gravity. In Fig. 2 there are found some weak rings corresponding to Fe_3O_4. The ferromagnetic inclusion of the high Curie point (575°C) material (2) played a rôle in holding the Invar particles on the razor edge, even after they had reached the Curie point (120°C). In fact, according to electron microscope studies it is plausible that the temperature of the object could reach 500°-600°C only with some difficulty (3).

Supporting experiments.—Figure 3 is a double diagram in which the diffraction pattern of the specimen irradiated with the electrons (0.0299Å, 0.1 ma) for 2 min and that irradiated for 4 min were superimposed by means of a double exposure technique. In this diagram there is no ring eccentricity due to the Lorentz effect, since the temperature of the specimen always exceeded the Curie point so that it behaved paramagnetically.

Figure 4 is a double diagram which consists of the diffraction pattern of the specimen irradiated with a very weak electron beam (0.0299Å, 0.03 ma) for 2 min and that irradiated for 4 min. It was possible to observe a crystalline pattern even from paraffin with this weak beam (4). Since the melting point of paraffin was about 50°C, the temperature of the Invar specimen was kept under this temperature

[1] The l-value was estimated as follows. The diffraction pattern of the specimen in its ferromagnetic state below the Curie point (*e.g.*, Fig. 3) and that of a nonferromagnetic gold foil were superimposed by means of a double exposure technique (1) The ring eccentricity here measured made it possible to calculate l in Eq [1], since ΔB in this equation was equal to the saturation induction of Invar (15000 gauss)

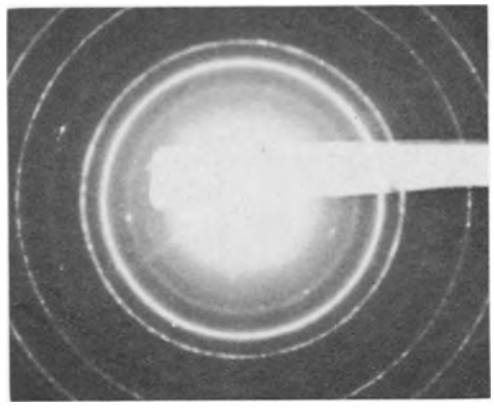

Fig. 3. Double diagram from the hot specimens heated over the Curie point (120°C). No ring eccentricity.

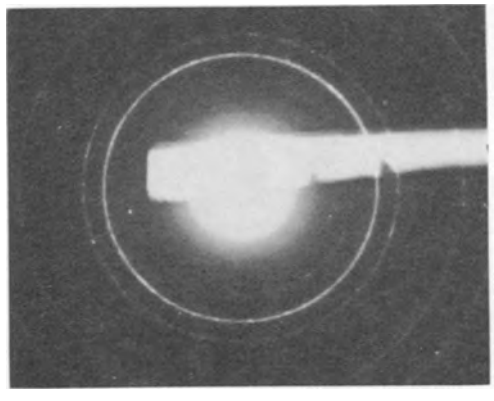

Fig. 4. Double diagram from the cold specimens kept at 50°C. No ring eccentricity.

in the case of Fig. 4. In Fig. 4 there is found no ring eccentricity. It is therefore concluded that the two magnetic states of the specimen shown in Fig. 4 are also below the Curie point.

Conclusion

In the present study, an electron beam was utilized for heating the specimen as well as for its diffraction and magneto-analysis. As the temperature of the specimen heated with the electronic irradiation can be controlled, it is possible to study the magnetic transition of the Fe-Ni system by the present process.

Technical Feature

Plasma Thermionic Converters

E. W. Salmi

Los Alamos Scientific Laboratory, Los Alamos, New Mexico

Within the last year or so, a great deal of attention has been given to a method of direct conversion of heat energy to electricity which is generally termed "thermionic conversion." There are several variations on the approach to this problem. At Los Alamos, we have been concerned primarily with the cesium plasma diode, which we have also called a "plasma thermocouple." This work was initiated as part of the advanced nuclear propulsion studies under the Rover Program.

Before going into our experimental program let us examine the manner in which a plasma can be used for generating electricity. The word plasma usually is associated with the Sherwood project. While the fusion reaction requires temperatures in the millions of degrees, it is possible to generate plasmas at much lower temperatures. In fact, several gaseous elements form plasmas at temperatures around 2000°C. Of all the available elements, cesium with an ionization potential of 3.87 v is ionized the most easily. One can produce a plasma by introducing a little cesium vapor into a metal container and heating everything to about 2500°K. This is illustrated in Fig. 1. If the cesium pressure is at 0.1 mm Hg, then about 10% of the atoms will be ionized. This is strictly thermal ionization and does not depend on the nature of the container walls. The plasma will be electrically neutral so that the numbers of electrons and ions per unit volume are equal. However, in thermal equilibrium the mean velocities of the electrons and ions will not be equal. In a cesium plasma the mean velocity of the electrons is some 500 times the mean velocity of the ions and, therefore, the electron current across any arbitrary boundary will be 500 times the ion current. Under these circumstances if a small probe is introduced into the plasma as illustrated in Fig. 1, one will draw an electron current which is of the order of 500 times the ion current. The next question is, what voltage does one obtain? This is illustrated in Fig. 2. The left-hand side of the graph shows what the electrostatic potential diagram would be in the steady state (1, 2). The electrochemical potential for the electrons is constant and uniform everywhere. The electrochemical potential is the sum of the chemical potential and the electrostatic potential. Since the chemical potential of an electron in a metal is generally different from the chemical potential of an electron in a plasma there will exist an electrostatic potential difference, equal to the difference between the chemical potentials of the electrons in the metal and the plasma, as indicated in Fig. 2. On the right-hand side are shown two of the many possibilities which may arise at the probe-plasma interface. If the probe is cooled, a monolayer of cesium may form on its surface, resulting in a work function of about 1.8 v as indicated. In the upper right-hand side the case is illustrated in which the probe draws no net current. The electron current and ion current are equal. In order to reduce the electron current into the probe there must exist an

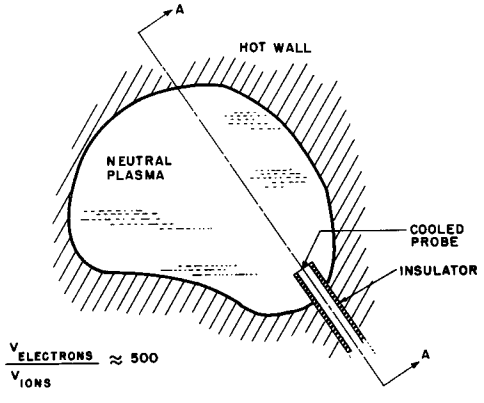

Fig. 1. Idealized model

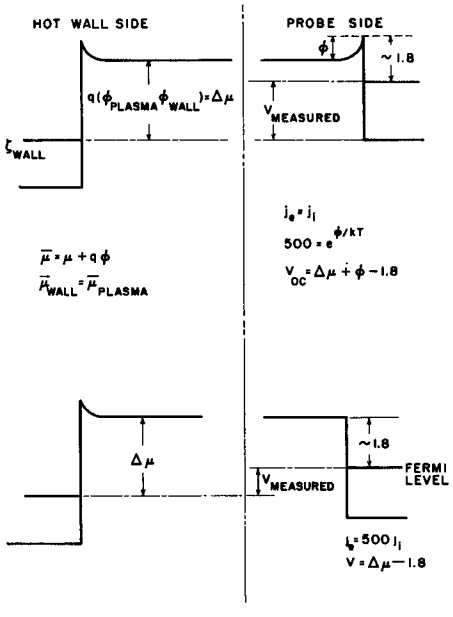

Fig. 2. Electrostatic potential diagrams

electrostatic sheath potential in the plasma at the probe-plasma interface. This potential, ϕ, must reduce the electron current by a factor of 500. Hence, we have the equation

$$500 = \exp\left(\frac{\phi}{kT}\right)$$

for the "open circuit" case (3). If a voltmeter is placed between the probe and the hot metal container one will obtain a voltage which is

$$V = \Delta\mu + \phi - 1.8$$

By lowering the voltage of the probe one begins to draw current to the probe and around the external circuit. Lowering the sheath potential ϕ increases the electron current. The particular case for which ϕ has been reduced to zero is illustrated in the lower right hand side of Fig. 2. The probe is at the same potential as the plasma and the electron current will be 500 times the ion current. These currents can be calculated from the thermodynamic equilibrium equations. The expected voltage is

$$V = \Delta\mu - 1.8$$

since in this case ϕ is zero. The power output of the device would then be the voltage V times the net current.

The above conditions are rather idealistic. However, the calculations for a cesium pressure of 0.1 mm of Hg and a temperature of 2500°K give a current of 50 amp/cm^2 and a voltage of 1.7 v. The resulting power output would be about 80 watts/cm^2. This is the type of performance one can hope for.

The experiments to date have not approached this idealistic model. In most experiments the geometry has consisted of two flat plates, so that the probe is not a small perturbation of the system but becomes one-half of the container. The cesium near the collector is, therefore, not near equilibrium with the hot walls. Also, since the hot wall is only one-half the container and must supply all the electrons which are picked up by the collector one runs into electron emission limitations from the hot wall. Despite these experimental difficulties 30 watt/cm^2 has been observed by increasing both the cesium pressure and emitter temperature (3). With this geometry the maximum short circuit current was about 60 amp/cm^2.

There have been various modifications in the experimental geometry, some of which have tended to approach the idealized model (4). In trying to interpret the data some difficulty is encountered in determining the area of the collector. Although this area is uncertain, it is believed that in several types of experiments the observed values corresponded to as much as 50 watts/cm^2. Along with this value a short circuit current of 130 amp/cm^2 was measured.

These are some of the results which have been achieved in the laboratory and most of the results have been reported in various articles. In all this work the heat source has been electrical.

About a year ago there was performed the first test in a reactor which utilized fission as a heat source. The results of this experiment also have been reported previously (5). The cell design used was complex to the point of being of little value as part of a reactor. Since the first experiment, attempts have been made to simplify the construction and to develop a cell which would be useful as a part of a reactor. In Fig. 3 is shown what is called a "triple-cell experimental rod," a device now being tested in the Omega West Reactor. The diameter across the rod is about ⅝ in. This rod consists of three cells stacked in series. Each cell consists of an emitter, or in keeping with our idealized model, a hot wall of UC:ZrC. Next comes a Cs vapor-filled gap of about 1 mm width and then a collector. Fissions in the enriched UC:ZrC keep the emitter temperature at about 2100°C. Depending on the Cs pressure and other variables, the collector runs at about 400°C. Since the Omega West Reactor is a water tank reactor, the cell will be in cool flowing water. A layer of thermal insulation is placed outside the collector which establishes the temperature gradient between the 400°C collector and the 40°C water. The water also carries away the waste heat from the cell. The emitter is held in place by a thin Nb tube which is attached to the adjacent cell so that the cells are in series. The collectors are electrically separated by small insulator spacers which are also shown in Fig. 3.

In the experimental cell there is shown a Cs bath, the temperature of which may be varied for experimental purposes. In order to establish a uniform Cs pressure in the three cells, a series of small holes are drilled into the collector at the junctions between cells. In an actual reactor the Cs pressure would be at a fixed known value and a Cs pool would be established at the bottom end of the rod and kept at a fixed temperature by the bottom cell.

Once this experimental rod has been developed one can see how to develop a reactor. Instead of stacking three cells, 10 or 20 cells can be placed in series, forming a rod about 2 ft in length. This is now a fuel element for a reactor. Several hundred of these rods can be put into a standard type of water tank reactor and it will become critical. By adding electrical connectors and putting in various control rods,

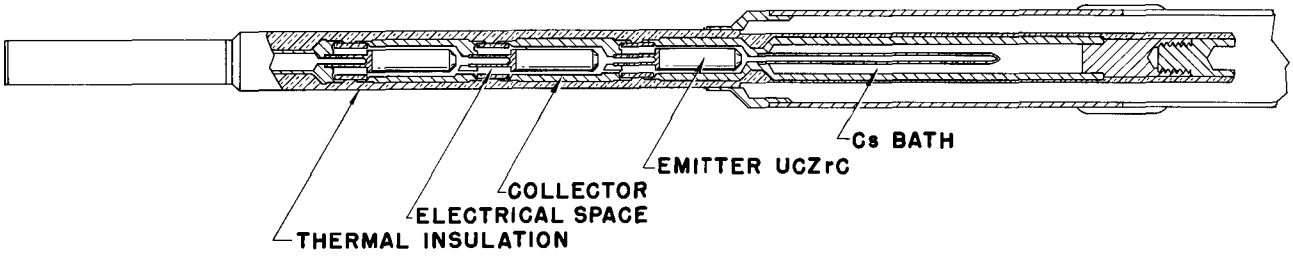

Fig. 3. Triple-cell experimental rod

one has a reactor which generates electricity directly.

Aside from the simplicity of this type of reactor there is another fundamental property of the cell which has not been mentioned. This is the temperature of the probe or collector. Normally the collector temperature is run near equilibrium with the Cs vapor pressure temperature. In some electrically heated experiments the collector temperature was increased to about 1500°K. Under these circumstances the open-circuit voltage did drop. However, the current at lower voltages remained constant, and as a result the power output also remained constant. If this remains true in further experiments, the device will be ideally suited for outer space application. A fundamental difficulty in outer space is the necessity of dumping waste heat by means of thermal radiation. If one can dump the waste heat at a high temperature, the radiator problem will be greatly reduced.

Although very attractive, outer space applications do not exhaust the potential of the thermionic converter. The reactor described earlier consisting of a bundle of rods in a tank of water may have a particular appeal in maritime propulsion and in special situations such as remote installations, if it can meet reasonable lifetime and efficiency requirements.

Present reactors fall into many different categories: fast, thermal, gas cooled, water cooled, breeders, and so forth. The same variety of direct conversion reactors is, in theory, possible using the plasma cell in one of its many forms as the fundamental building block.

Finally, a particularly interesting application of the water moderated reactor is in commercial power production. It will be recalled that the heat thrown off by the collector of the thermionic cell is still at a relatively high temperature. This heat can be used to produce steam in the usual manner and to run turbines with the further production of electrical power. This use of the plasma cell as a "topping cycle" should push up the over-all efficiency of atomic power plants to a very interesting value in the years to come.

Manuscript received April 21, 1960. This work was performed under the auspices of the Atomic Energy Commission.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

Technical Review

Practical Neutron Activation Analysis for the Electronic Scientist

J. P. Cali and J. R. Weiner

United States Air Force Cambridge Research Laboratories, Air Research and Development Command, Bedford, Massachusetts

ABSTRACT

Neutron activation analysis is an extremely sensitive analytical method for determining trace impurities in semiconductor materials. Theoretical aspects are discussed, and procedures are outlined. Parameters which determine sensitivity are considered, as well as the techniques whereby they may be varied to increase sensitivity. Tables are included which list elements that can be determined by neutron activation analysis, their half-lives, and minimum detectable amounts. Also tabulated are elemental matrix materials of electronic interest together with naturally occurring associated impurities which are determined by neutron activation analysis and other methods. These matrices are also ranked according to extent of flux perturbations, degree of self-activation, and ease of chemical separation.

Since the advent of transistors, thermoelectric, and other semiconductor materials whose electronic properties are wholly or principally dependent on minor constituents, the importance of trace impurity analysis is apparent. With today's increased specialization, the need for communication between related fields of interest has become necessary. For this reason, it is hoped that this paper will familiarize the electronic scientist with some of the aspects of the determination of trace impurities by the relatively

new and ultra-sensitive method of neutron activation analysis.

Neutron Activation Analysis

Description of method.—Neutron activation analysis, as an important and practical analytical method, became feasible only with the advent of the nuclear reactor, because, as will be shown, a high flux of neutrons is necessary to achieve the desired detection sensitivity. Many excellent references exist which give the general principles of the method (1-3, 5). It is, in fact, the extreme sensitivity of this method which makes it valuable as an analytical tool for the determination of trace impurities in concentrations too low to be detected by more conventional methods as, for example, emission spectroscopy.

The principal nuclear reaction occurring when a stable isotope of an element is irradiated with thermal neutrons is the n, γ reaction. The resulting product nucleus is, in general, a radioactive species of the same element one mass unit higher than the original stable nucleus. Decay of the product nucleus is usually by beta or gamma emission, although other modes of decay are possible, *e.g.*, K-capture or alpha emission. Because radioactive atoms can be detected in relatively small numbers, the possibility exists for a sensitive method of detection. The subject of competing nuclear reactions to give the same product nucleus as that formed by the n, γ reaction, and the question of second order reactions, while interesting, are not covered here; the interested reader may find a full account in the cited general references.

In practice, the material of interest is irradiated in a reactor, exposing all impurities and the matrix to an intense flux of thermal neutrons. Depending on the reaction cross section, number of atoms present, time of irradiation, and other quantities covered in Eq. [1] below, the n, γ products of the impurities and matrix are formed in varying amounts. It is now necessary to separate each activity; this is usually done by employing radiochemical separations. The separated radioactivities are then counted and from a knowledge of the various parameters involved, a calculation leads to the concentration of the original impurity which gave rise to the induced, measured activity. The various parameters involved are related as follows:

$$m = \frac{AD(t)}{\phi N f \sigma (1 - e^{-\lambda t})} \qquad [1]$$

where m is the minimum detectable mass, in g, of the trace element; A is the atomic weight of the trace element in g/g at.; $D(t)$ is the minimum detectable disintegration rate, in disintegrations/sec, of the activated impurity. Also, in this term are corrections for assay (aliquoting) and losses due to incomplete recovery during the radiochemical separations (chemical yield); ϕ is the thermal neutron flux, in thermal neutrons/sec cm^2; N is Avogardo's number (6×10^{23} at./g at.); f is the fractional abundance of the target nuclide; σ is thermal neutron reaction cross section in cm^2/ target at.; and $(1 - e^{-\lambda t})$ is the saturation factor, where t is the time of irradiation, in sec, λ is the decay constant of the activity produced, in reciprocal sec.

The actual procedure which would be used in the analysis of a trace impurity in a semiconductor is now considered. Although the method is of general applicability, a specific example is used for clarity, namely, the determination of trace arsenic in silicon metal. The steps are:

1. Weigh out a gram or so of silicon. Place in a quartz needle a weighed out small amount of pure arsenic.
2. Etch (if the state of material allows) the silicon to remove surface contamination.
3. Place the silicon and the quartz needle in a suitable irradiation container.
4. Irradiate in a nuclear reactor for 5 days at highest possible flux.
5. Open the irradiation capsule. Re-etch the silicon and dissolve in suitable reagents (in this case nitric-hydrofluoric acid mixture) and add a known amount of stable arsenic (about 10 mg).
6. Use suitable radiochemical procedures to separate the arsenic (which now carries with it the induced radioactive arsenic) from all other possible induced activities (not quite so hard as it seems, since group separations, scavenging, etc., remove interfering activities in a few steps).
7. Obtain the carrier arsenic in suitable form and weigh. Mount in a suitable way and count the radioactive arsenic. Compare this count with a portion of the radioactive arsenic standard from the quartz needle. Make all corrections to the unknown count for chemical yield, assaying, weight of sample, and finally compute the mass of trace arsenic by the following:

$$M_{As} = \frac{M_{std} \times C_{As}}{C_{std}}$$

where M_{As} and M_{std} refer to the masses of the unknown arsenic and the weighed or standard arsenic, respectively, and C_{As} and C_{std} refer to the counting rate of the unknown arsenic and the known arsenic, respectively.

Theoretical sensitivity.—The sensitivity for any given element is defined as the minimum amount which can be determined under a given set of conditions. These conditions are given either directly from Eq. [1] or are implicit in it and are: 1, magnitude of the thermal neutron flux of the reactor in which the material is irradiated; 2, thermal activation cross section of the target nuclide; 3, length of time the sample is irradiated; 4, half-life of the radioisotope produced by the n, γ reaction on the target nuclide; 5, efficiency of the radiation detector in measuring the radiation produced from the decaying radionuclide; 6, amount of high cross-section material in the sample which might interfere in the separation of the desired element, or more seriously, cause flux attenuation and self-shielding; 7, loss of activity due to radiochemical separations and/or aliquoting procedures; 8, minimum amount of activity required to measure accurately the half-life, and in certain cases, the maximum beta energy of the radionuclide; 9, amount of sample available for

analysis; and 10, time required from end of irradiation to the measurement of the induced activity.

From this list, it can be seen that several of these conditions can be varied in order to attain greater sensitivity of detection should this be required. Increased sensitivity is attained by irradiation at higher neutron fluxes for longer periods of time, assuming for the latter condition, of course, that saturation has not occurred (conditions 1 and 3); by increasing the efficiency of the detection of the measured radiation, as for example, using an internal flow counter *vs.* a Geiger counter (condition 5); by increasing the amount of matrix material under irradiation (condition 9); by decreasing the loss of activity due to chemical manipulations, assaying, and aliquoting procedures (condition 7); and finally, for those induced activities having short half-lives, reducing the elapsed time from the end of irradiation to the measurement of the activity (condition 10). Conditions 2, 4, and 6 are absolutely invariant and, for a given radiation measuring system, and as a practical matter, so is item 8.

Practical sensitivity.—In the previous section, those factors which affect the sensitivity of the neutron activation method have been considered from a theoretical viewpoint. In this section, a list of elements which can be determined by this method, giving practical minimum detectable amounts, without, however, considering the effect of the matrix, which is taken up in a later section, are shown in Table I.

The minimum detectable amounts are computed for the following conditions: 1, thermal flux: 10^{13} neutrons/sec cm^2; 2, minimum detectable activity: 10 distintegrations/sec. This is, in general, the amount of radioactivity required to confirm the half-life and maximum beta energy of the measured radionuclide. However, from practical considerations, losses of 50% each for aliquoting and chemical yield are included. This requires then, 40 disintegrations/sec before these losses yield the required 10 disintegrations/sec [$D(t) = 40$ d/s]; 3, 1-g sample size; 4, time of irradiation is until saturation occurs, or five days, whichever is first. Saturation is considered attained when the value of $e^{-\lambda t}$ is 0.05 or less; 5, no consideration in the calculations is made for loss of activity by decay after irradiation. For isotopes having a half-life greater than 12 hr this factor may be neglected; for those less than 12 hr, but greater than 2 hr, a correction lowering the sensitivity by several percent would have to be applied, but is not considered here.

Table I gives a list of those elements easily determined by this method, showing both the nuclear reaction of interest together with the half-life of the produced nuclide. In general, only elements giving induced activities with half-lives greater than 2 hr have been considered. However, for special cases, half-lives greater than a few minutes can be determined using special techniques. The rare earth elements, although extremely sensitive, have not been included, as they are not of general electronic interest, except in other rare earth matrices where the extremely high cross sections of the matrix make for a very difficult analysis.

The minimum detectable amount has been calculated from Eq. [1]. It should be noted, however, as is not the case for many similar compilations, that this calculation is extremely conservative, giving values which are readily obtainable in any laboratory, assuming of course, that the matrix material is not of high cross section, which problem is discussed next.

Table I. Elements determinable by N.A.A.*

Element	Nuclear reaction of interest	$t_{1/2}$	Minimum detectable amount, μg
Na	$Na^{23}(n,\gamma)Na^{24}$	14.97h	3×10^{-4}
Si	$Si^{30}(n,\gamma)Si^{31}$	2.63h	5.8×10^{-2}
P	$P^{31}(n,\gamma)P^{32}$	14.22d	5×10^{-3}
S	$S^{34}(n,\gamma)S^{35}$	87d	0.5
Cl	$Cl^{37}(n,\gamma)Cl^{38}$	37.29m	1.7×10^{-3}
K	$K^{41}(n,\gamma)K^{42}$	12.52h	3.4×10^{-3}
Ca	$Ca^{44}(n,\gamma)Ca^{45}$	164d	1
Sc	$Sc^{45}(n,\gamma)Sc^{46}$	83.9d	3.3×10^{-4}
Cr	$Cr^{50}(n,\gamma)Cr^{51}$	27.8d	6×10^{-3}
Mn	$Mn^{55}(n,\gamma)Mn^{56}$	2.576h	2.9×10^{-5}
Fe	$Fe^{58}(n,\gamma)Fe^{59}$	45.1d	1.5
Co	$Co^{59}(n,\gamma)Co^{60}$	5.24y	5×10^{-3}
Ni	$Ni^{64}(n,\gamma)Ni^{65}$	2.564h	2×10^{-2}
Cu	$Cu^{63}(n,\gamma)Cu^{64}$	12.80h	1.4×10^{-4}
Zn	$Zn^{68}(n,\gamma)Zn^{69}$	13.8h	2.4×10^{-3}
Ga	$Ga^{71}(n,\gamma)Ga^{72}$	14.3h	2.4×10^{-4}
Ge	$Ge^{76}(n,\gamma)Ge^{77}$	11.3h	7×10^{-2}
As	$As^{75}(n,\gamma)As^{76}$	26.4h	1×10^{-4}
Se	$Se^{74}(n,\gamma)Se^{75}$	121d	5×10^{-2}
Br	$Br^{81}(n,\gamma)Br^{82}$	35.87h	3.4×10^{-4}
Sr	$Sr^{88}(n,\gamma)Sr^{89}$	51d	2.4
Y	$Y^{89}(n,\gamma)Y^{90}$	64.2h	7×10^{-4}
Zr	$Zr^{96}(n,\gamma)Zr^{97}$	17.0h	0.2
Mo	$Mo^{98}(n,\gamma)Mo^{99}$	66h	1×10^{-2}
Ru	$Ru^{102}(n,\gamma)Ru^{103}$	39.8d	2×10^{-2}
Pd	$Pd^{108}(n,\gamma)Pd^{109}$	13.5h	2×10^{-4}
Ag	$Ag^{109}(n,\gamma)Ag^{110m}$	253d	1×10^{-3}
Cd	$Cd^{114}(n,\gamma)Cd^{115}$	53h	3×10^{-3}
In	$In^{113}(n,\gamma)In^{114}$	50d	6×10^{-3}
Sn	$Sn^{120}(n,\gamma)Sn^{121}$	27.5h	2×10^{-2}
Sb	$Sb^{121}(n,\gamma)Sb^{122}$	2.8d	3×10^{-4}
Te	$Te^{126}(n,\gamma)Te^{127}$	9.4h	5×10^{-3}
Cs	$Cs^{133}(n,\gamma)Cs^{134}$	2.07y	3×10^{-3}
La	$La^{139}(n,\gamma)La^{140}$	40.2h	1×10^{-4}
Hf	$Hf^{180}(n,\gamma)Hf^{181}$	44.6d	5×10^{-3}
Ta	$Ta^{181}(n,\gamma)Ta^{182}$	115d	2×10^{-3}
W	$W^{186}(n,\gamma)W^{187}$	24h	1×10^{-4}
Re	$Re^{185}(n,\gamma)Re^{186}$	89h	3×10^{-5}
Os	$Os^{192}(n,\gamma)Os^{193}$	31h	2×10^{-3}
Ir	$Ir^{193}(n,\gamma)Ir^{194}$	19h	2×10^{-5}
Pt	$Pt^{196}(n,\gamma)Pt^{197}$	18h	6×10^{-3}
Au	$Au^{197}(n,\gamma)Au^{198}$	2.70d	2×10^{-5}
Hg	$Hg^{202}(n,\gamma)Hg^{203}$	47d	1×10^{-2}
Tl	$Tl^{203}(n,\gamma)Tl^{204}$	3.56y	0.1
Pb	$Pb^{208}(n,\gamma)Pb^{209}$	3.30h	4.8
Bi	$Bi^{209}(n,\gamma)Bi^{210m}$	5.01d	0.1

* Only for the conditions set forth in this paper. Special cases are not considered.

Matrix Problem

In order to obtain reasonable sensitivity in the use of this method, fairly large sample weights are desirable. This can, however, pose three problems, not necessarily or usually mutually exclusive: (*a*) the effect of neutron beam perturbations by materials of high absorption cross section; (*b*) the problem of handling a large amount of induced radiation of the matrix; and (c) the ease with which the matrix is chemically separated from the trace impurities. These criteria are discussed in order and finally tabulated for a group of matrices in Table II.

Table II. Matrices for N.A.A. ranked according to perturbation, induced activity, and ease of chemical separation effects

Group No.	Criteria of group: Total flux perturbations		Induced activity for standard irradiations given		Half-life of induced activity	Elements arranged in descending order of ease of separation
A	5% or less	and either	less than 10 mc	or	less than 12 hr	Si, C, Pb, Ba, Bi, Mg, Ti
B	5% or less	and either	10-1000 mc	or	greater than 12 hr	Ni, Te, Sn, Fe, Zn, Ge
C	5% or less	and	greater than 1000 mc	and	greater than 12 hr	As, Se, Cu, Y, La, Cr, P, Ga
D	5% to 90%	and either	10-1000 mc	or	greater than 12 hr	Mo
E	5% to 90%	and	greater than 1000 mc	and	greater than 12 hr	Hg, W, Ta
F	greater than 90%					Re, Gd

Total flux perturbation effect.—There are two simultaneous and different perturbation effects which occur when an absorbing material is placed in a neutron flux. The first is the attenuation, sometimes referred to as self-shadowing, of the neutron beam as it is absorbed progressively in its passage from the surface to the interior of the sample. Depending upon the neutron absorption and reaction cross sections, the interior of a given sample will "see" less of the unperturbed flux than will the exterior portions. When the cross sections are sufficiently high, the evaluation of this effect becomes important. The second perturbation effect is that caused by the flux gradient resulting when a neutron absorbing material is placed in an unperturbed neutron field. This effect, like the first, is directly concerned with the cross sections of the absorbing material and is similarly difficult to evaluate; in general, it will vary from reactor to reactor.

In any given situation, these perturbation effects must be determined empirically, but for the purposes of this paper, the approach given in reference (6) by Lewis of the Materials Testing Reactor, Idaho Falls, Idaho, is used. In reference to Table II, materials have been grouped according to total flux perturbations, using calculations similar to that of the cited reference. Flux perturbations of less than 5% are negligible and occur in those matrices easiest to work with, other effects being equal; perturbations between 5 and 90% give a range of materials intermediate in difficulty; and finally, those materials whose total perturbation effects are greater than 90% are not recommended for neutron activation analysis, except in very special and unusual circumstances.

Induced radiation effect.—As was explained, not only the trace impurities, but also the matrix material will become radioactive upon irradiation. The quantity of radiation induced in the trace components is negligible when considered from the handling and health safety aspects, but the radiation induced in a gram or more of high cross-section matrix material is significant. The usual radioanalytical laboratory can handle up to 10 millicuries of activity, using only general laboratory equipment and minimal lead shielding, remote handling equipment or other specialized gear. From 10 to 1000 millicuries of activity can be handled by experienced personnel, but requires a complete and well equipped "hot" or high level laboratory. Above 1000 millicuries of activity, only trained people working in the best environment should be considered. Remote handling equipment, especially designed fume hoods, proper shielding, and automatic radiation detection devices are mandatory for working at this level of radiation.

Concurrently with the radiation intensity, the half-life of the induced activity must be considered. For short-lived activities, the intensity of the induced radiation will fall off rapidly and it is then possible to wait for a short period before starting the radiochemical separation process. Materials whose activities have half-lives less than 12 hr are considered to be in this category.

Ease of chemical separation effect.—A very unfavorable matrix element, considering the first two effects only, may under certain conditions be reconsidered should its chemical properties be such that it is easily, rapidly, and specifically removed by chemical manipulations from the induced trace activities. In Table II the elements in each group have been arranged in descending order according to this effect.

Table II has taken all these considerations into account and lists a group of elements of present or possible future electronic interest, according to the criteria given.

In general, should the element of interest fall into Groups A, B or C then no great problems should arise and activation analysis can be successfully done. Sensitivities generally will be as in Table I since 1-g samples are usually feasible within this class. Elements falling into Groups D and E will require considerable attention and complete "hot" facilities. The difficulty of working with these classes is great but not insurmountable, and the sensitivities for the trace impurities will probably decrease by a factor of approximately 10, since smaller samples will undoubtedly have to be used.

Elements classified in Group F present great difficulty and, because very small sample sizes must be used, it is probable that other methods of analysis will yield more sensitive results.

Summary

In Table III, a group of elements of present or potential electronic interest have been listed. The trace impurities tabulated are those found, usually in the part per million range, upon careful spectrographic analysis of the highest purity materials available at present.

An illustration shows how the information contained in this paper could be used by the electronic scientist.

Table III. Matrices of electronic interest and naturally occurring associated impurities

Matrix element	Associated impurities: Determination by N.A.A.	Associated impurities: Determination by other methods*
Carbon	Si, Na, Fe	Mg
Magnesium	Zn, Fe, Mn, Pb, Si, Ca, K, Na, Cu, Ni, Ag, Sn	Al
Silicon	Ga, In, P, As, Sb, Fe, Cu, Zn	B, Al
Phosphorus	Ca, Fe	
Titanium	Sn, Si, Fe, Ca, Na, Cu	Al, Mg
Chromium	Fe, Ca, Cu, Si, Ni	Al, Mg, Ti
Iron	Si, Mn, Ni, Cu, Ag, Na, Cr, Mo	Al, Mg, Ti
Nickel	Fe, Si, Na, Ca, Cu, Ag, Mo, Cr	Al, Mg
Copper	Si, Ca, Pb, Ag, Ni	Mg
Zinc	Pb, Ca, Cu, Fe, Na, Si, Ag, K	Al, Mg, Ti
Gallium	Sn, Pb, Tl, Cu, Ag, Na, Ca	Mg
Germanium	Ca, Cu, Ag	Mg
Arsenic	K, Na, Fe, Si, Ag	
Selenium	Si, Na, Fe, Ni, Ag, Ca, Cu, Mn, Te	Al, Mg, Ti
Yttrium	Fe, Si, Na, Cu, Ag	Al, Mg, Tb, Dy
Molybdenum	Si, Fe, Na, Ca, Cu	Mg
Tin	In, Ge, K, Ag, Ca, Fe, Pb, Si, Na, Bi, Cu, Zn, As	Al, Mg
Tellurium	Ag, Mn, Ca, Si, Na, Cu, Fe, Pb, Se	Mg
Barium	Ca, Fe, Si, Cu, Mn, Na, Sr	Al, Mg, Ti
Lanthanum	Ca, Si, Sn, Fe, Pb, Cu, Na	Mg, Pr, Nd
Gadolinium†	Pb, Ca, Si, Fe, Na, Cu	Mg, Tb, Sm, Eu
Tantalum	Cu, Na, Si	Al, Nb
Tungsten	Mo, Fe, Ca, Si, Cu, Na	Mg
Rhenium†	Fe, Si, Ca, Na, Cu	Mg
Mercury	Cu, Ag, Ca, Na	Mg
Lead	Cu, Ca, Fe, Si, Ag	Al, Mg
Bismuth	Fe, K, Si, Ca, Cu, Pb, Ag, Na	Al, Mg

* Magnesium, aluminum, titanium, and certain rare earths can be done using special techniques under carefully controlled conditions.
† These elements are not recommended for N.A.A.; they fall into Group VI.

PROBLEM; Determine in the part per million range (or lower) the Periodic Group III impurities in silicon carbide.

1. Consider first the matrix. Use Table II to determine the ease with which an analysis could be performed. (Note: when considering compounds, treat each element separately.) In reference to Table II, both silicon and carbon are in Group A, presenting no problem for activation analysis. A compound such as bismuth telluride, where the bismuth falls into Group A, but the tellurium falls into Group B, would be considered to be a Group B classification.

2. Consider the sensitivities of the trace impurities to be analyzed. Table I shows boron and aluminum absent; therefore, other methods would have to be considered for those two elements. However, gallium, indium, and thallium all fall within the sensitivities required.

3. In normal high-purity material (before further purification) what is the expectation of finding these elements? Consider Table III. Here they are absent in carbon, but both gallium and indium are found in silicon. It should be realized, however, that this Table III considers impurities at the spectroscopic level, generally about 1 ppm.

A whole group of materials of electronic interest has been covered. Most of the II-IV compounds are represented, *e.g.*, magnesium silicide, magnesium stannide, and magnesium plumbide. Many of III-V compounds, such as gallium arsenide and indium antimonide, are represented. The semiconductor metallics, germanium, silicon, and silicon carbide, are given. The thermoelectrics are represented by bismuth telluride and bismuth selenide.

In a general survey of this type, it is impossible, practically, to cover every possible permutation of trace and matrix element. However, it is hoped enough general and specific information has been imparted to the electronic scientist so that he may better understand the problems encountered in the important area of electronic materials.

For those interested in obtaining more details, the following extensive bibliographies by Meinke (7, 8), are cited.

An excellent handbook on activation analysis has been prepared by Koch and is invaluable for workers in this field (4).

Manuscript received Feb. 2, 1960; revised manuscript received Aug. 10, 1960.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

Discussion Section

This Discussion Section includes discussion of papers appearing in the JOURNAL of the Electrochemical Society, Vol. 106, No. 6 (June 1959), and Vol. 107, No. 1, 3, and 6 (January, March, and June 1960). Discussion not available for this issue will appear in the Discussion Section of the June 1961 JOURNAL.

Chemical Etching of Silicon, I. The System HF, HNO_3, and H_2O

Harry Robbins and Bertram Schwartz (pp. 505-508, Vol. 106, No. 6)

B. A. Irving[1]: The authors present measurements of the etch rate of silicon in mixtures of nitric-hydrofluoric acids of various concentration and interpret these in terms of a two-stage diffusion-controlled reaction involving thermal and chemical autocatalysis. However, the chemical kinetic basis of this interpretation seems misleading. This discussion seeks to clarify some points in this and to show how an empirical rate expression may be deduced in accord with all the experimental observations.

Chemical autocatalysis takes place when one of the products of a chemical reaction is able to catalyze the reaction itself. Cretella and Gatos,[2] in a paper published after Robbins and Schwartz's paper had been submitted, report investigations of an analogous autocatalytic process, the oxidation of germanium by nitric acid. Nitrous acid produced by the oxidation acts as an intermediate catalyst. Similar reaction schemes, based on the results of Vetter,[3] can be written for the oxidation of silicon. The initial slow reaction is with HNO_3 or NO_3^- to produce nitrous acid.

$$2\epsilon^- \text{ (from Si)} + 3H^+ + NO_3^- \rightarrow H_2O + HNO_2 \quad [1]$$

The nitrous acid reacts with more nitric acid to give N_2O_4 which rapidly can oxidize silicon and eventually produce a double quantity of nitrous acid.

$$HNO_2 + HNO_3 \rightarrow N_2O_4 + H_2O \text{ slow} \quad [2]$$

$$N_2O_4 \rightarrow 2NO_2 \quad [3]$$

$$2\epsilon^- \text{ (from Si)} + 2NO_2 \rightarrow 2NO_2^- \quad [4]$$

$$2NO_2^- + 2H^+ \rightarrow 2HNO_2 \quad [5]$$

The initial reaction [1] soon becomes swamped and the rate of oxidation then is determined by the availability of HNO_2 and, hence, by the amount of reaction already taken place. It is, therefore, an exponential function of time. When the rate has reached a certain value, however, there is adequate HNO_2 and the availability of HNO_3 becomes a limiting factor. The rate then becomes constant in time with HNO_3 (or equally H^+ and NO_3^-) diffusing to the surface at a steady rate and the surface concentration of HNO_2 is maintained constant, the balance between the net rate of production by the reaction and the rate of loss by out-diffusion.

The difference between the etch rate of ground and polished surfaces lies in the time required for the steady-state etch rate to be reached. The activation energy for the reaction [1] and [4] on ground surfaces (containing many dislocations) is expected to be less than for a more perfect etched or carefully polished surface,[4] and, therefore, the catalyzed reaction gets started more readily. Adding nitrous acid (nitrite or nitrogen oxides) similarly helps initiate the catalyzed reaction.

The way the steady-state etch rate varies with concentration (the measured etch rate-concentration function) reflects the availability of nitric acid (HNO_3) at the surface since reported etch rates are "steady-state" values. The diffusion gradient of HNO_3 (or H^+ and NO_3^-) will be affected by increases in the bulk nitric acid concentration, tending to increase the concentration at the surface. The increase in rate expected from this also increases the concentration of HNO_2 at the surface which increases the rate still more. Similarly, the heat of reaction increases the rate, as a higher etch rate is equivalent to higher rate of liberation of heat and, hence, an increased surface temperature. This, in turn, affects the diffusion rates to and from the surface in the way outlined by Robbins and Schwartz. The diffusion gradient, the surface concentration of nitrous acid, and surface temperature are all power functions of the bulk concentrations. The etch rate will, therefore, be some power function of the nitric acid concentration. The index is expected to be greater than 1 but not necessarily integral. A plot of log (etch rate) against log (nitric acid concentration) at 80% hydrofluoric acid concentration, taken from Robbins and Schwartz's Fig. 2, is shown in Fig. 1 published here. This has a slope about 2 and indicates an etch rate approximately proportional to the square of the nitric acid concentration.

The second stage of the dissolution process is the reaction of the oxidized silicon with hydrofluoric acid to give soluble silicofluoride ions or silicon tetrafluoride.

$$Si - 4\epsilon^- + 6F^- \rightarrow SiF_6^{2-} \quad [6a]$$

$$Si - 4\epsilon^- + 4F^- \rightarrow SiF_4 \quad [6b]$$

The reaction may be written with either F^-, or HF, or HF_2^-, all of which exist in hydrofluoric acid solutions.[5] This reaction is not chemically catalyzed but is, of course, hastened by a rise of temperature. The reaction is not expected to be kinetically of sixth or fourth order as the numerous addition steps will not necessarily have equal rates and the slowest step will be rate determining. A plot of log (etch rate at 60% nitric acid concentration) against log

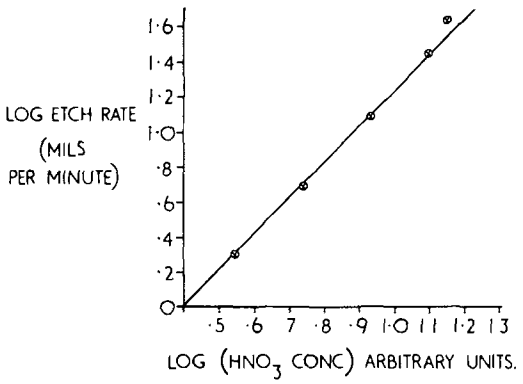

Fig. 1

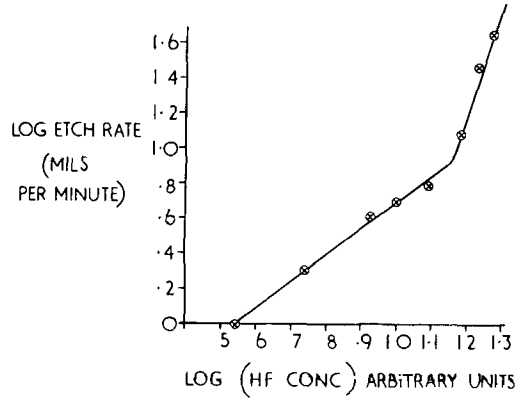

Fig. 2

(hydrofluoric acid concentration), taken from Fig. 2 of Robbins and Schwartz's paper, is shown in Fig. 2 published here. The slope is about 3/2 on the left and rises to about 6 at the right, though the latter figure is doubtful. The rate is approximately proportional to the 1.5 up to 6 power of the nominal hydrofluoric acid concentration.

Combining the two partial rate expressions gives: Rate $\propto$ (nitric acid concentration)^2 (hydrofluoric acid concentration)^n, $n = 1.5 \rightarrow 6$ [7]

The approximate linear plots of Robbins and Schwartz's Fig. 3 can be explained using the above rate expression. If the fraction of nitric acid is x, then the fraction of hydrofluoric acid is $(1 - x)$ and rate $\propto x^2 (1 - x)^n$, $n = 1.5 \rightarrow 6$; therefore: log (rate) $= 2 \log x + n \log (1 - x) +$ const.

Plots of $2 \log x + n \log (1 - x)$ against x for x between 0.1 and 0.9 give curves of the general form shown in Robbins and Schwartz's Fig. 3. The position of the maximum etch rate depends on the value of n and can be estimated by differentiating the rate expression, equating to zero and solving for x. A value of $n = 4.5$ gives a maximum at $x = 0.3$ in agreement with the "no added water" curve of Robbins and Schwartz's Fig. 3. This value for n is reasonable because the acid strengths correspond to the portion of Fig. 2 where the slope is about 4.5. A value of about 6 would be applicable in the strongest acid mixtures and 1.5 for the diluted etchants (etch rate 1-2 ml/min). The position of the maximum varies accordingly from $x = 0.25$ for the most concentrated acids ($n = 6$) to $x = 0.56$ for the diluted etchants ($n = 1.5$). This is in accord with Robbins and Schwartz's results for various levels of added water.

It is seen, therefore, that, although the reaction is diffusion controlled, an empirical rate expression [7] can be deduced which is in satisfactory agreement with all the experimental results and which is to be preferred to the exponential function indicated by Robbins and Schwartz. This expression should not be interpreted stoichiometrically, but the reactions taking place may be inferred by comparison with other data on the reduction of nitric acid and the composition of acidic fluoride and silicofluoride solutions.

Harry Robbins and Bertram Schwartz: In our discussions of the chemical etching of silicon[6,7] in work subsequent to that being discussed by Mr. Irving, we have considered several alterative mechanisms for the oxidation process. One of these is similar to the mechanism discussed by Mr. Irving. We feel that the situation is considerably more complex than that outlined by him, and are inclined to consider that the mechanism of Abel and Schmid[8] makes a substantial contribution to the over-all reaction. This mechanism involves the oxidation of silicon by HNO_2 as the oxidant. The HNO_2 is formed autocatalytically in a two-step reaction as follows:

$$HNO_3 + HNO_2 \rightleftarrows N_2O_4 + H_2O \qquad [1]$$

$$N_2O_4 + 2NO + 2H_2O \rightleftarrows 4HNO_2 \qquad [2]$$

The NO for the reaction is available, since it is the reduction product of HNO_2. We also feel that the direct reaction of HNO_3 with silicon is also possible under certain conditions, so that there exist several parallel paths for the oxidation step. In our study of the temperature dependence of the reaction, we have found at least two "activation energies" that we have associated with the oxidation step, and which lend support to the possibility that more than one oxidation mechanism may be important in the over-all reaction.

The steady-state reaction via HNO_2 need not involve the diffusion of HNO_3 to the silicon surface as implied by Mr. Irving. Reactions [1] and [2] may well take place within the boundary layer, since the HNO_2 at the silicon surface may be depleted by reaction with the silicon, so that the concentration of HNO_2 will be a maximum within the boundary layer. Under this condition, the situation becomes exceedingly complex, involving concentration gradients of NO, HNO_2, N_2O_4, and HNO_3 within the boundary layer, and complicated interactions between these species, as suggested by Spahn and Schmid.[9]

The situation is complicated still further by the oxide removal process, and by the probability that the reaction is not strictly diffusion controlled over the entire range of compositions of etching solution we have considered. Under the latter condition, as we have discussed elsewhere,[7] the practice of using bulk solution concentration values in a rate equation cannot be justified, but it becomes necessary to take

[6] H. Robbins and B. Schwartz, *This Journal*, **107**, 108 (1960).

cognizance of the actual concentrations existing at the surface of the semiconductor, and the nature of the surface itself may then also influence the kinetics. These and other problems have made exceedingly difficult the derivation of a kinetic expression that would be valid over even a very limited range of compositions.

With respect to the kinetic expression derived by Mr. Irving, we wish to note first that the expression will be valid only on the no-added water line, and cannot be used in the form presented where the sum of the weight fraction of HF and HNO_3 does not equal 1. We have also plotted the expression

$$\log R = 2 \log X + n \log (1-x)$$

as a function of x, for values of $n = 6$ and $n = 4.5$, and it was seen that the curves were only a very crude approximation to the data published. Furthermore, if one takes the empirical rate expression

$$\log R = 2 \log x + n \log (1-x) + \log A$$

where A is the constant of proportionality in the expression

$$R = A\, x^2\, (1-x)^n$$

and calculates A by inserting the values of the measured etch rates on the no added-water line, the values of A so obtained vary by as much as three orders of magnitude. We are, thus, not inclined to agree with Mr. Irving that the empirical expression is in satisfactory agreement with the experimental data.

Electrolytic Reduction of Thorium Oxide

L. H. Meyer, (pp. 43-47, Vol. 107, No. 1)

J. R. Chalkley[10]: It would seem necessary to refer to the problem of oxyhalide formation in the systems Dr. Meyer has been considering.

In the fused chloride system, it has been shown that thorium oxychloride plays a vital role in the electrolysis.[11] Thorium oxide does not dissolve in the NaCl-KCl eutectic melt, but the oxychloride is soluble. (It is also soluble in water.) It decomposes at low Th^{4+} concentrations into the oxide and tetrachloride, and it has a low decomposition potential, depositing a finely divided mixture of metal and oxide. The oxychloride is formed by dissolving thoria in melts containing higher concentrations of thorium tetrachloride, and it is necessary that these higher concentrations should be avoided in any chloride cell used for the electrolytic reduction of thoria. But, even at the lower concentrations, it has been shown conclusively that $ThOCl_2$ is formed as a direct product of the anode reaction (anodic chlorination), and that its rate of decomposition (to ThO_2 and $ThCl_4$) is not sufficiently rapid to prevent its appearance in the catholyte and the deposition of a fine, low-grade deposit.

It is misleading to draw direct conclusions from the anode gas analysis; theoretically, chlorine would be expected to be evolved if an inert anode could be used. As evidence for this, it is easily demonstrated that oxygen will displace chlorine from a thorium tetrachloride melt. The graphite anode, however, plays an important part in the electrolysis as illustrated by the following equations, which also show that chlorine is the primary product in the anode:

$$ThOCl_2 \rightleftharpoons ThO^{++} + 2Cl^-$$

$$ThCl_4 \rightleftharpoons Th^{4+} + 4Cl^-$$

At the anode:

$$Cl^- \rightarrow Cl$$

$$ThO_2 + 2Cl + C \rightarrow ThOCl_2 + CO_2$$

$$ThO_2 + 4Cl + C \rightarrow ThCl_4 + CO_2$$

It is interesting to note that chlorination with molecular chlorine under similar conditions forms only the tetrachloride directly, the oxychloride being formed during the later stages by the back-reaction:

$$ThO_2 + ThCl_4 \rightleftharpoons 2ThOCl_2$$

It would not be justifiable to extend this behavior to cover similar reactions in the fluoride system, since it is known that many oxides are appreciably soluble in fused fluoride melts. On thermodynamic evidence, oxygen would then be the primary product at the anode, but, on present evidence, the possibility of oxyfluoride formation in the melt cannot be discounted.

The fused chloride system has been shown to be unfavorable for the operation of a direct oxide electrolytic process. Nevertheless, the two-stage process in which thoria is directly and completely chlorinated in situ in the melt and then electrolyzed[12,13] is, over-all, equivalent to the oxide electrolytic process. Very high efficiencies are obtained by this process, and, as with most fused chloride systems, the following advantages over the corresponding fluoride systems are shown:

(*A*) Lower operating temperatures.

(*B*) Easier leaching conditions due to higher chloride solubilities. 'Stripping' of thorium from the melt is advocated, but thorium in leach liquors is effectively recovered by oxalate precipitation.

(*C*) Less corrosive conditions, giving a wider choice of refractory and insulator materials.

Influence of Electrode Surface Conditions on the Electrical Strength of Liquefied Gases

D. W. Swan and T. J. Lewis (pp. 180-185, Vol. 107, No. 3)

A. H. Sharbaugh[14]: It is gratifying to note the general agreement of Dr. Lewis' values for the electric strength of *liquid* nitrogen and our measurements on *gaseous* nitrogen at high pressures. We observed values of the order 1.8 mv/cm at densities which are about one-quarter of the liquid density.[15] Thus, it would appear that there is no marked discontinuity in electric strength in passing from the gaseous to liquid phase.

[15] *1957 Ann. Rep., Conf. on Elec. Ins.*, p. 32.

I should like to call attention to two earlier examples of the influence of the anode properties on the measured values of electric strength of hydrocarbon liquids. The first was observed in n-hexane where we measured a decrease of about 10% in the electric strength when a smooth flat stainless steel anode was roughened by grit blasting.[16] The "hill-to-valley" depth of the roughened surface was of the order of 10% of the 70μ gap separation. A second example was reported for some measurements in benzene where solutions with different concentrations of electrolyte were employed as anodes. In this case, the effect was interpreted as being due to the space-charge enhancement of the applied field by positive ions emitted from the anode.[17]

Molecular Structure and the Electrical Strength of Liquid Hydrocarbons

T. J. Lewis (pp. 185-191, Vol. 107, No. 3)

P. K. Watson[18]: The model which has been proposed appears to have at least two notable defects: It indicates that the mechanism of breakdown in liquids takes place by means of an electron multiplication process, and it implies that the breakdown strength of a liquid should be virtually independent of an applied hydrostatic pressure.

Now, on the basis of our recent experiments on high-field conduction currents in hexane in the microsecond region, we have concluded that there is no significant multiplication process in hexane even at fields of 1.3 mv/cm.[19]

Moreover, recent experiments have indicated that the breakdown strengths of liquids are strongly pressure dependent, even for pulses as short as 1 μ sec.[20]

Obviously, there is a correlation between electrical breakdown strength and some parameter associated with molecular structure, but the relationship must be more indirect than Dr. Lewis has indicated.

A. H. Sharbaugh[21]: By analogy with Townsend-type breakdown in gases, a theory of liquid breakdown which involves an electron multiplication (α-process) predicts that the value of the product $\alpha\delta$ will be approximately constant for wide ranges of gap width δ and ionization coefficient α. At *constant* δ, we have observed a 50% decrease in the electric strength E_b of liquid hexane when the electrode area is increased from $\sim$ 0.2 to 3 cm^2.[22] Since α, if it exists, would be expected to be a strong function of E, it is difficult to reconcile this experimental observation with the hypothesis of a multiplication process for breakdown in liquid hexane.

T. J. Lewis: The statement by Dr. Watson, that the model implies that breakdown occurs by an electron multiplication process and should be independent of an applied hydrostatic pressure, is not really correct. The criterion set up is one for the necessary field to overcome various loss processes and so provide some electrons of sufficient energy to contribute effectively to the next stage in the breakdown sequence.

Only when all the succeeding stages of the breakdown (some of which may be pressure dependent) are maintained in a reasonably constant manner, i.e., C constant, will comparison between experiments be possible in terms of this criterion. Such a situation should arise for a series of similar hydrocarbons.

One should not proceed too far by analogy with gas discharges in expecting clearly measurable values of α since the actual value might be small or only significant when breakdown is imminent or even masked by the other processes embodied in C. Even when α is small, however, the liquid still can exert a marked influence through the loss process envisaged.

The results mentioned by Dr. Sharbaugh, in which a decrease in strength of n-hexane is observed when the electrode area is increased at constant gap width, provide evidence, I believe, not for liquid mechanisms but for quite a different aspect of the subject. It should be recalled that these measurements were made using the microsecond pulse technique. Under these conditions, an analysis of the variation of strength with area according to the concepts outlined in Abstract 13[23] will indicate that the observations are exactly in agreement with a statistical model of the breakdown process and do not, therefore, shed any light on the possibility of a multiplication process.

A New Statistical Theory for the Breakdown of Liquid Hydrocarbons

B. W. Ward and T. J. Lewis (pp. 191-195, Vol. 107, No. 3)

Oliver H. LeBlanc, Jr.[24]: It has been shown experimentally by Goodwin and Macfadyen and by Crowe that the time lags observed with application of short pulses are directly proportional to the electrode spacing. This seems to me to be clear evidence that the time lag must be formative and not statistical.

P. K. Watson[25]: For a time lag to be ascribed to a statistical process, similar to the well-known effect in gases, it is necessary to postulate the nature of the event for which one is waiting. In the gaseous case, this event is the arrival of an initiating electron, and Dr. Lewis has suggested that, by invoking a similar phenomenon for liquids, one can explain the dependence of breakdown strength upon pulse width in the microsecond region.

[23] "A New Statistical Theory of the Breakdown Process and the Reinterpretation of Pulse Breakdown Measurements in Liquid Hydrocarbons" by T. J. Lewis, ECS Meeting, Philadelphia, Pa., May 1959.
[24] Research Lab., General Electric Co., P. O. Box 1088, Schenectady, N. Y.
[25] Research Lab., General Electric Co., P. O. Box 1088, Schenectady, N. Y.

This hypothesis is not, in fact, consistent with the experimental facts:

(*A*) The currents which are observed in liquids, under microsecond pulses of voltage, at fields in the range 1 to 1.5 mv/cm, are of the order of milliamp per cm^2.[26] Assuming a value for electron mobility of the order of 10^{-3} cm/sec/v/cm,[27] this gives an electron emission rate of 10^{13} electrons/sec/cm^2 from the cathode. It is difficult to see how such a copious emission can be consistent with statistical time lags in the microsecond region.

(*B*) If, however, one supposes that the probability of an electron initiating a breakdown is very small (say 1 in 10^6 or so), then it might be argued that the experimental evidence is still consistent with a statistical time lag, in that one is awaiting the emission of a very large number of electrons from the cathode. This again, however, is at variance with the observed facts: If, as has been suggested, the electron emission from the cathode is a field-assisted thermionic process (Schottky emission), then one would expect any statistical time lags to be strongly temperature dependent. In fact, the experiments of Kao and Higham indicate that the time lags are independent of temperature.[28]

Finally, it may be thought that the electrons are field emitted: In this case, however, one would expect a marked reduction in time lag if, by some means or other, one were able to increase the field needed to cause breakdown. This can be done by changing the hydrostatic pressure applied to the liquid, and Kao and Higham find that in hexane, for example, there is no change in the critical time lag, in going from atmospheric pressure, up to 25 atm, despite a very marked increase in the breakdown strength.

Thus, one is forced to conclude that the observed time lags in liquids are not consistent with a statistical model.

T. J. Lewis: The present theory does not preclude the existence of a formative time lag. In fact, it states that both statistical and formative times exist and that the latter is expected to be dependent on the electrode spacing, thus leading to the results obtained by Goodwin and Macfadyen and by Crowe. The important result, which may not have been adequately presented in the paper but which can be properly developed in a full treatment, is that the formative time is not that associated with the "knee" of the electric stress-pulse duration curve, but is a much smaller quantity.

Dr. Watson's concluding comment is that the observed time lags in liquids are not consistent with a statistical model. I submit that the experimental evidence obtained by many different workers employing short-duration pulses is overwhelmingly to the contrary. The reasons are:

(*A*) When a proper statistical analysis is made both of the method used and the results obtained for the electric strength as a function of pulse duration, the existence of a statistical process becomes very evident. Failure to take account of the nature of the experimental method has led to erroneous conclusions in the past.

(*B*) If a step-function voltage pulse is employed instead of microsecond pulses, the breakdown time lag can be measured directly and has obvious random fluctuations.

We have made measurements on n-hexane under both categories (*A*) and (*B*) above to confirm this, and it is important to note that it is *not* necessary to postulate the nature of the random process in order to establish these experimental facts.

However, it is profitable to proceed further by enquiring into the nature of the random events which give rise to the effects noted. In the paper, I have attempted to do this by postulating a random process of rate *IW* which is partly cathode and partly liquid dependent. It would be wrong to assume at this stage more than the property that *IW* increases with field, provided all other conditions remain constant. It is certainly not justifiable to dismiss the evidence for a statistical time lag as Dr. Watson does, simply because *I* in the presence of hydrocarbon does not conform to vacuum emission laws.

If *I* is identical with the electron emission rate from the cathode and that is, in the worst case, 10^{13} electrons/sec and concentrated on a single emission site, then it is true than *W* would need to be $< 10^{-6}$ to give time lags of the right order. Further consideration indicates that this is not at all unlikely. In fact, values of *W* very much less than this are probable, if only the most energetic electrons in the liquid are capable of initiating a breakdown. Even when *W* is of this order of smallness, one is not awaiting the emission of a large number of electrons since any electron, even the first, may lead to breakdown.

The form of *IW* chosen in the paper to illustrate the theory was unfortunate in that it did not indicate that large changes in *I* and *W* can be tolerated provided *IW* remains of the right order of magnitude.

tained by firing at low temperatures, preferably at or below 1000°C. Noticeable orientation will occur in material fired at 1090°C. The differences in the patterns are large enough to obscure positive identification, since the orientation tends to suppress those lines which distinguish 2:1:1 from the similar pattern of $Ba_2P_2O_7$. The x-ray data were obtained on a General Electric diffractometer, XRD-5, using CuK radiation, nickel filter.

An Investigation of the Reaction between Aluminum and Water

W. J. Bernard and J. J. Randall, Jr. (pp. 483-487, Vol. 107, No. 6)

F. J. Burger and D. M. Cheseldine[31]: This paper confirms a number of results which we obtained in the course of work carried out under Canadian Government Contract DRB 700129, "Development of Aluminum Electrolytic Capacitor, ECRDC Project C44." These were summarized in the First and Second Quarterly Reports of November 1958 and February 1959, respectively.

In our investigation, two methods were used to determine the degree of hydration of the product of the reaction of hot deionized water on aluminum.

In one method, the volume of hydrogen evolved during the reaction was measured directly and correlated with the weight increase of the aluminum specimen. The ratio of these two quantities varies according to the degree of hydration of the oxide formed, as illustrated, e.g., by equations [1] and [2], which represent the formation of mono- and trihydrates, respectively.

$$2Al + 4H_2O = Al_2O_3 \cdot H_2O + 3H_2 \quad [1]$$

$$2Al + 6H_2O = Al_2O_3 \cdot 3H_2O + 3H_2 \quad [2]$$

Calculations show that for a weight increase of 1 mg the volume of hydrogen at NPT is 1.02 cc in the case of monohydrate formation, and 0.66 cc in the case of trihydrate.

In a typical experiment, a specimen of 99.99% pure, etched aluminum foil (measuring 2 in. x 2 in. x 0.0035 in., and having attached to one of its sides a tag 2 in. long by ¼ in. wide) was immersed in deionized water ($\rho_{25°C} > 10^6$ ohm-cm) at 90°C, as follows.

The weighed specimen was placed under an inverted short-stemmed glass funnel and secured by leading the tag out through the stem of the funnel and turning its end over. Funnel and foil then were completely immersed in the hot water and an inverted burette filled with water placed over the stem of the funnel to collect the evolved hydrogen. After a suitable reaction time (say 1 hr), the foil was quickly removed from the water, dried either at 110°C or *in vacuo* at room temperature, and reweighed.

The volume of hydrogen, measured at room temperature and atmospheric pressure and corrected for 0°C, was found to be 32 cc.

Corrections for barometric pressure, water vapor pressure, and losses due to solubility of hydrogen in water were not applied. The corresponding weight increase of the foil specimen after drying under vacuum at room temperature was 43.5 mg, *i.e.*, a weight increase of 1 mg was accompanied by evolution of approximately 0.74 cc of hydrogen (NPT). The hydration calculated from these figures is 2.4 moles H_2O and 1 mole of Al_2O_3. The mean value obtained by this method from 7 separate experiments was 2.8 moles of water.

In our second series of experiments, applying the method of Lewis and Plumb[32] in which the oxide is stripped in an aqueous solution containing 2% CrO_3 and 5% H_3PO_4 at 85°C, we found a somewhat lower figure for the hydration. In these experiments, too, the same type of etched, 99.99% pure Al foil was used. Foil specimens were immersed in boiling deionized water for 5, 30, and 60 min. The times required for stripping these layers were about 10, 30, and 40 min, respectively. The weight changes observed, namely, first, after boiling and, second, after stripping the aluminum foil, are shown in Table I published here. In each of these cases, the foil was

Table I. Weight changes on, first, boiling and, second, stripping 4-sq.-in. etched aluminum foil

Reaction time (min)	5	30	60
(*A*) Weight increase after boiling (mg)	60.8	98.2	119.2
(*B*) Weight loss after stripping (mg)	98.3	159.8	193.6
Ratio $\frac{(A)}{(B)}$	0.62	0.63	0.63

[31] The Telegraph Condenser Co., (Canada) Ltd., 50 Bertal Rd., Toronto 15, Ont., Canada.

[32] J. E. Lewis and L. C. Plumb, *This Journal*, 105, 499 (1958).

dried in vacuo at room temperature for ½ hr before weighing.

The composition of the reaction product is shown to be independent of reaction time in the range covered by reference to the bottom line of the table which lists the ratio of combined oxygen and hydrogen (weight increase) to hydrated alumina (weight loss). The mean of this ratio, being 0.63, corresponds to 2.1 moles H_2O per mole of alumina, the values for mono- and tri-hydrate being, respectively, 0.55 and 0.665.

Both methods, therefore, support the view that the hydrate formed is not mono-hydrate as has been commonly assumed hitherto, but is of a higher order.

Growth of Single Crystal Silicon Overgrowths on Silicon Substrates

Albert Mark (pp. 568-569, Vol. 107, No. 6)

R. C. Sangster[33]: Very similar work was reported by Sangster, Maverick, and Croutch.[34] The lead paragraph reads as follows: "A study has been made of the feasibility of growing Si crystals by the reaction of gaseous $SiBr_4$ with H_2 at the surfaces of hot Si seed filaments. The immediate objective has been to produce deposits of a purity and a crystal perfection sufficient for semiconductor device purposes. An ultimate objective has been the deposition of arbitrary, complex, p-n junction structures by control of the types and amounts of impurities deliberately introduced into the process gas stream. This is a partial report covering the more interesting observations and results." Included were descriptions of the apparatus used, an analysis of the deposition process with respect to both the fundamental phenomena involved and the effects of process variables, microphotographs of epitaxial single crystal silicon deposits, description of the optimum experimental conditions, and some preliminary electrical results on epitaxially grown p-n junction structures. The authors feel that the current interest in techniques of this sort is quite justified and long overdue. We hope that Mr. Mark's contribution will help stimulate further activity in this field.

June 1961 Discussion Section

A Discussion Section, covering papers published in the July–December 1960 JOURNALS, is scheduled for publication in the June 1961 issue. Any discussion which did not reach the Editor in time for inclusion in the December 1960 Discussion Section will be included in the June 1961 issue.

Those who plan to contribute remarks for this Discussion Section should submit their comments or questions in triplicate to the Managing Editor of the JOURNAL, 1860 Broadway, New York 23, N. Y., *not later than March 1, 1960.* All discussion will be forwarded to the author(s) for reply before being printed in the JOURNAL.

Some Practical Aspects of Copper Refining in a Multiple System Tank House

M. A. Mosher

Raritan Copper Works, Perth Amboy, New Jersey

Weird Character of the Tank House

In this day of rapid revolution, startling innovation, and overnight obsolescence in industrial processes and equipment, the electrolytic copper tank house stands and has stood for nearly three-quarters of a century as a fixed and stubborn example of resistance to radical change. In the great copper, zinc, and nickel industries so completely dependent on it, the tank house seems to be considered a fundamental thing, comparable in our physiology to the process of metabolism, and in nature to "Old Man River" who "just keeps rollin' along."

The typical copper tank house with its hundreds of cells and thousands of electrodes and millions of gallons of circulating solution, is for the greater part of each 24-hr day a quiet and unspectacular place, with only the faint purring of pumps and the gentle flow of electrolyte through the tanks to indicate that it is actually functioning. Almost unique among the great producing units of modern industry, the tank house makes most of its production in majestic and peaceful silence, in marked contrast to the ceaseless roar of furnaces, the din of machinery, and the noisome reactions of large chemical processes.

Of course there are a few hectic hours in each day when a tank house, like a restless infant, has to be fed and changed, but that is only to keep it healthy and behaving properly.

The Tank House Boss

In line with these unique characteristics of the operation, long exposure to tank house work tends to develop a rather peculiar type of chief operator or superintendent, and having been one of these, I will briefly describe him for you, even though by comparison with the masterful and dynamic operators of other types of processes, he may seem drab and uninteresting.

He tends to become a slave of the established routine which he has worked out, the hard way, to get the best results. He learns to live with and keep alert to a staggering number of small easily overlooked operating details, because he knows from bitter experience that disregard of any of them may upset his whole show. He is slow to arrive at conclusions about process difficulties because he knows that dozens of inter-related factors are involved in every operating crisis he has to deal with. He develops a militant aversion to any radical innovations or changes in his methods of operation because he feels their adoption may result in complications which will jeopardize vital production. And, finally, he develops a great patience in the face of operating adversity, realizing that, in most cases of process sickness in a tank house, there is no miracle-drug cure.

Contrary as these characteristics of a good tank house operator may seem, there is much justification for them in tank house work for the following reasons:

1. The tank house process is essential for economically providing the standardized high-purity product on which his company or division depends for its existence. This is a tremendous responsibility for its operator, and consciousness of this fact naturally makes him conservative and jealous of his time-proven methods and procedures.

2. The tank house operator knows that it takes months or even years successfully to work out worthwhile changes or innovations, because every move must be made with care and patience to avoid upsetting the scheduled flow of large-scale continuous production.

3. No matter how eagerly the tank house operator may want process improvement through research, he knows from many a disappointment that the best of research results can fail miserably when applied to full-scale commercial operation. In fact there are few other industrial operations where laboratory or small-scale tests will provide so little usable data for full-scale application.

Tank House Improvements

You may wonder why I have tried to give you a picture of the typical tank house superintendent, but through it I think we have arrived at the main reason why changes and improvements in tank house operation for the past half century have been somewhat limited in scope, and chiefly in the area of construction materials, physical arrangement, and improved mechanical equipment for handling anode input and cathode production. These advances can be listed as follows:

Improved building walls and roof construction, using such materials as glazed hollow tile and Porete roof slabs that afford insulation against loss of heat and minimize condensation when outside temperature is low.

Conversion to reinforced concrete cell construction to replace wood.

Improved types of solution line insulation to provide protection against the passage of stray electrolytic current, such as the use of plastic pipe and tubing to replace lead and rubber.

Use of heat exchangers constructed of corrosion-proof materials, in place of lead pipe heating coils. This more efficient solution heating equipment has made possible an increase of about 10°F (5.6°C) in the accepted temperature for electrolyte entering the cells.

Larger cells to permit the use of higher circuit amperage and to reduce the number of unit loads of anodes and cathodes to be handled by crane.

Improved addition agents and better addition agent control.

Improved methods for inspection of cells in operation, particularly the introduction of the Gaussmeter for the detection of shorted cathodes.

Continuous filtration of make-up solutions.

Improved pump design and construction, using stabilized stainless steel.

The racking of anodes at the casting furnace and the mechanical washing and loading of cathode production in the tank house were introduced about 35 years ago. At about the same time the method of stripping starting sheets was changed from horizontal to vertical handling. That about sums up the improvements in mechanical handling since overhead electric cranes for tank-load lifts were introduced in the early 1900's.

Present Day Equipment and Operation

The general acceptance and adoption of most of these advancements by the various refineries in the last two decades has resulted in a fair degree of standardization in both equipment and operation. We can therefore discuss these accepted essentials of present day tank house equipment and operation with assurance of their almost general application.

Our discussion will be confined to the Walker Multiple System lay-out with the electrodes in parallel in each cell and the cells themselves in series in the electrolytic circuit. In the original Walker system current was passed from tank to tank by means of a conductor bar of small cross section placed on the common partition between adjacent tanks. The contact end of the cathode rods of the first tank rested on the conductor bar in alternation with the contact lugs of the anodes in the second tank. This arrangement has been largely superseded by the Whitehead contact which eliminates the conductor bar by having the contact end of the cathode rods rest directly in a slot in the contact lug of the anodes. As much as 5 mv of *IR* drop per cell is saved by this direct contact.

Electrolytic Cells

Two general types of reinforced concrete construction have proved satisfactory. One type comprises the assembly of precast slabs to form a row or tier of cells with partitions common to two tanks. The use of replaceable planks of heavy wood for the bottoms of these cells is generally favored. The precast concrete elements are so fitted and interlocked that only a few bolts and stays are required to make the entire tier a rigid construction unit. All types of cells have a bottom outlet for the removal of electrolytic slime, and in many designs another outlet is provided in the end wall of the cell a few inches above the bottom for the decantation of electrolyte prior to the removal of slime. Bottom outlets discharge into a system of launders which convey the slime slurry by gravity to pumps in the cellar. The other type of construction is the cast-in-place monolithic tier of reinforced concrete.

Insulating slabs of glass or stoneware are placed between the tank bottoms and the supporting piers which rise from a 7 to 8 ft cellar. Tiers or rows are usually designed in pairs as sections. The section is the operating unit in practically all tank houses, as the electrolytic current bus bars are so arranged that the current can be conveniently applied to or cut off from it to permit removal or replacement of anodes, cathodes or electrolyte.

Eight-pound 6% antimonial lead is still universally used for cell linings, but there is considerable testing and experimentation with several types of acid-resisting plastic materials.

Solution Lines and Tanks

Solution lines for conveying electrolyte to and from the cells have traditionally been of lead with lengths of insulating rubber tubing at the cell inlet and outlet. However, polyvinyl tubing is replacing rubber in many tank houses and there have recently been several installations in which p.v.c. pipe and p.v.c. lined launders have replaced lead pipe and lead linings. Increasing use of plastics in place of lead has resulted from the need to eliminate conducting paths through which destructive current can stray from the electrolytic circuit.

Lead-lined steel or steel skeleton tanks are still favored for storage, settling, and mixing of tank house solutions, although there have been many trial installations of plastic-lined tanks.

Pumps

Centrifugal pumps of all types, both horizontal and vertical, are in general use, but lead construction has been almost entirely abandoned in favor of stabilized stainless steel alloys. Use of the latter metal makes it necessary to protect fully the pumps from electrolytic corrosion resulting from stray current which gives the pump positive polarity.

Electrolyte—Composition and Temperature

The aqueous solution of copper sulfate and sulfuric acid used in electrolytic copper refining can vary widely in chemical composition, specific gravity, and temperature and still give satisfactory results in the production of high-purity cathode copper.

The content of these electrolyte constituents is usually adjusted to compensate for the presence of contaminating salts which accumulate from the solution of anode impurities. For example, sulfuric acid content can range from 150 to 220 g/l, but in most tank houses is maintained near 200 g/l since this concentration has a high electrical conductivity and usually avoids the anode polarization which results from the reduced solubility of impurity salts caused by high acid content. Likewise copper content as sulfate may range from 40 to 55 g/l but is usually maintained at 45 g/l. This content insures pure copper deposition, yet allows for the presence of reasonable amounts of soluble impurities. The copper content of the electrolyte tends to increase by about 1.5% of the copper deposited. A sufficient amount of electrolyte is therefore continually passed through plating-out or liberator cells equipped with lead anodes. This maintains the desired level of copper content in the entire body of electrolyte, and the copper thus removed is of normal high purity.

The beneficial effect of temperature in maintaining solubility of the salts is important. Electrolyte temperature can range from 120°F (48.9°C) to 150°F (65.6°C) and most tank houses use 140°F (60°C) or higher at the cell inlet to insure high solubility as well as to lower specific gravity, which facilitates movement of the electrolyte through the cell.

Of the soluble impurities which accumulate from normal corrosion of the anode, arsenic, antimony, bismuth, and nickel give the operator the most concern and make it necessary for him to keep close control of copper and acid content as well as temperature. Of these four anode impurities, nickel remains almost entirely soluble in the electrolyte. Much of the arsenic, antimony, and bismuth forms complex compounds, probably arsenates, which are insoluble and precipitate with the slime. While the electrolyte can safely tolerate nickel up to 20 g/l and arsenic up to 15 g/l, antimony and bismuth can become troublesome when they exceed 0.5 g/l. Difficulty with

electrolytic impurities can be minimized by reducing the sulfuric acid content to as low as 125 g/l, and holding copper content down to 45 g/l. The total amount of soluble impurity elements should not be permitted to exceed 30 g/l.

Any appreciable amount of soluble selenium and tellurium, introduced through return solutions from the leaching of electrolytic slime, can cause havoc in the tank house, since these elements cement out on the cathode surfaces and destroy the continuity of crystal growth. The result is a coarse, granular deposit which in extreme cases becomes nonadherent and falls from the cathode.

It should be noted that soluble impurities in the electrolyte appreciably increase its resistivity and can become a significant factor in the cost of electric power.

Electrolyte Purification

Except for minor modifications, the general procedure for removing arsenic, antimony, and nickel to maintain reasonable electrolyte purity is as follows:

The required volume of electrolyte is diverted continuously through liberating cells for plating out the copper. The solution is then further electrolyzed in outdoor tanks to deposit arsenic and antimony. The resulting high-acid nickel-bearing solution is evaporated to approximately 60° Be', which precipitates the nickel as a crude sulfate. With proper washing and centrifuging this product is marketable. The resulting "black acid" and wash waters are returned to the electrolyte, or subjected to acid distillation to remove iron, calcium, magnesium, sodium, and potassium salts. It is possible to remove appreciable amounts of calcium and magnesium salts by isolating batches of decopperized solution and letting these salts crystallize out at outdoor temperature.

Electrolyte Conditioning

Early in the development of electrolytic copper refining it was found that the electrolyte required certain additions to produce consistently firm and relatively smooth cathode deposits free from entrapped impurities and sprouting growths which would short circuit to the anodes. Common salt to introduce chloride ions was the first of these additions and is supposed to have been adopted after the benefits of an accidental intake of sea water for solution make-up had been noted at an east-coast refinery. Most refineries now add salt or hydrochloric acid to maintain a chlorine content of 0.02 to 0.035 g/l. The exact function of the chloride ion is not well understood, but it precipitates dissolved silver and improves the physical characteristics of the cathode deposit. Several refineries have noted difficulty with sandy, nonadherent cathode deposit when chlorine content was permitted to fall below 0.008 g/l.

Organic additions are also necessary in order to obtain a fine-grained, firm cathode deposit which remains relatively free from sprouts and protrusions during many days of plating. Animal glue, a complex protein, has long served as the most effective organic addition agents, apparently due to the slight cathode polarization which it causes. Other organic compounds work well in conjunction with glue but not to the extent of displacing it entirely. Among these are casein, thiourea, and sulfonated products such as goulac and bindarene from sulfite liquors, and Avitone, a sulfonated petroleum derivative. Orzan A, an ammonium ligno-sulfonate and Separan, a flocculating agent, are also used by certain refineries. These sulfonated compounds appear to modify the action of glue, tending to decrease its polarization effect and counteracting the excessive hardness and sprouting of the deposit which can result from an overdose of glue alone. Several refineries find that an addition of light petroleum oil emulsified in electrolyte is beneficial in tempering the action of glue. Each refinery has developed from experience an organic addition agent formula which gives the best results under its own process conditions, and the amounts added vary widely. Per ton of cathode deposition, glue additions range from 0.01 to 0.3 lb, the usual amount being about 0.1 lb. Modifying agents are added in a ratio of 2, 3, or 4 times the weight of glue. Addition agents are dissolved or emulsified in relatively large volumes of water and continuously introduced in the circulating electrolyte reservoirs, preferably by mechanical reagent feeders.

Daily evaporation of water from the electrolyte averages 2-3% of the total volume being heated and circulated through the cells. This evaporation has to be carefully and continuously replaced, either with clean water or "make-up" solution, which results from the washing of cathodes and anode scrap, or from the leaching and washing of electrolytic slime. Make-up solution must be thoroughly blended and kept warm, so that it will mix readily when added continuously to the circulating electrolyte. If water is required in addition to available make-up solution, it should be clean and warm and added in a small stream at a point where it will mix in thoroughly. Making up evaporation is a critical item in tank house operation, since careless addition of solution or water causes localized dilution of the electrolyte. This can quickly upset the proper functioning of all cells receiving it.

The cathode surfaces in cells receiving diluted electrolyte even for a short period will show areas of needle or whisker-like copper deposit, which will later develop into short-circuiting growths.

Electrolyte Heating

Low pressure steam is universally used by means of heat exchangers, immersion heaters, or closed coils. Depending on building construction and climate, steam requirements average roughly one pound for each pound of cathode production. It is important that during cold weather building ventilation be regulated to maintain a minimum temperature of 80°F (26.7°C).

Karbate (resin-bonded carbon) tubes are used for conducting the electrolyte through heat exchangers. Stabilized stainless steel jackets carry the stream in immersion or plate coil heaters, and lead pipe is used for closed coils. The Karbate tube heat exchanger has been in favor in recent years because of its compactness and high rate of heat transfer.

Whatever the type of heating apparatus used, the condensate water is usually collected and utilized through a separate hot water system for all process washing and electrolyte make-up purposes. This avoids eventual contamination of the electrolyte with prolonged use of raw water and is an important factor in the economy of using steam for heating.

Electrolyte temperature much below 120°F (48.9°C) will, with most refinery electrolytes, permit salting-out of sulfates and bring on anode polarization which upsets the electrolysis by increasing the cell voltage to the decomposition voltage of the copper sulfate electrolyte. When this occurs the operators dub the cells "crazy."

Circulation of Electrolyte

The heated electrolyte must circulate through each cell at a rate which will prevent too great a loss of temperature between the inlet and outlet and maintain the proper ion concentrations at the electrode surfaces. For good operation this temperature drop is seldom permitted to exceed 10°F or 5.6°C. The required rate of flow

varies with the size of the tank and the room temperature but usually falls within the range of 3.5-6 gal/min. Excessive rate of flow tends to interfere with the settling of the electrolytic slime which sloughs from the anodes.

Once a satisfactory rate of electrolyte flow has been established, it is most important that it be maintained constantly and kept uniform in all cells. Otherwise not only the electrolyte temperature, but the beneficial effects of the organic addition agents will vary from cell to cell.

In most refineries the circulating electrolyte is pumped to a head tank from which it feeds by gravity to the sections of electrolytic tanks. Some refineries, however, pump directly into the supply lines. In this case care must be taken to avoid intake of air at the pump, as air entrained in the electrolyte will form small bubbles on the cathode surfaces and prevent copper deposition wherever they cling, thus having the effect of increasing the current density.

Anodes

The impure anodes, cast from blister or converter copper after it has been furnace refined to remove sulfur, usually have a copper content of 99+%. Oxygen content is usually within the 0.10 to 0.30% range, and in most cases the percentages of the various impurity elements, exclusive of silver, are in the second or third decimal place. Silver plus gold seldom exceeds 30 oz/ton or 0.10%.

In different refineries, anode dimensions vary from 27 to 36 in. in width, from 31 to 39 in. in length, and from 1¼ to 2 in. in thickness. Anodes are universally cast flat with two ears or lugs at one end. This permits them to be hung vertically, and the longer of the two lugs acts as the conductor for the inflow of current. Weight per anode ranges from 440 to 700 lb, and anode life under electrolysis is scheduled at from 21 to 42 days, leaving a scrap remainder of 12 to 20%. Scrap anodes are washed free of adhering slime and returned to the anode furnace for remelting.

In most refineries anode life is about 4 weeks, during which period the cells produce two sets of deposited cathodes. This affords an economical operating schedule and permits the use of a standard rotation for taking out cathode production, replacing anodes, and removing slime from the cells. In some cases where nodularized cathode deposition results from the requirement to electrolyze with high current density or with troublesome anode impurities, it is necessary to plate three or four sets of cathodes during the life of the anode.

After casting, anodes are hung by their lugs and evenly spaced in racks which hold a cell load, so that they can be placed in the cells in unit crane lifts of several tons. While in the racks it is important that the individual anodes be plumbed to hang vertically. This is accomplished by a slight bending of the lugs, using a heavy hammer. Also at this time the contact area of the long lugs is cleaned or polished.

Cathodes

The thin starting sheets of electrolytic copper which are hung between the anodes, and in most refineries at each end of the cell, are usually produced as a 24-hr deposit on smooth, oiled plates or blanks of hard rolled copper which are themselves hung as cathodes in special cells operated for this purpose. In order to eliminate the necessity for surface oiling, there has been considerable experimentation with stainless steel blanks, but passivity to corrosion has been found to decrease with use, and surface repolishing becomes necessary. A deposited sheet, 0.02 to 0.03 in. thick, is peeled from each side of each blank every working day. After stripping, the blanks are re-oiled if necessary and returned to their cells. Strips cut from the same sheet deposit are formed into loops and affixed to each sheet by punching or spot welding so that a copper rod can be threaded through them. These rods support the sheets when they are later hung in the production cells; they also serve as current conductors.

The anodes used in the cells for depositing sheets are usually 2 in. wider and 1 in. longer than the anodes in production tanks. This insures adequate deposition around the edges of the blanks even after 75% of the anode has been corroded away. Starting sheets are usually 2 in. wider and 1 in. longer than the anodes used in production cells. This avoids the formation of a heavy border of deposition during the early days of production plating while the regular anodes still retain their full area.

Before being hung in production cells as cathodes, starting sheets must be "flapped" or flattened so that they will hang straight and not touch the adjacent anodes. In most refineries the flapping is done by hand, but machines are being developed which perform both flattening and affixing of loops.

To permit effective flattening, the sheets must be soft and pliable and free of springiness. The deposition surface must be free of roughness which would promote nodular growth. As a result of these requirements, the composition and conditioning of the electrolyte for the starting sheet cells must be controlled closely and handled through a circulation separate from those which supply the production cells. It is best to use only glue as addition agent. Due to the presence of oil on the blanks, the amount of glue necessary may be 0.2-0.3 lb/ton in order to insure a smooth, tough, fine-grained deposit. Copper content of starting sheet electrolyte is usually maintained between 45 and 50 g/l and acid content between 180 and 190 g/l. The temperature of the electrolyte entering cells should be no less than 140°F (60°C). Cathode current density in excess of 23 amp/ft² tends to cause rough deposition.

Production Cathodes

In the production cells, the starting sheets are spaced carefully in relation to the adjacent anodes, and anode lugs and cathode rod ends are all checked for good current contact. With electrolyte up to normal level and at proper temperature and flow, the section is ready for operation. Current is applied, and deposition continues until the scheduled growth of the cathodes has been completed. Current is then shut off from the section of cells and the cathodes are withdrawn by crane, thoroughly washed with hot water by immersion or spray, and loaded for transportation to furnaces or the market.

The copper content of the completed cathode should be 99.98+% with the percentages of most of the impurity elements in the fourth decimal place. Sulfur and iron content as high as 0.002% can be tolerated. Silver content should not exceed 0.35 oz/ton.

Cathode Current Density

The amount of current through each cell can be set to obtain the desired production of cathode deposit within a fairly wide range of current density. For economic reasons the operation is seldom carried on at less than 10 amp/ft² of cathode surface. Under high production demand, many refineries have operated at 25 or 26 amp/ft², but 15 to 20 amp/ft² is generally preferred. Higher current density tends to produce a rougher deposit and often causes excessive short circuiting from sprouting cathode growths.

Cathode Current Efficiency

Current efficiency is considered a measure of good tank house operation since it is an index of the production obtained for the investment in power and labor, the two chief items of operating cost. Under ideal conditions 1 amp deposits 0.06274 lb of copper per 24-hr day per cell. Using the average of hourly amperage readings taken during the life in days of the cathodes in a cell or section of cells, a theoretical weight of deposition is calculated. When the completed cathodes are removed they are weighed, and the net weight of deposition is divided by the calculated theoretical deposition. A current efficiency of 90% is considered good, but many refineries average 94% or better. The chief cause of reduced current efficiency is short circuiting between adjacent cathodes and anodes. Another cause of lowered efficiency is stray current loss through tank linings and solution lines, which, however, seldom exceeds 2 or 3%.

Power Yield

Since power is measured and paid for in kilowatts, some concern has to be given to the voltage component by minimizing resistances wherever possible in the electrolytic circuit. The source of d-c power is located as close as possible to the cell room, main bus lines are of ample size, anode-to-cathode spacing is set at the minimum which will avoid short-circuiting, and all conductor contacts are kept clean. Both electrolyte temperature and acid content are maintained at values which reduce electrolyte resistivity. As current density is increased, power yield tends to decrease, and this explains why most refineries prefer to operate at moderate current density provided it will enable them to meet their production requirements. Power yield varies widely among different companies in a range of from 6 to 12 lb of copper per kilowatt hour.

Scheduling

The section of tanks, made up of two tiers or rows through which the electrolytic current flows across and back again to the main bus, is the normal unit of operation in the tank house. The tiers are seldom more than a foot apart, and to permit the current to leave the main bus bar and flow across the first tier and return to the bus across the second tier, there is a gap in the bus bar similar to the space between the tiers. This gap is easily bridged by dropping a short piece of bus bar across it and clamping it to maintain good contact. This short piece of bus is called a "lock" or "jumper" and when it is clamped in place the section is "locked out" or "jumpered"; the current is shunted past the section through the lock. This permits removal of completed cathodes and anode scrap, the cleaning of tanks, and finally reloading with new anodes and starting sheets. A scheduled removal of completed cathodes is called a "pulling" or "drawing." When only full-grown production cathodes are removed to be replaced with starting sheets, it is often called a "copper." When both cathodes and fully corroded anodes or scrap are removed and the slime cleaned from the tanks, the drawing is called a "mud."

It is highly desirable for smooth tank house operation to be able to pull the sections on a regular schedule so that they are unloaded and reloaded in the same rotation, cycle after cycle. Such a schedule evens out the work for the loading and unloading crews as well as for the inspection groups who keep the cells operating properly while under electrolysis. To establish and operate a pattern schedule efficiently it is necessary that the anodes be of uniform weight, that current amperage be held closely to the designated figure, and that the ampere efficiency be maintained at a predetermined satisfactory figure. The latter requirement is the most difficult to control since it involves consistently good performance of both the loading and inspection crews as well as the maintenance of uniformly satisfactory conditioning and circulation of electrolyte. Within limits it is possible to adjust a pattern schedule to an increase or decrease in production requirements, but a full cycle is required to complete the adjustment.

Where it is not possible to maintain a regular schedule due to uncontrollable variations, it is general practice to schedule section pullings approximately two weeks in advance.

Cell Inspection and Correction during Electrolysis

All of the items of tank house materials, equipment, and procedure center around the proper operation of the individual cells under electrolysis, so that their inspection and the prompt correction of any malfunctioning become of paramount importance. Competent and sustained good performance on the part of both supervision and operators assigned to cell inspection is most essential.

Satisfactory electrolysis requires that the flow of current be equal and uniform through each anode and cathode in the cell. To achieve this, two things are necessary: first, all electrode contacts must be kept clean for good conduction and, second, cathodes and anodes must be kept evenly spaced with no contact in the cell, either above or in the electrolyte.

Whenever these conditions are not maintained, the distribution of current among the electrodes becomes uneven due to their being in parallel. The current which faulty electrodes fail to receive is taken by electrodes with good contact, resulting in wide variations in current density. Cathodes operating under high current density develop undesirable surface growths which may result in short-circuiting contacts, through which the current flow is excessive and deposits no copper. The ampere efficiency of the cell is lowered proportionately.

The same condition develops when starting sheets come in contact with adjacent anodes because of surface irregularities or poor spacing. To the operator all anode-to-cathode contacts are known as "shorts" or "hot sheets" as the supporting rod of a shorted cathode becomes hot to the touch due to the excessive current it is carrying.

To perform their inspection and correction work, the operators, designated as "inspectors," "metermen," "hotsheetmen," or "section men," work on top of the tanks, their weight being suported by the closely spaced cathode rods.

The meterman uses a millivoltmeter whose terminals are connected to two copper prongs attached to a 3-ft stick so that he can walk along each cell and make contact with the prongs between each anode and cathode just beneath the surface of the electrolyte. Because of the parallel arrangement, normal anode-to-cathode voltage is approximately the same as the cell voltage and ranges from 0.18 to 0.35 v. When the meterman observes a low reading he chalk-marks the electrodes involved so that the condition causing it can be corrected by a hotsheetman. He usually checks the cathode rod by touch, and, if it is cool, the cathode rod or anode lug contact is fouled. If the rod is hot, the cathode is shorted to one or the other of its adjacent anodes.

Until a few years ago the hotsheetman detected shorted cathodes by going over the cells and touching all cathode rods to locate those which were hot. This method has been largely superseded by the use of the Gaussmeter, which is mounted on a stick and passed over the cathode rods as the operator proceeds along the cell. The stronger magnetic field surrounding the rod of a shorted

cathode with its excessive current flow shows a high reading on the Gaussmeter.

As promptly as possible after faulty contacts have been located and marked, the section men make the necessary corrections. Contacts are wiped or shined with sandpaper. While they are still not too heavy, usually up to the fourth day of deposition, shorted cathodes are lifted out of the electrolyte for correction. The operator uses a flat iron blade or "knife" to remove shorting growths and smooth out any irregularities. Corrected cathodes are returned with special care as to spacing to avoid recurrence of the shorting.

It is highly essential that inspection and correction work be performed thoroughly and competently during the first three or four days of deposition. A section of cells with new starting sheets may have as high as 25% of shorts and faulty contacts. In order to obtain proper over-all current efficiency shorts should be reduced to less than 3% for the fourth day of deposition.

In order to check their performance properly, hotsheetmen usually work in small groups or in pairs on designated sections of cells. The work is laid out so that all cells can be gone over for correction at least twice, and the sections of young copper three or four times each day. Most refineries confine the correction work to the day shift, but some find it worthwhile to have a small crew of competent operators follow up on the second shift to give additional attention to sections of young cathodes. A single meterman usually can check by millivoltmeter the sections of cells covered by several groups of hotsheetmen. One voltmeter inspection per section per day is considered adequate.

It should be noted that too much inspection can defeat its own purpose since the additional walking on the cathode rods may move them out of alignment and cause new shorts. This is especially true when the cathodes are still light in weight.

Recommendations

This tedious review of some of the hundreds of little details involved in good tank house operation has touched only lightly on the electrochemistry of the copper refining process. Competent research has done a good job of keeping abreast of the needs of the various refiners for special adaptations and modifications of the basic process to suit it to their individual requirements for the production of pure electrolytic copper from their particular type of crude blister. I hope I have made clear what I stated at the outset, that despite the world's dependence on tremendous tonnages of electrolytically refined copper, the techniques of good tank house operation have seen little change in recent times and still depend to a great extent on hand labor performed under rather unfavorable working conditions.

With the decreasing availability of the required type of labor and the constantly increasing rate of wages, especially in this country, it is time that more serious consideration be given to radical improvements in tank house operation, particularly to the problem of efficient cell performance during electrolysis. Here are a few suggestions of things to come and many of them are on the drawing boards or being developed on the job at the present time:

1. Anodes with uniformly good physical characteristics. This means positive control of weight within narrow limits during casting, sound lugs of uniform thickness, and perfect flatness so that they hang vertically when racked in tank loads. They must be free of blisters, protrusions, and fins, and the contact surface of the long lug should be ground or shined to clean metal.
2. Starting sheets should be produced, stripped, flattened, looped with rods in place and hung in racks by mechanical means to eliminate the present arduous hand-handling. It is not too much to suggest that means could be devised to place them in the cells by crane a tank-load at a time, instead of one at a time by hand.
3. Improved control facilities should be installed to insure proper conditioning and supply of electrolyte so that composition, clarity, temperature, and flow can be held within narrow limits of variation with a minimum of hand juggling.
4. Anode scrap as well as cathode production should be washed, bundled, and loaded out by mechanical means.
5. In the construction of tank house buildings more consideration should be given to insulation against variations in outside temperature, and adequate ventilation facilities should be provided to improve working conditions and to minimize vapor condensation as well as variations in humidity and rate of evaporation.
6. Full advantage should be taken of the rapid development of acid-resisting steels and plastics to replace iron and lead in tank house equipment. In this connection, cells should be fully protected on the outside as well as inside, especially when made of concrete.

We have taken a brief look into the aging anatomy, complex functions, and obvious needs of the tank house, the work-horse of the copper industry. If doing so has been mildly interesting to the uninitiated, a little helpful to the embryo operator, and a bit provocative to the tank house graduate, it will more than have served its modest purpose.

Feature Section

Electrochemistry as We Enter the Sixties

Presidential Address*

William C. Gardiner

Since this is the first meeting of The Electrochemical Society in the 1960's, I propose to compare electrochemistry today and our Society as it is today with electrochemistry and the Society at the start of previous decades. This should be of interest to all of you at this time.

I have reviewed the Proceedings of the Society for the annual meetings in the springs of 1910, 1920, 1930, 1940, and 1950. It may be necessary to remind some of you that these dates do not coincide with the tenth, twentieth, and so on, anniversaries of the Society because it was founded in 1902.

It was very interesting for me to read about the activities of our predecessors. The pages are filled with the names of men who contributed greatly to the science and technology of electrochemistry as well as other fields.

In 1910, President Leo H. Baekeland, known to all of you as the inventor of Bakelite, opened the meeting in Pittsburgh with a talk on "Science and Industry." He gave a forceful discourse on the merits of the scientist and engineer and their contributions to progress and industry, giving enlightenment on what a research scientist can do and the way he works. He would still be far from satisfied with the recognition given to scientists and engineers in America.

On Friday, a special train carried the members around to various steel mills and other plants in the Pittsburgh area. It was reported that, at the informal dinner in the evening, "Section 'Q' was strongly in evidence, enjoying itself with its usual ABANDON." On Saturday afternoon, a General Public Meeting was held in Carnegie Music Hall where Professor Joseph W. Richards spoke on "What the Electrochemical Industries are Accomplishing."

In 1920, Professor Wilder D. Bancroft of Cornell was President, and opened the meeting in the Rogers Building at M.I.T. with a paper on "Contact Catalysis" in which he reviewed the theories of catalysis as of that time. He then conducted a "Symposium on Colloid Chemistry." On Friday, joint sessions were held with the A.I.E.E. on "Electrically Produced Alloys" in the morning and then, in the afternoon, *eight electric cars* took the guests to General Electric at Lynn, Mass. It was reported that "A printed itinerary gave all the details of the visit with great accuracy, and it was carried according to plan with military precision." Afterward, the informal dinner was graced by the presence of "our esteemed friend, Professor Elihu Thompson."

On Saturday, they met at Harvard University where Professor T. W. Richards welcomed the Society. He said that there was an historical reason for visiting Harvard occasionally because Benjamin Thompson, later to become Count Rumford, walked ten or more miles from North Woburn to Harvard Hall to hear John Winthrop's lectures on natural philosophy. About 30 years later, Count Rumford founded The Royal Institution where Davy and Faraday did their great work in electrochemistry. It is to be regretted that we no longer take advantage of meeting on the campuses of some of our leading universities.

By 1930, the Presidential Address had become an evening affair when Dr. Francis C. Frary spoke in St. Louis on "Research as a Vocation." He pointed out that character and temperament are more important than an applicant's technical training, and discussed the value of intellectual integrity, personality, imagination, and curiosity. These are inherent in the character of a good researcher. Training can improve such things as observation, manipulation, attention to detail, accuracy, care in observing and recording data, clarity of thought, and expression; broad training is desirable on fundamentals of science, languages, and mathematics

I noted several other items of interest that occurred at the St. Louis Meeting in 1930. There was final acceptance of the formal resolution for incorporation of the Society. Also, the Joseph W. Richards Memorial Fund was established by a gift of Dr. E. G. Acheson to meet the expenses incurred by inviting and entertaining distinguished guests from foreign countries. We might regret that this fund is so small, because we are inviting more and more foreign scientists to participate in our meetings and can do so only through the benevolence of our National Science Foundation.

In the spring of 1940, we met at Galen Hall, Wernersville, Pa. Professor H. Jermain Creighton of Swarthmore, in his talk on "Forty Years of Electrochemistry," reviewed the development of electrochemical theory. The Society was struggling to recover from the depression, and he challenged 100 fellow members to bring in two new members apiece to bring the number of members back to the pre-depression level. Our membership has increased but we have lost the pleasure of being able to meet in such beautiful surroundings.

When we met in Cleveland in 1950, Professor A. L. Ferguson quoted from letters that he had solicited from former Presidents of the Society and others in speaking on "What the Society Would See if It Looked in a Mirror." He analyzed opinions that had been expressed on the training of electrochemists, on the professional standing of electrochemistry, electrochemists, and our JOURNAL. He noted that there were 337 Charter Members in 1902 and that the membership had risen to 2279 in 1921, then decreased in the depression to 1156 in 1936. It was more or less static from 1936 to 1942 but had increased to 2000 in 1950. He thought that the diverse interests of industrial and academic people had

* Delivered at the Chicago Meeting, May 3, 1960.

caused the loss of both to either purely engineering or purely scientific societies. However, the management of The Electrochemical Society had been revised to become more representative of all groups. Professor Ferguson regretted the inadequate facilities for training electrochemists in universities and the general lack of appreciation of the importance of electrochemistry in their departments of chemistry.

The character of our meetings has changed tremendously. In the first four decades, we all met together and there was only one activity at a time. There was much more opportunity for people of different interests to meet and learn about the other fellow's problems. Plant trips were a big feature of the programs. Five Divisions were operating in 1940 but they still could plan their activities without overlapping. By 1950, there were nine Divisions, and simultaneous technical sessions were in operation. We still have nine Divisions but, at this meeting, there are as many as seven simultaneous sessions. Plant trips are becoming rare. Besides the conflict with technical sessions, I think that this is due partly to having to restrict our meetings to the larger cities where traffic problems and distances discourage local committees from planning trips. I wonder whether this is a good trend. I remember that I have gained considerable benefits from such trips, myself.

Publication of our JOURNAL, formerly called the TRANSACTIONS, is one of the most important functions of the Society. As you look at the books on the shelf, there is not a very obvious change through the years except for a change in color and a change in dimensions. However, the content of new scientific knowledge in our JOURNAL has changed considerably. The annual volume of the world's scientific literature is enormous so we must limit manuscripts to original work reported as concisely as possible. Our editors are necessarily very critical and exacting. In 1910, there were 24 papers presented and published. At this meeting in 1960, 214 papers are scheduled. I cannot say how many will be eligible for publication. The papers of special symposia are now being published in book form so that those who wish may obtain the complete collection. This permits publication of reviews by experts without burdening the JOURNAL. During the first four decades, published articles averaged 14 pages and preprints were distributed before the conventions. The necessity for economy has reduced preprints to abstracts and the average length of a published paper in 1950 was 7 pages and, so far this year, it has averaged 5.3. We must reduce every paper to the minimum required for the clear presentation of new material.

The editorial burden is carried by 14 Divisional Editors assisting the Technical Editor. These men are experts in their field but rely further on specialists to review each paper. In addition, there are the News Editor, the Book Review Editor, and over all, the Editor. All of this is done on a voluntary basis by members of our Society. I am sure that most of you, from time to time, have contributed in this way. I have heard criticisms of our JOURNAL to the effect that the quality of papers is not high or that publication takes too long. I know that these matters are also of chief concern to our editors and that they are continually striving to improve the JOURNAL as a service to you. It is also your JOURNAL. It publishes the papers you write and edit. This is a democratic institution, so he who can do better should not hide his light under a bushel but should volunteer his services. Our Managing Editor and her assistant are staff employees. Someday we may be affluent enough to enlarge our staff with people who are qualified to do the technical editing. This might reduce the time required to prepare a paper for publication.

What are electrochemists working on to contribute in the 1960's? In reading the program of this meeting, I see many contributions to the Electronics industry; electrolytic capacitors, luminescence, semiconductors (new materials, theory, preparation, and device technology). In Electrothermics and Metallurgy, I see papers on refractory metals, rhenium, vanadium, and iron. The Industrial Electrolytic and Theoretical Electrochemistry Divisions have a joint symposium to discuss electrochemical engineering as a unit process.

What are the contributions of electrochemistry to the space age? Electrothermics and metallurgy have contributed refractory materials for nose cones and the many special alloys in rockets. Fused salt electrolysis produces titanium, beryllium, and other "rare" metals. Some of the exotic high-energy fuels, fluorine, hydrogen, and hydrazine, depend on electrochemical production or electrochemically produced raw materials. New light batteries power the electronic circuits, printed electrochemically and utilizing electrolytic capacitors, transistors, and other semiconductor devices for their guidance and broadcasting systems.

And can we dream about a few advances that will be made in the sixties! Our fastest growing Division (Electronics) will discover new and better phosphors, new semiconductors to give more efficient rectifiers and transistors. Electrothermics and Metallurgy will contribute cheaper "rare" metals and alloys. Electrolytic cells may reach capacities of half a million amperes. Electrodeposition will be extended to the "rarer" metals. The Battery people will make the fuel cell practical as well as develop many special batteries. Corrosion will be better understood and, I hope, markedly reduced. And, finally, we expect the Theoretical Division to extend our knowledge of electrochemistry in all its branches and lead us into new fields yet to be discovered.
