
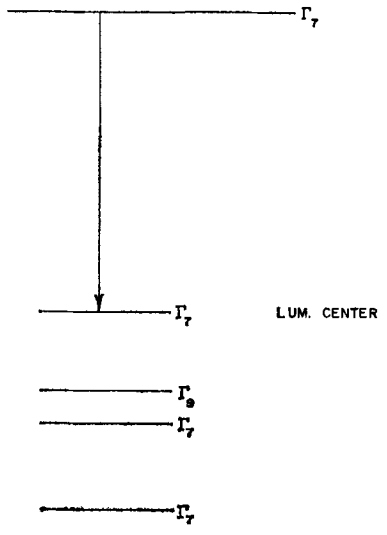

Fig. 6. Schoen-Klasens model with Γ_7 symmetry luminescent center.

(IV) The 6200Å emission should be polarized independently of the polarization of exciting radiation since excitation only creates free carriers.

(V) Polarized infrared radiation (17.7μ) should quench the polarization of fluorescence by promoting the holes in the Γ_9 valence state to the lowest Γ_7 valence band: a hole in the latter does not give rise to polarized radiation.

(VI) The 3μ *IR* quench band, which promotes electrons from the "center" level to the conduction band should be operative for both polarizations.

As will be seen, these predictions should be helpful indeed to the decision among competing models.

While the polarization of the 4500Å ZnS emission would be generally understandable in the identical type of L-K framework, the entire ZnS problem is complicated by the structure faulting which exists, and which contributes considerable complexity to the "band" structure of an actual specimen (11). A true test of (I)-(VI) above for ZnS should be made

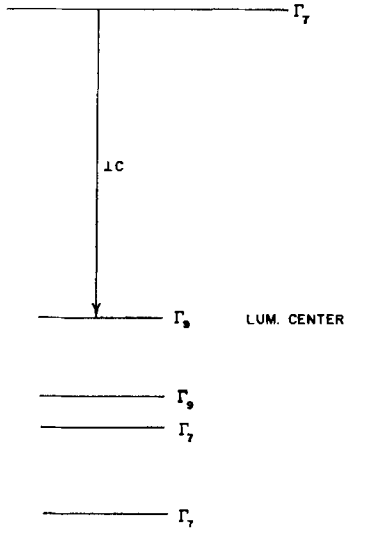

Fig. 7. Schoen-Klasens model with Γ_9 symmetry luminescent center.

on perfect hexagonal crystals, [cubic ZnS (zinc blende) shows no polarization (Table I)]. The structure sensitivity of the ZnS results, then, resides in the lack of polarization of emission in the "cubic" regions of a mixed crystal, as well as in the unknown effect which occurs for an activator within a fault plane region.

We now turn to some alternate models which would be consistent with polarization findings. The first class of alternate models we consider are S-K "band" models. Immediately we are led to several S-K models: one with ground state Γ_7, Fig. 6, one with ground state Γ_9, Fig. 7, and finally types whose ground "state" is actually a complex of several states, Fig. 8a, b. We shall, in the interest of brevity, only focus on salient features of each of these models, in particular emphasizing important differences which may be observed between each of these models and the L-K model which was discussed in some detail.

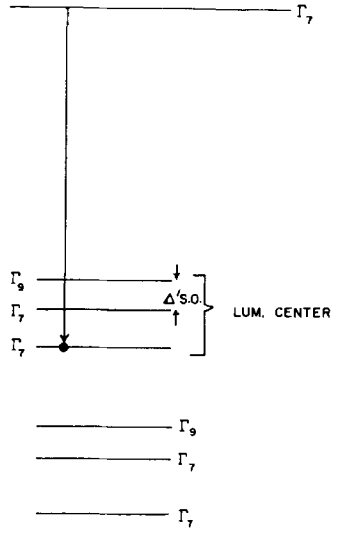

Fig. 8a. Schoen-Klasens model with three ground states. One electron is assumed in the center, normally, and the polarization should not be temperature dependent.

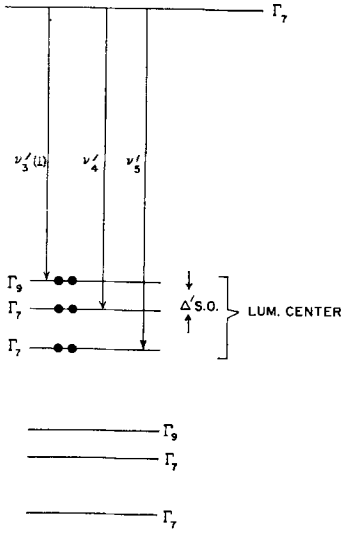

Fig. 8b. Schoen-Klasens model with three ground states. Six electrons are assumed in the "unexcited" ground state. Polarization may then be temperature dependent, if a single hole is captured by the center and reaches equilibrium among the three states.

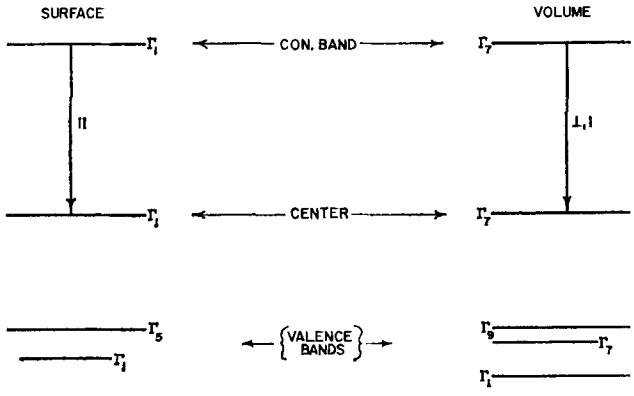

Fig. 9. Possible model for the ZnO polarization results. Assuming greater ionicity on the surface, we may classify states neglecting spin-orbit effect, while in volume the spin-orbit splitting is assumed necessary. This yields different selection rules on surface and volume.

The model in Fig. 6 requires that the transition $\Gamma_7 - \Gamma_7$, allowed for both polarizations by selection rules, shall have different strength for $\perp$ than for $||$. (In particular $I_{\perp} > I_{||}$). This model would predict a temperature independent polarization of luminescence.

The model of Fig. 7 would produce polarization ($\Gamma_7 - \Gamma_9$ transition) perpendicular to c, but to explain the lack of complete polarization some alternate mode of recombination with the center must be provided. As in the previous case, the polarization should be temperature independent.

A model more in the actual S-K spirit is that of Fig. 8a, b in which the ground "state" of the center consists of several levels, duplicating the valence band structure at k = 000, so a ground state trio of states is shown for the center. Now we may assume either that one, or six, electrons normally populate the ground states of the center. In the one electron in center case, Fig. 8a, according to the sequence which is assumed to apply for a S-K type model, at the instant of recombination, the free electron which will recombine to yield light sees the empty trio and recombines with any of the three available levels with some probability which is *a priori* fixed. If the center has only one electron in its normal ground state, it is clear that there will not be a temperature dependence for the polarization, since at the instant of recombination the entire ground state trio is empty. Temperature can only affect the state which the electron occupies after recombination, or before the valence band hole captures this electron to prepare the center for recombination. Neither of these will affect the polarization of emitted fluorescence. If in the unexcited state, the center is filled (13), i.e., consists of six electrons, Fig. 8b, (two in each doubly degenerate state of the trio) we have the possibility of temperature dependence of the polarization. This follows from the fact that the center will capture one hole, if the irradiation produces free holes and electrons, and this hole will reach thermal equilibrium between the various ground levels of the center. The particular state with the hole in it is the only state available for recombination; hence, the possibility of a tem-

perature dependence. If there is a temperature dependence, it should follow an equation formally identical to Eq. [1] as would the L-K model since the controlling factor is the Boltzmann distribution of hole occupancy of the center ground states. In fact, if the ground states of the center are replicas of the valence band k = 000 states, the only possibility for distinguishing this Schoen-Klasens model and the Lambe-Klick model would be in the *numerical values* of the constant Δ' arising in Eq. [1] for edge and 6200Å emission, and in the IR quench frequency. It is unlikely that the center states' spacings and that of the valence bands at k = 000 should be identical, even though the various splittings arise, in the center as in the bands, from crystal symmetry and spin-orbit effects. Consequently, the decisive factors here will be the numerical values obtained if the fluorescence should prove temperature dependent. Note that the last three "S-K" models dispense with the assumption of a highly symmetric Γ_7 state for the "ground" state of the center, and may therefore be considered more "complicated" than the L-K model.

This concludes our consideration of simple "band" models which are in the spirit of L-K and S-K models and which would account for polarization. These band models are based on the k = 000 band order of states of Fig. 4, and would perhaps require revision if the band edges in particular sulfides were not at k = 000; certainly revision would be required if the order of band states were determined to be different from that we have taken. Rather than pretend to completeness by considering models based on these contingencies, we feel it preferable to consider the various possibilities already discussed (particularly, the simple L-K model) as working hypotheses and await the results of experiments—among them those proposed in (I-VI) above to help with the decision.

Two-Oscillator Models

As indicated in Lempicki's paper, models which involve separate absorption and emission oscillators have been successfully employed in accounting for fairly complicated data on polarization of fluorescence in solutions, and in certain ionic phosphors. In a certain (non-classical) sense the band models discussed above are two-oscillator models, since absorption in the lattice and emission at the center are distinct processes. However, more usual models of this class would be of a type where one "atom-like" center (polarizable dipole) absorbs the radiation and then either suffers some internal rearrangement (radiationless transition to another excited electronic state) and then emits, or actually transfers the excitation energy to another center where it is degraded by photon emission (14). A more recent variant of two-oscillator models would involve exciton creation (absorption step), migration, and then decomposition at the center (emission step) (15). Perhaps, even a single-triplet exciton conversion step may account for the needed stability of an exciton which would undertake such a process.

Assuming an absorption (excitation) process which would (for 3650Å irradiation) not leave a memory (i.e., polarization of fluorescence is seen to be independent of the polarization of the exciting radiation) the polarization of fluorescence then gives us information about the states involved in the emission. For processes of this kind, it is natural to assume that the emitting center will be located at a site and, therefore, possesses the site symmetry which, in wurtzite crystals, is C_{3v}. The wave functions of the emission center would then belong to irreducible representations of this site group (see Table V) and the optical selection rules would also then be appropriate. It would be then natural to construct as a model of the electronic states of the emitting center one derived from "s" and "p" type wave functions split in the appropriate manner in the existing crystal field. Such a model can easily be constructed from the information in Table V: depending on whether spin-orbit effect should be included will depend on the particular symmetry assignments of center states. Again, with respect to the L-K model more fully discussed above, it is evident that temperature and IR quench effects on the polarization, if they exist, should be quite different for the emission center-site model than for the L-K band model.

Discussion

It should be clear that the presently available polarization data alone are insufficient for the purpose of coming to an unequivocal conclusion about the nature of the centers, and in particular, even for deciding among the various band models or even between band models and "two-oscillator" models. We are led by a chain of plausibility arguments involving all the known properties of centers in the sulfides, to prefer band models, and within the class of band models to prefer the L-K model because of its relative simplicity. Many assumptions have been made in the process of formulating this chain including assumptions about the band structure (which seems supported by the evidence now available) and the symmetry of the center. Detailed theoretical analysis of the validity of the L-K model would be most fruitful if the model had been better established by virtue of additional experimental results.

In this context, then, we anticipate that the polarization studies can be most helpful in delineating properties of the various models which could be used to differentiate them, for example, by means of symmetry designations of the states of the center. In addition, one may make use of correlations by studying a simple sulfide system and then correlating the results and model obtained on such a system with that which would be appropriate for a more difficult system. For example, one may study polarization in hexagonal crystals and extrapolate the results to cubic systems since it is likely that a continuous correlation between hexagonal and cubic systems exists. In addition, the knowledge obtained for the 6200Å CdS emission by studying polarization may be carried over to the corresponding ZnS emission band (17): the former system being a "cleaner" one structurally and, hence, less ambiguous to interpret.

Acknowledgments

It is a pleasure to thank A. Lempicki for much discussion of his work. Dr. G. Neumark has also participated actively in discussions of the various models and her comments have been helpful, particularly in regard to S-K models. The author also wishes to thank Mrs. A. White for carefully typing the entire manuscript.

Manuscript received Nov. 9, 1959. This paper was prepared for delivery before the Philadelphia Meeting, May 3-7, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

APPENDIX I

Temperature dependence of polarization.—Consider the conduction state Γ_{7c} and only the two uppermost valence states Γ_9 and Γ_{7v} (see Fig. 5). Let the number density of holes in either valence state be given by p_9 and p_7 and neglect the lowest Γ_7 valence band. Then the intensity of emission polarized perpendicular to c is given by

$$I_{\perp} \cong p_9[M(\nu_3)]^2 + p_7[M^{\perp}(\nu_4)]^2$$

where $M(\nu_3)^2$ involves some constants (effective mass, etc.) and the square of the matrix element for the optical transition Γ_7-Γ_9 from the center state to the valence band, and $(M^{\perp}(\nu_4)^2$ involves the square of the matrix element for the Γ_7-Γ_7 transition for light polarized to c. For the intensity emitted || c we obtain

$$I_{||} \sim p_7[M^{||}(\nu_4)]^2$$

where $M^{||}(\nu_4)$ is similarly defined. Hence

$$I_{\perp}/I_{||} = \frac{p_9}{p_7}a + b$$

where a and b are ratios of constants. Assuming a Boltzmann distribution of holes between the upper two valence states, which are separated by the spin-orbit splitting energy $\Delta_{s.o.}$, we obtain

$$I_{\perp}/I_{||} = ae^{\Delta_{s.o.}/kT} + b$$

for the temperature dependence of fluorescence polarization.

APPENDIX II

Polarization in ZnO.—The zinc oxide results (Table I) are, of course, even more fragmentary and less capable of unique explanation than the corresponding results for the sulfides. However, some intriguing possibilities suggest themselves if we examine the selection rules for group C_{6v} (Table III). Again, we note that the measured polarization of room temperature surface luminescence (mainly *parallel* to c) is only partial, which suggests either a cluster of final (or initial) states or a transition between only two discrete states, allowed for *both* polarizations with different strengths depending on polarization.

It is possible to argue that the ZnO surface and volume luminescence are connected in the sense that they originate from the same center (atomic surroundings) but perturbed, with a wave function changed due to location on the surface or in the volume. Thus, we may imagine that

$$\Psi \text{ surface} = \Psi \text{ volume} + \lambda\Psi^{(1)}$$

for the center wave function depending on its location. Since a change in wave function in the first order (of a perturbation) will produce a second order change in energy, the luminescence may have approximately the same wave length, but considerably changed polarization properties, since polarization will involve the perturbation of the wave functions, through their optical matrix element, in the first order.

Suppose the surface of the crystal, due to distortions, is more ionic than the volume so that at the surface the net oxygen charge is nearly —2 while in the volume it is $-2 + \delta$ due to an overlap of charge density on the zinc ion, the latter having charge $(+2 - \delta)$. Since the net spin-orbit splittings will be a resultant of splittings on both Zn and O, with the latter's contribution small, we might expect to consider states on the surface nearly neglecting the spin-orbit effect while those in the volume include this. We are led to a model shown in Fig. 9 Physically, we are arguing that the surface Γ_7 state is more nearly Γ_1-like than the volume state and, hence, that $I_{||}/I_{\perp} > 1$ at the surface.

Other speculations involving L-K models and the same argument about wave function distortion would make use of the Γ_5-Γ_6 selection rule (surface) and the change of $\Gamma_5 \rightarrow \Gamma_9 + \Gamma_7$ in volume, with a corresponding change of selection rules to allow both polarizations in emitted light.

Evidently, for ZnO, as well as for the sulfides, studies of the temperature and IR effects on the polarization are required.

Effect of CdS Addition in ZnS:Cu, In and ZnS:Ag, In Phosphors

Eugene F. Apple

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

ZnS:Cu,In and ZnS:Ag,In phosphors each can show two emission bands under 3650Å excitation, namely, in the green (short) and orange (long) with Cu and in the blue and yellow with Ag activator. Addition of CdS causes the ratio of intensities of the short to long wave-length emission to increase. This observation is interpreted using the donor-acceptor associated pair model proposed recently for the long wave-length emission process.

ZnS phosphors coactivated with Ga or In and activated with Cu or Ag exhibit long wave-length emission bands (under u.v. excitation) in addition to the short wave-length emissions which peak at 5200Å with Cu and 4450Å with Ag. Kroger and Dikhoff first reported the former emissions with peaks at 5700Å and 6800Å in samples containing Ga and In coactivators, respectively. According to these authors (1) the spectral distributions of the bands were relatively independent of the particular activators involved.

More recently, Apple and Williams again studied the ZnS: (Cu or Ag), (Ga or In) phosphors and found that the spectral distribution of the long wave-length emission depends on the identity of the activator, as shown in Fig. 1, and the coactivator, as shown in Fig. 2. In most phosphors studied, both the long and short wave-length emission bands were observed. However, by changing the concentration of activator and coactivator, or the identity of the coactivator, or the temperature at which the phosphor was excited, the ratio of intensities of the short to long wave-length emissions, I_s/I_l, could be varied over a wide range (2).

The study reported in this paper concerns the effect of CdS addition on the ratio of emission intensities, I_s/I_l, in ZnS:Cu, In and ZnS:Ag, In phosphors. In ZnS phosphors exhibiting both the short and long wave-length emissions or the long wave-length emission only, addition of CdS causes an increase in I_s/I_l. Above 25-30 mole % CdS the long wave-length emission band is not observed at temperatures as low as −195°C. Effects of activator-coactivator concentration and temperature on the ratio I_s/I_l are included as well as typical glow curve measurements. These effects are interpreted using the model for the long wave-length emission proposed by Apple and Williams.

Experimental Results

Preparation of phosphors.—Mixtures of prefired ZnS and CdS (both from General Electric Company, luminescent grade) containing from 0 to 50 mole % CdS were ground and ballmilled until uniform. These mixtures were used in preparation of all the phosphors. The impurities, Cu, Ag, and In, were added to the mixtures as aqueous solutions. After slurrying with water the phosphor preparations were dried at 100°C, ground in a mortar, and fired at 1100°C in a stream of H_2S[1] for 2 hr. The phosphors were air-cooled to room temperature in the

H_2S stream. The mole % CdS and the gram-atom fraction of impurities identified with the samples throughout this paper correspond to the amounts present before firing.

Emission spectra at room temperature.—Emission spectra, under 3650Å excitation obtained from a G. E. mercury lamp, #H100-FL4, with Corning No. 5860 and Kopp No. 41 filters, were recorded on an automatic spectroradiometer which plots radiant energy flux vs. wave-length. Room temperature spectra of a typical series, hex. (Zn, Cd)S: 10^{-5} Cu, In are shown in Fig. 3. The spectra have been normalized so that the intensity of the predominant peak is 100. The ratio of relative intensities, I_s/I_l, which is about 1.16 in the 2.5% CdS sample, goes up with increasing CdS content until, with 20% CdS and above, the emission is entirely in the short wave-length band.

The emission spectra for hex. (Zn, Cd)S: 10^{-4} Ag, In at room temperature are shown in Fig. 4. In this series the phosphor with no CdS shows predominantly the long wave-length emission. As the CdS content is increased the relative intensity ratio, I_s/I_l, increases until at 20% virtually all the emission occurs in the short wave-length band. Hexagonal (Zn, Cd)S: 10^{-4} Cu, In gives similar results.

In both groups of phosphors the spectral distribution of the short wave-length emission as measured at the peak intensity moves to longer wave-lengths, i.e., lower energy, at the rate of about 0.017 ev/mole % CdS whereas the rate with the long wave-length emission is only about 0.003 ev/mole % CdS. The long wave-length spectra were measured at —195°C where the other emission does not interfere as much, as will be shown in the next section. However, because of the broadness of the spectra at the emission peak, the latter rate is only very approximate. Above 25% CdS, no long wave-length emission is observed even at —195°C in any of the samples measured. All the emission spectra were very reproducible on repeat samples prepared under the same conditions.

T dependence of emission.—The *T* dependence of emission was measured by recording spectra as the sample contained on a large Cu block was cooled slowly from about 250° to —195°C. Spectra for hex. (0.95 Zn 0.05 Cd)S: 10^{-5} Cu, In at temperatures from 245° to —80°C are shown in Fig. 5. This phosphor achieves its maximum brightness at about 210°C. The ratio of I_s/I_l increases with increasing temperature. Above about 0°C, a plot of log I_l/I_s vs. $1/T°K$ on any (Zn,Cd)S:Cu, In phosphor gives a linear relationship as is shown in Fig. 6. From the slope of this line, the difference in energies of the two types of centers is obtained (2). This energy decreases with increasing CdS content; for example, in (Zn, Cd)S: 10^{-5} Cu, In, it decreases from 0.34 ev to 0.24 ev in the range 0 — 10% CdS. Measurements were limited to samples containing 10% or less CdS because of the increased overlap of the short and long wave-length bands at higher CdS concentrations. In addition, the measurements were limited to Cu-activated phosphors because of the marked temperature quenching above 80°C observed in Ag-activated samples.

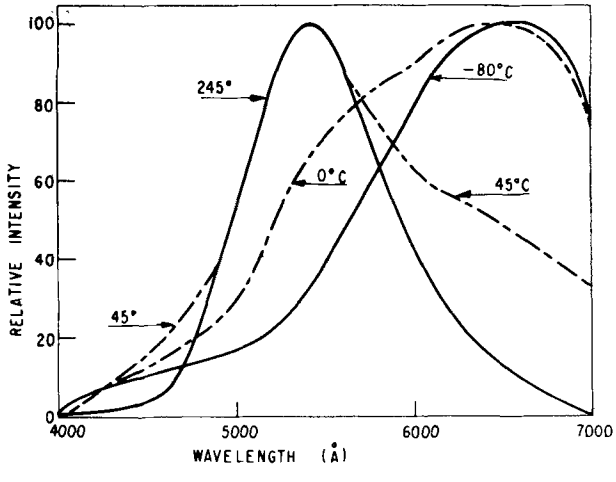

Fig. 5. Emission spectra of hex. (0.95 Zn, 0.05 Cd) S:10^{-5} Cu, In measured at the indicated temperatures.

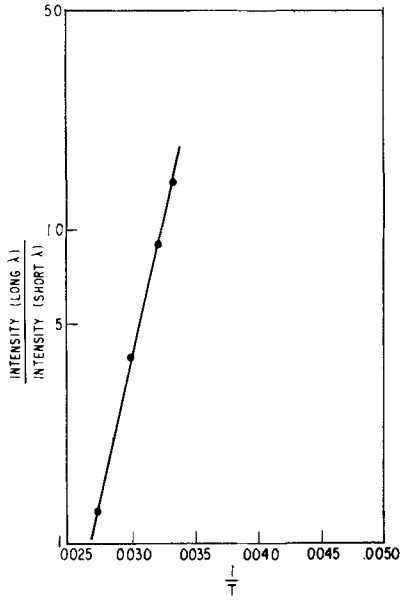

Fig. 6. T(°K) dependence of emission in (0.97 Zn, 0.03 Cd) S:10^{-5} Cu, In under u.v. excitation.

Effect of activator-coactivator concentration.—In a particular series with constant Cd content, increase in the concentration of activator (and coactivator) over the range 10^{-6} to 5 x 10^{-4} g-atoms/mole (Zn, Cd)S results in a decrease in the ratio of relative intensities, I_s/I_l, when excited at a given temperature. This data on the effect of concentrations is consistent with that already reported for ZnS:Cu,In or ZnS:Ag, In phosphors (2).

Glow curve measurements.—Glow curve measurements were made on the hex. (Zn, Cd)S: 10^{-4} Cu, In series. The phosphors were excited for 5 min with a BH-4 lamp at —195°C after which they were warmed in the dark at a rate of 10°/min. An RCA 5819 PM tube was used as detector. The glow peaks shown in Fig. 7 move to lower temperatures with increasing CdS content. This effect of CdS is consistent with the results obtained by Hoogenstraaten with Al, Ga, and Cl donors (3).

Discussion

(Zn, Cd)S phosphors showing only what in this paper is called the short wave-length emission band have been studied extensively by many people. It has been shown that ZnS and CdS form solid solutions over the entire range and that in the 0-30 mole % CdS range, the absorption edge, as deduced from reflectance spectra, moves at the rate of about 0.020 ev/mole % CdS to lower energies (4). In turn, in (Zn, Cd)S:(Cu or Ag), (Al or Cl) phosphors the spectral distribution of the short wave-length emission moves to longer wave lengths, i.e., lower energies, at the rate of about 0.018 ev/mole % CdS (5). The donor levels assumed to be introduced by the coactivator become shallower with increase in CdS concentration as indicated by the thermal glow measurements. The rate in this case in the 0-30% region is about 0.012 ev/mole % CdS (3).

In the present study both the shift in the short wave-length emission to longer wave lengths and the shift in glow curve maxima to lower temperatures with increase in CdS content are qualitatively consistent with the data already reported by other

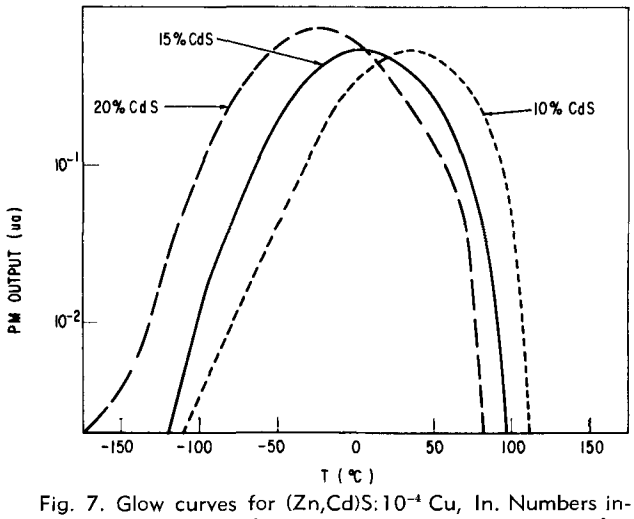

Fig. 7. Glow curves for (Zn,Cd)S:10^{-4} Cu, In. Numbers indicate mole per cent CdS. Excitation: BH-4 lamp at —195°C; heating rate 10°/min.

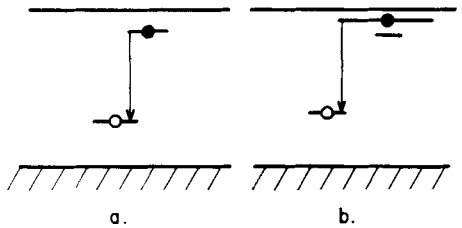
authors. Because of the very broad glow curves in evidence in (Zn, Cd)S:Cu, In phosphors it is probable that the ground states of the donor levels are distributed over a range of energies so that a unique value for a trap depth is not too meaningful. (In this paper, trap depth and ground state of the donor level are synonymous.) Johnson has obtained evidence that such a distribution exists in the several ZnS:Cu,Al and ZnS:Cu,In phosphors he has analyzed (6). The glow curves indicate, however, that the distribution of traps becomes shallower (with respect to the conduction band) with increasing CdS content. The temperature dependence of emission data for (Zn,Cd)S: 10^{-5} Cu,In also shows that the ground state of the donor level becomes shallower with CdS addition. The spectral distribution of the long wave-length emission in ZnS:Cu,In or ZnS:Ag,In changes at the rate of about 0.003 ev/mole % CdS in the 0-25% range.

In a phosphor showing both the long and short wave-length emission bands it would be expected that the bands should gradually merge with increasing CdS content because of their different rates of displacement. Beyond the point of mergence only one emission band should be observed since the donor levels are then shallow. As a result, transitions involving the ground state of the donor (between highly associated pairs) or an excited state of the donor (between loosely associated pairs) or the conduction band (between unassociated pairs) to the ground state of the activator would be virtually indistinguishable. In the (Zn,Cd)S:Cu,In or (Zn,Cd)S:Ag,In phosphors studied the bands are not observed to merge completely because the CdS, in addition to causing the bands to move as stated, also effects a change in their relative intensities. Increase in CdS content causes an increase in the ratio I_s/I_l so that (Zn,Cd)S phosphors showing both the short and long wave-length emissions or the long wave-length emission only, will, with substitution of 25-30% CdS for ZnS, show only the short wavelength emission even at —195°C. Perhaps the long wave-length emission could be observed at still lower temperatures. This newly observed effect of CdS on I_s/I_l is thought to be directly connected with the

decrease in donor (coactivator) depth attending the increase in CdS content.

Two models have been proposed for the long wave-length emission process in ZnS. Using the data of Kroger and Dikhoff, Klasens proposed that the long wave-length emission was due to the radiative recombination of a free hole with an electron trapped at a coactivator. As an alternative he suggested (7) that the radiative transition may involve recombination of a hole in a "waiting state" located above the filled band with an electron trapped at a coactivator. The nature of the waiting state was not clearly defined, but the idea was probably invoked to minimize the large difference in energies between the observed thermal and optical trap depths. The optical depth on the Klasens model, which would be approximately the difference between the band gap energy and the energy at the peak of the long wave-length emission, is about 1.3 ev greater than the thermal trap depth reported by Hoogenstraaten (3). Klasens also reported that the addition of 20% CdS in ZnS:Ag,In caused the peak of the long wave-length emission measured at −183°C to shift from 6100 to 6200Å or only 0.03 ev. This shift is considerably less energywise than the corresponding shift with CdS addition in the short wave-length emission.

More recently, Apple and Williams suggested another model for the long wave-length emission process which is based on the fact that the spectral distribution of this emission depends on the identity of both activator (Cu or Ag) and coactivator (Ga or In). They suggested that both species are involved in the luminescent center and concluded that the radiative transition giving rise to the long wave-length emission is between a coactivator-activator pair sufficiently close to each other in the lattice so that the ground state wave functions of the two overlap. This luminescent transition is shown on the band model in Figure 8a. In most of the phosphors they prepared, both the long and short wave-length emission bands were observed. By changing the concentration of activator and coactivator, or the coactivator identity, or the temperature at which the phosphor was excited, the ratio of intensities of the short to long wave-length emissions, I_s/I_l, could be varied over a wide range. Using an analysis based on the new model for the long wave-length center and on the Prener-Williams model for the short wave-length center (8) (shown in Fig. 8b) the authors were able to account qualitatively for the effects of the foregoing parameters on the ratio of intensities of the two emission bands. In the latter model, luminescence is attributed to transitions between coactivator-activator pairs which are not so highly associated as those giving the long wave-length emission.



a. b.

Fig. 8. Band theory models for the (a) long and (b) short wave-length (8) luminescent centers.

Apple and Williams suggested that the ratio of intensities of the short to long wave-length emission in ZnS: (Cu or Ag), (Ga or In) was dependent on at least two factors, the ratio of occupational probabilities of the emitting states of the short and long wave-length centers and the ratio of fractions of coactivator-activator (or donor-acceptor) pairs involved in each of the two types of centers. They said that the difference in the peaks of the emission spectra of the two bands is a measure of the difference in energies of the emitting states of the two types of centers and that the ratio of occupational probabilities, $P_{(\epsilon_s)}/P_{(\epsilon_l)}$, of the emitting states is given approximately by:

$$P_{(\epsilon_s)}/P_{(\epsilon_l)} \approx e^{\frac{-he}{kT}\left(\frac{1}{\lambda_s}-\frac{1}{\lambda_l}\right)} \quad [1]$$

where λ_s and λ_l are the wave lengths at the emission peaks of the respective bands. In ZnS phosphors this factor greatly favors the long wave-length emission; it is dependent on the depth of the ground state of the donor (which is the emitting state of the long wave-length emission). For example, at temperatures where thermal equilibrium applies, the ratio of intensities of the short to long wave-length emission is greater in ZnS:Ag,Ga than in ZnS:Ag,In because the ground state of Ga is 0.08 ev shallower than that of In (according to thermal glow measurements) (3). The value for $(1/\lambda_s - 1/\lambda_l)$ is smaller in the former case which leads to a more positive value of $P_{(\epsilon_s)}/P_{(\epsilon_l)}$. Also, at room temperature I_s/I_l is much larger in cubic than in hexagonal ZnS:Cu,In, due presumably to the fact that the donor ground state due to In is shallower in cubic than in the hexagonal phase (9).

The model suggested by Apple and Williams will be used to interpret the results of the effect of CdS addition on the emission in ZnS:Cu or Ag, In phosphor since this model is most consistent with the experimental results thus far obtained.

The increase in the ratio of intensities of the short to long wave-length emissions with increase in CdS content may be due to the change in the ratio of occupational probabilities of the emitting states, which change is a direct consequence of the gradual decrease in the depth of the ground state of the In level with CdS increase. From Eq. [1], I_s/I_l would increase with increasing CdS because the term $(1/\lambda_s - 1/\lambda_l)$ becomes smaller. As the short wave length approaches the long wave-length emission peak, $(1/\lambda_s - 1/\lambda_l)$ becomes so small that the actual mergence of the two peaks is not observed since before this point, the ratio of occupational probabilities has increased to such an extent that the short wave-length emission is overwhelmingly favored.

As was pointed out by Apple and Williams, the ratio of fractions of pairs contributing to the two emissions greatly favors the short wave-length emission and tends to balance out the occupational probability effect except where this ratio becomes large as with increasing CdS. In a series containing

a constant amount of Cd, the decrease in the ratio of intensities, I_s/I_l, with increasing concentration of activator and coactivator is due to the increase in the fraction of pairs contributing to the long wave-length emission. These results are consistent with those found previously for ZnS: (Cu or Ag), (Ga or In) phosphors.

In summary, CdS addition in ZnS:Cu,In or ZnS: Ag,In causes an increase in the ratio of short to long wave-length emission intensities. This increase is due to the increase in the ratio of the occupational probabilities of the emitting states of the two centers. Although other models could possibly be used to interpret these results, the fact that the spectral distribution of emission of the long wave-length center is dependent on the identity of both donor and acceptor is taken as evidence that the long wave-length luminescent transition is between associated donor-acceptor pairs as already pointed out (2).

Preliminary measurements show that CdS has the same general effect in ZnS:Cu,Ga or ZnS:Ag, Ga as in ZnS:Cu,In or ZnS:Ag,In.

Acknowledgments

The author wishes to thank the following people: Mrs. D. J. Weil for preparation of samples; Dr. F. J. Studer and Miss G. Lloyd for measurement of spectra; Dr. P. D. Johnson and Mr. F. C. Mostek for measurement of thermal glow curves; and Dr. J. S. Prener and Dr. F. E. Williams for review.

Manuscript received Nov. 16, 1959. This paper was prepared for delivery before the Philadelphia Meeting, May 1-5, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Growth and Heat Treatment of Zinc Sulfide Single Crystals

A. Kremheller

General Telephone and Electronics Laboratories Inc., Bayside, New York

ABSTRACT

Zinc sulfide crystals grow readily from the vapor phase if small traces of certain impurities, such as zinc oxide and copper, are present. The decrease of ambient impurity concentration leads first to very thin, flexible, ribbon-like crystals which are hexagonal, and finally to nucleation with little growth. The purity of crystals depends not only on the composition of the starting material but also on the purity of the combustion tube employed; contamination during growth leads to an impurity gradient in crystals and to impurity variations among crystals. Crystals usually exhibit disorder of the crystal structure, although pure cubic or hexagonal structure can be achieved by annealing or quenching. Heat treatment also changes the impurity content and attendant properties, such as physical color, luminescence behavior, electrical properties, and disorder of the crystal structure.

There has been considerable interest in the growth of zinc sulfide single crystals during the past decade (1-3) because it is expected that the mechanisms of photoluminescence, photoconductivity, and electroluminescence will be better understood by studying single crystals. Natural zinc sulfide crystals are available in large size; however, they contain comparatively high impurity concentrations, usually of the order of 1% by weight. Since commercial applications of zinc sulfide phosphors require small quantities of additives, such as a few parts per million of activator and coactivator, natural crystals have been of but little importance in such researches.

Another requirement in preparing crystals for research purposes appears to be the proper control of the crystal structure (4). Synthetic crystals grown by the conventional vapor phase methods (3) exhibit one-dimensional disorder (3, 5-7, 8) consisting of randomness, mixed hexagonal-cubic structure in the same crystal, and the presence of polytypes which are intermediate between the hexagonal and cubic crystal systems.

Alfrey and Taylor (9) came to the conclusion that "unfortunately, single crystals (of zinc sulfide—the author) are difficult to grow and the amount and nature of the activators cannot be controlled, so that crystals grown by different experimenters will differ in constitution." The present paper shows how some of these difficulties have been overcome. It describes some experiments dealing with the preparation of zinc sulfide single crystals of controlled chemical composition and crystal structure. Previously reported observations (3, 8) are extended and, in many cases quantitatively corroborated;

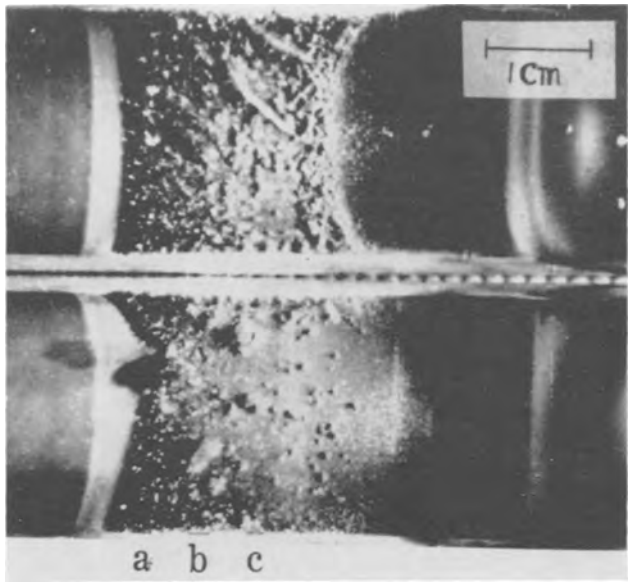

Fig. 1. Longitudinally split tube with crystals; regions a, b, c, as indicated in Table VII.

some new results are presented which appear to have experimental and theoretical implications as to the preparation of single crystals.

Experimental

The single crystals of zinc sulfide which have been investigated in the course of these studies were prepared from the vapor phase by sublimation. The growth method employing a U-shaped transparent quartz cooling finger which permits the control of nucleation, crystal structure, and morphology of crystals has been described previously (3). This technique is not described in any detail because the main experimental results are generally available (10). Recently Matsumura, *et al.* (11) have confirmed our observations (3, 8) in the course of investigating very thoroughly the growth and morphology of zinc sulfide single crystals obtained by the cooling-finger technique. Their observations are in essential agreement with many of our unpublished results; however, we were led by experimental circumstances to some additional investigations which are discussed here.

In another variation of vapor phase sublimation, a longitudinally split mullite tube is placed inside the mullite combustion tube (Fig. 1). This method leads to the growth of large voluminous crystals, which can be sampled readily and accurately from the various growth regions in the split tube. These large, oblong crystals were used mostly in the diffusion experiments described below.

Growth of pure single crystals.—The crystal growth on a cooling finger has been conducted as part of an attempt to prepare large crystals of high purity. Since the quartz combustion tube tends to break when cooled to room temperature after every experiment,[1] it was decided to keep the quartz tube continuously above 1000°C. In this way it was possible to conduct up to 30 growth experiments without loss of the quartz combustion tube. Consequently the cooling finger arrangement became a necessity for removing the crystals after growth was completed. In addition, since the cooling device can be removed rapidly from the hot zone, completely hexagonal crystals are obtained readily by temperature quenching.

[1] Quartz crystallizes in the tridymite form with an attendant volume increase of 15% when cooled to 900°C.

* Quantitative spectrographic analysis by T. Veleker, Sylvania Electric Products Inc., Towanda, Pennsylvania.

Activated crystals are grown readily by this technique, with the desired level of activation depending on the additives physically admixed to the zinc sulfide powder or kept in a separate quartz boat; however, difficulties were met in preparing very pure crystals by the cooling-finger technique.

It was observed that the yield of crystals decreased with successive growth experiments. There was a trend to very thin, plate-like crystals with consecutive experiments. These thin tissue-like crystals were very flexible and exhibited interference colors in reflected light. After several experiments, nucleation still took place on the cooling finger, but the nuclei no longer grew into visible crystallites.

A correlation between the decrease in the rate of crystal growth and the increase in the purity of the crystals has been observed. Table I indicates that a gradual decrease of contamination occurs with successive growth experiments. It appears that the quartz tubes and boat are gradually cleaned, and the incorporation of impurities through the vapor phase and from the quartz substrate decreases accordingly.

There is additional proof that impurities are instrumental in the growth of zinc sulfide single crystals. The growth of crystals could again be brought about by using a quartz cooling finger which had not been used previously. The introduction of copper metal or zinc oxide powder into the boat was similarly effective in stimulating crystal growth.

Influence of tubing material.—The physical appearance, growth habit, and impurity content of crystals depend markedly on the tube material employed for crystal growth. As indicated above, there is a decrease in impurity levels with the successive use of a given transparent quartz tube. This purification effect occurs also with opaque quartz, while the increase in purity of crystals grown in consecutive experiments in mullite tubing has not been studied; however, crystals of successive batches became gradually light-yellowish to colorless in color and greenish-blue photoluminescent, while the first batch was dark-brown and nonphotoluminescent. Table II indicates average values of the tube composition and starting zinc sulfide powder which are based on several quantitative spectrographic analyses. The zinc sulfide powder is essentially spectrographically pure, while the tube ma-

terial is obviously the main source of contamination during growth.

The impurities are given as an average from several spectrographic determinations on randomly sampled crystals, Table III. One finds, as expected, that crystals grown in combustion tubes containing many impurities are contaminated accordingly. However, even the appearance and physical properties of the crystals depend on the kind of tubing material employed (Table IV).

One finds many crystals grown on the cooling finger that are not photoluminescent because they are very pure, while some crystals grown on the wall of the mullite tube are not photoluminescent because they contain too many impurities.

In general one observes also that the volume-to-surface ratio of crystals increases markedly with the impurity content. Some indication was found that traces of Ni, Co, and Fe in conjunction with Cu are very instrumental in introducing a brown to dark-brown physical color.

Nonuniformity in impurity content.—There has been considerable mention of the fact that the crystals of a specific batch differ widely with respect to purity and perfection of the crystal structure (9, 12, 13). While a partial analysis of these problems has already been presented (3, 8) in previous communications, additional evidence on the origin and elimination of these difficulties is given in the present paper. In this section three problems will be dealt with: (*a*) a comparison between the impurity level of the crystals and the material remaining in the boat, (*b*) spectrographic determination of impurities in the crystals grown in contact with the combustion tube wall and of the crystal fraction not in contact with the wall, and (*c*) the change of impurity level with location in longitudinally split tubes. The data are again averages of several experiments and show the typical features that cause the nonuniformity in purity from crystal-to-crystal and within single crystals grown by vapor phase methods.

Table V. Impurities, in per cent by weight, in single crystals and starting material after growth is completed

Element	Crystals on cooling finger	Powder in quartz boat
Al	0.001	0.0005
Ca	0.0002	0.0001
Cu	0.005	0.002
Fe	0.0007	0.0003
Ni	0.0005	0.0002

Table VI. Impurities, in per cent by weight, incorporated from the vapor phase and by solid-state diffusion

Element	Crystal fraction from wall	Crystal fraction not in contact with wall
Al	0.005	0.0005
Cu	0.015	0.003
Fe	0.001	0.0005

Table V shows that some impurities are incorporated preferentially in the single crystals on the quartz cooling finger in a mullite combustion tube. This becomes apparent when one compares the analyses of crystals with those of the contaminated residual starting material which was kept in a transparent quartz boat.

The powder in the boat also increased in particle size, but since the single crystals are much larger, one may assume that the impurities that are preferentially accumulated may cause the rapid growth, i.e., they may act as mineralizers.

In the second investigation, about half of every single crystal grown on the wall of the longitudinally split tube was broken off, and spectrographic analyses were run on both these and on the parts remaining in contact with the tube wall.

It was found, as indicated in Table VI, that the crystal fraction in contact with the wall contains a higher impurity level than crystals into which impurities were preferentially incorporated by vapor phase diffusion. This result confirms previous observations (14) which indicated an impurity gra-

dient in cadmium sulfide crystals grown by a similar method.

The local impurity distribution from crystal-to-crystal can be studied when a longitudinally split tube is used, which also facilitates the sampling of crystals. Crystal growth starts at a sharp boundary which is near 1080°C (region a in Table VII and Fig. 1); the largest crystals grow in this region; they are brown to dark-brown in physical color. As the color lightens with the location farther from this dark region, the crystals become gradually smaller, the particle size following about an exponential dependence with the distance. Table VII shows the impurities found, and the photograph (Fig. 1) shows the split tube with crystals.

Control of impurity content and crystal structure by heat treatment.—It has been indicated above that the growth of very pure and large crystals in a reasonable reaction time leads to intrinsic difficulties. Therefore, it did not appear desirable to grow crystals of high purity, but instead an attempt was made to achieve this objective (i.e., the preparation of single crystals of controlled crystal structure and chemical composition) by heat treatment after crystal growth was completed.

Copper is considered to be the most important impurity because of its role as an activator and its relatively high concentration (Table III) in the large crystals which were grown in mullite tubing. The observation of Riehl and Ortmann (15) that copper diffuses readily into the zinc sulfide lattice suggested a method for purification. The purification method depends on impurity diffusion from the crystal into pure zinc sulfide powder in which the crystal is embedded. A variation of this method may also be used to activate crystals by diffusion in the opposite direction. The times and temperatures involved in purification by this process are indicated in Table VIII; some additional results are given in Fig. 2.

A large number of crystals have been heat treated in this way, and one observes that the purification process leads to various attendant changes. The brown physical color diminishes and the transparency increases; the electrical resistivity increases by

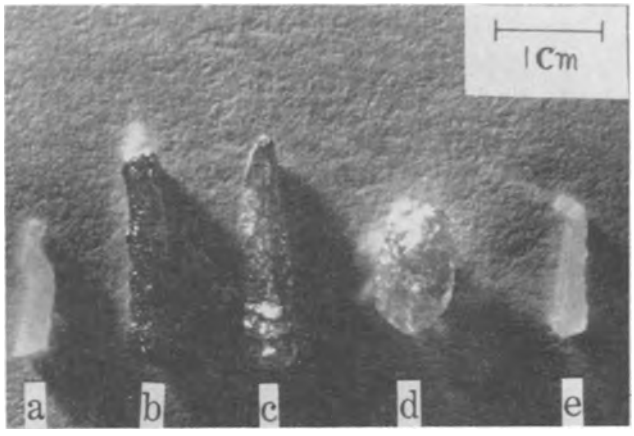

Fig. 2. Zinc sulfide crystals before and after annealing at 1000°C: (a) Piece of crystal b, annealed for 100 hr, pure embedding powder changed 3 times, (b) original, not annealed crystal, (c) crystal annealed for 32 hr in pure powder, (d) crystal annealed for 50 hr, and (e) crystal annealed for 200 hr, embedding powder changed 5 times. Crystals a-e were made cubic by a second annealing of 5 hours at 900°C in pure zinc sulfide powder.

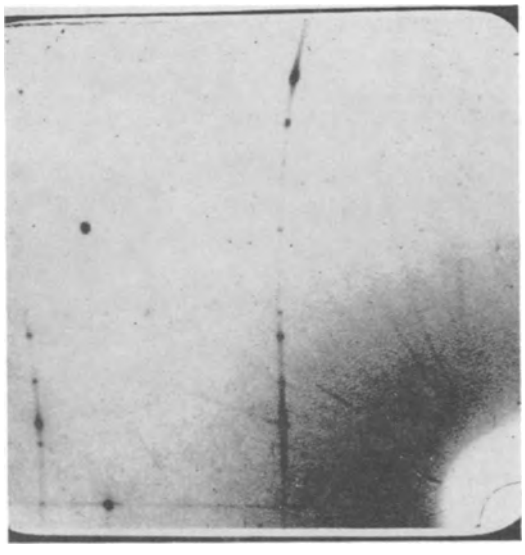

Fig. 3. X-ray diagram of a mixed hexagonal-cubic zinc sulfide crystal rotated about the c-axis; randomness, and 4- and 6-layer polytypes are observed.

several orders of magnitude; crystals turn photo- and electroluminescent or frequently change their emission color; changes in crystal structure also take place in many cases.

The crystal structure is usually quite disordered if zinc sulfide single crystals are grown on the wall of the combustion tube. The disorder consists of randomness, mixed hexagonal-cubic structure in the same crystal, and the presence of polytypes. An x-ray diffraction pattern of such a disordered crystal is shown in Fig. 3; the crystal has been rotated about the c-axis. The photograph shows the presence of mixed hexagonal-cubic structure, randomness as indicated by the blackening between the distinct spots, and the presence of 4- and 6-layer polytypes.

These disordered crystals are usually observed if one permits the furnace to cool at the rate governed by its heat capacity. If completely cubic crystals (Fig. 4) are desired, it is usually sufficient to keep

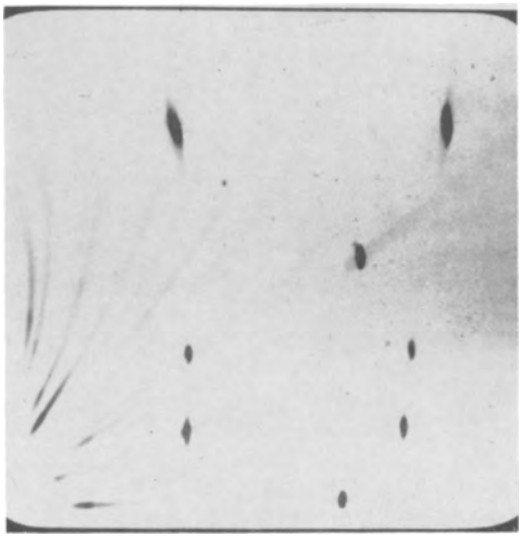

Fig. 4. X-ray diagram of cubic zinc sulfide single crystal rotated about the 111-direction.

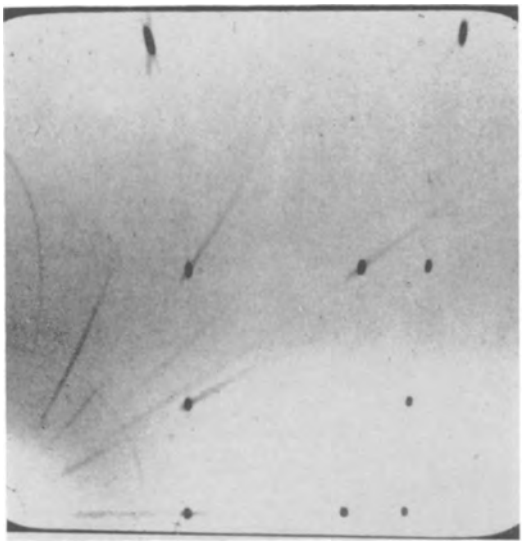

Fig. 5. X-ray diagram of hexagonal zinc sulfide single crystal rotated about the c-axis.

the crystals for 5 to 10 hr near 900°C. In this way one can combine the purification or activation of the crystal with the alteration of the crystal structure, so that a cubic crystal of controlled activator content is obtained.

The method employing the cooling finger also permits the preparation of completely hexagonal crystals (Fig. 5). The U-shaped cooling finger with crystals on the tip can be removed easily and rapidly from the hot condensation zone, so that the crystals are quenched after growth is completed (Fig. 6). It has been observed in all these cases that hexagonal crystals are formed, and therefore one may assume that crystals grew in this form under the growth conditions employed. This result is readily obtained when the cooling finger is used, while growth on the wall of the combustion tube does not permit rapid temperature quenching.

Hexagonal crystals can also be activated or purified by heat treatment after growth, although it is necessary to keep the annealing temperature below 800°C so that no transformation of the crystal structure (3) occurs while diffusion of foreign atoms

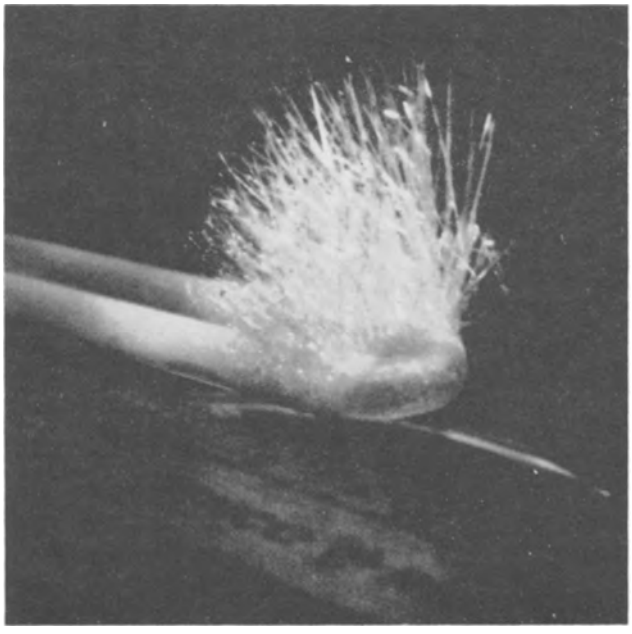

Fig. 6. Hexagonal crystals grown on the tip of the U-shaped quartz cooling finger.

(15) is taking place. In this way it has been possible to obtain pure or activated crystals belonging to the hexagonal system.

Conclusion

Certain impurities appear to be necessary when zinc sulfide single crystal growth is to proceed from nuclei. One may speculate that such mineralizers may facilitate the formation of screw dislocations, so that no need for the formation of a "two-dimensional nucleus" exists.

This behavior leads to inherent difficulties when an attempt is made to grow large pure crystals. Therefore, heat treatment with attendant diffusion has been employed in preparing large single crystals of controlled chemical composition. This annealing technique also eliminates the impurity gradient within a given crystal and impurity variations among crystals that depend on the growth site within the combustion tube.

Heat treatment also permits the deliberate control of the crystal structure, so that pure cubic or hexagonal crystals with or without a desired degree of randomness can be obtained, although the latter and the occurrence of polytypes appear to be markedly dependent on the presence of small amounts of foreign elements (3).

As a next step in investigating some pertinent problems, a detailed study of the impurity dependence of the crystal structure and disorder and their correlation with the appropriate free energy changes appears to be indicated. Such investigations should finally permit one to overcome the difficulties still remaining to be solved in the preparation of zinc sulfide single crystals of controlled chemical composition and crystal structure.

Characteristics of the {111} Surfaces of the III-V Intermetallic Compounds

Harry C. Gatos and Mary C. Lavine

Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts

ABSTRACT

Surface characteristics of the {111} crystallographic planes of the III-V intermetallic compounds (zinc-blende structure), and in particular those of InSb, are discussed. The polarity of these compounds along the <111> directions leads to pronounced physical chemical differences between the {111} surfaces terminating with group III atoms and those terminating with group V atoms. Differences in etching, dislocation etch pit formation, and electrode potential are presented. Dislocation etch pits form on the group III surfaces and not on the group V surfaces of the six compounds investigated (InSb, GaSb, AlSb, InAs, GaAs, and InP). A proposed interpretation is based on the relative reactivity of the group III and group V atoms as affected by their bond configuration and the polarity of the zinc-blende structure.

A number of investigators have reported on the etching characteristics (1-5) and other surface properties of the III-V compounds (4, 6). InSb has been principally employed because of its availability.

Among the various crystallographic planes, the {111} are of special interest because the III-V compounds (zinc-blende structure) exhibit polarity along the <111>directions. Thus, there is significant difference between parallel {111} surfaces, arbitrarily designated as {111} and $\{\bar{1}\bar{1}\bar{1}\}$ as shown in Fig. 1. The outermost atom layer in each surface consists of either group III or group V atoms which are triply bonded to the lattice. This results from the fact that the {111} surfaces can be created only by cuts between planes such as AA and BB (Fig. 1) where atoms are singly bonded to one another. A surface configuration containing atoms singly bonded to the lattice, resulting, for instance, from a cut AB'B' is not stable (4, 5, 8). Furthermore, slip on the {111} planes occurs between AA and BB rather than AA and B'B'.

Dislocation etch pits are found only on the {111} and not on the $\{\bar{1}\bar{1}\bar{1}\}$ surface (1, 2, 5, 6). The identification of the two types of surfaces in InAs and GaSb was achieved recently by Warekois and Metz-

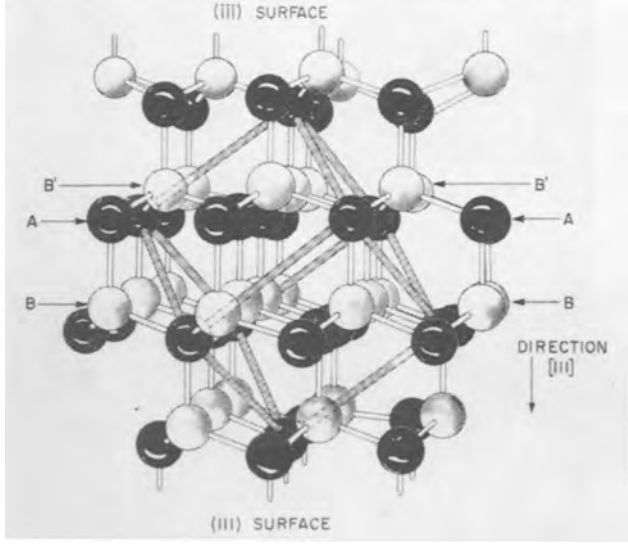

Fig. 1. Crystal structure (zinc-blende) of the III-V intermetallic compounds; the unit cell is indicated. •, group III atoms; ○, group V atoms.

ger (9). They showed by x-ray techniques that in InAs and GaSb the {111} planes developing dislocation etch pits terminate with the group III atoms. This has been also shown for GaAs (10), and for InSb and other III-V compounds (11).

In the present paper, the etching characteristics and the formation of dislocation etch pits in III-V compounds are discussed, and an interpretation is advanced for the observed differences between the two types of {111} planes and the formation of dislocation etch pits on the {111}and not on the $\{\bar{1}\bar{1}\bar{1}\}$ surfaces.

Experimental

Reactivity of the {111} Surfaces

Quantitative differences in reactivity between the A[1] and B surfaces were determined by measuring their etching rates. For this purpose, high-purity InSb samples were employed having exclusively A or exclusively B surfaces. They were actually tetrahedrons having as all four sides either only A or only B surfaces. Each set of A and B tetrahedrons was prepared from the same single crystal of InSb by grinding the surfaces to the proper orientation as determined by x-ray diffraction. The geometric relationship between an A and a B tetrahedron is shown in Fig. 2 and can be conveniently related to the diagram of Fig. 1.

At room temperature and above, the etching rates of both types of surfaces in a number of oxidizing media are controlled by the diffusion of the oxidizing species in solution to the surface of the sample as has been shown for InSb and for other III-V compounds (12). Consequently, no difference in rates is observed at these temperatures. However, the etch patterns of the two types of tetrahedrons are different since the nature of the attack is not necessarily a function of the dissolution rate. On the A tetrahedron dislocation etch pits appeared on all four sides whereas no dislocation etch pits appeared on the B tetrahedron. This experiment certainly eliminates the possibility that the etching behavior of the crystallographic surface under study is affected by adjacent surfaces of different orientation and chemical reactivity.

[1] For convenience, group III atoms will be designated as A atoms and group V atoms as B atoms; {111} surfaces terminating with A or B atoms will be designated as A or B surfaces, respectively.

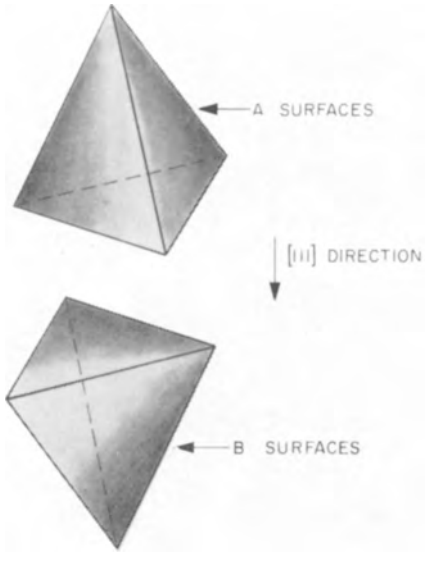

Fig. 2. Geometric relationship between tetrahedron A having exclusively group III atom surfaces, i.e., (111), $(1\bar{1}\bar{1})$, $(\bar{1}\bar{1}1)$, $(\bar{1}1\bar{1})$ and tetrahedron B having exclusively group V atom surfaces, i.e., $(\bar{1}\bar{1}\bar{1})$, $(\bar{1}11)$, $(1\bar{1}1)$, $(11\bar{1})$. Compare with Fig. 1.

The etching of both tetrahedrons proceeds at the same rate at 25°C with an activation energy of approximately 5 kcal, which is characteristic of diffusion-controlled dissolution processes (13, 14). At lower temperatures, however, the rates diverge, that of the A surfaces falling to one-tenth the rate of the B surfaces at 4°C. The activation energy associated with the etching of the A surfaces rises to approximately 25 kcal, which is characteristic of chemical activation-controlled processes, whereas the etching of the B surfaces remains diffusion-controlled. Clearly then, in the case of InSb, surfaces terminating with Sb atoms have a far greater tendency to react than those terminating with In atoms. This undoubtedly prevails at room temperature but cannot be detected by etching rate measurements since diffusion of the oxidizing species to the surface is the rate-determining step.

The above difference in reactivity was also confirmed by electrode potential measurements. InSb electrodes, one exposing an A surface and one exposing a B surface, were prepared from one single InSb crystal. In various etching media in the vicinity of 0°C, they exhibited significant differences in electrode potential (75 mv or greater). The electrode with the In surface was always more noble than that with the Sb surface, consistent with the rate measurements.[2] Electrodes prepared from different InSb ingots also showed the same potential difference as those prepared from the same ingot. On the other hand, electrodes with the same type of surface (either In or Sb) exhibited no potential difference within experimental error (5-10 mv).

Etching Characteristics

General Remarks.—Surface heterogeneities usually serve as centers for the initiation of preferential etching and etch pits. Such heterogeneities can result from cold work and from dislocations intersecting the surface. The morphological growth of etch pits or etch patterns, however, depends strongly on the nature of the chemical etchant. More often than not, slow acting etchants reveal surface heterogeneities (16). Fast etchants tend to dwarf local differences in surface reactivity and lead to chemical polishing.

In some instances virtually all of the dislocations can be revealed individually by employing slow etchants. The etch pit count can then serve for dislocation density determinations (17). In general, however, an etching agent which develops dislocation etch pits does not necessarily reveal all of the

[2] The dissolution rate of a metal in acid oxidizing media is usually determined by the reduction rate of the oxidizing agent (15), and the dissolution potential of the metal approaches its reversible value. This also applies to the present case, regardless of temperature. Thus, the more noble dissolution potential of the A surfaces clearly indicates that they have a lesser tendency to react than the B surfaces.

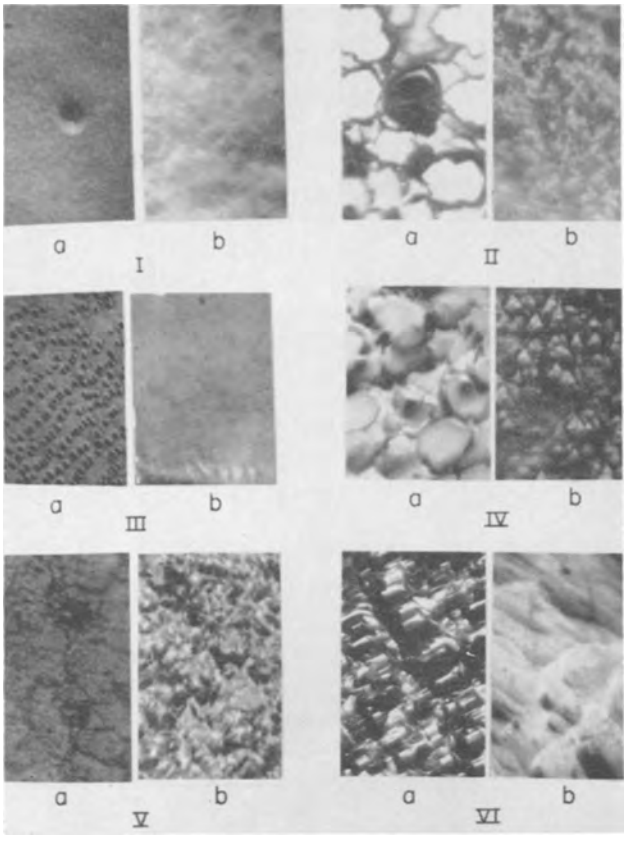

Fig. 3. {111} surfaces (a) terminating with group III atoms and $\{\bar{1}\bar{1}\bar{1}\}$ surfaces (b) terminating with group V atoms of III-V compounds. The compounds, the composition of the etchants in parts by volume, the etching time and temperoture are: I, InSb; 2 conc. HNO_3:1 conc. HF:1 glacial CH_3COOH; 4 sec; 25°C.(315X). II, InAs; 0.4N Fe^{+++} in conc. HCl; 30 min; 25°C (525X). III, GaSb; 2 conc. HNO_3:1 conc. HF:1 glacial CH_3COOH; 15 sec; 25°C (315X). IV, GaAs; 0.2N Fe^{+++} in 6N HCl; 10 min; 82°C (1500X). V, AlSb; 1 30% H_2O_2:1 conc. HF:1 H_2O; 1 min; 25°C, followed by 1 conc. HCl:1 conc. HNO_3; 2 sec; 25°C (525X). VI, InP; 0.4N Fe^{+++} in conc. HCl; 1.5 min; 25°C (525X). (All magnifications are before reduction for publication.)

dislocations terminating at a given surface. The fact that distinct dislocation etch pits have not been observed on the $\{\bar{1}\bar{1}\bar{1}\}$ planes certainly does not imply that these surfaces are not intersected by dislocations.

Dislocation etch pits.—In order to establish whether or not the appearance of dislocation etch pits on the A surfaces alone is a general phenomenon, several III-V compounds were studied under varied experimental conditions. InSb, GaSb, AlSb, InAs, GaAs, and InP in single crystal form and of relatively high purity were employed. The surfaces were ground to within 1 degree of the desired orientation as determined by x-ray diffraction. A variety of etching media (inorganic and organic acids) were employed, containing different oxidizing agents such as HNO_3, H_2O_2, Fe^{+++}, MnO_4^-, $Cr_2O_7^=$, Ce^{++++}, and $V(OH)_4^+$ at various concentrations. Etching experiments were performed for periods ranging from a few seconds to 2 hr and at temperatures up to 82°C. Under such varying conditions, a multitude of etch figures were obtained. In no instance, however, were dislocation etch pits observed on the B surfaces of any of the compounds. Dislocation etch pits were developed on the A surfaces of all six compounds. This occurred in many preferential etchants (leading to etch figures) as well as in nonpreferential etchants (leading primarily to chemical polishing). Representative examples for the compounds employed are shown in Fig. 3. It should be noted that etchants acting preferentially on the A surfaces showed preferential action on the B surfaces also, but did not reveal dislocation etch pits on the latter.

Etch figures on the {111} surfaces of InSb.—In some instances, the same etchant can act both preferentially and nonpreferentially depending on the reaction time and surface pretreatment. Figure 4 shows A surfaces of InSb etched in Fe^{+++} etchant for various times. It is noted that the dislocation etch pits grow with time. Although not shown, the dislocation etch pits for the cases corresponding to Fig. 4-VI and 4-VII were larger than those in Fig. 4-V. Simultaneously the etch figures grow in size and merge into each other. They are shallow at all times with relatively flat {111} bottoms and grow sidewise. It is believed that in this case, heterogeneities originally present in the abraded surface contribute greatly to the initiation of the patterns shown in Fig. 4-I. As the cold worked layer is removed, etching proceeds rather uniformly and eventually leads to a chemical polish except for the areas immediately adjacent to the dislocations. For the same etchant, the cold-worked layer is removed in shorter times by increasing the temperature and therefore the etching rate. Figure 5-I shows that a

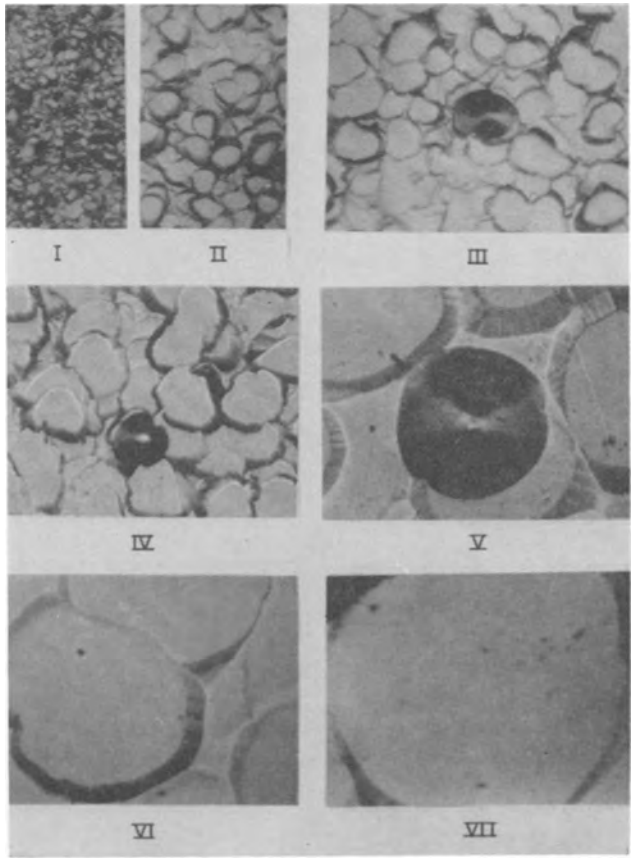

Fig. 4. {111} A surfaces of InSb etched in 0.4N Fe^{+++}—conc. HCl (515X) for various times. I, 5 min; II, 10 min; III, 15 min; IV, 20 min; V, 30 min; VI, 60 min; VII, 90 min.

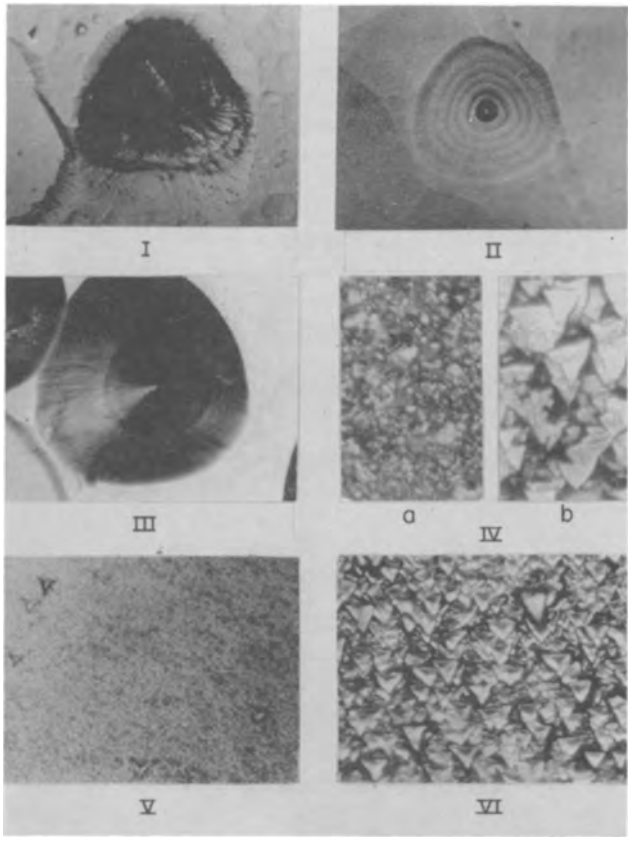

Fig. 5. {111} surfaces of InSb. I, Surface A etched for 5 min at 82°C in 0.4N Fe^{+++}— conc. HCl (515X). II and III, surface A etched for 4 sec in 2 conc. HNO_3:1 conc. HF:1 glacial CH_3COOH at 25°C, subsequently etched for 30 min in 0.4N Fe^{+++}—conc. HCl at 25°C (515X). IV, Surface B, etched for 5 min (a) and 90 min (b) at 25°C in 0.4N Fe^{+++}— conc. HCl (515X). V, Surface B of cases II and III (515X). VI, Surface B of case I (515X).

surface etched at 82°C for 5 min resembles that obtained at room temperature in 30 min. Consistent with this, essentially no preferential etch patterns appear if the surface is pretreated in a fast non-preferential etchant and subsequently etched by Fe^{+++}. Some dislocation etch pits, as the one shown in Fig. 4-II, did not form during the pretreatment with the fast etchant. Those developed during pretreatment (Fig. 5-II) grew further in the Fe^{+++} etchant (Fig. 5-III).

The etch patterns of the B surfaces persist longer than those of the A surfaces. It can be seen in Fig. 5-IV that in 90 min (Fig. 5-IVb) the growth of the etch figures on the B surface is appreciably less than the corresponding etch figures on the A surface of Fig. 4-VII. Figures 4-I and 5-IVa represent opposite sides of an {111} wafer; the same is true for Fig. 4-VII and 5-IVb for 5-II and 5-V, and finally for 5-I and 5-VI. Actually, in many cases, etch figures are revealed on the B surfaces while the A surfaces appear chemically polished.

Each side of the triangular patterns on the {111} surfaces is parallel to an <110> and perpendicular to a <211> direction. It is not uncommon for the A surfaces to develop hexagonal-type patterns with each of their sides again parallel to an <110> direction (Fig. 6-I). On occasion, the {110} planes develop intersecting the surface at an angle of 60°

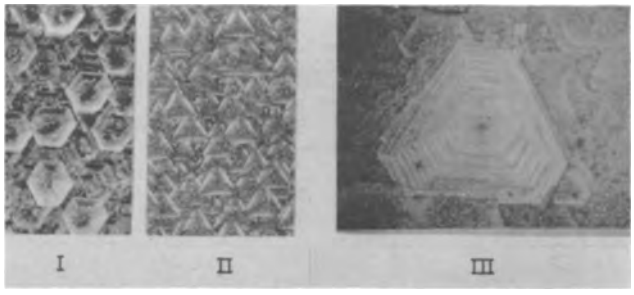

Fig. 6. {111} InSb surfaces etched for 30 min at 82°C in 0.2N Fe^{+++}—6N HCl. I, surface A (145X), II, surface B (145X), III, surface A (315X).

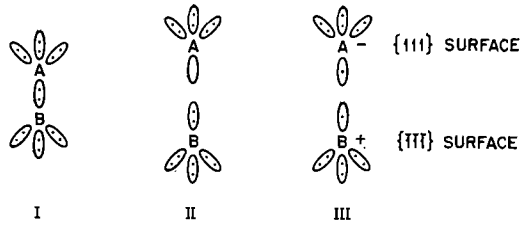
along the sides of the triangular or hexagonal patterns and lead to inverted pyramid-like etch patterns as can be seen in Fig. 6-I and to some extent in Fig. 6-II. An etch figure with a distinct terrace-like structure surrounding a dislocation etch pit is shown in Fig. 6-III.

Apparently, it is through the advancement of their sides that etch patterns grow. It will be recalled that at the temperature under consideration the over-all dissolution rate is the same for both A and B surfaces. The flat {111} bottoms of the etch figures on the A surfaces are not attacked as fast as the {110} planes mentioned above or any planes intersecting the surface at a steep angle along the sides of the etch figures. The chemical reactivity of the B surfaces on the other hand is much greater than that of the A surfaces. Consequently, the bottoms of the etch figures on the B surfaces are attacked appreciably, and their growth sidewise does not proceed as fast as on the A surfaces. This accounts for the fact that the etch figures of the A surfaces become rounded and grow faster than those of the B surfaces under the same experimental conditions. It is for the same reason that the etch figures of the B surfaces persist even under conditions under which the A surfaces appear chemically polished.

Discussion

Atomic Model for the A and B {111} Surfaces

Regarding the differences in behavior between A and B surfaces, it is proposed that the B surface atoms are very reactive chemically, since they are only triply bonded to the lattice, whereas their normal valence is five. Surface A atoms, also triply bonded to the lattice, must be appreciably less reactive since they are normally trivalent. The bond configuration of the zinc-blende structure (sp^3 tetrahedral hybrid orbitals) is illustrated schematically for the {111} direction (I). The formation of an A and a B surface (by a cut between planes AA



and BB of Fig. 1) can be represented as in II or III where both A and B atoms retain their tetrahedral

bond configuration. In II, atom B acquires both electrons; in III, atoms A and B acquire one electron each from the pair of electrons corresponding to the bond being broken. Case III is thermodynamically improbable since the ionization potential associated with the formation of B^+ is much greater than the electron affinity associated with the formation of A^-. Case II is considered as the most likely to occur as it leads to electrically neutral surfaces. In considering case II it is not possible to decide unambiguously whether or not A or B atoms are more reactive on the basis of the hybrid orbitals involved. However, it is reasonable to state that in etching processes where oxidizing (electrophilic) agents are involved, B atoms are more reactive than A because they have an unshared pair of electrons available for oxidation. Similarly, A atoms could possibly have a greater tendency to react with nucleophilic agents (unshared pair of electrons), but this case does not concern us at present.

The above valency or hybrid orbital model shows that B surface atoms should be more reactive than A in electrophilic ambients. Thus the model accounts for the observed differences between the A and B surfaces. It also accounts for the formation of dislocation etch pits on the A surfaces as shown below. The presence of the filled unshared electron orbitals on the B surfaces and the unfilled orbitals on the A surfaces points to pronounced differences in electronic phenomena between the two surfaces. These phenomena include surface conductivity, photoconductivity, surface recombination velocity, and others.

Obviously the model does not take into consideration possible surface states nor does it involve quantum mechanical aspects. However, it does account for the experimental results. A quantum mechanical verification should prove of considerable interest.

Edge dislocations in the zinc-blende structure.—It has been shown that in the zinc-blende structure, slip occurs on the {111} planes and along the <110> directions (5). The dislocation axis in this structure is parallel to the <110> direction and forms a 60° angle with the Burgers' vector (18). Considering the polarity of the zinc-blende structure it is apparent that α[3] and β dislocations can intersect both the A and the B surfaces. Venables and Broudy (5) showed that for InSb, only one type of dislocations leads to the formation of dislocation etch pits on the {110} and probably on the {111} surfaces. If their work is viewed in the light of Warekois' (11) identification of the crystallographic polarity of InSb the observed dislocations are α (In) dislocations. Atom models of 60° edge dislocations intersecting an {111} surface are shown in Fig. 7 and 8.

Since dislocation etch pits result from only one type of dislocations and since these pits do not develop on both the A and the B surfaces, it appears that elastic strains associated with edge dislocations in the III-V compounds do not play a significant role in etch pit formation. Rather, the formation of dislocation etch pits is controlled primarily by the specific chemical differences between the A and the B atoms on the {111} surfaces and at the dislocations as affected by their bonding characteristics along the polar <111> direction and the dislocation axis.

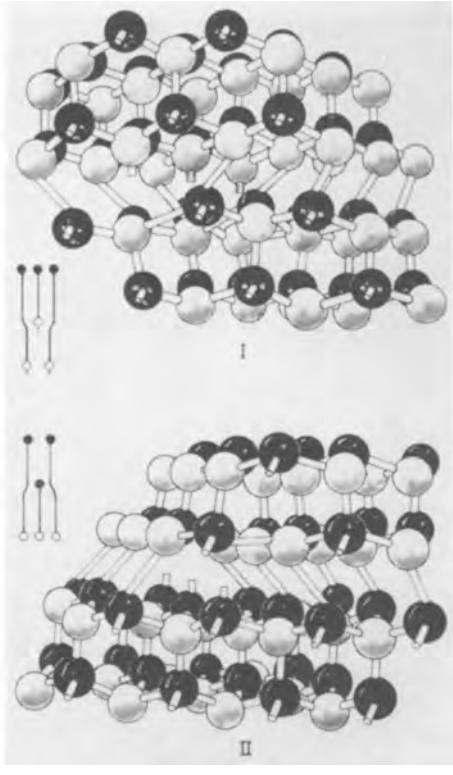


Fig. 7. Atom models showing a 60° edge dislocation intersecting the A surface. Surface of interest is defined by the atoms with protruding bonds. I, Dislocation terminating in a row of B atoms; II, dislocation terminating in a row of A atoms.

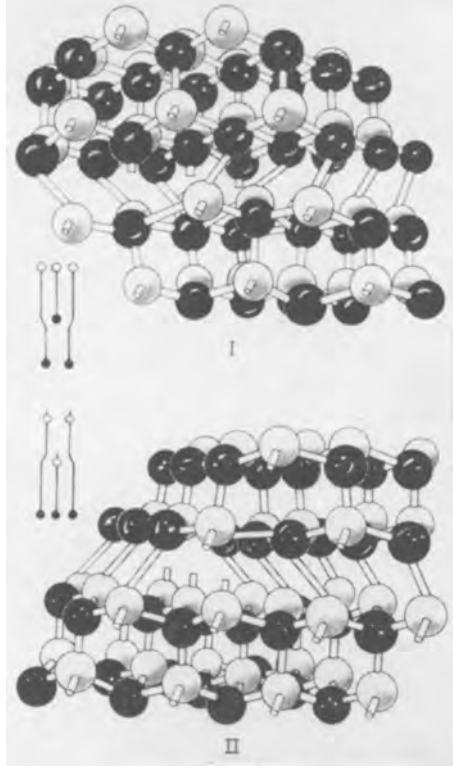

Fig. 8.Atom models of a 60° edge dislocation intersecting the B surface. Surface of interest is defined by the protruding bonds. I, Dislocation terminating in a row of A atoms; II, dislocation terminating in a row of B atoms.

[3] Dislocations with a row of triply bonded A atoms will be designated as α dislocations, and those with B atoms will be designated as β.

Etching and dislocation etch pit formation on the {111} surfaces.—Since both α and β dislocations intersect the A and the B surfaces, there are four possibilities: Aα, Aβ, Bα, and Bβ. As shown in Fig. 7 and 8 the α dislocations terminate with a divalent A atom (A_2) on the A surfaces and the β dislocations terminate with a divalent B atom (B_2) on the B surfaces. In the cases Aβ and Bα the terminal dislocation atom is trivalent (B_3 and A_3, respectively) and actually it does not lie in the outermost surface layer. Regarding the relative reactivities of the triply and doubly bonded surface atoms it is reasonable to state that $B_2 > B_3$ and $A_2 > A_3$ (it will be recalled that $B_3 > A_3$). Singly bonded A or B surface atoms are not being considered since such a surface configuration is unstable, as pointed out above. If it were stable, no difference in behavior would be expected between the A and the B surfaces. Finally, the quadruply bonded atoms immediately below the outermost surface layer are considered stable when compared with the triply bonded surface atoms.[4]

Etching and etch pit formation will be considered from an atomistic point of view. Although simplified, such an approach seems desirable at this time, particularly in dealing with covalent crystals.

Considering first {111} surfaces not intersected by edge dislocations (Fig. 1), it appears that the removal of triply bonded surface atoms (A atoms in the case of A surfaces and B atoms in the case of B surfaces) must be associated with the rate-determining step of the etching process. The atoms immediately below the outer surface atoms become singly bonded and, therefore, extremely unstable, as the outer surface atoms to which they are bonded are removed. It is because the outer surface atoms play such a significant role in the behavior of the {111} surfaces that major differences are observed between the A and the B surfaces.

The A and B surfaces intersected by edge dislocations are now considered:

Case Aα (Fig. 7-II).—The terminal A_2 atom of the dislocation is the first one to react. Then two B_3 adjacent atoms, which will react faster than any A_3 surface atoms, are exposed. As these B_3 atoms react, four A_2 surface atoms are exposed as well as an A_2 atom of the dislocation. Thus, it is apparent that the attack proceeds faster along the dislocation than over the rest of the surface leading to the formation of a dislocation etch pit.

Case Aβ (Fig. 7-I).—Strictly speaking the terminal B_3 atom of the dislocation does not belong to the outermost surface atom layer, and its role in the etching process is not expected to be of primary importance. Even if this B_3 atom is attacked before the A_3 surface atoms, then two A_2 surface atoms are exposed but the next atom of the dislocation remains bonded to three A_3 atoms. It is apparent from the diagram that in such a case the attack does not necessarily proceed preferentially along the dislocation, but rather in a layer-like fashion over the surface.

Case Bα (Fig. 8-I).—This case is in many respects similar to the Aβ case. Actually, the formation of dislocation etch pits is even less favorable here. The terminal atom of the dislocation is A_3 which is less reactive than the surface B_3 atoms.

Case Bβ (Fig. 8-II).—Although this case is analogous to Aα, it does not lead to the formation of dislocation etch pits. As the terminal dislocation atom B_2 is attacked, two A_3 atoms are exposed which will not react as fast as the B_3 surface atoms. These A_3 atoms delay the exposure of the next B_2 dislocation atom until the surrounding B_3 surface atoms are attacked. Hence, no preferential attack along the dislocation axis takes place.

[4] Surface configurations with "steps" and "kinks" will not be considered at this time. They will be treated in a future communication.

Summary

Dislocation etch pits were observed on the {111} surfaces terminating with group III atoms in six III-V intermetallic compounds (InSb, GaSb, AlSb, InAs, GaAs, and InP) in a number of etching solutions. In all six compounds no dislocation etch pits were observed on the {111} surfaces terminating with group V atoms. In addition to this difference, at low temperature the group III {111} surfaces exhibit appreciably smaller etching rates and more noble electrode potentials than the group V surfaces. Furthermore, etch figures develop on the group V surfaces in etchants which chemically polish the group III surfaces. This applies even under conditions in which both types of {111} surfaces exhibit the same etching rates.

An atomic model is proposed with unshared filled tetrahedral orbitals in the case of B surfaces and unfilled orbitals in the case of A surfaces. The model accounts for the observed differences between the two types of surfaces and points to further differences in electronic properties.

Acknowledgment

The authors are indebted to Mrs. M. J. Button for assisting with the experiments, to E. P. Warekois for identifying the surfaces by x-ray diffraction, and to Dr. A. J. Rosenberg for suggesting the use of tetrahedrons in determining the etching rates of the A and B surfaces.

Manuscript received Oct. 8, 1959. This paper was prepared for delivery before the Columbus Meeting, Oct. 18-22, 1959. The work reported in this paper was performed by Lincoln Laboratory, a center for research operated by Massachusetts Institute of Technology with the joint support of the U. S. Army, Navy, and Air Force.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Etching Behavior of the {110} and {100} Surfaces of InSb

Harry C. Gatos and Mary C. Lavine

Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts

ABSTRACT

Preferential and nonpreferential etching characteristics of the {110} and {100} surfaces of InSb were investigated. Since {111} facets develop in the etch figures of these surfaces, the morphology of the etch figures reflects the crystallographic polarity of InSb along the <111> directions. Dislocation etch pits were found both on the {110} and on the {100} surfaces. The role of the relative reactivities of the various crystallographic planes in the over-all etching behavior of InSb and the effect of cold work are discussed.

InSb and other III-V intermetallic compounds with the zinc-blende structure have two types of {111} surfaces, i.e., one type terminating with group III atoms (A surfaces) and one terminating with group V atoms (B surfaces). The two types of surfaces, resulting from the crystallographic polarity of the <111> directions, exhibit markedly different physical chemical properties (1). Thus, it was found that the B surfaces of InSb are far more reactive than the A surfaces in oxidizing (electrophilic) agents. It is expected that the same applies to the {111} surfaces of the other III-V intermetallic compounds. This difference in reactivity was shown responsible for the fact that dislocation etch pits appear on the A surfaces and not on B surfaces of six III-V compounds investigated (InSb, GaSb, AlSb, GaAs, InAs, InP).

Since the zinc-blende structure exhibits no polarity in the <110> and <100> directions, no differences in behavior are expected among the various {110} surfaces or the various {100} surfaces. It will be shown, however, that in certain etchants {111} facets develop on the {110} and {100} surfaces, and consequently the <111> polarity of zinc-blende structure is reflected in the etching behavior of these surfaces.

It is the purpose of the present paper to demonstrate the role of the <111> crystallographic polarity on the etching behavior of the {110} and {100} surfaces of InSb and show that this behavior is consistent with the atomic model proposed to explain the relative reactivities of the A and B surfaces of the III-V intermetallic compounds (1). The effects of surface heterogeneities introduced by cold work are also discussed.

{110} Surfaces

In the present study wafers used were cut from high-purity InSb single crystals. The parallel sides of the wafers were ground to within 1° from the {110} orientation as determined by x-ray diffraction. Before etching they were ground with 1600 mesh garnet powder.

Two types of etchants were employed: (*a*) preferential etchants leading to the formation of etch figures, and (b) fast nonpreferential etchants resulting in the formation of dislocation etch pits on an otherwise chemically polished surface. A number of nonpreferential etchants can be employed successfully; among various preferential etchants studied the one consisting of 0.2*N* Fe^{+++} ions in 6*N* HCl was found the most suitable.

Typical results obtained with the preferential etchant are shown in Fig. 1-I. Upon cursory exami-

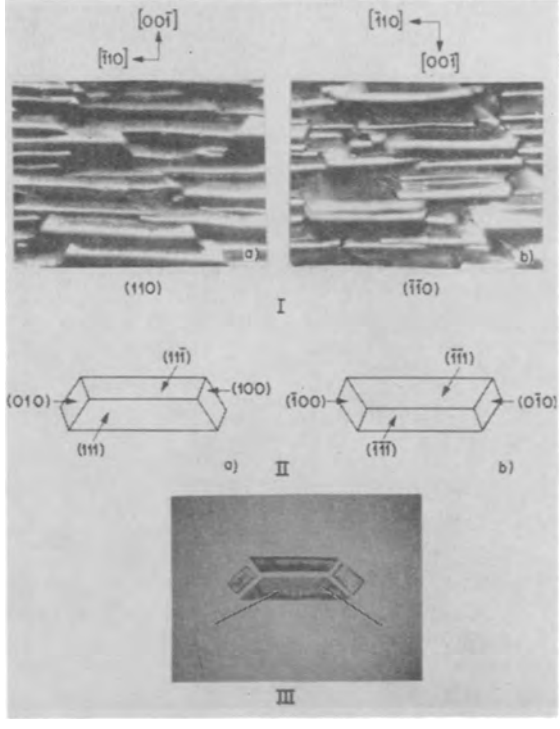

Fig. 1. Etch figures on {110} surfaces of InSb developed with 0.2N Fe^{+++} in 6N HCl at 82°C. I, opposite faces of an {110} wafer, 1500 X. II, schematic diagram of individual etch figures. III, exploded view of an etch figure; each facet was photographed individually while positioned parallel to the field of observation; arrows point to dislocation etch pits (approx. 800 X). (All magnifications are before reduction for publication.)

nation no difference is apparent between the two etched sides (Ia and Ib) of these wafers. Goniometric analysis of the etch figures shows that their elongated facets are {111} planes bounded by {100} planes as illustrated schematically in Fig. 1-II. The planes designated as (111) and $(\bar{1}\bar{1}1)$ are A planes whereas those designated as $(11\bar{1})$ and $(\bar{1}1\bar{1})$ are B planes. It can be seen that in an etch figure the A planes develop to a greater extent being less reactive than the B planes. As a result of this, and by considering the geometry of the zinc-blende structure and the relative position of the A and B planes (1), the trapezoid-like figures on the opposite {110} faces should appear inverted when the wafer is rotated about the $[\bar{1}10]$ direction as it can be seen clearly in Fig. 1-II.

The difference in size between the A and B facets of the etch figures varies according to the etching conditions. If the {110} surfaces are exposed to the preferential Fe^{+++} etchant without first removing the cold worked layer introduced by abrasion, the difference in over-all size between the A and B planes is not very pronounced. However, if the cold worked layer is removed by a fast nonpreferential etchant and then the surface is etched with the Fe^{+++} etchant, the A planes essentially predominate over the B planes and the {110} surfaces acquire a scale-like (shingle-like) appearance.

It was considered of interest to find out whether or not the etching behavior of the microscopic A and B facets of the etch figures resembles that of the A and B surfaces of InSb. It was possible to develop dislocation etch pits on the A facets of the etch figures but not on B facets, in accord with the behavior of ordinary A and B surfaces. Furthermore, the A and B facets of the etch figures were unambiguously distinguishable by their over-all appearance which was typical of the A and B surfaces, respectively, etched in the Fe^{+++} etchant. It should be pointed out that the A and B facets are best examined microscopically when positioned parallel to the field of observation. They form a 35° angle with the {110} surface. In the present case an ordinary metallograph was employed and the {110} wafers were positioned at the appropriate angles by means of suitable platforms. An exploded view of an etch figure is shown in Fig. 1-III. The arrows in the A facet point to dislocation etch pits.

Nonpreferential etching revealed distinct dislocation etch pits in a background of chemically polished

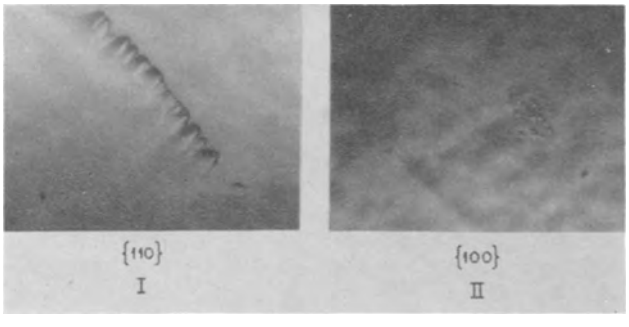

Fig. 2. Dislocation etch pits on the {110} and {100} surfaces (540 X). Etchant (in parts by volume): 5 conc. HNO_3; 5 conc HF; $2H_2O$.

Table I. Etching rates of various crystallographic planes of InSb

Plane	Etching rate	
	Etchant 1, mg/cm²/min	Etchant 2, mg/cm²/sec
{111}—B	0.2_5	7.8
{100}	0.2_2	7.8
{110}	0.2_6	2.5
{111}—A	0.2_3	0.5

Etchant 1: 0.2*N* Fe^{+++} in 6*N* HCl; 10°C; Etchant 2: in parts by volume, 2 conc. HNO_3; 1 conc. HF; 1 glacial CH_3COOH; 4°C.

{110} surface as shown in Fig. 2-I. The over-all etching rate of the {110} surfaces was determined by employing samples bounded entirely by {110} surfaces. Results are shown in Table I together with rates of the A, B, and {100} surfaces. It is seen that in the Fe^{+++} etchant the various surfaces exhibit essentially the same etching rate since, in this case, the over-all etching process is controlled by the transport of oxidizing species of the etchant to the InSb surface. Consequently, no conclusions can be drawn about the relative reactivity of the various surfaces. In the nonpreferential etchant, at 4°C, the A surfaces exhibit the lowest rate. Under these conditions etching of the A and the {110} surfaces is under chemical activation control (activation energy approximately 25 kcal/mole) whereas etching of the B and the {100} surfaces is under diffusion control (activation energy approximately 5 kcal/mole). These results are discussed further below.

{100} Surfaces

The {100} wafers employed in these experiments were prepared as the {110} wafers. As shown in Fig. 2-II, dislocation etch pits are revealed by nonpreferential etching, but they are appreciably smaller than the etch pits developing on the A or even the {110} surfaces under similar experimental conditions. Dislocation etch pits on the {100} surfaces of InSb or other III-V intermetallic compounds have not been reported in the literature. Yet, {100} surfaces like the {111} and {110} surfaces are intersected by the 60° edge dislocations of the zinc-blende structure.

On the {100} surfaces of InSb preferential etchants develop etch figures which are similar to those reported for GaAs (2). Figures 3-Ia and 3-Ib show the preferentially etched parallel surfaces of an {100} wafer. It is seen that the longer dimension of the rectangular etch figures on the one side of the {100} wafer is at a right angle to the longer dimension of the etch figures on the opposite side of the wafer. The etch figures are bounded by <110> directions.

Goniometric examination revealed that the etch figures are truncated tetragonal pyramid structures, the four sides being {111} planes. The top plane of the truncated pyramid is either flat {100} or has higher order planes (usually {411}) forming a shallow angle (approximately 19°) with the <100> direction. Between individual truncated pyramids occasionally pits are observed which are inverted pyramid-like depressions with flat {100} bottoms. The geometry of the etch figures is shown in Fig.

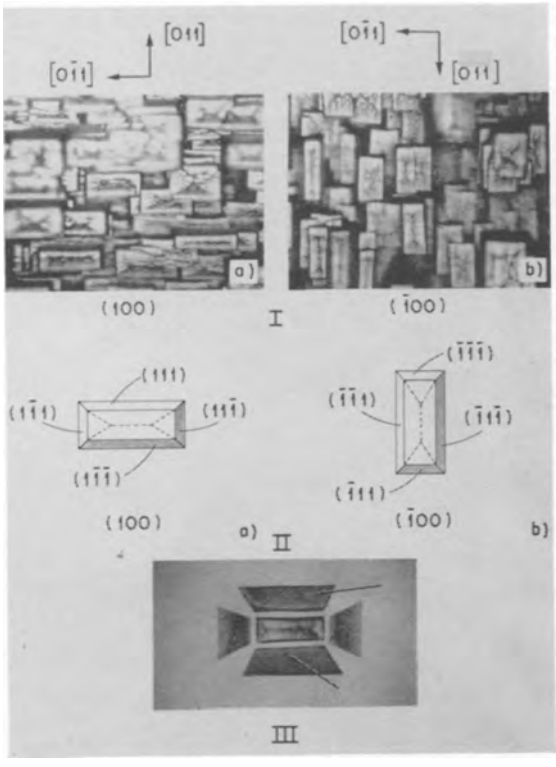

Fig. 3. Etch figures on {100} surfaces of InSb developed in 0.2N Fe^{+++} 6N HCl at 82°C. I, opposite faces of an {100} wafer, 1500 X. II, schematic diagram of individual etch figures; higher order planes occasionally present are indicated with dotted lines. III, exploded view of an etch figure; each facet was photographed individually while positioned parallel to the field of observation; arrows point to dislocation etch pits (approx. 800 X).

3-II. Here also the A facets [(111), ($\bar{1}$1$\bar{1}$), (1$\bar{1}\bar{1}$), and ($\bar{1}\bar{1}$1)] of the etch figures develop to a greater extent than the B facets [($\bar{1}$11), (1$\bar{1}$1), (11$\bar{1}$), and ($\bar{1}\bar{1}\bar{1}$)] and the etch figures appear as rectangular parallelograms rather than squares when viewed parallel to the <100> direction.

With techniques similar to those employed in the case of the {110} surfaces it was possible to develop and record conical dislocation etch pits on the A facets of the etch figures and to reveal on the individual facets the typical appearance of preferentially etched A and B surfaces. An exploded view of an etch figure is shown in Fig. 3-III. The arrows in the A facets point to dislocation etch pits.

If the cold-worked layer of the {100} surfaces is removed by chemical polishing prior to preferential etching the A facets develop to a much greater extent than the B facets. In addition the flat {100} facets are not developed and the etch figures become elongated structures as shown in Fig. 4.

The over-all etching rates of the {100} surfaces shown in Table I were obtained with samples bounded entirely by {100} surfaces.

Discussion

The development of certain crystallographic planes during crystal growth, as well as the distribution and morphology of etch figures, is associated with mechanisms which constitute a complex and controversial problem. The present results contribute to the elucidation of one of the aspects of

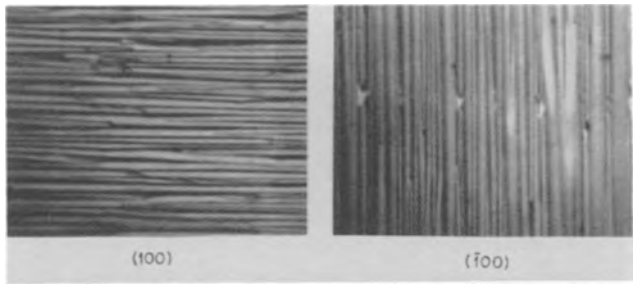

Fig. 4. Opposite faces of an {100} wafer of InSb etched with 0.2N Fe^{+++} in 6N HCl at 82°C following removal of the abraded surface in a nonpreferential etchant (1500 X).

this problem, i.e., the role of relative reactivity of the various crystallographic planes in the formation of dislocation etch pits and the morphology of etch figures. Of particular interest in the present case is the fact that two types of crystallographically equivalent {111} planes are involved.

In the case of InSb it was shown conclusively that in oxidizing etchants the A surfaces are far less reactive than the B surfaces [see Table I and also ref. (1)]. This difference in reactivity was considered the controlling factor for the observed differences in etching behavior between these two types of surfaces and in particular for the formation of dislocation etch pits on the A surfaces and not on the B surfaces. In the present study it was possible to confirm these differences in behavior on microscopic A and B facets of individual etch figures.

Differences in etching rates among the various surfaces of InSb are masked in many oxidizing media, as in the case of the Fe^{+++} etchant (Table I), since the etching rates are controlled primarily by transport processes in the etchant, even at low temperatures. However, as evidenced by the results of Table I for the nonpreferential etchant, it is believed that the reactivity of the principal crystallographic planes of InSb decreases in the following order (3)

$$B\ \{111\} \gtrsim \{100\} > \{110\} > A\ \{111\}$$

The {110} surfaces have both A and B atoms triply bonded to the lattice and, therefore, are more reactive than the A surfaces but less reactive than the B surfaces. Ideally {100} surfaces can consist of either A or B atoms; however, real {100} surfaces consist of both A and B atoms which are only doubly bonded to the lattice. Consequently the {100} surfaces are more reactive than the {110} surfaces. This reasoning does not show clearly whether or not the {100} surfaces are less reactive than the B surfaces. Doubly bonded B atoms are more reactive than triply bonded B atoms but doubly bonded A atoms are most likely less reactive than triply bonded B atoms (1). As will be pointed out below, however, the reactivity of the {100} surfaces is probably somewhat smaller than that of B surfaces.

For a dislocation etch pit to develop (or an etch pit in general) it is necessary that etching proceeds faster in the direction of the pit than on the surface surrounding it. It was shown (1) that this condition is met in oxidizing media only when dislocations consisting of a row of triply bonded A

atoms (α dislocations) intersect the A surfaces of III-V compounds. Apparently, in the zinc-blende structure, the elastic strains present in the direction of the dislocations do not enhance the reactivity to an appreciable extent under the present etching conditions. The conical etch pits presently observed on the {100} surfaces are attributed to dislocations on the basis of their morphology, which is typical of dislocation etch pits in the diamond and zinc-blende structure, and because rows of such etch pits were observed along low angle boundaries on the {100} surfaces. Like the etch pits of the A and {110} surfaces, the etch pits of the {100} surfaces are also believed to be due to α and not due to β dislocations [cf. ref. (4)].

By employing suitable InSb cylinders Venables and Broudy (4) found that dislocation etch pits become smaller in going from the {111} to the {110} surfaces. They reported no dislocation etch pits on the {100} surfaces. The conditions for dislocation etch pit formation on the {110} surfaces are not as favorable as on the A surfaces where the relatively low reactivity of the A surface atoms is essentially responsible for the formation of pits. The high reactivity of the atoms of the {110} surfaces and especially of the {100} surfaces prevents pronounced preferential attack along the dislocation axis.

The etch figures appearing during preferential etching of InSb surfaces consist of low indexed crystallographic facets and represent limiting etch forms. The elongated shape of the etch figures of the {100} surfaces (Fig. 4) is the result of the very high reactivity of the B planes. On both the {110} and {100} surfaces the more reactive B {111} facets develop to a lesser extent than the A facets. Since slow reacting planes predominate during etching of concave surfaces, the development of the etch figures is probably preceded by the formation of concave etch pits. No effort was made to follow the growth steps of the etch figures under the present, very rapid etching rates.

As in the case of {111} surfaces of InSb (1) here also cold work modified the preferential etching behavior. Cold-worked surfaces develop better defined etch figures than the surfaces from which the cold work has been removed (compare for example Fig. 3-I and 4). Actually in the case of {111} surfaces it was found that certain etchants act preferentially when cold work is present and lead to chemical polishing in the absence of cold work. Cold-worked surfaces are heavily populated with imperfections such as complex networks of dislocations, presenting numerous high energy centers which react appreciably faster than the rest of the surface and lead to the formation of etch pits.

Since the thickness of the cold-worked surface layer is estimated to be of the order of a few microns, these pits do not propagate to any great extent but rather develop into the steady-state shape of the etch figures. The observed excessive overlapping of the etch figures (Fig. 1 and 2) is suggestive of the multitude of centers for the initiation of etch pits. The varying size of these primary etch pits is very likely responsible for the varying dimensions of the etch figures. High reactivity centers for pit nucleation are present in all real surfaces but obviously to a much lesser extent than in those with a damaged layer. If active centers are assumed as necessary for the initiation of etch pits which develop into etch figures, then no etch figures should be expected to form on a flat, imperfection-free surface [cf. ref. (5)]. Such surfaces are not encountered in reality.

Cold work usually results in enhanced reactivity. In the case of the {100} surfaces the enhanced reactivity of the A and B planes decreases the difference in their reactivities and, thus, the etch figures of the {100} surfaces become rectangular as shown in Fig. 3 rather than elongated shapes as shown in Fig. 4.

From the experimental results and the preceding discussion it is apparent that the formation of dislocation etch pits and the over-all morphology of the etch figures is strongly affected by the relative reactivity of the principal crystallographic planes.

Manuscript received Oct. 8, 1959. This paper was prepared for delivery before the Columbus Meeting, Oct. 18-22, 1959. The work reported in this paper was performed by Lincoln Laboratory, a center for research operated by Massachusetts Institute of Technology with the joint support of the U. S. Army, Navy, and Air Force.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Polarographic Reductions of Benzyl Halides

Leland W. Marple, Leif E. I. Hummelstedt,[1] and L. B. Rogers

Department of Chemistry and Laboratory for Nuclear Science, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

A polarogram for benzyl chloride in a supporting electrolyte of lithium chloride has a dip in the limiting current due to electrostatic repulsion from the interface of the monovalent anion produced by transfer of the first electron. The dip is decreased by the presence of electronegative substituents on the ring and is eliminated by a moderate concentration of surface-active tetramethylammonium ions in the solution.

Benzyl bromide and iodide each undergo two widely separated one-electron reduction steps at concentrations less than $10^{-4}M$. At higher concentrations, adsorption phenomena are encountered in the region of potential between the two waves due to the presence of bibenzyl, a by-product of the first reduction step.

The exploratory work of von Stackelberg and Stracke (1) showed that reductions of organic halogen compounds became easier on going from chloride to bromide to iodide. The over-all reaction usually involved replacement of the halogen atom with a hydrogen atom. The half-wave potentials were independent of *p*H, showing that addition of hydrogen did not occur in the rate-determining step, but after the transfer of electrons.

The steps in the polarographic reduction of an organic halogen compound, RX, can be represented by the following reactions (1, 2):

$$RX + e^- \rightarrow RX^- \quad [1]$$

$$RX^- \rightarrow R\cdot + X^- \quad [2]$$

$$R\cdot + e^- \rightarrow R^- \quad [3]$$

$$R^- + H_2O \rightarrow RH + OH^- \quad [4]$$

In some cases, side reactions (1),

$$2\,R\cdot \rightarrow R:R \quad [5]$$

or (3)

$$RX + Hg \rightarrow RHgX \quad [6]$$

are known to occur. It is generally assumed that addition of the first electron is the slow step and that reactions [2], [3], and [4] are relatively rapid because only one wave is usually observed for each halogen atom replaced.

Most aliphatic halogen compounds appear to reduce like carbon tetrachloride, for which no stable intermediates (ions or radicals) are believed to exist. Although the over-all reaction usually involves replacement of the halogen with a hydrogen atom, in the reduction of 1,2-dibromoethane, the principal product is reported to be ethylene (1). This reduction must involve virtually simultaneous transfer of two electrons, followed by elimination of two bromide ions and formation of a double bond. Normally, formation of a divalent negative intermediate must be considered improbable.

We felt that the addition of an aromatic ring to the carbon having the halogen atom, or the presence of a double bond in the 2-position should tend to increase the stability of intermediates in the reduction process. This was indeed found to be so. The first intermediate formed by benzyl chloride, the monovalent negative ion, $[C_6H_5CH_2Cl]^-$, appears to have a relatively long life-time. The chief evidence for the existence of such a long-lived intermediate is the appearance of a dip in the limiting current plateau. (Ring-substituted derivatives of benzyl chloride also have dips in their polarograms.) Similar dips in the polarograms for inorganic anions have been studied extensively by Frumkin and his coworkers (3, 5). It is generally agreed that the phenomenon is the result of electrostatic repulsion of a reducible anion from the negative electrode surface.

Current dips were not observed for either benzyl bromide or iodide. Instead, the present study indicates that a long-lived neutral species, either a stable free-radical or a dimer is formed. Mass-spectrometric evidence has confirmed the latter. The only other case where a stable product of a one-electron transfer has been reported is that for reductions of allyl mercury halides (3).

Results

Benzyl Chloride

The polarogram for this compound conformed to the general description of the process for the removal of a halide insofar as a single wave was obtained and its position was relatively independent of *p*H (see Fig. 1). Unlike most organic halides, its polarogram had a marked dip in the limiting-current plateau, a phenomenon that was observed under a variety of conditions. The dip was eliminated by the presence of $0.07M$ tetramethylammonium ion. Because dips in the limiting currents of anions are similarly affected, a negatively charged species of relatively long lifetime must be involved.

The polarograms can be explained by assuming that the limiting current prior to the onset of the

dip corresponds to a two-electron transfer. As the potential of the electrode becomes more cathodic, progressively more of the product formed by reaction [1] is repelled from the surface of the electrode before reaction [2] (followed by [3] and [4]) can take place. In the presence of tetramethylammonium ion, however, repulsion of the ion is not as significant so that reaction [2], and those that follow, can proceed to completion. In that connection, it is interesting to note that the presence of calcium ion (0.49*M*) had no effect on the current dip. According to Reinmuth (6), this indicates that ion-pair formation is not the primary effect, but instead the structure of the double-layer. In addition, a temperature increase to 35°C, which would favor more rapid dissociation of the intermediate ion, did eliminate the dip.

There are two additional points of interest in connection with the effect of tetraalkylammonium salts. First, von Stackelberg and Stracke, in their broad survey of the polarography of organic halides, used 0.1*M* tetraethylammonium bromide as a background electrolyte. As a result, they observed no dips in their limiting currents. Second, in the present investigation it was found that large amounts of tetraalkylammonium salts produced a cathodic shift in the wave (Fig. 1) which was attributed to blocking of the electrode surface (7-9). Hence, the use of tetraalkylammonium salts to eliminate such current dips may result in shifts of the half-wave potential in either direction (2, 10).

In the case of benzyl chloride, the dip in the limiting current reached a value approximately one-half the maximum, indicating complete repulsion

α, 3, 4-Trichlorotoluene	1.40×10^{-3}	—0.908	0.87
1-(Chloromethyl) naphthalene	8.3×10^{-4}	—0.953	0.85

of the organic ion. The fact that the value for limiting current was not corrected for a change in $m^{2/3}t^{1/6}$ with potential probably accounts for a ratio slightly smaller than 0.5. At potentials of —1.3, —1.5, and —1.7 v, the current proved to be diffusion controlled. Furthermore, the relative size of the dip appeared to be independent of concentration as low as $10^{-5}M$ where the correction for residual current was larger than the reduction current.

In Table I are listed the results on other related compounds which showed current dips. Note that the compound having two chlorine atoms in the ring gave the smallest dip, the compound with one chlorine in the ring, next. There may be many contributing factors but, in this case, the chief factor appears to be the greater distribution of charge which decreases the repulsion of the anion by the electrode. This hypothesis is supported by the smaller dip found on going from a benzene ring to a naphthalene ring. Furthermore, the presence of only 0.01*M* tetramethylammonium ion was sufficient to eliminate the small dip obtained with α-chloromethyl naphthalene.

Substitution in the ortho position appears particularly efficient in decreasing the dip. This suggests that there is a steric factor that aids the elimination of chloride ion.

Finally, Table I indicates that the presence of a larger number of chlorine atoms on the ring appears to produce a less cathodic half-wave potential. However, it should be pointed out that the locations of the waves are strongly influenced by adsorption.

The presence of adsorption effects is clearly evidenced in the original polarograms for benzyl chloride, particularly in low percentages of methanol. The dashed curve in Fig. 1A was obtained in 2% methanol. During the drawn-out initial portion of the wave, the individual drop shapes were quite characteristic of adsorption. Following the gradual rise at the beginning of the polarographicwave, the current increased rapidly to the limiting-current plateau. Much the same behavior was found in 20% methanol, but at 51% methanol adsorption behavior had almost disappeared. At 80% there was no evidence for adsorption either in the individual drop shapes or in the polarograms as a whole. All of the compounds in Table I showed similar adsorption behavior although most of them showed more evidence of it in 51% methanol than did benzyl chloride. Adsorption effects will be discussed later in more detail.

Benzyl Bromide and Benzyl Iodide

While polarograms for benzyl bromide had no current dips, they did show two distinct reduction steps at concentrations from 1 x 10^{-5} to about 1 x $10^{-4}M$. Only below 1 x $10^{-4}M$ were two diffusion-controlled waves of equal height obtained. A typical polarogram is shown in Fig. 2B.

It is clear that each wave must correspond to a one-electron reduction. The first wave must be due to formation of the monovalent ion. The large separation of the first and second waves indicates that the radical produced by decomposition of the monovalent ion is not easily reduced further, probably because of a rapid conversion to bibenzyl according to Reaction 5. The absence of a current dip in the plateau of the second wave indicates that decomposition of the monovalent ion is, as expected, much faster in the case of the bromine compound than for chlorine.

The behavior of benzyl iodide, at concentrations between 1 x 10^{-5} and 2 x $10^{-4}M$, was virtually identical with that of benzyl bromide. Not only were two diffusion-controlled waves of equal height obtained but, in addition, the half-wave potentials for the first and second waves agreed, within experimental error, with the values obtained for benzyl bromide. Again, no dip in the limiting current was observed.

At concentrations higher than about $10^{-4}M$, the first waves of both benzyl bromide and benzyl iodide did not increase with concentration as fast as the second. Although the limiting current for the second wave had normal drop shapes and continued to be diffusion controlled, the shapes of the tracings for individual drops became increasingly characteristic of strong adsorption in the range of potential covered by the first wave. Changes in limiting current with mercury height gave plots falling between diffusion and adsorption control. The limiting current had a temperature coefficient of 2% per degree which did not differentiate between the two but did rule out kinetic control. Furthermore, the foot of the second wave acquired the desorption characteristics reported previously for the benzyl chloride wave (Fig. 2B). At concentrations greater than millimolar, behavior was quite erratic and two additional poorly shaped waves appeared between the usual first and second waves.

The electrocapillary curves shown in Fig. 2 not only confirm the presence of adsorption but give further insight with respect to the differences that were observed. A comparison of Fig. 2A and 2B shows that a marked decrease in drop time occurred in the region of the first wave and continued to the second wave. Upon passing through the second reduction the drop time returned to that of the background electrolyte. The decrease in the region of the plateau of the first wave is not attributable to bromide ion produced in the reduction or by the slow hydrolysis of benzyl bromide. (Note the negative slope of the limiting-current plateau in Fig. 2B. However, the presence of 0.1*M* bromide ion did affect the electrocapillary curve on the positive side of the maximum.) In the limiting-current region of the first wave, bibenzyl is strongly adsorbed whereas toluene, the final reduction product, and benzyl alcohol, the hydrolysis product, are not adsorbed at the millimolar level. This indicates that the product of Reaction 5, bibenzyl, was the main source of the adsorption effects.

Adsorption of the reduction product of the first wave is less pronounced at higher concentrations of alcohol. Figure 2C shows that there is little adsorption in 80% methanol probably due to greater competition for the surface from methanol as well as to greater solubility of the product. The somewhat greater adsorption found in the case of benzyl iodide in alkaline solutions of 51% methanol may reflect the faster decomposition in this medium of its monovalent ion compared to that formed by benzyl bromide (see Fig. 2D). As a result, a somewhat higher concentration of bibenzyl would be produced at the surface.

Other aspects of adsorption were examined briefly. First, it was possible to show that, at low concentrations of benzyl bromide, the half-wave potential for the first reduction was sensitive to the presence of surface-active anions and hydroxide; in the presence of 0.092*M* sodium hydroxide or 0.10*M* potassium bromide the wave appeared at more cathodic potentials than in the presence of chloride, in which the wave was, in turn, more cathodic than that in nitrate. There was also a corresponding shift in the electrocapillary curve.

The effect of the presence of bromide ion was studied originally because of its presence due to decomposition of benzyl bromide in alkaline solutions. Hydrolysis led to erratic results for half-wave potentials, particularly in the case of benzyl iodide, which decomposed even faster. Decomposition was slower in higher concentrations of methanol and at the same time, the half-wave potentials were shifted

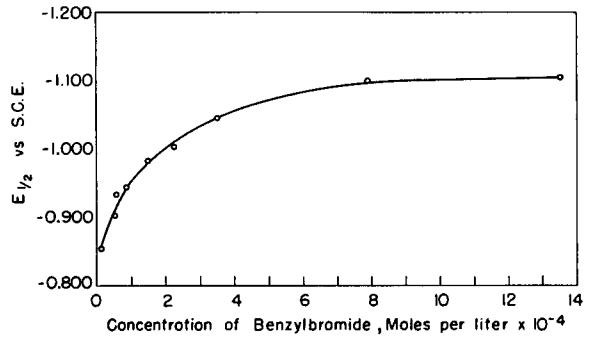

Fig. 3. Effect of concentration of benzyl bromide on its half-wave potential in 51% methanol that is 0.092M in sodium hydroxide.

to more cathodic values. These shifts indicated that a charged species was being produced by the reaction and ruled out the possibility that the neutral halide was undergoing ionization prior to reduction.

The position of the second wave for benzyl bromide was a function of concentration. Thus, there was approximately a 250 mv cathodic shift on going up from 1 x 10^{-5} to 1 x $10^{-3}M$. At higher concentrations the wave remained constant, probably due to attainment of maximum sorption (see Fig. 3). Benzyl chloride showed a similar but much smaller dependence on concentration.

It is important to note that the half-wave potential for each wave of benzyl bromide agreed with the corresponding one for benzyl iodide within experimental error. Agreement of the first waves, which involve different reducible species, was surprising but can be rationalized in terms of virtually simultaneous electron transfer and halide elimination. On the other hand, agreement of the half-wave potentials for the second waves is to be expected because the same intermediate, the benzyl radical, is undergoing further reduction in each case. The resulting carbanion undoubtedly reacts with the solvent to form toluene.

From the electrocapillary curves in Fig. 2, it was quite clear that bibenzyl, or a closely related compound, must have been formed in the first reduction steps of the bromide and iodide derivatives. However, the presence of bibenzyl was later confirmed by making mass-spectrometric studies of products isolated from extracts of large-scale electrolyses. A $10^{-4}M$ solution of benzyl bromide in 50% methanol containing 0.1M potassium bromide was electrolyzed at −0.5 v vs. S.C.E. using a mercury-pool cathode until the current had decreased to a negligible value. The solution was again made $10^{-4}M$ in benzyl bromide and electrolysis continued. A white solid precipitated before the end of the electrolysis, and it gave the typical mass-spectrometric pattern of bibenzyl. Masses of 182 and 91 were particularly prominent. The original benzyl bromide showed no trace of mass 182.

Another electrolysis was carried out in which droplets of excess benzyl bromide were present at all times. A mass spectrogram of an ether extract, from which the more volatile materials had been pumped off, clearly indicated the presence of large amounts of $C_6H_5CH_2C_6H_4CH_2Br$ (masses 260 and 262), or one of its isomers, and $C_6H_5CH_2C_6H_4CH_2$ (mass 181) and the corresponding metastable peak at 126. The presence of relatively small amounts of bibenzyl was indicated by the small peak at mass 91 and the fact that mass 182 was somewhat higher than that expected from the isotopic ratio of carbon in a fourteen-carbon species. The formation of such a halide can be explained easily by the presence of the large excess of benzyl bromide in the solution. A reaction product of this type might well lead to the appearance of the additional polarographic waves which appeared in millimolar solutions of benzyl bromide (and iodide). Large peaks at masses 165 and 166 were also found in this extract but could not be explained satisfactorily.

Neither of the above electrolysis products gave any indication of masses for $C_6H_5CH_2HgBr$ or $C_6H_5CH_2Hg$. Generally, the peaks for HgBr and $HgBr_2$ were roughly equivalent and were found to the same extent in blank electrolyses. However, as one might expect small amounts of benzylmethyl ether (mass 122) formed by solvolysis were present but there was no benzyl alcohol (mass 108).

A similar experiment, in which an air-free suspension of benzyl bromide (in 50% methanol containing 0.1M potassium bromide) was shaken with mercury (no potential applied), showed no evidence of a spontaneous reaction leading to an organo-mercury compound. The small amounts of mercury present were also found in the blank. Therefore, there is no basis for suggesting that the electrochemical reduction of benzyl bromide (and probably the iodide) is preceded by a reaction with mercury or that the benzyl radical attacks mercury after being formed. In the case of the corresponding allyl halides, prior chemical reaction may indeed occur (3), but the proposed dissociation to form RHg^+ prior to reduction seems unlikely, except for one of the compounds, because of the reported cathodic shift in reduction potential as the dielectric constant of the medium was lowered.

Experimental Details

Polarograms and electrocapillary curves were obtained as before (10). The organic halides were the purest obtainable from Eastman Kodak Company and were used as received. Stock solutions were prepared in pure methanol from which aliquots were taken to prepare polarographic solutions. Polarograms were run at 25°C and a line drawn through the maximum currents for use in the figures. Limiting currents were tested for diffusion control by plotting reduction current vs. square root of the mercury height; a straight line was interpreted as an indication of diffusion control. Temperature coefficients of the limiting currents were also studied between 2° and 35°C and, except for the dip of benzyl chloride, were found to be close to 2%/C°.

Mass spectrometric studies were made on a CEC Model 21-103C. In every case, masses were scanned to at least 400.

Acknowledgment

The authors are very much indebted to Professor Klaus Biemann and his associates for running the mass spectrometric analyses and providing vital de-

tails for interpretation of those results. This work was supported in part by the United States Atomic Energy Commission under Contract AT(30-1)905.

Preparation of Boron from Boron Carbide

David R. Stern

American Potash & Chemical Corporation, Whittier, California

ABSTRACT

A process to prepare elemental boron from boron carbide is presented. Included is evidence that the process is one of anodic transfer. Boron of at least 99.8% purity can be made directly from technical grade materials. Purity is a function of electrolysis voltages and boron carbide purity. Current efficiencies in excess of 95% are obtained and preferred electrolysis conditions are stated.

Preparation of elemental boron has been discussed by a large number of investigators (1-19). Not all processes give sufficient purity. Filament and arc discharge techniques have generally been regarded as the preferred methods of securing a high-purity crystalline boron (2, 3, 5-8, 11, 12, 17, 19). New interest in elemental boron as thermistors and possible semiconductor devices has reemphasized the problem of attaining higher purities. McCarty and coworkers (18) have discovered new low-temperature crystalline modifications of elemental boron.

Vapor phase deposition techniques are generally limited by metallic filament contamination. Impurities are generally tantalum, tungsten, molybdenum, carbon, and titanium (2, 3, 7, 11, 12, 17, 19). Another disadvantage with these contaminants is that they are not removed with secondary upgrading techniques. Deposition on a filament of elemental boron and lower decomposition temperatures are significant contributions (7, 19).

Desire for a potentially higher purity product without heavy metal contamination focused attention on an electrolytic approach. Andrieux, Cooper, and others have developed electrolytic reductions (4, 9, 10, 14-16).

This research effort has resulted in an electrolytic process for boron, which is an anode transfer technique (13). This transfer technique has been applied both to elemental boron and boron carbide. Feasibility studies were conducted on a laboratory exploratory basis in small cells. The scope of this paper is limited to the bench scale preparation of elemental boron from boron carbide.

Experimental Procedure

Cell.—A cross section of the cell used in this investigation is presented in Fig. 1. The unit consisted of a porous carbon basket with a porous carbon diaphragm. Carbide was packed between the diaphragm and porous basket. This cartridge unit was lowered into a dense graphite crucible by steel rods. Removal and recharging with boron carbide could be accomplished without a complete cell shutdown.

External heating was accomplished using graphite resistors. Cell temperatures were measured with Chromel-Alumel thermocouples inserted into the recesses in the centering post and the hollow cathode which was also a thermowell.

An argon blanket could be maintained over the entire cell.

Electrolyte.—The electrolyte consisted of sodium chloride, potassium chloride, and potassium fluoborate with an initial composition of 40-40-20 wt %, respectively. During the course of electrolysis, cathode deposits are withdrawn periodically. Occluded electrolyte is water leached and can be recovered and recycled.

Electrolysis.—After the anode compartment was packed with boron carbide, sufficient predried salt is added to cover the carbide. This cartridge charge was then placed in the heating furnace and melted under argon. Whenever fresh salts, a new diaphragm, or new crucible were used, pre-electrolysis was performed at 2.5 v from ½ to 1 hr before actual electrolysis. The pre-electrolysis deposit acted as a scavenger of impurities and was a direct means of purifying the electrolytic system. A cathode was

then inserted to a known depth so that a given cathodic current density could be set initially.

At completion of electrolysis the cathode was raised and allowed to cool. To recharge the boron carbide, the cartridge unit was raised, salt allowed to drain, and a new unit inserted.

Processing.—Figure 2 is a photograph of a typical cathode deposit. This deposit was placed in a polyethylene beaker of distilled water on removal. Upon standing in the water the deposit would break off the rod and was wet ground in an iron mortar and leached twice with 10% hydrochloric acid. It was then washed free of acid, rinsed with acetone, and vacuum dried under argon.

The final sample was then weighed and analyzed. Most samples were analyzed for total boron content, sodium, iron potassium, silicon, nitric acid insolubles, and water soluble boron.

Experimental Results

Product purity.—The purest elemental boron resulting from this investigation was 99.8%. This purity was obtained using commercial reagents without any prior purification or recrystallization. Control of the electrolysis and atmosphere were the only precautions taken. Major impurities were sodium, silicon, iron, and carbon. These generally could be limited to less than a total of 0.2%. Lower levels of impurities were sodium 0.05%, silicon 0.07%, iron 0.05%, and carbon (as B_4C) 0.06%. These lower levels, however, were not obtained simultaneously in one sample.

Effect of cell voltage.—An important factor contributing to product purity is cell voltage. A typical relationship between sodium impurity and cell voltage is presented in Figure 3. At voltages between 0.9-1.0 v sodium contents were as low as 0.05%, but no smooth correlation was obtained. It must be pointed out that anodic current density is not constant in this system.

A similar relationship can be shown for the silicon and iron impurities, but the final level of these impurities are also dependent on the processing technique.

These results indicate that the concentration of major impurities in the product is a direct function of cell voltage, the higher the cell voltages the higher the impurities.

Electrolytic decomposition of the fluoborate and alkali halides occur at higher voltages. These reactions are indicated by the liberation of chlorine and adversely affect the current efficiency of the process as well as product purity.

As long as sodium is a component of the electrolyte, there will be some sodium contamination, but by maintaining voltage below 1.2 v, sodium content may be kept below 0.2%.

Origin of other contaminants.—Table I lists the typical spectrographic analyses of the new raw materials entering the process and the materials of con-

struction. Boron carbide contains the major contaminants except for the calcium in the fluoborate. Thus, purity of the elemental boron is closely allied to the purity of boron carbide. Silicon and iron are anodically transferred in this process.

Pre-electrolysis yields a deposit containing approximately 14% iron, 12% silicon, and only 16% boron.

Figure 4 presents product purity as a function of cumulative electrolysis. These results indicate that whenever a new charge is electrolyzed the purity is low probably due to moisture and the impurities in the boron carbide and the salts.

After an initial conditioning period the purity increases and remains high during most of the remaining electrolysis. Drop off in purity is attributed to higher transfer voltages resulting from the build-up of carbon in the anode compartment as boron is depleted. If the product covering 90% of the electrolysis time were combined into a single sample, an average product purity of 98% would result. The maximum purity attained was 99.8% boron.

Effect of temperature.—High-purity product is obtained at good current efficiencies within a temperature range of 700°-850°C. No definite relationship between temperature and product purity has been noticed within this range. Although a detailed study of the phase relationship of the KCl-NaCl-KBF_4 mixture has not been made, operation above the KCl-NaCl eutectic 660°C must be employed. Above 850°C loss of the fluoborate increases

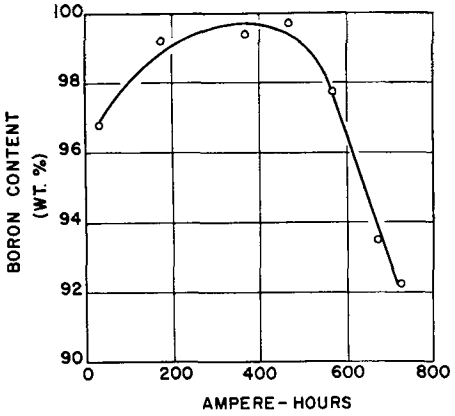

Fig. 4. Product purity as a function of cumulative ampere-hours.

and deposits tend to fall from the cathode. A compromise temperature of 800°C was adopted for the major part of this investigation.

Current density.—Cathodic current density has been varied between 12 to 75.0 amp/dm^2. High current efficiencies are obtained throughout this range. No significant correlation was found between initial current density and boron purity.

Boron material balance.—It has been stated that boron was derived from the carbide and that fluoborate was only a carrier salt. Previous electrolysis systems (4, 9, 10, 13-16) have operated at higher voltages and consequently have not been anodic transfer processes.

Table II lists some experiments, which offer some proof that in this system boron is derived from the anodic boron carbide.

The following points should be noticed: (*a*) experiments conducted without boron carbide (regardless of a carrier) gave no product below 1.3 v; (*b*) experiments conducted without fluoborate (with B_4C) also gave no product even up to 2.2 v; (*c*) the solvent for the carrier salt may be pure KCl, NaCl, or halide mixtures; (*d*) at voltages higher than 3 v boron trichloride is formed.

Analyses of the boron carbide also give evidence of the boron being extracted. These data are presented in Table III.

Final proof of boron transfer is presented in Table IV. Examination indicates that a total of 61 g of elemental boron was extracted on the cathode deposit during electrolysis, whereas only 12 g of boron was available initially in the fluoborate and 11 g of this were accounted for at the completion of electrolysis.

Cell electrolyte.—Cell electrolyte analyses have indicated that concentrations of sodium, potassium,

and chloride ions do not change appreciably during electrolysis. Concentrations as a function of cumulative ampere-hours are presented in Fig. 5. All concentrations are relatively constant except that of the fluoride ion. This is contrary to what is expected in the electrolysis of a halide-fluoborate system where the potassium fluoride concentration increases as boron fluoride is reduced to boron. The boron concentration at the start increases for a short period of time. This probably represents the solution of boron from the carbide. This observation is illustrated vividly in Fig. 6 when the fluoride to boron mol ratios are plotted as a function of electrolysis time. The ratio in fluoborate is four, while an inspection of the curve shows a decrease to a ratio of two. Chemical analyses of the purge gas indicate that some fluoride is lost from the system as boron trifluoride, but the rate of solution of boron from the carbide more than compensates for that volatized from the system. Material balance data indicate that the physical quantity of fluoborate lost is relatively small and can be made up by fluoborate additions.

Electrolysis data.—Current efficiency for this system is based on the following electrode reaction:

$$B^{+3} + 3e \rightarrow B^{\circ} \qquad [1]$$

Some data on electrolysis are presented in Table V. High current efficiencies are obtained and energy consumption is low. A pound of 94-99% boron requires from 3-4 kwhr of electrical energy.

Summary and Conclusions

An electrolytic anode transfer process for the preparation of high-purity elemental boron from boron carbide has been presented. Evidence that the process is one of anodic transfer is included.

The following conclusions concerning this method of preparing elemental boron can be set forth:

1. Boron of at least 99.8% purity can be made directly from technical grade materials without prior purification treatment.
2. Elemental boron can be prepared in purities at least equal to that attained via vapor deposition processes without the corresponding heavy metal contamination.
3. Major impurities are sodium, silicon, iron, and carbon. The total of these impurities can be reduced to 0.2% or less.
4. Impurity levels in the boron are a function of the electrolysis voltage and purity of the boron carbide.

795	1.0	5.3	23	17.1	11.3	97	3.2
800	1.0	3.7	23	12.9	8.4	101	3.0
810	0.9	5.8	52.5	39.6	10.7	90	3.1
810	1.0	4.1	66	35.7	8.2	94	3.4
800	1.0	5.7	30	21.7	5.1	92	3.6

5. Voltages less than 1.2 v, cathodic current densities between 12.0 and 75.0 amp/dm^2, and 800°C are the preferred conditions of electrolysis.

6. Current efficiencies for this anodic transfer process are high. Efficiencies in excess of 95% are easily obtained. Energy consumption is 3-4 kwhr/lb boron.

7. The application of this technique as a secondary upgrading technique for higher purity borons has been postulated.

Acknowledgment

The author would like to express his appreciation to Mr. Aiji Uchiyama and Mr. Quentin H. McKenna who conducted both the laboratory and bench scale work on this project.

Manuscript received Oct. 12, 1959. This paper was prepared for delivery before the Chicago Meeting, May 1-5, 1960.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Contribution to the Theory of Current Distribution in Local Cells

Carl Wagner

Max-Planck-Institut für physikalische Chemie, Göttingen, Germany

ABSTRACT

The distribution of the anodic current density in local cells involving anodic dissolution of a metal and reduction of oxygen as the cathodic reaction is calculated for a diffusion controlled limiting cathodic current density.

Statement of the Problem

Corrosion of metals in aqueous solutions may in general be accounted for by the superposition of anodic and cathodic reactions. The anodic reaction which is the dissolution of a specified metal is inherently confined to the surface of that metal. Cathodic reactions involve reduction of oxidizers, e.g., reduction of elemental oxygen to water, or evolution of hydrogen from hydrogen ions. If only one metal without inhomogeneities is present, anodic and cathodic reactions occur randomly at its surface (1), and the net current density vanishes everywhere. In the presence of chemically inert inclusions, conducting oxide layers, or other electronic conductors which are in electrical contact with the metal, cathodic reactions may also occur at the surface of these materials. In the latter case referred to as local cell action, there is a net current flowing inside the electrolyte from the metal which is dissolved as anode to the other material as cathode. The occurrence of cathodic reactions at the other materials increases inherently the rate of dissolution of metal as the anodic reaction and thus aggravates corrosion. If the dissolving metal is directly adjacent to cathodic areas, the rate of attack is especially high at the boundary. Thus conditions favoring local cell action are to be avoided if possible in order to minimize corrosion. This, however, is not always easy to accomplish. Therefore, it is desirable to formulate rules of thumb in order to estimate the potential dangers resulting from local cell action.

Current distributions in local cells have been calculated by Waber and his associates (2-7). For coplanar adjacent cathodes and anodes shown in Fig. 1, the current density next to an anode-cathode boundary becomes infinite if polarization is disregarded (2). Thus for a realistic approach, polar-

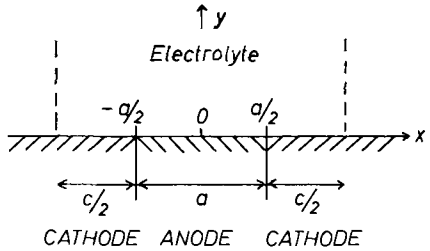

Fig. 1. Anode with adjacent cathodes

ization must be taken in account in estimating the maximum local corrosion rate at an anode-cathode boundary. If both the anodic and the cathodic polarization curve can be approximated by straight lines involving the same slope, the potential distribution in the electrolyte can be obtained in terms of a Fourier series or integral and therefrom the local current density can be calculated (3,4). Calculations for other conditions seem desirable. In what follows calculations are presented for a diffusion controlled limiting cathodic current density in solutions containing oxygen.

In accord with Waber it is assumed that there are no solid corrosion products which impede diffusion and conduction in the electrolyte.

General Presuppositions

The electrical potential ϕ in an electrolyte involving a constant electrical conductivity obeys the Laplace equation

$$\text{div grad } \phi = 0 \qquad [1]$$

For a single cathodic and a single anodic reaction and for a constant electrical potential in the metallic conductors, the boundary conditions can be formulated as (8)

$$\phi \text{ (anode)} + \eta_a(J_a) = \Phi_a \qquad [2]$$

$$\phi \text{ (cathode)} - \eta_c(J_c) = \Phi_c \qquad [3]$$

where ϕ (anode) and ϕ (cathode) are the electrical potentials in the electrolyte next to the anode and the cathode, respectively, Φ_a and Φ_c are constants, and η_a and η_c, respectively, are the absolute values of the overpotentials of the anodic and the cathodic reaction corresponding to the absolute local current densities J_a and J_c. Since cations are supposed to migrate from the anode toward the cathode, ϕ (anode) is more positive than ϕ (cathode).

At the anode, metal is dissolved and simultaneously the oxidizer, e.g., oxygen, is reduced cathodically. The net current density at the anode, $J_a - J_c$, is equal to the product of the specific conductivity σ of the electrolyte and the absolute value of the local potential gradient, $\partial\phi/\partial n$, normal to the surface of the electrode according to Ohm's law,

$$[J_a - J_c = \sigma|\partial\phi/\partial n|] \text{ anode} \qquad [4]$$

At the cathode, reduction of oxidizer, e.g., oxygen, is supposed to be the only electrode reaction. Thus

$$[J_c = \sigma|\partial\phi/\partial n|] \text{ cathode} \qquad [5]$$

To obtain solutions for the potential and the current distribution from Eq. [1] to [5], the polarization curves must be known for both the anodic and the cathodic reaction. In particular, it is possible to calculate the local current densities at both the cathode and the anode as the intensities of sources and sinks with the help of an integral equation (8). This method has been found to be profitable for calculating the current density distribution in cells used for the deposition of metals. So far, linear polarization curves have been assumed. It is possible, however, to formulate and to solve the integral equation also for other types of cathodic or anodic polarization curves with the help of numerical methods.

Under most practical conditions, the polarization curves are not known and not easy to determine. Consequently, for practical purposes one has to rely on direct observations of corrosion rates rather than on calculations based on polarization curves. Direct observations always refer to a special set of conditions. To predict corrosion rates under somewhat different conditions, it is, therefore, necessary to make conjectures and extrapolations. To this end, this paper presents calculations for conditions which are idealized yet characteristic of practical situations.

In most practical cases, corrosion involves reduction of oxygen as the cathodic reaction. The current density J_c at the cathode as a function of the negative value of the local single electrode potential rises first exponentially owing to activation control and finally tends to a limiting value $J_{c(max)}$ corresponding to diffusion control. The value $J_{c(max)}$ is proportional to the concentration of oxygen in the bulk electrolyte and moreover depends on the convection of the electrolyte. This type of polarization curve is well known from polarographic investigations. The behavior of the cathode may, therefore, be approximated by

$$J_c \cong 0 \text{ if } -E_c < -E_{c(1/2)} \qquad [6]$$

$$J_c \cong J_{c(max)} \text{ if } -E_c > -E_{c(1/2)} \qquad [7]$$

where $E_{c(1/2)}$ denotes the half-wave potential at which $J_c = J_{c(max)}/2$.

According to Delahay (9), the value of $J_{c(max)}$ may not be single-valued because oxygen is reduced either to H_2O_2, or to H_2O especially at lower single electrode potentials. In the latter case the maximum current density is twice as much as for reduction to H_2O_2. This, however, is irrelevant for the calculation of the order of magnitude of local cell action.

The equilibrium single electrode potential $E_{a(eq)}$ of the dissolving metal is assumed to be more negative than the half-wave potential $E_{c(1/2)}$ of oxygen where signs of potentials are chosen in accord with the Stockholm convention. The difference

$$\Delta E = E_{c(1/2)} - E_{a(eq)} \qquad [8]$$

is, therefore, assumed to be positive.

In a solution containing oxygen and under conditions precluding local cell action, a metal exhibiting a high activation polarization on dissolving may assume essentially the half-wave potential of oxygen. Under these conditions ΔE is balanced mainly by the overpotential of the dissolving metal,

$$\Delta E \cong \eta_a(J_a = J_{c(max)}) \qquad [9]$$

Thus neither increase of oxygen supply nor local cell action affects the rate of metal dissolution to a significant extent.

The following considerations refer, therefore, to more reactive metals such as zinc which exhibit a relatively low activation polarization on dissolution. It is assumed that without local cell action the corrosion rate is controlled by diffusion of oxygen, i.e.,

$$J_a \cong J_{c(max)} \quad [10]$$

Moreover it is assumed that the anodic polarization curve may be approximated by a straight line over a sufficiently wide range corresponding to the relation

$$E_a - E_{a(eq)} = \eta_a = J_a h_a \quad [11]$$

where E_a is the electrode potential of the anode with a current density J_a and $h_a = dE/dJ_a$ is a constant.

In the case of local cell action, the maximum corrosion rate is attained if the dissolving metal is polarized to the half-wave potential $E_{c(1/2)}$ of the cathodic reaction. The corresponding potential shift is $\eta_a = \Delta E$ and the current density J_a is equal to $\Delta E/h_a$ according to Eq. [11]. For a significant rise of the anodic dissolution rate of a metal due to local cell action it is, therefore, necessary that $\Delta E/h_a >> J_{c(max)}$, or

$$\Delta E/h_a J_{c(max)} >> 1 \quad [12]$$

Coplanar Cathodes and Anodes

Coplanar cathodes and anodes are considered as one of the most important practical cases involving local cell action. The two-dimensional geometry of the electrodes is shown in Fig. 1 and is identical with the geometry considered by Waber and Rosenbluth (3). The anode is supposed to have a finite width a. The cathodes at either side of the anode are supposed to consist of another chemically inert material involving a high electrical conductivity. The width of the cathodes and the depth of the electrolyte are assumed to be infinite.

According to previous calculations for similar situations (3, 4, 8), one may anticipate two different limiting cases determined by the magnitude of the dimensionless ratio a/k_a where a is the width of the anode and $k_a = \sigma h_a$ is the so-called polarization parameter.

I. If $a << \sigma h_a$, polarization enforces a nearly uniform anodic current density, the potential drop in the electrolyte becomes insignificant, and $E_a \cong E_{c(1/2)}$. Hence, in view of Eq. [8] and [11]

$$J_a = \Delta E/h_a \quad [13]$$

II. If $a >> \sigma h_a$, the potential in the electrolyte along the anode is nearly constant whereas the anodic current density varies greatly and is especially high at the anode-cathode boundary. Under these conditions, an approximate solution of the current distribution may be obtained by calculating first the potential and current distribution in the electrolyte for vanishing polarization of the anode and introducing subsequently the effect of anodic polarization as a perturbation.

In view of Eq. [6] and [7], the Laplace equation for the electrical potential ϕ in the electrolyte as a function of the coordinates x and y is to be solved for the boundary condition

$$\phi = 0 \text{ at } |x| \leqq a/2,\ y = 0 \quad [14]$$

$$\partial\phi/\partial y = J_{c(max)}/\sigma \text{ at } a/2 \leqq |x| \leqq (a+c)/2,\ y = 0 \quad [15]$$

$$\partial\phi/\partial y = 0 \text{ at } |x| > (a+c)/2,\ y = 0 \quad [16]$$

Equation [14] refers to the anode of width a at which the potential ϕ is supposedly constant and equal to zero by definition. Equation [15] refers to those sections of the cathodes where the single electrode potential is more negative than the half-wave potential. Equation [16] refers to farther sections of the cathode.

The distance (a+c)/2 at which the local single electrode potential is equal to the half-wave potential $E_{c(1/2)}$ of the cathodic reaction is not explicitly given but implicitly by the condition that the electrical potential ϕ at $|x| = (a+c)/2$, $y = 0$ must be equal to the negative value of the difference ΔE between the half-wave potential $E_{c(1/2)}$ of the cathodic reaction and the equilibrium single electrode potential $E_{a(eq)}$ of the anode,

$$\phi[|x| = (a+c)/2, y = 0] = -[E_{a(eq)} - E_{c(1/2)}] = -\Delta E \quad [17]$$

An approximate solution may be obtained by disregarding the occurrence of current lines beyond the broken lines in Fig. 1 corresponding to the boundary condition

$$\partial\phi/\partial x = 0 \text{ at } |x| = (a+c)/2,\ y > 0 \quad [18]$$

An analogous problem has been considered in conjunction with cathodic protection (10). Using Eq. [36] of a previous paper (10) with the notation of the present paper, one has

$$\phi = \frac{J_{c(max)}}{\sigma}\left\{ y + \frac{a+c}{\pi}\,\mathrm{Re}\left[i \sin^{-1}\frac{\sin \pi z/(a+c)}{\sin \pi a/2(a+c)} \right] \right\} \quad [19]$$

where $z = x + i\,y$ is the complex variable used in conformal mapping. Equation [19] satisfies the Laplace equation and the boundary conditions stated in Eq. [14], [15], and [18].

Substitution of Eq. [19] in Eq. [17] yields

$$\frac{\sigma\,\Delta E}{J_{c(max)}} = c\left\{ \frac{1 + c/a}{\pi\, c/a} \cosh^{-1}\frac{1}{\sin[\pi/2(1+c/a)]} \right\} \quad [20]$$

The expression in braces is equal to ½ if $c/a << 1$, and equal to 2.28 if $c/a = 1000$. Thus, for most practical situations, the expression in braces may be assumed to be equal to unity in order to obtain the order of magnitude of c. Hence

$$c \sim \sigma\,\Delta E/J_{c(max)} \quad [21]$$

The value of c may be considered as the effective width of the cathodic areas which determines the magnitude of the amount of oxygen reacting at the cathode.

The potential at the anode is equal to zero by definition according to Eq. [14]. The potential at the cathode is given by Eq. [19],

$$\phi(|x| > a/2, y = 0) = -\frac{(a+c)\,J_{c(max)}}{\pi\,\sigma} \cosh^{-1}\frac{\sin[\pi x/(a+c)]}{\sin[\pi a/2(a+c)]} \quad [22]$$

From Eq. [19] and Ohm's law the net current density $J_a - J_{c(max)}$ at the anode is obtained as

$$J_a - J_{c(max)} = -\sigma \left(\frac{\partial \phi}{\partial y}\right)_{|x| < a/2,\, y = 0}$$

$$= J_{c(max)} \left\{ \frac{\cos\left(\frac{\pi x}{a+c}\right)}{\left[\sin^2\left(\frac{\pi a/2}{a+c}\right) - \sin^2\left(\frac{\pi x}{a+c}\right)\right]^{1/2}} - 1 \right\} \quad [23]$$

The validity of Eq. [19] to [23] is restricted because of the underlying approximations. First, it must be recalled that the cathodic current density is a continuous function of the electrode potential in contrast to the step function suggested in Eq. [6] and [7] on which Eq. [15] and [16] are based. Second, current lines spread beyond $|x| = (a+c)/2$ in contradistinction to the boundary condition in Eq. [18] used instead of Eq. [16]. Third, anodic polarization has been ignored but must be considered.

If $c >> a$, i.e., according to Eq. [21], if

$$\sigma \Delta E/a J_{c(max)} >> 1 \quad [24]$$

most of the potential drop in the electrolyte occurs in front of the anode where current lines are crowded. Approximations used for the calculation of the potential ϕ far away from the anode, especially at $x \geqq (a+c)/2$, are, therefore, virtually irrelevant for the validity of Eq. [23]. Deviations from Eq. [23] are mainly due to anodic polarization. Pertinent calculations are presented below.

If conversely $c << a$, i.e., if

$$\sigma \Delta E/a J_{c(max)} << 1 \quad [25]$$

most of the potential drop in the electrolyte occurs in front of the cathodes where current lines are crowded. Consequently, if $c << a$, use of approximations at the outer boundary of the cathodes, i.e., $|x| \geqq (a+c)/2$ causes a much greater error than in the former case where $c >> a$. Even if $c << a$, however, Eq. [22] and [23] yield the correct order of magnitude of ϕ and J_a next to the anode-cathode boundary if anodic polarization is negligible.

Since current lines ending at the cathode at $|x| < (a+c)/2$ spread beyond $|x| = (a+c)/2$, the decrease of the potential along the cathode with increasing distance x is less steep than has been calculated from Eq. [19] based on Eq. [18] according to which current lines beyond $|x| = (a+c)/2$ are precluded. The magnitude of this error may be estimated by comparing the variation of the potential at the surface of a galvanic couple involving constant current densities J at the cathode and the anode of equal width b/2 for conditions indicated in Fig. 2a and 2b. The potential distribution in the electrolyte can be calculated readily by superimposing the potentials resulting from line sources and sinks (11). In this way the change in the potential along the cathode of Fig. 2a without current lines beyond the boundaries of the electrodes is found to be

$$\phi(x = b/2) - \phi(x = b)$$

$$= \frac{bJ}{\pi^2 \sigma}\left[\int_{\pi/4}^{3\pi/4} \ln \sin \eta \, d\eta - \int_{0}^{\pi/2} \ln \sin \eta \, d\eta \right] \quad [26]$$

$$= 0.74 \; (bJ/\sigma)$$

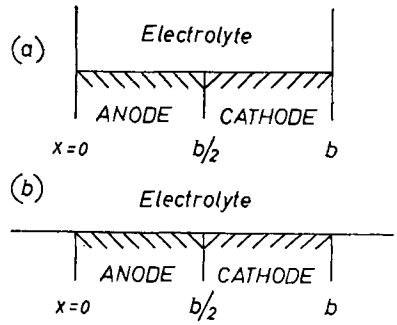

Fig. 2. Galvanic couples for estimating the effect of sidewise spreading of current lines on the potential drop along the cathode according to Eq. [26] and [27].

whereas for conditions shown in Fig. 2b with current lines expanding sidewise,

$$\phi(x = b/2) - \phi(x = b)$$

$$= [(2 \ln 2)/\pi] \; (bJ/\sigma) = 0.44(bJ/\sigma) \quad [27]$$

The ratio of the values calculated in Eq. [25] and [26] is 1.7. Thus cutting off the space for the spreading of current lines beyond $|x| = (a+c)/2$ in Fig. 1 by using Eq. [18] instead of Eq. [16] does not affect the order of magnitude of the above calculations even if $c << a$ as far as the vicinity of the anode-cathode boundary is concerned.

According to Eq. [23], the anodic current density at the anode-cathode boundary $x = a/2$ tends to infinity as in other problems where polarization at a boundary is disregarded (2, 3, 8). Thus polarization must be taken in account in order to obtain a realistic result. To this end, an approximate method indicated in Fig. 6 of a previous paper (8) may be employed as is shown in what follows.

Equations [22] and [23] have been derived for vanishing anodic polarization. If anodic polarization is considered to be a minor perturbation, Eq. [22] and [23] may still be used as first-order approximations except for the immediate vicinity of the anode-cathode boundary.

For each of the limiting cases $c >> a$ and $c << a$, one obtains from Eq. [22] and [23]

$$J_a(x \leqq a/2) = A(a/2 - x)^{1/2} \quad [28]$$

$$\phi(x \geqq a/2) = -B(x - a/2)^{1/2} \quad [29]$$

The symbols $\leqq$ and $\geqq$ mean "slightly smaller than" and "slightly greater than," respectively. The constants A and B are calculated below in Eq. [39] and [42] for $c >> a$ and in Eq. [48] and [52] for $c << a$.

Since anodic polarization does occur, the potential at the anode is lowered by $h_a J_a$. In view of Eq. [14]

$$\phi = -h_a J_a \text{ if } x < a/2 \quad [30]$$

Substitution of Eq. [28] in Eq. [30] yields

$$\phi(x \leqq a/2) \cong -h_a A/(a/2 - x)^{1/2} \quad [31]$$

In Fig. 3 the potential in the vicinity of the anode-cathode boundary is shown as curve I and curve II calculated from Eq. [31] and [29], respectively. Two divergent branches are obtained. This divergence is due to the fact that the anodic current density tends

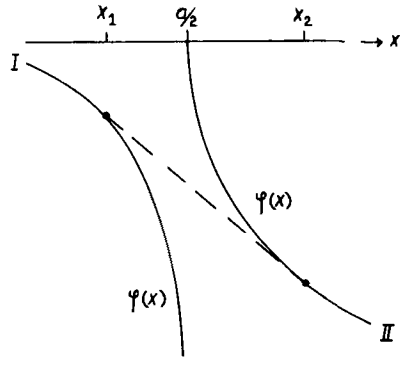

Fig. 3. Potential ϕ (x, y = 0) near the anode-cathode boundary at x = a/2.

to infinity at x = a/2, y = 0 if anodic polarization is disregarded. Actually, the potential must be represented by a smooth curve. To obtain an approximation, one may draw the common tangent line pertaining to curves I and II, which is indicated by the broken line between the coordinates x_1 and x_2 in Fig. 3.

Equating the slopes of the tangent lines at $x = x_1$ and $x = x_2$ and the slope of the broken line in Fig. 3, one obtains with the help of Eq. [29] and [31]

$$-\frac{h_a A}{2(a/2-x_1)^{3/2}} = -\frac{B}{2(x_2-a/2)^{1/2}} = \frac{-B(x_2-a/2)^{1/2} + h_a A/(a/2-x_1)^{1/2}}{x_2-x_1} \quad [32]$$

Upon solving Eq. [32] for $(a/2 - x_1)$ and $(x_2 - a/2)$, it follows that

$$a/2 - x_1 = 3^{1/2} h_a A/B \quad [33]$$

$$x_2 - a/2 = 3^{3/2} h_a A/B \quad [34]$$

With the help of Eq. [31] and [33] the potential at the cathode boundary is obtained as

$$\phi(x = a/2, y = 0) = \phi(x = x_1, y = 0) + (a/2 - x_1)(\partial\phi/\partial x)_{x=x_1, y=0} \cong -(3^{3/4}/2)(h_a AB)^{1/2} \quad [35]$$

Hence the anodic current density at the anode-cathode boundary (x = a/2) is found to be

$$J_a = -\phi(x = a/2)/h_a \cong (3^{3/4}/2)(AB/h_a)^{1/2} \quad [36]$$

Next the values of A and B for the two limiting cases c >> a and c << a are calculated.

1. If c >> a, the cosine in Eq. [23] is nearly equal to unity and the sine functions may be approximated by their arguments. Hence Eq. [23] becomes

$$J_a \cong \frac{(a+c)}{\pi(a^2/4 - x^2)^{1/2}} J_{c(max)} \text{ if } c >> a \quad [37]$$

For the vicinity of the anode-cathode boundary at $x \lesssim a/2$, it follows from Eq. [37] that

$$J_a \cong \frac{a+c}{\pi[a(a/2-x)]^{1/2}} J_{c(max)} \cong \frac{c}{\pi[a(a/2-x)]^{1/2}} J_{c(max)} \quad [38]$$

Upon comparing Eq. [28] and [38] it follows that

$$A \cong \frac{J_{c(max)}\, c}{\pi a^{1/2}} \text{ if } c >> a \quad [39]$$

If c >> a and $x \lesssim a/2$, the sine functions in Eq. [22] may be approximated by their arguments. Thus

$$\phi(x \lesssim a/2, y = 0) \cong -\frac{a+c}{\pi\sigma} J_{c(max)} \cosh^{-1}(2x/a) \quad [40]$$

For $x \cong a/2$, the inverse hyperbolic cosine function has an argument close to unity and therefore may be approximated by

$$\cosh^{-1}(2x/a) = \cosh^{-1}[1 + 2(x - a/2)/a] \cong 2[(x - a/2)/a]^{1/2} \quad [41]$$

Substitution of Eq. [41] in Eq. [40] yields Eq. [29] with

$$B \cong \frac{2}{\pi} \frac{(a+c) J_{c(max)}}{\sigma a^{1/2}} \cong \frac{2}{\pi} \frac{c\, J_{c(max)}}{\sigma a^{1/2}} \text{ if } c >> a \quad [42]$$

Upon substituting Eq. [39] and [42] in Eq. [36], using Eq. [21], and omitting numerical factors of the order of unity, the anodic current density at the anode-cathode boundary is found to be

$$J_a(x = a/2) \sim \left(\frac{\sigma}{a h_a}\right)^{1/2} \Delta E \text{ if } c >> a \quad [43]$$

2. If c << a and $x \sim a/2$, the trigonometric functions in Eq. [22] and [23] may be approximated by the following expressions

$$\sin\frac{\pi x}{a+c} = \cos\left[\frac{\pi}{2}\left(\frac{a+c-2x}{a+c}\right)\right] \cong 1 - \frac{1}{2}\left(\frac{\pi}{2}\frac{a+c-2x}{a+c}\right)^2 \quad [44]$$

$$\sin\frac{\pi a/2}{a+c} = \cos\left(\frac{\pi}{2}\frac{c}{a+c}\right) \cong 1 - \frac{1}{2}\left(\frac{\pi}{2}\frac{c}{a+c}\right)^2 \quad [45]$$

$$\cos\frac{\pi x}{a+c} \cong \cos\frac{\pi}{2}\frac{a}{a+c} = \sin\frac{\pi}{2}\frac{c}{a+c} \cong \frac{\pi}{2}\frac{c}{a+c} \quad [46]$$

Upon substituting Eq. [44] to [46] in Eq. [23] and omitting terms of higher order, it follows that the current density J_a next to the anode-cathode boundary $(a/2 - x << c)$ is

$$J_a \cong \frac{c}{2[c(a/2-x)]^{1/2}} J_{c(max)} \quad [47]$$

Upon comparing Eq. [28] and [47], it follows that

$$A = (c^{1/2}/2)\, J_{c(max)} \text{ if } c << a \quad [48]$$

Substitution of Eq. [44] and [45] in Eq. [22] yields the potential at the cathode next to the cathode-anode boundary,

$$\phi(x \gtrsim a/2, y = 0) = \frac{(a+c) J_{c(max)}}{\pi\sigma} \cosh^{-1} f(x) \quad [49]$$

where

$$f(x) = \frac{1 - \frac{1}{2}\left[\frac{\pi}{2}\frac{a+c-2x}{a+c}\right]^2}{1 - \frac{1}{2}\left[\frac{\pi}{2}\frac{c}{a+c}\right]^2} \quad [50]$$

If $c << a$ and $(x - a/2) << c$, $f(x)$ may be approximated by

$$f(x) \cong 1 - \frac{1}{2}\left[\frac{\pi}{2}\frac{a+c-2x}{a+c}\right]^2 + \frac{1}{2}\left[\frac{\pi}{2}\frac{c}{a+c}\right]^2 \cong 1 - \frac{1}{2}\left[\frac{\pi^2 c(a/2-x)}{(a+c)^2}\right] \quad [51]$$

Substituting Eq. [51] in Eq. [49] and using the first term of a series expansion for the inverse hyperbolic cosine function involving an argument close to unity, one obtains Eq. [29] with

$$B \cong \frac{c^{1/2} J_{c(max)}}{\sigma} \quad \text{if } c << a \quad [52]$$

Upon substituting Eq. [48] and [52] in Eq. [36], using Eq. [21], and omitting factors of the order of unity, the anodic current density at the anode-cathode boundary is found to be

$$J_a(x = a/2) \cong \left[\frac{\Delta E\, J_{c(max)}}{h_a}\right]^{1/2} \quad \text{if } c << a \quad [53]$$

For the current density J_a at the center of the anode the following relations are obtained.

1. If $c >> a$, it follows from Eq. [37] for $x = 0$ with the help of Eq. [21] and omission of factors of the order of unity that

$$J_a(x = 0) = \frac{2(a+c)}{\pi a} J_{c(max)} \cong \frac{\sigma \Delta E}{a} \quad [54]$$

2. If $c << a$, it follows from Eq. [23] and [46] that

$$J_a(x = 0) \cong J_{c(max)} \quad [55]$$

i.e., local cell action at the center of a sufficiently large anode is insignificant since J_a tends to the value determined by the local rate of oxygen supply.

Discussion and Conclusions

According to the foregoing considerations the local current density J_a for dissolution of a metal may be determined

1. by the rate of oxygen diffusion

$$J_a \cong J_{c(max)} \quad [56]$$

in accord with Eq. [10], or

2. by the potential drop in the electrolyte (resistance control) corresponding to the relation

$$J_a \sim \sigma\, \Delta E/a \quad [57]$$

which is deduced in Eq. [54] for the center of an anode of width a with adjacent cathodes if $c >> a$, or

3. by anodic polarization control corresponding to the relation

$$J_a = \Delta E/h_a \quad [58]$$

which has been obtained above as Eq. [13] for sufficiently narrow anodes ($a << \sigma\, h_a$).

The current density J_a at an anode-cathode boundary may be given by Eq. [43] if $c >> a$ and thus be equal to the geometrical mean of the right-hand members of Eq. [57] and [58] corresponding to a combination of resistance and anodic polarization control.

Alternatively, J_a at an anode-cathode boundary may be given by Eq. [53] if $c << a$ and thus be equal to the geometrical mean of the right-hand members of Eq. [56] and [58] corresponding to a combination of oxygen diffusion and anodic polarization control.

The validity range of the various approximations is determined mainly by the values of two dimensionless groups, N_1 and N_2,

$$N_1 = a/k_a = a/\sigma h_a \quad [59]$$

$$N_2 = \Delta E/h_a J_{c(max)} \quad [60]$$

The group N_1 is the ratio of the width a of the anode and the corrosion parameter k_a which in turn is defined as the product of the conductivity σ and the slope h_a of the potential-current density curve of the anodic reaction. The corrosion parameter $k_a = \sigma h_a$ is equal to the thickness of the electrolyte which yields a potential drop equal to the overpotential η_a of the anodic reaction at a given current density. The value of $N_1 = a/\sigma h_a$ is decisive for the uniformity of the current density at the anode. If $N_1 << 1$, the anodic current density is virtually uniform. Conversely, if $N_1 >> 1$, the anodic current density is much higher at the edges of the anode than at the center.

The group N_2 is the ratio of the potential difference ΔE defined in Eq. [8] to the overpotential $\eta_a = h_a J_{c(max)}$ pertaining to an anodic current density which is equal to the cathodic current density $J_{c(max)}$. The corrosion rate is significantly increased by local cell action only if $N_2 >> 1$,

The increase in corrosion rate due to local cell action may be represented by the ratio Q of the current density of metal dissolution with local cell action to that without local cell action. If the latter value is equal to the maximum current density of oxygen reduction in accord with Eq. [10], the value of Q becomes

$$Q = J_a/J_{c(max)} \quad [61]$$

So far, limiting cases have been considered, and it has been assumed that either $N_1 << 1$, or $N_1 >> 1$, etc. Since the approximate formulas for $N_1 << 1$ and $N_1 >> 1$ become identical if $N_1 = 1$, etc., it is not necessary to state $N_1 << 1$ or $N_1 >> 1$ but simply $N_1 < 1$ or $N_1 > 1$. Thus one has four principal cases listed in Table I whose occurrence is determined by the values of the dimensionless groups N_1 and N_2. Figure 4 shows the ranges of these cases graphically.

The summary presented in Table I involves considerable simplifications since factors of the order of unity have been omitted. Such a simplified rep-

Table I. Limiting cases of local cell action for conditions shown in Fig. 1

Q (edge)	1	N_2	$N_2/N_1^{1/2}$	$N_2^{1/2}$

resentation seems to be adequate for most purposes because in practice the basic data for a rational analysis such as the rate of oxygen supply and the slope of the anodic polarization curve are, in general, estimated rather than precisely known.

To illustrate the significance of the various cases, representative values of N_1 and N_2 are calculated. The value of ΔE is of the order of 1 v. The value of $J_{c(max)}$ depending on convection of the electrolyte can be expected to lie between 10^{-5} and 10^{-3} amp/cm^2. The electrical conductivity σ ranges in most cases between 5 x 10^{-4} for fresh water and 5 x 10^{-2} ohm^{-1}cm^{-1} for sea water. The slope $h_a = dE/dJ_a$ of the anodic polarization curve of a fairly reactive metal such as zinc in a 10^{-4}M Zn^{2+} ion solution is estimated to be of the order of 10^2 v/amp cm^{-2} corresponding to an exchange current density of 10^{-4} amp/cm^2, whereas less reactive metals such as iron or nickel exhibit higher values depending on the value of J_a.

For reactive metals, $N_2 = \Delta E/h_a J_{c(max)}$ lies, therefore between 10 and 10^2, i.e., is greater than unity. Consequently, cases II, III, and IV are expected to occur. According to Table I, Q(edge) $= J_a$(edge)/$J_{c(max)}$ is equal to N_2, $N_2/N_1^{1/2}$ and $N_2^{1/2}$ for cases II, III, and IV, respectively. For $\Delta E = 1$ v, $h_a = 10^2$ v/amp cm^{-2}, and $J_{c(max)} \cong 10^{-4}$ amp/cm^2 one obtains, therefore, values of Q(edge) between 10 and 100.

To have a value of $N_1 = a/\sigma h_a < 1$ corresponding to case II with uniform corrosion, the width a of the anode must be less than 5 x 10^{-2} cm in fresh water and less than 5 cm in sea water. Otherwise, case III or IV involving a higher corrosion rate at the edge of the anode than at the center occurs. If $N_2/N_1 = \sigma \Delta E/aJ_{c(max)} > 1$, case III occurs. If conversely $N_2/N_1 < 1$, case IV occurs. For $\Delta E = 1$ v, and $J_{c(max)} = 10^{-4}$ amp/cm^2, the width of the anode for a transition from case III to case IV is $a \cong 5$ cm

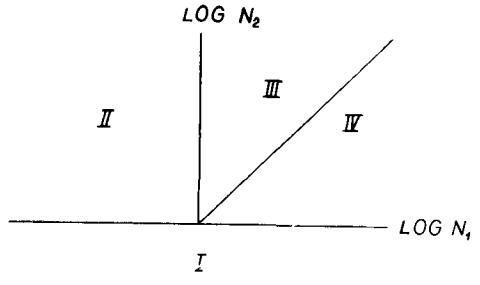

Fig. 4. Ranges of the dimensionless group $N_1 = a/\sigma h_a$ and $N_2 = \Delta E/h_a J_{c(max)}$ for the limiting coses I, II, III, and IV listed in Table I.

in fresh water and $a \cong 500$ cm in sea water. If the width of the anode is less, i.e., case III prevails, the current density J_a decreases with increasing width a of the anode at both the center and the edge. If conversely the width of the anode exceeds 5 cm in fresh water, or 500 cm in sea water, i.e., case IV prevails, J_a (center) tends to $J_{c(max)} = 10^{-4}$ amp cm^{-2} and J_a(edge) is found to be 10^{-3} amp cm^{-2} independent of the width of the anode and the conductivity of the electrolyte if $h_a = 10^2$ v/amp cm^{-2}.

The foregoing calculations refer to a value of $J_{c(max)} = 10^{-4}$ amp/cm^2 as an average representative value. In view of a rather large variability of $J_{c(max)}$ with the oxygen concentration in the bulk electrolyte and the intensity of convection, the dependence of the various phenomena on the magnitude of $J_{c(max)}$ is of special interest. If $N_1 > 1$ and $N_2 > N_1$, i.e., $J_{c(max)} < \sigma \Delta E/a$, case III is realized. The values of J_a at both the center and the edge of the anode are independent of $J_{c(max)}$, i.e., the rate of oxygen supply. On increasing the oxygen supply, N_2 becomes less than N_1 and, accordingly, case IV is realized. Then J_a(edge) is proportional to the square root of $J_{c(max)}$ and J_a(center) $\cong J_{c(max)}$. It is noteworthy that J_a is found to be virtually independent of the rate of oxygen supply if the supply is low, in particular if the oxygen concentration in the electrolyte is low. This is an important characteristic of local cell action contrary to usual rules of kinetics. The lower the oxygen concentration in the electrolyte, the greater is the effective area of the cathodes to which oxygen diffuses. In view of this compensation the rate of corrosion for cases II and III is controlled not by oxygen diffusion but by the resistance of the electrolyte and by anodic polarization.

The scheme in Table I and Fig. 4 is not strictly applicable to less reactive metals such as iron or nickel involving higher values of $h_a = dE/dJ_a$ which are not constant but depend on J_a. Under these conditions, only certain trends can be stated. First, in the case of metals exhibiting a large activation overpotential on dissolving, case I corresponding to a value of $N_2 < 1$ is favored, i.e., local cell action is not likely to enhance corrosion of a metal such as nickel. Second, if $N_2 > 1$, case II involving uniform attack is expected to occur with anodes of greater width than has been calculated above for a more reactive metal such as zinc since $N_1 = a/\sigma h_a$ is inversely proportional to h_a. The lower the reactivity of a metal, the lower is the rate of attack since J_a for case II is inversely proportional to h_a. Third, the less reactive a metal, the lower is the effect of

local cell action at edges since J_a(edge) is inversely proportional to $h_a^{1/2}$ for cases III and IV according to Eq. [43] and [53], respectively, if $h_a = dE/dJ_a$ is constant.

Although local cell action aggravates corrosion, the potential danger is not unlimited as is shown by the foregoing discussion. In many practical cases, the effect of local cell action is even less severe, if in contradistinction to an important presupposition introduced above, solid corrosion products are formed and constitute some kind of protective layer especially at locations involving a high initial attack.

The foregoing considerations refer to reduction of oxygen as the cathodic reaction. It is important to recall that evolution of hydrogen is another cathodic reaction which does occur in parallel and may prevail under certain conditions. The characteristics of local cell action due to oxygen reduction and to hydrogen evolution differ in some respects. In particular, in the case of hydrogen evolution as the predominant cathodic reaction the corrosion rate is increased considerably by small areas of a material involving a low hydrogen overpotential in a matrix of a less noble metal such as zinc at which the hydrogen overpotential is high. In contrast, in most practical cases where corrosion is due to reduction of oxygen, the cathodic current density is independent of the nature of the solid conductor because J_c is close to the limiting value $J_{c(max)}$. Under these conditions, inclusions of foreign materials affect the corrosion rate only to a minor extent. For this reason, only large cathodic areas have been considered above.

The conclusions drawn in this paper differ in some respect from those drawn by Waber and his associates (2-7, 12) because the analysis in the present paper presupposes a limiting current density of the cathodic reaction, whereas Waber, *et al.* assume linear polarization curves for both the cathodic and the anodic reaction. Both approaches supplement each other. In particular, if hydrogen evolution rather than oxygen reduction takes place as the cathodic reaction, and local depletion of hydrogen ions is not a decisive factor, Waber's analysis may be considered to be more relevant.

Effect of Hydrogen Pressure on the Hydrogen Overvoltage on Bright Rhodium

Sigmund Schuldiner

U. S. Naval Research Laboratory, Washington, D. C.

ABSTRACT

The effect of hydrogen pressure on the hydrogen overvoltage on bright, active rhodium was determined. The data indicated that the overvoltage mechanism was controlled by the $2H_{ads} = H_2$ step. Kinetic parameters for the mechanism were quantitatively determined including the surface coverage with adsorbed atomic hydrogen. A Langmuir adsorption isotherm resulted from the relationship between surface coverage with atomic hydrogen at equilibrium and the partial pressure of molecular hydrogen above the solution.

It has been shown in a previous study of the effect of hydrogen pressure on the overvoltage on bright platinum (1) that pressure effects can be used to determine kinetic parameters and to establish a reasonable reaction mechanism. In the investigation reported here pressure effects on hydrogen formation and ionization reactions on bright rhodium were studied. By using this metal in rapidly stirred, strong acid solution, diffusion effects were virtually eliminated, and it was possible to make a quantitative determination of the kinetic parameters.

Experimental

Breiter, Kammermaier, and Knorr (2) showed that the properties of an "aged" rhodium electrode are different from those of a "new" electrode. This was confirmed by this investigation. On a new rhodium electrode it was found that at first the overvoltage was relatively high, but that on repeated anodic and cathodic cycling to high polarization values (−0.4 v cathodic and > 1 v anodic) a reproducible electrode of high activity was obtained.

The general experimental techniques were the same as those previously used (3, 4). The cell was constructed of Teflon and is shown in Fig. 1. The rhodium (99.5 + %) cathode was prepared by melting the tip of a 0.025 in. thick rhodium wire with a hydrogen/oxygen flame and forming a small sphere. The wire was then inserted into the 0.02 in. hole

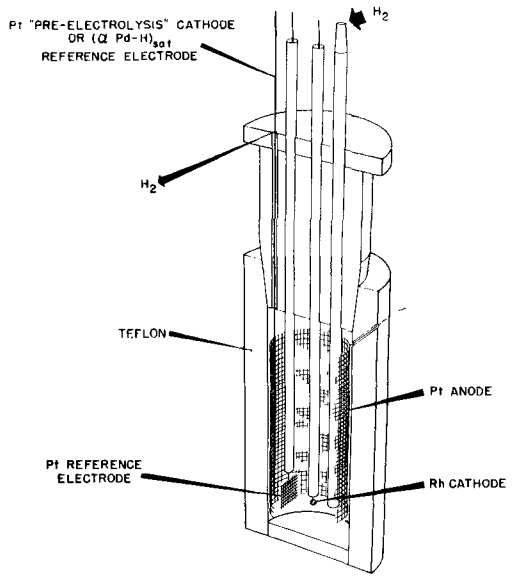

Fig. 1. Electrolytic cell

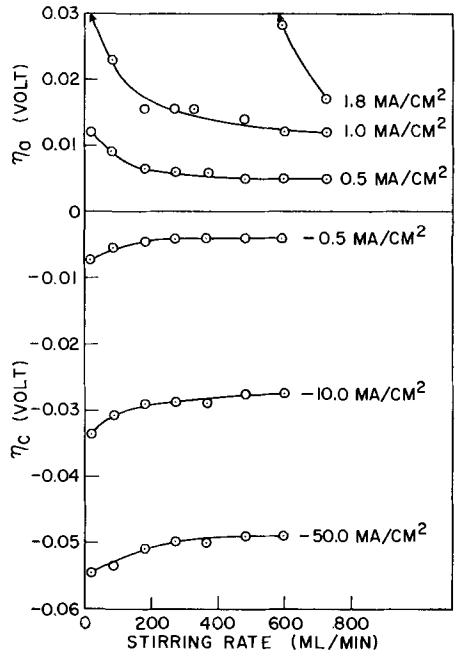

Fig. 2. Effect of stirring rate (P_{H_2} = 1 atm) on η_c and η_a

in the Teflon rod shown in Fig. 1. A molten polyethylene seal was made between the bottom of the Teflon rod and the rhodium wire. The resulting rhodium electrode then consisted of a bead at the end of a 2 mm exposed length of wire. The total apparent area of exposed rhodium was 0.10 cm². The solution was in all cases 1M H_2SO_4. Purified gases consisting of either pure hydrogen or mixtures of hydrogen and helium were bubbled through the acid solution in the cell. The method of preparation of the gas mixtures and the determination of the hydrogen partial pressure are described in a previous paper (1).

After the solution was pre-electrolyzed and the rhodium electrode was activated by repeated anodic and cathodic polarization, repeated measurements were taken at each partial pressure of hydrogen under both anodic and cathodic polarization. Overvoltages at each current density were time independent. The reference electrode to cathode interface *IR* drop was determined by interrupter measurements (3). The data given are average values of individual runs. The precision of an individual reading was better than 0.5 mv. The maximum deviation of the average values was ±0.5 mv at low overvoltages and ±2 mv at high overvoltages. The temperature was 27° ±1°C.

Experimental Results

Concentration polarization effects were minimized by rapid stirring with gas. Figure 2 shows the effect of stirring rate on overvoltage for pure hydrogen. The data show that a value is reached after which the overvoltage is independent of stirring rate. Stirring rates in excess of these values were used for all measurements.

Cathodic overvoltage, η_c, vs. log apparent current density curves at different hydrogen pressures are shown in Fig. 3. Figure 4 shows the anodic overvoltage, η_a, vs. log apparent current density curves. At low current densities a linear relationship between the anodic and cathodic overvoltages and apparent current density was found and these results are shown in Fig. 5.

From the experimental data shown in Fig. 3-5, kinetic parameters and a reaction mechanism can be determined.

Calculation of Kinetic Parameters

The Tafel slopes of ~0.0295 shown in Fig. 3 indicate that the reaction mechanism is a fast discharge of hydronium ions followed by a slow combination of hydrogen atoms, H_{ads}, to molecules;

$$H_3O^+ + e^- = H_{ads} + H_2O \qquad [1]$$

$$2H_{ads} \xrightarrow{\text{slow}} H_2 \qquad [2]$$

This mechanism is confirmed by the limiting anodic current densities found in Fig. 4. These limiting current densities would be caused by the coverage of adsorbed hydrogen atoms on the rhodium surface dropping to zero. It will be shown later that the limiting current densities shown in Fig. 4 are not due to a diffusion process.

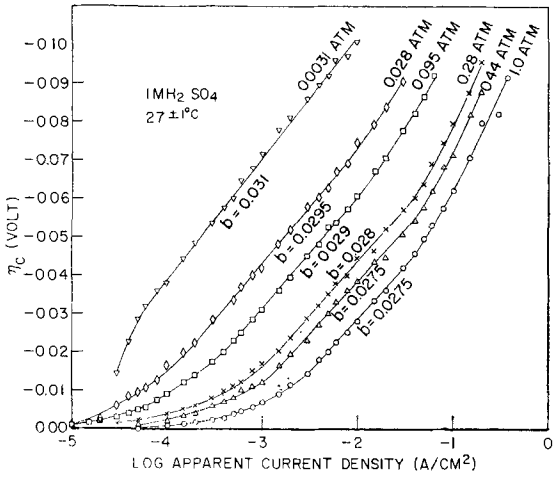

Fig. 3. Relations for η_c vs. log ($-i_c$)

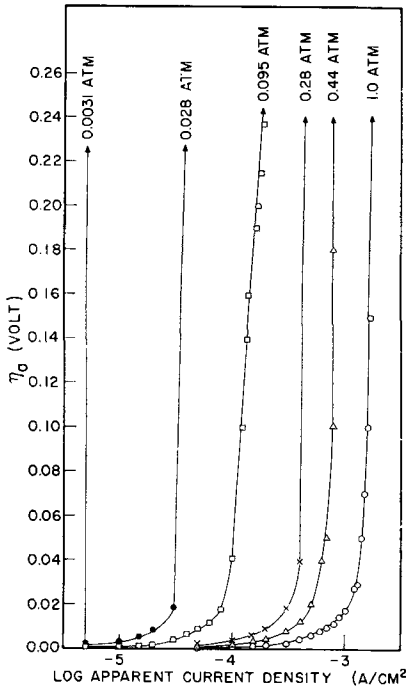

Fig. 4. Relations for η_a vs. log i_a

The equations (1) for this mechanism are:

$$i_c = i_{o,c}\frac{(1-\theta)^2}{(1-\theta_0)^2}[\exp(-2\eta_c\mathbf{F}/RT)-1] \qquad [3]$$

$$i_a = i_{o,a}\frac{(1-\theta)^2}{(1-\theta_0)^2}[1-\exp(-2\eta_a\mathbf{F}/RT)] \qquad [4]$$

where i_c, i_a are the applied cathodic and anodic current densities respectively; $i_{o,c}$, $i_{o,a}$ are the cathodic and anodic exchange current densities, respectively; η_c, η_a are the cathodic and anodic overvoltage, respectively; θ is the fraction of available surface covered with atomic hydrogen; θ_0 is the fraction of available surface covered with atomic hydrogen at zero current density, (equilibrium); and R, T, and $\mathbf{F}$ are the gas constant, absolute temperature and the Faraday, respectively.

At overvoltages near equilibrium $\theta \approx \theta_0$ and Eq. [3] and [4] can be simplified to:

$$i_c = i_{o,c}[\exp(-2\eta_c\mathbf{F}/RT)-1] \qquad [3a]$$

$$i_a = i_{o,a}[1-\exp(-2\eta_a\mathbf{F}/RT)] \qquad [4a]$$

The values of $i_{o,c} = -i_{o,a}$ can therefore be determined for various values of hydrogen partial pressure, P_{H_2}, by plotting i_c vs. $[\exp(-2\eta_c\mathbf{F}/RT)-1]$ and i_a vs. $[1-\exp(-2\eta_a\mathbf{F}/RT)]$. These plots are shown in Fig. 6.

The values of θ_0 and θ can be determined in the following way. If one plots i_c vs. $[\exp(-2\eta_c\mathbf{F}/RT)-1]$ throughout the entire range of values determined, the curves shown in Fig. 7 are obtained. The deviation at higher current densities, where θ is significantly greater than θ_0, from the straight line fit found

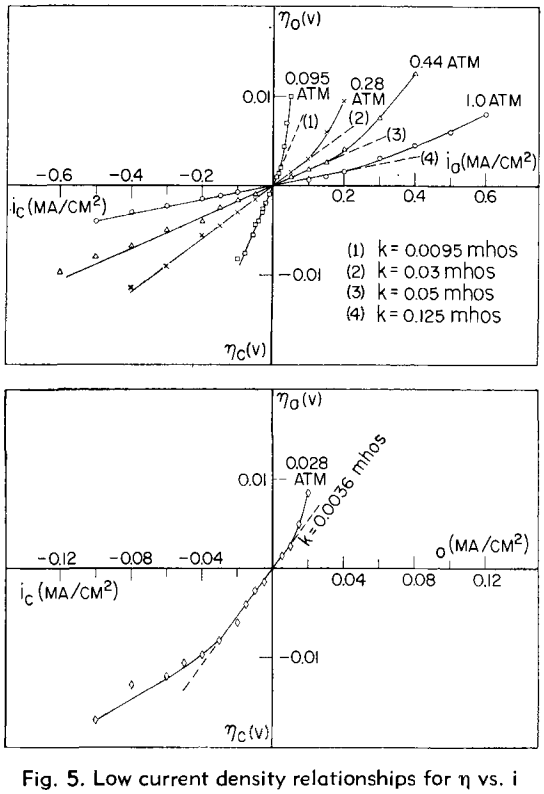

Fig. 5. Low current density relationships for η vs. i

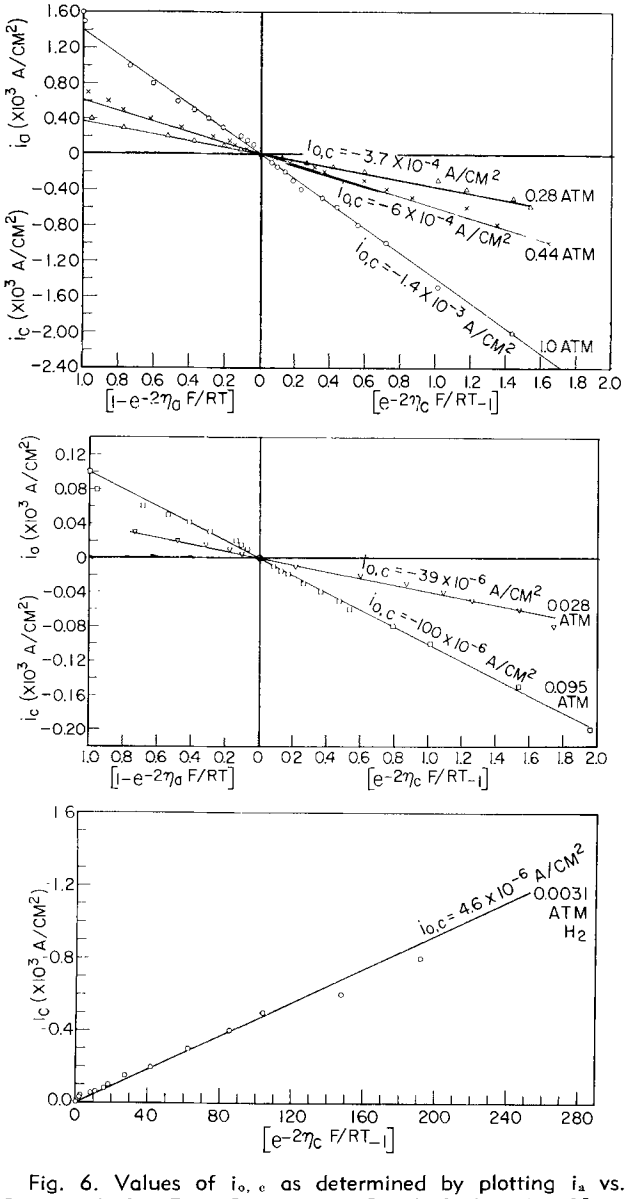

Fig. 6. Values of $i_{o,c}$ as determined by plotting i_a vs. $[1-\exp(-2\eta_a F/RT)]$ and i_c vs. $[\exp(-2\eta_c F/RT)-1]$.

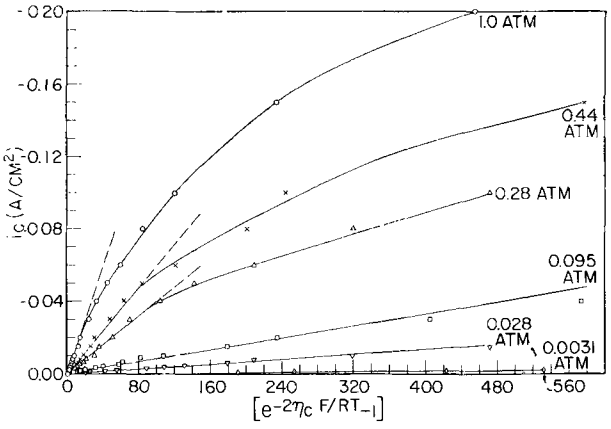

Fig. 7. i_c vs. $[\exp(-2\eta_c F/RT) - 1]$

at low current densities is a function of the ratio $(1-\theta)^2/(1-\theta_0)^2$. Hence in order to linearize these curves one would have to plot i_c vs. $(1-\theta)^2/(1-\theta_0)^2$ $[\exp(-2\eta_c \mathbf{F}/RT)-1]$. One can then solve for $(1-\theta)^2/(1-\theta_0)^2$ using Eq. [3]. Since the slow combination step, Eq. [2], of the reaction mechanism in the absence of a back reaction can be written as follows

$$i_c = \vec{k}_2 \theta^2$$

and since

$$i_{o,c} = \vec{k}_2 \theta_0^2$$
$$i_c/i_{o,c} = \theta^2/\theta_0^2 \qquad [5]$$

By simultaneous use of Eq. [3] and [5] one can solve for θ_0 and θ when $\eta_c > 0.03$ v, then

$$\theta_0 = \frac{[\exp(-2\eta_c \mathbf{F}/RT)-1]^{1/2} - (i_c/i_{o,c})^{1/2}}{(i_c/i_{o,c})^{1/2}\{[\exp(-2\eta_c \mathbf{F}/RT)-1]^{1/2}-1\}} \qquad [6]$$

and

$$\theta = (i_c/i_{o,c})^{1/2}\,\theta_0 \qquad [7]$$

The limiting cathodic current densities, $i_{c,L}$, were determined from Eq. [5]. When $i_c = i_{c,L}$, $\theta = 1$, hence

$$i_{c,L} = i_{o,c}/\theta_0^2 \qquad [8]$$

The limiting anodic current densities, $i_{a,L}$, were determined from Eq. [4]. When $i_a = i_{a,L}$, $\theta = 0$ and since η_a is a large positive number, $\exp(-2\eta_a \mathbf{F}/RT) \approx 0$, hence

$$i_{a,L} = i_{o,a}/(1-\theta_0)^2 \qquad [9]$$

The rate constants for the over-all reaction, $k = \pm(di/d\eta)_{\eta\to 0}$ (the sign is negative for the cathodic and positive for the anodic directions) near equilibrium where there is a linear relation between η and i were determined from Fig. 5. The stoichiometric numbers, μ, were calculated from the Horiuti (5) relationship

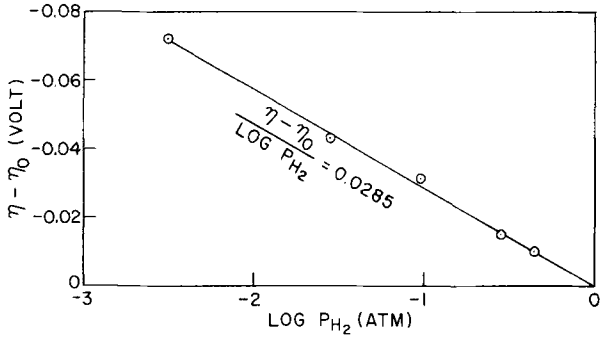

Fig. 8. η-η_0 vs. log P_{H_2}

$$\mu = 2i_{o,c}\mathbf{F}/kRT \qquad [10]$$

Table I lists the kinetic parameters which were determined as indicated above. In addition the experimentally determined values of $i_{a,L}$ are shown for comparison with the calculated values.

Discussion

Several investigators have established (1, 6-11) that at a given current density in the linear Tafel region the hydrogen overvoltage on a cathode is related to the hydrogen pressure by the expression

$$\eta = \eta_0 + (RT/2\mathbf{F}) \ln P_{H_2} \qquad [11]$$

where η, the overvoltage, is defined as the potential difference between the working electrode and a reversible hydrogen electrode in the same solution, η_0 is the overvoltage at 1 atm of hydrogen and P_{H_2} is the partial pressure of hydrogen above the solution. A plot of $\eta - \eta_0$ vs. log P_{H_2} for the data which was taken at 27°C should therefore give a straight line with a slope of 0.0295 v. Figure 8 shows such an experimental plot with a slope of 0.0285 v. The agreement is very good which not only confirms Eq. [11] but also serves as a verification of the hydrogen partial pressure values.

The effects of current density on surface coverage with atomic hydrogen, θ, for various P_{H_2} values are shown in Fig. 9. Here i_c is plotted vs. θ^2. According to Eq. [5], when the back reaction is negligible there should be a linear relation between i_c and θ^2 with a slope of $i_{o,c}/\theta_0^2$. As shown by Eq. [8], when $i_c = i_{c,L}$ the slope is simply $i_{c,L}$. Since, when the back reaction is negligible, the surface coverage should be only a function of current density independent of P_{H_2}, a slope of $i_{c,L}$ should apply for all the data shown in Fig. 9. The average $i_{c,L}$ values of −1.49 amp/cm^2 given in Table I has been drawn through each set of points shown in Fig. 9. As can be seen the fit of this

slope through the points at θ^2 values below 0.06, which corresponds to a θ value of 0.245, is good. The poorer fit at higher θ^2 values is undoubtedly due to the assumption of a Langmuir isotherm (12) in the derivation of Eq. [3] and [4]. A better fit would probably be obtained by use of a Temkin (13) isotherm at coverages above 0.2. However, the use of the Langmuir isotherm for the calculation of kinetic parameters in the present paper is valid since θ_0, and $i_{a,L}$ represent low and zero coverage, respectively, whereas $i_{c,L}$ represents full coverage. The Langmuir isotherm does apply to these conditions.

The Langmuir isotherm is

$$\theta_0^2/(1-\theta_0)^2 = KP_{H_2} \qquad [12]$$

The data for this isotherm is plotted in Fig. 10 and an excellent fit to a straight line intersecting the zero point is obtained. The calculated K value is 0.0009. The Langmuir isotherm shown in Fig. 10 confirms the fact that the atomic hydrogen coverage of the rhodium surface at equilibrium is low. It also confirms the electrode mechanism postulated and the method of calculating the kinetic parameters. In addition, since the anodic part of the curves shown in Fig. 6 show a good linear fit from zero overvoltage to about the point where the limiting anodic current density is reached, one can conclude that $\theta_0 << 1$. This is because during anodic polarization the value of θ must range from θ_0 at equilibrium to zero at the limiting current density. If this range of values was a significant fraction of unity then one could not obtain a linear fit using Eq. [4a].

A further confirmation of the applicability of the calculations used is the stoichiometric number, μ,

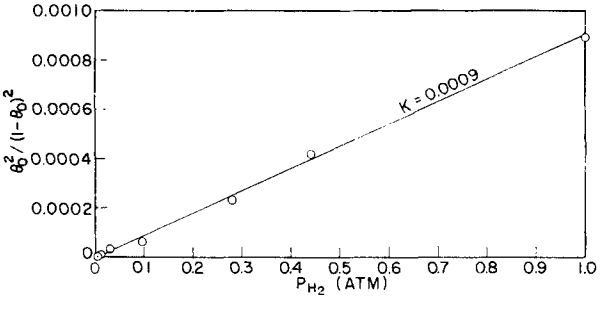

Fig. 10. Langmuir adsorption isotherm, $\theta_0^2/(1-\theta_0)^2$ vs. P_{H_2}

being close to unity and the agreement between the experimental and calculated anodic limiting current densities shown in Table I. There is always a possibility that some hydrogen is dissolved in the metal near the surface, and this would tend to result in making the experimental error in the direction of higher $i_{a,L}$ values. This is generally observed in Table I comparing the experimental $i_{a,L}$ values with the calculated values.

Ershler (14) by use of charging curves, Eucken and Weblus, and Breiter, Knorr, and Völkl (15) from a-c impedance measurements have concluded that the surface of a platinum metal is covered largely with atomic hydrogen at the hydrogen equilibrium potential. The results given here and in previous papers from this laboratory (1, 16) have shown that the surface of platinum metals is covered only sparsely with atomic hydrogen at equilibrium. It is conceivable that both results may be correct. For example, a layer of atomic hydrogen may exist just beneath the metal surface or is so incorporated in the metal surface that it is in effect a part of the metal. If this atomic hydrogen is not in equilibrium with the molecular hydrogen in solution, then it may be detected by charging curves, or by a-c methods but would not play a part, except possibly as a catalyst, in the hydrogen surface potential-determining reaction at equilibrium. It could be that such a layer is formed by the activation procedures used with platinum metals which generally consist of alternate anodic and cathodic treatment. Such a layer may also exist even at very low hydrogen partial pressures. It is noteworthy that the a-c impedance measurements of Breiter, Knorr, and Völkl (15) gave virtually the same high surface coverage for Pt metals in both hydrogen and nitrogen saturated solutions. The transitory nature of highly activated platinum (17-19) in highly purified solutions may be due to such a layer of atomic hydrogen being decreased in time rather than to the accumulation of impurities on the surface.

Diffusion effects in this investigation must be negligible under the experimental conditions used. The reason for this can be seen from the fact that $i_{a,L}$ values are always greater than $i_{o,a}$ values. If diffusion were important, when $\theta_0 << 1$, $i_{a,L}$ values must always be smaller. This can be seen from the relation

$$1/i_{a,L} = (1-\theta_0)^2/i_{o,a} + 1/i_{o,d} \qquad [13]$$

where $i_{o,d}$ is the so-called diffusion exchange current density. This means that for the system reported here $i_{o,d}$ must be much larger than $i_{o,a}$.

Another verification of the kinetic analysis used in this paper would be an experimental determination of $i_{c,L}$. This was impossible to achieve with the technique used in this investigation. This is due primarily to the large coverage of the metal surface with hydrogen bubbles at current densities approaching 0.5 amp/cm^2. New techniques are being considered with which it is hoped that this difficulty may be overcome and a determination of $i_{c,L}$ may be possible.

Technical Notes

Effect of Oxygen on the Active-Passive Behavior of Stainless Steel

Norbert D. Greene[1]

M tals Research Laboratories, Union Carbide Metals Company, Division of Union Carbide Corporation, Niagara Falls, New York

The usefulness of potentiostatic polarization methods for studying passivity of metals has been demonstrated (1-7). These techniques are used here to determine whether dissolved oxygen has any effect on the active-passive behavior of stainless steel. The passivating inhibitor mechanism proposed by Stern (8) assumes that the presence of small quantities of oxidizing agents (or passivators) does not affect appreciably the anodic dissolution kinetics of a metal. This study is a direct test of this assumption. Further, it is also useful in testing the validity of theories which attribute passivity to the retardation of anodic dissolution by adsorbed oxygen from solution (9-11).

Type 430 stainless steel in sulfuric acid was chosen for this study because its active-passive transition is reproducible and does not vary with time, and the critical anodic current density is sufficiently high so that spontaneous passivation does not occur in oxygen-saturated solutions.

Experimental

Potentiostatic anodic polarization measurements were conducted with apparatus and techniques described in detail elsewhere (7, 12). Electrodes were machined from Type 430 stainless steel (15.90% chromium, 0.30% manganese, 0.054% carbon, 0.31% silicon, 0.005% phosphorus, and 0.011% sulfur) furnace-cooled after 1 hr at 780°C. Polarization measurements were conducted in hydrogen- and oxygen-saturated sulfuric acid solutions.

[1] Present address: Department of Metallurgical Engineering, Rennselaer Polytechnic Institute, Troy, New York.

Electrodes were pre-exposed to the test solutions for 15 to 20 hr prior to polarization measurements. All tests were performed at 24° to 26°C.

Results

Figure 1 shows anodic polarization data for Type 430 stainless steel in hydrogen-saturated normal sulfuric acid. The active corrosion potential is indicated on the ordinate. This curve is typical of most active-passive metals (1-7). As the potential is increased, current density increases to a maximum, here called critical anodic current density, I_c. The corresponding potential is called the primary passive potential, *Epp*. At potentials more noble than *Epp*, current decreases, eventually to very small values, and becomes time-dependent. Above approximately 0.900 v, current again increases with potential and oxygen evolution occurs. The current maximum at 0.050 v is not significant in the passivation process and is not considered further here.

Although Fig. 1 is an applied current polarization curve, other studies, to be reported later, demonstrate that it closely approximates actual anodic dissolution rate over a wide range of potentials. At potentials above reversible oxygen potential (0.900 v) and within approximately 50 mv of the active corrosion potential, significant distortion occurs because of contributions from oxygen and hydrogen evolution, respectively.

Figure 2 shows the polarization of Type 430 stainless steel in oxygen-saturated normal sulfuric acid. In contrast to the behavior in hydrogen-satu-

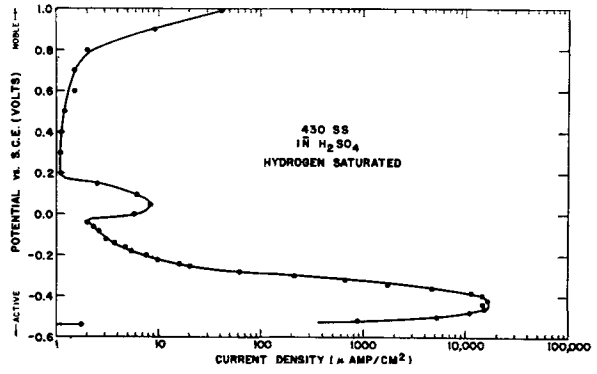

Fig. 1. Anodic polarization of Type 430 stainless steel in hydrogen-saturated 1N sulfuric acid.

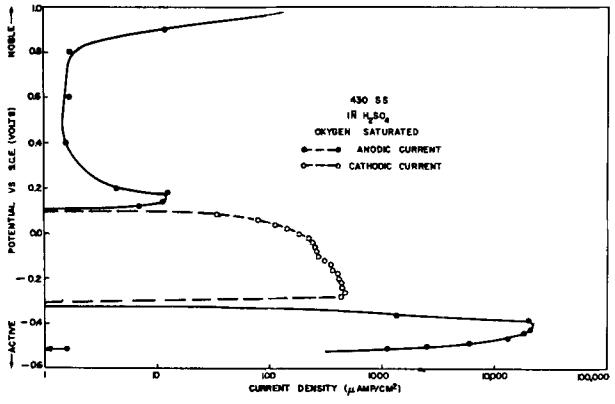

Fig. 2. Anodic polarization of Type 430 stainless steel in oxygen-saturated 1N sulfuric acid.

rated acid, this system demonstrates two stable mixed potentials as evidence by the appearance of the cathodic loop between −0.300 and 0.100 v. In this environment, Type 430 stainless alloy can exist in either the active state at −0.517 v or the passive state at 0.100 v.[2] Since both active and passive states are stable, the system does not spontaneously transform from one to the other. However, the alloy can be repeatedly transformed from one state to the other by application of suitable anodic or cathodic currents. Thus, the limiting diffusion current of oxygen in an oxygen-saturated solution is sufficient to maintain stable passivity but insufficient to cause spontaneous passivation. For descriptions of cathodic loops, spontaneous passivation, and other phenomenological features of active-passive metals, see (2, 5, 8, 14).

Similar experiments were performed in 5 and 10*N* sulfuric acid and are summarized in Table I.

[2] Although the initial passive potential of this system was 0.100 v, the time-dependency of passive dissolution (4, 7, 13) produced a slow shift in the noble direction. After 48 hr in the passive condition, this potential increased to 0.345 v.

Table I. Primary passive potentials (Epp) and critical anodic current densities (I_c) of Type 430 stainless steel in sulfuric acid

Potentials = v vs. SCE; current = ma/cm²

Acid concentration	Hydrogen saturated		Oxygen saturated	
	Epp	I_c	*Epp*	I_c
1*N*	−0.420	17	−0.420	21
5*N*	−0.340	26	−0.340	29
10*N*	−0.260	40	−0.280	43

All oxygen-saturated solutions exhibited cathodic loops during anodic polarization. Differences between hydrogen-saturated and oxygen-saturated solutions shown in Table I are within the limits of experimental accuracy.

Discussion

Figures 1 and 2 and Table I demonstrate that oxygen, in sufficient concentration to maintain passivity of Type 430 stainless steel, does not affect anodic dissolution of this alloy. Thus, passivity cannot be attributed to the retardation of anodic dissolution by the adsorption of oxygen from solution as proposed by several investigators (9-11). Although oxygen adsorption undoubtedly occurs on stainless steel surfaces, it does not retard dissolution. The fact that stable passivity has been observed in the absence of oxygen (5) offers additional evidence that passivity is not caused by adsorbed oxygen.

The presence of oxygen does not measurably affect dissolution kinetics of Type 430 stainless steel in sulfuric acid. Therefore, for this system, the assumption that anodic and cathodic partial processes are mutually independent (4, 8) is correct. For predicting both the effectiveness of passivating agents and the relative passivating tendencies of alloys, this assumption can probably be generally applied, as shown by the success of recent studies of this nature (2, 7, 8).

Although a mechanism for passivity cannot be deduced from the measurements performed here, this study further confirms the phenomenological description of passivity proposed by Stern (8). Simply, any oxidizer capable of producing a mixed potential within the passive potential region can produce stable passivity. In this sense, oxygen demonstates no specific property; its behavior is typical of any strong oxidizing agent.

Summary

1. It is shown that the presence of oxygen has no apparent effect on the anodic dissolution kinetics of Type 430 stainless steel. The primary passive potential and the critical anodic current density are essentially the same in the presence or absence of dissolved oxygen.

2. The passivating inhibitor theory described by Stern is supported by this study.

3. Results of this study are not consistent with adsorbed oxygen theories of passivity.

A Controlled Diffusion Process for Indium in N-Type Germanium

F. Barson, M. J. Dyett, C. Karan, and W. E. Mutter

Product Development Laboratory, International Business Machines Corporation, Poughkeepsie, New York

In the fabrication of NPN diffused base transistors, one conventional process starts with N-type germanium and diffuses a P-type skin into its surface. An N-type emitter dot is then alloyed into the diffused skin to complete the NPN structure.

One complication which arises, particularly during the diffusion process, is that of thermal conversion; that is, when germanium is heated above about 500°C and cooled fairly rapidly, additional acceptor levels appear in the bulk of the crystal (1). The density of these thermal acceptors is often great enough that N-type germanium is completely converted to P-type.

The cause of this thermal conversion in germanium is associated primarily with the introduction of copper into the material. Copper is apparently usually present in trace amounts on the surface and, due to its very high diffusivity at elevated temperatures, spreads rapidly throughout the bulk of the germanium where it acts as an acceptor center (2, 3). In addition, quenches from high temperatures may introduce acceptor levels of another kind, which are apparently due to quenched-in lattice defects (4, 5). Except with very rapid cooling rates, however, this latter type of thermal acceptor is not too troublesome.

Several investigators have suggested means of minimizing thermal conversion due to copper contamination. Annealing the germanium at 500°C precipitates the copper in clusters which are electrically inactive (2, 6); however, since the copper is not actually removed from the sample by this method, further heating cycles may cause conversion to occur once more. A vacuum heat treatment, on the other hand, removes the possibility of conversion by actually evaporating the copper from the sample, maintaining its resistivity (7). Another method is to clean the germanium in potassium cyanide prior to any proposed heat treatment (8, 9). The cyanide forms soluble complexes with copper, removing it before it can diffuse in and be troublesome. Finally, it has been shown that certain molten metals in contact with germanium, due to their high solubility for copper, act as getters which extract the copper from the germanium (10-12).

It is this last method which has been employed in the present work to develop a practical process for diffusion into N-type germanium. By a proper choice of the getter metal, it has been found possible not only to retain the original resistivity of the N-type germanium wafer, but also to use this metal as a source of acceptor impurities for the diffusion itself.

Method and Results

Approximately 0.1 mil thickness of indium metal was evaporated onto one side of the N-type germanium wafers to be diffused. The wafers were then placed, indium side down, on a graphite slab and heated in a wire-wound furnace under an atmosphere of slowly flowing forming gas. The temperature used for the diffusion was 875°C. At this temperature, the molten indium film under the germanium provided enough indium vapor in the furnace so that a P-type skin formed by diffusion on the upper sides of the wafer.

In this way, the indium served both as a getter to remove copper from the sample and also as a source of the acceptor impurity for diffusion as well. The thickness of the P-type skin so formed could be controlled by the length of time that the sample was held at high temperature. Following the diffusion, the samples were cooled and the indium film, presumably now containing any copper originally present in the germanium, was removed from the bottom of the wafers by lapping.

The resistivities of the wafers were measured by the four-point probe method prior to the evaporation, and again after the diffusion (on the lapped, N-type surface). Seldom was the density of thermal acceptors introduced by the process found to exceed 1×10^{14} cm^{-3}. This means that germanium in the range of 3-6 ohm-cm suffered an increase in resistivity of less than 0.5 ohm-cm.

The junction depth X_j for a diffusion was measured by beveling a portion of the surface at a low angle and locating the junction with a thermal probe mounted on a sensitive depth gauge. To estimate C_o, the surface concentration for the indium diffusion, the familiar error function distribution was evaluated at the junction:

$$C_j = C_o \operatorname{erfc} X_j/2\sqrt{Dt}$$

Assuming a diffusion coefficient of 1.5×10^{-12} cm^2/sec at 875°C, C_o was calculated to be about 5×10^{18}

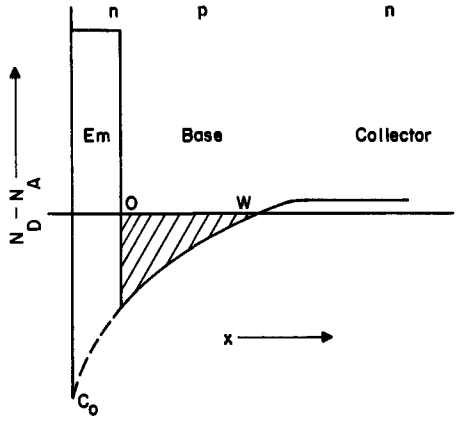

Fig. 1. Impurity distribution in a transistor made by the process described. Shaded area represents $\int_o^w P\,dx$.

cm^{-3}. The assumed diffusion coefficient is in good agreement with that determined by several earlier investigators (13-15); furthermore, the resulting C_o was consistent with sheet resistance measurements made in a manner similar to that of Backenstoss (16) for silicon diffusions.

In order to point out a practical difficulty in making transistors of the indium-diffused material described above, we recall that the fabrication process is now to alloy an N-type emitter into the P-type skin. This results in an impurity distribution somewhat as shown in Fig. 1. The emitter efficiency for this structure can be shown to be (17):

$$\gamma = \frac{1}{1 + \frac{\mu_p}{\mu_n} \frac{\int_o^w P\,dx}{L_{pe} N_o}}$$

Notice that the integral, which represents the shaded area in Fig. 1, should have a small value to give a high emitter efficiency. This means that if C_o is large, the emitter must be alloyed very close to the collector junction (that is, the base must be very narrow) to preserve a high emitter efficiency. This calls for very precise control of alloying; for placing the emitter junction at too shallow a depth results in low emitter efficiency, while placing it at too great a depth results in alloying completely through to the collector junction. There are several ways to lower C_o in the indium diffusion process so as to decrease the slope of the impurity distribution and thus allow more leeway in the emitter alloying process. A method which was both simple and effective was to use an evaporated film of both indium and tin together as a getter-source and then to perform the diffusion exactly as described in the original process, a single-zone furnace sufficing.

We recall that, for an ideal solution, the vapor pressure of the solute is proportional to its mole fraction in the solution (Raoult's law). Hence, we would expect that as the concentration of indium in the evaporated tin-indium film was decreased, the vapor pressure of the indium at diffusion temperatures would similarly decrease, and with it the C_o of the diffusion process. That this is actually the case is illustrated in Fig. 2 which shows the C_o for several diffusions using indium and tin-indium films on the germanium wafers. The values of C_o are based once more on junction depth measurements and an assumed diffusivity of $D = 1.5 \times 10^{-12}$ cm^2/sec at 875°C. The limits of probable error shown are largely due to uncertainty in the junction depth measurement, which was about ± 0.02-0.03 mil. The trend, however, is clear, demonstrating the variation of C_o which is possible with the method described.

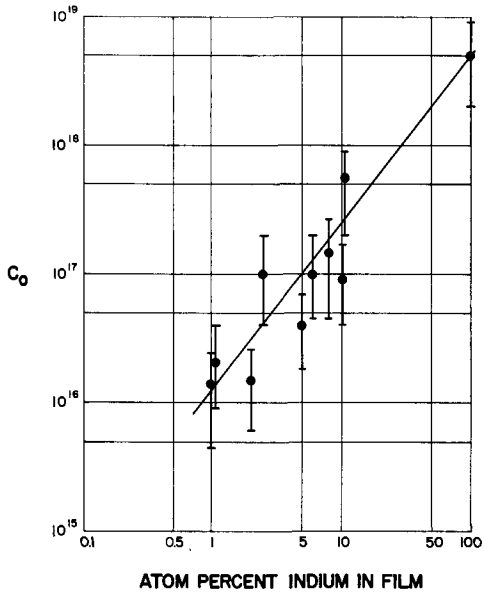

Fig. 2. Surface concentration C_o as a function of the evaporated film composition.

Tin was selected as the second metal to dilute the indium, partly because it is reportedly inert electrically in germanium (18) and partly because, due to its low vapor pressure, it did not itself evaporate appreciably during the longer diffusion runs. It should perhaps be pointed out that, although it is the atom percent of indium in the evaporated film which is plotted in Fig. 2, the actual molten film during diffusion was a ternary solution of indium, tin, and also germanium dissolved at the diffusion temperature. Thus the data presented apply only to the case described, in which the film is in physical contact with the germanium during diffusion.

Conclusion

The experimental results presented show that molten indium metal in contact with germanium can be used not only as a getter to prevent thermal conversion, but also as a simultaneous source of indium vapor for diffusion into the germanium. Furthermore, by diluting the indium with tin, the surface concentration of indium in the diffused skin can be reduced controllably. This, plus the fact that only a simple, one-zone diffusion furnace is required, makes the process an easy and practical one for producing diffused skins on germanium for diffused base transistor manufacture.

Acknowledgments

The authors are indebted to Mr. P. Ostapkovich for his advice and assistance in arranging the ex-

perimental work, and to Mr. B. Szabo for sheet resistance measurements.

Manuscript received Sept. 21, 1959. This paper was prepared for delivery before the Ottawa Meeting, Sept. 28-Oct. 2, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Technical Feature

The Double Layer in Electrochemistry[1]

A. N. Frumkin

Institute of Electrochemistry of the Academy of Sciences of the U.S.S.R., Moscow, U.S.S.R.

In every group of phenomena there is some specific feature which leaves its mark on the science dealing with these phenomena. As it seems to me, a specific feature of this kind in the case of electrochemical processes is the existence of the electric double layer at the metal-solution interface. Perhaps I am not quite impartial in this statement, as I, if I may say so, stood at the cradle of the double layer theory, but still I think that there are many elements of truth in it.

There is nothing exceptional in the fact that when two phases come into contact there appears a double layer at the interface. The ions, as any other solute, tend to be distributed between the phases in accordance with the difference in their standard chemical potentials. But, as their large electric charges inhibit the separation of ions in considerable quantities, the distribution equilibrium is secured by attaining a certain difference of electric potentials with a simultaneous formation of a double layer at the interface, which necessitates the transfer of but small quantities of ions from one phase to the other, provided the area of the interface is not very great. The laws governing the value of this equilibrium potential difference were established long ago by Gibbs and Helmholtz; for the form of these laws which is familiar to chemists we are indebted to Nernst and Lewis. The importance of these relationships cannot be overemphasized; however, one must keep in mind that they tell us nothing about the mechanism of the establishment of the potential difference or about the structure of the double layer being formed.

[1] Palladium Medal Address delivered at the Chicago Meeting, May 3, 1960.

At the present time we get our knowledge about the structure of the double layer in the first place from a-c measurements of electrode capacities or by other similar methods. Earlier data which I had to consider when I began to study this problem (more than 40 years ago) were based on measurements of electrocapillary curves, i.e., of the relation between interfacial tension σ and potential difference ϕ. In order to determine from these data the electric properties of the interface, one must use the Lippmann-Helmholtz equation

$$\frac{\partial \sigma}{\partial \phi} = -\epsilon \qquad [1]$$

where ϵ is the charge density on the metal surface.

The application of Eq. [1] to experimental data showed in a number of cases a rather complex relationship between σ and ϕ. The majority of scientists of that time thought that the double layer should behave as a flat condenser, i.e., that ϵ should be proportional to ϕ. They explained the deviations observed by the inaccuracy of Eq. [1], although the latter is strictly deduced from the principles of thermodynamics. Even such an authority in the field of chemical thermodynamics as van Laar held this view. Only the French physicist Gouy found a better approach to the theory of electrocapillarity. But Gouy worked at a provincial university at Nancy which he left but seldom, and his works were little known to scientists interested in physicochemical problems. In any case, when I presented a paper with the experimental confirmation of the correctness of Eq. [1] and some critical remarks on the

theory of van Laar to the "Zeitschrift für physikalische Chemie," it was at first rejected by the Editor.

In this paper the electric charges were determined from the current strength necessary for charging a growing mercury drop, just in the same way as it is often done at the present time, and $\partial\sigma/\partial\phi$ was calculated from electrocapillary curves (1). There still remained a contradiction which could not be removed for a long period of time: the double layer capacities as directly measured by Krüger, Bowden and Rideal, Erdey-Gruz and Kromrey always proved to be much smaller than the capacities calculated from electrocapillary data using Eq. [1] or found from experimental values of ϵ. This discrepancy seemed to be so firmly established that even attempts to give it a theoretical explanation were made. Thus a hypothesis was suggested according to which the capacity measured by means of an alternating current must be exactly equal to one-half the capacity obtained from electrocapillary data (2). However Proskurnin and Frumkin showed in 1935 (3) that the discrepancies observed were caused by a different and much more trivial circumstance, viz., the presence of organic impurities which penetrate the capillary of the capillary electrometer slowly, but easily reach the unprotected surface of a mercury electrode used in capacity measurements. It was found that when such impurities are carefully eliminated both methods of capacity determination give identical results. Overcoming the difficulties connected with capacity measurements in dilute solutions enabled us to find a capacity minimum at the point of zero charge, which was a strong confirmation of the theory of the diffuse double layer (4).

Somewhat later Grahame adapted the a-c method to capacity measurements on a growing mercury drop (5), which permitted the requirements to be lowered in respect to solution purity and to increase the precision of the method.

The demonstration of the correctness of the Lippmann-Helmholtz equation and the development of methods of direct capacity measurements formed a sound basis for the investigation of the structure of the double layer and for the verification of the theory of the double layer on the metal-solution interface. I shall not dwell here on the well-known history of the development of this theory which is associated with the names of Helmholtz, Gouy, and Stern. Considerable advances were made in the postwar period by David Grahame, whose untimely death was a great blow to all his friends and colleagues. By introducing the concept of a difference in the distances of closest approach of anions and cations to the metal surface, Grahame succeeded in giving a satisfactory picture of the relationship between the double layer structure and the concentration of the electrolyte for the case when ions are attracted by coulombic forces only, i.e., when the phenomenon commonly called specific adsorption is absent (6).

Such an agreement between theory and experiment is somewhat surprising, as the fact that the solution side of the double layer is composed of individual ions was not taken into consideration in the development of the theory, or in other words, the ionic charges were, so to say, smeared parallel to the metal-solution interface. Indeed, the theory developed on this basis cannot account for the experimentally observed dependence of the double layer structure on the concentration in the presence of a marked specific adsorption of anions. On my suggestion Esin and his collaborators (7) and later Ershler (8) attempted to work out a theory of a discrete double layer and to remove these discrepancies. Ershler's concepts recently were developed further by Grahame (9); several papers by Parsons (10) also are concerned with this problem. However, despite the efforts exerted, in my opinion we are not yet in possession of a fairly satisfactory quantitative theory of the double layer in which this discrete structure would be taken into account. Some success in this direction was achieved recently by Levich and Kiryanov (11).

Grahame supposed, following Gouy in this, that inorganic cations, unlike anions, do not display any specific adsorbability on the metal-solution interface; in the case of cations such an adsorbability was ascribed only to large organic cations. The investigations carried out in the past years at the Moscow University showed, however, that this assumption is not quite justified (12). Thus, the adsorbability of the Tl^+ ion on the mercury surface, as seen from Fig. 1, in which the electrocapillary curves for solutions of H_2SO_4 with additions of Tl_2SO_4 are shown, can be compared with that of the Br^- ion. A certain adsorbability also is displayed by the lead ions and a very small, although a clearly detectable one, even by the ions of the alkali metal Cs^+ (13). These phenomena are much more pronounced in the case of cation adsorption on the surface of the solid metal platinum (14). Proving the existence of a specific cation adsorption is, in my opinion, important in connection with the role that the adsorbed atoms (or adions) are supposed to play in the electrodeposition of metals (15-17).

The presence of a double layer at the mercury-solution interface affects a number of its properties, for instance interfacial tension, adhesion between metal and solution, and others. I shall discuss here only one of these properties, viz., mobility in an

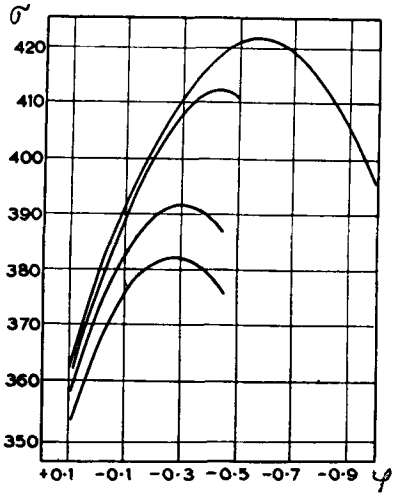

Fig. 1. Electrocapillary curves in N KNO_3 + 0.01N HNO_3 + x N $TlNO_3$ solutions. Curves from top to bottom: x = 0; 0.01; 0.1 and 0.2 (NCE).

electric field. When an electric field is applied, the mercury drop in the electrolyte solution comes into motion. The mechanism of this motion, first observed by Christiansen (18), essentially differs from that of the well-known electrokinetic motion. Its velocity, in the case of identical field tension and solution viscosity for drops having a radius a of the order of 1 mm, may exceed that of electrokinetic motion by five orders of magnitude. The mechanism of these movements is best illustrated by the simple example of an ideal polarized positively charged drop with a Helmholtz double layer. In this case, the distribution of the lines of force of the external electric field in the vicinity of the drop (Fig. 2) is similar to their distribution in the vicinity of an insulator, in other words they are tangential to the drop. Under these conditions the electric field acts on the outer sheet of the double layer, but not on the inner one, as the field tension within the metal is equal to zero due to its high electric conductivity. Thus, the effect of the field on the outer sheet of the double layer is not compensated for (to be more precise, it is compensated by the forces applied at a considerable distance from points B and D to the poles of the drop A and C). Under the influence of these forces the mercury in the drop comes into a vortical motion, as is shown in Fig. 3, and the reactive repulsion from the surrounding medium causes the drop to move along the field lines. The mathematical theory of this motion developed by Levich and myself (19) gives the following expression for the drop velocity v, the field tension at a sufficient distance from the drop being equal to E

$$v = \frac{a\epsilon E}{2\mu+3\mu^1+\epsilon^2/\kappa} \qquad [2]$$

where μ and κ denote the viscosity and the electric conductivity of the solution and μ^1 the viscosity of mercury.

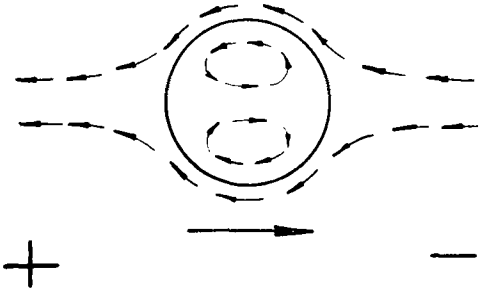

Fig. 3. Motion of a positively charged mercury drop in an electrolyte solution under the action of the electric field. The small arrows show the direction of the motion of the solution and mercury at any point, the big arrow, the direction of the motion of the drop as a whole.

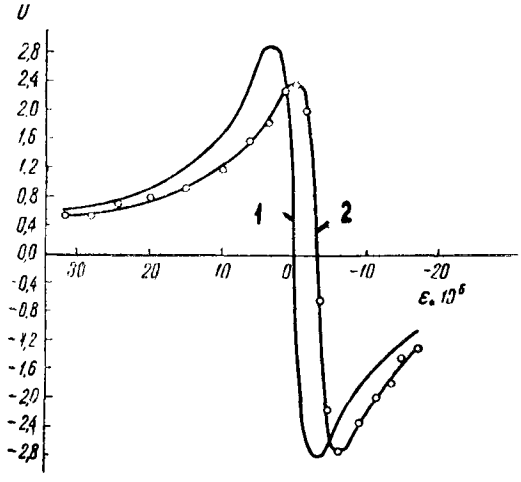

Fig. 4. Relationship between the mobility of mercury drops in a 0.02N KBr solution in glycerol and the charge density ϵ; $\kappa = 1.9 \times 10^{-5}$; $\mu = 2.8$. 1, Computed from Eq. [2]; 2, experimental data. μ in cm/sec v; ϵ in coulomb/cm^2.

Equation [2] was verified on mercury drops falling in a viscous glycerol solution and deflected by a horizontal electric field; definite electric charges were imparted to the drops before they broke off from the capillary (20). As seen from Fig. 4, the theoretical calculations are confirmed by experiments; the slight shift of the experimental curve is caused by the presence of oxygen traces which gradually made ϵ somewhat more positive (it is very difficult to remove oxygen completely from the viscous solution). For small values of ϵ, Eq. [2] gives mobility values of the same order as those which would be found in the case of a sphere having a free charge with the density ϵ. At first sight, this seems surprising, as the charge of the metal side of the double layer is completely compensated by the charges with an opposite sign which are located in the ionic sheet of the double layer. However, as I have already mentioned, a compensation of charges does not lead to a compensation of forces. With increase of ϵ, v increases, reaching a maximum at

$$\epsilon = \kappa^{1/2}(2\mu + 3\mu^1)^{1/2} \qquad [3]$$

and then decreases. This can be accounted for by the fact that the transfer of charges by the moving mercury surface results in an electric field directed opposite to the impressed field and diminishing its effect (this has not been taken into account in plotting Fig. 4, which therefore holds true only for small values of ϵ). A similar inhibiting effect is also observed in the case of a drop moving under the action of forces of a different nature, e.g., gravity, which results in a somewhat unexpected relationship between the velocity of the falling drop and its

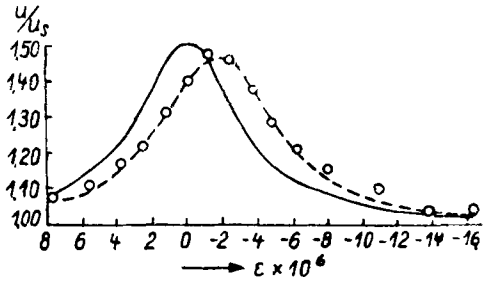

Fig. 5. Ratio of the rate of fall of a mercury drop in a glycerol solution saturated with Na_2SO_4 to that calculated by Stokes formula as a function of the charge density ϵ; $\kappa = 8.1 \times 10^{-6}$, $\mu = 7.2$. Solid curve, calculated values; circles, experimental data.

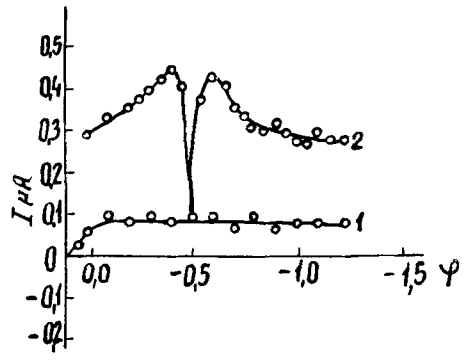

Fig. 6. C.v. curves in 0.28×10^{-4} N $Hg_2(ClO_4)_2$ + 0.002N $KClO_4$ corrected for charging current (NCE). 1, In the absence of an external field, 2, with the external field applied, E = 0.47 v/cm.

charge (21). A more detailed analysis permits us to conclude that in a viscous medium an uncharged drop must fall one and a half times faster than a charged one. The relationship between the velocity of the fall and the charge observed experimentally is compared in Fig. 5 with the theoretical dependence; the velocities of the fall are referred to that of a strongly charged drop, which is in accordance with Stokes law. The slight shift of the experimental curve with respect to the theoretical one can be accounted for quantitatively, if the depolarizing effect of the oxygen traces is taken into consideration.

The electrocapillary motion of droplets with metallic conductivity may arise in any electrolyte. A method was proposed recently to make use of this motion in extracting sulfide inclusions from molten slags (22).

Electrocapillary movements underlie the so-called polarographic maxima. The tangential movement of the drop surface calls forth an extra supply of the depolarizer which, according to Levich (23), is proportional to the square root of the tangential velocity. This fact makes it possible for currents in excess of the normal limiting diffusion current, which can be computed with the help of Ilkovic's equation, to pass through the cell. However, under the usual working conditions of a dropping electrode, the electric field causing the movement of the drop surface depends on complex geometrical conditions at the capillary tip; it is also influenced by the effect of convective diffusion of the depolarizer on the concentration polarization. Moreover the polarization curves are distorted by ohmic potential drops in the solution. Therefore the development of a quantitative theory of polarographic maxima presents great difficulties, which account for the chaotic state of this problem in modern polarographic literature. I shall not dwell here on the attempt made in this direction by myself and Levich, although, as it seems to me, we succeeded in explaining the basic features of the phenomena observed (24). I prefer to confine myself to the consideration of a case, when the polarographic maxima of the first kind may, so to say, be observed in an idealized form. To achieve this in the place of the mechanism of self-generation of motion, which is operative in the case of polarographic maxima of the first kind, we must provide a possibility to generate motion by means of an electric field which would be independent of the current on the drop. For this purpose a dropping mercury electrode was placed in an electrolyte solution and an electric field was applied to the latter by means of two subsidiary electrodes, the ratio of the supporting electrolyte and of the depolarizer concentrations being chosen in such a way that no polarographic maximum of the first kind should occur under normal conditions (25). The results obtained with 0.28*N* $Hg_2(ClO_4)_2$ + 0.002*N* $KClO_4$ are given in Fig. 6. Current-voltage curve 1 was obtained without the application of an external electric field, curve 2 with the application of a field having a gradient of 0.47 v/cm. This curve, which is of an unusual shape, is in close agreement with Eq. [2]. Its left-hand branch, corresponding to positive values of ϵ, greatly resembles the positive polarographic maxima of the first kind, as they are observed when the concentration of the supporting electrolyte is not too low. Polarograms obtained under normal conditions, however, show no second maximum at negative values of ϵ. I cannot discuss here the causes of this discrepancy, which, however, may be explained on the basis of the theory mentioned above (24).

The theoretical interpretation of the so-called maxima of the second kind, which depend on the flow of mercury out of the capillary, is much simpler than the interpretation of the maxima of the first kind. In this case, it is of fundamental importance to take into consideration the same inhibition of the surface motion by the double layer charges, which results in the decrease of the velocity of a falling charged drop. The maxima of the second kind play an important role in the theory of the rotating mercury drop electrode of Kolthoff and Okinaka (26).

Of special interest is the question about the relationship between the double layer structure and the nature of the metal. The latter may have an effect on the capacity of the Helmholtz layer as well as on the potential of zero charge. At the present time we are in possession of sufficient experimental data only on the second point. Let us consider first liquid metals. The information which we can obtain on this subject from measurements in

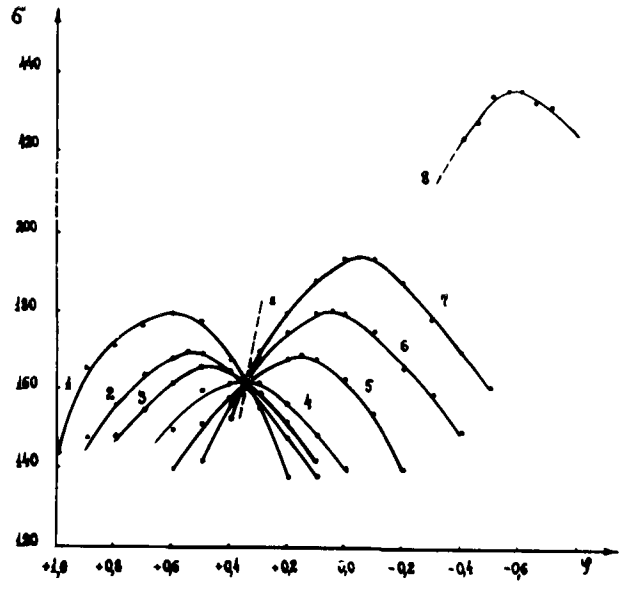

Fig. 7. Electrocapillary curves of Te-Tl alloys in LiCl + KCl. 1, Te; 2, 3.83 at. % Tl; 3, 10.9%; 4, 22.1%; 5, 42.3%; 6, 53.7%; 7, 65.2%; 8, Tl. Reference electrode Pb, LiCl + KCl, 0.1% $PbCl_2$.

aqueous solutions is naturally limited; we get more data with molten electrolytes. Electrocapillary phenomena in melts have been particularly investigated at the Sverdlovsk University (27). Electrocapillary curves for the Te-Tl system, plotted from measurements made by Kusnezov, *et al.*, are shown in Fig. 7. This system is characterized by an exceptionally great difference in the positions of the electrocapillary maxima, i.e., of the points of zero charge, which is as large as 1.25 v. The double layers at the metal-electrolyte interface at the point of zero charge being eliminated, the value given is similar in many respects to the Volta potential between the respective metals measured in vacuum (28). If the orientation of molecules of the solvent and the specific adsorption of ions are not taken into consideration, this value can be regarded as a kind of Volta potential in a material medium. I have already dealt with this problem in a paper which I presented at the 7th Annual Symposium on Colloid Chemistry at Baltimore about 30 years ago. At the present time a similar point of view is held by many electrochemists, e.g., Temkin (29), Rüetschi and Delahay (30). In my opinion, the determination of zero charge potentials gives the most direct answer to the question about the relationship between the difference of potentials between the poles of a galvanic cell with electrodes from different metals and the corresponding Volta potential, which has greatly attracted the attention of electrochemists since the beginning of the 19th century.

However, the similarity between the differences of zero charge potentials and Volta potentials does not necessarily result in a complete coincidence of these values, as the zero charge potentials may be influenced in a varying degree on the two electrodes by the preferential adsorption of one of the ions of the melt or by the orientation of the molecules of the solvent; the presence of a material medium may also have some effect on the distribution of the electronic cloud in the surface layer of the metal.

As a result of these complications the potential difference between water and mercury at the zero charge point of mercury is not equal to the sum of the galvani-potentials at the water-gas and vacuum-mercury interfaces, but exceeds it by an amount which was found by me to be equal to 0.30 v (31). Using more recent values of the Volta-potential between mercury and aqueous solutions (32), and of the zero charge potential of mercury (6) we get the value 0.26 v for this quantity. The assumption that the difference between the potentials of zero charge of two metals coincides with the Volta-potential between them is equivalent to the assumption that there exists a relationship between the zero charge potential and the electronic work function w, which can be expressed by the equation (33)

$$\phi_N - w = \text{constant} \qquad [4]$$

In accordance with the foregoing this relationship can only be approximate; it is not likely that one can make it more exact by introducing a certain coefficient before w, as has sometimes been suggested (34). The problem of the relationship between ϕ_N and w was recently discussed also in American literature (30, 35, 36). In the author's opinion, in order to verify these relationships at the present time, first it is necessary to be in possession of more exact experimental data both on the electronic work function and especially on the zero charge potentials.

The problem of investigating the double layer structure becomes more complicated when dealing with solid metals, although in the place of interfacial tension measurements, which cannot be carried out in this case, there appears an opportunity to study the effect of the double layer on such properties of metals as hardness (37-39), friction (40, 41), electrokinetic potential (42), stability of suspensions or sols. Unfortunately, the interpretation of results obtained from such measurements is not always as unambiguous as it is in the case of electrocapillary measurements. Very much was expected from capacity measurements on solid electrodes, in particular from the determination of zero charge potentials by means of the location of the capacity minimum in dilute solutions of electrolytes (43). However, the investigations carried out hitherto have only partly justified these expectations, as it is not always possible to obtain with solid metals capacity-potential (C,ϕ) curves comparable with those for mercury. Such a curve for the surface of a Zn monocrystal in 0.1N KCl (44), together with curves for Hg and liquid Ga (45) in the same electrolyte, is shown in Fig. 8. The capacity of the Zn monocrystalline surface within the frequency range of 1-10 kilocycles changes but little with frequency (by 5-8%) in contrast to what is observed in the case of polycrystalline zinc. This makes us suppose that the dispersion of the capacity, which interferes with capacity measurements on solid metals, is at least partially accounted for by the unevenness of the surface and the presence of micro-

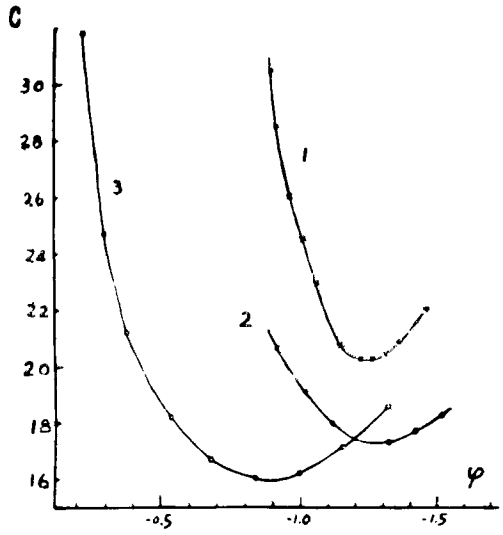

Fig. 8. Relationship between the differential capacity C and the potential ϕ in 0.1N KCl (NHE). 1, Zn monocrystal; 2, liquid Ga (according to Grahame); 3, Hg.

scopic cracks, although other explanations have been given to this phenomenon as well (46).

A curious inference can be made from determinations of zero charge potentials by means of the capacity minimum in dilute solutions (as well as from the hardness maximum) in the case of Pb and PbO_2 electrodes (47). The zero charge potential ϕ_N of PbO_2 is located at 1.8 v vs. NHE, the zero charge potential of Pb at —0.7; the difference between these two values is 2.5 v, which is even greater than the difference of potential between the poles of a lead storage cell.

With the help of capacity measurements Leikis has studied in detail the behavior of a silver electrode. As shown in Fig. 9, a pronounced minimum is observed in a dilute solution of Na_2SO_4 on the C,ϕ curve of silver; the silver wire had been subjected to cleaning with moist glass powder and boiling in an alkaline solution. This minimum disappears with an increase in solution concentration. The zero charge potential found in this way is equal to —0.7 v vs. NHE which coincides approximately with the results of electrocapillary measurments on molten silver

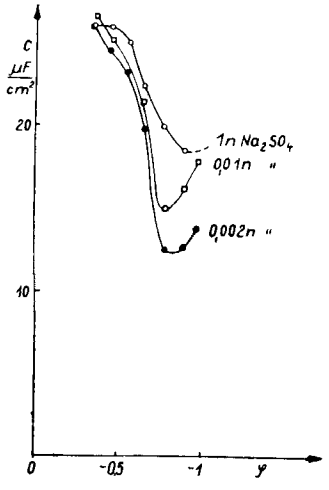

Fig. 9. Differential capacity of an Ag electrode in Na_2SO_4 solutions (NHE).

($\phi_N = -0.6$), but not with other data in the literature. The investigation of the effect of the solution concentration and of the presence of surface active anions and organic substances confirms the correctness of this ϕ_N value.

Leikis's experiments produced a noteworthy result. In electrochemical measurements wide use is made of a technique for cleaning electrode surfaces by means of vigorous cathodic polarization. But if a silver electrode is subjected to cathodic polarization in N Na_2SO_4 up to $\phi = -1.25$ v vs. NHE, the conditions of the surface, as it can be inferred from capacity measurements, change markedly, and at $\phi = -1.35$ v this change becomes irreversible. C,ϕ curves obtained with such an electrode differ widely from normal curves.

There exists still another reason why care must be exercised in interpreting the results of the measurements of C,ϕ curves when solid electrodes are used. In the presence of adsorbed hydrogen or oxygen on the electrode surface along with the double layer capacity a pseudocapacity is measured, the value of which depends on the exchange current between the adsorbed layer and the solution (48). In these cases the minima observed on C,ϕ curves may represent pseudocapacity minima and therefore tell us nothing about the zero charge potential. Apparently, such is the case with active platinum electrodes (49), and this accounts for the relationship observed between the location of the minimum on C,ϕ curves of Pt and the pH of the solution (50). While making measurements in dilute solutions at high frequencies Kabanov and Birinzeva could find no capacity minimum on platinum which could be interpreted as corresponding to the most diffuse state of the double layer at the point of zero charge (51). This is possibly due to a marked heterogeneity of the surface of an activated platinum electrode.

It is evident that in the case of an extremely heterogeneous surface the measurable potential of zero charge represents a certain mean value at which occurs the transition from a preferential anion adsorption to a preferential cation adsorption. Such a potential of zero charge does not necessarily correspond to the most diffuse structure of the double layer.

In the case of solid electrodes with a large surface, the formation of the double layer causes marked changes in the composition of the solution, which are known to produce errors in pH measurements with the help of platinized platinum electrodes if the system is insufficiently buffered. The determination of these changes in the composition can serve as a method for the investigation of the double layer structure. This method was applied successfully to such substances as platinum and activated carbon. Two results obtained recently may be mentioned in this connection. As the zero charge potential for platinum is more positive than the normal hydrogen potential, this metal is negatively charged when placed in a hydrogen atmosphere in acid solutions. The formation of the double layer, for instance in an acidified N Na_2SO_4 solution, is accompanied therefore by a transfer of hydrogen ions to the solution and by an increase in solution acidity, which can be

measured if platinized electrodes are used. However, in the presence of surface active halogen anions, the mechanism of the establishment of the equilibrium potential difference is changed; with the increase of the anion adsorbability the double layer formed by negative charges on the metal surface and cations attracted by them is replaced by a double layer with a negative sheet formed by adsorbed anions. In the case of a *N* NaI-solution acidified up to *p*H ~ 3, as has been found by Balashova and Kasarinov (52), the potential difference due to the adsorption of anions becomes so great that at the equilibrium hydrogen potential the sign of the charge of the platinum is reversed. Under these conditions the formation of the double layer is accompanied by a decrease in the solution acidity, and not by an increase in the latter.

A hydrogen electrode with a still better developed surface can be made by depositing some platinum on the surface of activated carbon. Such platinized carbon in a hydrogen atmosphere adsorbs from neutral solutions of salts considerable amounts of cations, which are replaced by hydrogen ions. The magnitude of the adsorption effect depends on the final *p*H of the solution just as would be expected from the theory outlined, if one assumes that ϕ_N for "hydrogen" carbon is equal to 0.03 v (53).

The idea according to which the electrolyte adsorption on activated carbon is a process connected with the establishment of the equilibrium potential difference was met with opposition. A number of scientists preferred to interpret these phenomena on the same lines, as is done in the case of adsorption on ion exchange resins, i.e., without taking into account the electronic conductivity of carbon. However, the "electrochemical" theory of electrolyte adsorption on carbon received recently a conclusive corroboration in the investigations carried out by Strazhesko at the Ukrainian Academy of Sciences in Kiev (54). Strazhesko found that the acidification caused by cation adsorption from solution increases markedly (2-3 times), when solutions in nonaqueous solvents, e.g., acetone, are used instead of aqueous ones. Such a phenomenon, quite inexplicable on the basis of the "chemical" theory of electrolyte adsorption on carbon, can be interpreted, if one assumes that the zero charge potential of carbon, as well as that of mercury, is shifted toward more positive values when molecules of acetone are substituted for those of water. In this case at the reversible hydrogen potential the carbon surface must really carry a more negative charge in a nonaqueous solvent.

An original method for the determination of the zero charge point of platinum was proposed recently (42, 55). The presence of the diffuse double layer causes two metallic surfaces in an electrolyte solution to repel and prevents them from drawing together. Voropaeva, Derjaguin, and Kabanov measured the force necessary for establishing at different potentials a conducting contact between two crossed platinum wires immersed in a dilute KCl solution. As seen in Fig. 10, there is a pronounced minimum on the curve showing the relationship

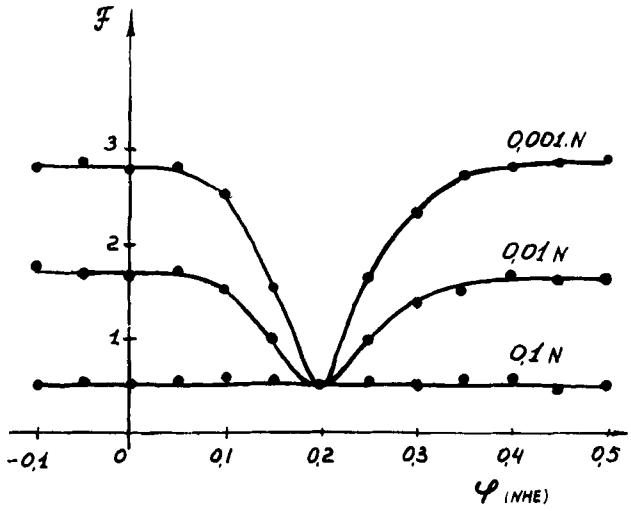

Fig. 10. Relationship between the potential and the force F, which must be applied in order to establish a contact between two platinum wires in KCl solutions.

between the force and the potential, at the zero charge potential. The value of ϕ_N found in this way is in good agreement with the results of adsorption measurements. It is not quite clear why in this case we do not meet with the difficulties, which were encountered during the attempts to determine the location of the zero charge potential of platinum from the capacity minimum in dilute solutions.

When dealing with the problem of points of zero charge, the supposed existence of an essential difference between the case of a reversible electrode and that of an ideal polarized one has been sometimes mentioned in the literature (30, 56). It seems to me however that there are no theoretical grounds for such a differentiation (39). Although the mechanism of the formation of the double layer in these two cases is, generally speaking, different, its structure and, consequently, the physical meaning of the zero charge potential must be similar. In accordance with this it was possible to show that the change in the double layer capacity with electrolyte concentration at the zero charge potential of thallium amalgams in dilute solutions of electrolytes proceeds in conformity with the same laws as those for mercury, although the equilibrium concentration of Tl^+ ions in the solution at the zero charge potential reaches in this case a measurable value (57).

The concept about the existence of the electric double layer was not made use of in the first investigations of the kinetics of electrochemical processes. This could not have been expected, since at the time the net velocity of electrochemical processes was associated with purely chemical or diffusion steps. Only after the idea of the finite velocity of electrochemical steps proper and of their dependence on the interfacial potential difference had been introduced in the theory of electrode processes (Audubert, Butler, Erdey-Gruz, and Volmer), did it become possible to combine the double layer theory and the principles of electrochemical kinetics. The first attempt in this direction was seemingly made by the author (58); it was supposed

that the reacting particles follow the Boltzmann distribution law and that only a part of the potential difference is effective in determining the rate of the process. The original conclusions referred to the case of the hydrogen ion discharge. If we generalize the expression obtained for the case when an electron is transferred to a particle carrying n charges, where n can be either positive or negative, the result assumes the following form (59)

$$i = \mathrm{K} \exp\left[-\alpha(\phi-\phi_1) - n\phi_1\right] F/RT \qquad [5]$$

where i is the current density, c the bulk concentration of the reacting particle, if necessary corrected for concentration polarization, and α a constant satisfying the condition $0<\alpha<1$. The problem of the physical interpretation of the value α is yet open to discussion and in practical use of the equations of electrochemical kinetics α must be considered as an empirical constant. An accurate determination of the meaning of ϕ_1 is of great importance. The value ϕ_1 was regarded primarily as the potential in the center of the charge of the reacting particle at its equilibrium location in the Helmholtz layer, although the possibility to refer it to the location of the charge center in the transition state of the reaction should be considered too.[2] As was shown by the experiments of Bagozky (62) and others, Eq. [5] expresses exactly the relationship between the H_3O^+ ion discharge rate in KCl + HCl solutions and the concentrations of the components, if the value ϕ_1 is considered as the potential in the plane of the closest approach of cations to the electrode surface and this potential is computed on the basis of the classical theory of the diffuse double layer. Thus, neglecting the details of the double layer structure involves no great errors in the case when the reacting particle is an H_3O^+ cation, repelled by K^+ or H_3O^+ cations which form the ionic sheet of the double layer. However, much greater difficulties were encountered, when a different group of reactions was considered, i.e., the electroreduction processes of multivalent anions, during which the reacting particles are attracted by the ions present in the ionic sheet of the double layer. These reactions, which have been studied in detail in Moscow since 1949, are characterized by an anomalous form of c.v. curves (59, 63). Namely, the usual increase in the current, which occurs when the cathodic polarization is increased, is followed by a sharp falling off, taking place at potentials in the vicinity of the zero charge potential or more negative than the latter. When the potentials become still more negative, the current rises again. In many but not in all cases (64) these anomalies disappear with an increase in the concentration of the supporting electrolyte. As an example of these anomalous c.v. curves, a curve for the reduction of the $S_2O_8^{2-}$ ion on an amalgamated rotating disk electrode in the presence of $0.01N$ Na_2SO_4 is shown in Fig. 11.

The pecularities of the electroreduction of multivalent anions are explained by the repulsion between the reacting particle and the negatively

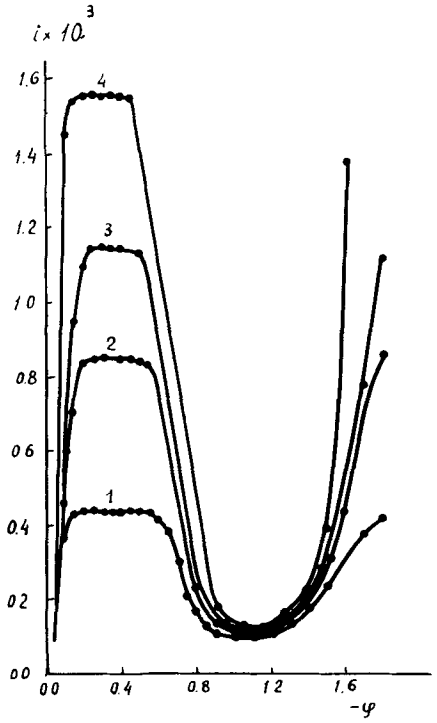

Fig. 11. C.v. curves for the reduction of 10^{-3} N $K_2S_2O_8$ in the presence of 10^{-2} N Na_2SO_4 on a rotating amalgamated disk electrode. Rates of rotation: 1, 650; 2, 2800; 3,5000; 4, 9000 rpm.

charged electrode surface. In Eq. [5] this effect is accounted for by the term containing ϕ_1; in fact, it is easy to show, that at $n = -2$ or $n = -3$ and with a reasonable value assumed for α, Eq. [4] represents a c.v. curve with a minimum in the region of potentials corresponding to negative surface charges. Although in some cases the experimental c.v. curves, corrected for concentration polarization, can be expressed even quantitatively by means of Eq. [5], a more detailed study of this problem shows that the concepts used as a basis in the derivation of this equation in this case are insufficient. As it is beyond the scope of this paper to discuss all the aspects of the problem, which, moreover, have been dealt with lately in a number of reviews (65), I intend to mention only the following point. Equation [5] is derived on the assumption that within the double layer the reacting particles follow the Boltzmann distribution law. As Levich's calculations have shown (66), this distribution cannot be realized at sufficiently high current densities in the case when the sign of the charge of a reacting multivalent particle is opposite to that of the charge of the electrode surface, if the distribution of potentials is in accordance with the classical theory of the double layer. In fact the rate of the penetration of such particles through the double layer and therefore the rate of their transfer from the bulk to the electrode surface under the conditions stated would be insufficient. Moreover the theoretical rate values obtained under these assumptions are several orders of magnitude lower than those observed.

It seems to me that the only way to overcome this difficulty is to take into consideration the discrete

[2] An equation similar to Eq. [5] and differing from the latter only in that 1/2 is substituted for α, was recently deduced on a different basis, that of a theory developed by Marcus (60, 61).

structure of the ionic sheet of the double layer and the interaction between the reacting anions and the neighboring cations. Another solution of this problem would be to assume that not those anions which are predominant in the bulk of the solution react on the cathode, but ionic pairs with a smaller charge, as, for instance, the $MeS_2O_8^-$ ions in the case of a $Me_2S_2O_8$ solution (66, 67) and $Me_2Fe(CN)_6^-$ ions in the case of a $Me_3Fe(CN)_6$ solution. But difficulties are encountered if we are to follow this hypothesis consistently, i.e., improbably low values must be ascribed to α. Furthermore the thickness of the reaction layer in the case of reactions of the type

$$Me^+ + S_2O_8^= \rightleftharpoons MeS_2O_8^- \qquad [6]$$

in all probability is so small that the formation of those ionic pairs which react on the electrode must take place within the double layer. Thus, if we accept this assumption, we still must make an allowance for the interaction between oppositely charged ions within the double layer.

It appears that in that range of potentials for which reliable determinations of the c.v. curves can be made, it is possible to account for the phenomena observed during the reduction of multivalent anions by means of the theory of slow discharge, taking into account the formation of cationic bridges in the double layer. But involuntarily one is led to think that at sufficiently negative potentials a different mechanism of the electrode process is possible, consisting of a transfer of electrons from the electrode to particles located at distances comparable with the thickness of the diffuse double layer. As such a transfer would remove the difficulties connected with the repulsion of anions by the electrode surface, it would seem that in the case of anion reduction the most favorable conditions for such a mechanism are realized. Gurney was the first to point out the possible role of such electronic transfers in discharge processes (68), although the example chosen by him–the hydrogen ion discharge–was undoubtedly not suitable, as the high value of the adsorption energy of the product of the reaction–the hydrogen atom–makes the discharge at a distance from the metal surface energetically unfavorable. We must admit however that the feasibility of such transfers even in the case of anion reduction has not hitherto been corroborated by experiment, although we do not have sufficient reasons to deny their reality in the case when the cations of the electrolyte, as for example Li^+ cations, have a relatively low tendency to form ionic pairs. The research work in this direction must be continued, particularly taking into account what is known about the existence of solvated electrons in many solvents. Generally speaking, it may be said that the state of our knowledge about the transfer of electrons over long distances in the case of electrode processes is about the same as in the case of redox reactions occurring in the bulk of the solution.

The idea of the importance of the structure of the double layer for the kinetics of electrode processes has gradually become firmly established in electrochemistry, as for instance is shown by the review of Breiter, Kleinerman, and Delahay (69). However, one must mention the progress made in research in another, at first sight opposite, direction. Investigations carried out after the war, in particular in Czechoslovakia, have shown that the net rate of a great number of electrode processes is determined by chemical reactions resulting in the formation of an electroactive substance from inactive components in the bulk of the solution and therefore, as it would seem, independent of the double layer structure. At present it appears, however, that such a contraposition of these two concepts would be incorrect, as in a number of cases the thickness of the reaction layer becomes comparable with that of the diffuse double layer (70). Under these conditions it is necessary to take into consideration the effect of the electric field of the double layer upon the kinetics of the process, although it is a chemical and not an electrochemical one. Unfortunately we know as yet very little how this is to be done.

I have dealt hitherto only with the direct effect of the double layer on the reactions on the electrode. But its indirect effects are perhaps of still greater importance. The adsorption of surface active ions and of neutral molecules depends on the electric field of the double layer and these ions and molecules, in their turn, may act as catalyzers or inhibitors in electrochemical processes. It would be beyond the scope of the present paper to dwell on this problem, the study of which has given us many conclusive proofs of the existence of a close connection between the structure of the interface and the kinetics of the electrode processes (71, 65). However, I want to consider at least one particular case, that of the adsorption of anions which do not take a direct part in the electrode process. I have chosen this case because its consideration brings us, in a sense, to the limits within which we may use those very elementary concepts on whose basis Eq. [5] and some other similar relationships were deduced. In accordance with Eq. [5] the specific adsorption of anions must shift the ϕ_1 — potential toward more negative values and consequently increase the velocity of the processes of cation reduction. As might be easily proved, this conclusion holds for anodic processes of cation formation as well. It was first confirmed in the work of Jofa, Kabanov, *et al.*, for the case of the discharge of hydrogen ions on a Hg cathode (72) and later for a number of other reactions, many of which are well known from polarographic literature (73). However, at present, we know that in some cases the adsorption of anions on solid electrodes results not in an acceleration, but in a retardation of reactions of discharge and of formation of cations (74, 75). Thus, the adsorption of the Br^- ion and particularly of the I^- ion greatly retards the ionization of H_2 on a Pt electrode (76, 77), as well as the ionization of the hydrogen on the β phase of the Pd-H system (78). Apparently, the bond between the adsorbed anion and the metal surface becomes so firm in these cases that it is the modification of the properties of the electrode surface by the adsorbed

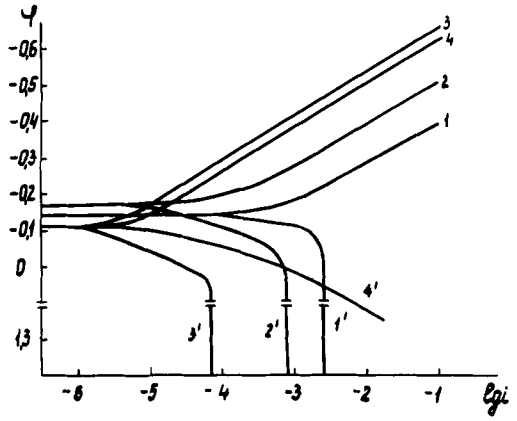

Fig. 12. Cathodic and anodic c.v. curves for stainless steel. 1, 1^1 10N H_2SO_4; 2, 2^1 10N H_2SO_4 + 0.01N KBr; 3, 3^1 10N H_2SO_4 + 0.001N KI; 4, 4^1 10N H_2SO_4 + 0.2N KI. The potentials are referred to a hydrogen electrode in 10N H_2SO_4.

anions, which results in a kind of passivity, that is of principal importance and not the change in the distribution of the potential in the double layer. This passivity probably is caused by the saturation of the free valencies of the electrode surface by chemisorbed anions and is accompanied by a decrease in the double layer capacity (79). The fact that this phenomenon is observed with solid electrodes only suggests that it is connected somehow with the presence on the electrode surface of active centers with high values of adsorption energies which strongly influence the kinetics of the process. An interesting example of this kind of action of anions is seen in the behavior of a stainless steel with 17% Cr and 9% Ni in the presence of I^- ions (80). As shown in Fig. 12, the addition of I^- ions to 10*N* H_2SO_4 increases the hydrogen overvoltage and facilitates the anodic passivation of steel. The inhibition of the cathodic and anodic processes results in a great diminution (4000 times) in the rate of the spontaneous dissolution of this steel in 10*N* H_2SO_4. The dissolution rate passes through a minimum at a I^- ion concentration of about 0.01% and increases again with further increase in the latter, not attaining, however, its original value. As it appears to me, these results show conclusively that metal passivation does not necessarily involve the covering of the surface with a protective layer forming a phase.

The investigation of the effect of anions on the kinetics of electrode processes permits us to draw the conclusion that the development of the theory of the double layer on the basis of purely electrostatic concepts must be considered as only a step in the building up of a surface chemistry of metals on a wider scale.

My address was concerned with the double layer on the metal-solution interface, but in order to understand their electrical properties it is essential to compare phenomena occurring on different kinds of interfaces. In a paper presented at the 7th Symposium on Colloid Chemistry I gave particular consideration to the comparison between the orientation of organic molecules on the metal-solution and solution-gas interfaces. It is very instructive as well to compare the results of electrocapillary measurements in solutions containing aromatic compounds (71, 81) with the results of determinations of the electron work function in the presence of adsorbed layers of molecules of this kind (82). Great attention has been paid lately to the problems of the semiconductor-vacuum and the semiconductor-electrolyte interfaces. The application of ideas developed in the investigation of the metal-electrolyte interface to the study of these interfaces has already given important results and undoubtedly will be still more fruitful in the future.

Brief Communications

Preparation of Solid Electrodes for Hydrogen Overpotential Studies

A. C. Makrides and M. T. Coltharp[1]

Metals Research Laboratories, Union Carbide Metals Company, Division of Union Carbide Corporation, Niagara Falls, New York

The importance of minimizing the amount of impurities in solution in hydrogen overpotential measurements has been stressed repeatedly (1). Following the example of Frumkin and his co-workers (2), pre-electrolysis is used extensively to this end. In purified solutions, hydrogen overpotential on mercury follows the Tafel equation with closely reproducible exchange current and Tafel slope (3). Results with solid electrodes vary widely, however. Deviations from Tafel behavior and time dependence of the overpotential at any given current density have been reported frequently (4, 5).

We have measured hydrogen overpotential on nickel ("spectroscopic" purity) by the direct method. Unlike previous work with this system (6), results were time independent and coincident curves were obtained with increasing and decreasing current densities. This study will be reported in detail later. The method used to prepare electrodes, which we believe applicable to similar studies with other metals, is presented here.

Nickel electrodes were cleaned by immersion in a chromic-sulfuric acid solution ("cleaning solution"), followed by washing with boiling conductivity water. Upon immersion in alkaline (0.1*N* NaOH) test solutions, electrodes exhibited passive potentials (>0.200 v vs. hydrogen in the same solution). They were activated by cathodic polarization at 2 ma/cm^2 for about 5 min. Rest potentials were within 2-3 mv of the reversible hydrogen potential. After a run, which generally required about 100 min, the electrode was passivated by anodic polarization at about 40 μa/cm^2 and left in this condition until the next run whereupon the electrode was again activated by cathodic polarization as described above. Reproducible results were obtained over a period of about two days. For longer times, the rest potentials became increasingly positive and overpotentials became time dependent, particularly at higher current densities. It is probable that for the longer times adsorbed impurities, probably dissolved glass, were not removed by passivation (anodic polarization to 1.0 v).

The Tafel slope was 0.110 v at 30°C, not much different from that reported by Bockris and Potter in their study of hydrogen overpotential on nickel (6). However, the exchange current in 0.1*N* NaOH was 1.5 x 10^{-5} amp/cm^2, i.e., about 30 times larger than 5 x 10^{-7} amp/cm^2 given in (6).

The possibility that these results can be attributed to a film of high specific area formed by reduction of the passive layer was ruled out by runs in 0.1*N* HCl. In this solution nickel activates spontaneously, the oxide apparently dissolving. The electrode was in solution for about 4 hr. It corroded at a rate of about 4 x 10^{-5} amp/cm^2 with a rest potential of —0.014 v against hydrogen. The equivalent of about 300 surface layers (~ 180 x 10^{16} atoms) dissolved during this time. Results were entirely analogous to those in alkaline solutions, i.e., overpotentials were time independent and ascending and descending curves agreed closely. The Tafel slope, 0.100 v, was essentially that reported in (6) while the exchange current was 5 x 10^{-5} amp/cm^2, or about 40 x the value 1.2 x 10^{-6} given in reference (6)

The time dependence of the overpotential, the inability to retrace a polarization curve with the same electrode, the deviation from the Tafel relation of the steady-state curves, and the low exchange currents reported in (5) and (6) must therefore be attributed to impurities adsorbed on the electrode,

[1] Present address: Department of Chemistry, University of Texas, Austin, Texas.

probably prior to its exposure to solution. Electrodes were pretreated in (6) by heating in hydrogen at about 350°C.

Common methods of preparing solid electrodes involve either etching or heating in hydrogen at temperatures below the softening point of borosilicate glass (6). Etching does not remove all impurities, a fact demonstrated by the existence of a variety of compounds which inhibit dissolution. Heating in vacuum or in hydrogen apparently is not effective unless temperatures approaching the melting point of the metal are used ("flashing") (7). In the method presented here the electrode is exposed to highly oxidizing conditions. Impurities are probably displaced by negative ions at the large positive potentials (> 1.0 v) attained. Further, it is generally found that organic impurities are adsorbed to a smaller extent on oxides than on metals; at the same time, they are adsorbed less strongly in the oxidized than in the reduced form (8). It is expected, therefore, that on reducing or dissolving the passive layer a "clean" electrode surface is produced.

"Active," reproducible platinum electrodes have been obtained by anodic polarization (9). Recently, Walker and Adams (10) cleaned platinum electrodes for polarographic studies in a manner similar to that presented here. This method can be employed with all metals which do not dissolve markedly under highly oxidizing conditions and which can be activated by a cathodic current. The surface can be regenerated after one or more runs if the metal passivates in the test solution at small anodic current densities (for example, nickel in *0.1N* NaOH).

Periodic Phenomena at a Nickel Electrode in Sulfuric Acid

Jörg Osterwald[1] and Heinz-Gerhard Feller[2]

Corrosion Laboratory, Department of Metallurgy,
Massachusetts Institute of Technology, Cambridge, Massachusetts

In connection with electrochemical investigations of nickel-copper and chromium-nickel-iron alloys we observed positively and negatively damped oscillations occurring at the nickel electrode in sulfuric acid. This type has not yet been described in the literature, although periodic phenomena at a nickel electrode are known (1, 2). Although investigations of this new type could not be completed during our stay in the United States, we should like to summarize the most important experimental results obtained so far.

The polarization curve for transpassive nickel in *1N* sulfuric acid at 25°C obtained potentiostatically is shown in Fig. 1. If one tries to measure the same curve galvanostatically, this is only possible for current densities below A. Above A the electrode potential does not become stable, but oscillations occur. Near A these oscillations are almost sinoidal (see right part of Fig. 2b), while they become more and more deformed with higher current densities. If one increases the current density beyond B, the potential jumps to a value lying above C on the other branch of the polarization curve. This phenomenon is remarkable, because usually the other

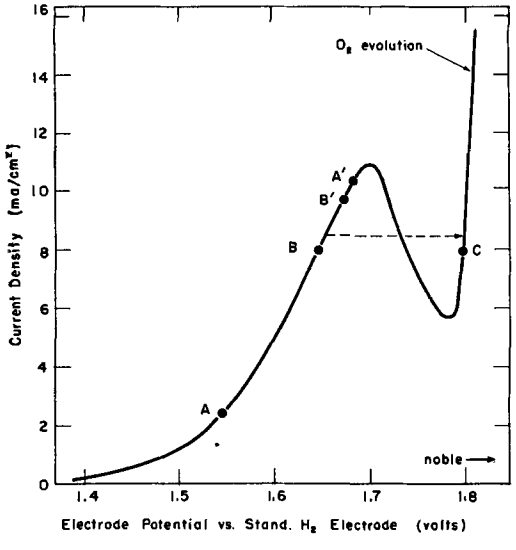

Fig. 1. Polarization curve of nickel in the transpassive region at 25°C obtained potentiostatically.

branch of a polarization curve can only be reached by applying a current density greater than the value related to the maximum.

As already mentioned, a constant potential is obtained below A under galvanostatic conditions, but

[1] Present address: Max-Planck-Institut für physikalische Chemie, Göttingen, Germany.
[2] Present address: Institut für Metallkunde der Technischen Universität, Berlin, Germany.

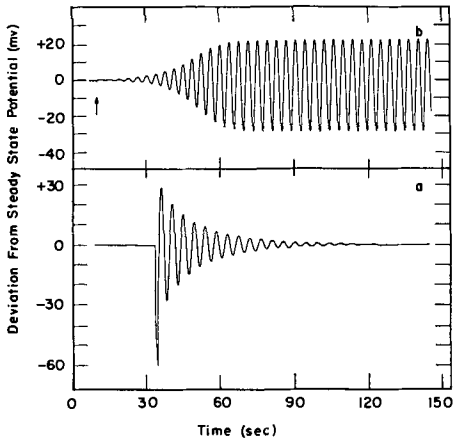

Fig. 2. Oscillations of potential under galvanostatic conditions (original oscillograms); T = 25°C. a, Damped oscillations, c.d. = 2.26 ma/cm²; b, negatively damped and steady oscillations, c.d. = 2.87 ma/cm².

a small positive or negative additional current pulse stimulates damped oscillations (Fig. 2a). With the exception of the first oscillations after the stimulating pulse the deviation ΔU from the steady-state potential may be described by the following equation:

$$\Delta U = \Delta U_0 e^{-\lambda t} \cos (2\pi\nu t + \delta)$$

ΔU_0 depends on the height of the pulse, while the damping constant λ and the frequency ν are only functions of the current density applied continuously. The phase angle δ depends on the zero point of the time scale.

In the region above A, oscillations occurring with increasing amplitude or, in other words, with negative values of λ can be observed by means of a special technique. A potential of the region above A is applied potentiostatically to the electrode. Then the galvanostatic circuit is adjusted to a current density equal to that which corresponds to the potentiostatically applied potential. If one now applies this current density to the cell immediately after having disconnected it from the potentiostatic circuit, one observes sinoidal potential oscillations, which eventually turn to steady oscillations. Figure 2b gives an example. The arrow marks the point at which the cell was switched from the potentiostatic to the galvanostatic circuit.

Using the same technique we found that above B' in Fig. 1 again steady oscillations occur under galvanostatic conditions, while above A' damped oscillations can be observed.

With decreasing acid concentration the whole region between A and A' becomes smaller, until first the region between B and B' disappears and finally at approximately 0.3*N* sulfuric acid only damped oscillations occur. The damping constant λ, however, has a minimum at a certain current density, to which a maximum of the frequency corresponds approximately.

A more quantitative description of the phenomena and an attempt at a theoretical explanation will be given after further information has been obtained, especially for the dynamic behavior of the nickel electrode under potentiostatic or other than galvanostatic conditions.

Conductivity of Silver Iodide Pellets for Solid-Electrolyte Batteries

J. N. Mrgudich[1]

Laboratory for Insulation Research, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

Silver amalgam electrodes were found to provide polarization-free contacts for the measurement of the conductivity of compressed AgI powder pellets. Correlation of the conductivity data with x-ray diffraction studies established the presence of a deformed hexagonal phase as an important factor in determining pellet conductivity. Deformation can be induced by compression, but care must be taken to avoid transformation into the face-centered cubic phase with some resultant decrease in conductivity. Preliminary evidence is presented that hexagonal deformation can be induced by suitable thermal or mechanical pretreatment of the AgI powder.

Lehovec and Broder (1) showed that thin sections of certain solid ionic conductors can serve as electrolytes of electrochemical battery systems. Such "solid-electrolyte" batteries, because of inherently easier control and confinement of the electrolyte, promise significant improvement over conventional batteries using liquid electrolytes.

Some of the advantages are illustrated by a cell made by the author in December 1952. Its active components were a sheet of Ag foil as anode, a pellet of compressed AgI powder as electrolyte, and a pellet of 50% AgI and 50% African MnO_2 as cathode. Cross-section diameter was 1.27 cm and overall volume was about 0.15 cc. Despite this small volume the open-circuit voltage, after nearly six years of unsealed storage at ambient room temperature, dropped by only 4% (from 0.56 to 0.54 v) since February 1953. The short-circuit flash current remained substantially constant at 17 μamp. The Ag electrode, except at its periphery where atmospheric oxygen resulted in tarnishing, remained uncorroded.

The most serious shortcoming of such solid-electrolyte systems is their very low flash current, usually measured in μamp/cm^2 of electrode area. This manifestation of high internal resistance follows directly from the fact that the room-temperature conductivity of even the best solid ionic conductors lies six to eight orders of magnitude below that of conventional battery electrolytes. In consequence, unless the room-temperature conductivity of suitable solid ionic conductors can be increased by at least four orders of magnitude, the practical use of the otherwise eminently promising solid-electrolyte batteries will be limited to microwatt power applications.

The purpose of this investigation was to study and develop methods for increasing the room-temperature ionic conductivity of AgI. Silver iodide was chosen because of its reported relatively high room-temperature ionic conductivity, its apparently simple conduction process which involves only Ag^+ ions moving through a fixed I^--ion lattice, and the substantial absence of interfering electronic conduction.

[1] Present address: U.S. Army Signal Research and Development Laboratory, Fort Monmouth, N. J.

Unfortunately AgI is not easily prepared in the form of single crystals stable at room temperature, and there is today little theoretical interest in conductivity measurements on compressed powders. Nevertheless, in view of eventual applications which will of necessity resort to the use of multicrystalline electrolyte in the form of compressed powders, evaporated films, chemical deposits, or painted layers, measurements on such powders and efforts to increase their ionic conductivity are meaningful in a practical sense. Furthermore, multicrystalline electrolytes profit from increased ionic mobility along interfacial surfaces so that, even if single crystals were available, there would be a need for study of the conductivity of compressed powders.

Polarization Phenomena in Measurements of Ionic Conductivity

It is well known that if a d-c voltage is applied across an ionic conductor, the resultant flow of current decreases with time (2, 3). To avoid such polarization effects, a-c voltage (usually 1000 cps), four-probe sample holders, pulse techniques, or combinations thereof are applied. These measures may be adequate when sample temperature is high or when sample conductivity is low. However, blocking layer effects become more pronounced as the temperature drops or as conductivity increases. Brennecke (4), for example, confirming earlier work by Lehfeldt (5), found that d-c conduction through various alkali halides obeys Ohm's law at high temperatures but begins to deviate as temperature decreases. Johnston (6), studying AgBr at room temperature, reported that the a-c conductivity was a function of frequency (even up to 10,000 cps) and that this dependence increased with samples of higher conductivity (about 10^{-7} ohm^{-1} cm^{-1}). There is thus no certainty that conventional methods for minimizing polarization are adequate for a study whose objective is the synthesis of materials exhibiting extraordinarily high ionic conductivities (about 10^{-8} or better) at room temperatures.

Use of Amalgamated Silver Electrodes

In the course of some preliminary studies it was found that application of quite small d-c voltages

across an AgI pellet between identically amalgamated Ag electrodes yielded a remarkably stable current flow. This constancy led to efforts to use such amalgamated electrodes in the development of an apparently polarization-free d-c method for the measurement of the conductivity of AgI pellets.

The amalgamated electrodes were prepared by rubbing Hg onto disks of clean and polished Ag sheet (1.525 cm diameter, approximately 0.15 cm thick). Just before use the electrodes were wiped clean and residual scum removed by rinsing the surface with clean, distilled Hg dropping from a burette.

Pellets of AgI (1.525 cm diameter) were made by compression in a hand-actuated laboratory press (capacity 1120 kg/cm², 16,000 psi). Since the objective was to carry out extensive tests of the reproducibility of a new method, we required ready availability of a relatively large amount of uniform AgI. Most of this work used two different grades of powdered, commercial AgI made homogeneous by thorough mixing after passing through a 35-mesh screen. After compression, the pellets were gently smoothed with 3/0 emery paper to remove peripheral feathering and surface glaze. Then they were placed between identically amalgamated Ag electrodes backed by Pt electrodes to prevent solder contamination of the amalgamated electrodes (Fig. 1).

The voltage across the array could be changed by adjusting the value of the decade-box resistance R_2. Three voltage ranges (0.0001, 0.001, and 0.01 v) sufficed for most of the work. The galvanometer (Leeds and Northrup, D'Arsonval, 0.008 μa/mm deflection at 1 meter) was calibrated for each voltage range by use of a standard calibrated decade resistance replacing the array. Switch S served as an easy means for reversal of current direction to check for the presence of polarization.

Figure 2 compares the results of conductivity measurements on a given pellet of AgI between clean, polished Ag electrodes before and after electrode amalgamation. The slight upward trend of the

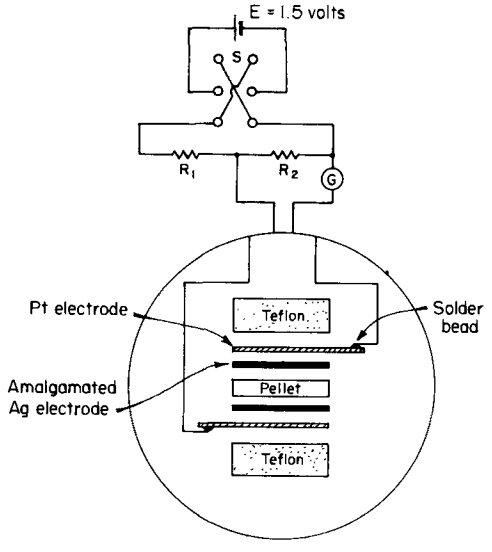

Fig. 1. Exploded view of conducting array, with circuit used to permit easy reversal of applied d-c voltage.

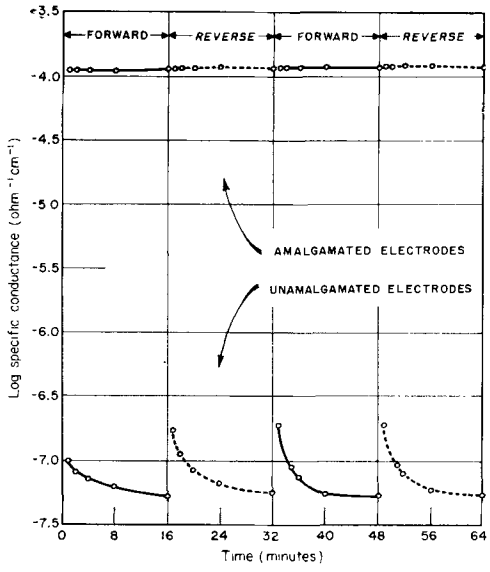

Fig. 2. Elimination of polarization through use of amalgamated silver electrodes.

amalgamated-electrode curve is undoubtedly due to an observed 1°C rise in room temperature during the 64-min run. The lesser fluctuations within each 16-min run fall easily within the errors induced by small random variations of the galvanometer zero. These fluctuations, however, are trivial when viewed in the perspective of Fig. 2 and its very strong evidence of absence of polarization with amalgamated electrodes.

Considerable time and effort were spent in demonstrating that this method allows for the reproducible determination of the conductivity of AgI at room temperatures. Repeated assembly, measurement, disassembly, electrode reamalgamation, and remeasurement on the same pellet, and variations of pellet dimensions showed that the conductivity is both reproducible and independent of pellet thickness, i.e., that it complies with Ohm's law (Table I).

In a further evaluation of the method, Westphal[2] carried out some a-c measurements of conductivity as a function of frequency. He showed (Table II)

300,000	—	—	1.55	1.61	1.49	1.62
1,000,000	1.55	1.52	1.58	1.62	1.50	1.63

All conductivities are given in $(ohm^{-1}cm^{-1}) \times 10^{+4}$. Pellets were made of Mallinckrodt silver iodide powder compressed at 702 kg/cm² and were approximately 16 days old at the time of measurement.

that with Ag paint or evaporated Ag electrodes the a-c conductivities approached constancy only above 10,000 cps and even then yielded values that varied with sample thickness. It will be noted that similar a-c measurements using amalgamated electrodes gave conductivities independent of both frequency and sample thickness.

The major precaution that must be taken with amalgamated electrodes is avoidance of scum. When this is realized, the results are readily reproducible and the pellet, even after week-end contact with the electrodes, shows no discoloration or evidence of reaction with Hg (formation of HgI_2 or Ag_2HgI_4). Addition of weights to the assembled vertical array is of no significant effect up to 100 g. Beyond this point the conductivity decreases by about 6% at 200, 13% at 500, and 19% at 1000 g. This effect seems to be due to squeezing out of a mobile amalgam interface.

When an amalgamated array is first assembled, it exhibits a variable transient voltage that dies away to a fraction of a microvolt within about 10 min. Although this may be due to a slight difference in the temperature of the two electrodes [Reinhold (7) has shown that a difference of 1°C in the relative temperatures of the electrodes of an Ag-AgI-Ag array near room temperature can result in a voltage difference of about 1000 μv], it is more likely that amalgam redistribution is involved since the top electrode is always initially negative with respect to the bottom. Careful conductivity measurements, of course, must await practical disappearance of these transients.

Effect of Compression Pressure on Pellet Conductivity

Although description of a d-c method for measurement of the conductivity of AgI is the major objective of this paper, a few very preliminary applications have been made.

Table III gives the room temperature conductivities of pellets of Mallinckrodt AgI compressed at various pressures and temperatures. The low-temperature compressions were made by quick compression of pre-assembled cavity, plug, sample, and plunger after chilling the pressure chamber and sample overnight at —10°C. Likewise, the high-

Table III. Conductivities of pellets as function of compression pressure at different temperatures

Compression pressures		Compression temperatures, °C		
kg/cm²	psi	−10°	27°	95°
140	2,000	0.43	0.65	0.96
281	4,000	1.08	1.23	1.17
421	6,000	1.38	1.36	1.31
562	8,000	1.43	1.37	1.31
702	10,000	1.56	1.48	1.27
843	12,000	1.58	1.55	2.30
983	14,000	1.61	0.89	—
1220	16,000	1.80	0.74	2.66

All conductivities are given in $(ohm^{-1}cm^{-1}) \times 10^{+4}$. Pellets compressed at −10°C and 27°C were 24 days old at the time of measurement; those at 95°C were 4 days old.

temperature compressions were made on preheated assemblages.

The most interesting feature of Table III is the conductivity "break" observed beyond 843 kg/cm² in the room-temperature series. This break was confirmed with a second run of Mallinckrodt AgI and was also observed using the Allied Chemical material.

Suspecting that a phase change was associated with the conductivity break, x-ray diffraction techniques (Norelco diffractometer, filtered Cu radiation, scanning speed of 1°/min, chart speed of 1.27 cm/min) were applied to a study of the second room-temperature pressure series using *unpolished* Mallinckrodt pellets. It is known that there exist at least three modifications of AgI (8). The γ phase, yellow, stable up to about 137°, is face-centered cubic with $a_o = 6.502$Å. The β phase, orange, stable from 137° to about 146°C, but apparently metastable at room temperature, is hexagonal with $a_o = 4.59$ and $c_o = 7.49$Å. The α phase, brown, stable only above 146°C, is body-centered cubic with $a_o = 5.044$Å. It is particularly interesting to note that the axial ratio for the hexagonal phase is very close to the 1.633 value characteristic of ideal close packing. As Manson (9) pointed out, this means that all strong γ-cubic lines will face at nearly the same positions as strong hexagonal lines although there

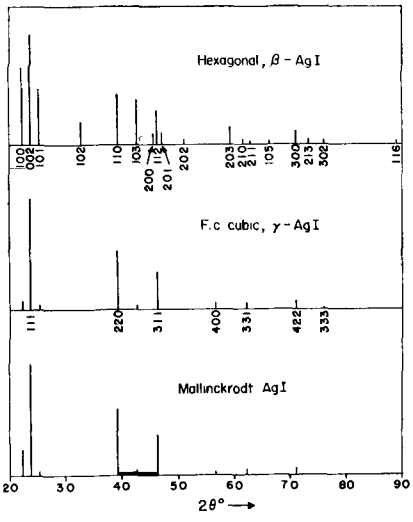

Fig. 3. X-ray diffraction angles and relative intensities of β and γ silver iodide.

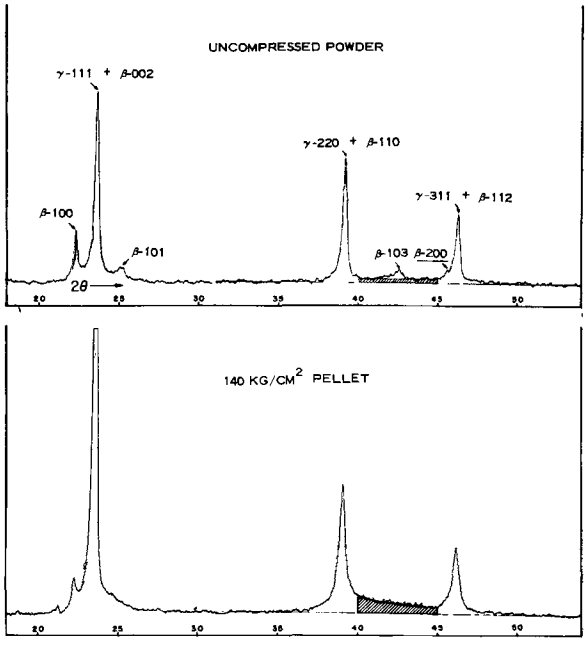

Fig. 4. Structural changes associated with initial compression of AgI powder.

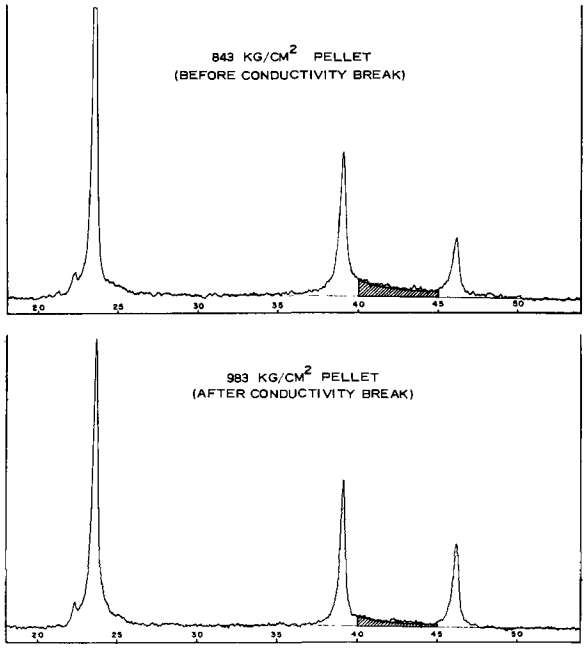

Fig. 5. Diffraction traces of pellets before and after conductivity break.

will be lines in the hexagonal pattern not present in the γ-cubic. The two upper charts of Fig. 3 (practically pure γ and β materials obtained from Mr. Manson[3]) illustrate these line coincidences. The bottom chart shows that the Mallinckrodt material is essentially γ-cubic with easily detectable amounts of β-hexagonal.

Figure 4 illustrates diffraction differences between uncompressed Mallinckrodt powder and a pellet compressed at room temperature at 140 kg/cm² (2000 psi). There is a sharp increase in the $\gamma(111) + \beta(002)$ intensity, all β lines tend to disappear, the entire region between 2θ values of 39-46° becomes abnormally fogged (shaded area), and all cubic lines tend to broaden with asymmetric tailing of the base.

The sharp increase in $\gamma(111) + \beta(002)$ intensity indicates a pressure-induced orientation of grains of one or both phases. The other three effects can be explained on the basis that pressure broadens all hexagonal lines. Such line broadening is indicative of strong deformation of hexagonal crystallites and/or pronounced grain fragmentation. The fact that line broadening occurs at relatively low pressure (even at 35 kg/cm², 500 psi) and the logical assumption that grain deformation precedes grain fragmentation favor acceptance of the lattice-deformation viewpoint.

X-ray traces of pellets compressed at pressures up to 843 kg/cm² (12,000 psi) were essentially the same as for the 140 kg/cm² (2000 psi) pellet. Relatively marked changes took place, however, in the pressure range corresponding to the conductivity break (Fig. 5). There was a decrease in the $\gamma(111) + \beta(002)$ intensity, a decrease in shaded-area fogging, and an increase in line symmetry with some indications of line sharpening. These changes in the diffraction patterns may be due to a pressure-induced tendency for the disappearance of deformed hexagonal phase, probably by conversion to γ-cubic. The associated drop in conductivity is strong evidence of the importance of the deformed hexagonal phase as a conductivity-imparting ionic "solder."

At higher pressure (1,220 kg/cm², 16,000 psi), shaded-area fogging, while still present, diminishes in a manner consistent with the slightly lowered conductivity (cf. Table III).

Some Exploratory Measurements

It has been found that the conductivity of pellets decreases slowly with time. There is a linear relationship between log specific conductance and log time. This is reminiscent of the linear relationship known to exist in metal deformation where per cent recovery of yield stress varies linearly with log time and can be construed as evidence supporting the lattice-deformation concept.

Using a special sample holder (Fig. 6) which employed pools of liquid silver amalgam, it was possible to make a preliminary study of the effect of increasing temperature on the conductivity of a pellet compressed at 702 kg/cm² (10,000 psi) at

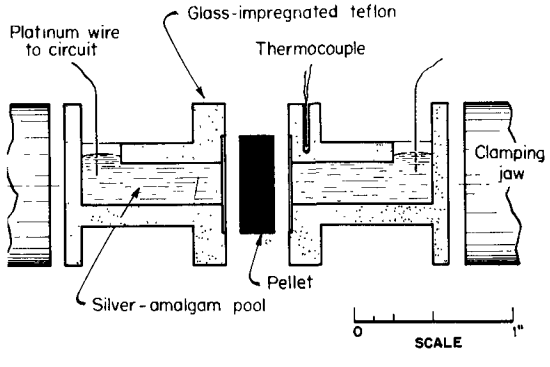

Fig. 6. Conductivity cell using liquid amalgam pools

[3] Air Force Cambridge Research Center, Bedford, Mass.

room temperature. Evidence of a temperature-accelerated relief of hexagonal deformation was noted during an overnight stand at about 75°C. Further temperature increase resulted in a tremendous increase in conductivity, from 7.2 x 10^{-4} ohm^{-1} cm^{-1} at 132°C to 9 ohm^{-1} cm^{-1} at 138°C. Pellet color changed from greenish yellow to speckled orange with little, if any, change in pellet dimensions. It seems probable that a phase transition from essentially γ-cubic to essentially equally dense β-hexagonal took place. Overnight standby at 138°-139°C resulted in a drop in conductivity to 1.2 ohm^{-1} cm^{-1}. Further increase in temperature resulted in a *drop* to about 1.0 x 10^{-1} ohm^{-1} cm^{-1} at 146°C beyond which temperature the pellet color changed from speckled orange to solid tan-brown (probably a transformation of β-hexagonal to α-cubic) with no significant increase in conductivity. The pellet underwent sharp expansion. For all practical purposes this expansion concluded the temperature run. Cooling to room temperature gave a canary-yellow pellet (compared to the original greenish-yellow) and a conductivity estimated at 1 x 10^{-7} ohm^{-1} cm^{-1}. Repeated temperature cycling (room temperature to 180°C) with the expanded pellet showed that pellet-color changes were remarkably consistent; invariably canary yellow below 137°, speckled orange between 137°-146° and tan-brown above 146°C. Furthermore, the conductivity changed sharply only at about 137°C, indicating that the transition from γ-cubic to β-hexagonal is probably more important with respect to conductivity than that from the β-hexagonal to α-cubic.

Time was not available for the preparation of the large quantities of pure γ and β AgI needed for a careful study of the effect of compression temperature and pressure on structurally homogeneous phases. It has been shown, however, that pellets of Manson's purest γ and β materials, at room-temperature compression pressures of 281 kg/cm^2 (4000 psi), gave conductivities of 1.9 and 3.5 x 10^{-5} ohm^{-1} cm^{-1}, respectively. Both of these are significantly lower than the 281 kg/cm^2 pellet of the Mallinckrodt γ-β mixture at 12.3 x 10^{-5} ohm^{-1} cm^{-1}. A possible explanation of this anomaly of a mixture having a conductivity higher than either of its two components may lie in the residual deformation present in the uncompressed Mallinckrodt powder (cf. shaded area, top trace of Fig. 4) and absent in the Manson pure-hexagonal material.

X-ray examination of Allied Chemical AgI showed it to be (like the Mallinckrodt material) a mixture of γ and β phases. Grinding in a mechanical mortar for 2 hr resulted in the line tailing, abnormal fogging, and line broadening characteristic of hexagonal deformation. The conductivities of 281 kg/cm^2 pellets of ground and unground materials were 22.4 and 8.0 x 10^{-5} ohm^{-1} cm^{-1}, respectively, indicating the possibility of inducing hexagonal deformation by mechanical pretreatment of the starting material.

In a quick and incomplete study of the effect of heating and cooling of Allied Chemical AgI it was found that heating the powder in air to 140°, 165°, and 200°C, followed by slow cooling to room temperature, resulted in no significant change in the x-ray traces. However, a sample heated to 200°C for 2 hr and then quenched by sprinkling into a pool of liquid air did show deformation of the hexagonal phase. No conductivity measurements have been made thus far, but thermal shock treatment of powders seems promising.

Prognosis

The work here reported demonstrates that the conductivity of a pellet of compressed AgI can be increased substantially. It does not appear premature to prognosticate conductivities at least one order of magnitude higher (i.e., ca. 10^{-3} ohm^{-1} cm^{-1}) than any yet observed. At this value the conductance of a pellet of 1 cm^2 area and 0.01 cm thickness would correspond to an "electrolyte" resistance of about 10 ohm. Ignoring other resistance sources within the cell, this electrolyte resistance would permit a flash current of about 50 mamp with a cell of 0.5 v open-circuit voltage. Such current outputs would definitely widen the applicability of solid-electrolyte batteries.

However, availability of a highly conductive solid electrolyte, although necessary, is not a sufficient condition for satisfactory battery operation. For example, the conductivity of the cathodic depolarizer must also be high, both from the standpoint of ions entering through the electrolyte from the anode and of electrons entering through the external circuit. Furthermore, volumetric changes associated with discharge (anode consumption and depolarizer expansion) require some compensating physical mobility of the electrolyte or suitable design characteristics. These problems need further study.

Acknowledgment

The author is indebted to Professor A. R. von Hippel and Dr. A. Smakula for many hours of helpful discussion, and to Dr. D. S. Tannhauser and Mr. A. D. Bedrosian for continuing counsel and guidance. Furthermore, he acknowledges the effective co-operation of many members of the Fort Monmouth organization and of the staff and graduate students of Massachusetts Institute of Technology. He is grateful, also, to Professor G. S. Brown, Head, Department of Electrical Engineering, for status as a member of the School for Advanced Study.

Manuscript received Sept. 16, 1959. This work was made possible by a one-year Secretary of the Army Research and Study Fellowship award.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Sine Wave Pulse Current Tester for Batteries

K. Kordesch and A. Marko[1]

Research Laboratory, Union Carbide Consumer Products Company, Division of Union Carbide Corporation, Cleveland, Ohio

ABSTRACT

An instrument has been developed which measures the voltage of a battery during discharge, eliminating its ohmic component. The instrument is portable operated on 60 cycle alternating current and features direct meter readings (instead of an oscilloscope). Its simplicity and ruggedness make it especially suited for development and production control tasks. Results of measurements on different types of cells are presented to illustrate the wide applicability of the instrument.

The intention of the authors was to develop a simple and reliable instrument for the evaluation of battery performance under load conditions. The method of measuring polarization and internal resistance values by means of periodic current interruption was chosen because these parameters are very characteristic for a battery system.

Square wave generators have been used frequently to study the characteristics of electrodes of galvanic systems. The literature reports many of these devices, some of them quite useful in research and development laboratories. However, most of these instruments are complex, use an oscilloscope, and are not suitable for rugged performance conditions. Furthermore, they require highly skilled personnel for interpretation of the measurements (1-3).

The principle of a circuit which enables us to subject a cell to a periodically interrupted discharge (pulse current load) and measure the voltage of the cell between the discharge periods is shown in Fig. 1 (4). In position one, 1, the double pole vibrator switch, S, connects the cell on test to a discharge circuit consisting of a variable resistor, R, and an ammeter, A. In position two, 2, of the switch, the cell is charging a capacitor, C, to the potential existing during the current off-time. A high resistance voltmeter, V_1, indicates this voltage. If the vibrator switch operates at a frequency of at least 50 cycles, the polarization of the cell reaches a steady-state value corresponding to the load current indicated by the ammeter. A booster battery prevents the discharge current from changing too much when the cell voltage changes. The voltmeter, V_2, indicates the terminal voltage of the cell being tested.

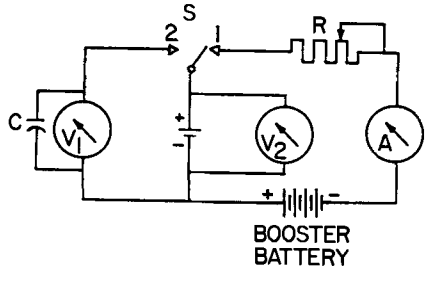

Fig. 1. Vibrator circuit

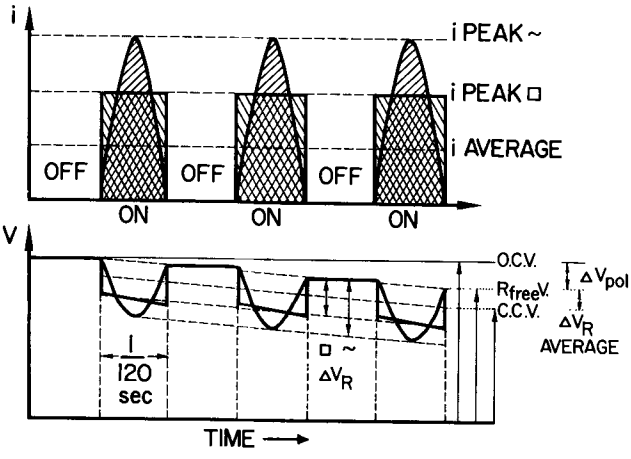

Fig. 2. Effect of square or sine wave pulses on a battery system.

Figure 2 shows in an artist's sketch the oscillographic curves obtained from a battery system subjected to a pulse current. First, only square wave pulses shall be discussed in connection with the just mentioned vibrator switch circuit. The current pulses are pictured in the upper section of the sketch. With an equal "off" and "on" time (1/120 sec) the average current is one half of the peak current. The galvanic cell responds to this average current indicated by a moving coil instrument of the common d-c ammeter-type. In the lower part of the sketch, the effect of the current pulse on the voltage of the cell is shown. Only a few pulses are shown in the drawing, but it should be understood that the system will reach a certain steady state, e.g., after 1 min of closing the circuit, the readings may be taken. The voltage of the cell without the resistance component, R_{free} V, is represented by the top level of the pulse curves. The terminal voltage, CCV, is represented by the average value of the pulses (½ of the square pulse). The difference between the OCV and the R_{free} voltage indicates the sum of all slow polarization effects in the cell system (ΔV_{Pol}), the difference between the highest points and the lowest points of the pulse curves represents the resistance

voltage drop caused by the corresponding peak current. The resistance value in ohms is calculated by dividing $\Delta V_{R\square}$ by the current i peak □. It is important to note that the same value is obtained by dividing the difference between the R_{free} voltage and the CCV (ΔV_R average) by the average current. The circuit shown in Fig. 1 provided meter indications of $i_{Average}$, R_{free} Voltage, the initial OCV and the later CCV. From these figures one can calculate the polarization and resistance components of the voltage drop caused by the load condition (ΔV_{Pol} and R). The pulse frequency can be chosen from a range between 30 and 400/sec in which no differences have been found in practical cell testing. Mechanical vibrators operate in the 50-100 cycle range, the later discussed electronic switch circuit uses the line frequency of 60 cycles. A too low pulse frequency causes deviation due to recuperation effects during the "off" time; too high frequencies introduce capacitance errors. However, if we consider that the accuracy of common good meters is not better than one half of a per cent, we do not need a better reproducibility of our measurements than ±5 mv (for a 1-v cell). This is the case with all depolarizers tested (manganese dioxide, nickel oxides, lead dioxide, silver oxides) and with most of the available anodes (zinc, cadmium, lead).

The vibrator circuit of Fig. 1 has been used in battery testing circuits with the main objective of studying the polarization characteristics of cells under heavy load conditions. Powerful depolarizers such as silver or nickel oxides polarize to such a small extent that resistance variations obscured the measurements of polarization effects (5).

Mechanical switching proved to be inadequate for high currents; contact bouncing sometimes caused erroneous meter indications. The production of exact square waves by means of mercury switches or electronic circuits could not be solved with a simple apparatus. The inherent capacitance-rounding of square waves and the "cable ring" effects with longer leads were additional reasons for investigating a circuit employing rectified sine wave pulses for test purposes.

The sine wave pulses needed for the polarization of the cell are conveniently taken from the 60-cycle a-c line. Figure 2 shows the effect of half-wave sine pulses of the same mean current value as the square wave pulses. The actual discharge current is one-third of the peak current in accordance with calculations of the mean values of rectified waves. The factor for the ideal, non-truncated half-sine wave for the period 0-360° is $1/\pi$. In a moving coil instrument with D'Arsonval movement the torque on the coil is proportional to the current; therefore the meter reads the average value, which corresponds to the coulometric value of the current. A hot wire, dynamometer or other square law (RMS) instrument cannot be used in this case because its deflection represents I^2R, in our case about 1.45 times larger than the average current (6).

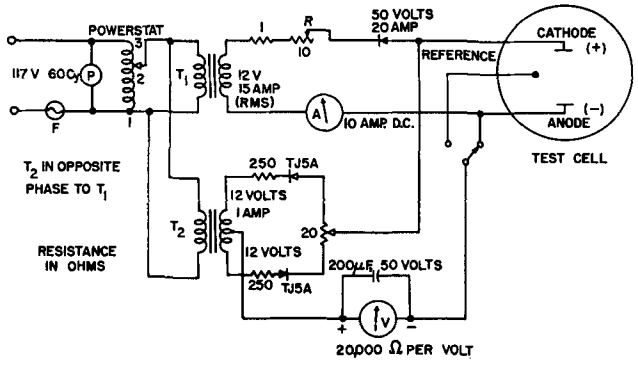

Fig. 3. Sine wave pulse current tester

Figure 3 shows the circuit diagram of one of the most versatile versions of the test instrument. A powerstat transformer circuit, T_1, produces a 12-v alternating current which is rectified and used as a single-phase pulse current to discharge the test cell. The current is regulated at the input of the powerstat and also by means of a variable resistor R. The a-c voltage should be at least six times the cell voltage to assure a clean sine wave shape. The average value of the current is indicated by the ammeter A. In order to connect the voltmeter, V, to the cell between the current pulses (same principle as the vibrator circuit in Fig. 1) a gating circuit is employed represented by a second small transformer T_2 and a double diode bridge. This gating circuit has the purpose of producing alternatingly a very low resistance path and an extremely high resistance connection between the (+) terminal of the voltmeter and the cathode of the test cell. The (−) terminal of the voltmeter is continuously connected to the anode of the cell (or a reference electrode, if desired). The proper timing of the gating circuit is enforced by an alternating current introduced into the bridge by means of transformer T_2. This alternating current does not add or subtract any potential between the center tap of the transformer and the tap of the balancing potentiometer, but it "opens" or "closes" the two diodes in the bridge circuit in opposite phase to the current pulses of the transformer circuit T_1. The voltmeter V indicates the voltage of the capacitor which is charged only during "off current" periods. The proper value of the capacitor is dependent on the resistance of the voltmeter, but not critically. The gating diodes should be of a very high forward/backward current ratio, preferably over 1000:1. Transformer T_2 may be replaced by an additional winding on T_1, but in practice it turned out to be far more convenient to use a separate small transformer for the gating unit, which can be separated completely from the power section in cases where it is desired to subject many cells in series to the pulse current but measure the R_{free} voltages of individual cells.

A reference electrode can be used for the independent measurement of the polarization of cathodes or anodes. The position of the reference electrode is not critical because electrolyte resistance effects are also eliminated.

In some cases where an extension to higher pulse frequencies was desired (e.g., in studies of magnesium electrodes showing passivation effects) we used an audio generator to produce the pulse currents. For work on high resistance batteries (organic depolarizers, solid electrolyte cells) we changed the

silicon diodes of the gating circuit to vacuum tubes and the 20,000 Ω/v meter to a vacuum tube meter (the capacitor across the voltmeter should then be in the range of 1-10 μF).

The principal circuit has been used by the authors for eliminating the disturbing ohmic resistance component in oxygen sensing elements operating on the air-depolarized cell principle, and in connection with fuel cell studies a similar circuit was described at the Electrochemical Society Meeting in October, 1956 (7). Variations of it have been employed for experimental state of charge determination of Ni-Cd batteries (8).

The data obtained with our interrupter have been checked many times against a precision square wave (electronically) switching instrument,[2] and as far as any useful battery system was concerned, no deviation could be detected. With modern rectifier and transistors, the whole instrument can be made small-sized, the largest components being the transformer, the ammeter, and voltmeter. There is no limitation to the current or voltage range of the batteries to be tested; the circuit can be adapted easily to any test requirement.

In order to demonstrate the versatility of the instrument examples of test results with different battery systems are given in the following figures. Differences in depolarizer mix formulation (Fig. 4), influence of geometrical construction (Fig. 5), and system variations (Fig. 6) express themselves in characteristic polarization and resistance curves.

In Fig. 4 (Leclanché cells) Cell A is a regular D-size cell and cell B is a D-size photoflash cell. Both cells have been discharged with a 500 ma pulse current and the R_{free} voltage and the *CCV* are shown as obtained on a simultaneous recording. The ohmic resistance values are calculated from the differences. The cathode of cell A is manufactured mainly from natural ore, the bobbin of cell B contains a large percentage of artificial MnO_2 and more graphite. The gradual loss of depolarizing power or the increase of cell resistance on light intermittent duty or after long storage periods shows up in a similar way if periodic checks (e.g., 1-min tests) are made during the life time of the cells (5, 8).

Figure 5 shows the characteristics of two D-size alkaline MnO_2 cells with powder zinc anodes. Cell

[2] Constructed by Professor E. Yeager, Western Reserve University, for the Research Laboratory of Union Carbide Consumer Products Company.

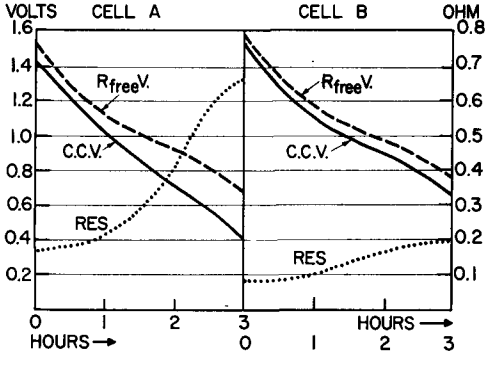

Fig. 4. Discharge characteristics of a standard D-size cell (A) and a photoflash cell (B) 500 ma.

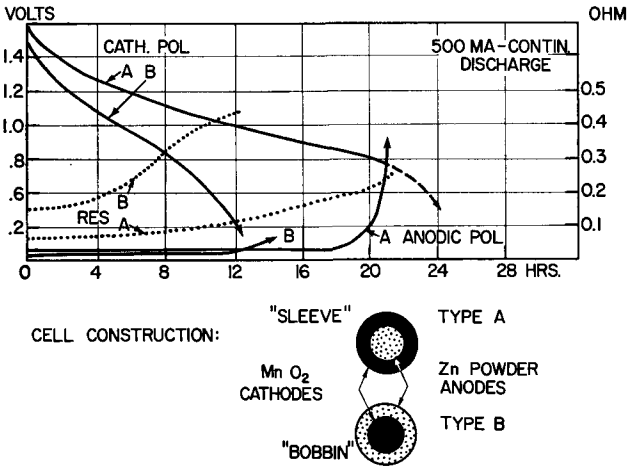

Fig. 5. D-size alkaline MnO_2 cells on 500 ma. Discharge (constr. A and B).

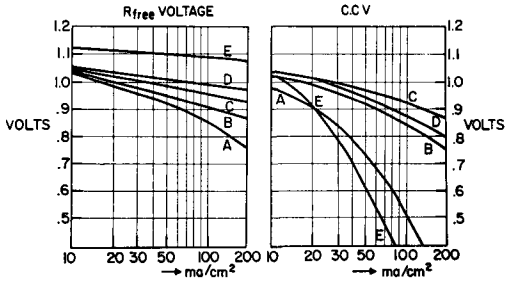

Fig. 6. Terminal voltage and ΔV_{Res} free voltage of hydrogen-oxygen fuel cells. Geometry: A, parallel tube electrodes; B, concentric tube electrodes; C, D, E, parallel plate construction. Electrolytes: A, B, C, 30% KOH at 60°C; D, molten caustic at 200°C; E, fused carbonates, 500°C.

A contains a sleeve type cathode, cell B is made with a bobbin type cathode. In these diagrams only the R_{free} voltages and the resistance values are plotted vs. time. The average discharge current is 500 ma. Here the R_{free} voltage curves are named "polarization curves;" they are measured against a zinc reference electrode positioned between cathode and anode. This gave the possibility to record the anodic polarization curve also.

Figure 6 shows a collection of performance data characteristic for different types of hydrogen-oxygen fuel cells. R_{free} voltage curves are shown on the left side of the figure and *CCV* curves are shown on the right side of the figure. The current density is on a logarithmic scale to cover a wider range. It demonstrates how important it is to know the R_{free} voltage curves to judge performance characteristics. From the terminal voltages (right side) one would say that cell C is the best, cell D the worst; but a look at the corresponding curves on the left side indicates that E has the lowest polarization drop, A the highest. The observed differences are partially due to geometry factors and partially caused by different operating conditions. The R_{free} voltage curves of Fig. 6 agree very well with the values calculated from independent a-c bridge measurement of cell resistances. The advantage of using a pulse current instrument for such studies is the freedom of variation caused by uncontrolled resistance changes during the duration of the test. Lead wire

and contact resistance errors are eliminated. The "true" voltage of the chemical system is directly indicated on the voltmeter.

The pulse current tester described has also been used for charge control purposes. The R_{free} voltage reading is a better indication of the state of charge than the *CCV* because it is not influenced by conductivity changes in the electrolyte or gas film phenomena in the gassing period of the charging procedure. The use as a sensing circuit for automatic constant voltage charging units has been proposed (5). The gating circuit can be used in connection with thyratrons and magnetic current regulators (8). Adaptation to full wave rectifier circuits is achieved by a C-R phase shift arrangement in the gating bridge, "connecting" the voltmeter only during the very short current off period between the two rectified half-waves (the counter voltage of the cell causes truncated sine pulses).

An Investigation of the Reaction between Aluminum and Water

Walter J. Bernard and John J. Randall, Jr.

Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

It was found that the film formed on aluminum by the action of water between 80° and 100°C consists of a hydrate of aluminum oxide containing as much as 32% water, rather than stoichiometric $Al_2O_3 \cdot H_2O$, as previously reported in the literature. The reaction is not instantaneous but is delayed by the presence of the natural oxide film on the metal. It was also concluded that hydrated oxide growth does not depend on the movement of aluminum ions through the film.

When pure aluminum is immersed in boiling water, there is an initial period during which no visible reaction occurs, followed by hydrogen evolution and the production of an adherent layer of hydrated oxide. The discharge of gas occurs at first at several widely separated points and then quickly spreads over the entire surface of the metal. The rate of hydrogen evolution soon decreases and is barely perceptible after 10 min or so, although weight measurements show that oxidation of the metal continues beyond this point. Considerable literature exists on the subject of this oxidation, but we are unaware of any previous mention of the existence of the inhibition period. In this paper we are suggesting an explanation for this inhibition period and present some new evidence for the composition of the oxide film which is formed, as well as some observations on the mechanism of film formation.

Experimental

The metal used was 0.003 in. thick high-purity Alcoa aluminum foil, with a guaranteed minimum Al content of 99.986%. Representative samples of this material (Alcoa analysis) gave the following concentration of impurities: 10 ppm Cu, 10 ppm Fe, 10 ppm Si, and 40 ppm Zn. Specimens used had a surface area of 100 cm^2.

Degreased specimens were prepared by soaking in trichloroethylene, rinsing in benzene, and then drying under vacuum.

Foil specimens were electropolished in a bath recommended by Jaquet (1) for a period of 2 min at a current density of 9 ma/cm^2. The solution was cooled in an ice bath and constantly stirred with a magnetically driven stirring bar during polishing. The foil was washed thoroughly with distilled water in order to remove the last traces of the electropolishing solution, since the presence of minute impurities may affect the subsequent reaction with water (2).

Hydrations at 100°C were carried out in Pyrex beakers which were cleaned scrupulously before each run. Specimens were suspended in the water from Pyrex rods. The presence of glass had no noticeable effect on the reaction even after a reaction time of 1 hr, as shown by the fact that a few parallel experiments in Teflon beakers gave essentially the same results. The reaction water had a conductivity of about 1.2×10^{-6} ohm^{-1} cm^{-1} and was preboiled for 15 min before using in order to expel

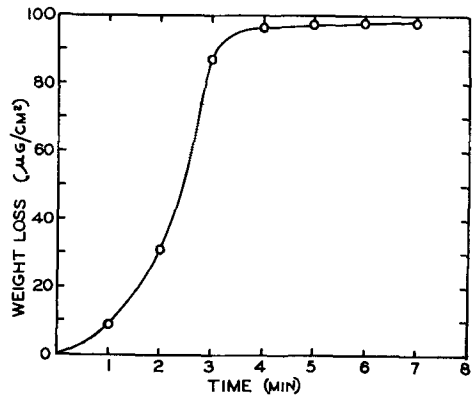

Fig. 1. Rate of removal of hydrated aluminum oxide from the surface of aluminum by CrO_3-H_3PO_4 stripping solution at 85°C. Reaction time with water was 1 hr at 100°C.

dissolved gasses. Reactions at lower temperatures were made in flasks kept in a thermostatted bath. The water was not maintained in an inert atmosphere. For these runs the foil was held in a perforated glass cup which was joined to an extension of a 45/50 $\overline{\$}$ joint. The assembly could be removed easily and quickly at the end of the reaction to be quenched in room-temperature water.

The extent of the reaction was determined by weight changes involving the dissolution of the hydrated oxide film in a solution of 2% CrO_3 and 5% H_3PO_4 at 85°C; the attack of this solution on the underlying metal is reported to be extremely slow (3). The behavior of the stripping solution for a typical hydrated specimen is shown in Fig. 1. After all the oxide is removed the rate of attack on the base metal is only 0.2 $\mu g/cm^2/min$ which is sufficiently slow for our purposes. The method was calibrated by checking the weight loss of anodic films of known weight.

A source of error in this method would result if the hydrated oxide were not completely stable during reaction and if part were lost by dissolution or through mechanical action. However, we were unable to detect the presence of aluminum in the water after a reaction time of 60 min. On the other hand, we observed that, if the water had been used for reaction for a period of some hours, a subsequent oxidation gave slightly higher results than were obtained in freshly prepared water. The reason for this is not clear.

Hydrated oxide was obtained free of metal by dissolving the aluminum in a hot solution of bromine in methanol. It was necessary to wash the oxide thoroughly in order to remove the products of the reaction. This was accomplished by refluxing the oxide in several changes of methanol. The final product was dried at 80°C for 2 hr.

Thermogravimetric analysis was carried out on a Chevenard Recording Balance which was used with a maximum sensitivity of 0.5 mg/mm of chart. The maximum temperature attainable was 1000°C and the heating rate was 2.5°C/min.

Density measurements were made hydrostatically in toluene.

The measurement of the hydrogen evolved in the reaction of the hydrate and the underlying metal was made in an all-glass apparatus. A 10 ml gas burette was connected by capillary tubing to a 12 mm reaction tube containing the sample. The tube was sealed and the entire system was flushed with argon before reaction. The sample was heated quickly to 600°C and held at that temperature for an hour before removing the furnace; Pyrex glass was satisfactory under these conditions. Water from the hydrate was absorbed in a P_2O_5 trap at the exit of the furnace and, therefore, did not contribute to the volume change in the system. This was verified by decomposing $NiSO_4 \cdot 6H_2O$ under the same conditions, whereby the water was absorbed quantitatively. A sample of the isolated hydrate of alumina was also decomposed in this manner and gave no volume increase in the apparatus.

Debye-Scherrer powder patterns were made with samples mounted in a 57.3 mm Phillips powder camera, using CuKα radiation. Exposure times were of the order of 16 hr.

All weighings were made on a Brinkmann-Sartorius Microbalance to the nearest 10 μg.

Results and Discussion

Composition of the film.—It is generally accepted that the product of the reaction above 80°C is boehmite, α-$Al_2O_3 \cdot H_2O$; the characteristic electron diffraction pattern of this compound has been observed by Harrington and Nelson (4), Hart (5), and Kerr (6). Some of the characteristic lines of the boehmite pattern have also been obtained by us by x-ray diffraction. The very diffuse patterns obtained by us and others indicate a poor degree of crystallinity. This evidence is not sufficient to establish the reaction product as pure boehmite, although further support for this composition is given by Bryan (7), whose gravimetric analysis led to the conclusion that the surface product consists of nearly stoichiometric $Al_2O_3 \cdot H_2O$. Bryan's analytical method is subject to criticism, however, on the basis of some of our findings and there is evidence to show that the reaction product contains water considerably in excess of that required for the monohydrate. Bryan reported the water content of the film to be 15.5%, as compared to 15.0% for the theoretical value for the monohydrate. This was determined by heating the metal to 600°C after reaction and measuring the weight loss. However, we have found that this leads to low results because part of the water in the film reacts with the base metal during heating to produce more oxide. If, instead, the hydrated product is separated from the metal by dissolving the aluminum in methanol-bromine solution (8) and then dehydrated, we find that the water content may be as high as 32%. The same results may be obtained by weighing the foil before and after reaction and then removing the reaction products by dissolving in a chromic acid-phosphoric acid solution and reweighing. By the use of the appropriate calculations the three measurements lead to the total weight of hydrated oxide and the amount of water present. This latter procedure is a more convenient method and has been used for the measurements of the rates of reaction discussed below.

We have also shown that the hydrated surface oxide reacts with the base metal during heating by measuring the volume of hydrogen evolved under these conditions. In a typical experiment, a sample of aluminum with an area of 100 cm^2, which had been treated with boiling water for 60 min, produced 1.5 ml of hydrogen when heated to 600°C for 1 hr in an inert atmosphere. This corresponds to 1.2 mg of water, which would not have been detected by Bryan's method, out of a total hydrated oxide weight of 10.9 mg and a water content of 3.0 mg. A more pronounced effect was obtained by the use of etched foil, for which the true surface area is not precisely known but is several times greater than for smooth foil. With this material, volume increases of 5-6 ml were observed under the same conditions.

Finally, the measured density of the oxide was found to be 2.4 ±0.1 g/cm^3, as compared to 3.0 for pure boehmite (9).

The form in which the excess water is combined in the surface product is not known. The composition of the film most frequently approximates that of a dihydrate, but this probably has no significance. It could be postulated that the contribution of an appreciable quantity of trihydrate would give the observed composition but there is no physical evidence to show the presence of either of the two known trihydrates. Thermogravimetric analysis shows that a large fraction of the water is loosely bound and is lost before the expected range of decomposition of boehmite. This is shown by the comparison of the thermograms of the hydrated oxide and pure boehmite[1] in Fig. 2. The thermogram shown here was obtained from the oxide formed at 100°C. Nearly identical traces were observed for the products formed at 80° and 90°C.

Reaction mechanism.—Hart (5) has suggested that the growth of the hydrated oxide occurs by outward migration of aluminum from the metal and offers as evidence the observation that anodic films which have been stripped from the metal and then treated with boiling water do not give the electron diffraction pattern of boehmite. Kerr (6) has modified this experiment so that part of the underlying metal was allowed to remain in contact with the anodic film and then carried out the hydration reaction. Electron diffraction then indicated the presence of boehmite only in the vicinity of the islands of metal. According to these observations, the mechanism of boehmite formation must involve the movement of aluminum to the oxide-water interface, since the anodic oxide itself does not appear to become hydrated.

1.45	16	1.43	Weak
1.43	9	1.40	Weak
1.38	6	1.36	Weak
1.31	15	1.31	Weak

* Only the 12 strongest diffraction lines of boehmite are listed.

On the other hand, Spooner (10) has shown by x-ray diffraction patterns that boiling water transforms isolated oxide to boehmite, and MacLennan (11) has reported that there is no essential difference in the impedance characteristics between isolated and nonisolated oxide films which have been exposed to boiling water. Both of these observations have been made with nonbarrier films (formed in sulfuric acid), but we have also confirmed Spooner's results using barrier films formed to 100 v in ammonium borate solution, taking great care to remove the underlying metal completely, and hydrating for 20 min at 100°. This has also been confirmed by Hinde, Kellet, and Harris (12). A comparison of our x-ray diffraction data for a hydrated anodic film and ASTM data for boehmite is given in Table I. Furthermore, thermogravimetric analysis of this substance gave results which are identical to those obtained from the hydrate in Fig. 2. These observations are in direct contradiction to those of Kerr and Hart, but repeated and careful study leaves no doubt that the presence of metallic aluminum is not necessary for the conversion of anodic oxide to "boehmite."

In the attempt to determine the kinetics of the direct reaction between aluminum and water, we have made the assumption that the formation of oxide occurs at the metal-oxide interface. This is based on the discussion in the preceding paragraph, the physical nature of the final product and the rate at which the consecutive reaction—the hydration of the oxide-occurs.

The final hydrated oxide is completely unlike the coherent film formed by anodic oxidation, consisting of loosely connected particles. This is shown by examination of the oxide after removal of the underlying metal. When in contact with the metal this oxide is probably of a highly porous nature and could be penetrated easily by water, thus making it unnecessary to consider an ionic mechanism for oxide growth.

A further condition which must be met for the reaction to occur at the metal-oxide interface is that

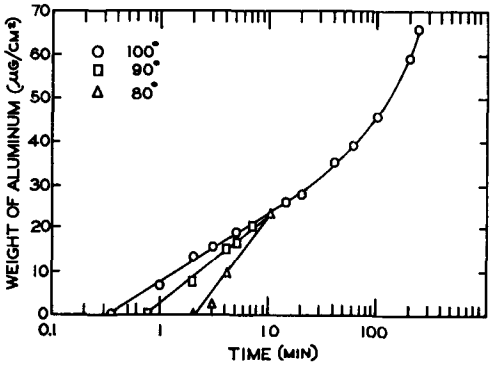

Fig. 3. Weight of aluminum reacted vs. time of immersion in water at 80°, 90°, and 100°C. Data corrected for amount of pre-existing oxide on degreased foil.

the hydration step take place as soon as the oxide is formed. There is some justification for this belief, since, as shown in the following section, anodically formed films are hydrated at a very rapid rate. Calculations show that the rate is greater than the rate of hydrated oxide formation on the metal. There is, of course, no evidence to show that the transitory oxide formed in the water reaction is identical to the anodically formed oxide, but the physical similarities of the final hydrated product of each would lead one to believe that this is the case.

In view of these considerations it would be expected that the rate-determining process would be the diffusion of water through the film, although the kinetics may be complicated to an unknown extent by the rate at which evolved hydrogen is transported from the reaction surface. It should also be recognized that the rate of oxide growth is also strongly influenced by the specific impurities present in the metal; the absolute data presented here, therefore, apply only to aluminum of the composition described earlier.

If the process occurs uniformly over the surface of the metal and if the rate of diffusion of water is dependent on the thickness of the film, a parabolic law would be expected to govern the growth; independence of film thickness would result in a linear rate law. In the cited paper by Hart a constant growth rate is reported, but this is open to question since the change in thickness was followed for only 2 min. The initial rate is extremely rapid and could probably be fitted to a linear plot, but it soon decreases, as shown in Fig. 3. However, a parabolic law also fails to fit the observed data over a reasonable period of time. In Fig. 3 the weight of aluminum reacted at 100°C is plotted as a logarithmic function of time. In this plot the weight of aluminum reacted, rather than the weight of the oxide or the total weight of product formed, is used in order to avoid the assumption of a constant composition of product, since the calculated amount of water in the surface film was found to vary from 23% to 32%.

We have also plotted some of the data obtained from experiments at 80° and 90°C. Results for longer reaction times are not included because of the failure to obtain satisfactorily reproducible results. The observations are anomalous in some respects. There is a marked increase in the inhibition period with decreasing temperature, but about 10 min after reaction starts there is little difference in rates for the first 2 hr. After that time the rate at 100° is significantly greater than at the lower temperatures.

At 100°C an apparent logarithmic rate law is observed for the first 30 min or so, followed by a reasonable fit to a parabolic law up to about 250 min. The nature of the hydration process would not lead us to believe that a true logarithmic law of the type discussed by Uhlig (13) is operating here, but rather that the apparent logarithmic dependence is fortuitous. The fact that a simple parabolic dependence is not observed over the entire time interval studied suggests that a uniform, homogenous reaction layer is not formed, at least in the beginning, or that the evolution of hydrogen complicates the kinetics to a greater extent than was assumed. It is also possible that a form of lateral growth, postulated by Evans (14), may explain this behavior.

The thicknesses of the films are greater than reported by Hart from his electron diffraction measurements. After 1.5 min (on electropolished specimens) he observed a film thickness of 100Å, whereas our calculated thickness under the same conditions, based on the weight of the film and the measured density, is 1500Å.

Inhibition period.—The previously unreported inhibition period is believed to be due to the presence of the existing oxide film on the metal; foil which has been electropolished shows a much smaller inhibition period. The time required for hydrogen to be evolved on degreased foil at 100°C is about 20-22 sec, on foil cleaned in cold H_2SO_4-$K_2Cr_2O_7$ solution it is 15-18 sec, and on electropolished foil 5-11 sec. The fact that the electropolished specimens do not show an inhibition time of zero is a result of the very thin film which is formed on the foil during the washing period after removal from the electropolishing bath. Thin films of aluminum, vacuum-deposited on glass, show an apparent inhibition period of 1-2 sec if transferred rapidly from the vacuum apparatus to boiling water, but it is difficult to observe the effect because the boiling water tends to rupture the thin metal film. However, what appears to be an instantaneous reaction with boiling water is observed with aluminum which has been freshly abraded with a stainless steel point.

The properties of the natural oxide film on aluminum have not yet been elucidated completely. The thickness of the film is dependent on the history of the metal and its environment; a summary of the many investigations of this subject has been given by Hart (15). It is generally agreed that after an initial rapid growth of oxide on the pure metal further growth occurs at a very slow rate at room temperature, and that the thickness of the film probably never exceeds 100Å. In the course of our work we have made direct measurements of the film weight (on acid-cleaned foil) by the stripping method and have found it to be 4.0 $\pm$0.4 $\mu g/cm^2$. If the film were to consist of α-Al_2O_3, the densest form of alumina, the oxide film would be 100Å thick. Since there is little doubt that the film does not consist of α-Al_2O_3, but of some less dense form of alumina, it must be considerably thicker than 100Å.

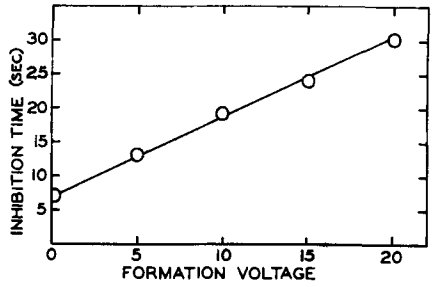

Fig. 4. Inhibition time for the reaction of electropolished aluminum foil with water vs. the thickness of anodic oxide on the foil.

Hunter and Fowle (16) consider the film to consist of a barrier layer about 10Å thick on the metal surface, with a porous layer above the barrier, but it is difficult to reconcile this model with our observations of the inhibition period. If electropolished aluminum foil is anodically oxidized to a specific voltage, up to 25 v, and then subjected to the action of boiling water, the entire oxide film is eventually penetrated and visible hydrogen evolution occurs. The time required to penetrate the film, in addition to the inhibition period characteristic of the foil pretreatment, is approximately proportional to the thickness of the anodically formed layer. This is shown in Fig. 4. At the current density used (0.1 ma/cm^2) the thickness of the anodic oxide is 11.9Å/v (17), and the penetration (or hydration) rate of the oxide is, therefore, about 12Å/sec. The pre-existing film on acid-cleaned foil, on the other hand, is penetrated only at the rate of 0.7Å/sec if the barrier portion alone of the film is responsible for the inhibition period. If this is true, then the naturally formed barrier film must be physically quite different from the anodically formed amorphous films. On the other hand, if the porous portion of the film also contributes to the inhibition period, it would be expected to become hydrated during the process. This would result in an easily detectable weight change. No such weight change occurs, and we have concluded that the pre-existing film is probably penetrated without hydration during the inhibition period.

In connection with the hydration of anodically formed aluminum, an interesting observation was made concerning the spatial relationship of the two oxides. Degreased foil shows no weight gain during the first 18-sec immersion in boiling water, but the same foil which has been anodically formed to 25 v before reacting with water shows a weight gain of 1.5 μg/cm^2 during the first 18 sec. Electropolished foil, which has been similarly formed, showed the same weight gain under these conditions. This indicates that anodic formation occurs on the solution side of the pre-existing oxide film, and that anodic growth takes place by aluminum ion movement through the film. This is in agreement with the conclusion of Lewis and Plumb (18) and is analogous to experiments made by Young (19) on tantalum.

Corrosion Behavior and Passivity of Nickel-Chromium and Cobalt-Chromium Alloys

A. Paul Bond[1] and H. H. Uhlig

Corrosion Laboratory, Department of Metallurgy,
Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

Pure Ni-Cr alloys containing up to 29% Cr and Co-Cr alloys containing up to 23% Cr were prepared in vacuum. Corrosion rates in sulfuric and nitric acids, corrosion potentials, and critical current densities for passivity were determined at 25°C. It is concluded that specific alloying proportions of passive compositions are better evaluated in relation to electron configuration of the alloy system by critical current densities than by potential or corrosion rate measurements.

Much work on the corrosion behavior of iron-chromium alloys has been published and is useful to an understanding of conditions favoring passivity in alloy systems. Similar data for the cobalt-chromium system have not been reported. For nickel-chromium alloys most of the previous work involved rather impure metals and often ill-defined experimental conditions. Data reported by Rohn (1) and Pilling and Ackerman (2) indicate that as Cr content is increased, corrosion rates of the Ni-Cr alloys in oxidizing media are decreased. Grube (3) showed that in 1*N* HNO_3, the alloys become passive and their corrosion rates reach a minimum at about 10% Cr.

In the present work, relatively pure Ni-Cr and Co-Cr alloys were investigated for the low Cr solid solution range. Particular attention was paid to the quantitative alloying proportions required to achieve passivity.

Experimental Procedure

Alloys were prepared from high-purity Cr purchased from the Electro Metallurgical Company, carbonyl Ni (99.93% Ni) furnished by courtesy of the International Nickel Company, and high-purity Co (99.97% Co) supplied by courtesy of the Cobalt Information Center at Battelle Memorial Institute. Induction melting was carried out under a vacuum of 10^{-5} mm Hg, with the melt contained in a "Morganite" high-purity aluminum oxide crucible. No deoxidizers were added. Samples were cast in a helium atmosphere by drawing the melt into 8 mm diameter "Vycor" tubes and plunging the ingots into water. The helium was purified by passage over Mg chips at 640°C and, in later experiments, over Ti sponge at 800°C. In both cases the helium was passed through a trap surrounded by liquid nitrogen before entering the furnace.

Homogenization of castings was carried out at 1100°C for 12 hr in silica tubes using a helium atmosphere followed by a water quench. The Co-Cr alloys, which were hard and rather brittle, were used in the as-homogenized condition, while the Ni-Cr ingots were cold rolled to a thickness of 2.5 mm, given a 15-min anneal at 1000°C, and water quenched. Composition of each alloy was determined by chemical analysis.

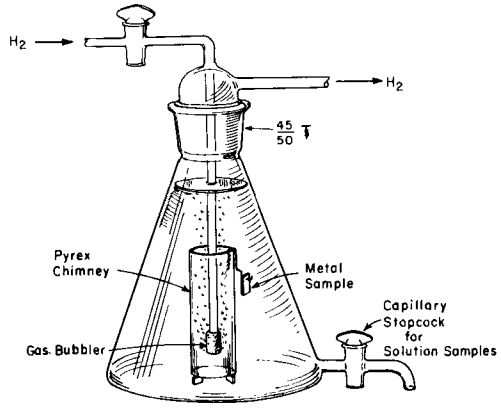

Fig. 1. Cell for measuring corrosion rates by weight loss and solution analysis.

Corrosion rate measurements were carried out in an air thermostat maintained at 25° ±0.5°C, using 2000 ml cells of the type shown in Fig. 1. Laboratory compressed air, filtered by means of glass wool and charcoal, was bubbled through the cells at the rate of 40 ml/min as determined by a flow-meter provided for each cell. Solutions were prepared from laboratory distilled water and reagent grade chemicals.

Specimens of Ni-Cr alloys for corrosion rate determinations were cut as rectangular coupons measuring approximately 3 cm long, 0.5-1 cm wide, and 0.2 cm thick. A hole 0.3-0.4 cm in diameter was drilled near one end so that the sample could be hung from a glass hook. These specimens were abraded smooth, finishing with 600 grit silicon carbide wet polishing paper. After washing with distilled water and wiping dry, specimens were immersed in boiling benzene for 5 min. This was followed by pickling in hot 6*N* H_2SO_4. Pickling was continued until the surface was sufficiently etched to reveal the microstructure of the metal. After pickling, samples were thoroughly washed with distilled water and dried in a desiccator.

[1] Present address: Diamond Fuze Laboratory, Washington, D. C.

Corrosion rates were measured by colorimetric analysis of aliquots of the test solution in which specimens were immersed. By periodic sampling, corresponding weight loss was calculated as a function of time. For Ni the dimethylglyoxime method (4) was used, and for Co the thiocyanate method (4). Conventional gravimetric weight loss measurements were also made and checked with weight losses calculated from analysis of the solution. All runs were continued for sufficient time to reach a constant corrosion rate.

Electrodes for polarization measurements were similar in size and shape to the corrosion rate specimens. Nickel wire was silver soldered to a stem which was machined on the electrode. A Teflon gasket between the electrode and a Pyrex tube was compressed by means of a nut and machine screw silver soldered to the nickel wire, in order to exclude the electrolyte from contact with any metal other than the electrode proper.

Potential measurements were made using a portable potentiometer in series with an electronic pH meter employed as a high resistance galvanometer. An Ag-AgCl, 0.1*N* KCl electrode was the reference electrode. Constant polarization current was supplied by 30 dry cells in series with an adjustable resistance.

Critical current densities for passivity were determined in a cell fitted with two auxiliary Pt electrodes and arranged so that the alloy electrodes could be pickled within the cell with 1:1 H_2SO_4, washed, and the test electrolyte introduced without exposure to air. Test solution and distilled water for washing were contained in 5-gal carboys connected to the cell by glass tubing. Deaeration was accomplished by prepurified grade nitrogen which had been passed over copper turnings at 450°C. The Luggin capillary of the salt bridge filled with the test solution was placed adjacent to the alloy electrode.

Critical current densities for passivity were measured by two methods. For Ni-Cr alloys, the "indirect" method was used. This consisted of applying a series of constant anodic currents slightly above the critical current density and measuring the times required to reach the passive potential. Current density i was then plotted against the reciprocal of time t for passivity in accord with the relation $i - i_c = K/t$, where i_c is the critical current density (5, 6). This relation is linear for currents not exceeding the critical current density by more than a factor of 2 or 3, and can thus be extrapolated to reciprocal time = 0 to obtain i_c. The value K represents the number of coulombs per unit area required to achieve passivity.

For the Co-Cr alloys, the "direct" method was used (7). This consisted of applying a given current and observing the potential. The lowest current which passivated the electrode was taken as the critical current density. At currents below the critical, polarization was continued until the potential changed at a rate less than 2 mv/min. The two methods give comparable values for i_c, as was demonstrated by similar measurements for the Fe-Cr alloys (8).

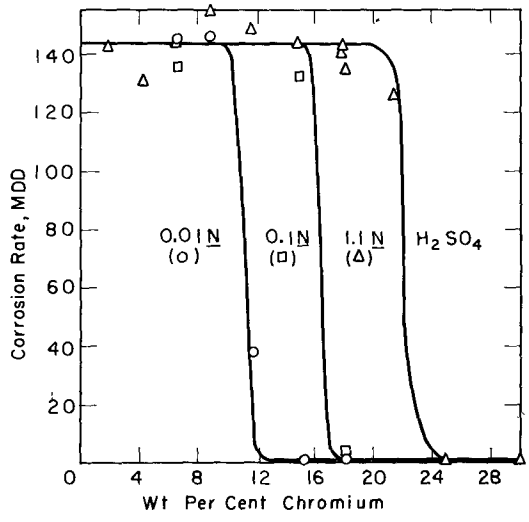

Fig. 2. Corrosion rates of Ni-Cr alloys in aerated H_2SO_4, 25°C, 4-day runs.

Corrosion potentials were also measured in the above cell. The electrodes were prepared in the same way as specimens for the corrosion rate determinations.

Experimental Results

Nickel-chromium.—Corrosion rates were measured in several media. In deaerated 1.1*N* (5%) H_2SO_4, 25°C, 10 day runs, corrosion rates were low, being of the order of 1 mdd, and showed little variation with chromium content.

In Fig. 2 the results of 4-day runs in aerated 1.1, 0.1, and 0.01*N* H_2SO_4 are shown. It can be seen that the corrosion rates of the active alloys are all the same within experimental error, the standard deviation being 6.3 mdd as determined from replicates. However, alloys containing more than a critical amount of Cr show a corrosion rate of practically zero, corresponding to the passive condition. These passive alloys sometimes showed an initial weight

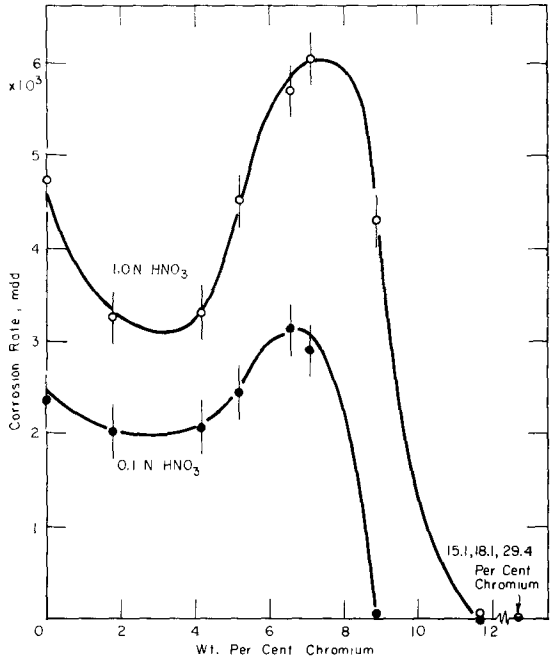

Fig. 3. Corrosion rates of Ni-Cr alloys in HNO_3, 25°C, 1-day runs.

loss as determined by colorimetric analysis, after which any further change was very slight. It should be noted that higher acid concentration shifts the passivity limit to higher chromium contents.

Figure 3 shows corrosion rates of these alloys in 1.0 and 0.1*N* HNO_3 as determined by one-day runs. Confidence limits (95%) were calculated by standard statistical methods (9). It can be seen that the initial Cr additions had little effect on the corrosion rate, causing only a slight decrease. Further additions caused a marked increase, with a peak occurring around 7% Cr. This type of behavior was also observed by Rohn (1) and Pilling and Ackerman (2), while Grube (3) found only a horizontal arrest but not a peak. The transition from activity to passivity is quite abrupt, coming between 7.1 and 8.9% Cr in 0.1*N* HNO_3, and between 8.9 and 11.7% Cr in 1.0*N* HNO_3.

Corrosion rates were also determined in 1*N* H_2SO_4 to which was added 25 g of hydrated ferric sulfate per liter. In this case only one run was made, all samples being placed in the same cell. The data of Table I show that this solution is much more strongly corrosive toward the two alloys which remained active than is 1.0*N* HNO_3. The initial major critical passive composition is shifted to lower Cr content, now lying between 4.2 and 6.6% Cr. These corrosion rates were determined by the conventional weight loss method only, since the high concentration of iron in the solution interferes with the colorimetric determination of nickel. However, since in other oxidizing media studied, these alloys, when in the active condition, exhibited a constant corrosion rate from the beginning of the run, it seems reasonable that this was also true in this case. The active alloys were left in the solution 6 hr, the others for 2 days.

Corrosion potentials of Ni-Cr alloys in deaerated (H_2-saturated) 1.1*N* H_2SO_4 showed no systematic variation with chromium content and, in fact, the potentials of these alloys were not far removed from the potential of the reversible hydrogen electrode. Corrosion potentials in 0.1 and 1.0*N* HNO_3 are shown in Fig. 4. There is a more or less continuous ennobling of the corrosion potential with increasing chromium content with a slight peak being observed in the region of 4-6% Cr.

Critical current densities for passivity were determined for these alloys in N_2-saturated 1.1*N* H_2SO_4 by the indirect method. The results are shown in Fig. 5 and 6. These curves have similar shape, but with the absolute values of critical currents considerably larger in 1.1*N* than in 0.01*N* H_2SO_4. It appears that in both cases the critical current density decreases sharply as Cr is increased to the vicinity of 14%, after which the decrease in critical current density becomes much less steep. Coulombs per square centimeter for passivity in 1.1*N* H_2SO_4 range from 0.3 for high Cr alloys to 2.0 for low Cr alloys.

Cobalt-chromium.—In contrast to the Ni-Cr system, the Co-Cr alloys do not have a single phase structure. Pure cobalt itself in the annealed condition is a mixture of hexagonal close-packed and face-centered cubic phases, and this behavior is reflected in that of the alloys. There is some disagreement as to the Co-Cr phase diagram (10, 11), but there is agreement that at the annealing temperature of 1100°C all alloys used in this work would be in a single phase field. Also, Wever (10) reported that x-ray data revealed only the face-centered cubic and hexagonal close-packed phases in alloys of 20 and 30% Cr quenched from 1000°C. Since the

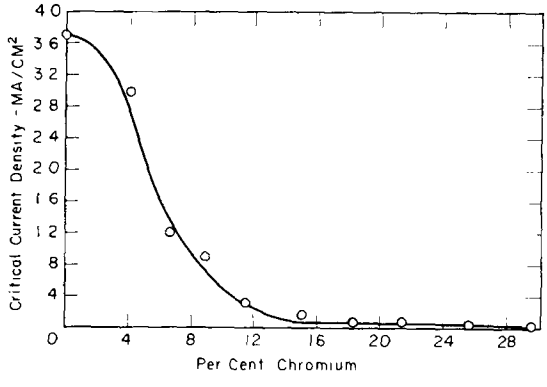

Fig. 5. Critical current densities for passivity of Ni-Cr alloys in N_2-saturated 1.1N H_2SO_4, 25°C.

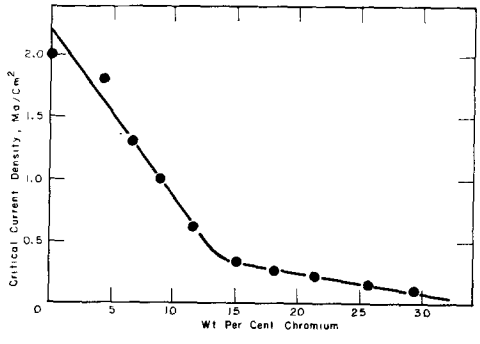

Fig. 6. Critical current densities for passivity of Ni-Cr alloys in N_2-saturated 0.01N H_2SO_4, 25°C.

temperature of the transformation is relatively low (500°-850°C), and the equilibrium two-phase field between the high- and low-temperature modifications is narrow, it appears that very little diffusion would take place during quenching. Therefore, it is probable that the two phases present in the alloys as tested had the same chemical composition.

Kröhnke and Masing (12) studied the corrosion potential and anodic and cathodic polarization behavior of face-centered cubic and hexagonal close-packed Co in 0.1 and 2.0*N* HCl. They found the two crystalline modifications to behave identically. One of us also found that body-centered and face-centered cubic 18-8 stainless steels corrode at essentially the same rates in several media (13). From this it appears reasonable to conclude that the behavior of the Co-Cr alloys was not greatly affected by the presence of two different crystalline forms. Metallographic examination showed that the microstructures of all these alloys are similar and that the observed changes in electrochemical behavior do not correspond to any change in microstructure.

Corrosion rates of the Co-Cr alloys in 0.1 and 1.0*N* HNO_3 are shown in Fig. 7. Time of test ranged from hours to days depending on whether the corrosion rate was high or low. Uniform corrosion was observed in all cases. Pure Co has a corrosion rate about 10 times higher than pure Ni, and the active alloys also show higher rates than do the Ni-Cr alloys. The shapes of the corrosion rate-composition curves also differ for the two alloy systems in that the initial Cr addition causes a marked decrease in corrosion of the Co alloys and no maximum is found. There is, however, a discontinuity in slope in the region from 2 to 4% Cr, similar to the more pronounced change in the Ni-Cr system. The onset of passivity in HNO_3 begins at about 12% Cr, since alloys containing more Cr corroded at a rate of 0 mdd in 0.1 *N* HNO_3 and 0 to 7 mdd in 1.0*N* HNO_3.

Corrosion potentials of these alloys in 1.0*N* HNO_3 are shown in Fig. 8. A pronounced shift toward more noble potentials is observed as Cr content is increased, but it is not possible on the basis of these data alone to draw any conclusions regarding critical composition limits for passivity.

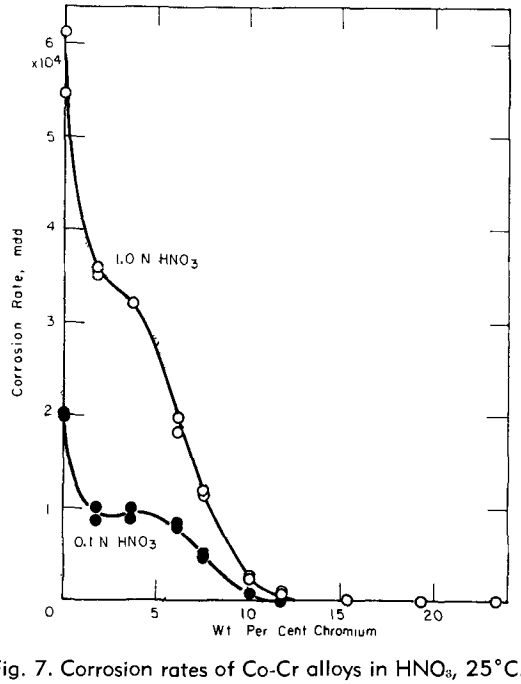

Fig. 7. Corrosion rates of Co-Cr alloys in HNO_3, 25°C.

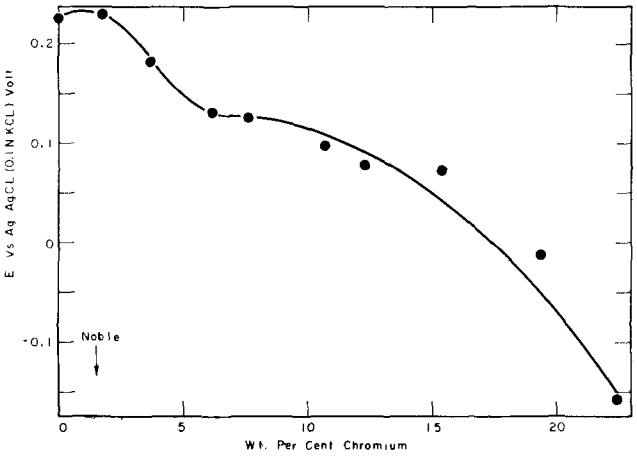

Fig. 8. Corrosion potentials of Co-Cr alloys in 1.0N HNO_3, 25°C.

Figure 9 is a plot of critical current densities with composition, obtained by the direct method. Pure Co, as well as alloys containing up to 6.2% Cr, have very high critical currents, while a sharp drop occurs in the vicinity of 8% Cr, followed by a levelling off again. These data give a clear indication of a critical composition in the vicinity of 8% Cr, as well as indicating that for alloys of this or higher Cr content the critical current density (~1 ma/cm²) is low enough for self-passivation of the alloys to be possible in strongly oxidizing media.

Discussion

Nickel-chromium alloys.—In deaerated 1.1*N* H_2SO_4 the corrosion of Ni and Ni-Cr alloys appears

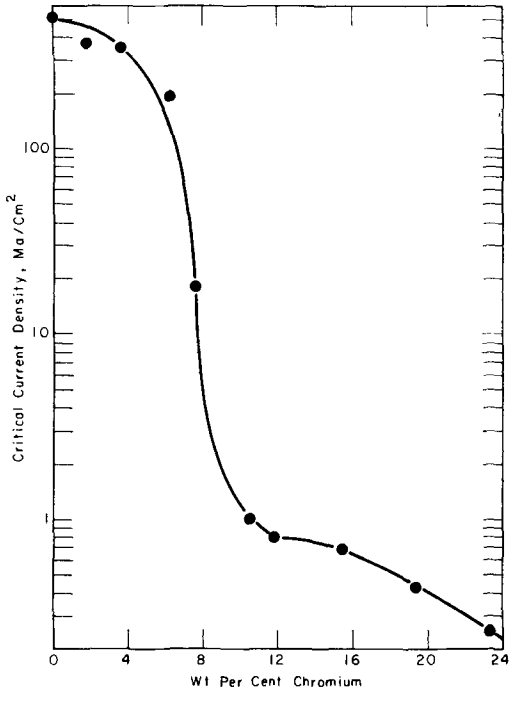

Fig. 9. Critical current densities for passivity of Co-Cr alloys in N_2-saturated 1.0N H_2SO_4, 25°C.

to be largely under anodic control. This is suggested by the fact that the corrosion potentials are not far removed from potentials of the reversible hydrogen electrode. This means that the local cathodes are only slightly polarized.

On the other hand, in aerated sulfuric acid the corrosion rates of the active alloys appear to be controlled by diffusion of dissolved oxygen to the metal surface. This is indicated by the fact that the corrosion rates of the active specimens are essentially independent both of alloy composition and acid concentration. It is also indicated by correspondence of the corrosion rate (140 mdd = 5.3 x 10^{-5} amp/cm^2) to the limiting diffusion current density for oxygen, i.e., in accord with the equation $i = (DnFc/\delta)$, where $D = 2 \times 10^{-5}$ cm^2/sec, $n = 4$, $F = 96{,}500$ coulombs/equiv., $c = 2.5 \times 10^{-7}$ moles dissolved O_2/cc, and δ the thickness of the stagnant diffusion layer is assumed equal to 0.035 cm. The latter value of δ is consistent with observed values.

That the corrosion rates of the active alloys should be anodically controlled in deaerated acid and cathodically controlled in aerated acid is in no way self-contradictory. In deaerated acid, the cathodic process is reduction of hydrogen ions to gaseous hydrogen, while in aerated acid the cathodic reaction involves reduction of dissolved oxygen by hydrogen ions to form water. The standard free energy change for the latter reaction is much greater than that of the former, so that in aerated solution the difference between the open circuit anode and cathode potentials is much greater than in deaerated solution. Thus a very large current would be necessary to polarize the local anodes to the open circuit cathode potentials, and long before this happens the limiting diffusion current for oxygen is reached and becomes the rate-determining step.

In all the oxidizing media used in this work the Ni-Cr alloys exhibited a critical composition, that is, alloys containing less than the critical amount of chromium for passivity corroded relatively rapidly compared to those containing more than the critical percent. The term passive, as used in this discussion, is limited to the case of a metal which is polarized to a potential more noble than its Flade potential in the given environment and has an accompanying comparatively low corrosion rate. In the case of those alloys which are passive under a given set of conditions, it can be assumed from previous discussions (7, 14-16) that the local anodic current produced by corrosion of the active alloy exceeded the critical current density for passivity. In this way the low corrosion rate of the passive state follows in sequence the higher corrosion rate of the active state.

It appears to be a general rule that whenever the current density equivalent to the corrosion rate approaches the critical current density passivity is established. The present data bear out this relationship. The corrosion current densities are always less than the critical current densities to an extent dictated by the anode-cathode area ratio, a low ratio accounting for a greater observed difference between the two values than a high ratio.

Based on the fact that the passive film on Fe, Cr, and Cr-Fe alloys is equivalent to about 0.01 coulomb/cm^2 (8) or less, the value of 0.3 to 2 coulomb/cm^2 for Ni-Cr alloys indicates that anodic dissolution of the alloy precedes passivity. The same is true of iron the value for which is about 1 coulomb/cm^2, and as Franck (6) showed, an insulating film of perhaps $FeSO_4$ forms first, favoring high current densities within pores of this film necessary to achieve the passive state. This situation is also borne out by a relatively low initial slope of potential vs. time at constant applied current density for Ni-Cr alloys preceding a rapid fall of potential to the noble passive value, whereas for stainless steels which passivate without initial salt film formation, the potential fall is immediate, and coulombs for passivity are a direct measure of the amount of passive film substance on the surface.

The rather wide variation in the amount of Cr needed to passivate these alloys in different media is a result of the different corrosion rates, anode-cathode area ratios, and critical current densities which prevail in these media. In the case of aerated sulfuric acid, only the critical currents and not the corrosion rates of the active alloys were reduced as the acid concentration was reduced. Decreases in acid concentration correspondingly lowered the critical amount of Cr required for passivity because critical current density decreases with increasing Cr. Since the critical Cr compositions fall in a region where critical current density is changed only slowly with Cr content, small changes in the critical current density for passivity by means of decreasing acid concentration shifted the critical Cr content markedly.

In nitric acid, corrosion rates as well as critical currents were raised as acid concentration was increased. The increase in corrosion rate is probably due to increase in concentration of nitrate ion, which is reduced at the local cathodes, while increase in hydrogen ion concentration increases observed critical current densities. The observed increase in Cr necessary to produce passivity in these alloys on increasing acid concentration indicates that the higher critical current density brought about by increased acid concentration outweighs the effect of increased corrosion current. By adding ferric ions to 1*N* H_2SO_4, a corrosion rate higher than that in 1*N* HNO_3 was obtained at approximately the same hydrogen ion concentration, so that the critical amount of Cr was decreased from about 12 to 6.6% Cr as is seen from data of Table I and Fig. 3.

In retrospect, all the data show that passivity limits for these alloys as obtained from corrosion data reflect not only the basic properties of the alloy system, but also depend strongly on the environment. Important are the nature of the anion, depolarizer concentration, surface *p*H, degree of stirring, etc. This is especially true of a system such as Ni-Cr, because critical current densities do not vary as sharply with composition as they do in the Cr-Fe alloys as shown, for example, by data of King and Uhlig (8).

The variation of critical current density with alloy composition appears to be the important funda-

mental property of alloys capable of becoming passive. The shape of the critical current-composition curve is found to be nearly the same in 1.1 and 0.01*N* H_2SO_4 (Fig. 5 and 6) even though the critical currents are much smaller for the lower acid concentration. In both cases a change in slope occurs or a practical minimum is reached in the vicinity of 14% Cr. This is the figure which it would probably be most profitable to compare with the prediction of a critical composition at 8.2% Cr made by one of us (17) based on electron configuration in the alloy system. Other than the simplified assumptions made in the theoretical calculation, difference between theory and observation may also be a result of experimental factors, such as a possible difference between surface composition from bulk composition of the alloys caused by preferential corrosion of one of the alloy components.

Cobalt-chromium alloys.—The behavior of the Co-Cr system was similar to the Ni-Cr system, as might be expected. Differences in shape of the corrosion-composition curves in nitric acid indicate that Cr alloyed with Co, even in small amounts, decreases the corrosion rate (Fig. 7), while in the Ni-Cr system, Cr markedly increases the corrosion rate just short of the passive composition (Fig. 3). This may be related to the possibility that Co is a better catalyst than Ni for reduction of NO_3^-, which in turn is consistent with a much higher corrosion rate of pure Co than pure Ni in HNO_3. This being the case, if Cr is an intermediate catalyst, an addition of Cr to Co will increase cathodic polarization of Co-Cr alloys while decreasing it for Ni-Cr alloys.

The effect of Cr on the critical current densities of the Co-Cr alloys (Fig. 9) was much more pronounced than in the Ni-Cr system (Fig. 5, 6). In this respect, behavior of Co-Cr alloys is similar to the behavior reported for Fe-Cr alloys (8). The critical current densities for the Co alloys containing more than 10% Cr were about the same or somewhat lower than those of the corresponding Ni-Cr alloys, but the low Co-Cr alloys and pure Co had much higher critical current densities. For this reason, the critical composition is clearly indicated as close to 8% Cr. This is in reasonable agreement with the 6.2% Cr predicted by the electron configuration theory (17).

Dissolution of Nickel in Acid Ferric and Ceric Solutions

Phoebus M. Christopher and Cecil V. King

Department of Chemistry, New York University, New York, New York

ABSTRACT

Dissolution rates of nickel cylinders rotated in acidified solutions of $FeCl_3$ and $Ce(SO_4)_2$ have been measured. The rates are transport-controlled, but the Ni surface becomes extremely rough, and first-order constants are obtained only if a uniform degree of roughness is maintained during runs. The values of the rate constants then depend on the structure of the metal, e.g., whether it has been annealed, mechanically worked, etc.

The rate of dissolution of nickel in ferric alum solutions was measured by Van Name and his coworkers (1), who found it to be approximately the same as that of several other metals in the same reagent. The authors regarded the dissolution to be controlled by diffusion, or by convective-diffusive transport, of ferric ion to the metal surface.

The present study shows that a polished nickel surface becomes very rough in acidified ferric and ceric solutions, more so in the former than in the latter. This is at least partly due to preferential dissolution at grain boundaries and at flaws in the mechanically worked metal. It indicates that, while the cathodic reaction (reduction of ferric or ceric

ions) probably occurs equally well at any point on the surface, the anodic reaction (formation of aqueous Ni^{++}) is not uniformly distributed. The rough surface of a rotating cylinder increases turbulence in the solution, at least near the interface, which results in larger dissolution rates than are found with smooth cylinders. The effect of roughness has been studied by Makrides and Hackerman in the dissolution of steel (2). These authors decided that roughness may increase the effective surface area at high rotational speeds, where the effective thickness of the boundary layer is small.

Experimental

Cylinders were cut from a nickel anode bar (99.6% Ni, supplied by International Nickel Co.) which had been rolled to an elliptical cross section. They were 2.52 cm long and 1.9-1.7 cm in diameter when in use. They were mounted on a shaft with only the peripheral surfaces exposed to the solutions. Some specimens were annealed by heating at 850°C for 2 hr in argon and cooling over a period of 4-5 hr in the same gas.

The reaction vessel was a square bottle (which has the effect of baffles in the solution), equipped with a tube passing through a hole in one side to admit nitrogen. The solution volume was 400 ml in all cases. Solutions were deaerated since preliminary runs showed that oxygen is reduced freely. All experiments were carried out at 18°-21°C. C.P. $FeCl_3$ was used directly while U.S.P. $Ce(SO_4)_2$ was recrystallized twice. All ferric solutions were made up with 1M HCl and all ceric solutions with 1M H_2SO_4. Dissolution was followed by weighing the cylinders after 2- to 10-min runs.

Results and Discussion

The first experiments were carried out with specimens which were polished with 2/0 emery paper initially, but not repolished when they were removed and weighed. At 3000 rpm the surface very quickly became rough, and the weight loss increased in successive equal time intervals in the same solution; for example in 0.05M $FeCl_3$ (initially) the dissolution rate had doubled after half the ferric ion had been reduced. Figure 1 is a plot of log (a-x) for two unannealed cylinders run in this manner. In 0.02M $Ce(SO_4)_2$ the rate became first-order after

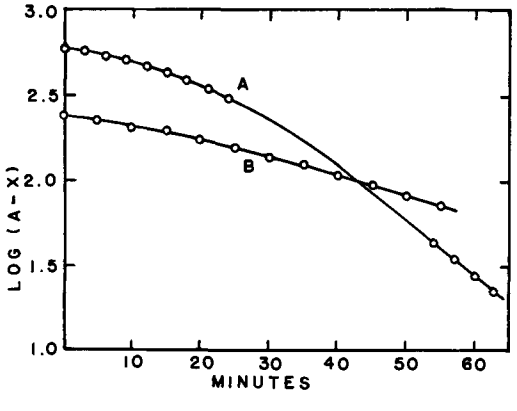

Fig. 1. Unannealed cylinders, polished initially and allowed to roughen with time. A, 0.05M $FeCl_3$ + 1M HCl. B, 0.02M $Ce(SO_4)_2$ + 1M H_2SO_4.

25 min, while in 0.05M $FeCl_3$ a somewhat longer time was required. Values of k (from the slopes, see Eq. [1] below) varied from 0.39 to 1.9 cm/min in the ferric solution, and from 0.34 to 0.71 cm/min in the ceric solution. Examination showed that the surface became rougher in the $FeCl_3$.

Thereafter runs were made in two ways: (a) the cylinder was polished initially and after each short immersion, to keep it as smooth as possible; or (b) the specimen was etched before use until there was no further effect on the rate. In both cases consistent rate constants k were obtained with the first-order equation:

$$k = \frac{2.3\,V}{A\,t} \log \frac{a}{a-x} \qquad [1]$$

where V is in cm^3, A in cm^2 (the apparent or projected area), and the other symbols have their usual meanings. Since the metal cylinders dissolved at a steady rate of 0.5 mg/10 min in the 1M HCl solution after all ferric ion had been reduced, a corresponding correction was applied to all weight losses. Dissolution in 1M H_2SO_4 after ceric ion was reduced was negligible.

Table I gives mean values of k for several runs of 60- or 70-min duration with unannealed cylinders. It is evident that the exact values of k obtained with polished samples depend on the time period chosen for immersion between polishings; the value 0.78 for $FeCl_3$ is twice that found from the initial slope of the log $(a - x)$ plot in Fig. 1 This does not, however, apply to the ceric solution.

In addition to the uncertainty of reproducibility with polished cylinders, it became evident that different unannealed cylinders reached different maximum rates after etching. This was probably due to lack of uniformity of structure of the anode bar from which they were cut. Part of the roughness took the form of irregular grooves along the length of the cylinders, in the direction in which the bar had been rolled, and the appearance varied from one cylinder to another. For these reasons some of the cylinders were annealed in order to obtain more uniform structure. On etching, the surface appeared much rougher than that of unannealed specimens, and dissolution rates were higher in most cases. Table II gives some values of k from single short runs designed to test the effect of solution concentration.

The rate constant in $FeCl_3$ apparently can vary from about 1.0 to a maximum of 2.2 cm/min under these conditions, depending on the past history of the metal, but for any one specimen it is reproducible and is independent of reagent concentration. In $Ce(SO_4)_2$ it is possible that the degree of roughness reached depends somewhat on concentration. The dissolution in 0.05M $FeCl_3$ of an annealed specimen,

0.10	1.06	2.11	1.05

polished initially, was similar to that shown in Fig. 1, but maximum roughness had not been reached after 55 min in the same solution.

A few runs were made in 0.02M $FeCl_3$ at other rotational speeds, and values of k are plotted in Fig. 2. While the values are consistent among themselves, it will be seen that these cylinders had their own characteristic rates.

The following empirical equation represents dissolution rates for smooth cylinders in a number of cases (3):

$$k = 0.010\ U\ (D/\nu)^{0.8} \qquad [2]$$

where U is peripheral speed, D, diffusion coefficient, and ν, kinematic viscosity. The lower dashed line of Fig. 2 represents this equation, using $D = 7 \times 10^{-6}$ cm²/sec for $FeCl_3$ (4) and $\nu = 9.36$ cm²/sec (the value for 1M HCl). The equation is of course inadequate in this case. At 17,000 cm/min it gives $k = 0.54$; for a smooth copper cylinder in $FeCl_3$ King and Weidenhammer (4) found 0.56 cm/min.

For roughened cylinders Makrides and Hackerman (2) proposed the equation:

$$k = (1.25 + 5.76 \log d/h)^{-2}\ U\ (D/\nu)^{0.644} \qquad [3]$$

where d is the cylinder diameter and h is the average height of surface irregularities. Microscopic examination of annealed Ni cylinders, etched in $FeCl_3$ to maximum dissolution rate, showed a fairly uniform groove depth at grain boundaries of about 0.05 cm. The upper dashed line of Fig. 2 represents Eq. [3] using this value of h and with D and ν as before. It obviously gives a much better prediction of the magnitude of the experimental values. The exponent 0.644 on the inverse of the Prandtl number D/ν has not been verified, and the function is quite sensitive to this exponent; e.g., with a value of 0.8, Eq. [3] gives almost the same slope as the lower dashed line of Fig. 2. Also, Eq. [3] predicts that k should vary with cylinder diameter, but this has not been tested.

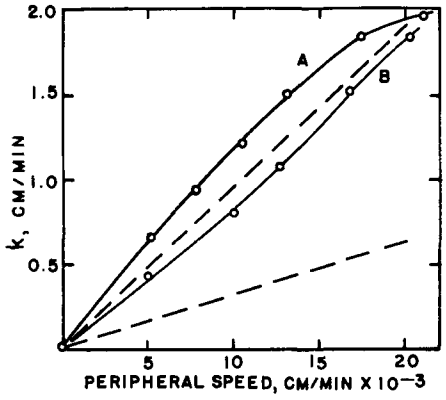

Fig. 2. Rate constant vs peripheral speed in 0.02M $FeCl_3$ + 1M HCl. A, annealed cylinder. B, unannealed. Lower dashed line, Eq. [2]. Upper dashed line, Eq. [3].

Oxidation of Niobium in the Temperature Range 350°-750°C

D. W. Aylmore, S. J. Gregg, and W. B. Jepson

Department of Chemistry, University of Exeter, Exeter, England

ABSTRACT

The kinetics of the oxidation of niobium in dry oxygen at 1 atm pressure have been measured at temperatures in the range 350°-750°C with some additional measurements at 0.1 atm. At 350°C, in tests lasting 270 hr, the oxidation is protective, but at 400°C and above the metal oxidizes, apart from an initial period, at a constant rate with a second breakaway reaction (rate transition) at 450° and 500°C but not at higher temperatures. The anomalous temperature coefficient of the linear rate has been confirmed. The specific surface of the oxide scale has been measured and, apart from an anomaly at 400°C, is shown to decrease with increasing temperature of oxidation and this is ascribed to sintering. The oxidation kinetics of a purer batch of niobium were also investigated. The effect of moisture is to decrease the rate at 400° and 450°C, whereas at 600°C the rate is unchanged.

There have been a number of kinetic studies of the oxidation of niobium both in air and in oxygen. Inouye (1) has investigated the oxidation in dry and in moist air at atmospheric pressure at temperatures in the range 400°-1200°C and has found that the effect of moisture was to increase the linear rate

at 400°C and to decrease it at 600°C. Klopp, Sims, and Jaffee (2) have measured the rate of oxidation in both dry oxygen and ordinary air at temperatures in the range 600°-1200°C and have investigated the penetration of oxygen into the metal. The comprehensive study by Bridges and Fassell (3) has dealt with the oxidation in oxygen at pressures from 1 to 41 atm at temperatures over the range 400°-800°C; the linear rate of oxidation was found to be pressure dependent and the temperature coefficient of the reaction was shown to be negative from 550° to 650°C. Gulbransen and Andrew have dealt with the kinetics at 0.1 atm of oxygen in two separate investigations (4, 5) covering the temperature ranges 250°-375°C and 375°-700°C, respectively; at temperatures up to 375°C the metal oxidized according to a parabolic rate law over the first 2 hr, the period of the studies, but at higher temperatures the reaction, after an initial protective stage, underwent a breakaway [Gulbransen and Andrew (5) use "rate transition"] and the rate of oxidation increased up to the constant value, that of the linear rate. The linear rate was found to be almost independent of temperature between 550° and 625°C. More recently, Cathcart, Campbell, and Smith (6) have confirmed the breakaway and shown it to be associated with the development of small, blister-like cracks in the oxide film. Goldschmidt (7), following earlier work by Brauer (8), has re-investigated the polymorphic forms of the oxide product, niobium pentoxide, and shown that there are in fact two, and not three, such forms, viz., the α- or "low-temperature" modification which transforms spontaneously to the β- or "high-temperature" modification even at room temperature.

The present work constitutes an investigation of the oxidation kinetics at temperatures in the range 350°-750°C in oxygen at pressures of 1 atm with some additional measurements at 0.1 atm. The anomalous temperature coefficient of the reaction has been confirmed, and a second breakaway has been found to occur both at 450° and at 500°C but not at higher temperatures; this absence of second breakaway is believed to be due to a sintering of the oxide, which is confirmed to some extent by measurements of the specific surface of the oxide scale. Approximate calculations from these measurements lead to a value for the average crystallite size which is in good agreement with that found by Goldschmidt (7) using x-ray methods. The results for the kinetics in moist oxygen are in disagreement with those of Inouye (1) for moist air; the course of the oxidation differs little from that in dry oxygen.

Experimental

The main kinetic study was carried out by gravimetric determination of the weight gain of the sample on a thermal balance in an oxygen pressure of 1 atm. The niobium sample was contained in a basket of platinum gauze (to hold any fragments of oxide spalling from the metal) which was suspended in the reaction chamber by a length of platinum wire hooked to the underside of the balance pan; at the start of the run the furnace, pre-set to reaction temperature, was raised into position round the reaction chamber and thermal equilibrium was reached within about 10 min. The arrangement was similar to that previously described (9), except that the oxygen was additionally dried by passing it over "Linde" molecular sieves (10).

In addition, several runs were carried out at 0.1 atm using a quartz spring balance of conventional design, while the early stages of the oxidation at two temperatures were examined using a low sensitivity quartz microbalance (11, 12) (precision: 4 μg); with both these techniques, oxygen was admitted to the outgassed sample at reaction temperature.

The bulk of the work was carried out with material (niobium A) obtained from Murex Ltd. in the form of 1/16 in. thick sheet (analysis: C, 0.1%; Al, 0.03%; Si, 0.02%; Fe, 0.03%; Cr < 0.01%; Mn < 0.01%; Cl < 0.01%; Pb < 0.01% and Ta 0.3 to 0.4%). Samples in the form of a rectangle (4 x 1.5 cm) were cut from the sheet and abraded down to Grade 00 emery under petroleum ether and finally degreased in benzene vapor. Some additional runs were also carried out with a purer material (niobium B) in the form of 0.010 in. thick sheet (analysis: C, 0.0162%; Ta, 0.143%; Fe, 0.008%; Zr, 0.65%; Ti, 0.013%; N, 0.028%; O, 0.107%). This latter was kindly donated by Dr. K. F. Andrew and was of the same batch as that used in his study (5) with Dr. E. A. Gulbransen.

Results

Oxidation of Niobium A in Dry Oxygen

At 350°C, the first temperature studied, the weight gain of a sample exposed for 265 hr was only 0.5 mg cm^{-2}, and as far as could be judged, the rate of oxidation decreased with time.

Curves for the increase in weight (mg/cm^2 of geometric surface) against time were obtained for temperatures at 50° intervals in the range 400°-750°C, and the runs were continued at all temperatures, except 400°, until the sample had been oxidized to completion.

The course of the oxidation at 400°C is shown in Fig. 1; the rate increases over the branch OA becoming constant after about 8 hr in agreement with earlier work (3). Runs at this temperature were continued for 230 hr, after which time about 25% of the metal was oxidized, and the rate of oxidation was constant over this period. At 450°, however, the rate increased only for the first 30 min, after which it decreased (AB of Fig. 2), becoming constant after

4 hr; the early stages of the oxidation at this temperature were investigated in more detail on the microbalance at 7.6 cm oxygen pressure. From the curve of Fig. 3 which is typical, it is seen that after breakaway at X the rate increases to a maximum value (1.4 mg cm^{-2} hr^{-1}) at A and then decreases. Presumably if the run could have been carried out for a longer period, the rate would ultimately have become constant as in Fig. 2. The weight gain of 70 μg cm^{-2} at which breakaway occurred is in agreement with earlier work (5). The curve corresponding to complete oxidation of the metal is shown in Fig. 4, and it can be seen that the linear branch BC persists for only about 20 hr; at C the rate of oxidation increases, so that a second breakaway can be said to have occurred, and then decreases until at D a further section of the metal undergoes a second breakaway reaction and the metal oxidizes to completion.

At 500°C the material oxidized at a constant rate from the start of the run (Fig. 2) for a period of about 6 hr, after which it began to increase (Fig. 5); toward the end of the run there was a second breakaway reaction and the metal then oxidized to completion at a much higher rate. At 550° and 600°C the kinetics again conformed to the linear rate law from the start of the run; now there was no second breakaway and the linear rate was maintained until about 75% of the metal had been consumed, after which the rate began to fall off (Fig. 5). This was probably due to a decrease in the area of metal undergoing oxidation. The behavior at 650°C was rather similar, except that the decrease in rate occurred after only 25% of the metal had been oxi-

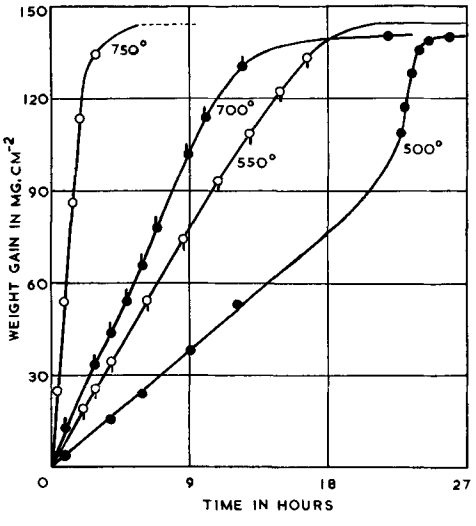

Fig. 5. Oxidation of niobium at 500°, 550°, 700°, and 750°C in dry oxygen.

dized, and cannot therefore be due to a decrease of sample area.

At 700°C the oxidation curve showed no clear linear branch (Fig. 5); after decreasing for the first 5 hr, the rate increased and then slowly decreased again. At temperatures of 550°C and above, no second breakaway was obtained in any of the runs.

At least three runs were carried out at each temperature, and the linear rates at 400°C and at temperatures from 500° to 650°C were in good agreement, often within 2-3% of the mean; at 450°C the spread in values of the rate was wider (about 15%). The times for which second breakaway occurred (450° and 500°C) agreed within about 10% of the mean. The average linear rates for each temperature are given in Table I and are plotted in Fig. 6

Table I. Oxidation rates of niobium in dry oxygen

Temp, °C	Rate, mg $cm^{-2}h.^{-1}$	Temp, °C	Rate, mg $cm^{-2}h.^{-1}$
400	0.163	600	35.7
450	1.31	650	8.72
500	4.0	700	16.9*
550	8.52	750	64*

* Approximate values only.

in the Arrhenius form; values from the literature (1, 5) are included for comparison.

As will be seen, the rate at 650°C is less than that at 600°C, and in order to confirm the apparent negative temperature coefficient of the reaction between these two temperatures, two additional experiments were carried out. In the first, a sample was oxidized for 10 min at 635°C and the linear rate measured, the temperature was then raised in steps of 10° up to 695°C and the linear rate measured at each temperature; in the second, the linear rate was measured at a number of temperatures in the range 685°-595°C, the temperature being lowered stepwise. The results, which are given in Fig. 7, show that over the range 600°-650°C the linear rate does in fact decrease with increasing temperature of oxidation.

The Oxide Product

The weight gain corresponding to complete oxidation of the metal agreed to within 0.01%, after making due allowance for oxidation of the impurity elements, with that calculated for niobium pentoxide (1).

The product obtained on oxidizing the metal to completion at 450°C consisted of a mixture containing approximately equal weights of scale and of fine powder, the latter being composed of particles with diameters up to 50μ, with the majority in the 5-10μ range. Since the product obtained on oxidizing a sample to a weight gain corresponding to a point on branch BC (Fig. 4) was composed only of scale, it may be concluded that the powdered oxide only forms after the second breakaway (point C). Microscopic examination of the metal surface after second breakaway revealed the presence of deep craters which in some cases extended to the opposite face (Fig. 8).

The percentage by weight of scale in the product resulting from complete oxidation of the metal increased with increasing temperature of oxidation, and at 550°C, the lowest temperature at which second breakaway did not take place, the product contained 90% scale. The oxide obtained at each temperature was carefully sieved through platinum gauze (80 mesh/linear in.) to separate the powder from the scale, and the specific surface of the latter was then measured by the method of krypton sorption (13); for the 400°C sample, which was only partially oxidized, a fragment of scale was detached from the metal for the specific surface measurement. Previous work (13) has shown that repeat determinations of the specific surface agree within ±1%. As can be seen from Fig. 9, the specific surface S of the oxide scale varies over a comparatively wide range, from 0.9 $m^2\ g^{-1}$ to 19.8 $m^2\ g^{-1}$ for the oxides formed at 750° and 450°C, respectively.

An approximate estimate of the size of the individual crystallites making up the scale can be obtained by arbitrarily assuming the latter to be made up of equal-sized cubelets of edge-length 1. Using the expression (14)

$$l = \frac{6}{S\rho}$$

where ρ is the density of the oxide, the 450° and 750°C products then correspond to crystallite sizes of 0.061μ and 0.68μ, respectively. These values are in reasonable agreement with those found by Goldschmidt (7) using x-ray analysis. The decrease of specific surface with increasing temperature of oxidation from 450°C upwards (Fig. 9) points to the scale having sintered after it has been formed. This is substantiated by an experiment where the scale

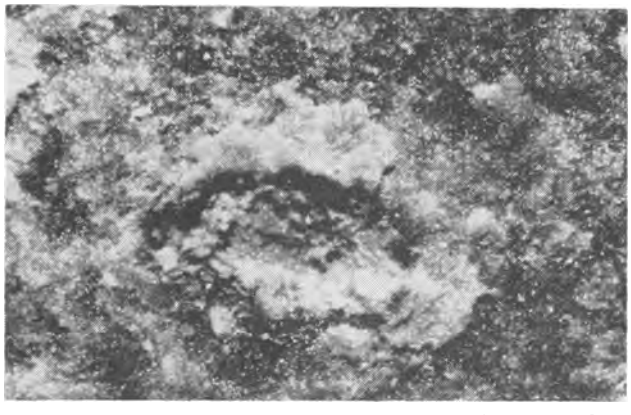

Fig. 8. Characteristic appearance of the metal surface after second breakaway, oxidized at 450°C for 47 hr. Magnification 200X before reduction for publication.

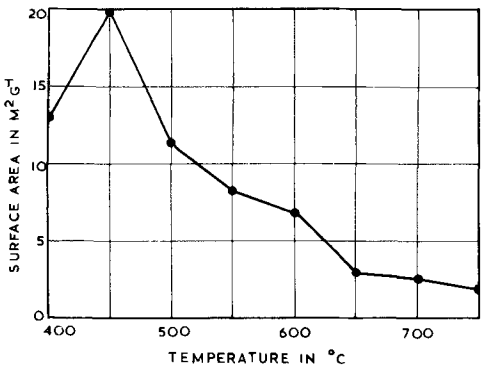

Fig. 9. Specific surface of the oxide scale as a function of oxidation temperature. The times of oxidation were 247 hr (400°), 122 hr (450°), 29 hr (500°), 24 hr (550°), 5 hr (600°), 20 hr (650°), 11 hr (700°), 4.5 hr (750°C).

formed at 500°C was heated for a period of 5 hr in oxygen at 700°C, when the specific surface fell from 11.3 to 5.9 $m^2 g^{-1}$. The rate of sintering of the scale will depend both on the time and temperature of heating, and since the rate of oxidation is not a single-valued function of temperature (see Fig. 6), the fact that a smooth curve cannot be drawn through the experimental points of Fig. 9 is readily understood. Thus, the specific surface of the 600°C product is apparently too large with respect to the 550° and 650°C products, but the oxidation time was only 5 hr for the first, as compared with 24 and 20 hr, respectively, for the last two products.

That sintering should occur is hardly surprising, for the temperature of oxidation expressed as fraction of the melting point (7) of the oxide (1733°K) ranges from 0.39 to 0.59, and, as is well known (15), solid-state processes are greatly accelerated at temperatures above a critical value T_c, characteristic of the solid but lying within the range $0.39T_f$ to $0.53T_f$, where T_f is the melting point of the solid.

Oxidation of Niobium A in Moist Oxygen

Samples of niobium were oxidized in moist oxygen saturated at 25°C (1.8 wt %), at 400°, 450°, and 600°C. At each temperature the course of the oxidation was very similar to that in dry oxygen (Fig. 1 and 2) although at 400°C (Fig. 1) 13 hr elapsed before the rate of oxidation became constant, while at 450°C (Fig. 4) the second breakaway was retarded. The linear rates at 400° and 450°C, viz., 0.133 and 0.97 mg cm^{-2} hr^{-1}, are somewhat less than the corresponding values for dry oxygen (0.163 and 1.31 mg cm^{-2} hr^{-1}, respectively), while at 600°C the linear rate in the moist gas was the same, within experimental error, as that in the dry.

The present results are in marked disagreement with those of Inouye (1) for moist air (1.39 wt %) who found that the rate at 400°C was increased by a factor of about 30 and the rate decreased at 600°C by some 40%.

Oxidation of Niobium B in Dry Oxygen

Samples of the purer material, niobium B, were oxidized at a number of selected temperatures in order to compare both the shape of the oxidation curve and the linear rate with those of niobium A. The oxidation behavior of the two batches of metal differed markedly in that second breakaway and the associated formation of powdery oxide occurred much more readily with niobium B. Thus at 600°C, second breakaway occurred with niobium B after oxidation for 1 hr and the oxide product was largely made up of powder (84%) whereas with niobium A no second breakaway was detected; the two products also differed in appearance (Fig. 10); moreover the linear rate for B (30 mg cm^{-2} hr^{-1}) is significantly less than for niobium A (35.7 mg cm^{-2} hr^{-1}). At 650°C second breakaway occurred (Fig. 11) after about 10 minutes' oxidation and the linear rate could not be measured.

At 550°C and 0.1 atm of oxygen the linear rate of oxidation of niobium B was again less than that of niobium A (1.9 compared with 2.2 mg cm^{-2} hr^{-1}), and second breakaway occurred (Fig. 12) after about 45 minutes' oxidation. A comparison of the linear rate for niobium A at 550°C and 0.1 atm oxygen pressure with that for 1 atm oxygen pressure shows that the rate is pressure dependent.

Discussion

It would appear that at 350°C the oxidation of niobium is protective although experiments of much longer duration are needed to settle this point conclusively in view of the fact that the weight gain of the sample after 270 hr (500 μg cm^{-2}) is considerably larger than that for which breakaway occurs at the higher temperatures. At 400°C and above, the oxidation is nonprotective and the metal oxidizes until it is all consumed. Gulbransen and Andrew (5) were unable to detect a first breakaway (cf. Fig. 3) at 525°C and above; similarly in the present work a run on the microbalance at 550°C and 7.6 cm oxygen pressure failed to show a breakaway. This is probably because the rate of oxidation is so large that breakaway occurs before the first reading can be taken on the microbalance; thus after 90 sec the weight gain was 150 μg cm^{-2}, a value which is considerably greater than the 70 μg cm^{-2} for which breakaway occurred at 450°C.

In a recent electron microscope study, Cathcart, Campbell, and Smith (6) have shown that breakaway, and therefore the onset of nonprotective oxidation, is associated with the formation of blister-like cracks in the oxide film. They suggested that the oxide layer thickened by anionic diffusion and that the volume expansion resulting from the build-up of new oxides at the metal/oxide interface produced compressive stresses which ultimately caused the oxide to fracture. Presumably oxygen gas then is able to enter the newly formed crack and allow a new continuous oxide layer to form and to thicken until the compressive stresses reach the fracture strength of the oxide, when a further crack appears. This process will be occurring at points all over the metal surface, and although the thickness of uncracked oxide will never be uniform, it can be regarded as statistically maintaining a constant thickness and so acting as a barrier film.

The specific surface measurements, together with earlier measurements of pore volume (14), show the oxide scale to be porous to oxygen, so that the rate of oxidation must be controlled either by the rate of diffusion of reactant across the barrier film or else by the rate of solution of reactant in the latter. Since the oxidation rate is pressure dependent the barrier film model would (on the basis of the Wagner theory of parabolic oxidation) require the oxidation to proceed either by diffusion of oxygen ions between interstitial positions or by diffusion of Nb^{5+} ions between vacant cation sites. Because of the large positive charge of the Nb^{5+} ion, anionic diffusion seems the more likely. However, either possibility would require a metal-deficient oxide, whereas niobium pentoxide itself is in fact oxygen deficient, although niobium containing comparatively large amounts of tantalum (~1.4%) gives an oxide product which contains greater than the stoichiometric content of oxygen at temperatures near to 450°C (16) (niobium A contains 0.3-0.4% tantalum). It must however be remembered that the structure and composition of the barrier film may differ greatly from that of the scale; the former may in fact be the adherent black substrate found by Klopp, Sims, and Jaffee (2) and shown to contain both NbO and Nb_2O_5.

It is also important to realize that the marker experiment of Cathcart, Campbell, and Smith (6) does not provide evidence for anionic diffusion, in that the conditions (4 hr oxidation at 450°C) were such that breakaway had occurred so that the sample was presumably covered with a layer of porous oxide; and the marker would be expected to remain on the outer surface of the scale irrespective of the type of diffusion through the barrier film. In other words, a marker experiment will not distinguish between the passage of oxygen gas and the diffusion of oxygen ions. Marker experiments on the oxide layer before breakaway would be useful in establishing the type of diffusion, although the experimental difficulties would be considerable (17,18) in view of the small thickness of film involved.

Concerning the shape of the oxidation curves, the initial increase in rate at 400°C (branch OA, Fig. 1) is consistent with the model discussed above, and almost certainly corresponds to a progressive extension of the area of metal undergoing nonprotective oxidation, the point A denoting the completion of this process. Similarly, the increase at 450°C (from X to A of Fig. 3) probably arises from the same cause but the marked decrease along AB (Fig. 2) indicates that the barrier film is increasing in thickness; possibly the development of cracks in the barrier film is influenced by the thickness of scale above it. That the rate of oxidation at temperatures of 500°C and above is constant from the start is clearly because the rate had become constant before the weight gain of the sample was sufficient to be detected on the thermal balance. Certainly the results of Gulbransen and Andrew (5), and also the present results at 550°C and 0.1 atm, clearly show that the rate does in fact decrease to a constant value.

The fact that the linear rates of oxidation, when plotted in the Arrhenius form, do not fall on a straight line (Fig. 6) is probably the most striking feature of the oxidation of niobium. Neither niobium (19) nor niobium pentoxide (7) shows any phase changes in the temperature range of the present investigation, so that any explanation along these lines can be discounted. The reason why the linear rate decreases from 600° to 650°C is not clear, though this effect could come about as the result of a change in the type of diffusion through the barrier film from, say, anionic to cationic. The temperature coefficient of either process will be positive, but from 600° to 650°C the type of diffusion could be mixed, the proportion of the one increasing at the expense of the other with increasing temperature. Simultaneous cationic and anionic diffusion has recently been put forward, for example, to interpret data for the oxidation of zirconium (20).

It is known that the oxidation of niobium is accompanied by diffusion of oxygen into the underlying metal and that the penetration increases with time (2). Second breakaway could thus come about along the lines suggested by Pemsler (21) for zirconium oxidation: namely by detachment of the barrier film from the metal in consequence of the

changing stresses produced in it by the embrittlement of the metal; some evidence for this is provided by the observation that with niobium B the black film is found adhering to the oxide scale after breakaway has taken place. This model is consistent with the absence of second breakaway at 550°C and above; indeed, the ready sintering of the oxide scale at these temperatures points to a high degree of plasticity, which might be expected to be present in the barrier film itself.

The reaction mechanism after the second breakaway is not clear, but the powdery form of the oxide suggests that individual grains of metal have become separated, possibly because of penetration of oxygen down the grain boundaries. Certainly the saturated vapor pressure of niobium at 450°C is so small (22) (an extrapolation from 2000° gives 10^{-42} mm) as to exclude completely any possible reaction between niobium vapor and oxygen, a mechanism which has been suggested (9) to explain the reaction following the second breakaway of magnesium in oxygen.

The fact that the course of the oxidation of niobium in moist oxygen is essentially the same as in the dry gas (except for small changes in the linear rate) is consistent with the fact that niobium pentoxide does not form any hydrates so that only a small fraction of the sites at the oxide/gas interface is likely to be occupied by chemically adsorbed water, and as a consequence the amount of "water" entering the barrier film will be small. With magnesium (9), on the other hand, the effect of water is to increase the linear rate over that in the dry gas by as much as tenfold and to suppress second breakaway, facts consistent with the existence of the hydroxide $Mg(OH)_2$ and the consequent strong adsorption of water on magnesium oxide.

A question, which has already attracted some interest (7), is whether oxidation for a short period at a much higher temperature will anneal out the compressive stresses in the oxide film, and so prevent first breakaway. This point has been tested by Goldschmidt, who found that breakaway still occurred; presumably the rate at which the stressed oxide is formed is greater than the rate at which the stresses are alleviated. This view is supported by the fact that breakaway occurs after a smaller weight gain the higher the oxidation temperature. If the oxide film were annealed in the absence of thickening, that is to say in vacuo, it is conceivable that breakaway could not take place. However, in an experiment where a sample was oxidized at 450°C for 10 min, annealed *in vacuo* for 170 hr at 900°C, and then re-exposed to oxygen at 450°C, breakaway still occurred, the curve of oxidation being the same in shape as that for the un-annealed specimen, with the linear rate actually greater by some 50%.

Acknowledgments

The authors are grateful to Dr. K. F. Andrew for the gift of the niobium sheet, to Mr. E. R. Braithwaite for carrying out the particle size determination of the oxide powder, and to Professor G. K. T. Conn for allowing them the use of the Vickers projection microscope. They are also grateful to the U. K. Atomic Energy Authority for the financial support which they have given to this work.

The Difference Effect and Anodic Behavior of Zirconium Dissolving in Hydrofluoric Acid

M. E. Straumanis, W. J. James, and W. C. Custead

Departments of Metallurgical and Chemical Engineering, University of Missouri, School of Mines and Metallurgy, Rolla, Missouri

ABSTRACT

Zirconium dissolving in hydrofluoric acid exhibited a positive difference effect of such an efficiency that the hydrogen volume developed by the internal polarization current was completely overbalanced by the effect. As with other metals the effect was independent of the concentration of the acid and was accompanied by a strong shift in potential of the Zr electrode toward noble values (passivation). Similar potential changes were also recorded in presence of salts or more noble metals while they were displaced by the Zr. Simultaneously, the rate of dissolution of Zr dropped (nearly to zero with Pt^{4+} additions). In the latter case the black hydride film on the surface disappeared and the Zr turned bright and shiny (passive Zr). A decrease in formation of the hydride film was observed in other cases of anodic polarization. The activity of Zr returned when the anodic current was cut off. As the effect of local currents, due to anodic polarization is reduced to a minimum, the high rate of dissolution of Zr is explained by direct chemical action of Zr with molecular HF.

Only three metals have been investigated in the authors' laboratories for the difference effect exhibited in acids: zinc, titanium, and aluminum. The results obtained with a fourth metal, zirconium, are summarized in the present article.

As discussed previously (1) the difference effect provides information about the polarizability of a metal, without making potential measurements. It reveals the true passivation ability of the metal in a certain solvent being under an anodic current.

Zirconium in HF exhibits a positive effect, meaning that the rate of dissolution V_1 of zirconium, as measured by the rate of hydrogen development, is decreased to V_2, while an anodic current is passing the surface of the zirconium electrode (Eq. [1]):

$$\Delta = V_1 - V_2 \qquad [1]$$

Thus, the difference effect, Δ, expressed in $mm^3\ cm^{-2}\ min^{-1}$, having the dimensions of a rate, is in this case positive. Actually the effect indicates the decrease in rate of dissolution of the metal while under an anodic current.

Procedure and Materials

The measurement of the difference effect was carried out as previously described (2). However, a larger three-necked boiling flask of 500 cm^3 capacity, holding 300 cm^3 of acid, was used instead of the smaller flask, and a stirrer rotating about 200 rpm was added. The stirring rate had little influence on the difference effect itself. A zirconium electrode (3) of 1 cm^2 area exposed to the acid, was always placed 5 mm from a platinized platinum electrode (3). The reactor flask was immersed in a thermo regulated water bath of 25° ±0.1°C. The hydrogen evolved was collected in a gas burette.

The rate of dissolution V_1 in $mm^3\ cm^{-2}\ min^{-1}$ of the zirconium electrode was determined; then the circuit from this electrode to that of platinum was closed (through a milliammeter and a resistance), the current I flowing through the cell was registered, and the rate V_2 was determined from the total rate V_t: $V_2 = V_t - 6.97I$, where 6.97 is the volume of H_2 in mm^3 produced by 1 ma/min. Substituting in Eq. [1] the values for V_2, Δ can be calculated:

$$\Delta = V_1 - (V_t - 6.97I) \qquad [2]$$

High-purity zirconium[1] was used for the anodes. It contained O_2-0.11, N_2-0.05, Fe-0.04, and Hf-0.01% by weight. After rolling the metal the stress was relieved by annealing in vacuum for 30 min at 700°C. From this sheet, approximately 1.6 mm thick, square anodes of 1 and 3.8 cm^2 area were cut. Reagent grade HF (48%) was used for the preparation of solutions of seven normalities. All operations with the acid were performed in polyethylene, polystirole, or wax lined glass vessels.

The Difference Effect

Unlike titanium the reaction of zirconium with HF (neglecting fluoride complexes) proceeds according to Eq. [3] (4):

$$Zr + 4HF \rightarrow ZrF_4 + 2H_2 \qquad [3]$$

This reaction was rechecked several times for Zr/H_2 ratio and was found to be quite accurate (5, 6). One gram Zr develops 491.43 cm^3 of hydrogen at standard conditions, or 1 mm^3 of the gas corresponds to 0.002035 mg Zr.

Although the rates of self-dissolution of Zr in HF are well reproducible (within a few per cent) (5),

this is not at all essential in determining the difference effect. The independence of the effect from the rate follows from the fact that the same value for the effect is obtained in various concentrations of the acid, in which the rates of self-dissolution vary vastly. However, to obtain conformable results, a constant rate of dissolution is of importance. Therefore, the measurements of the effect were started only then when, after the irregular initial period, the rate of self-dissolution became fairly constant, reaching the maximum. Furthermore, rate determinations were made before and after application of the anodic current; the adjacent rates were taken as an average for the self-dissolution. To show the magnitude of the figures involved and the procedure of calculations, data obtained in 0.3*N* HF are summarized in Table I. The constant K, which shows the reproducibility of Δ-measurements, was calculated from (8)

$$\Delta = KI \qquad [4]$$

by substituting KI for the Δ in Eq. [2]:

$$K = 6.97 + \frac{V_1 - V_t}{I} \qquad [5]$$

As shown in Table I all measurements resulted in a positive Δ-effect, but unlike previous studies V_1 was always larger than V_t (Eq. [5]) resulting in K values appreciably larger than 6.97 mm³/ma min, the differences exceeding the limit of error of the determinations. To eliminate the possibility of a systematic error, additional runs in the same apparatus were made using a Ti electrode instead of Zr. However, the average value of K, which was smaller than 6.97 (V_t was larger than V_1) agreed within 2% with that previously obtained (2). This was an indication that no systematic errors were involved in the determinations, and measurements were continued with Zr in 6 other concentrations of HF. As a result, the Δ-effect, calculated from Eq. [2] and plotted against the anodic current density, gave a straight line (Fig. 1), the inclination of which was independent of the concentration of the acid exactly as observed for Ti (2), Al [in acid (1) and in base (7)] and Zn (8). The variation of the electrode area (3.8 cm² anodes were used for runs in 0.2 and 0.3*N* HF) had no apparent effect on the result. Figure 1 also shows that the Δ-effect is proportional

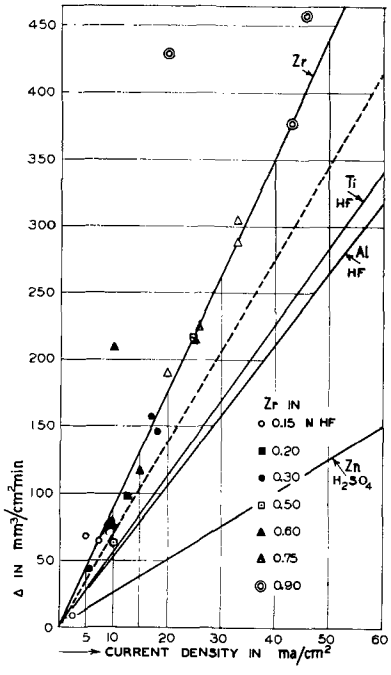

Fig. 1. Difference effect on Zr vs. current density in 7 different concentrations of HF at 25°C. Effects on Zn, Al, and Ti are given for comparison. The dashed line shows the rate of H_2 (= 6.97I) evolution at the cathode by the current.

to current density (Eq. [4]). The K-values calculated were as follows. In 0.15N HF: 8.09, 13.8, 3.56, and 9.17; in 0.2N HF: 7.72 and 8.07; in 0.3N—see Table I; in 0.5N: 8.68 and 6.17; in 0.6N: 8.68, 21.0, 7.73, and 8.65; in 0.75N: 9.21, 9.50, and 8.73; in 0.9N: 9.93, 22.9, and 8.74 $mm^3\ ma^{-1}\ min^{-1}$. Despite the relatively large fluctuations in the K-values, which may be attributed to sudden changes in the rates of self-dissolution while the Zr electrode was under the anodic current, there are only two constants less than 6.97. The mean from all measurements is 9.8; disregarding the less probable values (3.56, 13.8, 21.0, and 22.9), $K = 8.6$ with an average deviation of ± 0.7 is obtained. If the difference from 6.97 had resulted from errors of experimental nature one would expect a random distribution of K values below 6.97.

The average value of $K = 8.6 \pm 0.7$ $mm^3\ ma^{-1}\ min^{-1}$ for Zr dissolving in HF means that the rate of self-dissolution of Zr is reduced by 8.6 mm^3 by each milliampere minute flowing anodically through 1 cm^2 of the electrode. As 1 ma min produces (on the cathode) only 6.97 mm^3 H_2, then the current (developed by the Zr electrode itself), not only annihilates this volume, but even decreases the rate of self-dissolution by an additional 1.6 mm^3. This is a behavior not anticipated previously (1). Nevertheless the just mentioned 23% difference is real; it results from a large number of measurements, which in the average were reproducible within 10%, as could be shown by parallel experiments in 0.15N HF. Thus, an anodic current strongly passivates the Zr electrode, and any means (see below) which cause currents should passivate such an electrode.

Potentials and Rates

Potential of zirconium in pure HF.—Before making a study of the influence of an anodic current on the potential of a Zr electrode, the behavior of the electrode in pure HF was explored by measuring the emf of the cell

Zr|HF, salt bridge (sat. KCl sol.), 1N KCl, Hg_2Cl_2|Hg

and reducing the measured potential of the Zr electrode to the hydrogen scale by adding +0.242 v. The HF solution was always stirred (300 rpm).

The general trend is that the dissolution potential (ϵ') of the Zr electrode is very negative (around −0.90 v in 0.5N HF) right after the immersion, but quickly becomes more positive with time, approaching a steady potential in about 1 hr or more. It becomes more negative with increasing concentration of the acid (5). The potential-acid concentration curve is very similar to that obtained with Ti or Al in HF (1). However, the potential is sensitive to any change occurring on the surface of the electrode, like film formation or breakdown. Thus, the separate measurements made in the same concentration of acid at different times do not agree too well. Nevertheless, the effect of additions of ions of more noble salts to the acid upon the dissolution potential of Zr is so pronounced that there is no doubt about the reality of such measurements.

Potentials in presence of more noble metal salts.—Salt additions of $PtCl_4$, $AgNO_3$, and $AuCl_3$ to the 0.1N HF (300 cm^3) were made to give 0.001M solutions for each salt. As shown in Fig. 2 the potential of the Zr electrode shifts considerably toward more noble values immediately after the addition of the salts, as with Al (9). This shift was considerably higher in the case of Pt and Ag (Fig. 2; A, C). Direct observations of the Zr electrode showed that after the addition of noble metal salts the initially black surface (Zr hydride film) (10) turned shiny, the rate of dissolution (H_2-evolution) dropped, and the black (white in the case of $AgNO_3$) loose deposit of the displaced metal started to appear on the zirconium surface. The potential of the metal remained noble as long as there were noble metal ions (Pt^{4+}, Au^{3+}, Ag^+) in the solution. However, the loose deposit did not adhere well to the shiny zirconium surface and gradually broke off. When there was no longer any replacement of the deposit from the solution, the potential of the Zr started to drop (Fig. 2, D) and the rate of dissolution increased again. Thus, the behavior of Zr is just opposite to that of other active metals (Zn, Cd, Fe, Al in HCl): as long as there is a deposit on its surface, the metal is passive; its activity (in HF) returns when the deposit is gone. Aluminum in HF behaves somewhat similarly as its rate of dissolution is retarded by Ag^+, Pt^{4+} and other ions, but is increased by Au^{3+} and Ni^{2+} ions (9).

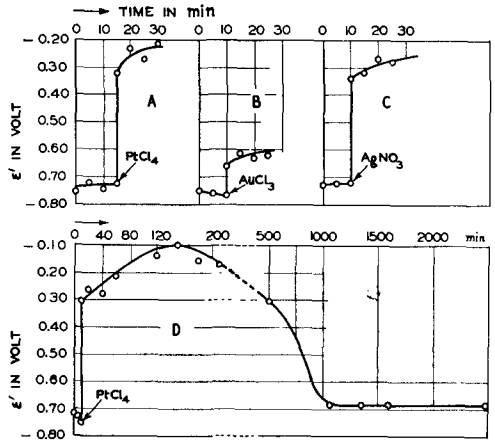

Fig. 2. Effect of salt additions on the potential of Zr dissolving in 0.1N HF, hydrogen scale.

Dissolution rates in presence of noble metal salts.—The change in rate of dissolution was followed from pressure measurements of the evolved hydrogen. A typical curve is shown in Fig. 3. After start-

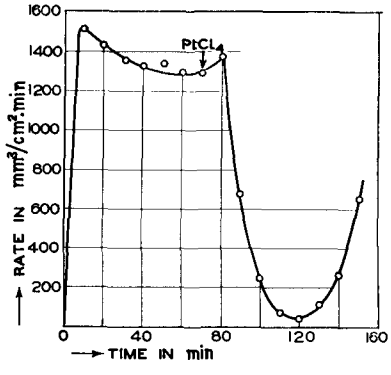

Fig. 3. Effect of $PtCl_4$ addition (0.001M) on the rate of dissolution of Zr in 0.5N HF.

ing the run, the rate of dissolution first increases, (short induction period), then slowly decreases. Upon the addition of the $PtCl_4$ solution the rate increased about 6% in the first 10 min and then decreased in 50 min by 96% resulting in an almost complete passivation of the Zr. However, the Pt deposit adhered loosely, and as before during the potential measurements, began to drop off. Simultaneously the rate of dissolution increased sharply. In the case of $AgNO_3$ and $AuCl_3$ additions, the rate dropped by 18 and 38% respectively and was still decreasing at the termination of the experiments.

In all three cases the zirconium surface under the loose deposit was bright, shiny, and heavily pitted, unlike that observed during the dissolution in pure acid.

The deposits in all three cases were identified by x-rays as the pure respective metals. Thus, there was a definite parallelism between potential and rate measurements.

Anodic Polarization of Zirconium

The anodic polarization of zirconium was investigated by Hackerman and Cecil (12), by van Ryssel-berghe and associates (13, 14) and others (15). The experiments were made in sodium chloride, carbonate, borate, and other aqueous solutions. In view of the peculiar behavior of zirconium in HF, it seemed worthwhile to make anodic potential measurements of the metal in this acid.

To avoid contamination of the Zr-Pt cell by other than hydrogen gases, no external emf was used at first, but only the current produced by the Zr itself (3). Its potential was measured, as usual, using a capillary touching the dissolving Zr surface. The results obtained are shown in Fig. 4. The strong influence of the anodic current on the dissolution potential of Zr is evident. The increase in potential is stronger the more dilute the acid. This effect is much more pronounced than in the case of Al (1) and already resembles a true anodic passivation. Thus, the internal anodic current (produced by the Zr electrode itself, and used in the Δ-effect measurements) as well as the external strongly shifts the potential of the electrode toward nobler values; simultaneously the rate of self-dissolution of the Zr drops. This is in agreement with the passivation of Zr observed in the presence of ions of more noble salts. However, no shiny surface was observed in absence of these salts.

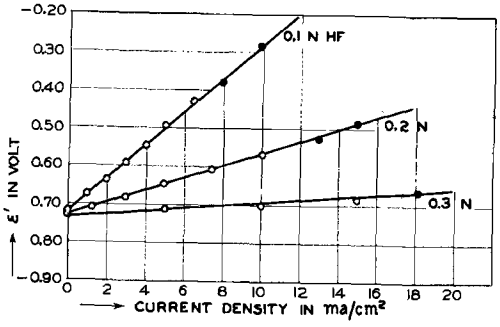

Fig. 4. Potential-current density curves of Zr dissolving anodically in HF (hydrogen scale). Each point is an average of at least two measurements. Solid points are obtained from measurements using an external current.

Discussion

It follows from these experiments that the dissolution of Zr in HF is strongly influenced by the action of local currents. However, this effect is opposite to that of other common metals, where the rate of dissolution is greatly increased by the presence of impurities. When noble metals are deposited on Zr, they cause a slight increase in the rate of dissolution (see Fig. 3) followed by a rapid decrease to nearly total passivation. The explanation is that the current produced by the deposited noble metal after an initial increase in dissolution shifts the anodic potential so far to noble values (see Fig. 2, A,B,C) that the local cathodes on Zr become inactive, i.e., their emf becomes too small to work effectively (1), and the dissolution ceases.

The positive difference effect, the direct potential measurements under anodic polarization, and the dissolution rates with noble metal salt additions testify to the strong passivating action of the anodic current. The difference effect is so strong that the work of the polarizing current is not only completely neutralized, but even overbalanced so that the action of the internal polarization current becomes more than 100% effective (K is 8.6 $mm^3\ ma^{-1}\ min^{-1}$ instead of 6.97– the hydrogen value of the current). Conversely the falling off of noble metal particles from the Zr surface causes the potential to become more negative and causes an increase in rate of dissolution (Fig. 2, D). The reasons for passivation by the anodic current are not yet known. However, it was observed that the initially dark surface (hydride film) of the active metal turned shiny upon passivation (e.g., when noble metal particles were deposited on Zr). Thus, the anodic current prevents hydride film formation by reducing the formation of hydrogen at the anode and apparently promotes the formation of a new film of unknown composition (oxide?). The effect observed by Stern on Ti (16) may be explained similarly. Formation of such passivating layers would reduce the rate of diffusion of molecular HF to the active surface and would account for a higher activation energy, as observed by Vander Wall and Whitener (17), while dissolving Zr in HF-HNO_3 mixtures, rather than in pure HF alone (11).

If now an anodic current passivates the surface of dissolving Zr (and Ti) (2), the fast dissolution rate of Zr in HF (with the anodic current off) can be explained by a chemical reaction of Zr metal with HF, outside the action of local currents, by collision of HF molecules with Zr atoms on the surface of the metal. An anodic current which makes the potential of the metal much more noble then acts as mentioned above. Our own rate measurements (11) as well as those of Smith and Hill (18) and of Vander Wall and Whitener (17) also suggest in the main a chemical action of HF. Some attempts have been made to explain the mechanism and rates of such action by the velocity of dissolution of corrosion products formed on the surface of the metal in the acid; e.g., an attempt was made to show that the dissolution of Fe in HCl is controlled by the rate of hydrolysis of $FeCl_3$ formed on the surface of the metal, or the rate of Al dissolution by the velocity

of dissolution of $Al(OH)_3$ in the acid (19). However, our experimental and theoretical attempts to explain similarly the process of dissolution of Zr in HF with ZrO_2 as an intermediate product failed.

Oxidation of Zirconium and Zirconium Alloys

H. A. Porte, J. G. Schnizlein, R. C. Vogel, and D. F. Fischer

Chemical Engineering Division, Argonne National Laboratory, Lemont, Illinois

ABSTRACT

The rate of oxidation of zirconium followed a cubic rate law in the temperature range 400°-900°C at oxygen pressures of 50, 200, and 800 mm. At 200 mm the activation energy was calculated to be 42.7 ± 0.7 kcal/mole.

The oxidation of zirconium binary alloys containing 1, 2, and 4 atom % of aluminum, beryllium, carbon, chromium, cobalt, copper, hafnium, iron, lead, molybdenum, nickel, niobium, platinum, silicon, tantalum, tin, titanium, tungsten, uranium, and vanadium was studied at 700°C and 200 mm oxygen. For those additives which are soluble in zirconium the initial oxidation rates are explained by a valency effect; the breakaway phenomenon is explained in terms of a 15% deviation of the ionic radius from that of zirconium. X-ray and electron diffraction studies indicate that for some alloys the breakaway coincides with a polymorphic transformation in the zirconium dioxide film.

The reaction of zirconium with oxygen at high temperatures has been studied by several investigators (1-8). A comparison of the results shows discrepancies concerning which rate law, cubic or parabolic, best describes the oxidation kinetics. For example, Gulbransen and Andrew (1) studied the reaction on foil specimens between 200° and 425°C and reported that the parabolic rate law fit their data. But Belle and Mallett (2) showed by replotting the same data in a different fashion that the cubic rate law was obeyed, implying that the interpretation of data can be somewhat arbitrary in some cases.

In another study (3) Gulbransen and Andrew found that between 400° and 600°C the method of surface preparation influenced the reaction kinetics. Mechanically polished foils obeyed the cubic rate law and reacted faster than chemically polished foils which obeyed the parabolic rate law. A later study by Charles, Barnartt, and Gulbransen (8) on the prolonged (up to 500 hr) oxidation of zirconium foils at 350° and 450°C confirmed the cubic rate law for mechanically polished specimens.

There is some reason to suspect that the size and shape of samples may influence the reaction kinetics. Belle and Mallett (2) studied the oxidation reaction on rod specimens between 575° and 950°C and found that the cubic rate law fit the data. On foil specimens in approximately the same temperature range, Cubicciotti (4), Fassell (5), and Garibotti, Green, and Baldwin (6) observed the parabolic rate law.

There is even some evidence that the particular rate law which is followed depends on the temperature range. In a recent study by Kofstad (7), zirconium was oxidized under conditions of linearly increasing temperature. It was shown that between 650° and 950°C the cubic rate law was obeyed and

between 950° and 1100°C the parabolic rate law fit the data.

Some investigators (1, 4, 5) have studied the effect of pressure. The concensus was that pressure has little or no effect on the reaction of zirconium with oxygen.

The reported work on the reaction of zirconium alloys with oxygen has been confined previously to zirconium-tin alloys for which important uses have been found in the field of nuclear reactor engineering. Mallett and Albrecht (9) have studied the oxidation of 1.5 and 2.5 weight % tin alloys at high temperatures. Gulbransen and Andrew (10) studied the reaction of Zircaloy-2 and -3a with oxygen. In both investigations tin was found to increase the rate of oxidation.

Nitrogen also reacts with zirconium, but at a much slower rate than has been found for the reaction with oxygen. Several studies (1, 6, 11-13) have been made, and most investigators agree that the parabolic rate law is obeyed. The product of the reaction at all temperatures has been identified as golden-yellow zirconium nitride. There is some evidence (1) that the presence of small traces of oxygen in the nitrogen noticeably accelerates the rate of the reaction.

Some work has also been done on the reaction of zirconium (11, 14, 15) and zirconium alloys (14, 16-18) with air. In general, the reaction rate is higher in air than in either nitrogen or oxygen alone. Both zirconium dioxide and zirconium nitride have been identified as products of the air reaction. The data on alloy oxidation indicate that in most cases additives to the metal do not improve the resistance of zirconium to oxidation in air.

The purpose of this study was to investigate the fundamental processes involved in the oxidation mechanism. The experimental approach was as follows. First, the influence of such variables as surface preparation and sample form was determined. Next, temperature and pressure dependence studies covering the temperature range 400°-900°C at three pressures, 50, 200, and 800 mm, were made. However, the major effort was devoted to studying the kinetics of the reaction of numerous zirconium alloys with oxygen at 700°C. Simultaneously, an investigation was made of the structure of the oxide films produced.

Experimental

Method.—The reaction of zirconium and zirconium alloys with oxygen was measured by a volumetric method. Essentially, the apparatus consisted of a reaction chamber which was connected through stopcocks to a pressure regulator, a gas buret, and a vacuum system. With the exception of the reaction tube, which was made of quartz, the apparatus was made entirely of Pyrex. The system was evacuated by a two-stage glass mercury-diffusion pump backed by a mechanical pump.

The reaction tube, which was supported in a vertically mounted resistance furnace, consisted of two parts which were joined by a means of a greased ball joint (below the furnace and cooled by a jet of air). Sealed to the lower section was an evacuated inner tube which extended well into the furnace hot zone and filled most of the cross-sectional area of the reactor, thus minimizing the volume of gas exposed to the temperature gradient at the lower end of the furnace. The metal sample rested on top of a long thermocouple well which passed through the center of the inner tube of the reactor.

The reactor was joined by a greased, ground glass joint to a 2-mm capillary line leading to the pressure regulator and the gas buret. The water jacketed gas buret was connected with a flexible tube to a similar buret which served as a mercury reservoir. As the sample consumed oxygen, the pressure in the reactor decreased slightly, causing mercury in the pressure regulator to make contact with a sealed-in tungsten wire. A zero current relay closed the power circuit to a motorized rod runner which raised the mercury reservoir. Mercury flowed into the gas buret, increased the pressure in the system, and the electrical contact in the pressure regulator was opened.

Coupled with the rod runner was a precision helically wound potentiometer (Helipot) which translated the position of the reservoir into an electrical potential. Changes of this potential, recorded on a strip chart potentiometer-recorder, were proportional to the movement of the reservoir and, thus, were proportional to the volume of oxygen consumed by the sample. By application of the gas laws and the measured sample area the consumption could be expressed in micrograms of oxygen per square centimeter of surface. After calibration, sensitivities from 0.05 to 12 $\mu g/cm^2$ were determined, depending on oxygen pressure and the choice of buret diameter.

A hinged-type Hevi-duty combustion tube furnace was used for runs at 700°C and below while a platinum-wound Marshall furnace was used for runs above 700°C. The furnace temperature was controlled to ±3°C by a proportional controller operated by the output from a thermocouple located at sample level outside, but near the reactor.

Before the start of the run the specimen and reaction tube were evacuated at room temperature for 16 hr at pressures of less than 10^{-5} mm to minimize the reaction of zirconium with gases present in the vacuum system during the heat-up period. After establishing thermal equilibrium at the desired temperature, the run was started by closing off the high vacuum line and admitting oxygen to the reaction chamber.

Unless otherwise specifically indicated, all runs were made on specimens which were machined parallelepipeds, 1 x 1½ x 2 cm. Freshly polished specimens were used for each run.

X-ray diffraction investigations of the oxide films were carried out by means of a Norelco X-ray diffraction powder camera (114.59 mm diameter). For electron diffraction investigations, an RCA electron diffraction unit Model EMU-2 was used.

Materials.—Table I shows the principal impurities in the arc-melted Grade I crystal bar zirconium used in the oxidation studies on pure zirconium.

To study the effect of impurities on the oxidation properties of zirconium a series of binary alloys with

Table I. Analysis of zirconium. Chemical analyses for C, H, N, O; all other elements determined by spectrograph analyses

Si	50	50

additives at three nominal concentration levels, 1, 2, and 4 atom %, was obtained.[1] The actual analyzed alloy compositions are given in Table IV. Arc-melted Grade I crystal bar zirconium having the analysis also given in Table I was used in the preparation of these alloys.

The oxygen used in these experiments was taken directly from the tank without further purification. Mass spectrographic and dew point analyses showed the following typical impurities (in volume per cent): argon 0.1; carbon dioxide 0.06; nitrogen 0.2; and water 0.005.

Effect of surface preparation.—To determine whether massive parallelepiped samples would show an effect similar to that reported by Gulbransen and Andrew (3) on foils a study was made in the range 400°-700°C. Table II presents a summary of the data. At least two runs were performed for each method of polishing at every temperature and average results are listed.

Mechanically polished specimens reacted somewhat faster at 400° and 500°C than chemically polished specimens, but at 600° and 700°C there was no significant difference in reaction rates. This is essentially the same conclusion reached by Gulbransen and Andrew.

The cubic rate law best expressed the data from all methods of polishing, although in the range 400°-600°C the log-log slopes obtained from chemically polished samples were slightly higher than those obtained from mechanically polished samples. At 700°C the log-log slopes were insensitive to sample pretreatment. Thus, the rate law obeyed by parallelepiped samples was independent of surface preparation.

The reproducibility was good for all methods of polishing. Therefore, since the 600-grit mechanical polish was found to be the quickest and simplest, it was used in all of the pure zirconium and alloy studies.

Effect of sample shape.—In going from massive metal to foil the surface area per unit weight is increased. At the same time several other factors which may possibly influence the rate are affected. Metallurgical condition of the metal, i.e., grain size, crystal orientation, strains, etc., are changed. Also, certain impurities may be introduced during the rolling operations. It would be necessary to separate and study each of these variables to investigate thoroughly the effect of foil samples on reaction rate. Such a study was beyond the scope of this investigation. However, two runs were made on 0.25-mm (10-mil) foils which had been cold rolled from sponge zirconium. The foil samples were polished through 600 grit and run at 700°C and 200 mm oxygen pressure. The slopes of the log-log plots were 0.35 in both cases, in good agreement with the parallelepiped samples. The cubic rate constants were found to be 2.3 x 10^7 and 2.8 x 10^7 $(\mu g/cm^2)^3$/min, somewhat larger than values obtained from parallelepiped samples. The more rapid reaction on foil specimens may be explained in part by a higher heat of reaction caused by the increased surface area to mass ratio. Examination of the product immediately after one of the foil runs revealed an adherent black oxide film similar to those formed on the parallelepiped samples.

Effect of temperature.—Oxidation rates were measured at various temperatures in the range 400°-900°C at an oxygen pressure of 200 mm. Plots of the log of the weight gain vs. the log of time for typical runs at these temperatures are given in Fig. 1. The straight lines indicate agreement with the general rate expression $W^n = kt$. The values of n can readily be obtained since the slope of the line on this type of plot is $1/n$.

From the values of $1/n$ listed in Table III it is seen that the reaction rate is best expressed by the cubic rate law, $W^3 = kt$. The value of $1/n$ increased slightly from 400° to 800°C and then dropped a

Table II. Effect of surface preparation on the reaction of zirconium with oxygen (Oxygen pressure, 200 mm)

Temp, °C	Surface preparation	Slope of log-log plot, $1/n$	Cubic rate constant, k, $(\mu g/cm^2)^3$/min
400	Mechanical polish—600 grit[a]	0.29±0.00	(11±5.2) × 10^2
400	Chemical polish[b]	0.36±0.01	(5.9±2.0) × 10^2
500	Mechanical polish—600 grit	0.31±0.01	(3.5±0.1) × 10^4
500	Chemical polish	0.33±0.01	(2.1±0.3) × 10^4
600	Mechanical polish—600 grit	0.33±0.01	(1.2±0.4) × 10^6
600	Chemical polish	0.37±0.01	(1.1±0.3) × 10^6
700	Mechanical polish—600 grit	0.34±0.02	(1.6±0.2) × 10^7
700	Mechanical polish—0.5μ[c]	0.36±0.01	(1.5±0.1) × 10^7
700	Attack polish[d]	0.36±0.02	(1.3±0.1) × 10^7
700	Chemical polish	0.35±0.01	(1.5±0.2) × 10^7

[a] Specimens ground down with successively finer grades of silicon carbide paper to 600-grit paper. Water used as lubricant.
[b] Composition of chemical polish solution: 45 parts H_2O, 45 parts HNO_3 (conc), and 10 parts HF (48%).
[c] Extension of the 600-grit polish with Linde A abrasive on Miracloth lap.
[d] Mechanical polish through 0.5μ in which 1 ml HF (48%) and 0.5 ml HNO_3 (conc) are added to 98.5 ml of Linde A abrasive.

[1] Zirconium binary alloys were prepared by Oregon Metallurgical Corporation, Albany, Oregon.

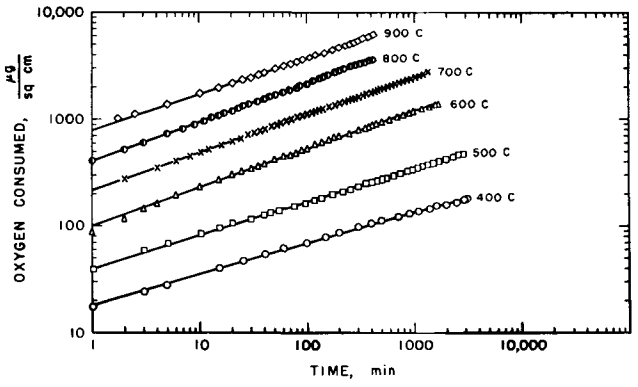

Fig. 1. Effect of temperature on the reaction of zirconium with oxygen.

bit at 900°C. There is no apparent reason for the increasing trend in the value of $1/n$; however, the drop from 800° to 900°C may be attributed to the transformation from α to β zirconium which occurs at 862°C. The cubic rate law constants listed in Table III were obtained from plots of W vs. $t^{1/3}$.

A plot was made of the log of the cubic rate constants vs. $1/T$ for the temperature range 400°-900°C. The equation of the best straight line through the points was determined by the method of least squares and the activation energy was calculated to be 42, 700 ± 700 cal/mole by the Arrhenius-type equation, $k = Ae^{-E/RT}$. The corresponding rate constant for the reaction in $(\mu g/cm^2)^3$/min was

$$k = (5.94 \times 10^{16})e^{-42,700/RT}$$

In comparison, Belle and Mallet (2) obtained an activation energy of 47.2 kcal/mole and Charles, Barnartt, and Gulbransen (8) calculated a value of 38 kcal/mole.

The length of the runs, as indicated in Table III, varied from a minimum of 400 min to several thousand minutes in some cases; however, the run length had no effect on either the log-log slopes or the cubic rate constants. No breakaway phenomena were observed in any of the runs, even at the higher temperatures. One run at 800°C was carried out for longer than 5600 min without giving any sign of a breakaway.

Table III. Cubic rate constants for the reaction of zirconium with oxygen

(Oxygen pressure, 200 mm)

Temp, °C	Length of run, min	Slope of log-log plot, $1/n$	Cubic rate constant, k, $(\mu g/cm^2)^3$/min
400	3235	0.29	1.6×10^8
400	4275	0.29	5.6×10^2
500	4238	0.30	3.5×10^4
500	2860	0.32	3.6×10^4
600	1660	0.33	1.6×10^6
600	4250	0.34	8.9×10^5
700	1415	0.29	1.5×10^7
700	1400	0.31	1.8×10^7
700	1400	0.33	1.5×10^7
700	1400	0.33	2.0×10^7
700	1323	0.35	1.7×10^7

700	1345	0.36	1.3×10^7
700	1408	0.36	1.4×10^7
800	5645	0.36	1.3×10^8
800	400	0.37	1.3×10^8
800	413	0.38	1.3×10^8
800	415	0.39	1.3×10^8
900	400	0.32	5.3×10^8
900	418	0.34	5.3×10^8

The reaction produced a shiny blue-black oxide at all temperatures. A few white specks were observed on the surface of the oxide at 900°C.

Because of the high solubility of oxygen in zirconium (29 atom %), the reaction is somewhat complicated. A sample which had been run at 900°C was mounted in Bakelite, polished, and then a photomicrograph was taken. The thickness of zirconium dioxide, as measured from the photomicrograph, was found to be 22 μ; the thickness calculated from the amount of oxygen consumed was 41 μ, based on the assumptions that (*a*) the ratio of the real to measured surface area was one and (*b*) the only product formed was zirconium dioxide having a density of 5.73 g/cc. Evidently, an appreciable solution of zirconium dioxide in zirconium takes place at 900°C.

Effect of pressure.—The effect of variation in pressure on the reaction rate kinetics was determined. Runs were made at oxygen pressures of 50, 200, and 800 mm in the temperature range from 400° to 900°C. The data showed that the oxidation rate was relatively insensitive to pressure. The values of the log-log slopes indicated the cubic rate law at all pressures. The cubic rate constants agreed very well at the different pressures, and no apparent trend could be seen at any temperature. These results confirm the work of other investigators who found no pressure effect.

Effect of additives to zirconium.—The study of the effect of small amounts of impurities on the oxidation kinetics of zirconium was carried out using a series of binary zirconium alloys. These were alloys of zirconium with aluminum, beryllium, carbon, chromium, cobalt, copper, hafnium, iron, lead, molybdenum, nickel, niobium, platinum, silicon, tantalum, tin, titanium, tungsten, uranium, and vanadium. Each binary system included three nominal compositions, 1, 2, and 4 atom %, except that the 4 atom % tungsten alloy was impossible to fabricate.

The experimental conditions used were 700°C and 200 mm of oxygen. The choice of a particular temperature and pressure was somewhat arbitrary, but was dictated by certain important considerations. It was desirable to work at some high temperature in the alpha zirconium region, so that the oxidation would take place at a conveniently measurable rate at reasonable pressures. This limited the temperature range from approximately 600°C to the alpha to beta transformation temperature, 862°C. Certain metals, e.g., cobalt, copper, chromium, iron, molybdenum, nickel, niobium, platinum, tantalum, titanium, tungsten, uranium, and vanadium, could be expected to lower the transformation temperature (19). Therefore, it was decided to work at 700°C, which was far enough below 862 to be sure that beta zirconium was not present in any of the alloys. Another factor in favor of choosing 700°C as the

[a] The log-log slope applies only to the portion of the run before breakaway.
[b] Cubic rate law constants [10^7 (μg/cm²)³/min] unless preceded by p which signifies parabolic rate law constant [10^4 (μg/cm²)²/min]. Both apply only to the portion before breakaway.

temperature at which to make the study was that in a recent study (9) on the high-temperature oxidation of two zirconium-tin alloys it was reported that the minimum times for breakdown of the protective properties of the films occurred at 700°C.

The kinetic data for the oxidation of the alloys are presented in Table IV. In most cases duplicate 1400-min runs were made with each alloy composition and the results averaged.

A number of alloys oxidized similar to pure zirconium. Many others, however, exhibited the oxidation phenomenon usually referred to as "breakaway." In these cases the oxidation kinetics changed from an initially cubic or parabolic rate to a faster essentially linear rate of oxidation. When the data were plotted in the usual fashion, log oxygen consumed vs. log time, it was found that, after the initial straight line portion of the plot, an upward curvature took place which eventually leveled off into another straight line portion. The "breakaway time" and "breakaway weight" were defined as the time and oxygen consumed at the last point on the initial straight line portion of the oxidation curve. Within a given system the breakaway weights and breakaway times usually decreased with increasing additive concentration as illustrated in Fig. 2 for the tin alloys.

An examination of the results revealed that the alloys could be grouped conveniently according to four types of reaction behavior as indicated in Fig. 3.

Many of the alloys and pure zirconium (Group I, Fig. 3) oxidized according to the cubic rate law and did not exhibit breakaway phenomena. Slopes of log weight gain vs. log time plots were in the range 0.28 to 0.40. The cubic rate constants ranged from 0.78 x 10^7 to 3.5 x 10^7 (μg/cm²)³/min.

The 1 and 2 atom % tantalum and the 4 atom % vanadium alloys (Group II, Fig. 3) oxidized according to the parabolic rate law and did not exhibit

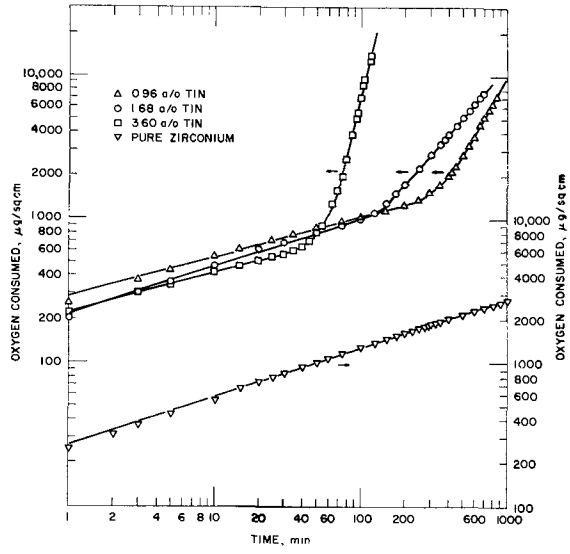

Fig. 2. Reaction of zirconium-tin alloys with oxygen at 700°C and 200 mm oxygen pressure.

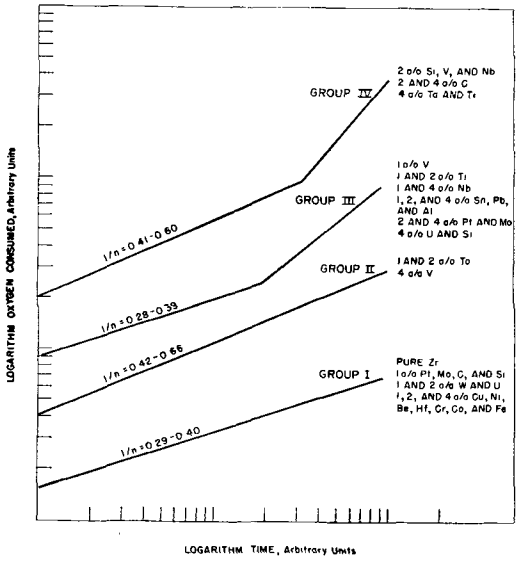

Fig. 3. Oxidation of various zirconium alloys at 700°C and 200 mm oxygen pressure, general oxidation characteristics.

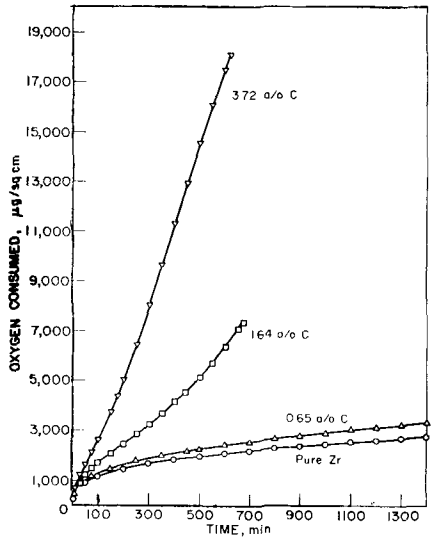

Fig. 5. Oxidation of zirconium-carbon alloys at 700°C in 200 mm oxygen.

breakaway phenomena. They had log-log slopes in the range 0.41-0.66. The parabolic rate constants were 39.5 x 10^4, 30.5 x 10^4, and 29.0 x 10^4 $(\mu g/cm^2)^2/min$, respectively.

Another large group of alloys (Group III, Fig. 3) oxidized initially according to the cubic rate law but later exhibited breakaway phenomena. The cubic rate constants ranged from 0.81 x 10^7 to 251 x 10^7 $(\mu g/cm^2)^3/min$. Breakaway times ranged from 6 to 655 min, and breakaway weights ranged from 439 to 9468 $\mu g/cm^2$. After the breakaways, faster linear rates, ranging from 1.7 to 292 $\mu g/cm^2/min$, were followed for the duration of the runs.

The last group of alloys (Group IV, Fig. 3) oxidized initially according to the parabolic rate law but later exhibited breakaway phenomena. The parabolic rate constants ranged from 2.2 x 10^4 to 90.8 x 10^4 $(\mu g/cm^2)^2/min$. Breakaway times ranged from 23 to 500 min, and breakaway weights varied from 1076 to 15,975 $\mu g/cm^2$. The faster linear rates after breakaways ranged from 6.8 to 33.1 $\mu g/cm^2/min$.

Of the 20 binary alloy systems investigated only the copper, nickel, beryllium, and hafnium alloys showed any increased resistance to oxidation as compared with pure zirconium. The oxidation behavior of the copper alloys is illustrated in Fig. 4.

In some alloy systems, as typified by the carbon system (Fig. 5), the lower concentration alloys oxidized at slow initial rates without a breakaway while the high concentration alloys oxidized at faster initial rates (sometimes even following a different rate law) and then exhibited breakaway.

Widely different types of breakaway phenomena were observed. For instance, in the tin system (Fig. 2) the breakaways were distinct and obvious, while in the titanium system (Fig. 6) the breakaways represent little more than a gradual increase of an already fast rate.

A description of the films formed during the oxidations has been included in Table IV. For the alloys where no breakaway occurred, the oxide films were

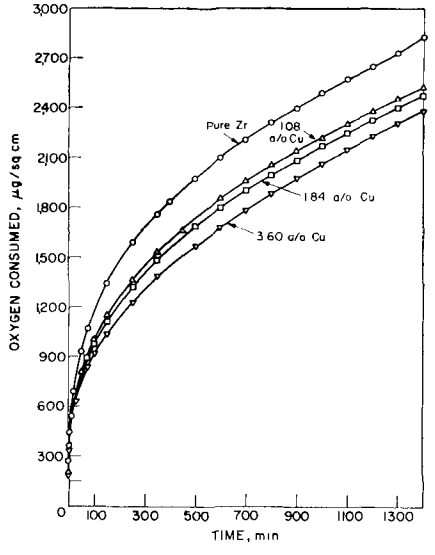

Fig. 4. Oxidation of zirconium-copper alloys at 700°C in 200 mm oxygen.

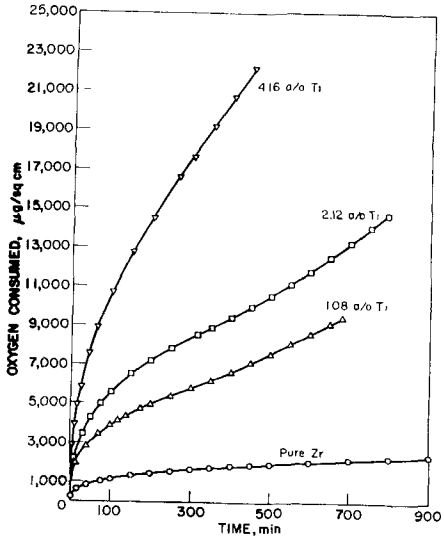

Fig. 6. Oxidation of zirconium-titanium alloys at 700°C in 200 mm oxygen.

usually black or gray and very adherent. In contrast, the films observed after the breakaway occurred still may have been adherent but were generally light-colored and cracked or porous.

Discussion

Mechanisms.—Several studies have been made to determine the mechanism of formation of the oxide film on zirconium. By employing inert markers it has been observed (9, 21) that the oxidation proceeds by oxygen (anion) migration through the oxide film toward the metal-metal oxide boundary. In another study (22) it was reported that anodic oxidation of zirconium at room temperature under low electric fields also proceeds by anion migration through the zirconium dioxide.

Consideration of the size of oxygen ions shows that they are too large to occupy interstitial positions in the zirconium oxide lattice. Therefore, it may be concluded, at least in thin films without cracks, that anion diffusion takes place by lattice defects or holes.

Measurements of thermoelectric power[2] on films of pure zirconium and zirconium-tin alloys gave negative values (9). Thus, it may further be concluded that these films were anion deficit semiconductors (n-type).

A few attempts have been made to provide a theoretical basis for the cubic rate equation. Mott (23, 24) derived a cubic rate equation based on the premise that diffusion of cation vacancies is rate controlling, where the number of vacancies is proportional to the number of negative ions per unit surface area and to a linear field set up by the ions. Engell, Hauffe, and Ilschner (25) derived a similar equation based on migration of positive holes and diffusion of lattice vacancies. Both of these derivations were based on p-type oxide films. A different approach has been taken by Uhlig (26) who recently derived a cubic rate equation based on electron flow from the metal as the controlling step in the oxidation process. This equation would be applicable for films of thickness up to several thousand angstrom units in which case the space charge in the oxide is important.

An attempt to explain the cubic oxidation of titanium has been made by Kofstad and Hauffe (27). They suggested that, in view of the high solubility of oxygen in titanium, the cubic rate law could be interpreted in terms of diffusion of oxygen through the outer layer of oxygen-enriched titanium. Since zirconium also has a high oxygen solubility, it is probable that the cubic oxidations of zirconium and titanium follow a similar mechanism.

Thus, it is not altogether surprising that the oxidation of zirconium, which ostensibly proceeds by inward oxygen diffusion, does not obey the simple parabolic rate law because the oxidation kinetics are complicated by oxygen dissolution in the outer layer of zirconium metal.

Correlation of isothermal rate data with Wagner-Hauffe theory.—According to the Wagner-Hauffe (28) semiconductor approach to alloy oxidation, foreign ions of lower valency than zirconium should increase the rate of oxidation, since they create more lattice defects. Conversely, ions of valency higher than zirconium should reduce the concentration of oxygen ion defects and thus decrease the oxidation rate. Although this theory was derived for oxidation obeying the parabolic rate law, it is not necessarily limited to this, since it has been found to apply to the case of zinc, which followed a logarithmic rate law (29).

A condition which must be met for the Wagner-Hauffe theory to apply is that the metal which is added to zirconium must share in the film formation but must not give rise to the formation of a new phase. Examination of the oxide films formed on several alloys was attempted by x-ray and electron diffraction, but because the alloys were so dilute it was impossible to determine whether or not a new phase was formed since neither additive metal oxides nor unoxidized additive metals could be detected. Thus, it is necessary to predict the composition of the films from available solubility data.

Since solubility equilibrium does not have an opportunity to be established in the oxide phase in experiments with the conditions of this study, it is believed that solubility data for the oxide systems are not germane. A more appropriate way of predicting the composition of the oxide film is in terms of the solubility of added metal in zirconium before oxidation. Thus, if the added metal is in true solution in the metallic state, it is assumed that segregation into two distinct oxide phases will not occur on oxidation, even if the oxide of the added metal is insoluble in zirconium dioxide. This statement should be true for reasonably dilute alloys and for temperatures sufficiently low that the mobilities of the metal ions in the oxide phase are low. For the problem under immediate consideration both of these conditions are true.

In the case of a metal insoluble in zirconium, the alloy probably consists of agglomerates of the second metal randomly situated throughout the zirconium. Then, when oxidation occurs, these islands of additive metal produce additive metal oxide which remains as a separate oxide phase.

In Table V data are presented for the alloy systems which were studied in this program and which are in the category of the additive metal being reasonably soluble (greater than 1 atom %). The Wagner-Hauffe theory should be applicable to these systems. Only for the case of lead does the prediction of the theory disagree with the experimental data. Lead is an exceptional additive in that its Goldschmidt ionic radius is 52% greater than that of zirconium. All of the other additives considered in this table have ionic radii less than that of zirconium. The oxide of lead most likely formed, PbO, is also thermodynamically the least stable additive oxide of the series by many kilocalories. Therefore, for these two reasons lead can be considered unique. As predicted by theory, none of the additives which were soluble in zirconium increased the oxidation

[2] To determine the type of conduction (electrical) in a semiconductor it is necessary to make measurements of thermoelectric power. If the current is carried exclusively by electrons then the thermoelectric power will be negative, whereas the thermoelectric power must be positive if the current is carried by the positive holes.

Table V. Prediction of initial oxidation behavior and breakaway phenomena of some zirconium alloys

Initial oxidation rate predicted to increase if oxidation number of additive is less than 4. Breakaway predicted to occur if ionic radius of additive differs from Zr^{4+} by 15% or more.
Consideration restricted to zirconium alloys whose additive solubility in alpha zirconium is greater than 1 atom % (a/o).

[g] Experimentally demonstrated that TaO formed when Ta reacts with ZrO_2 at 1700°C [W. A. Chupka, J. Berkowitz, and M. G. Ingram, *J. Phys. Chem.*, **26**, 207 (1957)].

resistance because none had oxidation numbers greater than four.

The agreement of experimental results with predicted results is actually better than indicated by six metals out of seven. The phase diagrams in the literature indicate that beryllium, carbon, chromium, cobalt, copper, iron, molybdenum, nickel, platinum, silicon, tungsten, uranium, and vanadium are relatively insoluble in zirconium at 700°C. These additives, therefore, should not follow the predictions of the valence effect of Wagner-Hauffe theory. In the 13 cases cited, 11 do not follow the prediction and only 2 (vanadium and iron) follow the prediction. However, the oxide of vanadium, V_2O_5, has a low melting point (675°C) and thus is not typical. The other additive (iron) shows a slightly increased rate of oxidation which follows the prediction despite the very low solubility in zirconium. It is felt that no single theory is adequate to explain the oxidation rate effects of additives which are not soluble in zirconium, for which the Wagner-Hauffe theory does not apply . In these cases it is necessary to consider the properties of the individual oxides concerned such as preferential oxidation relative to zirconium, protective nature of the oxides, diffusion rates of ions in the oxides, and electrical conductivities of the oxides.

Breakaway phenomenon and ionic radius.—The breakaway phenomenon is a general characteristic of high-temperature zirconium corrosion and oxidation. It has been observed to occur in high-temperature water (20), in air (6, 14, 15, 30) and in oxygen (6, 9, 10). The interpretation given to the breakaway has been that, since the volume ratio of zirconium dioxide to zirconium is 1.5, the oxide grows under compressive strain and, at a certain film thickness, cracks to release the compression, thus leading to the breakaway. According to the assumed model, when zirconium alloys containing soluble additives are oxidized the film produced consists of additive metal dispersed in zirconium dioxide. If the ionic radius of the additive ion is sufficiently different from the ionic radius of zirconium, it is reasonable to expect that the lattice of zirconium dioxide will become distorted and breakaway will occur at a lower film thickness than is the case with pure zirconium.

As an extension of this reasoning a general rule, which appears useful in predicting the occurrence of the breakaway phenomenon, was formulated. This rule is that a breakaway will occur when the Goldschmidt ionic radius of the soluble additive element differs by 15% or more from the ionic radius of zirconium.

Reference to Table V shows that all 7 soluble additives (aluminum, hafnium, lead, niobium, tantalum, tin, and titanium) follow the rule. Actually, 19 out of 21 alloy compositions obeyed the rule, the only exceptions being the lower concentration tantalum alloys.

For insoluble additives the oxide film consists of zirconium dioxide and separate agglomerates of additive metal oxide. In the low concentrations encountered in this study these additives should not have any effect on the breakaway. This was borne out experimentally since out of 38 alloys containing insoluble metals, 27 did not show breakaways during the period of observation. In the 11 cases where breakaway did occur the additive metal oxide may have interfered with the adherency of zirconium dioxide to zirconium, but there are probably several causes for this effect, and any relationship between breakaway and ionic radius of insoluble metals is undoubtedly coincidental.

Structure of zirconium dioxide film.—In one study (31) concerned with the growth of oxide films on zirconium in high-temperature water, it was reported that an initial film of tetragonal zirconium dioxide transformed to the monoclinic oxide after which the corrosion proceeded at an accelerated rate.

In a recent electron-diffraction and kinetic study (30) of the oxidation of zirconium and some of its alloys with aluminum, tin, and titanium in air it was proposed that the breakaway is associated with a phase transformation in the film of zirconium dioxide. According to the theory advanced, the initial film formed on zirconium is the cubic polymorph of zirconium dioxide. As the oxidation progresses the film transforms to the tetragonal and finally to the monoclinic (stable) form of zirconium dioxide. The breakaway, it was reported, coincides with the last transformation.

To test this hypothesis and to obtain a better understanding of the mechanism of oxide film growth on zirconium alloys, electron and x-ray diffraction analyses have been obtained on oxidized zirconium alloy samples.

The oxide structures observed on 16 different alloys after oxidation to selected extents are presented with the oxidation data in Table VI.

Of the 13 samples (pure zirconium and 12 alloys) examined after less oxidation than the breakaway

weight, 9 showed the face-centered cubic structure (3 of which had another unknown phase), 2 showed an unknown body-centered cubic structure, and 2 showed the monoclinic structure.

Of the 9 alloys oxidized beyond breakaway, 3 showed the face-centered cubic structure (2 of which had another unknown phase), and 6 showed the monoclinic structure.

Some of the unidentified phases found may be binary or ternary compounds with the alloying element. To identify the unknown phases would involve an extended research program beyond the scope of this investigation.

Although a majority of the alloys showed a relationship between the oxidation kinetics and the change of structure of the oxide film, careful consideration of the data show enough exceptions to the predicted sequence of polymorphic transformations to make it clear that there is no rule which is applicable *a priori* to all zirconium alloy systems.

The predicted sequence of phase transformations in the zirconium dioxide film and the relationship to the oxidation kinetics as outlined above is probably an oversimplified explanation which may be applicable for pure zirconium and some zirconium alloys but cannot be extended to include all zirconium alloys.

In order to understand better the mechanism of oxide film growth on zirconium, more information concerning the nature of the film must be obtained. The most promising way of accomplishing this appears to be through further electron diffraction studies of oxide films.

Acknowledgment

The assistance in the laboratory of A. Porter and of student aides, V. Sidhu and P. Tonne, is gratefully acknowledged. The authors are indebted to V. H. Munnecke for assistance in procurement of the alloys, D. S. Flikkema for x-ray diffraction analyses, and H. Knott and M. Mueller for electron diffraction studies.

Manuscript received Sept. 8, 1959. Work on this paper was performed under Contract No. W-31-109-Eng-38, U. S. Atomic Energy Commission.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

High-Field Conduction Currents in Liquid n-Hexane under Microsecond Pulse Conditions

P. Keith Watson and A. Harry Sharbaugh

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

A novel pulse technique has been developed for measuring conduction currents due to millisecond, microsecond, and submicrosecond pulses of voltage. Using this method, a study has been made of conduction currents in liquid n-hexane at fields from 0.1 to 1.4 Mv/cm and at gap spacings from 2.5 to 25 mils. No evidence for electron multiplication was obtained at fields below 1.25 mv/cm, but there are marginal indications of the beginning of an α-process above 1.3 Mv/cm.

At fields near breakdown extremely large values of current have been measured; the authors' calculations indicate that these currents originate at microscopic points on the cathode surface. Because of the large current density and the high local field, the energy input to the liquid at the tips of these asperities is possibly as large as 10^7 watts/cm^3. This could lead to local vaporization of the liquid to form a bubble even in times as short as a few microseconds. If a bubble is so formed, then breakdown of the liquid could readily proceed by subsequent growth of the bubble across the gap to form a spark channel.

Considerable progress has been made in the measurement of electric breakdown strength in the liquid phase through the use of rectangular pulse techniques (1-3), and such methods of measurement are now widely used. On the other hand, measurements of conduction currents in insulating liquids have continued to rely on d.c. (2, 4, 5), presumably because of the experimental difficulties inherent in making reliable measurements of currents under short pulse conditions.

With the advances that have taken place in electrometer design and in pulse techniques during the past few years, it has become possible to surmount these difficulties, and we have developed a method for measuring conduction currents at high fields due to millisecond, microsecond, and submicrosecond pulses of voltage.

In a series of preliminary experiments, a comparison was made between the d-c and pulse methods (6). The measurements were made under virtually identical chemical and physical conditions, the only differences being in the methods used for applying the voltage and for measuring the resulting conduction currents in the liquid.

The present paper describes the extension of the pulse measurements to the high-field region, stresses of the order of 1.5 Mv/cm having been attained in some of the experiments. Thus the current measurements have been extended to include field strengths which approach the highest breakdown fields reported for hexane.

Experimental Technique

Equipment.—The hexane used in the experiments was first purified, using previously described techniques (7). It was then passed through silica gel, refluxed over sodium, and distilled into an electrolyzer, in which it was subject to a field of 10 kv/cm for 24 hr to remove the last traces of polar impurities. Finally, it was allowed to pass into the test cell via an ultra-fine fritted glass filter (average pore size, 1 μ). From the test cell, the hexane could be returned to the still for recycling.

The test cell was an integral part of the purification system; it was made of glass, with optical windows to allow microscopic examination of the test gap. A number of electrode sizes were used, ranging from 3/16 to 1 in. diameter across the flat portions; these surfaces were flat to within 0.05 mils, and their edges were provided with Rogowski profiles. The electrode material was stainless steel. An electrical contact method was used for determining the gap zero, and a micrometer was used for setting the gap length. A capacitance test was developed for determining the degree of parallelism of the electrodes.

D-C measurements.—Our d-c measurements were carried out over a range of gap lengths from 2.5 to 25 mils and up to field strengths of 300 kv/cm. When voltage was applied to the liquid, there was a pronounced initial current decay, which lasted some minutes, until the current settled down to its steady-state value, which was often several orders of magnitude smaller than the initial value. These findings are in agreement with those of Whitehead (8), Nikuradse (9), and others, but little attention appears to have been paid to this disturbing phenomenon by recent workers (2, 4, 5).

This fall in current is probably due to the build up of polarization charges in the vicinity of the electrodes, thus resulting in a distortion of the field in the liquid as a whole. On the basis of these and other results there seems to be good evidence for

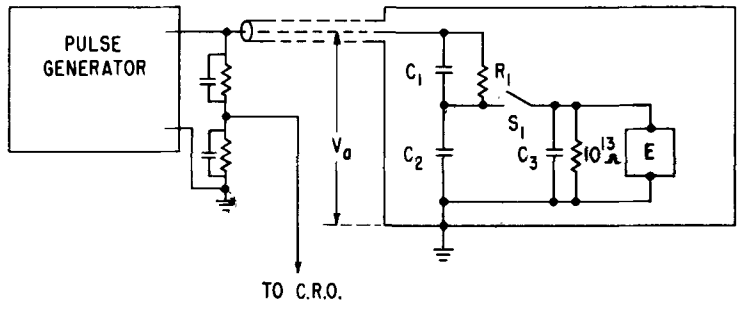

Fig. 1. Circuit used for pulse measurements of conduction currents. V_a is the applied voltage; C_1, capacitance of conduction cell; C_2, storage capacitor; C_3, input capacitance of the electrometer circuit; R_1, resistance of the liquid; S_1, switch; E, electrometer.

suspecting that d-c conduction current measurements in liquids are of an extremely complex nature and are unreliable as a guide to pre-breakdown phenomena.

Pulse measurements.—The pulse measurement technique which we have developed is to be described in detail elsewhere; briefly it is based on the fact that a voltage pulse, V_a, applied to a series circuit consisting of a resistance, R, and capacitance, C, leaves behind on the capacitor a charge proportional to $(V_a/R)\tau$. Here τ is the pulse duration, which must be short compared to the time constant CR.

In the present circuit, shown schematically in Fig. 1, a rectangular voltage pulse is applied to the series combination C_1R_1 and C_2, where C_1 is the capacitance of the conduction cell, R_1 is the resistance of the liquid, and C_2 is the capacitance of the high quality storage capacitor.

After the voltage pulse has passed, the charge remaining on C_2 is measured by closing the switch, S_1, and reading the voltage V_3 on the electrometer. The resistance R_1 is then given by,

$$R_1 = \frac{V_a C_2 \tau}{V_3(C_1 + C_2)(C_2 + C_3)}$$

The limit of sensitivity of the method is governed by background noise. A charge of 10^{-12} coulombs on C_2 can be measured with an accuracy of about 5%, and this error decreases with increasing charge magnitude. This charge sensitivity corresponds to a current of 1 μa for a pulse of 1 μsec duration; obviously, the current sensitivity increases linearly with pulse width. Moreover, by integrating the charge over a train of pulses, the sensitivity may be increased.

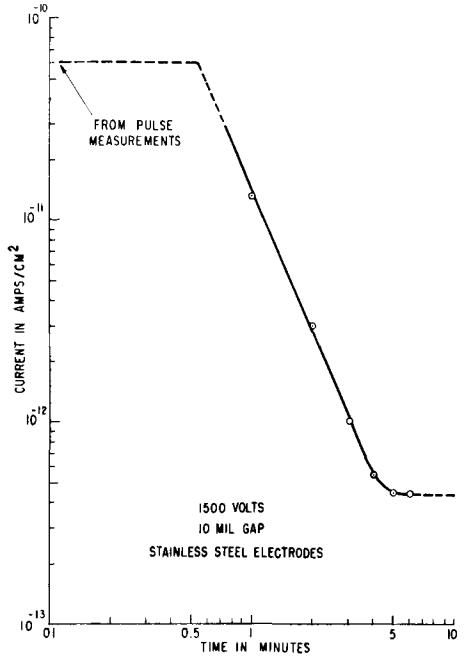

Fig. 2. Time dependence of typical d-c current measurements in n-hexane.

Experimental Results

Comparison between d-c and pulse measurements.—The results obtained using the pulse method are quite different from d-c results. The main differences are as follows: first, the absolute magnitudes of the currents obtained are orders of magnitude greater than for d.c.; and second, in the range 10 msec to 1 μsec the magnitudes of the pulse currents are independent of the duration of the applied field, whereas, in the d-c case, the currents decrease with time.

The d-c decay has been analyzed in the light of the pulse measurements, and a typical series of d-c measurements is shown in Fig. 2. These currents were measured at 1-min intervals during the first six minutes after the application of voltage to the liquid. It will be seen that the initial value of the d-c sequence is, in fact, of the same order as the corresponding pulse measurement, whereas the final d-c value is a factor of 10^{-2} smaller.

Pulse measurements at high fields.—We have used the techniques described above to make current measurements in hexane as a function of magnitude and duration of applied voltage, and also of gap width.

The results obtained fall naturally into two ranges of field strengths: the first covers the sub-breakdown range, from 100 v/mil (40 kv/cm) up to 1200 v/mil (500 kv/cm), and the second includes the range from 1500 v/mil up to fields in excess of 3700 v/mil (1.5 mv/cm). Breakdown of hexane can occur throughout the latter range, although the actual value of breakdown voltage depends on a number of other variables such as pulse width, gap width, and electrode surface.

Our results in the sub-breakdown range are plotted in Fig. 3, which shows the current density as a function of applied voltage for gap widths of 5 through 20 mils. These results were obtained using 10 msec pulses of voltage, but virtually identical results were obtained with pulse widths as short as 100 μsec. The dashed lines in the figure are curves of constant field strength. These are virtually horizontal throughout the range, that is, the currents

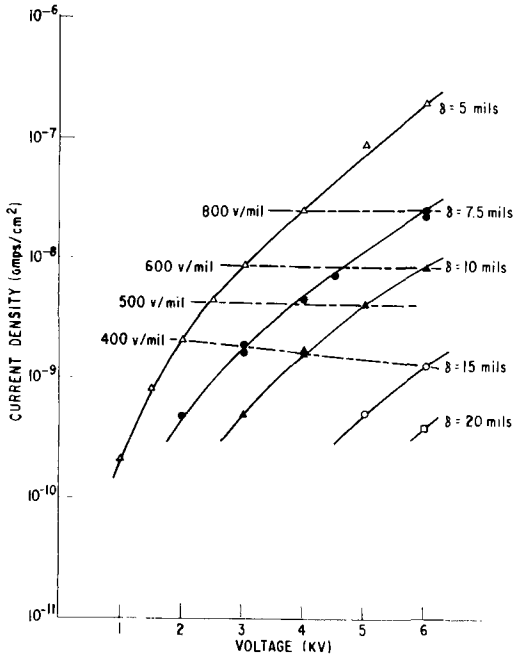

Fig. 3. Dependence of current density on voltage, n-hexane, stainless steel electrodes, 10 msec pulse width.

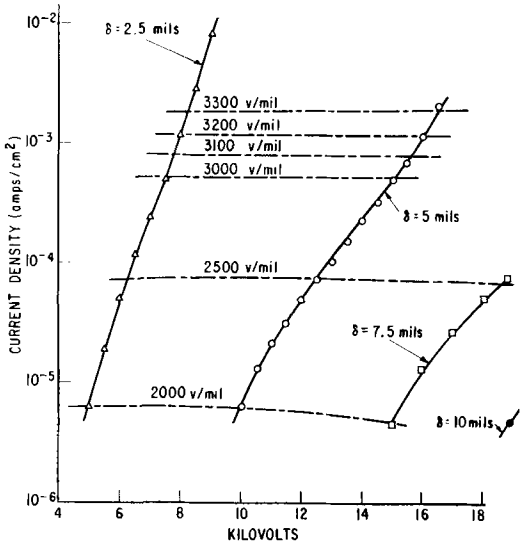

Fig. 4. Dependence of current density on voltage, n-hexane, stainless steel electrodes, 5, 3, 1.5 μsec pulse widths.

are essentially independent of gap width at all field strengths shown in the figure.

At field strengths of the order of 1200 v/mil (0.5 Mv/cm) breakdown occasionally occurred; after only one such breakdown, the current magnitude increased very markedly. This effect was attributed to decomposition products arising from breakdown in the liquid. These spuriously high currents continued to be obtained even after changing the sample, and in order to restore the former low value of conductivity, it was necessary to remove the electrodes and clean them. In order to make current measurements at higher values of field, it was necessary to use single pulses of voltage rather than trains of pulses. It was also necessary to resort to shorter pulse widths and so make use of the well-known increase of breakdown strength with decrease in pulse width.

Despite the use of short pulses, occasional breakdowns still occurred. Fortunately, at fields above about 1 Mv/cm, the electronic conduction currents are usually so much larger than the ionic currents that one can continue to use a sample, even after several breakdowns have taken place. After each breakdown, the sample conductivity was checked at a lower field in order to determine if any increase in current had occurred as a result of the breakdown. If a measurable increase was found, it was compensated for in the subsequent analysis.

The test then proceeded at a shorter pulse width until breakdown occurred again, at which point the pulse was shortened further. This procedure was followed, down to a pulse width of 0.5 μsec (the shortest pulse which the generator would deliver).

By means of this technique we have been able to make current measurements at fields as large as 1.4 Mv/cm; the results obtained are shown in Fig. 4.

Wherever possible, the measurements have been made at a number of gap spacings, and from this data we have plotted the constant field lines shown in Fig. 4.

As in the lower field region, we see that the constant field lines are essentially horizontal up to fields of 3100 v/mil (1.2 Mv/cm); this indicates that the measured currents are independent of gap width up to this field. At fields of 3200 and 3300 v/mil there may be evidence of a slight increase of current with gap width.

In concluding this description of the results we may summarize as follows: The currents are independent of pulse width, within the limits of experimental accuracy over the range from 10 msec to 1 μsec. The currents are proportional to electrode area and are independent of gap width up to fields of 3100 v/mil (1.2 Mv/cm).

Finally, it may be noted that the accuracy of the method of measurement is well indicated by the constant field lines; errors in the setting of voltage, gap width, and pulse width would lead to erratic constant field lines. However, as may be seen in Fig. 3 and 4, even a fourfold change in gap width does not appear to incur any appreciable deviation from a smooth curve.

Discussion of Results

Evidence for Electron Multiplication

One of the most controversial points in the interpretation of conduction and breakdown measurements in liquids concerns the presence (or absence) of an electron multiplication process in the liquid. Those who interpret behavior at high fields by means of a Townsend model are prone to favor the existence of an electron multiplication, or "α-process," and some have published d-c conduction data which are consistent with this model (2, 5, 9).

On the other hand, there are others who doubt the existence of an α-process in liquids and have d-c measurements to support their point of view (4, 10). The possibility of resolving this problem is regarded as one of the most important aspects of the present work.

The only satisfactory method for detecting and measuring a multiplication process involves the determination of the gap width dependence of conduction currents at constant field strength. In the presence of multiplication, currents will increase with gap width in accordance with the equation $I = I_0 \exp \alpha\delta$; that is, at constant field, the current should increase exponentially with gap width. I_0 is the current emitted at the cathode and will be field dependent. In the present work we have measured the current over a wide range of fields and at a limited number of gap widths in an attempt to determine whether or not such a multiplication process exists in liquid hexane.

The current obtained at fields up to 1 Mv/cm show no sign of increasing with gap width, indeed, at the lowest fields there is some evidence of a decrease of current with increasing gap, although this effect may not be real.

On the other hand, the currents at the very highest fields do show a slight increase with gap width, which might be indicative of an incipient α-process. We have therefore carried out a statistical analysis of the data at fields above 1 Mv/cm in order to determine whether this rise is significant.

The ratio of currents at gaps of 5 mil and 2.5 mil was taken as our statistic. The mean of these ratios at the eleven highest field strengths was 0.993, with a standard deviation of 0.075. Applying Bessel's correction to obtain the best estimate of the standard deviation, σ, of the parent population, we obtain $\sigma = 0.079$. Obviously, the mean ratio does not differ significantly from unity, so that there is no evidence for an α-process in the bulk of the data above 1 Mv/cm.

The ratios of the currents at the two highest fields were then examined: Their mean is 1.08, and the standard error of the mean for a sample of two is $S_2 = 0.079/\sqrt{2} = 0.056$, so that the mean ratio differs from unity by $1.43 \times S_2$. Now, the probability that a normally distributed statistic will differ from the mean by +1.43 standard deviations by chance alone is 7.6%, so that the observed results are possibly significant, but further evidence is required before the existence of a multiplication process can be established.

Thus we conclude that there is no evidence for an α-process at fields up to 1.2 Mv/cm, but that there are marginal indications of the beginning of such a process at 1.3 Mv/cm.

Electron Emission Processes at the Cathode

We have presented, above, the observations that lead us to conclude that electron multiplication in the gap is relatively unimportant. Therefore it is assumed that the observed field dependence of the current is explicable in terms of electron emission from the cathode, and the various possible emission mechanisms are examined below.

One possible source of current is field emission as described by the Fowler-Nordheim equation

$$I = 6.2 \times 10^{-6} \frac{\mu^{1/2} S}{(\mu + \phi)\, \phi^{1/2}} E^2 \exp (-6.8 \times 10^7 \phi^{3/2}/E)$$

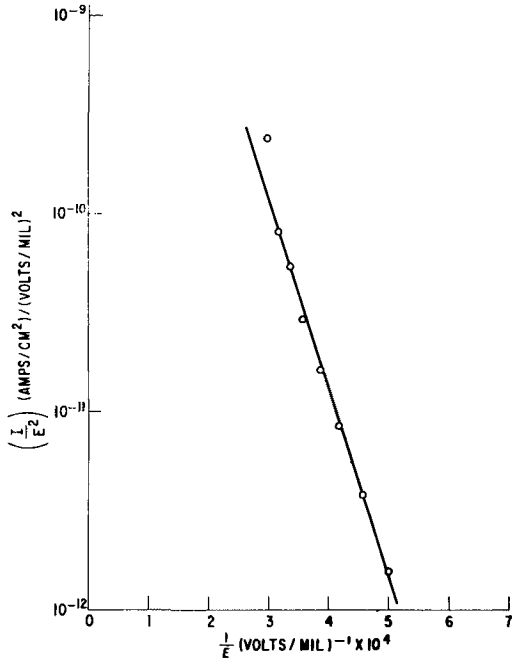

Fig. 5. Field emission plot, n-hexane, stainless steel electrodes.

Here μ is the Fermi level of electrons in the metal, and is usually taken as 5 e.v., ϕ is the work function in e.v., S is the emitting area in cm^2, and I is the current in amps. Figure 5 shows that our data give a good fit to this equation although this in itself does not constitute sufficient evidence for its validity. From the slope and intercept of the straight line in the figure, we calculate a value of $\phi = 0.25$ e.v. and an emitting area $S = 8 \times 10^{-8}$ cm. These values are lower than one might expect.

More realistic values for the work function ϕ are obtained if one takes into account the roughness of the metallic surface. As is well known, although a surface may be highly polished, it is still microscopically rough and local fields at the tips of asperities may exceed the applied field by orders of magnitude. We have taken this into account by introducing a field multiplication factor M and have recalculated ϕ and S as a function of M. The results are given in Table I. The work function becomes more reasonable at a field multiplication of ten, but our largest observed currents (greater than 10^{-3} amp) would then lead to local current densities of 10^6 amp/cm^2 for an emitting area of 10^{-9} cm^2; this is obviously unreasonable.

However, it has been shown by Jones and Morgan (11) and Goodwin (12) that the difficulties with the Fowler-Nordheim equation can be resolved by invoking the presence of an oxide layer on the cathode; this is obviously present in the case of our stainless steel electrodes.

Table I. Dependence of field emission parameters on M

M	ϕ (e.v.)	S (cm^2)
1	0.25	8×10^{-8}
10	1.2	2×10^{-9}
100	5.4	8×10^{-11}

Table II. Dependence of field emission parameters upon M for surface with oxide layer

M	ϕ_1	S
1	0.25	8×10^{-2}
10	1.2	2×10^{-3}
100	5.4	8×10^{-5}

The emission of electrons through such a barrier has been examined by Jones and Morgan on the basis of an analysis by Stern, Gossling, and Fowler (13). The equation derived by the latter shows that the theoretical current is given by

$$I = 6.2 \times 10^{-6} \frac{\mu^{1/2} S}{(\mu + \phi_1)\ \phi_1^{1/2}}\ E^2 \times \left[\exp\ (-6.8 \times 10^7\ \phi_2^{3/2}/E)\ \frac{\phi_1}{\phi_2} \right] B$$

where ϕ_1 is the work function of the metal, ϕ_2 is the work function of the oxide layer, and B is the barrier term

$$B = \exp \left\{ -6.8 \times 10^7 \left[\frac{\phi_1 + \phi_2 + (\phi_1 \phi_2)^{1/2}}{\phi_1^{1/2} + \phi_2^{1/2}} \right] a \right\}$$

where a is the film thickness. It will be seen that the only major difference between the Stern-Gossling-Fowler equation and the Fowler-Nordheim equation lies in the barrier term.

Inserting typical values for ϕ_1 and ϕ_2, and assuming an oxide film thickness of 10^{-7} cm, we obtain $B = 10^{-6}$. Using this factor we have recalculated Table I to yield the values shown in Table II. As before, S is the total emitting area per unit of electrode surface; it arises from the combined effects of many individual surface irregularities. These values for the emitting area are much more reasonable than those calculated on the basis of the Fowler-Nordheim equation. Taking $M = 10$ as representative, we obtain current densities of the order of 1 amp/cm^2 at the tips of the asperities.

We note, however, that a current density of this magnitude may lead to appreciable space charge distortion of the applied field. This results in a decrease of the field at the cathode and ultimately to space charge limitation of the current.

A calculation of this effect is complicated by the nonuniformity of emission from the cathode. Nevertheless, we may make a rough estimate as follows: assume that the local current density at the points is 1 amp/cm^2, and that this current density decreases with the square of the distance from the center of the asperity, tending toward the measured current density of 10 ma/cm^2 at the anode. For a hemispherical boss of radius 10^{-4} cm and an electron velocity of 10^4-10^5 cm/sec (14), we obtain a reduction of 10-100 kv/cm in the cathode field. This suggests that some space charge limitation of the cathode currents may occur at slightly higher fields. For the moment, however, we have chosen to ignore the effect, and to assume that the field in the gap is determined solely by the applied voltage and the electrode geometry.

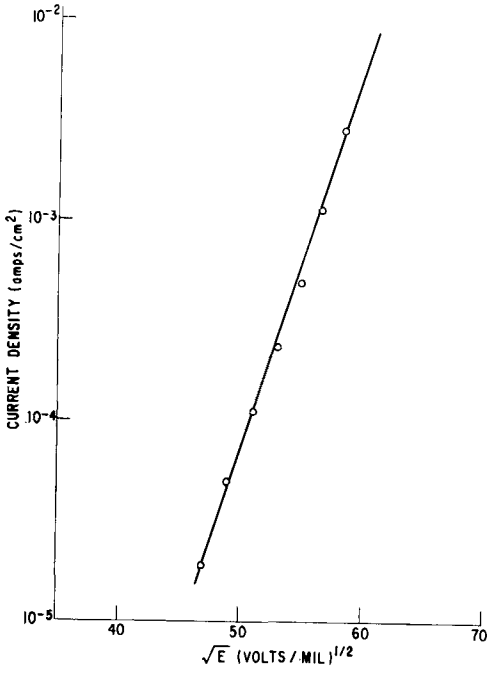

Fig. 6. Schottky plot, n-hexane, stainless steel electrodes

Another possible source of current which should be considered is field-enhanced thermionic emission of electrons, as described by the Schottky equation:

$$I = I_0 \exp\ [4.4\sqrt{E}/\sqrt{\epsilon T}]$$

Here I_0 is the thermionic current density at an absolute temperature T, and ϵ is the dielectric constant of the medium adjacent to the emitting surface. Figure 6 shows that our data from 0.2 Mv/cm to 1.4 Mv/cm give a good fit to this equation although, as observed in the case of the Fowler-Nordheim equation, this in itself does not prove that the equation is applicable. From the slope of the straight line in Fig. 6 and a knowledge of T and ϵ, we compute a value of five for the field enhancement factor M. From the zero field intercept of this line we obtain a value of 10^{-14} amp/cm^2 for I_0; in order to account for a thermionic emission current of this order at room temperature, one needs to postulate a work function of the order of 1.25 e.v.

It should be pointed out that the computed value of ϕ is very insensitive to the value of I_0; a change of 10^5 in I_0 changes the work function by 25% in the opposite direction. However, taking into account the uncertainty with which we know the value of the work function for emission into a liquid, we conclude that the magnitude of the observed current is consistent with that to be expected from field-enhanced thermionic emission.

In order to distinguish between Schottky emission and field emission, it is proposed to repeat our conduction measurements as a function of temperature.

Conclusions

On the basis of our measurements we arrive at the following conclusions:

1. An electron multiplication process does not play a significant role in conduction and, therefore, in breakdown in hexane.

2. Currents originate either by Schottky emission, or by field emission, from asperities on the cathode; in the latter case, their magnitude would be influenced strongly by an oxide layer on the cathode.

3. The average energy input to the liquid near breakdown is unexpectedly large (about 10^4 watts/cm^3). At the tips of the asperities the energy input may be as large as 10^7 watts/cm^3, and this could lead to local vaporization of the liquid in times as short as a few microseconds.

4. Thus we conclude that liquid breakdown involves the formation of a vapor bubble at the cathode and its subsequent growth toward the anode, bridging the gap with a vapor channel of low electric strength.

It has long been recognized that cavitation may play a role in the breakdown of liquid dielectrics, bubbles being formed either from dissolved gas (15, 16) or by the local vaporization of the liquid itself (17). Indeed, the fact that the breakdown strength of a liquid is pressure dependent is direct evidence that a change of phase is involved in the breakdown mechanism (18-20).

We believe, however, that until the present work was carried out, the mechanism of formation of these bubbles was unknown; we anticipate that this knowledge will enable us to extend our understanding of the breakdown mechanism.

On the Physical Characteristics and Chemical Composition of Electroluminescent Phosphors

Paul Goldberg and S. Faria

General Telephone and Electronics Laboratories Inc., Bayside, New York

ABSTRACT

Through controlled removal of surface layers, it was found that surface chemical barriers are not responsible for electroluminescence in zinc sulfide phosphors. Polycrystalline phosphors are shown to be almost uniform with respect to chemical, physical, and electroluminescent properties as one passes from the surface into the crystallite bulk. Electron micrographs show the character of the particles as successive layers of phosphor surfaces are removed by acid etching. The experimental results at progressive stages of etching are interpreted in terms of an inefficient surface layer and of decreased particle size after etching. Regions capable of serving as the site of field intensification are held to exist throughout the volume of the particles.

If a phosphor is to emit visible light on exposure to an electric field, the phosphor must first accept energy from that field. The mechanism by which this is done is a major problem of electroluminescence research. Only a few phosphor types are known to absorb electrical energy and emit light. It is important to elucidate the nature of the physical and chemical differences between these phosphors and similar but nonelectroluminescent materials. At least one difference in zinc sulfide phosphors is held to be the presence of a barrier region in the electroluminescent particles which leads to impact ionization of luminescent centers (1, 2). Throughout the literature one finds emphasis placed on a chemical inhomogeneity in the crystal which is held to serve as the barrier site (3-6). Presumably no electroluminescence would be found were this inhomogeneity removed. It is the aim of the present work to explore the surface and volume of electroluminescent zinc sulfide to ascertain the degree of physical and chemical uniformity and to relate the results to current concepts.

It has been stated that the barriers responsible for electroluminescent excitation reside on the phosphor surface. Supporting this view are the following two experiments: (i) Zalm has deposited copper sulfide on a nonelectroluminescent zinc sulfide phosphor, and, by this simple process, converted a nonelectroluminescent phosphor into one which is electroluminescent. Cyanide washing removed the copper sulfide and destroyed the phosphor's ability to be field-excited (5); (ii) Destriau performed etching experiments to remove phosphor surfaces and found that this caused an initial improvement followed by ever diminishing sensitivity of the electroluminescent materials (7). In contrast, barriers inside powder particles have been proposed from observations on the spatial distribution of emission from individual grains (8). In single crystals both surface and volume barriers were reported, again from observations on location of light emission (5, 9-12).

Regarding the barrier composition some qualitative ideas have been formulated by various workers (4-6). The preparation of electroluminescent phosphors usually involves copper concentrations above that which yields maximum photoluminescent intensity. The barrier may thus be related to this copper excess. Zalm associates the barriers with conducting particles of copper sulfide on the phosphor surface (5).

In the work reported here, the principal experimental approach was the step-by-step removal of portions of the phosphor mass by chemical etching. At each successive etching stage the properties of the phosphor were studied. These properties include the phosphor cell emittance and electrical loss as functions of voltage. Electron microscopy and x-ray diffraction of the powders were employed as auxiliary analytical tools. Chemical analyses for copper were also performed. To the extent that phosphor material is removed uniformly from the surfaces, these measurements reflect properties of the phosphor as a function of depth into the crystal. In etching experiments of this type it is clear that account must be taken of changes in particle size and possibly in particle shape.

Experimental Technique

Phosphors and analytical methods.—The phosphors studied were mainly of the ZnS:Cu,Cl type. They contained 0.08% Cu by weight and were green-emitting below 1 kc. In most of the work the electroluminescent phosphor was first fractionated by elutriation to yield specimens with improved uniformity of particle size distribution. A potassium silicate solution was employed as a dispersing agent for the settling from aqueous solution. The phosphors were etched with solutions of 6*N* HCl by agitation of the mixtures at 60°-80°C. The progress of the etching was monitored by weight loss due to H_2S evolution. Specimens etched to various extents were obtained by either of two methods: (i) etching of a large mass of phosphor with periodic sampling, and (ii) etching of individual samples to the desired mass reduction. The two methods led to roughly comparable results. The electron micrographs were recorded of representative samples with a minimum of nine photographs per sample. Direct platinum-shadowed carbon replicas were employed throughout.

X-ray diffraction patterns were obtained with a recording diffractometer. Quantitative spectrographic analyses for copper for each stage of etching were also tabulated. In a few instances, particle size distribution data were obtained with a Coulter particle size apparatus (13).

Optical and electrical measurements.—The brightness data were taken with a demountable electroluminescent cell 25 x 25 x 0.150 mm in size with a castor oil dielectric at a phosphor volume fraction of 0.33. Brass and conductive glass (500 ohms per square) served as electrode materials. The detector was an RCA 1P21 photomultiplier corrected by a Wratten No. 106 filter to yield an approximate eye response. The brightness was recorded with a Photovolt Model 520 photometer calibrated with a Spectra 100 ft-L standard brightness source.

The measurement of electrical losses was achieved with a bridge circuit which measured the capacitance and the equivalent parallel resistance of the test cell.

Experimental Results

Electroluminescent properties of etched phosphors.—The brightness L and electrical loss of the etched phosphors were measured as a function of voltage V. In Fig. 1 the brightness data are shown plotted as log L vs. $V^{-1/2}$ for a constant frequency of 1 kc. Two effects should be noted: (i) after initial etching the brightness is improved at all voltages, and (ii) subsequent stages of etching give increased slopes as would be expected from decreases in particle size (14, 15).

The efficiency, η, of this group changes with extreme etching according to the trend established by Lehmann for efficiency variation with particle size

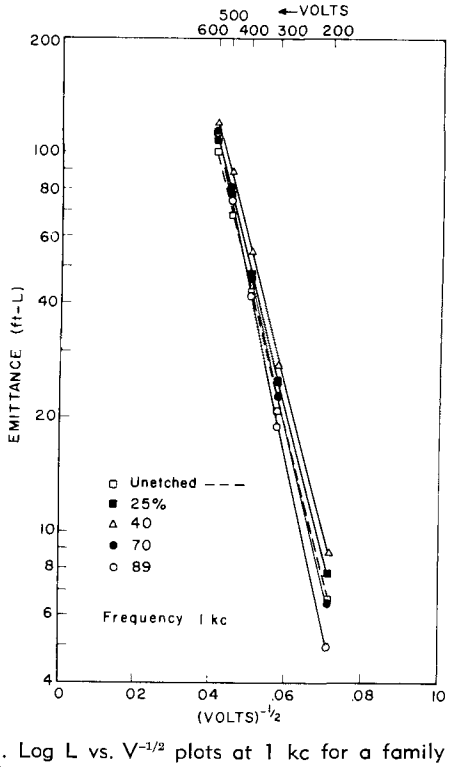

Fig. 1. Log L vs. $V^{-1/2}$ plots at 1 kc for a family of phosphors subjected to various amounts of etching.

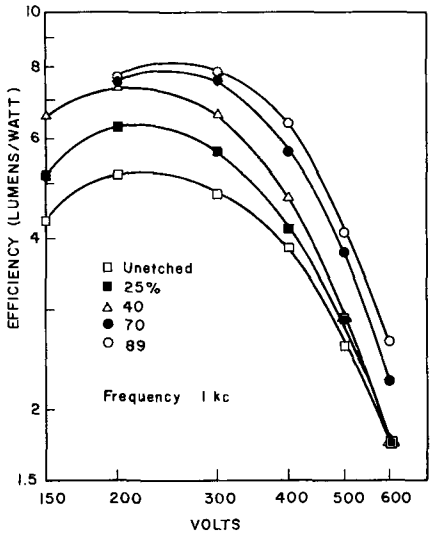

Fig. 2. Log η vs. Log V for phosphors in Fig. 1, frequency is 1 kc.

(14). Figure 2 contains data of log η vs. log V at a constant frequency of 1 kc with the degree of etching as a parameter. The voltage at which maximum efficiency occurs remains fixed for the initial stages of etching. Heavy etching occasions a shift in this voltage which is probably a consequence of smaller particle size. The maximum efficiency depends only slightly on frequency with the optimum range falling near 300 to 400 cps.

The improved brightness and higher efficiency resulting from extensive etching of these phosphors do not appear to be a consequence of the particular phosphor synthesis employed. Thus in addition to the ZnS:Cu, Cl already mentioned, the following phosphors, etched to remove between 60% and 90% of the phosphor mass, all show as high or higher levels of brightness and efficiency as before etching: ZnS:Cu,Cl-Pb (16); ZnS:Cu,Al (4); Zn(S,Se):Cu,Br (17); and ZnS:Cu,Cl-Mn.

Chemical analyses for activator inhomogeneity.—The aim of these chemical analyses was to probe the chemical homogeneity of the phosphor on the assumption that the particle mass was removed uniformly.[1] Table Ia gives results of spectrographic analyses for copper in the remaining solids as a function of degree of etching. The relative particle size is specified in Table I with the diameter of the unetched material designated as unity. The mean diameter of the unetched phosphor is 8.3μ as measured by the gas adsorption (BET) method and 22μ as determined with the Fisher Sub-Sieve Sizer. Table Ib gives similar data for another phosphor of different average copper content. Before analyzing for copper, the powders were washed with 1% potassium cyanide solution to remove any loosely bound Cu_2S which forms by precipitation on exposed surfaces subsequent to destructive etching.

The values in Table Ia show that the samples possess gradients in Cu concentration of less than 5×10^{-6} g at Cu/mole per micron of crystal. This value is determined by the precision of the analyses.

[1] The absence of specific etch geometry in most of the etched phosphors suggests that all surfaces experience about the same degree of dissolution.

Table Ia

Wt. % removed by etching	Fraction of initial size (calculated) [a]	Wt % Cu found (±a.d.)	No. of samples analyzed
0	1.00	0.065 ± 0.002	4
25	0.91	0.066 ± 0.002	3
33[b]	0.87	0.065 ± 0.002	2
70	0.67	0.067 ± 0.003	3
89	0.48	0.069 ± 0.002	4

Table Ib

Wt. % removed by etching	Fraction of initial size (calculated)	Wt % Cu found (±a.d.)	No. of samples analyzed
0	1.00	0.15 ± 0.015	2
50	0.79	0.16 ± 0.015	2
90	0.46	0.15 ± 0.015	2

[a] Calculated from weight loss assuming spherical geometry.
[b] This sample is not included in the measurements shown in Fig. 1 and 2.

The results do not rule out the existence of an inhomogeneous impurity distribution. Significant activator concentration gradients may be too small to be detectible by methods described above. It appears, however, that there is no bulk activator phase residing on the surface of these phosphors which is of critical importance to electroluminescence.

Electron Microscope Studies

Unetched electroluminescent phosphors.—The appearance of the grains is mainly globoid. The surfaces are on the whole mottled by tiny protuberances or crater-like depressions with dimensions of a half micron or less. Terracing, characterizing the original crystal growth, is found in localized regions. Striations are also evident in restricted parts of most grains. The terracing and striations are the only surface features indicating a high degree of crystallinity. Prismatic faces are conspicuously absent. A typical particle is shown in Fig. 3.

Etched electroluminescent phosphors.—Materials at the initial stages of etching show little of the

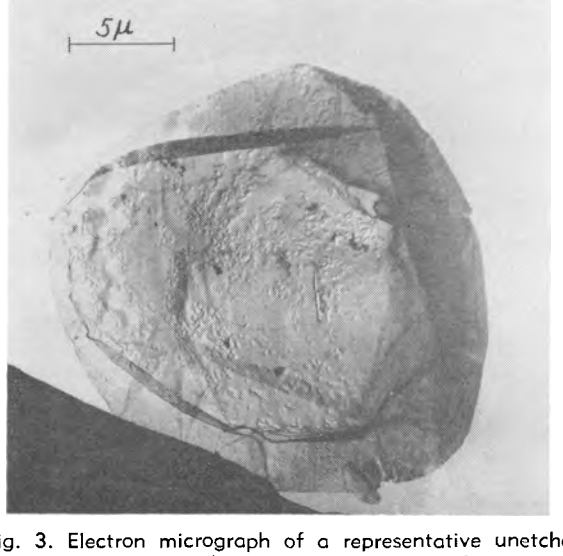

Fig. 3. Electron micrograph of a representative unetched electroluminescent particle showing a mottled surface.

Fig. 4. Electron micrograph of an etched electroluminescent particle, about 40% mass removed. This general appearance is preserved at higher degrees of acid etching.

mottled surface character and are apparently chemically polished. Here the geometry is more characteristic of a crystalline substance. Crystal faces can be discerned in a representative particle shown in Fig. 4. These are disturbed by small bumps, regions of striae, and irregular depressions. Only rarely is an etch pit of regular geometry found. This character persists through all stages of etching. From this information (and the x-ray data) a picture of fragmented crystal order emerges for the electroluminescent particles.

After about 90% of the phosphor mass is removed, the photographs show a distinct reduction in particle size. If a spherical geometry is assumed, a reduction in mass by 90% is equal to a reduction in diameter of about 50% which is on the average the order of the observed decrease in size. Some particle size distribution measurements were made which show that mass removal was achieved by attacking particles of all sizes rather than the fine ones preferentially. Figure 5 shows the histogram of size distribution by volume (or weight) of an unetched phosphor. Figure 6 is the distribution of this phosphor after etching away 80% of the mass. The significant feature is the shift in the apparent mean size from approximately 35-40μ to about 25-30μ showing extensive etching of the larger grains. The electroluminescent properties of these two phosphors are related in the same way as already described in Fig. 1 and 2 for the unetched and the heavily etched phosphors.

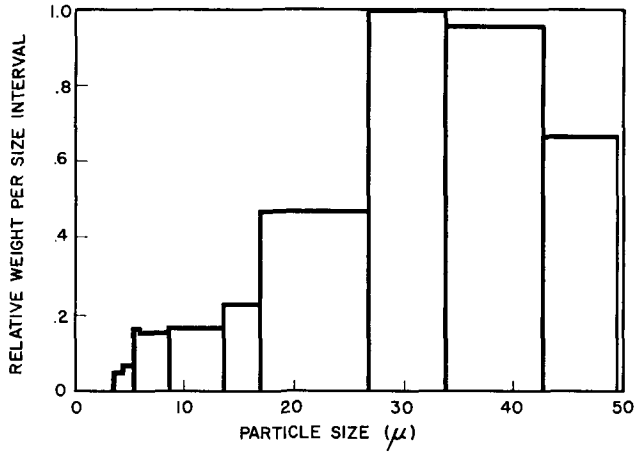

Fig. 5. Distribution of particle size by volume (or weight) of a representative unetched electroluminescent phosphor; measurement range is 3.4-49 μ.

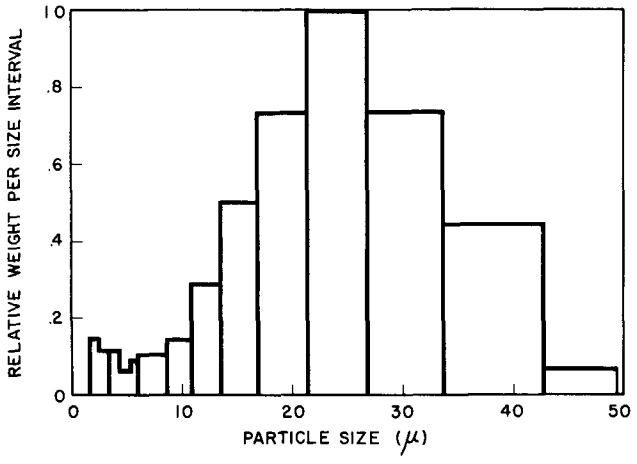

Fig. 6. Distribution of particle size by volume (or weight) of the phosphor shown in Fig. 5 after etching away 80% of the mass; measurement range is 1.7-49 μ.

Nonelectroluminescent phosphor particles of the ZnS:Cu,Cl type show qualitatively about the same degree of structural discontinuity as do their electroluminescent counterparts. There are, however, in these materials none of the striations seen in the electroluminescent phosphors.

Specific etch patterns.—In one specimen an etch geometry of an unusual character was found. The specimen was etched to 93% mass removed.[2] Two representative particles are shown in Fig. 7. The char-

[2] The etching procedure was different here. First 80% of the mass was etched away; the phosphor was dried and etched again with fresh acid.

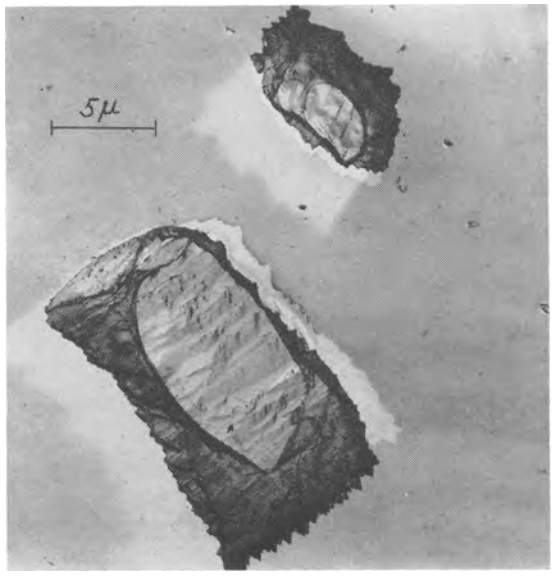

Fig. 7. Uncommon geometry in a highly etched electroluminescent specimen (93% mass removed) showing pyramids on one end. The crystal structure of the powder, of which this particle is representative, is cubic with little or no hexagonal content.

acteristic shape is oblong with one end showing well-defined pyramidal peaks. The peaks fall mainly into two groups whose average angles are 62° 51′ (±1° 40′) and 70° 45′ (±2° 10′), respectively. These particles show cubic structure in the x-ray diffraction pattern with a small hexagonal content and some birefringence. They possess ridges running normal to the direction in which the peaks point. Peaks within one particle are found which point in directions which are out of parallel with others by about 5° of arc. Also, the lateral ridges are, in some particles, out of parallel by as much as 13°. These facts point to structural units whose boundary divides the particle parallel to the direction of the pyramids.

It is possible that the occurrence of peaks only on one side of each particle is a consequence of the absence in the sphalerite lattice of a structural center of symmetry. Recently White and Roth (18) have shown how asymmetric etch patterns in GaAs wafers (sphalerite structure) etched in (111) planes correlate with the noncentrosymmetric structure. We may thus postulate that the peaks in Fig. 7 point in the <111> direction. This contention is supported by x-ray diffraction patterns obtained from individual particles in the etched specimen. Wolff has reported that in ZnS crystals the rates of dissolution by HCl of (111) faces and $(\bar{1}\bar{1}\bar{1})$ faces are different. He suggests that this is a consequence of structural asymmetry along the <111> direction and that the face made up primarily of sulfur atoms is attacked at the greatest rate (19). Thus we postulate that the pyramids in Fig. 7 appear on the "sulfur" face.

The light output from a sampling of fifteen particles from this material was followed visually with a microscope arrangement similar to that of Waymouth and Bitter (20). In all but one case the particles were distinctly more luminous with the elongated axis parallel to the applied field rather than perpendicular.

Crystal structure.—The structure of the family of phosphors which have undergone successive etching is, to a first approximation, uniform throughout the lattice. The dominant form is cubic in most of the electroluminescent materials reported upon here. The nature of the phosphor synthesis is such that the cubic structure may have occurred as a consequence of either low-temperature annealing or of milling the hexagonal form at a stage following crystallization. The diffraction patterns show some subtle qualitative changes at various stages of etching. A small residual hexagonal component existing in the unetched phosphor is reduced in the more heavily etched phosphors. Also, from observations on line breadth in the back reflection region, the highly etched grains are found to have a greater degree of order than the unetched phosphor. Assuming that strong etching exposes the particle cores, the ordering effect may arise from a slower cooling rate in the inner layers after the synthesis. In support of this the interiors are found to have a stronger blue component in the photoluminescence than the unetched parent phosphor. Leverenz states that the shorter wave lengths are favored by slower cooling (21).

Discussion

The results show that the polycrystalline phosphors are nearly homogeneous in chemical, physical, and electroluminescent properties as one passes from the surface and penetrates deeply into the crystallite bulk. One exception to this is the existence of a thin inefficient surface layer much like that found in cathode ray phosphors (22).[3] Following the removal of this layer, the electroluminescent properties vary with the extent of etching in a fashion like that previously described for particle size reduction (14, 15). The results are at odds with the concept that a surface chemical phase is responsible for the potential barrier and thus for the source of electroluminescence excitation, since strong electroluminescence persists following the removal of substantial amounts of surface material. It would appear that the phosphor particle's surface modifies its electroluminescent capability, but does not serve as a site of intrinsic electroluminescent properties. Such modification of a solid's bulk properties by its surface is often encountered in other areas of semiconductor studies.

The most acceptable physical description of electroluminescent particles is one in which regions capable of serving as the location of field intensification are to be found throughout the electroluminescent particle. The location within the particle of the site which finally serves as the active barrier is not certain. The following, however, does appear well founded on the basis of the above experiments: if the site of field intensification exists on or near the particle surface, removal of this surface brings new barrier sites into play with equal capabilities for the generation of electroluminescence. The particular site which serves as a barrier may depend on particle orientation, shape, and contact with other particles. It appears likely as a consequence of arguments based on particle size effects that only one or two barriers are operative in a particle at any one time (15).

The concepts proposed here are in disagreement with Zalm's model (5) of a conducting surface phase. The source of the diagreement lies in the fact that electroluminescence which is produced by impurity activation at high temperatures and that arising from the deposition of conducting phases on nonelectroluminescent phosphors are different in two important ways. First, the field-excited emission from an otherwise nonelectroluminescent phosphor with a copper sulfide surface phase is orders of magnitude below that of products synthesized by conventional methods. Second, conventional electroluminescent phosphors cannot be deactivated by washing with a cyanide solution. Thus, we find that a phosphor which was refluxed with a 50% KCN solution loses little if any of its sensitivity.

The experiments of Larach and Shrader (6) do not offer convincing evidence for a region near the

[3] Kremheller proposes that etching, and therefore roughening, of the surface of some phosphors improves light output owing to decreases in multiple internal reflections (23).

particle surface which is richly interdiffused with copper, as they maintain. They have performed no chemical analyses as a function of penetration into the crystal volume. It would be of interest to know if their phosphors experience the same type of changes described in this report or if the materials lose sensitivity following destructive etching.

Destriau's work on etching of electroluminescent phosphors (7) may, on the basis of this report, be thrown into different perspective. His measurements were of the minimum voltage required for visibility as a function of the extent of etching. The course of his curve shows an initial decrease (sensitivity increase) followed by a monotonic increase (sensitivity decrease). This is the same pattern followed by the data in Fig. 1 in the low voltage region. Initial etching increases sensitivity; heavier etching produces an apparent sensitivity decrease which is more precisely a consequence of particle size change.

One finds subtle effects on penetrating the grains which, in the second approximation, show the grains to be inhomogeneous. These are the bluer photoluminescence and more ordered structure of the internal regions. The relation, if any exists, of these effects to electroluminescence cannot be made on the basis of the above experiments.

Acknowledgments

It is a pleasure to acknowledge many helpful discussions with Drs. D. H. Baird, A. K. Levine, R. N. Summergrad, and Mr. C. F. Tufts. Also thanks are due J. T. Ragusin for aid in phosphor preparation, S. Weisberger for chemical analyses, Mr. Tufts for the electron micrographs and the Crystallography Staff for x-ray work.

December 1960 Discussion Section

A Discussion Section, covering papers published in the January-June 1960 JOURNALS, is scheduled for publication in the December 1960 issue. Any discussion which did not reach the Editor in time for the June 1960 Discussion Section will be included in the December 1960 issue.

Those who plan to contribute remarks for this Discussion Section should submit their comments or questions in triplicate to the Managing Editor of the JOURNAL, 1860 Broadway, New York 23, N. Y., *not later than September 1, 1960*. All discussion will be forwarded to the author(s) for reply before being printed in the JOURNAL.

Preparation and Properties of AlSb-GaSb Solid Solution Alloys

J. F. Miller, H. L. Goering, and R. C. Himes

Battelle Memorial Institute, Columbus, Ohio

ABSTRACT

Ingots of the quasi-binary GaSb-AlSb alloy were prepared by progressive casting and zone casting at various rates of crystallization. Results of x-ray diffraction studies, metallographic studies, hardness determinations, and chemical analyses indicate that, with the possible exception of a narrow composition range between 10 and 30 mole % AlSb which was not investigated, solid solution prevails in the system. Bulk specimens of single phase, solid solution alloy were obtained by use of low linear rates of crystallization (0.05 in./hr), while at higher rates of crystallization (¼ to 1¼ in./hr) two intermingled solid phases were characteristically obtained.

Vegard's law was found to be at least roughly applicable; with lattice constants for the alloys ranging between values of 6.0963Å for pure GaSb and 6.1361Å for pure AlSb. Optical energy gaps determined for alloy specimens increased regularly with cell size from a value of 0.68 ev for GaSb to a value of 1.74 ev for AlSb. Values of electrical resistivity and hole mobility for the relatively impure alloy specimens were also intermediate between those for the compounds in a like state of purity.

Liquidus data are also presented for the system.

In recent years, there has been considerable interest in systems composed of two intermetallic compounds of the A^{III} B^{V} type (e.g., GaSb-InSb, InAs-InSb, etc.). This interest arises because of the possibility of obtaining semiconducting materials, the properties of which can be varied over a continuous range of values. Since regular variation of the structure-sensitive properties with composition can be expected only for those systems or composition ranges in which solid solution occurs, the majority of previous investigations (1-8) in this area have been concerned chiefly with the existence of such ranges in the various systems.

In a number of instances, however, apparently conflicting results have been reported. In the case of the system GaSb-InSb, for example, Koster and Thoma (1) report a degenerate eutectic diagram with no appreciable terminal solid solution, while Kolm, Kulin, and Averbach (2) report approximately 10% solid solution at each end of the diagram. On the other hand, results reported by Goryunova and Fedorova (3), Woolley, Smith, and Lees (4), Woolley and Smith (5) indicate that a complete range of solid solution exists in this system. Similarly conflicting conclusions have been reached regarding the systems InAs-InSb (3, 5, 6), AlSb-InSb (1, 5), and AlSb-GaSb (1, 5). Woolley and Smith (5) suggest that the discrepancies exist because, in some instances, the samples were in a metastable state. Results of those investigations for which adequate information is given regarding thermal history of the materials (e.g., cooling rate during crystallization, or time and temperature used for heat treatment) appear to be consistent with this observation. Satisfactory evaluation of all previous work is not possible, however, since in some cases no details are given concerning heat treatment of specimens. Firm conclusions regarding the precise nature of these systems therefore must be based to a large extent on the results of additional investigations.

This investigation was concerned with temperature-composition relationships for the system AlSb-GaSb and with pertinent physical properties of the alloys obtained. The study is incomplete in the sense that full characterization of the system and full development of certain of the analytical and preparative techniques have not yet been realized. Data presented do, however, furnish much new or confirmatory evidence regarding the nature of this particular system, and it is believed that certain of the techniques which are discussed may be applicable to other alloy systems of this type.

Experimental Procedures

All samples studied were prepared by direct reaction at elevated temperatures, of proper proportions of highly purified elements[1] sealed in quartz or Vycor under an atmosphere of pure argon. Atmospheres of hydrogen, used in some early experiments to suppress oxidation, were not considered to be satisfactory. Numerous small voids, which apparently were formed by precipitation of the gas from solution on freezing, were always present in alloy specimens solidified under hydrogen. In work with compositions other than pure GaSb, temperature of each sample was initially held in the range 1060°-1080°C (just above the melting point of AlSb) for a period of one-quarter hour to react the elements and homogenize the melt before proceeding with the experiment. Since the glasses (quartz, Vycor, etc.) are attacked rapidly by molten samples containing Al or AlSb, internal crucibles or boats of pure graphite[2] were used for such compositions.

[1] Gallium, 99.995 + %; aluminum, 99.992 + %; antimony, 99.996 + %.

[2] National Carbon Co., AUC grade.

Differential thermal analysis was employed in making the phase-diagram study. Samples were contained in graphite cells which had a graphite thermocouple well extending into the center of the sample chamber. Graphite was used as a reference material. Both temperatures and temperature differential were recorded continuously by means of a dual-unit Brown Electronik Potentiometer-Recorder. At cooling rates of 3°C/min, well-defined thermal arrest points were obtained. Thermometry of the apparatus was calibrated by measuring the freezing points of high-purity lead, antimony, and germanium. The measured freezing point of GaSb, 702°C, which is in good agreement with values of 703°C and 706°C reported by others (1, 6), served as a check on the calibration.

Alloy ingots were prepared by two techniques: progressive casting and zone casting. Progressive casting, in which crystallization is caused to progress at a controlled rate along an initially wholly molten ingot, maintained in a horizontal position, was used for exploratory purpose. [This method of crystallization has been termed normal freezing by Pfann (10).] Because of the variation of composition with distance along a progressively cast ingot (except at an invariant point or in the case of an ideal solution), a number of specimens having different compositions usually can be obtained from a single ingot.

Relatively large specimens of uniform composition are, however, required for certain physical studies (e.g., solidus determinations, chemical analyses, etc.). Zone casting, which is essentially single-pass zone melting, was investigated as a potential means of obtaining such specimens. Theoretically, for a system or composition range in which the components form solid solutions, this method of casting should yield ingots which are of uniform composition over a considerable portion of their length. If a macroscopically homogeneous charge is used, composition of the recrystallized ingot should change appreciably in only the first several and the final zone lengths. When material of a given composition (representing some point on the solidus of the system) is used as the main charge, and material of the corresponding liquidus composition is used as a charge in the first zone length, then composition of the recrystallized ingot should vary only in the final zone length. Solid charges consisting of either air-quenched ingots or thoroughly blended lots of the alloy material in powder form were recrystallized in this way. Induction heating was employed for all casting experiments, and the rate of movement of the ingot through the induction coil was considered to be rate of crystallization. Molten zone-length to ingot-length ratios of 0.2 to 0.25 were used for the zone casting. Alloy ingots were cast progressively under a number of conditions, and specimens from selected locations in these ingots were examined by use of x-ray diffraction, metallographic techniques, and hardness tests.

In preparing specimens for metallographic examination, a staining etch of 10 g $FeCl_3$, 1000 ml H_2O, and 100 ml concentrated HCl was used. In Knoop hardness determinations, 100 and 500 g indenter loads were used. Except for Sample PC-1-4, which spanned a range of progressions, all samples taken for x-ray, optical, electrical, and chemical analyses were from thin slab-like sections which were cut along planes normal to the longitudinal axes of the ingots so as to minimize the effect of variations in composition.

X-ray diffraction studies were made on powder samples prepared by grinding the bulk specimens under anhydrous benzene. The diffraction patterns were obtained by use of Ni K radiation and a 114.6 mm diameter Debye-Scherrer camera. In determining precision lattice constants, results were corrected for film shrinkage and other errors (11) by extrapolating the plots of apparent lattice parameters against the function $\frac{1}{2}[(\cos^2\theta/\theta) + (\cos^2\theta/\sin\theta)]$, where θ is the Bragg angle.

Infrared transmission spectra were obtained at room temperature for polished platelets of the compounds and alloys ranging in thickness from 0.003 to 0.010 in. The Beckman D U, Beckman Model IR-2, and Perkin-Elmer Model 21 spectrometers were used for the wave-length ranges, 0.4 to 1.5, 0.65 to 2.0, and 2.0 to 15 μ, respectively, as was required. In determining optical energy gap, cutoff wave length was taken as that wave-length at which value of the Beer-Lambert absorption coefficient reached a value of 200 cm^{-1}. Use of this convention has yielded values for a number of other semiconducting compounds (12) which are generally in good agreement with other published values (e.g., room temperature values of 0.16 ev for pure InSb, 0.35 ev for InAs, 1.32 ev for InP, and 1.39 ev for GaAs).

In making the electrical measurements, both antimony films and solder contacts were used to eliminate the very high contact resistance exhibited by the alloys, especially by those rich in AlSb. The antimony films were formed *in situ* by use of hot concentrated KOH as a reducing agent. Tungsten probes then were held in contact with the films by spring tension. The solder contacts, made with Sn-Pb solder and aluminum solder flux, appeared to be more reliable for low temperature measurements. All Hall data were taken at a field strength of 5000 gauss.

For chemical analyses, the samples were dissolved in alkali. The total amount of antimony present was determined by titration with potassium bromate. Aluminum and gallium were converted to the mixed oxides and the total amount present was determined gravimetrically. The fraction of each present in the mixture was calculated then by the classical method.

Experimental Results and Discussion

Physical properties of GaSb *and* AlSb.—As a first step toward characterization of the system, pertinent physical properties of the compounds GaSb and AlSb were measured. The values obtained, which are summarized in Table I, were determined for specimens prepared from high-purity elements as has been described. Purity of the specimens studied, as deduced from electrical measurements, was about 2×10^{17} impurity atoms/cm^3.

The lattice constants, 6.0963Å for GaSb and 6.1361Å for AlSb, are roughly equal in magnitude to those reported by Blunt, *et al.* (13, 14), but are

Table I. Physical constants of GaSb and AlSb

	Melting point, °C	Lattice constant (a_0), A	Optical energy gap (ΔE at 300°K), ev	Knoop hardness
GaSb	702	6.0963 ± 0.0003	0.68	309
AlSb	1050(25)	6.1361 ± 0.0003	1.74	304

reversed in order of assignment, i.e., Blunt assigns the larger value to GaSb. The cell size for GaSb is slightly higher than that obtained by Kolm, *et al.* (2). However, values reported here, which represent the results of a number of determinations, are in good agreement with other reported values (5, 15), are consistent with expected interatomic distances for these compounds calculated according to Pauling (16), and are consistent with the cell size-composition relationship observed in our studies of the alloys.

The optical energy gap for GaSb, 0.68 ev, agrees reasonably well with other published values (17-20), which all fall in the narrow range between 0.67 and 0.71 ev. On the other hand, published values for the optically determined band-gap width of AlSb at 300°K (18, 20-22) range from 1.52 to 1.7 ev, while that obtained in this work is 1.74 ev. Some disagreement is to be expected because of the different methods used to select the cutoff wave length, but the wide divergence of reported values indicates that other factors such as sample purity and surface condition probably are involved also. For example, AlSb is slowly attacked by atmospheric water vapor. As is indicated in Fig. 1, presence of the products of this reaction on the surface of the specimen drastically alters the spectrum, and may be responsible for some of the low gap values reported.

The difference between Knoop hardness values, 309 for GaSb and 304 for AlSb, is insignificant. However, for systems in which the components form solid solutions, hardness passes through a maximum at some intermediate composition because of the effects of lattice distortion (23, 24). It is possible, therefore, to use hardness measurements as an analytical tool.

Temperature-composition data. — Differential thermal analysis of selected alloy compositions

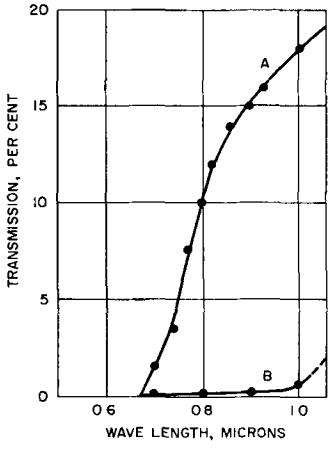

Fig. 1. Transmission for Specimen of AlSb. A, Protected from atmosphere; B, after 20-hr exposure to atmosphere.

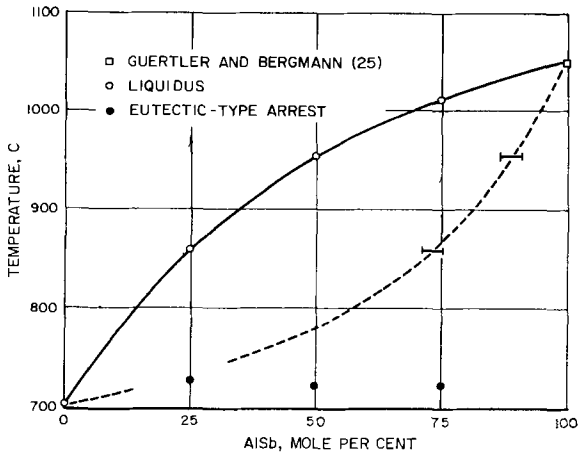

Fig. 2. Thermal data for GaSb-AlSb system

yielded accurately reproducible data on the liquidus of the system. These data are plotted in Fig. 2. Cooling curves were obtained for four compositions, at 0, 25, 50, and 75 mole % AlSb. Each liquidus point plotted represents the average of three determinations for which precision and accuracy were within the range indicated by the circle about the point. The AlSb point is that of Guertler and Bergmann (25). In each of the alloy samples, freezing took place over a wide temperature range, and near the end of freezing a "eutectic-type" arrest was noted which consistently occurred slightly above the freezing point of GaSb. The shaded circles on the plot show these latter halts.

The data are consistent with those to be expected for a system with a miscibility gap in the solid, but could also result from nonequilibrium conditions. Stohr and Klemm (26), for example, initially obtained similar data for the Si-Ge system but were able, after annealing samples for extremely long periods at temperatures slightly below the expected solidus, to demonstrate the existence of an uninterrupted range of solid solutions in that system.

Since sizeable, homogeneous alloy specimens were not available, solidus studies were not undertaken on the AlSb-GaSb system. Results of other types of studies to be discussed, however, show that wide ranges of solid solution exist in this system also and, further, strongly suggest that complete solid solution can be obtained as has been reported (27). Location of the dotted solidus curve was approximated from the results of x-ray diffraction studies (Table II) on recrystallized alloy ingots, PC-1, PC-2, ZC-1, ZC-2. As is indicated in the Fig. 2, these results suggest that if a miscibility gap exists, it is restricted to a relatively narrow composition range between about 10 and 30 mole % AlSb.

Casting.—Data for Ingot PC-1, which was progressively cast from a melt containing 75 mole % GaSb at a rate of ¼ in./hr, are typical of results obtained for ingots cast at relatively high linear crystallization rates (i.e., ¼ to 1¼ in./hr). Results of the x-ray analysis (Table II) show that two crystalline phases were present in the ingot. The minor[3] phase was very similar to pure GaSb and

[3] Major and minor are arbitrary designations used to show qualitatively the extent to which each exists.

* Fraction of the ingot crystallized in advance of sample location.
† Major and minor are arbitrary designations.

persisted throughout the ingot.[4] The major phase appeared to be a concentrated solid solution of the two compounds, the composition of which varied in a regular manner with progression along the ingot (Fig. 3a). Lattice parameters indicate that near the head (first to freeze) of the ingot this phase contained high concentrations of AlSb, and that the concentration of AlSb present in this solid phase decreased with progression of the solid-liquid interface along the ingot as concentration of AlSb in the melt was lowered. Beyond a point between 55 and 76% progression, where the supply of AlSb in the melt apparently was exhausted, this phase was no longer precipitated. Lattice parameters for this major phase correspond to those for solid solutions containing 75 to 29 mole % AlSb, as calculated by Vegard's law.[5]

While the polyphase nature of the AlSb-rich portion of the ingot suggests a broad miscibility gap, results of a single annealing experiment, which was carried out with a specimen from this progressively cast ingot, indicate that the polyphase material does not represent an equilibrium precipitate. Sample PC-1-4 was ground to a fine powder and was annealed for 96 hr at 650°C in an evacuated ampoule prior to examination. This anneal treatment appeared to have homogenized the polyphase material, converting it to a single-phase powder with a somewhat diffuse x-ray pattern.

Results of metallographic studies agreed with those of the x-ray analysis. In the first portions of

[4] Due to the slow evolution of antimony from the melt during recrystallization, the last portions of the ingots to be frozen were metallic (gallium) and therefore were not analyzed.

[5] Vegard's law has been found to hold for the systems, GaSb-InSb, GaAs-InAs, and InAs-InP [see ref. (6) and (9)] and has been shown at least roughly applicable in this research (see Table IV).

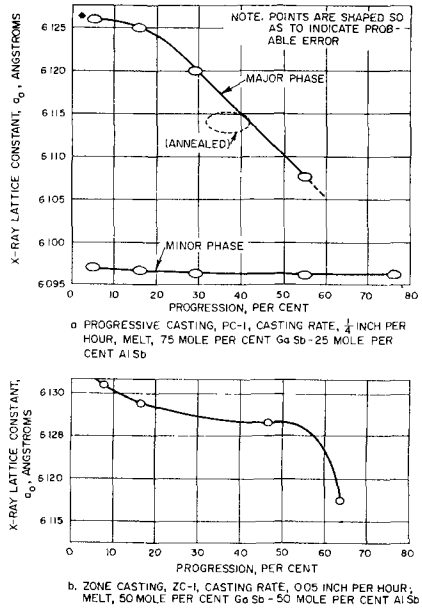

Fig. 3. Cell size as a function of progression along cast ingots.

ingots cast at relatively high linear crystallization rates (≧¼ in./hr) two distinct phases were present, while only a single GaSb-rich phase was present in the last portions. Knoop hardness values were determined for the two phases by carefully placing the indenter on selected crystallites. Values for the minor phase were consistently low, averaging about 310, which is close to the KHN for pure GaSb. Values for the major phase, however, were significantly higher, ranging up to 348, as would be expected for concentrated solid solutions.

It was possible, by use of a very low rate of crystallization, to prepare single-phase ingots of the solid-solution alloy. This is shown by the results of x-ray diffraction analyses (Table II) of samples from the ingots which were cast at a rate of 0.05 in./hr. Lattice parameters for the single-phase solid solutions thus obtained indicate that concentrations of AlSb present in the solutions ranged from 11 to 92 mole %, assuming Vegard's law to apply throughout the range.[6] Results of metallographic studies also

[6] Note the precipitous drop in cell size between progressions 54 and 74 in Ingot ZC-2. Further note that in these ingots, no cell sizes corresponding to AlSb contents between 11 and 29 mole % have been observed. If, as these results suggest, a miscibility gap exists, Vegard's law should not be expected to hold near the solubility limit.

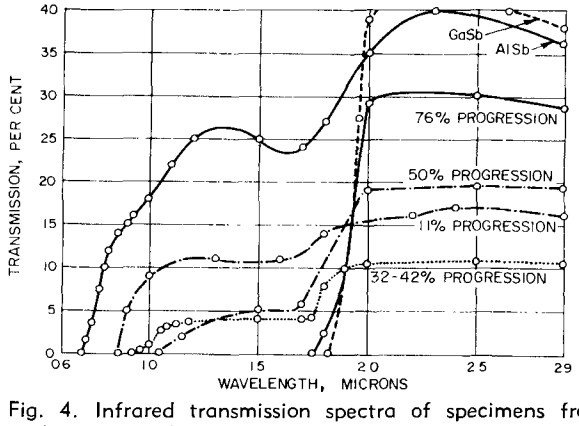

Fig. 4. Infrared transmission spectra of specimens from typical progressively cast ingot PC-1 and of the compounds GaSb and AlSb. Ingot PC-1: Casting rate, ¼ in./ hr; melt, 75 mole % GaSb-25 mole % AlSb.

indicated that these ingots were single phase, solid-solution alloys. Knoop hardness, determined at random locations on a section from the center of Ingot PC-2, progressively cast from a melt containing 50 mole % GaSb was 335 ±7.

The plot of lattice constant vs. progression for Ingot ZC-1 (Fig. 3b), which was prepared by zone casting a charge containing 50 mole % GaSb, follows the relationship expected for a system, or range of compositions, in which the components form solid solutions. Extent of the nearly flat portion of the curve indicates that this technique offers promise as a method for producing sizeable homogeneous specimens of the alloy.

Ingot ZC-2 was formed by zone casting a charge made up of two alloy compositions (an alloy containing 75 mole % GaSb in the first zone length, and an alloy containing 50 mole % GaSb in the remaining length) in an attempt to produce an ingot of more uniform composition. Variation of lattice constants, however, indicates that the estimated location of the solidus, which was used to select the compositions and was based on knowledge of the system at that time, was in error. Composition varied near the head of the ingot, but was again nearly constant over a considerable range of progression in the central regions.

Optical data.—Infrared transmission spectra of specimens from the polyphase Ingot PC-1 are shown in Fig. 4 along with those of the compounds GaSb and AlSb. Energy gap values, summarized in Table III, were computed from these spectra according to the convention described above, which yields gap values generally consistent with other physical parameters for the respective specimens. The spectrum of the specimen taken at 76% progression is seen to be nearly identical with that of GaSb, and shows an absorption edge which corresponds to an energy gap of 0.69 ev. Reading from short to long wave lengths, spectra of the other three specimens each shows a sharp rise in transmission followed by a plateau which is in turn followed by a second sharp rise to peak transmission and then gradual decline to the long wave tail. This is the type of spectrum one might expect for a specimen composed of individual crystallites of two different phases with unequal energy gaps, providing that the crystallites were so disposed that those of one phase do not interfere with transmission through those of the second. (Such disposition of crystallites is quite probable in the polyphase specimens studied.) If such were the case, the threshold of transmission should correspond to that of the second phase.

Applying this interpretation, and normalizing to equal peak transmission for the two phases, energy gaps calculated for specimens at 11, 32, and 50% progression are 1.43 and 0.72 ev, 1.28 and 0.70 ev, and 1.12 and 0.70 ev, respectively. Note that the smaller gap in each case is very nearly equal to that measured for GaSb, as are x-ray lattice constants for the minor phase in each of the specimens from this ingot. It is also possible that manifestation of the absorption band attributed to spin orbit splitting (28), which is present in the spectra of p-type AlSb (and which can also be seen in the spectra of AlSb and of the single phase samples presented here), is responsible for the behavior observed in the vicinity of 1.7μ. However, the plateau and second rise in transmission are very sharply defined, particularly for the samples at 32-42 and 50% progression, whereas gradual changes are characteristic of the absorption due to the spin orbit splitting.

Table III. Optical data for cast ingot*

Sample	Progression along ingot, %	Mole % AlSb (by Vegard's law)	Absorption edge, mμ	Energy gap, electron-volts

ZC-2-4	74	11	1670	0.74

*Ingot	Casting rate	Charge (mole %)
PC-1	0.25 in./hr	75 GaSb—25 AlSb
PC-2	0.05 in./hr	50 GaSb—50 AlSb
ZC-1	0.05 in./hr	50 GaSb—50 AlSb
ZC-2	0.05 in./hr	75 GaSb—25 AlSb in first zone 50 GaSb—50 AlSb, remainder

Regardless of the phenomena responsible for the 1.7μ absorption, there is little doubt that the spectra show, by the different wave lengths for threshold transmission for the various specimens, the presence of materials with various energy gaps, which decrease from about 1.4 to 0.7 ev with progression along the ingot. It seems clear that these are the energy gaps of solid solutions that increase in GaSb content with progression along the ingot.

Spectra for single phase specimens from the zone cast ingots (Fig. 5 and 6) show well-defined absorption edges, the locations of which indicate that energy gaps for these single phase alloys ranged from 1.55 to 0.74 ev. The relatively small changes in energy gap over rather wide ranges of progression for the zone-cast ingots (Fig. 7), again indicate that this technique offers promise as a method for producing single-phase alloy of uniform composition.

Electrical data.—Electrical measurements have been made both at room temperature and over a range of temperatures for a number of the alloy specimens, but to date, these studies have not progressed far enough to permit the drawing of accurate conclusions. Data for single-phase specimens from Ingot ZC-2, which are presented in Table IV, show a regular variation of resistivity with composition. Figures 8 and 9 show variation of resistivity, Hall coefficient, and mobility as a function of temperature for Sample ZC-2-2. The curves appear to be typical of those generally obtained in the extrinsic region for an impure, high energy gap semiconductor. Mobility for the alloy (Fig. 9) appears to exhibit an approximate $T^{-3/2}$ temperature dependence above 700°K, suggesting that lattice scattering predominates here.

Correlation of Data

More comprehensive analysis was made of material present in zone cast Ingot ZC-2 than of any other material treated in this study. Results of chemical, x-ray, optical, and electrical analyses for four single-phase specimens from this ingot have been summarized in Table IV. The chemical anal-

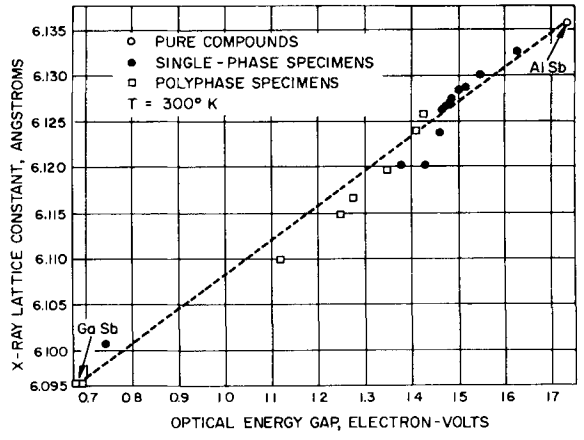

Fig. 10. Energy gap vs. cell size for solid solutions of GaSb-AlSb.

yses were run on very small samples and therefore must be assigned rather wide error limits. Nevertheless, the results constitute direct evidence that concentrated solid solution alloy was obtained. Compositions determined by chemical and x-ray analyses agree reasonably well, differing by only about 2 mole % (beyond stated limits of error) at maximum, thus confirming the applicability of Vegard's law in this system, at least for rough composition determination. The increase in carrier concentration with progression along the ingot probably results from the segregation of an impurity (or impurities) during recrystallization, but could also rise from loss of antimony.

Figures 3 and 7 show variation in lattice constant and energy gap with progression along typical ingots. These two sets of data were combined by eliminating the common variable, percentage progression, where this could accurately be done (i.e., where both parameters had been determined for a single specimen, or in regions of regular variation for the parameters). The combined data have been plotted in Fig. 10. Although there is some scattering of the points, an approximately linear relationship between energy gap and cell size is indicated.

Summary

Ingots of GaSb-AlSb alloy were crystallized from melts (cast) under various conditions. Results of x-ray and metallographic studies, hardness tests, optical transmission studies, and chemical analyses of alloy specimens indicate that:

1. Solid solution prevails in the system, with possible exception of a narrow composition range between 10 and 30 mole % AlSb, which was not investigated.

2. Bulk specimens of single phase, solid solution alloy can be prepared by use of low linear rates of crystallization (0.05 in./hr).

3. At higher linear rates of crystallization (¼ to 1¼ in./hr), two intermingled solid phases are characteristically obtained.

4. The zone casting technique offers promise as a method for producing single phase alloy of uniform composition.

5. An approximately linear relationship exists between lattice parameter and composition of the single phase GaSb-AlSb alloys.

6. An approximately linear relationship exists between lattice parameter and energy gap of the single phase GaSb-AlSb alloys.

The Diffused Shot-melting Technique for Making Germanium and Silicon p-n Junction Devices

I. A. Lesk

Semiconductor Products Department, General Electric Company, Syracuse, New York

ABSTRACT

The diffused shot-melting technique involves the melting and resolidifying of a piece (conveniently obtained in the form of shot) of semiconductor on a wafer of the same material (having essentially the same melting point) to form a single crystal boundary region, and the subsequent diffusion of impurities across the interface. Shot-melting may be done so quickly that the interface coincides with the original surface of the wafer. Impurity contents of the shot and wafer may be chosen so that a variety of p-n junction devices results after diffusion, and several junctions may be made on the same wafer by this process to form more complex structures. Although lifetime and resistivity changes generally occur, they can often be minimized by subsequent treatment such as alloy gettering or annealing. Simplicity and flexibility of diffused shot-melting have made it a convenient laboratory technique for making many semiconductor devices.

It is often necessary in the study and design of solid state structures to make a fairly large number of devices having different impurity concentrations and geometries in order to test theories and ideas as they are generated. For greatest versatility, the processes used should be simple and flexible. Although many excellent device fabrication techniques already exist and are used in manufacturing, development, and research, diffused shot-melting has some unique advantages that make its application particularly inviting in some cases.

Shot Melting

The shot melting technique involves the melting and resolidifying of a piece [conveniently obtained in the form of shot (1)] of semiconductor on a wafer of the same material (having essentially the same melting point) to form a single crystal boundary region. Melting of the wafer is prevented by providing a large vertical thermal gradient. Figure 1 illustrates this process, the example chosen being a p-type region on an n-type base. In Fig. 1(a), the shot is placed on top of the n-type wafer. The shot is generally polycrystalline, containing an impurity concentration up to 1% or so. When the heat source, located above the semiconductor pieces, is turned on, the shot starts to melt from the top. The liquid surface contour forms a section of a sphere, so that by the time the shot is all molten it has only a very small area of contact with the n-type pellet, Fig. 1(b). The pellet will not start to melt at this point because of the large vertical temperature gradient, provided by placing the heater above the work and by resting the n-type wafer on a large thermal capacity support. The shot is completely melted because heat is entering it from the top, and very little heat is leaving the bottom by conduction due to the small area of contact with the wafer. This condition lasts but a very short period of time (of the order of a second), following which the molten sphere suddenly spreads at an extremely rapid rate and immediately freezes back part way into a pyramidal shape, Fig. 1(c). At this time the heat source may be removed so the structure freezes the rest of the way, Fig. 1(d). If the heat source were not turned off, the pyramid and then the wafer would subsequently melt.

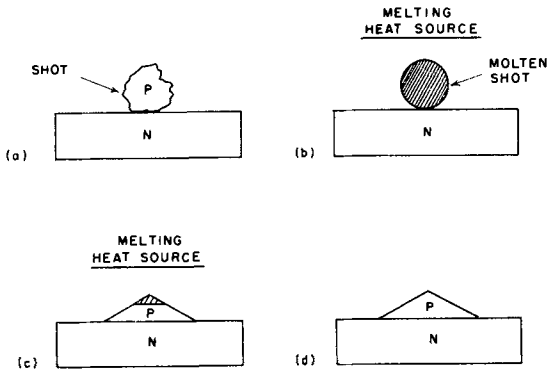

Fig. 1. Steps in the shot-melt process. (a) Shot (p-type) placed on wafer (n-type); (b) heat source turned on, shot just finished melting; (c) heat source unchanged, shot suddenly spreads on wafer and partly refreezes; and (d) heat source turned off, remaining part of shot frozen.

The shot-melt process would be of limited general use in semiconductor device technology were it not for the following two properties.

1. The p-type semiconductor region that forms adjacent to the n-type pellet is single crystal growing epitaxially on the pellet. After a short distance (of the order of a mil) it becomes polycrystalline. However, a single crystal region this thick is more than adequate for most devices. Figure 2 is a photomicrograph of a silicon shot-melt structure section, showing the p-n junction, the n-type pellet, and the grown p-type single crystal region which ends in polycrystalline p-type silicon. The pattern brought

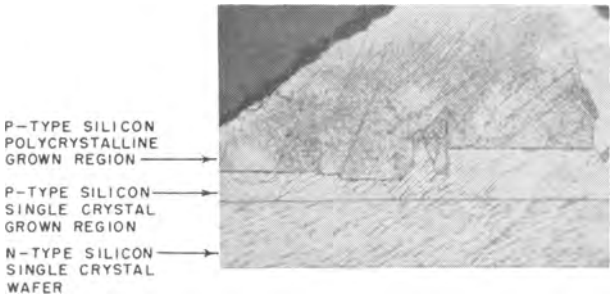

Fig. 2. Photomicrograph of silicon shot-melt p-n junction structure showing single crystal grown region. X190.

out in the single regions by the etch (10% sodium hydroxide, 15% sodium nitrite in water at about 100°C) shows that they have the same orientation.

2. If a very large thermal gradient is maintained, the boundary between pellet and shot-melt regions will coincide very closely with the original surface of the pellet. That is, the penetration of the molten shot into the pellet surface is exceedingly small. Figure 3 is a photomicrograph of a germanium pellet with shot melt regions on both sides (pnp structure) showing that the planes of the p-n junctions are flat and coincide closely with the original surfaces of the pellet. As sometimes occurs with large shot-melt regions, two small voids may be seen in the bottom (p-type) grown region.

The following explanation is proposed to account for the lack of penetration of the molten region into the pellet surface. When the shot first becomes entirely molten, it does not make intimate contact with the pellet. Surface oxide on the pellet may be at least partially responsible for this, since silicon appears to remain at this stage longer than germanium. When intimate contact between the molten and solid semiconductor regions is established at the point of contact between the sphere and plane, lateral wetting is greatly enhanced, and the area of intimate contact quickly increases. As each new incremental area of contact forms, thermal flow to the cooler substrate quickly freezes a small volume of the molten material onto the substrate. As spreading proceeds, the heat content of the shot becomes depleted, so the already deposited regions get thicker. Hence, crystal growth takes place radially as well as upward, the final diameter of the pyramid being determined by the heat content of the molten sphere as well as the temperature, thermal capacity and surface condition of the pellet. If larger shot are used, the spreading will proceed until limited by the edges of the pellet (c. f. bottom region, Fig. 3).

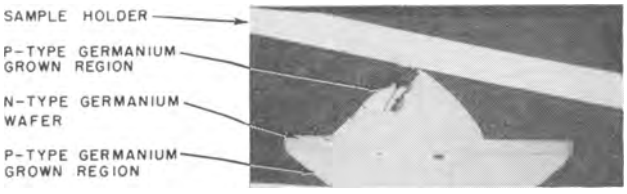

Fig. 3. Photomicrograph of germanium double shot-melt p-n-p junction structure showing how original surface of n-type wafer is preserved. X40.

Diffused Shot-Melting

Because of the short heat cycle during shot melting, little diffusion of the common donor and acceptor impurities takes place even though the temperature is high. Hence, an abrupt boundary exists between the two regions. If graded junctions are required, a diffusion cycle (most conveniently done in a separate furnace) may be subsequently used. When a diffusion cycle follows shot-melting, the complete process will be referred to as diffused shot-melting.

The shot may be made to contain two (or more) impurities. If the ratios of majority to minority impurity concentrations and diffusion coefficients are chosen in the right ranges, then the minority impurity will diffuse ahead and become the majority impurity in a narrow region of the pellet adjacent to the shot-pellet interface. Figure 4 illustrates this process to make a germanium pnp transistor structure.

The impurity concentrations in the grown shot region adjacent to the pellet may be calculated from those in the (uniformly doped) molten shot by taking into account their distribution coefficients. However, since the growth rate is variable, so will be the distribution coefficients (2, 3). The impurity concentration in the shot melt region probably is that governed by the equilibrium distribution coefficient, in a thin plane adjacent to the pellet, and increases with distance into the pyramid because the growth rate increased with distance into the pyramid. For diffused bases, the impurity concentration is critically dependent on that in the source region in a layer approximately as thick as the diffused base itself. For very thin diffused bases, therefore, a first approximation (4) is to assume diffusion from a region of high uniform impurity concentration (determined by the equilibrium distribution coefficients) into a region of low uniform impurity concentration (that of the original pellet). In practice, this approximation has worked well.

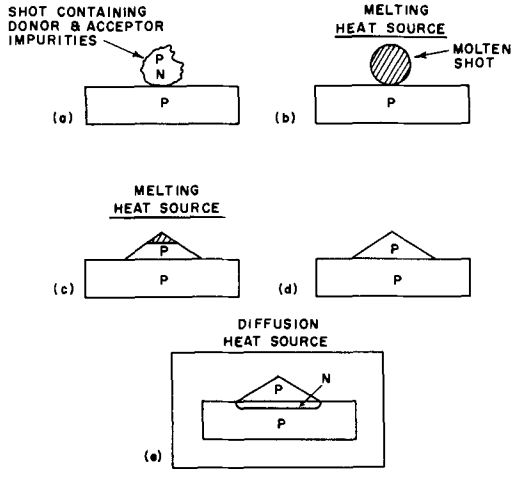

Fig. 4. Steps in the diffused shot-melt process. (a) Shot (containing donor and acceptor impurities) placed on wafer (p-type); (b), (c), (d) same as in Fig. 1; and (e) structure heated, n-type layer formed in wafer by diffusion.

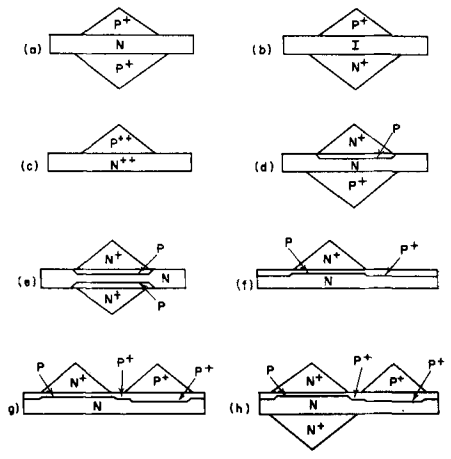

Fig. 5. Some example of shot-melt and diffused shot-melt structures. (a) pnp transistor; (b) pin diode; (c) tunnel diode; (d) pnpn switch; (e) npnpn symmetrical switch; (f) npn transistor; (g) npn transistor with 2 shot-melt contacts; and (h) npn transistor with 3 shot-melt contacts.

Application to Some Semiconductor Devices

Some examples of shot-melt and diffused shot-melt devices, all of which have been made and tested, are shown in Fig. 5. Figure 5(a) illustrates a pnp transistor made by melting shot on either side of a wafer. A similar structure, made to yield a pin diode, is shown in Fig. 5(b). A shot melt structure in which both p-type and n-type regions are degenerate, Fig. 5(c), has a tunnel diode characteristic. This requires a p-n barrier width of at most a few hundred angstroms, giving proof of the abrupt nature of the impurity transition at the boundary between shot and wafer. Figure 5(d) illustrates a pnpn switch, made by diffused shot-melting with double doped shot on one side of the wafer, singly doped shot on the other. This may be extended somewhat to make a symmetrical npnpn switch, as shown in Fig. 5(e).

Surface diffusion can be done at the same time as the bulk diffusion. A structure made in this way is depicted in Fig. 5(f), in which the surface diffused layer is left on only the top side of the wafer. The surface concentration of the vapor diffused layer must be less than that in the shot if a p-n junction is not to form over the surface of the pyramid. In Fig. 5(g) a singly doped p-type shot is placed beside the doubly doped shot (left), and the device diffused in an atmosphere containing an acceptor impurity. The result is a transistor structure, the left pyramid serving as the emitter, the right one as the base. This device is made somewhat more complex in Fig. 5(h), where an n-type impurity doped shot, to serve as a collector contact (bottom) is made before (or after) the diffusion cycle. In this figure, the surface diffused layer is removed from all wafer surfaces except the top one.

Devices made by the diffused shot-melting technique often did not have electrical characteristics as good as those made by other techniques. This is because there is a severe lifetime degradation during the shot-melt cycle, junction size is hard to control, lateral junction spacing [i.e., Fig. 5(h)] is not easy to reproduce, and resistivity often changes when the starting value is high. Nevertheless the ease and versatility with which semiconductor p-n junction structures may be made by diffused shot-melting make its use particularly attractive in some cases. The structures have no low melting components to limit fabrication and assembly techniques. Diffusion is from a volume source, so, except in structures where surface diffused layers are also required, no precise atmospheric control during diffusion is needed. Also, some or all of the lifetime and resistivity degradation produced during the shot-melt cycle can be removed by processes such as surface alloy gettering or annealing during or subsequent to the diffusion cycle.

Acknowledgment

The help of Mrs. L. Roehrig and N. E. Collins in fabricating the structures, and of C. V. Bielan and F. A. Carranti in making the metallographic sections and photomicrographs, is greatly appreciated.

Manuscript received Nov. 18, 1959. This paper was prepared for delivery before the Columbus Meeting, Oct. 18-22, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Polarographic Studies in Acetonitrile and Dimethylformamide

V. Behavior of Aromatic Ketones and Aldehydes

S. Wawzonek and A. Gundersen

Department of Chemistry, State University of Iowa, Iowa City, Iowa

ABSTRACT

Benzophenone, acetophenone, p-methoxyacetophenone, benzaldehyde, and anisaldehyde are reduced stepwise polarographically in anhydrous dimethylformamide. Large-scale electrolytic reduction of benzophenone indicates that the ketyl anion is formed as a stable intermediate since, in the presence of carbon dioxide and ethyl iodide, benzilic acid and diphenylethylcarbinol are formed, respectively. Acetophenone, benzaldehyde, and anisaldehyde form principally pinacols under these conditions. The reduction of p-methoxyacetophenone is complicated by tar formation.

Previous polarographic studies in acetonitrile and dimethylformamide have shown that this method is capable of furnishing evidence for the existence of stable anion-free radicals in the reduction of aromatic hydrocarbons (1, 2) and semiquinone anions in the reduction of quinones(3).

In the present study the polarographic behavior and electrolytic reduction of aromatic ketones and aldehydes has been investigated to determine whether ketyl anions are produced in dimethylformamide.

Experimental

The solutions were studied in a cylindrically shaped cell with a mercury pool anode and fitted with side arms for the anode connection and for admission of nitrogen. All measurements were made in a water thermostat at 25° ± 0.1°.

The current-voltage curves were obtained with a Sargent Model XII polarograph having a current scale calibration of 0.00497 μa/mm at a sensitivity of one.

The dropping mercury electrode was operated at 60 cm pressure and had a drop time of 3.42 sec in dimethylformamide (open circuit). The $m^{2/3}t^{1/6}$ value was 1.96 $mg^{2/3}$ $sec^{1/2}$.

The dimethylformamide was purified in a manner similar to that reported previously (1). The compounds were obtained from stock and purified by crystallization or distillation.

Electrolytic Reductions

The electrolytic reductions of the various carbonyl compounds were carried out at a platinum anode and mercury cathode in a similar manner to that described earlier (1). The area of the cathode was 65 cm^2 and the line voltage was 80 v. Typical procedures are illustrated below. The results are given in Table II.

Benzophenone.—A solution of 5 g of benzophenone and 7.72 g of potassium iodide in 300 ml of dimethylformamide was deoxygenated with nitrogen for 1 hr. Direct current was allowed to pass through the cell for 20 hr and gave a blue solution.

The catholyte and anolyte were poured into 50 ml of 10% acetic acid solution and the solvent was removed under reduced pressure at 100°. Extraction with ether followed by removal of the solvent gave an oil which was soluble in isopropyl alcohol and in hot petroleum ether. Benzopinacol, if present, would be insoluble in these solvents. When the petroleum ether was cooled, 2.8 g of benzohydrol melting at 66°-68° was obtained. A mixture with an authentic sample melted at the same point. The benzophenone which remained in the petroleum ether was determined in some of the experiments as the oxime.

Benzophenone and carbon dioxide.—A solution of dimethylformamide (300 ml) containing potassium iodide (7.72 g) and benzophenone (5 g) was deoxygenated with carbon dioxide for 1 hr. Electrolysis was carried out for 20 hr while a stream of carbon dioxide was passed through the solution. The cathode compartment remained colorless during the electrolysis. Removal of the solvent under reduced pressure gave a residue which was extracted with ether. The ether insoluble portion was found to be water soluble. Upon acidification of the aqueous solution benzilic acid (3.1 g) melting at 149°-152° precipitated. A mixture with an authentic sample melted at the same point.

Benzophenone and ethyl iodide.—A solution of potassium iodide (7.72 g) and benzophenone (20 g) in dimethylformamide (300 ml) was deoxygenated with nitrogen for 1 hr and then electrolyzed for 15 hr. During the electrolysis, oxygen-free ethyl iodide was dropped into the cathode compartment. Removal of the solvent under reduced pressure was followed by extraction with ether. The yellow oil (17.5 ml) obtained was freed of benzophenone by refluxing with hydroxylamine hydrochloride (9 g) and potassium hydroxide (15 g) in ethanol (30 ml) and water (6 ml) for 5 min. The solution was poured into 1*N* potassium hydroxide (200 ml) and extracted with hexane. After concentration and cooling of the hexane solution 3.2 g of diphenylethylcarbinol melting at 93°-95° was recovered. A

mixture with an authentic sample melted at the same point.

Acetophenone.—A solution of dimethylformamide (300 ml) containing 17 g of tetrabutylammonium iodide and 20 g of acetophenone, was deoxygenated with nitrogen for 1 hr and then electrolyzed for 14 hr. The resulting solution was poured into 600 ml of water containing 20 ml of acetic acid. Extraction with ether was followed by concentration to 100 ml. The resulting solution on mixing with 200 ml of hexane, concentrating, and cooling gave 6.0 g of meso-acetophenone pinacol melting at 117°-120°. A mixture with an authentic sample melted at the same point.

Results

The polarographic data obtained for the various aromatic ketones and aldehydes in various solutions are given in Table I. The waves in all cases were well defined. The addition of water shifted both waves to more positive potentials.

The half-wave potentials of the second wave for benzophenone, acetophenone, and benzaldehyde are more negative than those reported by Given (4). Since the addition of water shifts the second wave to more positive potentials, the latter study was probably carried out in dimethylformamide which was not completely anhydrous.

To help formulate electrode reactions and identify intermediate species large-scale electrolytic reductions were carried out with benzophenone, acetophenone, benzaldehyde, *p*-methoxybenzaldehyde, and *p*-methoxyacetophenone in the presence and absence of carbon dioxide. An electrolysis also was performed with benzophenone in the presence of ethyl iodide. Complete analysis of the products from compounds other than benzophenone was prevented by the formation of tars and oils. Results are summarized in Table II.

Discussion of Results

Examination of the results in Table I indicates that aromatic ketones and aldehydes are reduced stepwise at the dropping mercury electrode in anhydrous dimethylformamide. In contrast to its effect on the waves of hydrocarbons and quinones addition of water caused little change in the first wave, but caused a shift of the second to more positive potentials and an increase of the diffusion current in some examples. The double waves found are similar to those reported in aqueous alkali by Ashworth (5) and would suggest the following general mechanism of reduction for these compounds.

$$R_2C{=}O + e \rightarrow R_2C{-}O^- \text{ (1st wave)}$$

$$R_2C{=}O + 2e \rightarrow R_2C{-}O^- \text{ (2nd wave)}$$

Evidence for these electrode reactions is the observation made in the large-scale electrolytic reduction of benzophenone. In solutions in dimethylformamide containing potassium iodide, in which only the first polarographic wave is obtained, a blue coloration is produced. A similar color is reported for the monosodium derivatives of benzophenone in liquid ammonia (6).

The presence of the intermediate ketyl anion for benzophenone was further demonstrated by the electrolysis of benzophenone in the presence of carbon dioxide and ethyl iodide with potassium iodide as a supporting electrolyte; benzilic acid and diphenylethylcarbinol were formed, respectively. If the reduction is carried out in the absence of these reagents or in the presence of water, the blue color is discharged, slowly in the first case, and benzophenone and benzohydrol are obtained. Changing the supporting electrolyte to lithium iodide produced similar results.

Treatment of metal ketyls in hydrocarbon solvents or ether with ethyl bromide and carbon dioxide produces similar products together with benzophenone (7, 8). The reaction with water likewise results in the formation of benzophenone and benzohydrol (9).

The formation of the ketyl anion also has been demonstrated with electron resonance studies by Austen, *et al.* (10) of solutions of benzophenone reduced electrolytically at controlled potentials in dimethylformamide.

Determination of n for the waves of benzophenone using a micro cell (11) with 0.5 ml of a solution of benzophenone ($2 \times 10^{-3} M$) containing tetrabutylammonium iodide as a supporting electrolyte gave values of 1.54 and 1.82 respectively for the two waves. When the electrolysis was limited to the first wave by using potassium iodide as the supporting electrolyte, no appreciable decrease in the concentration of benzophenone occurred. The latter behavior indicates that the ketyl anion formed is reoxidized at the anode to benzophenone.

Table II. Large-scale electrolytic reductions of aromatic ketones and aldehydes in dimethylformamide

Compound	Amperes: Start	Amperes: Finish	Time of electrolysis	Products formed
HCON$(CH_3)_2$—0.155*M* $(C_4H_9)_4NI$ (300 ml)

20 g $C_6H_5COCH_3$	0.60	0.05	14	Acetophenone pinacol (5.1 g)
20 g $C_6H_5COCH_3$ + excess CO_2	0.60	0.05	14	Atrolactic acid (1.0 g)
20 g C_6H_5CHO	0.60	0.05	19	Hydrobenzoin (7.3 g) Benzaldehyde (5 ml)
20 g C_6H_5CHO + CO_2	0.60	0.05	24	Hydrobenzoin (6.1 g)
20 g p-$CH_3OC_6H_5COCH_3$	0.60	0.05	27	2, 3-Dianisylbutadiene-1, 3 (traces)
20 g p-$CH_3OC_6H_5COCH_3$ + CO_2	0.60	0.05	20	p-Methoxyatrolactic acid (traces)
20 g p-$CH_3OC_6H_5CHO$	0.45	0.15	20	Hydroanisoin (1.9 g)
20 g p-$CH_3OC_6H_5CHO$ + CO_2	0.40	0.10	24	Hydroanisoin (1.3 g)
HCON$(CH_3)_2$—0.155*M* KI (300 ml)				
5.0 g $(C_6H_5)_2CO$	0.50	0.10	20	Benzohydrol (2.8 g)
5.0 g $(C_6H_5)_2CO$ + CO_2	0.60	0.10	20	Benzilic acid (3.1 g)
20 g $(C_6H_5)_2CO$ + 20% H_2O	2.5	1.0	12	Benzohydrol (17.1 g) Benzophenone (1.5 g)
20 g $(C_6H_5)_2CO$ + C_2H_5I	0.70	0.05	15	Diphenylethylcarbinol (3.2 g) Benzophenone (16.6 g)
HCON$(CH_3)_2$—0.155*M* LiI (300 ml)				
20 g $(C_6H_7)_2CO$	0.50	0.05	14	Benzohydrol (2.76 g) Benzophenone (14.75 g)

Logarithmic analysis of the reduction wave for benzophenone in potassium iodide solution showed a slope of 0.051. A similar analysis in the presence of tetrabutylammonium iodide showed a slope of 0.070 for the first wave and a slope of 0.080 for the second. Both waves show some kinetic character and are irreversible.

Since the ketyl anion is stable in dimethylformamide it is possible that the second wave may represent a

$$(C_6H_5)_2\dot{C}—O^- + e \rightarrow (C_6H_5)_2\ddot{C}—O^-$$

direct reduction of this ion to the dianion. The latter would react more readily with the solvent or water than the ketyl anion and give benzohydrol. The smaller diffusion current observed for this wave may be caused by the repulsion of the ketyl anion from the electrode.

The dianion is a much stronger base than the ketyl anion and would react irreversibly with water to form the carbinol anion.

$$(C_6H_5)_2\dot{C}—O^- + H_2O \rightarrow (C_6H_5)_2\underset{H}{C}—O^- + OH^-$$

Further reaction of the latter with water would be reversible. The second wave therefore should be influenced more by the addition of water and this behavior was observed.

Acetophenone when reduced electrolytically in the presence of carbon dioxide gives only a 4% yield of atrolactic acid. In the absence of carbon dioxide acetophenone pinacol was obtained.

Under similar circumstances, p-methoxyacetophenone gave only traces of acidic material and considerable amounts of tar. Distillation of the tar gave a small amount of 2, 3-di-p-anisylbutadiene-1, 3. This compound without doubt resulted from the pinacol.

Benzaldehyde on reduction alone gave a 43% yield of hydrobenzoin. In the presence of carbon dioxide the yield of hydrobenzoin was reduced to 30%, but no mandelic acid was formed.

The reduction of anisaldehyde resulted in considerable amounts of tar and a 5% yield of hydroanisoin.

The different behavior observed for the acetophenones and benzaldehydes in these large-scale electrolyses from that of benzophenone is apparently dependent on the stability of the intermediate ketyl anion

$$2R_2—\dot{C}—O^- \rightleftarrows R_2C(O^-)—CR_2(O^-)$$

or the extent of its dimerization to the pinacolate anion.

The results obtained with benzophenone would point to a stable ketyl anion since carbonation produces a high yield of benzilic acid. Under the same conditions the ketyl anions from acetophenone and benzaldehyde and their methoxy derivatives are less stable and either dimerize or undergo reactions which form tars.

The actual mechanism for the reaction of the benzophenone ketyl anion with various reagents is still not known. This anion is no doubt a resonance hydrid and

$$(C_6H_5)_2C{-}O^- \leftrightarrow (C_6H_5)_2\underline{C}{-}O\cdot$$

could undergo a direct reaction with the reagents involved.

$$(C_6H_5)_2\underline{C}{-}O\cdot + CO_2 \rightarrow (C_6H_5)_2C(COO^-){-}O\cdot$$

The resulting product from the reaction with carbon dioxide would take up an electron in the electrolytic reduction and form the benzilate anion.

$$(C_6H_5)_2C(COO^-){-}O\cdot + e \rightarrow (C_6H_5)_2C(COO^-){-}O^-$$

In the same reaction of metal ketyls in hydrocarbon solvents another ketyl anion would furnish the electron necessary.

$$(C_6H_5)_2C(COO^-){-}O\cdot + (C_6H_5)_2C{-}O^- \rightarrow$$

$$(C_6H_5)_2C(O^-)COO^- + (C_6H_5)_2C{=}O$$

A similar mechanism is implied for the formation of benzohydrol in the electrolytic reduction of benzophenone in dimethylformamide by Austen, *et al.* (10).

Disproportionation of the ketyl anion to benzophenone and the dianion, which could undergo similar reactions, is considered not to be feasible energetically (12).

$$2(C_6H_5)_2C{-}O^- \rightarrow (C_6H_5)_2\bar{C}{-}\bar{O} + (C_6H_5)_2CO$$

The possibility of the formation of the pinacolate anion followed by its dissociation into benzophenone and its dianion as

$$2(C_6H_5)_2\underline{C}{-}O^- \rightleftarrows (C_6H_5)_2C(O^-){-}C(O^-)(C_6H_5)_2 \rightleftarrows$$

$$(C_6H_5)_2C{=}O + (C_6H_5)_2\underline{C}{-}O^-$$

proposed by Acree (13) cannot be completely eliminated as a basis for the reactions of the ketyls.

Manuscript received Aug. 12, 1959. This paper was prepared for presentation at the Buffalo Meeting, Oct. 6-10, 1957 and is based on the Ph.D. thesis of A. Gundersen (June 1960). The research was supported by the Office of Ordnance Research under Contract DA-11-022-ORD-1868.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Preparation and Refining of Yttrium Metal by Y-Mg Alloy Process

O. N. Carlson, J. A. Haefling, F. A. Schmidt, and F. H. Spedding

Institute for Atomic Research and Department of Chemistry, Iowa State University, Ames, Iowa

ABSTRACT

Yttrium metal was prepared by the reduction of YF_3 with calcium forming a low melting Y-Mg intermediate alloy. Magnesium was removed by sublimation to produce yttrium metal sponge. A method is described for removing oxygen and fluorine from the alloy by extraction with fused yttrium salts. The results of electron beam melting and zone refining are also presented. Some properties of yttrium metal of 99.9% purity obtained by the extraction refining process are discussed.

Recent interest in the possible uses of various rare earth metals as reactor materials led to this investigation of the preparation of high-purity yttrium metal. An acceptable absorption cross section for thermal neutron (1.31 barns), relatively high melting point (1500°-1550°C), resistance to attack by liquid uranium and uranium alloys (1), and its potential as a new alloying element in high-temperature materials are some of the properties that are responsible for the increasing interest in the metallurgy of yttrium.

Thompson (2), Trombe (3), and Daane and Spedding (4) have previously prepared experimental quantities of yttrium metal. The principal objective of this investigation was the preparation of yttrium metal in higher purity and larger quantities for use in the development of fabrication procedures and in the investigation of the properties of yttrium and its alloys.

The basic process described in this paper is the reduction of YF_3 with calcium in the presence of magnesium to form a low melting Y-Mg alloy. The reaction was carried out at 950°C in a refractory metal crucible under an inert gas atmosphere. Anhydrous $CaCl_2$ was added to the charge to flux the high melting CaF_2 produced by the reaction. A refining step in the process consisted of a fused salt extraction in which some of the interstitial impurities were extracted from the molten Y-Mg alloy. The magnesium was sublimed out of the alloy by heating *in vacuo*, yielding a metallic sponge which was subsequently arc melted into a massive yttrium ingot. The resulting yttrium metal was evaluated by spectroscopic and chemical analyses and by metallographic examination. The hardness, fabricability, and other properties of the metal were also determined.

Materials

In the preparation of high-purity yttrium it is essential that all reactants be of the highest possible purity since most of the impurities in these materials end up in the metal product.

It was recognized from the outset that high-purity YF_3, with a minimum of oxide contamination, was a prerequisite if that material were to be used as the starting salt. The details of the preparation of the YF_3 employed in these studies are given in an Ames Laboratory report (5).

A few pounds of YCl_3 were prepared for use in refining experiments. Yttrium metal sponge was converted to the chloride by reacting it with anhydrous HCl gas at 700°C. The crude product was purified by redistillation *in vacuo* at 950°C. The purity of the best YCl_3 and YF_3 that were obtained is estimated as 99.9%.

Anhydrous $CaCl_2$ of analytical grade purity (greater than 99%) was obtained from the J. T. Baker Co. Since this material contained small amounts of water, it was further dehydrated by heating to 450°C in a stainless steel vessel under a dynamic vacuum. When high-purity $CaCl_2$ was required, as in the extraction experiments, the chloride was given an additional treatment by passing anhydrous HCl over the vacuum-dried salt at 500°C.

Commercially pure calcium metal obtained from the New England Lime Company was vacuum redistilled at 900°C as described by Smith, *et al.* (6). Table I gives the analysis of the calcium after distillation.

Magnesium metal was distilled in the same apparatus at a temperature of 850°C. The carbon content was reduced to 0.02 wt % by this procedure, nitrogen to 0.005 wt %, and oxygen to less than 0.01 wt %.

Reduction of YF_3

Yttrium fluoride can be reduced by calcium in the presence of $CaCl_2$ and magnesium metal to form an Y-24 wt % Mg intermediate alloy. The alloy and slag produced in the reaction are both molten at 950°C, thus making it possible to carry out the reduction in a refractory metal crucible under an inert gas atmosphere. Calcium chloride was selected as the fluxing agent since it forms a low melting eutectic with CaF_2. It also decreases the density of the slag which is an important factor if complete separation from the alloy phase is to be achieved. Removal of the magnesium from the alloy and melting of the yttrium sponge are discussed in a later section of this paper.

Table I. Analysis of redistilled calcium metal

Element	Wt %
Magnesium	0.300
Carbon	0.020
Nitrogen	0.005
Aluminum	0.003
Iron	0.003
Manganese	0.002
Nickel	0.002

Apparatus and procedure.—A sketch of the apparatus used in the reduction process is shown in Fig. 1. The temperature of the retort was measured by a thermocouple placed on the exterior wall surface.

Several refractory metals and oxides were tested as crucible materials and tantalum was found to be the most inert. Most of the small-scale, high-purity experiments were carried out in tantalum; however titanium crucibles were used in the large reductions and in the more routine experiments.

The reductions were carried out in the following manner. Massive pieces of magnesium and calcium were transferred to the reduction crucible, and a mixture of YF_3 and $CaCl_2$ was loaded into the charging hopper. A typical charge consisted of 1500 g YF_3, 1350 g $CaCl_2$, 680 g calcium, and 290 g Mg. The unit was evacuated by means of a mechanical pump prior to placing the retort in the gas furnace.

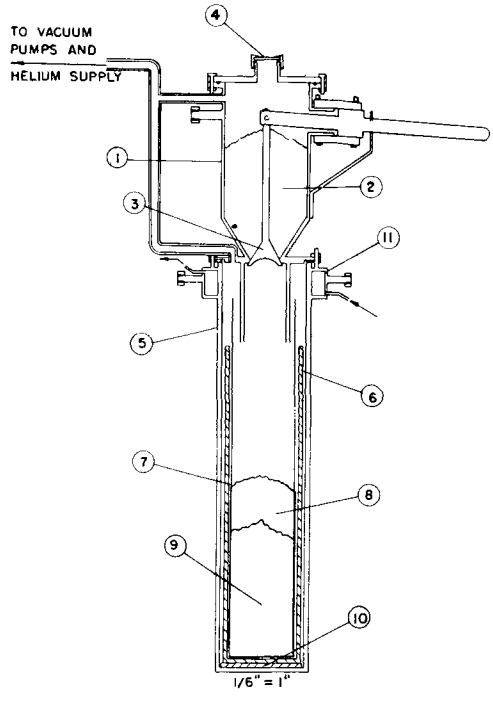

Fig. 1. Schematic drawing of reduction retort and charging hopper; 1, charging hopper; 2, $CaCl_2$ and YF_3; 3, control valve; 4, sight glass; 5, steel retort; 6, Ti or Fe retaining crucible; 7, Ti crucible; 8, Mg; 9, Ca; 10, graphite disk; 11, water jacket.

When the temperature of the retort had reached 800°C, helium gas was admitted and a pressure of 1-5 psi (gauge) was maintained in the system throughout the remainder of the run. When a temperature of approximately 900°C was attained as indicated by a thermocouple immersed in the molten calcium-magnesium phase, the YF_3-$CaCl_2$ mixture was added slowly from the hopper into the heated zone of the reaction crucible. The absence of a sharp temperature rise during the reduction process indicates that the reaction is either endothermic or only slightly exothermic.

At the completion of the run the hot retort was raised from the furnace, placed in a rack, and tilted to a few degrees from the horizontal. By allowing solidification to occur in this position, the slag and alloy could be removed more easily thus avoiding damage to the reduction crucible.

Experimental results.—A comprehensive investigation was made of the effects of reaction conditions, physical state and purity of the ingredients, proportion of the reactants, and handling procedures on the quality and yields of the yttrium metal obtained.

From experiments in which various oxides were added to the reduction charge, it was concluded that any oxides present in the reactants are transferred quantitatively to the Y-Mg phase during the reduction. Comparisons between granular and massive calcium revealed that yttrium prepared from granular calcium contained an average of 0.1 wt % more oxygen than that prepared from massive metal. This differential was observed with calcium on which the grinding and screening operations were carried out in a specially designed dry room. For this reason, the use of freshly distilled calcium and magnesium in massive form is strongly advocated if the oxygen content is to be kept as low as possible.

The composition of the intermediate alloy was set at 24 wt % magnesium, a composition that lies close to the intermediate phase, Y-Mg (7). This alloy possesses the properties of brittleness, low melting point, and relatively high density that are essential to the success of this process. The proper proportions of the other reactants were determined experimentally. A 10 wt % excess of calcium reductant gives a metal recovery of greater than 99% of theoretical; a smaller excess results in some decrease in yield. The critical slag composition was also determined by adjusting the YF_3-$CaCl_2$ ratio in the charge. A slag composition of 52 wt % $CaCl_2$ gave best slag-metal separations and highest metal yields.

Tests showed that the alloy picks up significant amounts of oxygen after a brief exposure to air saturated with water vapor but not from oxygen of the air. Therefore the crushing and transferring of the alloy were handled in a dry box filled with helium.

In spite of these precautions the oxygen content of the best yttrium prepared by this method was in the range of 0.1-0.2 wt %. This is shown along with other analytical data in Table II. The values represented are averages from a large number of reductions made in titanium crucibles. Statistical treatment of these data indicate that the standard deviation for the larger values reported is ± 0.01% or less.

Table II. Major impurities in yttrium metal prepared by the calcium reduction of yttrium fluoride

Impurity	Wt %	Impurity	Wt %
Oxygen	0.170	Nitrogen	0.015
Titanium	0.150	Silicon	<0.015
Fluorine	0.080	Copper	0.004
Nickel	0.035	Magnesium	0.003
Iron	0.030	Calcium	0.001
Carbon	0.020	Total rare earths	<0.050

Magnesium Removal and Arc Melting

The volatile components of the alloy must be removed almost completely before the resulting sponge can be arc melted. At the same time care must be exercised to avoid melting and spattering during the initial stages of the magnesium and calcium removal. As a first step the alloy was crushed into pieces approximately ½ in. in diameter in a jaw crusher enclosed in the dry box.

The sublimation was carried out in a 6-in. diameter stainless steel retort equipped with a condenser. The alloy was placed in a titanium vessel inside the vertical retort. The system was evacuated to a pressure of 10^{-4} mm Hg at the outset, and this pressure was maintained throughout the run. The retort and its contents were heated to 900°C in an electric furnace, held at this point for 4 hr, and then increased to 950°C and held for a period of 20 hr. The magnesium vapors were collected on the condenser which was cooled by a flow of air. The yttrium obtained in this manner was a bright, porous sponge containing approximately 0.01 wt % magnesium and calcium.

The yttrium sponge was consolidated into ingot form by arc melting. The sponge was compacted into electrodes, and these were generally arc melted into 1-lb evaluation ingots in an inert gas atmosphere. In processing larger amounts of yttrium, the sponge was consummably arc melted twice with the second melting being carried out under a dynamic vacuum. The steps in this melting operation are represented by the three forms of the metal shown in Fig. 2. About 90 lb of metal are shown in each processing step.

Refining of Yttrium

In an effort to remove some of the impurities from yttrium, particularly oxygen and fluorine, several

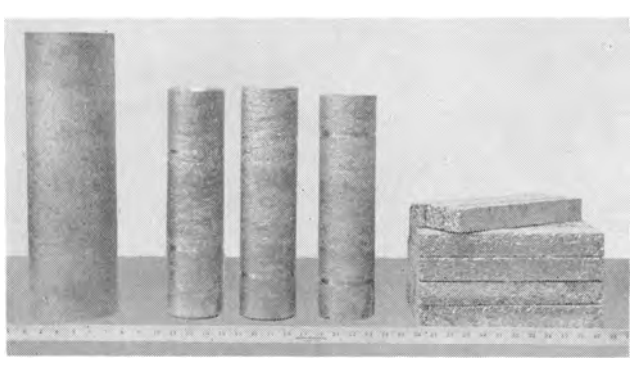

Fig. 2. Six-inch diameter ingot (left); 4-in. diameter ingots (center); and 27 sponge compacts or electrodes.

refining techniques were tried. The more successful methods are discussed in this section.

Refining of Y-Mg alloy with a fused salt.—It was observed that the oxygen content of the Y-Mg alloy was reduced significantly after being in contact with a fused salt containing YF_3 or YCl_3. Several experiments were run in an attempt to gain some understanding of this phenomenon.

The same apparatus that was used in the reduction of YF_3 was employed in these experiments, but with one modification. The charging hopper was replaced by a vacuum head through which the shaft of a stirring rod was inserted. A titanium or tantalum paddle was attached to this shaft and was rotated inside an "O" ring seal. Approximately 0.5 wt % titanium was dissolved by the yttrium alloy when both the reduction and extraction steps were carried out in a titanium crucible with a titanium stirrer. No detectable contamination from the crucible was encountered when a tantalum system was used.

The slag from a regular reduction was removed and the extractant, such as YF_3 and $CaCl_2$, was added to the alloy in the crucible. The alloy and salt phases were brought to the molten state (950°C), the stirrer was lowered to the fused salt-alloy interface and rotated slowly for approximately 30 min to insure adequate mixing during the extraction.

A mixture of YF_3 and $CaCl_2$ was investigated extensively as the extractant salt. Extractions with mixtures of varying composition were run on 1200-g portions of Y-Mg alloy of uniform composition. In one series a fixed quantity of YF_3 was used and the amount of $CaCl_2$ was varied. From this it was observed that the $CaCl_2$ concentration is not critical as long as enough is present to flux the YF_3 properly.

In another series the amount of $CaCl_2$ was held constant and the amount of YF_3 was varied. As is seen from the data in the upper half of Table III, 650 g of fluoride in the extractant produces the maximum purification and increased amounts have no additional effect. Since the alloy contains a sufficient amount of residual calcium to reduce approximately 150 g of YF_3, no decrease in the oxygen content was observed when this amount of fluoride was used in the extractant mixtures.

Further understanding of the extraction process was gained from experiments using two different grades of YF_3 and Y-Mg alloy. The data in Table III show the effect of the oxygen concentration in the alloy and in the YF_3 on the amount of extractant required to produce the maximum decrease in oxygen content. For alloy containing 0.20 wt % oxygen, only 650 g of high-purity YF_3 (0.04 wt % oxygen) was required to decrease the oxygen content of the yttrium to 0.05 wt %, whereas a greater quantity of the lower grade fluoride was required to produce the same purification. For alloy containing 0.5 wt % oxygen, the 650-g quantity of high-purity fluoride did not give metal of maximum purity, although the oxygen content was lowered appreciably. A greater amount of this quality of YF_3 was required to decrease the oxygen content of the alloy from 0.50 to 0.06 wt %.

In an attempt to determine if the form of the oxide influences the distribution of oxygen between the two phases, 0.1 wt % of oxygen was added as MgO, CaO, Y_2O_3, and YOF to successive reductions. As was indicated earlier in this paper, oxygen from all of these compounds is transferred to the alloy phase in the reduction step. The results of this series of experiments indicated that the form of the oxide in the reduction charge does not appear to have any effect on the degree of purification obtained by the fused salt treatment.

Other salt mixtures were investigated as possible extractants of oxygen and fluorine from the Y-Mg alloy. The results of a series of tests using various extractants on alloy initially containing 0.20 wt % oxygen and 0.12 wt % fluorine are summarized in Table IV. The data in the table show that both oxygen and fluorine are extracted by fused YCl_3 and that the fluoride content can be lowered substantially by a contact with $CaCl_2$.

As can be seen from Table IV the purest metal was obtained by extraction with YF_3-$CaCl_2$ followed by a second extraction with YCl_3. This two-stage extraction was performed several times to ascertain the reproducibility of the method. Yttrium metal of the purity shown in Table V was obtained on repeated experiments. The metal prepared in this way was used for metal evaluation, determination of physical constants, and microscopic examination.

The extractant salts are readily recoverable and can be reduced to the metal or used again in refining experiments. The $CaCl_2$ is leached from the salt mixture and anhydrous HF gas is passed over the residual fluoride at 750°C. This results in a quality of YF_3 equivalent to that of the original material. The YCl_3 likewise can be reclaimed by vacuum sublimation.

Table III. Results of experiments using YF_3-$CaCl_2$ extraction mixtures on 1200-g portion of Y-Mg alloy

YCl_3	0.060	0.035
Double extraction with YF_3-$CaCl_2$	0.030	0.070
YF_3-$CaCl_2$ followed by YCl_3	0.018	0.007

Table V. Analyses of yttrium metal refined by double extraction method

Impurity	Wt %	Impurity	Wt %
Iron	0.030	Copper	0.004
Nickel	0.020	Nitrogen	0.002
Oxygen	0.015	Calcium	0.001
Silicon	<0.015	Hydrogen	0.001
Tantalum	<0.010	Magnesium	0.001
Carbon	0.009	Titanium	0.001
Fluorine	0.006	Total rare earths	<0.050

Electron beam melting and zone refining.—Several pounds of yttrium sponge containing 0.045 wt % oxygen and 0.060 wt % fluorine were electron-beam melted by the Temescal Metallurgical Corporation. Analysis of the ingot after two melting operations gave 0.045 wt % oxygen and 0.004 wt % fluorine.

An yttrium rod containing 0.052 wt % oxygen and 0.065 wt % fluorine was zone refined at a rate of 6 in./hr. After two zone passes, segments of the bar were again analyzed. The oxygen content showed no significant change, but the fluorine content decreased to 0.002 wt %. No differences were observed in the oxygen or fluorine concentrations at either end of the zone-melted region.

Thus, it appears that fluorine can be removed from yttrium metal by electron beam melting and by zone refining, *in vacuo,* but oxygen is not affected. The major portion of the fluorine is removed as a volatile compound in both methods although the exact species has not been determined.

Properties of Yttrium Metal

Although many of the physical properties of yttrium have been measured previously, a few properties of the higher purity yttrium obtained from this investigation were determined for purposes of comparison. Melting points have been observed from as low as 1450°C to as high as 1550°C for metal of differing purity. Eash (9) reported a value of 1515°C on metal that contained 0.2 wt % oxygen as the major impurity. Since the lattice parameters and melting point of a metal are often sensitive to oxygen content, it appeared desirable to determine these constants for the purer metal. The melting point of 99.9% purity yttrium prepared in this investigation was determined to be 1495° ± 5°C. This determination was made using an optical pyrometer method (10) in which a small hole was drilled into an yttrium rod. The specimen was heated by passing a high current through it, and the temperature within the hole was continuously observed until melting was evident.

Likewise, there are differences in the reported lattice parameters of yttrium. Spedding, Daane, and Hermann (11) reported values of $a = 3.6474$Å and $c = 5.7306$ for the metal that was available to them while parameters of $a = 3.662$Å and $c = 5.752$Å were obtained for the metal prepared in this investigation. The theoretical density of this material was 4.46 g/cc as compared with a measured density of 4.45 g/cc.

Yttrium metal of this quality has a hardness of 35-45 Brinell (500 kg load) and can be worked extensively at room temperature. A specimen was rolled from an original thickness of 0.250 in. to a final thickness of 0.012 in. with no intermediate anneal. This represents a reduction in thickness of greater than 90%. A photograph of the original coupon and of a section of the 18-in. ribbon obtained by cold rolling is shown in Fig. 3. A cylinder, 0.25 in. in diameter before swaging, is shown in the photograph; another cylinder, 0.125 in. diameter after cold swaging, is also shown.

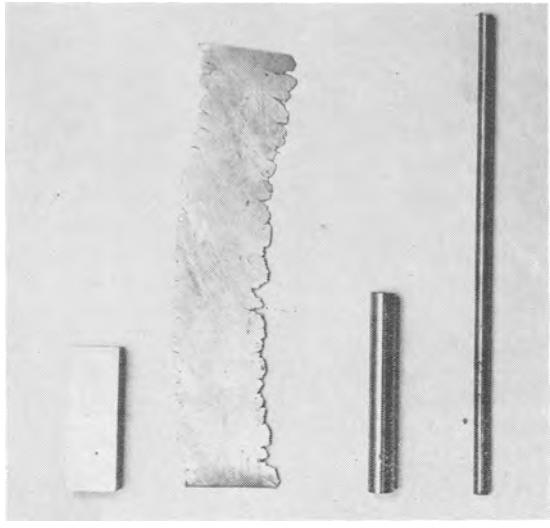

Fig. 3. Yttrium specimen before and after cold rolling to 90% reduction in thickness (left) and before and after swaging (right).

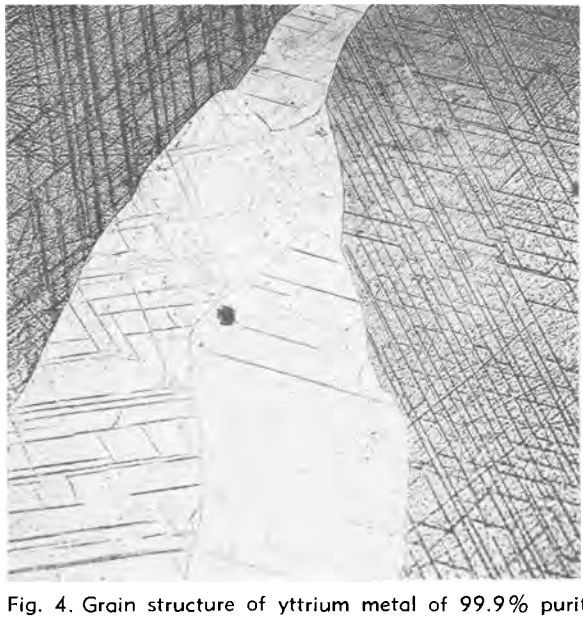

Fig. 4. Grain structure of yttrium metal of 99.9% purity. Etchant: conc. HNO_3. Magnification 250X.

Photomicrographs of yttrium metal of 99.9% purity are shown in Fig. 4 and 5. The coarse grain structure of the arc cast metal can be seen from Fig. 5. The lines that extend across the grains are characteristic of high-purity yttrium. These appear to be deformation bands believed to have been introduced by strains during solidification.

Summary

A process for preparing yttrium metal is described. The basic process consists of the formation of a low-melting intermediate Y-Mg alloy which is subsequently converted to yttrium sponge metal.

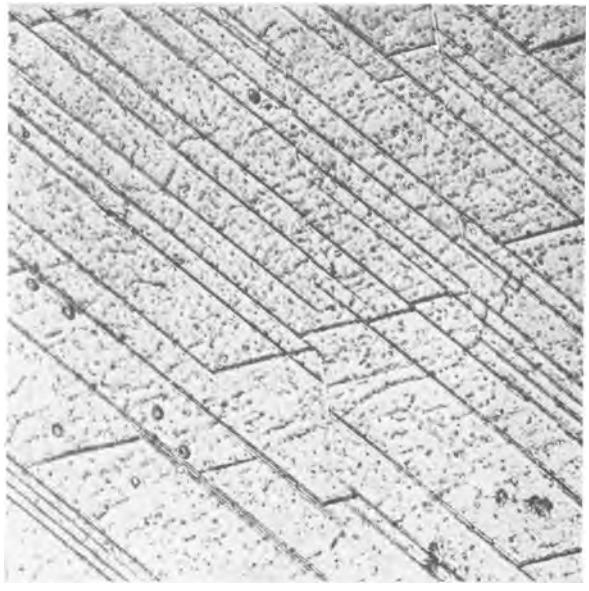

Fig. 5. Enlargement of same area as Fig. 4 showing deformation bands and small inclusions. Magnification 500X.

Several refining procedures are described. One of these involves the extraction of oxygen from the molten Y-Mg alloy by a fused salt containing YF_3 or YCl_3. Fluorine can be removed by an extraction treatment on the alloy or by electron beam melting or zone refining of yttrium metal.

Yttrium metal of 99.9% purity was prepared by methods described in this paper. The melting point, lattice parameters, and hardness were determined on metal of this purity and the cold working characteristics and microstructure were studied.

Acknowledgments

The authors would like to express their gratitude to Dr. V. A. Fassel and members of the spectroscopic group of the Ames Laboratory and to Dr. C. V. Banks and his associates for performing the multitude of chemical analyses. They would like to acknowledge the assistance of C. Moore, I. Jensen, M. Hedberg, R. Griffith, E. Ritland, and M. Thompson in performing these experiments.

Manuscript received Nov. 20, 1959. This paper was prepared for delivery before the Chicago Meeting, May 1-5, 1960. Paper is Contribution No. 815; work was performed in the Ames Laboratory of the U. S. Atomic Energy Commission.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Exchange Current Measurements in KCl-LiCl Eutectic Melt

H. A. Laitinen, R. P. Tischer,[1] and D. K. Roe[2]

Department of Chemistry and Chemical Engineering, University of Illinois, Urbana, Illinois

ABSTRACT

Exchange currents have been measured of some liquid and solid metal electrodes (Cd, Zn, Pb, Bi, Ag, Ni, Pt) and one redox system (V^{3+}/V^{2+}) in a KCl-LiCl eutectic melt at 450°C. Measurements over a hundredfold concentration range permitted calculation of the heterogeneous rate constant and of the transfer coefficient. Two relaxation methods were used: the double pulse method as developed by Gerischer and Krause and the voltage step method as described by Vielstich and Delahay. In cases where both methods were applied independently to the same system the results were in good agreement. The purity of the eutectic melt was improved considerably by filtration and by displacement of heavy metal ion impurities with metallic magnesium. The evaluation of voltage step measurements was revised by allowing for the effect of the finite charging time of the double layer. Agreement was not found with the theory of the double pulse method given by Matsuda, Oka, and Delahay, perhaps because of some additional process, other than diffusion, taking place in a period of time comparable to the duration of the first pulse. On the basis of the reaction of platinum with cadmium at 450°C it is possible to account for the observations made earlier in this laboratory by C. H. Liu and H. C. Gaur on the emf and polarization behavior of cadmium-plated platinum electrodes.

In recent years the increasing importance of fused salts in many fields of science and technology has incited a considerable number of investigations of their properties. Molten salts have found much interest as media for electrochemical processes in connection with their applications in metallurgy, analytical and synthetic chemistry and, more recently, in high-temperature galvanic cells. Relatively few studies, however, have been made of the rates of electrode processes in molten salts, because such electrode processes can be expected to be very fast and their study would therefore require elaborate techniques. The relaxation methods developed recently for the study of fast reactions in aqueous solutions are most suitable for fused salt studies. Doubts have sometimes been expressed as to whether these methods would be able to avoid the interference of diffusion as a rate-determining process, since diffusion in molten salts (1) is often not faster than in aqueous solutions at room temperature. It is possible, however, to distinguish between diffusion-controlled and charge transfer controlled reactions even in fused salts, and diffusion effects can be eliminated under the proper experimental conditions.

The first successful application of a relaxation method to electrode reactions in fused salts was made by Randles and White (2). In a low melting nitrate eutectic the rate of the reaction $Ni^{2+} + 2e^- + Hg = Ni\ (Hg)$ was evaluated from a-c impedance measurements. Measurements were attempted on several other metal ion-metal amalgam reactions, but they were found to be too rapid for the method.

Laitinen and Osteryoung (3), about the same time, sought to use the same a-c technique with platinum electrodes in the KCl-LiCl eutectic. Direct interpretation of the measurements was not possible because of complicating experimental conditions which caused a very large frequency dispersion of the resistance and capacitance measurements.

Under more amenable experimental conditions, primarily with a melt prepared from dry salts, Laitinen and Gaur (4) were able to make more refined measurements of the same type. Although the frequency dispersion of the measurements on platinum microelectrodes was still present, the data were interpretable by the introduction of a correction for adsorption of the reducible ion (5). The correction was necessary to remove the "inverted" character of the reaction impedance, in which the resistive component is smaller than the capacitative component. While there is no direct evidence that this is a valid correction, the resulting exchange currents for the cadmium and zinc couples appear to have reasonable values, as will be confirmed in this paper.

Hill (6) measured the impedance behavior of silver electrodes using $AgNO_3$ as the solute in a ternary nitrate melt, of silver-plated tungsten electrodes in LiCl-KCl eutectic containing dissolved AgCl, and of tungsten electrodes in Ti(III)—Ti(II) systems in the LiCl-KCl eutectic. In all cases the residual capacity and resistance of the solvent were markedly frequency dependent Many of the faradaic impedance plots were "inverted."

Interpretation of a-c impedance measurements requires the elimination of the double layer capacity. The residual capacity has, in general, been found to be a function of frequency in fused salts. The other relaxation methods, potential step and current step, are made at relatively very short times, which corresponds to high frequencies in the a-c method,

[1] Present address: Gebr. Böhler and Co. AG, Düsseldorf-Oberkassel, Germany.
[2] Present address: Shell Development Co., Emeryville, California.

and should be less ambiguous since the measured resistance and capacitance show less frequency dispersion at high frequencies.

The double pulse method developed by Gerischer and Krause (7) is potentially capable of measuring extremely rapid electrode reactions. The problem of charging the double layer is dealt with directly by the use of two current pulses. The first pulse is as short as possible (1 μsec) and is adjusted in height to just charge the double layer. The second pulse is much smaller and of longer duration. The overvoltage resulting from the second pulse is measured directly with an oscilloscope.

A theoretical analysis of the double pulse method has been given by Matsuda, Oka, and Delahay (8). They show that the concentration change at the electrode surface during the charging pulse cannot always be neglected and that the true reaction resistance can be obtained by extrapolation to zero duration of the first pulse.

The other method used in this investigation is the voltage step method (9). In principle, it is a potential step method, but a reference electrode provided with a Luggin capillary is not used. The voltage applied to the cell is constant, but the potential of the indicator electrode is not constant during the passage of current because of the changing iR drop in the cell. The actual potential can, however, be obtained by subtracting the product of the measurable current and resistance from the known voltage step. The charging current, of course, obscures the oscilloscopic observation of the kinetically controlled current during the initial period of electrolysis, so an extrapolation procedure is used. The method is well suited to fused salt measurements because of the low cell resistance; the charging current duration is thereby shortened. It has the obvious limitation that, with very rapid reactions, diffusion may become the rate-controlling process before the charging is completed. It is possible, however to distinguish between kinetic and diffusion control from the current-time behavior.

Theoretical

Relaxation methods which employ pulse techniques depend on current or voltage measurements at very short times, before diffusion becomes the rate-determining process. During the first moment of electrolysis a large fraction of the current charges the double layer and prevents direct observation of the faradaic process.

In the double pulse method (7) this problem is overcome by charging the double layer with a very short current pulse. The electrolyte resistance is compensated for by a bridge circuit as shown in Fig. 5 in the experimental section. The height of the first pulse is adjusted so that the potential transient, after the charging pulse, starts out with a horizontal tangent, the idea being that the potential for a short moment is constant and therefore the entire current is faradaic because no portion of the current is used for charging. From the potential measured at this moment and from the magnitude of the second pulse measured by the potential drop across the compensating resistor it is then possible to calculate the transfer resistance X, from which the exchange current density is obtained by

$$i_o = \frac{RT}{n\mathbf{F}XA} \qquad [1]$$

where A is the electrode area and the other symbols have their usual significance. One of the limits of this method is encountered with high rates corresponding to very low transfer resistances that are less than 1% of the electrolytic resistance. There are two reasons for this limitation: (a) It is not possible to adjust the compensating resistor for the electrolyte resistance accurately enough by the available procedure. (b) For a ratio of electrolytic resistance to transfer resistance equal to 100, the differential input of the amplifier must be balanced to within 0.1%, even if an accuracy of only 10% is required in measurement of the transfer resistance. This difficulty can be overcome to a certain extent by using lower concentrations. Unfortunately there then arises the other difficulty, mentioned in the original paper by Gerischer and Krause (7) and analyzed quantitatively by Delahay and co-workers (8), that diffusion becomes rate determining after a time comparable to the duration of the charging pulse. Thus the range of concentration that can be investigated successfully with this method becomes smaller and smaller with increasing reaction rate.

In the voltage step method (9) the faradaic current, observed after the charging current has become negligible, is extrapolated back to zero time. The calculation of the exchange current density is immediate from the measured "zero time" current $i_{t=0}$, the known voltage step V and the total resistance of the system R_T. Similar to the above equation

$$i_o = \frac{RT}{n\mathbf{F}A} \frac{i_{t=0}}{(-V - i_{t=0}R_T)} \qquad [2]$$

The sign of V is given by the European convention; when negative, the current is cathodic (positive). Therefore the quantity on the left is always positive, as it should be.

The definition of the exchange current density is

$$i_o = n\mathbf{F}k_h^\circ C_{Ox}^{1-\alpha} C_R^{\alpha} \qquad [3]$$

where k_h° is the standard heterogeneous rate constant at the standard (formal) potential of the couple, C_{Ox} and C_R are the concentrations (in mole cm^{-3}) of the oxidized and reduced forms of the couple and α is the transfer coefficient. From a series of measurements at different concentrations the transfer coefficient is obtained from the slope of a plot of log i_o vs. log C_{Ox} (C_R is constant in the case of a metal/metal ion system using pure metal electrodes). The value of k_h° can then be calculated from Eq. [3]. In the case of a redox system, such as V^{3+}/V^{2+}, it was more convenient experimentally to vary the ratio by oxidizing V^{2+} to V^{3+} with a constant current. The transfer coefficient was calculated by plotting i_o/C_O vs. C_R/C_O, since

$$i_o/C_{Ox} = n\mathbf{F}k^\circ_h(C_R/C_{Ox})^{\alpha} \qquad [4]$$

The current which charges the double layer obeys the relation

$$i_{ch} = \frac{V}{R_T} \exp\ (-t/R_T C_{dl})$$

where C_{dl} is the differential double layer capacity. In the essential absence of any reducible or oxidizable species, only the charging current will be observed. A semilogarithmic plot of current vs. time has an intercept of V/R_T and a slope of $1/(2.303R_TC_{dl})$. In this way the solution resistances were measured. Also a series of measurements was made over 1.8 v potential range, from which a differential double layer capacity/potential curve was calculated (see Fig. 14).

In the voltage step method, it is assumed that the kinetically controlled current rises instantaneously to a maximum after the application of the voltage step and then decreases linearly with the square root of time until diffusion becomes rate determining. During the charging of the double layer, the potential of the electrode is given by

$$V_t = V[1-\exp(-t/R_TC_{dl})]$$

assuming that the faradaic current is much smaller than the charging current. From this equation it is obvious that the potential is zero at the instant the voltage step is applied. Therefore the kinetic current is not at a maximum, but is zero. During the next several microseconds, the kinetic current should increase as the potential increases and finally reach a maximum when the charging current becomes negligible. Therefore the extrapolated value of the kinetically controlled current at zero time is larger than it should be because the observed current is higher than the current theoretically derived for the condition of infinitely rapid charging of the double layer.

In Fig. 1 is shown the experimental current-time curve of the reduction of V^{3+} to V^{2+}. The charging current is also shown, as measured at the same potential with the same platinum microelectrode. The difference between the two curves is the faradaic current and the figure shows that it corresponds with the general shape described above. In the bottom half of the figure is plotted the current against the square root of time; the linear portion has been extrapolated to zero time. This extrapolation was then transferred to the top graph.

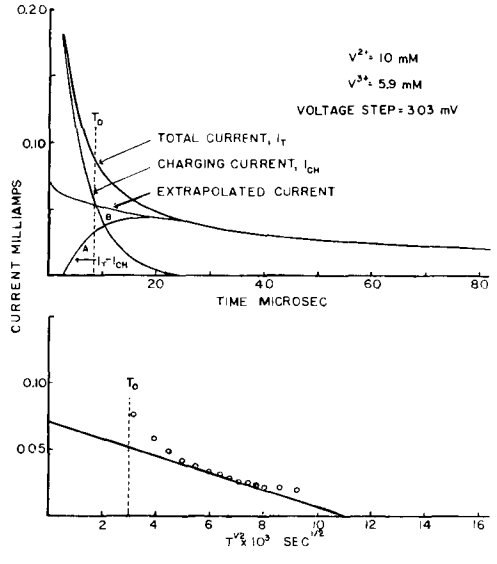

Fig. 1. Current-time curve of V^{3+}/V^{2+} and charging curve

If the charging current were not finite in duration, the faradaic current would have a value at zero time which would be somewhat lower than that shown in the lower graph of Fig. 1. Therefore at one point, which may be called the "effective zero time," the extrapolated faradaic current is equal to the hypothetical current at zero time. This point has been chosen in a way which is only a first approximation, but is nevertheless intuitively satisfying. A vertical line is drawn on the current time graph at such a point, t_o, on the time axis, that the area A under the faradaic current-time curve to the left of the line is equal to the area B between the extrapolated and the observed curves. The current value on the extrapolated line at t_o is then called the "effective zero time" current, i_{t_o}, and is used to calculate the exchange current. The potential across the cell at the same time is equal to the applied voltage, V, minus the product of the total current, i_T, and the total resistance, R_T. The current i_{t_o} is smaller than the extrapolated current at $t = 0$, but the total current, faradaic plus charging, is larger so that the iR correction is larger. Since the exchange current is proportional to the quotient of the current and the corrected voltage step, $(-V - iRT)$, the two effects tend to cancel.

In the treatment of the experimental data, the above method of calculating the exchange current resulted in a significant improvement in the case of the slower reactions. The values for zinc and cadmium, calculated by both methods were within 4% of each other, which is less than the experimental error. However if the circuit resistance was increased, so that the charging time was longer, great deviations in the calculated exchange current resulted unless the modified procedure was applied.

Experimental

Preparation and purification of the KCl-LiCl *eutectic melt.*—Reagent grade KCl and LiCl require extensive drying as well as purification before the resulting eutectic melt is suitable for electrochemical studies. Prolonged vacuum drying and the use of HCl gas during the fusion of the salts has been shown to remove all of the water and reverse the hydrolysis of LiCl (10, 11). Further purification is necessary to remove the heavy metal ion impurities and the decomposition products of what is presumably an organic solvent residue.

The most convenient and expedient method for the removal of heavy metal ions, which are present to the extent of 0.0005% or about 0.4 mM in the molten eutectic (calculated as lead), was found to be simple displacement with a more active metal. Magnesium is ideally suited in this medium because of its very negative standard potential (−2.58 v vs. 1M platinum reference electrode) (12). It is expected that the small concentration of Mg^{2+} will have a negligible effect on the electrode processes of interest here; the most active metal used was zinc, with a standard potential of −1.56 v (12).

The index of melt purity used in this laboratory is the residual current (10), measured with a 26-

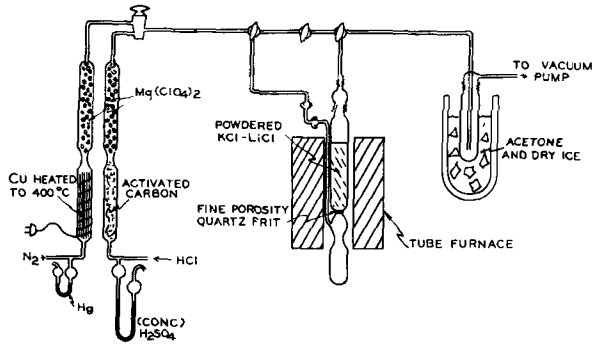

Fig. 2. Apparatus for purifying the melt

gauge platinum microelectrode, ground flat to expose only the cross section of the platinum wire, with an apparent area of 0.13 mm^2. In melts treated with magnesium, the residual current was in the range of 0.08 to 0.4 μa at a potential of −2.0 v vs. a platinum reference electrode. Up to a potential of about −1.5 v, the residual current was anodic by a few hundreths of a microampere. Without treatment with magnesium, the residual current was cathodic over the entire potential range, reaching about 1 to 2 μa at −2.0 v.

Individual batches of the eutectic melt were prepared in the apparatus shown in Fig. 2. Approximately 150 g of KCl-LiCl eutectic mixture, previously powdered in a ball mill, was placed in the vertical Vycor tube. A few tenths of a gram of magnesium turnings or powder was added to the salts. The pressure was reduced to 0.01 mm Hg by a Cenco vacuum pump. After about 12 hr of vacuum drying at room temperature, the furnace was turned on and the temperature was increased slowly over a 36-hr period. Before the temperature increased to the melting point of the eutectic (352°C), the system was vented to dry HCl gas, which had been passed over activated carbon to remove possible hydrocarbon impurities. When the salts were molten, additional HCl was admitted through the small side tube and up through the fine porosity quartz frit. Treatment with HCl for 1 hr is more than enough to drive out the last traces of water. The apparatus was then evacuated with a water aspirator, connected to the system through the dry ice-acetone trap, to remove the HCl gas. Three evacuations, each followed by a nitrogen flush through the quartz frit, removed nearly all of the HCl. Then the molten eutectic was filtered by evacuation below the quartz frit. The ampoule was heated with a gas burner during the filtration. When the process was completed, the tube furnace was raised to expose the constriction in the tube, just below the Vycor-Pyrex graded seal, and the ampoule was sealed off with a torch. When the eutectic mixture is cool, it will not stick to the walls of the ampoule if it is completely dry. "Wetting" of the glass is indicative of the presence of oxide (13).

Fused salt apparatus.—The major part of the apparatus is similar to that previously used in this laboratory (10, 12). The melt was contained in a 6-cm diameter Pyrex tube, about 35 cm long. After thorough cleaning with boiling 70% $HClO_4$, the tube was dried and the ampoule was placed inside. The tube was then heated under vacuum for a time, to remove surface water from the glass. Before the melting point of the eutectic was reached, the system was vented to dry, oxygen-free argon, and the ampoule tip was broken. When the eutectic became molten, the ampoule was raised to allow the melt to drain out and then removed. The cell compartments were then added. In these kinetic studies, simple 20 x 100 mm test tubes were used as cells. The resistance of the cells was reduced somewhat by slightly blowing out the side of the tube, or by sealing in a fritted glass disk. The other electrodes, platinum reference and carbon rod, were contained in the usual fritted glass tubes. The microelectrode was positioned just above the counter electrode in the same compartment. Cell resistances were of the order of 2-3 ohms. Silicone stoppers, because of their superior heat resistance, were used to cover the opening of the cell.

The furnaces were of the vertical tube type and had small windows or peepholes in the side to facilitate the adjustment of the electrodes. Temperature control was provided by proportional or on-off controllers. Short time variations were less than 1°C.

A flowing atmosphere of argon, dried with $Mg(ClO_4)_2$ and deoxygenated over hot copper, was maintained at all times to prevent the entrance of air and moisture.

Electrodes.—Two basic microelectrodes were used in all the kinetic measurements: tungsten sealed in Pyrex or uranium glass and platinum sealed in "soft" glass. Although lead glass (Corning 0120) makes a very good seal with platinum, the lead ions in the immediate vicinity of the seal are reduced when the electrode is used in fused salts at 450°C. This reduction is evidenced by a hump in the polarographic current voltage curve, starting at about −0.9 v vs. a platinum reference electrode. The shape of the hump depends on the polarization rate, but the area under the curve is the same for a given electrode. After a cathodic polarization, the metal-glass seal is black; anodization restores the original appearance of the seal. Several other "soft" glasses were tried, but they either failed to maintain a tight seal with the platinum or were quickly etched by the molten salts. Upon request, the Corning Glass Works kindly prepared a special batch of glass (Corning 010, G-164-EC) which was no longer available. This glass contains no lead oxide, has a very low conductivity and a coefficient of thermal expansion close to that of platinum. Although this glass is slightly etched after several hours in the melt at 450°C, in all other respects it is very satisfactory.

It was found that platinum does not serve as a suitable indicator electrode when coated with a liquid film of low melting metal such as cadmium, zinc, or bismuth. To illustrate the effect, the results of a brief study of the alloying of platinum with cadmium at 450°C will be given. A piece of platinum foil of 1 cm^2 area was plated with 10 mg of Cd from aqueous solution. Upon heating in an evacuated tube for 1 hr at 450°C, the weight of the specimen was unchanged. Upon dissolving the cadmium with

aqueous HCl, a spongy layer of platinum was left on the surface. The total weight of platinum was unchanged; the weight of the spongy layer which was presumed to have been alloyed was determined by carefully scraping it off and weighing it by difference. From the weight of the cadmium and spongy platinum, the composition of the alloy was calculated to be 64 mole % Cd and 36 mole % Pt. This corresponds closely to a compound Cd_2Pt, which has long been known (14) and which has a melting point of 745°C (15). Platinum dissolves readily in liquid Cd at 450°, but with a limited film of Cd, the solid alloy Cd_2Pt is formed and its further diffusion into Pt is very slow. The standard potential of a liquid Cd pool, measured with a tungsten contact, calculated from several series of potential-concentration measurements, differed only 6 mv, in the negative direction, from the value reported by Laitinen and Liu (12). The latter values had been obtained by measurements with a platinum microelectrode soon after plating it during the course of recording a cathodic polarogram. Similarly, the potential of a freshly zinc plated platinum electrode agreed with that of a pure zinc pool. The only potential which was found to be significantly different was that of bismuth, as reported elsewhere in this paper. It is probable that the surface alloy formation of cadmium and zinc may be responsible for the very different results reported (4) from a-c and steady-state current-voltage measurements for the kinetics of the cadmium and zinc couples at plated platinum surfaces.

Tungsten electrodes were prepared from 0.7 to 1 mm diameter rods sealed into Pyrex or uranium glass. The cross-sectional surface was polished to a mirror bright finish with 4/0 emery paper. Prior to use, the surface was cleaned in alkaline hydrogen peroxide, rinsed, and dried. Tungsten was not used as the active electrode material. When a clean tungsten microelectrode was inserted into a pool of liquid cadmium or zinc, a small droplet of the metal would adhere to the surface. This type of microelectrode has many of the advantages of a hanging mercury drop, but the area is not reproducible. Since no evidence of surface contamination with time has been found, the practice was to use the same droplet for a series of measurements at different concentrations. The area was determined by measuring the dimensions of the solidified metal with an ocular micrometer. The geometry of the drop corresponded satisfactorily to a segment of a sphere.

The other liquid metals, i.e., bismuth and lead, used in the kinetic studies would not adhere to a clean tungsten surface. Consequently, bismuth was plated onto the same type of electrode from a concentrated solution of Bi^{3+} in the melt. A layer of about 10^{-3} mm thickness exhibited the same potential as a bismuth pool; the activity of the deposit was therefore unity. Visual inspection showed that the entire surface was covered with bismuth. An alternate method was used to make a lead electrode. The cross section of a tungsten-Pyrex seal was ground out to a small cup and the end of the electrode was bent 180°. The reproducibility of the size of the lead drop in the cup was not satisfactory, and there was a variation of the cell resistance and measured data with changes of the position of the drop in the cup.

Microelectrodes of the metals which are solids at 450°C were made by plating platinum electrodes of the type described with the desired metal from aqueous solutions. The deposit was lightly polished with emery paper and washed with water. The apparent surface area was used in the calculation of the exchange current density.

In the kinetic measurements of the V^{3+}/V^{2+} couple, a platinum ball electrode was used. The end of a 26-gauge platinum wire was heated just to the melting point in a hydrogen-oxygen flame. If the wire was then removed slowly from the flame, a very smooth sphere resulted. This was sealed into Corning G-164-EC glass so that only a hemisphere of platinum was exposed. From differential capacity measurements, with an a-c bridge, at a frequency of 1000 cycles sec^{-1}, in 1M $HClO_4$ solution, it was shown that the roughness factor of this type of electrode is about half the roughness factor of a platinum microelectrode polished with 4/0 emery paper. Comparisons were also made with a piece of platinum foil which had a known roughness factor[3] of 1.12. At a potential of +0.6 v vs. SCE, the capacity/cm^2 (apparent) of the "fire polished" ball was nearly the same as the capacity/cm^2 (true) of the platinum foil.

The low melting metals were added to the test tube compartments as liquids. The cleaned and dried pieces of metal were melted above the compartment in an argon filled Pyrex tube, ending in a small capillary. If any metal oxide was present, it tended to cling to the walls of the tube above the capillary. Electrical contact with the pool counter electrode was made with a tungsten rod sealed in Pyrex; the end of the rod protruded a few millimeters beyond the seal.

Counter electrodes of the metals which are not liquids at 450°C were made from foils of the metal under investigation. A large piece of about 12 cm^2 area was fashioned into a right cylinder. Electrical contact was made with a platinum wire spot welded to the foil.

After the counter-electrode was in the filled cell, the potential was measured against a platinum reference electrode. Even in the most carefully purified melts, the potential corresponded to a low concentration, 0.3 to 0.4 mM, of metal ions. With noble metals, such as platinum and bismuth, the spontaneous concentration was much lower (0.01 to 0.05 mM), as might be expected. If magnesium had not been used in the purification of the melt, the spontaneous concentration was several millimolar. The potential also became more positive with time, indicating an increase in the concentration. It is suspected that silica, leached from the glass, is responsible for the slow oxidation of most of the metals studied.

The concentration of the metal ion was changed by anodizing the counter electrode with a constant current for a known time. From the potential meas-

[3] The roughness factor of a 100-cm^2 area foil was evaluated by the krypton adsorption (B.E.T.) method through the kind cooperation of Professor Norman Hackerman, of the University of Texas.

urements at each concentration, it is possible to calculate the initial concentration. Analysis of the contents of several cells after the experiments confirmed the reliability of this procedure.

Vanadous solutions were prepared by anodizing vanadium metal. It was then necessary to filter the solution into another compartment, because finely divided vanadium metal appeared in the solution. A platinum foil cylinder was placed in the solution to oxidize a fraction of the vanadous ions to the vanadic state with a constant current. The solution was vigorously stirred to avoid concentration polarization. The platinum foil also served as the unpolarizable counter electrode during the kinetic measurements.

Platinum reference electrodes were constructed and used exactly as previously reported (16). The same is true of the carbon rods used as working electrodes for the anodization and cathodization of metals and solutions. The volume of the eutectic in the cells was determined by argentometric titration of the chloride.

Electronic equipment-double pulse method.—A block diagram of the electronic circuit for application of the double pulse is shown in Fig. 3. The Tektronix Oscilloscope 535/S2 was used for triggering the pulses. (The delaying sweep of this scope can be released by a push button, which in turn triggers the main sweep.) The gate from the main sweep was fed into the pulse generators, Tektronix 161 and 163, through a capacitor and a resistor. The relative position of the pulses could be adjusted by the input

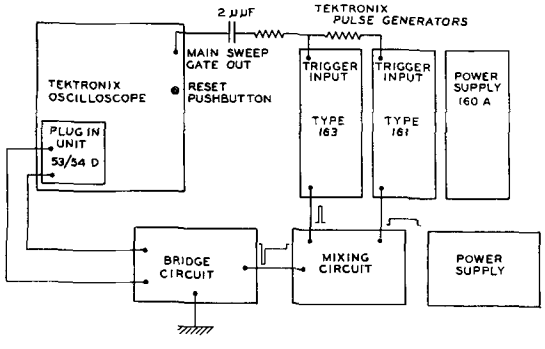

Fig. 3. Block diagram of the electronic circuit for the double pulse method.

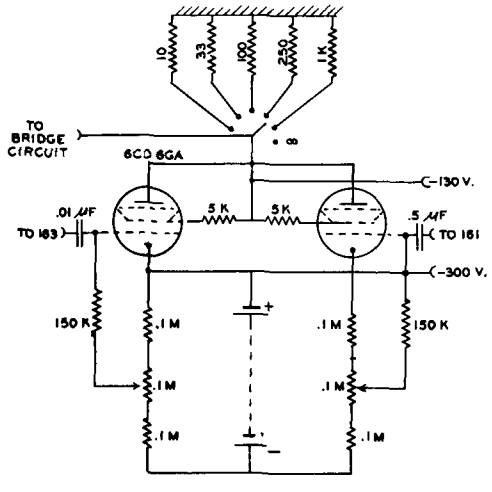

Fig. 4. Circuit for mixing the two pulses

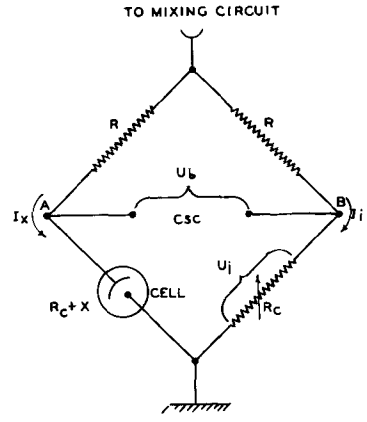

Fig. 5. Bridge circuit for compensating electrolyte resistance.

controls of the generator. The two pulses were mixed in the circuit shown in Fig. 4. The beam power tubes of this circuit are able to pass pulses up to 200 ma. The actual limitation in our measurements was given by the output voltage of the 163 generator which furnished the charging pulse. The grid bias of the beam power tubes was adjusted to a residual current of about 1 μa, which is considered to be negligible. The resistors in the plate circuit were built in for testing purposes. The bridge circuit shown in Fig. 5 was applied as outlined in the introduction. A little slug tuned coil in series with the resistor R_c was used to compensate for the higher inductivity of the cell circuit. In some later experiments two Tektronix 121 preamplifiers were added to improve the frequency response of the system. The rise time was then limited by the pulse generators (0.2 μsec.). The preamplifiers are linear up to an output of 1 v. This limited the current applicable to the cell to

$$\frac{1 \text{ volt}}{\mu(R_c + R_x)}$$

where μ is the amplification of the preamplifiers, R_c is the electrolyte resistance, and R_x is the transfer resistance.

The two pulses used in this method need not be constant current pulses, as has been the usual practice. Using small resistors in the upper branches of the bridge may cause the current to vary somewhat with time, but at the same time improve the frequency response of the equipment. The current I_x, the polarization U_x, and the corresponding transfer resistance X can be calculated from the voltages measured across the bridge U_b and across the compensating resistor U_i with the following formulas:

$$I_x = \frac{U_i R - U_b R_c}{R\ R_c} \cong \frac{U_i}{R_c}$$

$$U_x = \frac{U_b(R + R_c)}{R} \cong U_b$$

$$X = \frac{U_b(R + R_c)R_c}{U_i R - U_b R_c} \cong \frac{U_b R_c}{U_i}$$

The resistors in the upper branches of the bridge are R and the compensating resistor is R_c. The ap-

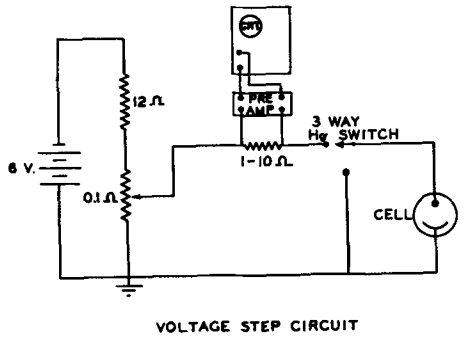

Fig. 6. Circuit for the voltage step method

proximations hold for $R>R_c$. In these measurements U_b was always of the order of magnitude of U_t, or smaller. The above equations, which have been derived for a d-c bridge, should provide a good approximation for the conditions under which the values are measured. From these formulas, an estimate can be made of the necessary value of the resistors in the upper branches of the bridge which will avoid the necessity of corrections in the evaluation. For most of the measurements, resistors R of 10 ohms were used. In checking the effect of the duration of the first pulse, where a constant current is essential, 100-ohm resistors R were substituted without, however, any appreciable difference in results.

Voltage step equipment.—The circuit diagram of the voltage step apparatus is shown in Fig. 6. Its design and function are quite simple. The desired voltage step (usually 2-7 mv) is set by moving the contact on the voltage divider. The exact value was measured to within 0.01 mv with a Student-type potentiometer. The current through the voltage divider was about 0.5 amp, so the resistance across which the voltage step was developed was only 0.005-0.016 ohms. The microelectrode was short-circuited to the counter electrode through the three-way mercury switch. When the switch was moved to the other position, the break occurring before the make, the voltage step was applied between the two electrodes. The current was measured as an iR drop across the precision resistor R_m. The signal was amplified through a video preamplifier (17), modified to operate differentially, and was observed on the screen of a Tektronix 535/S2 oscilloscope equipped with a 53/54 D plug-in preamplifier. The maximum usable sensitivity of the equipment was 0.2 mv/cm and the upper limit of the bandwidth was 0.45 mc. With a 5-ohm measuring resistor, currents could be measured to an estimated ± 2 μa The accuracy of the electronic equipment was periodically checked with a potentiometer and was always within 1%. Sweep rates of 10 or 20 μsec/cm were generally used.

The current time curves were photographed on 35-mm Kodak Plus-X film. The beam intensity and grid line illumination were adjusted to give only a minimum exposure. The image on the negative was very fine and when enlarged to twice the size of the oscilloscope screen, the lines were less than a millimeter wide. The enlarged curves were traced on graph paper with the aid of a french curve. Current-time points from the traced lines were then plotted as current vs. the square root of time.

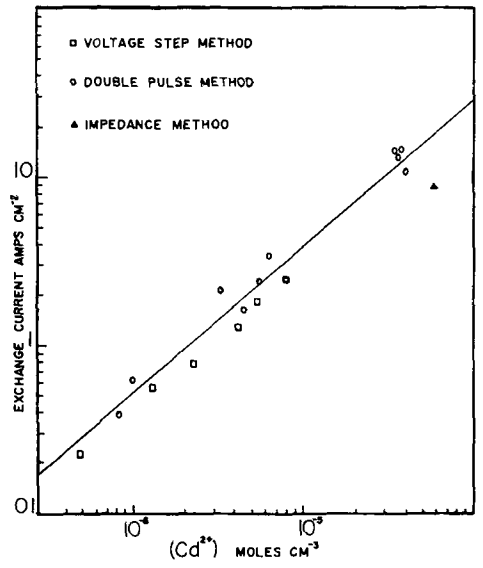

Fig. 7. Exchange currents measured on cadmium

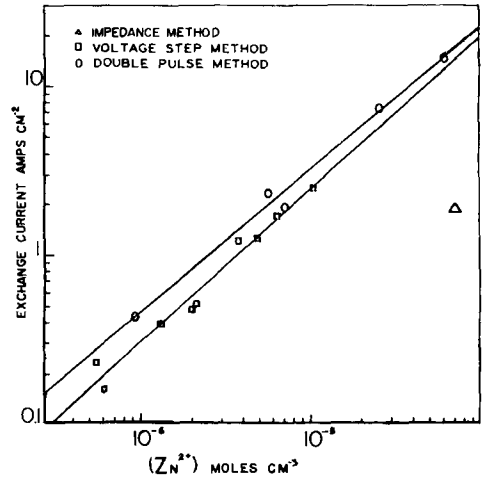

Fig. 8. Exchange currents measured on zinc

Results

Cadmium and zinc.—The cadmium and zinc couples were the first ones studied in this investigation. They were known to be fast reactions, not only from polarographic behavior, but from the a-c impedance measurements (4) described earlier. The earlier impedance measurements were conducted with a polished platinum electrode in melts of a lesser purity. Therefore some difference might be expected between these results and those of Laitinen and Gaur (4).

The exchange currents corresponding to a wide range of Cd^{2+} and Zn^{2+} concentrations are shown graphically in Fig. 7 and 8. On these log-log plots, a linear relation is expected from Eq. [3], with a slope equal to $1-\alpha$. The results of both methods are included on the graphs, as well as the point determined earlier by Laitinen and Gaur. Considering the assumptions that were necessary in the evaluation of the latter experiments and the fact that platinum was used as an electrode, the agreement is surprisingly good.

Each point on the graphs is the average of a series of measurements taken with polarizations between 1 and 10 mv. There was no systematic difference between the results obtained with anodic and cathodic polarizations. The majority of the voltage step measurements were taken in the cathodic direction.

The influence of temperature was investigated in the case of cadmium by measuring the exchange current at 400°, 450°, and 500°C. The activation energy calculated by the Arrhenius equation and was found to be 3 ± 1 kcal mole^{-1}.

Since zinc has a melting point within the range of temperatures investigated, measurements were taken on liquid as well as on solid zinc. Within the limits of accuracy, no difference was observed. This result is similar to the observation of Gerischer and Krause (7) on mercury in a perchloric acid/water eutectic.

Additional experiments were performed with zinc and thallium; no quantitative results can be given for the latter metal because the electrode area was not known. The purpose was to test the influence of the rise time of the double pulse equipment and the extent of the correction obtained when the reaction resistance was extrapolated to zero length of the first pulse. The results for zinc are shown in Fig. 9. Similar behavior was observed with thallium. These results are not in accord with the theory presented by Matsuda, Oka, and Delahay. The dependence of the reaction resistance upon the length of the first pulse was much greater than required by the theory, but still within the over-all limits of accuracy of these measurements (±10%). Calculation of diffusion coefficients from the experimental dependence led to ridiculously low values.

The improvement of the frequency response by using two preamplifiers as mentioned above, enhanced the discrepancies, showing that the poorer rise time of the original equipment was not responsible. Data obtained with and without high rise time equipment differed by 20% when the first pulse was 3 μsec long. But when the values were extrapolated to zero length of the first pulse the results differed by a factor of 2 or more. The shorter the first pulse the bigger was the difference between the two sets of measurements. To explain these results one has to assume some additional process interfering at very short times. The frequency dispersion of the residual capacitance (4) in this melt might be present at these short times. However it does not seem likely that a dispersion which is caused by the establishment of a new steady state on the metal surface with adsorbed ions can occur so rapidly. A quantitative explanation for this effect is still pending and so for the sake of consistency the results listed in Table I are those obtained without taking into account the dependence on the length of the first pulse.

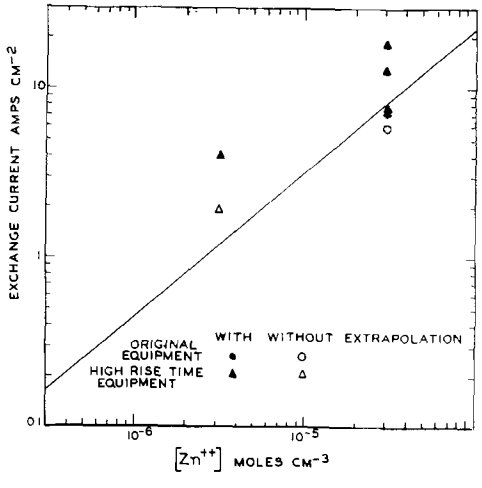

Fig. 9. Exchange currents measured on zinc to test the influence of rise time and extrapolation to zero length of the first pulse.

Lead.—With lead, as also with bismuth and thallium, the hanging drop electrode could not be used because the metal did not adhere to the tungsten surface. Double pulse measurements were taken with a lead drop in the cup-type electrode. Results are shown in Fig. 10. The large variation is due to the difficulties encountered with the cup electrode and because of the uncertainty in the surface area measurements. The best results were obtained with a very small drop which did not fill the cup.

Bismuth.—Although the kinetic data for the reaction $Bi^{3+} + 3e^- = Bi(lq)$ lack precision, primarily because of the volatilization of $BiCl_3$ from the melt, there is no doubt that it is the slowest reaction of all those investigated. The transfer coefficient is larger than that of any of the other metal ion-metal couples. Figure 11 illustrates the dependence of the exchange current on the Bi^{3+} concentration as determined by the voltage step method. The "effective zero time" currents were used to calculate the

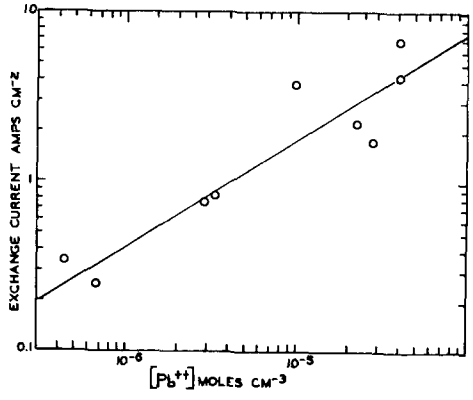

Fig. 10. Exchange currents measured on leod

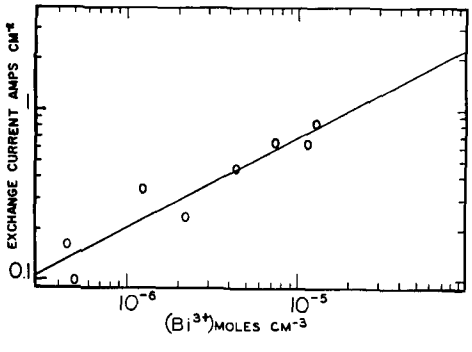

Fig. 11. Exchange currents measured on bismuth

exchange currents according to the method presented in the beginning of the article.

The standard potential of the bismuth couple was calculated from five separate series of measurements of the bismuth potential as a function of concentration. To minimize the error caused by the volatilization of $BiCl_3$, the contents of the compartment were analyzed for bismuth. The average value of $E°$ was -0.640 ± 0.010 v compared to the molar platinum electrode. This is the only case where the potential measured with a tungsten electrode in contact with a metal pool differed appreciably with the potential measured with a plated platinum electrode, as reported by Laitinen and Liu (12). When a platinum electrode was inserted into the same compartment with the tungsten electrode and then plated, the potential corresponded to the one given before, but differed from the potential of the tungsten electrode by nearly 0.1 v. If the platinum electrode was inserted into the bismuth pool, it quickly dissolved. The thermal emf between platinum and tungsten is negligible.

Platinum,[4] *nickel, and silver.*—For solid electrodes there was no difficulty in determining the apparent surface area, which was used in the calculation of the exchange current density. Silver sometimes recrystallized in the melt forming fine whisker-like fibers, causing an increase in exchange current. In such cases, after polishing and cleaning the electrode the measured values were the same as before.

Figure 12 shows the results obtained with these solid metals by the double pulse method without the high rise time preamplifiers. Some of the exchange currents of the silver couple have been calculated by extrapolation to zero length of the first pulse. As can be seen, such points are within the limits of precision of the measurements.

Vanadium(III)-vanadium(II). — This electrode couple is distinctly different from the above examples because both forms of the couple are solvated ions. The exchange current is then a function of two concentrations. The data cannot be compared with the metal ion/metal couples because of the lack of a common reference concentration. The plot of $i_o/(V^{3+})$ vs. $(V^{2+})/(V^{3+})$ shown in Fig. 13 results in a straight line, as expected from Eq. [4].

From measurements at 400°, 450°, and 500°C, the activation energy was found to be 2.8 ±0.4 kcal mole^{-1}; a value which is surprisingly close to that of the cadmium couple.

Evaluation and compilation of the measured data. —Table I contains the kinetic data calculated from the measurements with the two methods. The rate constant $k_h°$ is listed as well as the molar exchange current, $°i_o$. Since the calculation of the rate constant required an extrapolation of over four orders of magnitude to an imaginary concentration of 1 mole cm^{-3}, no limits of error are given. The molar exchange current, i.e., the exchange current at a concentration of 1 mole liter^{-1}, is considered to be a more suitable measure of the rate of an electrode reaction.

[4] Qualitative observations were made of the anodic behavior of platinum in a melt containing about 0.1 mole liter^{-1} Pt^{++}. At positive polarizations of about 100 mv, the current-voltage curve has an unstable region. The anodic current suddenly drops to less than 100 μa cm^{-2}. A layer of $PtCl_2$ is formed at the electrode surface. The slow dissolution of this layer is now the rate determining process. It was possible to apply cell voltages up to 5 v without much increase in current, because of the ohmic drop in the layer. Some chlorine is evolved, but only at much higher polarizations, due to the iR drop in the layer, than at a carbon surface. The amount of current required for the formation of the layer shows that it is a thick salt layer and not a passive layer. After switching off the current, the cell voltage immediately drops to 1 v and then, within milliseconds to seconds depending on the time of anodization, decreases to its equilibrium value. The quantitative investigation of these phenomena requires the application of an electronic potentiostat because of the unstable region in the current voltage curve. This observation may prove useful in developing a method for electrolytically polishing platinum.

Discussion

In general, the exchange currents of the electrode reactions in this melt at 450°C are not much

Table I

	Molar exchange current amp cm^{-2}	α	k_h^0, cm sec^{-1}
Both methods			
Cd^{2+}/Cd	210 (±50)	0.13 (±0.05)	0.4
Double pulse			
Zn^{2+}/Zn	150 (±30)	0.16 (±0.05)	0.3
Pb^{2+}/Pb	30 (±15)	0.38 (±0.06)	0.01
Ag^{+}/Ag	190 (±50)	0.16 (±0.05)	0.65
Ni^{2+}/Ni	110 (±20)	0.25 (±0.06)	0.1
Pt^{2+}/Pt	40 (±10)	0.27 (±0.06)	0.03
Voltage step			
Zn^{2+}/Zn	150 (±20)	0.10 (±0.05)	0.4
Bi^{3+}/Bi	8 (±3)	0.5 (±0.1)	0.0009
V^{3+}/V^{2+}	30 (±2)	0.67 (±0.05)	0.3

higher than those of the fastest reaction so far investigated in aqueous solutions. The transfer coefficient was somewhat lower, except in the case of bismuth, lead, and vanadium(III)/vanadium(II), which were the three slowest reactions found. The obvious similarity in the behavior of several systems with otherwise differing chemical properties suggests a common discharge mechanism which presumably involves the exchange of metal ions between the electrode and chlorocomplex species in solution.

In the previous work on impedance measurements (3, 4) and in the double pulse method employed here, certain features of the observations do not behave in accordance with the simplest reaction model of a one-step charge transfer mechanism involving diffusing species. In particular, the "inverted" capacitance-resistance behavior, which can be caused by specific adsorption of the electroactive species (5), was explained on this basis by Laitinen and Gaur. A similar "inverted" behavior of capacitative and resistive components of impedance can be predicted, at least over a limited frequency range, for a dissociation reaction preceding the charge transfer reaction if the rate of dissociation reaction is less than or comparable to the rate of the charge transfer reaction (18).

It is therefore instructive to consider qualitatively the effects of adsorption and of prior dissociation on the double pulse and voltage step methods. The effect of adsorption of electroactive species would depend on whether the adsorbed layer represents an *additional* reaction path (parallel admittance) as assumed in the treatment of impedance measurements (4, 5) or whether prior adsorption is a step in the main reaction path (series admittance). In the former case, both the double pulse and voltage step methods would respond (for rapid charge transfer to the adsorbed phase) by showing an abnormally large double layer capacity. Indeed, a purely capacitative correction for adsorption was found adequate in several cases of impedance measurements (5), and in any case the resistive component of this correction is very small. For a slow charge transfer reaction to the adsorbed phase, a large time constant would be introduced into the reaction of the adsorbed phase, but in this case the main charge transfer reaction would also be expected to be slow. In the voltage step method the time constant for the charging process was found to be normal even in the presence of an electrode reaction. In the double pulse method, the charging is forced to happen in the short time interval of the first pulse. As has been already mentioned, the detailed behavior of the double pulse method does not comply with the simple charge transfer reaction model.

For prior adsorption as a step in the main reaction (the series admittance model), the effect would be similar to, although not identical with, that of a prior dissociation. All methods of measurement would be affected by the rate of the prior step if its rate were comparable to or slower than the transfer of charge.

Independent proof of the reality of specific adsorption or dissociation is needed before definite conclusions as to reaction mechanism can be reached. The irregularities in the a-c impedance measurements and the unexpectedly large dependence of the measured reaction resistance on the duration of the first pulse in the double pulse indicate, however, that simple charge transfer control does not prevail.

Manuscript received Dec. 9, 1959. This paper was prepared for delivery before the Philadelphia Meeting, May 3-7, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

A Study of the Oxidation of Hydrogen at Platinized Platinum Electrodes

Thomas C. Franklin and Samuel L. Cooke, Jr.[1]

Chemistry Department, Baylor University, Waco, Texas

ABSTRACT

A coulometric technique using a polarograph was used to study the oxidation of hydrogen at platinized platinum electrodes. The results obtained by this technique are in agreement with results obtained by charging curve and a-c bridge techniques. This technique showed the presence of two forms of hydrogen adsorbed at the surface of the platinum, and it also showed the presence of hydrogen absorbed in the platinum. A study of the effect of pH on the current voltage curves suggested that absorbed hydrogen migrated as a charged species, probably H_3^+.

The oxidation of hydrogen at platinum electrodes has been investigated by a number of workers. Bowden (1) and Butler (2-4) and co-workers studied the process using charging curve techniques. Frumkin and other Russian workers (5-13) followed this with a detailed study of the oxidation of hydrogen on platinum electrodes using similar charging curve techniques. A group of German workers (14-19) have studied the same problem using both alternating current bridge and charging curve techniques.

In Frumkin's work three arrests can be noted in the curves between the potential of the hydrogen electrode and the oxygen region in sulfuric acid solutions. The first two were grouped together as being caused by the process of removing adsorbed hydrogen. The third was attributed, along with another possibility, as being due to the process of removing hydrogen from the interior of the platinum.

Two maxima were obtained in capacitance of the electrode vs. polarizing potential curves plotted from data obtained in the bridge experiments. Eucken and Weblus (14, 15) attributed these effects to the presence of two different forms of adsorbed hydrogen on the surface of the platinum.

In a study of the competition between hydrogen and organic molecules for sites on the platinum electrode (20) the amount of hydrogen was measured by electrooxidation of the hydrogen using a polarograph and by measurement of the number of coulombs used in the oxidation. In conjunction with this study of poisoning, a study was made of the oxidation of hydrogen using this coulometric technique. It was felt that this technique was more rapid than the charging curve experiments of Frumkin and that it did not involve the special equipment needed for the bridge method or the high speed charging curves obtained by workers such as Breiter.

Experimental Materials and Method

The hydrogen electrodes used in this work were made by plating a 1 to 2 cm length of 20-gauge bright platinum wire with platinum black after the manner of Clark (21). A 3% solution of chloroplatinic acid with 0.06% lead acetate present was used as the plating bath. The electrode was washed with distilled water, cleaned of old platinum black with *aqua regia*, checked for surface cleanness by observing the uniformity of hydrogen evolution in 6*N* HCl, and then plated for a prescribed length of time at 2-10 ma. Since no visible evolution of hydrogen occurred at the current densities used, it was presumed that the discharge of platinum was the only significant process occurring. The number of coulombs passed could thus be used as an estimate of the thickness of the platinum black. To obtain a reproducible electrode, the thickness of the platinum black was controlled by the number of coulombs passed (22). Electrodes identical within 1% could be prepared under very carefully controlled conditions.

After plating, the electrodes were washed in a vigorous stream of redistilled water, charged with hydrogen in the electrolyte to be used, and placed in the hydrogen-saturated electrolyte in the apparatus for study. Equilibrium occurred almost immediately as indicated by the cell maintaining a constant potential, which was measured with a L&N K-2 potentiometer.

The apparatus is pictured in Fig. 1. The physical arrangement of the apparatus is shown in the inset.

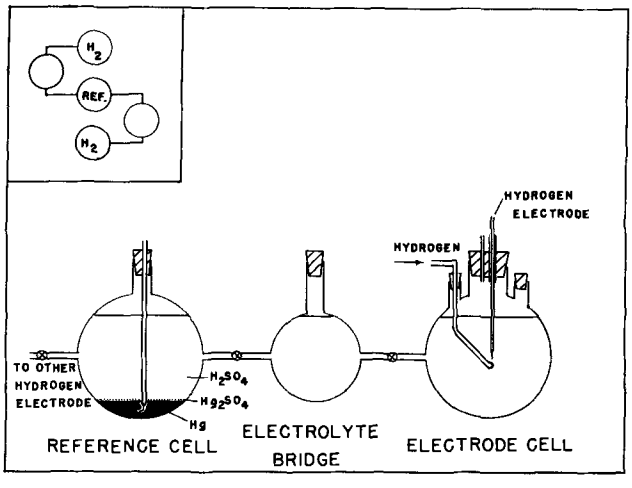

Fig. 1. Apparatus. Inset: physical arrangement

[1] Present address: Interscience, Inc., Richmond, Virginia.

The S-shaped arrangement permitted study of two electrodes with only one reference electrode. The complete apparatus was maintained at 25.0°C. The reference half-cell was Hg, Hg_2SO_4 in sulfuric acid and Hg, HgO, NaOH in basic solutions. The sodium hydroxide and sulfuric acid were of the same concentration as the electrolyte in the hydrogen electrode cell.

A series of runs were made in the *p*H range between 2*N* sulfuric acid and 2*N* sodium hydroxide. This was done by adding sulfuric acid to sodium hydroxide and *vice versa*. The *p*H was determined from the hydrogen electrode.

The hydrogen was prepared in a zinc-sulfuric acid Kipp generator and was bubbled through two wash bottles containing electrolyte. In the neutral and basic runs, the gas was first bubbled through strong sodium hydroxide to remove any acid carried over from the generator. Contact between hydrogen and rubber tubing was minimized, and all rubber was digested for two days in hot, concentrated sodium hydroxide and washed with distilled water before use.

In the early phases of the problem an investigation was made of the effect of various purification techniques on the results of the experiments. Several sources of hydrogen were used, including commercial tank hydrogen, Kipp generator hydrogen (using two different sources of zinc and two different sources of sulfuric acid), and electrolytically generated hydrogen. The hydrogen was purified in several different types of trains. Some runs were made in an all-glass apparatus and others were made in which the rubber connections were replaced with Tygon. The apparatus was in all cases soaked for 24 hr or longer, in some cases with distilled water and in others with the solution to be studied. Some experiments were carried out in sulfuric acid solutions that had been pre-electrolyzed overnight according to the procedure of Schuldiner (23). In all of these experiments the results were essentially the same. The presence of a poison decreased the amount of hydrogen at the electrode surface but did not change the general shape of the curves.

Hydrogen was bubbled into the cell for at least twice as long as necessary for potentiometric equilibrium. The cell was then permitted to stand for at least an equal amount of time. Then the hydrogen at the electrode was electrolytically oxidized using a Sargent Model XXI polarograph to record the current-voltage curve for the oxidation. When the cell resistance was greater than 500 ohms it was necessary to insert a compensation circuit. This circuit differed in design but not in principle from that of Nicholson (24). A lathe wound compensating slidewire was placed adjacent to the balancing slidewire of the recorder and an extra contact was constructed on the regular contact mount of the recorder. The current-voltage curves were also current-time curves for the oxidation process, and the area under the curves was proportional to the number of coulombs needed for the oxidation. The compounds used were all of reagent grade. The water was triply distilled.

Data and Results—Sulfuric Acid Solutions

A typical current-voltage curve for the oxidation of the hydrogen present at platinized platinum in 2*N* sulfuric acid is shown in Fig. 2. Three very distinct maxima are observed and are indicated by Roman numerals. A fourth maximum is observed when the voltage is allowed to sweep beyond the region where hydrogen is oxidized. Previous workers (25, 26) have shown the fourth maximum to be due to the formation of a surface oxide of platinum. These maxima are not experimental artifacts as is shown by the fact that they were obtained under a wide

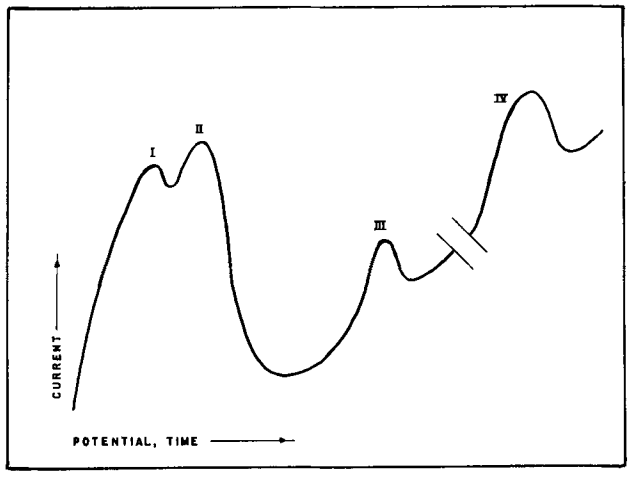

Fig. 2. Typical current-voltage curve for hydrogen oxidation on a platinized platinum anode in 2N sulfuric acid.

5	510 min after oxidation No. 4.
6	10 min after oxidation No. 5.
12	10 min after oxidation No. 11, the potential was allowed to sweep through the point of formation of the oxide of platinum.
13	10 min after oxidation No. 12.

Roman numerals denote the maxima. Origin of curves shifted along current axis.

variety of conditions including variations in the voltage sweep rate, the temperature, and the electrode plating conditions. Rotating the electrodes made the curves irregular but did not essentially change the area under the three maxima caused by the oxidation of hydrogen.

Figure 3 shows the effects of (*a*) time since the previous oxidation, (*b*) formation of the first surface oxide of platinum, and (*c*) successive oxidations on the shape of current-voltage curves in sulfuric acid. To prevent the curves from overlapping, the origin is shifted along the current axis. The first and second maxima are observed to develop with successive oxidations and after formation of the oxide. The third maximum is prominent in oxidations No. 1 and 5 and poorly defined in the other oxidations. The third maximum grows slowly as compared to the first two maxima. This is shown by Fig. 4 which represents the relation between area under the third maximum and time since the previous oxidation. The difference in rate of growth of this maximum and of the other two maxima can be appreciated when it is realized that in less than 3 min a similar plot for maxima I or II would go beyond the range of Fig. 4, and equilibrium would be reached in 10 min.

From these data it can be concluded that the first two maxima are a result of the oxidation of two forms of hydrogen adsorbed on the surface of the platinum. This is shown by the fact that the area under these maxima increases with repeated oxidations (Fig. 5) (the expansion and contraction of the crystal lattice on oxidation and then reduction increased the surface area) and by the fact that the area under these maxima decreased following a Freundlich adsorption isotherm in the presence of poisons (20). The third maximum presumably corresponds to the oxidation of hydrogen absorbed in platinum. It is a well-known fact that hydrogen absorbs in metals more slowly than it adsorbs on metals (27).

The above interpretation agrees with the interpretations of the Russian workers (5-13) in that they observed the slow forming absorbed hydrogen. It agrees with the German workers (14-19) in that they distinguished between the two forms of adsorbed hydrogen. Breiter (16-19) observes a third form of surface hydrogen to which this technique is insensitive. However, the interpretation of the two forms of adsorbed hydrogen as hydrogen adsorbed on oxygen, and on platinum (14), might just as well be interpreted as chemically and physically adsorbed hydrogen, respectively.

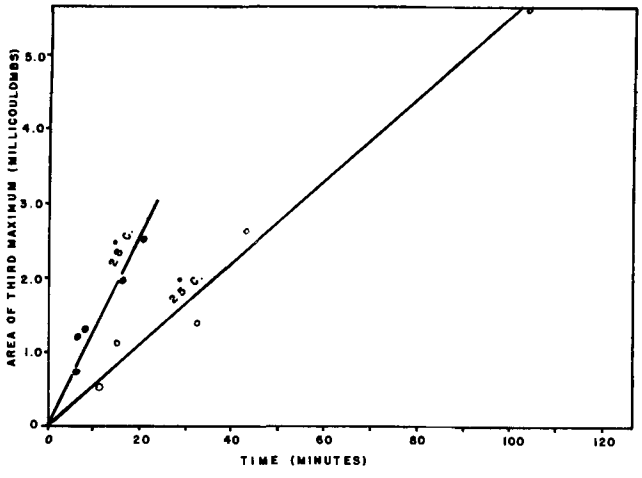

Fig. 4. Effect of time on the area under third maximum in acid solutions.

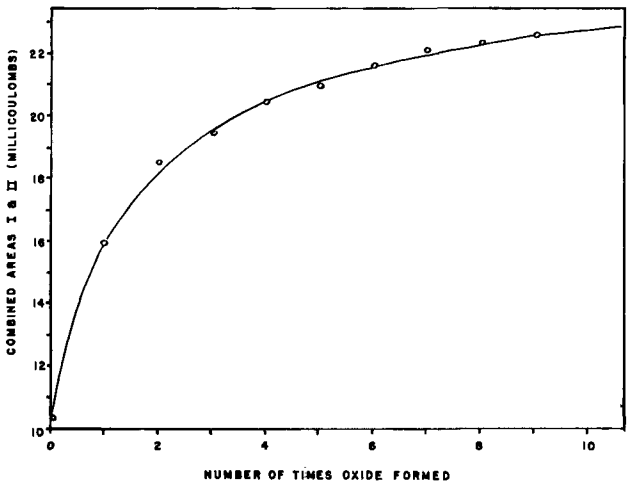

Fig. 5. Effect of oxide formation on combined areas I & II in acid solutions.

Basic and Neutral Solutions

The three maxima were still observed in 2N sodium hydroxide. However, two things made the hydrogen electrode in basic solutions more difficult to study: (*a*) The three maxima are very close together and thus there is a tendency for one or more of them to become ill-defined; (*b*) all three forms of hydrogen were completely replenished in the 10 min normally allowed between oxidations (in acid solutions it took over 3 hr for the absorbed hydrogen to reach equilibrium). Some experiments indicate that this difference in rate was due to poisoning of the electrode by sulfate ion.

Although no quantitative studies, such as those in sulfuric acid, could be made, a qualitative comparison was made of the effects of (*a*) time since the previous oxidation, (*b*) formation of the first oxide of platinum, (c) successive oxidations, and (*d*) hydrogen evolution, on the area under the curves in the neighborhood of each maximum in 2*N* sulfuric acid and 2*N* sodium hydroxide. This comparison is shown in Table I.

Table I. Summary of results in acidic and basic solutions

Effect on the area under the curve in the region of each maximum.

Maximum	Successive oxidations	Time since previous oxidation	Oxide formation	Hydrogen evolution
		Basic Solutions		
I(A)	Increase	No effect	Increase	Increase
II(B)	No effect	Increase	No effect	No effect
III(C)	No effect	No effect	Increase	No effect
		Acidic Solutions		
I	Increase	No effect	Increase	Increase
II	No effect	No effect	Increase	No effect
III	No effect	Increase	No effect	No effect

From these results it was concluded that the last two maxima had shifted their relative positions and the I, II, and III maxima in basic solutions correspond in acidic solutions to I, III, and II, respectively. This was further indicated by the fact that if one momentarily generates hydrogen on the electrode in basic solutions and then oxidizes it, one obtains the current-voltage curve shown in Fig. 6 containing only the two peaks I(A) and III(C) corresponding to the two surface forms of hydrogen (I and II in acid solutions). To study further this shift, the behavior of the current-voltage curves was investigated at intermediate *p*H values.

The potentials of the maxima relative to the normal hydrogen electrode are plotted as a function of *p*H in Fig. 7. The data for each maximum are on straight lines, except for a deviation in the *p*H range from 6 to 10. This deviation is attributable to a decrease in the *p*H at the electrode surface in the unbuffered solutions due to the generation of hydrogen ions during the oxidation. There was a definite shift in the relative positions of maxima II and III (acidic) as one goes from acidic to basic solutions. The potentials at which the two surface forms (maxima I and II in acid) are oxidized shift by 0.054 and 0.044 v in the negative direction for each unit rise in *p*H. It is expected that a reversible oxidation producing one hydronium ion for each electron will shift the potential by 0.059 v per *p*H unit. The deviation of these two slopes from the expected value may be due to a voltage drop caused by the resistance of the solution. The effect was more pronounced for the second surface form since the current was much higher. The potential for the maximum corresponding to the oxidation of the absorbed hydrogen (III in acid) shifts by 0.094 v per *p*H unit. This high slope shows that the absorbed hydrogen migrates as a charged species to the surface where it is oxidized. This slope corresponds most nearly to the reaction $H_3^+ = 3\ H^+ + 2e^-$, whose potential should shift by 0.089 v per *p*H unit. Because of the uncertainty of the resistance correction, the formula of the charged species could be different, but this experiment suggests that absorbed hydrogen must be a charged species. The presence of H_3^+ absorbed in platinum has been indicated by a number of workers (28), and Pearson (29) has concluded that in the absence of water the hydrogen ion prefers to associate with the hydrogen molecule.

Summary

From current-voltage curves for the oxidation of hydrogen at platinized platinum electrodes in aqueous sulfuric acid, it was concluded that three forms of hydrogen are involved. These three forms, in order of ease of electrolytic oxidation, are postulated to be two forms of adsorbed hydrogen and one form of absorbed hydrogen, in agreement with the conclusions of other workers. Hydrogen is absorbed into platinum much more rapidly from sodium hydroxide solutions than from sulfuric acid solutions. The effect of *p*H on the current-voltage curves suggests that absorbed hydrogen is present as a charged species, probably H_3^+.

From these experiments, it can be concluded that the present technique, the use of current-voltage curves (with a constant voltage sweep rate) can be used for a study of the behavior of hydrogen on metal electrodes. This technique is faster than the slow charging curve technique and not as difficult experimentally as the a-c bridge or fast charging curve techniques. In agreement with the work of Frumkin (7, 12) and Eucken and Weblus (14) it showed the presence of two forms of hydrogen adsorbed on the surface of platinum differing in ease of oxidation, and the presence of hydrogen absorbed in the metal.

One of the major disadvantages of this technique is the presence of a residual current that must be subtracted. A residual current is present because of

the oxidation of molecular hydrogen in solution diffusing to the surface. For some reason the absorption of hydrogen in platinum from basic solutions is much more rapid than in acid. The reverse process, the diffusion of hydrogen from the interior of the metal to the surface, causes a high residual current in basic solutions. However, in sulfuric acid solutions especially, one can obtain a measure of the amount of hydrogen present at the electrode surface in the different forms by taking the area under each maximum and subtracting the area due to the residual current.

Technical Notes

Charging Curves for Germanium Electrodes

W. W. Harvey, S. Sheff, and H. C. Gatos

Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts

The assertion has been repeatedly made in the literature [e.g., ref. (1-3)] that germanium surfaces in aqueous solution are covered with an oxidic layer. This assertion seems to be based on thermodynamic considerations and on the observation by Turner (4) that, during anodic dissolution, approximately a monolayer of surface oxide or hydroxide is present. However, direct experimental evidence for the existence of an oxidic layer on a germanium electrode not polarized anodically has been lacking. Accordingly, the chemical state of the surface was re-investigated using the method of charging curves, i.e., plots of electrode potential vs. time at constant current density.

Results and Discussion

Figure 1 shows the changing character of the charging curves obtained in 1.0*N* H_2SO_4 on progressive removal of dissolved oxygen [cf. ref. (2, 4)].

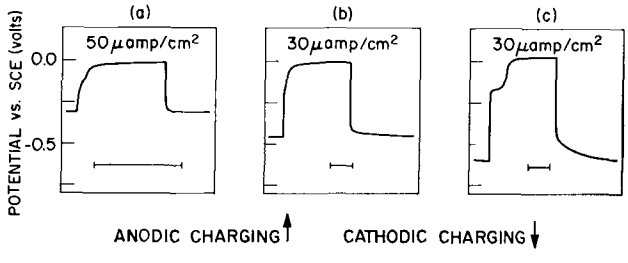

Fig. 1. Changing character of charging curves for germanium on displacing dissolved O_2; horizontal markers represent 10 sec on the abscissa; (a), 1.0N H_2SO_4, as made up; (b) and (c), following N_2 bubbling.

After the concentration of oxygen has been reduced to a low value by prolonged bubbling of purified inert gas, a charging curve such as illustrated in Fig. 2(a) can be obtained. Further removal of oxygen by cathodic reduction results in increased

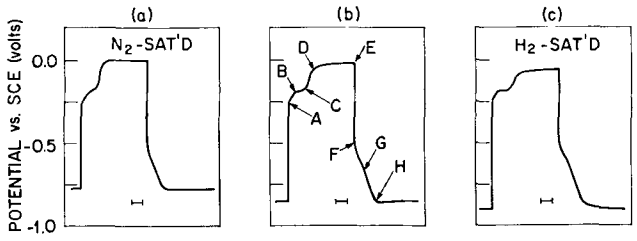

Fig. 2. Charging curves obtained in 0.1N H_2SO_4 after prolonged bubbling of purified N_2; markers represent 150 μcoulomb/cm^2(5 sec) on the abscissa. (a), Initial charging behavior at 30 μa/cm^2; (b), behavior after repeated cycling; (c), same, except solution H_2-satd.

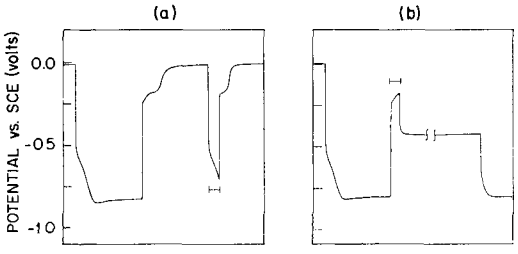

Fig. 3. Examples of charging curve analysis (actual tracings) in 0.1N H_2SO_4; width of markers is equivalent to 150 μcoulomb/cm^2.

polarization during the cathodic step, as shown in Fig. 2(b) and (c). A second consequence is the development of the segment $\overline{BC}$ of the anodic curve. Charging curves similar to those of Fig. 2 but with the cathodic portion extending in a third stage to a more negative potential have also been obtained, particularly at somewhat higher current densities than reported here.

The charging curves have been analyzed in several ways (see below and also Fig. 3); the main features are interpreted as follows: the change in potential along $\overline{AB}$ results from the anodic oxidation of hydrogen atoms chemisorbed during $\overline{GH}$ (by cathodic reduction of hydrogen ions); along the horizontal portion of $\overline{BC}$, hydrogen molecules on the solution side of the interface are oxidized (to hydrogen ions); following this, germanium surface atoms are oxidized. Reversing the current after the final anodic potential has been reached brings about the reduction of the anodically formed surface oxide in the interval $\overline{FG}$.

It is of interest to note that the sequence of processes during charging is different for germanium and platinum, whose charging behavior has been studied most extensively. The first stage of the anodic polarization curve for platinum (5) corresponds to the ionization of cathodically formed hydrogen (6) and consists of an initial horizontal portion (ionization of free hydrogen in the solution), followed by a linear increase of potential (ionization of chemisorbed hydrogen). The second stage for platinum is a rapid increase of potential, corresponding to charging of a double layer. For a polarized germanium electrode, on the other hand, it is evident that an appreciable change in the total semiconductor-electrolyte potential difference must occur before the electric field at the interface has been altered sufficiently to bring about the oxidation of cathodically formed hydrogen or the reduction of anodically formed surface oxide.

In a separate experiment, it was shown that the steady-state anodic reaction in hydrogen-saturated solution is the same (viz., germanium dissolution) as in nitrogen-saturated solution, and so it was established that molecular hydrogen is not oxidized during the anodic dissolution of germanium. In addition, it was shown by chemical tests that metagermanic acid (the product of anodic dissolution) is not reduced to a lower valence state at the germanium cathode.

The charging curves of Fig. 2 and 3 were obtained with hemispherical electrodes (p-type) to insure uniform current distribution at the semiconductor surface. (Similar curves were obtained using disk-shaped n- and p-type electrodes with {111} orientation.) Taking 7.5 x 10^{14}/cm^2 as the average density of atoms at the real surface and using the value 1.3 as the roughness factor of chemically polished germanium (7,8), it is readily calculated that one electron per surface atom is equivalent to 1.56 x 10^{-4} coulomb/cm^2. By analyzing spectrochemically for germanium entering the solution during repeated anodic-cathodic charging, it was possible to obtain essential information relevant to the oxidation of germanium surface atoms in the initial stages of the anodic process. Thus, it was found that at 30 μa/cm^2, germanium dissolved is equivalent to 18 sec of the 30-sec anodic stage of Fig. 2(b); i.e., a charge equivalent to 12 sec (3.6 x 10^{-4} coul/cm^2, or 2.3 electrons per surface Ge atom) at the stated current density is consumed in the oxidation of chemisorbed hydrogen, free hydrogen, and germanium surface atoms. Further, by successively decreasing the cycle duration, it was found that anodic dissolution begins at the inflection in $\overline{CD}$ (i.e., roughly midway between C and D in the figure); however, oxidation of surface atoms is not completed until the steady-state anodic dissolution potential is reached (beyond D). For the specimens employed, the surface coverage by chemisorbed hydrogen during steady-state cathodic charging was equivalent to approximately 0.6 atom layer.

It is evident from the data presented that the anodic formation of surface oxide or hydroxide requires less than two electrons per surface germanium atom. In fact, as indicated by the coulomb equivalent of $\overline{FG}$ [(Fig. 3(a)], not more than one electron per surface atom is required in this process. Time-lapse studies have shown further that in the absence of dissolved oxygen (and other oxidizing substances which attack germanium), chemical species chemisorbed onto, and presumable covalently bonded to germanium as a result of electrolytic processes remain chemisorbed indefinitely.

If a properly prepared germanium surface is polarized cathodically without prior anodic treatment, only the hydrogen reduction portion [beginning at G in Fig. 2(b)] of the charging curve is observed. The same result is obtained if, following a series of charging cycles, the electrode is polarized anodically only to B [see Fig. 3(b)]. These observa-

tions constitute the most direct evidence available at present for the absence of an appreciable oxidic layer on germanium surfaces in nonoxidizing aqueous environments.

Conclusions

It was shown that in dilute H_2SO_4 not more than one electron per germanium surface atom is required during the anodic formation of a surface oxide or hydroxide layer and that the equivalent coverage by chemisorbed hydrogen during cathodic charging is closer to 0.5 than to 1.0. It was further shown that virtually oxide-free germanium surfaces can be obtained in aqueous electrolytes.

Acknowledgment

The authors wish to acknowledge the assistance of Mrs. M. J. Button with some of the experiments.

Manuscript received Jan. 15, 1960. The work reported in this paper was performed by Lincoln Laboratory, a center for research operated by Massachusetts Institute of Technology with the joint support of the U. S. Army, Navy, and Air Force.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

A Comparison of Etching and Fracturing Techniques for Studying Twin Structures in Ge, Si, and III-V Intermetallic Compounds

J. W. Faust, Jr. and H. F. John

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

In many cases the detection or location of twins is accomplished most easily by etching. If the etchant is judiciously chosen, one can locate the twin boundary and also determine the orientation of the material on either side of the boundary (1). Three methods of revealing twins by etching and a new method of revealing twins by fracturing are discussed below.

Techniques for Revealing Twins by Etching

1. Preferentially etch a lapped surface. The twin boundary is revealed by the change in the characteristic etch pits as a result of the orientation difference across the boundary. If the orientations of the faces across the twin plane are not equivalent, then a step will also be produced at the boundary as a result of the etch rate being a function of the orientation.

2. Chemically or electrolytically polish a lapped surface. The twin will be revealed as a groove (if the orientations of the faces across the twin plane are equivalent) or as a step (if the orientations are not equivalent).

3. Immerse a mechanically polished surface in a chemical polish or a preferential etch for a very short time. The twin line will be revealed as a groove.

Any of these methods can be applied to the study of twin structures in semiconducting materials; however, difficulties in interpretation can arise if the twins are very closely spaced, and particularly if the etched surface is perpendicular to one of the <211> directions. Billig (2) in his study of twin structures in "dendritic" Ge does not give any details of his experimental technique; however, examination of his photomicrographs indicates that he must have used method 3, i.e., the dendrite cut perpendicular to its length, polished, and etched in a preferential etch. Since his technique reveals not only the twin lamella but also dislocations, a complete analysis of the cross section is impossible in many cases.

Of the three etching techniques, method 3 (employing a chemical polish on a mechanically polished surface) is particularly useful when properly

interpreted; however, our new technique of fracturing thin sections of Ge, Si, or III-V compounds is more rapid and more easily interpreted.

Interpretation of Etch Patterns

As an illustration of the problem involved in interpreting etch patterns obtained according to method 3, let us choose a section of Ge containing three closely spaced twins and cut this section into two pieces, A and B, such that the cut is perpendicular to the <211> directions, as shown in Fig. 1. If sections A and B are mechanically polished and then given a 10-sec CP4 etch,[1] it is found that side A has a definite groove and two faint lines, while side B has two definite grooves and a faint line. In many cases the twins are spaced so close together that one or both of the faint lines will be "lost" in the definite etch groove. Figure 2 shows this apparent etching anomaly for sides A and B. This apparent anomaly is merely the result of the action of the etch on the {111} planes and the effect of the energy of the twin plane on the etch rate. The CP4 is slightly preferential to the {111} planes; however, it is not preferential enough to keep the etch from acting as a chemical polish. Because of the twin boundary energy, the etch attacks more rapidly at the twin boundary starting a groove. If {111} planes converge on the twin plane from the surface, as shown by twin planes marked 2 in Fig. 1, atoms can be removed along these exposed planes also; the result will be a definite groove. If, however, the {111} planes diverge from the surface at a twin boundary, as shown by twin planes marked 1 in Fig. 1, atoms cannot be removed from these unexposed {111} planes, and the result will be a faint groove caused only by the attack of the etch as a result of the energy associated with the twin plane. The number of definite grooves, n, can be found

from the number of twin planes, t, by the following formulas:

For an odd number of twin planes, where A and B have the significance shown in Fig. 1,

side A $\quad n = (t-1)/2$
side B $\quad n = (t+1)/2$

For an even number of twin planes

side A or B $\quad n = t/2$

Interpretation of Fracture Surfaces

The cleavage planes for germanium and silicon are the {111} planes. Upon careful fracturing, these materials break on their cleavage planes. This technique is suitable for use on thin sections cut from grown crystals or on dendritic crystals which grow naturally in the <112> direction. In this technique a line is scribed across the {111} face parallel to the [110] direction to control where the fracturing is to occur; fracturing is accomplished by bending. Each twin plane changes the direction of the {111} cleavage planes as shown in the diagram in Fig. 3; thus each line represents a twin boundary. Figure 4 is a photomicrograph of a fractured Ge dendrite that contained 3 twin boundaries. Electron micrographic examination of such a twinned structure showed no additional twins. The cleavage surfaces show some fracture steps but are, for the most part, excellent. In some cases where the twin lamella ends before reaching the edge of the section, a single twin or grain boundary can extend to the edge; even the grain boundaries are faithfully revealed by this technique, as shown in Fig. 5. This technique has revealed as many as 13 twins in a distance of 20μ as shown in Fig. 6. In a few cases we have observed that cleavage takes place on {112} planes; this is illustrated in Fig. 7 by the fact that the edges of the fracture are in focus with the middle of the Ge section. This method also works well for dendrites of silicon and the III-V intermetallic compounds, although for the latter, the interpretation is somewhat difficult because of the secondary cleavage plane (3).

Acknowledgments

The authors wish to express their thanks to Dr. R. Stickler for the electron microscopic examination.

Bonding and Semiconductivity Relationships in Bi_2Te_3 and CdI_2 Type Structures

C. H. L. Goodman

Research Laboratories, The General Electric Company Limited, Wembley, England

It appears of interest to point out a possible relationship between layer structures of Bi_2Te_3 and CdI_2 types.

In a previous paper (1) a simple bonding scheme was put forward for Bi_2Te_3 which satisfactorily accounted for the 28 valence electrons in a manner consistent with the observed semiconductivity of this compound. A related bonding scheme seems possible for the 3-layer CdI_2 structure: I atoms, with the same coordination as the outer Te atoms in

5-layered Bi_2Te_3, would employ p^3 (plus s^2, lone pair) bonding orbitals while the metal atom, with 6-coordination like Bi in Bi_2Te_3, would employ sp^3d^2 hybridized bonding orbitals.[1] The 16 valence electrons of CdI_2 form 2-electron covalent-ionic bonds within the triple I-Cd-I layer structure, I-I inter-layer bonding being of van der Waals' type in agreement with Hartman's calculations (4).

Following (5) this scheme indicates that $A^{II}X_2^{VII}$ and $A^{IV}X_2^{VI}$ compounds with CdI_2 structure (e.g., CdI_2,$ZrSe_2$) should be semiconductors or insulators [in agreement with the findings in ref. (6) and (7) for example] while compounds such as $NiTe_2$ should be metallic [in agreement with the findings in ref. (8)]. Furthermore, ignoring bond-length effects, the greater electronegativity differences for $A^{II}X_2^{VII}$ compared with $A^{IV}X_2^{VI}$ compounds should lead to considerably lower energy gaps for the latter, which, by the same argument, should have higher energy gaps than related $A_2^{V}X_3^{VI}$ compounds with Bi_2Te_3 type structure.

Not all CdI_2 type compounds can be described in this way. Thus Ag_2F requires a scheme with resonating p^3 bonds, (which give rise to Ag-Ag interlayer bonding and accommodate all 9 valence electrons), and, following (5), should also be a semiconductor.

[1] This would appear to require d-orbital contraction; see for example ref. (2). Promotional energies for such bonding orbitals would in any case be much less than those suggested from spectroscopic data for free atoms, as has been pointed out by Wilmshurst (3).

The nature of the bonding in $A^{IV}X_2^{VII}$ compounds such as PbI_2 is less clear. Eighteen valence electrons must be accommodated in closed sub-shells or bonds for the criteria for semiconductivity given in ref. (5) to be satisfied. This might be achieved by p^3d^3 (+lone pair) bonding orbitals for A^{IV} atoms, although coordination symmetry argues somewhat against this view. More detailed bond studies along these lines would appear of interest.

The Adhesion of Vapor-Deposited Molybdenum Coatings

S. T. Wlodek[1] and J. Wulff

Department of Metallurgy, Massachusetts Institute of Technology, Cambridge, Massachusetts

The reduction of molybdenum pentachloride with hydrogen has often been proposed as a method of producing a dense molybdenum coating (1, 2). The exploitation of this process has been advanced recently by a theoretical treatment of the plating kinetics (3) and the development of a technique capable of plating large articles (4) with vapor deposited molybdenum.

The purpose of this note is to report on the factors which control the adhesion of the molybdenum coating, restricting the discussion to the formation of the plate on a metallic base. The most important variables which affected the adherence of the molybdenum plate studied in this investigation were: purity of raw materials, sample preparation, and the chemical composition of the material being coated.

Experimental

The plating technique used in this study was basically the same as that described by Spacil and Wulff (3). High-purity molybdenum pentachloride was prepared by the chlorination of molybdenum powder followed by the redistillation of the resultant product to prepare a fraction free of oxychloride contamination. After purification by passing over copper gauze (500°C), followed by a dry ice trap and a magnesium getter (500°C), hydrogen (36 l/hr) was passed over solid molybdenum pentachloride and saturated with the pentachloride vapor. The degree of saturation was kept constant by adjusting the temperature (100-120°C) of the pentachloride so that the color of the resultant gas mixture compared to an empirically arrived at standard (saturated solution of methyl orange in water diluted 1:400 in alcohol). The H_2-$MoCl_5$ gas mixture was then introduced into the reaction chamber where the plate was deposited on the inside of 0.5-in. diameter, 4.0-in. long tubes of the material to be plated. The reduction conditions in the actual plating chamber were 900°C and a pressure of 2.0 cm Hg. The whole system was constructed of Pyrex or Vycor.

After plating, the relative room temperature adherence of the base metal-molybdenum plate assembly was determined by compressing the sections of the as-plated tubing to 50% of the initial diameter and by completely flattening sections taken parallel to the length axis of the original as-plated tube. As shown in Fig. 1, these tests allowed an empirical characterization of five classes of adhesion; the first representing a bond strength which

[1] Union Carbide Metals Company, Niagara Falls, N. Y.

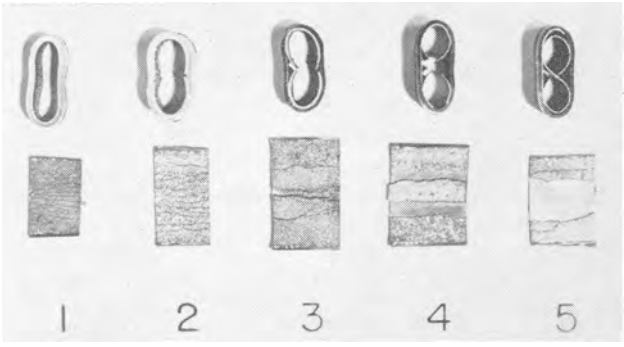

Fig. 1. Typical results of adhesion tests showing examples of the five main classes of adhesion.

exceeded the tensile strength of as-plated molybdenum; the fifth a bond weak enough to result in the complete exfoliation of the coating after testing.

In regard to the role of plating conditions on adherence, the effect of sample preparation and accidental contamination of the pentachloride with oxychlorides were found to be critical. Surfaces cleaned by chemical etching were found preferable to those prepared by mechanical cleaning. The presence of oxychlorides in the plating system, which were subsequently reduced to produce layers of MoO_2 in the plate, destroyed any adherence, even if the oxide films were less than 10^{-4} in. thick. In addition, if an oxide-contaminated molybdenum plate was deposited on iron or nickel, bulging or blistering of the plate would occur often (Fig. 2). Since this structural defect was observed only when MoO_2 was present at an interface highly permeable to hydrogen, the blistering could have been produced by entrapment of steam due to the reduction of the molybdenum oxides by the hydrogen that can diffuse through the nickel or iron base.

The effect of sample composition on the adherence of the as-plated molybdenum was studied by plating specimens of pure iron, 1020 and 1030 plain carbon steel, 18-8 stainless steel, pure copper and nickel, and Inconel. In addition, pure iron, and in some cases low carbon steels, electroplated with

Table I. Effect of base material on adherence

Base material	Thickness of molybdenum plate, in. × 10^3	Adhesion rating*
Pure copper	28.0	2
Pure nickel	7.0	1
Inconel	3.0	1

Rhodium (0.0006-in.) plated iron	8.0	1
Chromized 1020 steel	3.0	5
Nickel plated (0.0003-in.) 1030 steel**	2.0	1

* See Fig. 1 for classification of adhesion ratings.
** Replacement nickel phosphide coating, all other electrolytic.

nickel, cobalt, copper, chromium, and rhodium were also evaluated. As indicated in Table I, satisfactory as-plated adhesion of the molybdenum plate could not be obtained on pure iron, stainless, low-carbon steel, or on chrome-plated surfaces. Nickel, copper, and Inconel, or any of the iron or steel samples which had been electroplated with nickel, cobalt, copper, or rhodium before vapor plating with molybdenum exhibited excellent as-plated adherence.

Metallographic examination of samples of pure iron, 18-8 stainless steel, or chromium-electroplated iron, vapor plated with molybdenum did not indicate that surface oxide films on these materials were responsible for the poor adherence. Since appreciable amounts of iron and especially chromium chlorides were produced during plating experiments on iron- and chromium-rich surfaces, reaction with chlorides must have occurred during the plating of these materials. The degree of reaction was strong enough to remove any oxide films originally present.

Mo-Rh	1	Epsilon	1500	18

* As measured on samples annealed 100 hr at 900°C after plating. Identification of phases after Hansen and Anderko (6).

Evidence of grain-boundary attack of chromium-rich surfaces but not of chromium-free steels was often noted.

Although the carburization (Fig. 3) of the molybdenum plate deposited directly on a steel was believed to be the main reason for the poor adhesion always found with carbon steel specimens, the poor bonding exhibited by stainless steel, pure iron, or chromium-plated specimens was not found to be related to the formation of brittle films of intermetallic compounds at the molybdenum-base metal interface. Indeed, no correlation was found between the hardness (Table II) or width of the intermetallic phases that form on prolonged annealing (100 hr at 900°C) in the iron-molybdenum, nickel-molybdenum, copper-molybdenum, cobalt-molybdenum, or rhodium-molybdenum systems and the as-plated adherence. It should be stressed that these observations were made on specimens whose integrity on metallographic examination was excellent (Fig. 4 and 5).

In addition, the excellent relative bond strength of vapor-deposited molybdenum to pure iron electroplated with nickel, copper, cobalt, or rhodium

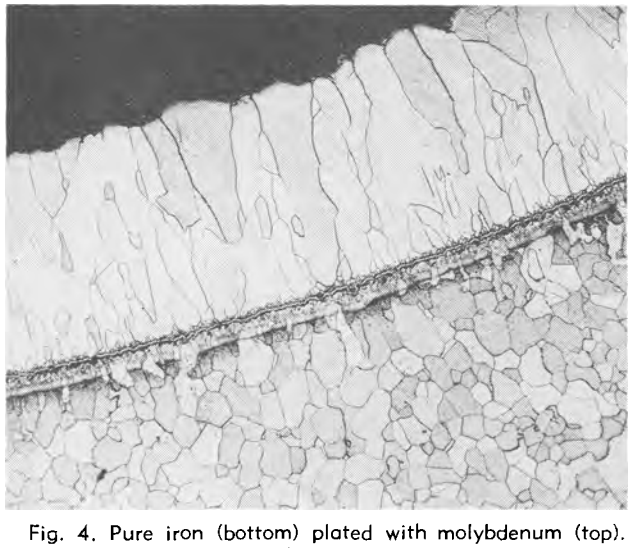

Fig. 4. Pure iron (bottom) plated with molybdenum (top). Note the Mo_6Fe_7 band. Etched with nital and alkaline ferricyanide. Magnification 75X before reduction for publication.

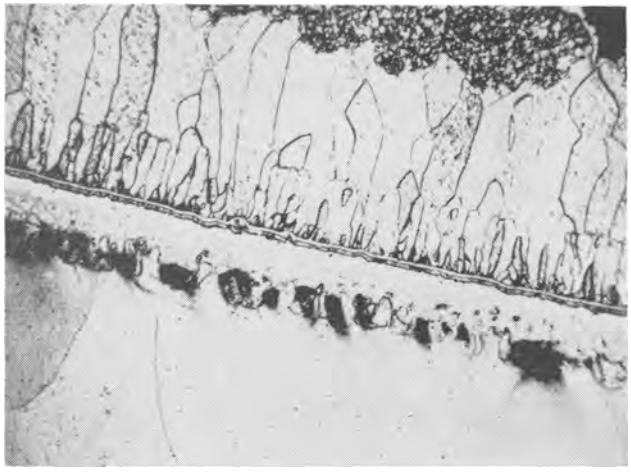

Fig. 5. Rhodium (0.0006 in.) electroplated pure iron (bottom) and vapor plated with molybdenum (top). Note thin gray band of the molybdenum-rhodium epsilon phase. Etched with nital and alkaline ferricyanide. Magnification 200X before reduction for publication.

remained completely unaffected by the 100-hr anneal at 900°C as long as the electroplate was thicker than 0.001 in. The poor bond strength of pure iron to pentachloride molybdenum was not improved by the same anneal.

Discussion

These results indicate that if carburization or oxide contamination of the molybdenum plate is prevented, the nature of the intermetallic phases that form at the molybdenum-base metal interface does not govern the as-plated adherence. In addition, the adherence of the plate after prolonged annealing is also only slightly affected by the growth of brittle intermetallic bands. The only correlation between the adherence of pentachloride molybdenum and the nature of the surface on which it is deposited seems to be a chemical one. In brief, metals such as iron or chromium which form chlorides more readily than molybdenum (5) were always found to be unsatisfactory surfaces for vapor deposition. Conversely, surfaces rich in copper, nickel, cobalt, or rhodium, all of which form less stable chlorides than molybdenum (5), consistently provided an excellent bond to pentachloride reduced molybdenum. Since appreciable amounts of chromic chloride or ferric chloride were always found in the exhaust system following plating experiments on iron- or chromium-rich surfaces, some experimental justification for associating poor adherence with chloride reactivity exists. It is suggested that the formation of chlorides involving the constituents of the metal being plated on, destroys the adherence by contaminating the surface. Also, since this reactivity occurs only with surfaces that form more stable chlorides than molybdenum, a replacement reaction could occur between the molybdenum chloride gas and the constituents of the surface. Since any reduction of the molybdenum chlorides by such elements as iron or chromium will produce a plate of higher chlorine, iron, or chromium content than that obtained by hydrogen reduction, a lower purity material of lower ductility, and thus poorer adherence, could form.

It is not possible to associate the poor adherence of vapor-deposited molybdenum to iron- or chromium-rich surfaces with the presence of oxide films on the steel or chromium surface. Any films of iron oxide present on the sample would be reduced by the hydrogen and chloride plating environment, while the chromic oxide films would be etched off by the chloride attack. The contention that affinity for oxygen does not characterize a strata to which poor adherence is to be expected is borne out by the excellent adherence found in deposits formed on rhodium-plated steels or pure Inconel, surfaces that possess a high affinity for oxygen but good resistance to chloride formation.

From these studies, it is possible to conclude that adherent coatings of molybdenum can be vapor plated onto surfaces which are free of carbon or constituents that form more stable chlorides than molybdenum. The coating system must, of course, be so designed as to eliminate oxygen contamination of the plate. By pre-treating samples containing carbon, iron, or chromium with an electroplate of copper, cobalt, nickel, or rhodium, adherent coatings can be applied to almost any material stable at the plating temperature. In closing, it is possible to suggest that similar criteria may govern the adherence of chromium, tantalum, or tungsten coatings when they are produced by chloride reduction.

Growth of Single Crystal Silicon Overgrowths on Silicon Substrates

Albert Mark

U. S. Army Signal Research and Development Laboratory, Fort Monmouth, New Jersey

A single crystal silicon overgrowth has been produced on a silicon substrate. This phenomenon confirms a fundamental principle for silicon showing that it is possible to have a vapor phase chemical reaction between the solid and vapor of one of its compounds. The silicon monolayers grow by accretion of atoms from the generating medium and assimilate as a single crystal overgrowth to the (100) orientation of the silicon substrate.

The reaction is based on the reduction of silicon tetrachloride by hydrogen, $SiCl_4 + 2H_2 \rightleftharpoons Si + 4HCl$, using a slow growth process. The deposited silicon layer or film has an orderly atomic lattice and continues the internal lattice structure of the substrate crystal without boundary layers at the interfaces. In this respect, the silicon layer is synonymous with and is an extension in three dimensions (growth in volume) of the original substrate surface over its entire periphery.

The deposit growth imitates and assumes the same growth pattern as initially exposed after an acid etch of the substrate face prior to a run. Rosette-like formations found in loosely masked areas continue their geometry in extending out and embracing the limits of their original boundary area. These appear to grow more prominently along their outer boundaries with the internal areas gradually filling in as the growth continues. The mechanical quality of the grown surface therefore is dependent to a great extent on the initial substrate geometrical configuration.

The deposit growth eventually assumes a dense jet black glassy surface which is difficult to distinguish from the original substrate face. Fully developed, this characterizes the ideal mechanical overgrowth surface. If the entire substrate face is loosely masked with a cover crystal, a denser, more uniform quality overgrowth results. This is apparently due to reduced heat losses at the crystal interfaces.

Electron diffraction studies of the overgrowths described were made at Purdue University by H. J. Yearian, Professor of Physics. His summation statement of his report follows: "From these results it may be concluded that all of the regions studied were single crystals of at least fair quality. On those

specimens for which a mask had been used, the deposits were thick enough to insure that the results represent the deposit and not the substrate."

The significance of an overgrowth layer of silicon can best be realized by enumeration of some of the probable electronic applications.

1. Application for fabricating surface devices (silicon deposited and growing out from a surface). —(*a*) An overgrowth of single crystal silicon of an opposite conductivity type to that of the silicon substrate crystal on which it is grown will act as a "surface junction." This implies a diode structure form. (*b*) An overgrowth of single crystal silicon acting as a surface junction can be processed to high or low resistivity values. (*c*) An overgrowth of single crystal silicon can be of the same conductivity type as the silicon substrate forming intrinsic pp^+ or nn^+ regions. (*d*) An overgrowth of single crystal silicon as a wide area film will act as a matrix with its surface containing innumerable junction points through proper masking techniques. (*e*) An overgrowth of a single crystal silicon film with a large area junction structure could be made sensitive to various forms of radiation, for example, for use in solar cells.

2. Multilayered devices.—(*a*) Alternate overgrowths of single crystal silicon films on parent or foreign substrates, each with its own discrete resistivity or conductivity type, will alternately act as high resistance I regions, pn and np junctions, and pp^+, nn^+ regions. (*b*) An overgrowth of single crystal silicon can be an active or passive element when used or incorporated into micromodule circuits.

3. Miscellaneous uses.—(*a*) An overgrowth of single crystal silicon allowed to grow to only an extremely thin film will act as a base region permitting the fabrication of very high frequency devices. (*b*) As an overgrowth of single crystal silicon on a foreign substrate with a lattice distance closely matching that of silicon. In this type of device, the substrate, if a metal, would act as the support media and as one pole of an electrical contact.

The perfection and extended use of this process in all its variations will permit the utilization of silicon in presently unexplored device areas thereby broadly increasing its usefulness as a semiconductor material.

Acknowledgment

The author wishes to express his thanks and gratitude to Professor H. J. Yearian and associates of Purdue University for the efforts expended in making the electron diffraction studies and evaluation of the samples.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Brief Communications

The JOURNAL accepts short technical reports having unusual importance or timely interest, where speed of publication is a consideration. The communication may summarize results of important research justifying announcement before such time as a more detailed manuscript can be published. Consideration also will be given to reports of significant unfinished research which the author cannot pursue further, but the results of which are of potential use to others. Comments on papers already published in the JOURNAL should be reserved for the Discussion Section published biannually.

Submit communications in triplicate, typewritten double-spaced, to the Editor, Journal of The Electrochemical Society, 1860 Broadway, New York 23, N. Y.

Discussion Section

This Discussion Section includes discussion of papers appearing in the JOURNAL of The Electrochemical Society, Vol. 105, No. 1 (January 1958) and Vol. 106, No. 4, 6, 7, 8, 10, and 11 (April, June, July, August, October, and November 1959). Discussion not available for this issue will appear in the Discussion Section of the December 1960 JOURNAL.

The Anodic Oxidation of Zinc and Zinc-Tin Alloys at Very Low Current Density

S. E. S. El Wakkad,[1] A. M. Shams El Din, and H. Kotb
(pp. 47-51, Vol. 105, No. 1)

(NOTE: The following is Dr. Shams El Din's reply to the discussion by M. Prazák which appeared in the December 1959 Discussion Section, p. 1072. These comments reached the Editorial Office too late to be included in December.)

A. M. Shams El Din: Tin and zinc form a simple eutectic system containing about 8% zinc, so that the electrodeposited alloy containing 20-25% zinc consists of the eutectic plus some free zinc.[2] Because zinc is the more electronegative of the two components, the electrode behavior of the alloy is to a great extent determined by the zinc and not by the tin. Thus, for example, in aerated 3% potassium chloride solution at room temperature, the electrode potential of the alloy vs. the saturated calomel electrode is approximately −1.0 v. The corresponding values of pure tin and pure zinc are −0.45 v and −1.02 v, respectively.[2]

Despite this fact, the tin of the alloy still manifests itself and exerts some of its properties on the general behavior of the alloy. The final behavior of the alloy need not, therefore, be the algebraic sum of its constituents. In the curves given in our original paper and also in the curve accompanying the comments of Dr. Prazák, it is clearly shown that the tin of the alloy oxidizes after the zinc. How much the tin oxide(s) film will affect the behavior of the zinc is difficult to tell, but the main fact is that it does affect it. This is also observed from other corrosion experiments employing techniques such as salt spraying and humidity tests. Thus, for example, salt spraying experiments (20% salt solution) with pure zinc result in the formation of dense white corrosion products which are not observed in the case of the alloy despite its free zinc content.[2] Humidity tests also reveal the superiority of the alloy to the zinc. Apparently, such difference in behavior between the alloy and zinc is to be attributed to the presence of tin.

The interesting finding of Dr. Prazák, that the behavior of the alloy is not the sum of its components, might be due to the fact that after the initial dissolution of the zinc the concentration of the tin at the surface of the alloy becomes higher than the corresponding value in the bulk of the alloy.

The occurrence of two current humps in the polarization curve of zinc in Dr. Prazák's Fig. 1 does not necessarily mean, in our opinion, a building of a new oxide of zinc. If zinc is able to form two oxides, then it should reveal this property also in the galvanostatic curves as do the other metals.[3] The first current hump in Fig. 1 starts at a potential of about −1.2 v which is in good agreement with the potential of the system Zn/ZnO at this *p*H value. A corresponding step is also reported in our paper. The second, smaller, oxidation step starts at about −0.6 v, and a similar step is not observed in our polarization curves. In our opinion, the second step observed in the potentiostatic experiments of Dr. Prazák corresponds to the thickening of the already present oxide film. Simultaneous dissolution in the form of zincate is also to be expected. The constancy of the current associated with this process over an increasing potential range of about 1.8 v suggests a corresponding increase in the resistance of the system electrode/electrolyte. The solution side of the system cannot be the cause of an increase in the resistance, first, because it is a good conductor, and, second, because in the polarization curve of zinc given in Fig. 1 there occur two different constant currents, a fact which reflects the conclusion that the solution side of the system cannot be the cause of resistance increase. The constancy of the current is, therefore, to be ascribed to the increase in the resistance of the oxide film. This can occur through an increase in the thickness of the film and/or the closing of the pores of the oxide. Such processes will have the ultimate result of decreasing the conductivity of the surface film.

Probably, if the effect of variables such as the alkali concentration and the presaturation of the solution with zinc oxide on the limiting current of the second step were to be studied, a clearer insight could be gained concerning the nature of the process(es) taking place at the electrode surface.

Before such understanding of these processes at the surface of both the zinc and the alloy electrodes is achieved, the suggestion of a homogenous passive layer growing on the surface of the nonhomogenous Sn-Zn alloy is to be considered as *ad hoc*.

Other than this point, the interesting observations of Dr. Prazák are in full agreement with ours. Thus, the polarization curve of the alloy shows clearly the oxidation of both the zinc and tin at their respective potentials. The quantities of electricity consumed in the building up of zinc and tin hydroxides on the alloy are less than those for pure zinc and tin alone.

Controlled Potential Reactions of Cadmium and Silver in Alkaline Solution

G. T. Croft (pp. 278-284, Vol. 106, No. 4)

Indra Sanghi[4]: We have reported some galvanostatic and potentiostatic experiments with zinc[5, 6] and have similar work with cadmium in progress. While the experimental procedure is different from that used by Dr. Croft, some of the basic inferences from the data are very similar. For this reason, I offer the following comments.

In his paper, Dr. Croft has measured currents, at constant overpotential, as a function of time. He found that, after sufficient time had elapsed, current and time were related by an equation of the type $I = F(\phi)\ t^{-1/2}$. From this, he took the oxide to obey the parabolic growth law and interpreted $F(\phi)$ as a function relating the rate of reaction to the overpotential. His basic assumption that the application of the above equation to the currents, *measured after sufficient time,* implies that the oxide grows from the beginning to the end in a parabolic manner is not quite clear, particularly as Charlesby[7] had shown that the rate equation would depend on the time range during which the growth is studied. In fact, he has defined the various thickness ranges in which the logarithmic, the cubic, and the parabolic laws can successively define the oxide layer growth under the same conditions and on the same electrode, the parabolic law taking over when the films have thickened to a definite extent. Moreover, Delahay[8] and Bieri[9] have shown that for the study of the $It^{1/2}$ relationship the first few minutes are very crucial in order to derive any theoretical conclusions as, later on, convection and other effects interfere. Further, Dr. Croft found that currents at equivalent times after application of the same anodic potentials were not generally reproducible. There is then some doubt about the significance of the so-called constancy of $It^{1/2}$ at large values of time.

Our own galvanostatic and potentiostatic studies[10] on Cd, similar to those on Zn,[5, 6] do not lead to a constant I^2t in all cases where the passivation was reached within a few minutes (10 min).

Dr. Croft found that for Cd electrodes $F(\phi)$ has at least one maximum and often two, most probably between 18 and 40 mv overpotential. The significance of this observation is not clear. It is doubtful as to how far these represent actual layer growth. Our potentiostatic measurements reveal that, in KOH concentrations ranging between 1 and 3.5 N, active dissolution occurs during the first 50 mv overpotential. Only when the overpotential is raised beyond 50 mv, a uniform coherent oxide layer starts to thicken, with decrease of current rate. According to our ideas, the predominant layer growth occurs in the current plateau region, clearly revealed by our potentiostatic measurements, at a nearly constant rate over a wide overvoltage range (ca 1400 mv) before oxygen evolution commences. This wide range of study has, perhaps, been overlooked by Dr. Croft.

Essentially, this layer grows as oxide, and only at the oxide/electrolyte interface is it partially converted into $Cd(OH)_2$. The electrode, may, therefore, be pictured as $Cd/CdO/Cd(OH)_2/KOH$ solution.

Dr. Croft's observation that a higher current is required to force the electrode to oxidize at 30 mv than at 97 mv is clearly explained by our potentiostatic measurements which show that in the active dissolution region a higher current is sustainable at a lower overpotential than the smaller currents that can be sustained at high overpotentials in the "pseudo passivation region" of 1400 mv extending from ca -0.7 to $+0.7$ v vs. the Hg/HgO/N KOH half-cell.

For the triangular wave transients, Dr. Croft prepolarized Cd anodically at 1 ma/cm^2 till ϕ rose to 30 mv anodic when the current was turned off and later subjected to triangular waves. Our constant current polarization curves indicate that in 5N KOH (as used by Croft) 1 ma/cm^2 would increase the overpotential by 30 mv in less than a minute; surely it would not suffice to render the electrode truly passive. Moreover, the effect of this very short anodic polarization would be mostly lost during the prolonged period in which the current is turned off and the electrode is allowed to come to the equilibrium potential. Thus, the exact significance of this procedure is not quite clear.

Perhaps it was this factor of observing the Cd surface in the active region and/or after leaving it in the electrolyte on open circuit for sufficient time that was responsible for Croft's observation of only $Cd(OH)_2$ on the electrode surface. On the other hand, x-ray and electron optical observations of Huber and Lake and Casey have clearly shown the presence of CdO.

Similarly, Croft's observation of the change of oxidation rate, from the initial logarithmic rate to a parabolic rate later, may be explained on the basis of Charlesby's theories as indicated above.

Our detailed results are under publication separately.

George T. Croft: Dr. Sanghi is quite correct in the statement that the $F(\phi)t^{-1/2}$ relationship[11] *implies* that the hydroxide grows from the beginning to the end in a parabolic manner. On the other hand, it is clear from Fig. 2 of the discussed paper that the entire growth process is not described by a parabolic law and, in fact, most of the oxide growth does not follow the parabolic law. However, the *current* (rate of growth) does fit a parabolic relation for a time equal to about 70% of the total time of observation.

During this time, the electrode is in such a state that, if it were suddenly forced to oxidize at a constant current density of about 1 ma/cm^2, the electrode potential would go immediately to the oxygen overpotential for the electrode. An electrode in such a state will, for purposes of this discussion, be considered passive or pseudopassive. It is for electrodes in the passive or pseudopassive state that the parabolic law appears best to fit the data. Fixed and sweeping potential measurements of $F(\phi)$ were made, using electrodes in the passive state.

It would, therefore, be more accurate (and perhaps less confusing) to say that Eq. [1] describes the current for a time greater than t_p where t_p is the time required for passivity to set in.

As regards the influence of convection currents in the electrolyte, we found that the current through the electrode (fixed potential) in the passive state was unchanged if the electrolyte was stirred. If one is studying a reaction whose electrode potential is determined by the concentration in solution of the ion undergoing electron exchange at the electrode-solution interface, the true electrode potential can be observed for only short periods of time because, as the reaction proceeds, local concentration changes cause convection currents which give rise to anomalous results.[12] Evidently, we are not studying a phenomenon related to convection because of the long time involved and the failure to observe convection effects directly.

A controversy exists over the products of the electrochemical reaction of cadmium in alkaline solution. Immediate analysis (by x-ray techniques) of reaction products formed prior to onset of passivity and after passivity sets in shows consistently no signs of CdO. $Cd(OH)_2$ is the only reaction product we detected in our laboratory by x-ray techniques. This result is confirmed by the work of Uno Falk,[13] who made a specific search for CdO in an x-ray diffractometer study of cadmium oxidation and reduction *in situ*. He found only Cd and $Cd(OH)_2$. By weighing experiments, he also verified the reaction as $Cd + 2OH^- \rightarrow Cd(OH)_2 + 2e$. Salkind[14] has also shown that only $Cd(OH)_2$ forms during oxidation of cadmium in alkaline electrolytes.

Oxide Nucleation and the Substructure of Iron

E. A. Gulbransen and K. F. Andrew (pp. 511-515, Vol. 106, No. 6)

J. L. Walter and C. G. Dunn[15]: The authors state that the growth of oxide nuclei may be related to the number and arrangement of dislocations in the underlying metal crystal. They also state that the nucleation centers become ordered along definite crystallographic directions when the iron is annealed in impure hydrogen. They conclude that water vapor in the hydrogen is responsible for ordering of the nucleation sites.

Our studies of grain growth in high-purity iron and silicon iron annealed under slightly oxidizing conditions indicate that the nonrandom oxide patterns correlate with the patterns of thermal etch that exist at the surface of grains of certain orientations.

It is known that iron[16] and silicon iron[17] will thermally etch when annealed in atmospheres containing a small amount of water vapor or oxygen. Thermal etching will not occur if the atmosphere is sufficiently pure. Grains having orientations near (100) and (111) at the gas-metal interface thermally etch to striations. The thermal etch steps become curved when the low index planes (100) and (111) are within 1-2 degrees of the plane of a slightly uneven surface.

Fig. 1. 1000 X before reduction for publication

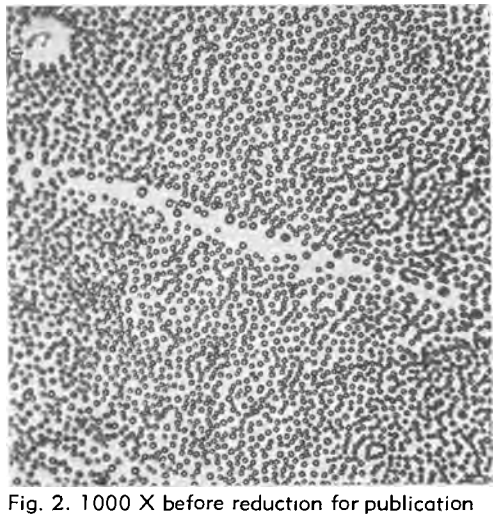

Fig. 2. 1000 X before reduction for publication

The interaction between the thermal etch steps and oxides is clearly seen in Fig. 1 of this discussion. This is a photograph of a sample of high-purity iron annealed for 24 hr at 875°C in tank argon. The oxides formed circular patterns similar to those shown by the authors' Fig. 5. A nearly random distribution of oxides on a grain near (112) is shown in Fig. 2 of this discussion. This was a sample

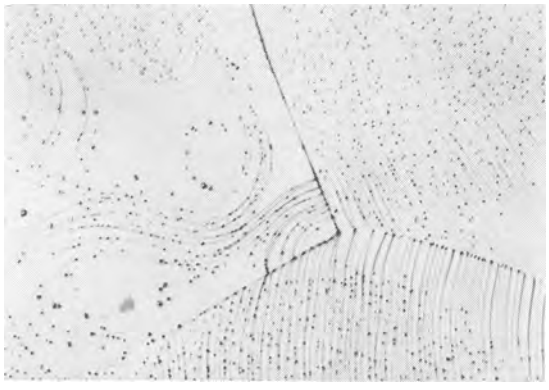

Fig. 3. 500 X

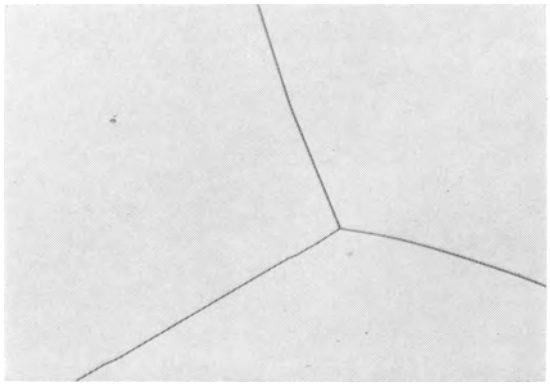

Fig. 4. 500 X

of high-purity silicon iron annealed at 1200°C for ½ hr in tank argon. Grains of this orientation do not show strong thermal etch patterns.

Fig. 3 of this discussion shows a variety of oxide patterns. This sample of high-purity silicon iron was annealed for 1 hr at 1300°C in purified argon. The dew point of the argon was −98°F. All three grains had (100) planes within 3° of the plane of the sample. It can be seen that the oxides, in general, form in rows along the thermal etch steps. Bending of the thermal etch steps at the groove formed by the intersection of the grain boundary with the sample surface is clearly visible. The average number of oxides, measured at the area shown in the photograph, was 9.1 x 10^6/cm^2. After photographing the above area, carbon was added to the sample and it was then electropolished and electroetched in chrome-acetic acid to produce etch pits at dislocation sites. Figure 4 of this discussion shows the same area as is shown in Fig. 3 after the treatment to reveal dislocations. A separate test showed that the amount of carbon added was sufficient to decorate the dislocations introduced by deformation. It is evident that there is no relationship between the oxides at the surface and the dislocations present in the metal since the number of dislocations in the sample was estimated to be approximately 10^4/cm^2.

It is concluded that the pattern of the oxides at the surface of high-purity iron and silicon iron is determined by the nature of the surface discontinuities rather than by the arrangement of dislocations in the underlying metal crystal.

E. A. Gulbransen: The resemblance of thermal etching patterns to oxide nucleation patterns has been pointed out to us by Hoar [18] and by Fraser [19] as early as 1953. We feel that there may be a resemblance between the two phenomena, but we disagree with the conclusions of Walter and Dunn.

Unfortunately, the experiments of Walter and Dunn given here are inconclusive. The spots on their Fig. 3 were assumed to be oxide but were not proven, while the value of 10^4/cm^2 for the number of dislocations in Fig. 4 appear to us to be absurd. Silicon iron is a poor material to use to demonstrate the relationship between dislocations and oxide nuclei. At 1300°C, selective evaporation occurs and a film of silica probably is formed on the surface. Solid phase reactions could occur which would leave residual material on the surface.

Since writing our paper, we now feel even stronger that nucleation centers exist in metals. These centers are involved not only in the formation of initial oxide nuclei but in the formation of oxide whiskers and platelets[20]. These nucleation centers can be oriented by stress, [21] impurities in the metal, and by the nature of the reaction environment.[22] Studies are now being made in our laboratory to elucidate these problems. Whether these nucleation centers can be related to the present concepts of dislocations is problematical at the moment. Most of the present concepts of dislocations have been developed on the basis of mechanical properties and the very complicated phenomena of etch pits.

Rectification by Zircaloy 2 in High-Temperature Water

J. N. Wanklyn and R. Aldred (pp. 529, Vol. 106, No. 6)

P. Cohen[23]: In 1950, the writer experienced the same difficulties reported by the authors, namely electrolytic corrosion of zirconium at 600°F, using 60-cycle current at about 6 v, in heating a zirconium specimen in a heat transfer corrosion test. Failure of the test specimen occurred in 200 hr.

The problem is a general one where electrical heating of zirconium in high-temperature water is required for prolonged periods. In seeking a solution to the problem, the effect of frequency on the electrolytic corrosion of zirconium in NaCl solutions was investigated at room temperature. The corrosion efficiency decreased rapidly and monotonically with increasing frequency, reaching very low values in frequency range 400 to 1000 cycles. Since it could be most readily procured, a 400-cycle 50-kva aircraft type generator was obtained. Coupled with an available 3000-amp 100-kva transformer, the 400-cycle generator was used in subsequent tests of the same type.[24] Actually, 1000-cycle motor generator sets of the size required for this type of work are also available and may be more satisfactory.

On an Ion-Exchange Property of Manganese Dioxide

A. Kozawa (pp. 552-556, Vol. 106, No. 7)

Alfons Krause[25]: In his investigation, Kozawa found an exchange between zinc ions and H+ ions on the surface of MnO_2, which he explained as occurring through hydration of the surface; however, not every MnO_2 is suitable for the exchange. It is well known, and also mentioned by Kozawa, that MnO_2 cannot be hydrated when annealed at an excessively high temperature, whereas less annealed samples do add water, in spite of being practically water free. We are dealing here with active and inactive MnO_2, and differences in structure have not been considered by Kozawa in his exchange-scheme. According to this over-simplified scheme, each oxide theoretically should be able to add water, regardless of whether or not this is possible in practice.

In my opinion, these differences can be accounted for by the radical structure[26] which accounts for the active state, i.e., the active sites of a metal oxide. The actual model of the normal structure of MnO_2 is not so important, but rather that only two types of radicals may be found in active MnO_2, namely, R≡Mn- and R≡Mn-O-.[27] The latter is an electron acceptor and a potential anion. It also can be considered as a Lewis acid. The radical R=Mn-, however, is an electron donator and a possible cation. The radicals disappear only by strong annealing due to a "healing" of the MnO_2 lattice, thus making the oxide practically inactive:

R≡Mn- -O-Mn≡R → R≡Mn-O-Mn≡R (schematic)
(active) (inactive)

The radical MnO_2 is enabled to add H_2O molecules as expressed in the following equation:

$$R{=}Mn- + H_2O + -O{+}Mn{\equiv}R \rightarrow 2R{\equiv}Mn\text{-}OH$$

The resulting hydroxide reacts further with ammoniacal zinc oxide solution which is, in fact, an exchange of hydrogen for zinc:

$$2\,R{\equiv}Mn\text{-}OH + [Zn(NH_3)_2Cl_2] \rightarrow$$

$$2\,R \equiv Mn\text{-}O\frac{Zn}{2} + 2\,NH_4Cl \qquad [1]$$

For nonradical, i.e., inactive MnO_2, the equations cannot be applied.

The exchange process, incidentally, may be considered in another way, namely that the MnO_2 assumes the function of a chromatographic column. Here, also, the radical structure of MnO_2 is essential as was shown previously for Al_2O_3.[28] Through the action of ammonia, the chromatographic column (MnO_2) assumes a negative charge, whereupon zinc ions can be taken up. This is, in fact, an inhibited coagulation of the chromatographic MnO_2[28]:

$$(R{\equiv}Mn\text{-})_2 + (-O\text{-}Mn{\equiv}R)_2 + [Zn(NH_3)_2Cl_2] + 2H_2O \rightarrow 2\,R{\equiv}Mn\text{-}OH + 2NH_4^+ + 2\,(O\text{-}Mn{\equiv}R)^- + Zn^{++} + 2\,Cl^- \rightarrow Zn(O\text{-}Mn{\equiv}R)_2 + 2\,R{\equiv}Mn\text{-}OH + 2NH_4^+ + 2Cl^- \qquad [2]$$

Akiya Kozawa: It seems reasonable to assume that the ion-exchange reaction mostly takes place only on the surface of MnO_2, since the ion-exchange reaction attains at a equilibrium in a short time and it is reversible on *p*H change of the solution (Fig. 9 of the paper). On the surface of MnO_2, there exist unsatisfied chemical bonds which might correspond to "Radicals," R≡M- and R≡M-O- mentioned by Professor Krause. The final surface structure of the MnO_2 with the adsorbed zinc ion, $(R{\equiv}Mn\text{-}O)_2Zn$, proposed by Professor Krause [*See* Eq [1] and [2]; I think there is a mistake in Eq. [1], which should be $2R{\equiv}Mn\text{-}OH + Zn(NH_3)_2Cl_2 \rightarrow (R{\equiv}Mn\text{-}O)_2Zn + 2NH_4Cl$], is quite similar to that shown in Fig. 10. Difference between the two mechanisms is as follows: as the surface of MnO_2 before zinc adsorption, he is considering R≡Mn-OH resulting from radicals R≡Mn-O- and R≡Mn- by adding H_2O molecules, and I am considering $R{\equiv}Mn\text{-}OH_2$ by a simple hydration. I do not have experimental results to distinguish between the two. It is, however, well known that metal ions hydrate in aqueous solutions, and so it would be permissible to consider a hydration of manganese ions on the surface of ionic crystal of MnO_2 in an aqueous solution.

Professor Krause considers that the active sites of MnO_2 surface, namely the radical structures, are essential for the ion-exchange adsorption. However Fig. 6 shows that the amount of the ion-exchange (zinc adsorption) is proportional simply to the surface area measured by gas adsorption (B.E.T. method), regardless of those samples, active MnO_2 or inactive MnO_2, which were prepared by annealing the active MnO_2 below 450°C. According to my experimental results, the saturate adsorption of zinc ion in Fig. 8 corresponds nearly to the monolayer coverage, that is, every two manganese atoms on the surface of MnO_2 adsorb one zinc ion as shown in Fig. 10. From these facts only active sites would not be essential, but rather all the surface of MnO_2 may be responsible for this zinc adsorption.

The Significance of the Flade Potential

M. J. Pryor (pp. 557-562, Vol. 106, No. 7)

H. H. Uhlig[29]: Dr. Pryor's model for the passive film on iron introduces another assumed structure additional to structures he quotes assumed previously by others. Unfortunately, for the present state of knowledge in this field, any of these models is not readily proved or disproved. There are only fragments of circumstantial evidence which support one model over the other, but as yet no critical experiment has been performed or offered.

We have come to accept an adsorbed film model of the passive film over all others because it appears to fit in with the greatest number of observations. These observations have been summarized in a previous paper.[30] Among the important lines of evidence are that those metals and alloys (transition group) best able to chemisorb their environment are also those that tend to be passive. Furthermore, the alloying relations leading to optimum catalytic

[29] Corrosion Lab., Dept. of Metallurgy, Massachusetts Institute of Technology, Cambridge 39, Mass.

[30] H. H. Uhlig, *Z. Elektrochem.*, **62**, 626 (1958).

properties which depend on chemisorption are similar to those leading to optimum passivity. In addition, the calculated free energy of formation of the chemisorbed passive film on iron is close to the observed value based on measured heat of adsorption.

On the other hand, Dr. Pryor's model suggests that all metals on which semiconducting oxides form should exhibit passive properties. This is not the case. Copper on which a p-type Cu_2O film forms, or zinc on which an n-type ZnO film forms, are not passive in nitric acid or in any aqueous environment in the same sense as are iron and chromium.

The formation of ferric ions on corrosion of passive iron in sulfuric acid is readily explained by local action cells of which the adsorbed passive film represents a large cathodic area in contact with exposed iron at very small pores, in accord with measurements of porosity in the passive film by Vetter.[31] High current densities established at the small anode sites account for corrosion products of valence 3 rather than, 2, an effect which is readily observed during anodic polarization of iron in sulfuric acid employing increasing current densities.

M. J. Pryor: Professor Uhlig's comments are representative of an entirely different view as to the cause of passivity of metals (i.e., adsorption as opposed to three-dimensional film formation). These different views on the nature of passive surfaces must, of necessity, lead to different interpretations of the meaning of the Flade potential. Since these opposed views on the mechanism of passivation are well known, it appears idle to reiterate them in detail at this time.

In order to explain the Flade potential, it previously has been deemed necessary to assume the initial existence of either a two-phase passivating oxide film or an adsorbed passivating layer of some type. Neither concept has received any significant experimental support from structural studies of passive iron surfaces. Accordingly, it appears to be more logical to develop an explanation of the Flade potential based on the breakdown of a crystallographically single-phase passivating γ-Fe_2O_3 film. The present work shows that such a model adequately can explain the Flade potential, provided that a change in defect structure with thickness is assumed. Such changes in defect structure with thickness have been suggested previously for sulfide films on silver.[32]

Professor Uhlig believes that our paper implies that all metals which carry semiconducting oxides should develop passivity as, for instance, by immersion in concentrated nitric acid. Such a hypothesis is nowhere claimed in the article nor is such an implication intended. Instead, we have pointed out that the Flade potential observed on iron can be related well to electrochemical reactions involving protective γ-Fe_2O_3 films having a p-n defect structure. We further have pointed out how such a film structure may develop during the passivation of iron.

In order for a semiconductive surface film to confer passivity to a metal, it is necessary for the film to have either a high electronic resistance, a high ionic resistance, or both. Furthermore, the surface film must be nonporous and compact. If such is not the case, as for instance with copper which forms low-resistance semiconductive films, then passivation in the normal sense will not occur. It is also significant to note that such metals do not normally exhibit a Flade potential.

It appears that one of the advantages of the present model lies in its ability to cover aspects of the Flade potential which have received only cursory attention in the past. For example, most previous investigators have been concerned primarily with measurement of the potential itself. Rather less attention has been directed to the duration of the potential arrest. It is of interest to note that repeated anodic passivation and activation of an iron specimen in sulfuric acid results in a steady and quite spectacular increase in the duration of the Flade potential arrest. This increase in the duration of the potential arrest does not appear to be particularly sensitive to the time for which the specimen is permitted to remain in the active state. Furthermore, differing means of interrupting the polarizing current appear greatly to influence the length of the Flade potential arrest. These observations are difficult to rationalize on the basis of electrochemical reactions unrelated to the defect state of the surface oxide films. They also tend to confirm the general validity of the approach contained in our article.

Peter F. King[33]**:** Dr. Pryor is to be congratulated for his valuable attempt to explain the Flade potential. His explanation is more satisfying than some of those which have been attempted in the past. The semiconductive oxide approach has some things in its favor, but there are also some shortcomings. One of these is the small amount of reaction necessary to bring about passivity, which is not sufficient to produce an oxide film 50Å thick. It is true that the argument may be made, and may be valid, that the onset of passivity has never been studied on an absolutely clean metal surface and that the small amount of reaction usually measured may, indeed, be only the growth of the excess oxide ion concentration necessary in Dr. Pryor's theory. Even if oxide is not present initially, oxidation of iron and its alloys in passivating media occurs in an apparently logarithmic fashion with time, as shown by the recent work of Brasher[34] and Stern.[35] It is likely that this oxidation results in defect oxides of the type postulated by Dr. Pryor. However, we do not feel that this oxide determines the Flade potential, as it is only the result, not the cause, of passivity.

We contend that the cause of passivity is a layer of chemisorbed oxygen produced on initial immersion of the metal into the passivating medium. One would expect, from (*a*) the approximate equivalence of the Flade potential obtained on iron after anodic passivation with the passivation potential,[36] and (*b*) the equivalence of the thickness of the film

on passive iron at the Flade potential[37] to the amount of reaction which occurs during the passivation process,[38] that the superior oxide decays first during activation. The result (just before activation occurs) is a film which is almost equivalent to the film formed during the passivation process.[39]

The major argument in favor of the conclusion that chemisorbed oxygen is the cause of passivity in the case of iron and the iron-chromium alloys in aqueous environments, apparently overlooked by Dr. Pryor, is the equivalence of the experimentally observed Flade potential with that calculated, albeit roughly, from the heat of adsorption of oxygen on iron.[40] It is hoped that similar comparisons can be extended to other cases, such as the alloys of iron and chromium, where the Flade potentials have been measured but the heats of adsorption are not yet available.

M. J. Pryor: Dr. King's discussion is appreciated and raises several important points. It is first worth while to point out that the interpretation of the Flade potential advanced by Professor Uhlig and Dr. King[41] and that advanced by the writer have one important feature in common. Both interpretations involve the reduction of oxygen association in some manner with the passive iron surface. The main disagreement centers around the manner in which this oxygen is disposed on the passive surface (i.e., as an adsorbed layer or as part of a nonstoichiometric oxide film) and whether this oxygen per se is responsible for passivity.

Several factors, as pointed out in the reply to Professor Uhlig's discussion, favor the view that the oxygen is associated with a nonstoichiometric oxide film. These include the sensitivity of the length of the Flade potential arrest to the manner in which the passivating potential is interrupted. If, for instance, passivation of iron is achieved anodically in 1.0*N* sulfuric acid at a potential of +0.8 v (hydrogen scale) and the polarizing voltage is interrupted, then a characteristic length of Flade potential arrest may be determined. This duration depends on the time of anodic polarization, the voltage applied, and the specimen history. If the specimen is polarized for the same time at 0.8 v and the polarizing potential is then reduced smoothly and quickly to 0.6 v after which the polarizing voltage is again interrupted, the length of the Flade potential arrest is greatly shortened. In extreme conditions, the arrest may be virtually eliminated. Such an observation fits well with the concept of a p-n layer of γ-Fe_2O_3 in which the distribution of p-type defects is field stabilized. It is also a difficult observation to explain on purely electrochemical grounds unrelated to the defect structure of a three-dimensional surface film.

While the agreement between the calculated "heats of absorption" for the $O \cdot O_2$ layer referred to by Dr. King and the Flade potential[41] is impressive, it should be realized that there is a very broad assumption involved in these calculations. In the absence of supporting data, application of results of Tompkin[42] on chemisorption of dry gaseous oxygen to the rather specialized $O \cdot O_2$ layer, believed by Uhlig and King to exist under passivating conditions, appears to be of uncertain technical validity. Unless this extrapolation can be experimentally justified, it should be realized that the agreement between the calculated heats of adsorption and the Flade potential is speculative in nature.

Surface to Volume Considerations in the Palladium-Hydrogen-Acid System

J. P. Hoare (pp. 640-643, Vol. 106, No. 8)

Gilbert W. Castellan[43] and Robert J. Fallon[44]: We believe that the results obtained in this investigation can be given a simpler interpretation than the one proposed in the article. We have made an extensive investigation [45] of the rate of entrance of hydrogen into palladium in sulfuric acid solution. This investigation shows quite clearly that the rate-determining step is transport of molecular hydrogen through the diffusion layer of aqueous solution at the surface of the metal. The subsequent steps, dissociation at the surface, penetration of the metal skin, and diffusion in the bulk metal, are comparatively fast. We also noticed that the length of the 0.050-v plateau is inversely proportional to the rate of increase of H/Pd with time. We developed the rate equation. It turns out that the rate is a function of area-to-volume ratio, the geometry of the specimen, and the rate constants for the several steps. The author finds that the length of the 0.050-v plateau is a linear function of volume-to-area ratio. This is at best only qualitatively in agreement with the rate equation. There are two important reasons for this: the author used three different geometries, bead, foil, wire; and we believe that he did not give sufficient attention to the stirring in the solution.

Three points in the author's interpretation need further discussion: (*A*) slowness of penetration of the metal skin; (*B*) the irregular "step" type of curve reported for the relative resistance vs. time; (*C*) the "overshoot" of the α-plateau.

(*A*) Skin penetration: If penetration of the metal skin were the slow step, slow compared to transport to the surface, and compared to dissociation, then a layer of H atoms should accumulate on the surface. This surface concentration of H atoms should approach that which is appropriate to the β-alloy and the potential of the electrode should be zero and not 0.050 v.

(*B*) In over 400 experiments on the measurement of relative resistance vs. time, we never observed the step-wise behavior reported by the author. We believe that the reason for this is that in our experiments the cell was small, the wire was a simple loop or helix, the hydrogen flow produced good stirring and established a definite diffusion layer at the wire surface. In the author's experiments the

[42] Quoted by B. Trapnell, "Chemisorption," p. 215, Academic Press Inc., New York (1955).

[44] Institute of Molecular Physics, University of Maryland, Baltimore, Md.

[45] R. J. Fallon and G. W. Castellan, *J. Phys. Chem.*, **64**, 4 (1960).

cell is long, 19 cm, and the wire is stretched diagonally across the cell. He says that the flow rate of hydrogen was approximately constant but gives no clue as to where the hydrogen was introduced, or how fast or steady the flow rate was. We have not observed the plateau at about $R/R_0 = 1.065$ reported by Flanagan and Lewis[46] and by the author; however, in our experiments the rates of absorption were usually much faster and our resistance vs. time curves do show a change in slope in this region. The typical dependence of R/R_0 which we observe[45] is quite similar to that reported in Fig. 2 of Flanagan and Lewis.[46]

If the flow rate of the hydrogen is constant as the author claims, and stirs the solution well enough to establish a definite diffusion layer at the metal surface, then we can see no reason for the step type of curve which he observes in the relative resistance vs. time.[45] On the other hand, if the stirring is erratic, such an irregular curve should be observed.

(C) The "supersaturation" or "overshoot" of the α-potential: If, as the α-alloy reaches the saturation limit, the supply of hydrogen is restricted (due to poor stirring), then the hydrogen enters very slowly and the β-phase has a longer time in which to nucleate. The supersaturation which occurs before the β-alloy forms is small and no overshoot is observed. If, on the other hand, an ample supply of H_2 is maintained as the α-limit is reached, the H_2 enters quickly and the supersaturation reaches a noticeable value before the β-phase nucleates. This is exactly analogous to supercooling. If the melt is cooled very slowly, supercooling is less likely to occur; if it is chilled rapidly, it may well supercool. We observe that the overshoot is consistently more pronounced for smaller wires. This supports the above explanation. The author observes the overshoot in the exact circumstances where the stirring is likely to have been very good—the open helix of wire. We do not believe that an extraordinary surface film is responsible for this behavior. Also, we have observed the overshoot too consistently for it to be an accident in preparation.

J. P. Hoare: Although Castellan and Fallon have done very fine work, a few comments may be in order. As one knows, when a palladium sample is immersed in a water solution of sulfuric acid, the surface will be covered with adsorbed water molecules. When molecular hydrogen is bubbled through the solution, some of these molecules will enter the outer Helmholtz plane[47] which is the closest approach of a particle to the surface without being physically adsorbed. Then, the hydrogen will be adsorbed, probably by complexing with the adsorbed water to give hydrogen atoms adsorbed on the surface. These will then be dissolved in the metal. The concentration of particles on the surface will contribute to the magnitude of the potential. Castellan and Fallon suggest that, if the solution of hydrogen by palladium is the slow process, one must have a build-up of adsorbed hydrogen atoms on the surface and a potential of 50 mv would not be observed. This may not be the case since the build-up of hydrogen concentration may take place in the double layer as molecular hydrogen, if such a build-up of hydrogen exists. It may be possible that the H_2 in the double layer will not be adsorbed until certain surface conditions are met which are controlled by the solution process of hydrogen entering the palladium metal.

Castellan worked with very small diameter wires. The reported work by Hoare indicated that the step-wise form of the charging curves was most pronounced on wires of larger diameters. The plateau at $R/R_0 = 1.065$ is very short on curves taken from wires of small diameter and might well be missed. A step-wise curve can occur if the resistance is a function of the distortion in the palladium lattice which is a function of the way in which the β-phase nucleates. If the β-phase nucleates by the sudden merging of domains of the β-phase, a series of steps may be reflected in the resistance-time curves. Fedorova and Frumkin[48] have arrived at similar conclusions.

As far as the supersaturation effect is concerned, it has been this author's experience that the overshoot only occurs on electrodes which have been cleaned and activated without additional mechanical stress being applied in the mounting of the electrode. This is the case for Castellan's work. If, however, as was done here, the wire, after being prepared, is wound about a polyethylene form or stretched in mounting, the overshoot on the charging curve is not found. This suggests that a film similar to that proposed in the author's paper has been broken up by the mechanical stress and the palladium surface is exposed. Only if the film is intact, as with Castellan's work, will the overshoot be observed since then the palladium surface will not be exposed until the film has been dissolved. It is the solution process of the film that causes the overshoot in the charging curve.

The Relation of Gas Composition to Current Efficiency in an Aluminum Reduction Cell

T. R. Beck (pp. 710-713, Vol. 106, No. 8)

Jack D. Hamlin[49]**:** I have read with great interest the development presented by Dr. Beck. Endeavoring to understand fully his development, independent calculations have been made, and a development results which leads to somewhat different conclusions.

Allow me to attempt to make my point by considering the electric current as two components. First, there is that fraction of the total current which is the current that is a part of the electrochemical reaction. The second part of the current is that fraction of the total current which is not taking part in the electrochemical reaction. This part is electronic conduction, or in an analogous way, it is current that is shunted around the electrochemical path.

Now consider only the fraction of the current that takes part in the electrochemical reaction. In

[46] T. B. Flanagan and F. A. Lewis, *Trans. Faraday Soc.*, 55, 1409 (1959).

[47] D. C. Grahame, *Chem. Rev.*, 41, 441 (1947).

[48] A. Fedorova and A. Frumkin, *Zhur. Fiz. Khim. USSR*, To be published.

[49] Development Engineering, Reynolds Metals Co., P. O. Box 191, Sheffield, Ala.

terms of the author's Eq. [1], this amount of current produces 4 moles of aluminum and n moles of carbon dioxide. Subsequentially, $\left[\frac{2x}{3}\right]$ moles of aluminum are reoxidized by reaction with CO_2—from Eq. [2]. A point I wish to emphasize is that if n moles of CO_2 are produced initially then 4 moles of aluminum are also produced initially.

Now consider the fraction of the current that did not take part in the electrochemical reaction. Let us assign a value to this fraction of $\frac{Z}{100}$. We can now ask the question: If all of the current had taken part in the electrochemical reaction, how much aluminum would have been produced initially? The answer is:

$$4 \div \left(1 - \frac{Z}{100}\right), \text{ moles}$$

I, therefore, offer that if n moles of CO_2 actually are produced initially as expressed in Eq. [1] and used in Eq. [6b] then, likewise, 4 moles of aluminum are initially produced and, consequently, Eq. [6a] becomes,

$$\% \text{ CE} = 100\left[\frac{4 - 2/3x}{4}\right]\left[1 - \frac{Z}{100}\right]$$

If x is then solved for in this equation and equated to x as solved for in Eq. [6b], an equation for current efficiency results that is different from that presented in the paper.

$$\% \text{ CE} = \left(\frac{y - n + 6}{3}\right)\left(\tfrac{1}{2}\% \text{ CO}_2 + 50\right)\left(1 - \frac{Z}{100}\right)$$

or

$$\% \text{ CE} = k(\tfrac{1}{2}\% \text{ CO}_2 + 50)$$

Using the data presented by Dr. Beck, the corresponding values of k are as follows:

Anode bake temp, °C	k
959	1.01
1,070	0.98
1,150	0.96

T. R. Beck: I am grateful to Mr. Hamlin for pointing out that my derivation does not properly account for electronic conduction. My assumption that electronic conduction and loss of aluminum or other reduced species to the lining or atmosphere were exactly equivalent was incorrect. I wish to amend my derivation to properly include electronic conduction.

Assume that Z is the per cent loss of equivalent aluminum by the mechanisms presented in the paper: (a) escape of sodium from cell; (d) formation of sodium and/or aluminum carbide with lining; (e) oxidation of aluminum during tapping. Assume Z' is percentage of current carried by mechanisms: (b) direct oxidation of reduced species at anode; (c) electronic conduction. In Eq. [4a]:

$$\frac{A}{A + B} = \left(1 - \frac{Z'}{100}\right)$$

$$A = 4$$
$$C = 2/3\,x$$
$$D = 4\frac{Z}{100}$$

Eq. [6a] therefore becomes:

$$\% \text{ CE} = 100\left[\frac{4 - (2/3)x - 4\,Z/100}{4}\right]\left(1 - \frac{Z'}{100}\right)$$

Eq. [6c] becomes:

$$\% \text{ CE} = \left[\frac{6 - n + y}{3}(50 + \tfrac{1}{2}\% \text{ CO}_2) - Z\right]\left(1 - \frac{Z'}{100}\right) \text{ and}$$

Eq. [10] becomes:

$$\% \text{ CE} = [g(50 + \tfrac{1}{2}\% \text{ CO}_2) - Z]\left(1 - \frac{Z'}{100}\right)$$

Although not necessarily true for all aluminum cells, there are good reasons for believing that electronic conduction was not significant in the 10,000-amp experimental cell. Electronic shunt losses can be divided into several types: 1. losses through faulty insulation exterior to the bath; 2. electronic conduction through the bath; 3. short circuits between anode and cathode by metal splashing; 4. electronic conduction between anode and cathode through accumulated carbon "dust," sloughed from the anodes, floating on the bath surface.

It is certain that there were no significant shunt losses exterior to the bath for the experimental cell, although these have been known to occur in commercial cell lines. The work of Frank and Foster[50] indicates that electronic conduction is not significant through cryolite melts. There were no indications of short circuits by metal splashing in the experimental cell. This, however, can occur in large, high amperage, commercial cells in which large electromagnetic forces acting on the metal pad are developed. It is doubtful that there was significant shunt loss through carbon dust because there was only a small amount in the cell, its conductivity was poor because it was loosely packed, and the carbon lining was insulated from it by a layer of frozen cryolite or "ledge." There was noticeably more "dust" in the cell when using the low-bake temperature anodes. If electronic conduction through the dust were significant, then Z' would have been larger for the low-bake temperature and the value of k calculated by Mr. Hamlin would be smaller, whereas the reverse was true.

It should be pointed out that error in metering of cell current also would be reflected in the value of Z', making it either plus or minus. The shunt and ammeter for the experimental cell were calibrated and known to be accurate to $\pm\frac{1}{2}\%$.

Whether direct oxidation of reduced species at the anode occurs is not known, so it is not certain that Z' was zero. On the other hand, there was considerable direct evidence that Z was not zero. As was stated in the paper, pockets of sodium metal were frequently found condensed in the cell "crust."

[50] W. B. Frank and L. M. Foster, *J. Phys. Chem.* **61**, 1531 (1957).

Metallic sodium was also found in the carbon lining, and it has been observed in linings of commercial cells. It is well known that sodium and/or aluminum carbide is found in used cell linings.

Since there was direct evidence that Z was greater than zero and there was no evidence that Z' was not zero, I believe that my analysis of the data is correct as it stands.

Influence of Silicon on the High-Temperature Oxidation of Copper and Iron

J. W. Evans and S. K. Chatterji (pp. 860-866, Vol. 106, No. 10)

J. L. Meijering[51]: The authors conclude that the diffusivity of oxygen in Fe is much greater than is commonly supposed. However, their results agree satisfactorily with subscale measurements[52] on iron containing Al, and only the large discrepancy with respect to the measurements of Bramley, *et al.*,[53] is apparent. The latter authors treated their deoxidizing experiments with Fe containing 0.09% oxygen by weight as if the oxygen was homogeneously dissolved, which led to a far too small value of the diffusion coefficient D_o. It now is certain that the solubility c_o is quite small, and then the experiment in footnote 53 can be shown to lead to a value of about 1.5×10^{-11} cm²/sec for c_oD_o at 1000°C,[52] if c_o is expressed as atomic fraction. This is a third of the value deduced from the internal oxidation experiments with Fe containing 1% Al and, in view of the various uncertainties, this must be considered as satisfactory.

For comparison, we roughly calculated c_oD_o from the 998°-run of the authors, using the equation

$$c_oD_o = x\,(x + x_s)\,c_{Si}/t,$$

where x_s is the thickness of the metal layer converted into scale. This equation is valid only for small values of c_{Si}, the atomic fraction of silicon in the alloy. It is readily deduced from section 3 of footnote 54 (see below), if one assumes that each Si atom captures only 2 oxygen atoms in the subscale. This is not certain, and the proportionality of x_s with $\sqrt{t}$ (assumed in deriving the equation) is also not well fulfilled. Nevertheless, the value 3×10^{-11} cm²/sec found from the subscale thickness x and the weight increase after 5 hr at 998°C can be said to be in agreement with the results of footnotes 52 and 53.

J. W. Evans and S. K. Chatterji: We are grateful to Dr. Meijering for pointing out that our results relating to the diffusivity of oxygen in iron confirm his own experiments with aluminum in iron, and those of Bramley, *et al.*, which he has corrected, and sincerely regret not referring to his work.

Although we were aware that the oxygen solubility assumed by Bramley was probably too high (*see* Kitchener, Bockris, Gleiser, and Evans[55]) and, therefore, led to a too low value for the diffusivity, we see that our original remarks did not imply this.

We would like at this time to correct an error in the orignal paper. In the list of References, Ref. 18 should read: J. W. Evans and S. K. Chatterji, *J. Phys. Chem.*, **62**, 1064 (1958).

On the Measurement of the Temperatures of Unenclosed Objects by Radiation Methods

A. G. Emslie and H. H. Blau, Jr. (pp. 877-880, Vol. 106, No. 10)

Tibor S. Laszlo[56]: This paper is a valuable contribution to an old and still controversial problem. There is complete agreement on the fact that the dual color pyrometer operates on the assumption that the emissivity does not change with the change in wave length. The controversy begins where the validity of this assumption is considered. There are several reported data on dual color pyrometry with remarkably good accuracy (± ¼% at 1700°K). It is possible that in these cases the experimental conditions were such that the fundamental assumption was valid. The value of the present work lies in the fact that it furnishes information on the magnitude of error when the emissivity does change with wave length.

This writer cannot but completely agree with the authors' conclusion that the emissivity has to be *measured* at the temperature where the optical pyrometer is to be used. The paper quotes an emissivity measurement method (Ref. 5) at high temperatures, using the solar furnace, which was suggested by the writer. In the frame of the paper, however, the procedure appears too difficult to perform. The method, as described briefly in the following, is really rather simple.

For each solar furnace there is a fixed concentration factor, i.e., the ratio between normal incident solar radiation intensity and heat flux at the focal zone. This factor can be determined by the method presented in the reference. Once this factor is known, the emissivity determination consists of a normal incident solar flux measurement using a pyrheliometer and of a simultaneous brightness temperature measurement at the sample in the focal zone using an optical pyrometer. From the incident solar flux, the flux at the focal zone can be calculated and, from this, the black body temperature of the sample. Knowing both the black body and brightness temperature, the emissivity can be calculated.

A. G. Emslie and H. H. Blau, Jr.: A number of methods have been suggested for temperature measurement in imaging furnaces. The method[57] which we have found most suitable involves direct measurement of the spectral reflectance of the hot specimen. Both the absolute temperature of the specimen and the spectral reflectance (and hence spectral emittance) can be determined from measurements of three intensities: the monochromatic intensities emitted and reflected by the hot speci-

[56] Research and Advanced Development Div., Avco Manufacturing Corp., Wilmington, Mass.

[57] H. H. Blau, Jr., "Measurement of Flux Emittance and Related Properties," *Proc. Int. Symposium on High Temperature Technology, Stanford Research Institute, 1960.*

men, and the monochromatic intensity incident on the hot specimen. The measurements can be performed with an optical pyrometer or other suitable instrument. This method requires no assumptions of equality of spectral and total emittance or of absence of conductive and convective heat losses by the sample as would seem to be the case with Laszlo's method.

Herbert W. Newkirk[58] and **B. B. Brenden**[59]: We have the following remarks regarding Emslie and Blau's article.

The basic principle of the two-color pyrometer is that, when the ratio of the radiant intensities from the sample at two wave lengths is determined, the unknown emissivity is eliminated. Eq. [6] assumes at least gray-body conditions, that is, the emissivities at the chosen wave lengths are equal. In general, the gray-body assumption over a wide spectral interval is not valid. However, narrower spectral intervals can usually be found for incandescent solids for which the gray-body assumption is valid. The choice of the wave-length interval will be determined by the amount of radiant energy available and the sensitivity of the ratio to temperature changes.[60] It is considered good practice in two-color pyrometry to make measurements of spectral emissivity for the material in question in order to select the optimum spectral interval.[61]

It is highly unlikely that the ratio of the emissivities for any incandescent solid at the two wave lengths can be greater than 1.2. In the case of tungsten, for example, the ratio of emissivities is 1.1 at 3600°K with $\lambda_1 = 0.47\ \mu$ and $\lambda_2 = 0.65\ \mu$. Thus, the error in the determination of the true temperature using a two-color pyrometer cannot be greater than 2% at this temperature. This accuracy is equal to or considerably better than that attained with conventional pyrometers. Furthermore, two-color pyrometers offer the advantage of providing an electrical output which can be used to drive a recorder, operate control instruments, etc.

Finally, two-color pyrometers are much less affected by smoke, fumes, and emissivity changes during experiments than single-color pyrometers or total radiation pyrometers. Work in this laboratory[62-64] has indicated that the increased accuracy, automation, freedom from emissivity effect, and a temperature limit above 4000°K are features of two-color pyrometers which can be used advantageously in many areas of high temperature research.

A. G. Emslie and H. H. Blau, Jr.: Experience shows that the two-color pyrometer can be used for accurate temperature measurement in special cases such as those quoted by Newkirk and Brenden. The conclusions given in our paper are nevertheless strictly true and serious errors are often introduced if equal emittance at the two wave lengths is assumed. For example, the ratio of emittances at 0.46 and 0.65 μ is 1.97 for pure copper. This difference would lead to a temperature error of 5% at 1000°K. In fact, gray-body behavior has been observed to be the exception rather than the rule.[65]

The Action of Nickel and Cobalt in Electroluminescent Zinc Sulfide Phosphors

P. Goldberg (pp. 948-954, Vol. 106, No. 11)

W. Lehmann[66]: (*A*) What do you know about the mean particle sizes and the particle size distributions of your samples? We know now that they may have marked influence on the voltage dependence of electroluminescence.

(*B*) If the measurements of the voltage dependence of electroluminescence of your samples had been extended to more decades of the brightness, could not a deviation from either equation [i.e., $n = 0$ and $n = 1$ in $L = AV^n \exp(-b/V^{1/2})$] be expected?

Paul Goldberg: (*A*) It is unlikely that particle size effects or size distribution effects exert any influence (in these experiments) over the changes in voltage dependence of electroluminescence occasioned by the incorporation of nickel or cobalt. All of the specimens in Fig. 4 and 5 of the paper under discussion, including the control, were prepared under identical thermal conditions from separate portions of a single, previously crystallized phosphor. The modifier was incorporated by solid state-diffusion. No data exist as to size or distribution of sizes of the materials in question. It is improbable, however, that the diffusion process, which occurred at 800°C, changed the size or distribution within the family of phosphors. From previous experience with similar preparations, the mean particle size probably lies between 20 and 30 μ. The distribution of sizes is most likely log-normal.

(*B*) It is possible that the voltage dependence of electroluminescence could change were the measurements extended outside the reported range. The burden of the data in Fig. 4 and 5 is to show that phosphors with varying modifier concentrations, when measured in the same range of applied field, exhibit a change in functionality within the group. We have not tested whether this change in functionality occurs in ranges of applied field not covered in the original publication.

Oxygen Overpotential in Molten Carbonates

George J. Janz, Francisco Colom, and Fumihiko Saegusa

Department of Chemistry, Rensselaer Polytechnic Institute, Troy, New York

ABSTRACT

The overvoltage of the oxygen evolution reaction on Pt electrodes has been measured in a ternary mixture of molten Na_2CO_3-Li_2CO_3-K_2CO_3 with current densities up to 50 ma/cm^2 and temperatures up to 1000°C. Two well distinguished regions in the overvoltage-log current density relation are observed. At current densities less than 1 ma/cm^2 the marked dependence of the oxygen overpotential on the composition of the gas flow and on temperature are characteristic of a concentration-type overpotential most probably due to the build-up of oxide-ion in the melt. In the range of about 1-50 ma/cm^2, the oxygen overpotential seems activation controlled. From the temperature coefficient of the overpotential, a value for the energy of activation for oxygen evolution of 10.4 ± 1.1 kcal mole^{-1} is obtained. The role of the platinum electrode as an oxygen ion electrode in the over-all process corresponding to the oxygen evolution reaction:

$$CO_3^{-2} \rightarrow CO_2 + O + 2\bar{e}$$

is discussed.

Studies of the oxygen overpotential in molten salts have been quite limited. Agar and Bowden (1) have investigated oxygen evolution on Ni and Pt electrodes in fused NaOH up to 340°C, whereas in molten nitrates a study of this process at temperatures up to 250°C has been reported by Karpatscheff and Patzug (2). Some measurements on the oxygen overpotential for sulfates, silicates, phosphates, and carbonates dissolved in fluorides, and for a Na,K/CO_3 mixture at 700°-900°C have been reported by Flood and Forland (3). The present communication describes the results of further measurements of the oxygen overpotential in molten carbonates. A ternary mixture, Li, Na, K/CO_3 (m. 403°C) was used to extend the temperature range for the studies over a much wider range. Platinum was selected for this study since results of emf measurements of oxygen ion activity in Na,K/CO_3 (4) and Na/SO_4,CO_3 (5) mixtures had confirmed that the CO_2-O_2, Pt electrode behaves as an oxygen-ion electrode in these melts.

Experimental

Chemicals.—Sodium, potassium, and lithium carbonates (Reagent Grade) were recrystallized, and dried at 500°C under CO_2 atmosphere. The purified carbonates were stored in a desiccator over P_2O_5 until required for use. In order to extend the measurements to the widest possible temperature range, the ternary mixture (6): 22.8% Li_2CO_3, 27.4% K_2CO_3, and 49.8% Na_2CO_3, m. 403°C was selected for the present investigation. The homogeneous melt of this composition was prepared preliminary to the measurements in a small auxiliary furnace using a CO_2 atmosphere and platinum crucible.

Apparatus.—The experimental assembly, illustrated schematically in Fig. 1, consisted of an electrically heated furnace, B, closed by a water-cooled brass top, A, supporting the ceramic tubes of the thermocouple well, gas delivery tube, and electrode leads, C, E, F, G, respectively, leading to a 20 ml capacity platinum crucible, D, which contained the melt and also served as the cathodic electrode. The latter was supported, as shown, on an alundum base. The anode was a platinum foil of 2 to 4 cm^2, and the reference electrode was a fine Pt wire placed nearby. A series of alundum disks above the crucible served as baffles to minimize heat losses. Two thermocouples, a Pt-Pt 10% Rh couple observed on a recording controller (L&N Speedomax H) and a chromel-alumel couple observed manually with a potentiometer were placed at the same level close to the cell in the furnace. The electrical circuit was the conventional arrangement for the direct measurement of electrode polarization. The d-c current source consisted of four 45-v batteries in series and

a cascade of variable resistors through which the current was drawn.

The gases, CO_2 and O_2, were bubbled through the melt when measurements were in progress using a gold tube extension on the alundum gas inlet, E. The gases were passed through drying trains containing successively silica gel, P_2O_5, and silica gel, monitored on flowmeters, and mixed before entering the melt.

Measurements.—Exploratory measurements with relatively high current densities, 200 ma/cm^2 showed platinum present in the melts after the ex-

periments (due to attack of the crucible). Small coherent gray particles, presumably platinum, were noted after dissolution of the melt in water after the measurement and the crucible showed attack. Using current densities of 50 ma/cm^2 and less, no insolubles were noted in the above test after an experiment, and no visible corrosion of the crucible was noticeable. While these observations qualitatively showed that corrosion did not occur to a great extent in the duration of the experiments, the possible formation of surface oxides electrochemically on the platinum anode is not ruled out. To condition the anode, and thus obtain higher reproducibility in measurements, the first measurements in each experiment were made at relatively high temperatures (700°-900°C). Current densities were restricted to an upper limit of 50 ma/cm^2 in all measurements in view of the above observations relative to corrosion effects.

The results of the measurements for the range 420°-1000°C in the ternary carbonate mixture are summarized in Table I. The resistive potential drop for an electrode separation of 0.1 cm may be estimated as 6 mv maximum at c.d. of 20 ma/cm^2 from the specific conductivity of molten carbonates at 800°-900°C. The correction may be neglected since the value is less than the limits of accuracy of the measurements. The composition and rate of the gas bubbling through the melt, and the overpotential measurements for the run-up ($i\uparrow$) and run-down ($i\downarrow$) are given, with several checks to illustrate the reproducibility of the results at various current densities. The procedure in general was to apply a high c.d. to the anode initially and subsequently decrease the polarization current gradually to a low value. After the first run-down, the current was increased to its initial value for a check run. Overpotential measurements were made immediately after each current change; a minimum of approximately 10 min was required in each case for the potential to reach constancy. At the temperature limits, 420° and 1000°C, only a few measurements were made.

Results

Analyses of the data summarized in Table I gave a series of curves, of which three are illustrated in Fig. 2 to show the relation between the overpotential, η, and logarithm of current density, log i, in molten carbonates for oxygen evolution. The curves in Fig. 2 were selected to illustrate the results at the three temperatures, 480°, 600°, and 900°C, with the same gas mixture and flow rate in each case. Inspection shows that these curves exhibit two well distinguished regions in each case. At low c.d. (<1 ma/cm^2) the overpotential changes with increasing temperatures until the η — log i relation is very nearly parallel to the abscissas (Fig. 2) at the higher temperatures (near 1000°C). In the c.d. range of 1-50 ma/cm^2 the slope of the η — log i relation is very nearly constant at any one temperature, and shows a smaller temperature dependence in contrast to the preceding region. Temperature coefficients of the overpotential at constant current density $(\partial\eta/\partial T)_i$ from these data are summarized

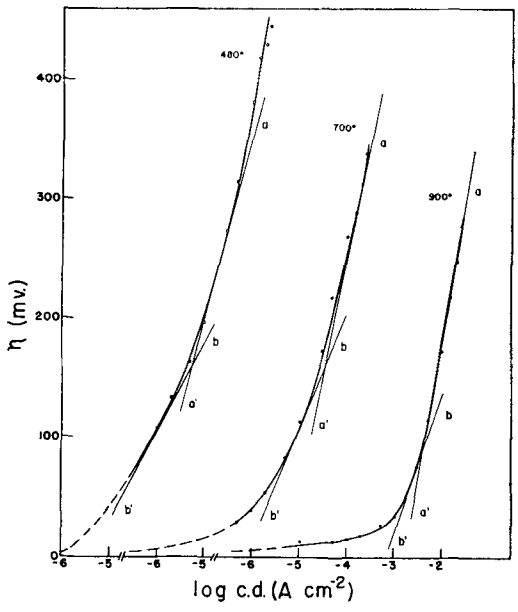

Fig. 2. Oxygen overpotential-current density relations in molten carbonates as a function of temperature. Data are for: A, 480°C; B, 600°C; C, 900°C; and a gas flow in each case of: CO_2, 50 cc/min; O_2, 42.8 cc/min. The lines a-a' and b-b' are theoretical.

in Table II. Inspection of the results shows that for the two temperature ranges, $(\partial\eta/\partial T)_i$ is much less at lower c.d. than at higher c.d., the difference being approximately an order of magnitude.

Since molten carbonates are not chemically inert to O_2 and CO_2, the variations in the rates of flow for the gas mixture bubbling through the melt cannot be interpreted simply as a stirring effect on overpotential. The dependence of η on the gas composition could be checked readily by variation of the CO_2/O_2 ratio in the feed gas. The results at 515°C are illustrated in Fig. 3. It is readily noted that the overpotential is markedly less when the concentration of O_2 in the gas mixture is increased at low c.d. (<1 ma/cm^2) whereas it is essentially independent of this variable at higher c.d. (>1 ma/cm^2).

At constant overpotential, the temperature dependence of current density may be expressed by:

$$\left(\frac{\partial \ln i}{\partial T}\right)_\eta = \Delta H/RT^2 \qquad [1]$$

The results analyzed accordingly for values of η equal to 0, 200, and 300 mv, where the data for the former were gained by extrapolation, are illustrated in Fig. 4. The slopes of the lines were calculated by the least-squares method. The values for ΔH thus found were 10.4 ±1.1 kcal/mole for $\eta = 0$, and 9.1 ±1.1 kcal/mole for $\eta = 200$ and 300, respectively. The variation in ΔH is less than the probable error and may be taken as constant, i.e., 9-10 kcal/mole in molten carbonates.

Table II. Temperature coefficient of oxygen overpotential in molten carbonates

Temperature range	420°-600°C		600°-1000°C	
c.d. (ma/cm^2)	0.05	20	0.05	20
$(\partial\eta/\partial T)_i \times 10^3$ (v/°C)	—0.5	—1.05	—0.06	—0.25

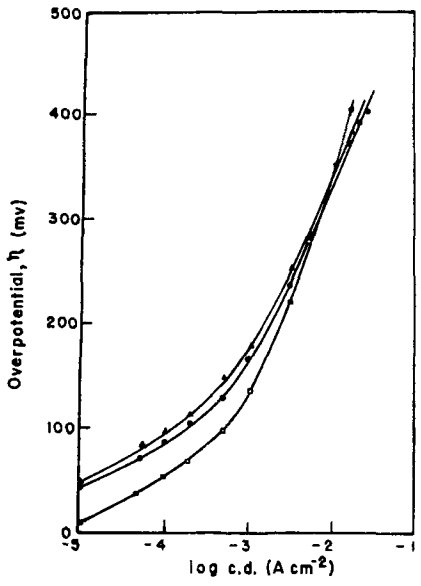

Fig. 3. Oxygen overpotential-current density relation in molten carbonates as a function of gas composition. Composition and flow rates of gas; upper curve, CO_2, 50 cc/min; O_2, 42 cc/min; middle curve, CO_2, 4.4 cc/min; O_2, 3.7 cc/min; lower curve, O_2 only, 42.8 cc/min (measurements at 515°C).

Whereas the melts were white after the experiments in the present investigation, some attack on the Pt with the formation of platinum oxide on the electrode seems not improbable. The data from related experiments having Pt in contact with molten carbonates (6-8) confirm some chemical attack in these basic melts, most probably an oxidation of Pt with simultaneous reduction of the alkali metal oxide species from the thermal dissociation of the molten carbonates.

Discussion

Reference has already been made to the emf studies of the $Pt(O_2)$ electrode in molten Na, K/CO_3 (4) and Na/CO_3, SO_4 (5) mixtures in which measurements confirmed that this electrode really behaves as an oxygen (oxide ion) electrode in such basic melts. In the present investigation the reproducibility of the measurements in the $\eta - i$ cycles, and the reproducible zero overpotential at zero c.d. in each experiment are most readily understood in the function of the $Pt(O_2)$ electrode as an oxygen-ion electrode in carbonate melts.

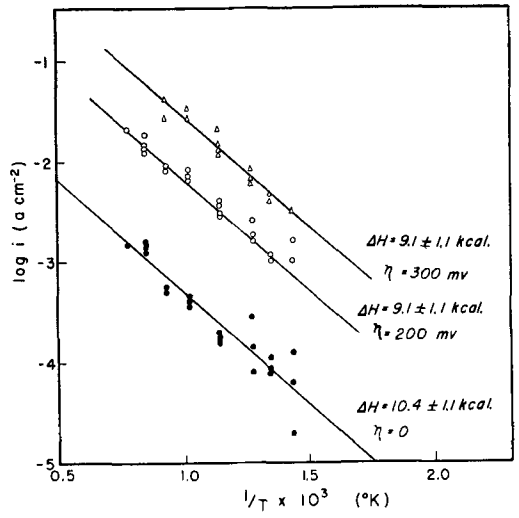

Fig. 4. Temperature dependence of the current density at constant oxygen overpotential in molten carbonates.

Relative to this point, the thermal dissociation of the alkali metal carbonates to the corresponding oxide and CO_2 is well established; the most recent investigation in this field being that of Motzfeld (6) for Na_2CO_3 up to 1050°C using the Knudsen effusion technique. While no such measurements have been reported for the ternary carbonate melt, there is little doubt that the carbonates in the mixture dissociate into the oxide ion and CO_2. In the present study it seems most likely that the activity of the oxide ion is given by the expression:

$$a_{O^{-2}} = K \frac{a_{CO_3^{-2}}}{p_{CO_2}} \qquad [2]$$

in accord with the dissociation equilibrium for the carbonates:

$$CO_3^{-2} \leftrightarrows CO_2 + O^{-2} \qquad [3]$$

for which both the rate of dissociation and the equilibrium will be functions of the temperature in the conventional manner.

Some information on the nature of the electrode processes contributing to the over-all reaction:

$$CO_3^{-2} \rightarrow CO_2 + O + 2\bar{e} \qquad [4]$$

at the anode can be gained from the dependence of the overpotential on current density and temperature.

In general the overpotential is expressed in terms of the logarithm of current density by the following equations:

$$\eta_c = \frac{RT}{n\mathbf{F}} \ln\left(1 - \frac{i}{i_o}\right) \qquad [5]$$

and

$$\eta_a = a - \frac{RT}{n\alpha\mathbf{F}} \ln i \qquad [6]$$

where η_c and η_a are the overpotentials for concentration and activation controlled electrode processes, respectively, and where the latter equation is the well-known Tafel equation. Both types may arise in the present system for, if the carbonate dissociates to form the oxide ion, both (*a*) the transfer of the oxide ion from the bulk of the solution to the layer of the melt in contact with the anode by migration or diffusion, and (*b*) the discharge of the oxide ion directly to form atomic oxygen

$$O^{-2} \rightarrow O + 2\bar{e} \qquad [7]$$

or, in view of the probable formation of oxides on the anode surface

$$O^{-2} + M \rightarrow M{-}O + 2\bar{e} \qquad [8]$$

followed by processes such as

$$M{-}O + M{-}O \rightarrow M + O_2 \qquad [9]$$

leading to oxygen evolution, undoubtedly are steps in the over-all process.

In the case of activation control [i.e., (*b*) above] with $\alpha = 0.5$, the slope of the $\eta - \log i$ equation is

equal to 2.303 $RT/\mathbf{F}$ for a two electron transfer in the electrode process (i.e., $n = 2$). For concentration polarization with $n = 2$ in this system, a slope of 2.303 $RT/2\mathbf{F}$ is to be predicted. The theoretical slopes for activation and concentration type overpotential, a-a' and b-b', respectively, are shown in Fig. 2.

The temperature coefficient of η at constant current density, from the preceding equations, is given by

$$\left(\frac{\partial \eta_c}{\partial T}\right)_i = \frac{\eta_c}{T} - \frac{RT}{\mathbf{F}}\left(\frac{i}{i - i_o}\right)\left(\frac{\partial \ln i_o}{\partial T}\right) \qquad [10]$$

and

$$\left(\frac{\partial \eta_a}{\partial T}\right)_i = -\frac{E}{RT^2} \Big/ \left(\frac{\partial \ln i}{\partial \eta}\right)_T = -\frac{E}{\alpha \mathbf{F} T} \qquad [11]$$

Using the value of 9-10 kcal/mole found in the present investigation as the activation energy for anodic oxygen evolution, $(\partial \eta_a/\partial T)_i$ is predicted as approximately equal to -1.0×10^{-3} v/°C in the range 500°-600°C, and -0.6×10^{-3} v in the neighborhood of 1000°C. On the other hand, it has been found for a number of cases that $(\partial \eta_c/\partial T)_i$ is generally less than $(\partial \eta_a/\partial T)_i$ by approximately one order of magnitude. Comparison with the experimental results (Table II) shows that the temperature dependence of η found is consistent with the above concepts in the first approximation.

Some additional support for the above interpretation of the $\eta - \log i$ relations is seen in the effect of the composition of the gas flow on η. The change in the composition of the gas ($CO_2 + O_2$), i.e., the change in p_{O_2}, is related to the oxygen ion activity (refer Eq. [2]). The decrease in η (see Fig. 3) in the region of low c.d. when oxygen only is bubbled through the melt is thus as predicted for concentration rather than activation overpotential in this range. As indicated earlier the present experiments do not lend themselves to check the effect of stirring (by changes in the gas flow rate) since the melt is not chemically inert to the gas used for this purpose. A decreasing importance of the region of concentration polarization at low c.d. would be predicted with increasing temperatures, i.e., enhanced thermal decomposition of the carbonates and thus increased oxide ion activity at more elevated temperatures, in light of the above. This effect is clearly illustrated by the present results (e.g., see Fig. 2).

In summary, the preceding considerations show that the experimental results are more readily understood in accord with the carbonate dissociation-oxide ion scheme rather than through the direct electrochemical oxidation of the carbonate ion, and that the overpotential is in large part the concentration type in the region of low c.d. (<1 ma/cm^2) and the activation type at higher c.d. (1-50 ma/cm^2).

A point that frequently arises in the field of high-temperature chemistry is the need for an estimate or "forecast" of the behavior of systems at higher temperatures, largely owing to the lack of the necessary data for the high-temperature systems. A comparison of the results of the present study with the values found for oxygen evolution on Pt in aqueous electrolytes is thus instructive. In molten carbonates, the value of ΔH, the activation energy for the over-all process in the region of higher current densities from the present results is in the range 9-10 kcal mole^{-1}. In 0.1N NaOH, 0.1N HNO_3, and 0.2N H_2SO_4, the values for the parameter are (9) 13.8 ± 0.6, 18, and 22.1 kcal mole^{-1}, respectively.

Acknowledgments

The authors wish to acknowledge with thanks stimulating suggestions by Dr. T. Forland (Norway), Dr. D. E. Douglas (General Electric Co.) and Dr. N. D. Greene (R.P.I.) in the course of this investigation.

Manuscript received Sept. 28, 1959. Research for this work was supported by the Office of Naval Research, Chemistry Branch, under ONR Contract Nonr 591-(10).

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

Study of the Recuperation Reaction in the Leclanche Dry Cell

M. P. Korver, R. S. Johnson,[1] and N. C. Cahoon[2]

Research Laboratory, Union Carbide Consumer Products Company, Division of Union Carbide Corporation, Cleveland, Ohio

ABSTRACT

The cathodic reaction in the Leclanché dry cell has been described previously as consisting of two steps. The first of these steps is the electrochemical reduction Mn^{IV} to Mn^{II}. The second step is the chemical reaction of Mn^{II} produced in the first step with unreacted Mn^{IV} to form an insoluble Mn^{III} compound. Two chemical reactions can occur producing MnOOH and $ZnO \cdot Mn_2O_3$, manganite and hetaerolite, respectively. The latter reactions, termed recuperation reactions, have been subjected to analysis and rate studies to determine the effects of factors such as *p*H, concentration, and temperature. These reactions are found to be slow enough to limit dry cell operation under certain conditions. The more active depolarizers, such as electrolytic MnO_2, show more rapid recuperation reaction than the natural MnO_2 ore. The basic concepts of heterogeneous chemical kinetics have been applied to this problem, and a simple mathematical equation was found which was applicable to all the data. These findings, correlated with previous results, support the cathodic reaction mechanism theory previously presented.

Progress in dry cell technology for many years was based largely on empirical efforts since only meager fundamental data were available. The reaction,

$$Zn + 2NH_4Cl + 2MnO_2 = ZnCl_2 \cdot 2NH_3 + Mn_2O_3 + H_2O \quad [1]$$

was accepted as representative of the operation of a battery. Early experimental work in this laboratory (1) by French and MacKenzie resolved the cathodic portion of reaction [1] into two separate reactions. The first of these is the electrochemical reduction of Mn^{IV} to Mn^{II}, reaction [2]; the second is the chemical removal of Mn^{II} by further reaction with unused Mn^{IV} to form the Mn^{III} reduction product. From more recent findings (2), it appears that the chemical reactions at the cathode can be represented by two distinct types of chemical processes. Reactions [3] and [4], the "recuperation reactions," involve removal of the Mn^{++} produced by the primary reaction. These can be shown as follows:

$$MnO_2 + 4H^+ + 2e = Mn^{++} + 2H_2O \quad [2]$$

$$MnO_2 + Mn^{++} + 2(OH)^- = 2MnOOH \quad [3]$$

$$MnO_2 + Mn^{++} + 4(OH)^- + Zn^{++} = ZnO \cdot Mn_2O_3 + 2H_2O \quad [4]$$

Reaction [2] found an important application in the utilization test (3), a rapid means of evaluating manganese dioxide depolarizers on the laboratory bench. However, certain samples of depolarizers did not perform as well in experimental cells as results of the utilization test had indicated. It was obvious that some other factor limited the service of these particular depolarizers. An important example was synthetic pyrolusite prepared by the thermal decomposition of manganese nitrate (4). This material gave efficient depolarization in the utilization test, but its effectiveness in experimental cells was substandard. It seemed probable that the rates of the recuperation reactions might be critical for the group of samples. This paper presents the results obtained from a study of several depolarizer samples.

Experimental

To study the reactions between MnO_2 and Mn^{++}, a solution containing manganous chloride is reacted with solid manganese dioxide. The progress of the reaction is followed by observing the decrease in Mn^{++} concentration.

In first attempts to establish a satisfactory method of studying the rate of the recuperation reaction, it was found that an increase in temperature increased the rate of the reaction to such an extent that accurate temperature control in a thermostat became necessary. For example, one depolarizer sample studied at pH 7 was completely reduced to MnOOH at 35°C in about 8% of the time required at 21°C. This finding is in accord with the well-known observation that the electrical output of a dry cell on a standard flashlight test, such as 4 ohm HIF, is increased a considerable amount by an increase in temperature, such as given above, when other factors do not interfere with cell operation. Thus, cell performance at practical temperatures can well be limited by the recuperation reaction rate. Similarly, other factors, such as depolarizer type, electrolyte pH, etc., were found to be as important as the temperature in influencing the reaction rate. From this work, both technique and apparatus were finally selected for precise control of the variables.

In conducting an experiment, approximately one mole of MnO_2 along with one-half liter of 2M NH_4Cl solution is introduced into the reaction vessel, a six-necked, three-liter flask. This mixture is stirred, and high-purity nitrogen is bubbled in for at least an hour. A second flask (serving as a reservoir) in the water bath contains a liter of solution 2M in NH_4Cl and 1.5M in $MnCl_2$. This also has nitrogen bubbled through it to purge the solution of dissolved atmospheric oxygen. The contents of the reservoir flask are allowed to equilibrate with the bath held constant within 0.5° and the *p*H is adjusted with concentrated NH_4OH to the proper value. The liter of solution is then pumped from the reservoir into the reaction flask by using a small pressure of nitrogen. A calomel half-cell and a glass electrode are suspended in the reaction mixture. These electrodes are connected to a L&N Speedomax recorder-controller which in turn controls an automatic pump. Since in the recuperation reactions hydroxyl ions are consumed, the pump injects a standardized quantity of NH_4OH into the reaction mixture when the *p*H falls below a predetermined value. By this method, the solution *p*H is automatically maintained within 0.3 of a *p*H unit.

During the course of the reaction, small samples of slurry are extracted and immediately centrifuged. The supernatant liquid is then put through a sintered glass filter. A 5 ml portion is retained for analysis. The quantity of Mn^{++} is determined by the method of Lingane and Karplus (5). From these values of concentration and the total volume of solution, the uptake of Mn^{++} can be obtained.

Discussion

It is well known that Mn^{++} reacts with manganese dioxide (6). It is also recognized by others that this reaction is important in the functioning of the dry cell (7). However, physicochemically the reaction has not been too well characterized and there appears to have been no work done on the kinetics of the reaction. Cowley and Walkley (8) have reported some work on this reaction in connection with the cause of the potential drift of manganese dioxide electrodes.

A study (9) has been conducted on the isotopic exchange in the MnO_2-Mn^{II} system. Although it is not definitely stated by Pullman and Haissinsky, the work in this laboratory suggests that they used acid solutions. They concluded that the exchange reactions occur much faster with precipitated oxides than with those prepared by the ignition of $Mn(NO_3)_2$. The latter were of the pyrolusite type.

The recuperation reactions are of a heterogeneous type in which a solid reacts with a solution to form an insoluble product on the surface of the original solid phase. As with all heterogeneous reactions, the problem of diffusion—or mass transfer—of the reactants to the reacting surface—or interface—imposes an additional limitation to the over-all reaction rate. Under certain circumstances, this diffusion may become rate controlling. As the reaction progresses at the solid surface, the surface area of the MnO_2 is diminished progressively. The new solid phase formed on the surface of the original solid can further significantly retard the diffusion of the reactants toward the reaction zone.

Interpretation of Results

Let Z define the total moles of divalent manganese consumed at any time t (in minutes) per mole of MnO_2 initially present. The moles of MnO_2 present at time $t = 0$ are readily calculated from the weight of the starting material and its "free MnO_2" [3] content, which is obtained by the usual methods of ore analysis. From Eq. [3] and [4], it is obvious that $Z = 1$ when the reaction is completed, provided the process is stoichiometric.

Representative data for electrolytic MnO_2 are shown in Fig. 1. Here Z is plotted as a function of time t (in minutes). During this experiment, the temperature was maintained at 43.95° ±0.05°C and solution *p*H held at 5.40 ±0.15. The experimental data may be represented quite well by the relation:

$$\frac{t}{Z} = \frac{t}{b} + \frac{1}{k} \qquad [5]$$

where b and k are constants selected by the conventional method of least squares.

By taking the limit as t approaches zero, it is seen that Z also approaches zero. At the other limit, as t becomes infinitely large, Z approaches b. Thus, b represents the maximum value of Z. If the reaction was stoichiometric and it went to completion, then b would be unity.

By differentiating once and with the proper substitutions, one obtains

$$\frac{dZ}{dt} = k\left(1 - \frac{Z}{b}\right)^2 \qquad [6]$$

Clearly, this is the rate expression for the process under conditions of constant temperature and *p*H, and with a given starting material. The constant k is the specific rate constant and dZ/dt is the instantaneous rate in terms of moles uptake of Mn^{++} per

[3] Free MnO_2 is the amount of MnO_2 in the depolarizer which is available to react electrochemically.

mole of MnO_2 initially present per minute. When the reaction is half completed, that is, at the half-life ($t = t_{0.5}$), the instantaneous rate is one-fourth of k. For reasons pointed out later, the half-life rate $\left[\frac{dZ}{dt}\right]_{t=t_{0.5}}$ is a useful quantity in this study.

In Fig. 1, the t/Z values obtained in this experiment are plotted as a function of t. It is seen that, except for the initial readings, the data conform to a straight line well within the range of the experimental error. From Eq. [6], one sees that for any given finite time there is a finite, single value for the rate. At time zero, the rate is numerically equal to k and as time increases the rate becomes slower. As the time becomes infinitely large, the reaction approaches completion and the reaction rate tends toward zero. Thus, it is seen that Eq. [5] and [6] not only fit the experimental data but also possess the necessary qualities of a rate expression.

Equation [6] shows that the rate is proportional to the square of the fraction of unreacted MnO_2 that is present. The reaction might be considered to be second order with respect to this unreacted portion; however, the order of reaction is of little significance in a system as complex as that of MnO_2.

A number of manganese dioxide samples from different sources has been studied. These have been tested in the temperature range of 21°-45°C and within the solution pH interval of about 4.8-6.6. The values of temperature and pH are those which appear to be comparable to the ones found in actual dry cell testing. Further work showed that Eq. [5] served as the best mathematical representation of the data from experiments using all types of manganese dioxides studied. Thus, the equation has a general application to this kinetics problem.

Reaction rate as a function of temperature.—In Fig. 2, the logarithm of the rate at the half-life is plotted as a function of pH. The lines are isotherms. Starting materials were electrolytic MnO_2, synthetic pyrolusite, and African ore. Values of k, b, and the reaction rates at the half-life for electrolytic MnO_2, African ore, activated MnO_2 (10), and synthetic pyrolusite appear in Table I. For a given oxide, the vertical distance between the lines gives the change in the logarithm of the rate at the half-life with the change in temperature. Using the well-known Arrhenius equation, $k = se^{-\Delta H_a/RT}$, and the change in the rate with temperature variation, one can evaluate ΔH_a, the apparent energy of activation.

For three of the oxides studied, the values in kilocalories are:

Electrolytic MnO_2	26. ± ? kcal/mole
African ore	17. ± 4 kcal/mole
Activated ore	22. ± 4 kcal/mole

Although only one set of values was available for calculation of the apparent energy of activation of electrolytic MnO_2, the value is presented so that a general order of magnitude for the calculation is available for comparative purposes. The average value of about 20 kcal for the apparent energy of

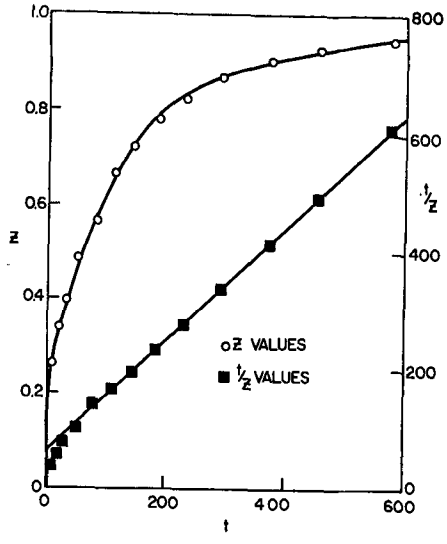

Fig. 2. Logarithm of the reaction rate as a function of temperature and solution pH.

activation confirms that the fundamental reaction involved is not under diffusion control (11).

It is likely that the lower the energy of activation, the more rapid is the reaction. On this basis, African ore, for which the lowest value is presented, should be the most active depolarizer. However, actual test and battery performance show African ore to possess the lowest recuperation reaction rate of this group of depolarizers. Therefore, we must conclude that the value of s in the Arrhenius equation, concerned with such factors as depolarizer surface area, crystal type and structure, particle size, etc., is important in influencing the recuperation reaction rates.

Reaction rate as a function of solution pH.—If one assumes a linear relationship and the fact that pH involves the logarithm of the hydrogen ion activity, one can show that

$$\left.\frac{dZ}{dt}\right]_{t=t_{0.5}} = K(OH^-)^m \qquad [7]$$

where K is a constant, m is the slope of the straight lines in Fig. 2 and (OH^-) is the hydroxyl ion concentration. Theoretically, the above would be correct for only one temperature and at constant mean ion activity coefficient. However, with the narrow temperature and pH ranges, Eq. [7] is no doubt a close approximation. The slopes of the lines for African ore are 0.49 ±0.01.

If the hydroxyl ion concentration in the bulk of the solution were the important factor, then from the chemical reaction, Eq. [3], one could suggest that the rate should be proportional to the square of the hydroxyl ion concentration. The data show that this is not the case. What is important is the concentration of the hydroxyl ions in the immediate vicinity—no doubt sorbed on the surface—of the MnO_2 particles. The concentration on the surface is, of course, influenced by the concentration in the bulk of the solution. This phenomenon of preferential ion adsorption is well recognized.

Reaction rate as a function of stirring speed.—With the particular experimental setup, it was found that changing the stirring speed from 480 to 390 rpm had no appreciable effect on the reaction rate. These values represent the useful range with the present apparatus. At stirring speeds below 390 rpm, the solid phase tends to form a mass in the bottom of the reaction vessel and hence is removed from the reaction system. With the plastic stirrer and the all-glass reaction vessel, it seemed unwise to increase the stirring speed much above 480 rpm. With this limited range of stirring speeds, however, it is doubtful whether the boundary regions of the particle would be changed and the diffusion varied to any extent.

Reaction rate as a function of oxide type.—A comparison of the reaction rates for the different oxides and the logarithm of the rate of recuperation reaction at the half-life (under conditions of 21°C and a solution pH of 6.5) are shown in Table II. As would be expected, a correlation exists between reaction rate and the general order of dry cell performance. In spite of the fact that there is a correlation, the true relationship between "rate" and "service" is no doubt complicated. On this account, it is considered unwise to attempt to predict the battery quality of manganese dioxide from recuperation rate measurements alone.

Table II. Reaction rate of representative MnO_2 samples at the half-life

Type of MnO_2	$\mathrm{Log}\left\{\left.\frac{dZ}{dt}\right]_{t=t_{0.5}} \times 10^5\right\}$
Activated ore	2.38
African ore	0.660
Synthetic pyrolusite	0.013
Electrolytic MnO_2	2.13

Reaction Mechanism

A plausible mechanism for this topochemical process has been proposed. In the absence of zinc, the chemical reaction is described by Eq. [3]. Before the reaction can occur, the reducing agent (Mn^{++}) and hydroxyl ions must first be adsorbed on the surface. After adsorption, the reduction of the MnO_2 occurs. At the site of reaction, a layer of Mn^{+++} oxide is formed. The x-ray diffraction pattern shows that this product is isostructural with the mineral manganite, MnOOH. Half of the mass of the material is formed by the reduction of the MnO_2 and the other half is produced by oxidation of the adsorbed Mn^{++}. A microscopic examination of the particles taking part in the reaction shows that the particles have actually increased in size. All four samples studied had approximately the same particle surface area of 0.20-0.50 m^2/g, even though the screen analysis showed differences in the per cent through the 200 mesh screen. Particle surface area is the term given to the total external area of all of the particles in a 1-gram sample and is calculated from settling rate curves.

At first, the MnO_2 particles are adjacent to the solution phase and the reaction goes fairly rapidly. Once the reaction has been initiated, the MnO_2 is separated from the adsorbed reactants by a layer, or film, of MnOOH. This layer offers a resistance to the reaction and the rate is slowed down. It has been shown that the rate is proportional to the second power of the fraction of remaining, unreacted MnO_2.

The reduction of the MnO_2 could be accomplished by the migration of hydrogen ions and electrons across the manganite barrier, going from the outermost surface toward the unreacted MnO_2. This process of an ion migration in manganese oxides has been recognized previously (12). These adsorbed divalent manganese ions lose an electron. They are thus oxidized to the trivalent state and are immediately precipitated as MnOOH. Under most conditions, the trivalent manganese ion is unstable.

The various oxides obey the same rate equation and they have the same characteristics, such as apparent energy of activation, of the same order of magnitude. It is thus concluded that all of these manganese dioxides react through the same mechanism. The slowest rate was that displayed by syn-

thetic pyrolusite. This can be attributed to the fact that pyrolusite has a lower oxidation potential than a more reactive form, such as electrolytic MnO_2. This so-called recuperation reaction is an oxidation-reduction process. The MnO_2 is the oxidizing agent and the divalent manganese is the reducing agent.

When zinc is present in solution as dissolved zinc chloride, the resultant reaction product is hetaerolite ($ZnO \cdot Mn_2O_3$) rather than manganite. It is probable that the zinc occurs in the solid phase by virtue of a coprecipitation process along with the Mn^{++} that becomes oxidized and precipitated. When the reaction product is hetaerolite, the reaction rate is about the same as in the absence of zinc. An example of this is shown in Fig. 2. It is highly possible that the hydrogen ions and electrons migrate more rapidly through a hetaerolite layer than through a barrier of manganite. It is conceivable that this by-product layer on the surface of the manganese dioxide particle could constitute a barrier to prevent the completion of the recuperation reaction. If this were true, it should result in a change in the slope of the observed reaction rate. At this time, we have seen no evidence for such interference.

The Nitric-Hydrofluoric Acid Pickling of Zircaloy-2

M. A. DeCrescente,[1] P. F. Santoro, A. S. Powell, and R. H. Gale

Materials Development Laboratory, Nuclear Division, Combustion Engineering, Inc., Windsor, Connecticut

ABSTRACT

The dissolution of Zircaloy-2 has been studied in the temperature range 15.6°-37.8°C in unagitated and agitated hydrofluoric-nitric acid solutions. The dissolution rate was found to increase with HF concentration and agitation. The energy of activation for the Zircaloy-2 pickling process compares very well with the value for the unalloyed zirconium pickling process, 3.3 kcal/mole. The energy of activation does not depend on agitation.

Smith and Hill (1) studied the rate of dissolution of unalloyed zirconium in hydrofluoric-nitric acid mixtures using Zr^{95} as a radioactive tracer. They reported an energy of activation of 3.3 kcal/mole for the process. The pickling of Zircaloy-2 (1.45 w/o Sn, 0.133 w/o Fe, 0.044 w/o Ni, 0.08 w/o Cr) was studied by Friedl, *et al.* (2) in order to determine the safe limits of pickling bath operation. A value of 5.0 kcal/mole for the energy of activation was calculated from a temperature-dissolution rate study. Friedl postulated that (*a*) the differences in agitation used in the two studies may account for the observed differences in the temperature dependency of the dissolution rate, or (*b*) a real difference in the energy of activation existed. In the study carried out by Hill and Smith, the pickling rate of zirconium increased with stirring rate up to a point beyond which the rate remained constant. Their experiments were carried out on the "flat" part of the pickling rate-stirring rate curve. The pickling investigation by Friedl on Zircaloy-2 was carried out at a constant stirring rate, 100 rpm, presumably on the sloping part of the pickling rate-stirring rate curve. Both investigators agree that un-ionized hydrofluoric acid is the active etchant.

The work of Smith and Hill has established that the dissolution of zirconium is HF diffusion controlled and not adsorption or reaction controlled. The high energy of activation obtained by Friedl, if real and independent of agitation, would indicate that the alloying elements have provided a diffusion barrier less permeable to the HF. The work reported here was initiated (*a*) to resolve the effect of alloying constituents in the pickling of Zircaloy-2 and (*b*) to explain the variable results encountered in production pickling. The effect of hydrofluoric acid concentration, temperature, and agitation on the pickling of Zircaloy-2 in $HF-HNO_3$ mixture would be determined for this purpose.

Experimental

Vapor blasted reactor grade Zircaloy-2 specimens were degreased with ethyl alcohol, washed with a synthetic detergent, rinsed with demineralized water, and stored in a vacuum desiccator. The pickling was carried out in a 1-liter polyethylene beaker immersed in a constant temperature water bath

* Area = 0.0975 dm^2.

(±0.1°C). A preliminary study showed that the pickling rate was independent of area and vapor blast pretreatment (3). The temperature of the pickling solution was measured with a paraffin-coated thermometer. All specimens were pickled for 2 min in 700 ml of fresh solution prepared from C.P. reagents and deionized water just prior to use, rinsed 4 min, dried and stored in a vacuum desiccator until weight changes were determined.

Initially, the pickling was carried out in unagitated solutions (runs 1-20). In order to minimize local concentration and temperature effects, subsequent tests were carried out in solution, agitated by means of a polyethylene stirrer (Runs 27-32). Dissolution rates were measured over the hydrofluoric acid (Baker and Adamson reagent grade, 40 w/o) concentration range, 2.5 to 4.0 v/o. Forty v/o nitric acid (Baker Analyzed reagent grade, 70 w/o) was used in each case. These concentrations represent the composition of standard zirconium production pickling solution (2).

Results

Dissolution of Zircaloy-2 in unagitated solution.—Pickling rates were determined by measuring the change in weight of a Zircaloy-2 specimen after 2-min exposures to pickling solutions freshly prepared for each determination. Table I contains the pickling rates of Zircaloy-2 in unagitated HF-HNO_3 solutions.

The observed rates plotted against HF concentrations (40 v/o HNO_3) at 15.6°, 21.1°, 26.7°, 32.2°, and 37.8°C gave straight lines through the data.

Effect of agitation on pickling.—The dissolution of Zircaloy-2 in 3.5% HF-40% HNO_3 was studied at 21.7°C (71°F) at a series of stirring rates. A plot of these data appears in Fig. 1. The increase in pickling rate with stirring is characteristic of a diffusion-controlled mechanism.

A series of experiments were carried out in 3.5% HF-40% HNO_3 at a stirring rate of 500 rpm in order to determine if local temperature and concentration effects have any influence on the temperature dependence of the pickling rate.

The influence of agitation on the observed pickling rates can be explained as follows:

As the dissolution reaction proceeds, the concentration of reactants immediately surrounding the specimen in an unstirred solution may decrease below the bulk concentration, especially if the rate of diffusion of reactants to the specimen's surface is low. An apparent decrease in pickling rate results. Mixing serves to remove any concentration gradients which may be found. Also the temperature of the solution at the metal surface may increase above the bulk temperature if the heat of reaction is not effectively dissipated. An apparent increase in the pickling rate results. Although the two effects, diffusion and temperature, counterbalance each other it can be seen by comparison of the pickling rates in unagitated solution (Table I) to the rates in agitated solution that the temperature effect is the more important of the two. Mixing facilitates dis-

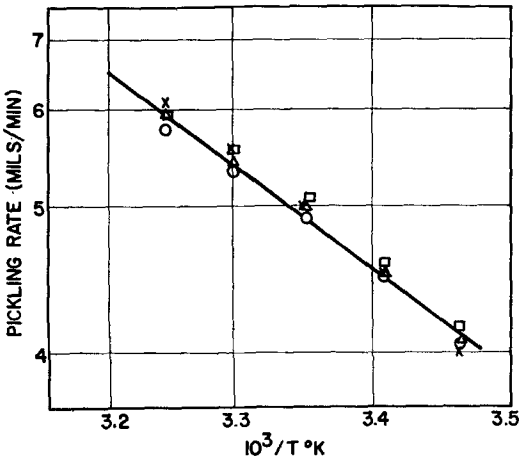

Fig. 3. Pickling rate per mole of HF, [pickling rate]/[HF] vs. 1/T°K, unagitated.

sipation of the heat of reaction and provides a uniform temperature throughout the bath.

Kinetic treatment.—A plot of pickling rate (mils/min) at 2.5, 3.0, 3.5, and 4.0% (unagitated solution) vs. reciprocal absolute temperature yielded straight lines (Fig. 2). Very close agreement of the slopes was observed and a value of 3.3 kcal/mole for the energy of activation of the pickling process resulted.

v/o HF	2.5	3.0	3.5	4.0
E_{act} (kcal/mole)	3.2	3.4	3.2	3.4

Under conditions of high acidity (HNO_3), all of the fluoride present exists as undissociated HF. The rate data obtained, therefore, were recalculated on the basis of HF concentrations, i.e., rate/[HF], and log rate/[HF] plotted against $1/T°K$ (Fig. 3). The four lines in Fig. 2 are resolved into one straight line. This behavior indicates that the rate of pickling of Zircaloy-2 is dependent only on the concentration of undissociated HF at constant tempera-

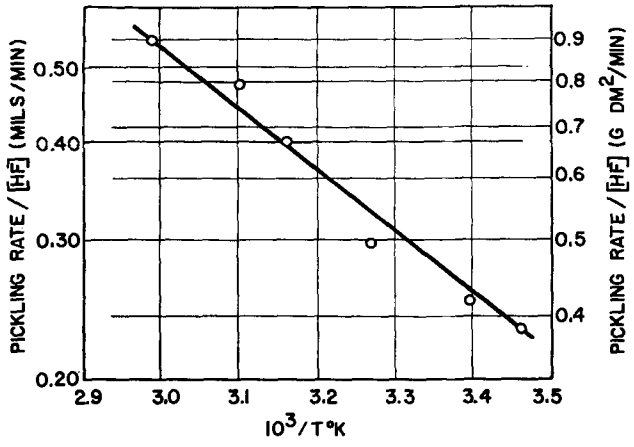

Fig. 4. Pickling rate vs. 1/T°K agitated

tures. Nitric acid does not directly take part in the pickling reaction but its presence insures complete association of HF.

When an Arrhenius plot was prepared from the pickling data obtained using agitated baths (500 rpm), an energy of activation of 3.6 kcal/mole resulted (Fig. 4). The agreement between the activation energies in the agitated and unagitated solutions is well within experimental error. It is evident from this agreement that the heat of reaction and the thermal properties, e.g., heat capacity, of the solution remain constant within experimental error in the temperature range studied.

The experimental energy of activation for the Zircaloy-2 pickling process, 3.2-3.6 kcal/mole, agrees quite favorably with the results of Smith and Hill (3.3 kcal/mole) obtained with pure Hf-free zirconium. A diffusion process identical to the one described for unalloyed zirconium must be postulated as the rate-controlling step.

It is apparent therefore that alloying zirconium with Sn, Fe, Cr, Ni does not alter the zirconium pickling mechanism. The permeability of the diffusion layer to HF is not affected by alloying. Neither can the high energy of activation observed by Friedl be attributed to the effect of stirring. It is interesting to note that the Zircaloy-2 used by Friedl had been rejected for pressurized water-reactor application because of stringer-like corrosion. The discrepancy in the energy of activation observed by Friedl *et al.* may be related to the stringer corrosion susceptibility of the material.

Hydrogen Pickup in Various Zirconium Alloys during Corrosion Exposure in High-Temperature Water and Steam

Stanley Kass

Bettis Atomic Power Laboratory, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

The hydrogen pickup during corrosion in high-temperature water and steam of various binary and ternary alloys of zirconium with iron and tin has been studied. The total hydrogen content of specimens exposed to 400°C steam was found to be greater than that of specimens exposed to 360°C water. Furthermore, the per cent of theoretical hydrogen absorbed in the various alloys was markedly affected by the binary or ternary alloy addition. The per cent theoretical hydrogen absorbed by binary zirconium-iron alloys increased as the iron content was increased from 0.3 to 1.5 weight per cent (w/o) and the value for zirconium-tin alloys increased slightly as tin was increased from 0.5 to 0.9 w/o. The hydrogen pickup behavior of ternary zirconium-tin-iron alloys reflected the behavior of zirconium-iron binary alloys.

Several facts relating to the hydrogen pickup of zirconium alloys during corrosion in high-temperature water are known. Goldman and Thomas observed the amount of hydrogen pickup by zirconium exposed to degassed water is proportional to the amount of corrosion, and when corrosion testing is carried out in hydrogenated water, more hydrogen is picked up than when the corrosion medium is degassed water (1). The latter is believed to occur because more hydrogen is available for reaction in the hydrogenated water than is available only from the stoichiometric amount produced during the corrosion processes. Goldman and Thomas also noted that higher corrosion rates and higher hydrogen pickup rates occur in Zircaloy-2 as the initial hydrogen content of the metal is increased. Recently, workers at Battelle Memorial Institute, Columbus, Ohio, confirmed the observation that the amount of hydrogen pickup is proportional to the amount of corrosion (2). Previously reported experiments by Thomas and Kass showed that pre-oxidation of Zircaloy-2 in dry oxygen at 400°C has no effect on the 400°C steam corrosion kinetics (3). The interchangeability of the corrosion data obtained in both dry oxygen and steam indicates that the corrosion of Zircaloy-2 in 400°C steam is not associated with corrosion product hydrogen. On the other hand, it was observed that crystal bar zirconium exhibits spalling (breakaway) in high-temperature steam but not in dry oxygen, suggesting that hydrogen is in some way related to "breakaway" in the corrosion of zirconium.

Recent studies have determined the hydrogen pickup in Zircaloy-2 during corrosion for extended periods in high-temperature water and steam (4). These studies show there is a definite increase in the hydrogen content of Zircaloy-2 during corrosion testing and this hydrogen increase is independent of the initial hydrogen content, up to about 1000 ppm, after which the rate of hydrogen uptake rises sharply with increasing initial hydrogen content.

The studies described below were undertaken to determine hydrogen pickup in various binary and ternary alloys of zirconium with iron and tin during corrosion exposure in 360°C (680°F) water and 400°C (750°F) steam.

Experimental Procedures

Materials.—Fifteen-pound ingots were double arc-melted from high-purity tin, iron, and reactor-grade sponge zirconium[1] at the Bureau of Mines, Albany, Oregon. The ingots were forged and rolled at 788°C (1450°F) to 0.190-in. strip and then cold rolled with intermittent vacuum anneals at 788°C to 0.017-in. strip.

Experimental techniques.—Foils 1.5 x 4 x 0.017 in. were bright etched in an aqueous solution containing 39% HNO_3 and 3.5% HF at 100°F for sufficient time to remove 0.001 in. per surface. After washing and soaking in tap water for 6 to 8 hr to remove all residual etchant, the foils were rinsed in alcohol and air dried. Four foils from each ingot were degassed at 800°C for 48 to 72 hr in vacuum (less than 10^{-6} mm Hg). After degassing, the 1.5 x 4 x 0.015-in. foils were sheared into 0.5 x 0.5 x 0.015-in. specimens and submitted to corrosion tests in 360°C water at saturation pressure and in 400°C steam at 100 atm using methods and precautions outlined previously (5, 6). Weight gain measurements were made periodically. A minimum of two specimens per alloy were removed periodically from the corrosion test and were analyzed for hydrogen using the hot vacuum extraction method.

Experimental Results and Discussion

Tables I and II show the corrosion weight gains and total hydrogen contents of the various alloys after each of the exposure periods. (The contribution of the hydrogen uptake to the weight gain has been regarded as negligible; thus the weight gain

[1] Arc-melted reactor grade zirconium contains approximately 300 ppm iron, 20 ppm chromium, 20 ppm nickel, <10 ppm tin, <40 ppm nitrogen.

value is considered being due solely to oxide film formation.) The tables contain an additional entry, per cent theoretical hydrogen which is defined as the ratio of hydrogen pickup in the sample to the stoichiometric amount of hydrogen produced by the corrosion reaction, $Zr + 2H_2O = ZrO_2 + 4H$.

Corrosion behavior.—Maximum corrosion resistance in 360°C water was shown only by the alloys which contain iron as binary or ternary additions. The unalloyed zirconium samples gained weight throughout the test and exhibited adherent oxide films. The addition of 0.5% tin to zirconium resulted in lower weight gains, but the 0.88% tin alloy yielded weight gains higher than unalloyed zirconium. The two iron binary alloys demonstrated an improvement in corrosion resistance. Furthermore, iron additions greatly improved the corrosion properties of zirconium-tin alloys.

The steam data further verified the noncorrosion resistant nature of unalloyed zirconium and zirconium-tin alloys. The addition of 0.5% tin delayed spalling from 42 to 56 days, but the 0.88% tin alloy

spalled between 14 and 28 days exposure. Small additions of iron were again observed to produce corrosion resistant material; however, the 1.5% iron alloy failed by spalling after 56 days of exposure. Beneficial effects on the properties of zirconium-tin alloys were also observed to occur with iron additions. The 0.25% iron alloy, with or without tin, exhibited the best corrosion resistance.

Hydrogen contents.—The total hydrogen contents of the various alloys are noted to increase with increasing corrosion exposure, and higher hydrogen uptakes are obtained at 400°C than at 360°C. (It should be noted that all specimens were initially degassed to approximately 2 ppm hydrogen.) In water, the unalloyed zirconium is seen to pick up the largest amount of hydrogen while the 0.93% tin-0.25% iron alloy exhibited the lowest total hydrogen content. In steam, very high hydrogen uptakes are noted. The addition of 0.5% tin produced essentially no change in the hydrogen pickup of unalloyed zirconium, but the 0.88% tin alloy showed a higher hydrogen uptake. Small additions of iron to zirconium or zirconium-tin alloys produced markedly lower total hydrogen contents. It is also noted that the hydrogen uptake of zirconium-iron alloys increases with increasing iron content.

Relationship between corrosion and hydrogen uptake.—Examination of the hydrogen pickup of the zirconium alloys during aqueous corrosion shows that there is an initial period in which the rate of hydrogen pickup decreases with time, followed by a period in which a new rate operates. This behavior is consistent with the corrosion reaction of zirconium and its alloys (hence, with the rate at which the hydrogen is produced) which is characterized by the relationship $W = kt^n$. It does not necessarily follow, however, that the hydrogen should be picked up at an identical rate because the hydrogen pickup process depends on many other variables including nature of the original film, alloy content and distribution, concentration gradient of hydrogen from the metal oxide interface to the center, rate of hydrogen diffusion at testing temperature.

If the 360°C weight change and hydrogen content data are plotted as functions of time on logarithmic scales, reasonably straight lines with the following slopes are obtained:

Alloy	Weight gain slope	Hydrogen slope
Unalloyed Zr	1.76	2.10
0.51% Sn	0.85 then 2.32	0.22 then 3.92
0.88% Sn	1.63	1.89
0.29% Fe	0.40 then 1.32	0.20 then 0.88
1.54% Fe	0.77	1.19
0.93% Sn + 0.25% Fe	0.45 then 0.55	0.35 then 1.34
0.50% Sn + 1.54% Fe	0.78	0.84

The corrosion slopes represent the exponent "n" in the equation relating weight gain and time. Thus, only the iron bearing alloys are seen to be corrosion resistant in 360°C water. High hydrogen slopes are associated with high corrosion slopes, indicating a relationship between corrosion and hydrogen pickup. If the hydrogen uptake behavior follows an exponential rate law, then equations of the form $H = Kt^{n'}$, where n' is the hydrogen slope, are to be expected. Remarkable similarity between the values of n and n' for each of the alloys is observed.

If it is assumed that the diffusion of hydrogen is a controlling step in hydrogen buildup, then parabolic relationship between hydrogen content and time is to be expected. A slope of 0.5, which indicates parabolic behavior, does not appear in these instances.

When the hydrogen data of the corrosion resistant alloys (those containing iron) are reviewed, it is apparent that the increase during the initial exposure period is great, then the hydrogen increase becomes smaller. The fact that hydrogen pickup decreases after the first exposure period requires an explanation. One possible mechanism is that the oxide film acts, in some way, as a barrier to the diffusion of hydrogen ions, protons, hydroxyl ions, to the metal-oxide interface. This suggests that the hydrogen pickup of samples oxidized in a nonhydrogenating medium subsequently transferred to a hydrogen producing medium should not show large increases in hydrogen content.

Factors influencing the behavior of ternary alloys.—The following analysis and comparisons were made in an attempt to observe whether the behavior in water and steam with respect to hydrogen pickup of the ternary alloys is directly influenced by the behavior of the component binary alloys. A more convenient way of examining the hydrogen absorption phenomenon during aqueous corrosion exposure is to express the amount of hydrogen picked up by the specimens as a function of the amount of hydrogen liberated by the specimens during corrosion. In this manner differences in the corrosion resistance of the alloys under study can be normalized.

Figures 1 and 2 summarize the behavior of the per cent theoretical hydrogen of the zirconium-tin and zirconium-iron binary alloys in 360°C water. The curve pertaining to the tin alloys initially shows a minimal value at approximately 0.5% tin. After prolonged exposure (greater than 112 days), no differences are observed between the 0.5 and 0.9% alloy. Different behavior is noted for the effect of iron. The per cent theoretical hydrogen increases with increasing iron concentration. It is thus apparent that iron contributes to the pickup of hydro-

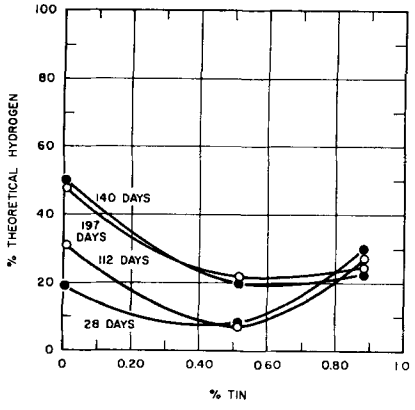

Fig. 1. Hydrogen pickup of zirconium-tin alloys in 360°C water.

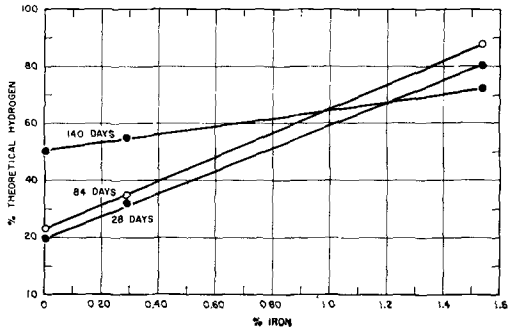

Fig. 2. Hydrogen pickup of zirconium-iron alloys in 360°C water.

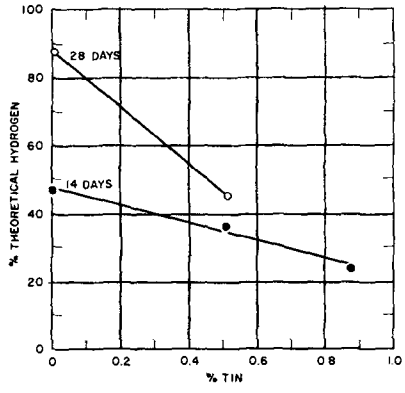

Fig. 3. Hydrogen pickup of zirconium-tin alloys in 400°C steam.

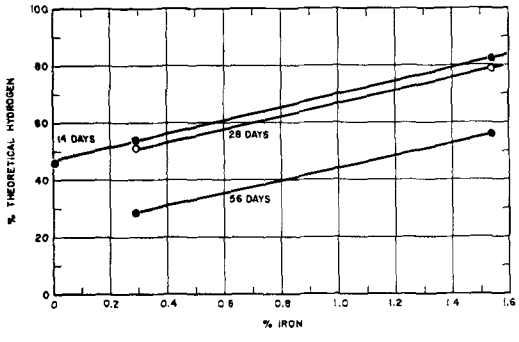

Fig. 4. Hydrogen pickup of zirconium-iron alloys in 400°C steam.

gen during water corrosion while the influence of tin is slight.

Figures 3 and 4 show the same alloys after exposure to 400°C steam. Although the data are very limited because of the low corrosion resistance of binary tin alloys, the per cent theoretical hydrogen is indicated to decrease with increasing tin content. The iron containing alloys show an increase in per cent theoretical hydrogen as the iron content is increased from 0.29 to 1.5 w/o. The higher iron concentration reproducibility exhibited higher per cent theoretical hydrogen after all test periods than the low iron alloy.

The manner in which the per cent of theoretical hydrogen varies with time for simultaneous tin and iron additions in 360°C water is shown in Fig. 5. It

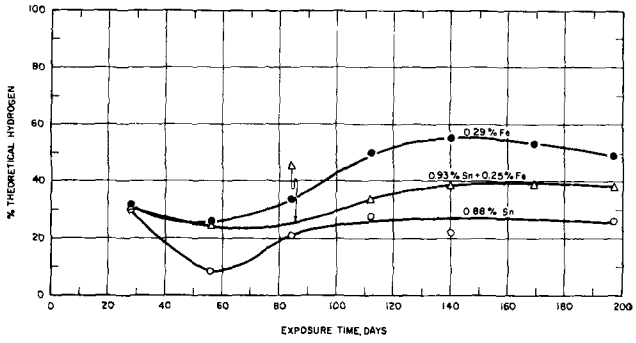

Fig. 5. Hydrogen pickup of zirconium—1% tin—0.25% iron alloy in 360°C water.

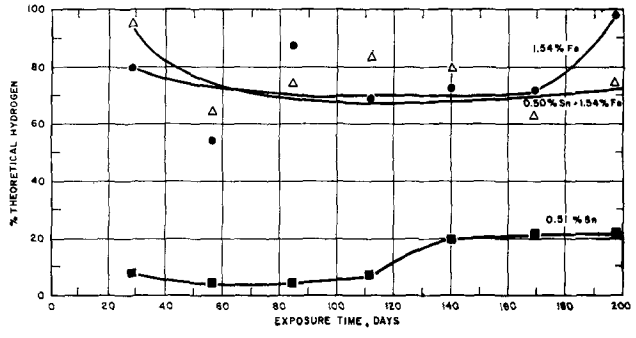

Fig. 6. Hydrogen pickup of zirconium—0.5% tin—1.5% iron alloy in 360°C water.

is observed that the ternary alloy shows per cent theoretical hydrogen between the values obtained for the tin and iron binary alloys. The tin binary alloy exhibits the lower value while the iron binary alloy exhibits a higher value.

Figure 6 shows similar summary plot of the alloys representing the 0.5% tin-1.5% iron alloy in 360°C water. Here it is noted that the ternary alloy clearly reflects the behavior of the binary iron alloy with respect to the pickup of hydrogen during corrosion exposure.

A New Explanation of Gas Evolution in Electrically Stressed Oil-Impregnated Paper Insulation

Z. Krasucki, H. F. Church, and C. G. Garton

British Electrical and Allied Industries Research Association, Leatherhead, Surrey, England

ABSTRACT

In void-free oil-impregnated paper, gas evolution starts at a critical stress which is markedly dependent on the degree of dryness of the paper. The gas first formed arises from decomposition of water in the cellulose, the nature of the impregnant having little effect. Subsequent more rapid gassing resulting from decomposition of the oil is a secondary process depending on ionization within gas bubbles previously formed. Study of the fundamental primary process suggests that water absorbed by the cellulose is ionized by electron bombardment in regions of high stress and is then decomposed electrochemically.

Although alternative materials are available, paper impregnated with an insulating liquid is still widely used as the insulation for high voltage cables and inductive windings or as the dielectric for capacitors where reliability under moderate temperature conditions and low cost are of importance.

If gas pockets within the stressed insulation are avoided, life under a-c stress is usually long. It is known however that in oil-impregnated paper, electrical discharges occur above a certain critical value of applied stress, E_i, even if the paper is so well impregnated that no voids are present initially. If the voltage be maintained at the discharge inception level, the discharges increase rapidly in magnitude, sometimes to several times the initial value within the first minute, and life may be very limited. E_i is directly dependent on the hydrostatic pressure on the oil, but when different makes of oil-impregnated paper capacitors were compared at the same internal pressure (normal atmospheric) mean values of E_i covering a range of 5:1 were observed. The cause of these large differences was not known. The effects of such factors as the density and type (rag or kraft) of paper, and the viscosity and iodine number of the oil, on discharge inception stress are relatively very small (1).

When observations on electrically stressed oil-impregnated paper are made under the microscope, the onset of discharges coincides with the sudden appearance of a gas bubble in the oil. A systematic study has been made to determine which part of an oil-paper dielectric gives rise to gas formation in the absence of initial gas bubbles, and to elucidate the mechanism of the process.

When electrical discharges take place within a gas bubble already present, they generate further gas through decomposition of the oil, and the bubble increases in size. This paper, however, is not concerned with the rate of gas production in oil once gaseous ionization has started; the latter phenomenon has been investigated extensively, is known to be dependent on the nature of the oil and the presence of additives, and gassing tests have been developed to assist in the selection of oils where they are required to withstand discharges.

The novel feature of the present work is the attempt to investigate the primary process of the formation of the first gas bubble.

The conditions under which gas could be evolved when oil alone was stressed were first investigated; afterwards a number of solid dielectrics, including capacitor paper, cellophane, polyethylene, polystyrene, polyethylene terephthalate, glass, and mica, were studied immersed in oil or other liquids.

Tests in Oil Alone

When oil is filtered completely free from particles and fibers and is not supersaturated with dissolved gas, gassing cannot normally be induced to take place by the application of electric stress using immersed metal electrodes without breakdown occurring simultaneously. The following exceptions to this are known.

(i) Gas evolution under stress has been reported at very low pressures even from degassed oil (2), but the origin of the initial gas phase is not known.

(ii) With one electrode in the form of an extremely sharp needle (radius 1 μ or less) and several millimeters spacing between the electrodes, localized intrinsic breakdown of the oil at the needle point, with gas evolution, is possible without general breakdown ensuing. With normal transformer and capacitor oils under these conditions, the gas bubbles produced move away from the point at such high velocity that they are difficult to observe. If, however, an extremely viscous liquid is used so that the products of the localized breakdown (carbon and gas bubbles) remain where they are formed, breakdown channels may gradually grow from the point and lead eventually to general breakdown. Tree-like conducting channels formed in this way in hexachlordiphenyl are illustrated in Fig. 1.

These exceptional methods of initiation of gassing are not believed to occur in normal oil-impregnated paper dielectrics, e.g., in capacitors and cables. First, these systems normally operate at near atmospheric

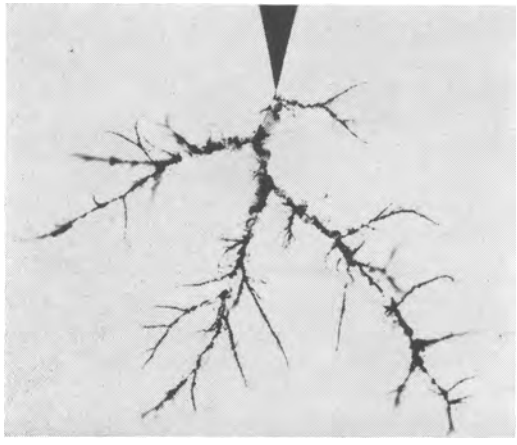

Fig. 1. Breakdown channels in hexachlordiphenyl

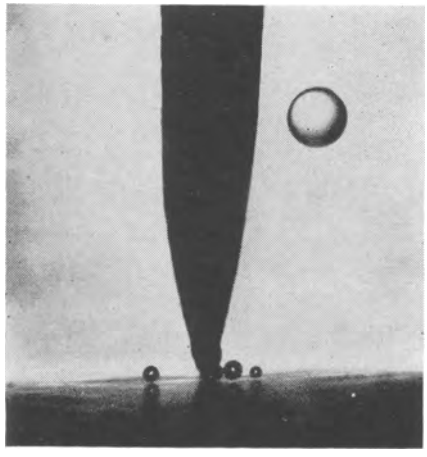

Fig. 3. Evolution of gas at the point of contact between a needle electrode and solid dielectric (cellophane).

or higher pressure. Second, the applied stress is usually insufficiently high for local intrinsic breakdown to take place except perhaps in the case of dielectrics containing abnormal conducting inclusions or other localized faults which would lead to failure on proof test. Gassing by the mechanism discussed later in this paper and consequent failure by the action of discharges usually occur at much lower electric stresses than those required for intrinsic failure. The observations reported here do however suggest how manufacturers can raise discharge inception stress of liquid-impregnated paper insulation and increase working stress.

Effects of Stress on Liquid-Solid Mixed Dielectrics

When moist cellulosic fibers bridge the gap between electrodes in oil, they give rise to gas formation at relatively low electric stress. Gas bubbles are formed only when the fibers form a continuous bridge between the electrodes, and evolution is then observed at points of contact between the fibers and the electrodes. Evolution of gas has also been observed at points where fibers touch one another in the electrode gap provided bridging occurred.

In an effort to understand the cause of this, various solid-liquid mixed dielectrics were studied, using thin sheet solid material and simple electrode forms.

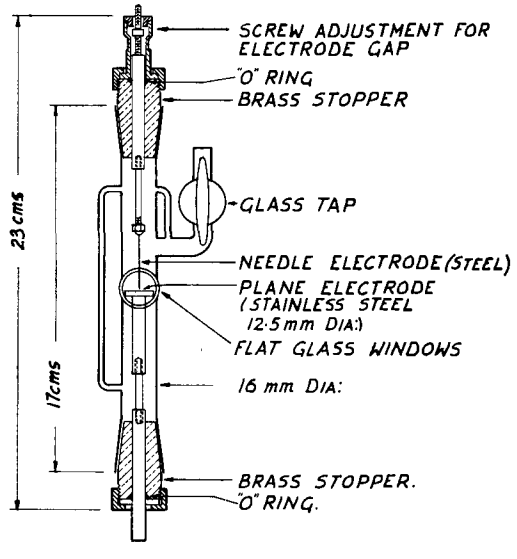

Fig. 2. Test cell

In the first experiments the sheet dielectric material to be tested was attached to the plane electrode of the test cell shown in Fig. 2. The other electrode was a needle of about 40 μ radius at the tip which could be moved relative to the plane electrode. The electrode gap could be observed with a microscope through optically flat windows. The cell was designed so that vacuum impregnation of the system with dielectric liquids could be effected, and tests if required could be carried out at reduced pressure. The following observations were made at atmospheric pressure:

(i) With the cell filled with filtered mineral oil no gassing was observed below the breakdown voltage so long as a gap existed between the needle and the solid dielectric attached to the plane electrode, whatever the nature of the solid.

(ii) With the solid insulation in the form of undried cellulose (cellophane or paper in equilibrium with ordinary room atmosphere) and the needle touching the solid, small gas bubbles were evolved continuously at the point of contact above a critical applied stress. Figure 3 shows gas evolution at the point of contact between the needle electrode and sheet cellophane immersed in mineral oil. The gas bubbles moved rapidly away from the needle and, in degassed oil, dissolved in a few minutes. The phenomenon was observed with both a-c and d-c applied stress but not necessarily at the same magnitude of stress. The onset of gassing coincided with "discharge inception" when the system was connected to a discharge detector.

(iii) The critical gassing stress increased with the state of dryness of the cellulose. With cellulose (paper or cellophane) which had been in equilibrium with air almost saturated with water vapor, gassing commenced at a stress of 6-7 v (peak) per micron. For cellulose exposed to ordinary room air (relative humidity say 65%), the critical stress was considerably higher (about 70 v/μ for two thicknesses of 10 μ capacitor paper) and this rose several times with further drying until with very dry paper or cellophane no gassing was observed below the breakdown stress (280 v/μ for two thicknesses of

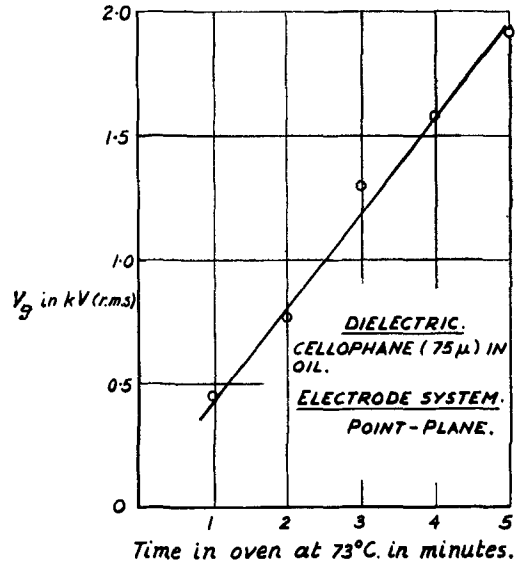

Fig. 4. Dependence of minimum voltage for gas evolution (V_g) on dryness of oil-immersed cellophane.

10 μ paper). The rather lower critical stresses observed in actual capacitors with moisture free paper dielectric are presumably due to the occurrence of sites with an enhanced local stress from conducting particles or thin places in the much larger area involved.

The effect of progressive oven drying on the voltage V_g at which gas evolution commenced at the needle electrode for cellophane of 75 μ thickness, previously exposed to atmospheric humidity, is shown in Fig. 4.

(iv) With solid dielectrics of relatively low water absorption, e.g., polyethylene, polystyrene, polyethylene terephthalate, polytetrafluorethylene, mica, and glass, no gassing was observed up to stresses approaching breakdown [in most cases 400-600 v (peak) per micron] even after long exposure to high humidity. Stresses which could be applied to these materials without gassing or breakdown occurring after exposure to almost 100% R.H. for periods of ½-1 hr are shown in Table I, which also includes gassing stresses for cellulosic materials which had been exposed to the damp atmosphere before immersion in the oil.

(v) Other materials of high water absorption, e.g., cellulose triacetate and gelatine, behaved like cellophane and paper, i.e., when damp gassing occurred at low stress, but the gassing stress increased with drying. Results for cellulose triacetate and gelatine in the damp condition are included in Table I.

(vi) Evolution of gas under electric stress from incompletely dried cellulose occurred when a silicone fluid, carbon tetrachloride, pentachlordiphenyl, or carbon disulfide was substituted for mineral oil, the minimum gassing stress being substantially unaffected by the change of immersion medium. Carbon disulfide is especially interesting in that it is not expected to yield gaseous decomposition products. The gas bubbles must therefore arise from the solid or its contained moisture.

Since the voltage at which gas is evolved from oil-impregnated cellulose increases with increasing dryness of the cellulose, it should be possible to increase the discharge inception voltage of an oil-impregnated paper capacitor by special attention to the drying of the dielectric. Measurements were therefore made of resistivity and discharge inception voltage on samples of rag paper (40 μ thickness) dried to different degrees. Vacuum dried paper was allowed to regain moisture to the required degree and immediately immersed in oil and assembled into a small capacitor with aluminum electrodes under the oil. The electrodes were flat foils 6 μ thick, pressed on to the dielectric the area of which was 4 cm^2. A-C discharge inception voltages were measured with a detector sensitive to 0.5 p coulomb. The results are shown in Fig. 5 where discharge inception stress E_i is plotted as a function of resistivity of the impregnated paper. E_i increased with increasing resistivity by a factor of 4 between paper in equilibrium with room atmosphere and "dry." The resistivities shown in Fig. 5 are considerably lower than corresponding resistivities for ordinary rolled paper capacitors. This is due to the tight clamping employed in the present tests which gave a more intimate contact with the paper.

Table I. Evolution of gas from solid dielectrics which had been exposed to damp atmosphere

Substance	Thickness, μ	Behavior under electric stress	Gassing stress, v (peak)/μ
Polyethylene	45	No evolution of gas bubbles at voltages up to the breakdown voltage 3.4 kv (peak)	>76
Polystyrene	12	No evolution of gas bubbles at voltages up to 7 kv (peak)	>580
Polyethylene terephthalate	12	No evolution of gas bubbles at voltages up to 4.7 kv (peak)	>390
Polytetrafluorethylene	17	No evolution of gas bubbles at voltages up to 7 kv (peak)	>410
Mica	10	No evolution of gas bubbles at voltages up to the breakdown voltage 5.4 kv (peak)	>540
Glass	150	No evolution of gas bubbles at voltages up to the breakdown voltage 10 kv (peak)	>67
Capacitor paper	10	Evolution of gas bubbles at about 70 v (peak)	7
Cellophane	75	Evolution of gas bubbles at 420 v (peak)	6
Cellulose triacetate	30	Evolution of gas bubbles at about 570 v (peak) (BDV = 2.46 kv (peak))	19
Gelatine	33	Evolution of gas bubbles at 280 v (peak)	7

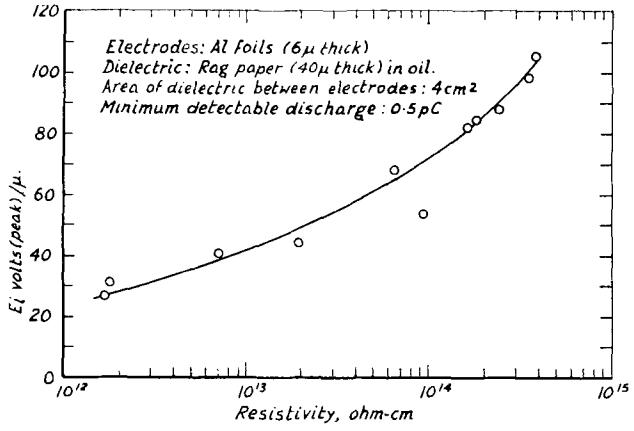

Fig. 5. Variation of discharge inception stress (E_i) with resistivity of oil immersed paper.

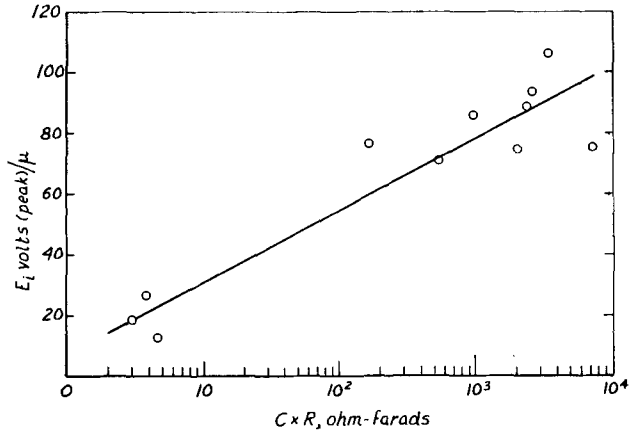

Fig. 6. Dependence of discharge inception stress (E_i) of kraft paper capacitors (C = 0.02μ F) on C x R.

In addition to the above tests on clamped plate capacitors, some normally wound 0.02 μF kraft paper units (4 paper layers x 10 μ) were impregnated in the laboratory with capacitor oil. The insulation resistance was varied by vacuum drying the units to different degrees before impregnation. Only a few tests have been made so far, but the results shown in Fig. 6 indicate that the more thorough the drying process the greater is the E_i value of the capacitor. Although precise measurements of moisture content of the paper dielectric of these capacitors were not made, these results and others suggest that E_i increases from 15 to more than 100 v (peak) per μ as moisture content decreases from a few per cent to to less than 0.1%.

Discussion of Results

The observations reported here strongly suggest that the gas initially generated in electrically stressed paper impregnated with a dielectric liquid is derived from water contained in the cellulose. Provided gas bubbles are not present initially, the threshold value of stress for gassing at normal pressures is low only with impregnated materials containing an appreciable amount of absorbed moisture, and is increased by drying. The gas observed is not water in the vapor phase formed, say, through local heating at points of contact between the electrodes or conducting inclusions and the cellulose; bubbles of steam produced in this way would condense in a small fraction of a second, contrary to the observed life of the bubbles of several minutes.

Water in liquid form can be electrolyzed readily into its constituent gases at a frequency of 50 cps at suitable current density. Experiments, in which the gas evolved from moist electrically stressed paper under an insulating liquid was collected, also showed that an explosive mixture of hydrogen and oxygen was formed from the water with both d-c and a-c (50~) voltages, although under mineral oil some of the oxygen may be absorbed immediately by oxidation of the oil. The average leakage current density through an oil-impregnated paper capacitor, however, is insufficient to account for the observed rate of gas evolution at the discharge inception stress on the basis of electrolysis of the water (3), unless some mechanism exists to cause a great increase in current in a few very small areas where abnormal stresses are present. Such a local enhancement of conductivity cannot be explained by moisture movement toward high stress regions; theoretical considerations based on energy of sorption of water in cellulose rule this out as a major effect even at stresses of the same order of magnitude as the intrinsic strength of cellulose. Experimental results have confirmed this.

Tests performed on paper in various states of dryness show however that its conductivity increases very greatly as the breakdown stress is approached especially when it is moist. Figure 7 shows the effect of varying the d-c measuring voltage on the resistivity of 28 cm² areas of kraft capacitor paper 20 μ thick (2 x 10 μ layers) after conditioning in various atmospheres. The observed great increase in conductivity of cellulose containing moisture at high stresses may be a consequence of electron emission from the electrodes, the electron bombardment of

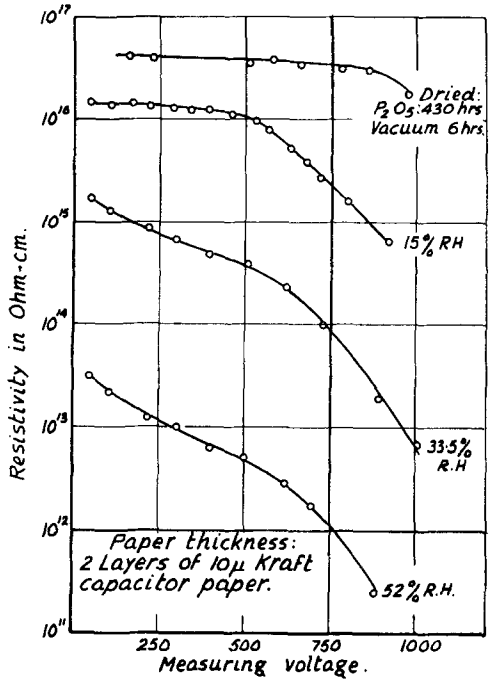

Fig. 7. Effect of measuring voltage on resistivity of paper in various states of dryness.

the cellulose causing dissociation of the bound water molecules. Although the maximum applied stress in Fig. 7 is only 0.5 mv/cm, locally it may be several times higher due to stress concentration at the edges or at any microscopic irregularities on the electrodes, and because of variations of thickness of the paper and the presence of conducting inclusions. Stresses of more than 1 mv/cm would certainly be sufficient for electron emission.

It is possible therefore that gas evolution in a capacitor commences at local points of stress concentration, say near the site of a conducting inclusion in the paper or at electrode edges, where the resultant high degree of dissociation of the water would lead to rapid electrolysis.

Such a mechanism would explain why discharge inception stress in oil-impregnated paper capacitors is not greatly affected by time of application of d-c stress or frequency of a-c stress and is little dependent on temperature which has a very considerable effect on leakage current at working stress. In a well sealed capacitor, temperature may have an indirect effect on discharge inception stress by causing a change of pressure, but at constant pressure the effect of temperature is small. It is clear therefore that a simple electrochemical mechanism based on average currents at working stress is inadequate, but that an explanation involving electron emission at high stress is in agreement with experimental observations.

The practical value of this work is that it demonstrates the importance of very thorough drying of oil-impregnated paper insulation if the highest possible working stress is required.

ZnS:Cu, Cl and (Zn, Cd)S:Cu, Cl Electroluminescent Phosphors

A. Wachtel

Research Department, Westinghouse Electric Corporation, Bloomfield, New Jersey

ABSTRACT

Procedures for the preparation of ZnS:Cu,Cl and (Zn,Cd)S:Cu,Cl EL[1] phosphors are based on firing in an atmosphere containing elementary S. Cl-incorporation is controlled by firing in capped silica tubes or in open boats in a current of $N_2 + S_2Cl_2$. Dependence of brightness on activator concentration is established on the basis of presumably constant excess Cu as Cu_2S. The use of Pb was found to be disadvantageous. Introduction of Cd causes formation of the hexagonal phase and a (Cu,Cd)S compound and simultaneous decrease of electroluminescence brightness as well as dependence of electroluminescence emission color on Cd concentration. A two-step firing procedure is given by means of which this effect may be partially avoided.

This paper deals with efforts to improve the brightness and maintenance of blue and green emitting EL phosphors, as well as attempts to prepare phosphors emitting at longer wave lengths by means of partial substitution of Zn by Cd. While a considerable amount of data on the preparation of ZnS:Cu, Cl EL phosphors has appeared in the literature (1), the experimental procedures used in the present study are based on those developed by Lehmann (2). These may be summarized as follows:

1. The highest EL output is obtained for compositions prepared with only ZnS, Cu, and Cl and preferably excluding other cations such as Pb.

2. A considerable improvement of the phosphor is obtained by firing in an atmosphere containing elementary S. It is believed that this improvement is due to reduction of the number of S-vacancies and consequently deep traps which otherwise tend to form.

The second point necessarily implies that the addition, or presence after firing, of ZnO is detrimental. This is contrary to data first obtained by Destriau (3) and then by a number of workers in the field [a review as well as original data have been published by Wendel (4)]. An explanation may be offered in terms of a model for the EL excitation mechanism as proposed by Lehmann (5) according to which electrically conducting inclusions in ZnS crystallites similar to the Cu-rich surface layers proposed by Zalm, Diemer, and Klasens (6) and by Zalm (7) provide sufficient local intensification of the applied field. Accordingly, either ZnO or Cu_2S may play such a role. Lehmann, has shown experimentally that Cu_2S is preferable.

[1] Electroluminescence or electroluminescent is hereafter abbreviated EL.

Experimental Techniques

Unfired mixes were prepared by slurrying pure ZnS (RCA No. 33Z19) with aqueous solutions of $Cu(C_2H_3O_2)_2 \cdot H_2O$ and NH_4Cl, followed by drying, addition of S and remixing. Firing was usually done in 10 g quantity of material filled into transparent silica tubes, 75 mm long, 15 mm ID, and 17 mm OD, closed at one end and capped with similar tubes 18 mm ID and 20 mm OD. Several such tubes could be arranged in a larger silica tube near its closed end and protected with an atmosphere of purified N_2 in the usual manner. All fired phosphors were washed in NaCN solution followed by H_2O and alcohol, and were then dried and screened.

EL-brightness readings were performed with a Spectra Brightness Spot Meter,[2] using a demountable cell filled with 40% (by volume) suspensions of phosphor in castor oil. Since small geometrical deviations of the cell assembled at different times could not always be avoided, the effective field strength across the phosphor layer was standardized by operating the cell at a voltage such that a standard phosphor (also included) had a predetermined brightness.

ZnS:Cu, Cl Phosphors

Mechanism of Cl incorporation.—The amount of Cl incorporated at a given concentration of Cu was estimated in a relative but sensitive manner by visual comparison of the blue-green hue of emission of the fired phosphor. Preliminary investigations indicated that the Cl content decreases with increasing batch size and increases slightly with firing time and the volume of the firing container used, so long as this volume is small enough to permit the phosphor mix to be surrounded by a saturated atmosphere of its own thermal decomposition products. For larger sample sizes fired, an empirical relationship

$$\%\mathrm{Cl} = x(0.97 + 0.003 \text{ g ZnS})$$

was found to result in equal emission color, where x is the amount of Cl added to a 10-g sample.

The observations suggested that, during the initial stages of firing, thermal decomposition releases substantially all of the added Cl to the atmosphere. As the firing proceeds this Cl is subsequently absorbed at a slower rate. The sulfur added appears to decrease strongly the Cl incorporation inasmuch as it causes a shift in emission to shorter wavelengths (8), i.e., in favor of the blue emission band. This may be compensated for by higher Cl additions such as presently described.

The EL brightness was found to reach a broad maximum for firing temperatures in the neighborhood of 950°C. Singly fired phosphors were usually characterized by nonhomogeneous Cl content, i.e., a mixture of more bluish and more greenish emitting portions. Grinding and refiring with no additions other than S always resulted in homogeneous, brighter, and more reproducible phosphors. During the refiring, about 30% of the incorporated Cl is lost, which must be compensated for in the initial unfired composition, since after firing the rate of Cl incorporation is strongly reduced. Firing times of 1.5 hr were found to result in equilibrium conditions.

Activator concentration.—An EL ZnS:Cu, Cl phosphor is known to require the presence of a high concentration of activator sites (9, 10) whose formation is, for present purposes, assumed to be a function of coactivator (Cl) incorporated, so long as the molar concentration of Cu appreciably exceeds that of Cl. The performance of an EL phosphor depends, however, not only on the amount of incorporated (at least partially charge-compensated) Cu, but also on the conducting phase of Cu_2S whose formation depends on, and is a function of, the presence of excess Cu during the firing process.[3] Conditions for keeping this constant and at a near-optimum value were empirically determined for 10-g quantities fired to obey the relationship

$$\text{mole \% Cu} = 0.55 + 0.45 \text{ mole \% Cl}$$

Under present conditions, the sintering of the phosphor appears to be determined entirely by the amount of excess Cu_2S formed, so that a rapid, although approximate and only relative, estimate of excess Cu concentration could be made in this manner.

Phosphors prepared with Cl additions up to 30 mole % and corresponding additions of Cu showed approximately equal sintering. Figure 1 shows the EL brightness obtained at two frequencies over a portion of this range of compositions. The fact that an EL output appreciably higher than zero is noted for no Cl addition may be explained by a small Cl content of the raw materials, and the brightness found at this point was noted to be quite variable, depending on the particular lot of ZnS used. The similarity of the curves to the dependence of brightness on Al addition as noted by Froelich (11) is quite evident. It is also interesting to note that compositions resulting in maximum EL brightness are such that about 25% of the added Cu is retained after NaCN washing, which is the same figure reported by Froelich (12) for ZnS:Cu, Mn phosphors fired at 1100°C in H_2S. The practical aspects of these results are presented in more detail in a recent

[2] Photo Research Corp., Hollywood, Cal.

[3] NaCN-washed EL phosphors show an increase in green/blue ratio of emission and lose most of the EL when refired at the original firing temperature (950°C).

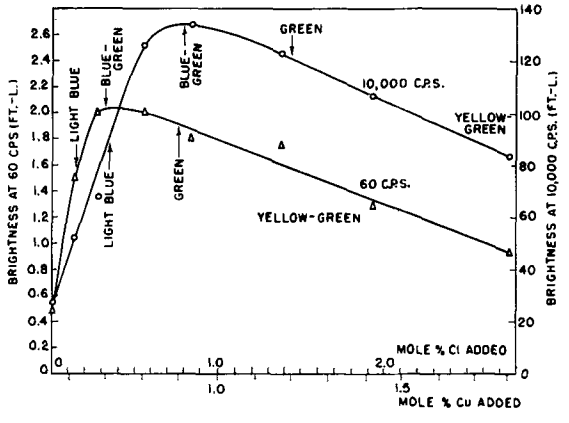

Fig. 1. Brightness of ZnS:Cu, Cl phosphors fired with 5 wt % S at 950°C, 2 x 90 min, as a function of activator addition. The Cl additions specifically refer to 10-g quantities fired in silica tubes of 13.5 ml volume.

Table I. Typical activator additions and retained concentrations (in mole %) for 10-g batches of ZnS, fired at 950°C—2 x 90 min

	Light blue	60 cps green	10,000 cps green
Cu added	0.62	0.71	0.89
Cu retained after NaCN washing	0.033	0.105	0.50
Cl added	0.14	0.34	0.75
Cl retained	0.095	0.16	0.32

patent (13). Table I shows typical values of Cu and Cl found by chemical analysis of NaCN-washed phosphors designed for light blue emission, as well as maximum brightness at 60 and at 10,000 cps excitation, respectively.

Effect of Pb.—Because of the frequent use of Pb (15) in the preparation of EL phosphors, its effect was also investigated. Table II shows the results obtained, where the first three samples (except for S) represent a composition obtained by averaging a number of representative formulations described in the patent literature. Samples 4, 5, and 6 differ only in the use of extra NH_4Cl, so as to compensate for the effect of Pb which consists of volatilizing excess Cl as $PbCl_2$.

In samples 7, 8, and 9, an attempt was made to duplicate present compositions, except that Pb was also used which, in turn, required higher Cl additions so as to maintain a blue/green hue of emission color similar to that presently representing optimum activation incorporation. Sample 10 is a normal control phosphor prepared without Pb.

It can be seen that in all cases the use of Pb resulted in a strong reduction of EL as compared to the control. Since the use of 5 mole % Cl alone would result in a nearly 100% coactivated and almost non-EL phosphor, any advantages of the use of Pb, as observed by others, is probably restricted to cases where raw materials with high Cl content were employed.

Effect of ZnO.—Figure 2 shows the effect of increasing additions of ZnO to compositions designed either for 60 cps or for 10,000 cps excitation. The initial slight increase in brightness lies within the reproducibility of phosphor preparation and measurements.

The presence of ZnO results in an effect similar to an increase in Cl addition. Most of the S added

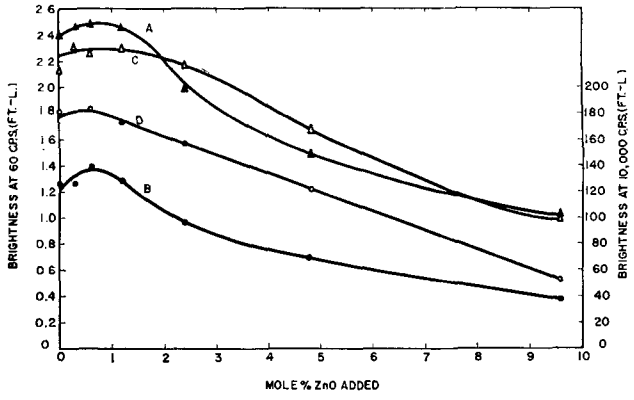

Fig. 2. Brightness of ZnS:Cu, Cl phosphors with activator additions designed for 60 cps and for 10,000 cps excitation, respectively, as a function of ZnO added before firing. A, 60 cps phosphor excited at 60 cps; B, 60 cps phosphor excited at 10,000 cps; C, 10,000 cps phosphor excited at 60 cps; D, 10,000 cps phosphor excited at 10,000 cps.

evaporates before reaction with ZnO can occur; the remainder, however, may react with ZnO and can no longer decrease incorporation of Cl. Moreover, Kröger and Dikhoff (14) have shown that oxygen itself causes preferential association with Cu and has a definite solubilizing effect. Since the decreased brightness observed may therefore be interpreted as merely a departure from optimum final activator and Cu_2S concentrations, a number of phosphors were prepared with about a tenth of the usual additions of Cl so as to match the green/blue ratio of emission of normal phosphors. The best results obtained were, however, only about one-third of the output normally obtained at 60 cps, while at 10,000 cps the EL was comparatively negligible. Similarly poor results were obtained by firing phosphors without free S, even in the absence of ZnO.

Effect of alkali chlorides.—The incorporation of Cl, although subject to the parameters described above, appeared to be independent of its form of addition, so long as no extraneous cation is included. On the other hand, the addition of Cl in the form of alkali chlorides as originally reported by Beutler and Prener (16) results in a shift in emission color to the blue.[4] With increasing atomic weight of the cation, the shift becomes more pronounced. The

[4] On the basis of enough Cl to result in green emission color if introduced as NH_4Cl, $ZnCl_2$, or HCl. Otherwise, there is, of course, no color shift.

mechanism whereby this occurs has not been ascertained but seems to resemble the Cl-gettering action of K_2CO_3 as described by Ranby (17) and could be interpreted either as decreasing incorporation of the chloride due to decreasing solubility of the K-salt in the ZnS lattice, or decreasing association of chloride with Cu activation sites (18, 19) due to increasing association of the Cl with the alkali metal ions. The effect is, of course, noticeable only at Cu concentrations well above those normally employed in photoluminescent phosphors. Table III shows the results of adding 2.75 mole % Cl as alkali chlorides to ZnS with 0.75 mole % Cu, where the effective Cl concentration of the fired phosphors was estimated on the basis of emission color. With the exception of the values for Rb and Cs which are very uncertain due to the difficulty of comparing deep hues, the points may be plotted as a straight line of log Cl vs. log atomic weight of the cation.

The EL output of the blue-emitting phosphors (such as those fired with KCl) does not differ significantly from normal blue-emitting ZnS:Cu, Cl prepared without KCl but with a sufficiently low addition of NH_4Cl. The output of the greener-emitting phosphors fired with NaCl and LiCl is, however, considerably poorer. It may be noted that the emission color of the phosphor fired with LiCl matches that of a normal EL phosphor fired with 0.75 mole % NH_4Cl (optimum for 10,000 cps excitation) while the EL brightness is only about 60% of such a control sample.

It was interesting to observe that high concentrations of KCl also inhibit the effective incorporation of additional Cl added in an "available" form (i.e., as NH_4Cl, $ZnCl_2$, etc.) to the extent that for each mole per cent KCl present, about 0.5-0.75 mole % NH_4Cl is required to shift the emission color from blue to green. Here again, however, green-emitting phosphors prepared in this manner are characterized by very poor output.

The effect of KCl on maintenance of output during operation is particularly pronounced. Table IV shows the result of measurements in PVCA (polyvinyl chloride acetate copolymer) dielectric taken at 4000 cps on phosphors fired with variable additions of KCl and NH_4Cl. The last two rows represent normal control phosphors. It can be seen that the maintenance of the blue-emitting control phosphor is quite poor, but can be improved by a factor of 5 by the use of KCl. Inasmuch as the maintenance of ZnS:Cu, Cl phosphors increases with activator concentration (20), it seems not too far fetched to visualize that the very high Cl additions made in the present manner somehow become available with respect to their influence on maintenance, although without corresponding formation of green-emitting centers.

Use of S_2Cl_2.—The firing technique as described earlier in this paper was developed mainly because the composition of the atmosphere surrounding the phosphor during firing is a function of the composition of the unfired mix, so that the Cl incorporation could be controlled in a simple manner. Incorporation of Cl from a continuous supply such as HCl, introduced from the outside, would presumably continue until all of the Cu has been transformed into

green-emitting Cu-Cl centers. followed by eventual conversion of the ZnS into $ZnCl_2$. In order to limit this reaction, mixtures of HCl + H_2S are generally employed, and investigations of a quantitative nature pertaining to such reactions have been published by Kröger, Hellingman, and Smit (9) and by Kröger and Smit (21).

As mentioned before, the role of S in similarly limiting the incorporation of Cl has been verified experimentally, although only in a qualitative manner. However, unlike H_2S, the S constitutes an oxidizing environment during firing which is advantageous for the formation of good EL phosphors. In order to carry this one step further, the addition of Cl in elementary form was considered. The most convenient manner of accomplishing this was in the form of S_2Cl_2 added to the N_2 by aeration in a gas scrubbing bottle. For this purpose, no S or halide was added to the unfired mix, which was placed in an open boat near the closed end of the firing tube. It turned out that the equimolecular addition of S and Cl effected in this manner resulted in Cl incorporation to the extent normally obtained for phosphors designed for high-frequency excitation. The phosphors were characterized by a lighter (less yellow-green) body color after NaCN washing, and a stronger dependence of brightness on applied voltage. Details pertaining to the preparation of this type of phosphor have also been described (22).

(Zn, Cd)S:Cu, Cl Phosphors

The same firing technique, using capped silica tubes as described, was used throughout this phase of the investigation. The CdS raw material was RCA33C291. The Cu and Cl additions were generally maintained at those suitable for high-frequency excitation, so as to favor the long wavelength emission band.

Figure 3 shows the results of substituting an increasing molar percentage of CdS for ZnS. A small addition (3.3%) results in the expected shift in emission color to yellow-green and somewhat improved brightness. Increasing additions of Cd, however, rapidly decrease the output of the phosphors. While this may be caused partly by the introduction of deep traps associated with Cd as proposed by Zalm (7), three additional phenomena were noted, particularly in the region of rapid decreasing EL:

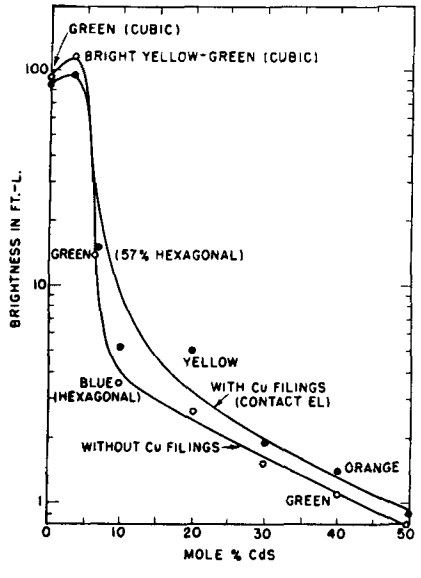

Fig. 3. Effect of Cd concentration on EL and contact-EL of (Zn, Cd)S:Cu, Cl phosphors. Measurements taken at 1000 v, 8,000 cps in 200 μ castor oil cell with 25 μ Mylar protection.

1. Formation of hexagonal phase. The first two points in Fig. 3 represent samples which are 100% cubic, the third sample is 57% hexagonal, and the rest are 100% hexagonal. It should be mentioned that Zalm (7) also considered the cubic phase of ZnS to be more suitable from the standpoint of EL, while Jaffe (23) noted a corresponding decrease of EL on introduction of Mg into ZnS, occurring simultaneously with formation of hexagonal material.

2. A shift in EL excited emission color back to shorter wave lengths. The emission color of (0.9Zn, 0.1Cd)S was greenish blue, although its photoluminescence was green-yellow as expected for this composition. No explanation of this phenomenon can be given at present.

3. Formation of a dark-colored separate phase, insoluble in NaCN solution. When prepared in pure form, this material is black and shows a hexagonal x-ray diffraction pattern very similar to that of CdS. Chemical analysis shows 18.5% Cu. Its exact identity has not as yet been established, although it appears to be some type of (Cd, Cu)S.

The decreasing EL output caused by the introduction of Cd into ZnS:Cu, Cl phosphors appears to occur simultaneously with the formation of hexagonal material and is associated with the formation of the (Cd,Cu)S phase. Phosphorescence observed in such phosphors strongly indicates that the mechanism in which high activator concentrations normally quench phosphorescence in ZnS:Cu, Cl phosphors is disturbed. Since, on the other hand, the characteristic ultraviolet-excited fluorescence is not so strongly influenced, the following mechanism may be proposed. The Cu_2S inclusions tend to be associated primarily with the cubic modification of the base material. Introduction of more than a few per cent of Cd causes formation of a hexagonal phase which allows the excess Cu to combine with CdS to form a separate compound which is not capable of fulfilling the same role of field intensification as Cu_2S. At the same time, depletion of this excess Cu disturbs the Cu-equilibrium of the system during firing and lowers the activator concentration of the phosphor to the point whereby persistent phosphorescence may be observed. Removal of the Cu_2S effectively destroys the EL-excitation mechanism.

The hypothesis was tested by mixing the phosphors with Cu-filings and subjecting them to contact-EL (24). Because of this comparatively inefficient manner of EL excitation, as well as the lower activator concentration of the (Zn, Cd)S:Cu, Cl phosphors, the increase in brightness obtained was small. On the other hand, the normal shift in EL-excited emission color was now observed. This

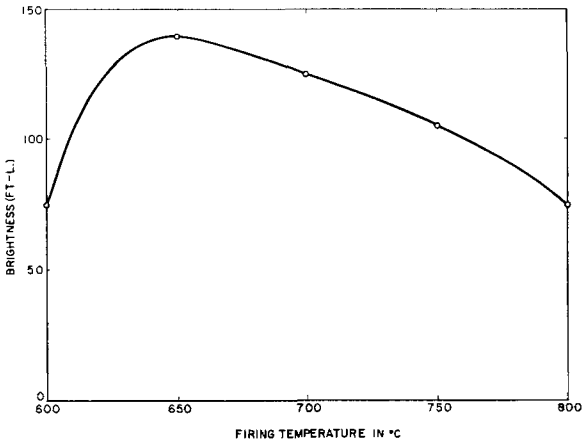

Fig. 4. Brightness at 600 v, 10,000 cps excitation of (9Zn:1Cd)S:Cu, Cl prepared from ZnS:Cu, Cl phosphor + CdS as a function of firing temperature. Firing times, 1 hr.

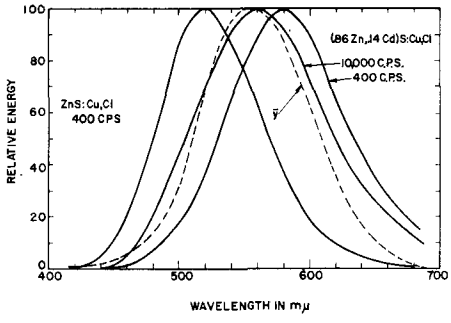

Fig. 5. Spectral distribution of (0.86 Zn, 0.14 Cd)S:Cu, Cl in comparison with that of green-emitting ZnS:Cu, Cl and sensitivity of human eye.

means that, at high Cd concentration, the slightly brighter orange contact EL represented a considerably higher emittance than the slightly less bright green, normally excited EL. It should also be mentioned that cubic or hexagonal photoluminescent ZnS:Cu(0.01%), Cl performed about equally well when subjected to contact EL.

Among several methods tried to overcome this interference, only one was at least partially successful: A normally prepared, but not NaCN-washed, green-emitting ZnS:Cu, Cl EL phosphor is mixed with unfired CdS and S and refired at a lower temperature. Figure 4 shows the effect of refiring temperature on 0.9 ZnS:Cu, Cl + 0.1 CdS which can be seen to be quite critical. At the present stage of development, the procedure is, however, not very reproducible and apparently subject to the particle size and technique of mixing of the two components to be refired. At best, 14 mole % CdS have been incorporated into ZnS:Cu,Cl without formation of the separate (Cd, Cu)S phase and formation of hexagonal structure. Figure 5 shows the emission spectra obtained at two frequencies of excitation of a (0.86Zn, 0.14Cd)S:Cu,Cl phosphor prepared in this manner. Although the spectral distribution at 10,000 cps resembles the eye-sensitivity distribution more closely, the brightness obtained was only about one-third that of the green-emitting ZnS:Cu,Cl phosphor prior to refiring with CdS. However, it should be mentioned that even refiring at 650°C of ZnS:Cu, Cl without CdS addition resulted in decreased brightness, generally to the extent of about 25%. The method is therefore a compromise designed to effect maximum incorporation of CdS with a minimum of chemical interference. Etching of such phosphors in HCl revealed that they are not homogeneous, inasmuch as the emission color continuously shifted to shorter wave lengths with increasing time of etching. This type of phosphor may therefore represent an optically filtered system of little practical importance.

Summary

Procedures for the preparation of lead-free ZnS:Cu,Cl and (Zn, Cd)S:Cu,Cl have been presented, based on firing of the raw materials in an oxidizing atmosphere containing sulfur vapor. The dependence of EL output on activator concentration is meaningful only for phosphors fired with additions of Cu such as to result in presumably similar concentrations of excess Cu_2S and consequently similarly efficient excitation processes. Control of incorporated Cl may be effected by firing in capped silica tubes or by firing in N_2 + S_2Cl_2. Alkali chlorides decrease the incorporation of Cl, more so with increasing atomic weight of the cation. Experiments with KCl have resulted in blue-emitting phosphors with greatly improved maintenance.

Substitution of Zn by Cd decreases the emittance as well as the dependence of EL-excited emission color on Cd concentration which is normally observed with ultraviolet excitation. This effect occurs simultaneously with formation of hexagonal (Zn, Cd)S and a (Cd,Cu)S compound which is insoluble in NaCN solution. A two-step firing procedure may be employed by means of which this interference is partially avoided through formation of a non-homogeneous optically filtered system. The brightness of such phosphors, however, is low.

Acknowledgments

The writer wishes to thank Mr. G. Scanlon and Miss I. Walinski for preparation and brightness measurements of phosphor samples, as well as Dr. W. A. Thornton and Dr. C. K. Lui-Wei for data on maintenance and crystal structure, respectively. He also wishes to thank Dr. H. F. Ivey for reading and suggesting improvements in the original manuscript.

Gold-Activated (Zn,Cd)S Phosphors

M. Avinor[1]

Philips Research Laboratories, N.V. Philips' Gloeilampenfabrieken, Eindhoven, Netherlands

ABSTRACT

Gold is shown to produce three emission bands in CdS at 640, 800 and 1150 mμ. The long wave band appears only when a coactivator is used while the short wave bands are observed with activation by gold alone. The 1150 mμ band in CdS is shown to correspond to the 530 mμ gold band in ZnS.

The greenish fluorescence of gold-activated zinc sulfide is well known (1-3), but the properties of the luminescent centers have been investigated only limitedly. It was generally assumed in earlier work that they differed considerably in character from the centers of copper and silver in zinc sulfide. This was attributed to the theoretical possibility of gold being incorporated in the trivalent as well as the monovalent state. By using trivalent metals as coactivators instead of halogens, Kröger and Dikhoff (4) showed that the gold band was composed of two bands at 470 and 530 mμ, and that the latter became predominant by coactivation.

There is some likelihood of confusing the short wave band of gold at 470 mμ with the self-activated band of zinc sulfide at 460 mμ. However, the short wave band seems to be really due to gold because the two gold bands remain distinct even when the activator concentration is increased to 1 mole % (5). At such high activator concentration the self-activated band is usually completely suppressed. The two gold bands were assumed (4) to correspond to the "blue" and "green" bands of copper, although the order of the coactivated bands of silver (435 mμ), copper (516 mμ) and gold (530 mμ) does not correspond to their order in the periodic system.

Recently a further attempt was made by Henderson, Ranby, and Halstead (6) to find a correlation between the luminescent properties of Cu, Ag, and Au in ZnS and in (Zn,Cd)S phosphors. These authors did not control the atmosphere in which they fired their phosphors and they used chlorine coactivation through the addition of fluxes. No systematic correlation between the bands of the various activators could be found, although the authors claimed to have demonstrated three emission bands for copper and gold and two bands for silver.

The short wave silver band in ZnS was shown by Van Gool (7) to be situated at 388 mμ, by starting from CdS and tracing the shift of the emission bands in a series of mixed (Zn, Cd)S crystals up to ZnS. The short and the long wave bands are rather well resolved in CdS. In the present work we investigated the emission bands of gold by starting from CdS and following the bands as more and more of the cadmium was replaced by zinc.

[1] On leave of absence from the Scientific Department, Ministry of Defense, Israel.

Experimental

The aluminum coactivator was added to the pure base material as a solution of the ammonium alum, and the gold was added as a solution of the chloride. The powders were dried at 120°C overnight and then fired in small quartz test tubes at 950°C for 2 hr in a stream of pure hydrogen sulfide. After withdrawal from the furnace the tubes were allowed to cool, again in a stream of hydrogen sulfide. The products were ground and refired in hydrogen sulfide at 1100°C for 1 hr. An activator concentration of 2.10^{-4} atom per mole was used, which is about the optimum concentration for these sulfide phosphors. No fluxes were used.

The present experiments were limited to activation by gold alone or gold balanced by an equal molar concentration of a trivalent coactivator. Phosphors with activator to coactivator ratio different from unity were not investigated. It is known, however, that in the case of copper and silver additional emission bands may appear (4, 7).

The emission was measured by a recording spectrophotometer with photomultiplier or lead sulfide detector, and the usual corrections were applied for obtaining equal energy spectra. Excitation was by the ultraviolet, blue, and green lines of a high-pressure mercury lamp for phosphors containing a high proportion of CdS. Filters were used to remove progressively the longer wave lines as the emission bands shifted towards the ultraviolet. For 20 mole % or less of CdS the 313 mμ line of mercury was used, unless otherwise indicated. In this way the excitation was mostly fundamental for the various compositions and allowed detection of both the impurity and the edge emission.

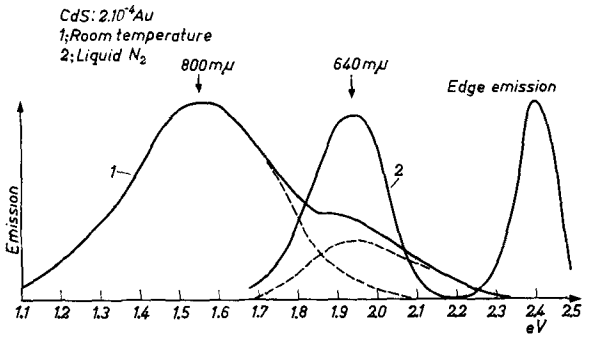

Fig. 1. Emission spectrum of gold-activated CdS at room and liquid nitrogen temperature.

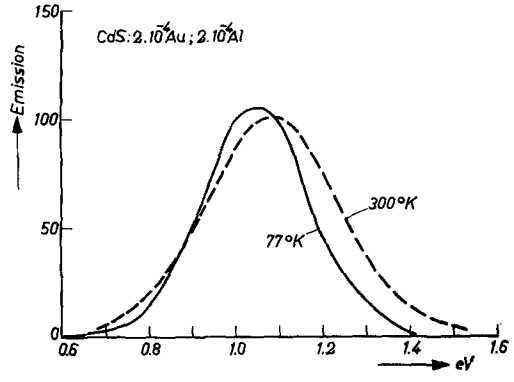

Fig. 2. Emission spectrum of CdS activated by equal amounts of Au and Al at room and liquid nitrogen temperature.

Results

We find that whereas copper (8) and silver (7) are known to give two emission bands each in CdS, gold produces three distinct bands. Two bands are found at 640 mμ and 800 mμ when gold alone is used as an activator (Fig. 1). The third band appears as the only band at 1150 mμ when the gold activator is balanced by a trivalent coactivator such as aluminum (Fig. 2). The same emission band is also found when indium is used instead of aluminum. On cooling to liquid nitrogen temperature it shows only a slight shift toward longer wave lengths (Fig. 2), and no other emission bands appear. When zinc is substituted for cadmium in the host lattice this band is displaced in a regular manner toward shorter wave lengths (Fig. 3, 4) and appears at 530 mμ in zinc sulfide. Thus the 1150 mμ coactivated gold emission in CdS corresponds very well to the emission bands of coactivated silver and copper at 730 and 1020 mμ, respectively (Fig. 4).

The optical absorption of the coactivated gold centers in CdS extends beyond the fundamental absorption edge (Fig. 5) and gives the powder a reddish brown body color. In this respect, too, the coactivated gold centers resemble closely the coactivated centers of copper and silver.

Omission of the coactivator shows important differences between gold and the other activators. The short wave emissions of copper and silver appear in CdS when the activator concentration exceeds the coactivator concentration. With no coactivator at all gray products are obtained on firing in

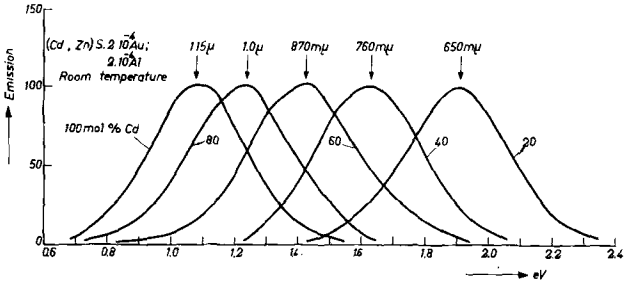

Fig. 3. Emission spectra of (Zn,Cd)S phosphors activated by gold and aluminum at room temperature.

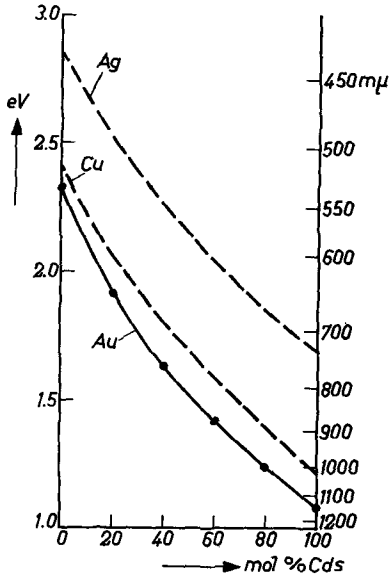

Fig. 4. Shift of emission peak of coactivated (Zn,Cd)S phosphors activated by Au, Cu, and Ag. Room temperature.

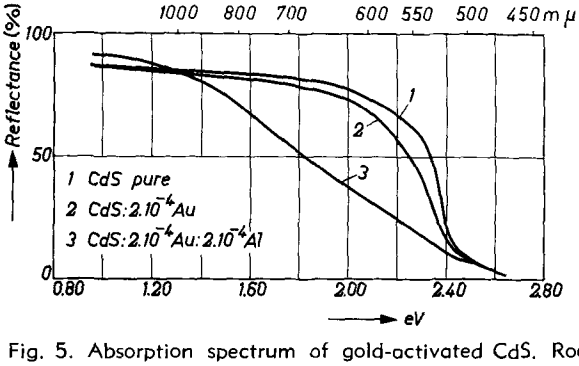

Fig. 5. Absorption spectrum of gold-activated CdS. Room temperature.

an atmosphere of hydrogen sulfide, indicating that much of the activator remains unincorporated as the free sulfide. Gold alone as an activator, however, is well incorporated in CdS with only a small change in the absorption spectrum (Fig. 5). Two emission bands have been found in this case (Fig. 1) at 640 and 800 mμ. The small amount of chlorine introduced with the gold (which was added as gold chloride) is probably driven out by the current of hydrogen sulfide on firing, and its effect as a coactivator is not felt. This is supported by the observation that the two bands are both different from the coactivated band, that these bands do not appear in a coactivated phosphor, and also by the slight effect on the

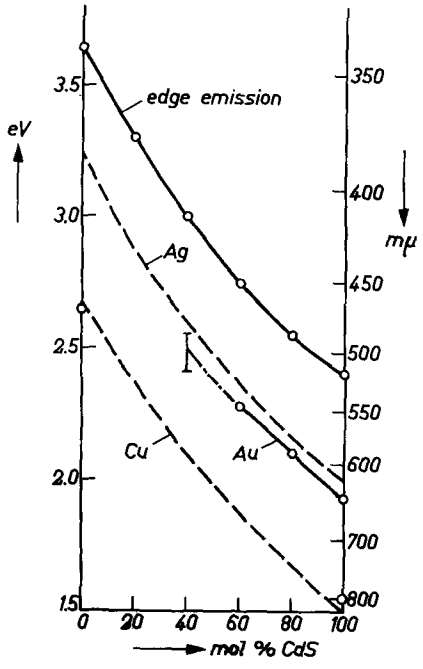

Fig. 6. Shift of emission peak of the short wave bands of (Zn,Cd)S phosphors activated by Au, Cu, and Ag. Liquid nitrogen temperature.

absorption spectrum. The coactivated band appears, together with other bands, when high chloride concentrations are used, as in the experiments of Henderson, *et al.* (6).

The 640 mμ band predominates at low temperatures in CdS activated by gold alone, but in contrast to coactivated phosphors the edge emission is not suppressed (Fig. 1) so that the visible emission looks yellow. Indeed, it is remarkable that for high zinc content and fundamental excitation the edge emission surpasses in intensity the activator emission (Fig. 7).

On introducing zinc into the lattice the 640 mμ band is displaced towards shorter wave lengths, but its intensity falls quickly so that the band cannot be traced into the zinc-rich region (Fig. 7). Further interference arises from the strong edge emission and from the coactivated band which comes up even without addition of coactivator as the zinc content is increased. However, if normal displacement of the band with zinc content is assumed (Fig. 6), this band should appear at about 400 mμ in zinc sulfide. No such emission has been reported to date.

The 800 mμ band which appears at room temperature in CdS activated by gold alone (Fig. 1) is rather wide and of weak intensity. Its intensity is about 10% of the intensity of the 640 mμ band at low temperatures. The displacement of this band with zinc content also could not be followed because of interference from other bands as the zinc content was increased. If we assume normal displacement with zinc content, we see (Fig. 6) that this band should correspond to the 470 mμ gold band in ZnS.

It is interesting to note that in gold-activated ZnS with higher gold concentration the coactivated band at 530 mμ appears even when no coactivator is added. In Fig. 8 is given the emission of ZnS(Au) for long wave u.v. excitation so that interference from the

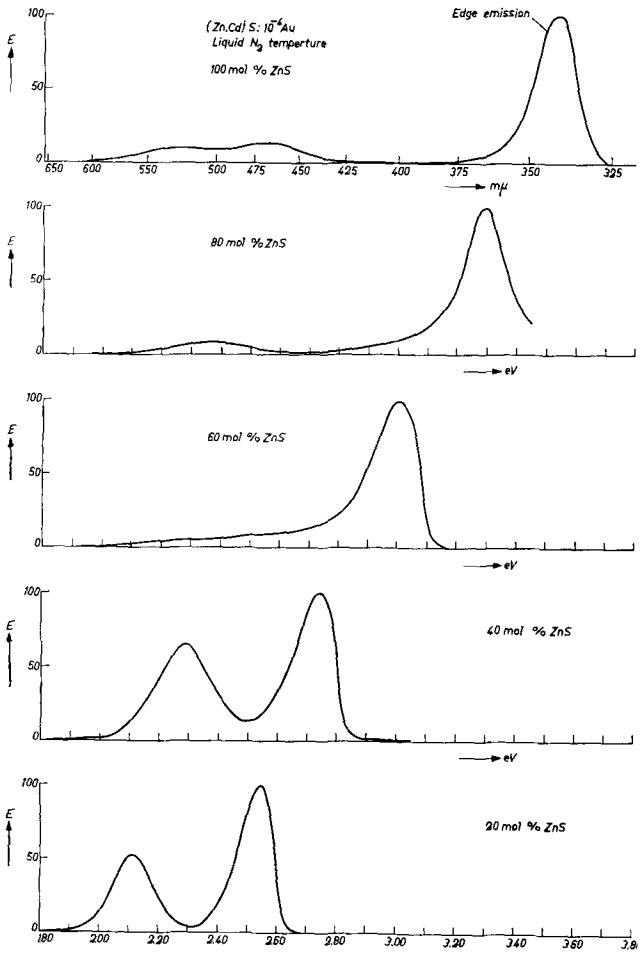

Fig. 7. Emission spectra of gold-activated (Zn,Cd)S phosphors at liquid nitrogen temperature. Fundamental excitation was used for each composition. Intensities were normalized with respect to the "edge emission."

edge emission is eliminated. We see that both the coactivated band at 530 mμ and the short wave band at 470 mμ appear in comparable intensities. The emission can be well accounted for by assuming

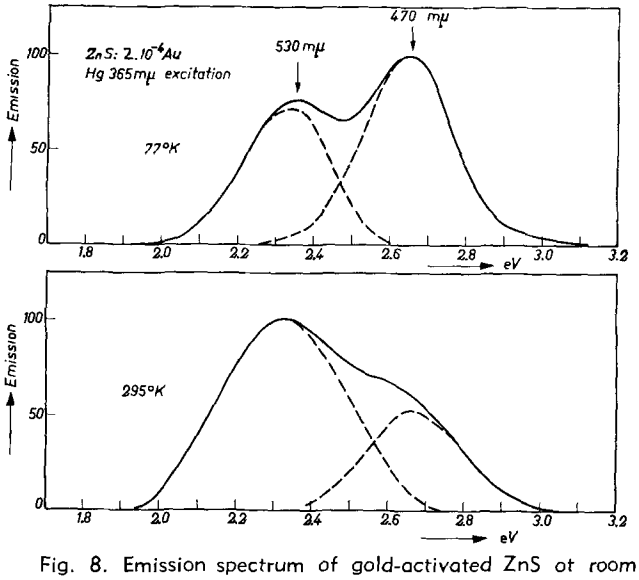

Fig. 8. Emission spectrum of gold-activated ZnS at room and liquid nitrogen temperatures. Resolution into sub-bands was done assuming that these change only in intensity, and not in position, with temperature.

these two bands to change only their relative intensities and not their position with temperature.

Discussion

The emissions of coactivated gold phosphors were found to correspond closely to coactivated copper and silver emissions over the whole range from CdS to ZnS, and it may be concluded that in this case gold is incorporated in the same state as the other activators. In view of the work of Henderson, *et al.* (6) it is interesting to note that chlorine, and presumably also other halogens, do not fully coactivate gold in (Zn,Cd)S phosphors. Such a marked difference between the halogens and the trivalent metals has not been observed for activation by copper and silver.

On the other hand, the short wave emission bands of gold show notable differences from the short wave bands of copper and silver. The nature of these centers is still unknown.

Acknowledgment

The author wishes to express his thanks to Dr. G. Diemer for helpful discussions and to Dr. A. Bril for measurement of the emission spectra.

Electrolytic Reduction of Nitro- and Dinitronaphthalenes

R. N. Boyd and A. A. Reidlinger

Department of Chemistry, Washington Square College, New York University, New York, New York

ABSTRACT

The polarographic reduction of mono- and dinitronaphthalenes was studied in buffered solutions at four different *p*H values. The relative wave heights of the multiple waves could be reasonably interpreted in terms of certain electron changes, and these were also checked by coulometric measurements on electrolyses run at controlled potentials. The first stage in reduction appeared to be a four-electron change. At *p*H 2.1 reduction often proceeded to completion, but there was polarographic evidence of intermediate stages for the homonuclear dinitro compounds. At *p*H 11, 1,4-dinitronaphthalene shows a two-electron change which may be due to a quinoid intermediate, as may a ten-electron change at *p*H 9.4 for the same compound.

The polarographic behavior of numerous dinitro derivatives of benzene has been investigated by Pearson (1), Bergman and James (2), and others, but very little has been done (3-5) with nitro compounds in the naphthalene series. Therefore, all ten possible dinitronaphthalenes were prepared, and the polarographic reduction of 5 x 10^{-4}M solutions of the nitro compounds in 80% ethanol was studied in four buffered solutions.

Electrolytic reductions at constant potentials of 2 — 5 x 10^{-4}M solutions of the nitro compounds in 80% ethanol were carried out at *p*H 2.1 using a stirred mercury cathode. The amount of current passed in each reduction was measured by a silver coulometer, and these coulometric values were compared with the relative wave heights of the polarographic curves in order to determine the particular reduction processes associated with each wave.

Experimental

Nitro compounds.—The nitro- and dinitronaphthalenes were prepared by previously published procedures, and the melting points of the products agreed with the literature values.

In particular, 2,3-dinitronaphthalene was prepared by the method of Chudozilov (6), m.p. 170-170.5° (Lit.: 170.5-171°), since the procedure given by Hodgson and Turner (7) led to a product which, although claimed to be the 2,3-isomer, melted at 159° and was found in the present work and by Ward (8) to be 1,7-dinitronaphthalene (mixed m.p. of alleged 2,3-isomer and authentic 1,7-isomer gave no depression).

Polarographic and coulometric procedure.—The polarographic and constant-potential coulometric studies were carried out with the same equipment, in the same manner and in the same buffers, as described for the work with the nitrotetralins (9), except that 2,6-dinitronaphthalene was run at a concentration of 1.0 x 10^{-4}M because of its extremely low solubility in 80% ethanol.

Polarographic data are given in Table I and constant-potential coulometric data in Table II.

Discussion

In Table II there is a comparison of the n values estimated from the relative wave heights of the polarographic curves and those obtained by coulo-

[a] The values of $E_{1/2}$ are in volts vs. S.C.E., and those of i_d/C are in μa/mmole/l. A question mark indicates that the wave is too indefinite to assign values with any degree of certainty. The pH values listed are the apparent values for the ethanolic solutions used in the electrolyses. The values of i_d/C are the sums of the individual wave heights.

metric analyses. It is evident that there is fairly good agreement between the two sets; and there is excellent agreement between them in the cases where the polarographic waves are well defined. It appears likely that for these compounds the electrolytic processes are the same at a stirred mercury cathode as at a dropping mercury electrode.

As has been found with derivatives of benzene (1, 2) and tetralin (9), the first of the multiple waves obtained from the polarographic reductions of nitro derivatives of naphthalene is usually one corresponding to a four-electron change, the transformation of a nitro group to a hydroxylamino group. This is especially true when the reductions are carried out at the higher pH's.

Kasagi (3) reported a single wave for "mononitronaphthalene" (presumably the 1-isomer) at about —0.9 v. Apparently the electrolytic medium he used, benzene-ethyl alcohol-lithium chloride, was alkaline (comparable to pH 11 in the present work). Thus his report of two waves of equal height for "dinitronaphthalene" (probably the 1,5-isomer) at potentials below —1.0 v agrees with the present results for 1,5-dinitronaphthalene at pH 11 or even at pH 9.4, and the two waves (as well as that for the mononitro compound) represent four-electron changes.

The constancy of wave height reported by Bezuglyi and Ogdanets (5) for "mononitronaphthalene" over a pH range of 2 to 12, and the variation of $E_{1/2}$ with pH for 1- and 2-nitronaphthalene reported by Imoto (4), also agree with the present findings.

Figure 1 shows two polarographic curves; curve A is a polarogram (uncorrected for residual current) that was obtained from a solution of 1,2-dinitronaphthalene at apparent pH 2.1; curve B is a polarogram (uncorrected for residual current) that was obtained from the same solution after an electrolysis in which a quantity of electricity equivalent to 3.9 electrons per molecule of dinitro compound had been passed through the cell. It can be seen that curve B is approximately two-thirds the height of curve A, and that it has the same half-wave potential as the second wave in A. The conclusion that can be drawn from these facts are the

[a] E_r is the potential of the cathode (vs. S.C.E.) at which the reduction was carried out; n is the number of electrons involved in the reduction. The apparent pH was 2.1.
[b] Estimated to nearest integral number of electrons from wave heights of the polarographic curves.
[c] At pH 6.4 and —0.80 v, n was 8.17. When E_r was raised to —1.30 v, n was 12.47.

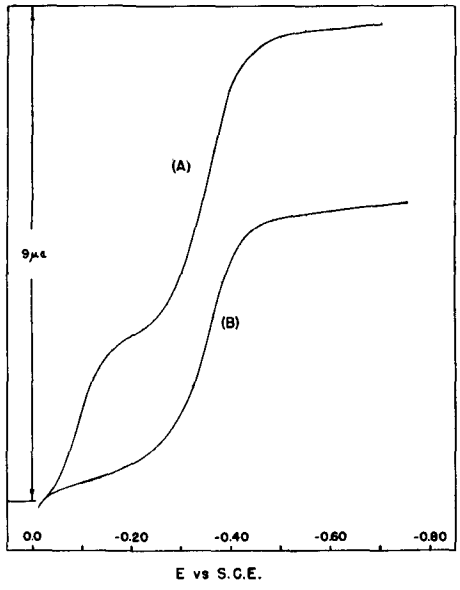

Fig. 1. Polarograms of 1,2-dinitronaphthalene at pH 2.1. A, Original nitro compound; B, after reduction equal to 3.9 electrons per molecule.

following: (*a*) the first wave of curve A corresponds to a four-electron change; (*b*) the second wave, which is twice the height of the first, undoubtedly represents an eight-electron change; (*c*) the intermediate reduction product, most likely an hydroxylamine, was stable enough in the acidic solution to yield a satisfactory polarogram.

The chemical (and electrolytic) reduction of nitro compounds in acid solution leads to the formation of amines, and it is highly probable that those polarographic reductions of dinitro compounds which require twelve electrons lead in acid to complete reduction with the formation of diamines. As the *p*H increases, reduction becomes more difficult and the polarographic curves show that eight- and ten-electron changes are commonly found. At *p*H 11 the curves are too diffuse in some cases to permit interpretation. At this *p*H the rate of condensation of intermediate products can be appreciable, and the diffuseness is probably due to secondary processes involving these condensation products.

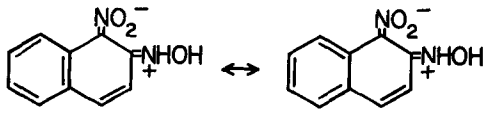
It can be seen from Table I that, as the *p*H increases, the separation between the component waves for the dinitro compounds also generally increases. Pearson (1) found this to be true for dinitrobenzenes and dinitrotoluenes [as the present authors did for the tetralin series (9)] and it is attributed to a decrease in salt formation as the medium becomes more alkaline. For if $-NR_2$ or —NHOH is an electron-releasing group but $-NR_3^+$ (and presumably $-NH_2OH^+$, too) is electron-attracting, one should expect that the nitro group in an N-arylhydroxylamine would accept electrons (be reduced) less readily than a nitro group in an N-arylhydroxylammonium salt.

The difference in the relative ease of reduction between 1-nitronaphthalene and 2-nitronaphthalene is smaller than that found for the corresponding 5- and 6-nitrotetralins (9). An examination of molecular models showed that if there were any interference between the 1-nitro group and the hydrogen atom of the 8-position, it was much less than the interference at corresponding positions in 5-nitrotetralin (9). Hence it is reasonable that 1- and 2-nitronaphthalene resemble each other more closely than do 5- and 6-nitrotetralin [or o- and m-nitrotoluene (1)].

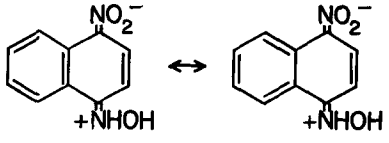
The polarograms obtained in the present work for 1,3-dinitronaphthalene bear a striking similarity to the curves obtained previously for compounds of similar "meta" structure, namely m-dinitrobenzene (1, 2), 2,4-dinitrotoluene (1) and 5,7-dinitrotetralin (9). In general, present results for the homonuclear dinitronaphthalenes (except for the 2,3-isomer which as a β,β-isomer is unique in structure) agree with the findings for *ortho-*, *meta-*, and *para*-dinitro groups in the benzene (1, 2) and tetralin series (9).

Where two nitro groups are "ortho" or "para" with respect to each other in the homonuclear dinitronaphthalenes, the greater separation of the component waves can be attributed to a lessening of the positivity (and hence reducibility) of the nitro group in the initially formed nitrohydroxylamine. For example, resonance should play a greater part in the stabilization of the 1,2- and 1,4-deriva-

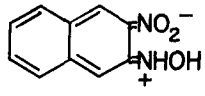
tives (I and II, respectively) than it does in the case of the 1,3- or 2,3-derivative (III).



I



II

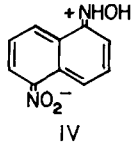


III

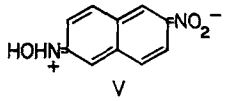
No important extra structures can reasonably be drawn for the 1,3-isomer; in the instance of 2,3-dinitronaphthalene only one quinoid structure (III) can be drawn, and it can make only a small contribution to the resonance energy. This may account for the anomalous behavior of the 2,3-isomer, which was not unexpected. The decrease in the positivity of the nitro group in the nitrohydroxylamine derived from 2,3-dinitronaphthalene certainly would not be so great as that in the 1,2- and 1,4-isomers, and hence the separation of the component polarographic waves should be less marked.

At *p*H 6.4, and in alkaline solutions, all the heteronuclear dinitronaphthalenes except the 1,8-isomer are reduced in much the same manner. The first wave corresponds to a four-electron change, and the second wave to an eight-electron change.

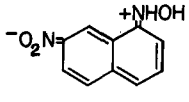
From Table I it can be seen that the separation of the component waves is distinctly greater in the curves obtained from 1,7-dinitronaphthalene than in the curves obtained from 1,5-, 1,6-, and 2,7-dinitronaphthalene, and is greatest of all in the curve for 2,6-dinitronaphthalene. Of the heteronuclear nitrohydroxylamines, quinoid structures can be drawn only for the 1,5-, 2,6-, and 1,7-isomers (IV, V, and VI, respectively).



IV



V

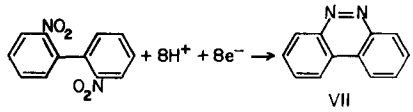


VI

The quinoid structure for the 2,6-isomer (V) is undoubtedly the most important of these (2,6-naphthoquinone, for example, is the only known heteronuclear naphthoquinone); and, therefore, the reducibility of the remaining nitro group should be most affected. It is notable that 2,6-dinitronaphthalene also shows a four-electron wave in acid solution (as well as at *p*H 6.4 and in alkaline media). The occurrence of a four-electron step in acid solution indicates an unusual stability for the hydroxylamine stage (V), since reduction in acid generally leads to a diamine (or some other highly reduced product).

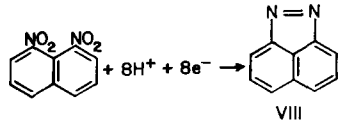
The separation of waves for the 1,7-isomer is less (only one p-benzoquinoid ring, VI) than for the 2,6-isomer, and it is in accord with conjecture that the separation for the 1,5-isomer (no p-benzoquinoid ring, IV) is not appreciably greater than for the 1,6- and 2,7-isomers, for which one can write no quinoid structures at all.

1,8-Dinitronaphthalene is the only dinitronaphthalene that does not show an initial four-electron wave in any of the buffered solutions studied. It has been reported (10) that 2,2'-dinitrobiphenyl also does not give a four-electron wave at any of the *p*H values studied; instead, its first wave at *p*H 6.4 corresponds to an eight-electron change. Large-scale reduction (11) at a controlled potential and at *p*H 6.4 showed benzo(c)cinnoline (VII) to be the major reduction product obtained from 2,2'-dinitrobiphenyl.



VII

It is possible that the polarographic reduction product from 1,8-dinitronaphthalene at *p*H 6.4 (and at higher *p*H values) is correspondingly 1,8-naphthopyrazole (VIII).



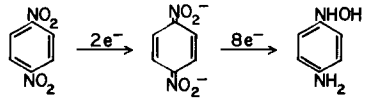
VIII

At *p*H 2.1 the probable ten-electron reduction could be interpreted as the formation of the dihydro derivative of the pyrazole (corresponding to the formation of a hydrazo compound). Under acidic conditions, where a low coulometric value was obtained for 1,8-dinitronaphthalene, the electrolyzed solution became deep purple in color. When the electrolysis was carried out at *p*H 6.4 the final solution was orange-yellow in color; yet it, too, turned to purple on standing in contact with air. It has been shown (10) that the dihydro derivative of benzo(c)-cinnoline undergoes dismutation to give a mix-

ture of benzo(c)cinnoline and 2,2'-diaminobiphenyl. Perhaps the dihydro derivative of the pyrazole also is similarly unstable.

A nine-electron change, such as found for 1,5- and 1,6-dinitronaphthalene, may be the result of two concurrent electrode processes (1); it would be awkward to account for an odd-electron change in any other way.

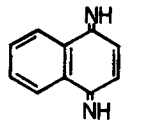
The polarographic curve for 1,4-dinitronaphthalene at *p*H 11 displays an unusual wave that appears to be associated with a two-electron step. This curve is very similar to the one that Holleck and Exner (12) obtained from 1,4-dinitrobenzene in alkaline solution. Holleck and Exner studied the reduction of the three isomeric dinitrobenzenes at the dropping mercury electrode over a wider range of *p*H values than is found in the work of Pearson (1). They stated that 1,4-dinitrobenzene gave very peculiar multi-stage curves that were caused by two concurrent processes. They claimed that in alkaline solution a two-electron change produced a stable quinone-like intermediate (IX) which was then reduced to N-(4-aminophenyl)hydroxylamine.



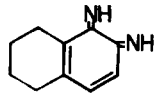
IX

It would be expected that the double bonds between the nitrogen atoms and the ring would be similar in stereochemical requirements to carbon-to-carbon double bonds, and therefore all the atoms must be in the plane of the ring. It is indeed interesting that 1,4-dinitronaphthalene and 1,4-dinitrobenzene can satisfy the steric demands and do exhibit a two-electron change at *p*H 11; whereas 5,8-dinitrotetralin, in which neither nitro group can ever be coplanar with the aromatic ring (9), gives a first wave at *p*H 11 which corresponds to a typical four-electron change, and there is no evidence of a two-electron step.

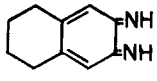
If one accepts the proposal of a quinoid intermediate for a two-electron step, one might reasonably extend the general idea and suggest that polarographic waves which appear to represent ten-electron reductions can be interpreted by means of quinoid structures, too, rather than as N-(aminoaryl)hydroxylamines (12). This would mean that the reduction product would be a quinone diimine. It is therefore possibly more than merely coincidence that at *p*H 9.4 the only compounds that show waves indicating ten-electron changes, 1,4-dinitronaphthalene, 5,6-dinitrotetralin (9), and 6,7-dinitrotetralin (9), are those for which diimines appear to be quite reasonable (X, XI, and XII, respectively).



X



XI



XII

However, it should be pointed out that the potential of −1.32 v (Table I) for reduction of the alleged 1,4-diimine to a 1,4-diamine does seem high for an analog of 1,4-naphthoquinone.

Acknowledgments

The authors wish to thank Dr. R. T. Schenck for his suggestions about apparatus, Morton Meadow for gifts of chemicals and time in the preparation of 1,7-dinitronaphthalene, and the DuPont Corporation for a generous gift of 1,5-dinitronaphthalene.

Manuscript received Dec. 8, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

Polarography of Some Aromatic Nitro and Carbonyl Compounds

Julia T. Gary and R. A. Day, Jr.

Department of Chemistry, Emory University, Atlanta, Georgia

ABSTRACT

The polarographic reduction of the nitro and carbonyl groups in 2-nitrofluorenone, 2,7-dinitrofluorenone, and 2,5-dinitrofluorenone has been studied in buffered solutions over a pH range of about 1-13. To aid in interpreting the electrode reactions, additional polarographic studies were made with several compounds containing only the nitro or carbonyl group. These compounds were fluorenone, 4-nitrobiphenyl, 4,4′-dinitrobiphenyl, 2.4′-dinitrobiphenyl, 2,5-dinitrofluorene, and 2-aminofluorenone, and the polarography was carried out under the same solution conditions. The number of electrons involved in the reduction steps of several of these compounds was measured using the controlled cathode potential technique. It was found that the characteristic double waves of the carbonyl group in fluorenone are merged into a single two-electron wave in the dinitrofluorenones. This effect is apparently a general one, caused by the decrease in stability of the intermediate free radical brought about by the hydroxylamine groups in the aromatic nucleus.

The polarographic reduction of relatively few compounds containing both nitro and carbonyl groups has been reported in the literature. The nitrobenzaldehydes have been most thoroughly studied (1-4), and it has been possible to assign the various waves to the different steps in the reduction of the nitro and carbonyl groups.

We were particularly interested in the effect that an amino (or hydroxylamino) group has on the carbonyl waves in compounds where both groups are attached to a single aromatic nucleus. An aromatic nitro group is normally reduced at a lower potential than a carbonyl group; hence, when the carbonyl group is undergoing reduction the other substituent in the aromatic nucleus is the amino or hydroxylamino, not the nitro group. It has been observed that, whereas an aromatic aldehyde is normally reduced in two well-separated one-electron steps in sodium hydroxide solutions, the waves are apparently merged into a single two-electron step in meta-nitrobenzaldehyde (2). In the case of ortho and para-nitrobenzaldehydes the waves remain separate (2).

The ketone fluorenone is well known for its tendency to reduce in two well-separated one-electron steps in both acid, neutral, and basic media. It was therefore, of interest to study the behavior of the carbonyl group in fluorenone in cases where a nitro group was substituted in the 2 or 7 position of the fluorene nucleus. As the work progressed some dinitrofluorenones were studied and to aid in the interpretation of their behavior of the following compounds is described herein: fluorenone, 2-nitrofluorenone, 2,7-dinitrofluorenone, 2,5-dinitrofluorenone, 2-aminofluorenone, 4-nitrobiphenyl, 4,4′-dinitrobiphenyl, 2,4′-dinitrobiphenyl, and 2,5-dinitrofluorene.

Experimental

Polarographic data were obtained with a L&N Electrochemograph Type E. Half-wave potentials were corrected for *IR* drop and for lag caused by galvanometer damping. The electrolysis cell, experimental procedure, and buffer solutions were the same as described previously (5). However, because of the low solubility of several of the compounds in ethanol-water mixtures, a mixture of water and acetone was employed. The compound of interest was dissolved in acetone, and the cell solution was made by mixing equal volumes of this solution with the appropriate aqueous buffer. A single capillary of Corning marine barometer tubing was used. Its characteristics were: droptime 5.0 sec, $m = 1.34$ mg sec^{-1}, determined in a water-acetone mixture, buffered with citrate-phosphate (apparent pH 5.0) with an open circuit. The calculated value of $m^{2/3}\ t^{1/6}$ was 1.59 $mg^{2/3}\ sec^{-1/2}$.

The coulometric measurements were carried out using a potentiostat of the Lingane-Jones type (6) and a hydrogen-oxygen coulometer. The cell, electrodes, and experimental procedures were essentially those recommended by Lingane (7).

Samples of 2-nitrofluorenone, 2-aminofluorenone, 2,5-dinitrofluorene, 2,5-dinitrofluorenone, and 2,7-dinitrofluorenone were kindly furnished us by the late Professor C. W. Bennett of Western Illinois State College (8). All other compounds studied were Eastman Kodak White Label chemicals. Reagent grade acetone was found to give no polarographic waves in the potential range normally employed.

Results

The half-wave potentials of the several compounds at different pH values are listed in Table I, along with measured and estimated values of the number of electrons consumed in the reduction process.[1] The behavior of the compounds will be discussed individually.

[1] A more complete list is available and may be obtained by writing to the authors.

Values of n given in brackets were estimated from the diffusion currents. Values not in brackets were measured coulometrically and rounded off to the nearest whole number.

Fluorenone gives two well-defined one-electron waves in both acid and basic media. In the pH range of about 7-9 the waves are merged. In ethanol-water solutions of low alcohol content these waves are usually separate over the entire pH range; however, they are merged in the pH range of 6-8 in solutions which contain a high percentage of alcohol (9) and it is not surprising to find them merged here in a medium which is fairly high in acetone concentration. The 2-amino derivative is reduced in a single 2-electron step throughout the acid range; separation into two waves was not observed until the pH was raised to about 11. At pH 12 the waves were well separated into two one-electron steps. This behavior is in accord with that previously observed for meta-nitrobenzaldehyde (2) except at the highest pH studied.

In the case of 2-nitrofluorenone it is apparent that wave 1 corresponds to the reduction of the nitro group to hydroxylamine, this being a 4-electron step. Wave 2 is obviously due to reduction of the carbonyl, and here too the wave is a 2-electron step. There was no evidence of separation of the carbonyl wave into two steps at any pH although the wave-height did decrease appreciably at high pH values. A third wave was observed at pH 1.4, and the coulometric n-value corresponded to a 2-electron step. This probably corresponds to reduction of the hydroxylamino group to the amine. The wave was not observed at higher pH values.

The behavior of 4-nitrobiphenyl was similar to that of nitrobenzene (10, 11) in the low pH region, two waves of four and two electrons, respectively, being formed. The second wave was not observed in neutral media but did reappear in solutions of pH greater than 8.6. This behavior is not observed with nitrobenzene and may result from the fact that the unsubstituted benzene ring can supply electrons to the substituted ring, thereby facilitating the release of the hydroxyl group and the formation of a reducible quinoid structure (12). A macroelectrolysis was carried out in 0.1M HCl at a potential of −0.50 v. The reduction product was isolated and recrystallized. The melting point (152°-154°C) indicated that the product was 4-hydroxylaminobiphenyl. The product gave a characteristic red color with concentrated sulfuric acid.

At low pH values the compound 4,4'-dinitrobiphenyl gave reduction waves of eight and two electrons, respectively. This contrasts to the behavior shown by p-dinitrobenzene (10) in giving two waves of four and eight electrons. Apparently both nitro groups in the diphenyl compound are reduced to hydroxylamine simultaneously, whereas the two groups in the benzene ring are reduced in separate steps. In the pH range of about 7-10, however, the 8-electron wave of dinitrobiphenyl does split into two 4-electron steps. It is probable that each 4-electron wave corresponds to reduction of a single nitro group to the hydroxylamine, rather than to reduction of the two groups simultaneously to the nitroso stage. At low pH the hydroxylamine can add a proton, and the resulting positively charged group makes easier the reduction of the second nitro group. At higher pH the free hydroxylamine can act as an electron-releasing group, thereby making the reduction of the second nitro group more difficult. This would account for the splitting of the 8-electron wave as the pH is increased. The 2-electron step mentioned above was not present in solution of

about pH 7, but did reappear about pH 8.5. Hence, from pH 8.5 to 10 there were three waves of 4, 4, and 2 electrons, respectively. About pH 10 the first two waves were merged again. Complete reduction of both nitro groups to amines (12 electrons) was not observed at any pH, whereas p-dinitrobenzene did show complete reduction up to pH 4.1 (10).

The behavior of 2,4'-dinitrobiphenyl was very similar to that of the 4,4'-isomer. The initial 8-electron wave split into two 4-electron steps at a lower pH (about 4) and the two did not merge again until about pH 11. This behavior more nearly corresponds to that of m-dinitrobenzene (10) which gives two initial 4-electron waves up to pH 9.2. Again, however, no more than 10 electrons were taken up by the biphenyl compound whereas Pearson found complete reduction of m-dinitrobenzene at low pH values (10).

The behavior of 2,5-dinitrofluorene was different from that of both the dinitrobenzenes and the dinitrobiphenyls. Only one wave, corresponding to an 8-electron reduction, was observed over the pH range of about 1-10. Apparently both nitro groups are reduced simultaneously even though they are in different rings, and rotation of the two rings with respect to one another is not possible. This remained the case even at higher pH values where the 8-electron wave of the dinitrobiphenyls split into two 4-electron steps. Two waves were observed around pH 11 and 12, but in such basic solutions side reactions of the reduction products complicate the picture and the mechanism is complex.

The behavior of the nitro groups of both dinitrofluorenones resembled that of the dinitrobiphenyls more than that of dinitrofluorene. At low pH there was an initial 8-electron wave which split above pH 4 into two 4-electron waves. The waves were merged again at high pH. With both compounds wave 2 is obviously produced by reduction of the carbonyl group. The half-wave potentials are very near the values of those of 2-aminofluorenone and those of the second wave of 2-nitrofluorenone. At all pH values the current corresponded to the uptake of two electrons, there being no indication of a separation into two one-electron steps, nor a significant decrease in current at high pH. Apparently the two hydroxylamino groups in the fluorene nucleus (meta to the carbonyl) greatly decrease the stability of the intermediate free radical formed by addition of one electron to the carbonyl group. The free radical is then reduced at its formation potential and dimerization does not occur. This effect is the same as that previously observed with m-nitrobenzaldehyde.

Both dinitrofluorenones give a 2-electron wave around −1.00 v at pH 1.4. This corresponds to the reduction of one hydroxylamine group to the amine. Wave 2 of 2,7-dinitrofluorenone in solutions of low pH corresponded to an uptake of four electrons. This is probably caused by over-lapping of the waves corresponding to the reduction of the carbonyl group and one of the hydroxylamino groups. In other words at pH 1.4 the 2,7 compound took up 14 electrons, corresponding to complete reduction of both nitro groups to amines, and the carbonyl group to the secondary alcohol. At pH values greater than 4 the reduction of the nitro groups stopped at the hydroxylamine stage, as is normally found for aromatic nitro compounds.

Manuscript received Jan. 18, 1960.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

Kinetics of the Oxidation of Pure Tungsten from 500° to 1300°C

E. A. Gulbransen and K. F. Andrew

Chemistry Department, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

Kinetic studies were made on the oxidation of tungsten from 500° to 1300°C for time periods up to 6 hr, and for oxygen pressures from 0.1 atm to 0.00132 atm. The rate data were fitted to the parabolic rate law. A number of deviations and transitions were observed. For all of the experiments the initial slopes of the parabolic rate law plots were smaller than the final values found for thick films. A transition in the rate of oxidation was observed for weight gains of 2500-4000 $\mu g/cm^2$ at temperatures of 650°-800°C. Photographs of the oxidized surface above 650°C show that oxidation occurs in a preferential manner at the edges. Pressure had a strong effect on the rate of oxidation for the experiments above 950°C. At 1200°C weight loss curves were observed for pressures as high as 0.1 atm. Above 1200°C the oxidation reaction is similar to the combustion of graphite. The rate of oxidation is limited by the volatility of WO_3, the diffusion of oxygen to the surface, and the diffusion of W_3O_9 away from the surface.

The behavior of tungsten and its surface oxides in oxidizing and neutral atmospheres and in vacuum at high temperature is an interesting scientific problem. This paper presents results of an extensive study of the following problems: (*a*) the effect of time and temperature on the rate of oxidation of tungsten from 500° to 1300°C, (*b*) the effect of pressure on the time course of oxidation at four temperatures, (c) physical structure and crystal structure of the oxide scale, and (*d*) mechanism of reaction.

The oxidation of tungsten below 500°C has been studied by Gulbransen and Wysong (1) and by Gorbounova and Arslambékov (2). Gulbransen and Wysong (1) found the oxidation to follow the parabolic rate law between 400° and 500°C. Deviations were found to occur at 550° and below 400°C. A heat of activation of 45,650 cal/mole was calculated from the parabolic rate law constant. Tungsten oxides were found to volatilize at temperatures as low as 800°C for thick oxide films. Thin oxide films were found to require a higher temperature for volatilization of WO_3. Gorbounova and Arslambékov (2) found that the heat of activation for the temperature range of 390°-487°C was dependent on the surface preparation. Oxidation experiments on electrolytically polished samples gave a heat of activation of 46,500 cal/mole from the parabolic rate law constant while studies on mechanically polished samples gave a heat of activation of 41,000 cal/mole.

Dunn (3) studied the oxidation of tungsten from 700° to 1000°C and found the parabolic rate law was followed. The temperature variation of the parabolic rate law constant was found to follow an exponential law of the Arrhenius type. An inflection was noticed at 850°-900°C and was attributed to a phase change in the oxides.

Scheil (4) studied the oxidation rate at 500° and 700°C over long periods of time and found a linear rate law. This was interpreted as evidence for the presence of a nonprotective film.

An intermediate type of rate law was suggested by Nachtigall (5) and Kieffer and Kolbl (6).

Webb, Norton, and Wagner (7) studied the oxidation of tungsten between 700° and 1000°C. The oxidation reaction was found to follow the parabolic rate law initially but transformed to a linear rate law for thick films. Two oxide layers appeared to form. In the outer layer a porous powdery yellow tungstic oxide WO_3 was formed, while in the inner layer a thin film of adherent oxide of uncertain composition was formed. Two rate processes were combined to give the over-all rate law. These were the parabolic rate law for the inner oxide layer and the linear rate law for the outer layer.

Baur, Bridges, and Fassell (8) studied the oxidation of tungsten rod and sheet from 600° to 850°C as a function of oxygen pressures from 20 to 500 psia. A linear rate law was found. Oxygen pressure increased the rate of oxidation. An equilibrium adsorption process was proposed to occur prior to the rate determining step.

Arkharov and Kozmanov (9) studied the composition of the oxide scale on tungsten between 500°-1350°C and the mechanism of reaction. They concluded that diffusion of oxygen was the rate-controlling process.

Semmel (10) studied the oxidation of tungsten in flowing air from 982° to 1371°C. The oxidation of tungsten was found to change from a linear to a parabolic rate law as the temperature was increased. Oxide melting was proposed to account for the decrease in oxidation rate above 1150°C.

Experimental

Kinetic studies were made using the vacuum microbalance method (11). Small strips of 5 mil tungsten sheet or small lengths of 9 mil wire were

suspended from a sensitive quartz beam microbalance operating inside an all glass and ceramic vacuum system (12). A 1-in. I. D. gas tight mullite furnace tube was used to enclose the sample. This tube was sealed directly to the all-glass vacuum system. No metal, rubber, grease joints or stopcocks were used in the reaction system. Pressures of less than 10^{-8} mm Hg could be attained after 24 hr of pumping (12).

To minimize the reaction of tungsten with the residual gases present in the vacuum system on heating to temperature the sample and furnace tube were pumped for several hours at a pressure of 10^{-6} mm Hg or lower. Purified oxygen was added after the furnace was raised and thermal equilibrium established. The time course of the reaction was followed semicontinuously by reading the balance position relative to a fixed point.

The furnace temperature was maintained constant to ±1.5°C by the use of a calibrated high sensitivity recorder controller and a calibrated Pt-Pt + 10% Rh thermocouple.

Two microbalances of different sensitivities were used. For rapid reactions a specially constructed low sensitivity microbalance was used having a sensitivity of 0.234 x 10^{-3} cm/μg. The high sensitivity balance had a sensitivity of about 0.9 x 10^{-3} cm/μg. Four sample sizes were used corresponding to surface areas of 2.69 cm^2, 1.34 cm^2, 0.61 cm^2, and 0.32 cm^2. The specimens weighed 0.3770 g, 0.1533 g, 0.07019 g, and 0.0315 g, respectively. The wire samples were 1 cm long, weighed 0.0078 g, and had surface areas of about 0.0743 cm^2.

Weight gains of 8 mg could be measured on specimens having a surface area of 0.32 cm^2 and weighing 0.0315 g. This weight gain was equivalent to 94% of the metal reacting with oxygen to form WO_3.

Specimens were prepared from Westinghouse high-purity 5 mil cold rolled tungsten sheet or 9 mil wire. The spectrographic analysis of the sheet was as follows: Al, 0.0001-0.001; Mn, not detected; Fe, 0.001-0.01; Si, 0.001-0.01; Mg, 0.0001-0.001; Mo, 0.001-0.01; Cu, < 0.001; Ag, 0.0001-0.001; Ni, 0.0001-0.001; and Ca, 0.0001-0.001.

Spectroscopic analyses of the tungsten wire were as follows: Al, 0.0004; Mn, < 0.0005; Fe, 0.0020; Si, 0.003; Mg, < 0.0005; Ni, < 0.0005; K, 0.0035; Mo, 0.0015; C, 0.005; O, 0.0024; N, 0.0005; H, 0.0007; Cd, 0.002.

Specimens were cut to shape by a small shearing machine with the specimen hot or cold. The hole for the supporting wire was drilled by a high velocity jet of Al_2O_3. A tungsten etch containing NaOH and $K_3Fe(CN)_6$ was used to remove the scale formed by heating during the shearing operation. Samples were next washed with distilled water.

The surface was polished with emery paper through 4/0 and finally cleaned with petroleum ether and absolute alcohol.

Each oxidation experiment was made with a new specimen. The experimental results were reproducible to 10% except for the temperature ranges where transition effects were observed.

Initially, cold sheared specimens were used. However, the oxidation curves were not reproducible due to excessive splitting of the metal during oxidation. This splitting effect opened up new areas of metal for reaction. Most of the results reported in this study were for hot sheared tungsten samples. Splitting also occurred for hot sheared samples but to a much lesser degree.

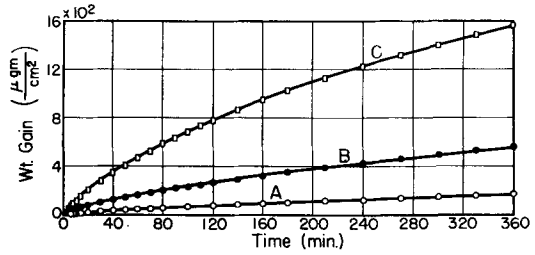

Fig. 1. Oxidation of tungsten, 500°-600°C, 0.1 atm. O_2, abraded, A—500°C, B—550°C, C—600°C.

Results

Effect of temperature.—Abraded hot sheared tungsten strip specimens were oxidized over the temperature range of 500°-1150°C at a pressure of 0.1 atm of purified oxygen. For the 500°-650°C temperature range the time period was 6 hr. At 1150°C, a time period of 6 min was sufficient for nearly complete reaction of the tungsten sample. Figures 1 to 4 show weight gain versus time plots of the experimental measurements. Weight gain is given in micrograms per square centimeter and time in minutes. No correction was made for surface area changes during reaction.

To relate the weight gain in micrograms per square centimeter to oxide thickness in Angstroms a factor of 67.5 could be used. This factor was calculated from a density of 7.16 for the oxide WO_3 and a surface roughness ratio of unity. However, thickness calculations based on this factor were subjected to three limitations for heavily oxidized specimens. Reaction occurs more rapidly at the edges, cracking introduces porosity in the oxide layer, and surface area for reaction decreases. The factor 67.5 is significant only for the early stages of the oxidation reaction.

Figure 1 shows the weight gain curves for the 500°, 550°, and 600°C runs. The rate of oxidation decreases as the oxide thickens which indicates that the oxide scale was limiting the rate of oxidation. Calculations based on Fig. 1 show an average oxide film of about 100,000Å thick was formed on tungsten at 600°C in 6 hr. For the same oxidation conditions a 2120Å thick oxide film was formed on nickel and a 32,600Å thick oxide film was formed on zirconium.

Table I shows a summary of the oxide weight gains after 5, 10, 60, 180, 360 min of oxidation for the complete set of experiments. The color of the oxide at the surface and edges and the stability of the oxide scale to cracking and splitting were also tabulated.

Figure 2 shows oxidation curves for the 600°-750°C runs. S-shaped oxidation curves were observed in some of the experiments. Rapid changes in rate of oxidation occurred in the weight gain vs. time curves for weight gains of about 2,500 to 3,000 μg/cm^2. Small yellow crystals of oxide were formed on the 650°C oxidized surface while green oxide

crystals formed on the edge of the samples oxidized at 700° and 750°C.

At 750°C a weight gain of 11,800 $\mu g/cm^2$ was found after 3 hr of reaction. Visual observations of the oxidized surface and the kinetic data show that tungsten has poor resistance to oxidation at 750°C. Rapid oxidation occurs in a preferential manner at the edges. Spalling occurred in some of the experiments. If cracking or spalling occurs so that oxygen can react more rapidly with the metal, a rapid change will occur in the rate of oxidation. Due to stresses at the sample edges, cracking occurs first at the edges.

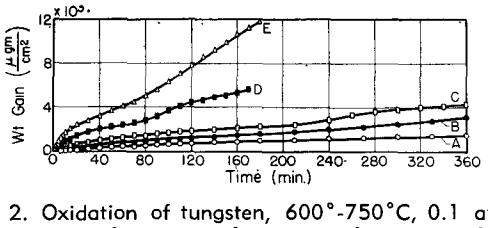

Fig. 2. Oxidation of tungsten, 600°-750°C, 0.1 atm. O_2, abraded, A—600°C, B—625°C, C—650°C, D—700°C, E—750°C.

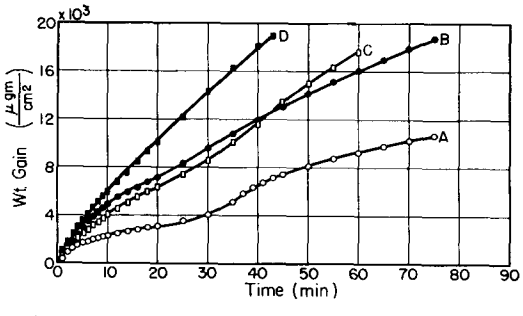

Fig. 3. Oxidation of tungsten, 800° to 950°C, 0.1 atm. abraded, A-800°C, B—850°C, C—900°C, D—950°C.

Figure 3 shows oxidation curves for the 800°-950°C oxidation runs. Again S-shaped curves were found at 800° and 850°C. A weight gain of 16,090 $\mu g/cm^2$ was observed at 850°C in 1 hr. Examination of the sample showed splitting had occurred at the edges. Calculations based on Fig. 1-3 shows that the increase in rate of oxidation with temperature becomes smaller above 800°C.

Figure 4 shows oxidation curves for the 950° to 1150° range of temperature. Reaction times of 6-45 min gave nearly complete reaction of the tungsten to form WO_3.

The 1100°C oxidation showed an initial reaction rate of 83.0 $\mu g/cm^2/sec$ and an average rate of 41.5 $\mu g/cm^2/sec$ for the 10-min run. Assuming a WO_3 scale is formed, the heat of formation of WO_3 contributes 0.34 $cal/cm^2/sec$ to the sample. Without radiation and convection losses this heat would raise the sample temperature 82°C/sec. Assuming black body conditions, radiation losses alone would limit the total temperature rise to 24°C. After the first minute of reaction the sample would assume a temperature rise of 12°C. However, convection currents in the gas would also transfer heat from the specimen and limit the temperature rise to less than 12°C.

If reaction occurs locally at the edges, local heating can occur which would lead to a higher temperature and a more rapid reaction at the edges. This factor combined with stress conditions at the edges leads to breakdown conditions for oxidation.

Figure 5 shows oxidation curves for the 1100° to 1200°C range of temperature using 9-mil wire specimens. The 1100° and 1150°C runs show initial weight gains. After 2-5 min of oxidation the specimens start to lose weight at a nearly constant rate. The 1200°C curve shows a weight loss immediately after adding oxygen. As fast as oxide is formed evaporation occurs.

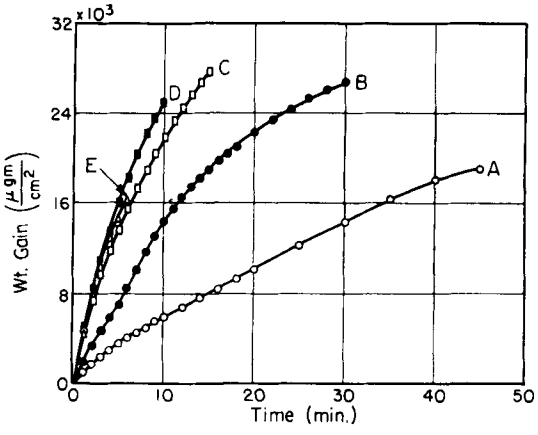

Fig. 4. Oxidation of tungsten, 950°C to 1150°C, 0.1 atm. O_2, abraded A—950°C, B—1000°C, C—1050°C, D—1100°C, E—1150°C.

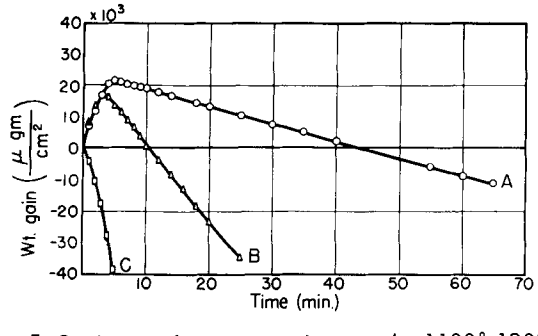

Fig. 5. Oxidation of tungsten, wire sample, 1100°-1200°C, 0.1 atm. O_2, abraded, A—1100°C, B—1150°C, C—1200°C.

The 1100°C run showed an average reaction rate of 85.5 $\mu g/cm^2/sec$ for the first 4 min of reaction. This compares to a value of 83.0 $\mu g/cm^2/sec$ for the initial reaction rate of a strip specimen of tungsten. The wire specimens were oxidized over a fairly long time period to show the effect of evaporation on the oxidation process. At 1200°C the theoretical rate of evaporation of WO_3 was faster than the rate of oxidation. The net result is a weight loss curve.

Above 1200°C the rate of oxidation at 0.1 atm of oxygen pressure was too rapid to measure on our microbalance apparatus. Oxidation and evaporation of the 9-mil tungsten wire specimen was complete in 1 or 2 min of reaction time. To extend our results to 1300°C the oxidation reaction was studied at a pressure of 0.0013 atm. Figure 6 shows the results. Weight loss in $\mu g/cm^2$ was plotted against time in minutes. S-shaped weight loss vs. time curves were found.

Figures 5 and 6 suggest that for temperatures of 1200°C and higher evaporation of WO_3 occurred as fast as the oxide was formed. The form of the oxidation curve was governed by diffusion of oxygen to the surface and geometrical considerations of the decreasing surface available for reaction. As oxide volatilizes the surface area of metal decreased and a slower rate of reaction resulted.

Effect of pressure.—For many metals the effect of pressure on the kinetics of the oxidation reaction is less important than time and temperature. For tungsten which forms a volatile oxide oxygen pressure and the pressure of inert gases are very important.

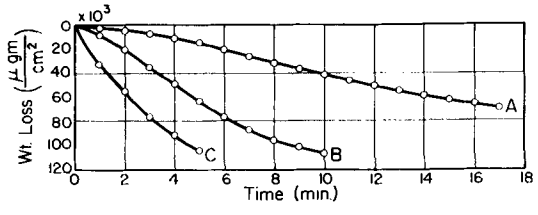

Fig. 6. Oxidation of tungsten, wire sample, 1200°-1300°C, 0.0013 atm. O_2, abraded, A—1200°C, B—1250°C, C—1300°C.

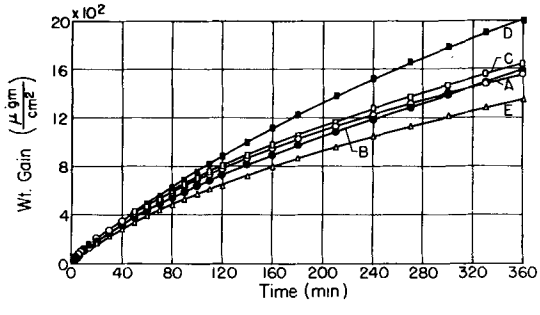

Fig. 7. Oxidation of tungsten at 600°C, effect of O_2 pressure, A—0.1 atm., B—0.068 atm., C—0.0355 atm., D—0.0132 atm., E—0.0079 atm.

Three temperatures were chosen for the studies on the pressure effect using strip specimens, 600°, 950°, and 1050°C. Additional experiments were made at 1000° and 1100°C. Figure 7 shows oxidation curves at 600°C for five pressures between 0.1 atm and 0.0079 atm. Each curve shows a slowly decreasing rate of reaction as the oxide thickens. Decreasing the oxygen pressure from 0.1 atm to 0.0132 atm slightly increased the rate of oxidation. The effect of pressure is small on the rate of oxidation. At 600°C the volatility of WO_3 was unimportant in the dry oxidation of pure tungsten. Figure 8 shows the effect of oxygen pressure on the rate of oxidation at 950°C together with the volatility curve of WO_3 (13, 14). Decreasing the oxygen pressure lowers the rate and extent of oxidation. The volatility of WO_3 and diffusion of WO_3 away from the surface has affected the time course of oxidation.

Figure 9 shows the effect of oxygen pressure on the time course of oxidation at 1050°C together with the volatility curve for WO_3 (14). At this temperature the oxygen pressure has a major effect on the time course of the reaction. For oxygen pressures of

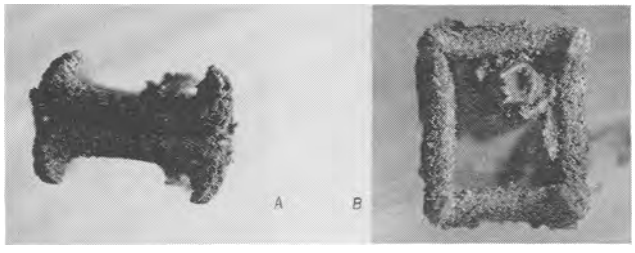

Fig. 12. Photograph Oxidized Tungsten Sample 950°C., 0.1 atm. O_2, 54 minutes, 20x, Hot Sheared, A. Edge, B. Surface.

0.0033 atm and lower, curves F and G, a weight loss is observed. This plot demonstrates the fact that two processes control the weight gain vs. time curves at 1050°C. The first process is the formation of the oxide scale and the second process is the volatility of WO_3 and its diffusion into the gas phase. The latter process is a function of the density of the oxygen atmosphere surrounding the specimen. Curve H shows the volatility curve of WO_3 in vacuum (14).

Table II summarizes the studies on the pressure effect at the temperatures of 600°-1100°C.

Figure 10 shows a study of the effect of oxygen pressure on the oxidation of wire specimens of tungsten at 1200°C for 7 pressures. Table III summarizes the data. Weight loss curves were obtained for all pressures at 1200°C. The maximum weight loss curve occurs at an oxygen pressure of 0.012 atm. The decrease in the rate of weight loss below 0.012 atm oxygen pressure is probably due to the lower rate of oxidation. Again S-shaped curves were obtained for the lower oxygen pressures. The S-shaped curve is due to the decrease in surface area.

Photographic studies.—To show the localized nature of the oxidation reaction at the edges a number of the oxidized samples were photographed at 20 X magnification. Figures 11-12 show photographs of both the edge and surface of the oxidized metal

samples for experiments at 750°C and 950°C. Table IV shows a summary of the oxidation conditions, weight gains, and photographic observations on these samples. Initial breakdown of the oxide-metal interface occurs at the edges during oxidation for both hot and cold sheared samples. However, breakdown occurs on the cold sheared surfaces at an earlier stage of the reaction.

Rate law correlation.—Both the linear and parabolic rate laws have been used to explain the oxidation rate of metals. The linear rate states

$$W = At + C$$

A surface or interface reaction may control the rate of oxidation. In the above equation W is the weight gain, t is the time, and A and C are constants. The parabolic rate law states

$$W^2 = At + C$$

Here the symbols have the same meaning as before. This equation has been derived from fundamental principles of diffusion (15, 16).

To test the application of the parabolic rate law and to show the existence of rapid changes in the rate of oxidation, plots were made of the square of the weight gain versus time over the temperature range. Because of the complex nature of the oxidation reaction of tungsten it is not expected that the parabolic rate law will hold over the complete time, temperature, and pressure conditions. Initial values of the constants probably represent diffusion controlled reactions. Changes from these conditions can be seen by the use of the parabolic rate law plots.

Figure 13 shows the parabolic rate law plot for the 500°C run. The plot shows a steady increase in the value of the rate law constant. An initial value of 4.18×10^{-13} $(g/cm^2)^2$ sec^{-1} was calculated for A. The value for the 5-6 hr time period was 1.75×10^{-12} $(g/cm^2)^2$ sec^{-1}. At temperatures as low as 500°C the protecting properties of the oxide decrease as the oxide thickens.

Similar plots for the oxidation runs at 550° and 600°C show curves like those of Fig. 13. At 625°C a

transition was noted from parabolic plots of the rate of oxidation data. Figure 14 shows the parabolic rate law plot of the 650°C run. A transition was found after 200 min of reaction or at an oxide thickness of 2400 $\mu g/cm^2$. After 300 min of reaction, Fig. 14 shows the parabolic rate law was again obeyed.

Transitions were found also for the oxidation runs at 650°, 700°, 750°, and 800°C. However, the weight gain for transition was larger. Table V shows the initial and final parabolic rate law constants.

Figure 15 shows a parabolic rate law plot of the 900°C oxidation run. The slope of the plot increased during the first 45 min of reaction to a nearly constant value. The initial value of A was 1.725×10^{-8} $(g/cm^2)^2$ sec^{-1} and the final value 1.45×10^{-7} $(g/cm^2)^2$ sec^{-1}. Similar parabolic rate law plots were found for the 950°, 1000°, 1050°, 1100°, and 1150°C runs.

This analysis suggests that the rate of oxidation of tungsten is not a simple function of the time of reaction. Adhesion of the oxide scale to the metal is very important. Localized cracking of the oxide scale may account for the rapid changes observed in the rate of oxidation.

Figure 16 shows a logarithmic plot of the parabolic rate law constants A vs. $1/T$. Three values from our earlier work (1) at 400°, 450°, and 500°C were included. In addition the data obtained by Dunn (3) and by Webb, Norton, and Wagner (7) were included in the plots. Since the parabolic rate law constants were time dependent, both the initial and final values of the constants from our data were plotted.

Three straight lines were drawn to represent the data. The dashed line in Fig. 16 was drawn to present the initial values of the parabolic rate law constants and the earlier values of Gulbransen and Wysong (1). The slope of the dashed line gave a heat of activation of 44,500 cal/mole. This value was found also by Gulbransen and Wysong (1) to explain the oxidation of tungsten for temperature of 400° to 500°C. Gorbounova and Arslambékov (2)

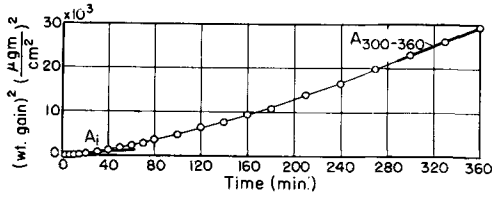

Fig. 13. Oxidation of W, parabolic plot, abraded through 4/0, 500°C, 0.1 atm. of O_2, $A_{initial} = 4.18 \times 10^{-13}$, $A_{300-360} = 1.75 \times 10^{-12}$ $(g/cm^2)^2$ sec^{-1}.

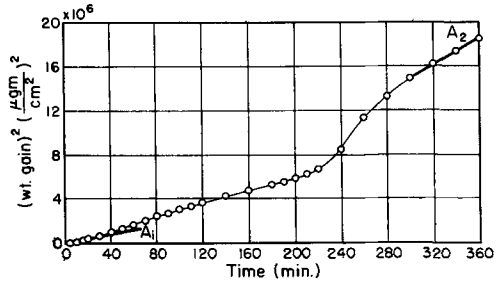

Fig. 14. Oxidation of W parabolic plot, abraded through 4/0, 650°C, 0.1 atm. of O_2, $A_{initial} = 3.33 \times 10^{-10}$, $A_{300-360} = 1.03 \times 10^{-9}$ $(g/cm^2)^2$ sec^{-1}.

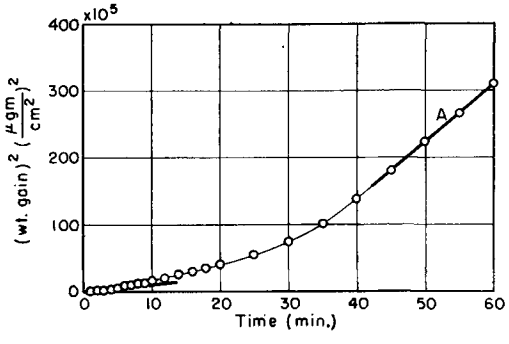

Fig. 15. Oxidation of W, parabolic plot, abraded through 4/0, 900°C, 0.1 atm. of O_2, $A_{45-60} = 1.45 \times 10^{-7}$ $(g/cm^2)^2$ sec^{-1}.

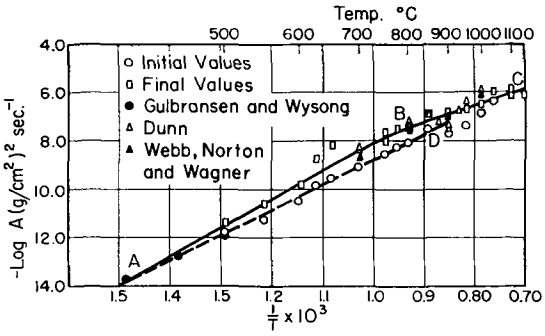

Fig. 16. Log A vs $\frac{1}{T}$, ΔH_{AB} = 54,500 cals per mole, ΔH_{BC} = 32,500 cals per mole, ΔH_{AD} = 44,500 cals per mole.

obtained values of the heat of activation for the low-temperature range of 300°-487°C of 41,000-46,500 cal/mole.

44,500 calories per mole probably represents the heat of formation of defects and the heat of activation of diffusion of metal atoms for the early stage of oxidation when the oxide film is protecting the metal. The final values for the parabolic rate law constants could be fitted by two straight lines. The values below 750°C were fitted by a straight line which gave a heat of activation of 54,500 cal/mole. The high final values for A found between 600° and 700°C were due to the transition stage in the oxidation process. Above 750°C the parabolic rate law constants were fitted to a line having a heat of activation of 32,500 cal/mole. No interpretation can be given to the final values of the parabolic rate law constants.

The parabolic rate data of the several groups of investigators were in fair agreement with our data.

Effect of surface treatment and sample pretreatment.—Three sample pretreatments are compared: no pretreatment, reduced in H_2 at 600°C, and preheated to 1000°C in vacuum of less than 10^{-6} mm Hg. The results show that the as-received and abraded sample oxidized a little slower than abraded samples given a hydrogen or vacuum pretreatment. For practical purposes the rate of oxidation at 600°C is nearly independent of atmospheric pretreatments.

Two surface pretreatments are compared: electropolishing and abrasion. Electropolishing was carried out in a KOH solution. The results show that the electropolished sample reacted at a little slower rate than the abraded sample.

Crystal structure studies of oxide scales.—An extensive study was made of the crystal structure of the oxide scales formed after oxidizing tungsten from 600° to 1100°C. A Guinier-Hägg (17-21) type of focusing x-ray camera was used to bring out the presence of minor phases in the oxide scale. Monochromatic NiK_α radiation was used.

Monoclinic WO_3 was the principal oxide found in the scale for the complete temperature range. Studies on a sectioned oxide scale showed the outer layer to be WO_3 and the inner layer adjacent to the metal WO_3 and W_4O_{11}. The crystal structures of the oxygen compounds of tungsten have been reviewed by Hägg and Magnéli (21). The x-ray diffraction method is not sensitive enough to show the oxide in contact with the metal.

Discussion of Mechanism of Oxidation

Experimental studies show that the time course of the oxidation curves depends strongly on the temperature, pressure, and the stress pattern of the metal at the edges. Eleven or more physical and chemical phenomena must be considered in developing a complete picture of the oxidation of tungsten. These are: (*a*) normal diffusion processes involving the formation of defects and the diffusion of metal or oxygen atoms through the oxide scale, (*b*) the adhesion of the oxide scale to the metal at the surface and at the specimen edges, (*c*) heat effects associated with the high rates of oxidation at the surface, (*d*) solid phase chemical reactions occurring in the oxide scale, (*e*) decrease in surface area as a result of scale formation, (*f*) diffusion of oxygen through the gas phase to the surface for reaction, (*h*) chemisorption of oxygen at the oxide or at the clean metal surface, (*i*) chemical reaction of oxygen at a clean metal surface, (*j*) desorption or evaporation of WO_3, (*k*) diffusion of WO_3 away from the surface into the gas phase, (*l*) decrease in surface area as a result of volatility of WO_3.

No one rate process can be used to explain the complex oxidation reaction of tungsten. At low temperatures the kinetics may be interpreted in terms of a simple diffusion process. However, at high temperature, the oxidation of tungsten closely resembles the combustion of graphite. It is useful to consider the reaction for three temperature ranges (*a*) 500°-600°C, (*b*) 650°-950°C and (*c*) 1000°-1300°C.

Mechanism of oxidation 500°-600°C.—For this temperature range and for lower temperatures the oxidation reaction is probably diffusion controlled. No evidence was found for local cracking at the specimen edges at 500°C after 6 hr of reaction. At 600°C some localized cracking was observed. A parabolic rate law plot of the 500°C data shows the rate law constant to increase with time. We conclude that the protective properties of the oxide scale are steadily becoming poorer. This may be a result of compositional changes in the oxide scale or to microscopic cracking of the oxide scale at the oxide-metal interface. These small cracks although not resulting in spalling give a short circuit for oxygen to reach the metal for reaction.

Composition changes are thermodynamically feasible and have been observed by Hickman and Gulbransen (22) in an earlier electron diffraction study. WO_3 is formed first and appears in the outer part of the scale. Solid phase reactions of tungsten with the higher oxide lead to the formation of WO_2 or other oxides of tungsten.

X-ray diffraction studies on the 600°C oxidized sample show no evidence for an oxide other than WO_3. This appears to conflict with the earlier studies of Hickman and Gulbransen (22). We interpret this discrepancy as due to the difficulties in sampling for our x-ray diffraction method and to the fact that Hickman and Gulbransen (22) worked at lower pressure and shorter oxidation times.

Pressure has only a minor influence on the time course of oxidation for this temperature range.

Mechanism of oxidation 650°-950°.—For this temperature range several new factors must be used to explain deviations from diffusion controlled oxidation. Residual stresses and strains in the metal at the edges give a highly localized oxidation reaction. Pressure also plays an active role at 950°C.

A rapid change is found in the oxidation curves at a scale thickness of 2000-4000 $\mu g/cm^2$. The change is one which leads to a more rapid oxidation. Localized edge type of oxidation develops and adhesion of the oxide scale becomes poor. Crystal structure studies show WO_3 to be the oxide formed.

We interpret the oxidation reaction in this temperature range as follows: A thin layer of oxide scale is formed according to the general laws of diffusion. After reaching a certain thickness the oxide cracks away from the metal at local areas. The cracked areas give access to oxygen and healing occurs until the critical thickness of oxide is again formed. This cracking process is a continuous one over the surface as a function of time. Since only the thin oxide film is formed under diffusion controlled conditions the major part of the oxide scale has little influence on the kinetics of the reaction.

Due to the intimate contact of oxygen with most of the oxide scale the highest oxygen containing oxide is formed, namely WO_3. This is observed in all of the x-ray diffraction studies. For thick oxide scales the only place where WO_2 could form would be in the thin oxide film at the metal-oxide interface.

Since oxygen pressure has a major influence on the time course of oxidation at 950°C the volatility of WO_3 in low oxygen atmospheres is beginning to influence the reaction.

Mechanism of oxidation 1000°-1300°C.—For this temperature range the mechanism of oxidation changes greatly with temperature and pressure. At 1000°C and 0.1 atm oxygen pressure an oxide scale is formed while at 1200°C and higher at 0.01 atm pressure no measurable oxide pickup is noted. However, a thin oxide scale may still be present on the metal. The oxide evaporates as fast as it is formed. We conclude the time course of oxidation is determined by the rate at which oxygen arrives at the surface, by diffusion of the volatilized oxide away from the surface, and by geometrical considerations of the sample surface area. At some temperature in this temperature range the theoretical rate of evaporation is greater than the rate of oxidation. This temperature depends on the oxygen pressure.

The mechanism of oxidation of tungsten at 1200°C and higher is similar to that observed in the combustion of carbon. Gulbransen (23) has derived rate equations for the combustion of artificial graphite under idealized conditions of low-temperature combustion at 425°-575°C and for small amounts of burning.

The combustion reaction of tungsten in oxygen is more difficult to study than the combustion of carbon since reaction variables are different. Oxide scales are formed on tungsten below 1200°C at 0.1 atm pressure. Therefore, studies must be made at temperatures above 1200°C where rapid reaction occurs. Sample area considerations are important and the time period of reaction is very short. Our present methods are not sufficiently accurate for us to apply the absolute reaction rate theory (24) and to analyze the rate-limiting processes.

Other interpretations.—Semmel (10) suggests that the change in the oxidation curves above 1150°C is due to melting of the oxide. No evidence was presented except that the high-temperature runs showed the specimen to have rounded edges. Volatilization of WO_3 could also account for the rounding of the edges. We have seen no evidence for melting in our studies.

Arkharov and Kozmanov (9) interpret the change in the rate of oxidation above 1150°C as due to a structural transformation in the oxide. We suggest from our studies on the effect of pressure that volatility of the oxide is the major factor controlling the oxidation reaction in the temperature range of 1100°-1200°C.

Summary

1. Rate measurements were made on the oxidation of tungsten from 500° to 1300°C, for times up to 6 hr, and for oxygen pressures from 0.1 to 0.00132 atm.

2. The effect of surface preparation and sample pretreatment was also studied.

3. The kinetic data were fitted to the parabolic rate law. However, a number of deviations were observed. For all experiments the initial parabolic rate law constants were smaller than the final values found for thicker films. A transition was observed in the rate of oxidation for weight gains of 2500 to 4000 $\mu g/cm^2$ at temperatures of 650°-800°C.

4. The parabolic rate law data plotted on a logarithmic plot as a function of $1/T$ showed three straight lines. The initial values of the rate law constants were fitted to a line which gave a heat of activation of 44,500 cal/mole. The final values were fitted to another line which gave a heat of activation of 54,500 cal/mole. Above 800°C the final values could be fitted to a straight line which gave a heat of activation of 32,500 cal/mole.

5. Pressure had a strong effect on the rate of oxidation for the experiments at 950°, 1050°, and 1200°C. For these temperatures the volatility of WO_3 must be considered. At 1200°C weight loss curves were observed for pressures as high as 0.1 atm. At this temperature, diffusion of oxygen to the specimen limits the rate of oxidation.

6. Photographs of the oxidized specimens for temperatures of 600°-950°C show that the oxidation of tungsten occurs in a preferential manner at the edges. This causes localized heating and further reaction.

7. The poor protective properties of the oxide scale on tungsten is attributed to three factors: (*a*) the rapid oxidation reaction, (*b*) the poor adherence of the oxide to the metal, and (*c*) the volatility of the tungsten oxides.

Thermodynamic Properties of the Aluminum-Silver System

Thomas C. Wilder and John F. Elliott

Department of Metallurgy, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

An electrode potential study of the liquid aluminum-silver system has been conducted with the cell

$$\mathrm{Al(1)} \mid \mathrm{Al^{+++}\ (in\ KCl + NaCl)} \mid \mathrm{Al\ in\ Ag(1)}$$

in the temperature range 700°-980°C. The activities of both components, F_i^M, F_i^E, F^E, and TS^E were determined for 700° and 900°C, and H_i^M and H^M for the temperature range of 700°-980°C. The activity curves are found to be similar in shape to those estimated by Chou and Elliott, but they are more ideal in the vicinity of pure Al. Values for log γ_{Al} in the liquid systems Al-Fe, Al-Fe-C, and Al-Fe-Si-C at 1600°C have been redetermined using the distribution data of Chipman and Floridis, and Chipman and Langenberg.

The reversible concentration cell has proven in many cases to be a valuable and reliable method for determining the thermodynamic properties of an alloy system. When properly arranged and operated reversibly, this type of cell can be used to measure the potential between a pure metal, usually the selected reference state, and its alloy with another metal or metals. This paper reports the results of an experimental study of the liquid aluminum-silver system between 700° and 980°C with the cell:

$$\mathrm{Al(liq)} \mid \mathrm{Al^{+++}(in\ molten\ KCl) + NaCl} \mid$$

$$\mathrm{[Al\ in\ Ag](liq)}$$

The driving force is the net transfer of aluminum from the pure state on the left to the alloy on the right. In this paper, the standard state for aluminum is the pure liquid metal. Several exceptions to this are noted as they arise.

The virtual cell reaction is

$$\mathrm{Al(pure\ liquid)} \rightarrow \mathrm{[Al\ in\ Ag](liquid)} \qquad (I)$$

with three Faradays being transferred per gram atom of aluminum. The several thermodynamic relationships based on the reversible potential E of the cell are:

$$\overline{F}_{Al} - F^{\circ}_{Al} = F^{M}_{Al} = -3\mathbf{F}E \qquad [1]$$

$$\overline{S}_{Al} - S^{\circ}_{Al} = S^{M}_{Al} = 3\mathbf{F}\left(\frac{\partial E}{\partial T}\right)_{X_{Al},\,P} \qquad [2]$$

Also from [1]

$$-3\mathbf{F}E = RT \ln a_{Al} \qquad [3]$$

In these equations **F** is Faraday's constant, 23,063 cal/v eq. It is assumed that the valence of the aluminum ion in the electrolyte is 3. Experimental considerations justifying this assumption are discussed later.

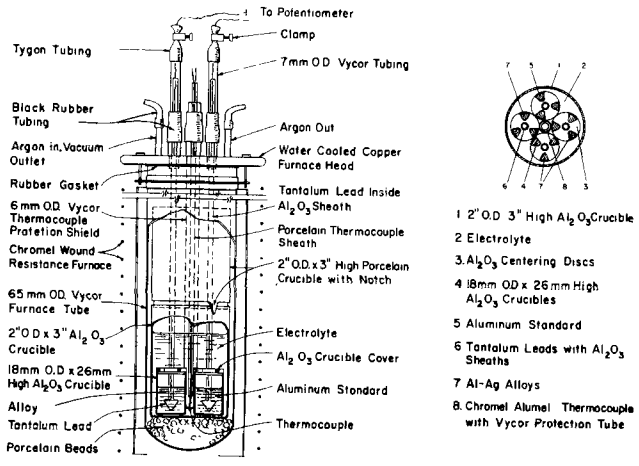

Fig. 1. Cell design. Left, 1A, cell apparatus (only 2 of 4 leads are shown; right, 1B, top view of cell.

The Experiments

Cell design.—Figures 1a and 1b show that each cell contained four electrodes, one of pure aluminum and the other three of aluminum-silver alloys. The metal electrodes were contained in doubly recrystallized pure alumina crucibles (Morganite). The large containing crucible and the sheathing for the tantalum lead wires were of 97% pure vitreous alumina. The small spiders which centered the leads in the electrode crucibles also were of high-purity alumina. The large upper porcelain crucible served as a thermal shield, and by means of holes in the bottom, it helped to guide and locate the cell leads. The chromel-alumel thermocouple was protected by a 6 mm Vycor tube. The lower end of this tube fitted into the central opening between the four electrode crucibles. The whole cell assembly was contained in a 65 mm Vycor tube that was fitted with a water-cooled brass top. Suitable fittings in the top permitted entry of leads, thermocouple sheath, and gas and vacuum connections so that the cell could be evacuated or pressurized as desired.

Cell preparation.—The initial step in making a cell was the preparation of the electrolyte. A sufficient quantity of an equimolar (azeotropic) mixture of KCl and NaCl (C.P.) was purified under vacuum produced by a mechanical pump. The mixture was slowly brought to fusion temperature and then held for 20 hr at 750°C. Several batches were purified by bubbling hydrogen chloride through the fused salt for approximately 10 hr which was followed by vacuum treatment. Cells containing electrolytes prepared in this manner produced potentials which were not as stable as with the straight vacuum treated electrolyte; hence, the simple vacuum treatment was used for all cells. Because of its high volatility, aluminum chloride was purified by subliming it at approximately 190°C under a vacuum of a few mm of Hg. The purified crystals were collected on a water-cooled Pyrex glass cold finger suspended 1 in. above the crude (C.P.) material.

The electrodes were prepared by weighing to the nearest 0.1 mg pieces of the appropriate pure metals. The three high-silver electrodes were prefused. All others were prepared by inserting bits of the pure metals in the electrode crucibles, and fusion occurred as the cell was brought to temperature. Analyses of the pure metals used are shown in Table I.

Table I. Lot analyses of pure metals

Tungsten, molybdenum, and tantalum wires were tried as leads initially. Only tantalum resisted attack by the aluminum alloys, and only slight attack was noted up to 900°C with exposure of 20 to 30 hr. Prolonged exposure at above 1000°C resulted in the wire splitting as a result of the formation of a solid brittle product. The temperature excursions used during the experiment were designed to avoid interference from this effect. The leads embrittled severely when exposed to the chloride vapors in the upper portion of the cell but not when in contact with the molten salt. Consequently, each lead was protected with an unbroken sheath of alumina from the electrode surface to the water-cooled head.

The clean cell crucible, alloys, electrode leads, etc., were completely assembled outside the large Vycor tube. With the thermal shield raised slightly above its normal position, the fused KCl-NaCl solution was transferred by a Vycor pipette from the purification tube to the cell. On solidification, the salt held the components of the cell securely in position so that the whole assembly could be handled as a single unit. This technique exposed the salt mixture to the air for a few seconds when it was liquid, and the upper surface after solidification was exposed for approximately ½ hr. In recognition that this was undesirable, a technique was devised for transferring the salt by syphon so it did not contact the air. This method greatly increased the difficulties of assembly and had no apparent effect on the performance of the cells, so it was abandoned in favor of the easier method.

After the salt had cooled sufficiently, pieces of purified $AlCl_3$ (about 5 g) were transferred quickly from a sealed container to the cell. Then the cell was placed in the large Vycor tube and the system was evacuated. This exposed the $AlCl_3$ to the air for no more than 30 sec. Subsequently, the cell tube was pressurized with purified argon and placed in the furnace. All cells were operated with an argon pressure of about 25 mm Hg above atmospheric pressure. Because of the very small pressure co-

efficient of the potential of this type cell, no corrections for the relatively small variations in atmospheric pressure were applied to the potentials read.

Operation of the cell.—A cell was run for approximately 30 hr. During this time potentials were steady and reproducible. A longer time at temperature was possible, but some of the electrolyte volatilized and condensed on the cooler portions of the system. Runs were discontinued before the level of the electrolyte was lowered sufficiently to interfere with the performance of the cell. The concentration of $AlCl_3$ did not change materially from the initial analysis, and repeated checks on the original and final weights of the electrodes showed virtually no change, within a few milligrams, in their weights from that charged. The electrolyte volatilized essentially without changing its concentration which indicated that the $AlCl_3$ had little effect on the azeotropic character of the base composition. At all times the electrolyte was colorless, transparent, and without sediment.

A cell was allowed to remain at 680°-700°C for 12 hr prior to the time measurements were taken. This permitted the cell to "stabilize" and fitted the work schedule. After this period, the potentials differed somewhat from the values obtained immediately after the new cell was brought to temperature. Several typical examples are shown in Table II. This stabilization procedure was followed because it resulted in the potentials being much less sensitive to the flow of small currents incident to taking measurements, and it has been found generally that the initial readings were not reproducible and apparently not reversible.

The temperature sequence followed in a run were usually approximated as follows: (*a*) 700°C, (*b*) 750°C, (*c*) 800°C, (*d*) 720°C, (*e*) 780°C, and (*f*) 850°C. On the high-silver side of the diagram, a similar pattern was followed with 9 or 10 readings being taken, and the final reading was at 983°C. Because of the volatilization problem, temperatures above 900°C were avoided if possible, but it appeared that satisfactory readings could be obtained at 1000°C. Slight attack of the leads and the thermocouple sheath and no attack of the alumina ware were observed in the high-temperature runs.

Sources of Error

Reversibility.—The major problems faced in the operation of a cell for establishing the thermodynamic relationships for a reaction such as Reaction I is that the cell function essentially in a reversible manner, and that the reaction occurring in the cell is actually the one ascribed to it. Several tests performed on the cells studied and a number of observations indicated that the cell used was reversible for the time and temperatures employed. The more significant of the observations were:

1. In seeking the null point at which the potentiometer potential balanced the potential of the cell, a small current from the potentiometer could be passed in either direction through the cell without disrupting the null point. In all cases the null point could be approached with assurance. The readings were not "soft" or vague.

2. Consistent readings were obtained for different cells which had alloy compositions that were the same. A potential reading at a given temperature could be reproduced again after the cell temperature had been raised or lowered. Also, there was no perceptible drift of the potentials with time.

3. The very slight attack on the ceramics and lead wires, the constancy of the $AlCl_3$ concentration in the electrolyte, the constancy of weight of the electrodes, and the absence of silver in the electrolyte indicated that side reactions or the replacement of aluminum by silver were of no consequence. Also, there was no sign of reaction with the other components of the electrolyte. Table III shows that the standard free energies of formation of the other components of the electrolyte were sufficiently low (negative) relative to that of $AlCl_3$ to avoid an exchange reaction.

4. Separate reference electrodes of pure aluminum agreed between themselves within an average of 0.1 mv. Potentials of duplicate alloy electrodes in different runs usually agreed within 0.15 mv at a given temperature. Duplicates were run on all but two of the alloys reported. (Rather than average readings, it was considered to be more suitable to use results from the one of a pair that showed the more stable readings.)

5. Results of a recent study (1) of the behavior of a number of metallic ions in the azeotropic composition of fuzed NaCl-KCl at 738°C indicated strongly that electrical conduction in the salt is essentially ionic. The presence of $AlCl_3$ in small concentrations and contact with liquid Al should not alter this.

Writing the virtual Reaction I and Eq. [1] through [3], as shown, assumes that only trivalent aluminum is present in the electrolyte. An indication that the concentration of monovalent aluminum must be very low can be obtained from the data in Table III and the reaction

$$AlCl_3 + 2Al = 3AlCl \qquad (II)$$

Assuming that the activity coefficient of $AlCl_3$ and AlCl are similar at low concentrations in the electro-

$Na(l) + 1/2Cl_2(g) = NaCl(l)$	−75,900[2]
$K(l) + 1/2Cl_2(g) = KCl(l)$	−78,800[2]
$1/3Al(l) + 1/2Cl_2(g) = 1/3AlCl_3(g)$	−42,400[2]
$Al(l) + 1/2Cl_2(g) = AlCl(g)$	−32,380 ± 3 kcal[3]
$Ag(s) + 1/2Cl_2(g) = AgCl(l)$	−18,500[2]

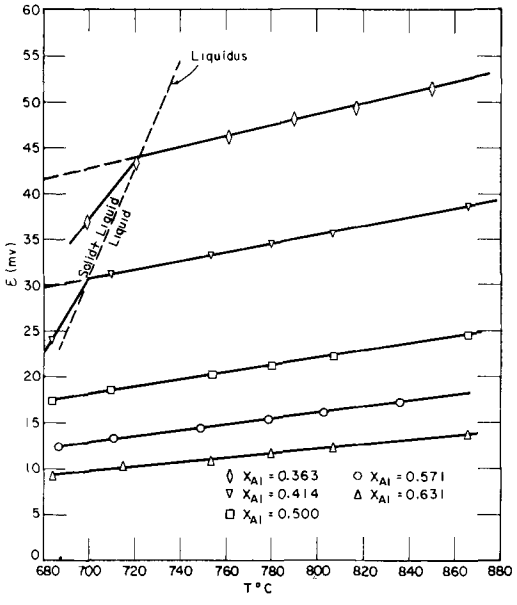

Fig. 2. Examples of emf vs. temperature plots for five liquid Ag-Al alloys.

lyte, and with N_{AlCl_3} equal to 0.01, N_{AlCl} is approximately 10^{-4}. This, with the clarity of the electrolyte and the constancy of the weight of the electrodes, was considered sufficient justification to conclude that Reaction II was of no significance in this work.

Other sources of error.—Temperatures were measured with chromel-alumel thermocouples made from a lot of wire that had been standardized against the melting points of Ag, Cu, Pb, Sn, and Al. No temperature gradients could be detected in the cell when the thermocouple was moved from the bottom of the crucible to the top of the electrolyte. Considering the uncertainty in the thermocouple calibration and uncertainties in the potentiometer circuit, it is estimated that the temperatures recorded were within ± 1°C of the true temperature.

A plot of E vs. °C yielded straight lines for all alloys at temperatures above the liquidus (Fig. 2). From these lines, potentials at several temperatures were obtained for subsequent calculations. Based on the scatter of experimental points about the line, it is estimated that a potential taken at 700° or 900°C (Table IV) for the subsequent calculations were within ±0.15 mv of the true value for cells in the composition range of $0.093 < X_{Al} < 0.857$. The uncertainty is greater for the electrodes which were very high in silver because it was necessary to extrapolate the potentials from the liquid region down to the temperatures of which calculations were made.

Experimental Results

The potentials for the various alloy electrodes at 700° and 900°C and the temperature coefficients of the potentials are shown in Table IV. These results have been converted into alpha and beta functions (4) for correlation and to facilitate subsequent calculations. The defining equations are:

$$\alpha_{Al} = \frac{\ln \gamma_{Al}}{(1-X_{Al})^2} = \frac{-3\mathbf{F}\,E/RT - \ln X_{Al}}{(1-X_{Al})^2} \qquad [4]$$

Table IV. Potentials of experimental cells for liquid Al-Ag solutions

and

$$\beta_{Al} = \frac{H_{Al}^{M}}{(1-X_{Al})^2} = \frac{-3\mathbf{F}\left[E - T\left(\frac{\partial E}{\partial T}\right)_{P,X}\right]}{(1-X_{Al})^2} \qquad [5]$$

Figure 3 shows the alpha function for aluminum at 700° and 900°C, and Fig. 4 shows the beta function which is applicable in the temperature range of 700°-950°C.

As X_{Al} approaches unity, the alpha and beta functions become very sensitive even to very small errors. In the limit, the functions must be finite and the extrapolation to this limit is based on the curve below $X_{Al} = 0.9$ rather than the points above this composition. At the other end of the composition

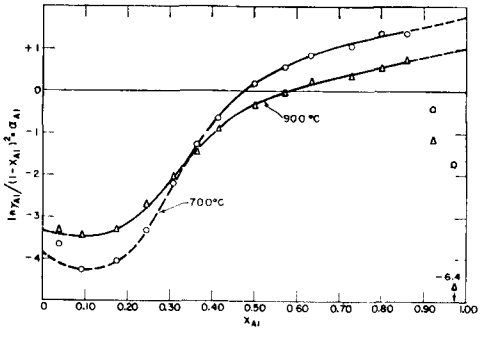

Fig. 3. Alpha function (α_{Al}) for liquid Al-Ag system. Dashed lines show extrapolation from higher temperatures.

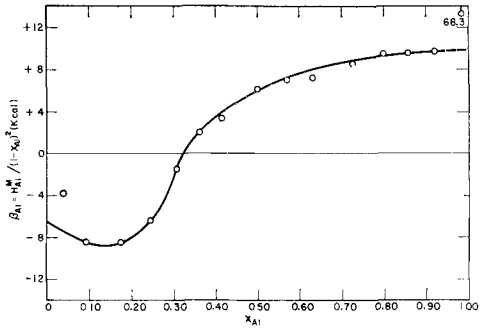

Fig. 4. Beta function (β_{Al}) for liquid Al-Ag alloys

Table V. Limiting activity coefficient of aluminum in liquid silver (γ°_{Al})

Temp, °C	$-\log \gamma^\circ_{Al}$	γ°_{Al}
950	1.36	0.044*
900	1.41	0.039*
800	1.52	0.030*
700	1.66	0.022*

* Liquid phase is metastable (mp pure Ag = 961°C).

scale, the point at $X_{Al} = 0.039$ has considerable uncertainty because the alloy was liquid only above 943°C. Thus it was necessary to extrapolate this point to the lower temperature by means of the value of dE/dT for this cell. This value had considerable uncertainty because the potential for the liquid phase could be measured only in the range of 943°-983°C. Figure 5 shows the alpha function at 950°C for which the limiting activity coefficient of aluminum in silver (γ°_{Al}) is 0.044. By the Gibbs-Helmholtz relationship and the limiting value of H^M_{Al} of −6460 cal/g atom the limiting value of the activity coefficient of aluminum can be obtained at various temperatures. The results given in Table V and the termini of the alpha function at pure silver in Fig. 4 are drawn accordingly.

Calculations

The alpha and beta functions for aluminum can be used to calculate the corresponding properties of silver by an application of the Gibbs-Duhem integration (4).

$$\ln \gamma_{Ag} = -\alpha_{Al} X_{Al} X_{Ag} + \int_{X_{Al}=0}^{X_{Al}} \alpha_{Al} dX_{Al} \qquad [6]$$

$$H^M_{Ag} = -\beta_{Al} X_{Al} X_{Ag} + \int_{X_{Al}=0}^{X_{Al}} \beta_{Al} dX_{Al} \qquad [7]$$

The molar excess mixing properties are

$$F^E = X_{Ag} RT \int_{X_{Al}=0}^{X_{Al}} \alpha_{Al} dX_{Al} \qquad [8]$$

$$H^M = X_{Ag} \int_{X_{Al}=0}^{X_{Al}} \beta_{Al} dX_{Al} \qquad [9]$$

The value of each integral on the right of Eq. [6] to [9] is obtained by determining the area under the appropriate curve in Fig. 3 or 4. From the results, the values of activities, activity coefficients and entropies can be found by usual thermodynamic formulas. The results of the calculations are included in Table VI.

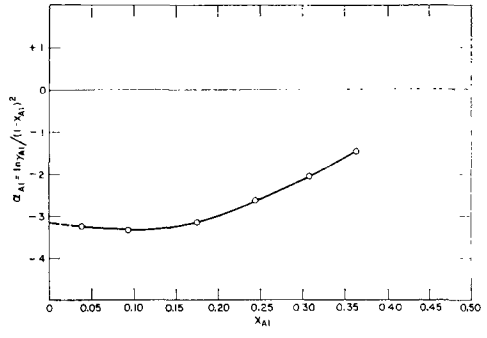

Fig. 5. Alpha function (α_{Al}) for silver-rich Ag-Al alloys at 950°C.

$$\left(\frac{\ln \gamma_{Al}}{(1X_{Al})^2}\right)_{X_{Al}=0} = \ln \gamma^\circ_{Al} = -3.16$$

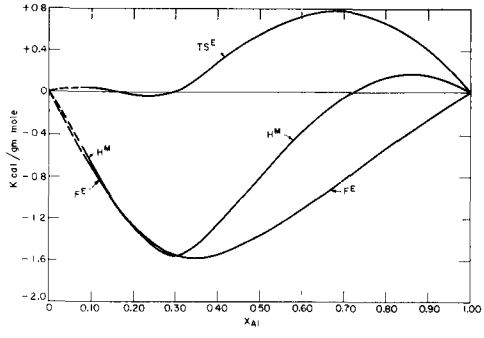

Fig. 7. Molar properties of mixing for Al-Ag system at 900°C.

Plots of the important functions are shown in Fig. 6 and 7.

Discussion of Results

The activity values obtained in this work are to be preferred over those calculated by Chou and Elliott (5) (Fig. 6), who obtained them by combining activities calculated from the phase diagram of the Pb-Ag system with data on the distribution of silver between liquid lead and liquid aluminum which was determined by Lorenz and Erbe (6). Hultgren and co-worker's (7) recalculation of Chou and Elliott's work using Kleppa's (8) calorimetrically determined heats of solution for the Pb-Ag system gives values of F^E for the Al-Ag system which are in reasonably good agreement with the present work. However, recent results by the present authors show a narrower solubility gap in the Ag-Al-Pb system than that reported by Lorenz and Erbe. These results will be reported in the near future, and a recalculation of the old Chou-Elliott results may be attempted in the light of the data now available. It is sufficient to say at this point that there is reasonable agreement between activities in the liquid phase obtained from the phase diagram calculations and those from the direct experimental results.

Activities in the Solid Phases

The results reported here have been used to estimate the activities in the solid phases in the Al-Ag system. This permits a comparison with the earlier

results of Hillert, Averbach, and Cohen's (9) measurements on solid alloys in this system.

A few potentials were obtained for alloys in the alpha phase (high Ag) as shown in Fig. 8. These potentials were extrapolated to 820°K (547°C) and corrected for the change of reference state of solid Al. The potentials obtained are in reasonable agreement with those of Hillert and co-workers.

In the composition range above $X_{Al} = 0.35$, the potentials of the liquid alloys were extrapolated to the liquidus temperatures to give the potentials at the corresponding solidus temperatures. When these potentials are then extrapolated to 820°K and corrected for the change in reference state, they result in an activity curve for aluminum having a very strong positive departure from ideality in the delta phase. Although the general character of the phase diagram and some uncertainty as to the position of the solidus line of the δ phase (9, 10) makes this calculation somewhat uncertain, there is a remarkably good agreement between the earlier results of Hillert, Averbach, and Cohen (9) (their Fig. 2) and those obtained here. It is to be noted that Wittig (11) recently has reported values of H^{M} for the ζ phase which are a little more exothermic than Hillert's values.

Activity Coefficients of Aluminum in Iron Alloys

The experimentally determined activities of aluminum in silver alloys and the enthalpies of solu-

tion reported here differ somewhat from those reported by Hillert, Averbach, and Cohen (9) which Chipman and Floridis (12) used to determine the activity coefficients of aluminum in iron alloys from the distribution of aluminum between liquid silver and iron alloys. In addition, Chipman and Floridis assumed that log γ_{Al} in liquid Al-Ag alloys was inversely proportional to the absolute temperature.

By use of the experimental results reported here, the values for the activity coefficients of aluminum in the Fe-Al, Fe-Al-C, and Fe-Al-Si-C systems at 1600°C have been recalculated from the data reported by Chipman and Floridis (12) on the distribution of Al between layers of Fe and Ag. The results are shown in Fig. 9, 10, and 11 and in Table VII. It is to be noted that $\epsilon_{Al}^{i} = (\partial \ln \gamma_{Al})/\partial X_i$ for the infinitely dilute solution of i in Al-Fe alloys. The correction applied by Chipman and Langenberg

devised by Chipman and Langenberg (13). However, the results obtained differ very little from those of the earlier authors and consequently retreatment of the data here is not warranted. The essential reasons for the agreement in spite of different values of $\log \gamma_{Al}^{(Fe)}$ being used is that the calculation uses the infinitely dilute solution of Al in Fe as the reference state. This virtually cancels the effect of the change in values of $\log \gamma_{Al}$. Also, the uncertainties inherent in the calculation are probably greater than the change which would arise from the new calculation.

Conclusion

The thermodynamic properties of the liquid Al-Ag system have been determined by means of a high-temperature reversible concentration cell. The results may best be summarized by referring to Fig. 6 and 7 and to Table VI.

Values for $\log \gamma_{Al}$ in the liquid systems Al-Fe, Al-Fe-C, and Al-Fe-Si-C at 1600°C have been recalculated using the distribution data of Chipman and Floridis (12) and Chipman and Langenberg (13).

Acknowledgments

The authors wish to express their sincere appreciation to the United States Atomic Energy Commission for their financial support of this study under Contract No. AT(30-1)-1888, and to Donald L. Guernsey and William T. Martin, Jr. for their analyses of the electrodes and electrolytes.

Manuscript received Dec. 3, 1959. This paper was prepared for delivery before the Philadelphia Meeting, May 3-7, 1959. It was submitted in partial fulfillment for the M.Sc. degree to the Department of Metallurgy, Massachusetts Institute of Technology.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1960 JOURNAL.

Gas Phase Charged and Electrolytically Charged Beta-Pd-H Alloys

James P. Hoare

Scientific Laboratory, Ford Motor Company, Dearborn, Michigan

ABSTRACT

Open-circuit potential vs. time curves were obtained on various palladium electrodes in hydrogen-stirred sulfuric acid solutions. Evidence is presented to show that the electrochemical properties of electrolytically charged β-Pd-H alloys are different from those of the gas charged alloys. Mechanisms for the charging processes involved are discussed.

Renewed interest in the mechanisms of the occlusion of hydrogen gas in palladium metal has prompted a re-evaluation of the earlier work with more modern techniques. It had been shown that β-Pd-H alloys formed by placing pure palladium metal in pure hydrogen gas under 1 atm are indefinitely stable (1) provided all oxidizing agents such as air or oxygen are excluded. Hoare, *et al.* (2) found that the gas charged β-Pd-H alloy had somewhat different electrochemical properties than the electrolytically charged β-Pd-H alloy; i.e., hydrogen is lost spontaneously from the electrolytically charged β-Pd-H alloy and its hydrogen overvoltage is lower. Flanagan and Lewis (3) made potential and relative resistance measurements on a thin (0.027 cm diameter) palladium wire in acid solutions. Although they were not able to reproduce the finding of Hoare and Schuldiner (4), they did confirm certain results reported by Ratchford and Castellan (5). However, recently (6) the results of Ratchford and Castellan have been shown to be compatible with those of Hoare and Schuldiner.

Contrary to what was found by Hoare and Schuldiner are the data reported by Flanagan and Lewis which show that, once the β-Pd-H alloy is formed electrolytically, hydrogen is not lost and the potential does not return to a positive value of 50 mv after the cathodic current is removed. This investigation is concerned with showing evidence for the existence of two kinds of β-Pd-H alloys and with a confirmation of the results reported by Flanagan and Lewis.

Experimental

In one series of experiments, potential measurements were taken on pure (99.5 + %) palladium cathodes made from 3 cm of 5-mil wire, 1 cm^2 plate of 2-mil foil, 1 cm^2 plate of 4-mil foil, 1 cm^2 plate of 4-mil foil whose surface was about 80% covered with polyethylene, and a bead melted from a strip of foil. In another series, both potential and relative resistance measurements were taken on a 15-mil palladium wire, 11 cm long and wound in the form of a toroid on a polyethylene ring. All experiments were carried out in 2*N* H_2SO_4 solution in a Teflon cell similar to that used before (7). The preparation of the triply distilled water, sulfuric acid solutions, palladium cathodes, and cell has been described elsewhere (4, 7). The hydrogen and helium gases were purified in standard multistage purification trains; the temperature of all experiments was 23° ±1°C. Relative resistance measurements were carried out as before (6). The hydrogen content of the Pd-H alloys was determined using ceric sulfate solutions (4). Electrical contacts to the cathodes were Pt wires imbedded in polyethylene to prevent any solution contact with the Pt or the weld area; the reference electrode is a Pt/H_2 electrode in the same solution.

Results and Discussion

Each palladium cathode was strongly anodized (about 0.1 to 0.5 amp/cm^2) for about 30 min and then cathodized for about 2 hr at a current density of such a magnitude that the electrode was polarized to at least −100 mv against a Pt/H_2 electrode in the same solution. Finally, the circuit was opened and the potential vs. the Pt/H_2 electrode was recorded as a function of time. During this entire procedure, the sulfuric acid solution was stirred constantly by a steady flow of purified hydrogen. These results are presented in Fig. 1, zero time being taken at the moment when the cathodizing current is broken.

From Fig. 1, it is seen that the potential-time curves show a definite dependence on the ratio of the exposed area to the total volume of the cathode. As the value of this ratio decreases, the time required to reach a steady value of zero volt increases. Also, a point is reached at which the potential vs. Pt/H_2

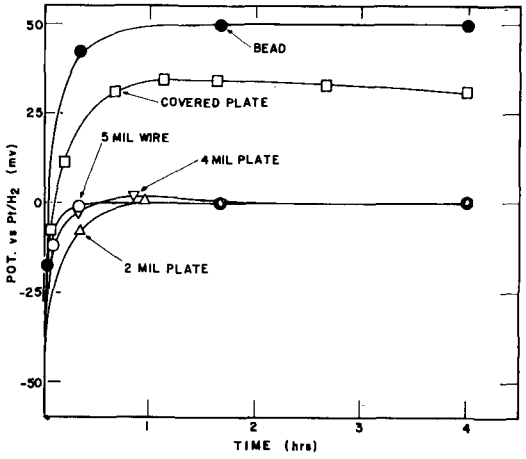

Fig. 1. Open-circuit potential vs. time curves obtained from previously cathodized palladium electrodes in H_2-stirred 2N H_2SO_4 solutions at T = 23° ± 1°C.

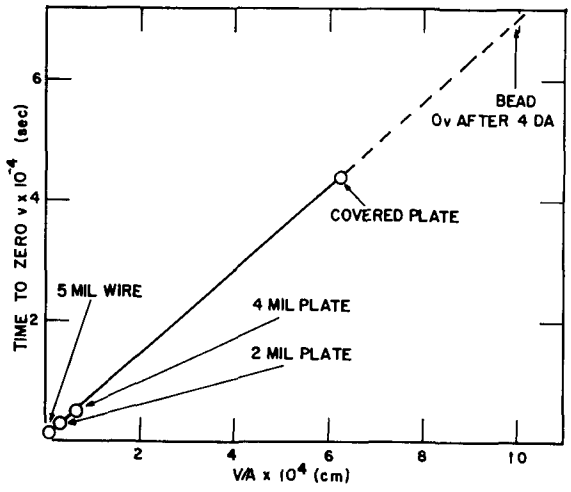

Fig. 2. Curves showing the length of time required for cathodized palladium electrodes to reach a steady value of zero volt vs. Pt/H_2 on open-circuit conditions as a function of the volume-to-surface ratio (V/A) of the electrode.

reverses sign and the curve passes through a maximum value. In fact, a cathode may be designed with a surface-to-volume ratio of such a value that the maximum value becomes a plateau at +50 mv. The palladium bead is such an example and this 50 mv potential was maintained for more than 30 hr before the drift to zero volt began. It was found that the exact shape of the curves was a function of the electrochemical history of the cathode, but the general form of the curves is that shown in Fig. 1. It is for this reason that all the cathodes, on which the curves in Fig. 1 were determined, were anodized and cathodized at approximately the same intensity and for the same duration with approximately the same hydrogen flow.

The volume-to-surface ratio (V/A) was determined (6); Fig. 2 shows that the time to reach zero volt after breaking the cathodizing circuit is a linear function of V/A. It is interesting to note that again (6) the bead falls to the left of this curve. Fallon (8) has also found that palladium beads after cathodization will return to the +50 mv value for a certain length of time.

In another series of experiments, the 15-mil palladium wire toroid was anodized and cathodized in the same manner as described above and the open-circuit potential after cathodization was recorded. The potential went to zero volt without going positive as shown in Fig. 3. However, if about 5-10% of the wire was covered with polyethylene near the weld area, the potential changed sign and, after passing through a maximum in a positive potential region, drifted back to a steady zero value. As long as the rapid flow of hydrogen was maintained, the potential would remain at zero volt indefinitely. Flanagan and Lewis (3) found that in certain cases the potential on their wires also went through a maximum value in a positive potential region.

After the wire had reached a steady value of zero volt, the hydrogen flow was reduced to a point where about one bubble passed through the solution per minute. When a potential reading was to be taken, the H_2 flow was returned to the original rate and the

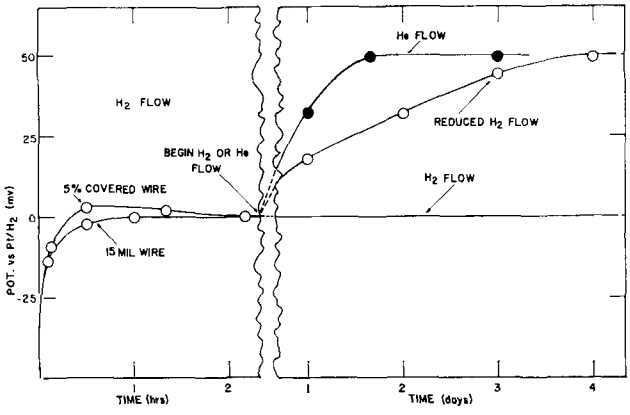

Fig. 3. Open-circuit potential curves obtained on a 15-mil Pd wire toroid after cathodization as a function of time. On the left side a rapid flow of H_2 is maintained at all times. On the right is shown the behavior when the H_2 flow is maintained, reduced to very low flow rates and replaced by He flow.

potential value recorded after the potential had remained steady for about 5 min; then the hydrogen flow was reduced again to the 1 bubble/min rate. The potential-time curve obtained is shown in Fig. 3. It is seen that a value of +50 mv was obtained after about four days.

It seemed possible that, with such a very low hydrogen flow rate, air could have entered the cell through the H_2-outlet tube and could have caused the rise to the positive values. To determine whether this was the case or not, purified helium gas was used to stir the solution rapidly at a steady rate. The potential-time curve obtained by repeating the experiment using He-stirring is shown in Fig. 3. Not only does the potential rise to a steady value of +50 mv, but also it rises faster, reaching the 50 mv value in less than two days. Potential measurements were taken by stopping the He flow and using an H_2 flow until the potential remained steady for about 5 min. The maximum total time for a reading required about 15 min.

The hydrogen content of the palladium wire toroids was determined by placing them in a known quantity of ceric sulfate solution (9), samples of which were titrated for ceric ion (4). These values for the hydrogen content were compared with those determined from Fischer's relationship (6, 10) by using relative resistance measurements which were taken concurrently with the potential measurements.

A palladium wire toroid which had been cathodized and which had come to a steady value of zero volt vs. a Pt/H_2 electrode was found to have an H/Pd atomic ratio of 0.63 using ceric sulfate solution and 0.67 from relative resistance measurements. This is in agreement with that found by other investigators, e.g. (3), and with that reported for a Pd electrode which had been anodized only and then permitted to reach a steady zero volt potential vs. Pt/H_2 (3,5,6). After a previously cathodized Pd wire toroid on open-circuit conditions had come to a steady value of zero volt vs. Pt/H_2 in H_2-stirred 2*N* H_2SO_4 solution, the H_2-stirring was replaced by He for about 72 hr. Then the toroid electrode was removed from the acid solution and placed in ceric sulfate solution in order to determine the hydrogen content of the electrode. Duplicate runs showed that the H/Pd atomic ratio was equal to 0.34 even though relative resistance measurements had given a value of 0.63. This agrees with the data reported in Fig. 4 of ref. (4).

These results may explain the conflicting findings reported by Hoare and Schuldiner and by Flanagan and Lewis concerning the open-circuit potential vs. Pt/H_2 of a previously cathodized palladium electrode in acid solution. As pointed out by Fallon (8), Hoare and Schuldiner reduced the flow of hydrogen to extremely low rates overnight (at least 16 hr/day). Under these conditions, as shown by Fig. 3 of this investigation, the potential eventually does return to +50 mv. It was also found in this investigation that the potential of those electrodes which exhibited positive potentials, such as those presented in Fig. 3, would drift slowly to zero if the very low H_2 flow or the He flow was replaced by a rapid stream of hydrogen gas.

In another experiment, a Pd wire was cleaned (7) and wound as a toroid on a polyethylene ring with Pt leads. This electrode was soaked in triply distilled water in a Teflon cell for about 48 hr. The cell was emptied and the Pd wire toroid sealed inside. Purified dry hydrogen was passed through the cell until the relative resistance reached a value of 1.61. This corresponds to the value for β-Pd-H. In another Teflon cell, 2*N* H_2SO_4 solution was prepared (7) and saturated with purified hydrogen for about 20 min. The gas-charged β-Pd-H toroid was then placed in this H_2-saturated acid solution. A potential of zero volt vs. Pt/H_2 was observed. Next, the hydrogen flow was replaced by helium and these conditions were maintained for about 72 hr. The relative resistance still had a value of 1.61. Finally, the toroid was removed from the acid solution and placed in ceric sulfate solution in order to determine the hydrogen content. In duplicate runs, it was found that the H/Pd atomic ratio was 0.57.

It is interesting to note that gas-phase charged β-Pd-H does not lose hydrogen in He-stirred H_2SO_4 solution while electrolytically charged β-Pd-H does. As reported before (2) these two types of β-Pd-H have very different hydrogen overvoltage characteristics. However, once gas-charged β-Pd-H is anodized in acid solution, the hydrogen overvoltage characteristics become identical to the electrolytically charged β-Pd-H. It was suggested that a film of molecular H_2 gas lies over the layer of adsorbed atomic -H and that, while cathodization does not break up this film, anodization does.

When an anodized palladium electrode in hydrogen-stirred acid solution is put on open-circuit conditions, atoms of hydrogen are transported from the double layer to the electrode surface through an adsorbed water molecule (2). These remove any oxides present thus exposing a pure palladium surface. Adsorbed hydrogen atoms then penetrate the metal skin and are dissolved into the body of the metal as protons. Since the penetration of the metal skin is assumed to be the slow process (6), hydrogen accumulates just inside the metal surface to the

maximum α-Pd concentration (H/Pd $\sim$ 0.03) and a potential of 50 mv more noble than Pt/H_2 is observed owing to the atomic hydrogen electrode reaction (11). As more hydrogen is dissolved, more Pd is converted to the α-Pd-H alloy. Only when the entire body of Pd is converted to the α-phase, will the β-phase nucleate and it is the length of the so-called α-plateau (6), observed in the potential-time curves, that represents the time required to charge the Pd to α-Pd.[1] The β-phase then grows from nucleation centers throughout the α-phase until an H/Pd atomic ratio of about 0.6 is reached when the solution process ceases and a potential of zero volt vs. Pt/H_2 is observed.

This same charging procedure is assumed to occur on pure dry Pd metal placed in a pure dry hydrogen atmosphere, except that hydrogen molecules do not have to displace adsorbed water molecules and the surface of the final β-Pd-H alloy obtained is covered with an adsorbed film of molecular hydrogen. In both cases, hydrogen ceases to be dissolved at an H/Pd atomic ratio of about 0.6.

If a palladium electrode is cathodized in H_2-stirred acid solution, the solvated hydrogen ions are discharged from the double layer to adsorbed atoms on the surface. As described above, the same charging processes from Pd to α-Pd-H to β-Pd-H also occur here. However, the solution process does not stop at H/Pd $\sim$ 0.6, but additional hydrogen may be forced into the Pd electrochemically at high current densities. It has been suggested (13) that this additional hydrogen enters the Pd lattice as atomic hydrogen since it may be possible that there is, at this concentration, enough dissolved hydrogen to form an H1-s impurity band. As a result, the electron is more closely associated with this band than with the Pd 4-*d* band (14). Hydrogen concentrations approaching H/Pd $\sim$ 1 may be obtained (15). Supersaturated β-Pd-H alloys are quite unstable and the additional hydrogen is lost rapidly after the cathodizing circuit is removed. Then if the H_2-flow is replaced by He-flow, more hydrogen will be lost till an H/Pd atomic ratio $\sim$0.35 is reached. However, an anodized Pd wire toroid which had never been cathodized previously and which had come to a steady value of zero volt vs. Pt/H_2 was placed in ceric sulfate solution after the H_2-flow had been replaced by He for about 72 hr. The hydrogen content so determined was equal to an H/Pd atomic ratio of 0.56. Yet, when an anodized electrode such as this is cathodized, the β-Pd-H obtained has all the characteristics of electrolytically charged β-Pd-H.

It appears from the above work that β-Pd-H alloys obtained by cathodization possess different stability properties than those obtained in other ways. It is suggested here that the β-Pd-H lattice formed electrolytically is much more distorted than

[1] It may be pointed out that Lacher (17) and Moon (18) have shown that α-Pd alloys are homogeneous solid solutions while these data suggest that such alloys are nonhomogeneous solutions. This discrepancy is only apparent since Lacher and Moon considered α-Pd alloys in a hydrogen environment where the partial pressure of the hydrogen was low enough (0-0.026 atm) that α-Pd was the stable phase with respect to the β-phase. In this investigation, the partial pressure of hydrogen was 1 atm and in this region the β-phase is the stable phase but cannot nucleate until the mass of Pd has been converted to the α-phase. Equilibrium is never achieved between the α-phase and the external hydrogen atmosphere and the α-phase exists only during the nonequilibrium charging processes.

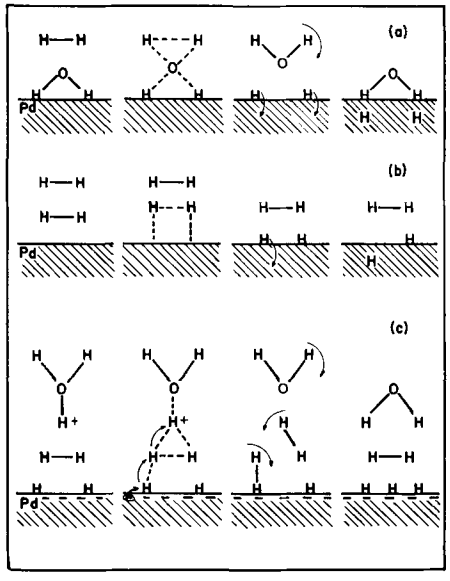

Fig. 4. Suggested possible mechanisms for the solution of hydrogen by palladium. Full lines represent stable bonds; dotted, bonds being formed or being broken. Water is adsorbed with H's next to Pd atoms since the potential at zero charge is positive to Pt/H_2 (2) and therefore a pure Pd surface has a negative charge. The hydrogen symbol, H, in step 4 of (a) and (b) inside the Pd metal represents a proton; the electron has been donated to the metal d-band. (a) Adsorption of hydrogen by previously anodized Pd from H_2-stirred acid solution by complexing with an adsorbed water, an open circuit. (b) Dry gaseous H_2 is adsorbed on dry Pd giving a Pd-H alloy whose surface is covered with an adsorbed layer of molecular hydrogen. (c) Discharge of a solvated proton on a gas charged β-Pd-H cathode; the adsorbed H_2 in step 3 can be desorbed as a free H_2-molecule or adsorbed as two H-atoms shown in step 4.

that formed from gas phase charging due to the formation of the super saturated β-phase. It may be possible that this extra distortion could modify the relative positions and widths of the *s*- and *d*-bands in such a way that the free energy is lowered by loss of hydrogen to an H/Pd atomic ratio of about 0.35 only for the case of the electrolytically charge β-Pd-H in acid solution in the absence of hydrogen or oxidizing agents.

Gas-phase charged β-Pd-H alloys cannot be converted to electrolytically charged β-Pd-H by cathodization alone because the adsorbed molecular hydrogen film prevents supersaturation of the alloy as shown by hydrogen overvoltage measurements (2). If, however, this film is destroyed by preanodization, then subsequent cathodization will result in a β-Pd-H alloy possessing all the properties of the electrolytically charged alloy (Fig. 4).

After the cathodizing current has been removed from certain palladium cathodes, the potential vs. Pt/H_2 swings to positive values before returning to the steady value of zero volt. Conceivably, this might be explained as follows. When the cathodizing circuit is broken, hydrogen above an H/Pd $\sim$ 0.6 is lost rapidly by the supersaturated β-phase. Since the lattice is highly distorted and since there is, without doubt, a readjustment of the partial pressure of hydrogen at points on the surface and within the metal itself, further hydrogen may be lost by inertia which is slowly restored afterward, giving

the observed swing to positive potentials with a subsequent drift to zero. The behavior of such electrodes has been explained by Fallon (8) in terms of the thickness of the diffusion layer at the electrode surface as a function of the stirring rate.

It may be mentioned here that the so-called α-Pd reference electrode, (Pd-H)α/H_3O^+, used by Schuldiner (14, 16) is a good reference electrode. This is true since such an electrode is prepared from an anodized Pd wire placed in a hydrogen atmosphere and it has been shown (6) that such an electrode will maintain a steady-state potential of 50 mv vs. Pt/H_2 for periods of time up to 48 hr or more. If the wire had been cathodized, this would not have been true. Also, Schuldiner's measurements were made within 8 hr so that this reference electrode system acted as though it were at equilibrium.

Summary

1. β-Pd-H alloys may be obtained by allowing a pure sample of palladium to absorb hydrogen either in a dry state from a gaseous hydrogen atmosphere or in hydrogen-stirred acid solutions after the palladium had been anodized. These alloys are stable (do not lose hydrogen) as long as all oxidizing agents are absent, even if the hydrogen atmosphere is removed.

2. β-Pd-H alloys may also be obtained electrolytically by cathodizing the palladium in H_2-stirred acid solutions. These alloys are stable only in a hydrogen atmosphere provided oxidizing agents are absent. If the hydrogen atmosphere is removed these alloys lose hydrogen until an H/Pd atomic ratio of about 0.35 is reached. If the hydrogen atmosphere is returned, the alloy will regain hydrogen till the H/Pd atomic ratio again reaches about 0.6. It is suggested that this behavior is due to the highly distorted lattice caused by the electrochemically produced supersaturated β-Pd-H alloys during cathodization.

3. β-Pd-H alloys obtained from anodized Pd in H_2-stirred acid solutions can be converted to the electrolytically charged alloy by cathodization since the supersaturated alloy is formed in the process. Unlike β-Pd-H obtained from anodized Pd, that obtained by dry gas phase charging possesses a protective hydrogen film which prevents the formation of the supersaturated lattice during cathodization and thereby prevents the conversion to the electrolytically charged alloy. However if this protective film is destroyed by pre-anodization, then cathodization does convert gas charged β-Pd-H to electrolytically charged β-Pd-H.

Brief Communications

The JOURNAL accepts short technical reports having unusual importance or timely interest, where speed of publication is a consideration. The communication may summarize results of important research justifying announcement before such time as a more detailed manuscript can be published. Consideration also will be given to reports of significant unfinished research which the author cannot pursue further, but the results of which are of potential use to others. Comments on papers already published in the JOURNAL should be reserved for the Discussion Section published biannually.

Temperature Dependence of Tafel Slope in the Formation of Very Thin Anodic Oxide Films on Niobium

George B. Adams, Jr., and Timothy Kao[1]

Department of Chemistry, University of Oregon, Eugene, Oregon

ABSTRACT

A kinetic study was made of the formation of very thin anodic oxide films on niobium at constant current over the temperature range −10° to 70°C. Formation voltages were limited to the range below the oxygen evolution potential to eliminate possible interaction of an electronic component of the current with the measured formation field. It was found that the measured temperature dependence of Tafel slope agreed with that predicted by the theory of Mott and Cabrera. Using this theory, a zero field interfacial barrier height of 1.19 ev and barrier half-width of 2.40Å were obtained. Values of the differential formation field are reported at current densities of 1000, 100, 10, and 1 μa/cm^2 at ten degree intervals over the temperature range studied.

Several investigators (1-3), working with tantalum, niobium, and zirconium, respectively, have reported an essentially temperature-independent Tafel slope in the kinetics of formation of anodic oxide films on these metals.

Their results are therefore not in agreement with the simple single-barrier theory of Mott and Cabrera (4, 5), but Dewald's theory (6) which incorporates the assumption of ionic space charge formation in the oxide film is capable of explaining the anomalous temperature dependence.[2]

These investigators worked with oxide films ranging in thickness from several hundreds to several thousands of angstroms. Under these conditions it is probable that a space charge is established in the steady state; some experimental evidence for the presence of space charge has been obtained by Young (7).

The Mott-Cabrera theory for formation of very thin oxide films on metals contains the assumption that no space charge is established in very thin films (<100Å). With the additional assumptions that the rate-determining step in the formation of the oxide is the high-field migration of metal ions from active surface sites on the metal across a metal-oxide interfacial potential energy barrier of height, ϕ, and barrier half-width, b, into interstitial positions in the insulating oxide film, the following equation is derived:

$$F = \frac{\phi}{bq} + \frac{kT}{bq} \ln (I/Ao) \qquad [1]$$

where F is the electrostatic field acting across the oxide film, q is the charge per metal ion, I is the ionic current density, m_s is the surface concentration of metal ions at active surface sites on the metal. V_s is the vibrational frequency of a surface metal ion, and $Ao = qm_s\nu_s$.

The aim of the present work was to test this theory with an applicable system, namely, for the growth of very thin anodic oxide films in which the metal ion is the mobile species in an otherwise insulating film.[3]

Experimental

The experimental techniques employed in this work have been described previously (8, 9).

Electrodes were made up from ½-in. annealed niobium rod (Fansteel research grade) cut into ½-in. lengths, each fitted with a vertical brass rod for handling and electrical contact. This assembly was then masked with six individual coatings of baked Formvar enamel. The plane circular face of each electrode was exposed by abrasion, to give a nominal area of 1.265 cm^2.

Electrode surfaces were prepared initially on a metallographic polishing wheel with No. 280 and No. 600 grit aluminum oxide abrasive slurries and finished with Linde B polishing alumina, to a highly reflecting surface. Electrodes were repolished after each run with polishing alumina.

The electrolyte was made up of 0.1N H_2SO_4 in 35% ethyl alcohol. This electrolyte was also used in the mercury-mercurous sulfate reference electrode. The solution was stirred mechanically during each run and renewed every 8 hr. Temperature was regulated to within ±0.1°C over the range −10° to 70°C with a Wilkens-Anderson refrigerated constant temperature bath.

Current densities from 1 to 100 μa/cm^2 were regulated to within ±0.5% with an electronic current regulator described previously (10). Current density of 1000 μa/cm^2 was regulated electronically with a regulator described by Teeter (11). Current was measured to within 0.5% with a Weston precision low resistance microammeter, model 627. Voltage was recorded on a L&N AZAR recorder using their

[1] Present address: Department of Pediatrics, University of Oregon Medical School, Portland, Oregon.

[2] This theory cannot, however, account for certain characteristics of transients which have been observed with these oxide films.

[3] It is assumed that the niobium ion, because of its small size, is the mobile species in the oxide film (2). The glassy film has an extremely low electronic conductivity (2).

model 7664-N electronic millivoltmeter as a high-input-impedance preamplifier.

Runs made at 1.0 μa/cm^2 were obtained by first polarizing at 100 μa/cm^2 and then dropping back to 1.0 μa/cm^2 on the same electrode surface. It was observed that there was considerably more scatter among the individual formation rates for these runs than for runs made at higher current densities.[4]

All voltage measurements were limited to the range below the potential for reversible evolution of oxygen. By restricting voltage measurements to this range, possible complications involving the action of electronic current on the observed field are avoided, since the ionic current efficiency is then unity.

Results

If Eq. [1] is obeyed, a plot of field vs. absolute temperature should be linear for constant current runs, and the slopes of the regression lines should increase with increasing current density. In addition the lines should extrapolate to a common intercept, ϕ/bq, at the absolute zero of temperature.

Equivalent statements are that the Tafel slope, $[\partial F/\partial \ln I]_T$, should vary in direct proportion to the absolute temperature, or that the barrier half-width, b, should remain constant with temperature.

The results of this investigation are presented in Table I and in Fig. 1.

Each point is the average of at least five individual runs. The lines shown are the least square regression lines. Equations for these lines, with standard deviations of slopes and intercepts are as follows:

$$F_{1000} = (9.88 \pm 0.16 \times 10^6) - (1.65 \pm 0.06 \times 10^4)T$$
$$F_{100} = (9.91 \pm 0.27 \times 10^6) - (1.80 \pm 0.09 \times 10^4)T$$
$$F_{10} = (10.00 \pm 0.26 \times 10^6) - (2.02 \pm 0.09 \times 10^4)T$$
$$F_1 = (11.15 \pm 0.44 \times 10^6) - (2.59 \pm 0.15 \times 10^4)T$$

The barrier half-width, b, was calculated from Tafel slopes [obtained from the regression lines as $(F_{1000} - F_{10})/4.606$], assuming a pentavalent niobium ion. Values of b so obtained ranged from 2.44 to 2.36Å, with a mean of 2.40Å.

[4] When making a 1.0 μa/cm^2 run the electrode is immersed continuously for an interval of more than an hour. At the higher temperatures it became necessary to recoat the electrode on one occasion because gross leakage had developed between the enamel mask and the rim of the electrode face. Slight leakage of this sort would give field values that were too low at the higher temperatures. The 1.0 μa/cm^2 runs would be affected to the greatest extent, because of the protracted immersion times required and the greater percentage effect for a given leakage.

Oxide density, 5 g cm^{-3} (2).

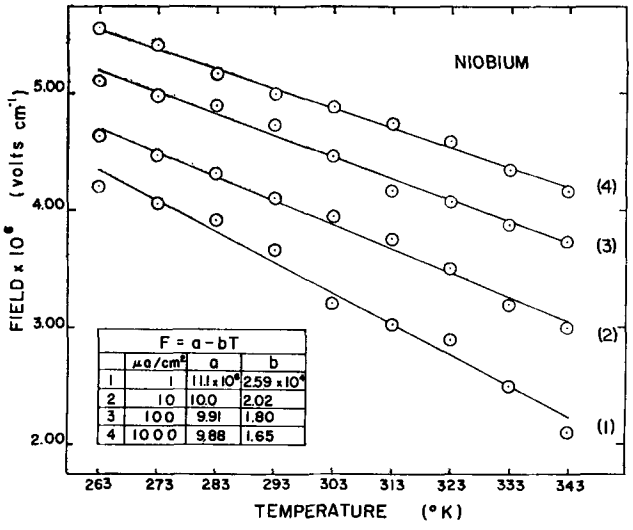

Fig. 1. Temperature dependence of field at 1000, 100, 10, and 1 μa/cm^2.

Using the mean half-jump distance, 2.40Å, and the mean intercept of the field-temperature regression lines for the three highest currents, 9.91 x 10^6 v cm^{-1}, the interfacial barrier height, ϕ, is 1.19 ev.

From the slopes of the regression lines at each current density, Ao can be determined. The resulting values are 1.0, 0.9, 1.9, and 500 x 10^7 amp cm^{-2}, in order of decreasing current density.

Taking $m_s \leq 8 \times 10^{14}$ atoms cm^{-2} and $V_s = 10^{13}$ sec^{-1} (2), one computes $Ao \leq 6 \times 10^9$ amp cm^{-2}, which is satisfactory, since m_s may be considerably less than the value estimated from the density of the metal.

Discussion

The present investigation indicates that the observed temperature dependence of Tafel slope for growth of *very thin* anodic oxide films on niobium is interpretable on the Mott-Cabrera theory for formation kinetics of such anodic films. Previous studies on niobium, reported by Young (11) were made with thicker, high voltage films. Those results are anomalous on the Mott-Cabrera theory in that the barrier half-width, b, was found to be temperature dependent. The present results are not contradictory, however, since that investigation was made with high-voltage films.

Values of differential formation field given in Table I are in general agreement (except for small differences in temperature coefficients) with those of Young (11) whose work was done with chemically polished electrode surfaces and thick films. A barrier half-width, b, of 2.40Å obtained in the present work is smaller than either of the values $a \geq 4.2$Å, $b \geq 3.1$Å reported by Young on the Dewald theory but is in good agreement with the 2.42Å reported by Vermilyea (12) for steady-state measurements.

Runs taken at the lowest current density were not used in the evaluation of ϕ and b. Considerably less precision was obtained with these runs, both individually and in the fit to the regression line.

For the remaining data, variation in Tafel slope with current density is of the same magnitude as the

standard deviations of slope. The trend with temperature, however, is unidirectional. Also the three intercepts agree within their respective limits of error.

The precision obtained in this investigation is less than that for similar measurements on high-voltage films (2). Nevertheless it is felt that the results obtained are significant and adequately explained by the Mott-Cabrera theory.

The general agreement between formation fields for both low- and high-voltage anodic oxide films obtained in the present work is contrary to what was observed previously with zirconium (8). This agreement with niobium is probably due to the fact that the ionic current efficiency is essentially 100% for polished niobium over the complete voltage range (2). There is therefore no depression of field due to electronic leakage, as reported for zirconium (8).

The agreement obtained between low- and high-voltage parameters again confirms the assumption (7) that oxide film formation occurs at unit current efficiency over the low-potential range below oxygen evolution.

High Current Electronic Interrupter for the Study of Electrode Processes

W. E. Richeson[1] and M. Eisenberg[2]

Stanford Research Institute, Menlo Park, California

ABSTRACT

The design of a fast, high current interrupter capable of handling up to 5 amp is presented. Through small modifications even larger currents can be handled. The electronic interrupter is exceptionally versatile, has a short rise time, a variable output current, and a switching rate from 500 cycles per second to any longer period desired. Interruption periods as short as 1.6 microseconds were found to be quite practical. The high speeds, short rise times, and sizable currents make this interrupter an outstanding device compared to past efforts in this field. The applications of the interrupter in the field of electrochemical kinetics are illustrated through experimental work. Potential-time traces for anodic dissolution of titanium were studied.

Polarization can be measured fundamentally in two different ways. In addition to the direct method involving many forms of liquid junction to a reference electrode and in which the current is maintained constant during the measurement, methods are available to measure the potential of a working electrode against a suitable reference electrode during a short interval following interruption of the electrolyzing current. The chief advantage of a pulse interrupter method is that it allows elimination of the *IR*-drop involved between the working electrode and the reference electrode. This becomes particularly important when the geometry of the cell or changes in the electrolytic conductivity in the boundary layer at the electrode are such that corrections and predictions of *IR* drops are not very certain. In addition to offering a method for the elimination of the *IR* drop corrections, the interrupter gives several other types of information about the reaction process. For instance, from the decay curve of the polarization potential of the working electrode, deductions about the nature of the process (whether it is under activation control or under mass transfer control) can be made. From the initial slope of such decay curves one can also calculate the pseudo-capacity of the electrode. The latter offers a basic tool for studying the double layer and diffused double layer [according to Stern's theory (1)]. Thus, interrupters are very important research tools yielding important information about electrode processes from both the equilibrium and the kinetic point of view.

The first modern electronic interrupter was described by Hickling (2) in 1937. This device, how-

[1] Present address: Farnsworth Electronics, Fort Wayne, Indiana.
[2] Present address: Lockheed Missiles and Space Division, Sunnyvale, California.

ever, was still comparatively slow and limited to currents of the order of 10-50 ma. Schuldiner and White (3) obtained current interruptions by applying a disabling pulse to one side of a diode which was in series with the electrolytic cell and a current source. The current capability was in the order of a few milliamperes. More recently, Drossbach (4) used thyratrons to interrupt the current in a circuit containing an electrolytic cell and a current source.

Breiter and Volkl (5) found, however, systematic errors in both thyratron interrupter devices of Hickling and Drossbach. Through the use of calibrated input pulses they found that the error in amplitude of the applied pulse as shown by the measuring thyratron increases as the width of the applied pulse near the peak decreases. The relationship is almost linear. For this reason the thyratron device was found to be more reliable for rectangular input pulses than for sinusoidal or other transient forms. The systematic error is particularly large at low values of potentials. A slight decrease in the systematic error can be achieved by increasing the anode grid potential above 300 v. However, this introduces additional difficulties in fluctuations of the firing point of the thyratron. In addition to these difficulties resulting from the use of thyratrons, the 3 circuits described above were limited by the type of current interruptions which could be obtained, as well as by the level of current that can be handled.

The electronic interrupter described in this paper avoids the use of thyratron tubes and employs an electronic switch consisting essentially of a number of type 6AS7 vacuum tubes operating in parallel. As described here, the interrupter is capable of handling up to 5 amp and performing many different types of interruptions. The "on" and "off" times and switching frequency can be varied practically at will. Furthermore, by addition of more tubes in parallel the current capacity of the interrupter can be increased without involving other major changes.

Design Considerations

The interrupter must act like a near perfect switch which can open and close rapidly without extraneous transients. The device must have a variable conduction level and must be capable of imposing a current function upon some specified steady-state current level. The level of operation must be from a few microamperes to large values, e.g., 5 amp. The period of conduction or no conduction, the ratio between conduction and nonconduction periods, and the frequency of operation of the interrupter should be variable over very wide limits.

The method selected was one in which an electron tube or a group of parallel electron tubes is placed in series with an electrolytic cell and a battery. This electronic switch is controlled by a pulse generator which has a very low output impedance (30 ohms) and a d-c coupling. The pulse generator has a function generator input. This portion of the circuit acts like a power amplifier which controls the electronic switch so that special pulse functions can be used. Provision is made for a potential source and a mercury switch so that the electronic switch will have a step function applied to it which is controlled by a push button. A third provision is for a time standard to be connected to the pulse generator. This standard drives a pulse generating circuit so as to generate symmetrical or asymmetrical pulses to control the electronic switch over very wide limits (1 μsec to a few tenths of a second intervals). Also on this chassis is the provision to vary the amplitude of the signal and the level of the d.c. to the electronic switch.

The effect of stray pickup would be to introduce noise and extraneous signals into the data. When a current is interrupted the circuit impedance becomes large and it may often become difficult to reduce stray pickup. Due to the fact that the input impedance of the measuring apparatus is large (10 megohms in this case), so as to prevent loading, the noise pickup picture becomes worse. The solution is to make leads short and keep all active portions of the circuit well shielded. Special precautions must be taken in order to prevent capacitively loading high impedance portions of the circuit by shielding these portions too tightly. Special precautions must be taken to prevent grounding loops and to hold stray inductance to a minimum. Large diameter, low resistance, low inductance leads were used when possible. In some cases coaxial and twisted leads to carry currents hence and forth were used in order to reduce the inductance of the system and to reduce radiation or stray pickup. Some portions of the circuit were by-passed with capacitors to reduce their inductive effects. Power line variations and noise were reduced by using voltage-regulated transformers and filters.

Design of Mode of Operation

Power supply.—Figure 1 shows the circuit of the power supply which feeds d-c power to the voltage regulation circuit of Fig. 2. The power supply is designed to supply 400 v d.c. at 1,000 ma. The voltage regulator (Fig. 2) has tubes V_{15}, V_{16}, V_{17}, and V_{18} in parallel which gives a total of 8 triode sections of the 6AS7 variety and can individually pass 125 ma. The maximum output of the regulator is about 1 amp at 100 v drop across these tubes. The tubes V_{19}, V_{20}, T_1, T_2, and T_3 form the error-detecting amplifier which drives the above series of regulator tubes. The voltage regulator tube T_4 produces a 150-v supply whose output current cannot vary by more than ± 12 ma about the steady-state current drawn from its 150-v output terminal.

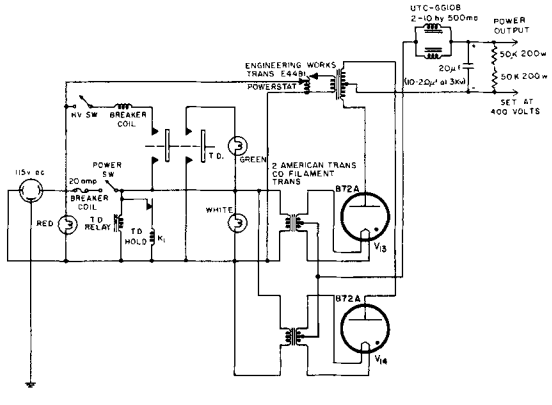

Fig. 1. Power supply

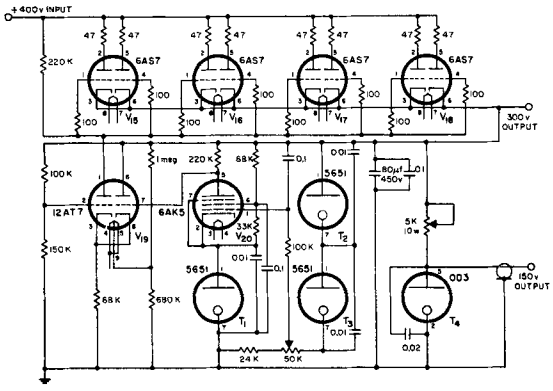

Fig. 2. Voltage regulation circuit. Capacity in $\mu\mu$f and resistance in ohms unless specified.

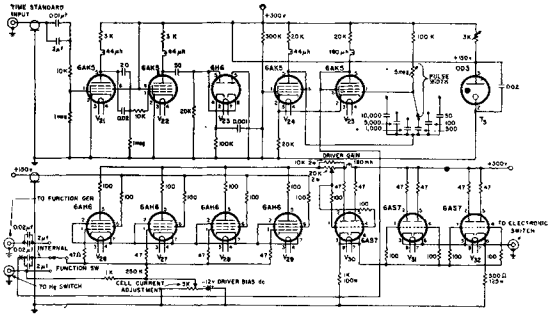

Fig. 3. Pulse generator. Capacity in $\mu\mu$f and resistance in ohms unless specified.

Pulse generator.—The pulse generator (Fig. 3) is the signal source for the electronic switch chassis. The output of the pulse generator is directly coupled to the electronic switch through a coupling box.

Starting with the time standard input jack, signals from the Time Standard (e.g., Hewlett-Packard model 202A) pass through tubes V_{21} and V_{22} which are overdriven amplifiers. When the signal leaves V_{22} it has a squared wave form. This square wave passes to V_{23} which is part of a differentiating and limiting circuit which is responsible for driving V_{24} with sharp positive pips. Tubes V_{24} and V_{25} with associated circuitry form a monostable multivibrator which forms a positive pulse of variable period for each positive pulse coming from V_{23} which is repetitive at the rate prescribed by the time standard. The periods of the positive pulses produced can vary from 2 μsec to 0.15 sec. This positive pulse is fed to point x which is a contact on a selector switch whose other contacts are "To Function Gen" and "Hg Switch." The wiper arms of this switch feed the grids of the parallel combination V_{26}, V_{27}, V_{28}, and V_{29}. This series of tubes forms an amplifier-inverter which feeds a signal to V_{30} which is a cathode follower. V_{30} feeds V_{31} and V_{32} in parallel which is another cathode follower which drives the "electronic switch." Because of the rise time desired and the impedance levels V_{26} to V_{32} were required. The potentiometer, "cell current adjustment," controls the bias on the combination V_{26}, V_{27}, V_{28}, and V_{29}. This controls the d-c level of the output to the electronic switch and therefore its current level. The driver gain control adjusts the magnitude as well as the d-c level of the signal to the electronic switch.

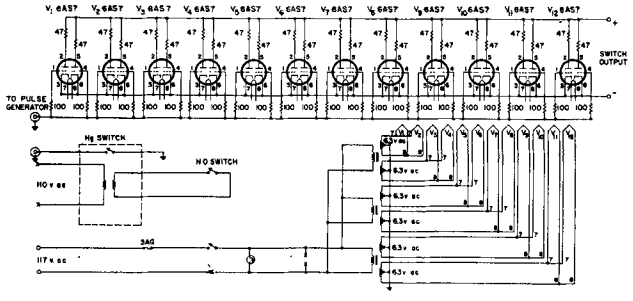

Fig. 4. Electronic switch. Capacity in $\mu\mu$f and resistance in ohms unless specified.

The "function switch" determines the derivation of the "electronic switch" control. The "function generator" position of input at this terminal will be amplified and will control the "electronic switch." Such a function generator might be the Hewlett-Packard low frequency function generator. When the selector switch is on "Hg switch" the pushbutton mercury switch (vide infra) will control the "electronic switch." If the pushbutton is pushed the mercury switch closes and shorts this position to ground. This removes the bias on V_{28} to V_{29} and causes their plate voltage to drop greatly. This step function cuts off the "electronic switch."

Electronic switch.—Tubes V_1 to V_{12} comprise the electronic switch in Fig. 4. With a 50 v drop across the switch, and the grid to cathode voltage equal to zero, the current can be about 5 amp. If the drop across the switch is 60 v, the current can be 6 amp, with a zero grid to cathode voltage. The total dissipation of the present set should not exceed 312 w for any long period of time such as days and weeks. The use of resistors in the plate and grid circuits were for the purpose of avoiding parasitic oscillations. The switch output terminals are in series with the electrolytic cell and the d-c power source.

There is a pushbutton on the panel which actuates a mercury switch. The closure of this switch is grounded. The contact of this switch is brought out to the panel, which allows cabling to one of the inputs to the pulse generator. This input on the pulse generator chassis is labeled "to Hg switch" (left side of Fig. 3).

Coupling box.—Figure 5 shows the coupling circuit between the pulse generator and the electronic switch. The function of this box is to couple the output of the pulse generator to the electronic switch, to set the level of current flowing in the electronic switch, and to assure against grid current being drawn by the electronic switch. The electronic switch current level adjustment should be so adjusted as not to give an indication on the meter M.

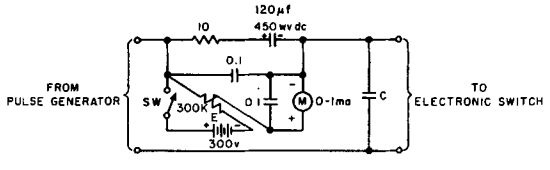

Fig. 5. Coupling box. C, determined the rise time desired; E, 200 v (tapped 300-v miniature battery); M, adjust driver bias control so that this current is always zero; R, electronic switch current level adjust.

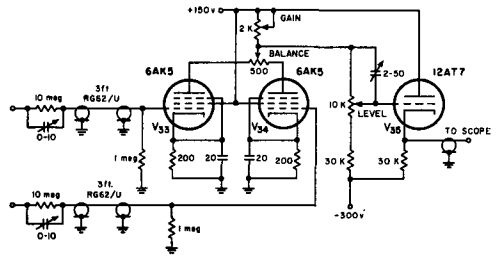

Fig. 6. Difference amplifier. Unless specified, R in ohms, C > 1 in $\mu\mu f$.

The capacitor C (1-50 μf) is included so that the rise time or decay time of the electronic switch may be adjusted.

Difference amplifier.—Tubes V_{33} and V_{34} form the difference amplifier in Fig. 6. The "balance control" is to make adjustments in the event that V_{33} and V_{34} may not have exactly the same characteristics. The gain control adjusts the gain of the difference amplifier. The level control adjusts the d-c level of the output of V_{35} which is a cathode follower. A variable capacitor, C, (2-50 μf) adjusts the shape of the leading edge of fast pulses so as to minimize distortion.

Possible modes of operation.—Figures 7, 8, and 9 present operational block diagrams of Interrupter Circuits No. 1, 2, and 3. The dotted-in capacitors present some of the more important distributed capacitances. Figure 7 shows the circuit which is possible without the use of a difference amplifier and

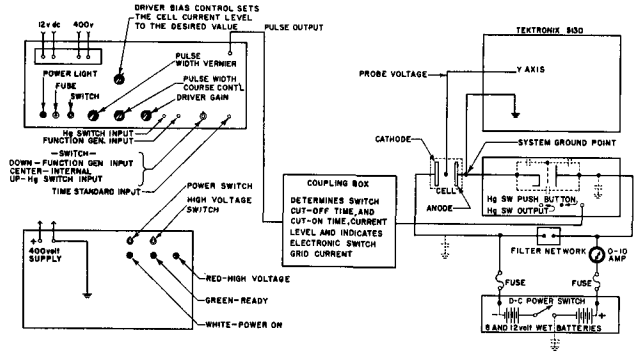

Fig. 7. Interrupter circuit No. 1

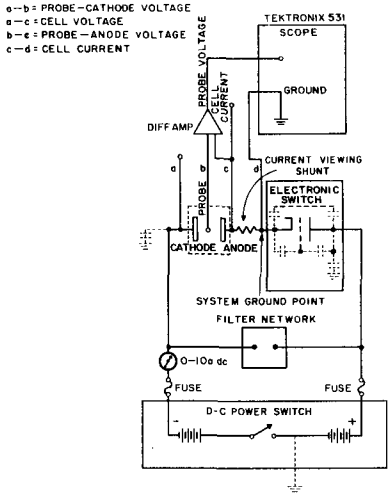

Fig. 8. Interrupter Circuit No. 2

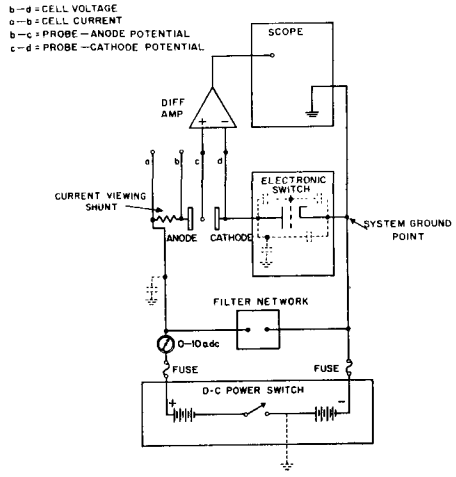

Fig. 9. Interrupter Circuit No. 3

Fig. 8 and 9 show what can be done with the use of difference amplifiers. Due to the existence of distributed inductances in the Interrupter Circuit No. 3 (Fig. 9) is the most desirable circuit since it would have the least ringing.

The method of coupling the electrolytic circuit with the interrupter device is illustrated in Fig. 7. On the right-hand side a bank of lead acid batteries is shown as the source of the electrolytic current. This current passes through an electronic switch (shown directly above the batteries) to the cell and is measured by an ammeter connected in series. The potential developed between the anode in the cell and the reference electrode (probe voltage) is viewed by means of a suitable oscilloscope (in this case Tektronix 513D or 531 was used). After suitable calibration of the oscilloscope in respect to the time as well as voltage axis, visual observations were followed out by photographic records taken with a Polaroid camera. Details of the individual components of the interrupter are shown in Fig. 2, 3, and 4. The voltage regulation circuit as shown in Fig. 2, has an input of +400 v (from the supply unit shown in the lower left-hand corner of Fig. 7) and gives a closely controlled output of either 150 or 300 v. This power is fed into the pulse generator (left upper corner of Fig. 7) whose details are shown in Fig. 3. As a time standard a Hewlett-Packard oscillator is used. Square waves of an adjustable frequency are employed. Whenever a single interruption is desirable a manual switch can be used instead of the time standard. The output of the pulse generator is fed into an electronic switch as shown in Fig. 4. This switch employs a bank of 12 type 6AS7 vacuum tubes. This bank of tubes is necessary to enable the switch to carry and interrupt electrolyzing currents up to 5 amp. The electronic switch is shown in the middle right-hand side of Fig. 7, representing the over-all interrupter circuit arrangement.

Application and Experimental Results

As one method of application of the electronic interrupter a study was made of anodic polarization of titanium. Other possibilities of employing the interrupter were not explored at this time. The main objectives were interruption studies employing elec-

trolyzing currents up to 5 amp for period durations as short as 1 μsec.

The experimental procedure consisted of electrolyzing the cell at a constant current for a sufficient time (usually 5-10 min) to achieve a constant polarization of the anode. Following the calibration of the oscilloscope the electrolytic current was interrupted and a simultaneous photographic recording of the trace on the face of the oscilloscope was taken. This technique was used whenever a full decay of the polarization was wanted. In cases in which the current had to be restored after a desired preset "off" period, this was usually done by employing the time standard as an input to the pulse generator. Usually 1 or 10 cps was used as a frequency for the interruption. In some cases for a given current density interruptions were made for varying (gradually increasing) periods of time. These ranged usually from as little as 1.5 μsec to as long as 4000 μsec. The rise time was found to be about 0.1 μsec.

Results were subsequently evaluated from the photographs of the oscilloscopic traces.

One of the typical experimental situations in studies of electrode kinetics is the inherent involvement of some unknown *IR* drop in the cell. Even under conditions where efforts have been made to reduce or eliminate such an *IR* drop, some small *IR* drops may still exist between the Luggin capillary leading to a reference electrode and the polarized working electrode under study. It is in situations of this type that the use of an interrupter is particularly advantageous.

One of the direct methods for the determination of single electrode polarization which avoids the use of the Luggin capillary with its complicated distortions of the equipotential surfaces and of the hydrodynamic conditions is the so-called "extrapolative method" (6).

This technique is based on the use of two reference electrodes connected to the cell at precisely known distances from the equipotential surface of the electrode itself. The *IR* drop between the electrode and the nearest reference is then calculated by extrapolating from three measurements, as indicated in Fig. 10. It is obvious that the validity of this method depends primarily on two factors; the first requires a uniform current distribution and the second is based on the assumption that the electrode process does not greatly affect the electrolyte conductivity in its immediate vicinity. The use of an electrolytic trough with well-matched electrodes at the end generally provides a uniform primary current distribution. In most solutions where an excess of supporting electrolyte is employed, the net change in electrolyte conductivity in the vicinity of an electrode at which no new ionic species is created, the conductivity changes are usually sufficiently small to make the extrapolative method useful. However, in the case of an anodic dissolution in an electrolyte which does not contain ionic forms of the metal, sizable changes in the conductivity in the immediate vicinity of the anode occur, and the comparison between the interruption technique and the extrapolation method would then definitely be revealing.

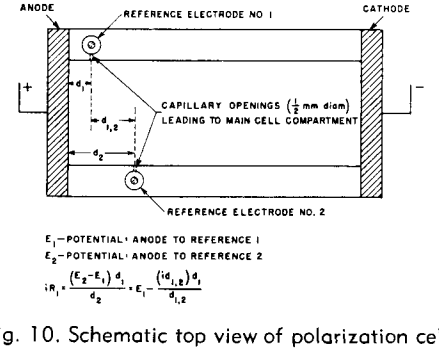

Fig. 10. Schematic top view of polarization cell

To test this point, as well as to evaluate the overall performance of the interrupter, the anodic polarization of a titanium sheet anode (Ti 75A) was studied in a solution (K-2) of the following composition: 11.5% (wt) HF; 6.2% H_2O; 15.0% tetrahydrofuran; 67.3% ethylene glycol at temperatures from 30° to 55°C. Vigorous stirring was employed in the bulk of the cell Table I shows the analysis of the data obtained from such interruption experiments. In addition, the last column shows *IR* drop calculations made by the direct extrapolative method. Bright nickel reference electrodes immersed in the same solution in a separate compartment were employed as shown schematically in Fig. 10. At the open circuit the titanium anode potential was negative in respect to the nickel reference electrode by 0.62 v. However, when polarized at a total current of 0.30 amp (i.e., a current density of 6 ma/cm^2) its potential shifted considerably into the positive direction to a value of +105 v. Upon interruption for a period of 2 μsec an instantaneous vertical drop of 0.4 v was recorded. This drop can obviously be assigned to the *IR* drop component of the potential difference involved between the nearest reference electrode and the polarized titanium anode. Following this rapid *IR* drop a somewhat slower decay of the actual net polarization of the anode began. Thus, as shown for an interruption period of 48 μsec, the potential decreased from 0.65 to 0.54 v during the period from 2 to 5 μsec (following the current break). This value decayed further to 0.40 v within the subsequent 43 μsec (see line 3, Table I).

In experiments employing a total current of 0.70 amp the *IR* drop component estimated from the decay curve was 0.7 v. This was lower than the 0.95 to 0.90 value estimated by means of an extrapolative method employed in the direct polarization measurements (last column of Table I). At this current level longer interruption periods were employed and it can be noticed that a decay of about 1.5 v occurred within 1000 to 2000 μsec. This generally is quite rapid compared with the decay one might expect from a pure diffusion mechanism (7). Similarly, it can be observed that at a total current of 2 amp (current density of 40 ma/cm^2) the anode polarization drops from 2.8 v to 0.30 v within 4000 μsec. This, compared with the zero current potential of −0.62 v, amounts to a decay of 72.7% of the total anode polarization within 0.004 sec. On the basis of these observations it may thus be concluded (8) that the anode polarization of titanium consists essentially (if not completely) of chemical polarization associated with

the activation energy required for the titanium dissolution reaction.

Another interesting conclusion from this work is that the IR drop values obtained from conductivities in the direct method of polarization measurements (last column Table I) are usually larger than the values obtained from the initial rapid drop in the potential-time trace obtained by the interrupter method. These differences become larger and more significant the larger the current densities employed. This, of course, is to be expected since sizable amounts of titanium ions are going into the solution in the immediate vicinity of the anode. The differences, especially at the higher current densities, are sufficiently large to demonstrate the importance of interruption techniques as a research tool in electrode kinetics.

The A-C Resistance of a Stainless Steel Electrode and Specific Adsorption

G. M. Schmid and Norman Hackerman

Department of Chemistry, University of Texas, Austin, Texas

ABSTRACT

The a-c resistance of a stainless steel wire electrode was measured in dependence of the type of electrolyte, the polarizing current density, and frequency of the measuring current. It is shown that K^+ is more adsorbed than Na^+ during cathodic polarization, and Cl^- more than F^- during anodic polarization. This method seems to be especially useful in testing the adsorbability of neutral surface active substances during d-c flow.

A wire electrode in contact with an electrolyte represents, with respect to passage of current along the length of the wire, a system similar to two resistors connected in parallel. Thus, when two contacts are made to the same electrode and an a-c or d-c potential is applied, a certain fraction of the total current flow chooses a path through the electrical double layer (edl) and the solution (1). The extent of this leakage can be found by measuring the impedance of the system and comparing it with the impedance of the electrode in air. In doing so, it must be remembered that the impedance of a metal

can vary with the uptake of gas, especially hydrogen (2).

The conduction phenomena of the electrode/electrolyte interface are determined by the structure and composition of the edl. The composition of the edl depends on the kind of electrolyte solution used and on the presence or absence of specifically adsorbed ions and neutral surface active substances. The structure of the edl depends on the potential of the electrode (3). It was found previously that the magnitude of leakage current in the system stainless steel/1.0M Na_2SO_4 depends on the polarizing d-c current density (p.c.d.), or alternatively on the potential of the electrode (4).

The leakage current, besides being governed by the edl, is limited by the conductivity of the solution. It was found to be negligible in the system stainless steel/0.001M Na_2SO_4. Furthermore, when using an electrolytic cell, the current, leaking from the test electrode into solution may also pass from the solution into the auxiliary electrode, comparable to a circuit with three resistors in parallel.

Measurements of the leakage current, i.e., the impedance of the system, between two contacts on the same electrode should permit conclusions to be drawn regarding specific adsorption. The leakage current will have to be compared with a system, the components of which are not specifically adsorbed.

Experimental

Essentially the same experimental setup was used as in previous work (4). Unless otherwise stated, the impedance of the test electrode was measured with 60 cps a.c. in a Wheatstone Bridge, using a Brown-Honeywell Recorder for continuous measurements, with a precision of 0.005 ohms. In order to obtain data on the frequency dependence of the leakage current, a General Radio Co. (GRC) Type 650-A Impedance Bridge was used between 100 cps and 16 kcps, with a Hewlett-Packard (HP) Widerange Oscillator Model 200 DC as power supply. The signal drawn from the bridge was preamplified in a HP Model 450-A Amplifier, filtered and amplified in a HP Model 300-A Harmonic Wave Analyser and observed on an oscilloscope, thus giving an accuracy of 0.01 ohms. Measurements between 550 kcps and 2 mcps were made with a GRC Type 821-A Twin-T Impedance Bridge combined with a GRC Type 1001-A Standard Signal Generator. Here the null-detector was a radio receiver.

Reproducible results, especially at the intermediate frequency range, were obtained only after pretreating the electrodes alternatively, anodically, and cathodically for about 1 hr (5).

In all cases, the test electrode was a type 302 stainless steel wire of 0.038 cm diameter and approximately 90 cm long. The auxiliary electrode was made of the same material and length. The two electrodes were arranged in a glass tube and kept apart 2 cm throughout. The polarizing d-c current was supplied by a Lambda Regulated Power Supply Model 32 M operated at 200 v d.c. or by a 180 v battery and controlled by a set of resistors. The power supply was connected to the upper end of the anode and the lower end of the cathode, thus preventing a d-c potential drop along the wires. All contacts were made outside the electrolyte. Interference of the two circuits was carefully minimized by the use of capacitors and chokes as filters. The potential of the test electrode was measured against a saturated calomel electrode (SCE).

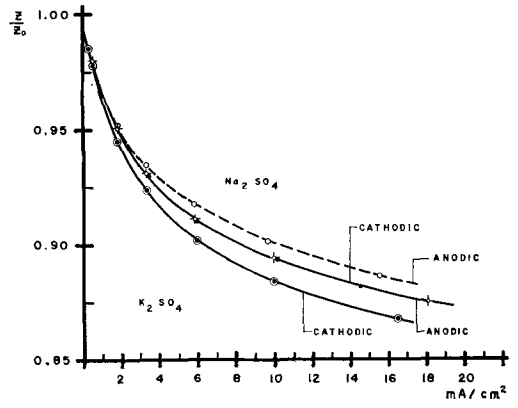

Fig. 1. Relative impedance vs. current density in 0.1M K_2SO_4 and 0.1M Na_2SO_4. (Curves for Na_2SO_4 cathodic and K_2SO_4 anodic coincide. Electrode: Type 302 stainless steel wire, 0.038 cm diameter, surface area 10.6 cm^2, Z_o = 6.556 ohms.

Results

Effect of cations.—The difference between impedance measurements with low-frequency a.c. in air and in solution is very small, either because the coupling capacity of the edl is too small and/or the coupling resistance is too large to allow a significant fraction of the measuring current to leak into solution. When the electrode is sufficiently polarized to make an electrochemical reaction possible, the capacity becomes appreciably higher and/or the resistance drops to low values (6). This causes an a-c leakage as shown in Fig. 1, where the impedance of a stainless steel wire is plotted against the p.c.d. for 0.1M Na_2SO_4 and 0.1M K_2SO_4. Since the anion is the same in both cases, one would expect the curves for anodic polarization to coincide. As stated above however, the leakage current is limited also by the conductivity of the electrolyte (Table I). The better conducting system, K_2SO_4, should in any case show a lower impedance at a given p.c.d., as was found experimentally. The distance between the anodic and cathodic curves is slightly bigger in the case of K_2SO_4, pointing to a more densily packed edl. It was concluded, therefore, that during cathodic polarization K^+ is somewhat more adsorbed than Na^+. This has been reported also on Hg (7) and Pt electrodes (8). In both solutions, the impedance curves for cathodic polarization run lower than those for anodic polarization. This means a larger capacity and/or smaller resistance of the edl on cathodic polarization (6).

+ Interpolated.

Effect of anions.—In solutions of the more common cations, the cathodic electrode reaction is H_2 evolution, and it is reasonable to assume that, at a given current density, differences in the behavior of the edl can be attributed to differences in the adsorbability of ions or neutral substances. An electrochemically inert species, like SO_4^{--}, can be taken as common anion. In varying the anion, however, frequently the anodic electrode reaction changes from anion to anion and with it the composition of the edl. Thus, with KF up to 1.0M and 0.1M KCl (at current densities > 3 ma/cm², see next paragraph) O_2 is evolved at the anode, with KBr up to 1.0M the electrode does not become passive in the current density region investigated and iron dissolution occurs, and with KI the anion is oxidized. The above assumption no longer holds and we can reasonably compare only the curves for 0.1M KF and 0.1M KCl with each other. An additional complication derives from the fact that the auxiliary electrode, only 2 cm away, may participate in the over-all conduction phenomena (4). This interference forces the impedance drops on both sides of the polarization curves to be of the same order of magnitude. So, in judging the effect of different ions on the leakage current, both cathodic and anodic impedance curves have to be considered together. With 0.1M KF and 0.1M KCl the impedance curves for cathodic polarization are also lower than the anodic impedance curves (Fig. 2). It seems to be a general rule that the conductivity of the edl at H_2 evolution is higher than at O_2 evolution potentials. The difference between cathodic and anodic curves is more pronounced on comparing F^- and Cl^- than on comparing K^+ and Na^+, showing a larger effect of anion adsorption. The gap is bigger in the case of Cl^-, which apparently can dehydrate more easily than F^- ions (8, 10). The generally smaller impedance changes in KF can be explained by its smaller conductivity.

It is interesting to note that the curve for 0.1M KI and 0.1M KBr differ remarkably, despite the fact that the solutions have about the same conductivity. This could be attributed to stronger adsorption of I^- combined with a higher edl capacity due to adsorbed I_2.

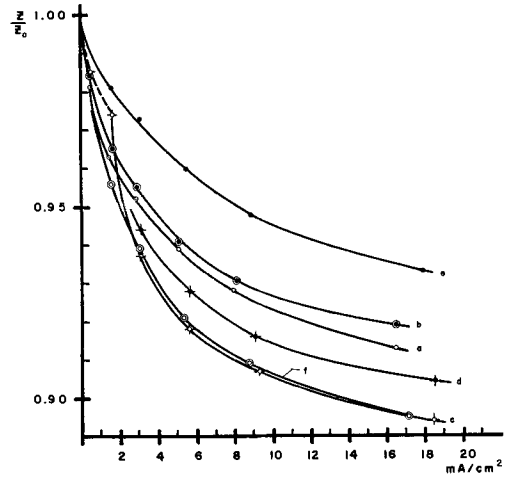

Fig. 2. Relative impedance vs. current density: curve a, 0.1M KF cathodic; curve b, 0.1M KF anodic; curve c, 0.1M KCl cathodic; curve d, 0.1M KCl anodic; curve e, 0.1M KBr anodic; curve f, 0.1M KI anodic. Electrode: Type 302 stainless steel wire, 0.038 cm diameter, surface area 10.5 cm², Z_0 = 6.520 ohms.

Effect of chloride.—Figure 3 gives recorder graphs of measurements in 0.1M K_2SO_4 and 1.0M KCl. In K_2SO_4 the impedance reaches its steady-state value for the corresponding polarizing current density or open-circuit conditions practically instantaneous. During current flow O_2 evolution takes place. In KCl however a sharp impedance drop occurs, followed by a slow increase to a maximum and a final steady-state value. The electrode exhibits a passive potential shortly after the first sharp drop, and gas evolution was observed. During the following increase a slow potential decay with a sudden breakdown at the impedance maximum was experienced. Gas evolution stops and the bright electrode begins to show dark pits. After the polarizing current is cut off, it takes roughly 1 to 2 min for the impedance to reach its steady-state value for open-circuit conditions. The time during which passivity is maintained is a function of temperature, current density, and KCl concentration. At room temperature stainless steel can be held passive in 0.1M KCl with current densities > 3 ma/cm². Current densities < 20 ma/cm² are not enough to maintain passivity in 1.0M KCl. Increase in temperature shortens the time of passivity. At an anodic current density of 20 ma/cm² in 1.0M KCl, the electrode is passive at 39°C for 38 sec only, whereas at 1°C passivity is maintained "permanently" even at considerably smaller current densities. The time during which passivity is maintained is not reproducible because of the large changes in surface involved (pitting, Fe dissolution). For these phenomena the following explanation is proposed. In the first moments of anodic polarization an adsorbed sheet of water dipoles is converted to chemisorbed oxygen (11). The strongly positive potential facilitates the subsequent adsorption of Cl^- ions. Gradually, adsorbed oxygen is partially replaced by adsorbed Cl^-, passivity breaks down, and the potential falls back to Fe dissolution values.

A passive stainless steel electrode provides for a large amount of leakage current (e.g., KF, Fig. 2, a and b). A fairly rapidly dissolving electrode shows less leakage current (e.g., KBr, Fig. 2, e), despite the fact that the adjacent layer of solution should be crowded with iron ions and have good conductivity. At a dissolving electrode, however, continuous regeneration of the surface prevents a high coverage with chemisorbed species, provided the surface changes fast enough. The importance of the inner edl for the contact between metal and solution is again emphasized. The peak in the impedance/time curve (Fig. 3) represents a maximum coupling impedance, the point, where the coverage with adsorbed oxygen is defective so that the passivity breaks down and iron dissolution begins. Chloride ion adsorption blocks the surface for the leakage current. In order to pass into solution by resistive coupling, the measuring a-c current would have to react with Cl^- or Cl_2 alternatively, which is not pos-

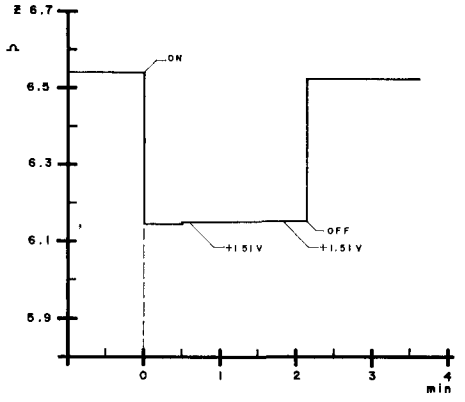

Fig. 3a. Impedance vs. time (recorder traces), 0.1M K_2SO_4, 5.8 ma/cm^2 anodic.

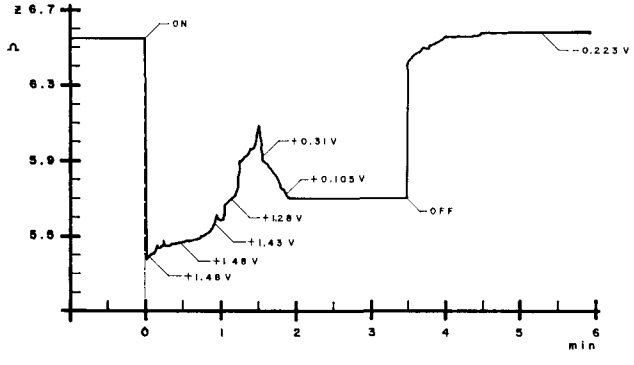

Fig. 3b. Impedance vs. time (recorder traces), 1.0M KCl, 9.3 ma/cm^2 anodic. Potential values with respect to SCE.

sible because of the high overvoltage for this step, thus leaving a capacitive coupling only.

To get further proof for this point of view the potential time pattern of the electrode during cathodic and anodic polarization in 0.5M KCl with a current density of 5 ma/cm^2 was observed on an oscilloscope. The electrode was made passive and the potential was allowed to decay under current flow. Immediately afterward short cathodic pulses (5-10 sec) were applied, and an attempt was made to passivate the electrode again between each cathodic pulse. The potential however never went beyond +1.0 v, showed a flat maximum, and dropped to about +0.2 v in a total elapsed time of 0.5 sec. Only prolonged cathodic polarization (>1.5 min) restored the ability of the electrode to become passive at once when anodically polarized. The negative potential of the electrode during cathodic polarization probably causes desorption of Cl^-. This process however requires some time. After short cathodic pulses there is still enough Cl^- left adsorbed on the surface to prevent the metal from becoming passive again. Prolonged cathodic polarization provides sufficient time for the Cl^- to be desorbed, thus enabling the electrode to achieve passivity when polarized anodically.

Frequency dependence of the leakage current.—The impedance of the electrode in air and in 1.0M Na_2SO_4 without polarizing current is practically the same at low frequencies. Up to about 100 cps the impedance in solution is independent of frequency (Fig. 4,a). The parallel resistance of the edl is high,

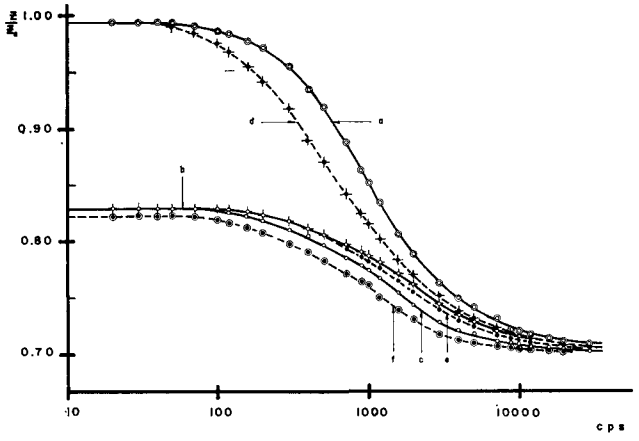

Fig. 4. Relative impedance vs. frequency: 1.0M Na_2SO_4: curve a, open polarizing circuit; curve b, 7 ma/cm^2 anodic; curve c, 7 ma/cm^2 cathodic. 1.0M Na_2SO_4 + 0.2M $(CH_3)_3N$: curve d, open polarizing circuit; curve e, 7 ma/cm^2 anodic; curve f, 7 ma/cm^2 cathodic. Electrode: Type 302 stainless steel wire, 0.038 cm diameter, surface oreo 10.8 cm^2, Z_o = 6.98 ohms.

the capacity small under these conditions. This causes the coupling to be negligible. At higher frequencies the impedance of the edl becomes smaller, permitting a larger part of the a.c. to leak into solution. Above 10 kcps this impedance becomes too small to control the leakage current. The coupling becomes "perfect" and the impedance of the system is governed by the constant impedance of the electrolyte. At about 1 mcps the skin effect (12) begins to show, causing the impedance to increase again.

The polarized electrode shows a considerably lower impedance at low frequencies, the parallel resistance of the edl being much smaller. Above 10 kcps the impedance coincides with the values obtained under open-circuit conditions, the coupling being "perfect" again.

Effect of surface active substances.—The frequency dependence of the leakage current was measured in 0.2M $(CH_3)_3N$ with 1.0M Na_2SO_4 as carrier and compared with a pure 1.0M Na_2SO_4 solution (Fig. 4). Under open polarizing circuit conditions, the greater capacity of $(CH_3)_3N$ becomes clearly visible in the intermediate frequency range, the maximum difference being about 0.3 ohms. Here the conductivity of the solutions and the reactions at the electrodes are the same in either case; the difference therefore can be due only to adsorption of the surface active substance on the electrode.

The capacity remains bigger with $(CH_3)_3N$ under polarizing conditions. The effect is larger on the cathodic side. It has been suggested that organic amines are purely cathodic inhibitors (13). One should expect therefore a stronger adsorption during cathodic polarization. Even in the low-frequency range, the impedance of the edl is lower in $(CH_3)_3N$ during cathodic polarization. It has been pointed out however that organic amines are anodic inhibitors as well (14). The curves for anodic polarization with and without $(CH_3)_3N$ coincide for low frequencies, the difference being small in the intermediate frequency range. This shows that the effect of anodic inhibition is probably smaller in this case.

Summary

It has been shown that measurements of the leakage current can be useful to test adsorption of ions and surface active substances, especially under polarizing current flow, where other methods, e.g., measurements of the edl capacity, do not give satisfactory results. The method is at its best where the leakage current in solutions with neutral surface active substances can be compared with a pure carrier solution. This can be done either by separate impedance measurements, as shown above, or by using two identical cells with the solutions to be compared as two arms in a Wheatstone Bridge and observing the error signal. The optimum frequency for the a-c measuring current is around 1000 cps. Difficulties have been met and are explained in cases, where changes in electrode reaction occurred, especially in potassium halide solutions. Nevertheless it has been possible to show that K^+ is more adsorbed than Na^+ and Cl^- more than F^- on stainless steel. An attempt has been made to explain the peculiar effect of Cl^-, which makes it impossible to maintain passivity even under anodic polarization with a current density high enough to passivate the metal initially.

Technical Notes

Magnesium-Sulfur Dry Cells

C. K. Morehouse and R. Glicksman

Semiconductor and Materials Division, Radio Corporation of America, Somerville, New Jersey

A study of the electrochemical characteristics of the various compounds and elements of the periodic system showed that sulfur has several characteristics which make it worthy of consideration for use as a cathode material in primary batteries. It has a greater ampere-minute capacity per unit of weight (100.3 amp-min/g) and volume (207.6 amp-min/cc) than the cathode materials used in conventional batteries. Although it has a lower reversible potential than the other cathodes, it does have a flat voltage-time discharge curve as measured by the half-cell technique previously described by the authors (1). By the use of this technique, the sulfur cathode has been found to operate at a potential of about —0.4 v (vs. N.H.E.) when discharged at a rate of 0.030 amp/g in a $MgBr_2$ electrolyte. The efficiency of this electrode, which was computed on the assumption that the reaction involves a two-electron change per sulfur atom, was in excess of 80%. In addition to its favorable electrochemical properties, sulfur has a low solubility in aqueous solutions and is readily available at low cost in this country.

The use of sulfur as a cathode material coupled with a zinc anode in a Leclanché-type cell was first described by Walker (2) in 1887. Other patents have been reported which deal with the addition of small amounts of sulfur to the cupric oxide cathode of the Lalande cell in order to raise the cell voltage

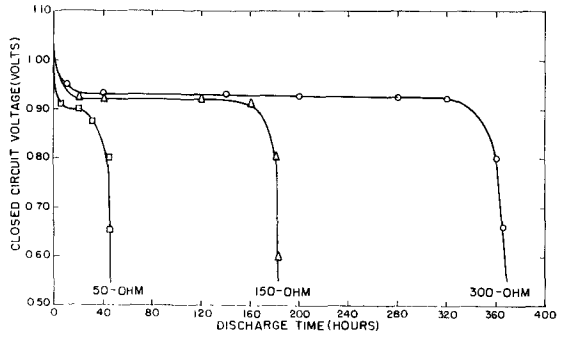

Fig. 1. AA-size $Mg/MgBr_2$/sulfur dry cells discharged continuously through 50-, 150-, and 300-ohm resistances at 21.1°±1.1°C (50% R.H.).

(3-8). These references refer to coupling sulfur with a zinc anode. Such cells have a low operating voltage and thus have practical limitations.

If a sulfur cathode is coupled with a magnesium anode, the reversible potential of the system calculated from free energy data is 2.2 v, assuming the following reaction occurs when energy is withdrawn from the cell:

$$Mg + 2\,OH^- + S = Mg(OH)_2 + S^= \qquad [1]$$

It is well known, however, that magnesium does not operate at its reversible potential in aqueous solutions. For example, in an aqueous *2N* $MgBr_2$ solution, saturated with $Mg(OH)_2$, AZ10A magnesium alloy has a potential (vs. N.H.E.) of 1.42 v under open-circuit conditions and operates at a potential of 1.29-1.32 v over a current density range of 0.5-4.0 ma/cm^2. Thus the operating potential of a magnesium-sulfur primary cell should be about 0.8-0.9 v.

Experimental

Magnesium-sulfur dry cells were assembled using an impact extruded AZ10A magnesium alloy AA-size can (height 4.62 cm, OD 1.32 cm, ID 1.12 cm). The magnesium cans were lined with a piece of salt-free kraft paper (5.72 x 5.72 x 0.005 cm thick), and an extruded slug of cathode mix was inserted in the lined can and consolidated. A carbon rod (height 4.54 cm, diameter 0.404 cm) containing a brass cap, was then inserted in the center of the cathode mix, and the cells sealed in the conventional manner with a rosin base wax. Each cell weighed approximately 10 g and contained about 5 g of cathode mix. The cathode mix, which consisted of equal parts by weight of Shawinigan acetylene black and sulfur mixed with 3% $BaCrO_4$, was wet to the proper consistency with an aqueous $MgBr_2 \cdot 6H_2O$ (500 g/l) solution containing 0.2 g/l $Na_2Cr_2O_7$.

The performance characteristics of the magnesium-sulfur AA-size dry cells of the above formulation and construction are shown in Fig. 1. These data were obtained by discharging the cells continuously through fixed resistances at 21.1° ± 1.1°C (70° ± 2°F) and 50 ±5% R.H.

The open-circuit voltage of the magnesium-sulfur dry cells ranges between 1.60 and 1.65 v; this high voltage is due to either adsorbed air in the cathode mix, or to the small amount of chromate which is added to inhibit the corrosion of the magnesium

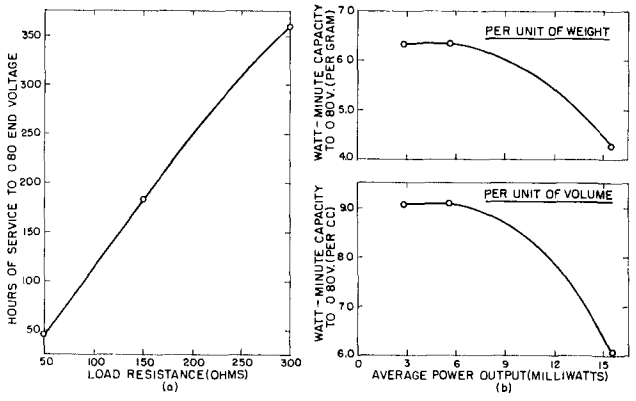

Fig. 2. Capacity data for AA-size $Mg/MgBr_2$/sulfur cells showing (a) hours of service to 0.80 v end voltage vs. load resistance; (b) watt-minutes per unit of volume and weight vs. average power output (capacity and average power computed to 0.80 end voltages from continuous discharge data).

anode. When current is withdrawn from the cells, the voltage falls to between 0.90 and 0.95 v, the operating voltage level of this system. Although these cells operate at a considerably lower voltage than the Leclanché and magnesium-manganese dioxide cells (9), they have a flat discharge curve and give considerably more hours of service to end voltages of 0.9 and 0.8 v than the two manganese dioxide dry cells.

The performance data in terms of continuous service to a 0.80 v end voltage vs. load resistance are presented in Fig. 2. Curves are also given showing the watt-minute capacity per unit of weight and volume as functions of the average continuous power output in milliwatts.

The magnesium-sulfur cell operates at about 0.90 v and offers promise for low drain applications. Its attractive features are high theoretical capacity, constancy of voltage during cell discharge, and the low cost of sulfur. It has problems similar to other magnesium cells. These are: delayed action, high impedance, and loss in capacity on light intermittent tests. The fact that hydrogen sulfide gas is liberated during cell discharge limits its broad applications.

Manuscript received Feb. 11, 1960. This paper was prepared for delivery before the Ottawa Meeting, Sept. 28-Oct. 2, 1958.

On the Anodic Oxidation of Columbium

Robert Bakish

The Alloyd Corporation, Cambridge, Massachusetts

Except for the work of Johansen, *et al.* (1), Young (2, 3), and Adams (4), the author knows of no work on the anodic oxidation of columbium. This communication discusses in brief some aspects of the anodic oxidation of this metal.

The work was done on columbium sheet supplied by Murex Ltd., Rainham, Essex, England, which analyzed as follows: Ta 0.58%, C 0.1%, Ni 0.03%, Si 0.013%, Fe 0.015%, Ti 0.081%, Al and Mg 0.01%, B, W, V traces ($\leqq$ 0.01%). The specimen were thoroughly degreased and etched in a 5:2:2 solution of H_2SO_4 (95%), HNO_3 (70%), and HF (48%) prior to formation which was carried out at constant current of 5.5 ma/cm^2 in 0.1% H_3PO_4 solution. Constant current and constant voltage power supplies capable of maintaining voltages and currents within 1% of output were utilized, and all measurements were carried out in constant temperature bath controlled to $\pm 0.5°$ of the working temperatures and with 1% instruments.

The oxide and its state of crystallinity were identified by standard x-ray diffraction powder techniques supplemented by electron diffraction in transmission. For the electron microscopy triafol replicas shadowed at 30° and 90° incidence with SiO were used.

The voltage current characteristics of columbium and their dependence on temperature as recorded with a two channel recorder are given in Fig. 1, which shows typical data for 1°, 25°, 60°, and 80°C. In these experiments formation at constant current to 300 v was followed by constant voltage once the 300-v value was reached. After the well-known exponential decay of the current to a relatively low value "leakage current plateau," depending on the formation temperature, this value is kept for some time and then rather abruptly increases. The time to current reversal is inversely dependent on temperature with the current hardly reaching a "plateau" value at higher formation temperatures but rapidly getting outside the range of the instrumentation used.

This voltage current behavior is the consequence of crystallization of the amorphous oxide film. The leakage current for samples formed to lower voltages and held under these respective voltages remains at the "plateau" value for considerably longer times, and for a 50-v formation at room temperature no reversal was observed for as long as 24 hr under voltage, which was the duration of the measurements.

The oxide itself is identified with the T-Cb_2O_5 oxide form as determined by Brauer (5).

The influence of the potential on the oxide topography is shown by the composite electron micrograph (Fig. 2) showing representative areas identi-

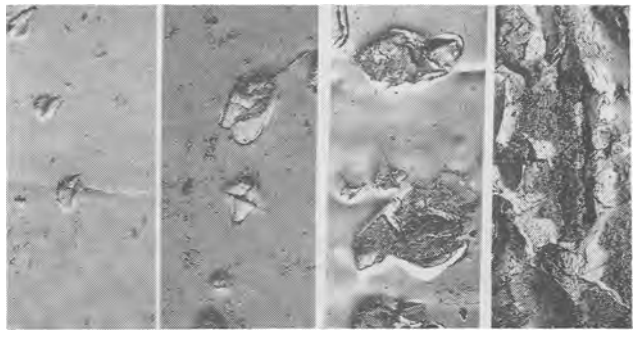

Fig. 2. Dependence of topography on formation voltage. Constant voltage formation to 100, 150, 175, 250. Magnification 5000X before reduction for publication.

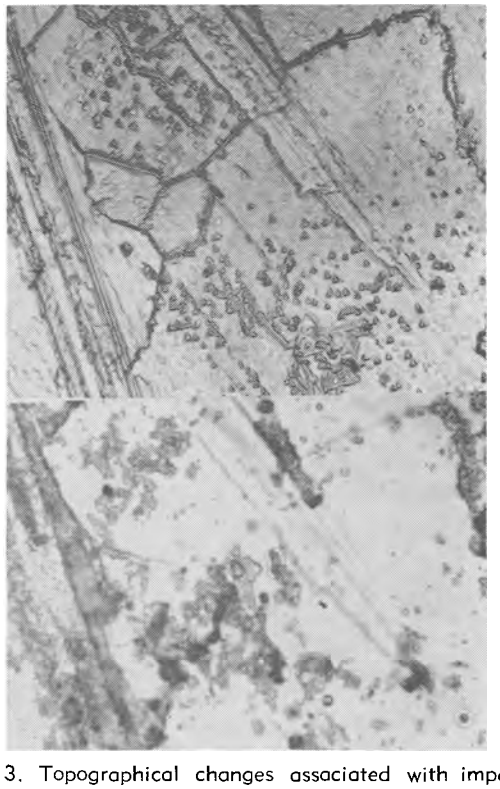

Fig. 3. Topographical changes assaciated with imperfections. Surface as etched and after formation to 320 v. Magnification 1000X before reduction for publication.

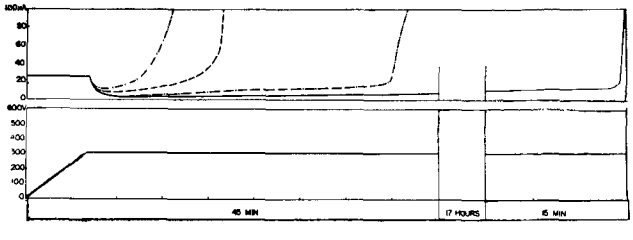

Fig. 1. Voltage-current characteristics of columbium formation. ——— 1°C 1/10% H_3PO_4; —.—. 25°C; — — — 60°C; —..—.. 80°C.

fied with the respective voltages. These observations were made after constant current formations to the voltages indicated. Above 250 v no replicating and, in turn, no electron microscopy are possible due to the disintegration of the oxide. The topographic changes of columbium on crystallization are both different and similar to these changes in tantalum. They are different in that none of the crystalline polygonal areas seen in tantalum (6) are observed here, and similar because here, as well as in tantalum, the crystalline oxide nucleates underneath and grows at the expense of the amorphous oxide, displacing it in the process.

An attempt to evaluate the possible role of cold work and imperfections was also made in this study, with Fig. 3 showing a representative specimen area containing a fine scratch before and after formation to 320 v. Observe the bulk of the crystallization taking place in the area delineated by the scratch and also in the vicinity of the dislocation etch pits (7), indicating, even though not conclusively, the possible catalytic role of imperfections in this crystallization process. It has already been shown that in tantalum crystallization takes place at preferred sites (8).

Results reported here show both similarities and differences between columbium and tantalum. The formation characteristics and the crystallization phenomena are common to both metals, but the greater ease of crystallization of columbium of this purity, as well as some details of the topographic changes brought about with the process, appear different. On the basis of this data, it cannot be asserted whether the observed differences are due to inherent differences between the two metals or to impurities in the columbium acting as crystallization nuclei.

Acknowledgments

The author wishes to thank Dr. M. Brönniman for the electron micrographs, and Dr. H. Müller for identifying the oxides. Mr. E. Muntner's and Mr. R. Cavaleri's assistance in the experimental work is acknowledged. The author is indebted to CIBA for permission to publish this work.

Manuscript received Nov. 2, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

The Reaction of Zirconium-Oxygen Alloys with Hydrofluoric Acid

M. E. Straumanis and T. Ejima

Department of Metallurgy, the University of Missouri School of Mines and Metallurgy, Rolla, Missouri

Metallic zirconium dissolves readily in hydrofluoric acid according to the equation (1, 2)

$$Zr + 4HF = ZrF_4 + 2H_2 \qquad [1]$$

However, the influence of oxygen in the metal on the amount of hydrogen developed is not yet known. There should be a difference in the behavior of such alloys as compared with similar ones of titanium: whereas the oxides of the latter up to Ti_2O_3, inclusively, dissolve in HF (2), no other oxides are known in the Zr-O system (3) except ZrO_2 which practically does not dissolve in the acid, as found by testing. Thus, the α homogeneous solid solutions up to 29 at. % oxygen and those of the two-phase region up to ZrO_2 (with 66.67 at. % oxygen) should differ in their reaction with HF. It is expected that the homogeneous solid solutions similar to Ti-O alloys (4), will react with the acid as follows

$$ZrO_x + 4HF = ZrF_4 + xH_2O + (2-x)H_2 \qquad [2]$$

By calculating the volume of H_2, Eq. [2], and comparing it with the experimental one the validity of [2] was checked.

ZrO_x Alloys and Experimental Procedure

Dried Zr powder[1] was used as a starting material. According to the manufacturer the composition of the powder was as follows: Zr-96.6, including about 2% of Hf, Al-0.1, Ca-0.1, Fe-0.5, and Mg-0.13 wt %, or altogether for the metallic part, 97.4%, the remainder being oxygen. However, the present investigation shows that the oxygen is dissolved in the metal not as such but is combined with ZrO_2, which forms a solid solution with the metallic Zr. This is in accordance with the results obtained by de Boer and Fast (5). Therefore, only 87.27% Zr is in the metallic state, and the total of metals present is thus 90.1%, the balance (9.9%) being ZrO_2. The amount of free metals found by this calculation was checked by analyzing the Zr powder by the combustion method (6). Weighed amounts of the dry powder were heated in air up to 1000°C so that complete oxidation occurred (it lasted up to 8 hr). From the composition of the sample given above it was calculated that each gram of the metallic part, which alone is capable of burning to ZrO_2, HfO_2, etc.,

† x—from combustion analyses.

absorbs during the combustion 0.3484 g of oxygen. Hence from the increase in weight and the original weight of the samples the amount of free metal and of ZrO_2 could be calculated. Results are shown in Table I: the Zr powder (sample II) contained 9.31% ZrO_2 or 2.42% oxygen (see Table II) instead of 2.57%, as it follows from the analysis of the manufacturer. This was regarded as a good agreement and, therefore, the Zr powder was used for the preparation of the ZrO_x alloys.

These were prepared by mixing weighed amounts of the dry Zr powder and ZrO_2, and by compressing them in a die under 1500 psi to make a briquette. The latter was heated at 1400°C for 4 hr under a vacuum (2 μ), then quenched in air of room temperature. The color of the samples was silvery gray. They were crushed, pulverized, and parts of the powder were analyzed by burning them in a porcelain crucible to the oxides. From the increase of the sample weight the amount of the metallic part (containing 96.86% Zr) was calculated; the remainder was then the weight of ZrO_2 in the sample before combustion. The volume of hydrogen (STP) which 1 g of samples should develop in HF was computed (487.1 cm^3 for the metallic part of them instead of 491.43 ml H_2, Eq. [1] for 100% Zr) and compared with the volume actually obtained in the dissolution experiments. Or, knowing from the combustion analysis the amount of oxygen present in the sample, the volume of hydrogen was also calculated from Eq. [2]. Both methods lead to the same result.

The volume of hydrogen developed by the samples was determined as described previously (4). However, the procedure is simpler than for Ti, because according to Eq. [1] no lower valency Zr salts are formed and hence no oxidation can occur. Therefore, the air of the apparatus does not have to be replaced by an inert gas or hydrogen. Besides, no side reactions occur and the final volume of hydrogen developed by the sample can be read easily from the gas burette.

Results

Qualitative experiments showed that the homogeneous Zr samples containing up to 29 at. % oxygen dissolve completely in dilute HF (0.3-*1N*). Sometimes a grayish residue is obtained, but it dissolves slowly and completely in water without gas evolution. It is probably $ZrOF_2$, formed because of hydrolysis ($ZrF_4 + H_2O \rightleftharpoons ZrOF_2 + 2HF$) which is a secondary reaction not affecting Eq. [2]. Samples of the two-phase region always leave a white residue identified as ZrO_2 by x-ray diffraction. However, ZrO_2 always remains behind if the homogeneous ZrO_x samples are heated at about 600°C in a hydrogen atmosphere: they absorb hydrogen which is then released upon dissolution in HF, but a residue of ZrO_2 is obtained. Evidently the dissolving hydrogen forces the ZrO_2 to aggregate to larger particles insoluble in HF.

For checking the validity of reaction [2] only samples from the homogeneous region containing up to 22% ZrO_2 (or 27 at. % oxygen) were used. As samples with a still higher oxygen content were difficult to prepare and to handle, no quantitative studies were made with them. From each sample of the homogeneous region, 3-4 combustion and 2-3 hydrogen evolution analyses were made. How good the separate analyses of one sample are and how the averages obtained by the two methods of analysis agree is shown in Table I on the example of Zr powder, used as starting material.

In the case of sample II the difference between the two methods is about 1.2%. However, the analyses by hydrogen evolution can be reproduced much better than those by the combustion method. The reason may be that ZrO_2 may absorb oxygen similarly as it happens with commercial TiO_2 (7) thus increasing the calculated free Zr amount in the samples; the difference of 1.2% may result in this way. This is evident further when one examines the analyses of 6 more samples of ZrO_x as shown in Table II.

Table II shows that the volumes of hydrogen observed and those calculated from the combustion method agree within 2%, whereby the hydrogen evolution method usually gives smaller volumes. If the x-values of the last column are used to make the calculations according to Eq. [2], an agreement within 0.9% with the volumes observed is obtained. In conclusion, although the results of the combustion and the hydrogen evolution method differ in a systematic fashion, the difference can be attributed to the further absorption of oxygen during the long heating period in the former. Therefore the validity of Eq. [2] is clearly established.

The homogeneous ZrO_x alloys behave as if they would consist of a solid solution of ZrO_2 in metallic Zr. This agrees with the statement of de Boer and

and Fast (5) that oxygen in ZrO_x is in form of O^{2-}. As in case of TiO_x (8) the volumes of H_2 developed by ZrO_x in HF can be used for a rapid determination of oxygen and free metal in those alloys.

Acknowledgment

This investigation was supported by the U. S. Atomic Energy Commission (AT (11-1)-73, Project 5). The authors are grateful to Dr. W. J. James, Professor at the Chemical Engineering Department of the School of Mines, for his interest in this work.

Manuscript received Dec. 28, 1959.

Gelatin Effects on Polarographic Half-Wave Potentials

A. J. Diefenderfer and L. B. Rogers

Department of Chemistry and Laboratory for Nuclear Science, Massachusetts Institute of Technology, Cambridge, Massachusetts

It is well recognized that the presence of relatively large concentrations of gelatin may lead to cathodic shifts of the half-wave potentials for irreversible reactions. A recent publication from our laboratory (1) reported that the irreversible second reduction of p-dinitrobenzene in weakly acidic solutions was shifted toward *less* cathodic potentials by the addition of small amounts of gelatin. This behavior has since been examined in greater detail because of its theoretical implications with respect to the role of gelatin in the electrical double layer.

Our most recent studies have confirmed the anodic shift using two other samples of gelatin. However, the effect has been shown to be due to an unexpected decrease in *p*H caused by impurities in the gelatin.[1] It was found that solutions of 0.50% gelatin prepared from warm (60°C) distilled water, which has just been boiled, reached *p*H values of 4.20 and 4.10 within an hour when stored at 25°C and 2°C, respectively, Several hours later, the *p*H values were 4.07 and 4.00. When approximately a 1-ml portion of such a solution was added to 50 ml of the weakly buffered alcoholic supporting electrolyte, an anodic shift was indeed found. However, when the original *p*H of the supporting electrolyte was restored by adding potassium hydroxide (which had been dissolved in an alcoholic solvent of the same composition), the half-wave potential returned to the value observed before the addition of gelatin. Thus, the reported anodic shift was not a property of the gelatin *per se*.

The nature of the impurities in our commercial gelatin, which produced the abnormally low *p*H value, are unknown and are of no further interest to us.

[1] According to G. Scatchard and O. L. Keller (private communication) pure gelatin would be stable under both the preparative and polarographic conditions employed in our study.

December 1960 Discussion Section

A Discussion Section, covering papers published in the January-June 1960 JOURNALS, is scheduled for publication in the December 1960 issue. Any discussion which did not reach the Editor in time for the June 1960 Discussion Section will be included in the December 1960 issue.

Those who plan to contribute remarks for this Discussion Section should submit their comments or questions in triplicate to the Managing Editor of the JOURNAL, 1860 Broadway, New York 23, N. Y., *not later than September 1, 1960*. All discussion will be forwarded to the author(s) for reply before being printed in the JOURNAL.

Brief Communications

Microscopic Observations on Electroluminescent ZnS:Cu Phosphors

Willi Lehmann

Research Department, Westinghouse Electric Corporation, Bloomfield, New Jersey

It is known that the emission of electroluminescence in ZnS:Cu phosphors is concentrated in randomly distributed small spots (1-4). It has also been assumed that electroluminescent ZnS:Cu phosphors contain copper sulfide (probably Cu_2S) as a separate phase segregated in cavities, etc., inside the phosphor particles (Cu_2S on the surface of the particles can be removed by suitable washing procedures) and that these segregations create localized regions of enhanced electric field strength near their edges (5,6). These segregations have now been observed microscopically. The experimental arrangement is shown in Fig. 1. The phosphor particles were stuck on a thin plastic layer between two aluminum electrodes evaporated onto a microscope slide. The space between the particles was filled with a highly refracting liquid [solution of phosphorus and sulfur in methylene iodide (7), $n = 2.06$] in order to obtain a clearer view into the ZnS particles. Even so, some refraction still remained and caused each particle to appear opaque near its edge if illuminated by white light from the rear. The limit of resolution of details inside the particles is estimated to be about 1 μ or somewhat lower.

Because of the smallness of the objects and their three-dimensional extension, the investigation was limited to visual observations. Dark segregations inside of many phosphor particles could be observed. They are frequently, but by far not always, thin and elongated, almost needle-like. They seem to be larger, on the average, in large particles, and *vice versa*. The emission spots of electroluminescence are visibly located directly at the ends of the segregations in many, but not in all cases. Some typical examples are shown in Fig. 2. Some emission spots cannot visibly be correlated to dark segregations; perhaps they are actually present but too small to be observed or are hidden by surface irregularities. In other cases, segregations are present without accompanying emission. It may be that these segregations do not have sufficiently sharp edges (submicroscopically) to create localized regions of high field strength. In agreement with old observations (1, 2), the light emission per spot occurs only once per cycle of the exciting voltage. The question whether the emission occurs when the end of the segregation is cathode or anode could not be decided.

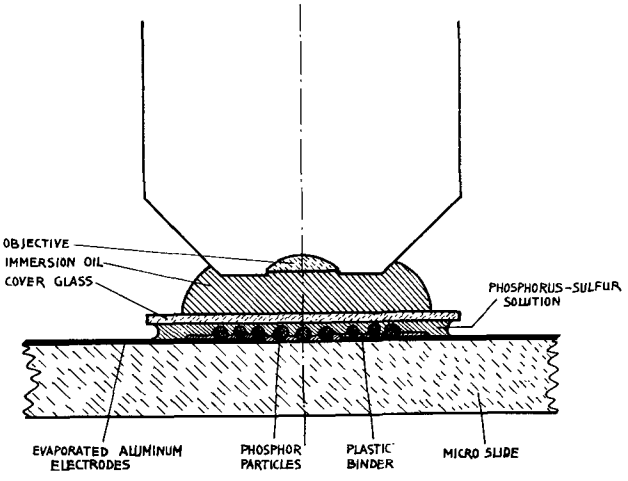

Fig. 1. Arrangement used in microscopic investigations

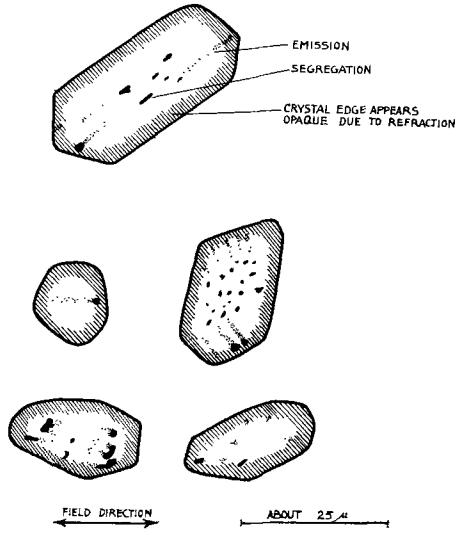

Fig. 2. Phosphor particles containing dark segregations and emitting spots.

The linear dimensions of the segregations approach 5 or 10% of the particle diameter in ordinary phosphor powders. Also the dimensions of the emitting spots range in this order which means that the emission intensity within an average spot is roughly 1000 times higher than the average over the whole phosphor. The brightness of a single spot does not steadily decrease with time (as the integrated emission of an entire electroluminescent cell does) but may undergo all sorts of irregular fluctuations including sudden disappearance after some time of operation or irregular oscillations with time. Even

a movement of two neighboring spots toward each other and complete union within about one or two minutes could be observed. These observations were made on phosphor particles excited by 20 kcps; the particles did not move under the influence of the electric field.

Purification of Tantalum Anodes during Sintering

C. J. B. Fincham and G. L. Martin[1]

Metals Division, National Research Corporation, Cambridge, Massachusetts

It is generally believed that the d-c leakage of a sintered-anode tantalum electrolytic capacitor is affected markedly by the chemical purity of the tantalum metal from which it is made. To substantiate this belief it would be necessary to correlate the d-c leakage of the capacitor with the impurity content of the sintered anode rather than with that of the original tantalum powder, since impurity levels change during sintering to an extent dependent on sintering conditions.

Houtz and Karlik (1) have studied the changes in impurity levels of carbon, oxygen, nitrogen, and general metallic contaminants during the sintering of tantalum anodes and correlated their results with the d-c leakage and life of the finished solid-electrolyte capacitors. However, other than their data on carbon, oxygen, and nitrogen, there is no published information on the quantitative changes in the levels of specific impurities during sintering.

The work reported here is a preliminary study of these quantitative changes during various sintering treatments and of the d-c leakages of the resulting anodes.

Sintered anodes were made from five different tantalum powders (three high-capacitance and two low-capacitance) by pressing pellets of known densities and heating the pellets under vacuum at several different conditions of time and temperature, as shown in Table I. The pelleting and sintering techniques used have been described in detail previously (2). The anodes were all cylindrical, 1.8 g in weight, and had an 'as-pressed' diameter of 0.25 in. Each sinter run was made with anodes of only one powder.

The powders and representative anodes from five batches were analyzed quantitatively for the following elements: O, C, N, Na, Al, Cr, Cu, Fe, Mo, Nb, Ni, Si, and Ti, with the results shown in Table I. The remaining anodes were not analyzed for O, C, N, or Na. Oxygen was determined by vacuum fusion,

carbon by combustion, nitrogen by micro-Kjeldahl, and sodium by flame-photometry. The remaining elements were determined spectrographically using the carrier technique, calibrated by synthetic standards, and, in the cases of Fe, Ni, and Cr, cross-checked by wet-chemical methods. During the spectrographic analyses of the anodes, the additional elements Co, Mg, Mn, Pb, and Sn were looked for but not detected (except Mg in one anode). The estimated limits of detection are given in Table I.

Anodes from the same batches as those analyzed were tested electrically for d-c leakage and capacitance by the following wet-cell method described in detail previously (2).

The anodes were formed at constant current (35 ma/g), in 0.01% phosphoric acid solution at 92°C, to 200 v, held at voltage for 2 hr, washed and dried. DC leakage was measured at 140 v after 2 min at voltage in 10% phosphoric acid solution at room temperature. Capacitance was measured in the same solution at 120 cycles/sec.

The measured ratios of d-c leakage (L) at 140 v (in microamps), to capacitance (C) (in microfarads), for a 200-v formation are given in Table I. In addition, for those batches of anodes for which complete analyses were obtained, measurements of leakage at 70 v for a 100-v formation and leakage at 35 v for a 50-v formation were made. These results are discussed below.

The analytical and electrical results for each set of powder and anodes are listed in Table I in increasing order of severity of sintering conditions. It can be seen that different impurities behaved differently during sintering. Iron and nickel decreased slowly with increasingly severe sintering conditions. Niobium was unchanged from the level in the powder under any sintering conditions tried, and chromium decreased to below the limit of detection under all sintering conditions tried. Silicon decreased on sintering in every case, but the results were erratic and the final levels did not correlate with severity of sintering conditions. Oxygen, carbon, and sodium decreased on sintering, although the extent of the decrease of oxygen was variable. In the powders where the initial nitrogen content was low, a slight increase in nitrogen level during sintering was observed (presumably due to "pick up" from outgassing or small leaks in the vacuum furnace). However, in the one high nitrogen powder (L-533), there was a marked decrease in nitrogen during sintering. Sodium, aluminum, copper, and titanium, when present in detectable amounts in the powder, all decreased during sintering.

Similar qualitative trends were found by Torti (3) in a study of the purification of tantalum during vacuum arc-melting, which takes place at much higher temperatures (> 3000°C). The main difference was in the relatively large loss of niobium observed during arc melting, compared with essentially no loss during sintering.

The correlation of purity of anode with d-c leakage is not so easily seen. However, one generalization perhaps can be made from these data, namely, that with the exceptions of niobium and oxygen none of the anodes with low leakage had any specific impurity at a high level relative to the group of data, whereas the high leakage anodes each had one or more impurities at a relatively high level. The anodes made from ET-76 appear to be an exception to this generalization, but the reason for this may be in the high copper level in the original powder which was introduced by accidental contamination in the course of handling. The copper was therefore essentially a surface contaminant, so that bulk analyses have little meaning with regard to the effective concentration of copper at the surface of the powder and anodes. High leakage due to copper contamination has occasionally been observed in other powders.

It is tempting to speculate that the high leakage of anode 1 of L-533 is due either to a high iron content (which was reduced by the more severe sintering conditions used for the low leakage anode 2) or to a high nitrogen level, presumably somewhere between 750 ppm in the powder and 285 ppm in anode 2.

To speculate further, the high leakages of both anodes made from L-450 might be attributed to high carbon contents, 58 ppm in anode 2, and presumably higher in anode 1. This would agree with the conclusions of Houtz and Karlik (1) that to obtain a satisfactory anode the carbon content must be less than 20 ppm.

However, attempts to place an exact limit on an acceptable impurity level must be tempered by the realization that the concentration of impurities at the surface can be either lower or higher than the impurity levels measured on the bulk of the metal.

Surface contamination of the powder (as in ET-76) or of the sintered anode (e.g., during the processing of the anode to make the finished capacitor) can give higher impurity levels on the surface than in the bulk.

Alternatively, the surface can be purer than the bulk if, during sintering, the rate of removal of impurities is limited by diffusion in the metal rather than by vaporization from the surface.

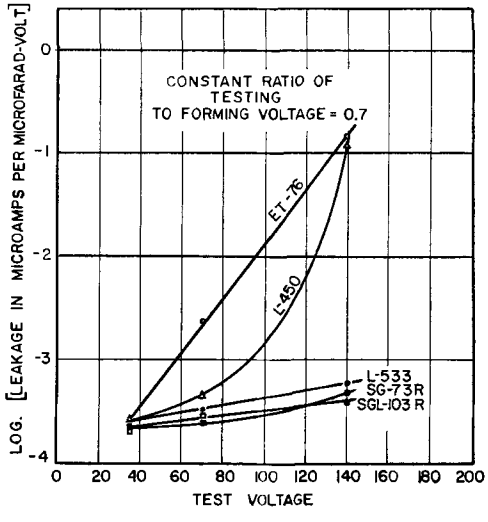

Fig. 1. Variation of d-c leakage per microfarad-volt with test voltage, for a constant ratio of testing to forming voltage and constant sintering conditions.

In discussing the effects of impurities on leakage, results shown in Fig. 1 are of great interest, where the logarithm of the d-c leakage (in microamperes per microfarad-volt) is plotted against test voltage, for a constant ratio of testing to forming voltage. As mentioned above, these measurements were made on anodes from the same batches as anode 4 of SG-73R and anodes 2 of each of the other powders. The results were plotted as leakage per microfarad-volt, since this gives a measure of leakage per unit surface area, irrespective of forming voltage. The points shown at a test voltage of 140 v are those shown as leakage per microfarad (for a 200-v formation) in Table I.

It can be seen from Fig. 1 that the rate of change of leakage with test voltage varies markedly between the different sets of anodes and that whereas at 140 v there is a difference of almost a factor of 400 between the highest and lowest leakage anodes, at 35 v the difference is about 30% and is approaching the limits of experimental error Therefore, it would appear that in any study of leakage vs. purity the maximum sensitivity of results can be obtained by working at the highest voltages.

Acknowledgment

Grateful acknowledgment is made to Dr. F. C. Benner and his analytical group who developed many of the analytical methods used and performed the analyses.

Investigations on the Reaction Mechanism of the Nickel-Cadmium Cell

S. Uno Falk

Svenska Ackumulator AB Jungner, Stockholm, Sweden

ABSTRACT

X-ray diffraction patterns from electrodes submerged in electrolyte have been obtained during charge and discharge by means of a special test cell, and the composition of the active materials has been determined. The question whether CdO or $Cd(OH)_2$ is formed during discharge has been subject to special attention. The low potential reaction of the positive plate has been studied. The emf and the dE/dT have been determined between —40° and +50°C at various states of charge.

The nickel-cadmium cell, the principle of which was patented by Jungner (1) in 1899, has provoked the interest of several investigators ever since, and many theories have been put forward concerning the reactions and thermodynamics of this system. However, opinions still differ in many essentials and this has caused us to publish the results of some investigations carried out to establish the reaction formulas of the nickel-cadmium cell and to elucidate the reaction mechanism.

The Reactants

It is generally agreed that the nickel-cadmium cell works according to the oxygen-lift system, i.e., oxygen (or hydroxyl ion) is transferred from one electrode to the other. This transfer is carried out by the electrolyte.

Opinions have differed appreciably as far as the composition of the compounds constituting the active substances is concerned. Thus, the following formulas have been suggested for the charged material of the positive electrode: $Ni(OH)_4$ (2), NiO_2 (3), $NiO_2 \cdot H_2O$ (4), $NiO_2 \cdot xH_2O$ (5), $Ni(OH)_3$ (6), $2Ni(OH)_3 \cdot 5H_2O$ (7), Ni_2O_3 (8), $Ni_2O_3 \cdot 1.2\ H_2O$ (9), $Ni_2O_3 \cdot 6H_2O$ (10), and β-NiOOH (5) and mixtures or solid solutions of these compounds.

Some of these substances have been referred to in investigations carried out on positive plates of nickel-iron cells, which, however, is of no importance, since the same positive active material is present in these cells.

For the discharged state the following formulas have been suggested: Ni (11), NiO (3), $NiO \cdot 4H_2O$ (4), $2NiO \cdot 9H_2O$ (10), $Ni(OH)_2$ (9), $Ni(OH)_2 \cdot 2H_2O$ (6), $2Ni(OH)_2 \cdot 6H_2O$ (7), Ni_3O_4 (12), and Ni_2O_3 (13).

Cd and CdH_2 (4) have been mentioned as constituents in the charged negative electrode, while CdO (14), Cd_2O (15), $CdO \cdot xH_2O$ (10), and $Cd(OH)_2$ (16) have been suggested for the discharged state.

The first part of these investigations was directed to establishment of the components present in the electrodes at various states of charge. For this purpose x-ray diffraction methods were used primarily.

Several other workers (17-24) used such methods to study different nickel and cadmium compounds. In the cases, however, where electrodes have been investigated, the x-ray exposures have been made on washed and dried samples which obviously may introduce sources of error. Removing the electrolyte may cause hydration changes and, moreover, oxygen may affect the active materials. Therefore, x-ray investigation of an active material in a nickel-cadmium cell should be carried out on a sample completely submerged in the electrolyte and subjected to charge or discharge. Only in that case the spectra obtained may be claimed to represent the true active substances. Application of a charge or a discharge eliminates the risk of decomposition of unstable substances that possibly could be formed when a current is passing, and accordingly otherwise escape detection. These points of view have, as far as we know, been duly taken into account only by Salkind and Bruins (25), who, in an extensive and meritorious investigation of the nickel-cadmium cell have, x-rayed parts of wet electrodes stored in sealed plastic bags and also worked with a Lucite cell, permitting charge and discharge of the electrodes during exposure. Thus, in the first case washing and drying have been avoided and, in the latter, a current is passing. Apparently, the position of the plates in the Lucite cell has permitted free access of the air.

A specially constructed cell was used. It contained one sintered electrode of the kind to be investigated, and one sintered electrode of opposite polarity. Sintered electrodes are used in these investigations, first, because steel ribbons do not screen the active materials and second, because the active materials are not mixed with other substances. Figure 1 shows the set-up. When the desired state of charge has been attained by charge or discharge, the test electrode is pulled sidewise from the counter electrode and is pressed against one of the walls of the plastic bag, making the electrolyte film as thin as possible. The plate is now inserted in the sample holder of the x-ray spectrometer, the part of the bag containing the counter electrode being placed at the side of

Fig. 1. the holder. The current is not interrupted during these manipulations, nor during the subsequent x-ray exposure. However, the current is sufficiently decreased during the exposure to permit recording the entire diffraction pattern without any appreciable change of the state of charge of the electrode. In this manner, positive as well as negative electrodes have been investigated at various states of charge. For the exposure Ni-filtered Cu K_α-radiation was used. The reflections were registered by means of a Geiger counter and a potentiometer recorder.

The Positive Active Material

Figure 2 shows x-ray patterns of fully charged, 1/3 discharged, 2/3 discharged, and fully discharged positive electrodes. The polyethylene peaks have been omitted from this figure.

The discharged positive material has proved to be $Ni(OH)_2$ of small grain size. This is indicated by the

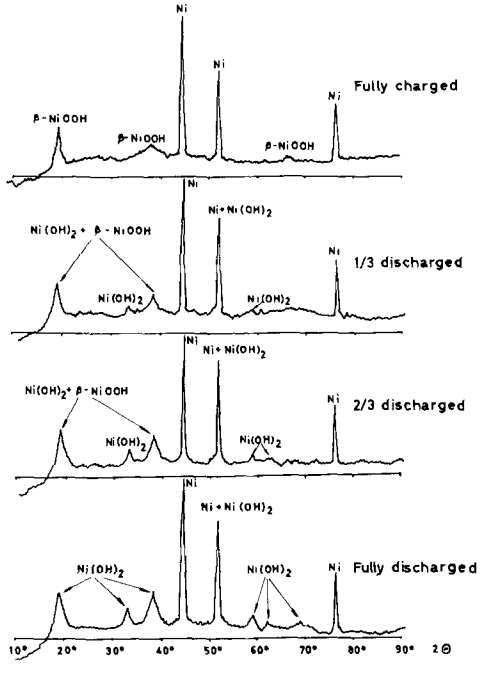

Fig. 2. X-ray diffraction patterns from positive electrode

conspicuous broadening of the $Ni(OH)_2$ lines as compared to, for instance, the Ni reflections. Broadening of the reflections may be due to several other causes, such as irregular lattice, mechanical crystal deformation or lacking chemical equilibrium. However, we have found by means of Hahn's emanation method (26, 27) that the broadening in this case is caused by very small crystals. The approximate crystal size may be calculated from this broadening. During charge this $Ni(OH)_2$ is successively transferred into a still more finely divided compound having a spectrum agreeing well with that of β-NiOOH. No traces of higher nickel oxides have been discovered even at strong overcharge. At discharge β-NiOOH is again transferred into $Ni(OH)_2$. These transformations do not imply a decrease of $Ni(OH)_2$ and an appearance of β-NiOOH reflections but instead some $Ni(OH)_2$ peaks decrease while others gradually are displaced toward β-NiOOH. This indicates the presence of a solid solution of β-NiOOH and $Ni(OH)_2$, further supported by the fact that the emf curve varies with the state of charge. This observation will be discussed later.

In our x-ray investigations of the charged positive material β-NiOOH was the highest nickel compound encountered, this being the case also after heavy overcharge. Naturally, this does not necessarily mean that higher compounds like NiO_2 are not present, as these may be amorphous to x-rays. At any rate, a freshly charged positive plate contains more active oxygen than corresponds to the formula founded on trivalent nickel. This was found by Foerster (9), who stated that the charged material consisted of a solid solution of NiO_2 and $Ni_2O_3 \cdot 1.2H_2O$. The opinion has been shared by several others, but Pitman and Work (28) recently considered it to be more likely that the excess of active oxygen is adsorbed by β-NiOOH. This theory is based on an investigation of the concentration of active oxygen in the electrode as related to the open-circuit potential after charge. If Foerster's theory were correct, the potential would vary linearly with the logarithm of the active oxygen concentration. However, Pitman and Work have observed that the potential decreases directly as a straight line with the oxygen concentration, indicating an oxygen adsorption, thus, as far as we can understand, disproving Foerster's theory. The freshly charged state should, according to Pitman and Work, be represented by the formulas $Ni_2O_3(O)_{ads}$ or $(\beta\text{-NiOOH})_2(O)_{ads}$. As we have found that β-NiOOH is present in the charged active material, the latter formula is considered correct.

The capacity available from the adsorbed oxygen is comparatively small: a freshly charged positive plate will yield 10-15% more capacity than a plate having rested some 24 hr after charge.

The secondary discharge reaction frequently appearing at a voltage of about 0.7 v was an object of interest as early as 1905-1910, when Foerster and Zedner performed some experiments. It has been established that the potential step in question originates from the positive electrode. The causes of the reaction have been widely discussed, but the source accepted nowadays seems to be the oxygen adsorbed

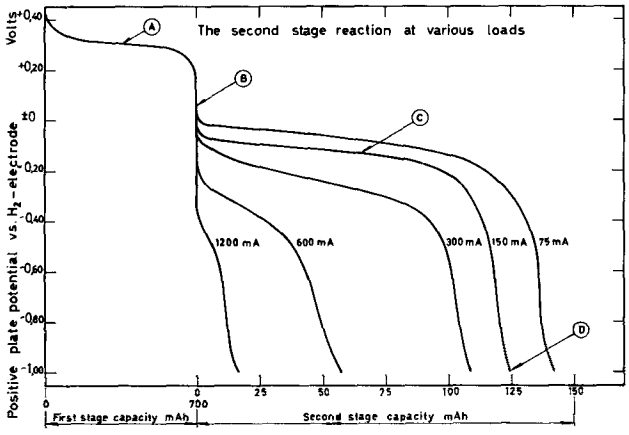

Fig. 3. Second stage reaction at various loads

by the graphite present in positive pocket electrodes, the step not appearing in plates without graphite. This explanation is not correct, as we have been able to find the potential step also in sintered positive electrodes, completely lacking graphite. The duration of the stage can be increased by repeated reversals. The reaction occurring at an anode voltage of about —0.15 v as measured against the hydrogen electrode may correspond to 20% of the total capacity. The step is dependent on the load; its shape at different loads is shown in Fig. 3.

X-ray diffraction patterns have been recorded of sintered positive electrodes, discharged in the polyethylene cell previously described to the points (A), (B), (C), and (D) according to Fig. 3. It was intended to obtain, if possible, the structure of the compounds causing the second stage reaction. However, no new compounds appeared in these patterns, nor were any significant changes of position or intensities of the $Ni(OH)_2$ reflections observed.

The opinion of Glemser and Einerhand (5) that $Ni_3O_2(OH)_4$ is the active compound in this case is not supported by any x-ray investigations carried out by these research workers. The presence of $Ni_3O_2(OH)_4$ should certainly be established by x-rays, but we have found neither this compound nor any other. We believe, therefore, that the step is caused by oxygen adsorbed by the nickel hydroxide. In order to obtain further proof of this theory the relationship between the secondary discharge stage and the ambient air pressure was studied. These investigations, carried out on sintered electrodes, corroborated the statement by Zedner (6) that evacuation will decrease the capacity of this stage. Oxygen is generally liberated with substantially less difficulty in the adsorbed state than when attached chemically to nickel, particularly as the possible nickel compound cannot be very highly oxidized. This circumstance in connection with the negative results of the x-ray diffraction tests substantiates our opinion that the secondary discharge reaction is caused by oxygen adsorbed by $Ni(OH)_2$.

Negative Active Material

Figure 4 shows x-ray diffraction patterns of negative electrodes in fully charged, 1/3 discharged, 2/3 discharged, and completely discharged states.

The discharged material consists mainly of $Cd(OH)_2$. However, a small amount of Cd is always

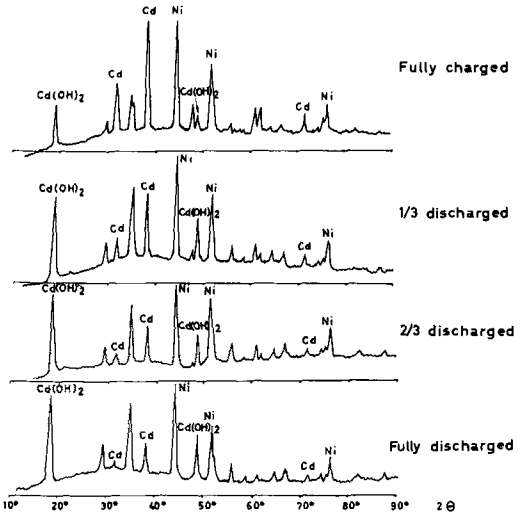

Fig. 4. X-ray diffraction patterns from negative electrode

present. During charge $Cd(OH)_2$ is successively transformed into Cd metal. In this case no solid solution is formed: Cd and $Cd(OH)_2$ spectra may appear simultaneously. This agrees also with the open-circuit voltage measurements carried out at different states of charge. The transformation of $Cd(OH)_2$ into Cd is not complete even after strong overcharge, as indicated by the x-ray pattern at this stage.

According to Troilius (4) a fully charged electrode probably contains a certain amount of CdH_2, which decomposes relatively rapidly after the end of the charge into Cd and H_2. If a discharge is carried out immediately after charge a potential drop appears that might be attributed to CdH_2. However, our x-ray investigations have not revealed any compound corresponding to CdH_2. Comparative tests on negative electrodes and unimpregnated nickel sinter have shown also that the pure nickel sinter after cathodic polarization exhibits a potential "tail" similar to the one noticed on negative electrodes. The value of the potential makes it likely that a pure oxidation of hydrogen adsorbed by the nickel sinter is the cause of this tail. These investigations show that hydrogen may be adsorbed by porous metals, thus giving some extra capacity on discharge. This observation makes it very probable also that the reaction at the negative plate is caused by adsorbed hydrogen. This theory is further corroborated by the fact that evacuation of a negative electrode after a complete charge is accompanied by a substantially less pronounced potential tail when discharged. The capacity excess caused by the adsorbed hydrogen is, however, very slight and in general quite negligible.

The investigations presented here show clearly that $Cd(OH)_2$ is the end product of discharge. However, several writers claim that CdO is formed, this opinion being recently conveyed by Lake and Casey (20) and Winkler (29) among others. According to Lake and Casey, CdO is formed as primary product on anodic oxidation, this oxide subsequently being transformed into $Cd(OH)_2$ in the presence of the alkaline electrolyte. These writers have themselves not been able to establish the presence of CdO, but make this assumption because a dark-colored compound is formed.

Experiments were carried out on charged negative plates, subsequently discharged with various, in some cases very high, currents in the previously described x-ray test cell. The cell has been adjusted on the strongest CdO line, and careful measurements have been made with maximum sensitivity to ascertain the recording of any intensity increase during discharge. All these tests have yielded negative results: in no case has CdO been traced.

Furthermore, plates have been used, the active material of which has been transferred into CdO by heating. After insertion in the sample holder of the x-ray apparatus KOH (sp gr 1.25) was added. The x-ray lines of $Cd(OH)_2$ increase instantaneously from zero to high values, while the CdO reflections weaken. These changes occur within a few seconds. As soon as the plate is touched by the electrolyte, the yellowish brown color changes into grayish white. Thus, it is obvious, that *if* CdO is the primary product of the discharge, which we by no means have been able to prove, this oxide is immediately transformed by the OH^--ions into $Cd(OH)_2$. Potential measurements indicate, however, as will be discussed later, that Cd is transferred directly into $Cd(OH)_2$.

Winkler's claim that CdO is the end product on discharge is supported by weighing negative plates of different states of charge immersed in the electrolyte, which apparently is a simple and reliable method incidentally used as early as 1904 by Schoop (30). The weight increase on discharge indicates, according to Winkler, the formation of CdO. He found an increase of 0.334 g/amp-hr, adjusted to the dry state, against the theoretical value 0.298 g/amp-hr for CdO. Winkler's paper does not indicate the electrolyte concentration used. If his cells were filled with KOH, sp gr 1.20, calculation shows that the weight increase obtained by Winkler and claimed to agree with formation of CdO, indicates $Cd(OH)_2$ just as well. This coincidence is simply due to the different densities of the two materials. In order to elucidate these matters Winkler's measurements have been supplemented by weighings in KOH of sp gr 1.05 and 1.42, these solutions giving larger differences between the theoretical weight increments. If KOH, sp gr 1.05, is used, the weight increase of the immersed electrode should be 0.245 g/amp-hr for CdO and 0.290 g/amp-hr for $Cd(OH)_2$. For KOH, sp gr 1.42, the corresponding values would be 0.227 and 0.169 g/amp-hr respectively.

Results are shown on Fig. 5.

It was found essential during these measurements that all concentration gradients of the electrolyte across the electrode surface were eliminated before taking the reading. It was also found necessary to remove gas bubbles remaining after the charge. Therefore, the electrolyte was stirred and the container was evacuated after every charge. Weighings were performed at equal intervals of time until constant weight was obtained. The values found on discharge were, in general, more reproducible than those obtained on charge. The diagrams indicated clearly that $Cd(OH)_2$ is the product of discharge. Thus, we consider it established beyond doubt that

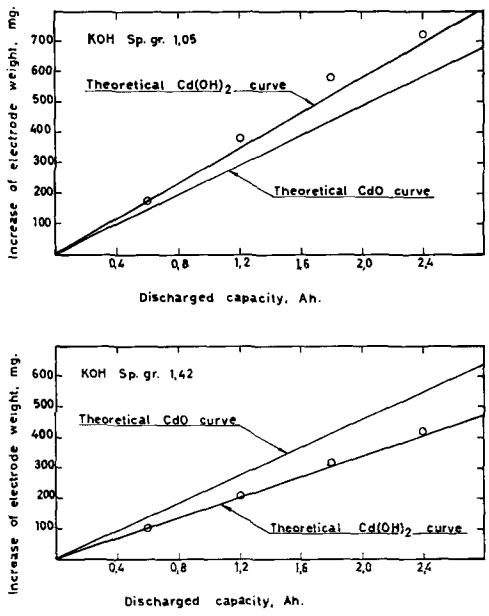

Fig. 5. Weighing of negative electrodes immersed in electrolyte.

$Cd(OH)_2$, not CdO, is the reaction product on discharge of the negative electrode.

The Electrolyte

Opinions on the participation of the electrolyte in the cell reaction have been and still are diverging. Frequently the reaction formula is written in a manner showing that the total concentration of the electrolyte does not change between charge and discharge (7, 31, 32). Condon and Odishaw (2) give a reaction formula according to which the electrolyte is diluted during discharge in a manner similar to the lead cell. According to Troilius (4) and Salkind (25) the total concentration of the electrolyte decreases on charge to regain its original value on discharge.

To clarify this point, potential measurements have been carried out on half charged sintered cells, previously filled with electrolytes of different concentrations. If the over-all concentration does not change in the working cell, then the emf obviously is independent of the electrolyte concentration. The cells were constructed without isolation between the electrodes which, furthermore, were widely separated from each other. Thus the ratio electrolyte/electrodes was substantially higher than is the case in normal cells. These steps were taken, first, to prevent diffusion phenomena on charge and discharge from affecting the measurements, second, to minimize the concentration variations on charge and discharge. Emf and plate potentials were measured. As is shown in Fig. 6, the cell emf increases with decreasing electrolyte concentration. A concentration increase from 5 to 45% causes an emf decrease of about 0.07 v. Consequently, the over-all concentration of the electrolyte is changing in a working cell.

The plate potentials have been measured against a Hg/HgO electrode and the values were corrected for the liquid potentials.

In the negative plate diagram a theoretical curve has been plotted that is based on the equation

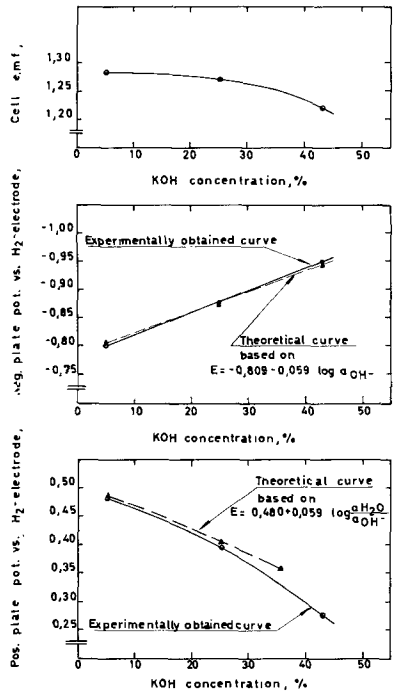

Fig. 6. Electrolyte concentration vs. open-circuit potentials

$$E = -0.809 - 0.059 \log a_{OH^-} \quad [1]$$

This curve is referring to the electrode reaction

$$Cd + 2OH^- \rightleftharpoons Cd(OH)_2 + 2e \quad [2]$$

and agrees evidently very satisfactorily with the experimental curve. Thus, this reaction may be considered as definitely established. As indicated by the formula no water participates in the reaction.

The positive electrode is more sensitive to variations of the electrolyte than the negative one, increasing its potential fairly rapidly when the electrolyte concentration is lowered. The formula indicated by the x-ray investigations is as follows:

$$Ni(OH)_2 + OH^- \rightleftharpoons \beta\text{-NiOOH} + H_2O + e \quad [3]$$

This formula gives the following relationship between electrode potential and electrolyte activities.

$$E = E_0 + 0.059 \log \frac{a_{H_2O}}{a_{OH^-}} \quad [4]$$

If we asume $E_0 = +0.480$ v and insert the activities of H_2O and OH^- for different electrolyte concentrations, the theoretical curve as shown in Fig. 6 is obtained. The agreement between this curve and the experimental one is clearly not very good. It is obvious, however, that the water activity enters into the equation for the electrode reaction. Water is thus formed on charging the nickel electrode.

Reaction Formulas

The main reaction of the positive electrode may, on basis of the previously given results, be written as follows:

$$2\beta\text{-NiOOH} + 2H_2O + 2e \rightleftharpoons 2Ni(OH)_2 + 2\,OH^- \quad [5]$$

This equation may, for better understanding, be split up in the following partial reactions:

$$2\beta\text{-NiOOH} + 2H_2O \rightleftharpoons 2Ni^{3+} + 6OH^- \quad [6]$$

$$2Ni^{3+} + 2e \rightleftharpoons 2Ni^{2+} \quad [7]$$

$$2Ni^{2+} + 4\,OH^- \rightleftharpoons 2Ni(OH)_2 \quad [8]$$

Thus, we can make the formal assumption that trivalent nickel ions are formed by dissolution and dissociation of β-NiOOH. On discharge they are transformed into bivalent nickel ions, which rapidly react with the hydroxyl ions of the electrolyte, forming nickel (II)-hydroxide.

However, it is also possible that the reactions take place directly in the interface between the active material and the electrolyte without dissolution and dissociation of β-NiOOH. Therefore, the given reaction steps are not to be considered as definite.

The main reaction at the negative electrode may be written

$$Cd + 2\,OH^- \rightleftharpoons Cd(OH)_2 + 2e \quad [9]$$

being the summation effect of

$$Cd \rightleftharpoons Cd^{2+} + 2e \quad [10]$$

$$Cd^{2+} + 2\,OH^- \rightleftharpoons Cd(OH)_2 \quad [11]$$

Thus, on discharge the cadmium metal is emitting bivalent ions, immediately reacting with the hydroxyl ions of the electrolyte to form cadmium hydroxide. A summation of Eq. [5] and [9] gives the formula of the total cell reaction

$$2\beta\text{-NiOOH} + Cd + 2H_2O \rightleftharpoons 2Ni(OH)_2 + Cd(OH)_2 \quad [12]$$

In the formulas given above purposely no regard has been paid to the roles of the adsorbed oxygen and hydrogen in the reactions, nor to the secondary discharge stage since all these reactions are of minor importance. The reactions may, however, be written as follows.

$$(\beta\text{-NiOOH})_2(O)_{ads} + H_2O + 2e \rightleftharpoons 2\beta\text{-NiOOH} + 2\,OH^- \quad [13]$$

$$Cd(H_2)_{ads} + 2\,OH^- \rightleftharpoons Cd + 2H_2O + 2e \quad [14]$$

$$Ni(OH)_2(O)_{ads} + H_2O + 2e \rightleftharpoons Ni(OH)_2 + 2\,OH^- \quad [15]$$

Formula [12] for the total cell reaction agrees with the one given by Salkind and Bruins (25).

The EMF and Its Temperature Coefficient

We may assume the emf of the nickel-cadmium cell to be affected primarily by three factors: state of charge, temperature, and electrolyte concentration. The influence of the third factor has been discussed previously.

The emf of the nickel-cadmium cell vs. the state of charge has previously not been subjected to any extensive studies. The relationship between the potential conditions of the nickel electrode and generally rather brief rest periods has on the other hand been investigated by several persons (9, 28, 33, 34).

The results of our x-ray investigations seem to indicate a continuous decrease of the emf with the falling state of charge, because the potential of the positive electrode would fall gradually due to the existence of a solid solution between β-NiOOH and $Ni(OH)_2$, while the negative potential would be

totally independent of the state of charge. In order to obtain a confirmation, measurements were carried out on pocket-type as well as sintered-type cells, which were discharged to different states of charge after previous charging and 5 days of rest. This latter period was introduced to diminish the influence of $(\beta\text{-NiOOH})_2(O)_{ads}$. Emf and electrode potentials were measured after a storage time of 0, 2, 4, and 8 weeks.

These experiments showed that the variations of the electrolyte concentration at various states of charge affected the potentials. The potential of the cadmium electrode, for instance, grew linearly more positive with higher state of charge. Independently of the storage time the potential difference between the 0 and 100% states of charge of the sintered cells amounted to about 11 mv. A check proved this value to agree with the potential change appearing in this type of cell due to the concentration variation of the electrolyte, when formula [12] is applied. Evidently, the magnitude of this difference depends on the ratio volume of active material to electrolyte volume. Naturally, the positive electrode was also similarly affected by the electrolyte variations.

In order to obtain more unaffected values of the relationship between potential and state of charge, tests were carried out as before but on special cells, having a high ratio between electrolyte volume and electrode volume. The specific gravity of the electrolyte in these cells was 1.25. Typical values of emf and electrode potentials as related to the state of charge after 2 weeks' storage at these measurements are shown in Fig. 7.

The curves indicate that the negative electrode potential of the sintered cells is totally independent of the state of charge. This implies the nonexistence of solid solutions of the active compounds. The pocket-type cells have a negative electrode potential which is slightly more negative at higher states of charge. This effect is probably caused by the addition of iron to the negative active material.

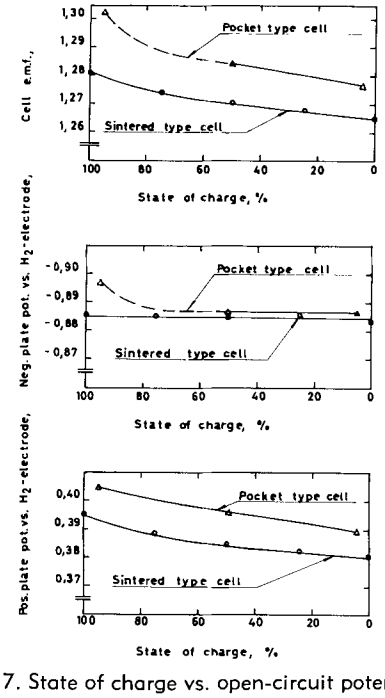

Fig. 7. State of charge vs. open-circuit potentials

The potential of the positive electrode of sintered as well as pocket-type cells is dependent on the state of charge and gradually falling with decreasing state of charge, thus indicating a solid solution of β-NiOOH and $Ni(OH)_2$.

Thus, emf is continuously decreasing with the falling state of charge. In agreement with the collected x-ray data this lowering is caused by the positive electrode.

It is a remarkable fact that the pocket cells consistently display slightly higher emf than corresponding sintered cells. The main part of this effect originates from the nickel electrode, although the cadmium electrode also contributes at higher states of charge.

The relationship between emf and temperature has not yet been subjected to quantitative investigations as far as the nickel-cadmium cell is concerned. This factor has, however, been investigated on the nickel-iron cell, the most extensive work carried out by Hosono and Watanabe (35).

In our investigation cells were tested with pocket as well as sintered electrodes, all discharged to 5, 50, and 95%, respectively, of the capacity after previous full charge. The electrolyte (sp gr 1.25) was covered by paraffine oil in all cells as protection against evaporation. After the discharge the cells were put at rest until the potentials varied only slightly from one day to another. Subsequently, emf and electrode potentials were measured at cell temperatures between about −40° and +50°C. The electrode potentials were all measured with Hg/HgO electrode filled with KOH, sp gr 1.25.

Values for the pocket cells proved to be reproducible at states of charge corresponding to 50 and 95% discharge, while the reproducibility at 5% discharge was less satisfactory and, furthermore, had dE/dT values deviating from the others. This effect indicates an instability and difference in character of the active material at 5% discharge. It is curious in this case that this instability is not dependent on the positive electrode but entirely due to the negative side. It would otherwise have been expected that the positive material would behave differently due to oxygen adsorption. These diverging values of the negative electrode might be due to influence from the iron powder present in the active material.

The sintered cells yielded reproducible values independent of the state of charge. Figure 8 shows typical emf values as related to the temperature on sintered as well as pocket cells. The figures show that all dE/dT values are negative, being more negative for pocket cells than sintered ones at all states of charge. Approximate values of the temperature coefficients of the emf and the electrode potentials are:

dE/dT	dE_a/dT	dE_k/dT
Pocket cells	Sintered cells	Pocket cells
−0.00030	−0.00018	−0.00006
Sintered cells	Pocket cells	Sintered cells
−0.00014	−0.00024	−0.00004 v/°K

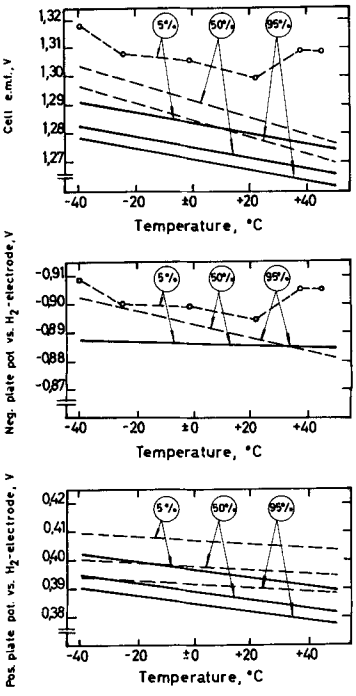

Fig. 8. Emf and electrode potentials vs. temperature. Dashed line, pocket type; solid line, sintered type.

dE/dT is somewhat dependent on the state of charge for pocket cells, of which a 5% discharge yields values disagreeing from the other ones. Otherwise the state of charge does not seem to have any greater influence on the temperature coefficient.

Salkind and Bruins (25) have found that the temperature coefficient of the nickel electrode of sintered cells is negative and decisive in agreement with the values given here.

The differences appearing between sintered and pocket cells as far as emf and dE/dT are concerned are supposed to be due to the presence of graphite in the positive and of iron in the negative pocket electrode.

Summary of Results

1. The main reaction of the nickel-cadmium cell on charge and discharge is
$$2\beta\text{-NiOOH} + \text{Cd} + 2\text{H}_2\text{O} \rightleftharpoons 2\text{Ni(OH)}_2 + \text{Cd(OH)}_2$$
2. The secondary discharge stage of the positive electrode is probably caused by oxygen adsorbed by $Ni(OH)_2$.
3. The high initial potential of the negative electrode after charge is caused by hydrogen adsorbed by Cd.
4. The emf of the nickel-cadmium cell is dependent on the activity of water in the electrolyte and consequently on the hydroxyl ion activity. An increase of the KOH concentration from 5 to 45% results in an emf decrease of about 0.07 v.
5. The emf of the nickel-cadmium cell depends on the state of charge, falling continuously with lower state of charge. This effect can be attributed to the existence of a solid solution between β-NiOOH and $Ni(OH)_2$ in the positive electrode.
6. The dE/dT value of the nickel-cadmium cell is negative. The magnitude is -0.00018 v/°K for sintered cells and -0.00030 v/°K for pocket cells.

Manuscript received Dec. 10, 1959. This paper was prepared for delivery before the Columbus Meeting, Oct. 18-22, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

Oxidation Properties of Tantalum Between 400° and 530°C

J. V. Cathcart, R. Bakish, and D. R. Norton

Metallurgy Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee; Alloyd Corporation, Cambridge, Massachusetts; and Sprague Electric Corporation, North Adams, Massachusetts, respectively

ABSTRACT

The rate of oxidation of tantalum in 1 atm of purified oxygen was measured at three temperatures between 475° and 530°C. The oxide was initially protective but became nonprotective as oxidation progressed. This kinetic behavior was correlated with metallographic and electron optical studies of oxidized Ta specimens, and it was shown that the oxide films became nonprotective through the formation of microscopic blister-like cracks in the oxide. A comparison between the oxidation characteristics of Ta and Nb is given.

In the course of an investigation of the factors which control the degree of protectiveness of oxide films, a study of the oxidation of tantalum in the range 400°-530°C was undertaken. An attempt was made to correlate the results of kinetic, metallographic, and electron optical studies in order to elucidate the oxidation mechanism for tantalum.

Previous investigations of the gaseous oxidation of tantalum have been limited either to rather low temperatures or to short times at higher temperatures. Thus Waber, *et al.* (1) determined the rate of oxidation of tantalum spectrophotometrically and reported a logarithmic form for the rate equation for temperatures from 320° to 450°C. Gulbransen and Andrew (2) observed rate curves of a parabolic type for the 120-min examination period which they employed at temperatures ranging from 250° to 450°C. Vermilyea (3) studied the oxidation rate of tantalum in the temperature range 50°-300°C, and Fassel and co-workers (4) investigated the effect of high oxygen pressure on the oxidation of tantalum at temperatures from 500°-900°C.

Procedure and Results

In the present research, rates of oxidation of tantalum were determined at 475°, 515°, and 530°C. Oxidation specimens were in the form of coupons 1 x 2 x 0.3 cm. Specimens were carefully mechanically polished and prior to oxidation were annealed overnight at a pressure of 10^{-6} mm Hg at the oxidation temperature.

Oxidation rates were determined from the decrease in oxygen pressure in a closed system as oxidation proceeded. Pressure changes were measured with a sensitive differential manometer similar in design to that previously used in a study of the oxidation rates of the alkali metals (5). Oxidations were performed in purified oxygen at approximately atmospheric pressure. The sensitivity of the manometer was such as to permit the detection of a 5Å change in oxide thickness on the tantalum specimens.

The results of these experiments are illustrated in Fig. 1 and 2 where data from representative experiments are given. The quantity of oxygen consumed per square centimeter is plotted against the time of oxidation. A protective film was formed during the early stages of oxidation, but with increasing time a transition period was reached in which the rate of oxidation increased. Finally, the film became virtually nonprotective, and the oxidation rate curve tended toward linearity. The length of the protec-

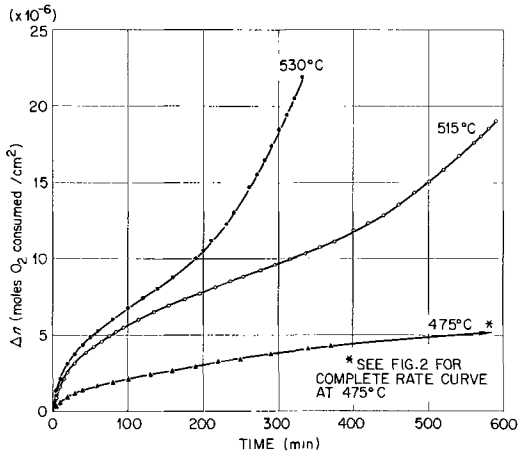

Fig. 1. Oxidation rate curves for Ta at 475°, 515°, and 530°C.

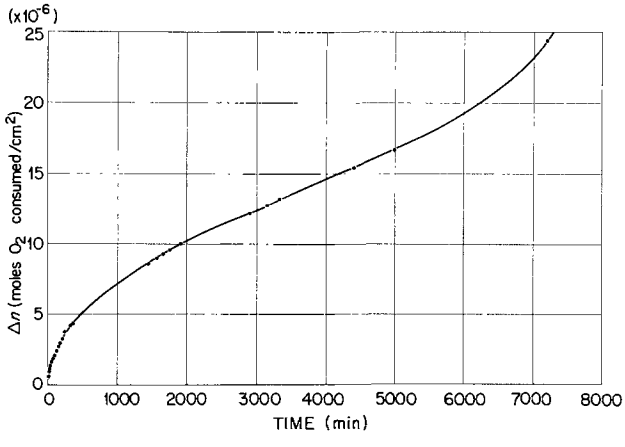

Fig. 2. Oxidation rate curve for Ta at 475°C

tive stage of oxidation varied inversely with temperature. Qualitatively the kinetic behavior of tantalum was very similar to that previously reported for niobium (6).

As a corollary to the rate measurements, the microtopography of the surfaces of oxidized tantalum specimens was examined. Tantalum coupons were prepared in the same manner as described above and oxidized for varying periods of time at temperatures ranging from 400° to 525°C. The oxidized specimens were then preshadowed with gold-manganin and replicated with carbon, and the replicas examined in an electron microscope.

The surfaces of freshly prepared specimens, either chemically or electrolytically polished, exhibited a texture suggestive of bubble-raft dislocation models (see Fig. 3). The origin of this texture is not understood, but it was obtained with a very high degree of reproducibility and persisted during the earliest stages of oxidation. Continued reactions resulted in the superposition on this texture of a pattern of acicular features. As may be seen in Fig. 4, these needle-like structures formed very regular arrays whose orientation varied from grain-to-grain of the substrate metal. This pattern was observed on oxidized specimens which previously had been annealed thoroughly and either chemically or electrolytically polished. On specimens which had been subjected to mechanical polishing only, no such pattern was formed, the oxide film produced under these circumstances exhibiting instead a slight, rather nondescript surface roughening. These results emphasize the relationship between the state of perfection of a metal surface and its oxidation characteristics. Prominent surface features of the oxide film formed on Ta are clearly related to the crystallography of the substrate metal.

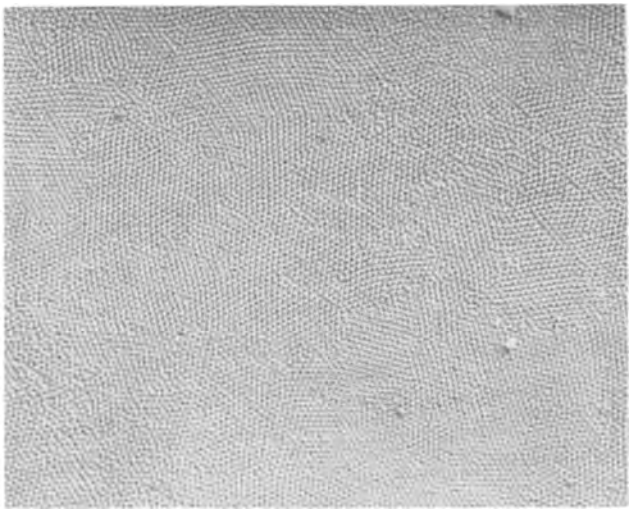

Fig. 3. Electron micrograph of the surface of an electropolished, unoxidized Ta specimen. Indirect carbon replica, Pd shadowed. 33,000 X (All magnifications are before reduction for publication.)

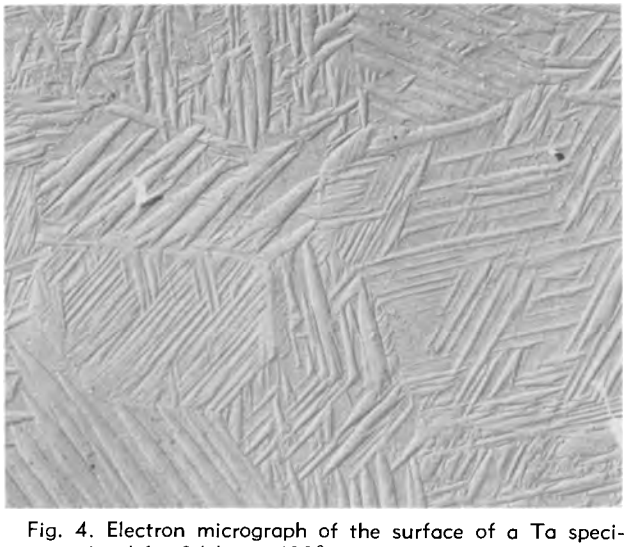

Fig. 4. Electron micrograph of the surface of a Ta specimen oxidized for 24 hr at 400°C. Direct carbon replica, preshadowed with gold-manganin. 7,500X.

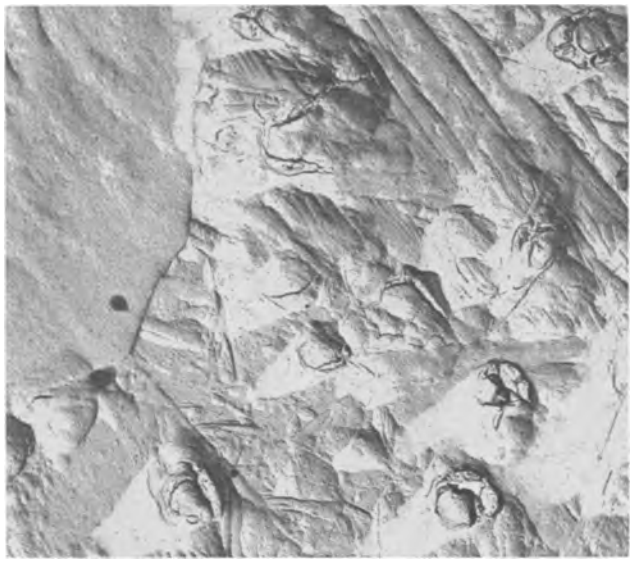

Fig. 5. Electron micrograph of the surface of a Ta specimen oxidized for 10 hr at 515°C. Direct carbon replica, preshadowed with gold-manganin. 12,500 X

At temperatures of 450°C and above, still further oxidation resulted in the formation of numerous cracks and blister-like ruptures in the oxide (see Fig. 5). Such cracks were found after 72, 48, and 4 hr of oxidation at 450°, 475°, and 500°C, respectively.

It was noted that the bubble-raft texture was visible on electropolished Ta specimens before oxidation and that it remained unchanged during subsequent oxidation. Thus the oxidizing of a Ta sample automatically constituted a marker experiment. Since the "markers" receded from the oxide/metal interface, it was concluded that anion diffusion occurred across the Ta_2O_5 film.

Further insight into the oxidation mechanism of Ta was obtained through a metallographic study of taper and cross sections through oxidized Ta specimens. Taper sections such as that shown in Fig. 6 indicated that the oxide film, rather than being confined to a layer parallel to the metal surface, extended into the metal in the form of slightly lenticular platelets parallel to {100} planes of the metal (7). The platelets of oxide appeared to be associated with the needle array observed on the surface of the oxide, and it was thought that the needles represented traces of the platelets on the surface. The formation of similar platelet-like sheets of oxide in

Fig. 6. Low-angle taper section through a Ta specimen oxidized 4 hr at 500°C showing traces of oxide platelets. Depth of cut into specimen increases from left to right. Specimen cathodically etched after polishing. 500 X

Ta was also observed at much higher temperatures and lower pressures of Gebhardt and Seghezzi (8).

Electron- and x-ray diffraction patterns of oxidized tantalum specimens revealed the presence of Ta_2O_5 only. The oxide was crystalline both before and after cracking of the films occurred.

Discussion

The oxidation of Ta proceeded through the formation of a very thin, relatively smooth surface oxide film followed by the production of small platelets of oxide extending into the metal parallel to {100} planes of the metal. The traces of these platelets were visible as acicular forms in the surface oxide. Continued oxidation eventually caused a rupturing of the covering oxide film.

This picture is consistent with the results obtained in the kinetic studies of the oxidation of Ta which indicated an initial protective stage of oxidation followed by a marked increase in the oxidation rate and the on-set of nonprotective oxidation. The increase in oxidation rate was related to the cracking of the oxide film.

It is of interest to compare the oxidation characteristics of Nb and Ta. Important differences exist between the oxidation of the two metals. Two of the major features of oxide films on Ta—the formation of platelets of oxide extending into the metal and the related array of needle-like structures observed on the surface of the oxide—have not been detected in Nb oxide films. On the other hand, striking analogies also have been found in the oxidation properties of the two metals. The oxidation kinetics of both are similar in that at low temperatures both form protective oxide films, for both there is a temperature range in which an initially protective film becomes nonprotective as the time of oxidation increases, and at high temperatures both metals exhibit linear oxidation rate curves. The transition from protective to nonprotective oxidation in both cases is accompanied by similar crack formation in the oxides. Both form analogous series of oxides, and Ta_2O_5 and Nb_2O_5 are crystallographically isomorphous with almost identical lattice parameters (9). Both Ta_2O_5 (10) and Nb_2O_5 (11) are metal-excess semiconductors. These data together with the results of marker experiments indicate that this departure from stoichiometry is due to the presence of anion vacancies in the oxide.

The mechanism of the formation of the oxide platelets is still under investigation; however, the production of the acicular features on the surface of the oxide and the eventual cracking of the oxide films appear to be related at least in part to the mode of diffusion in Ta_2O_5 and to the ratio of the volumes of equivalent amounts of oxide and metal. The model proposed to account for these phenomena is similar to that previously discussed for the oxidation of niobium (6).

If it is assumed, as suggested above, that the oxidation of Ta proceeds via an anion diffusion mechanism, it follows that the new oxide is formed at the oxide/metal interface (or at least that the bottom of the Ta_2O_5 layer if small amounts of the lower oxides are present). A volume increase of approximately 250% is required when Ta is converted to Ta_2O_5. This expansion, however, will be resisted by the already overlying layer of oxide, and the formation of new oxide will be accompanied by the plastic deformation of the existing oxide film. Thus the oxidation process itself continuously produces stresses in the oxide film. In terms of this hypothesis, the stresses resulting from the formation of platelets of oxide in the metal during the oxidation of Ta tend to cause the platelets to press against the layer of covering oxide, deforming this surface film and producing the acicular array already described. Continued oxidation leads to the build up of severe, localized stresses which eventually cause the rupturing of the oxide film.

Equilibrium Space Charge at the Contact of a Metal and a Pure Highly Insulating Liquid and Its Influence on High-Field Conductivity

M. J. Morant

Queen Mary College, University of London, London, England

ABSTRACT

The high-field conduction of a highly purified insulating liquid such as hexane may be largely influenced by electron emission from the cathode. Theoretical interpretations have so far neglected the fact that in equilibrium a space charge layer will probably exist at the contact of a metal and such a liquid, similar to that at a metal-semiconductor contact. The effect of this cannot be calculated without more information, but it does explain the observations that the conduction currents are relatively insensitive to cathode work function. A novel electrostatic method is described which, it is believed, can directly measure the potential of such an electronic double layer at the contact of a metal and a dielectric.

Conduction processes in highly purified insulating liquids are of fundamental interest apart from their value in helping to explain electrical breakdown under extremely high applied fields. A study of the electrical properties of such liquids would ideally give information on the types of charge carrier, their mobilities, trapping and recombination times, etc., and their relationships in determining the actual current and field distribution in a liquid with a given electrode configuration. The variation of the current with the controllable conditions of time, temperature, purity, electrode surface, etc., would follow, electrode processes being particularly important for possible electronic devices. However, little fundamental information is so far available because most of the methods used for investigating gases and solids cannot be used for insulating liquids. In spite of this, the correct interpretation of conductivity measurements alone should be able to provide much information if carried out over a wide enough range of experimental conditions, and particularly as a function of applied field strength. It has recently been shown (1) that with careful technique it is possible to measure the d-c conductivity of a highly purified simple hydrocarbon such as hexane right up to breakdown fields, and this can provide indications of the origins of the current-carrying charges. As field strengths of hundreds of kv/cm are required to obtain currents of about 10^{-10} amp in such liquids, it is not surprising that there have been inconsistencies in the findings of different investigators arising from differences of technique, purity of the liquid, and electrode preparation. Supplementary measurements, not involving conductivity, may therefore be of value in elucidating the critical factors. It is the purpose of this paper to introduce a new type of measurement that can be made on the interface of a highly insulating liquid (or solid) and a metal electrode without applying an external field of any kind. It is believed that this new effect gives the potential difference across an intrinsic space charge layer at the contact of a metal and an insulator.

Before describing the experimental method a brief review is given of the ways in which the electrodes could influence the conductivity, and it is shown that the effects of a double layer between the metal and the liquid must always be included.

Electrode Effects in Liquid Conductivity

Charge transfer in dielectric liquids is more complicated than in either gases or solids. Low energy electrons in a liquid may move in two ways, (i) transferring from molecule to molecule in the field direction, or (ii) trapped permanently to a single molecule which moves as a whole through the liquid. Within each molecule the electron can probably move comparatively freely, but the over-all mobility in the liquid is low whether the electron moves with the whole molecular ion or in a series of jumps between molecules. Charge is probably transferred in both the above ways simultaneously, an electron moving as a large molecular ion until a suitable molecular configuration occurs for the electron to transfer to a neighboring molecule. It may not be possible to distinguish, even theoretically, between the two transport mechanisms. In gases, electron transfer between an ion and a molecule is unlikely because of the low density; also, electrons can move freely between the molecules. In a solid the periodicity leads to a high electron mobility through the lattice, but a trapped electron (i.e., ion) has zero mobility. In both cases it is possible to distinguish between a free electron and an ion. This is not so in a liquid, and a new theoretical background may have to be developed.

Similar reasoning may hold for the transport of positive charge in a liquid. A positive ion may move in the same way as in a gas, but there is the additional possibility that the ion may be neutralized by the transfer of an electron from a neighboring molecule. In this way a positively charged electron vacancy could move through the liquid, corresponding to the movement of positive holes in a semiconducting solid. As for electron transfer it is probably impossible to distinguish between electron vacancies and ion movement. The proportion of the current carried by electrons or electron vacancies as compared with negative or positive ions will depend on the ease with which an electron can be transferred *between* molecules rather than for the whole molecular ion to move.

Any theory of the conduction of dielectrics has, in addition, to account for the origin of the current-carrying charges, and to explain how they are transferred between the insulator and the electrodes. Two distinct types of electrode process exist: (*a*) the electrodes may *emit* all the charged particles required to carry the current; or (*b*) the electrodes may *neutralize* charges which are produced naturally within the dielectric.

The first case includes electron emission from the cathode which is considered further below. Similarly, electron vacancies could be emitted from the anode by the extraction there of an electron, as in a semiconductor. Case (*b*) includes the normal electrolytic effects where the charge originates in the bulk of the liquid due to the dissociation of impurities, absorption of radiation, etc. Both positive and negative ions may be neutralized at the electrodes. When charges originate at the electrodes the conductivity will probably depend greatly on the electrode material, etc., but this is not so if the charge is produced within the liquid.

In general, electrodes can simultaneously perform both functions (*a*) and (*b*) above, e.g., as in a gas discharge where electrons are emitted from the cathode and positive ions neutralize there. Again, in a semiconductor there is a certain naturally occurring charge density (electrons, holes, and charged impurities) and additional charges (minority carriers) may be injected from a contact so that both types of process are operative.

In liquids, as in the other examples, the proportion of the charge carriers originating in the bulk and from the electrodes probably depends on the experimental conditions and on the applied field strength. For example, bulk impurities may account for the low-field conductivity and the emitted charges for the increase of the current with field strength. House (1) has produced evidence for collision ionization in hexane at the highest fields in certain conditions, this being another mechanism by which free charge can originate in the bulk. Whichever source of charge predominates, however, it is important to consider the equilibrium between the charges emitted from the electrodes and those produced within the liquid. It will be shown that one consequence of this is that a space charge layer will always exist in a dielectric liquid close to the electrodes, in the same way as at the contact of a metal and a semiconductor. This layer should greatly influence the charge transfer to the liquid even in cases where the electrode effects predominate.

Theories of the conduction of highly purified liquids have usually either entirely neglected the electrode effects or the presence of charges occurring naturally in the bulk of the liquid. Several authors (1-6) have attempted to explain the high-field conduction in terms of field-aided electron emission from the cathode, but it will be shown that this model must be seriously modified to allow for the production of free charge within the liquid also. The emission theories usually neglect the liquid apart from its dielectric constant, K, and its possible effect in lowering the work function of the metal, so that the conduction current is limited only by the cathode emission, and the electrons are implicitly regarded as being free within the liquid. At the high fields concerned, 10^4-10^6 v/cm, electron emission from the metal may occur by the Schottky process of field-aided thermionic emission, or by Fowler-Nordheim cold emission depending on the conditions. As in the case of electron emission into gases, the former is more likely to give agreement between experimental values and reasonable theoretical estimates of work function, field intensification, and emitting area (7, 8). Even so, the agreement is not perfect, and more elaborate models have been proposed to explain the emission (6, 9).

A serious objection to emission-limited theories of liquid conduction was first raised in 1937 by Plumley (4). Emission should depend on the work function of the cathode, possibly modified from its vacuum value by the presence of the liquid. Plumley showed that, within experimental error, brass and gold cathodes gave the same current in iso-octane up to 175 kv/cm. Thermionic emission (with the vacuum values of the work function) would have given currents in the ratio of 3.10^4:1. More recently, Green (6) has investigated the dependance of conduction currents in hexane on the cathode conditions and has found a variation over a range of about 100:1, but dependant more on the surface layer, as affected by heat treatment, than by the material of the cathode. House (1) found a maximum difference of only 3:1 between silver and chromium electrodes in hexane. Zaki (10), also working in this laboratory, has obtained similar results, and has also shown that differences of up to 100:1 in the high-field currents in hexane may result from the state of oxidation of the cathode. All these results suggest that the conduction is influenced by the cathode, but that it is unlikely to depend simply on the work function. It will be shown that this may be explained by considering the complete surface barrier when some of the free charge is produced within the liquid. But first it is necessary to consider the charge density at the interface of a metal and a dielectric liquid.

Equilibrium Space Charge

The electron density outside the range of image forces of a metal surface of work function ϕ is

$$n_0 = 2\left(\frac{2\Pi mkT}{h^2}\right)^{3/2} e^{-\phi/kT} \text{ cm}^{-3} \qquad [1]$$

Away from such a metal surface in a vacuum the electron density, $n(x)$, decreases indefinitely, and the electrostatic potential, V, rises as required by the Boltzmann distribution and Poisson's equation

$$n(x) = n_0 e^{-eV/kT} \quad [2]$$

and

$$\frac{d^2V}{dx^2} = -4\Pi ne \quad [3]$$

in the one-dimensional case. This is the "electron atmosphere" that always exists in equilibrium with a metal surface in a vacuum. It is distinct from the denser space charge that occurs when current is drawn. At the contact of a metal and an idealized dielectric, there is a similar electron atmosphere except that the dielectric constant, K, has to be included as a denominator in [3], and the electron density, n_0, may be very much greater than at the vacuum interface due to the lowering of the work function of the metal by the dielectric to a value ϕ^*. The difference $(\phi - \phi^*)$ may be regarded as the potential energy of the lowest electronic conducting level in the dielectric (Fig. 1a and b).

The potential rise in the electron atmosphere outside a plane metal surface is easily calculated from [2] and [3] (11). At room temperature the electron density is very low and in vacuum, for example, the potential rises to only 35 mv at a distance of 32 cm from a metal having a work function of 1 ev. The potential rise is even slower for practical values of ϕ. However, the result is very sensitive to *lower* values of ϕ as may be encountered at the contact with a dielectric. For instance if $\phi^* = 0.5$ ev the same potential rise occurs in $3 \cdot 2.10^{-3}$ cm. For two plane electrodes, solutions of [2] and [3] may also be found giving the potential in the enclosed electron space charge. Von Laue (12) and Fowler (13) have shown that the potential close to each electrode is scarcely affected by the presence of the other. In equilibrium the normal contact p.d. occurs between the electrodes and the potential in the gap reaches a peak at a position determined by the work functions. Skinner (14) has considered the current that would flow in an idealized dielectric, containing an electron atmosphere of this form, on applying an additional potential difference.

There are two respects in which a real dielectric may be expected to differ from this idealized case, and both affect the form of the potential variation. In the idealized dielectric the electron density can decrease continuously toward zero (limited only by the applicability of [2] and [3]), but in any real dielectric a lower limit is set by the naturally occurring charge density which, as explained above, will be formed in a liquid by the dissociation of impurities, absorption of stray radiation, and possibly by thermal excitation. For neutrality equal positive and negative charge densities must be produced in the bulk of the liquid. If an electron density n_1 cm^{-3} is formed the potential rise in the space charge between the metal and the bulk of the dielectric must be limited to

$$V_m = \frac{kT}{e} \log_e \frac{n_0}{n_1} \quad [4]$$

as shown in Fig. 1c. This potential difference can be regarded as a first approximation to the contact potential between the metal and the interior of the liquid due to the naturally occurring charge density in the latter. A space charge barrier setting up this potential is required for equilibrium at the interface in the same way as at the contact of a metal and a semiconductor. Equation [4] may in fact be derived from the true equilibrium condition which is the equality of the electrochemical potentials in each phase. Similarly the electron atmosphere in a vacuum is required to try to bring it into equilibrium with the metal.

The second specific effect of the dielectric is to concentrate this "equilibrium space charge" much closer to the interface than in a vacuum. In a real liquid dielectric, the electrons will not be distributed as a perfectly free gas, they will not diffuse far into the liquid, and Eq. [2] will no longer be valid. Any tendency for electrons to become trapped in or between molecules will concentrate the space charge layer even closer to the metal surface as shown in Fig. 1d. With a low effective work function an appreciable part of the equilibrium space charge could be within 10^{-4} cm of the metal.

When considering the emission of electrons into a vacuum the potential of the electron atmosphere is extremely small compared with other surface forces. In liquids, the theories of field-aided electron emission have also neglected the equilibrium space charge, although it now seems probable that it could give appreciable potential changes even within the range of image forces. For this reason the conductivity of liquids is unlikely to be explained by models for the emission of electrons into a vacuum. The above description of the equilibrium space charge applies strictly only when there is no applied field. Much more information about charge carriers, their mobilities, trapping effects, etc., will be required before it is possible to predict the influence of contact space charge on current flow in liquids even with low fields: the methods would be expected to be similar to those developed for metal-semiconductor contacts. The difficulties are even greater for high applied fields. The conductivity increases by anything up to six orders of magnitude between low fields and breakdown. Assuming that this is due to increasing current-carrying charge density in the bulk, the potential across the space charge in the contact region would fall by only 0.6 v (from Eq.

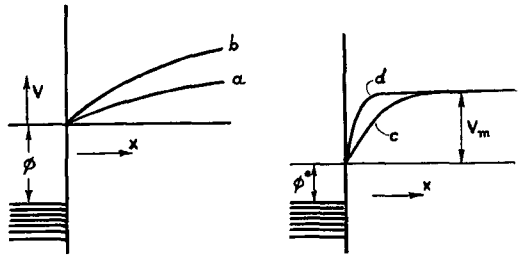

Fig. 1. Potential energy of an electron at the contact of a metal and a dielectric. (a) Vacuum; (b) idealized dielectric; (c) dielectric with bulk charge; (d) dielectric with bulk charge and trapping.

[4]). This emphasizes that the contact space charge rather than straightforward electron emission from the cathode is important up to the highest applied fields.

Although the current flow through the complete surface barrier cannot yet be calculated, the equilibrium space charge has one important consequence which is confirmed experimentally. Electron emission from a cathode to the surface region of a liquid is controlled by the modified work function, ϕ^*, of the metal. The space charge imposes the additional potential barrier, V_m, which from [4] and [1] is

$$V_m = \frac{kT}{e}\left\{\log_e 2\left(\frac{2\Pi mkT}{h^2}\right)^{3/2} - \frac{\phi^*}{kT}\right\} - \frac{kT}{e}\log_e n_1$$

or substituting numerical values, with $T \sim 300°K$, the total barrier height is

$$\left(V_m + \frac{\phi^*}{e}\right) = 1\cdot115 - \frac{1}{40}\log_e n_1 \text{ v} \qquad [5]$$

That is, the total potential barrier between the Fermi level of the metal and a conducting level in the liquid is independent of the work function of the metal, but it does depend on the liquid charge density. A low work function gives a high electron density at the interface and so a large space charge potential, and vice versa (Fig. 2). Thus the relative insensitivity of conduction currents in simple liquids to the cathode material is not incompatible with emission-limited conduction modified by the equilibrium space charge barrier. This removes the major objection to emission theories first stressed by Plumley and confirmed since. Although the barrier height is constant, a relatively small cathode dependence would still be expected due to differences of the barrier shape with ϕ^* and V_m.

It must be stressed that this model is highly simplified and that it assumes electronic equilibrium between the metal and the liquid. The presence of either positive or negative ions alters the double layer potential V_m, but whatever the details, some sort of space charge layer must exist at the interface for equilibrium. The experimental work described below also directly demonstrates the existence of such a space charge layer. At first sight the above model cannot account for the considerable effect of the state of oxidation of the cathode on the conductivity of dielectric liquids. The equilibrium space charge is unaffected by replacing a clean metal surface by an oxide of the same work function so the conduction currents should also be independent

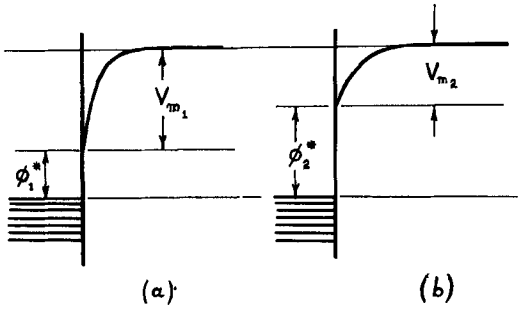

Fig. 2. Potential energy at the contact of a dielectric and electrodes of (a) low, and (b) high work function.

of the oxide work function. However, with current flow across an insulating oxide layer the equilibrium between the solid and the liquid may be seriously disturbed. Electrons may not be able to pass through the oxide layer quickly enough to maintain the equilibrium concentration, n_0, or the space charge potential V_m. The emission current would then be partly limited by the potential across the oxide layer. On the other hand, an unoxidized metal surface could always provide sufficient electrons to maintain the contact space charge in equilibrium right up to the maximum currents found in very pure liquids. Much more information is required before it is possible to differentiate between several possible mechanisms at the oxidized cathode.

Experimental Determination of the Space Charge Potential

It is not possible to detect the equilibrium space charge at the contact of a metal and a very highly insulating liquid by any of the classical methods of electrochemistry. However, a new type of electrostatic effect is described below which is believed to measure directly the potential of the double layer formed by the negative space charge and the positive charge induced on the electrode.

The measurement has similarities to the Kelvin method of measuring the contact or Volta potential between dissimilar metals. Plumley (4) and Macfadyen and Holbeche (15) have shown that the contact potential, measured in this way, is changed only slightly by totally immersing both electrodes in an insulating liquid. This would be expected unless the liquid reacted in different ways with each electrode. If there are contact potentials between each metal and the liquid, they cancel out around the circuit, and they cannot be detected by changing the total capacitance between the electrodes as in the Kelvin method. It is believed that this is overcome in the new method by measuring the change of potential of one of the electrodes when its *contact area* with the liquid is changed. The opposite electrode, usually earthed, remains totally immersed. A suitable arrangement is shown in Fig. 3a. An insulated conical electrode just pierces the surface of the liquid held in a metal cup. It is found that the potential of the cone changes reversibly as it is moved in and out of the liquid. Part of this change is due to the contact potential between the metal surfaces detected by the change in the total capacitance as in the Kelvin method, but this may be measured separately, and there is an additional potential change thought to be due to the charge transfer from the metal to the contact region in the liquid. Owing to the high insulation of both the metal and the liquid at the contact, the contact potentials round the whole circuit (including the liquid) cancel out extremely slowly, so that the contact potential across a single interface (where the contact area changes) may be detected. In this way it is a unique type of measurement.

A simplified theory by which the measured potential can be related to the double layer potential will be given. Figure 4 shows the charge distribution on the whole system arising from a double layer at

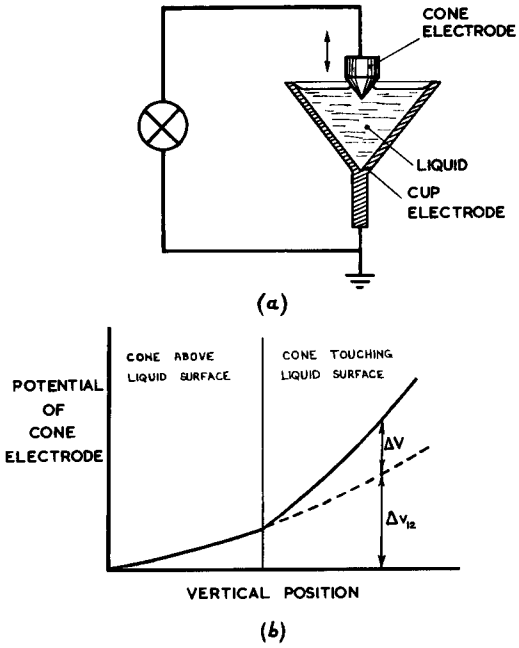

Fig. 3(a). Experimental arrangement for measuring the equilibrium space charge potential at the contact of a metal and an insulating liquid. Fig. 3(b). Form of the potential variation as the cone electrode touches the liquid surface.

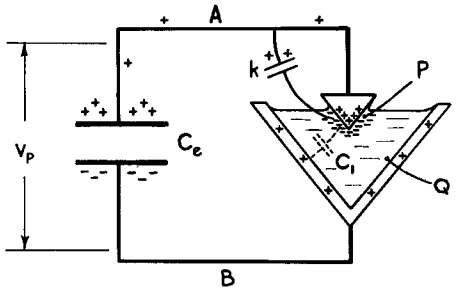

$$V_P = V_1 \frac{C_i}{C_i + C_e}$$

Fig. 4. Charge distribution due to double layer of potential v_1 at contact P.

the conical electrode, P. The charge at this contact is assumed to be positive on the metal and negative just inside the liquid, the potential difference being v_1. The metal A has lost negative charge as a whole to form this double layer. All this charge is concentrated just inside the liquid at P. Every element of capacitance, such as k, between the contact region of the liquid and the metal A must be charged to the double layer potential. Thus not quite all of the induced positive charge is on the contact surface of the metal. If the insulation of the system (including the liquid) is perfect, there are also induced charges on the electrometer (represented by the capacitance C_e, Fig. 4) and on the opposite metal electrode B. In the external circuit the double layer potential v_1 is divided capacitively by C_e and C_i, where C_i is the capacitance between the whole of the cup electrode B and the negative charge layer just inside the liquid at P. Therefore, due to the double layer at P, there exists a potential

$$v_p = \frac{v_1 C_1}{C_1 + C_e}$$

across the electrometer.

By similar reasoning, a double layer of the same polarity but of potential v_2 at the opposite interface of the metal and the liquid gives rise to a potential v_q across the electrometer. The two charge distributions are independent and the electrometer potentials may be added to give the net potential, v, due to the two double layers.

$$v = v_p + v_q = \frac{v_1 C_1}{C_1 + C_e} - \frac{v_2 C_2}{C_2 + C_e} \qquad [6]$$

where C_2 is the capacitance between the negative charge layer just inside the liquid at Q and the whole of the metal A.

In practice it is not possible to measure the steady potential v as it is swamped by stray charges left by contact potentials, etc., on setting up the system, so a difference method must be used. By slightly moving the cone electrode, the contact area with the liquid at P is changed without greatly changing the total capacitance between the electrodes. Therefore the potential of the spurious charges remains practically constant. However, the electrometer potential, v, due to the double layers is much more sensitive to contact area as the capacitance C_1 is due to the field between the negative charge at the contact and the whole of the opposite metal. The corresponding term C_2 associated with the opposite double layer of fixed area, at Q, is unaffected, to a first approximation, by the area change at P. Therefore for a small change of contact area at P, the change of the potential across the electrometer is given simply by

$$\Delta v = \frac{v_1 \Delta C_1}{C_1 + C_e} \qquad [7]$$

and if the capacitances of the system are known, v_1, the potential of a single double layer, may be directly measured.

The above treatment is very simplified, and the full analysis is not given here. The only basic assumptions that have to be made are that the negatively charged layers are thin compared with the dimensions of the apparatus, and that the equilibrium space charge at the contact is set up rapidly, i.e., within a second or two of changing the contact area. The full expression for Δv includes terms due to *both* the metal-liquid interfaces, and for the normal contact potentials between the electrodes (16). The partial and total capacitances of the system have to be examined in detail. Each one is of a few $\mu\mu$farad and of a distributed nature, so that the associated field has to be defined. A measuring technique must be devised for each partial capacitance without deforming the field by the introduction of probes. The analysis eventually gives the potential change, Δv, as a function of the penetration of the liquid surface by the conical electrode, in terms of the potentials v_1 and v_2. By initially preparing both electrodes in the same way, the double layers may be assumed to be the same, and they can be found from measurements of Δv by setting $v_1 = v_2$. Subsequently the double layer of the single contact between the conical electrode and the liquid may be investigated by keeping constant the surface treat-

ment of the opposing cup electrode. The effect of the preparation and material of the conical electrode may be found in this way.

In practice, measurements of electrostatic potentials of a few millivolts in systems of extremely high resistance and very low capacitance are confused by several spurious effects which may be difficult to eliminate or separate, and the present measurement is one of considerable difficulty. It is hoped to describe experimental details in full elsewhere (17). Our first work on this topic followed the discovery of the effect in solid insulation. In that case, the electrodes in contact with a block of the dielectric consisted of an earthed flat plate and a conical or spherical indenter connected to the grid of an electrometer valve (18, 16). Potentials of up to about 60 mv were obtained for a small change of the spherical contact area, but it is now known that these were largely due to the sensitivity of electrometer valves to the precise value of the external resistance: this varies with the contact area in the same way as the expected electrostatic charging (19). The effect is important for all measurements of small charges. It must be allowed for also in measuring the change of potential associated with the change of area of a metal-liquid contact. Comparatively large indicated potentials may also be due to contact potentials between metals. When the total capacitance, C_{12} between the electrodes is changed by slightly moving one of them, the potential changes instantaneously by

$$\Delta v_{12} = v_{12} \frac{\Delta C_{12}}{C_{12}}$$

where v_{12} is the contact potential. The contact p.d. plus the potential due to stray charges is measured independently by moving the conical electrode just above the liquid surface before making actual contact. The double layer effect, Δv, must then be absent. Figure 3b shows how Δv_{12} is extrapolated by independent measurements of the total capacitance, C_{12}, to separate the spurious and true double layer components of the measured change of potential after contact is made. It can be shown that this extrapolation is justified for nonpolar liquids as the change of C_{12} due to the dielectric constant of the liquid is negligible.

When allowance is made for these and other spurious effects, the reversible change of potential, Δv, is of the order of 1 mV/mm of penetration of a conical stainless steel electrode into hexane. The form of the potential variation agrees with that expected from the full expression for Δv in terms of the partial capacitances. Several other possible side effects that could account for the change in the electrode potential have been eliminated either by features of the experimental results or by experimental precautions, and no alternative can be found to the explanation of the measurements in terms of the interfacial double layer. Most of the work has been concerned with proving that this is so, and tests have so far only been made with stainless steel electrodes and highly purified n-hexane. Results show that the interfacial double layer always has the negative side toward the liquid as required for an electron space charge. The double layer potential, derived from Δv, is found to vary between 0.3 and 0.6 v depending on the electrode surface treatment, but an average value of about 0.42 v is obtained by leaving the electrode immersed in hexane for several days.

This result may be compared with the simple theory of the equilibrium space charge. The conductivity of hexane can be as low as 10^{-16} mho/cm. Assuming, for lack of precise information, that there are no bulk space charge effects, this corresponds to about 10^8 charge carriers per cm^3 for a mobility of 10^{-3} cm^2/v sec [LeBlanc (20)]. As such a low conductivity is found only in highly purified liquids, this may be the order of magnitude of the electron density formed in the liquid by stray radiation, etc. If this is so, Eq. [5] shows that the total height $(V_m + \phi^*/e)$ of the potential barrier between the metal and the liquid must be about 0.94 v, so that, if the double layer potential is 0.42 v, the average work function, ϕ^*, of the metal in contact with the liquid is only 0.52 ev. It is difficult to see how the work function of a normal metal surface could be lowered by more than about 0.5 ev by the purely electrostatic effects of a nonpolar liquid (16). The very low value found here for ϕ^* may indicate that there are weakly conducting levels for electrons in the liquid at a depth of about 4 ev, corresponding to the electron affinity of an insulating crystal.

Work on this new electrostatic method of detecting the equilibrium space charge at the contact of a metal and an insulating liquid is continuing, and it is hoped that it will be possible to correlate it with measurements of conductivity carried out on the purest possible samples up to breakdown field strengths.

Acknowledgments

Much of the work described above was carried out in 1951-1954 and was made possible by a maintenance grant from the Department of Scientific and Industrial Research. The current award of the Henley Research Fellowship to the author is also gratefully acknowledged.

Manuscript received March 1, 1960. This paper was prepared for delivery before the Philadelphia Meeting, May 3-7, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

The Incorporation of Sulfur in Electrodeposited Nickel, Using Thiourea as a Brightener and Leveler

ABSTRACT

The amount of sulfur incorporated into nickel electrodeposited from a Watts plating solution containing thiourea as a brightener and leveler has been investigated by radiotracer techniques and autoradiography. The nickel deposit contains sulfur, and the amount of sulfur increases with decreasing current density when the current density is determined by the external electrical circuit or by the geometry of the plating cell. Autoradiographs taken from oblique sections cut through the nickel deposit show the distribution of the sulfur within the deposit. When the nickel is deposited on a surface having a roughness comparable to that encountered technologically incorporation occurs on the peaks of the surface. Thiourea causes leveling which requires the peaks to be regions of lower current density. Therefore the incorporation of sulfur is higher in regions of lower current density when the current density distribution is determined by the behavior of thiourea on a rough surface. Incorporation probably occurs in layers in regions of the deposit which show a laminar structure.

The addition of small quantities of certain organic compounds to solutions used for the electrodeposition of nickel modifies the plating in two ways, brightening and leveling. The mechanisms of brightening and leveling present problems which are relevant to the study of the electrodeposition of metals and which have considerable technological importance. Any investigation of these mechanisms requires data on the extent to which an additive, or compounds derived from it, become incorporated in the nickel plate under various plating conditions. It is also important to know the extent to which anions are incorporated in the plating. Since the amounts of incorporation are too small to be determined conveniently by conventional methods of analysis, radiotracer techniques are very appropriate to these studies because their high analytical sensitivity may be combined with autoradiography to show in detail the distribution of the additive over the area of plating. Recently Beacom and Riley (1) have investigated the incorporation of sulfur compounds from sodium allyl sulfonate using an elegant counting technique and autoradiography to measure the differences between incorporation on the peaks and valleys of grooved cathodes. They found a greater incorporation of sulfur on the peaks than in the valleys, but the scale of their "simulated roughness" was more than two orders of magnitude greater than that which is encountered in practice.

Thiourea is an additive which produces both brightening and leveling, and this paper describes an investigation of the incorporation of sulfur into nickel plating from thiourea labeled with sulfur-35. A study has been made of the distribution of incorporated sulfur within nickel plated on a surface whose roughness is comparable with that of technological interest.

Experimental

The effect of current density on the incorporation of sulfur from thiourea has been studied by plating test cathodes in a Hull cell. The plating baths were supplied with S^{35}—labeled thiourea from a high specific activity stock solution. Plating solutions were prepared by adding labeled thiourea diluted with inactive carrier to a standard Watts' nickel plating solution. A volume of 300 ml of plating solution was used for each cathode which was plated

[1] Present address: United Kingdom Atomic Energy Authority, Wantage Radiation Labs., Wantage, Berks., England.

for 15 min at a total current of 3 amp at 55°C and pH = 4.0. The total concentration of thiourea was 10^{-3} g mole/l and the activity was 517 μc/l. The bath was agitated by a stream of nitrogen introduced along the bottom of the cathode. After plating, the cathodes were washed with cold water and boiled with two changes of distilled water. Autoradiographs were taken from these cathodes by pressing them in close contact with an appropriate photographic emulsion.

Further experiments to determine the effect of current density and thiourea concentration on incorporation were carried out using 1½ in. diameter mild steel disks plated in a cell consisting of an 800-ml beaker with a 1 in. paddle stirrer rotating at 120 rpm between the anode and cathode which were 2¼ in. apart. Four disks were plated at different current densities and thiourea concentrations using 500 ml of fresh plating solution containing 414 μc of S^{35} thiourea for each. All disks were plated at 55°C and pH = 4.0 with a copper coulometer in series with the plating cell. After plating, each disk was washed in the same manner as the Hull cell cathodes. Further boiling of the disks with distilled water caused no change in the incorporated activity.

The β activity of a circle, radius 0.406 cm, at the center of each disk was determined by counting with an end-window Geiger-Muller counter, the geometry of counting being controlled so that the activities of the four samples and a standard source could be compared.

The absorption coefficient for sulfur 35 β particles for the counting conditions used to determine the activities of the disks was determined using one of the disks as a source and nickel absorbers. The absorbers were placed close to the plated disk so that the counting geometry for the external absorbers was as similar as possible to that of the self-absorber. The value of the absorption coefficient in aluminum, the half life, and the absence of any gamma radiation detectable with a scintillation counter showed that all the activity on the disks was due to sulfur 35.

The thickness of the nickel plate at the center of each disk was measured by sectioning. The outside profile of the plating was supported by gluing to it a piece of soft copper sheet with Araldite. The disk was sectioned perpendicular to the plane of the plating, and the section face was polished and etched. The thickness of the plating was measured with a microscope fitted with a reticule eyepiece.

The plating conditions, the plating thicknesses at the centers of the disks, and the activities of the disks are shown in the first six columns of Table II.

To investigate the incorporation of sulfur from sulfate, two brass disks, E and F, were plated in a Watts' solution containing labeled sulfate but not thiourea. 500 ml of the solution contained 16 mc of $(S^{35}O_4)^{2-}$ and the disks were plated for 45 min at a current density of 3.97 amp/dm². The activity of a circle, radius 1.15 cm at the center of each disk, was compared with that of a standard by counting. These activities were very much lower than the activities of the disks plated in the presence of thiourea. Therefore to obtain reasonable counting rates, the counting efficiency was increased by mounting the disks much closer to the counter window. A standard was prepared by diluting 0.1 ml of the plating solution to 100 ml and evaporating 1 ml of the diluted solution onto a counting tray.

Table I

Disk	Surface finish center line avg roughness,* microns	Total conc. thiourea gmole/l	Total act. in bath, μc	Apparent current density, amp/dm²
G mild steel	1.12	10^{-3}	493	4.85
H mild steel	0.19	10^{-3}	493	4.85
K brass	1.17	10^{-3}	407	3.97

* Center line average roughness of length L of the surface equals $\frac{1}{L}\int_0^L |Y1|\, dl$ where y is the distance of the surface from the mean center line.

The distribution of the sulfur in nickel plated on a rough surface in the presence of thiourea has been studied by taking autoradiographs of sections cut obliquely through the plating. Disks were prepared on emery to give surfaces with scratches in one direction and various surface roughnesses. 500 ml of solution were used to plate each disk. Details of the surface and the plating conditions are summarized in Table I.

All disks were carefully cleaned before plating. The adhesion of the plating on disk K, which was used for taper sectioning, was further improved by cleaning it cathodically immediately before plating. The plating was sectioned at 5° to the plane of the plating. The outside profile of the nickel plate was supported by gluing to it a piece of soft copper sheet with Araldite. A 5° cut was then made in the brass, the section mounted in Perspex with the brass side outwards, and rubbed down on emery until a suitable profile appeared. The section was polished using normal metallographic techniques and etched with ammoniacal hydrogen peroxide. Autoradiographs were taken on Kodak A. R. 10 emulsion.

Results

Figure 1 shows autoradiographs of a Hull cell cathode (*a*) plated in a nitrogen-agitated bath and (*b*) in a bath without agitation, but in a nitrogen atmosphere. In Fig. 1, the current density increases along the cathode from left to right, and in all the autoradiographs, radioactive areas appear black.

Ratios of sulfur to nickel atoms in the plating can be calculated from the measured count rates. Suppose C counts/min, corrected for background and counter dead time, are obtained from 1 cm² of plating using a given counting geometry. Assume that the plating is of uniform thickness t cm and that it contains a uniform distribution P atoms of sulfur per atom of nickel. The specific activity of the thiourea in the plating bath S millicuries/g mole is equal to the specific activity of the sulfur in the plating in millicuries/g atom, assuming that there is no exchange of sulfur between thiourea, or sulfur in the plating, and sulfate ions during the deposition. A thin layer of plating thickness dx distance x from the free surface contains $(PSp/W)\ dx$ mc S^{35}/cm²

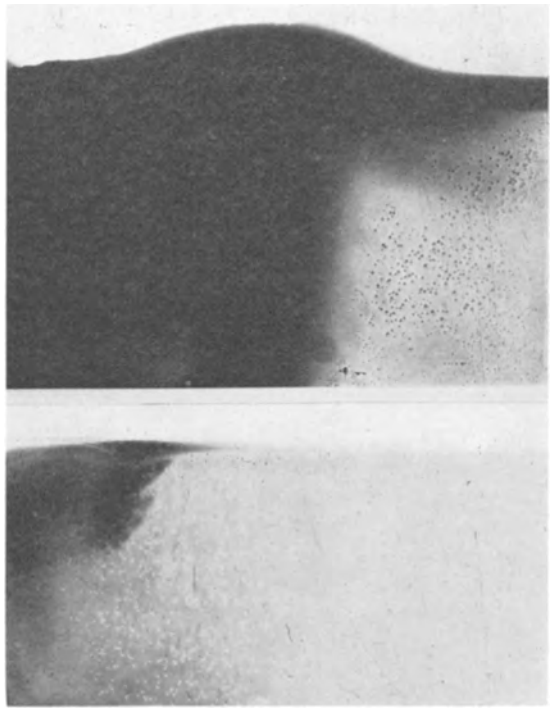

Fig. 1. Autoradiographs of Hull cell cathodes (full size before reduction for publication) (a) (top) plated in a nitrogen agitated bath, (b) (bottom) in a bath without agitation, but in a nitrogen atmosphere. The current density increases along the cathode from left to right and radioactive areas appear black.

where p, W are the density and atomic weight of nickel, respectively. The reduction of the count rate by absorption of $S^{35}\beta$ particles in thickness x of plating can be calculated approximately by assuming an exponential absorption with an absorption coefficient μ (2).

The thin layer at x contributes $(kPSp/W)e^{-\mu x}\,dx$ counts/min/cm^2 to the measured count rate where k is a constant depending on the geometry of the counting arrangement. Since the distance between the counter and the plating is large compared with the total thickness of the plating, k is independent of x.

Integration over the total thickness of the plating t and rearrangement gives

$$P = \frac{W}{kS}\,\frac{\mu}{p}\,\frac{C}{(1-e^{-\mu t})} \qquad [1]$$

A standard containing m millicuries of S^{35} gave C_m counts/min with the same geometry. This standard was sufficiently thin that the neglect of self-absorption does not introduce a significant error. Then $C_m = km$ and

$$P = \frac{mW}{S}\,\frac{\mu}{p}\,\frac{1}{(1-e^{-\mu t})}\,\frac{C}{C_m} \qquad [2]$$

The results of the nickel absorption measurements; $\log_{10}$ (count rate) plotted against absorber thickness (mg/cm^2) gave a line which was slightly convex away from the axes for a range of absorbers up to 10.7 mg/cm^2. A mean mass absorption coefficient was calculated from the gradient of the best straight line through the experimental points using the method of least squares. This gave μ/P = 2.303 x 0.132 = 0.304 cm^2/mg. For disks A, B, C, Table II, S = 0.414/0.5 x 10^{-3} = 0.828 x 10^3 mc/mole and for disk D 0.828 x 10^4 mc/mole. For disk A $(1-e^{-\mu t})$ = 0.986. The standard source of 0.104 microcuries of S^{35} gave 1012 counts/min.

$$P = \frac{0.104 \times 10^{-3} \times 58.7 \times 0.304 \times 10^3}{0.828 \times 10^3 \times 0.986}\,\frac{8612}{1012}$$

$$= 19.4 \times 10^{-3} \text{ atoms S/atom Ni}$$

Results for the other disks, Table II, column 7, have been calculated similarly.

The plating on disk H, Table I, was removed from the mild steel disk and the same area of plating counted from both sides. The activities measured from the two sides differed by 5.5%. The error introduced by the assumption that the sulfur is uniformly distributed in the plating is likely to be of similar magnitude.

The activities of disks E, F plated using labeled sulfate were E, 71.5, and F, 53.8 counts/min/cm^2. 16 mc of labeled sulfate were added to 500 ml of plating solution. The plating thickness at the centers of the disks was 27.7 μ and the activity of a standard which contained 0.032 μc of S^{35} was 3865 counts/min. The weight of this standard (0.1 mg/cm^2) showed that the neglect of self-absorption did not introduce a significant error.

These results give sulfur/nickel atom ratios, calculated using Eq. [2], of 0.33 and 0.25 atoms S/10^3 atoms Ni, respectively, taking the total concentration of sulfate in the plating bath as 1M. A nickel deposit plated under the same conditions was analyzed chemically for sulfur and gave a value of 0.37 atoms S/10^3 atoms Ni.

The autoradiographs, Fig. 2 and 4, show the distribution of sulfur incorporated in nickel plated on a rough surface. The plating on disks G and H was bright, and the original scratch lines still showed on G but did not show on H. Figure 2 shows an enlargement of an autoradiograph of disk G.

Table II

Disk	Current density, amp/dm^2	Total thiourea conc., gmole/l	Total wt. of nickel deposited, g	Plating thickness at center of disk, μ	Plating thickness at center of disk, mg/cm^2	Count rate, c/min/cm^2	Atoms S per 10^3 atoms Ni
A	8.6	10^{-3}	0.321	15.8	14.16	8612	19
B	4.3	10^{-3}	0.474	(24.8) *	22.17	16080	35
C	0.86	10^{-3}	0.488	34.7	30.9	30630	68
D	4.3	10^{-4}	0.482	24.3	21.6	18850	4

* Estimated by comparing the thicknesses on disks C, D and the total weights of nickel deposited on disks B, C, D.

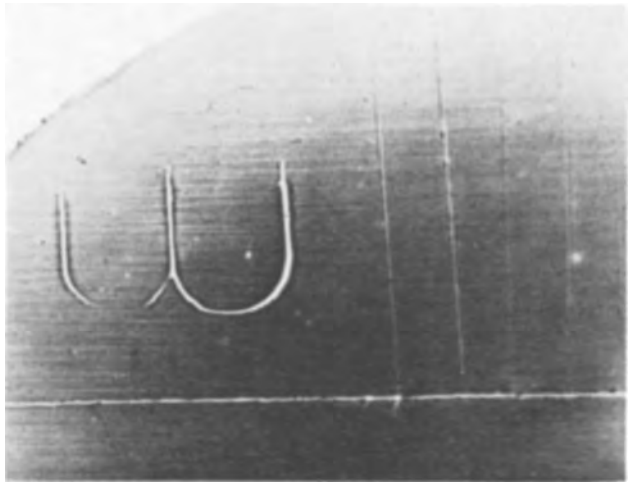

Fig. 2. Autoradiograph (5X before reduction for publication) of nickel plated on disk G which had parallel scratches in one direction. Center line average roughness of fine scratches 1.17 μ.

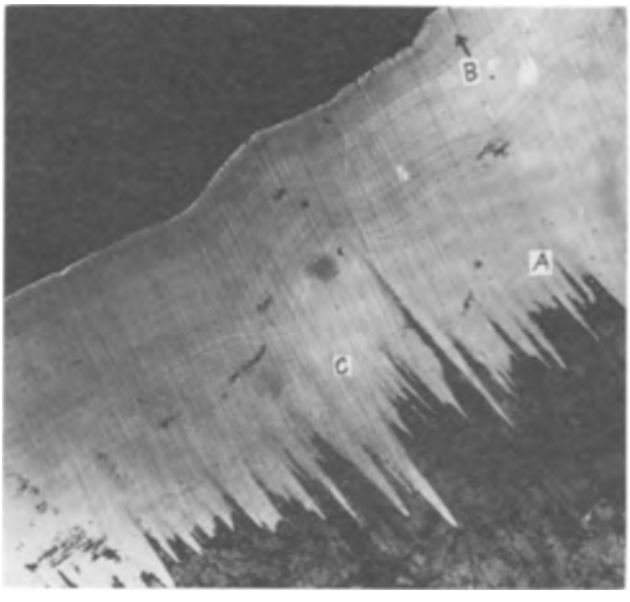

Fig. 3. Micrograph (150X over-all before reduction for publication) of a 5° taper section through nickel plated on a rough surface.

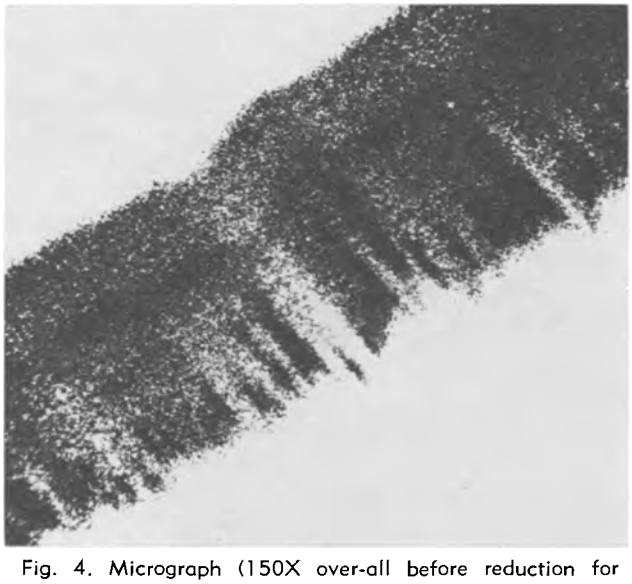

Fig. 4. Micrograph (150X over-all before reduction for publication) taken from an autoradiograph of the taper section shown in Fig. 3.

The taper section was cut from disk K which was plated at an apparent current density of 3.97 amp/dm^2 and its activity corresponded to an incorporation of 44 atoms S/10^3 atoms Ni, in agreement with earlier results (Table II). Figure 3 shows a micrograph of a taper section from disk K, and Fig. 4 is a micrograph at the same magnification taken from an autoradiograph of the section. In Fig. 3 and 4, sectioning at 5° increases the magnification perpendicular to the plane of the plating approximately eleven times. Figure 5 shows the principal features of part of the profile shown in Fig. 3 from which the extra magnification perpendicular to the plane of plating has been removed.

Discussion

Incorporation of sulfur–effect of current density.— The autoradiographs of the Hull cell cathodes show that considerable amounts of sulfur activity are associated with the nickel plated surface, and the cathode plated in the agitated bath shows clearly that the most active areas are those where the current density is lowest. A similar variation of incorporation with current density occurs on the cathode plated in the unagitated bath. High sulfur activity on plated specimens might arise from a uniform thin layer of sulfur-rich metal deposited in the initial stages of plating, which is subsequently covered by nickel containing less sulfur. Then, since the plating is thinner in regions of lower current density, less sulfur β-radiation would be absorbed in these regions, and they would appear to be regions of higher sulfur activity. This possibility was eliminated by plating another Hull cell cathode for 1 min, with the result that very little activity was found on the plate.

Errors in the measurement of the count rate, the volume of stock solution of S^{35} thiourea, and the weight of inactive thiourea added to the bath will introduce errors in the relative values of the sulfur/nickel atom ratios, Table II column 6. These errors are probably less than 10%. The radiochemical

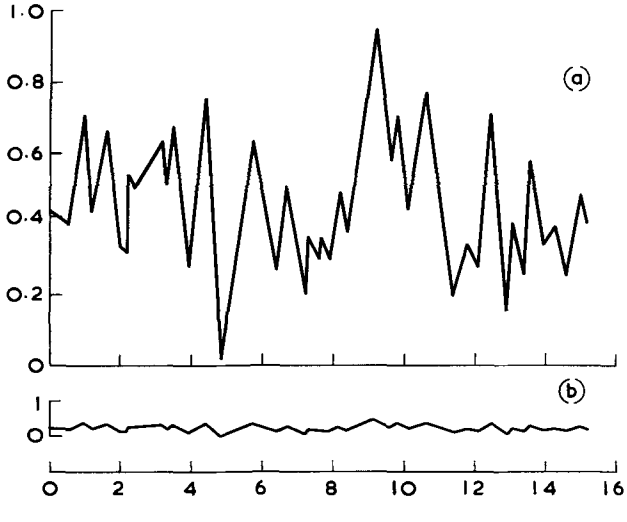

Fig. 5. Scale diagrams of the profile of the surface before plating (a) as seen in the taper section (b) when the additional 11X magnification introduced by the 5° angle of sectioning has been removed. 1 unit = 28 μ.

analysis gives results for a small area at the center of each disk. The plating thickness and therefore the current density decrease from the edge toward the center of a disk, and autoradiographs of the disks show more activity toward their centers. All the results reported in this paper show that incorporation of sulfur varies with current density so differences in current density distribution between disks can affect the relative values of the S/Ni ratios determined at the centers of the disks. The variations in plating thickness, Table II, show that there are appreciable differences in current density distribution between disks, and these differences will introduce errors in the relative values of the S/Ni ratios. The results on the Hull cell cathodes, Fig. 1, show that the amount of incorporation depends on agitation. The conditions of agitation for plating the disks were standardized as far as possible, but differences in agitation between different disks will also introduce errors in the relative values of the S/Ni ratios. It is difficult to assess the total error in the relative values of the S/Ni ratios introduced by differences in current density distribution and agitation, but the error is unlikely to be comparable with the differences in the ratios found for the disks, Table II. Therefore a comparison of the S/Ni ratios provides further qualitative evidence that incorporation of sulfur increases with decreasing current density.

The Hull cell cathodes show that incorporation varies greatly with agitation. Therefore the absolute magnitude of a S/Ni ratio is appropriate only to the particular plating conditions used for the disks.

The results for the incorporation of sulfur from sulfate are less accurate because of the much smaller quantities of sulfur involved.

The S/Ni ratios obtained from the disks show an increase in incorporation with decreasing current density, and autoradiographs of the disks show more activity toward their centers where the thickness of plating shows that the current density was lower than near the edges.

Since in all experiments incorporation was measured by the sulfur^{35} activity, no conclusions may be drawn concerning the chemical form in which sulfur is incorporated.

The deposit on the Hull cell cathode plated in the unagitated bath was much less bright and the general level of incorporation of sulfur much lower than on the cathode plated in the agitated bath. This suggests that brightening and incorporation may both be strongly controlled by the diffusion of thiourea through the solution boundary layer at the metal-solution interface.

Th results obtained using plating solutions containing labeled sulfate anions but no thiourea show that the incorporation of sulfur from sulfate is very much less than from thiourea.

Distribution of incorporation on a rough surface.— The nickel plating on disks G and H showed that thiourea was acting as a brightener and leveler. The scratches on disk G were not completely leveled by the plating, and the corresponding autoradiograph, Fig. 2, shows that, under these conditions, the incorporation of sulfur does not occur uniformly. The finer scratches on disk H were leveled completely, and the incorporation of sulfur showed no fine structure. This suggests that the incorporation depends on the surface profile and is higher either on the peaks or in the valleys. Now leveling requires the time averaged current density to be lower on the peaks than in the valleys, and a comparison of the micrograph and autoradiograph of the taper section (Fig. 3 and 4) shows that incorporation is much higher on the peaks than in the valleys. Therefore high incorporation is again associated with low current density. The dark "tails" to the peaks which show in the micrograph, Fig. 3, may result from the high incorporation of sulfur at these points.

As plating proceeds, the incorporation on peaks becomes weaker and is replaced by a more uniform incorporation which may be layered parallel to the plane of the plating.

Figure 4 suggests a layer of high incorporation immediately above the incorporation on the peaks and one, or possibly two, faint layers above it which appear more clearly when the autoradiograph is examined at a lower magnification. The depth of nickel perpendicular to the autoradiographed surface of the taper section increases linearly from zero at the outside edge of the section to a maximum of ca. 30 μ at the brass-nickel interface. Since the maximum range of S^{35} β-particles in nickel is 35 μ the intensity of radiation per unit area of this surface, and hence the photographic density would decrease monotonically across the autoradiograph of the section for a uniform distribution of sulfur in the plating. Therefore the dark bands which are apparent in the autoradiograph suggest that there are layers of higher sulfur incorporation in the plating. No incorporation of sulfur occurs in the initial filling of the valleys, and at C, where the outside profile of the plating shows that the two large valleys have not been completely leveled, incorporation is lower than at points where leveling is complete. Considerable incorporation of sulfur, showing some layering, occurs in the banded region of the plating. Although the resolution of the autoradiograph is not sufficient in general to show a detailed correlation between incorporation and the banding shown in the micrograph, the three short dark bands at A appear as regions of higher incorporation. At B, curvatures of successive bands and the outside profile of the plating show that local deleveling occurred a short time before the plating was stopped. There is a suggestion in the autoradiograph that the onset of deleveling may have been associated with a local reduction of incorporation.

The results and autoradiographs discussed above show that considerable incorporation of sulfur occurs when nickel is electrodeposited in the presence of thiourea, and that the incorporation increases with decreasing current density in systems where the current density distribution is determined either by the external electrical circuit, or the geometry of the system, as in the Hull cell, or the behavior of thiourea on a rough surface.

When the nickel is deposited on a surface having a roughness comparable to that encountered technologically, the incorporation occurs on the peaks of

the surface, in agreement with Beacom and Riley (1) whose results were obtained on a much larger scale of surface roughness. The layering of incorporated sulfur in regions of the plating where the micrograph shows a laminar structure supports the suggestion by Vanderkooi (3) that layering of the deposit may be associated with the incorporation of additive or compounds derived from it.

(Zn,Hg)S and (Zn,Cd,Hg)S Electroluminescent Phosphors

A. Wachtel

Research Department, Westinghouse Electric Corporation, Bloomfield, New Jersey

ABSTRACT

Solid solutions of (Zn,Hg)S prepared by firing in sealed silica tubes are cubic in structure. With suitable additions of Cu and a coactivator, photoluminescence and electroluminescence are obtained. The coactivators used were halides, Ga, or In. The electroluminescence in the red consists of two emission bands which do not appear to be analogous to the blue and green emission bands of Cu, Cl in ZnS. The quantum efficiency is of the same order of magnitude as that of ZnS:Cu, Cl, but the emission bandwidth is about twice as large and the red electroluminescence consists of emission located to a large extent in the infrared. HgS tends to retain the cubic structure of ternary (Zn, Cd, Hg)S systems provided that the Cd/Hg ratio does not exceed certain limits; until this is so, the introduction of Cd causes increased electroluminescence.

Efforts to prepare EL[1] phosphors emitting at longer wave lengths are usually based on substitution of lattice constituents so as to effect lattice expansion. In ZnS:Cu EL phosphors of Se for S has been investigated by Prener (1) and by Hegyi, Larach, and Shrader (2). Zn(S, Se) and ZnSe constitute good EL phosphors, although the frequency dependence of ZnSe:Cu is large compared to that of ZnS:Cu, so that the low-frequency response is unusually poor.

On the other hand, substitution of Cd for Zn has been shown to result in hexagonal systems with exceptionally poor EL response (3). It is therefore obvious that the effect of substitution of Zn by the next heavier member of the group IIB elements, namely Hg, was of interest. Due to the low sublimation temperature of HgS, its retention in ordinary firing at atmospheric pressure is known to be impossible at temperatures sufficient to cause activator incorporation. Wesch (4) has described a high-pressure furnace by means of which the preparation of pure HgS phosphors was mentioned. Kremheller and Levine (5) prepared (Zn, Hg)S and (Cd, Hg)S solid solutions by aqueous recrystallization under pressure and at temperatures well above the normal boiling point of water, and in a recent publication Kremheller, Levine, and Gashurov (6) describe some of the photoluminescent properties of activated (Zn, Hg)S and (Cd, Hg)S prepared by this method. In the present investigation, the mixed sulfides were prepared by firing in evacuated and sealed silica tubes. Although the pressure developed in the tubes is unknown, the application of hydrostatic pressure from the outside was not found to be necessary.

[1] Electroluminescence or electroluminescent is hereafter abbreviated EL.

Experimental Technique

In addition to the raw materials already described (3), HgS, Ga_2S_3, and In_2S_3 were used. HgS was prepared by reaction of the elements. Ga_2S_3 was prepared by slurrying ZnS with $Ga(NO_3)_3$ solution, drying, and firing in an atmosphere of H_2S. In_2S_3 was precipitated from aqueous solution in the presence of a ZnS carrier, filtered, and dried.

In order to avoid the development of excessive pressure in the sealed tubes, as well as to avoid the influence of gases not normally retained in firings at atmospheric pressure, it was necessary to accomplish complete thermal degassing and decomposition of volatile matter (NH_4-salts, acetate radical) prior to sealing the final mixture into the tubes. All firings were therefore conducted in two stages:

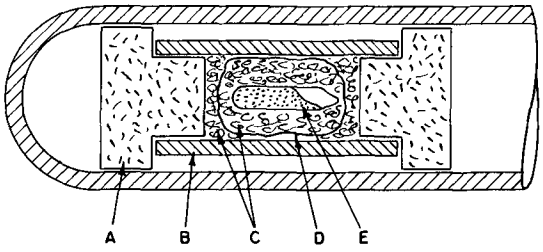

Fig. 1. Technique for firing phosphors with HgS. A, Fire brick; B, mullite tube; C, silica wool; D, silica cloth; E, firing tube.

1. A normal blue or green emitting ZnS:Cu EL phosphor is prepared at atmospheric pressure by known methods (3). The Cu-acetate and NH_4-halides (if any) decompose, and activator incorporation takes place. Traces of H_2O and air are expelled and particle growth of the ZnS facilitates subsequent degassing. The fired phosphor is, however, not washed in NaCN solution since the total amount of Cu added (now partially present as free Cu_2S) is required for the final synthesis of the mixed (Zn, Hg)S EL system.

2. The above product, hereafter referred to as the singly fired phosphor, is mixed with HgS as well as a small amount of S calculated to produce only a few atmospheres of pressure at the subsequent firing. This sulfur addition is necessary since traces of residual air would cause oxidation of S^{2-} and give rise to S-vacancies[2] and poor EL performance of the finished product. The mixture is transferred to a silica tube of 7 mm ID, 9 mm OD, and 40 mm length, closed at one end and provided with a constricted neck at the other end. The tube is evacuated by means of a mechanical oil pump for about 30 min and then sealed at the constriction. The sealed tube is fired at 900°C as shown in Fig. 1.

The thermal insulation afforded by the silica wool packing, as shown in the figure, is necessary to prevent separation of part of the HgS during cooling. The presence of CdS greatly diminishes this effect, and still more homogeneous products may be obtained by allowing the entire assembly to cool in the furnace, although this was rarely done because of obvious considerations of time limitation. Refiring times of 2 hr were found to be sufficient.

The washing procedure in NaCN solution is the same as used for normal green-emitting ZnS:Cu EL phosphors. Because of the small samples (about 2 g) usually prepared, simple grinding in a mortar and pestle was preferred. All figures for Cu and halide in phosphors specifically refer to amounts added before firing, and not to final compositions.

Measurements were performed with a Spectra Brightness Spot Meter,[3] using a demountable castor oil cell. In order to meet the contract requirements as to color, additional measurements were also taken with a red (NBS #3215) filter inserted in the optical path. The ratio between the respective readings served as a sensitive indication of emission color, and it was noted that small differences in this ratio caused large differences in brightness. To enable a valid interpretation of the relative performance of phosphors emitting with different colors, it was therefore necessary to compensate for this effect. The method used consisted of preparing phosphors that differed only in base lattice composition and plotting their relative brightness (based on 100% for the specified color) as a function of the filter ratio. Data on experimental phosphors could then be corrected to yield values hereafter referred to as "normalized brightness."

[2] In the presence of HgS, such reducing conditions result in the formation of metallic Hg, visible as a separate phase.

Results

Photoluminescence of (Zn:Hg)S phosphors.—Some basic information was obtained by firing photoluminescent ZnS:Cu (0.01%):NaCl phosphors with increasing additions of HgS at 750°C. Table 1 shows the unit cell dimensions obtained by x-ray powder diffraction. All phosphors (up to 80% HgS) were cubic, although the HgS used was hexagonal. HgS alone similarly fired was also hexagonal. The values can be plotted to give a reasonably good fit to a straight line. Figure 2 shows the emission spectra (3650Å excitation) as obtained on a Perkin-Elmer Universal Spectrometer. Figure 3 shows the diffuse reflection spectra in the near ultraviolet and visible regions obtained by illuminating through a Farrand monochromator and measuring the reflected radiation with a Bausch and Lomb monochromator adjusted to the same wave lengths. It may be noted that the regular manner in which the spectra shift to longer wave lengths is very similar to the effect of Cd substitution. The shift in emission caused by Hg is about four times greater than that caused by similar concentrations (in mole %) of Cd. It was noted that at low Hg concentration (5 mole %) the fluorescence was unusually weak.

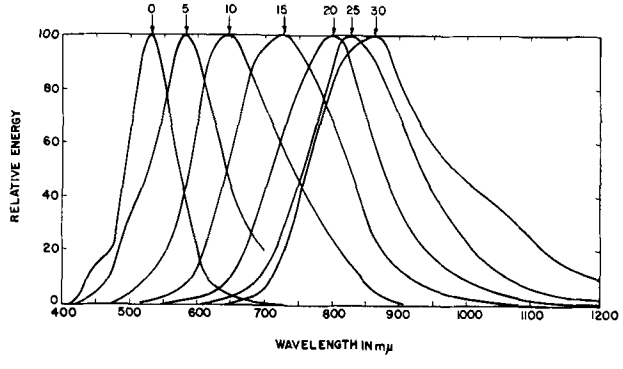

Fig. 2. Emission spectra of (Zn, Hg)S:Cu, NaCl phosphors. Numbers denote mole % HgS in phosphors. Excitation = 3650Å.

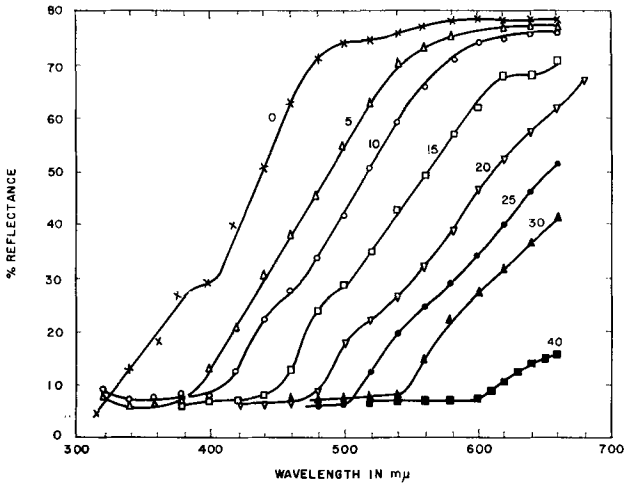

Fig. 3. Diffuse reflection spectra of (Zn, Hg)S:Cu, NaCl phosphors. Numbers denote mole % HgS in phosphors.

The decreasing concentrations of Cu and Cl resulting from increasing additions of HgS were not considered to appreciably influence the shape of the emission and reflection spectra, because Cl was present in excess and only the long wave-length emission band was developed.

Electroluminescent phosphors.—The activator requirements for EL are known to be greater than for photoluminescence. For the systems under investigation, they were also noted to vary with the type of coactivator used. In the case of Cl, additions of the order such as to produce optimum green-emitting singly fired ZnS:Cu, Cl phosphors proved to be too high not only for Cl, but also for Cu. Figure 4 shows the emission spectra of a series of (Zn, Hg)S:Cu(0.2%), Cl(0.075%) phosphors excited at 10,000 cps. The activator additions are such that the ZnS:Cu, Cl phosphor emits predominantly the blue Cu band and are optimum with respect to the orange or red emitting compositions. The emission band gradually shifts to longer wave lengths and broadens until above about 20 mole % Hg, a long wave length emission band increases quite suddenly in relative intensity. It will be shown that this cannot necessarily be identified with the "Cu-green" band emitted in more highly coactivate ZnS-Cu phosphors.

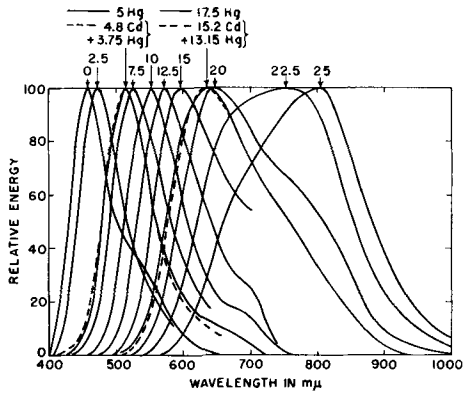

Fig. 4. Emission spectra of (Zn, Hg)S:Cu (0.2%): Cl(0.075%) and two (Zn, Cd, Hg)S:Cu (0.2%:Cl (0.075%) EL phosphors. Numbers denote mole % HgS in samples. Excitation = 10,000 cps.

The effect of Cd on the emission color was determined empirically for orange to deep red emitting (Zn, Hg)S. It was noted that the emission color of [(1 − x)Zn, xHg] S:Cu may be duplicated approximately by firing [(1 − 4n)Zn, 4nCd] S:Cu and refiring this with (x − n)HgS. However, substitutions of more than half of the original concentration of Hg by Cd result in a shift to longer wave lengths. Table II shows the effect on EL brightness of a series of orange-red emitting phosphors based on the original composition (0.8Zn, 0.2Hg)S:Cu (0.2%):Cl(0.075%). The table includes brightness readings of NaCN-washed aliquots of the singly fired (Zn, Cd)S:Cu, Cl phosphors. It also shows measurements by x-ray powder diffraction, so as to illustrate how in both cases the breakpoint in brightness coincides with the appearance of an appreciable percentage of hexagonal phase. These measurements also include values of interlattice spacings (d/n) of the 311 plane. Very similar results are shown in Fig. 5 on deep red emitting phosphors coactivated with Br + I or Ga and excited at 400 cps. This is in agreement with the observation made by Zalm (7), than in ZnS:Cu EL phosphors the cubic phase is preferable.

It can be seen that in all cases Cd increases the emittance of the system until interference by formation of hexagonal material occurs. It can also be

seen that in the presence of HgS a much higher concentration of Cd is permissible before this occurs. The optimum substitution of Hg by Cd appears to be in the neighborhood of 20-25% of the original Hg concentration. Most of the ensuing investigations were therefore performed on such (Zn, Cd, Hg)S:Cu phosphors. The two dashed curves in Fig. 4 represent the emission spectra of (Zn, Cd, Hg)S:Cu, Cl phosphors in which 25% of the Hg was replaced by Cd in the manner outlined above. The compositions are based on original Hg concentrations of 5 mole % (green emission) and 15 mole % (orange emission) and are seen to coincide closely with the emission spectra of the respective (Zn, Hg)S:Cu, Cl phosphors, but the brightness was appreciably higher.

It has been mentioned that optimum additions of Cu and Cl were smaller than those found useful in green-emitting ZnS:Cu, Cl phosphors(3). It was therefore interesting to note that the optimum addition of Br + I [4] was higher, namely similar to that for ZnS:Cu phosphors, although the estimated excess Cu_2S concentration still had to remain smaller than about 0.2 mole %. Such Br + I coactivated phosphors were about two to three times brighter than Cl-coactivated phosphors. In the case of Ga or In coactivation, phosphors were prepared with additions of Cu equal to 0.6 mole % more than the concentration of Ga or In added. Their normalized brightness, excited at 400 cps, increased linearly with coactivator concentration up to 0.125 mole % and then decreased. On the other hand, phosphors coactivated with 0.125 mole % Ga or In showed two brightness maxima with respect to Cu addition, as shown in Fig. 6. It can be seen that the first maximum is very sharp and more pronounced in the case of In coactivation. Prefiring at 1100°C [5] decreases the low Cu maximum. Ga-coactivated phosphors prefired at 1100°C show only a gradual increase in brightness, leveling off at about 1 mole % Cu.

Figure 7 shows the brightness of Br + I and of Ga coactivated (Zn, Cd, Hg)S:Cu phosphors as a function of Cd + Hg concentration. The activator concentrations are not optimized for either system but chosen so that the total Cu addition as well as the green emission color of the ZnS:Cu phosphors are the same. It is interesting to note that in the case of Br + I coactivation there occurs the same initial drop in output at low Hg concentrations as has been observed in the photoluminescent as well as the Cl-coactivated EL phosphors, while, on the other hand, the Ga-coactivated ZnS:Cu is characterized by comparatively poor output, presumably because of the greater trap depth caused by Ga (8, 9). Introduction of Cd + Hg [6] causes an increase in brightness well beyond the point of maximum luminosity (yellow green). This means that, except for the initial drop noted with halide coactivation, the radiant output of the phosphors increases at least up to the point of maximum observed brightness and possibly beyond that. In the case of Ga-coactivation, this might be explained by decreasing trap depth due to lowering of the conduction band, assuming that a similar effect occurs as noted by Klasens for Cd substitution (10). Unfortunately, the

[4] Equimolar mixtures of NH_4Br and NH_4I yielded slightly better results than NH_4Br alone. However, only a very small fraction of the added I^- is retained, so that additions were based on Br^- alone.

[5] To compensate for decreased particle growth in the absence of halides.

[6] The same relationship was noted in the absence of Cd.

scope of the present investigation did not permit independent measurements of radiance (such as by thermopile) or glow curves for these samples.

An indication of decreasing trap depth with increasing Cd + Hg concentration was noted, however, by visual observation of thermoluminescence. Similarly, a comparison of the frequency dependence of typical red-emitting phosphors as shown in Fig. 8 indicates decreased output of Ga and In coactivated phosphors at frequencies where no such decrease is evident with halide coactivated phosphors. It should be mentioned that at the red end of the spectrum, the usual variation in emission color with frequency represents variations in brightness which may be more pronounced than in the case of green-emitting phosphors, and that this effect therefore increases the slope of the frequency dependence curves. The phosphors were selected so that at intermediate frequencies their emission color approximately matches that of the ZnSe:Cu phosphor also shown in Fig. 8 for comparison. Therefore they do not necessarily represent specimens suitable for comparison of brightness as a result of optimum conditions of preparation.

It was of obvious interest to determine the actual quantum yield and efficiency of the red phosphor in comparison to a standard green-emitting ZnS:Cu, Cl EL phosphor. The following samples were selected for this purpose:

1. (0.754Zn, 0.133Cd, 0.113Hg)S:Cu, Ga prepared from (0.85Zn, 0.15Cd)S:Cu(0.9%), Ga (0.13%) by refiring with 11.25% HgS. Emission color, red.
2. (0.6945Zn, 0.163Cd, 0.1425Hg)S:Cu, Ga prepared from (0.81Zn, 0.19Cd)S:Cu(0.9%), Ga (0.13%) by refiring with 14.25% HgS. Emission color, deep red.
3. A normal ZnS:Cu, Cl green emitting phosphor.

Each phosphor was operated at 400 cps in the same castor oil cell and the brightness and power consumption measured as a function of applied voltage. In addition, each phosphor while in the same cell was operated at 400 cps and 600 v and the spectral distribution determined, using the same slit width and amplification of the spectrometer. The absolute heights of the resultant curves were therefore comparable. These were corrected for energy, quanta, and luminosity, but not normalized to equal peak heights. Table III gives the integrated values. It is apparent that under similar conditions of excitation the output in energy or quanta for the red phosphors is considerably smaller than for the green phosphor. Nevertheless, the differences in luminosity are much greater and are the main reason for the low brightness presently obtainable with the red-emitting phosphor.

The actual quantum yield was determined according to[7]

$$K = \frac{B\,A\,Q \times 10^{17}}{1.26L}$$

where K is the number of quanta emitted per second, A is the area of the cell in cm², Q is the integrated quantum output, L is the luminosity factor of the spectrum, and B is the brightness in foot-lamberts. Table IV shows the data calculated for each phosphor operating at the voltage where maximum luminous efficiency was observed. It can be seen that the quantum efficiency of the red-emitting phosphor is comparable to that of ZnS:Cu, Cl.

Efforts to increase the brightness without change in emission color appeared to require a narrowing of the spectral distribution with particular emphasis on increasing its slope on the short wave length side. It is well known that in ZnS:Cu phosphors either the blue or the green emission band can be

[7] Let the number of quanta emitted/cm²-sec $= K = \int \frac{C}{h\nu}\cdot\frac{dE}{d\lambda}\,d\lambda$, where C is a constant introduced to correct the arbitrary units in which the spectrum is measured to watts/cm². Then,

$$K = \frac{C}{hc}\int \lambda \frac{dE}{d\lambda}\,d\lambda = \frac{C\,Q}{hc}$$

The constant C may be determined from the measured brightness B (in foot-lamberts) and the spectral distribution as follows:

$$B(\text{ft-L}) = \frac{680\ \text{lpw}}{A\ (\text{ft}^2)}\int Cy\frac{dE}{d\lambda}d\lambda = \frac{680\times 929C}{A\ (\text{cm}^2)}\int y\frac{dE}{d\lambda}d\lambda = \frac{680\times 929CL}{A}$$

Therefore,

$$C = \frac{AB}{680\times 929L}$$

Since $hc = 1.99 \times 10^{-16}$ erg $= 1.99 \times 10^{-23}$ watt-sec,

$$\frac{Q}{1.99\times 10^{-23}}\cdot\frac{AB}{680\times 929L} = \frac{B\,A\,Q\times 10^{17}}{1.26L}$$

isolated by employing very low or sufficiently high ratios of coactivator to activator. If the broad spectral distribution of the red-emitting phosphors is the result of superimposed emission bands shifted to longer wave lengths but arising from the same centers, then similar variations in activator proportions should also influence the spectral distribution of the red-emitting phosphor in the same manner. Figure 9 shows, however, that this was not observed. The phosphors represented in the figure were prepared in an effort to maintain approximately the same emission color as measured by means of the filter ratio discussed above. This was reasonably successful but required that with increasing coactivator addition, the concentration of Cd+Hg had to be lowered. Nevertheless, the short wave-length emission band increases with such decreasing Cd+Hg concentration and is quite pronounced at a high coactivator concentration such as to result in only the green-emission band in ZnS:Cu phosphors. The increased brightness obtained at higher Br+I addition may now be explained at least partially by the increased slope of the short wave-length side of the emission spectrum.

Discussion

Perhaps the most important question concerning this study is why substitution of Zn by Hg results in good EL at emission colors similar to the photoluminescence emission colors of the respective phosphors, while substitution of Zn by Cd does not. For (Zn, Cd, Hg)S phosphors with a sufficiently high ratio of Cd/Hg so as to effect a decrease in EL, no evidence of a separate (Cu, Cd)S phase (3) could be observed. Therefore, the only clue in this direction is offered by the difference in crystal structure of the two systems.

It has been noted that hexagonal and cubic ZnS:Cu, Cl phosphors prepared with low Cu concentration (such as 0.01 mole %) perform about

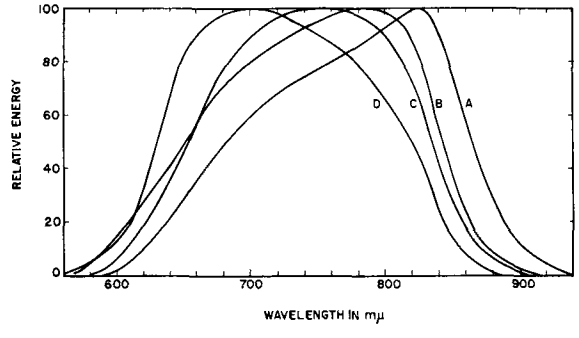

Fig. 9. Emission spectra of (Zn, Cd, Hg)S:Cu phosphors as o function of composition. Excitation = 400 cps. (A), 20.3% Cd, 18.7% Hg, 0.01% Br + 0.01% I; (B), 15.9% Cd, 13.8% Hg, 0.1% Br + 0.1% I; (C), 14.8% Cd, 11.1% Hg, 0.3% Br + 0.3% I; (D), 11.1% Cd, 9.3% Hg, 0.7% Br + 0.7% I.

equally well under artificially induced contact-EL (11). It must therefore be concluded that the better EL performance of cubic (Zn, Hg)S or cubic (Zn, Cd, Hg)S, as compared to the poorer performance of hexagonal (Zn, Cd)S or (Zn, Cd, Hg)S phosphors, results from differences in the means of EL excitation only. In the former case, the field intensifying Cu_2S inclusions are present and active. If in the latter case they are also present, then they are not active, possibly as a result of the different electrical nature of the barrier represented by the nonisomorphic junctions.

The sharp minimum in EL noted at low concentration of Hg is accompanied by a similar minimum of photoluminescence. At present, its appearance can not be explained. Inspection of Fig. 3 shows, however, that the weakly emitting (0.95 Zn, 0.05 Hg)S:Cu, Cl phosphor lacks the secondary hump in reflectivity near the absorption edge. According to an investigation by Froelich (12) the introduction of small amounts of Cu causes just such a hump in the diffuse reflection spectrum of ZnS. This suggests the possibility that at such critically low concentration of Hg, the incorporation of Cu is somehow hindered.

The identity of the long wave-length emission band is questionable since it is favored not by high coactivator concentration (as in ZnS:Cu) but by high Hg concentrations. Bowers and Melamed (13) proposed that the blue emission in ZnS:Cu, Cl may be identified with the "self-activated" blue caused by Zn-vacancies. It now appears that introduction of a sufficient concentration of Hg results in increasing probability that the vacancy becomes a Hg-vacancy. The decreased population of Zn-vacancies would result in the disappearance of the short wave-length band in favor of a different emission band as shown to occur quite abruptly in Fig. 4 and 9. Figure 2 shows that there is also slight evidence that a similar phenomenon occurs with low-Cu photoluminescent phosphors which are sufficiently coactivated so as to give rise to predominantly green (long wave-length band) emission in ZnS.

According to this mechanism, a similar phenomenon should occur on substitution of Zn by Cd. This, however, has not been reported. Instead, Van Gool (14) noted the opposite, namely, a relative increase in the short wave-length emission band of (Zn, Cd)S:Ag phosphors occurring with increasing Cd concentration. These measurements, however, were taken at 77°K while, with increasing temperature, the short wave-length emission band was more rapidly quenched. It is therefore also possible that the increase of relative intensity of the long wavelength emission band with increasing concentration of Hg is caused by increasing thermal quenching of

the short wave-length emission band. The characteristics of the two emission bands in red-emitting (Zn, Hg)S:Cu phosphors are such that at present, no definite conclusions can be drawn as to their origin.

Summary

Introduction of Hg into ZnS:Cu phosphors causes a shift in emission to longer wave lengths which, for moderate substitutions, is about four times as high as that caused by similar molar concentrations of Cd. At sufficient activator concentrations, EL is observed. For compositions emitting in the red end of the spectrum, the quantum efficiency of the EL was found to be of the same order of magnitude as that of green-emitting ZnS:Cu, Cl. This is attributed to the cubic modification of the system, as favored by the presence of HgS, even in ternary (Zn, Cd, Hg)S composition whose concentration of Cd would, in the absence of Hg, result in hexagonal and non-EL systems.

Procedures for the preparation of (Zn, Hg)S and (Zn, Cd, Hg)S EL phosphors have been described. All procedures involve firings with HgS in sealed tubes, using only prefired raw materials. Especially for low-frequency excitation, the substitution of Hg for Zn enables the use of Ga or In as coactivators, presumably due to a decrease in trap depth caused by lowering of the conduction band. For phosphors emitting in the red end of the spectrum, the relative heights of the two emission bands are primarily dependent on Hg concentration. Their identity cannot necessarily be assumed in terms of an analogy with the blue- and green-emission bands in ZnS:Cu phosphors.

From a practical point of view, the (Zn, Hg)S:Cu and (Zn Cd, Hg)S:Cu EL phosphors are preferable to the ZnSe:Cu EL phosphors, mainly because of their better response at low frequencies of excitation, the extent of which can be estimated roughly from Fig. 8. At higher HgS concentrations, EL emission occurring entirely in the infrared has been obtained; the writer does not know to what extent this can be accomplished with (Zn, Cd)Se:Cu EL phosphors. A serious disadvantage is, however, the high volatility of HgS which necessitates special techniques of phosphor preparation.

Acknowledgments

The writer wishes to thank Miss I. Walinski for preparation and brightness measurements of the phosphors, Mr. I. Meister for determinations of spectral distributions, Dr. C. K. Lui-Wei for x-ray diffraction measurements, and Dr. W. Lehmann for determinations of luminous efficiencies. Thanks are also due to Dr. H. F. Ivey for reading and suggesting improvements of the original manuscript.

Manuscript received March 11, 1960. This paper was prepared for delivery before the Chicago Meeting, May 1-5, 1960. This work was supported by Contract AF33(616)-5811 from the Wright Air Development Center.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

Crater Resistance of Submerged Arc Smelting Furnaces Simulated by a Simple Model

Oluf Chr. Bockman

Elektrokemisk A/S, Oslo, Norway

ABSTRACT

An electrolytic trough technique has been used to study the effect of size and shape of the smelting crater on the ohmic resistance of the crater of submerged arc smelting furnaces. The ohm-inch rule is demonstrated, and the correct use of this rule is discussed.

In designing submerged arc smelting furnaces, the anticipated ohmic crater resistance of the projected furnace is the key to the specification of the electrical circuit. Naturally, many workers have devoted themselves to the study of this problem. In 1933, Andrea pointed (1) out that the product of electrode diameter D and crater resistance R of electric smelting furnaces is fairly independent of furnace size. He defined a "peripheral ohm inch factor" r by

$$r = \pi DR \qquad [1]$$

Values of r for different smelting processes have been given by Udy [2] and by Kelly [3]. This factor has proved useful for calculating operating data in designing new furnaces and in scaling up results obtained by pilot tests.

Andrea apparently arrived at this rule empirically. He referred the crater resistance to the electrode periphery by introducing π in Eq. [1], presumably assuming that 1 in. of electrode periphery makes the same contribution to the conductance of the crater in small as well as in large furnaces.

Recently Morkramer (4) derived Eq. [1] by making the following simplifications. The current radiates hemispherically from the tip of the electrode; the charge has a uniform electrical resistivity; the distance from the tip of the electrode to the furnace bottom is very large. On making these assumptions, he demonstrates the r of Eq. [1] actually is the electrical resistivity of the charge.

The simplifications made by Morkramer are drastic. Equation [1] may, however, be derived by making quite a few much more realistic assumptions. This derivation is based on dimensional analysis as applied in the theory of models. Such a derivation may be of value in pointing out the limitations of Eq. [1].

Dimensional Analysis

The conditions prevailing in the smelting zone of an electric furnace are very complex. Actually, the physical properties of the zone and the variation of these properties within the zone are but little known. Probably, temperature and electrical resistivity vary within wide limits. Any calculation of crater resistance by classical methods therefore is bound to fail.

If it is assumed, however, that differently sized furnaces working on the same raw materials form geometrically and electrically similar systems, the theory of models may be used. These assumptions imply that the smelting craters of the furnaces compared have the same shape and the same size relative to electrode diameter and that corresponding points in the two furnaces show the same electric resistivity. Since electric resistivity depends on temperature and composition, corresponding points must also agree in these respects.

The electric current, on passing from the electrode to the charge, may form arcs. Even in submerged arc smelting furnaces the arcs may consume a part of the tip to hearth voltage. The arcs do not obey Ohm's law, the voltage varying in a complex manner which it is difficult to include in the dimensional analysis. The present derivation, therefore, is restricted to the cases where arcing is insignificant. It must also be assumed that the contact resistance between electrode and the charge is negligible. By the passage of the electric current through the charge, Ohm's law may safely be considered valid.

On these assumptions the ohmic voltage drop from the tip of the electrode to the furnace bottom may in principle be found by integrating along a current path according to

$$E = \int \rho i ds$$

where ρ is electric resistivity and i is current density at the increment ds of the path. The variation of ρ and i along the path is however not known. Similarly the electrode current may be found by integrating over any equipotential surface

$$J = \int i dA$$

where i is current density at the surface increment dA. The ohmic crater resistance then is

$$R = E/J = (\int \rho i ds)/(\int i dA)$$

On increasing the size of the system at constant electric resistivity and current density in the various parts of the system, it is seen that E increases with first power and J with second power of linear dimensions. The R therefore is inversely proportional to linear dimensions, which is the basic content of Eq. [1]. The assumption of equal current density in the two sizes of the system is not necessary, however, because E and J are affected in the same way by a change in the level of current density.

The same result may be obtained by a formal dimensional analysis. Since the systems in question are considered as geometrically similar, with corresponding points having equal electrical resistivity, the problem of the shape of the smelting zone and of the variation of resistivity within the zone drop out of the analysis. The only quantities entering the analysis, then, is ohmic crater resistance R, a representative value ρ for the electric resistivity of the charge in the smelting zone, and electrode diameter D representing the size of the system. By the theory of dimensional analysis (5) these quantities have to be arranged in dimensionless groups, which are arguments in the causal relationship. It turns out that only the group RD/ρ is formed. The relationship sought, therefore, is

$$F(RD/\rho) = 0$$

or

$$RD/\rho = \text{constant} \qquad [2]$$

which is equivalent to [1]

A different form of [2] has been reported previously (6).

$$P\rho/DE^2 = \text{constant} \qquad [3]$$

where E is ohmic voltage and P is power input. By the relation

$$E^2/P = R \qquad [4]$$

it is seen that [3] is equivalent to [2]. Solving [3] for E gives

$$E = \text{const.} \sqrt{P/D} \qquad [5]$$

Similarly, the electrode current J is found to be

$$J = \text{const.} \sqrt{PD} \qquad [6]$$

Different formulas have been proposed for relating power input to electrode diameter (1, 7, 8). Whatever relation is used, [5] and [6] are valid within the same range as [2].

Model Experiments

The validity of [2] may be demonstrated for the case of a simple model, where the smelting crater

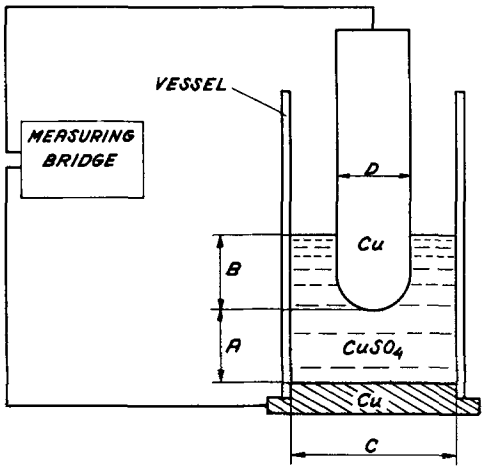

Fig. 1. Model arrangement

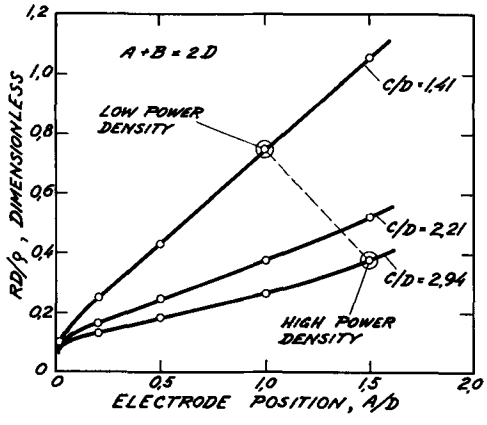

Fig. 2. Effect of electrode position and of size of smelting zone.

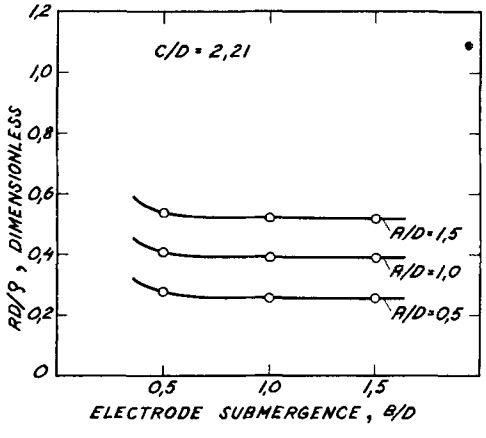

Fig. 3. Effect of electrode submergence

has been simulated by an electrolytic trough as shown in Fig. 1. Between the bottom plate and the electrode, both of copper, is filled an aqueous solution approximately 0.4M $CuSO_4$ and 0.1*N* H_2SO_4. The resistance is measured by a Philips conductivity measuring bridge PR 9500 at a frequency of 1000 cps. The system is made in two sizes, with 1 in. and 2 in. diameter of the electrode, respectively.

In Fig. 2 is shown results obtained for different values of the distance between bottom plate and electrode and for different ratios of vessel to electrode diameters, both at constant liquid level. In Fig. 3 the effect of electrode submergence into the liquid is shown. Corresponding measurements on the two sizes of the system are shown in Table I.

Table I. Values of RD/ρ for 1- and 2-in. electrodes

1.5	1.5	2.21	0.522	0.520

Discussion

The model used for simulating the smelting crater is simple and do not reflect all the complexities encountered in actual furnaces. The results, therefore, must be used with caution in interpreting actual furnace behavior. It is seen, however, that within the precision of the measurements Eq. [2] is verified for this simple system.

Within the assumptions made, however, the derivation of Eq. [2] by dimensional analysis is valid also for the complex system of actual furnaces. It is equally valid for three-phase furnaces as for the single electrode furnace simulated by the simple model, as the derivation is not restricted to any definite pattern of electric current. The basic requirement for the derivation is that the smelting zones of the furnaces compared are geometrically and electrically similar. Geometrical similarity implies equal relative electrode position and equal shape and relative size of the smelting zone. Electrical similarity implies that corresponding points of the two smelting zones have equal electric resistivity. The furnaces compared, then, will obtain identical patterns of electric current. This is a less restricting requirement than specifying any definite pattern of electric current and seems to allow a more realistic comparison of different-sized furnaces.

The general trend of measurements on the simple model agrees with everyday experience with smelting furnaces. The resistance increases when electrodes are raised. The shape of the curves on Fig. 2 may indicate the extent to which the voltage drop is concentrated at the tip of the electrode. The slopes of the straight parts of the curves of Fig. 2 correspond exactly to uniform current distribution in the cylindrical vessel. The resistance decreases with increasing diameter of the smelting zone. Most interesting, it is seen from Fig. 3 that the current is found by the model experiments to flow mainly from the very tip of the electrode to the charge. In actual furnaces, the high temperature and good electric conductivity of the smelting zone, as compared with the top of the charge, probably will make this effect still more pronounced.

The derivation of Eq. [2] assumes that the furnaces compared operate at the same relative electrode position and with the same relative size of the

smelting zone. For this to be true, the power input to the furnace must be related to electrode size in a definite manner. Actually, according to Kelly (3), the ohm-inch factor varies with the power density of the electrode. According to his data, furnaces operating at the same power density will show the same value of the ohm-inch factor. By increasing the power density, however, this factor will decrease markedly. By increasing the power input to a given furnace, however, the electrode has to be raised to maintain proper temperature of the metal pool. The size of the smelting zone will in turn increase, which more than offsets the increased distance between electrode and metal. The net result then will be a reduction in the crater resistance. These considerations are illustrated in Fig. 2 by the operating points for low and high power density of the furnace.

For the proper use of the ohm-inch factor, it is important to note that the conditions of the smelting zone may also be affected by the method of attending the furnace. The furnaces to be compared, therefore, must be charged, stoked, and tapped in the same way as far as these operations will influence the furnace performance. When the furnaces operate with substantial arcing of the electrodes, the derivation of Eq. [2] is not valid and the ohm-inch rule should be used with caution.

Most important, the resistivity of the charge depends on the nature of the raw materials used, especially on the nature of the reducing agent. The furnaces to be compared, therefore, must operate on the same raw materials, or at least on the same type of raw materials, if the ohm-inch rule shall apply.

Furnace operation practice differs widely between different works, and the raw materials quality may be highly different in different parts of the world. Two furnaces, operating the same process, picked out at random from different parts of the world most probably will not agree by the ohm-inch rule. In order to use the rule profitably, one has to see that the furnace operations agree with the assumptions underlying the rule. Most profitably the rule may be used internally within the works, when bigger furnaces have to be built, or when scaling up pilot plant results.

Acknowledgment

The author is grateful to Mr. H. Natvig and to Mr. T. Baasen for their helpful comments and discussion of the work. The experimental part has been done by Mr. B. Hogdahl.

Manuscript received Nov. 6, 1958. This paper was prepared for delivery before the Ottawa Meeting, Sept. 28-Oct. 2, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

Graphite Anodes in Brine Electrolysis

IV. Effect of Anolyte pH on Corrosion Rate in Chlor-Alkali Cells

L. E. Vaaler

Research Laboratories, National Carbon Company, Division of Union Carbide Corporation, Cleveland, Ohio

ABSTRACT

The effect of anolyte *p*H on cell efficiency and anode corrosion rate was studied in an experimental chlorine cell. With increasing *p*H, the expected decrease in current efficiency was observed with a resultant increase in the amounts of oxygen and carbon dioxide evolved. The relative increase in oxygen evolution is far greater than the carbon dioxide evolution. The results can be explained by a mechanism whereby the oxygen is formed from physically adsorbed oxygen, while carbon monoxide is formed from chemisorbed oxygen and oxidized to carbon dioxide by oxygen or dissolved chlorine. The increased corrosion resistance of impregnated graphite as compared to plain graphite may be due to the fact that filling of the voids decreases the effective area to one-third of the initial value.

A study of the behavior of graphite anodes in brine electrolysis, and in particular a determination of the rate at which they corrode, requires that the *p*H of the anolyte be well defined. In some cases *p*H is well defined by close control of such conditions of electrolysis as current density, temperature, and flux of electrolyte through the cell, and need be measured only occasionally. This is often true in cells without diaphragms. Janes (1) found that *p*H in an experimental chlorate cell was reproducible

under controlled conditions of electrolysis and proper adjustment of the acidity of the feed brine.

The situation is less satisfactory with diaphragm cells. Part of the hydroxide ion formed in the catholyte leaks through the diaphragm into the anolyte, and the amount of leakage is a function of the method of preparation and age of the diaphragm. It is difficult to obtain negligible leakage or even a reproducible leakage, with the result that *p*H is not closely maintained. Johnson (2) designed a very useful chlor-alkali diaphragm cell for the laboratory, and it has been used to evaluate various anode materials for many years. However, it has some limits as to precision, and variations in *p*H from cell to cell probably have an important bearing on this. This relates back to the difficulty in preparing the wrapped asbestos diaphragms used in these cells so that reproducible properties are obtained. This problem is also present in commercial cells with deposited diaphragms.

A mercury cathode cell contains no diaphragm but may act in an analogous manner because of hydrogen discharge at the cathode. The discharge produces sodium hydroxide, and it is difficult to maintain this constant, due to the many variables affecting it.

Chlorine cells operate in the *p*H range of 3 to slightly over 4 with current efficiencies of 90% or better. The *p*H is maintained in this range by the buffering action of the anode, which on discharge of oxygen and/or carbon dioxide forms sufficient acid to neutralize sodium hydroxide leaking through the diaphragm. The rate of graphite corrosion is determined to a large extent by the formation of carbon dioxide. The cell efficiency is determined largely by the formation of carbon dioxide plus oxygen. Thus, both the corrosion rate and current efficiency are sensitive functions of the *p*H.

The excellent and comprehensive work of Foerster (3) and others in the early 1900's was, nevertheless, limited because there were no suitable methods of measuring *p*H in the desired range. Some attempts to titrate the very dilute acid in the anolyte gave only approximate answers. The work most closely allied to the present study is that of Murray and Kircher (4), who measured the effect of several variables in a commercial Hooker Cell. Chloride concentrations were not the same at the various *p*H levels tried, but an empirical correction was made to relate directly current efficiency and *p*H. However, corrosion rate and *p*H were not similarly studied and only commercial oil-impregnated graphite anodes were used. Barr (5), using existing fundamental and practical data, developed useful relationships relating cell performance to *p*H and obtained good agreement with the results of Murray and Kircher. However, no prediction could be made of corrosion rate. Okada, Yashida, and Shiragami (6) studied *p*H in a Krebs-type mercury cell under production conditions, but close control was not possible. When the *p*H deviated upward to a significant degree from a statistical average, a drop in current efficiency was noted. Lacheisserie (7) plotted his experimental data on a *p*H-potential diagram showing stability regions for chloride, chlorine, and the various chlorine-oxygen compounds. One-molar solutions were electrolyzed at ambient temperature and an anode current density of 1 ma/cm^2. Thus, conditions were far different from those in a commercial cell.

The purpose of the work reported here was to determine the behavior of three anode materials in anolytes of known *p*H. The materials were plain graphite, impregnated graphite, and platinum; *p*H values ranged from 3.0 to 4.2. The porosity of a graphite anode increases as it is corroded, and the extent of porosity can influence the results of electrolysis. To eliminate variables due to porosity, anodes were used for only a few hours during which time corrosion was slight. The corrosion rate was calculated from the composition of the anodically formed gas rather than from weight loss, since the latter was very small over the period of an experiment. Rates calculated in this manner do not take into account loss of graphite due to the formation of sludge.

Experimental

Electrolysis cell.—Figure 1 is a diagram of the experimental cell. It is of the Wheeler type, with diaphragm and wire-screen cathode in the center, and is a modification of the laboratory cell described by Johnson (2). The anolyte was contained in a 6-in. diameter x 12-in. high glass jar. A polymethylmethacrylate cover sealed the cell and held all of the electrolysis and control apparatus. This included the cathode-diaphragm assembly, two opposed anodes, a resistance heater sealed into glass, thermometer, thermistor temperature-control bead, glass and calomel electrodes, brine inlet, a funnel containing acid or alkali for *p*H control, and orifices for sampling anolyte and anodic gas. These units were pushed through rubber stoppers that fitted in turn into the cell cover. The cover was sealed to the glass jar with a fluorinated paraffin.

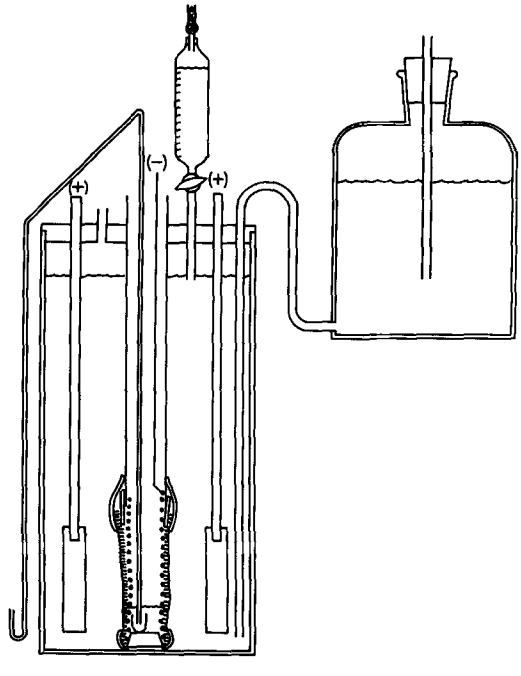

Fig. 1. Experimental chlorine cell

The cathode-diaphragm unit was assembled by partially inserting the end of a 1-in. diameter circular wire-gauze cathode into a glass tube. A rubber sleeve held the two units together and sealed the bottom of the glass tube from anolyte. A 3-in. length of the cathode projecting out of the tube was wrapped with a single layer of asbestos paper, held on with a further wrapping of permeable asbestos tape. Several turns of electrician's rubber tape held the ends of the asbestos tape in place, and a rubber stopper sealed the bottom of the cylindrical cathode. Catholyte was siphoned out of the cathode compartment through a glass tube of sufficiently small diameter to entrain gas bubbles and prevent their collection at the upper bend. A constant head was maintained in the electrolytic cell by means of the feed bottle design shown in Fig. 1.

Platinum sheet anodes 3 x 1¼-in. were bent lengthwise at right angles and positioned so that the bend projected toward the cathode. Graphite anodes were solid specimens ⅝ x ⅝ x 3-in.[1] The average current density for a cell current of 7.2 amp was 0.4 amp/in.^{2}. Independent experiments with an electrode whose front and back halves were separated by a thin strip of insulation showed that about 60% of the current is carried by the front half and 40% by the back half.

For the purpose of experiments at controlled *p*H, a simple diaphragm or partition to separate cathodic hydrogen from the anode gas may have been sufficient. However, the degree of manual control that can be obtained is much improved by use of an efficient diaphragm, since the frequency and amounts of additions that must be made are reduced. The diaphragm in the experimental cell was submerged under an anolyte head of several inches to minimize back-migration of hydroxide. In a Wheeler cell the diaphragm extends to the surface of the anolyte, at which point there is no flow of anolyte into the cathode chamber. Therefore, back migration is extensive at the anolyte surface and is most noticeable in small cells of limited depth.

Analysis.—Anode gas was collected and analyzed by a method used for production control (8). This involves absorption of chlorine and carbon dioxide into alkaline-arsenite solution and analysis of the unabsorbed gas for oxygen, carbon monoxide, hydrogen, and nitrogen in an Orsat apparatus.

A portion of the arsenite solution is acidified and carbon dioxide distilled over into 0.1*N* caustic solution. Barium chloride is added to precipitate the carbonate, and the amount of carbonate present is determined from the amount of acid needed to decompose it. Carbonate in brine was determined by the same distillation procedure, and carbonate in the caustic used for adjusting *p*H was analyzed by adding barium chloride and proceeding as above.

Chlorine (as chloride) in the absorbing mixture was determined by the Volhard procedure, but the simpler Mohr method was suitable for chloride in the anolyte after reducing dissolved chlorine with hydrogen peroxide. Active, or dissolved chlorine in the anolyte was determined by pipetting a sample directly out of the cell into a known amount of acidified ferrous ammonium sulfate, boiling for 7 min and titrating with permanganate. The analysis included chlorine, hypochlorite, chlorate, and any other oxidized chlorine compounds.

Experimental procedure.—The cell was operated continuously at 80°C and 7.2 amp, using platinum anodes. The feed rate was about 100 ml/hr. Under these conditions the anolyte *p*H approximated 3.8, and the catholyte caustic concentration was 110-120 g/l. When graphite anodes were to be studied, they were substituted for platinum at the beginning of an experiment. The *p*H was immediately adjusted to and held at the desired value for 1 hr. Analysis was made for chloride and dissolved chlorine in the anolyte and anode gas was collected for 1-2 hr. Dissolved chlorine was determined again after gas collection. The rate of flow of catholyte out of the cell was generally determined during gas collection.

Calculations.—The amount of dissolved chlorine generated per hour was calculated from a materials balance:

$$\text{Net chlorine dissolved: } = \left[\begin{matrix}\text{Anolyte through}\\ \text{diaphragm}\end{matrix}\right] \times \left[\begin{matrix}\text{Average dissolved}\\ \text{chlorine concentration}\end{matrix}\right] + \left[\begin{matrix}\text{Anolyte}\\ \text{volume}\end{matrix}\right] \times \left[\begin{matrix}\text{Change in dissolved}\\ \text{chlorine concentration}\end{matrix}\right] + \left[\begin{matrix}\text{Dissolved chlorine}\\ \text{removed by sampling}\end{matrix}\right]$$

This amount was expressed as the per cent of the current required to produce it or in cc of STP gas/hr. The flow of anolyte through the diaphragm was estimated to be 10% greater than the flow of catholyte out of the cell. The reduction in volume is due mainly to the decomposition of water into hydrogen and alkali. At *p*H 3.0, the amount of chlorine dissolved was found to be less than the experimental error in the above material balance and was neglected. An experiment at this *p*H was carried out using platinum anodes and stopping the flow of feed brine so that generation of dissolved chlorine could be detected simply by a change in concentration in the anolyte. No change in concentration could be detected over a period of 2 hr.

The amount of air in the sample was determined from the nitrogen present, and the total oxygen corrected for the amount in the air. The evolved Cl_2, CO_2, CO, and corrected O_2 were expressed as volume percent, assuming ideal gases. Further corrections were required for the CO_2 fed into the cell by the brine and by the alkali used for adjusting *p*H. The evolution of about 3 cc of CO_2 per hour could not be accounted for when platinum anodes were used, and a correction for this amount was made when graphite anodes were employed.

Since the corrections are on a volume per hour basis, it is convenient to know the volumes of gases generated per hour. Due to interruptions during gas sampling, leaks, etc., the gas sample could not be considered the total generated during the collection period.

[1] The two grades of graphite used were National Carbon Co. grades AGLR (unimpregnated) and AGLR-58 (linseed oil impregnated). The unimpregnated graphite had a bulk density of about 1.55 g/cc, corresponding to a porosity of about 30%.

The following calculation yielded the corrections, knowing the relative composition of the gas and amount of dissolved chlorine, including hypochlorite and chlorate. The symbols Cl_2, CO_2, CO, and O_2 denote volume per cent values in the sample and Cl_2' CO_2', CO', and O_2' gas produced by electrolysis in cc/hr. The gases requiring 2 and 4 Faradays per mole, respectively, are added so that:

$$x = Cl_2' + CO' \quad [1]$$

$$y = CO_2' + O_2' \quad [2]$$

then

$$\frac{2x + 4y}{1000} = 22.4 \times \mathbf{F} \times E/100 \quad [3]$$

where **F** is Faradays per hour and
E is nonchlorine current efficiency.

$$x + 2y = 112\,\mathbf{F}E = K_1 \quad [4]$$

A second equation in x and y is the following:

$$\frac{CO_2 + O_2}{100} = \frac{y + K_2}{x + y + K_2} = K_3 \quad [5]$$

where K_2 is the carbon dioxide corrected for in cc/hr and is a positive value.

All of the K's are experimental quantities, so [4] and [5] may be solved simultaneously for x and y.

$$y = \frac{K_3(K_1 + K_2) - K_2}{1 + K_3} \quad [6]$$

since:

$$\frac{CO_2' + K_2}{O_2'} = \frac{CO_2}{O_2} \quad [7]$$

substitution from [2] gives

$$CO_2' = \frac{y - K_2(O^2/CO_2)}{1 + (O^2/CO_2)} \quad [8]$$

Therefore, CO_2' can be determined from the value of y calculated from [6] and the ratio of O_2/CO_2 in the gas evolved. O_2' is then calculated from [2].

x can be determined from Eq. [4], and CO' related to it by a derivation similar to the above:

$$CO' = (CO/Cl_2 + CO)\,x \quad [9]$$

Cl_2' is then determined from [1].

Results

Data and calculations for the experiments are summarized in Table I. Each *p*H value represents an average of many readings taken during an experiment, most of which did not vary more than 0.1 unit from the mean. The change in dissolved chlorine during an experiment was not always determined, and values in parentheses are estimated. Regardless of the values shown for dissolved chlorine generated at *p*H 3, this was assumed to be zero. The gas composition shown is that after correction for CO_2 as described above and after inclusion of dissolved chlorine. The small values for carbon dioxide listed for platinum at *p*H 4.2 indicate a reasonably good materials balance for this gas, when none is generated at the anode. The value of 100 minus the chlorine current efficiency is that due to generation of CO_2, CO, and O_2.

Figure 2 is a plot of the nonchlorine current efficiency for the three anode materials which indicate the following order for *p*H 3 to 4:

Plain AGR > Impregnated Graphite > Platinum

At *p*H 4.2 the nonchlorine efficiency with the impregnated graphite is the same as or higher than that with plain graphite. According to the result the *p*H should drop when graphite anodes are substituted for platinum, since the chlorine current efficiency, controlled mainly by the diaphragm leakage, will remain approximately constant. A slight drop has been observed.

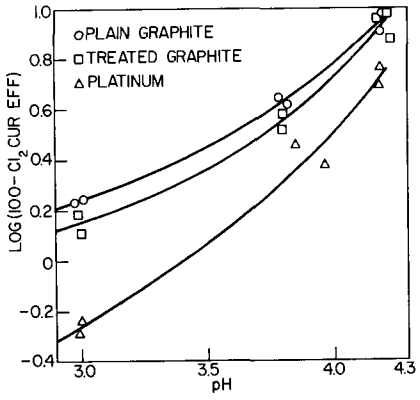

Fig. 2. Effect of pH on current efficiency

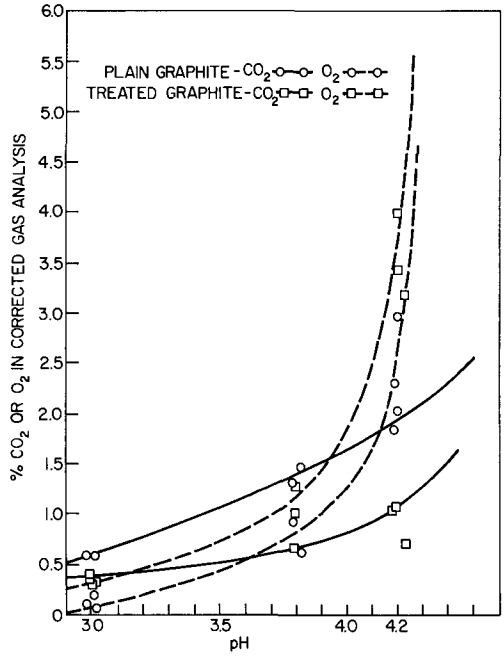

Fig. 3. Effect of pH on per cent O_2 and per cent CO_2

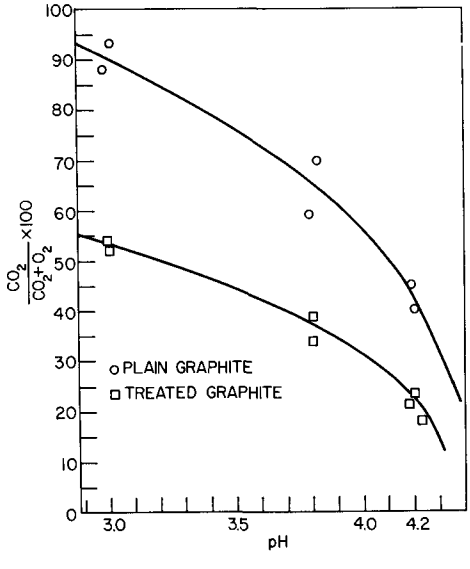

Fig. 4. Effect of pH on ratio $CO_2/CO_2 + O_2$

Figure 3 shows the marked contrast between oxygen and carbon dioxide variations with pH. The oxygen curves undergo a much larger change in slope over the pH range than do the carbon dioxide curves. This means that the slope of a CO_2/O_2 vs. pH plot becomes more negative with increasing pH, as shown in Fig. 4.

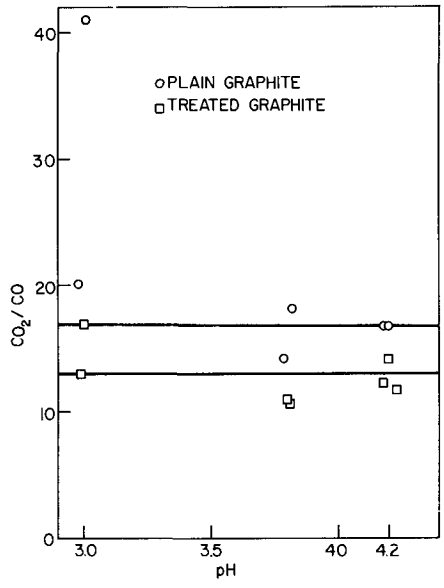

Fig. 5. Effect of pH on ratio CO_2/O_2

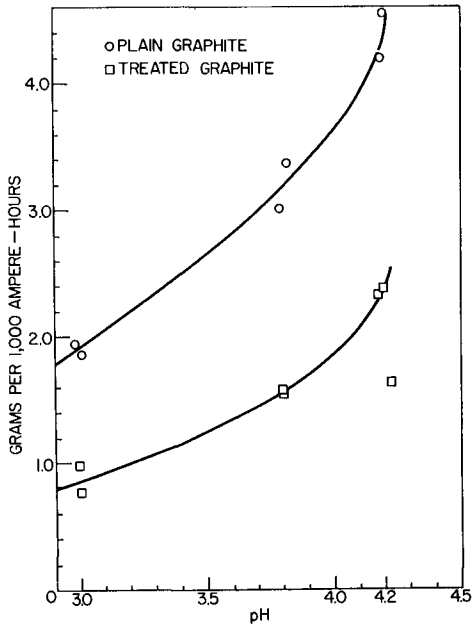

Fig. 6. Effect of pH on anode consumption

On the other hand, the ratio CO_2/CO is probably constant over the pH range. The ratios at pH 3.0 are uncertain, because the amounts of CO in the gas were too small to more than approximate. Figure 5 is a plot of the data and indicates a higher ratio for plain graphite than for impregnated graphite.

Figure 6 shows the variation in carbon consumption as calculated from the gas composition. The curve has the same trend as that for nonchlorine current efficiency, but is less steep because of the compensating effect of the decreasing CO_2/O_2 ratio.

The ratios of consumption for plain graphite compared to impregnated graphite for the three pH values are shown in Table II. The ratio of 2 is unaffected by pH.

Table II. Ratio of consumption of plain graphite relative to impregnated graphite

pH	Weight ratio
3.0	2.2
3.8	2.0
4.2	2.1

Discussion

The amounts of dissolved chlorine in the laboratory cell are much higher than in a commercial cell. With the latter, the amount corresponds to less than 5% of the current under normal operating conditions. This low value may be due to the higher temperature and greater degree of agitation used commercially. The agitation minimizes the formation of an alkaline layer in the anolyte in the vicinity of the diaphragm and thus reduces the amount of chlorate formation. The chemical formation of chlorate is the most reasonable explanation for high chlorine solubility in the laboratory cell, since it is favored by the large ratio of anolyte volume/anode surface. A large anolyte volume means a long hold time for chemical chlorate formation to take place. Electrochemical chlorate formation appears to be no more than expected as evidenced by the amounts of carbon dioxide and oxygen evolved. The very high dissolved chlorine values for impregnated graphite anodes at pH 4.2 appear to involve a further mechanism for solution beyond those operable for the other conditions.

When chlorine current efficiency is based on evolved plus dissolved chlorine, the laboratory and commercial cells compare favorably. This method of comparison is justified in studying anode performance, since the chlorine is formed at the anode regardless of whether it is evolved or dissolved. Results with impregnated graphite anodes in the experimental cell and the Hooker Cell investigated by Murray and Kircher (4) are compared in Table III. Their values are picked off of a curve of hydroxyl ion discharge, which does not include dissolved chlorine. These authors found that chemical chlorate formation was insignificant up to pH 4.2.

The higher chlorine current efficiencies indicated for platinum as compared to graphite reflect a higher overvoltage of oxygen relative to chlorine for the metal. The slightly higher chlorine current efficiency for impregnated as compared to plain graphite is probably related to the less extensive chemical attack by hypochlorite as a result of filling the pores.

The decrease in chlorine current efficiency with increasing pH is expected from the increase in concentration of substances that form oxygen (or CO and CO_2) by anodic oxidation or chemical decomposition. The equilibria and kinetics involved have been discussed in detail by Barr (5) and Murray and Kircher (4). The laboratory data, in confirming the effect of pH on current efficiency, point up the practical attractiveness of using an acid feed to keep anolyte pH low. The decrease in anode consumption is an added advantage. The practical considerations of providing corrosion-proof-containers and conduits for the acid brine as well as a possible decrease in diaphragm life must be balanced against the benefits of operating at lower pH.

Table III. Comparison of current efficiency losses in Laboratory and Hooker Cell

pH	Current efficiency loss	
	Lab. cell	Hooker cell*
3.0	1.4	1.0
3.8	3.6	3.2
4.2	9	6.0

* Values estimated from hydroxyl discharge curve in Ref. (4).

The change in CO_2/O_2 ratio with pH could be due to heterogeneous reactions taking place on the surface of the anode, with or without homogeneous reactions taking place in the vicinity of the anode or in the bulk of the solution. Any of the possible discharge mechanisms could result in adsorption of oxygen directly onto the anode, as could chemical attack of the graphite by hypochlorite. The over-all reaction for discharge of hypochlorite ion, postulated by Foerster (3) from experimental evidence in alkaline solution is:

$$6(OCl)^- + 3H_2O + 6e \rightarrow 6H^+ + 2ClO_3^- + 4Cl^- + \frac{3}{2}O_2$$

Since several steps are probably involved in this over-all reaction, there is the possibility of some intermediate product diffusing away from the anode and homogeneously decomposing to give molecular oxygen. Hypochlorous acid decomposes homogeneously to oxygen and hydrochloric acid. Lister (9) has found the rate to be insignificant except in the presence of a catalyst. Hydrogen peroxide can be formed anodically and decompose to oxygen and water. The question that arises when oxygen is formed from homogeneous reactions is whether such oxygen is available either to attack the anode or to oxidize carbon monoxide formed at the anode or whether it escapes as molecular oxygen and is unavailable as an oxidizing agent. Nevertheless, a mechanism can be proposed, based on the physical and chemical adsorption of all the oxygen supposedly formed, that agrees fairly well with the data.

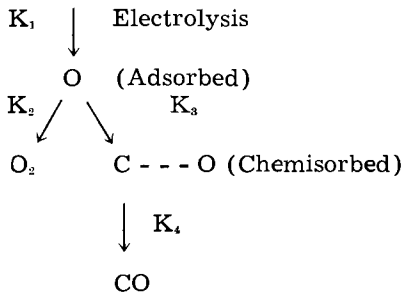
If, by analogy to mechanisms proposed for air oxidation (10-12), oxygen is adsorbed as a first step, desorption-combination can take place to form oxygen, or a carbon bond can break to form a carbon-oxygen compound. Eyring and Blyholder (10) found that CO was the primary product of air oxidation and ascribed this to its low energy of desorption. Sihvonen (11) proposed that CO comes from desorption of keto or ketene groups formed as a result of oxygen adsorption. He also maintained that α keto acids are obtained during electrolysis, which give rise to a mixture of CO and CO_2. In electrolysis, the presence of adsorbed oxygen need not be the direct result of adsorption of the element, but more probably is the result of oxidation of hydroxyl or hypochlorite ions already present on the surface which then dehydrate or dehydrohalogenate to leave adsorbed oxygen behind. Furthermore, hydroxyl radicals could desorb directly to form hydrogen peroxide which then decomposes to oxygen. This

mechanism is suggested by the fact that Sihvonen found that practically no oxygen was formed at a graphite anode in sulfuric acid solution where peroxide decomposition is slow, while in strong alkali, which readily decomposes peroxide, oxygen was the preponderant anodic gas.

The process for electrolytic oxidation will be assumed to involve the rapid physical adsorption of oxygen on the anode surface, a conversion of a part of this oxygen to desorbed molecular oxygen by a second order reaction and a conversion of the rest to chemisorbed oxygen by a first order reaction followed by rapid desorption of carbon monoxide. The monoxide is then oxidized almost completely to carbon dioxide either by the oxygen desorbed or by dissolved chlorine. The desorption of hydroxyl radicals to form hydrogen peroxide and then oxygen is also a second order reaction, provided the peroxide formation is the rate-determining step.

The following scheme represents the mechanism:

Oxygen source (OH^-, OCl^-, etc)



Volume percentages of oxygen and carbon dioxide in the evolved gases are proportional to their rates of formation. In accordance with the assumed mechanism, the volume percentage of carbon monoxide, which is the primary anodic product, is calculated from the volume percentage of carbon dioxide. These rates are proportional to the fraction of active surface sites covered by physically adsorbed and chemisorbed sites, respectively, so that by proper choice of units for the rate constants the following equations hold for the steady state:

$$C_{O_2} = K_2 \theta^2 \qquad [10]$$

$$C_{CO} = K_1 \phi = K_3 \theta \qquad [11]$$

where C_{CO} is volume per cent CO, C_{O_2} is volume per cent O_2, θ is fraction of active sites covered by physically adsorbed oxygen, and ϕ is fraction of active sites covered by chemisorbed oxygen.

$$C_{CO} = K_3 \sqrt{C_{O_2}}/K_2 \qquad [12]$$

which is the obvious relation for competing first and second order reactions leading to carbon monoxide and oxygen, respectively.

To test these assumptions it is necessary to recalculate the data to give CO and O_2 concentrations prior to oxidation of the CO and CO_2. Either oxygen or dissolved chlorine has been assumed to be the oxidizing agent. The results are plotted in Fig. 7, which shows C_{CO} vs. $\sqrt{C_{O_2}}$. Reasonable linearity within the accuracy of the data was obtained for all of the plots. Where it was assumed that oxygen oxidizes carbon monoxide, the lines came closer to the origin. A straight line through the origin indicates rate constants independent of the amount of surface covered with adsorbed atoms, a situation that is not apt to be strictly true. The rate of chemisorption (K_3) when θ and ϕ are very small would probably be higher than when the fractions covered are larger, because only the most active sites on the graphite would be reacting. More exactly, the curves should start at the origin with a slope that decreases with increasing C_{CO} due to a continual decrease in K_3. The Elovich equation [12], or other function with changing slope can be fitted to the data in such a manner that the line passes through the origin, but adds little to a further understanding of the reaction mechanism.

The difference in the results with plain and treated graphite can be explained on the basis of the decrease in area available for electrolysis resulting from the impregnation with oil. The curves in Fig. 7 may be represented as:

$$C_{CO} = A \sqrt{C_{O_2}} + B \qquad [13]$$

A similar equation can be written in which the amount of gas evolved per unit area is used rather than the total

$$C_{CO}/a = A' \sqrt{C_{O_2}}/a + B' \qquad [14]$$

where

$$A' = A/\sqrt{a} \qquad B' = B/a$$

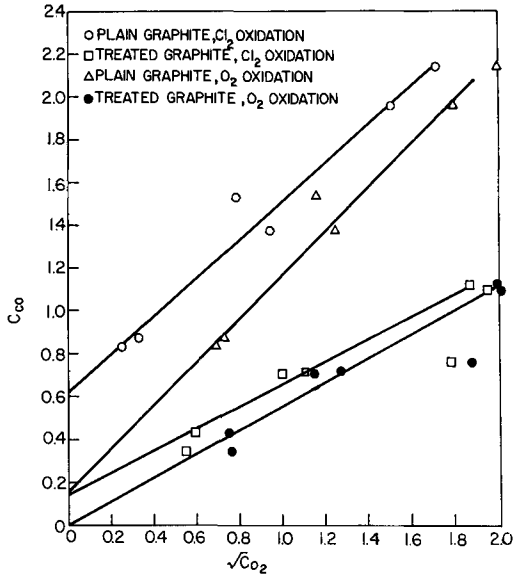


Fig. 7. Plot according to Eq. [12]

Table IV. Relative areas of plain and treated graphite

Graphite	Oxidizing agent	A	B	A_p^2/A_t^2	B_p/B_t
Plain	HOCl	0.89	0.62	3.0	4.1
Treated	HOCl	0.51	0.15		
Plain	O_2	1.02	0.15	3.5	
Treated	O_2	0.55	0		

Thus, in comparing two curves obtained in the same manner:

$$a_1/a_2 = A_p^2/A_T^2 = B_p/B_T \quad [15]$$

where subscripts p and T refer to plain and treated graphite, respectively. Results are shown in Table IV. The area ratio based on the squares of the slopes is probably much more accurate than that based on the intercept ratio, since the intercept is more uncertain, particularly when it is in the vicinity of the origin. Treatment appears to reduce the effective anode area 3 to 4-fold. This seems reasonable, although the possibility that additional oxygen is formed with treated graphite by the catalyzed decomposition of HOCl cannot be discounted. Cobalt is a suitable catalyst and is contained in the impregnating oil. Joost (13) considered that chemical attack by hypochlorite was an important factor in graphite corrosion, since the addition of cobalt was effective in inhibiting corrosion.

The proposed adsorption mechanism, while giving a reasonable explanation of events in the brine solution, would probably need to be modified to account for results in other media. However, Sihvonen's (14) results, in which he obtained more oxygen than CO_2 in strongly alkaline solution and much more CO_2 than oxygen in strong sulfuric acid solution, exhibit the same trend as the brine data.

In commercial cells the corrosion rate of plain graphite is about double that of impregnated graphite, in agreement with the experimental results in which the corrosion was not allowed to proceed to any extent. It remains to be determined whether such a short test is useful in determining practical corrosion resistances of various anode materials.

An Electrochemical Study of Uranium in Fused Chlorides

Derek L. Hill, Jeanne Perano, and Robert A. Osteryoung

Department of Chemistry, Rensselaer Polytechnic Institute, Troy, New York

ABSTRACT

The U(III)-U(O) and U(IV)-U(III) standard potentials in $MgCl_2$-NaCl-KCl eutectic, and the U(IV)-U(III) and UO_2(VI)-UO_2(IV) standard potentials in LiCl-KCl eutectic have been measured at 450°C. The values found are respectively, —2.25, —1.30, —1.25, and —0.285 v vs. the standard Pt(II)-Pt(O) reference electrode on the mole-fraction scale. Polarographic studies of the behavior of U(III), U(IV), and UO_2(VI) in LiCl-KCl eutectic at 450°C have been performed. The significance of the results with respect to certain industrially important processes is briefly noted. A coulometric titration procedure utilizing electrogenerated Pt(II) has been developed for an *in situ* determination of U(III) in LiCl-KCl and $MgCl_2$-NaCl-KCl eutectics.

Recent activity in the use of fused salt baths for the electrodeposition of pure uranium (1, 2) and for the extraction of fission products from a liquid metal fuel reactor (3) and other studies (4, 5) involving this metal suggested that an investigation of certain aspects of the electrochemical behavior of uranium in such solvents would be of interest.

Two chloride eutectic solvents were chosen for for study: (*a*) the binary LiCl (59 mole %)-KCl (41 mole %), mp 355°C, because it has been widely used in electrochemical investigations and would enable direct comparison of uranium electrode potentials to be made with those of other metals, and (*b*) the ternary $MgCl_2$ (50 mole %)-NaCl (30 mole

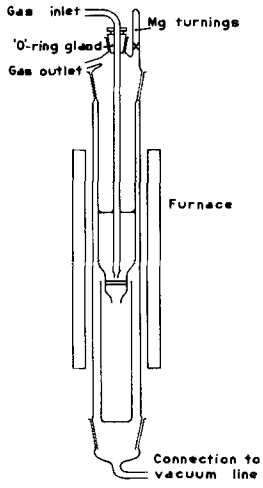

Fig. 1. Pyrex cell for melt purification

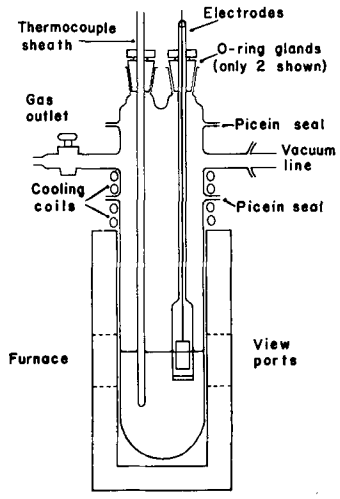

Fig. 2. Pyrex cell assembly

%)-KCl (20 mole %), mp 396°C, because of its suitability for the fission product extraction process.

Experimental and Results

Melt Purification

The apparatus for the dehydration and filtration of the eutectic solvents is shown in Fig. 1. Eutectic components of reagent grade and anhydrous magnesium chloride were mixed in the appropriate ratios and placed in the tube above the fine porosity frit, with the opening of the gas bubbler tube at the lower end, just above the frit. Anhydrous HCl gas was passed through the mixture for 30 min to displace air, and the nichrome-wound tubular furnace was then slowly heated over a period of about 3 hr, HCl passing all the while, until the mixture melted. After HCl had been passed through the melt for a further 30 min, it was replaced by a pure argon stream for 20 min, to remove dissolved HCl. At this point, clean magnesium turnings of Grignard quality were added from the side-tube, and stirred by the argon stream to react with residual impurities. The lower portion of the apparatus was then evacuated, and the melt was filtered into the crucible where it solidified. Finally the apparatus was filled with argon, the crucible was removed, quickly stoppered and transferred to a dry-box by way of a vacuum tunnel, and stored. As required, the weighed solid eutectic, usually about 160 g, was slipped out of the crucible and into the cell assembly, which fitted into a nichrome-wound Vycor tube furnace packed in an insulated container provided with a rear-lighted view-port at the melt level.

Cell Assembly and Related Apparatus

The cell assembly is shown in Fig. 2, the reference electrode and auxiliary cathode fritted compartments, and the titration electrode in Fig. 3 (a) and (b), respectively.

After the solidified eutectic had been placed in the cell and the flanged head carrying the electrodes, etc., had been placed in position, the whole assembly was evacuated overnight at about 10^{-5} mm Hg. It was then slowly warmed until the salt melted under vacuum, after which the temperature was controlled at 450°C by a chromel-alumel thermocouple contained in an immersed glass sheath, acting through a Barber-Coleman Wheelco furnace regulator.

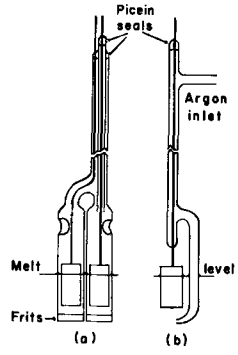

Fig. 3(a). Reference electrode and auxiliary cathode. Fig. 3(b). Argon-stirred titration electrode.

The fritted compartments were then lowered till the frits were just above the surface of the melt, where they were kept for 30 min to aid their outgassing. They were then immersed in the melt to a depth of about 2 cm, the cell was filled with pure argon which was then maintained at a steady flow through the cell; the melt filtered up into the compartments and reached its equilibrium level. The compartments each had a small hole above the melt level to avoid pressure differentials and to facilitate the insertion of the electrodes during the assembly of the cell. The reference electrode was then prepared coulometrically by the anodization at ~5 ma cm^{-2} of the Pt foil or Ag wire in one compartment, using the Pt foil in the other as cathode. The generation of Pt(II) and Ag(I) at 100% current efficiency under these conditions has been well established (6). Anodization was generally continued for a time sufficient to bring the mole fraction of Pt(II) or Ag(I) in the compartment to about $1 - 2 \times 10^{-3}$. The exact concentration was determined at the end of each experiment by the weight of eutectic contained in the compartment and the number of coulombs passed. The Nernst relation was then used to refer the potential of the reference electrode to the standard state of unit mole fraction.

Cylinder argon (99.995%) was passed through P_2O_5 and over titanium sponge at 900°-1000°C. Po-

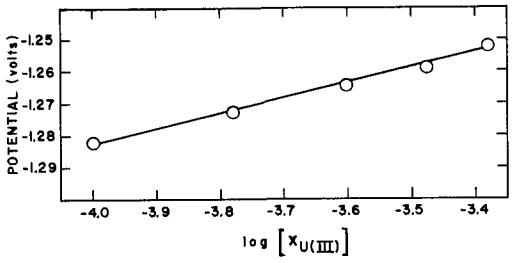

Fig. 4. U(III)-U(O) potential in $MgCl_2$-NaCl-KCl at 450°C. Ag(I)-Ag(O) reference electrode, 3.02 × 10^{-4} mole fraction of Ag(I).

larograms were recorded with a Sargent XXI recording polarograph. A Rubicon Model 2700 precision potentiometer was used to measure cell potentials. A Sargent coulometric current source was used in all constant current anodization or titration procedures.

U(III)-U(O) *Potential In* $MgCl_2$-NaCl-KCl

To a known weight of ternary eutectic, successive quantities of U(III) were introduced coulometrically by the anodization at about 10 ma cm^{-2} of a carefully outgassed pure uranium rod (analysis: Fe 0.003%, Mg 0.0008-0.003%, Si 0.0008%, Cu 0.0008%, Al 0.0005%). Current efficiency of 100% for this process is demonstrated in the present work and is discussed later. The potential of the uranium rod was measured against a Ag(I)-Ag(O) reference electrode after each addition, insuring uniform concentration in the deep red solution by argon stirring.

A plot of this potential against log [U(III)] at 450°C is shown in Fig. 4 and indicates that the Nernst relation is obeyed, the slope of the line (0.0470 v) being in close agreement with that calculated (0.0478 v) for a 3-electron transfer. Extrapolation to unit mole fraction of U(III) yields a value of −1.61 ± 0.01 v against a standard Ag(I)-Ag(O) reference electrode. Using the data of Laitinen and Liu (6) this value becomes −2.25 ± 0.01 v against a standard Pt(II)-Pt(O) reference electrode.

Polarography of U(III) *and* U(IV) *in* LiCl-KCl

The polarographic behavior of U(III) and U(IV) in the binary eutectic was studied using a Pt needle microelectrode prepared by sealing a length of 14 mil diameter Pt wire into 6 mm Pyrex tubing so that about 1.5 mm^2 projected from the seal. Measurements were made with respect to a Pt(II)-Pt(O) reference electrode. Again, U(III) was added coulometrically by the anodization of a pure uranium rod, which was raised out of the melt after each period of anodization. Current efficiency of 100% was found for this process also, and is discussed later.

By restricting the potential range in which the microelectrode was used to less than 1.5 v negative to the reference electrode, reproducible and well-defined waves for the oxidation of U(III) to U(IV) were observed. Figure 5 illustrates the polarograms obtained after successive additions of U(III). As the U(III) concentration was increased, the potential at which the polarographic current attained the residual value became increasingly negative, but, although the magnitude of the shift was of the right order, exact quantitative agreement with that calculated from the Nernst relation was not obtained. At a fixed potential, the polarographic currents due to successive additions of U(III) showed a linear relation to concentration, as illustrated in Fig. 6.

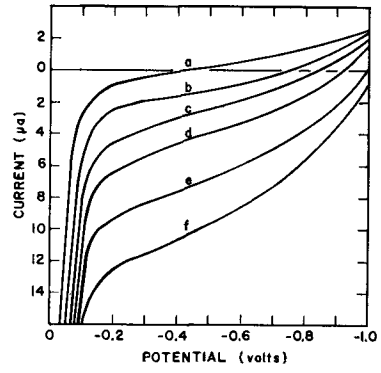

Fig. 5. Polarogroms for the oxidation of U(III) to U(IV) in LiCl-KCl at 450°C. Pt(II)-Pt(O) reference electrode, 1.14 × 10^{-3} mole fraction of Pt(II); microelectrode area 1.65 mm^2; melt weight 160 g; additions of U(III): a:0; b:12; c:28; d:44; e:68; f:92 mg. The current below the zero-axis is anodic.

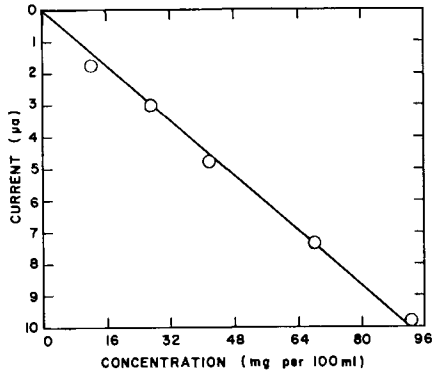

Fig. 6. Relation between U(III)—oxidation polarographic current and U(III) concentration in LiCl-KCl at 450°C (from Fig. 5, at −0.43 v).

Starting with a given concentration of U(III) in the melt, U(IV) could be added to the system by the reaction

$$2U(III) + Pt(II) \rightarrow 2U(IV) + Pt \qquad [1]$$

using Pt(II) generated coulometrically from an immersed Pt foil anode. On making successive additions of U(IV) in this manner, accompanied of course by the equivalent successive removals of U(III), the potential at which the polarographic current attained the residual value became less negative again, and the steady development of the U(IV) reduction wave was observed along with the simultaneous steady disappearance of the U(III) oxidation wave. With equal concentrations of U(III) and U(IV) in the melt, the point of zero current occurred at a potential very close to that found in the potentiometric titration procedure for the determination of the U(IV)-U(III) redox potential described below. The development of the combined U(IV)-U(III) polarograms is shown in Fig. 7.

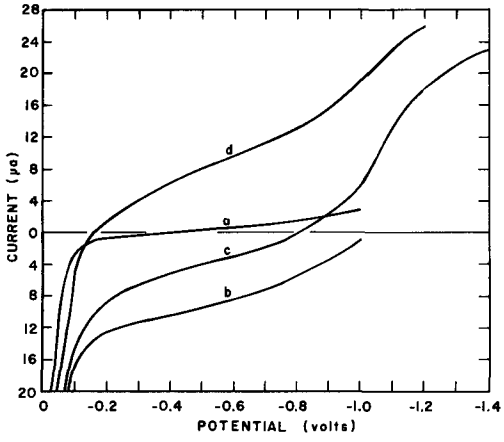

Fig. 7. Development of combined U(III) and U(IV) polarograms in LiCl-KCl at 450°C. Pt(II)-Pt(O) reference electrode, 1.14 × 10^{-3} mole fraction of Pt(II); microelectrode area 1.65 mm^2; a, residual current; b, U(III) oxidation (92 mg U(III) per 100 ml melt); c, U(III) oxidation, U(IV) reduction; d, Pt(II) reduction, U(IV) reduction. Current below the zero-axis is anodic.

Only indistinct waves for the reduction of U(III) to uranium metal were observed, at about —2.2 v, and it appeared that alloying occurred, both from the subsequent appearance of the microelectrode, and also because it was not found possible to obtain unequivocal anodic stripping curves corresponding to the dissolution of the uranium metal which should have been electrodeposited on the microelectrode. The use of a Pt microelectrode at such a negative potential, which is close to that corresponding to the deposition of lithium on Pt (~ —2.4 v), was detrimental to the reproducibility of subsequent polarograms, due to the difficulty of completely dissolving out the electropositive alloying elements from the Pt. The problem was accentuated by the decrease in the separation of the deposition potentials of the two metals by the alloy formation. Attempts to avoid this difficulty by the use of a tungsten or graphite microelectrode were not successful. Immersed, finely polished, flush-ground tungsten microelectrodes were attacked at the glass-metal seal and also gave irreproducible results, while a finely pointed, spectroscopic grade graphite rod immersed just in the surface of the melt gave very unsteady waves and appeared to disintegrate slowly.

A similarly surface-immersed graphite microelectrode was used to examine the behavior of approximately equal concentrations of U(III) and U(IV) at potentials more positive than can be reached with a Pt microelectrode. The U(IV)-U(III) combined wave was clearly shown, but no further waves were found between the potential at which this occurred and that at which chlorine was evolved.

Determination of the U(IV)-U(III) *Redox Potential*

In both the binary and ternary eutectics, when Pt(II) was electrolytically generated from an immersed Pt foil, reaction [1] occurred, and it was found that the potential of the Pt foil, measured against a Pt(II)-Pt(O) reference electrode at intervals between successive periods of anodization, followed typical potentiometric titration curves such as that shown in Fig. 8.

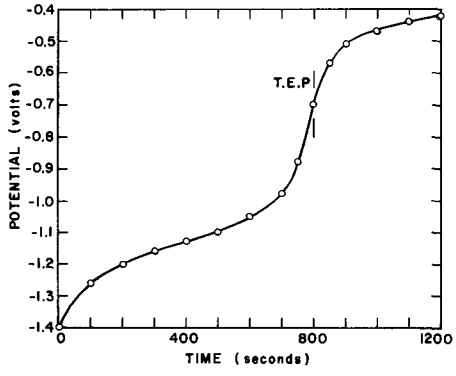

Fig. 8. Coulometric titration of U(III) with Pt(II) in $MgCl_2$-NaCl-KCl at 450°C. Pt(II)-Pt(O) reference electrode, 1.83 × 10^{-3} mole fraction of Pt(II); constant current, 48.25 ma, 1.2 × 10^{-3} equivalents U(III). T.E.P., theoretical end-point.

Titrations were performed with the argon-stirred Pt foil electrode shown in Fig. 3(b). During the course of the titration the initially dark red color of the melts due to U(III) gradually lightened, and just before the end points became light green in color, due to U(IV). Black, finely divided Pt was also seen in the melts. At the end of a titration the immersion of a uranium rod caused the melt to become red again due to the reaction

$$U + 3U(IV) \rightarrow 4U(III) \qquad [2]$$

Since both U(III) and Pt(II) were generated coulometrically, a theoretical end point could be calculated. In experiments with melts having very low residual impurity concentrations, as demonstrated by polarographic residual currents of considerably less than 1 $\mu a\ mm^{-2}$ at —1.0 v against the Pt(II)-Pt(O) reference electrode, the agreement between the amount of U(III) taken and the amount found was very close, as in Fig. 8. In many other experiments, the titration end points fell somewhat short of those calculated. As the initial concentration of U(III) in the melts was less than 600 ppm, it can readily be seen that in the case of a low molecular weight impurity such as oxygen, which reacts very readily with U(III) as described below, less than 10 ppm would be required to oxidize more than 10% of the initial U(III) concentration, and so the occurrence of low titration values is easily understood. Fortunately, this did not interfere too seriously with the determination of the U(IV)-U(III) redox potential which was taken from the relatively flat midportion of the lower branch of the curve. On the mole fraction scale the standard redox potentials found were —1.30 ± 0.01 v in $MgCl_2$-NaCl-KCl eutectic, and —1.25 ± 0.01 v in LiCl-KCl eutectic, with respect to the Pt(II)-Pt(O) couple at 450°C.

For a given experiment the shape of the lower branch of the curve can be calculated from the redox potential by means of the Nernst relation, and in general, good agreement was found with the shape obtained experimentally. Usually the initial potential, before any addition of Pt(II), corresponded to a U(IV) to U(III) ratio of ½% or less.

In view of the polarographic behavior of U(III), U(IV), and Pt(II) it was to be expected that amperometric end-point detection, using a Pt microelectrode at about —0.5 v vs. the working Pt(II)-

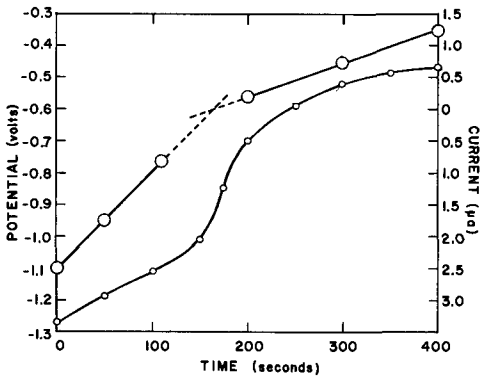

Fig. 9. Coulometric titration of U(III) with Pt(II) in $MgCl_2$-NaCl-KCl at 450°C, with amperometric end-point detection. Pt(II)-Pt(O) reference electrode, 1.75×10^{-3} mole fraction of Pt(II); constant current, 48.25 ma, 2.5×10^{-4} equivalents U(III). Microelectrode area 1.35 mm^2.

Pt(O) reference electrode, would be a convenient adjunct to the titration. In practice however, it usually presented difficulties, due in part to the necessity of waiting a considerable period of time after argon-stirring the melts for the current to become sufficiently steady to enable a reading to be taken, and in part due to the formation during the titration of finely divided Pt, which tended to become attached to the Pt microelectrode, and which was difficult to dislodge. A successful attempt to use this method of end-point detection is shown in Fig. 9 which also demonstrates that the polarographic behavior in the two eutectics was similar.

Preparation, Polarography, and Potentiometry of Uranyl Species

Solutions of the uranyl species were prepared in both eutectics at 450°C by bubbling dry oxygen (7) through the green solutions obtained by the addition of pure anhydrous uranium tetrachloride. The resulting solutions were clear yellow in color at low concentrations, and reddish-orange at high concentrations. The absorption spectrum in LiCl-KCl eutectic at 400°C was very similar to that observed for uranyl species in this solvent at the same temperature by Gruen (8), showing no evidence of the presence of U(IV), and x-ray patterns of the powdered yellow solid, obtained by grinding this solidified eutectic, showed lines characteristic of uranyl chloride. The reaction appeared to proceed smoothly and rapidly to completion with the evolution of chlorine. It was not possible to determine whether it proceeded directly, or through intermediate stages.

In other experiments it was observed that U(III) in solution in these melts also yielded clear yellow solutions rapidly when dry oxygen was bubbled in, but if moist air were used instead, partial precipitation, probably of oxides, also occurred.

To prepare for the polarographic and potentiometric work on the uranyl species, samples of a known weight of LiCl-KCl eutectic containing UO_2(VI) prepared directly in the melt from a known weight of UCl_4 were drawn up into several lengths of 6 mm glass tubing, quickly cooled to prevent the formation of concentration gradients, and sealed off to exclude moisture. Weighed samples of this solidified salt were later tapped out and added to LiCl-KCl solvent for study. This procedure provided a more convenient method for the introduction of known amounts of UO_2(VI) to the melt than does the direct addition of pure anhydrous UO_2Cl_2 powder prepared by the standard method of the reaction of UCl_4 with dry O_2 at 350°C.

Solutions of UO_2(VI) in LiCl-KCl at 450°C prepared in this way gave well-defined polarographic reduction waves at a Pt microelectrode with a Pt(II)-Pt(O) reference electrode; these are shown in Fig. 10.

If the process occurring were the reduction of UO_2(VI) to uranium dioxide, then by holding the potential of the microelectrode at a suitable value along the plateau, solid UO_2 should have been plated onto the electrode. At this point the microelectrode could be disconnected from the polarograph and its potential determined with the potentiometer. By repeating this procedure at various UO_2(VI) concentrations, a Nernst plot should have been obtained if a true equilibrium existed between the oxide and the uranyl species.

This postulate was tested and verified experimentally, and such a Nernst plot is shown in Fig. 11. The slope of the line (0.07166 v) is in good agreement with that calculated for a 2-electron process (0.07174 v). By extrapolation, the standard potential on the mole fraction scale for the UO_2(VI)-UO_2(IV) couple was found to be -0.285 ± 0.005 v against the standard Pt(II)-Pt(O) reference electrode.

Furthermore, a UO_2-plated Pt microelectrode should have produced a large anodic stripping current at potentials more positive than that for the

$UO_2(VI)$-$UO_2(IV)$ equilibrium if its potential were slowly shifted from a value on the plateau toward less negative values. This effect also was observed, and a typical combined deposition and stripping curve is shown in Fig. 12. The relation between wave height and $UO_2(VI)$ concentration is shown in Fig. 13.

Discussion

Results of the coulometric titration establish that U(III) was electrogenerated at 100% current efficiency in both eutectics. The value of the U(III)-U(O) potential in $MgCl_2$-NaCl-KCl eutectic is virtually identical to that found by Gruen and Osteryoung (9) in LiCl-KCl eutectic at the same temperature. Close correspondence of electrode potentials in different melts is not uncommon (10). The U(IV)-U(III) redox potentials observed in the present work provide a similar example. This correspondence of electrode potentials in different melts suggests that in many cases the behavior of the potential determining solute species is not dependent primarily on the nature of the solvent cationic species.

For the cell

$$(-)\mathrm{U}\left\{\begin{array}{l}\mathrm{U(III)}\\ \text{binary or ternary}\\ \text{chloride eutectic}\end{array}\right\}\left\{\begin{array}{l}\mathrm{Ag(I)}\\ \text{binary or ternary}\\ \text{chloride eutectic}\end{array}\right\}\mathrm{Ag}(+) \qquad \text{(I)}$$

the measured emf is in close agreement with that calculated from the established thermodynamic data for the pure compounds. This indicates that the free energies of solution of U(III) and Ag(I) are not very different, and are much smaller than the free energy change for the overall cell reaction, so that only the difference between two minor quantities is included in the calculation. For the cell

$$(-)\mathrm{Pt}\left\{\begin{array}{l}\mathrm{U(IV),U(III)}\\ \text{binary or ternary}\\ \text{chloride eutectic}\end{array}\right\}\left\{\begin{array}{l}\mathrm{Pt(II)}\\ \text{binary or ternary}\\ \text{chloride eutectic}\end{array}\right\}\mathrm{Pt}(+) \qquad \text{(II)}$$

a difference considerably greater than can be attributed to experimental error is found on making a similar comparison between measurement and calculation. Since for the cell

$$(-)\mathrm{Ag}\mid \mathrm{Ag(I)\ LiCl\text{-}KCl} \parallel \mathrm{Pt(II)\ LiCl\text{-}KCl}\mid \mathrm{Pt}(+) \qquad \text{(III)}$$

the same comparison leads to good agreement, it would appear that the difference between the measured and calculated values for the emf of cell (II) may be due to a comparatively large term involving the free energy of solution of U(IV). A possible interpretation of this is that U(IV) forms a chloro-

Table I. Comparison of measured cell potentials with those calculated from thermodynamic data[a] for the pure compounds at 450°C

Cell	Solvent eutectic	Potential measured	Potential calculated

complex of sufficient stability in the chloride melts to shift the measured U(IV)-U(III) potential to a value more negative than that calculated from the thermodynamic formation data.[1] Similar considerations have been used by Flengas and Ingraham (11-15) to explain such differences between experimental and calculated values. Table I lists the comparisons made in the present work.

The U(III) oxidation waves are somewhat drawn out and do not conform quantitatively in respect of either log $[i/(i_d - i)]$ vs. potential plots, or potential at the intersection with the residual current vs. log [U(III)] plots, probably due to the difficulties inherent in recording polarograms at a stationary solid microelectrode. Nevertheless, the polarographic behavior otherwise and the potentiometric titration of U(III) demonstrate clearly that the reaction

$$U(IV) + e^- \rightleftharpoons U(III) \qquad [3]$$

behaves in a electrochemically reversible manner in both melts. In addition, the linear relation between wave height and concentration of U(III), and especially the coulometric titration, provide useful *in situ* analytical procedures. This titration is unique in that it uses an oxidant electrogenerated directly from a metal. Coulometric titration with amperometric end-point detection in fused LiCl-KCl using electrogenerated Fe(III) as oxidant has been the subject of a recent paper (17).

The absence of further oxidation waves at a graphite microelectrode in the potential range between U(III) oxidation and chlorine evolution indicates that U(V) and U(VI) are unstable in the melt, and confirms the observation by Gruen (7) that no reaction occurs when chlorine is bubbled into a solution of UCl_4 in the binary eutectic.

It has long been known (18) that pure molten uranyl chloride can be electrolyzed to produce UO_2 at the cathode and Cl_2 at the anode. The present work with the uranyl species clearly demonstrates that the equilibrium

$$UO_2(VI) + 2e^- \rightleftharpoons UO_2(IV) \qquad [4]$$

can be established in the melt LiCl-KCl, and the movement of the UO_2 deposition potential toward less negative values as the $UO_2(VI)$ concentration is increased is readily understood. This work also confirms and extends the observation by Smirnov and Ivanovsky (19) that anodes of compacted UO_2 could be dissolved anodically in LiCl-KCl eutectic at 650°C, with the production of uranyl ions, and that it was possible to obtain weakly adherent electroplates of UO_2 on molybdenum cathodes. In the present work it was noticed that argon stirring of the melt drastically altered the potential of the UO_2-plated microelectrode in the direction consistent with the physical removal of the plate. Smirnov and Ivanovsky also studied the potential of a UO_2 anode at various current densities, and by extrapolation to zero current density obtained a potential of −0.57 v against a chlorine-chloride reference electrode at 550°C in a dilute but undefined concentration of $UO_2(VI)$. Using the value (20) of −0.216 v for the difference between the standard potentials of the Pt(II)-Pt(O) and Cl_2-Cl^- couples, the present work yields a value of −0.501 v for the $UO_2(VI)$-$UO_2(IV)$ standard potential against the standard Cl_2-Cl^- reference electrode on the mole fraction scale. That this is less negative than the value found by Smirnov and Ivanovsky is to be expected in view of the lower temperature and the use of unit mole fraction as the standard state.

The heights of the $UO_2(VI)$ reduction waves are seen to be an approximately linear function of concentration, but it is difficult to determine them accurately because they are not too steady, and the plateaus are not smooth lines. In this case the difficulties associated with the use of stationary solid microelectrodes are probably accentuated by uneven or rough growth and poor adherence of the oxide plate, and straight line plots of log $[(i_d - i)]$ vs. potential do not have the slope expected for a 2-electron process.

With regard to the electrodeposition of pure uranium from fused salt baths, the present work shows clearly that, in the preparation of uranium by the reduction of U(IV) in a chloride melt, the primary process proceeds stepwise, first to U(III), then to the metal. In view of the measured value of the U(IV)-U(III) redox potential, the majority of metal ion impurities in the melt can oxidize U(III) to U(IV), and this is the probable cause of the presence of U(IV) in the melts deduced from the initial potential of the indicator electrode in the coulometric titrations. Further, since both U(III) and U(IV) react rapidly with oxygen to form $UO_2(VI)$, the reduction of either U(III) or U(IV) from a melt contaminated by oxygen must result in the inclusion of UO_2 with the uranium deposit, and from the measured potentials, both U(III) and uranium metal should be capable of reducing $UO_2(VI)$ to $UO_2(IV)$. For the same reasons, the reversible redox equilibrium between uranium dissolved in a liquid metal and U(III) in a molten chloride solvent will be upset by oxygen impurities in the melt.

Electrochemical Study of Metallic Oxides in Fused Lithium Chloride-Potassium Chloride Eutectic

H. A. Laitinen and B. B. Bhatia

Noyes Chemical Laboratory, University of Illinois, Urbana, Illinois

ABSTRACT

The oxygen electrode does not behave reversibly in LiCl-KCl at temperatures of 400°-500°C, and at oxide ion concentrations of 0.1-0.2M. The following electrode systems behave reversibly as electrodes of the second kind: Cu/$Cu_2O,O^=$; Pt/PtO,$O^=$; Pd/PdO,$O^=$; Bi/BiOCl,$O^=$. The Ni/NiO,$O^=$ and Bi/Bi_2O_3,$O^=$ electrodes did not show reversible behavior. Because of the relatively high solubilities of the metal oxides, the applicability of the metal oxide electrodes to the measurement of oxide ion activity is limited to solutions containing oxide ion in concentrations comparable with, or greater than, that contributed by dissolution of the oxides. This limit is 10^{-3}M or higher, depending on the system. The relatively high solubility of heavy metal oxides in this solvent is attributed to the great complexing tendency of chloride ion. It is probable that these oxides would be much less soluble in nitrate and sulfate melts and thus their utility as acidity electrodes could be extended to lower oxide concentrations.

A molten alkali metal chloride solvent may be said to be "buffered" with respect to the addition of Lewis acids such as $AlCl_3$ because of the presence of a large excess of the weakly basic chloride ion. On the other hand, such a solvent can be rendered basic by the addition of substances such as oxide ion which are more strongly basic than chloride ion.

The purpose of the present investigation was to determine the feasibility of using the oxygen-oxide ion electrode or metal-metal oxide-oxide ion electrodes for the electrochemical measurement of oxide ion activity in molten lithium chloride-potassium chloride eutectic at 450°. A secondary objective was to determine the solubilities of metal oxides from emf measurements.

There is considerable evidence for the reversibility of the oxygen-oxide ion electrode at temperatures of the order of 1000°C in various melts containing oxyanions. The early work of Baur and Ehrenberg (1) on borates, silicates, etc., and of Treadwell (2) on metal oxides, using quartz or porcelain as an electrolyte and silver as the indicator electrode, had indicated that the oxygen-oxide ion was exhibiting reversible behavior.

Csáki and Dietzel (3) reported on emf measurements in cells involving platinum indicator electrodes in borate melts, but their interpretation of the results has been criticized by Flood, Forland, and Motzfeld (4). Antipin (5) used a graphite electrode, which had been anodized to make it behave as an oxygen electrode, as a reference electrode in cryolite at 1050°C. The investigations of Lux (6) largely in sulfate and phosphate systems at 950°C were the first which clearly showed the feasibility of oxide ion activity measurements using a platinum electrode with oxygen gas. Similar measurements were made by Flood and co-workers (4, 7, 8) who demonstrated that the dependence of the potential on oxide ion activity obeyed the Nernst equation.

Work at lower temperatures has been much more limited in scope. Rose, Davis, and Ellingham (9) made measurements involving oxygen electrodes in molten NaOH containing small concentrations of tin or lead at 400°-700° and found that the cells behaved reversibly. Hill and co-workers (10) measured emfs of cells of the type

M/MO/CaO in Li_2SO_4-K_2SO_4/Pt,O_2 [A]

at 550°-750°C and concluded that for iron, copper, and (at temperatures below 658°C) nickel, the cell emf agreed with that calculated from the free energy of formation of the metal oxide. Since both of the electrodes used by Hill, *et al.* theoretically responded equally to oxide ion activity, the cell emf data did not show whether the potentials of the two types of oxide ion electrodes individually varied properly with oxide ion activity. Selis and co-workers (11) in interpreting the galvanic behavior of a Mg-Ni cell in moist lithium chloride-potassium chloride eutectic, considered that the potential-determining systems were $Mg/MgO,O^=$ and either $Ni/NiO,O^=$ (at temperatures of 445°-535°C) or H_2, $Ni/OH^-,O^=$ (at temperatures of 390°-440°C). Once again, the individual electrode behavior against a reference electrode that was invariant with oxide ion activity was not determined.

In the present investigation, a platinum(II)-platinum electrode (12) was used as a reference for the measurement of the potentials of the oxygen-oxide ion electrode and of various metal-metal oxide-oxide ion electrodes as a function of the concentration of oxide ion.

Previous attempts to measure reversible oxygen potentials, using a platinum foil or graphite rod as an indicator electrode, had been unsuccessful (13). In the present study, a porous graphite electrode was used, again with unsuccessful results, as will be seen below.

For an electrode of the second kind, composed of a metal M, its sparingly soluble oxide $MO_{n/2}$, and free oxide ion, the Nernst equation is given by

$$E = E^\circ_{M^{n+},M} + RT/n\mathbf{F} \ln a_{M^{n+}} \quad [1]$$

$$= E^\circ_{M^{n+},M} + RT/n\mathbf{F} \ln (K_{ap}/a_{O^=})^{n/2} \quad [2]$$

$$= E^\circ_{M^{n+},M} + RT/2\mathbf{F} \ln K_{ap} - RT/2\mathbf{F} \ln a_{O^=} \quad [3]$$

where $E^\circ_{M^{n+},M}$ is the standard electrode potential[1] for the metal ion-metal electrode, and $K_{ap} = a_{M^{n+}}{}^{2/n} a_{O^=}$, is the activity product of the sparingly soluble oxide. The first two terms on the right hand side of Eq. [3] can be combined to give the standard potential of the electrode of the second kind, or

$$E = E^\circ_{oxide} - RT/2\mathbf{F} \ln a_{O^=} \quad [4]$$

which is the Nernst equation for the electrode reaction

$$MO_{n/2} \text{ (solid)} + ne^- \rightleftharpoons M + \frac{n}{2} O^= \quad [5]$$

From previous work on the electromotive force series in LiCl-KCl (12) it may be inferred that activities may be replaced by concentrations in Eq. [1]-[4] if a very dilute solution is chosen as the standard state, at least if the mole fraction of added solute is in the range 10^{-2} to 10^{-4}. For analytical purposes it will be convenient to adopt the molarity scale of concentration, although simple conversion factors to molality or mole fraction may be applied if desired. The formal potential $E^{\circ\prime}$, written to describe the electrode with soluble reactants at a concentration of 1M, will therefore be written as E°, the standard potential. At 450°C the Nernst factor $2.303RT/\mathbf{F}$ becomes 0.1434 v, so that the theoretical slope of the plot of potential against log C, the logarithm of molar concentration of oxide ion, becomes 71.7 mv if a solid uncharged oxide is formed, regardless of the valence of the metal. Deviation from this slope implies a different course of the reaction.

The metals in this study were chosen to have stable oxides at the operating temperature and to be comparatively noble, in order that the electrode potentials would not become excessively negative and therefore subject to interference by traces of reducible impurities in the presence of excess oxide.

Experimental

The eutectic mixture of 41 mole % potassium chloride and 59 mole % lithium chloride (melting point 352°C) was used as a solvent system at 450°C, the working temperature in this investigation. The technique of preparation and purification as described in a detailed form earlier (15, 27) was followed. The reference electrode was a platinum plate immersed in a platinum(II) solution prepared in a fritted glass compartment by anodic dissolution with a known quantity of electricity. After each experiment the reference electrode compartment was analyzed by titration for chloride to determine the amount of solvent, and the potential was corrected to a Pt(II) concentration of 1M by calculation using the Nernst equation.

The associated apparatus and equipment used in fused salt methodology has been described elsewhere (16-19).

The oxygen electrode was a porous graphite electrode, of a type described by Senderoff and Mellors (20), which was held in an oxygen atmosphere at 400°C for 5 hr before use.

In the study of metal oxides the solvent was compartmented into medium porosity fused alumina or zirconia tubes. Prior to their actual use the tubes were soaked in hydrochloric acid for a few days in order to remove any basic oxides incorporated as binding agents in the tubes. After this treatment, the tubes were washed thoroughly with distilled water and dried at 500°C before they were inserted in the melt. There was no evidence for the presence of any objectionable species in the melt due to the use of these tubes. The residual current was found to be the same whether alumina or zirconia tubes or fritted glass compartments were used. Glass frits were used only when the study was purely qualitative in nature, for instance, when it was desired to observe color changes in the system. The solutes, generally anhydrous metallic salts, were added to the compartmentation tubes with the aid of a small platinum scoop which was mounted on a glass handle. At times, coulometric generation of metal ions by anodic oxidation of pure metal foils or wires was employed. At the conclusion of each experiment, the chloride content of each compartment was determined by an argentometric titration as described elsewhere (12). Thus, knowing the volume of the solution in the compartment, the concentration of solute at the time of measurement could be calculated.

[1] The IUPAC sign convention (14), in which half-reactions are written as reductions and the sign refers to the sign of the charge on the metal, is used.

The anhydrous metallic oxides were prepared as follows: Calcium oxide, platinum(II) oxide, and bismuth(III) oxide were made by vacuum desiccation of commercially available anhydrous samples. Lithium oxide was prepared from an analytical grade sample of lithium hydroxide monohydrate according to a procedure outlined by Brauer (21). Nickel(II) oxide (22), copper(I) oxide (21), palladium(II) oxide (23), and bismuth(III) oxychloride (21) were prepared according to available procedures.

Results and Discussion

The oxygen electrode, when dipped into solutions 0.09M to 0.21M in lithium oxide, was found very slow to reach equilibrium at temperatures of 400°-500°C. After 6-7 hr, the potential usually had reached a constant value, the final potentials at 450°C being −0.212, −0.328, and −0.407 v against a 1M Pt(II) reference electrode, at oxide ion concentrations of 0.094, 0.167, and 0.21M, respectively. These data do not yield a linear semi-logarithmic plot, and the rate of change of potential with concentration is much greater than predicted by the Nernst equation. The slope of the "best" straight line is about 0.6 v rather than the theoretical 0.0717 v. Similar behavior was observed at 400° and 500°C. It is concluded that reversible behavior could not be achieved under the conditions of the present study. It is likely that carbon takes part in the potential-determining reaction, in view of the finding by Smirnov, *et al.* (24) that at 800°C in KCl-NaCl saturated with CaO, the potential-determining reaction of a carbon electrode is

$$2Ca^{++} + CO_2 + 4e^- \rightleftharpoons C + 2CaO$$

Consequently, the drifting potentials and nonequilibrium character in the present study are probably due to mixed electrode processes.

The following metal oxides were studied in this investigation: copper(I) oxide, nickel(II) oxide, platinum(II) oxide, palladium(II) oxide, bismuth(III) oxide. In addition, bismuth oxychloride was compared with bismuth(III) oxide. The general procedure was to add a weighed amount of an anhydrous metal oxide to the melt collected in a zirconia tube and to measure the potential after each addition, a metal rod or foil serving as the indicator electrode. A different procedure was followed with bismuth oxide and bismuth oxychloride since metallic bismuth is a liquid at the operating temperature in this investigation (450°C). A tungsten rod in contact with a bismuth pool was used as a bismuth electrode. After each addition of metal oxide, the solution was well stirred and left for 15-20 min before a potential measurement was made. In almost all cases studied, the melt was saturated with the first addition of oxide and no change in potential was observed on subsequent additions of oxide. For following the reversibility of these electrode systems, varying amounts of lithium or calcium oxide were added to establish the oxide ion concentration. These oxides are known to be fairly soluble in lithium chloride-potassium chloride eutectic.

To calculate the equilibrium concentration of oxide ion, it was necessary to take into account the contribution from the solubility of the metal oxide. To illustrate the procedure, the measurements on the Pd-PdO system are given in Table I. The measured emfs of cells of the type

Pt|Pt(II), (A molar)||CaO (B molar), PdO (solid)|Pd [B]

were first calculated to a platinum(II) concentration of 1M, to give the figures in the last column. From the standard potential of the Pd(II),Pd electrode (−0.214 v vs. 1M Pt(II)), estimates of the solubility product of PdO were made, using the stoichiometric concentrations of calcium oxide added (column 2). The two values (6.63 and 6.49 × 10^{-5}, respectively) estimated from the higher added oxide concentrations were averaged to give 6.56 × 10^{-5}. From the solubility product, using a quadratic solution, the corrected oxide ion concentrations were calculated. The oxide ion concentration of a saturated solution of PdO without added CaO would be expected to be equal to the square root of the solubility product, or 8.1 × 10^{-3}M. From the standard potential of palladium and the measured emf, a Pd(II) concentration of 9.38 × 10^{-3}M is calculated. This suggests that some initial oxidation of Pd, promoted by the presence of oxide ion, had occurred before the oxygen had been completely flushed from the system. A better estimate of initial oxide concentration is given by $K_{sp}/9.38 \times 10^{-3} = 7.0 \times 10^{-3}$M.

Table I. Potential of Pd, PdO Electrode at Various Concentrations of Added Oxide Ion

Total CaO added, mg to 8.3 ml cell	CaO added, stoichiometric molar conc.	[O=] corr, molar	*E* (Cell[B]), volt measured	*E*, volt, *versus* 1*M* Pt reference
0	0	7.0×10^{-3}	−0.2371	−0.3594
7.8	0.0168	2.06×10^{-2}	−0.2700	−0.3923
15.9	0.0342	3.60×10^{-2}	−0.2862	−0.4058
23.0	0.0494	5.07×10^{-2}	−0.2992	−0.4215

The solubility of each metal oxide was estimated by three procedures: (*a*) from the measured potential of the metal in a solution saturated with its oxide, (*b*) from measurements of the voltammetric (polarographic) diffusion current of a solution saturated with the oxide, and (*c*) from E°_{oxide}, defined as the standard potential of the metal, metal oxide electrode obtained from the experimental curve of electrode potential against logarithm of oxide ion concentration extrapolated to a concentration of 1M (Eq. [4]).

Two alternate procedures were used to prepare half-cells. In the first, a metal was dissolved anodically in the melt and lithium or calcium oxide was subsequently added. In the second, a weighed amount of anhydrous metal chloride was added to the melt containing the soluble calcium or lithium oxide. A brief discussion of each metal-metal oxide system studied will now be given. For each electrode system, a plot of logarithm of molarity of oxide vs. potential against 1M platinum reference electrode has been made. These plots are depicted in Fig. 1, 2, and 3. In each figure the points are connected

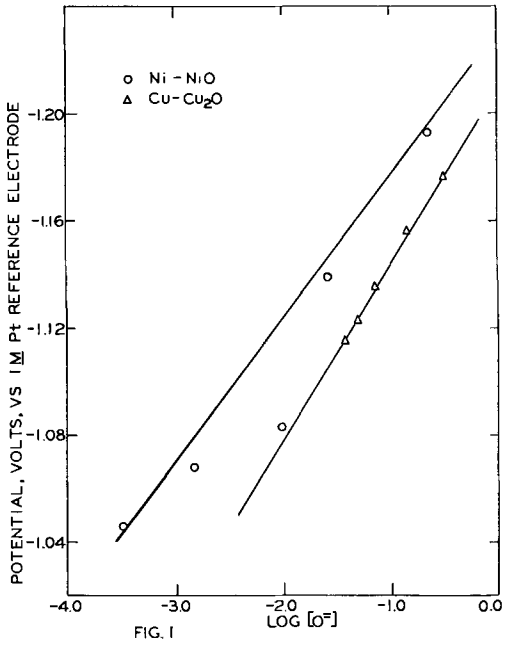

Fig. 1. Experimental behavior of Ni/NiO,$O^=$ and Cu/Cu_2O,$O^=$ electrodes. For comparison with theory, see text.

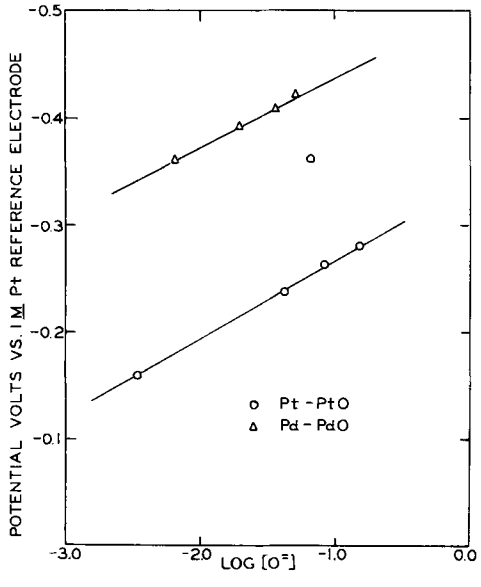

Fig. 2. Experimental behavior of Pt/PtO,$O^=$ and Pd/Pd,O,$O^=$ electrodes. For comparison with theory, see text.

by the best straight line. The experimental and theoretical slopes are compared in the text.

Nickel(II) oxide.—The nickel-nickel oxide couple, $NiO + 2e^- = Ni + O^=$, was the first to be studied. Nickel is known to form NiO as a stable oxide and no oxychloride of this metal is known. The concentration of nickel calculated from the potentials is 3.3×10^{-4} mole liter^{-1}. The concentration found from a polarogram taken of a saturated solution of NiO in the melt was 3.2×10^{-4} mole liter^{-1}. A plot of log [$O^=$] vs. E, shown in Fig. 1, showed a considerable departure from the theoretical slope and therefore indicated irreversibility of the system. The slope calculated by the least squares method is 53 mv as compared to a theoretical slope of 71.7 mv for a reversible half reaction. The E°_{oxide} value can approximately be quoted as —1.23 v which corresponds to

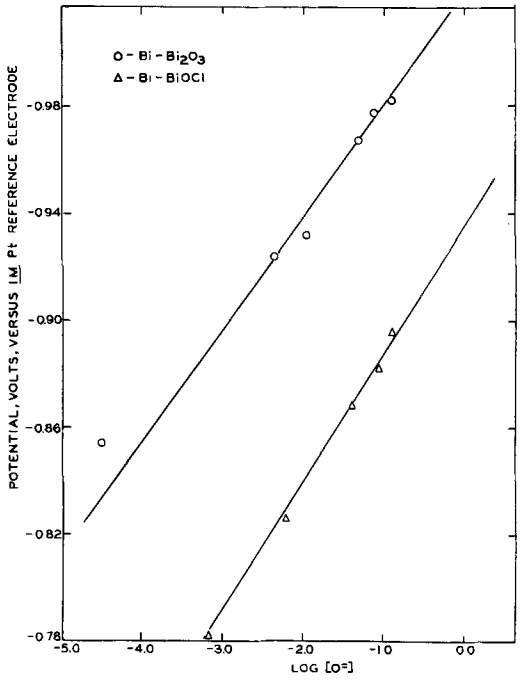

Fig. 3. Experimental behavior of Bi/Bi_2O_3,$O^=$ and Bi/BiOCl, $O^=$ electrodes. For comparison with theory, see text.

solubility of *ca.* 10^{-3} moles/liter, calculated from the theoretical slope. The experimental points on the figure are scattered and thus very little theoretical significance can be attached to the E°_{oxide} value. The value —1.23 v is more positive than expected from $E^\circ_{Ni^{++}-Ni}$ and solubility of NiO estimated polarographically (—1.297 v).

Two reasons may be advanced for the discrepancy between theory and experiment. First, the Ni(II)-Ni system may act irreversibly in the presence of excess oxide ion. This explanation is implausible because of the high exchange current of the Ni(II)-Ni electrode (24) and the moderate solubility of NiO in LiCl-KCl. Second, a higher nickel oxide, e.g., Ni_2O_3, may be formed. In this instance the measured potentials would be mixed potentials due to the presence of NiO and Ni_2O_3. This explanation appears to be more plausible, particularly because the formation of the latter oxide has been shown to be promoted by the presence of lithium oxide (25). Evidence for the existence of Ni_2O_3 at temperatures of 660°C and higher in molten lithium sulfate-potassium sulfate eutectic has also been published recently by Hill and co-workers (10).

Copper(I) oxide.—The solubility of Cu_2O, as determined from potential measurements and from a current-voltage curve, was 3.8×10^{-2} moles liter^{-1} and 5.8×10^{-2} moles liter^{-1}, respectively. A plot of log [$O^=$] vs. E shown on Fig. 1 gave a slope of 66.2 mv and the E°_{oxide} value, —1.207 v. The solubility calculated from the E°_{oxide} value was 6.95×10^{-2} moles liter^{-1} which is in agreement with the values obtained directly. Corresponding to the electrode reaction $Cu_2O + 2e^- \rightleftharpoons 2Cu + O^=$, the system Cu/$Cu_2O$,$O^=$ acts as an electrode of the second kind, but the application of this electrode as an indicator electrode for oxide ion is limited by the high solubility of Cu_2O.

Platinum(II) oxide.—A saturated solution of PtO in equilibrium with solid oxide when brought in contact with the platinum foil electrode registered a potential of −0.0546 v vs. a 3.28×10^{-2} M Pt(II) reference. This potential was stable over a long period (4-5 hr). From the potential the solubility of PtO was calculated to be 3.32×10^{-3} moles liter^{-1}. The effect of additional increasing amounts of CaO on the potential was also followed. A plot of log $[O^=]$ vs. E is shown in Fig. 2. The slope of the plot is 72.5 mv and E°_{oxide} is −0.3385 v. The solubility calculated from the E°_{oxide} value is 4.36×10^{-3} moles liter^{-1} which is in good agreement with the measured value.

In some experiments PtO was generated internally by anodizing platinum foil in the melt in the presence of an excess of CaO. Although the measurements agreed with those obtained by direct addition of PtO, the establishment of equilibrium was so slow that it took almost 24 hr to make four measurements. Stirring of the solution or passing of small current (*ca.* 1 μa), while the measurements were made, did not speed the attainment of equilibrium appreciably

Palladium(II) oxide.—Following the procedure explained above, the solubility of PdO from potential measurements was calculated as 9.4×10^{-3} moles liter^{-1}. The plot of log $[O^=]$ vs. E shown on Fig. 2 gives a slope of 74.2 mv and E°_{oxide}, −0.514 v. The solubility calculated from E°_{oxide} is 8.1×10^{-3} moles liter^{-1}. The attainment of equilibrium in this system was also extremely slow. From the experimental data, however, the electrode system appears to behave as a reversible electrode of the second kind.

Bismuth (III) oxide.—In studying the $Bi/Bi_2O_3,O^=$ system, a re-evaluation of the standard potential of the Bi(III)/Bi electrode was made. Using a tungsten electrode in contact with a molten Bi pool, a value of −0.63 v vs. 1M Pt(II)/Pt on the molarity scale was found. This value is in agreement with the value of −0.64 ± 0.01 v reported elsewhere (24), using a tungsten contact, rather than the previous value of −0.553 v originally reported (12), using a platinum contact. The disagreement may be attributed to alloy formation between platinum and liquid bismuth.

Experimental values of the potential of a bismuth electrode in the presence of sufficient solid Bi_2O_3 to form a solid phase, and with varying concentrations of oxide ion, added as CaO, are given in Fig. 3. The electrode potential followed the empirical equation

$$E = -1.023 - 0.042 \log [O^=] \qquad [6]$$

from which $K_{sp} = 3.2 \times 10^{-6}$ using Eq. [3]. The slope of the logarithmic plot (42 mv), however, does not agree with the theoretical value of 71.7 mv given in Eq. [4]. The value of K_{sp} can also be estimated from the potential of the bismuth pool in the presence of Bi_2O_3 but in the absence of added CaO (−0.8543 v vs. 1M Pt), from which $[Bi^{+3}] = 2.06 \times 10^{-3}$M. If it is assumed that $[O^=] = 3/2\ [Bi^{+3}] = 3.09 \times 10^{-3}$, a value of $K_{sp} = [Bi^{+3}]^{2/3}[O^=] = 5.0 \times 10^{-5}$ is estimated, differing by almost an order of magnitude from the estimate made from the intercept.

From the fact that the theoretical Nernst slope is not observed, however, it can be inferred that the simple solubility equilibrium of Bi_2O_3 is not reached. If Bi_2O_3 dissolves through the intermediate formation of BiO^+, the theoretical Nernst slope would not be affected as long as solid Bi_2O_3 were present at equilibrium. If Bi_2O_3 interacts to form a new solid phase of BiOCl and is present in excess so that both solid phases exist, then the equilibrium

$$Bi_2O_3(\text{solid}) + 2Cl^- \rightleftharpoons 2BiOCl(\text{solid}) + O^= \qquad [7]$$

would correspond to a fixed oxide ion (and therefore bismuth ion) activity. Addition of excess oxide would merely change the relative amounts of the two solid phases. On the other hand, if *all* the Bi_2O_3 were converted to a new solid phase of BiOCl, then, in accordance with the half reaction

$$BiOCl\ (\text{solid}) + 3e^- \rightleftharpoons Bi + O^= + Cl^- \qquad [8]$$

a Nernst slope of 2.3 $RT/3\mathbf{F}$ (47.8 mv) would be expected. The concentration of oxide ion, however, would depend on the amount of Bi_2O_3 as well as CaO which had been added. To clarify this point, a separate study of the $Bi/BiOCl,O^=$ electrode was made.

Bi(III) *oxychloride.*—The bismuth electrode in the presence of solid BiOCl and added CaO was found to obey the equation

$$E = -0.935 - 0.045 \log [O^=] \qquad [9]$$

in good agreement with the theoretical equation

$$E = E^\circ_{Bi^{+3},Bi} + RT/3\mathbf{F} \ln K_{sp} - 0.0478 \log [O^=] \qquad [10]$$

where $K_{sp} = [Bi^{+3}][O^=]$.

From the intercept, $K_{sp} = 4.2 \times 10^{-7}$. From the potential in the absence of added oxide (−0.782 v vs. 1M Pt), a bismuth ion concentration $[Bi^{+3}] = 6.6 \times 10^{-4}$ and $K_{sp} = 4.4 \times 10^{-7}$ are calculated, in good agreement with the value calculated from the intercept. Moreover, from the polarographic wave height for saturated BiOCl, a solubility of 6.9×10^{-4}, corresponding to $K_{sp} = 4.8 \times 10^{-7}$, was estimated.

It may be concluded that the electrode $Bi/BiOCl,O^=$ is behaving reversibly and that the above estimates of the solubility are therefore valid. It is interesting to note that these data indicate no appreciable interaction between Bi^{+3} and $O^=$ to form a complex such as BiO^+.

Returning now to the behavior of Bi_2O_3, it is clear from a comparison of Eq. [6] and [9] that, at the same added oxide ion concentration, the Bi_2O_3 electrode showed a more negative potential than the corresponding BiOCl electrode. If Bi_2O_3 were to interact according to Eq. [7] to produce BiOCl and oxide ion, the oxide ion concentration would be increased and qualitatively the electrode potential would be shifted in the negative direction as actually observed. The slope, however, would be affected because the oxide appearing from reaction [7] would exert more influence at low concentrations than at high concentration of added oxide ion. It appears probable that some interaction occurs between solid Bi_2O_3 and the melt, but that either the reaction is not as simple as represented by Eq. [7] or the system is slow to come to equilibrium, or

both. In an event, the $Bi/Bi_2O_3,O^=$ electrode cannot be regarded as a reversible oxide ion electrode.

Acknowledgment

The porous graphite used in the fabrication of the oxygen electrode was kindly provided by Dr. Seymour Senderoff, of the National Carbon Company. The authors extend their appreciation to the Office of Ordnance Research and the Diamond Ordnance Fuze Laboratory for the financial support of this project and for the research assistantship held by one of them (B. B. Bhatia).

Manuscript received Dec. 17, 1959. This paper was prepared for delivery before the Chicago Meeting, May 1-5, 1960.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

Solutions of Some Alkali Halides in the Pure Liquids and in Mixtures of N-Methylacetamide and Dimethylformamide

Lyle R. Dawson and Walter W. Wharton

Department of Chemistry, University of Kentucky, Lexington, Kentucky

ABSTRACT

Dielectric constants, densities, and viscosities of N-methylacetamide, dimethylformamide, and of mixtures of these liquids have been determined at five temperatures. Conductances, densities, and viscosities of solutions of sodium and potassium bromides and potassium iodide in various mixtures of these solvents have been measured at ten-degree intervals from 20° to 50°C. Variations in the dielectric constant of the solvent over the range 35-165 showed no influence on the degree of dissociation of these salts; they are essentially completely dissociated in all of the solvent mixtures studied. Differences in mobilities of the ions are explained in terms of various specific types of solute-solvent interactions.

During the past few years Dawson and co-workers have published from This Laboratory several papers describing the properties of solutions of electrolytes in solvents having high dielectric constants. Very large degrees of dissociation and correspondence with the theoretical Onsager (1) conductance relationships to concentrations much greater in these solutions than in water are attributable to a considerable extent to the high dielectric constants.

The investigation reported in this paper was designed to study the influence of large changes in dielectric constant on the degree of electrolytic dissociation and the mobilities of the ions of some univalent bromides and iodides. It was expected that

some insight into the comparative solute-solvent effects might be obtained also from the results of these studies.

Experimental

Apparatus and procedure.—The bridge assembly and procedures for conductance measurements as well as viscosity and density determinations have been described adequately in earlier papers (2-4). No significant change in the cell constants of the conductance cells could be detected over the temperature range for which they were used. The cells were held in a thermostated oil-bath maintained at a constant temperature to within ±0.1°.

Solvents.—The preparation and purification of N-methylacetamide (NMA) and dimethylformamide (DMF) has been described previously (5, 6). The solvents used in this work had specific conductances in the range 1 to 4×10^{-7} ohm^{-1} cm^{-1} at 30°.

Electrolytes.—The best obtainable commercial grades of sodium and potassium bromides were recrystallized twice from water and alcohol mixtures, fused, then stored in a desiccator over magnesium perchlorate.

Analytical grade potassium iodide was recrystallized twice, dried at 60° in a vacuum oven, then stored over magnesium perchlorate.

Solutions.—Solutions were prepared and dilutions made on a weight basis. All transfers were made in a dry atmosphere.

Dielectric constants of the solvents were measured (7) at 20°, 25°, 30°, and 40°. Extrapolated values were used for 50°.

Results and Discussion

All conductances were corrected by subtracting the conductance of the solvent from that of the solution. Limiting equivalent conductances were obtained by empirical extrapolation of plots of Λ vs. $\sqrt{C}$. Although there is some uncertainty in the Λ_0 values, they are believed to be accurate generally to well within 1%.

In the mixed solvent dimethylformamide (DMF)-N-methylacetamide (NMA) there are brought together isomeric components having approximately equal densities but widely differing viscosities and dielectric constants (Fig. 1). At 40°, the range of dielectric constants from 35 to 165 is spanned. Viscosities vary from 0.67 for DMF to 3.02 centipoises for NMA. Earlier work (4) has shown that sodium and potassium bromides and iodides are completely dissociated in pure NMA.

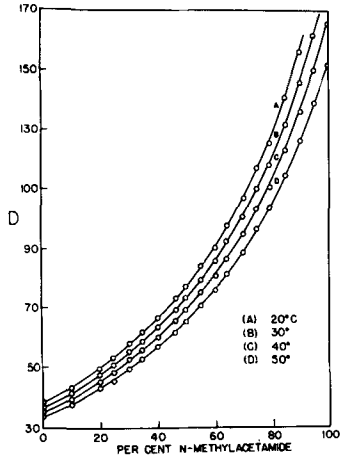

Fig. 1. Dielectric constants of the mixed solvents N-methylacetamide-dimethylformamide.

A summary of pertinent data for the solutions studied is presented in Table I.

Raman spectra and infrared studies (8) have shown that in NMA there exists a trans disposition of the oxygen atom and the amino hydrogen. Hydrogen bonding at these two points produces long chains of molecules leading to extremely high dielectric constants. In an unsubstituted amide such as formamide random associated forms occur which partially cancel contributions made by additional molecules and the dielectric constant is lower. If both amino hydrogens are replaced by alkyl groups, as in DMF, hydrogen bonding is not possible and the dielectric constant is relatively low.

Addition of a small amount of DMF to NMA greatly reduces both the dielectric constant and the viscosity by disrupting the long chains of molecules.

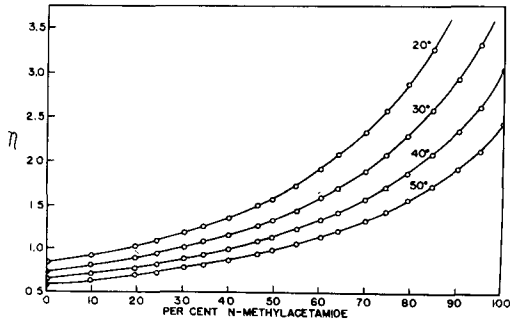

Fig. 2. Absolute viscosities of the mixed solvents N-methylacetamide-dimethylformamide.

Since the densities of the two pure components are so nearly equal, the degree of molecular association has little influence on the density of the mixture.

In all of the solutions studied the viscosity increases as the concentration of added electrolyte becomes greater (Fig. 2). This effect is more pronounced in mixtures richer in NMA. Increased viscosity may result from solvation of the ions by attachment of separate solvent molecules which are available in DMF or which may be produced in NMA by disruption of molecular chains. In addition, the viscosity of NMA solutions may become greater because of other changes in the solvent structure around the ions. In pure NMA the molecules are arranged in long chainlike groups. These linearly disposed molecular chains move past one another without great interference as the liquid flows. Nonelectrolyte solute particles which exert little influence on the solvent molecules encounter resistance which is not abnormally great as they move through the medium. Ionic solute particles at lower concentrations exert pronounced electrostatic attractive forces on various points along the solvent molecular chain but probably disrupt extensively relatively few of the solvent molecular groups. Under the influence of the electrostatic fields of these ions most of the molecular chains around them are only distorted so that they become serrated and curved. Then movement of the solvent units past one another or of solute particles through this medium is greatly hindered. It seems logical that this effect may be largely responsible for the unusual increase in viscosity with increasing concentration of added electrolyte which is observed in NMA solutions.

The absence of a maximum or minimum in the densities, viscosities, or dielectric constants of the solvent mixtures is an indication that compound formation between the components does not occur. The fact that on cooling a solvent mixture, essentially pure NMA crystallizes out, lends additional evidence that interaction between the solvent components is comparatively slight and primarily physical in nature.

Solutions of sodium and potassium bromide.—Plots of the equivalent conductance as a function of the square root of the concentration for sodium and potassium bromides (typical plots shown in Fig. 3-5) at ten degree intervals from 20° to 50° in both the pure components and in the 90-10 NMA-DMF mixtures are typical of highly dissociated electrolytes. Slopes of the KBr plots are slightly less

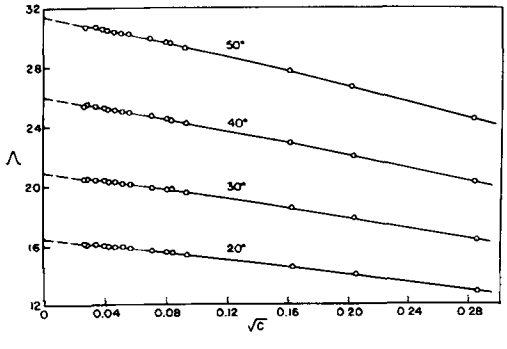

Fig. 5. Kohlrausch plots for solutions of sodium bromide in 90% NMA-10% DMF.

negative while those for NaBr are slightly more negative than the theoretical (Onsager) slopes. The higher charge density on the sodium ion would produce greater ion-solvent interaction than in the case of the potassium ion. This leads to a greater effective viscosity in the immediate environment of the sodium ion although the two alkali ion solvodynamic units may be of nearly equal sizes with equal limiting conductances. The greater solubility of the sodium compound lends support to this supposition.

Solutions of potassium iodide.—Potassium iodide is essentially completely dissociated in both of the pure constituents and in the various solvent mixtures (Fig. 6 and 7). In pure DMF the Λ_0 value for KI is about 1% less than for sodium and potassium bromides (Table I); in the 90-10 DMF-NMA mix-

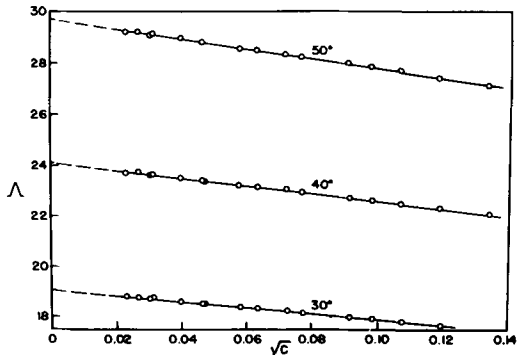

Fig. 6. Kohlrausch plots for solutions of potassium iodide in 98% NMA-2% DMF.

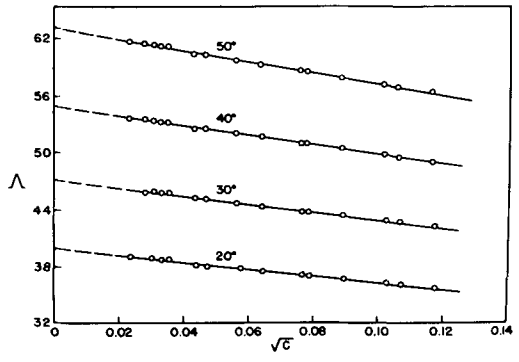

Fig. 7. Kohlrausch plots for solutions of potassium iodide in 48.67% NMA-51.33% DMF.

ture Λ_0 for KI is several per cent greater than for the other two salts.

Speculation concerning the possible mechanisms of solvation of bromide and iodide ions in NMA and DMF may be useful. Because of its smaller size and greater electronegativity, the bromide ion would be more likely to undergo hydrogen bonding through the amino hydrogen of NMA. Hydrogen bonding with DMF would not occur. In DMF solvation of an electron-donor ion could proceed through the electrophilic nature of the carbon atom in the carbonyl group (9). Solvation through electrostatic phenomena as ion-dipole or ion-induced dipole effects would be greater with the bromide ion because of its greater charge density. However, the more easily deformable electron atmosphere of the iodide ion makes it more susceptible to dipole-induced dipole attraction.

A comparison at 40°C of 22.99 for the limiting equivalent conductance of potassium iodide in NMA with the value of 21.04 for potassium bromide obtained by Dawson, Sears, and Graves (11) shows the bromide less conducting by about 10%. At 40°, the Λ_0 value for potassium iodide in NMA is less by a factor of 4.32 than it is in DMF. Λ_0 for potassium bromide, on the other hand, has been reduced by a factor of 4.74 at the same temperature. At this temperature NMA is 4.55 times as viscous as DMF. Thus it is seen that potassium iodide is about 5% more conducting and potassium bromide is about 5% less conducting than would be expected from viscosity effects alone. These data, in addition to the fact that the greater crystallographic diameter of the iodide ion would tend to make it less mobile than the bromide ion, constitute strong evidence that in NMA the bromide ion is solvated to a greater extent than the iodide ion. Similar results are obtained by comparing sodium bromide and potassium iodide.

The results of this investigation emphasize the differences in the behavior of the two halide ions in DMF and in NMA.

Acknowledgments

The authors are indebted to Dr. H. C. Eckstrom for valuable suggestions and to Mr. Murrell Pruitt for some confirmatory experimental work.

Financial support for part of this work was received from the National Science Foundation.

Manuscript received Dec. 31, 1959.

December 1960 Discussion Section

A Discussion Section, covering papers published in the January-June 1960 JOURNALS, is scheduled for publication in the December 1960 issue. Any discussion which did not reach the Editor in time for the June 1960 Discussion Section will be included in the December 1960 issue.

Those who plan to contribute remarks for this Discussion Section should submit their comments or questions in triplicate to the Managing Editor of the JOURNAL, 1860 Broadway, New York 23, N. Y., *not later than September 1, 1960.* All discussion will be forwarded to the author(s) for reply before being printed in the JOURNAL.

Brief Communications

Electronic Magnetoanalysis of an Iron Single Crystal

S. Yamaguchi

The Institute of Physical and Chemical Research, Tokyo, Japan

A piece of iron single crystal about 2 mm in diameter and 10 mm long was used for the experiments described below. One end of this rod was sharpened to a truncated wedge by grinding and then etching with hydrochloric acid. A small permanent magnet (coercive force about 300 Oersted) was attached to the other end of the specimen as indicated in Fig. 1. In this way the magnetic induction of the sample was kept saturated.

To study electron diffraction, an electron beam about 0.05 mm in cross section was allowed to graze the edge of the specimen (Fig. 1). The magnetic deflection of the incident beam can be measured by observing the shift in position of the diffraction pattern. The pattern from the iron crystal was measured with respect to the invariant position of the pattern from a nonferromagnetic gold foil. The patterns from the crystal and the foil were superimposed by means of a double exposure technique (1).

The pattern obtained from an unmagnetized sample (the same iron crystal with the permanent magnet removed) is shown in Fig. 2. The spots from the iron crystal fall on rings which are concentric with rings due to the gold foil. Most of the spots are actually located on rings produced by the gold, due to the near coincidence of the interplanar spacings of iron and gold; this indicates that the specimen contains no major internal stresses.

Figure 3 shows the pattern obtained from the magnetized sample. The spots due to the iron have shifted relative to the reference gold pattern; the shift shows the magnetic Lorentz effect.

Orientation—Figures 2 and 3 show that the incident beam was perpendicular to the (111) plane of the iron single crystal as well as to the magnetic induction $B_{0\bar{1}1}$ perpendicular to the $(0\bar{1}1)$ plane. The relations existing between the incident beam, the

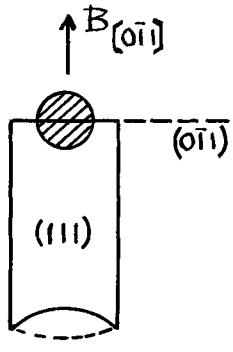

Fig. 4. Relation between the orientation of the specimen and the incident beam.

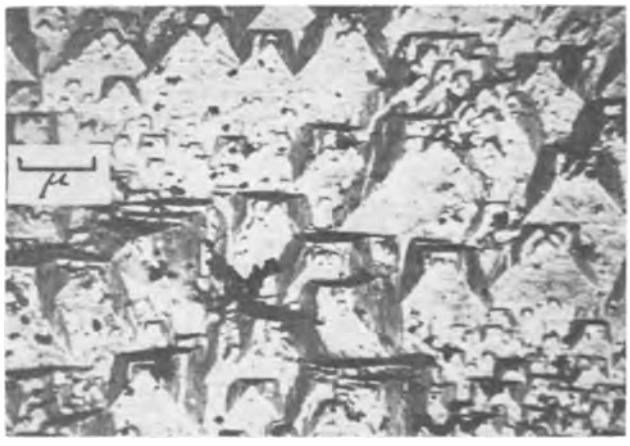

Fig. 5. Electron micrograph of the oxide film on and separated from the specimen.

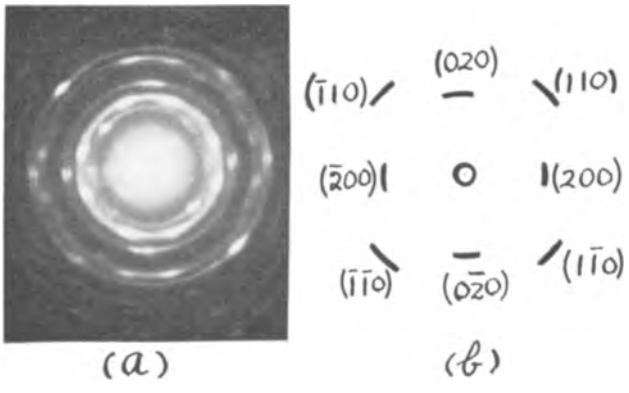

Fig. 6. (a) Diffraction pattern from the oxide film of Fig. 5 (Fe_3O_4). In (b) the Miller indices are assigned to the corresponding oriented diffraction arcs.

orientation of the specimen, and the direction of induction are illustrated in Fig. 4. Here the shadowed circle represents the cross section of the incident beam.

Electron microscopy.—An oxide replica film (thickness: about 200Å) formed on the stem surface of the specimen and then separated from it was enlarged by means of electron microscopy (Fig. 5).[1] Figure 5 pictures the octahedral (111) figures with regular orientation. This confirms the orientation of the specimen as determined by the diffraction process.

An electron beam running perpendicular to the oxide film face of Fig. 5 gave the diffraction pattern shown in Fig. 6(a). This pattern is characteristic of Fe_3O_4 crystals (magnetite, spinel type) oriented as illustrated in Fig. 6(b). In the case of Fig. 6 the incident beam was parallel to the (110) planes of the Fe_3O_4 crystals. It is therefore concluded that the (111) plane of the iron substrate is oriented perpendicular to the (110) planes of the Fe_3O_4 crystals. It is known empirically that there is a regular crystallographic orientation between a ferromagnetic substrate and the ferromagnetic oxide formed on it (2). The result obtained in the present experiment, $(111)_{Fe} \perp (110)_{Fe_3O_4}$, could serve for estimating the position of the iron crystal axis by means of the oxide replica process.

Magnetoanalysis.—The double diagram of Fig. 3 makes it possible to calculate the magnetic induction B of the specimen as a function of its crystal axis. We have a relation between the magnetic deflection of the incident beam readily measurable in Fig. 3 (ΔZ), and B. That is

$$\Delta Z = \frac{eL\lambda}{h} \int_0^l B\, dl \qquad [1]$$

where e is the electron charge (1.6×10^{-20} emu), L is the camera length (495 mm), λ is the wave length of the electrons, h is Planck's constant (6.6×10^{-27} erg sec), and l is the magnetic field traversed by the electron beam.

It is difficult to estimate the magnetic path l in the present experiment. The following process was employed to estimate the value of l. Since the magnetic induction of the specimen under the conditions in Fig. 3 is at saturation induction [B = 20000 gauss (3)], we can calculate the mean value of l according to Eq. [1]. Here it is assumed that B is homogeneous. We thus obtain $\bar{l} = 4\ \mu$, where $\lambda = 0.0288$ A and $\Delta Z = 0.27$ cm. This $\bar{l}$ —value can then be used for the further measurement of the B-H curve of the iron single crystal.

Stress Corrosion Cracking

D. van Rooyen

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

A mechanism in which stress corrosion cracks initiate and propagate in austenitic stainless steel in purely electrochemical stages was postulated by Hoar and Hines (1-5). Such a mechanism is supported by recent work (6) which demonstrated that no steps of mechanical fracture could be detected at any stage of the cracking process of 18-8 type stainless steel in boiling magnesium chloride solutions.

In order to account for observed rates of crack propagation, it was calculated that selective dissolution of the highly stressed advancing edge of a crack takes place at current densities of the order of 1 amp/cm^2. Hoar and West (7) demonstrated that 18-8 stainless steels can dissolve at such high current densities without much polarization, provided that the surface is yielding rapidly and provided that concentration polarization is avoided. They concluded that anodic dissolution is highly stimulated by the mechanically induced movement of the surface metal atoms. They further reported that similar tests on pure nickel gave no indication of such a mechanical effect in hot aqueous magnesium chloride.

While it is known that nickel and high nickel alloys do not suffer chloride stress corrosion cracking (8-13), it is uncertain whether their immunity arises in the initiation or in the propagation stage. It is important to know this, since the whole correlation made by Hoar and West between stainless steel and nickel is based on the assumption that cracks actually would not propagate into nickel under their conditions.

Studies on this mechanism of cracking are under way. Attempts are being made to compare the resistance of various alloys to crack propagation with their electrochemical behavior while corroding at high current densities in boiling magnesium chloride solutions. Specimens are prepared by arc depositing a layer of a susceptible material, such as 304 stainless steel, onto a strip of the material to be tested. The compound sample is then alternately rolled and vacuum annealed at 1065°C until the final thickness of about 0.045 in. is reached. The sample is given a final annealing treatment after machining the edges and is placed under direct load while in contact with the test solution which is contained in a glass cell. The load is high enough to cause cracks to start in the susceptible alloy, and their behavior is then studied at the boundary by subsequent metallographic examination. Parallel tests are next carried out in the way described by Hoar and West (7).

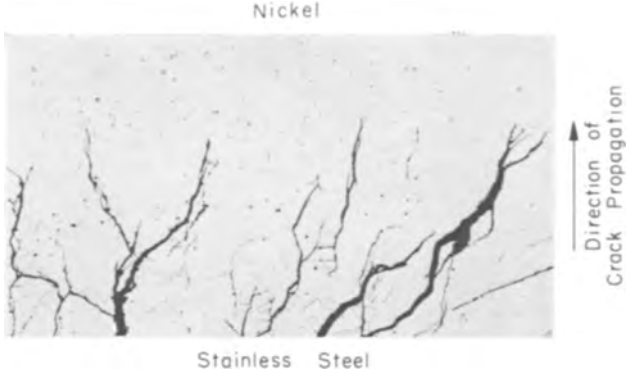

Fig. 1. Cracks stopping at steel-nickel boundary. Magnification 150X before reduction for publication.

Results so far on nickel have confirmed the absence of mechanical stimulation of its anodic dissolution. Furthermore, stress corrosion cracks, which start in the 304 type stainless steel of a bonded specimen, proceed to the nickel boundary where they stop, Fig. 1. It can be seen that the cracks penetrate a short distance into the thin intermediate layer that exists between the sensitive alloy and the nickel. After crack information and penetration in this particular experiment, the stress on the nickel was 43,000 psi, not allowing for any stress-raising effect at the tips of the cracks. Results to be reported later show that it is unlikely that a galvanic effect between the metals could account for the stopping of cracks at the boundary.

The results are in agreement with the electrochemical mechanism of cracking (1-5), although they do not directly constitute further proof.

Investigation of the Electrochemical Characteristics of Organic Compounds

V. Heterocyclic Nitro Compounds

R. Glicksman and C. K. Morehouse

Semiconductor and Materials Division, Radio Corporation of America, Somerville, New Jersey

ABSTRACT

A study of the electrochemical characteristics of nitropyridine and other heterocyclic nitro compounds shows that the cathode potential of these compounds during current flow is dependent on the aromaticity of the compound, as well as the type and position of substituent groups on the aromatic ring. The effect of these factors on the cathode potential is interpreted in terms of the electron density distribution in the molecule. Performance characteristics of magnesium dry cells containing 2,5-dinitrofuran and various nitropyridine compounds as cathodes are also presented.

Previous work by the authors (1, 2) has dealt with the effect of various types of groups and their position in the molecule on the cathode potential of aromatic nitro and nitroalkane compounds during current flow. As an extension of this work, a study of the electrochemical characteristics of heterocyclic nitro compounds and their use as cathodes in primary cells has been made and is presented in this paper.

Apparatus and Technique

A technique previously described by the authors (3) has been used to measure the operating potential during current flow and the coulombic capacity of the various heterocyclic nitro compounds. This technique consists in discharging at a constant current, in a large volume of electrolyte, a 0.5-g sample of the heterocyclic nitro cathode material mixed with 0.05 g of Shawinigan acetylene black. The change in cathode potential with time was measured with a L&N type-K potentiometer, using a saturated calomel reference electrode. Measured potentials were corrected for the *IR* drop associated with the apparatus and electrolyte by means of an oscillographic technique.

All half-cell potential data reported in this paper are referred to the normal hydrogen scale and include a liquid junction potential, which in most cases is small and can be neglected.

For most of the measurements an aqueous magnesium bromide electrolyte and a magnesium anode were used. For studying the effect of *p*H on potential, a zinc anode was employed with the acidic NH_4Cl-$ZnCl_2$-H_2O and basic NaOH-H_2O electrolytes.

Experimental Data and Discussion of Results

Nitropyridine and Nitroquinoline Compounds

A number of heterocyclic compounds possess the type of stability found in benzene. Among the more common heterocycles, pyridine is less easily substituted than benzene and, in general, surpasses it in aromatic character (4). On the other hand, the resonance energies of thiophene (31 kcal) and furan (23 kcal) indicated that these compounds are less stable than benzene (39 kcal) and pyridine (43 kcal) (5). The chemical reactivity of thiophene and furan, in general, is in good agreement with this fact.

Because substitution of aromatic compounds usually takes place through attack by electron seeking groups, positions that have the greatest electron density will be substituted most readily. However, a nitro group on a position of high electron density is more difficult to reduce than one on a position of low electron density (1, 2) and, therefore, one would expect the cathode potential of aromatic heterocyclic nitro compounds to be greater for those compounds which are less easily substituted, i.e., for the more highly aromatic systems such as pyridine.

The effect of aromaticity and group substitution on the electrode potential of heterocyclic nitro compounds was determined by half-cell potential studies of a number of nitropyridine and nitroquinoline compounds discharged continuously in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte at a rate of 0.005 amp/g. The half-cell discharge curves are presented in Fig. 1-5, and theoretical capacity and electrode efficiency data for these compounds are given in Table

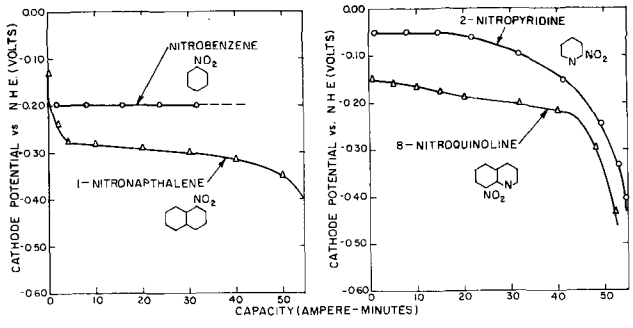

Fig. 1. Half-cell potential studies of various heterocyclic nitro compounds discharged in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte at a rate of 0.005 amp/g.

Table I. Theoretical capacities and electrode efficiencies of various nitropyridine and nitroquinoline compounds

Compound	Theoretical capacity, amp-min/g	Experimental capacity,* amp-min/g	Electrode efficiencies, %
nitrobenzene	78.4	—	—
2-nitropyridine	77.7	51.5	66.3
4-hydroxy-2-nitropyridine	69.0	56.8	82.3
2-chloro-5-nitropyridine	60.9	46.9	77.0

6, 8-dinitroquinoline	88.1	43.3	49.1

* Capacity calculated on the basis of a −0.40 v end potential.

I. The theoretical capacities were computed by means of Faraday's Law, assuming a 6-electron change per nitro group, and the electrode efficiencies were calculated from the data in Fig. 1-5, using a −0.40 v end potential to compute the capacities.

Figure 1 shows half-cell discharge data for nitrobenzene and 2-nitropyridine along with their corresponding bicyclic compounds, 1-nitronaphthalene and 8-nitroquinoline. The higher potential of 2-nitropyridine as compared with nitrobenzene is understandable in terms of resonance theory. In pyridine, the nitrogen atom has a greater attraction for electrons than has a carbon atom and decreases the availability of electrons. Thus, the effect of resonance in pyridine is to bring electrons from the α or 2 and γ or 4 positions to the nitrogen atom, which decreases the electron density at these positions relative to that at the β or 3 positions. The inductive effect is also operative, and because electrons are removed from the β positions of pyridine as well, this position too has a lower electron density than found in benzene. The nitropyridines then, because of the lower electron density in the vicinity of the reducible nitro group, should have a greater affinity for electrons and operate at higher cathode potentials than comparable nitrobenzene derivatives.

The effect induced by the nitrogen atom is similar to that found in nitrobenzene as evidenced by the fact that it is about as difficult to substitute on pyridine as on nitrobenzene. If this behavior is assumed to be caused by the similar ring electron densities of pyridine and nitrobenzene, it would be expected that the cathode potential of 2-nitropyridine would be comparable to that of o-dinitrobenzene. Half-cell

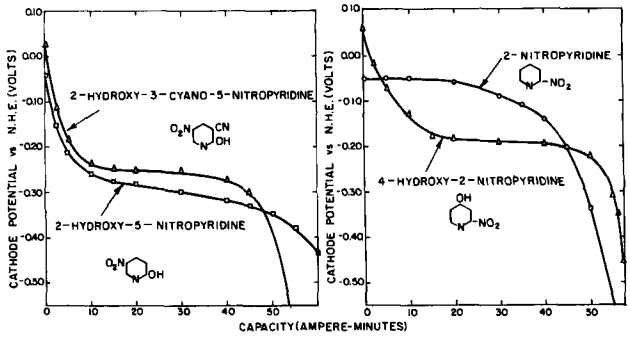

Fig. 2. Half-cell potential studies of various nitropyridine derivatives discharged in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte at a rate of 0.005 amp/g.

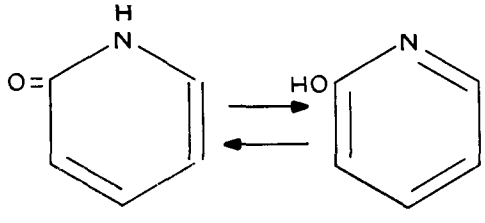
discharge studies of o-dinitrobenzene under similar conditions of discharge confirm this reasoning.

Figure 1 also shows that the simple monocyclic nitro compounds, nitrobenzene and 2-nitropyridine, operate at higher potentials than their corresponding bicyclic compounds. These results are consistent with the stronger aromatic character of the monocycles as compared with the bicylic compounds. Because quinoline is related to naphthalene similarly to the way pyridine is related to benzene, the higher operating potential of 8-nitroquinoline as compared with 1-nitronaphthalene is to be expected.

In Fig. 2 are half-cell discharge data for various nitropyridine derivatives discharged at a rate of 0.005 amp/g in magnesium bromide electrolyte. These results indicate that the effect of substituent groups and their position in the molecule on the potential of nitropyridine compounds closely parallels their effect on the potential of nitrobenzene derivatives. For example, the presence of the electron-repelling hydroxyl group in 4-hydroxy-2-nitropyridine causes the cathode potential of this compound to be 0.15 v lower than the potential of 2-nitropyridine. The magnitude of this effect is comparable to that found for the corresponding nitrobenzene derivatives. Similarly the substitution of an electron attracting —CN group in the -3 position of 2-hydroxy-5-nitropyridine results in a compound, 2-hydroxy-3-cyano-5-nitropyridine, with a higher operating potential than the parent compound.

The half-cell potential-time discharge curves of these hydroxy nitropyridine compounds show a striking similarity to those of the hydroxy aromatic C-nitroso compounds (6). As is the case with the latter compounds, the high initial operating potentials of the hydroxy nitropyridines decrease rapidly during the first 10 amp-min of discharge and then assume a constant value for the remainder of the discharge.

This behavior can be explained in the following way: both the 2- and 4-hydroxy pyridines are tautomeric with the pyridones: e.g.,



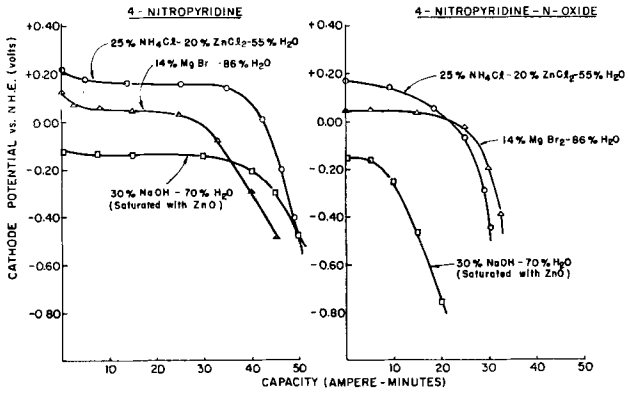


Fig. 3. Half-cell potential discharge curves of 4-nitropyridine and 4-nitropyridine-N-oxide discharged at a rate of 0.005 amp/g in various aqueous electrolytes.

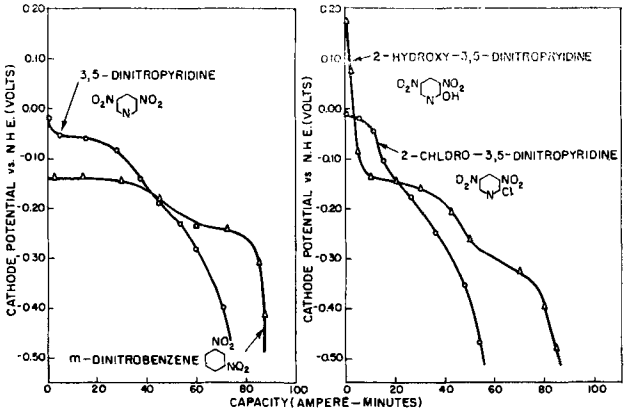

Fig. 4. Half-cell potential studies of various dinitropyridine compounds discharged in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte at a rate of 0.005 amp/g.

and it is believed that the high initial potential of these compounds is a result of the pyridone structure. However, during the discharge, hydroxyl ion is formed as a consequence of the cathodic reduction reaction, and a neutralization reaction occurs with time between the hydroxypyridine form and the alkaline electrolyte with the formation of the strongly electron-repelling phenoxide ion. At this point, the cathode potential is due to that of the hydroxypyridine salt, and it remains constant at the lower potential throughout the remainder of the discharge.

The higher potential of 4-hydroxy-2-nitropyridine as compared with that of 2-hydroxy-5-nitropyridine is attributed to the fact that the nitro group in the former compound is on a position of lower electron density than the nitro group in 2-hydroxy-5-nitropyridine and is thus more readily reduced. This behavior is apparent when the possible resonance structures of pyridine are considered Thus, it would be expected that 2- and 4-nitropyridine compounds would operate at higher cathode potentials than comparable 3-nitropyridine compounds.

In Fig. 3 the high cathode potential of 4-nitropyridine compounds is demonstrated by the half-cell potential discharge curves of 4-nitropyridine and 4-nitropyridine-N-oxide obtained by discharging these compounds at a rate of 0.005 amp/g in aqueous $MgBr_2$, NaOH, and NH_4Cl-$ZnCl_2$ electrolytes. The curves show that both compounds operate at about the same potential, indicating the effect of the N-oxide group on the electrode potential to be very small. In general, the electrode potentials of these 4-nitropyridine compounds increase with decreasing electrolyte pH, a result similar to that found for the aromatic nitrobenzene compounds. However, unlike the aromatic nitrobenzene compounds which have poor electrode efficiencies in strongly basic electrolyte, 4-nitropyridine operates at an efficiency of 62.7% in this electrolyte.

Figure 4 gives half-cell potential discharge data for various 3,5-dinitropyridine compounds discharged continuously in a 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte at a rate of 0.005 amp/g. The data show that the dinitropyridine compounds operate at higher potentials than their corresponding mononitropyridine compounds. For example 2-hydroxy-3,5-dinitropyridine, for its first discharge step, operates at a potential approximately 0.14 v higher than that of 2-hydroxy-5-nitropyridine. In addition to their higher operating potentials, the dinitropyridine compounds have higher theoretical ampere-minute capacities than the mononitropyridine compounds and consequently show more promise for use as cathode materials in dry cells.

The data in Fig. 4 illustrate that the effect of substituted groups on the potential of 3,5-dinitropyridine is similar to that found for the aromatic dinitrobenzene and mononitropyridine compounds. The 0.08 v lower potential of m-dinitrobenzene as compared with 3,5-dinitropyridine also agrees with theory.

The half-cell potential discharge curves of various nitroquinoline compounds given in Fig. 5 show that the various isomeric mononitroquinoline compounds operate at comparable potentials of about −0.15 to −0.20 v for most of their discharge life. As expected, the cathode potential of 6,8-dinitroquinoline is 0.1 v higher than the potentials of 6- and 8-nitroquinoline.

The electrode efficiencies of the nitropyridine and nitroquinoline compounds are in general quite high as indicated by the data in Table I. For the 3-(or 5-) nitropyridine compounds efficiencies of 77-95% are obtained, while the nitroquinoline compounds operate at electrode efficiencies ranging from 81-97%.

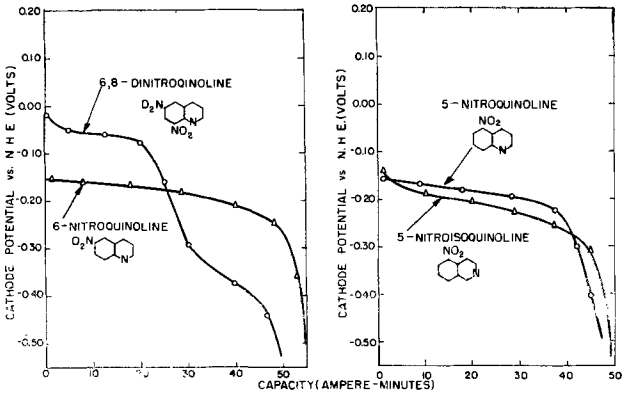

Fig. 5. Half-cell potential studies of various nitroquinoline compounds discharged in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte at a rate of 0.005 amp/g.

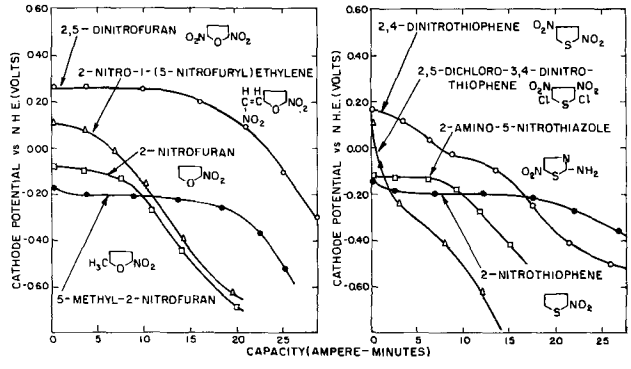

Fig. 6. Half-cell potential studies of various nitrofuran and nitrothiophene compounds discharged in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte at a rate of 0.005 amp/g.

However, the more strongly oxidizing 2- and 4-nitropyridine and dinitropyridine compounds have lower efficiencies.

Nitrofuran, Nitrothiophene, and Other Five Membered Heterocyclic Nitro Compounds

In Fig. 6 are half-cell potential discharge curves of various nitrofuran and nitrothiophene compounds. Despite the weakly aromatic character of furan as compared with benzene and thiophene, 2-nitrofuran operates at a higher cathode potential than either nitrobenzene or 2-nitrothiophene under similar conditions of discharge. The apparent anomalous behavior of 2-nitrofuran may be explained by the fact that furan is not a true aromatic compound, and any generalization based on aromatic behavior would not be pertinent for this compound. For example, furan behaves like a typical diene in the Diels-Alder reaction, while ring cleavage by mineral acid shows its vinyl ether character. However, resonance energy considerations show that furan has some characteristics of a typical aromatic substance as well. It is thus apparent that the unsaturation of the furan nucleus will frequently manifest itself as a diene or vinyl ether, rather than as a true aromatic system typified by benzene.

The data in Fig. 6 also illustrate the effect of substituted groups on the potential of 2-nitrofuran. The cathode potentials of 2-nitrofuran derivatives increase as the 5-position is substituted with increasingly stronger electronegative groups, i.e., in the order $—CH_3$, —H, $—CH{=}CHNO_2$, $—NO_2$. As with the other nitro compounds studied, the effect of substituent groups on the cathode potential of 2-nitrofuran can be explained by their effect on the electron density in the vicinity of the reducible nitro group.

It is significant that the increase in potential caused by the addition of a $—NO_2$ group to the -5 position of 2-nitrofuran is 0.15-0.20 v greater than the increase found for the addition of a $—NO_2$ group to the ortho, para, or meta position of nitrobenzene. In this respect the nitrofurans behave more like the nitroalkanes than like the aromatic nitro compounds. Moreover, the nitrofurans, like the nitroalkanes, have exceedingly poor electrode efficiencies in the $MgBr_2$ electrolyte, giving values ranging from 16-31% for the four compounds studied.

Table II. Theoretical capacities and efficiencies of various five membered heterocyclic nitro compounds

Compound	Theoretical capacity, amp-min/g	Experimental capacity,* amp-min/g	Electrode efficiencies, %
nitrobenzene	78.4	—	—
2-nitrofuran	85.5	13.6	15.9
2, 5-dinitrofuran	122	30.7	25.2
2-nitro-1-(5-nitrofuryl) ethylene	52.4†	14.2	27.1
2-methyl-5-nitrofuran	75.8	23.2	30.6
2-nitrothiophene	74.8	31.6	42.2
2, 4-dinitrothiophene	111	20.9	18.8
2, 5-dichloro-3, 4-dinitrothiophene	78.8	7.5	9.5
2-amino-5-nitrothiazole	67.0	14.5	21.6
1-nitronaphthalene	55.8	54.4	97.5
6-nitroindazole	59.1	51.9	87.8
6-nitrobenzimidazole	59.1	51.8	87.6
5-nitroindazole	59.1	16.5	27.9
5-nitrobenzotriazole	58.9	61.5	100
5-nitro-2-benzimidazol-ethiol	49.5	43.0	86.9

* Capacity calculated on the basis of a −0.40 v end potential.

† Theoretical capacity calculated on the basis of the reduction of furan nitro group only.

Figure 6 also gives half-cell potential discharge curves for various nitrothiophene derivatives and for 2-amino-5-nitrothiazole. Because thiophene undergoes the typical substitution reactions of aromatic compounds and is more reactive than benzene, its nitro derivative would be expected to operate at a lower cathode potential than nitrobenzene. However, the discharge curves in Fig. 1 and 6 show that both 2-nitrothiophene and nitrobenzene operate at comparable potentials of −0.20 v in the magnesium bromide electrolyte. The effect on the cathode potential of additional $—NO_2$ and —Cl groups on the thiophene nucleus is similar to that found with other nitro compounds as evidenced by the high cathode potentials of 2,4-dinitrothiophene and 2,5-dichloro-3,4-dinitrothiophene. However, the data in Table II show that these compounds operate at extremely poor electrode efficiencies.

The thiazoles, which are structurally similar to thiophene and to pyridine, show reactions similar to

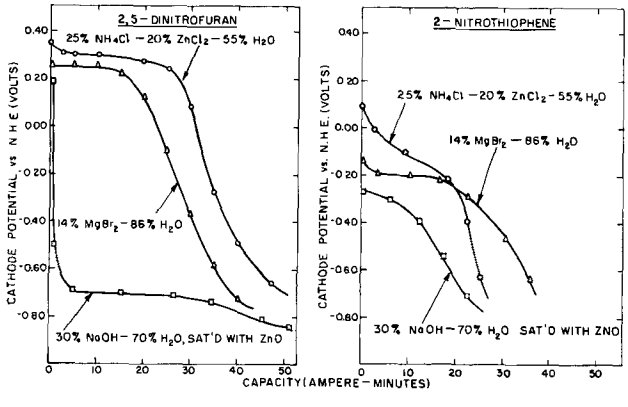

Fig. 7. Half-cell potential curves of 2,5-dinitrofuran and 2-nitrothiophene discharged at a rate of 0.005 amp/g in various aqueous electrolytes.

pyridine rather than those of thiophene. This behavior is particularly apparent in the resistance shown toward substitution reactions and is evidenced by the higher cathode potential of 2-amino-5-nitrothiazole as compared with nitrobenzene and 2-nitrothiophene.

Half-cell potential discharge studies were made on 2,5-dinitrofuran and 2-nitrothiophene to determine the effect of pH on the operating potential and capacity of these compounds. Figure 7 shows that the cathode capacity of 2,5-dinitrofuran increases only slightly with decreasing pH and is considerably less than the theoretical capacity (122 amp-min/g) of this compound. Similarly, 2-nitrothiophene shows no improvement in capacity with the more acidic NH_4Cl-$ZnCl_2$ electrolyte and actually shows a slight decrease. The poorer capacities obtained from these compounds in the strongly basic NaOH electrolyte are similar to those found for the aromatic nitro and nitroalkane compounds and can be attributed to the presence of side products which are formed by the condensation of the primary reduction products and to the poor stability of these compounds in this electrolyte.

In general the effect of decreasing electrolyte pH is to increase the cathode potential in agreement with theoretical considerations. It is interesting to note that the effect of pH on the cathode potential of 2,5-dinitrofuran is small, a relationship similar to that found for the nitroalkanes (2) but different from that found for the aromatic nitro compounds. The behavior of 2-nitrothiophene in this respect is closer to that of the aromatic nitrobenzene compounds.

In addition to the simple 5-membered heterocyclic compounds, each of the heterocyclic compounds can be fused to a benzene ring to give bicyclic systems which are comparable to naphthalene and quinoline. The half-cell potential discharge curves of various bicyclic heterocyclic nitro compounds are presented in Fig. 8. In general, these compounds, which contain two or three nitrogen atoms in the 5-membered ring, operate at potentials higher than that of 1-nitronaphthalene but lower than that of the nitroquinolines. As with the nitroquinoline compounds high electrode efficiencies are obtained with these bicyclic heterocyclic nitro compounds.

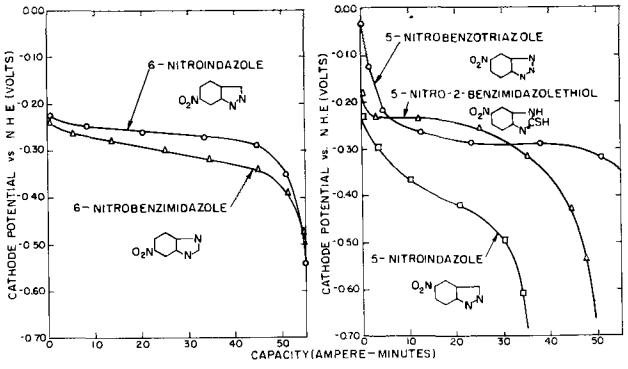

Fig. 8. Half-cell potential studies of various bicyclic heterocyclic nitro compounds discharged in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte at a rate of 0.005 amp/g.

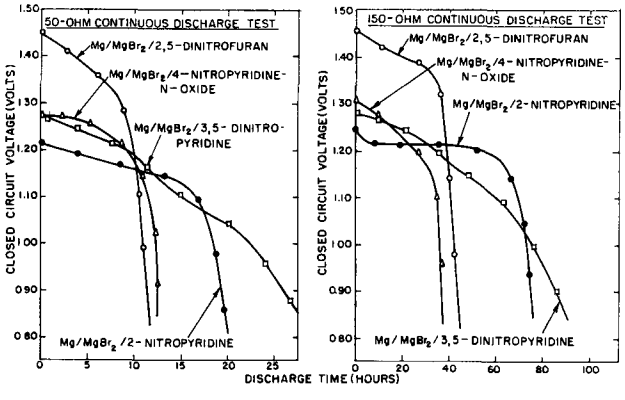

Fig. 9. AA-size magnesium dry cells containing various heterocyclic nitro compounds as cathodes discharged continuously through 50- and 150-ohm resistances.

Experimental Dry Cell Data

Experimental dry cells containing various heterocyclic nitro compounds as cathodes were assembled in the usual manner, using an AA-size can of impact-extruded magnesium AZ10A alloy and a magnesium bromide electrolyte. The cathode mix (weighing approximately 5 g) consisted of two parts by weight of Darco G-60 carbon black to one part by weight of the nitropyridine compounds. For cells containing 2,5-dinitrofuran as the cathode, two parts of the nitro compound was blended with one part by weight of Shawinigan acetylene black.

The performance characteristics of these Mg/$MgBr_2$/heterocyclic nitro AA-size cells on a 50- and 150-ohm continuous discharge test are shown in Fig. 9. The operating voltages of these cells closely parallel their half-cell potentials after corrections are made for the half-cell potential of the magnesium anode, which operates at a potential of about 1.3 v in this electrolyte. From the limited shelf-life data available, it appears that the cells containing the nitropyridine cathodes can be stored for extended periods of time without an appreciable decrease in cell performance, while the 2,5-dinitrofuran cells do not have an appreciable shelf life.

The use of heterocyclic nitro compounds as cathodes in dry cells appears to offer some advantages over the nitrobenzene compounds in that many of them operate at higher potentials at comparable electrode efficiencies. At present, these compounds are not as readily available as the nitrobenzene derivatives, being more difficult to synthesize; however, they offer a vast new source of potential cathode materials for future use. For example, considering only the pyridine compounds, almost every type of benzene compound has its analog in the pyridine series, and the number and types of pyridine derivatives are potentially as extensive as those in the benzene system.

Discharge of a Lead-Acid Cell through an R-L Circuit

J. J. Lander[1] and E. E. Nelson

Naval Research Laboratory, Washington, D. C.

ABSTRACT

Submarine cells of the lead-acid type were discharged through resistance-inductance circuits. The data are analyzed to show no contribution to voltage loss other than *IR* losses in the cell during the initial voltage transient; consequently, a method is provided for the determination of the internal resistance. Circuit geometry is an important factor determining the types of discharge curves which can be obtained.

It has been desirable for various reasons to determine the internal resistance and other electrical characteristics of lead-acid storage cells (1-5). Experimental determinations of the internal resistance have been more or less uncertain because of presumed effects contributed by polarization phenomena other than *IR* drop. In this work, measurements involving cell discharges through a resistance-inductance series circuit are shown which lead to a determination of the internal resistance of a fully charged cell.

Theory

When a constant voltage is discharged through a resistance-inductance circuit, current builds up with time and levels off to a constant value depending on the resistance and the inductance in the circuit, according to the equation

$$E = L\, dI/dt + RI \qquad [1]$$

If this relation is applied to the circuit shown in Fig. 1, it can be shown that the voltage change measured across V_T, after the switch is closed, will be given by the differential equation

$$dV_T/dt = -\left(\frac{R_o + R_I}{L}\right) V_T + \text{const.} \qquad [2]$$

At the instant the switch is closed, all the energy supplied by the voltage source is contained in the term $L\, dI/dt$, the value of I being zero. As time proceeds and I builds up, the voltage V_T will fall off logarithmically from its open-circuit value and approach a constant value as dI/dt approaches zero. If R_I is unknown, its value could be determined by measuring the voltage V_T and current with time. It would be given by dividing the current at any time into the difference between the open-circuit value of V_T and its value at the corresponding time. R_I might also be obtained from the slope of the dV_T/dt vs. V_T line if R_o and L were known.

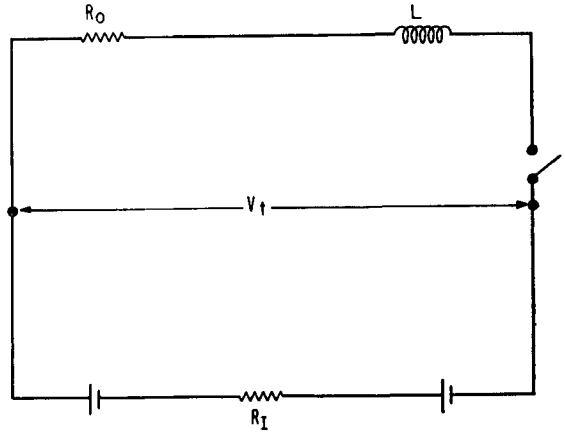

Fig. 1. An R-L series circuit

It might be assumed that a lead-acid cell discharging through an R-L circuit could be represented for some initial time interval by the circuit given in Fig. 1. The two potential sources would correspond to the positive and negative plates and V_T, the voltage measured across the cell terminals. It is not to be supposed that this circuit would represent the cell over a whole period of transient voltage, because other kinds of polarization besides *IR* drop are known. These would render the voltage source nonconstant, and Eq. [2] would not be adequate. If, however, the additional polarization should be slow to develop compared to the time necessary for the inductance field to be established, the proposed circuit would be a good representation of the initial voltage transient.

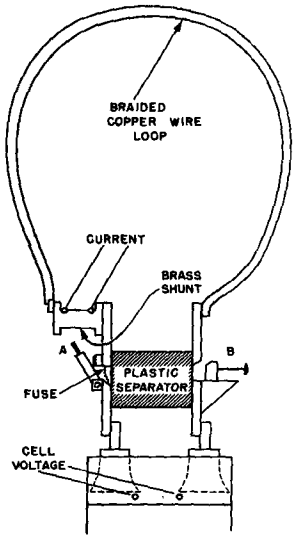

Fig. 2. Cell top and switch

Experimental Work

Experimental work consisted in discharging a fully charged submarine cell (~ 7000 amp-hr nominal capacity) through resistances of known values, while cell voltage and voltage drop across another small resistance in series were recorded as a function of time. The resistance consisted of ½ and 1 in. braided copper cables, or lengths of these in parallel, in series with a short, heavy brass tube of resistance 1.4×10^{-6} ohms. This tube was provided for measuring current. A switching device was mounted on the cell terminals as shown in Fig. 2. The cables were arranged in big loops, 4-5 ft in diameter to supply the inductance. It was attempted to keep the inductance loop relatively constant. Resistances were measured by running currents of about 100 amp through appropriate parts of the circuit and measuring voltage drops with a precision potentiometer.

In Fig. 2, A is a heavy six-bladed knife switch used to open the circuit; a fuse was placed in parallel to take the load when the switch was opened and then burn out to break the discharge circuit. The circuit was closed by driving the wedge switch B into its seat in the mounting. B was designed to make the circuit quickly and completely. All mechanically contacting parts were silver-plated to reduce contact resistance. Under best conditions the total resistance of the switch mounting could be reduced to $15\text{-}20 \times 10^{-6}$ ohms.

Procedure for making a run was as follows. The cell was charged to full gassing and then allowed to sit on open circuit overnight for the voltage to become steady. The shunt resistors were clamped into place with both switches open and their resistance values measured. Voltage connections were made to the recorder from the proper places in the discharge circuit; the knife switch was closed and the wedge switch slammed home. Current was allowed to run for the desired period; the circuit was broken and the cell charged for another run.

Cell voltages (V_p) were measured at the tops of the plates inside the cell, because preliminary data showed that measurements made across the cell terminals included enough inductance contribution

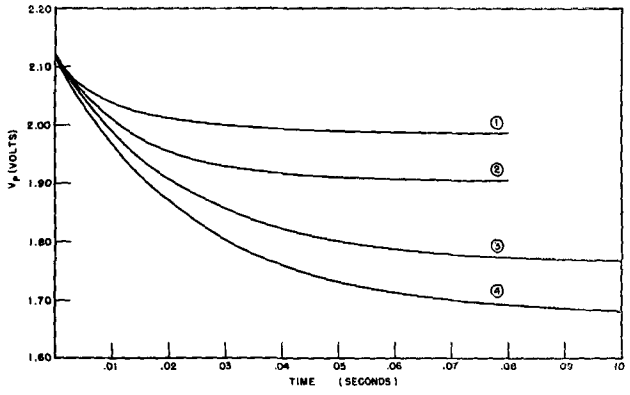

Fig. 3. Cell voltage vs. time

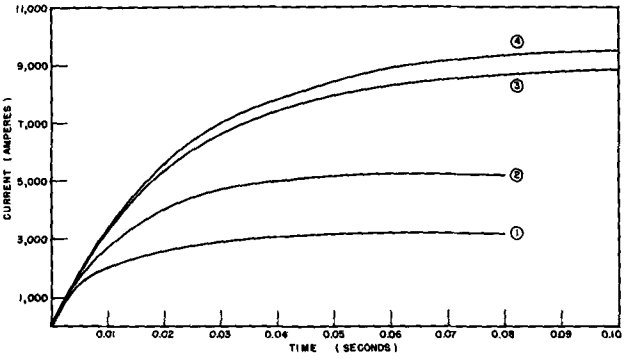

Fig. 4. Current vs. time

to render results very difficult to analyze quantitatively. Similarly, the short, heavy, brass tube was used so no appreciable inductance would be included in the current measurement.

A Brush recorder, type BL-202, was used to measure voltages. Time could be established to within 0.002 sec. This was considered to be of sufficient precision because the initial transients existed for times of 0.04-0.10 sec, depending on the L/R ratio, and because the measured voltages rose (from zero, in the case of current) and fell away (from OCV, in the case of cell voltage) very smoothly.

Data

Figures 3 and 4 show voltage decay and current rise curves over the first 0.1 sec or so, for the cell shorted through external shunts having resistances: 171, 193, 354, and 624×10^{-6} ohms. These data were all checked once and duplicate traces checked almost exactly when superimposed.

Discussion and Conclusion

The slopes of the voltage-time curves were measured and are shown plotted against the cell voltage in Fig. 5. The curves are linear; therefore Eq. [2] describes the discharges over these transient periods, i.e., these portions of the discharge data represent a constant potential driving current through an R-L circuit.

Presumably, the cell voltage might be constant over the ranges included in Fig. 5 and yet include some initial contribution, other than IR_l, to voltage decay. Therefore, the curves of Fig. 6 are shown where the voltage drop from open circuit is plotted against several values of current for each discharge.

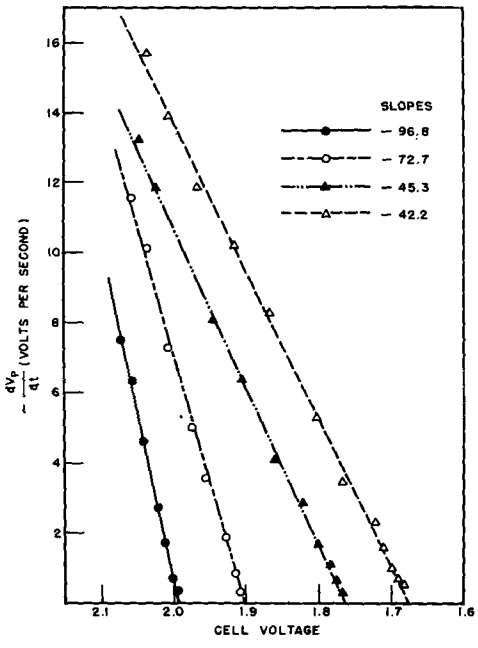

Fig. 5. $-dV_p/dt$ vs. cell voltage

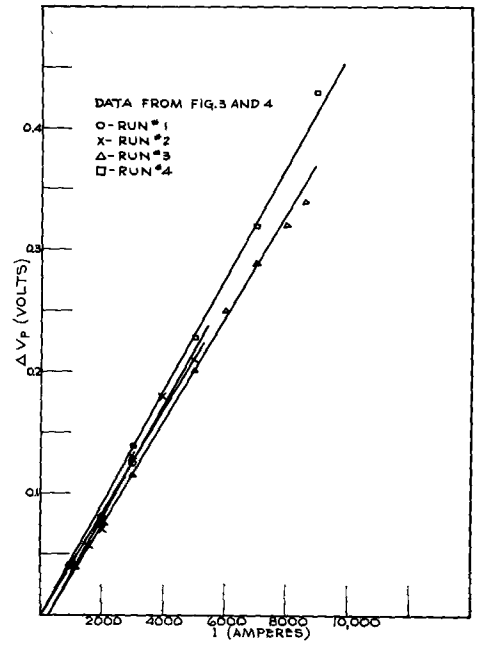

Fig. 6. Change in cell voltage vs. current, all runs

The curves are linear and nearly superimposable for each pair of runs and extrapolate through zero within 0.01 v.

It is concluded that there are no substantial (i.e., outside experimental error) contributions to voltage loss within the cell from sources other than *IR* loss over the discharge periods. The internal resistance obtained from the slopes of the curves of Fig. 6 has the value 43.7 ± 3.8 x 10^{-6} ohm. The resistance of the risers and lugs was measured during current flow and it contributes 10 x 10^{-6} ohm to the cell resistance measured at the tops of the lugs outside the cell, so total resistance of this cell in the fully charged condition was 53 x 10^{-6} ohm.

Values of inductance of the one-turn loop were estimated to be 5-8 x 10^{-6} henry (6). Values calculated from the slopes of the curves of Fig. 5, knowing R_o and R_I, ranged between 5 and 7 x 10^{-6} henry.

One run was made in which time was extended out to 2 sec, during which cell voltage and single electrode potentials were measured. For this run, no polarization was evident at the negative plate after 0.1 sec, the total contribution from sources other than IR_I loss being located at the positive plate. With somewhat over 9000 amp flowing, positive plate polarization amounted to 0.05 v at 2 sec, and it was still increasing slowly when the run was stopped at about 5 sec.

Discharge Voltages Measured at the Cell Terminals

It has been mentioned that cell-voltage taps were located at the tops of the plates inside the cell to avoid contributions from the $L\ dI/dt$ term. One set of data will be presented to illustrate the effect of including such a contribution with the voltage taps at the cell terminals.

The circuit was rearranged to approach a short-circuit condition by removing the cables and swinging the short, heavy, current-measuring brass tube between the tops of the plates forming the switch mounting, so the external resistance consisted of the switch mounting and the brass tube in series. Reference to Fig. 2 will aid in getting the picture. The inductance loop was then bounded by the plates of the cell, the cell risers and lugs, the plates and switches comprising the switch mounting and the brass tube. The inductance of the loop was estimated to have a value of about 0.3 x 10^{-6} henry. For this run a different cell was used than was used for obtaining the previous data. It had a different number of plates but had the same nominal capacity.

The data for the run is given in Fig. 7. The shunt voltage curve (current) rose smoothly from zero to a value corresponding to 34,300 amperes.[2] The cell

[2] A word should be said about current density. The gross positive plate area is 64,000 cm^2 for this cell. Particle size measurements indicate the actual area of the active material could be as high as 3000 x the gross area, so current density can be in the range 0.5 to 1.7 x 10^{-4} amp/cm^2 depending on current distribution.

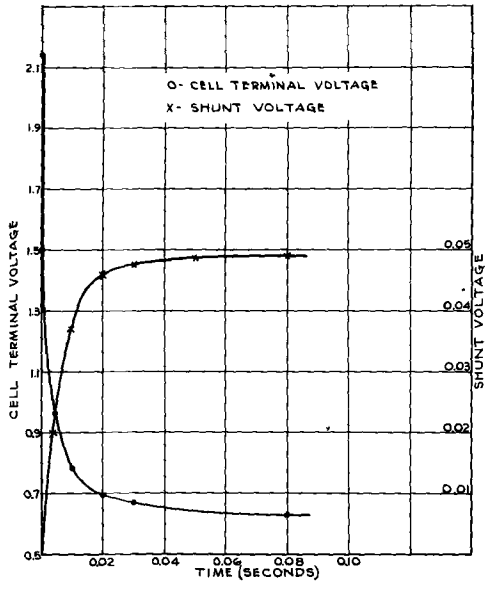

Fig. 7. Cell discharge data, voltage measured at cell terminals.

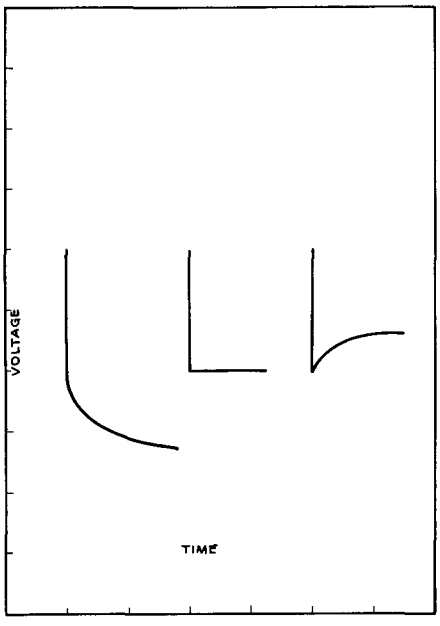

Fig. 8. Types of discharge curves possible in R-L circuits

voltage, however, fell immediately (i.e., within 0.002 sec) to a value of about 1.5 v, thereafter decaying smoothly to a value of 0.63 v.

Now, when the location of the cell voltage taps in relation to the geometry of the inductance loop is considered, it appears that the initial voltage drop could include 1/3-1/2 the initial $L\ dI/dt$ term. Furthermore, at zero time there can be no contribution from IR loss inside the cell because $I = 0$, or from electrochemical polarization because no current has passed. The conclusion that the initial voltage drop corresponds to an inductance contribution is inescapable.

The circuit inductance can be obtained from the time constant, i.e., t, when $I = 0.632\ I$ max. and total R in circuit from the equation: $L = tR$. t is 0.06 sec and R is approximated from the data assuming that when I levels off there is substantially no electrochemical contribution to polarization. If so, R_I is 43.7 x 10^{-9} ohm, R_o is 18.1 x 10^{-6} ohm, and L is 0.37 x 10^{-6} henry. Then, the initial voltage drop of 2.12-1.50 or 0.62 v is equal to $L_I\ dI/dt$, where L_I is the inductance contribution to the initial voltage drop measured at the terminals. dI/dt at zero time is 5.1 x 10^5 amp/sec from Fig. 7 and, therefore, L_I is 0.12 x 10^{-6} henry, i.e., within the estimated range of 1/3-1/2 of total L based on the circuit geometry.

One further point is to be made: by judicious selection of resistances in the latter circuit, polarization curves of the types illustrated in Fig. 8 could have been obtained, and this in a circuit containing R-L elements only. Of course, time constants would vary, depending on R, so the curves are illustrative only.

Manuscript received July 9, 1959. This paper was prepared for delivery before the Columbus Meeting, Oct. 18-22, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

ABSTRACT

An a-c square wave technique was used to study resistance and double-layer capacity during film formation on silver electrodes in KOH solutions. The peak in the voltage-time curve at constant current anodization is shown to coincide with complete surface coverage by Ag_2O and is not an ohmic resistance, but rather an overvoltage effect. Evidence for the existence of an unstable higher oxide than AgO (or additional oxygen) during oxygen evolution is presented. Microvolumetric gas measurements with large area electrodes on open-circuit decay also support this conclusion. The duration of the upper voltage plateau of the voltage-time curve during discharge of AgO electrodes is determined by contact phenomena among individual AgO particles, in particular by separation and passivation of the remaining AgO by insulating surface layers of Ag_2O.

Increased interest in the silver-silver oxide electrode has prompted a number of investigations about this system. However, the recent literature (1-15) shows a number of contradictions in the interpretation of the observed phenomena, in particular with regard to the presence of oxides higher than AgO on the electrode, and with regard to the shape of the voltage-time curves during constant current anodization and discharge of silver in KOH electrolyte.

It was decided, therefore to apply the a-c square-wave technique which was developed recently (16) to study films on lead electrodes. This technique in-

volved the superposition of an a-c square wave current on the polarizing d-c constant current.

Experimental

The experimental set-up is illustrated schematically in Fig. 1. It shows the electrolytic cell, with separate auxiliary electrodes for the supply of a-c and d-c currents, and the recording equipment to follow the a-c and d-c response of the test electrode through a reference electrode. The instrumentation has been described in detail (16).

Figure 2 is a photograph of the cell. The test electrode, consisting of a sheet of silver, was clamped against the bottom of the cell with a thin Teflon gasket to prevent leakage. An area of 1 cm^2 was exposed to the electrolyte. A special micro reference-electrode was constructed in the following manner. A 28 gauge platinum wire was bent into a flat loop, 2 mm in length, and one end was pinch-sealed into a 3 mm Pyrex tube. The loop was heavily gold coated by placing gold chloride crystals on it and decomposing them by heating, and then fusing the gold into the surface of the platinum. Contact to the platinum wire in the tube was made by filling the tube with soft solder and by inserting a copper wire into the molten solder. The gold was then wetted with mercury such that it filled the loop. Mechanical cleaning of the gold-coated loop improved the wetting with mercury. This reference electrode was then placed into the KOH electrolyte to be used and anodized briefly. Microelectrodes prepared in this way gave potentials within 0.1 mv of a standard HgO reference electrode. The microelectrode was placed into the Luggin capillary, which intersected the side wall of the electrolytic cell within 0.3 mm of the electrode surface. This minimized the ohmic drop in the electrolyte during measurements of electrode potentials and provided for an undisturbed linear electrical field. Since the microelectrode was only 3 mm from the electrode surface, frequency dispersion and capacitive pick-up were minimized.

Figure 3 shows examples of oscilloscope traces obtained with this equipment. The traces shown here were selected in order to demonstrate the advantage of using a micro reference-electrode over a macro-electrode and the advantages of a differential oscilloscope input over a single ended one. The traces are voltage-time curves. The sweep speed was 20 μsec/cm. The voltage scale was 5 mv/cm. The square wave current used had a frequency of 6250 cps and was 10 ma peak to peak.

Trace 1 was obtained using a conventional macro reference electrode and differential oscilloscope input (type 53/54 D Tektronix plug-in preamplifier). Here the electrolyte path between the reference

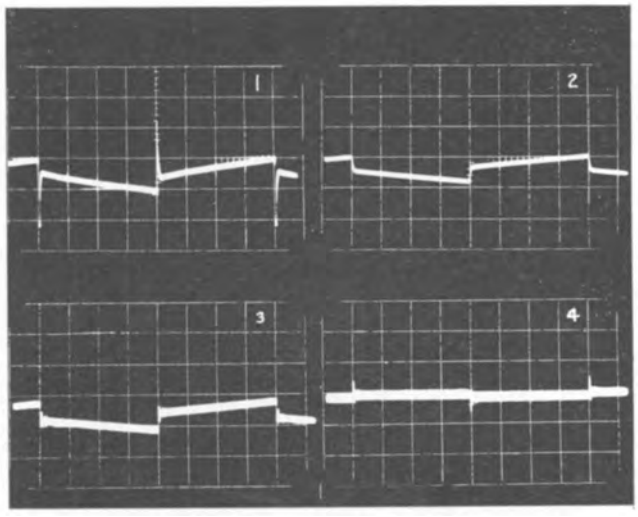

Fig. 3. Oscilloscope traces of voltage-time curves. Abscissa: time (20 μsec/cm); ordinate: voltage (5 mv/cm).

electrode and the working electrode was a Luggin capillary 8 cm long. Clearly visible is the overshoot of the trace due to capacitive pick-up. The duration of the transient spike at the moment of current reversal is between 2-3 μsec. This obscures the determination of initial slopes of the traces.

Trace 2 shows a similar curve, but taken with a microelectrode. It can be seen that the transient spikes are completely eliminated. The rise-time of the oscilloscope preamplifier was about 1 μsec in the 5 mv/cm range used here, and the reference electrode shows a perfect frequency response for this rise time. [When a wider band pass amplifier was used (type 53/54 B Tektronix plug-in unit), the rise time of the traces was found to be 0.1 μsec, or as good as the rise time of the square wave current used.] This shows that the arrangement used here is capable of following extremely fast electrochemical phenomena.

Trace 3 shows the effect of using a single-ended preamplifier (type 53/54 D Tektronix unit, used single ended) instead of a differential amplifier. The traces show extensive ringing and noise pick-up. At the low voltage signal levels used here even the resistance of the copper wires of the cable shields and the ground return paths represent considerable impedances. Even though all ground connections are made at the working electrode, high-frequency cable oscillations are detectable and a-c ground loops are set up.

Trace 4 was obtained by connecting the single ended amplifier between the square wave generator ground and the working electrode, which were short circuited by the cable shield. Trace 4 represents the difference between trace 2 and 3. In trace 2 the effects of all ground loops and spurious pick-up have been eliminated or cancelled electronically.

Pure silver sheet (99.99%) was etched in dilute nitric acid, washed with triple-distilled water, and air dried. The sample was cathodized at 3 ma/cm² in 30% KOH at 28°C for several minutes whereby hydrogen was evolved to remove any surface films of silver oxide. The current was reversed and the electrode anodized. The potentials were recorded and pictures were taken with the camera on the oscilloscope to determine the double layer capacity and resistance at rapid intervals during the anodization period of 5 min. Then the current was reversed and the oxide film discharged.

In a second phase of this investigation of the silver-silver oxide system, a microvolumetric study of oxygen evolved during the open-circuit decay of oxygen overvoltage was made. The oxygen evolved at constant temperature and pressure was measured as a function of time simultaneously with the decay of potential. The experimental set-up for this study has been described recently (17).

A standard AgO storage battery plate as produced by the Industrial Division of The Electric Storage Battery Company, containing 7 g of silver, was charged over prolonged periods of time at 50 ma in 30% KOH. The current was then interrupted and the potential allowed to decay to 0.52 v vs. Hg/HgO or 20 mv positive to the reversible AgO/Ag_2O potential. The plate was then charged at various

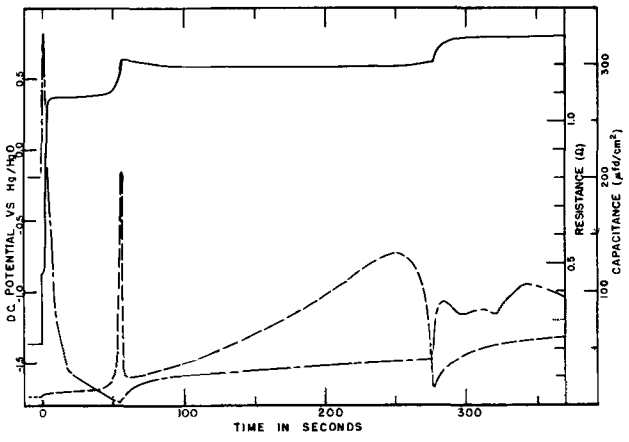

Fig. 4. Electrode potential (solid line), ohmic resistance (dashed line), and double layer capacity (dotted-dashed line) of silver during anodization at 3 ma/cm² as a function of time.

constant currents from 10 ma to 250 ma and the build-up of oxygen overvoltage recorded. After 24 hr of overcharge the currents were interrupted and the cell sealed simultaneously. The gas evolved during overvoltage decay was measured by the displacement of a drop of liquid in a calibrated capillary.

Results

The anodization curve of a 1 cm² sheet silver electrode is shown as the solid line in Fig. 4. The curve starts out at hydrogen evolution at 3 ma/cm². At $t = 0$ the current was reversed and the potential rose rapidly. After a sharp rise of 450 mv there was a slight arrest and then the potential rose smoothly to the Ag/Ag_2O potential at about +0.35 v.

After about 40 sec, the potential increased to a peak of +0.62 v, and decreased subsequently to about +0.57 v. The potential rose again after 250 sec to +0.6 v, after which a sharp break occurred, and the potential increased to +0.8 v. At the point of the sharp rise a cloud of fine gas bubbles was seen rising in the electrolyte.

The electrode film resistance calculated from the oscilloscope traces as recorded by the camera is plotted as a dotted line. The initial resistance is very low, about 0.03 Ω, and is due primarily to the gas bubbles adhering to the surface, and reducing the effective cross section of the electrolyte. As the current is reversed, the resistance shows a slight jump, but remains relatively constant at 0.04 to 0.05 Ω for about 40 sec.

At this time, the resistance builds up quite rapidly to a very high value of 0.8 Ω, and probably higher, indicating a rapid passivation of the surface. At the moment the potential reaches its peak, the resistance falls off such that within 1 sec the resistance has fallen to 0.1 Ω. During the course of the Ag_2O/AgO voltage plateau the resistance increases smoothly to a point about 30 sec before the third step in the voltage-time curve, or where O_2 is evolved. Here, rather than increasing as at the beginning of the Ag_2O/AgO plateau, the resistance takes a sharp dip, falling to a value of 0.06 Ω. After the oxygen evolution starts, the resistance builds

up smoothly as the oxide film thickness continues to increase slowly.

The curve showing the differential capacitance (as determined from the initial slope of the voltage-time oscillographs) is plotted as a dot-dash line. This curve reflects in a general way the inverse of the resistance-time curves, with several noteworthy exceptions. The initial capacity during H_2 evolution is about 200 μfd/cm^2, indicating a roughness factor of about 10 (assuming a double layer capacity of 20 μfd/cm^2 of true surface area). The momentary high capacity after reversal shows that some highly reversible reaction is in progress, but after the first 10-15 sec the capacity decreases nearly linearly to very low values of 1-2 μfd/cm^2. After the Ag_2O/AgO plateau is reached the capacity rises rapidly to 25 μfd/cm^2 and then more slowly to about 40 μfd/cm^2. When oxygen evolution starts the capacity increases abruptly and erratically, rising to a peak and decaying, rising to a peak and decaying, rising again, etc.

The discharge curve of a specimen that had been held at the oxygen evolution potential at 3 ma/cm^2 for 3 min is shown by the solid line in Fig. 5. The potential falls in about ½ sec to the Ag_2O/AgO plateau, but this drop is *not* instantaneous. The AgO plateau lasts for 100 sec, at 3 ma/cm^2 and then drops to the Ag_2O/Ag discharge potential. This second plateau lasts for 170 sec (longer than the first plateau) and then the potential falls off rapidly. A slight arrest is noted, at −0.75 v and then the potential drops to the H_2 evolution value.

The resistance curve during discharge shows a very different behavior from that obtained on anodization. The resistance of 0.3 Ω at oxygen evolution shows an initial rise which levels off at about 0.5 Ω. A more gradual increase sets in, which slowly accelerates until values as high as 2.5 Ω or more are reached. The resistance breaks down completely within 1/6 of a second, or the repetition rate of the camera we used, at the moment when the potential drops to the lower voltage plateau. The resistance falls to 0.04 Ω and gradually decreases to unmeasurably low values during the Ag_2O/Ag plateau.

After a sharp initial peak, the capacitance decreases about linearly as passivation progresses, decreasing to 1 or 2 μfd/cm^2 at the transition point. As the Ag/Ag_2O step progresses, the capacitance increases more or less linearly to very high values (greater than 4000 μfd/cm^2) and drops off sharply at the end of the second voltage plateau. A further peak in capacitance occurs during the small potential arrest, and then the capacitance decreases rapidly at H_2 evolution. It might be noted that the capacitance at this point is about 400 μfd/cm^2 as compared to 200 at the start of the run, indicating a roughening of the surface by a factor of 2.

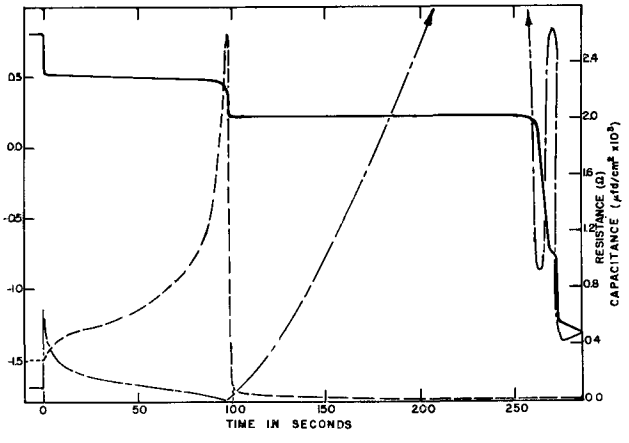

Fig. 5. Electrode potential (solid line), ohmic resistance (dashed line), and double layer capacity (dotted-dashed line) of a silver oxide film (produced by previous anodization of silver in KOH) during discharge at 3 ma/cm^2, as a function of time.

The results of the microvolumetric studies during oxygen overvoltage decay are shown on Fig. 6. These results were obtained with porous large-area electrodes. Figure 6A shows the plots of electrode potential vs. time on a logarithmic scale, for open-circuit decay from three different prepolarizing currents. Also shown is a plot of oxygen evolved vs. time during overvoltage decay on open circuit. Figure 6B shows a similar curve for the decay of oxygen overvoltage on PbO_2 in sulfuric acid. The results for PbO_2 (Fig. 6B, 6D, and 6F) are included here for purposes of comparison only, because they are representative of the decay of overvoltage on an inert electrode (17). Similar curves are obtained for decay of oxygen overvoltage on nickel in KOH, decay of hydrogen overvoltage on Zn and Cd in KOH, and Pb in H_2SO_4.

Figure 6C is a plot of the electrode potential during oxygen overvoltage decay vs. relative excess of oxygen, or vs. $V_T - V_X$, where V_T is the total volume of oxygen evolved to a potential 20 mv above the open-circuit potential, and V_X is the volume of oxygen evolved to any intermediate potential. Figure 6D shows a similar plot for decay of oxygen overvoltage on PbO_2 (17). Figure 6E illustrates a charging curve for build-up of oxygen overvoltage on AgO. The large-area electrodes were charged after being allowed to decay to a potential 20 mv above the reversible open-circuit potential, at different currents. Similar charging curves are shown in Fig. 6F for PbO_2.

Discussion

These results permit a detailed analysis of the mechanisms of the silver oxide electrode. In particular, the effects of the resistance of the surface films on silver are brought out clearly. The lower oxide, Ag_2O, has a very high electrical resistivity. Ag_2O powder was compressed into a hard, shiny pellet at 62,500 psi. The resistance was measured with an electrometer ohmmeter to be $7 \cdot 10^8$ Ω cm. (Using this value, a 1 cm^2 monolayer would have a calculated resistance of about 1 Ω. The extrapolation is, of course, very approximate, since a monolayer has different properties from bulk material.) From the length of the Ag/Ag_2O plateau in Fig. 4 and a surface roughness factor of about 10, the thickness of the Ag_2O film produced during the plateau is roughly 50-100 monolayers thick. It is apparent that the surface film of Ag_2O is nonuniform and that at the moment of complete coverage, the resistance must rise to relatively high values. This causes the sharp peak in the resistance curve.

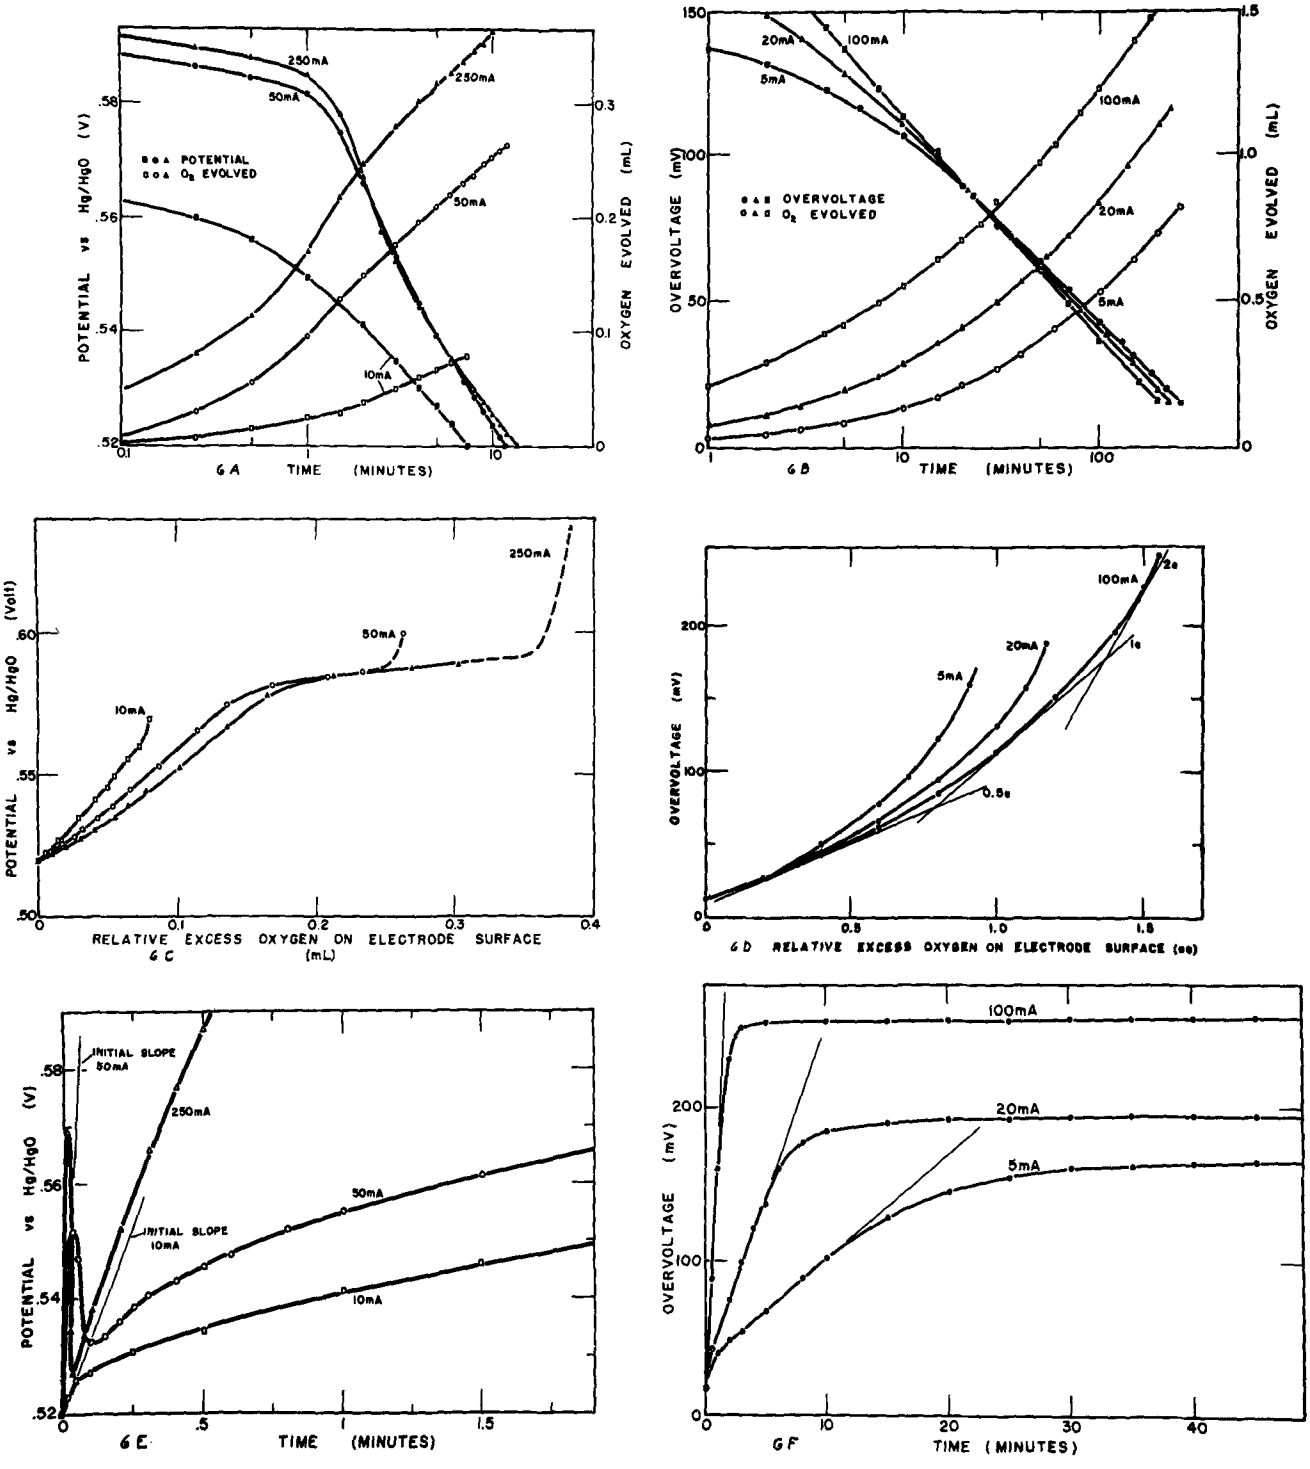

Fig. 6. Comparison of overvoltage and gas evolution data on AgO and PbO_2 electrodes. Fig. 6A, overvoltage decay and gas evolution during open-circuit decay of an AgO electrode in KOH. Fig. 6B, overvoltage decay and gas evolution during open-circuit decay of a PbO_2 electrode in H_2SO_4. Fig. 6C, electrode potential of AgO in KOH during decay as a function of gas evolved. Fig. 6D, electrode potential of PbO_2 in H_2SO_4 during decay as function of gas evolved. Fig. 6E, charging curves for oxygen overvoltage build-up on AgO electrodes. Fig. 6F, charging curves for oxygen overvoltage build-up on PbO_2 electrodes.

The peak observed in the voltage-time curve at the beginning of the AgO step is not directly due to an ohmic resistance effect since the ohmic resistance is in the order of 1 Ω and would produce a voltage increase of only 3 mv at 3 ma/cm². The peak is much higher and is produced rather by a concentration of the current into small localized areas, where the conversion of Ag_2O to AgO can proceed. This causes an increased overvoltage for the conversion reaction. The points where Ag_2O first converts to AgO are those where the Ag_2O film is thinnest and which were covered last. From these points the conversion spreads until the Ag_2O film is substantially oxidized. Simultaneously a further attack of metallic silver takes place. Any Ag_2O which is formed during this stage must be rapidly oxidized and can have only a transitory existence.

The resistivity of AgO was measured in the same

way as for Ag_2O, and was found to be $5 \cdot 10^8$ Ω cm. This is five orders of magnitude smaller than for Ag_2O.

During the upper plateau 0.6 coulombs of electricity are used in forming a film of AgO of "average" thickness of approximately $5 \cdot 10^{-6}$ cm. Since the resistivity is $5 \cdot 10^8$ Ω cm, the resistance of the film should be of the order of 0.25 Ω. This is of the order of the resistance actually measured, 0.53 Ω. This resistance value shows that there *cannot* be at any time during anodization a significant complete interface layer of Ag_2O present. On open circuit, a heavier film of Ag_2O can be present, formed by local action cells between AgO and Ag.

It is pointed out here that the limiting film thickness roughly of $5 \cdot 10^{-5}$ cm is of particular importance for the manufacturing of porous silver oxide electrodes for silver-zinc batteries. It is evident that only particles with a diameter less than 10^{-4} cm (1 μ) are readily and completely converted from metal to oxide.

At the end of the AgO plateau the resistance drops to values of 0.08 Ω. This drop should not be interpreted as a physical rupture of the layer and an exposure of silver to the electrolyte, because the oxidation of metallic silver has been shown to be small once a complete AgO film is formed, and ruptures therefore should not occur. It is proposed that a further incorporation of oxygen in the AgO film has taken place, producing a highly unstable film of a higher oxide than AgO. It is not clear how the additional oxygen is adsorbed in the individual crystallites. However, in any case, the resistivity of the film is changed.

Although little accurate data is available, it is often observed that when a metal oxide exists in several valence states, the resistivity decreases with increasing valence state. For example, PbO has a resistivity of $2\text{-}5 \cdot 10^7$ Ω cm and PbO_2 of 1 to $5 \cdot 10^{-4}$ Ω cm. Similarly, AgO has much lower resistivity than Ag_2O, and a possible higher oxide would have an even lower resistivity. Although this rule is not without exceptions, it could possibly account for the sharp drop in resistance observed at 250 sec in Fig. 4. Only very small parts of the AgO surface film need be converted to a highly conducting compound in order to produce the observed effect.

The rise in potential at the point of oxygen evolution is not due to an ohmic-resistance passivation, but rather to oxygen overvoltage on the limited number of sites of the higher, unstable oxide, concentrating the current to small local areas.

The capacitance peak at the beginning of the anodization curve shows that the reaction is here very reversible. The linear decrease during the first voltage plateau is due to a decrease in the available surface area. The capacity during the AgO step is small. This indicates that the surface film is now conductive, and that the capacitance is again due to the solid-liquid double layer. The erratic behavior of the capacitance during oxygen evolution is due to the instability of the higher silver oxide sites which may vary in number and size.

During discharge of the silver oxide film, shown in Fig. 5, the resistance is low at the beginning and increases quickly as the higher silver oxide sites disappear. The further increase in resistivity is due to build-up of Ag_2O on the surface toward the electrolyte, blocking the underlying AgO from reaction. The resistance rises to values greater than 2.5 Ω. When the electrode is substantially covered with Ag_2O, the local high current density polarizes the electrode to a potential where metallic silver can be produced. At this point, the resistance drops sharply due to the formation of filamentary crystals of silver, providing good electrical contact. The first voltage plateau during discharge is always observed to be substantially shorter than the second plateau, although the film consisted initially of almost pure AgO, and the total capacity to the end of the second plateau corresponds to a two-electron change. As explained above, this is due to a covering of AgO by Ag_2O. As the passivating layer of Ag_2O is converted to silver, further AgO can be discharged, by formation of more Ag_2O from a local cell of Ag and AgO. The energy corresponding to the 250 mv difference between the two plateaus is lost internally as heat. The electrochemical reactions for the oxidation of Ag and the reduction of AgO are fast. Thus internal local action in an electrode between Ag and AgO should proceed rapidly. The utilization of AgO in discharge of silver-zinc cells is illustrated in Fig. 7. Two standard commercial cells were made using chemically produced AgO in the positives. In one of these cells (upper circuit), a special inert conductive matrix[1] was incorporated which could establish electric contact to each individual AgO particle. In this manner, the passivation due to Ag_2O was greatly minimized, and all the AgO was utilized at the

[1] Subject matter of patent application.

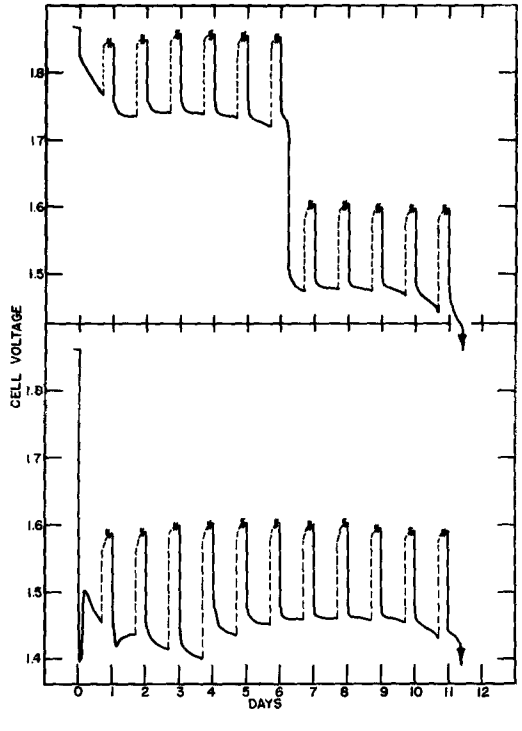

Fig. 7. Discharge curves of commercial silver-zinc cells with and without conductive, inert matrix in the silver electrode. The solid line is the cell voltage during discharge. The dotted line represents the recovery of cell voltage on open circuit.

higher voltage plateau, at close to 100% efficiency.

These cells were discharged for 6 hr/day and allowed to recover overnight. The discharge is shown in Fig. 7 by the solid line and the recovery by the dotted line. The initial sharp drop in voltage for the lower cell shows the insulating effect of the Ag_2O film, which quickly covered the surface of the AgO electrode. The voltage recovered somewhat as soon as some silver was produced. Overnight, most of the silver was reoxidized by the remaining AgO.

The upper curve is for an identical cell but with the conductive matrix. The discharge occurs at the higher plateau for the theoretical time, namely one half of the discharge. This results in an increase of 10% in the watt-hour output.

The decay of oxygen overvoltage on open circuit on an inert electrode is in general expected to follow, after an initial time period, a linear relationship with the logarithm of time, having a slope equal to the negative of the Tafel slope (17). It is noticed in Fig. 6A that the decay curve from 10 ma charge shows this normal behavior, while the decay curves from 50 and 250 ma show a characteristic inflection. The curves for evolved oxygen show similar inflections. The curves approach the same slope toward the end of decay only. The electrode potential tends to remain higher than normal for an initial period of time. Figure 6C shows this even more clearly. Several tenths of a cubic centimeter of oxygen are evolved while the potential remains at 0.585 ± 0.005 v, independent of the value of the prepolarizing current. This quantity of oxygen corresponds to 10 micromoles. No such potential plateau is observed for a "normal" electrode like PbO_2 (Fig. 6D).

The decay from 10 ma/cm^2 for AgO (Fig. 6C) also shows no such arrest, indicating that the charging potential was not sufficiently high to produce the higher oxide.

The arrest in oxygen overvoltage decay on AgO has been observed by other investigators (2, 15) but has been interpreted sometimes to be caused by hydroxyl-hydroperoxide ion couples and/or hydroxyl-oxygen couples (8, 15). This interpretation does not explain the high conductivity of the film at the point of oxygen evolution and, furthermore, the potential of such couples would not coincide with the plateau observed.

The charging curves of large-area AgO electrodes (Fig. 6E) which had previously been kept slightly above the Ag_2O/AgO potential, but below the potential of the plateau mentioned above, show a sharp initial peak unlike the smooth build up of oxygen overvoltage on PbO_2. These peaks possibly correspond to a nucleation phenomena for the higher oxide or the active sites of oxygen evolution.

Conclusions

1. The mechanism responsible for the peak in the anodization curve of Ag in KOH solution at the beginning of the AgO step (Fig. 4) is due to passivation, forcing the currents to small areas and producing a high overvoltage. It is *not* due directly to an ohmic resistance.

2. The reason for the shortness of the AgO step on discharge of an AgO electrode is an isolation of AgO by an Ag_2O film which is highly resistive.

3. By special electrode formulation the length of the AgO plateau can be extended to the theoretical length of ½ of the discharge time.

4. Evidence is presented for the existence of a conductive, unstable oxide of silver with an oxidation state higher than AgO. Because of its transitory nature, identification by means of x-ray diffraction techniques is difficult, if not impossible.

5. The use of an adequately designed cell and microreference electrode, together with a differential amplifier, permits single electrode studies at high frequencies, with electrode voltage rise-times better than 0.1 μsec.

The High-Temperature Aqueous Corrosion Resistance of the Uranium-5% Zirconium -1½% Niobium Alloy

J. E. Draley, S. Greenberg, and W. E. Ruther

Argonne National Laboratory, Lemont, Illinois

ABSTRACT

The uranium-5% zirconium-1½% niobium alloy shows good corrosion resistance, as gamma quenched, in water to about 315°C. Optimum heat treatment results in a rate of about 6 mg/cm²/day at 290°C. Moderate aging, e.g., 400°C for 2 hr, results in reduced corrosion rates in the initial stages of corrosion; however, corrosion resistance can be destroyed by overaging. After protracted exposure, samples fail; this is believed due to absorbed corrosion product hydrogen.

Operation of heterogeneous water-cooled nuclear reactors at high temperatures would be facilitated if the fuel were corrosion resistant. Since unalloyed uranium corrodes very rapidly in high-temperature water, considerable effort has been devoted to the development of corrosion resistant alloys of reasonably low alloy content and to the understanding of the corrosion mechanism. Much of this work has been summarized (1-5).

The development of a group of "distorted" alpha phase alloys of relatively low alloy content has been described (6). In this class, niobium has appeared to be the most valuable alloying element. Its loss of as-quenched corrosion resistance during heat treatment can partly be prevented by the ternary addition of zirconium. This paper is concerned with the detailed corrosion behavior of the uranium-5% zirconium-1½% niobium alloy.

This alloy was chosen as the fuel for the Argonne Experimental Boiling Water Reactor. The properties of a fissionable material are profoundly affected by nuclear radiation. Its effect on the corrosion behavior, as well as on some physical and mechanical properties, of this alloy has been described in detail elsewhere (7-9). It is sufficient to mention here that only small amounts of radiation greatly increase the corrosion rate of relatively resistant material.

Experimental Procedure

Alloys were vacuum melted and cast by the Foundry and Fabrication Group of the Argonne Metallurgy Division. The compositions of all those studied during this investigation, together with the crucible and mold material, are given in Table I.

Most samples were gamma quenched by heating at 1000°C in vacuum (suspended in tantalum wire basket) and quenching in Woods Metal at 125°C. Other samples were gamma treated by heating to 850°C in liquid metal or salt and quenching in various media. The method of heat treatment is indicated in the data.

Relatively low-temperature treatments subsequent to quenching are referred to as aging treatments. Because of the wide variation in times and temperatures of aging, three methods were used: (*a*) sample in an evacuated ampoule placed in electric oven (low temperatures, long times); (*b*) sample placed in Vycor tube furnace with flowing argon or helium (low and medium temperatures, short and medium times); and (*c*) sample immersed bare in liquid metal (high temperature, short time).

Table I. Composition of alloys tested†

Alloy	Zr	Nb	C, ppm	N, ppm	Si, ppm	Crucible material‡
H-203-T	3.93	1.77	10	35	200

† Unless otherwise indicated, composition is given as weight per cent. Analyses by Chemistry Division, ANL.

‡ Most casting was done into a water-cooled copper mold.

* Denotes those which were cast into heated graphite molds.

Samples were air cooled after aging. There were enough samples aged by two of these methods to indicate that the method used was not a significant variable.

Samples are described by the original casting number and the location (when known) with relation to the ingot, indicated as T (top), B (bottom), or C (center). Preparation of the material is described as c (as cast) or r (rolled). Thus L-170B-r indicates the bottom section of casting L-170 in the rolled condition. Compositions are given in weight per cent.

The high-temperature corrosion tests were conducted in stainless steel autoclaves, placed in forced convection ovens. In most tests, samples were insulated from electrical contact with a stainless steel

holder by means of synthetic sapphire rods. Some corrosion tests performed in the Argonne Reactor Engineering Division are also reported here. In these tests the alloy samples were allowed free contact with the bodies of the stainless steel test autoclaves. There was no noticeable effect of such contact.

Before the first period of test, samples were wet-ground to 400 grit metallurgical paper. Whenever the sample shape made this procedure impractical, it was electropolished in a perchloric-acetic acid (1 to 10) bath. Results indicate that there was no significant difference in corrosion behavior caused by this difference in procedure. Surface areas were measured, after which the samples were degreased in methyl alcohol, washed in distilled water, and weighed. After each test period each sample was cleaned of loose oxide with wet Kleenex, dried under vacuum, and weighed. Since very little of the corrosion product remained on the sample, weight losses closely approximated actual metal corroded. These values were plotted as a function of time, and the slopes of the curves so obtained are described as the "corrosion rate" (areas used in the computations were the original sample areas). These rates are expressed as mg/cm²/day (mcd).

Distilled water was used as the corroding medium unless otherwise indicated. This water was double distilled, passing through a cation exchange resin between the two distillation steps. The resistivity of the water was equal to or greater than one megohm-cm at the tap. The autoclave was filled with this water, heated to boiling, and the water discarded. The sample and its holder were placed in the autoclave; water was then added and again heated to boiling. A water sample was withdrawn and the autoclave sealed while the water was still boiling. The specific resistance of this water sample was measured as a check on water quality and cleanliness of the autoclave. The value was typically several hundred thousand ohm-cm. Fresh water was added in this way for each exposure so that during long tests the water was replaced each time the sample was examined.

Hydrogen analyses were performed in an apparatus in which the uranium alloy sample was heated into the gamma phase region (about 850°C). By means of two Toepler pumps the hydrogen was passed, through a paladium valve, into a calibrated volume where its pressure was measured. That the evolution of hydrogen is complete has been demonstrated by corroborative analyses run by combustion. For analyses of samples after corrosion test, the corrosion product was sometimes removed by grinding the samples clean, and sometimes it was left on and simply dried by evacuation at room temperature. For a few cases where both procedures were used on similar samples, the results were the same, inferring that the drying procedure adequately removed moisture, so that errors from this source are unlikely.

For metallographic examination the majority of samples were electroetched with the Ames solution at 15-30 ma/cm² at room temperature. This solution consists of eight parts (by volume) concentrated phosphoric acid, five parts ethyl alcohol, and five parts ethylene glycol. In some cases, electroetching was carried out in a 10% (by weight) chromic acid solution at room temperature using a current density of 10-15 ma/cm².

Results

Heat Treatment

Necessity for gamma quench.—The uranium-zirconium-niobium system has been thoroughly studied and analyzed (10, 11). The discussion here is limited to that necessary for an understanding of the relationship between heat treatment and corrosion resistance.

Between 677°C and the melting point the alloy (5 Zr + 1½ Nb) consists of a single phase (gamma). A two-phase (beta plus gamma) region exists in the narrow temperature range of 666°-677°C. Below 666°C, the structure depends on the heat treatment received by the material.

Alpha uranium is orthorhombic and lacks high-temperature corrosion resistance. The beta phase has a complex structure of tetragonal symmetry. Gamma uranium has a body-centered cubic lattice and has shown good corrosion resistance when retained by alloying.

Isothermal quenching from the gamma to the beta-plus-gamma region (and holding there for, say, 24 hr) followed by rapid quenching to room temperature produces alpha plus a martensitic (distorted alpha) phase. This structure is not corrosion resistant.

If the above procedure is followed except that the temperature of the isothermal quench is reduced to about 660°C, the room temperature structure consists of normal alpha and retained (metastable) gamma. This structure also lacks corrosion resistance.

Rapid quenching from the gamma phase to temperatures close to room temperature produces the martensitic (distorted alpha) structure. This structure is corrosion resistant. It is not known if the alloying elements are present as a submicroscopic dispersion or are in supersaturated solution. However, a second phase has not been detected at 2000X. This treatment and resulting structure is necessary for high-temperature corrosion resistance.

The rate of quench is very important. One typical method of heat treatment consists of holding the sample at 1000°C for 1 hr and then quenching in molten Woods Metal at 125°C. In one such operation the sample caught up in such a position that only about one-half was immersed in the Woods Metal. A subsequent three-day corrosion test at 300°C resulted in almost complete disintegration of that part of the sample which was not immersed.

Additional experiments confirmed the importance of quenching rate. A series of samples were heated in lead at 800°C and quenched in water, molten Woods Metal at about 125°C, oil, and liquid nitrogen. The first two groups of samples were satisfactory in water at 290°C. The latter two disintegrated in less than four days. It is indicated that the rate of quenching in oil and liquid nitrogen is lower than some critical required value. In the latter case

this is probably due to the presence of a vapor blanket.

Corrosion-resistant material is produced by quenching from temperatures in the range 725°-1000°C. The materials tested apparently were homogeneous at these temperatures, since corrosion behavior was independent of time at temperature during gamma treatment, in the range of a few minutes to 5.5 hr.

Aging characteristics.—The aging characteristics of the alloy are of importance from the point of view of particular uses. Of equal interest is the fact that a study of the aging process can lead to an understanding of the nature of the corrosion resistance and the mechanism of the loss of corrosion resistance.

Overaging destroys the corrosion resistance of the alloy. Failure of the alloy can take place either by complete disintegration or by cracking or spalling into several pieces. The latter is apparently a stage in the former. If an apparently sound piece which has cracked off is subjected to a short additional exposure, further severe cracking or complete disintegration usually takes place. This statement refers to cracking into several relatively equivalent pieces and not to minor chipping from the bulk of a sample.

As an arbitrary measure of the aging resistance of the alloy it was decided that a sample was resistant to the given combination of time and temperature if it did not fail in either of the above ways in two weeks of testing in degassed, distilled water at 290°C.

In Fig. 1, the area above the curve represents heat treatments which caused failure in less than two weeks. Combinations of time at temperature below the curve did not cause failure as it has been defined. This curve is based on castings H-317, H-416, H-419, and L-170 in the as-cast and rolled conditions. Samples were quenched from 1000°C (in vacuum) and aged in vacuum, argon, helium, or molten lead. Aging for times insufficient to cause "failure" reduced short-time corrosion rates, with the optimum close to 2 hr at 400°C. This effect is illustrated in Fig. 2. Satisfactory samples had a dark brown surface uniformly interspersed with shallow pits.

As the time of exposure was increased the corrosion rates of gamma quenched and gamma quenched

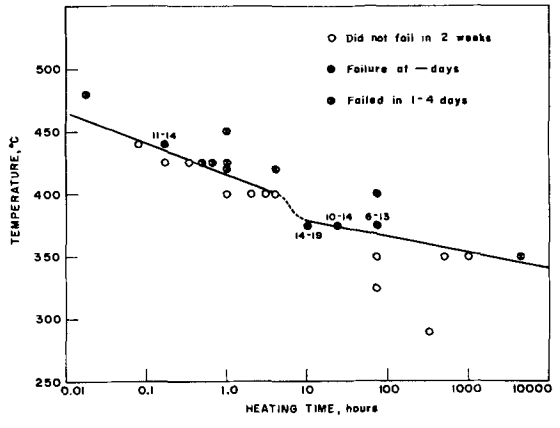

Fig. 1. Effect of heat treatment on corrosion life at 290°C of gamma quenched U-5% Zr-1½% Nb alloys.

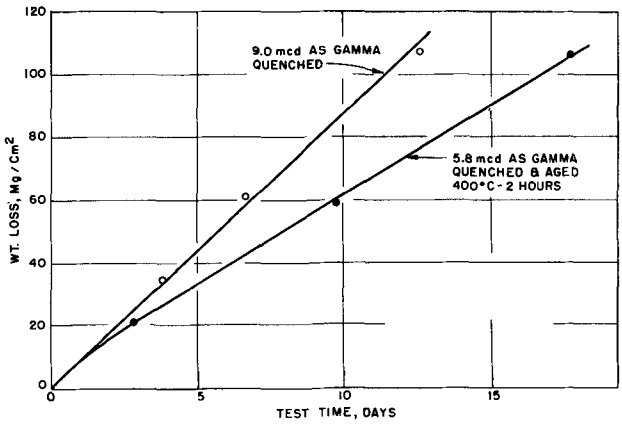

Fig. 2. Short-time effect of aging on corrosion rate of L170BC in water at 290°C.

and aged material generally became equal. In some cases the corrosion rate of gamma quenched material decreased (Fig. 3, curve 3). (This figure is also used to illustrate other ideas and will be referred to again.) It also appears that aging at 400°C decreased the corrosion life of the few samples tested for sufficient times.

To eliminate the possibility that aging occurred during test, cast samples of alloy H-317 were tested as quenched, as quenched and aged at 400°C for 2 hr, and as quenched and aged at 290°C for 312 hr. All samples showed appreciable periods of approximately equal corrosion rates.

Effect of hydrogen.—The standard heat-treatment procedure includes heating in a vacuum tube furnace at 1000°C. Considerable gas (believed to be largely hydrogen) is evolved in this process. In an effort to learn whether corrosion behavior is influenced by this gas, adjacent samples from the same rolled ingot were treated in vacuo and in molten lead.

The corrosion of these samples in water at 290°C is shown in Fig. 4. The sample heat treated in helium was included to reproduce the thermal history of the vacuum-treated sample. It is inferred that the gas content of the metal, as received, is detrimental to its corrosion properties.

A similar conclusion can be deduced from the corrosion of the sample quenched from salt (the

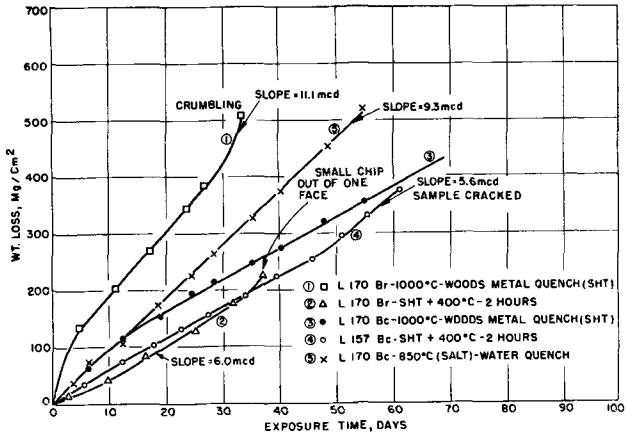

Fig. 3. Effect of heat treatment on corrosion resistance of U-5% Zr-1½% Nb alloys.

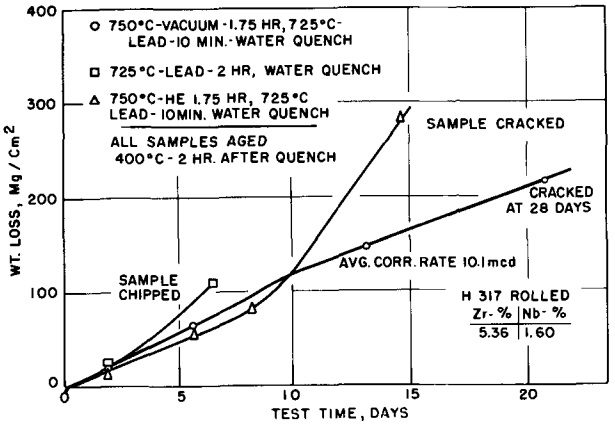

Fig. 4. Effect of gas removal on corrosion in water at 290°C of U-5% Zr-1½% Nb alloy.

eutectic of Li_2CO_3 and K_2CO_3), as shown in Fig. 3, curve 5. For the first twelve days its corrosion rate was the same as the sample, differing only by having the vacuum heat treatment. Subsequent to that time, however, the salt-treated sample continued to corrode at the same rate while the corrosion rate of the vacuum-treated sample decreased by 40%. The hydrogen content of this particular salt-treated sample was not determined; however, similar samples given the same treatment contained about 35 ppm hydrogen. Vacuum-treated metal contains little or no hydrogen.

Hydrogen can also be introduced into the sample by exposing it as the cathode in a hydrogen discharge tube. Such a sample (after 24-hr bombardment) was cracked after exposure to water and steam (because of autoclave leakage, part of the test involved a steam exposure) at 300°C for three days. A similarly tested, but nonbombarded, sample corroded in the normal manner.

Hydrogen analyses of corroded samples show direct correlation with the amount of metal corroded. In Table II such data have been treated to show the per cent of the hydrogen produced which was absorbed in the alloy. After a short initial period the percentage of hydrogen absorbed remained constant for similar samples from the same piece.

When samples from different sources were corroded, there was not always the same fraction of the produced hydrogen absorbed into the metal. It is interesting to observe in Table III, however, that the rate at which the hydrogen accumulated was approximately the same for all the samples, independent of their corrosion rates. The data from the second sample show that "loading" the material with hydrogen (by treatment in salt) before corrosion caused a higher corrosion rate. However, the absolute rate of hydrogen pickup by the sample (during corrosion) was not increased. As indicated above, an identical sample of the "loaded" material continued to corrode at the initial rate for at least 55 days, so that the shorter exposure time for the second sample in Table III does not invalidate the argument.

Table II. Hydrogen build-up as function of corrosion time (Water, 290°C; Alloy H-416C-c, gamma quenched, aged 2 hr at 400°C)*

Time, hr	Metal corroded, mg	H_2 in corroded sample, ppm	% of total H_2 produced that is found in sample
113	234	4.0	1.14
274	692	6.5	0.71
401 (Chip out of sample)	848	7.6	0.69
642 (Sample cracked into 3 pieces)	1127	13.9	0.71

* Four identical samples were tested for the times indicated. Initial hydrogen content (after heat treatment) was 0.9 ppm.

Table III. Hydrogen absorption in corroding alloy (Water, 290°C)

Sample and heat treatment	Test time, days	Average corrosion rate, mcd	% of H_2 produced that entered metal	Rate of hydrogen build-up in metal, $\mu g/cm^2$/day	Condition after test
H-416C-c Gamma quenched from vacuum, aged 400°C, 2 hr	26.7	8.6	0.7	1.09	Cracked
L-170B-c Gamma quenched from salt	18.9	9.4	0.6	0.95	No cracks
H-419B-r Gamma quenched from vacuum, aged 400°C, 2 hr	48.9	6.7	0.96	1.07	Cracked
L-170B-c Gamma quenched from vacuum	47.9	6.5	0.97	1.06	No cracks

Although the rate of hydrogen pickup was approximately the same, the corrosion-induced cracking was not. Assuming that this type of cracking is caused by corrosion product hydrogen, it must be supposed that high local hydrogen concentrations in the metal cause it, rather than the total amount present. The following experimental results support this hypothesis.

A quenched and aged specimen contained 0.9 ppm hydrogen. After about eleven days of testing at 290°C the sample was cut in half and analyzed for hydrogen. The results were 5.7 and 8.1 ppm (±0.1 ppm). It is significant that the piece with the higher hydrogen content had a subsurface crack which was revealed in sample preparation.

The salt-treated sample referred to in Table III contained about 35 ppm hydrogen after heat treatment. Very likely this was uniformly distributed in the body-centered cubic gamma uranium during the treatment. After an additional hydrogen build-up of 8 ppm during the corrosion test there was no evidence of cracking. Thus a total quantity of hydrogen which causes cracking in a sample in which it is not uniformly distributed did not cause cracking here. Perhaps the original (uniformly distributed) hydrogen enhanced the diffusion of the corrosion product hydrogen so that it too was uniformly distributed.

Table IV. Effect of aging on corrosion in water at 290°C and on hydrogen absorption

Sample*	Aging time at 400°C, hr	Corr. rate, mcd	Hydrogen content after 3-day test, ppm	Appearance of sample after test
1	0	13.5	60	Dull. Pitted
2	1	337†	832	Sample cracked into irregularly shaped piece and slurry. This piece in good condition.
3	2	450†	1220	Same as above.
4	3	616†	1340	Same as above.
5	4	—	—	Completely disintegrated.

* L-170BC—quenched from salt at 850°C.

† Based on remaining piece.

A group of samples which had been simultaneously quenched from salt were aged in a helium atmosphere at 400°C for various periods of time and tested for 71 hr in degassed, distilled water at 290°C. The aging times bracketed that for optimum corrosion resistance of a vacuum-treated sample, i.e., approximately 2 hr. Results are shown in Table IV.

The as-quenched sample reacted typically, indicating that the samples were adequately quenched. The behaviors of the aged samples were completely different from that of vacuum quenched and similarly aged metal in that the corrosion resistance was destroyed.

It seems likely that during the aging process the hydrogen concentrated, perhaps at grain boundaries. These concentrations might act as nuclei for further local hydrogen build-up, especially if the hydrogen is present as hydride. The analytical samples consisted of small pieces of metal close to cracked surfaces. As expected, very high hydrogen contents were found. It is also possible that the hydrogen content of the specimen increased the rate of transformation of the strained alpha to normal alpha, with resultant increase in corrosion.

When the hydrogen content of the alloy becomes greater than its solubility, it has been expected that a hydride phase will form. Efforts to observe such a phase in a number of samples of the sort previously discussed were unsuccessful. It was therefore attempted to obtain higher total hydrogen content as follows. A sample of L-170B-c was quenched from salt at 850°C and aged in helium at 400°C for 3 hr. It was then exposed to degassed, distilled water at 290°C for 24 hr. At the end of this period the sample had a rough, heavily pitted, irregular surface; it had corroded at an average rate of 2126 mcd. The hydrogen content was 1100 ppm. The unexpectedly high corrosion rate (as compared with data in Table IV) could have been due to an inadequate quench. However, the object of obtaining a sample with high hydrogen content for metallographic study was achieved.

The sample was examined metallographically after heat treatment, after corrosion, and after hydrogen analysis.[1] The respective hydrogen contents

[1] The hydrogen analysis produces a slow cooled alloy and the resultant structure is very complex. The sample was therefore gamma quenched and aged after analysis in order to produce a structure more conducive to evaluation.

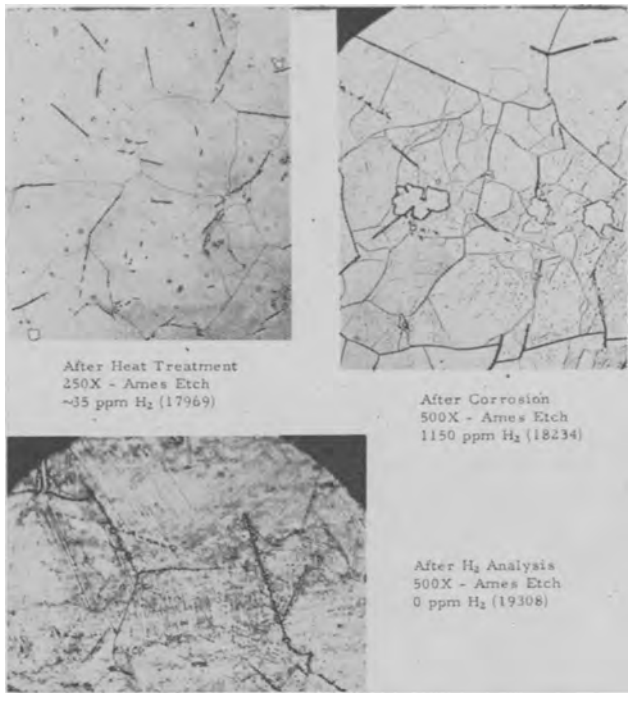

Fig. 5. Effect of hydrogen on structure of U-5% Zr-1½% Nb alloy.

were approximately 35, 1100, and 0 ppm. The photomicrographs appear in Fig. 5. Only the sample with the high hydrogen content has what may be described as a "salt and pepper" effect. This structure has been found in this alloy only in samples containing high hydrogen contents. It is therefore inferred that the structure is hydride.

The difficulty of forming the (proposed) hydride is in line with the report that the addition of as little as 0.5% zirconium to 10.5 and 12% molybdenum alloys virtually eliminates the precipitation of hydride (4).

It would be desirable to identify the new phase as the hydride in a more rigorous manner, for instance by x-ray or neutron diffraction. However, the highest hydrogen concentrations produced to date are below the threshold (2000 ppm or greater) of detection and identification by these methods. The particles are too small to be identified by standard microfocus x-ray equipment.

Effect of temperature.—Water temperature affects both the corrosion rate and the useful life of this alloy. As indicated earlier, simultaneous aging may occur at sufficiently high temperatures. Figure 6 is

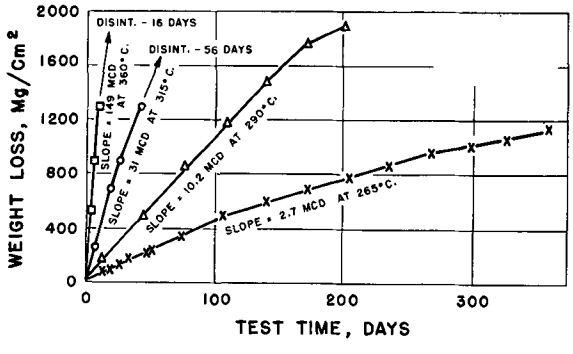

Fig. 6. Effect of temperature on aqueous corrosion behavior of gamma quenched alloy (H203r).

representative of tests performed by the Reactor Engineering Division. The effects of temperature on corrosion rate and life are illustrated.

Discussion

Structural Aspects

The quenched alloy has a martensitic "strained alpha" structure. Although optical metallography up to 2000X shows only a single phase structure, we have postulated a sub-microscopic second phase. Such a structure is possible if the rate of cooling is not great enough to prevent some decomposition before the temperature of the martensitic transformation is reached (12).

Moderate aging would complete precipitation of the second phase, if it were not already complete, and cause a slight growth of the second phase particles already present. We have attempted to confirm or disprove the existence and growth of the second phase by means of the optical microscope, x-ray diffraction, and electron microscope techniques.

Optical metallography has not been fruitful in revealing the relations between aging and corrosion behavior. Moderate aging produces a "cellular" structure within the martensite. Severely overaged samples, i.e., 475°C for 3 min, show what appears to be gross precipitation at grain boundaries. These changes are illustrated in Fig. 7, 8, and 9.

Several comments should be made concerning these figures. The dark lines are probably borides. This casting had an unusually high boron content, i.e., 15 ppm. The "overaged" sample also had the "cellular" structure, but it was impossible to show both the "cellular" structure and grain boundary effect with one etch, i.e., a longer etching time was required to develop the "cellular" structure. Neither the "cellular" structure nor the grain boundary precipitation could be shown to exist on the as quenched sample. The grain boundary effect was revealed only on the "overaged" sample.

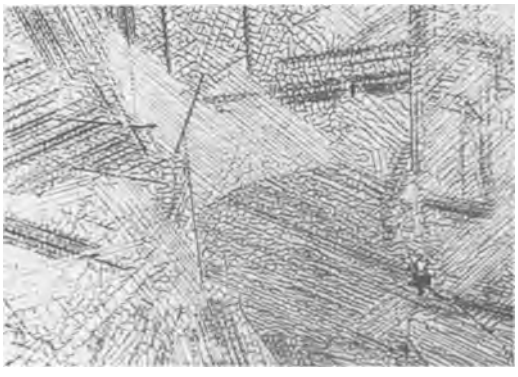

Fig. 8. L-170BC-gamma quenched and aged 400°C, 2 hr (moderate aging); Ames etch, VHN-566, 30 kg. Magnification 500X before reduction for publication.

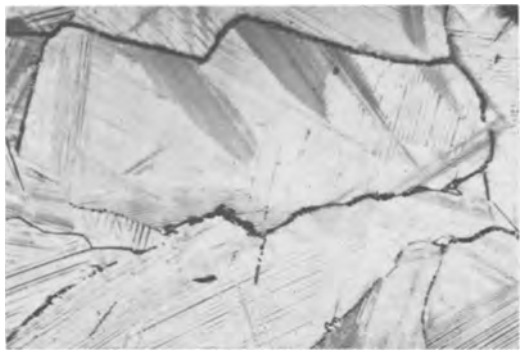

Fig. 9. L-170BC-gamma quenched and aged 475°C, 3 min (overaged), Ames etch, VHN-563, 30 kg.

X-ray diffraction results for a group of quenched and aged samples are more interesting. In Table V it is indicated that a significant return toward the lattice parameters of α-uranium accompanies increased aging. At the same time enough line sharpening was observed to indicate strain relief. These observations are consistent with the hypothesized growth of a fine precipitate. It would thus appear that agglomeration of the precipitate and return of the lattice dimensions to those of α-uranium are responsible for loss of corrosion resistance.

Etched surface textures, as revealed by electron microscopy (using direct, i.e., negative, carbon replicas) suggest that a precipitate is present in the as-quenched alloy, and that particle size increases as the alloy is aged. Figures 10, 11, and 12 are representative of quenched and aged samples, as seen at high magnification.

Any theory relating corrosion resistance to structure must explain the observation that resistance of the zirconium-niobium ternaries to aging is considerably greater than that of binary alloys containing up to about 6% niobium (6). There are at least two ways to explain the beneficial effect of zir-

Table V. (13) Effect of aging on lattice parameters and corrosion resistance

Aging† Temp, °C	Time	2θ Angle for (111)	Corrosion resistance at 290°C*
As-quenched		39.1	Good
425	10 min	39.3	Good
425	20 min	39.3	Good
425	40 min	39.35	Bad
425	2 hr	39.4	Bad
425	4 hr	39.5	Bad
440	5 min	39.35	Good
475	3 min	39.4	Bad
(α-Uranium)		39.5	Bad

* Good and bad indicate no failure and failure, in two weeks' exposure to water, respectively.

† All alloys quench from 1000°C.

conium as an additive to the uranium-niobium binary alloy. In the first, the addition of several per cent of zirconium will augment the grain refining action of the niobium and will very likely slow down agglomeration of the second phase during aging. Hence the distribution of the second phase will perhaps be more favorable initially, and the unfavorable effects of overaging will be retarded.

The second explanation deals with the nature of the second phase formed. At equilibrium the ternary alloy consists of alpha uranium and about 10% γ_1 (10), which is gamma uranium saturated with niobium and zirconium. The corresponding structure of the niobium binary alloys is α-uranium and γ_2 (niobium saturated with uranium). γ_2 is not found in the ternary system. It is entirely possible that the γ_1 phase agglomerates slower than the γ_2 phase; hence the ternary alloy overages more slowly.

Role of Hydrogen

Aqueous corrosion of uranium.—It is considered helpful to discuss some aspects of the mechanism of the aqueous corrosion of uranium and then to show how the situation is modified by alloying. The results of this investigation will be used to support the belief that hydrogen produced as a product of the corrosion reaction has a considerable influence on corrosion behavior.

As unalloyed uranium corrodes in air-saturated distilled water at room temperature it forms a thin continuous and protective film of uranium dioxide. Samples of the metal in this environment develop typical interference-color films, and the progress of corrosion can be estimated from the apparent film thickness. After sufficiently long exposure, however, points of local breakdown of this film are observed. At these points the corrosion product is fine granular uranium dioxide. Where this type of product is formed, the rate of corrosion is considerably higher. With further exposure these points of breakdown gradually spread, and it is inferred that eventually most of the surface would be corroding at the more rapid rate characteristic of the situation where the relatively unprotective corrosion product is formed (1). It is considered, and the idea is developed in a publication by two of us (14), that these points of local breakdown represent places at which corrosion product hydrogen reacts beneath the protective film to form uranium hydride. This hydride then prevents bonding between the oxide film and the metal. Since this bonding appears to be a necessary requirement for the stability of thin oxide films of this type, the corrosion product takes its more stable form, a mass of fine crystals.

It is essential that there be some oxygen dissolved in the water in order to have the protective film. The means by which the oxygen acts cannot be stated unequivocally, but it appears reasonable to suppose that oxygen adsorbed on the protective oxide film will prevent the entry of hydrogen into the film and, hence, will prevent access of hydrogen to the uranium surface. The fact that breakdown ultimately occurs indicates that the prevention of the entry of hydrogen into the oxide film is not complete. In the absence of dissolved oxygen, corrosion always proceeds on initially clean metal at the rate characteristic of the situation where there is no stable protective film (1).

As the temperature is increased it is perhaps more difficult to prevent the access of some of the hydrogen to the metal surface, and the solubility of oxygen in the water is reduced. Consequently there is a temperature above which the formation of the highly protective film is not observed on unalloyed uranium. In air-saturated water this temperature is about 60°-70°C. The addition of hydrogen peroxide to the water apparently increases this temperature somewhat (1).

Alloying.—By the addition of more than a minimum amount of zirconium the apparent sensitivity to the hydrogen effect can be considerably reduced, so that the protective film forms in boiling distilled water on a uranium-5% zirconium alloy (15, 16). The behavior of this alloy in boiling distilled water can be described in exactly the same terms as was the corrosion of unalloyed uranium in air-saturated distilled water at room temperature. Ultimately local breakdown of the oxide film occurs, and the film

does not form if oxygen is rigidly excluded from the water.

There are three mechanisms which appear reasonable as explanation for the effect of the alloying zirconium. In the first the incorporation of zirconium into the UO_2 lattice could make an inherently more stable film and could also make the process of hydrogen migration through it more difficult. That this is at least reasonable is indicated by the fact that the presence of zirconium in the oxide produced on these alloys has been observed to reduce the UO_2 lattice dimensions (16).

The second proposal for the protective action of zirconium is that a zirconium-containing phase in the surface layers of the metal acts as a getter for that hydrogen which does reach the metal surface. If, then, this zirconium phase is distributed in such fashion that it can getter all of the hydrogen reaching the surface, no uranium hydride should be formed, at least until the zirconium becomes saturated. According to this picture the ultimate breakdown of the oxide film occurs when this saturation is effected. Presumably the zirconium-rich phase can absorb hydrogen only at a given maximum rate. Oxygen might be effective by maintaining the rate of arrival of corrosion product hydrogen below this limit.

If the alloy content is increased so that the total rate at which the zirconium-rich phase can absorb hydrogen at the surface is equal to or greater than the rate at which hydrogen gets there (without any retardation, as by oxygen), then there should be no requirement for dissolved oxygen. 7.5% zirconium is apparently sufficient for this purpose in boiling water (15). Some gettering action by zirconium is indicated in uranium alloys, since it has been reported (4) that as little as 0.5% zirconium virtually eliminates the formation of internal hydride crystals during corrosion in gamma-phase alloys.

The third alternative considers that hydrogen diffuses rapidly into the strained phase (martensitic). Hence the entire surface would be gettering the hydrogen. This proposal is in accord with the fact that the strained lattice has larger parameters than the normal alpha structure (Table V). In other studies (17, 18), increasing lattice parameters (by tension) has been observed to cause the rate of hydrogen diffusion to increase, sometimes strikingly.

As previously noted (16), the altered properties of the oxide appear to be insufficient to explain the observed phenomena. There would be no obvious explanation for the sensitivity of the 5% alloy to oxygen in boiling water, nor would it be clear why there should be a critical minimum zirconium content to achieve corrosion resistance. The proposals relating to the disposal of hydrogen are therefore preferred and will be emphasized in the remainder of this discussion. Of these, the one based on the action of the precipitated phase is preferred. In addition to the observed activity of zirconium (as a getter) referred to above, the greater effectiveness of increased percentages of zirconium seems more readily explained on the basis of this hypothesis. (The martensitic transformation always seems to be at least nearly complete, as indicated by x-ray diffraction and the observed topography of corroded specimens.)

A fine random dispersion of the second phase is desirable for its most efficient operation. Improved dispersion of the second phase produced by aging the quenched material is accompanied by some production of normal α-uranium. This perhaps explains the reduced corrosion lifetime of those aged samples which have lower corrosion rates. Perhaps niobium is better than zirconium both as a hydrogen getter and as a grain refiner, explaining its observed superiority as an alloying constituent (1).

Damage by hydrogen.—Presumably the niobium and/or zirconium do not do a perfect job in providing protection. It is assumed that a small amount of hydrogen is available to the surface uranium. Very possibly this influences the corrosion rate, either by the formation of a small amount of uranium hydride or perhaps even by some disruption of the oxide by gaseous hydrogen formed beneath it.

When samples of the alloy described in this report are corroded in water they frequently become pock-marked or etched. Sometimes such localized corrosion is observed to make rather deep pits. This is probably an indication of the presence of impurity phases; whether the interface between such phases and the matrix are preferred sites for hydride formation is not known, but might be suspected. Subsequent reaction with the water could change the hydride to oxide.

It is known that some hydrogen diffuses into the metal. Thus, a constant rate of hydrogen pickup by corroding samples was observed, in terms of micrograms of hydrogen per square centimeter of corroding surface. It is presumably this hydrogen which initiates the formation of cracks (perhaps by formation of internal hydride) after prolonged corrosion exposure. The growth of oxide within the cracks probably leads to rupture and ultimate failure by a wedging action.

Both reduction of the corrosion rate and increase of the corrosion lifetime might be induced by the use of more efficient material (for hydrogen disposal), or its better distribution. In addition, it would be desirable to have the hydrogen in the metal uniformly distributed. This should provide increased corrosion lifetimes over those now observed for the reference alloy. Both objectives are perhaps at least partly achieved in those alloys in which the gamma phase is stabilized. The body-centered cubic gamma phase has a much higher multidirectional hydrogen diffusion rate than does the α-uranium; it might also provide a more efficient surface for the formation and liberation of hydrogen. Active cathodes on its surface should provide additional benefit, and apparently do (3).

Acknowledgment

The cooperation and interest of the following were of great aid in this study: C. R. Breden and A. H. Roebuck of the Reactor Engineering Division, ANL, directed the experiments on the long-time corrosion tests; G. Dragel performed the corrosion tests and is responsible for some of the photomicrographs;

E. J. Silk, on loan to the Metallurgy Division from Babcock and Wilcox, is responsible for some of the photomicrographs and aided in their interpretation.

Manuscript received Dec. 18, 1959. This paper was prepared for delivery before the Columbus Meeting, Oct. 18-22, 1959. Work on the paper was performed under the auspices of the USAEC.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

Inhibition of Acid Attack on Steel by Heavy Metal Ions

Joseph A. Shropshire

Products Research Division, Esso Research and Engineering Company, Linden, New Jersey

ABSTRACT

Ions of lead, tin, and cadmium were shown to inhibit the dissolution of steel in acid solutions in the absence of metal plating. A mechanism was postulated whereby sulfide ions produced by metal dissolution combined with the heavy metal ions to form a protective coating on the dissolving surface. Analytical studies indicated that both lead and tin ions were removed from acid solutions in contact with iron filings, in quantities too great to be explained by adsorption. Studies on the effect of increased acid concentration and varying sulfur content of the dissolving metal tended to substantiate the mechanism. The order of effectiveness of inhibition of ions of lead, tin, and cadmium was shown to coincide with the order of solubility of the respective metal sulfides.

Although the effect of foreign ions on the corrosion resistance of various metals has been studied extensively for a number of years, some controversy remains concerning the action of certain metal cations in reducing the attack on iron and steel by nonoxidizing acids. The action of As^{+++} in this respect has been recognized for many years (1, 2). More recently, Sn^{++} has been shown to exhibit an effect similar to arsenic in 1*N* H_2SO_4 and 1*N* HCl (3). As yet, however, no completely satisfactory mechanism to explain these phenomena has been advanced. The present work studies the effect produced by Sn^{++}, Pb^{++}, and Cd^{++} on the acid dissolution of steel and proposes a mechanism for inhibition applicable to these ions as well as to As^{+++}.

The rate of dissolution of iron or steel in a nonoxidizing acid such as H_2SO_4 or HCl has been shown to increase in the presence of certain ions capable of being reduced at local cathode potentials (3-5). In contrast, the presence of As^{+++} or Sn^{++} greatly reduces the attack on steel by 1*N* H_2SO_4 or 1*N* HCl. The action of As^{+++} has been attributed by previous investigators (2) to the high hydrogen overvoltage of metallic arsenic. Gatos (3) has established, however, that the presence of metallic arsenic alone on the steel sample does not cause a decrease in rate of dissolution. He has further studied the effects of As^{+++} and Sn^{++} and concludes that the inhibition is due to the following reactions at anodic sites on the metal surface:

$$Sn^{++} \rightarrow Sn^{++++} + 2e^-$$

$$5As^{+++} \rightarrow 3As^{+++++} + 2As^\circ$$

These reactions are postulated to compete with and suppress the primary reaction, the oxidation of iron.

In the present study, a comparison of the effects of Sn^{++} and Pb^{++} on the corrosion of steel in 1*N* HCl solution has been made. These two ions were chosen in light of the oxidation mechanism proposed to account for the effect of Sn^{++}, and the fact that Pb^{++}, while similar to Sn^{++} in most respects, differs greatly in oxidation stability. Thus the respective standard oxidation potentials indicate that Pb^{++} should not inhibit in the manner proposed for Sn^{++}.

$$Sn^{++} \rightarrow Sn^{++++} + 2e^- \qquad E^\circ = +0.15 \text{ v}$$

$$Pb^{++} \rightarrow Pb^{++++} + 2e^- \qquad E^\circ = +1.69 \text{ v}$$

Experimental Procedure

Weight loss measurements.—Corrosion rates were determined by conventional weight loss measurements. Two types of metal specimens were used: (*a*) SAE 1010 steel coupons measuring 1 x 1.5 x 1/16 in., (*b*) disk-shaped specimens (3/4 in. diameter, 1/8 in. thick) of vacuum melted electrolytic iron to which had been added varying amounts of sulfur. Elemental analysis of the 1010 steel gave the following results: C, 0.08%; S, 0.019%; P, 0.01%; Cu, 0.007%; Mn, 0.25%. Analyzed sulfur contents of the electrolytic iron samples ranged from 0.001 to 0.021%. Corrosion tests were carried out individually in stoppered Erlenmeyer flasks containing 500 ml of test solution. Specimens were suspended vertically from a small glass rod through a 1/8 in. hole near the top of the metal coupon. Prior to immersion, the test specimens were sand-blasted, scrubbed with powdered detergent, rinsed with cold water and acetone, and finally degreased with benzene and desiccated. All corrosion tests reported in this paper were carried out at 25.0° ± 0.5°C, and all test times were of the order of 20 hr.

Baker's Analyzed lead chloride and metallic tin were used to prepare the necessary stock solutions, and test solutions were obtained by appropriate dilution. The simple deaeration of test solutions (as used in Fig. 1) was effected by prolonged bubbling with nitrogen, after passing the gas through identical solutions for vapor content equilibrium. After bubbling of nitrogen was stopped, a slow stream of the gas was passed over the top of the solutions during weight loss runs. Constancy of rate for the dissolution reaction was established independently by following the cross-sectional area change of a 1010 steel probe via resistance measurements.

Experimental Results and Discussion

Effect of Sn^{++} and Pb^{++} on the Corrosion of Steel in 1N HCl

Both Pb^{++} and Sn^{++} inhibit the dissolution of steel in 1*N* HCl. The results of the rate studies, shown in Fig. 1, indicate that Pb^{++} is just as effective as Sn^{++}, and that, in fact, the data for both metal ions fall on the same curve. At this low *p*H, dependence of rate on the state of aeration was neither expected nor found. Microscopic inspection (500X) revealed no plating of metal in either case at these low ion concentrations and high acidity. (Later studies indicated that metal plated under similar conditions formed crystals which were easily visible at this magnification.) Utilizing standard methods, measurement of the potential of 1010 steel in 1*N* HCl as a function of plumbous ion concentration indicated no significant change from the value found in 1*N* HCl alone. The identical nature of the inhibition curves for Pb^{++} and Sn^{++} and the fact that oxidation to the plumbic state is impossible under such mild conditions suggest that most of the inhibition in both cases is attributable to a different mechanism than that previously proposed.

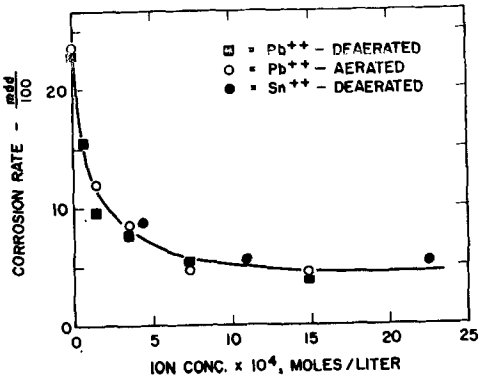

Fig. 1. Corrosion rate of 1010 steel in 1N HCl as a function of stannous and plumbous ion concentration.

Ion Removal Studies

Since no metal plating was observed, it was felt that the inhibition evidenced by both stannous and plumbous ions could be due to protection of the metal surface by the formation of an impervious layer of material. Studies were therefore carried out to determine if stannous and plumbous ions were removed from acid solution by contacting with iron filings. Two methods of contacting were employed: [1] percolation of 50 ml of the M^{++} — 1*N* HCl solutions through 30.0 g of Fisher 20 mesh iron filings (0.10% S) contained in a column with a glass wool filter, and subsequent analysis for changes in M^{++} concentration, and [2] agitation of 50 ml of the M^{++} — 1*N* HCl solutions with 30.0 g of Fisher 20 mesh iron filings in a separatory funnel, immediate filtration through glass wool, and subsequent analysis. Contact times in both cases averaged 5 min. Metal ion concentrations of the test solutions were identical to those which were shown to inhibit acid attack on steel.

Analyses for Pb^{++} were carried out by the dithizone method with final colorimetric determination. Tin determinations were made by a low concentra-

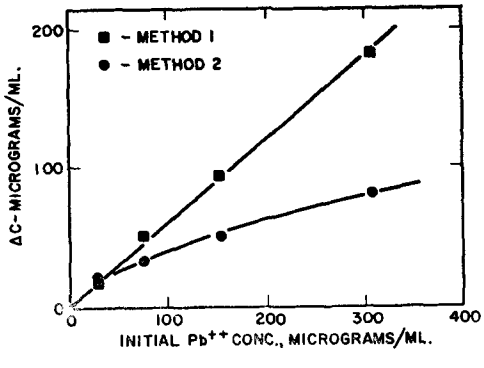

Fig. 2. Removal of plumbous ion from 1N HCl solution by contacting with iron filings. T = 25°C.

tion air-free iodine titration with complete reduction to the stannous state in a closed system with a carbon dioxide atmosphere. Due to analytical difficulties encountered at low concentrations, studies on tin were carried out at a single ion concentration known to give effective inhibition. All duplicate determinations agreed within 1%.

The change in lead ion concentration caused by contacting with iron filings is shown in Fig. 2, and the data obtained for Sn^{++} at a single concentration are given below:

Method	Initial Sn^{++} conc $\mu g/ml$	ΔSn^{++} conc $\mu g/ml$
1	534	320
2	534	249

The results indicate that more than half the metal ion can be removed from solution. If a surface area for the iron filings of 500 cm^2 is assumed (estimated on the basis of 30.0 g of spheres of radius 0.042 cm and density 7.86 g/cm^3), the amount of, e.g., Sn^{++} removed from solution corresponds to approximately three hundred times that needed for monolayer coverage of the surface. Thus, the removal of ions cannot be ascribed to adsorption phenomena. If metal ions were plated during this contacting process, the amount of ions removed would not be expected to decrease with agitation of the system. These facts led to the belief that metal ions were removed from the solution by precipitation as an insoluble species.

Mechanism

Examination of the possible reactions which could occur in the system led to the postulate that the steel (or iron) has a sulfur content sufficient to precipitate the sulfides of both lead and tin. Common steels have a sulfur content of 0.02-0.05%, the sulfur being in the form of metal sulfides. Dissolution of the surface of the metal in acid solution then results in the formation of hydrogen sulfide in the immediate vicinity of the surface. The hydrogen sulfide equilibrium is such that in 1*N* HCl solution, in which the dissociation is suppressed, sulfide ion concentrations of the order of 10^{-23} moles/liter can exist (6). Solubility products of plumbous and stannous sulfides (1.0×10^{-29} and 8×10^{-29}, respectively) (7) show that this sulfide ion concentration is sufficient to initiate the precipitation of the metal ions, even from 0.0001M solutions. Such sulfide concentrations are not grossly in excess since these divalent metal halides ionize incompletely (e.g., $[PbCl]^+ \rightarrow Pb^{++} + Cl^-$; $K_2 = 0.03$) (8). The increase of sulfide ion concentration in the layer adjacent to the surface should cause the solubility limits of the heavy metal sulfides to be exceeded at distances near enough to the surface to create a protective layer. The formation of such a layer would naturally depend on the distance from the surface at which precipitation occurs, and thus become a combined function of sulfide ion diffusion and metal ion concentration. This layer is looked on as being a barrier to diffusion of the participants in the partial reactions occurring at the surface, thus causing the over-all rate of dissolution to decrease. A further consequence of the buildup of sulfide ion in the diffusion layer is that a heavy metal ion approaching the surface would probably be converted to the sulfide before approaching closely enough for electron transfer, i.e., reduction to the metal, to occur. Direct reduction of the sulfides of lead and tin is considerably more difficult than reduction of the ions themselves and, thus, is not a likely reaction (9).

Table I. Corrosion rate of 1010 steel in 1N HCl in the presence of Cd^{++}

Molarity Cd^{++}	Rate— mdd / 100	Relative rate
0.00	23.8	1.00
0.01	12.8	0.54
0.10	10.7	0.45

Since the heavy metal sulfides exhibit a marked tendency toward colloid formation when precipitated from dilute solution, it is possible that agitation of the solutions while contacting with iron filings could result in precipitation of the sulfides at greater distances from the surface and in concentrations at which colloid formation would be favored. Thus a nonfilterable dispersion could give rise to the observed variation in ion removal by the two methods used. (It is felt that the "ion removal" data are such that adsorption as well as metal plating are improbable as explanations. It must be realized, however, that these data provide no positive evidence of sulfide formation.)

Cadmium Ion

If the sulfide formation mechanism as postulated above is the correct one, cadmium ion should also act as an inhibitor for the corrosion of steel in 1*N* HCl solutions. For cadmium, the solubility product of the sulfide (1.4×10^{-28}) (7) is such as to make it a borderline case, i.e., a lesser degree of inhibition is to be expected. More important, the second ionization constant for $CdCl_2$ as reported by Harned (8) is 0.01. Thus the $CdCl_2$ concentration required to produce precipitation of the sulfide in a solution approximately 1*N* with respect to Cl^- is increased one hundredfold. Results of weight loss measurements carried out in the presence of cadmium ion at two concentrations (Table I) indicate that concentrations of cadmium ion up to one hundred times those used for Pb^{++} and Sn^{++} produce only a 50% inhibition, and thus, the foregoing conclusions are qualitatively confirmed.

Effect of Solution Acidity

The degree of inhibition afforded by Sn^{++} and Pb^{++} was found to be greatly reduced in 3*N* HCl solution, as shown in Fig. 3. This evidence reinforces the sulfide mechanism, since the increase in acidity causes a sharp increase in the solubility of the sulfides of tin and lead. It is doubtful that the observed decrease in effectiveness of the metal ions would occur if metal plating were a major factor here, since the increase in acidity from 1*N* HCl to 3*N* HCl would result in a change of hydrogen discharge potential at a cathodic site of only a few millivolts. The same change in acidity, however, causes a ninefold decrease (ideally) in the sulfide ion concentration in the acid solution.

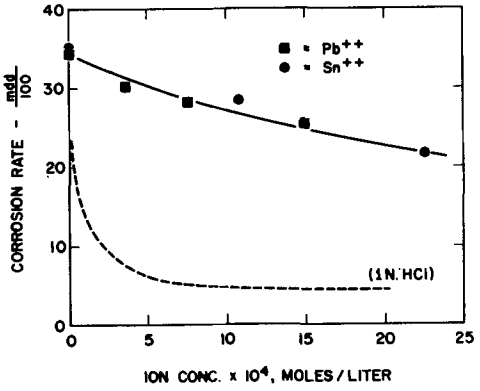

Fig. 3. Corrosion rate of 1010 steel in 3N HCl as a function of stannous and plumbous ion concentration.

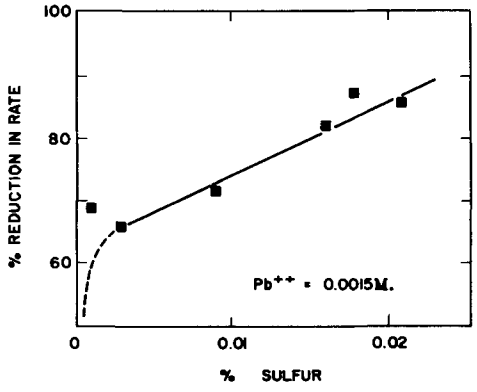

Fig. 4. Effect of sulfur content of electrolytic iron specimens on corrosion rate in IN HCl —0.0015M Pb^{++}. Per cent reduction calculated against rate in IN HCl alone.

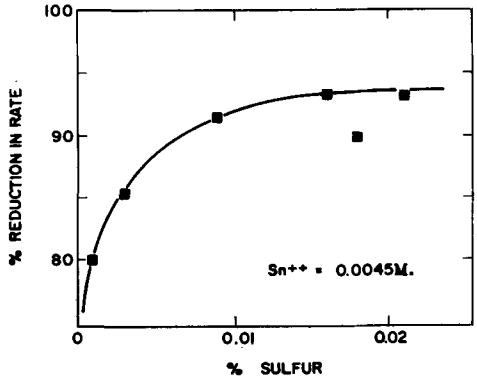

Fig. 5. Effect of sulfur content of electrolytic iron specimens on corrosion rate in IN HCl —0.0045M Sn^{++}. Per cent reduction calculated against rate in IN HCl alone.

The rate of dissolution of 1010 steel in 3*N* HCl in the presence of 0.01 mole/liter of cadmium ion was found to be 92% of the rate of dissolution in pure 3*N* HCl. This is undoubtedly due to the fact that cadmium forms the most soluble sulfide of the metals investigated. It is to be expected that cadmium ion would exhibit no effect whatsoever in solutions of slightly greater acidity.

Effect of Sulfur Content of the Metal

If the postulated sulfide formation mechanism is correct, it follows that sulfur content of the metal should play a determining role in the inhibition. Accordingly, a series of vacuum melted electrolytic iron samples which differed only in sulfur content was obtained. Weight loss measurements were carried out on these samples in 1*N* HCl alone and in 1*N* HCl containing low concentrations of Pb^{++} and Sn^{++}. The results of this study indicate that high levels of inhibition are obtained, and that the degree of inhibition in both cases increases with sulfur content of the sample (Fig. 4 and 5).

It is of interest to note that a saturation level is obtained with the use of a Sn^{++} concentration somewhat higher than that of Pb^{++}. Such a level admits to several possible explanations in light of the proposed mechanism. It is possible that maximum surface coverage has been realized and that the remaining attack represents reaction occurring by diffusion of reactants through the sulfide layer. Alternatively, it could be assumed that the majority of impurities and the majority of attack are centered about the grain boundaries of the metal lattice and that while this attack is inhibited by sulfide formation, a residual dissolution remains at crystal faces.

The apparent inconsistency of the data at 0.001% S in Fig. 4 is explained by the fact that microscopic examination (500X) revealed relatively large crystals of lead on this sample only. This observation conforms to the previous hypothesis that metal plating should not occur in the presence of an appreciable amount of sulfide ion. The plated lead in itself appears to be an effective inhibitor, probably due to its high overvoltage for hydrogen discharge. It is of interest to note that this behavior was observed only with Pb^{++}, which is reduced only slightly more easily than Sn^{++}.

The plating of metal ions at very low sulfur contents was reconfirmed by the observation that both lead and tin were plated from their 1*N* HCl solutions on electrolytic iron powder (trace sulfur) which had been sintered into coupons with a density of 6.5 g/cm³.

Conclusion

The presence of plumbous, stannous, and cadmium ions has been shown to inhibit the dissolution of iron and steel in 1*N* HCl. With the exception of iron specimens with extremely low sulfur content, no evidence of plating of any of the metals on the iron or steel samples has been detected. Both plumbous and stannous ions are removed from acid solutions in contact with iron filings, in amounts dependent on the mode of contacting. The removal of plumbous ion is linear with initial ion concentration. As yet, no satisfactory explanation for the linearity can be advanced. The inhibition afforded by Pb^{++} and Sn^{++} is markedly decreased by small increases in acidity of the solutions, and has been shown to be dependent on the sulfur content of the dissolving metal.

In view of these facts, it is postulated that the dissolution of a steel surface in a strong nonoxidizing acid produces sufficient sulfide ions to precipitate the respective heavy metal sulfides at the surface. This metal sulfide formation probably occurs at distances from the surface which are too great for iron discharge, and thus precludes metal plating. The precipitated layer of sulfide then restricts diffusion to and from the surface and causes a decrease in rate of the partial reactions. Since As^{+++} forms a sulfide which is insoluble even in strong acid solu-

tion, it is believed that the well-known inhibition effects of As^{+++} are accounted for by a similar mechanism. The concentration of ions required for maximum effectiveness appears to increase in the order $As^{+++} < Pb^{++} \simeq Sn^{++} < Cd^{++}$. This order is in agreement with the respective metal sulfide solubility products (7).[1]

A puzzling factor in the experimental results is that corrosion rates characteristic of each metal ion concentration were obtained after the first few minutes of reaction. The continued release of sulfide ions during the period of reaction would be expected to increase the thickness of the protective layer and thus cause a decrease of corrosion rate with time. It is possible that the film is established quite rapidly at the period when reaction rate is high and that subsequent reaction by slow diffusion of ions through the film does not add measurably to the "effective" film thickness. This would occur if the metal sulfide formed in the latter case by diffusion of $S^{=}$ through the film were loosely bound at relatively large distances from the surface.

It should be emphasized that, in accord with Gatos' observations on Sn^{++}, no plating of tin, lead, or cadmium on ordinary steel coupons was observed in these systems. Observation of the plating on electrolytic iron specimens and on steel coupons in less acid systems indicated that the metal deposits were semi-adherent and crystalline, and that even the most minute deposits were readily observable under the microscope.

Oxidation at anodic sites, as postulated by Gatos, is certainly not a factor in the inhibition evidenced by plumbous ion, although it could play a minor role in the case of Sn^{++}. Cadmium ion, at low concentrations, is probably stable in acid solutions insofar as reduction is concerned, and cannot conceivably function by the oxidation mechanism previously postulated for Sn^{++}.

The inhibition effects produced by As^{+++}, Sn^{++}, Pb^{++}, and Cd^{++} through formation of a sulfide layer at a dissolving steel surface are, of course, limited to a definite range of acidity. The upper limit of this range is governed by the solubility of the respective metal ion sulfides, being greatest for As^{+++} and lowest for Cd^{++}. The lower limit of the range is largely determined by the *p*H at which the sulfide in the test metal specimen becomes soluble in the corroding medium.

It should be mentioned that many metal ions (e.g., Cu^{++}) form sulfides of such low solubility as to make inhibition by this mechanism possible. However, if the system is capable of causing deposition of a low-overvoltage metal, either through reduction of the ions themselves or sulfides, then the concurrent increase in local cell current and subsequent galvanic cell action overshadows any possible inhibition effects. For Ni^{++}, indications exist that, dependent on the metal ion concentration of the system, both phenomena may occur (3).

[1] The author can find no published value for the solubility product of As_2S_3. However, it is well known that HgS and As_2S_3 are the most insoluble of the heavy metal sulfides (10).

Acknowledgments

The author gratefully acknowledges the helpful suggestions of Dr. J. S. Batzold, Dr. J. O'M. Bockris, and Dr. P. J. W. Debye during the course of this investigation.

Manuscript received Sept. 8, 1959.

Bridged Complexes and the Deposition of Tin-Nickel Alloys

Robert L. Rau[1] and John C. Bailar, Jr.

Department of Chemistry and Chemical Engineering, University of Illinois, Urbana, Illinois

ABSTRACT

The method of continuous variations has been used to determine the nature of the complex in solutions containing tin(II), nickel(II), and fluoride ions. This indicates the formation of $SnF_4^=$, which in turn forms $NiSnF_4$. Other complexes of the type $NiSnF_x^{4-x}$, where x is 1, 2, or 3, have been shown to form, also. These complexes may contain one or more fluoride bridges. There is no indication of complex formation in the absence of fluoride.

Since the introduction of a bright tin-nickel alloy plate by Parkinson in 1951, much interest has been aroused in the nature of the species responsible for the nearly constant one to one atomic ratio of tin-nickel in the plate.

Parkinson (1) has shown that tin and nickel are deposited in roughly equal atomic proportions, over a wide range of conditions, from solutions containing stannous chloride, nickel chloride, sodium fluoride, ammonium fluoride, and enough hydrochloric acid to give the solution of *p*H of 2.5. This plate is the intermetallic compound NiSn, which has been unattainable by any other method (2).

A more detailed study of the electrolyte used in the plating process has led to several interesting qualitative conclusions (3). When the cathode potential was plotted against current density for a series of solutions containing a constant amount of stannous chloride and increasing amounts of sodium fluoride, it was observed that the cathode potential became increasingly negative, indicating complex formation between stannous and fluoride ions. A similar study using nickel chloride in place of stannous chloride indicated little or no complexing between nickel and fluoride ions. A third study, in which increasing amounts of nickel chloride were added to a solution containing constant amounts of stannous chloride, sodium fluoride, and ammonium bifluoride, indicated that the addition of nickel chloride caused the potential at which tin plates out to become more negative. It was suggested that this could be due to the formation of a complex containing both tin and nickel.

Davies (4) has studied the interaction between fluoride and stannous ions by determining the effect of a change in fluoride ion concentration on the nature of the alloy deposit. The solutions studied had a constant nickel concentration but contained varying amounts of stannous and stannic tin (the latter being due to the air oxidation of the stannous ion). At low fluoride concentrations the deposits obtained had a matte surface and a tin content higher than that of the bright alloy, but with fluoride concentrations above certain critical values the typical bright appearance of the tin-nickel alloy was obtained. The fluoride concentration range in which this change took place was quite narrow. The bright tin-nickel alloy could be obtained only from solutions in which each stannous ion was associated with four fluoride ions and each stannic ion with six fluorides ions.

Further studies (4) have indicated that $SnF_6^=$ is more stable than $SnF_4^=$ and is not involved in the deposition of the tin-nickel alloy. If the tin-nickel electrolyte contains an insufficient amount of fluoride to complex all the stannous and stannic ions, there is uncomplexed stannous ion in the electrolyte, and the bright alloy is not deposited.

By comparing the transport numbers of the metallic ions in the electrolyte with calculated values for the simple metallic ions, the existence of a tin(II)-fluoride complex seemed to be confirmed (5). For solutions containing nickel chloride, the difference between the experimental and calculated values of the transport number of Ni(II) suggested that the nickel ion was part of a negatively charged ion. Since there is no evidence for complex formation between nickel(II) and fluoride in aqueous solution (6), Brook, *et al.* suggested that Ni(II) was associated with the stannous fluoride complex.

In spite of the reluctance of nickel(II) to form fluoride complexes, some combination of $SnF_4^=$ with Ni(II) seems to occur, but conclusive evidence for this has not been established. It was the object of this investigation to determine the nature of the species formed in the tin-nickel electrolyte, using the method of continuous variations (7-9) with refractive index as the measured property.

Experimental

The Zeiss dipping refractometer, which was used in this investigation, does not give a direct reading of refractive index, but for our purposes it was not necessary to convert the readings to refractive index values. The instrument is easily read to ± 0.03 scale units; if desired, these can be converted to refractive index values having an accuracy of 0.00002 units.

In a typical study, solutions approximately 0.1M were prepared by direct weighing of analytical grade reagents. In some cases concentrations were determined analytically (10). Portions of these so-

[1] Present address: Minnesota Mining and Manufacturing Co., St. Paul, Minn.

lutions were measured into glass stoppered flasks in such a manner that the first flask contained 90% by volume of solution A and 10% of B. The second flask contained 80% of A and 20% of B and so on up to 10% of A and 90% of B. In every case the total volume was 10 ml.

After the solution had been in a thermostat for 30 min, it was placed in the refractometer cup, the prism of the refractometer was put in position, and the assembly was immersed in the water bath for 20 min prior to reading. All readings were taken at 25°C.

The continuous variation curves were obtained by plotting the solution readings (n) minus the reading of pure water (n_o) vs. volume per cent of the two constituents. The deviation curves were obtained by plotting the difference between the values used in the continuous variation curves and the values obtained by assuming no interaction between the constituents against per cent composition. Such a plot gives a maximum deviation at the point corresponding to the ratio in which the two constituents react.

Preparation of solutions.—To eliminate the possibility of atmospheric oxidation of the stannous ion, the distilled water was boiled and saturated with nitrogen. All stannous solutions were stored under an atmosphere of nitrogen and were used within 24 hr after preparation.

To duplicate the optimum plating conditions (4), all solutions were brought to a *p*H of 2.5. In the preparation of standard stannous solutions, it was necessary to add acid to prevent hydrolysis. This gave the solution a negative *p*H. If, however, two moles of fluoride ion were added per mole of stannous ion, it was possible to prepare stannous solutions of *p*H 2.5. A Beckman model G *p*H meter was used.

In cases in which ammonium fluoride was a constituent of the solution, it was necessary to take into account the two ionization constants of hydrofluoric acid (11) in order to prepare an acid solution having a known unassociated fluoride ion concentration.

Continuous Variation Studies

Study No. 1—$SnCl_2$:$2NH_4F$ vs. NH_4F—In order to determine the nature of the complex formed between stannous and fluoride ions, a continuous variation study of $SnCl_2$:$2NH_4F$ vs. NH_4F was undertaken (Fig. 1). The deviation curve shows a maximum at 33% $SnCl_2$:$2NH_4F$, indicating a [Sn(II) + $2F^-$]:F^- reaction ratio of 1:2; the complex must have the composition $SnF_4^=$.

Study No. 2—$NiCl_2$ vs. NH_4F—The data are plotted in Fig. 2. The figure shows no deviation, indicating no reaction between the constituents under the existing conditions.

Study No. 3—$SnCl_2$:$4NH_4F$ vs. $NiCl_2$—This study was undertaken to determine whether there is any interaction between the constituents in a solution containing Sn(II), Ni(II), and F^- (Fig. 3). The deviation curve indicates a [Sn(II) + $4F^-$]:Ni(II) reaction ratio of 1:1.

Study No. 4—$SnCl_2$:$3NH_4F$ vs. $NiCl_2$—In order to determine whether four fluoride ions are necessary for Sn(II) and Ni(II) to become part of the same species, a solution containing Sn(II) and F^- in the ratio 1:3 was used in a continuous variations study. The deviation curve shows a maximum (and thus indicates compound formation) at a ratio of [50% Sn(II):$3F^-$] and 50% Ni(II).

Studies 2, 3, and 4 were repeated using SnF_2 and $Ni(ClO_4)_2$ instead of the chlorides. Where a greater difference in successive readings was desired, an

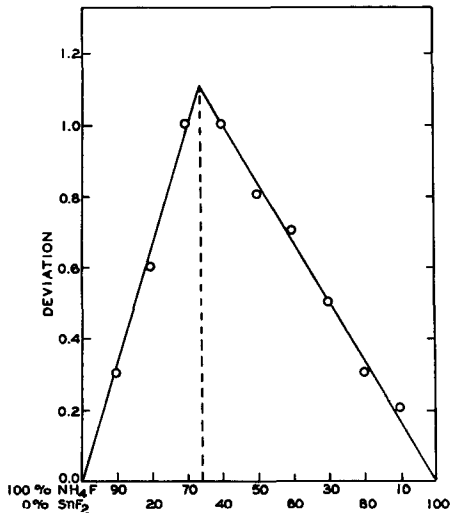

Fig. 1. 0.1M SnF_2($SnCl_2$:$2NH_4F$) vs. 0.1M NH_4F

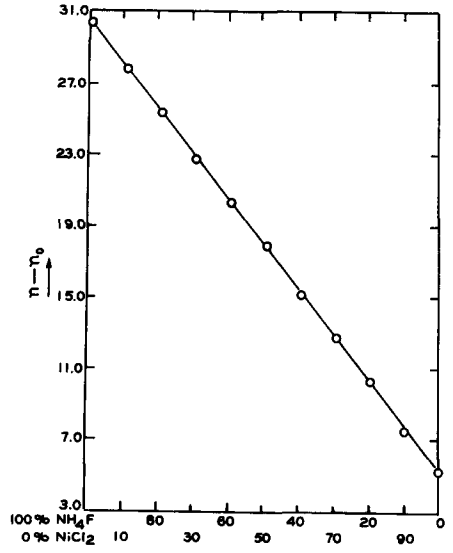

Fig. 2. 0.1M $NiCl_2$ vs. 0.1M NH_4F

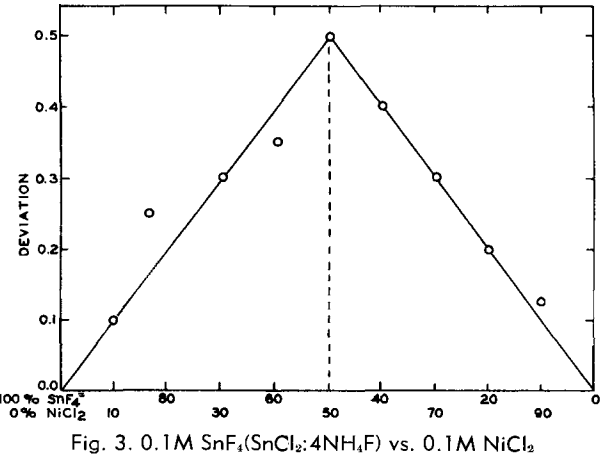

Fig. 3. 0.1M SnF_4($SnCl_2$:$4NH_4F$) vs. 0.1M $NiCl_2$

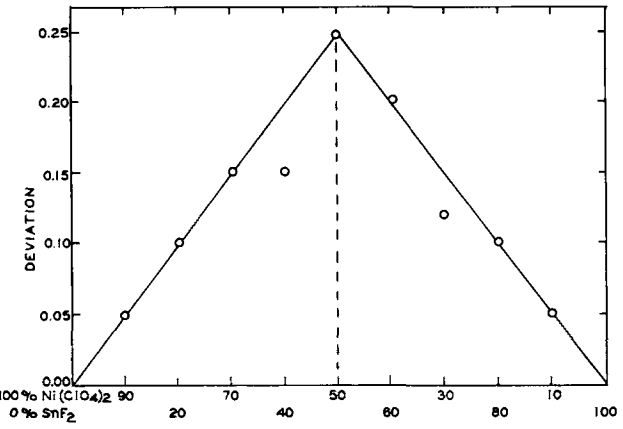

Fig. 4. 0.1M SnF_2 vs. 0.1M $Ni(ClO_4)_2$ + $NaClO_4$

inert salt such as $NaClO_4$ was added to one of the solutions. In all cases the results were exactly the same as those obtained with chloride ion present.

Study No. 4a—SnF_2 vs. $Ni(ClO_4)_2$ + $NaClO_4$—The data obtained using a solution of Sn(II) and F^- in a ratio of 1:2 as one of the constituents are plotted on Fig. 4. The curve shows a maximum deviation at 50% SnF_2 and 50% $Ni(ClO_4)_2$.

Study No. 5—SnClF vs. $Ni(ClO_4)_2$ + $NaClO_4$—To determine whether one fluoride ion is sufficient to allow Sn(II) and Ni(II) to become part of the same complex, a study of tin(II) chlorofluoride vs. nickel perchlorate was undertaken.

A 0.1M solution of tin(II) chlorofluoride (12) had a *p*H of 2.3 due to partial hydrolysis of the stannous ion. The nickel perchlorate solution was brought to a *p*H of 2.3 by the addition of perchloric acid.

After standing for 30 min the SnClF solution became slightly turbid, so the refractometer was immersed in the solutions for only 10 min. The readings for 100% SnClF before and after the formation of the turbidity did not change by more than the maximum experimental error. Figure 5 shows a maximum deviation at 50% SnClF and 50% $Ni(ClO_4)_2$ indicating a SnF^+:Ni(II) reaction ratio of 1:1.

Study No. 6—$SnCl_2$ vs. $NiCl_2$—To ascertain whether the presence of fluoride ions is necessary for the formation of the complex species, a continuous variation study of tin(II) chloride vs. nickel chloride was undertaken.

To prevent the hydrolysis of the stannous ion, the calculated quantity of stannous chloride was dissolved in a solution of 25 ml of water containing 2 ml of concentrated hydrochloric acid. The resulting solution had a *p*H less than zero. The nickel chloride solution was prepared in a similar manner.

The curve (Fig. 6) shows no deviation, indicating no reaction between stannous chloride and nickel chloride under existing conditions.

Discussion

In order to explain the constant composition of the tin-nickel alloy which is obtained over a wide range of conditions, several investigators have postulated the existence of a tin-nickel complex (3, 4). Except for the work previously cited, however, no

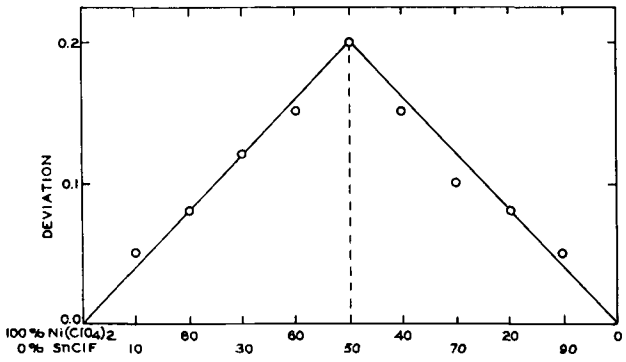

Fig. 5. 0.1M SnClF vs. 0.1M $Ni(ClO_4)_2$ + $NaClO_4$

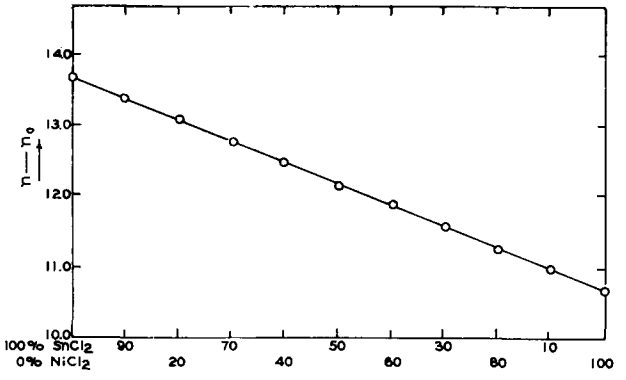

Fig. 6. 0.1M $SnCl_2$ vs. 0.1M $NiCl_2$

evidence has been offered in support of this hypothesis.

Study No. 1 indicates a [Sn(II) + $2F^-$]:F^- reaction ratio of 1:2, which is consistent with the formation of $SnF_4^=$. Davies (4) and Brook (5) have postulated the existence of $SnF_4^=$ from experimental data obtained by entirely different methods.

Study No. 2 indicates that Ni(II) forms no complex with fluoride ions under the conditions investigated. Similar results have been obtained by other investigators (6), although there have been some claims of complex formation between Ni(II) and fluoride (13).

Study No. 3 indicates that Sn(II) and Ni(II) are present in a 1:1 ratio in the complex species. If we assume that the only anions associated with either tin(II) or nickel(II) are the fluoride ions of $SnF_4^=$, the formula for the complex is $NiSnF_4$. Davies (4) and Brook have postulated the existence of such a complex.

If a metal ion and a complexing agent form a series of complexes for which the successive stability constants do not differ greatly, a solution of the constituent ions may contain appreciable amounts of all the possible complexes (14). If such a relationship exists in the tin(II)-fluoride system, a solution of constituent ions may contain SnF_3^-, SnF_2, and SnF^+ as well as $SnF_4^=$. The existence of all of these complexes has not been definitely established, but studies of tin(II) chloride and bromide systems indicate the simultaneous existence of successive complexes. Duke and Courtney (15) obtained values for the stability constants of $SnCl^+$, $SnCl_2$, $SnCl_3^-$, and $SnCl_4^=$, and concluded that an acid solution of the constituent ions contains some of each of these complexes. The determination of stability constants of Sn(II)-Br^- complexes led Vanderzee (16) to a

similar conclusion; the stability constants of the bromide complexes are smaller than those of the chloride complexes. We should therefore expect a solution of tin(II) and fluoride ions to contain all the ions $SnF_n^{(2-n)}$ (where n = 0, 1, 2, 3, and 4), each of these being more stable than the corresponding chloride or bromide complex. The concentration of each complex would be determined by the ratio of the concentrations of the tin and fluoride ions and the relative stability constants of the various complexes.

The electrolyte used by Parkinson in his studies of the tin-nickel alloy doubtless contains some of each of the possible tin(II)-fluoride complexes. The continuous variation studies reported here indicate that even one fluoride ion is sufficient to bind a tin(II) ion and a nickel(II) ion into a complex in which the metal ions are present in a 1:1 ratio.

Study No. 6, in which stannous chloride and nickel perchlorate were the constituents, showed no deviation from the "no reaction" curve, and it is assumed that $SnCl_2$ and Ni(II) do not form a complex under the conditions studied. It should be pointed out, however, that the conditions of Study No. 6 are not identical to those of previous studies. Because of the absence of fluoride ions, it was necessary to keep the *p*H below 2.5 in order to prevent the hydrolysis of the stannous ion.

As previously shown, $SnF_4^=$ is the predominant species in solutions containing an excess of fluoride ion, but other tin(II)-fluoride complexes may be present in the commercial electrolyte. Evidence for the formation of a 1:1 tin(II)-nickel(II) complex was obtained in all cases in which fluoride ions were present, but in the absence of fluoride ions there was no indication of tin-nickel complex formation. The conclusion that fluoride ions are necessary for complex formation is consistent with previous observations that the bright alloy plate cannot be obtained from solutions which do not contain fluoride (4).

The consistent 1.1 ratio of Sn(II):Ni(II) obtained in the continuous variation studies can be explained most easily by assuming that fluoride ions serve as bridging groups between the metals. Fluoride ions have not previously been shown to serve as bridging groups, but compounds which may contain fluoride bridges are known. Under extreme thermal conditions, the fluorides and chlorides of some alkaline earth elements combine to form compounds of the type $CaF_2 \cdot CaCl_2$, $SrF_2 \cdot SrCl_2$, and $BaF_2 \cdot BaCl_2$ (17). The complex $[Co(NH_3)_4BeF_4]^+$ (18) probably contains fluoride bridges.

From the continuous variation studies, we have concluded that only one fluoride ion is necessary for bridging in the tin-nickel complex, but we cannot be sure that only one fluoride ion acts as a bridging group when more are available.

Throughout this discussion it has been assumed that nickel(II) does not form complexes with fluoride ions, but that in the presence of a tin(II)-fluoride complex some type of association takes place. Apparently, no other similar cases have been reported, and we can offer no explanation for this seemingly inconsistent behavior. Because the phenomenon is of both theoretical and practical importance, other examples are being sought in the hope that they will shed light on the nature of the bonding in such mixed complexes. Fluoride complexes of Ni(II) have been reported, but their existence is not shown by the method of continuous variations. Evidently the conditions prevailing in this work were not conducive to their formation.

The formation of a tin(II)-nickel(II)-fluoride complex does not preclude the simultaneous existence of the individual ions in the electrolyte. Cuthbertson, *et al.* (3) have shown that complex species as well as the individual ions are present in the commercial electrolyte. It is, therefore, not illogical to assume the existence of the equilibria

$$NiSnF_x^{4-x} \rightleftharpoons Ni^{+2} + SnFx^{2-x}$$
$$\updownarrow$$
$$Sn^{+2} + X\,F^-$$

Under normal conditions, the simple ions are not discharged because their potentials are too high. If the concentrations of the constituent ions are high enough, the equilibrium shifts in favor of the formation of $NiSnF_x^{4-x}$, but in dilute solutions very little of the tin-nickel complex is formed. Electrolysis of such a solution would not be expected to give the tin-nickel alloy.

Retention of Chloride in Zinc Sulfide during Phosphor Preparation

A. Kremheller, S. Faria, P. Goldberg, and D. J. Bracco

General Telephone & Electronics Laboratories Inc., Bayside, New York

ABSTRACT

A concentration cell procedure, based on the method of Furman and Low, is employed to study chloride retention in zinc sulfide powders. Amounts of 0.001% by weight of chloride in 1 g of zinc sulfide can be determined quantitatively. Zinc sulfide powders with physically admixed or coprecipitated chloride are processed in open boats with variations in firing time and temperature; the retained chloride is determined. The chloride retained after displacement of surface chloride is defined as "'volume chloride." It is found that the retention of volume chloride in zinc sulfide is similar whether zinc chloride or sodium chloride is used as the flux; a peak concentration is observed in both cases after processing near 500°C. The experimental results are interpreted and found significant in elucidating the mechanism of the incorporation of chloride into zinc sulfide powder during phosphor preparation.

Although Tiede and Schleede (1) and recently Riehl and Ortmann (2) report that they have obtained luminescent zinc sulfide phosphors without employing a fluxing agent, commercial zinc sulfide phosphors are usually prepared with a fluxing agent, such as zinc chloride or sodium chloride. The presence of flux exerts a pronounced influence on the luminescence emission, crystal structure, and particle size. It is well known that the use of chloride flux has a beneficial effect during zinc sulfide phosphor preparation; however, the particular mechanism by which the chloride enhances the luminescence emission is not yet fully understood.

Schleede and Gantzckow (3) propose that a thin film of flux dissolves small particles of the base material with subsequent precipitation on large particles, and that the thin film sets up strain and disorder in the host lattice during cooling. The resulting lattice imperfections are considered by these authors as the cause of luminescence.

Guntz (4) is probably the first researcher who considers the possibility of flux action within the volume of the phosphor. Following a suggestion by Gugel (5), Smith (6) shows that the flux is able to form a solid solution with the base material. Kroeger and Hellingman (7) assume that chloride, i.e., the flux anion, is incorporated substitutionally into the host lattice. They find by quantitative chemical analysis 2 to 27 x 10^{-5} g atoms of chloride per mole of zinc sulfide in various phosphor samples. Their investigations aim at correlating the incorporated coactivator with the activator concentration and the luminescence mechanism; however, the authors point out that experimental difficulties lead to a ± 50% error in the determination of incorporated chloride, especially, since a certain part of the chloride may be too tightly bound for removal. Bube (8) was aware of this difficulty and removed 10% of the sample with nitric acid to dispose of occluded surface chloride before conducting a quantitative chloride analysis: in this case the possible error is given as ± 20%. There are some objections to Bube's procedure of removing surface chloride, in that small particles, corners, edges, specific crystallographic planes, and similar singularities may dissolve preferentially. Some chloride may still be held by surface forces. This fraction may not be completely removable by fractional dissolution and water washing; reprecipitation may also occur.

Froelich (9) observes that much of the initially added activator remains with the zinc sulfide phosphor after processing while almost all flux is lost, although it is apparent that coactivators have a beneficial effect on the phosphor obtained.

An attempt is made in the present paper to define and determine the amount of volume chloride that becomes incorporated into zinc sulfide during the process of phosphor preparation. The present study is considered as the first step in investigating and establishing the mechanism by which chloride helps to change a finely divided, nonluminescent zinc sulfide powder into a well crystallized, brightly luminescent phosphor. While the final objective of the investigation will be an attempt to correlate quantitatively the amount of chloride on and within the base material with luminescence emission and related properties of phosphors, this introductory exploration should establish a procedure for chloride determination and present some data on the quantitative chloride retention in zinc sulfide powder during phosphor preparation.

Experimental

In studying the incorporation of chloride into a phosphor, it is necessary to distinguish between chloride on the external surfaces and that which becomes incorporated into the volume. Palumbo and Levine (10) have shown that washing zinc sulfide powder with water until the filtrate shows no chloride does not assure that the surface is free of chloride. In a typical example, a sample of zinc sulfide powder precipitated in the presence of chlo-

ride may contain more than 1% by weight of chloride after water washing. The authors (10) find, however, that on leaching the water-washed sample with sulfate solution an appreciable fraction, for instance 30%, of the chloride appears in the leachate. It seems reasonable to assume that the sulfate ions displace chloride ions from the surface of zinc sulfide powder, so that the chloride remaining after displacement washing can be defined as volume chloride, i.e., that which is retained on enclosed internal surfaces and in the host crystal lattice. Accordingly, the determination of volume chloride is an experimental process during which the sample approaches asymptotically, after successive leachings with sulfate ion, a constant amount of retained chloride which is called volume chloride. The latter is, therefore, defined experimentally as the amount retained when the filtrate does not contain any detectable chloride, and when the retained chloride is found constant after additional displacement washings.

Chloride is determined by the concentration cell method of Furman and Low (11); this technique may also be employed in determining the concentration of other halides. The analysis is conducted by measuring the emf between two silver-silver chloride electrodes (Fig. 1) which are suspended in chloride solutions of different concentrations. One electrode is immersed in a chloride solution of concentration x and the other in a solution of concentration $0.01 + x$, where x is the chloride to be determined and the concentrations are in moles per liter. Electrochemical theory leads to the following equation at 25°C:

$$E = 0.0591 \log \frac{2(x + 0.01)}{x + (x^2 + 4P_o/f^2)^{1/2}} \qquad [1]$$

where E is the emf, x is moles of chloride per liter, P_o is the solubility product of AgCl in pure H_2O, and f is the activity coefficient. The value of the activity coefficient is found experimentally by using a solution with $x = o$ and measuring the emf. A graph of Eq. [1] facilitates the determination of x. For chloride analysis, zinc sulfide is washed in deionized water to remove the zinc sulfate and is then dissolved in hot dilute nitric acid. The acid solution is digested until the hydrogen sulfide is expelled; the sulfur which forms is removed by filtration. The volume is adjusted to 100 ml; two 25-ml aliquots are taken, to one 5 ml of water are added, to the other 5 ml of 0.06M NaCl. The aliquots are then placed into the arms of the concentration cell and the emf is measured. Bancie-Grillot and Grillot (12) indicate that chloride is lost if hot $4N$ HNO_3 is employed in dissolving zinc sulfide; however, in this laboratory careful checks with blanks containing known amounts of added chloride have shown no loss within the limit of chloride detection.

The results obtained by the concentration cell technique have been found to be reproducible and accurate. As little as 0.001% by weight of chloride in 1 g of zinc sulfide can be determined; the limit of detection is 0.0005%. In many cases gravimetric analyses have been run on selected zinc sulfide samples, with results that confirm the usefulness of the concentration cell procedure.

The zinc sulfide powders, zinc chloride, and sodium chloride used in these experiments are free of heavy metals to the limit of spectrographic detectability. Some of the zinc sulfide powders contain coprecipitated chloride in amounts specified below. The zinc sulfide described as chloride-free contains 0.0015 ± 0.0005% (Fig. 2) by weight of chloride. During phosphor preparation the samples are held in transparent quartz boats and heated in transparent quartz combustion tubes in an atmosphere of helium. Conductivity-grade deionized water is used for washing. The zinc sulfate used for leaching and the nitric acid for dissolution of zinc sulfide powder contain no chloride to the limit of detectability.

Results

The amount of added halide has a marked influence on the luminescence intensity and spectral distribution of the emission. Accordingly, it appears desirable to study quantitatively the history of added chloride during zinc sulfide phosphor syntheses. The mechanism by which chloride carries out its function of enhancing luminescence has not yet been established. Previous investigators have examined only the finished product. Our results show that the phosphor passes during its preparation through stages in which the amount of incorporated

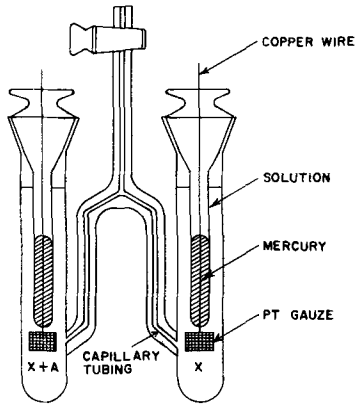

Fig. 1. Concentration cell with silver-silver chloride electrodes.

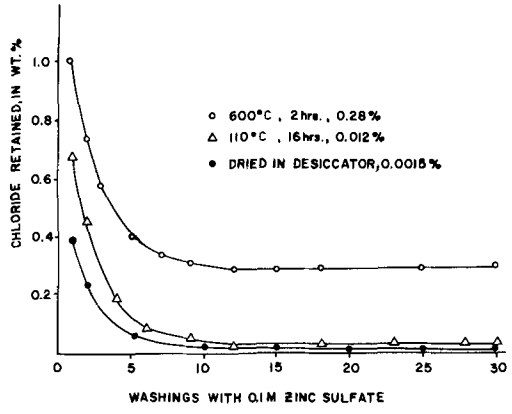

Fig. 2. Volume chloride retained after successive leachings with 0.1M zinc sulfate solution.

volume chloride is several orders of magnitude higher than that in the final phosphor. Data will be presented on the incorporation and retention of chloride in the volume of zinc sulfide as found during various steps of phosphor preparation from zinc sulfide powders with physically admixed or coprecipitated chloride coactivator.

Experimental definition of volume chloride.—Chloride-free zinc sulfide is mixed with 5% by weight of zinc chloride in solution. To check possible effects at room temperature, the slurry is placed in a vacuum desiccator at 25°C until it is completely dry. The dried mixture is then divided into eight 2-g portions. The first portion is leached once with 35 ml of 0.1M zinc sulfate, a second portion is leached twice with successive 35 ml portions of solution, and the remaining portions are leached in the same way for 5, 10, 15, 20, 25, and 30 times, respectively. The powder was separated from the leach solution by filtering through fritted glass filters and successive water washings. After separation, each portion is dissolved in nitric acid and the chloride content is determined as described above. The portion that had been leached only once contains 0.39% by weight of chloride, and after twenty leachings the retained amount decreases gradually (Fig. 2) to a constant value of 0.0015% by weight of chloride. Since this is the chloride content of the chloride-free zinc sulfide, it can be concluded that none of the added chloride became incorporated into the volume on drying at 25°C.

The same study is repeated on samples which are processed in a quartz combustion tube in one case for 16 hr at 110°C, and in another case for 2 hr at 600°C. After leaching, the samples are dissolved and their chloride contents are determined. Figure 2 indicates the number of times each sample has been leached and the resulting asymptotically attained volume chloride. It is seen that, in contrast to the result obtained by drying at room temperature, chloride is now incorporated into the volume of zinc sulfide powder during the heat treatment.

Influence of duration of heat treatment.—The amount of chloride incorporated into the volume of zinc sulfide, when zinc sulfide with physically admixed zinc chloride is heated at 600°C for 2 hr, is found above to be 0.28% by weight. In order to determine how the amount of incorporated volume chloride depends on the duration of heat treatment, zinc sulfide samples with 5% by weight of zinc chloride are heated at 750°C for 1, 4, 10, 20, and 30 min, and for 1, 2, 3, 4, and 8 hr. These samples are treated as above to determine the volume chloride. The data, which are presented in Fig. 3, show that chloride incorporation proceeds very rapidly. A peak value is attained within the first 10 min of heat treatment at this temperature. Thereafter, chloride begins to leave the volume as the sample remains at temperature. It should be noted that the amount of chloride in the volume of zinc sulfide after processing at 750°C for 2 hr is smaller than that incorporated during processing at 600°C for the same time. This result indicates the importance of the firing temperature, as discussed in the next part.

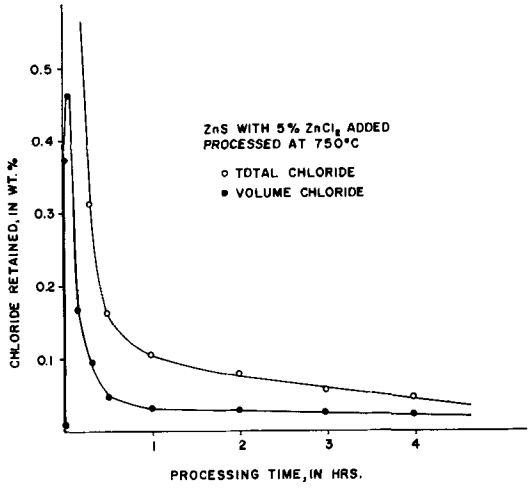

Fig. 3. Retention of total chloride and volume chloride as a function of processing time at 750°C.

Influence of the temperature of heat treatment.—It has been shown above that chloride is incorporated into the volume of zinc sulfide when heated with 5% zinc chloride. It is qualitatively clear from the above data that the amount of volume chloride incorporated first increases with temperature and then decreases as the temperature increases further. The present study is concerned with the quantitative nature of this temperature dependence. Zinc sulfide with 5% zinc chloride admixed is heated for 2 hr at various temperatures between 200° and 1100°C. External surface chloride is removed by the zinc sulfate leaching procedure, and the chloride content of the samples is determined; data are given in Fig. 4.

The peak value for the incorporation of chloride into the volume of zinc sulfide occurs near 500°C. The chloride retention curve rises about linearly to a maximum, and falls off so that the volume chloride diminishes to about 0.01% by weight at 800°C and to about 0.003% at 1100°C.

Usually a chloride other than zinc chloride is employed in phosphor synthesis; therefore chloride retention has been investigated when sodium chloride is added as the flux. The zinc sulfide samples with sodium chloride admixed are prepared in the same way as those containing zinc chloride. However, the amount of sodium chloride is changed to

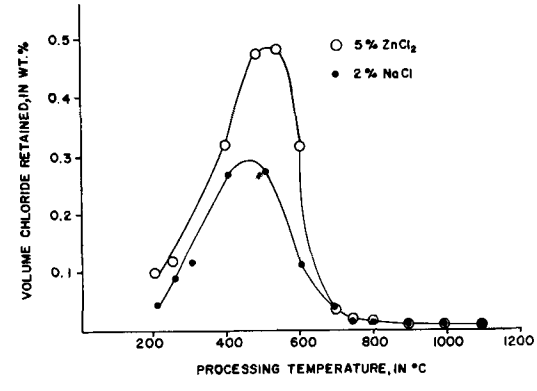

Fig. 4. Retention of volume chloride as a function of processing temperature for $ZnCl_2$ and NaCl addition; processing time is 2 hr.

2% by weight to approach a flux concentration often used in commercial practice. The zinc sulfide powders with the admixed sodium chloride are heated for 2 hr in the temperature range from 200° to 1100°C. The heat-treated powders are leached with zinc sulfate and then analyzed for volume chloride as before. The data, which are presented in Fig. 4, show the same general dependence of volume chloride on processing temperature as observed with zinc chloride, which has a much lower melting point than sodium chloride.

Retention of volume chloride in zinc sulfide containing coprecipitated chloride.—Chloride may be added to zinc sulfide either as a chloride salt after zinc sulfide precipitation from solution, as described above, or as coprecipitated[1] chloride formed when zinc sulfide is precipitated in the presence of a soluble chloride. In the latter case, amounts of about 1% by weight of chloride become incorporated into the volume of zinc sulfide during its formation.

As another, complementary part of studying the history of chloride incorporation during phosphor preparation, it appears of interest to observe the retention of volume chloride when coprecipitated chloride is present in the volume of zinc sulfide powder. For this purpose, zinc sulfide is prepared by passing hydrogen sulfide through a solution of zinc chloride acidified to pH 2.5 with hydrochloric acid. The zinc sulfide precipitate is filtered and leached with zinc sulfate solution until it attains a constant chloride content after several successive washings. The constancy of chloride is determined by analysis of the zinc sulfide sample as well as by the absence of chloride in the filtrate. The zinc sulfide prepared by this method contains 0.82% by weight of chloride which is all present in the volume.

Samples of zinc sulfide containing coprecipitated chloride are placed in quartz boats and heated in a quartz combustion tube at 400°C for 1, 4, and 16 hr, respectively, in an atmosphere of helium. Each specimen is leached twenty times with 0.1M $ZnSO_4$ after heating and then is dissolved to determine the chloride content. Figure 5 presents the data; almost all the volume chloride remains in zinc sulfide under the above processing conditions. The same experiment is performed by maintaining the zinc sulfide powder with coprecipitated chloride for various periods of time at 600°, 800°, and 1100°C, as shown in Fig. 5. It is found that the amount of retained volume chloride decreases rapidly with increasing processing temperature. The amounts of chloride remaining incorporated in the volume after heating for 4 hr at 600°C are comparable to the amounts of volume chloride incorporated when the chloride is introduced in the form of zinc chloride or sodium chloride by physical admixture.

[1] The term "coprecipitated" is used in the sense as given by I. M. Kolthoff and E. B. Sandell, Textbook of Quantitative Inorganic Chemistry, The MacMillan Co., New York, 1948, pp. 110-112.

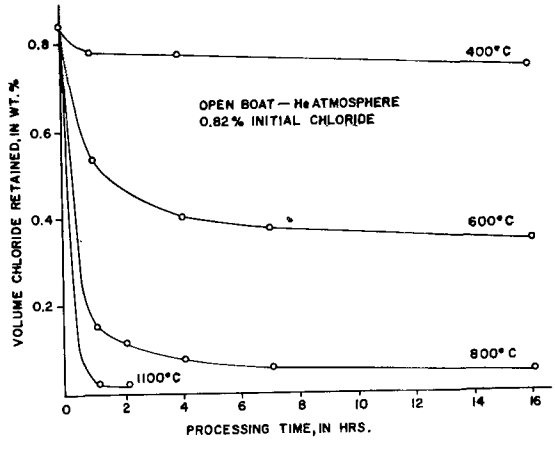

Fig. 5. Retention of coprecipitated volume chloride as a function of processing time and temperature.

Discussion

As part of the present investigation, it has been found that it is possible to define volume chloride as chloride not removed by successive leachings. One obtains reproducible values of volume chloride; these values depend on the conditions to which zinc sulfide powders containing either physically admixed or coprecipitated chloride have been subjected.

Following the explanation of Leverenz (13) for particle growth of Zn_2SiO_4, one can explain the incorporation of chloride into the volume of zinc sulfide as an attendant effect of particle growth. The admixed chloride coats the surface of the zinc sulfide grains which grow together and include chloride on contiguous surfaces. Chloride included in intergranular boundaries cannot be removed by leaching with sulfate ions and is, therefore, volume chloride as above defined. As the temperature increases (Fig. 4) to about 500°C, the number of intergranular boundaries also increases so that additional chloride becomes incorporated. When the processing temperature is increased above 500°C, the walls of the intergranular boundaries may start to sinter together so that chloride is expelled. At high temperatures many grain boundaries disappear, and particle growth takes place. A part of the volume chloride is then displaced to the external surface and volatilizes, while some may be retained on interior surfaces and some may become incorporated into the host lattice.

Sodium chloride flux shows essentially the same behavior as zinc chloride with respect to chloride incorporation into zinc sulfide. However, the two fluxes differ considerably in physical properties, such as vapor pressure and melting point. The similarity in behavior may indicate that chloride incorporation into the volume of zinc sulfide is essentially a property of the host material and the chloride ion, and to a lesser extent a property of the flux cation. The fact that zinc chloride has a lower melting point than sodium chloride, yet shows the same temperature dependence of chloride incorporation, tends to cast doubt on a mechanism of flux action that depends on the dissolving (3) of zinc sulfide by the fluxing agent. This result is in agreement with Bube (8) who finds that the amount of chloride retained is the same regardless of whether sodium chloride or hydrochloric acid is present during preparation of a copper-activated zinc sulfide phosphor. The concentration of retained chloride is about the same whether it is present origi-

nally as a coprecipitate or is admixed with the sulfide before firing. For this reason one is led to suspect that the actual mode of retention is the same in both cases.

As shown in Fig. 4, the volume chloride is a function of firing temperature for a given firing time. The volume chloride does not, however, by itself, determine the obtainable luminescence; maximum luminescence is usually obtained by firing at temperatures well above 500°C. Therefore, if a numerical correlation between the amount of incorporated chloride and luminescence is to be expected, one must consider the volume chloride to be composed of at least two kinds, one of which is effective in promoting luminescence. One hopes that future explorations will make it possible to distinguish between the various fractions of volume chloride, so that quantitative correlation with luminescence can be established. A first goal (14) will be to differentiate between lattice chloride and internal surface chloride.

Study of Ball Milling and the Determination of Lattice Chloride in Zinc Sulfide

A. Kremheller, S. Faria, and A. K. Levine

General Telephone & Electronics Laboratories Inc., Bayside, New York

ABSTRACT

Ball milling, followed by displacement washing, permits a distinction to be made between lattice chloride and internal surface chloride as parts of volume chloride. The surface area, which is determined by gas adsorption methods, increases rapidly in the beginning and then in a linear manner as a function of milling time. The extent of linearity between surface area and milling time is considered to be a measure of crystallinity. The data indicate that the maximal amount of lattice chloride becomes incorporated at a processing temperature near 700°C after a processing time of 2 hr. Zinc sulfide gradually loses its ability to luminesce under ultraviolet (u.v.) irradiation during milling; the logarithm of the luminescence emission is about proportional to the newly formed surface. It appears that the luminescence centers consist of lattice regions of about 0.2 μ in diameter, as is indicated by the observed minimal size of luminescent particles. The luminescence emission of milled samples can be restored by reprocessing, although the degree of restoration is highly sensitive to impurities introduced during milling.

Lenard and Klatt (1) were probably the first to observe that photoluminescence is considerably decreased during the destruction, e.g., by crushing, of phosphor particles. Wecker (2), Frey (3), and Broser and Reichardt (4) among others have confirmed this observation. Many researchers (5) have attempted to correlate the decay of luminescence intensity during phosphor destruction with the particle size, extent of destruction, and related parameters. However, some conclusions which have been attained are confounded by the method of particle size determination, as zinc sulfide particles usually agglomerate if they are below 1 μ in diameter. For instance, Frey (3) concludes from microscopic observations that the grain size of zinc sulfide approaches a constant value of 4 μ during ball milling, although he observes small particles (about 0.1 μ) when an electron microscope is used. Short and

Steward (6) attempt a correlation between photoluminescence intensity and crystal structure changes during grinding of zinc-cadmium sulfides. They find that the residual photoluminescence is an exponential function of the retained hexagonal structure fraction. Broser and Reichardt (4) were probably the first to consider the surface increase during ball milling of zinc sulfide phosphors. They determined the surface change and degree of destruction of the phosphor particles by an optical procedure based on reflection.

Results on grinding of zinc sulfide are only incidental to the present investigation, which is mainly concerned with a distinction between chloride present on internal surfaces and within the lattice. Zinc sulfide particles are destroyed in order to expose the incorporated volume chloride. The various fractions of chloride have been discussed in a previous publication (7), in which the need for determining lattice chloride and its possible implication on luminescence properties of zinc sulfide also have been indicated. The present paper consists essentially of the continuation of previous researches looking into the mechanism of flux action during zinc sulfide phosphor preparation. The present incidental results on ball milling appear, however, to be of such general interest in considering the mechanism of photoluminescence that their inclusion seems desirable.

Experimental

The zinc sulfide powder, processing procedure, and fluxing agent used have been specified in a previous publication (7) which also explains the determination of small amounts of chloride by the concentration cell procedure.

The ball milling is performed in 4-oz glass bottles with screw caps; 0.5 in. diameter procelain balls are employed for crushing the zinc sulfide particles. The speed of the ball mill, the number of balls, and the sample size are kept constant in all experiments. Dry milling is employed to avoid the decomposition of zinc sulfide which takes place, for instance, in the presence of water. It is found that the chloride contamination introduced by milling for 300 hr is below the limit of detectability, i.e., 0.0005% by weight, by the concentration cell procedure (7); however, amounts near 10 ppm each of copper, iron, lead, and silicon are detected. These impurities affect the restoration of luminescence during refiring of ball milled samples, as will be shown.

A simplified gas adsorption method (8) was employed for determining the newly formed surface area after ball milling. The simplified procedure reduces the time for one surface area determination by a factor of about ten when compared with the general Brunnauer-Emmett-Teller (B.E.T.) method, makes routine determinations feasible, and permits one to obtain a quantitative measure of the extent of destruction of phosphor particles during ball milling. Optical and electron microscope studies, as well as the general B.E.T. gas adsorption method, have been employed to confirm and supplement results obtained by the simplified method.

A semi-quantitative measure of the blue, green, and red luminescence intensity was obtained with a laboratory plaque tester (9) in which u.v. radiation from two germicidal lamps excites the phosphor to be tested. The emission from the phosphor is filtered, and the emission within the corresponding spectral range is measured with a photomultiplier tube, thus permitting a comparison of the luminescence emission from different phosphor samples to be made. We have found this method to be accurate, and the results are reproducible within ± 2%.

Results

Ball Milling and Surface Area

The average particle diameter of zinc sulfide decreases during milling, but the rate of decrease diminishes with milling time, as shown in Fig. 1. In this figure, three different initial particle sizes are represented; the size in microns is given for average equivalent spherical diameters. If one assumes that the crystallites are perfect, Rittinger's law (10) applies. This law states that the work consumed in particle-size reduction is directly proportional to the area of the newly formed surface. If the material is hard, which means that the cohesive forces are large, much work is needed to expose a given surface area.

The determination of the particle size is quite difficult and represents only an average value that is confounded by the fact that the particles are actually not spherical and are distributed over a variety of shapes according to their sizes (11). An improved sensitive index of the effect of milling is therefore the increase in surface area with milling time. Figure 2 represents this relationship. It is interesting to observe that the curves consist of two distinct regions. During the initial milling period the specific surface area increases rapidly, while there exists a linear relationship with extended milling times. The slope in the linear part is very nearly the same in all five cases, and the fracture of particles is still proceeding at the same rate after 100 hr of ball milling. The increase in specific surface area is larger for smaller particles than for the larger ones during the initial part of milling.

These results are readily amenable to an interpretation. The data can be explained tentatively by assuming that during the early stages of milling the increase in surface area is predominantly due to the breaking of particle aggregates, such as fracture along grain boundaries and similar imperfections,

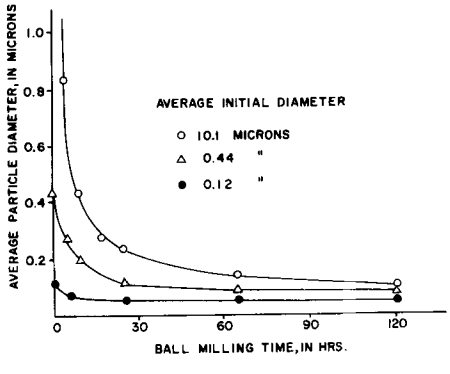

Fig. 1. Dependence of average particle diameter on milling time.

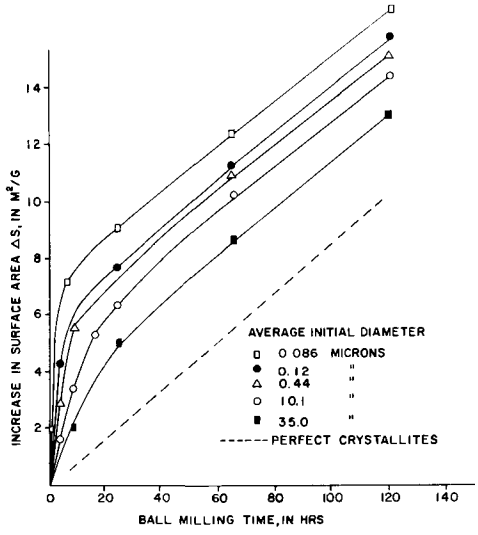

Fig. 2. Increase in surface area with milling time for various initial particle sizes.

while in the later stages of milling it is the fracture of single crystallites that is dominant. This explanation is also in agreement with the sequence of the curves in that the large particles can be expected to exhibit better crystallinity and fewer imperfections than the small ones. Generally, it may well be feasible to compare the crystallinity and degree of perfection of crystalline materials by evaluating these relationships, as given in Fig. 2.

Distinction between Internal Surface Chloride and Lattice Chloride

When the agglomerates and crystallites are broken up, the surface area of the powder increases. A portion of the volume chloride becomes exposed, and this can be replaced by displacement washings with zinc sulfate solution. Most of the chloride that becomes removable is exposed in the early stages of milling when agglomerates and imperfections are broken up. There will also be some loss of lattice chloride during the initial stage of ball milling; however, this amount can be estimated readily. If one assumes that the lattice chloride is uniformly distributed throughout the lattice, e.g., in a 1-g sample, one finds that about 1% of the volume chloride present will be exposed as lattice chloride if the increase in specific surface area is 10 m^2/g. On the other hand, if a portion considerably larger than 1% of the volume chloride becomes displaceable, essentially internal surface chloride must be exposed. In addition, one may expect also from Fig. 2 that mainly internal surface chloride becomes exposed during the initial stages of milling when agglomerates break up.

In a practical case, one would expect therefore that a diagram of the volume chloride as a function of the increase of specific surface area Δs will initially show an amount of chloride exposed per newly formed specific surface area, which is determined essentially by internal surface chloride which becomes displaceable; one can see this exemplified in Fig. 3. However, during subsequent milling essentially lattice chloride becomes exposed when the single crystallites fracture. The sample represented

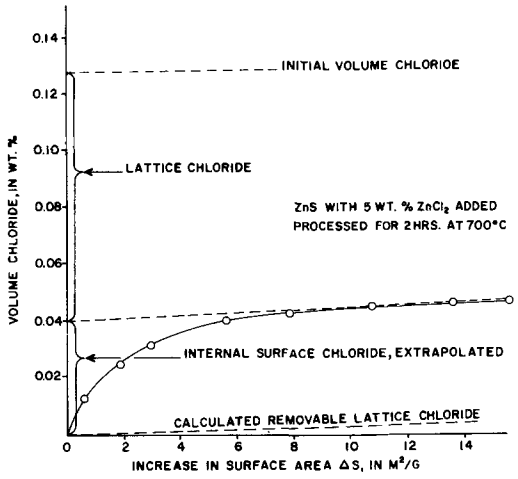

Fig. 3. Distinction between chloride on internal surfaces and within the lattice.

in Fig. 3 was processed for 2 hr at 700°C after 5% by weight of zinc chloride as a flux had been added. The volume chloride is 0.127% by weight, as indicated by the dashed horizontal line. After milling is started one finds that an increasing amount of chloride becomes exposed as the surface area is increased. After the increase in specific surface area is about $\Delta s = 10$ m^2/g, the amount of exposed chloride becomes a linear function of Δs. Since single crystallites rather than agglomerates fracture on further milling, it appears likely that lattice chloride is essentially exposed from here on. The straight part of the curve can be extended toward the ordinate of Fig. 3, so that an extrapolation to indicate the amount of lattice chloride present becomes possible. It is assumed in this estimate that the lattice chloride is uniformly distributed within the lattice and is exposed at a linear rate from the start of milling. In the sample shown in Fig. 3, the amount of internal surface chloride is found to be about 0.04% by weight, so that the incorporated lattice chloride amounts to 0.09%.

Other samples were treated in the same manner in order to distinguish between lattice chloride and internal surface chloride as parts of volume chloride. Results are given in Table I. The amount of internal surface chloride decreases as the crystallinity is improved at elevated processing temperatures. The lattice chloride concentration appears to have a peak near 700°C, although one could hardly draw definite conclusions because the determination of lattice chloride is not possible in a direct manner after sample processing at 500°C. In this case the slope does not change as in Fig. 3, but one obtains the impression that internal surface chloride is exposed even after a ball milling time of 350 hr. The

Table I. Chloride retained in zinc sulfide processed with 5% by weight of zinc chloride for 2 hr

Processing temp, °C	Wt % of chloride in Volume	Lattice	Internal surfaces
600	0.303	0.08	0.22
700	0.13	0.09	0.04
800	0.017	0.014	0.003

1000	0.0030	0.0025	0.0005

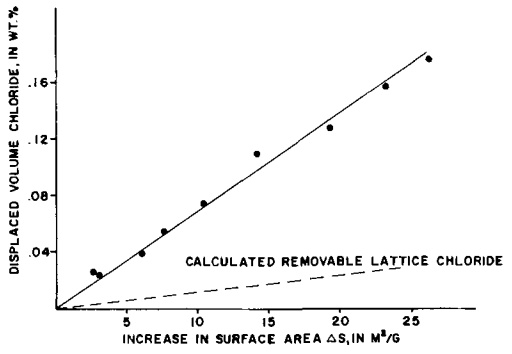

Fig. 4. Removal of coprecipitated volume chloride from precipitated zinc sulfide after milling.

behavior of this sample is very similar to that of zinc sulfide containing coprecipitated chloride,[1] as seen in Fig. 4.

The chloride flux, which is beneficial in preparing zinc sulfide phosphors, may also be present in the coprecipitated form. This is common commercial practice, for the same quality of phosphor is attained with a smaller amount of coprecipitated chloride as with admixed flux. It therefore appears valuable to know the way in which chloride is distributed in this case. A zinc sulfide powder containing 0.80% by weight of coprecipitated chloride was carefully washed with zinc sulfate solution until the amount of volume chloride was at the constant value of 0.73%. Portions of this material were milled for successive periods after which the surface increase and the amounts of displaceable chloride were determined. Figure 4 represents the amount of exposed volume chloride as a function of the increase in surface area during milling. The largest Δs corresponds to 350 hr of milling, during which time about 20% by weight of the initial volume chloride is rendered displaceable. From the nearly linear character of the curve one can surmise that all the chloride rendered displaceable is of one type. If this were uniformly distributed lattice chloride, one should expect a relationship between Δs and exposed chloride as shown by the dashed line in Fig. 4. When this is compared with the experimental results plotted in the upper line, it appears that the coprecipitated chloride is not uniformly distributed within the lattice. The data can be taken to mean that the chloride lies for the most part on internal surfaces of tightly agglomerated particles of the precipitated zinc sulfide powder. This incidental result is of importance to analytical chemists who are concerned with the manner in which coprecipitated ions are incorporated into a precipitate.

When the same zinc sulfide powder is processed for 2 hr at 700°C, one finds about 0.25% by weight of volume chloride of which about one half is lattice chloride. Therefore, the incorporation of volume chloride into the lattice is very similar in this case to that observed with zinc sulfide containing physically admixed chloride flux.

Decay of Luminescence Intensity during Milling

Several experimental samples of a luminescent zinc sulfide phosphor were milled for various lengths

[1] "Coprecipitated" is used in the sense as indicated in ref. (7).

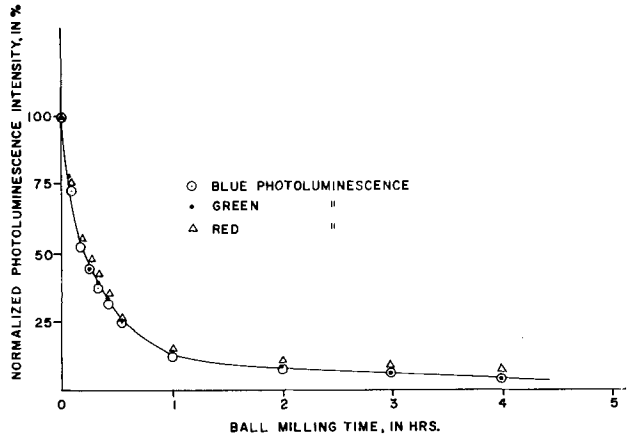

Fig. 5. Decay of photoluminescence intensity of zinc sulfide phosphor during milling.

of time; results are presented in Fig. 5. The blue and green photoluminescence emission decay somewhat faster than the red component. This different behavior of the red part of the emission after ball milling was also observed by Wecker (2). One finds that the ability to luminesce is essentially destroyed during the first 10 hr of milling when the agglomerates are broken up and the internal surfaces (cf. Fig. 2) are exposed.

Therefore, it appears that the exposure of internal surfaces may be intimately connected with the decay of luminescence intensity during the milling process. This consideration led us to plot the logarithm of the luminescence intensity B as a function of the increase of surface area Δs exposed during the ball milling. The resulting Fig. 6 indicates that the luminescence decreases about exponentially with increasing surface area. This means that the decrease in luminescence with the change in Δs is proportional to the instantaneous luminesence emission, i.e., $dB/d(\Delta s) = -aB$.

Another interesting result is that no particles below 0.2 μ were found to be photoluminescent in these very extensive experiments. It appears that a

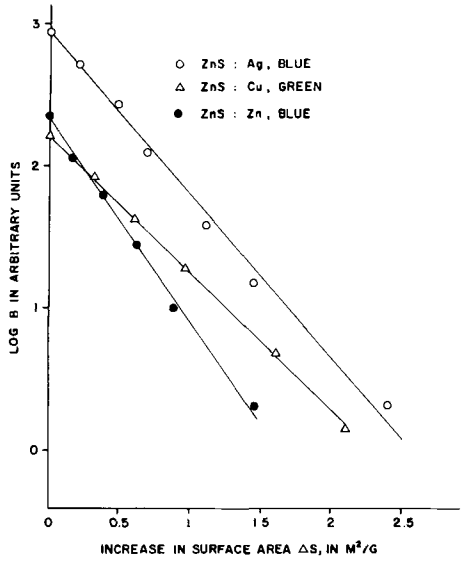

Fig. 6. Logarithm of the photoluminescence intensity B as a function of the increase in surface area Δs during milling.

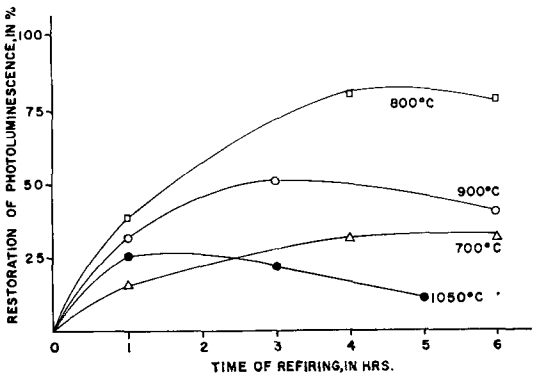

Fig. 7. Restoration of photoluminescence intensity by refiring after milling.

minimum cell size is required for photoluminescence; this is in agreement with conclusions stated by other authors (12-15).

Restoration of Luminescence Emission after Milling

Some experiments have been conducted to explore the restoration of photoluminescence by heat treatment of the milled phosphor. Figure 7 presents some data on recovery of photoluminescence by reprocessing at various temperatures. The extent of restoration is given in per cent of the green luminescence emission before milling as a function of processing time, and the temperature as parameter. If a sample that becomes nonluminescent during milling is held at 800°C for 4 hr the original luminescence is nearly restored, while on extended firing the intensity decreases again. The luminescence recovery was found to be optimum at 800°C. The restored luminescence intensity can be further increased by about 20% if chloride flux, such as 2% by weight of zinc chloride, is admixed or if the sample is quenched rapidly after refiring.

The average particle size increases during the refiring process, as can be determined readily by the gas adsorption method or by microscopic observation (11). The particle size also increases, however, in cases where the restoration of luminescence emission is counteracted by other processes, such as the diffusion of "killer" impurities introduced during ball milling; the extent of this contamination is indicated above. The degree of luminescence recovery and especially the maxima found for various processing temperatures and times become self-evident if impurity diffusion is assumed, as can be seen from Fig. 7. It appears likely that the degree of contamination was smaller in our samples than in those used by Broser and Reichardt (4), since they obtain maximum restoration with a 30-min heat treatment at 500°C.

Summary and Discussion

A study of the mechanism of flux action on the luminescence behavior of zinc sulfide has led to a method that permits one to distinguish between internal surface and lattice chloride. Previous investigations have led to ambiguous results because difficulties arose from the presence of occluded and internal surface chloride. The present study is based on the displacement of chloride ion by sulfate ion, surface area determination by the simplified gas adsorption method, and the use of milling as a means of exposing lattice chloride and internal surface chloride.

It was found that the internal surfaces are exposed mainly during the initial stages of milling, so that internal surface chloride becomes exposed preferentially and can be removed by ion-exchange washings. The slope of the curve of displaceable chloride as a function of the increase in specific surface area gradually approaches a constant value with additional milling, when essentially lattice chloride is rendered displaceable. Simple extrapolation permits one to obtain a quantitative estimate of the amounts of lattice chloride and internal surface chloride.

The instantaneous luminescence intensity of milled zinc sulfide phosphors is found to be an exponential function of the increase in specific surface area. The decrease in luminescence occurs essentially during the exposure of internal surface chloride. When luminescence emission is no longer perceptible, about 80% of the original lattice chloride is still incorporated within the phosphor lattice. It may therefore be concluded that the presence of lattice chloride alone is not sufficient for photoluminescence. A possible correlation may exist between the occurrence of luminescence and the requirement of a certain minimum cell size, since no photoluminescent particles have been observed below 0.2 μ in diameter. It appears possible that the exposure of internal surfaces is accompanied by the creation of trapping levels that lead to the observed decrease in luminescence with the increase in specific surface area.

Donor Concentration at the Surface of a Diffused N-type Layer on P-type Germanium

R. Glang[1] and W. B. Easton[2]

Diamond Ordnance Fuze Laboratories, Washington, D. C.

ABSTRACT

Four methods of evaluating the donor concentration at the surface of a diffused N-type layer on P-type germanium have been investigated. All methods assumed a complementary error function (erfc) distribution in the diffused layer. The methods required the use of experimental data for junction depth and sheet resistivity, and of published data for diffusion coefficients of group V elements and electron mobilities in germanium. The methods were applied to calculate the donor concentrations at the surfaces of a number of diffused samples. Under diffusion conditions, which were expected to result in an erfc impurity distribution, the actual concentration profile in the vicinity of the junction was shown to deviate from the erfc law. Due to this deviation, one of the methods of calculating the surface concentration was ruled out. With the other three methods, calculated surface concentrations agreed within a factor of 2 or 3. The disagreement is mainly caused by lack of precise information in respect to the electron mobilities in the diffused layer. Therefore, all the methods represent approximations only.

The preparation of diffused PN-junctions has become a widely used technique in the fabrication of semiconductor devices (1, 2). The electrical characteristics of these devices depend to a large degree on the properties of the diffused layer (3). Therefore, a quantitative knowledge of these properties is essential to the design of devices as well as to the experimental direction of the diffusion process. Some of these properties, for instance the junction depth and the sheet resistivity of the layer, are amenable to direct experimental determination. The concentration of the diffused impurity at the surface, however, cannot be measured directly; it has to be derived from other measured parameters. This concentration is generally referred to as surface concentration. There are several ways of determining the surface concentration (4), and the actual choice of the method will depend on the types of experimental data which are available.

The following discussions concern a special case of the diffusion process, characterized by the diffusion of a donor element from a source of constant vapor pressure into P-type germanium of uniform acceptor concentration. The diffusion temperature is maintained constant during the entire experiment. Furthermore, it is assumed that the indiffusion is not complicated either by a rate-determining layer or by evaporation from the germanium surface. If Fick's second equation of diffusion is solved for these boundary conditions, the complementary error function (erfc) is obtained as the general type of the impurity distribution (5):

$$N(x) = N_0 \text{erfc}\ (x/2\sqrt{Dt}) \qquad [1]$$

where $N(x)$ is the concentration of donors in the germanium at a certain distance, x, from the surface; N_0 is the donor concentration immediately at the surface; t is the diffusion time; and D is the diffusion coefficient of the donor element in germanium.

Figure 1 shows the concentration profile of the donors and, in addition, the initial acceptor concentration A, as functions of x. At a certain depth w, where these concentrations are equal and no excess charge carriers are available, the PN-junction is formed; at this depth

$$N(w) = A \qquad [2]$$

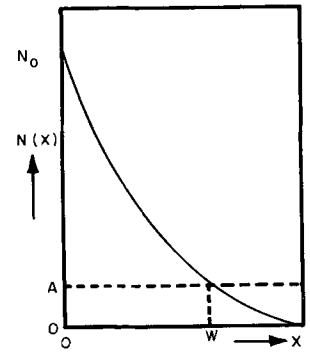

Fig. 1. Concentration of donors N(x) and initial concentration of acceptors A as a function of distance x from the surface of a diffused layer.

[2] Present address: Cornell University, Ithaca, New York.

Determination of the Surface Concentration

1. From the erfc distribution.—The simplest treatment of the problem of the surface concentration is obtained by substituting Eq. [2] in Eq. [1] and solving for N_0:

$$N_0 = \frac{A}{\text{erfc}(w/2\sqrt{Dt})} \qquad [3]$$

Values of the diffusion coefficients D for group V donor elements in germanium have been published frequently (6-10). The junction depth w can be determined experimentally, for instance by the techniques described by Bond and Smits (11). The initial acceptor concentration A can be obtained from Hall measurements on the P-type material prior to diffusion. Unfortunately, this simple method was found to be completely unsatisfactory, as will be shown and explained later on.

2. By differential etching.—N_0 may also be expressed in terms of conductivity of the surface layer. Four-point-probe measurements (12, 13) on diffused layers can be expressed in terms of the sheet conductivity σ_s of the entire diffused layer. Since the carrier concentration in the layer varies with depth, the total sheet conductivity is the integral of the differential

$$d\sigma_s = e \cdot \mu(N_x) \cdot n(x) \cdot dx \qquad [4]$$

where $\mu(N_x)$ is the electron mobility at a certain distance x from the surface and is a function of the total impurity concentration N_x at that depth; e is the electron charge. Assuming that all donors are ionized and that a fraction of them equal to the number of acceptors is not available for the conduction process,

$$n(x) = N(x) - A \qquad [5]$$

To obtain the sheet conductivity of a layer of finite thickness, Eq. [4] is integrated. For this purpose, the layer which is closest to the surface and extends into a depth Δx, small compared to the total junction depth w, will be considered. Within this shallow layer, an average value $\bar{\mu}$ can be used to approximate the mobility. Furthermore, the error function is expanded into a series, of which only the first term has to be considered as long as $x/2\sqrt{Dt}$ is small compared to 1. Then

$$N(x) \cong N_0\left[1 - \frac{2}{\sqrt{\pi}} \cdot \frac{x}{2\sqrt{Dt}}\right] \qquad [6]$$

With these simplifications, the sheet conductivity of the first surface layer of thickness Δx follows from integration of Eq. [4].

$$\Delta\sigma_s = e \cdot \bar{\mu}\left[N_0 \cdot [\Delta x - \frac{(\Delta x)^2}{2\sqrt{\pi Dt}}] - A\Delta x\right] \qquad [7]$$

Equation [7], solved for the surface concentration, yields

$$N_0 = \frac{\frac{\Delta\sigma_s}{e \cdot \bar{\mu}} + A\Delta x}{\Delta x - \frac{(\Delta x)^2}{2\sqrt{\pi Dt}}} \qquad [8]$$

Frequently it will be tolerable to further simplify this expression by neglecting second order terms.

The numerical solution of Eq. [8] requires knowledge of the differential sheet conductivity $\Delta\sigma_s$. This information is obtained by measuring the sheet conductivity of the diffused layer with a four-point-probe, then briefly etching the surface and taking another four-point-probe measurement on the new surface. The difference between the two sheet conductivities is $\Delta\sigma_s$. The thickness Δx of the removed surface layer may be determined either by using a calibrated etch or by another junction depth measurement after the etch. Attempts to derive Δx from the difference in the weight of the unetched and etched sample did not give satisfactory results. The average mobility in Eq. [8] has to be estimated either on the basis of a Hall measurement (14, 15) on the diffused layer, or by comparing the average resistivity $\Delta x/\Delta\sigma_s$ of the removed layer with resistivities obtained from published mobility data (16-18).

3. From average mobility approximations.—It is also possible to relate the surface concentration to the total sheet conductivity of the layer, if one succeeds in integrating Eq. [4] over the entire junction depth, i.e., from zero to w. This integration can be done algebraically by using the simplifying approximation of a constant average mobility throughout the entire layer. Obviously, this assumption will affect results more seriously than it did in the foregoing method, where it was applied for a thin sublayer only. With this simplification, the sheet conductivity of the diffused layer is represented by

$$\sigma_s = e\bar{\mu} \cdot [N_0 2\sqrt{Dt} \int_0^{w/2\sqrt{Dt}} \text{erfc } u\, du - \text{erfc}(x/2\sqrt{Dt})\, d(x/2\sqrt{Dt} - \int_0^w A\, dx] \qquad [9]$$

The first integral term can be transformed according to

$$\int_0^z \text{erfc } u\, du = \frac{1}{\sqrt{\pi}} - \int_z^\infty \text{erfc } u\, du \qquad [10]$$

Numerical values of the function $\int_z^\infty \text{erfc } u\, du$ have been published by Kaye (19), who uses the symbol "ierfc z" for this first repeated integral of the complementary error function. Introducing his symbol, with the understanding that

$$z = w/2\sqrt{Dt} \qquad [11]$$

and, furthermore, substituting the more commonly used sheet resistivity ρ_s for the sheet conductivity, where

$$\rho_s = \frac{1}{\sigma_s} \qquad [12]$$

the surface concentration follows from Eq. [9]

$$N_0 = z \cdot \frac{\frac{1}{w \cdot \rho_s \cdot e \cdot \bar{\mu}} + A}{1/\sqrt{\pi} - \text{ierfc } z} \qquad [13a]$$

For numerical solution, A, w, z, and ρ_s are determined as before. The product

$$w \cdot \rho_s = \bar{\rho} \qquad [14]$$

represents the average resistivity of the layer. Since data relating the electron mobility to the donor concentration are published for germanium (16-18) one may derive a graph giving μ as a function of the resistivity. This graph may be used to estimate the average mobility in the layer from the experimental value of the average resistivity as given by Eq. [14].

A more elegant way of interpreting Eq. [13a] requires a Hall measurement instead of a resistivity measurement on the diffused layer. The Hall measurement yields the average excess carrier concentration directly in the following terms:

$$\bar{n} = \frac{3\pi}{8} \cdot \frac{H \cdot I}{w \cdot e \cdot V_H} \qquad [15]$$

where H is the magnitude of the magnetic field, I is the current through the sample, and V_H is the measured Hall voltage. The average electron concentration $\bar{n}$ is given by:

$$\bar{n} = \frac{1}{w \cdot \rho_s \cdot e \cdot \bar{\mu}} \qquad [16]$$

and when substituted in Eq. [13a] leads to:

$$N_0 = z \cdot \frac{\bar{n} + A}{1/\sqrt{\pi} - \text{ierfc } z} \qquad [13b]$$

Further simplifications of Eq. [13a] or [13b] are possible, since A in most practical cases will be very small compared to $\bar{n}$. In addition, the term ierfc z converges rapidly to zero; for $z = 1.6$, for instance, the value of ierfc z is only 1% of $1/\sqrt{\pi}$, and therefore may be neglected.

4. From computer approximations.—The accuracy of the method described in the foregoing paragraph is limited by the assumption of a constant average mobility over the entire layer. Better results are to be expected if the variation of the mobility within the layer is considered. This consideration necessitates the use of a computer. For diffused layers in silicon and various types of impurity distributions, Backenstoss (20) has computed and published curves which relate the surface concentration to the average layer resistivity $\bar{\rho} = \rho_s \cdot w$. For germanium, however, similar data have not been published. In the following discussion, the individual steps of the computation process, which has been applied to obtain analogous curves, are outlined briefly. Only diffused N-layers on P-type germanium and erfc-distributions are considered.

In the general conductivity equation

$$\frac{1}{\bar{\rho}} = \frac{1}{\rho_s \cdot w} = \frac{1}{w} \cdot e \cdot \int_0^w \mu(N_i)[N(x) - A]\, dx \qquad [17]$$

$N(x)$ is assumed to be given by Eq. [1]. The mobility $\mu(N_i)$ is taken from the data of Conwell (17). This implies the assumption that the total impurity concentration approximately equals the excess donor concentration: $N_i \simeq N(x) - A$, which is true only if $N(x)$ is large compared to A. The integral was evaluated by Simpson's rule, using an IBM 704 computer. The computation is greatly simplified by the change of variable, $x = wu$. On substituting the latter and Eq. [1] in Eq. [17]

$$\frac{1}{\bar{\rho}} = e \cdot \int_0^1 \mu\,(N_0 \text{ erfc } zu - A) \cdot [N_0 \text{erfc}(zu) - A] \cdot du \qquad [18]$$

where $z = w/2\sqrt{Dt}$. The value of z is determined by assuming Eq. [1] as a first approximation for $x = w$, and solving for z by Newton's iteration method. This procedure defines an effective diffusion coefficient D, which has the advantage of making the resistivity a function only of the initial and surface concentrations. It will be shown later on that Eq. [1] does not give a true picture of the impurity distribution in the region close to the junction, and therefore the effective diffusion coefficient will not be a true value. However, diffusion coefficients of group V elements in germanium, published by different authors (6-10), vary within rather wide limits. Therefore, for the problem at hand, the effective D-value is certainly as good as one of the published values.

The complementary error functions used in the calculations were evaluated by means of the Rand approximation (21) of the form:

$$\text{erfc } y = \frac{2}{\sqrt{\pi}} \int_y^\infty \exp(-v^2)\, dv =$$

$$[1 + a_1 y + a_2 y^2 + a_3 y^3 + a_4 y^4 + a_5 y^5]^{-8}$$

An unsuccessful attempt was made to find a simple approximation for $\mu(n)$ or $n \cdot \mu(n)$. The latter was found to be approximately proportional to $(\log n)^4$, but the approximation was not close enough for computation. The values of $\mu(n)$ were therefore taken from Conwell's graph (17) in which they are plotted as a function of log n. The mobilities were found during computation by four-point Lagrange interpolation. The values of the average conductivity of the diffused layer, $1/\bar{\rho}$, were computed for various values of A and N_0. Results are shown in Fig. 2. The truncation and round-off errors in the calculation are negligible. Sources of possible errors are therefore the mobility data and the use of Eq. [1] to compute z.

Application of Methods and Discussion of Results

Numerous diffusion experiments were conducted in accordance with the conditions stated in the introduction. The source of the diffusing impurity and the wafers to be treated were kept together in a covered quartz boat, which was located in a vacuum tube furnace and heated to varied diffusion temperatures. The diffusion tube containing the boat was mantled by a graphite cylinder to pick up RF energy from an induction coil. Heating and cooling periods prior to and after the experiment were in the order of only 10 min. The diffusing donor im-

purity was arsenic obtained by evaporation from powdered master alloys containing arsenic in germanium.

Numerical values of the diffusion coefficients were based on data given by Smits (6); only in the computer approximations were effective D-values used. Junction depths were determined by angle lapping the diffused sample, depositing copper to delineate the junction, and subsequently making interference depth measurements (11). The average mobilities needed for solution by methods 2 and 3 were estimated from the average resistivity, again using the mobility data published by Conwell. In one case, the mobility was determined experimentally by Hall measurement on the diffused layer.

Experimental data and results of the calculations for 13 samples diffused in various runs are listed in Table I. On comparing the surface concentrations shown in the last four columns of the table, the most striking fact is that all values obtained by direct evaluation of the erfc equation (method 1) are unreasonably small. In order to investigate this phenomenon further, a few diffused layers have been analyzed by a method which has been mentioned by Smits (4). It consists of etching away the diffused layer in small steps and taking four-point-probe conductivity measurements between steps. In this way the average donor concentrations for each individual sublayer can be evaluated. In the immediate neighborhood of the junction, measurements are not possible, because the resistance of the remaining and extremely thin layer becomes very high and unreproducible.

An example of such a layer analysis is shown in Fig. 3. The circles indicate concentrations derived from measurements. The solid line is an erfc curve, calculated to fit the experimental points most closely.

[a] Initial acceptor concentration.
[b] Depth at which A = donor concentration $N(w)$.
[c] Sheet resistivity.
[d] Derived from Hall measurements.

The small square indicates the depth where the junction was determined to be located, using the angle lapping technique. From this figure, it can be seen that the true impurity distribution in the vicinity of the junction deviates strongly from the erfc curve; the true distribution in this vicinity is indicated by a dashed line. This deviation is larger than a possible error in the junction depth determination.

Other samples which have been investigated in the same way gave similar results. In the numerical evaluation of Eq. [3], too small a value of w will give an erfc value which is too high and, therefore decrease N_0. This effect has been observed in all cases and, therefore, it must be concluded that for diffusion conditions, as explained previously, the resulting impurity distribution follows the erfc curve in the major part of the layer, but deviates strongly in the neighborhood of the junction. Since the determination of the surface concentration by method 1 depends strongly on the validity of the erfc law exactly at the junction, this method is not suitable for a reasonable estimate of N_0.

The mechanism which causes this deviation of the impurity distribution is not fully understood. On a few samples, which had been used for a layer analysis, the acceptor concentration A was determined by Hall measurement after the diffused layer had been etched off completely. It was found that A was larger than it had been prior to diffusion, in one extreme case by a factor of two. This may be an indication of simultaneous indiffusion of copper during the diffusion process. It is well known that copper is a rapidly diffusing acceptor impurity in germanium, and the complete exclusion of traces of copper from the surface of the sample during the cleaning operations is extremely difficult (22). Copper atoms in the order of 10^{16}/ccm in the layer may at least partially account for the observed deviation in the distribution of excess donors. Near the surface the contamination with copper is negligibly small compared to that with arsenic. In greater depths, however, the arsenic concentration decreases and eventually becomes even smaller than the copper concentration. This happens close to the junction, and that is the region where the deviations appear.

The fact that the impurity distribution does not exactly follow the erfc law raises the question of how this deviation affects the other methods of calculation. There is obviously no influence on the differential etching method because all measurements involve only the region nearest to the surface of the diffused layer. The accuracy of this method therefore depends entirely on the accuracies of the estimate of the mobility and the thickness of the etched-off layer. Results are nearly independent of the value of the diffusion coefficient, since in Eq. [8], D occurs in a second order term only. This deviation certainly influences the results of methods 3 and 4 in some degree. However, these methods involve integration over all donors in the diffused layer. The small region near the junction, where the deviation from the erfc law becomes noticeable, does not contribute a substantial fraction of the total integral. Therefore, the effect of this deviation will be minor.

The accuracy of methods 2, 3, and 4 is limited mainly by the lack of precise information about the electron mobility in various parts of the diffused layer. The mobility data of Conwell, used for most of the calculations, refer to samples of homogeneous doping with no concentration gradient and as little compensated impurities as possible. Therefore, these values may not hold well for the diffused layers. For example, the electron mobilities for concentrations between 10^{19} and 5.10^{17}/ccm should range from 3000 to 1500 cm^2/v sec, according to Conwell. The average Hall mobility, however, has been measured on a sample of corresponding concentrations and was found to be only 930 cm^2/v sec. Because of the mobility values used for most of the calculations, results may be in error by a factor in the order of two. On the other hand, it may very well be that the experimental mobility value is too low, because the Hall measurements were made on N-type layers adjoining P-type bulk material, and the measured voltage depends on the effectiveness of the junction as an insulator between different regions. If a small leakage current passes through the junction, the Hall voltage will be affected by the presence of holes in the P-type region.

The rather crude assumption of a constant mobility throughout the entire layer is reflected in the last two columns of Table I. All data obtained according to method 3 are smaller than those of method 4 by a factor of about 2.5, whereas the values of the differential etching method are somewhere in between.

On comparing the surface concentrations of different samples calculated by the same methods, minor differences will be noted. These differences are due to the fact that master alloys with slightly varying amounts of arsenic, in the order of 10^{19}/ccm, have been used as sources of the diffusant. The first two samples listed in Table I, i.e., those bearing the designation "H5—", were diffused in the presence of a master alloy which was richer in arsenic than the other sources by a factor of about 10.

Summary and Conclusions

Four methods have been investigated in order to obtain data of the surface concentrations in diffused layers. These methods are not equally suitable for the purpose. The first method involves a junction depth measurement and the assumption of an erfc distribution extending throughout the entire layer and into the junction region. It leads to numerical results which disagree by more than one order of magnitude with resistivity and Hall measurements and with all calculations based on these measurements. The complete experimental analysis of diffused layers, by determining sheet conductivities and excess electron concentrations of individual partial layers, indicates that the distribution of donors in the neighborhood of the junction deviates from the erfc distribution. Therefore, the erfc equation fails to give true values of the surface concentration.

The remaining three methods rely on the fact that the conductivity of the diffused layer is related to the number of excess electrons in the N-type region. The fraction of the conductivity which is due to

carriers in the deviating part of the distribution curve is either not involved (method 2), or is negligibly small compared to the total quantity (methods 3 and 4). Therefore, these methods are not sensitive to deviations of the donor distribution in the region of the junction. Their accuracy depends, rather, on how closely the true relation between excess electron concentration and conductivity of the layer can be approximated. These methods allow fairly accurate calculations of the surface concentration. The major limitation of method 3 is that it employs the concept of a constant mobility. However, the relation between electron concentration and conductivity requires knowledge of electron mobilities in the diffused layer, and these are amenable to experimental determination only to a limited extent. Therefore, in the preceding calculations, the electron mobilities had to be estimated by comparison with data referred to germanium of similar but not exactly the same impurities as in the diffused layers. Consequently, these three methods can give only an estimate of the surface concentration. Considering the uncertainty in the mobility data as the main source of error, the surface concentrations obtained by either method 2 or 4 should not deviate from the true value by a factor larger than 2.

A Study of the Thorium-Tungsten-Boron System

Douglas T. Pitman and Dilip K. Das

Spencer Laboratory, Raytheon Company, Burlington, Massachusetts

ABSTRACT

A phase diagram for the Th-W-B system has been determined by x-ray diffraction of samples fired to a brightness temperature of 1800°C and furnace-cooled. A ternary compound was found with a probable composition of $ThWB_4$. This compound is monoclinic with lattice parameters: a = 12.25, b = 3.75, c = 6.14Å, and $\beta = 104.1°$. The stability of the thorium and tungsten borides and their reaction with ThO_2 were also investigated.

The hexaborides of the alkaline earth and rare earth metals and thorium with the general formula MB_6 have been investigated by Lafferty (1). He found that these borides had certain desirable properties that might make them good thermionic emitting materials. The hexaborides were found to be unstable in the presence of refractory metals such as Mo and W, and certain precautions had to be used to prevent their decomposition. However no work has been reported on the Th-W-B ternary system and the stability of the tungsten borides and thorium borides in the presence of thorium or boron. This information would be of importance for the design and conception of high-temperature cathodes and the interpretation of the emission mechanisms. The phase diagram of W-B has been reported by Kiessling (2) and Brewer, *et al.* (3). It has four intermediate phases: W_2B_5, W_2B, and a high- and low-temperature form of WB. The Th-B system has been reported in the literature by various authors (3-6) and has two intermediate phases: ThB_4 and ThB_6. Th and W do not form any compounds or solid solution and their eutectic composition is about 8 atomic per cent (a/o) tungsten with a melting point of 1475°C (7). Also of interest is the role of ThO_2 as an impurity in the thorium and its effect on the phases present in the ternary diagram.

Experimental

The ternary compositions were synthesized by reactive sintering of pressed powder compacts. The boron obtained from U. S. Borax Research Corporation had a maximum impurity of less than 0.4%. Westinghouse thorium had a maximum impurity

content of less than 2.2%. X-ray diffraction analysis showed that there was about 1.0% thoria in the thorium. The tungsten was obtained from Fansteel Metallurgical Corporation with a purity better than 99.8%. The particle size of these materials was less than 100 mesh. Spectrographic analyses of the starting materials B, Th, and W are given in Table I.

Ten-gram samples were weighed out and thoroughly spatulated. Five grams was then pressed at 10,000 psi to form a compact with a ¼ in. diameter and a thickness of about ½ in. These compacts were vacuum-fired to a brightness temperature of 1800°C for ½ hr and furnace cooled at a pressure of 10^{-4}-10^{-5} mm Hg. The sample temperature dropped from 1800° to 700°C in about 90 sec after the heat was turned off.

The small furnace in which the compacts were fired was placed inside a vacuum bell jar. The heater was a 1 in. diameter by 1½ in. long helix of six turns made from 0.080 in. tungsten wire. Three molybdenum heat shields were mounted around the heater coil. A viewing port was cut into the shields to allow the temperature of the sample to be measured with an optical pyrometer. The sample rested on a ThO_2 disk of a special design to give a minimum contact area between the compact and the disk. The disk was placed on a molybdenum pedestal that brought the sample up to the middle of the heater coil directly in line with the viewing port in the molybdenum radiation shields. This experimental arrangement avoided contamination of the sample and the loss of boron by diffusion into the container. Temperatures were measured with a L&N optical pyrometer, and all temperatures reported in the body of the paper are brightness temperatures. As many as three compacts could be fired simultaneously without physical contact between the individual specimens.

X-ray diffractometer traces or Debye-Scherrer powder photographs were made of all the fired samples in order to identify the crystalline phases. The powder photographs were taken with a 114.59 mm radius camera. Filtered copper Kα radiation was used for all x-ray work. Several samples were examined in the diffractometer using a high temperature camera (8) capable of reaching 2000°C in a vacuum of 10^{-5} to 10^{-6} mm Hg.

* All the samples have ThO_2 present in an amount of not more than 3%.

Results and Discussion

The phase equilibrium data used to determine the Th-W-B ternary diagram are given in Table II. This table lists the composition in atomic per cent, the firing temperature and time, and the crystalline phases as identified by x-ray diffraction.

Figure 1 is the proposed ternary diagram as determined by this experiment.

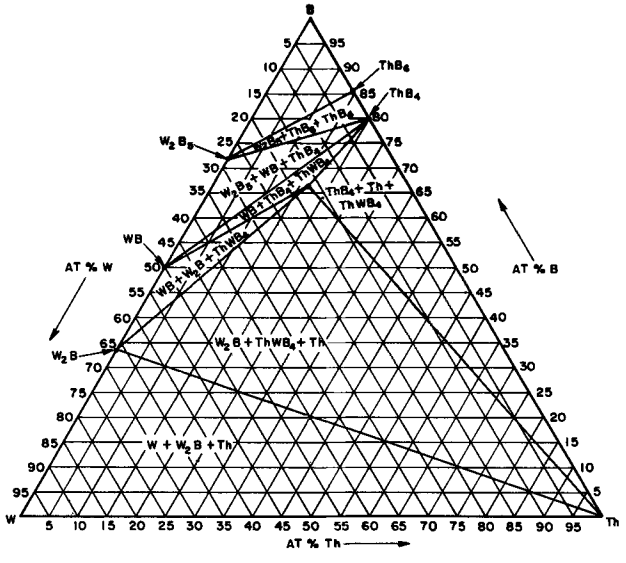

Fig. 1. Phase diagram of the system Th-W-B based on samples fired at 1800°C and furnace cooled.

It is known from the binary phase diagrams that the homogeneity ranges of WB and W_2B_5 are 48-51 a/o and 66.6-68.0 a/o B, respectively, while the homogeneity ranges of the other existing phases are too narrow to be measured. The assumption was made that all the compounds and elements in the binary systems could be represented as points on the ternary phase diagram.

The initial samples were chosen in order that their composition would fall on the intersections of lines drawn in the ternary field for all possible combinations of phase co-existence. This reduced the number of fired samples needed to establish the phase diagram. The analysis of these strategic samples showed which two phases could or could not co-exist, thus determining the locations and contents of every three-phase field, barring the existence of ternary compounds in these regions.

A ternary compound was found which could be represented by the formula $ThWB_4$. A number of samples were required to ascertain its composition. This phase was found to co-exist with W_2B, WB, ThB_4, or Th. Since the lattice constants did not vary with composition the homogeneity range is believed to be very narrow.

The ternary phase has the approximate composition $ThWB_4$ based on the following evidence. The sample, 50 m/o ThB_4 and 50 m/o W, was fired in the usual manner. Weight loss during the firing was found to be 2 w/o. The composition of the evaporant was found to be Th and B. X-ray diffraction and metallographic examination of this sample showed it to be primarily the ternary phase with a combined total of less than 2 w/o ThO_2 and WB. Also using the molecular formula, $ThWB_4$, and calculating the theoretical density on the basis of two molecules per unit cell, (crystal structure studies are described in the next paragraph), good agreement is obtained between the calculated and measured density. For the reasons above the most probable composition is $ThWB_4$.

Small crystals of the ternary phase could be obtained on the surface of samples which were in the vicinity of $ThWB_4$ in the phase diagram by firing them to 2100°C. Precession photographs were made using a small crystal 0.05 mm by 0.15 mm (Mo Kα, λ = 0.7107 Å). These photographs showed $ThWB_4$ to be monoclinic with a = 12.25 Å, b = 3.75 Å, c = 6.14 Å and β = 104.1°. The probable space groups are P_2, $P_{2/m}$, or Pm. The x-ray density, assuming two molecules per unit cell, is 5.6 g cm^{-3} while the measured density is 5.8 g cm^{-3}. The pycnometric value of the density is high because of the presence of a small amount of WB. The melting point of this phase is 2175° ± 25°C which is lower than the melting points of the surrounding borides: ThB_4, W_2B, and WB.

The diffraction data and the calculated hkl values for monoclinic $ThWB_4$ are presented for comparison along with those of ThO_2 and ThB_4 in Table III. It was also found that other refractory metals such as Mo or Re react with ThB_4 to form ternary compounds which are isomorphous with $ThWB_4$.

In the presence of W, ThB_4 is unstable with the result that W_2B is always the first product formed along with free Th. This reaction was examined by means of the high-temperature camera mounted on the Geiger counter diffractometer. It was found that in a 50 m/o W and 50 m/o ThB_4 sample, W_2B first appeared at a temperature of 1100°C with a decrease in the intensity of ThB_4 and W lines. As the temperature was raised the amount of W_2B continued to increase until at 1600°C the W_2B began to decrease with the formation of $ThWB_4$. Holding the sample at this temperature for 1 hr showed the components to be $ThWB_4$ with a small amount of W_2B. As the temperature was further increased to about 1800°C WB started to appear and $ThWB_4$ decreased slightly in intensity indicating that both B and Th were evaporating off from the surface.

* Data from Swanson and Tatge, National Bureau of Standards Circular 539.

Boron reacted with ThO_2 to form ThB_6 at a temperature of less than 1600°C. When the temperature was raised to 2100°C, ThB_6 disappeared and was replaced by ThB_4, with two moles of boron reacting with excess ThO_2.

Firing ThB_4 in contact with ThO_2 at 2300°C resulted in no reaction, reduction, or solid solution,

contrary to the postulations by Brewer, *et al.* (3). The phase ThX_2, which was reported by Brewer to be a solid solution between ThO_2 and ThB_4, was not found in any of the samples examined during this investigation, and it is quite probable that this phase involves some element other than B.

ThB_6 fired to 1600°C in vacuum showed no decomposition. The apparent instability that Brewer proposes for ThB_6 may be partly due to diffusion of boron into the molybdenum boride crucible that he used.

WB fired in contact with ThO_2 to 2100°C showed no apparent reduction of the ThO_2. X-ray examination revealed WB, W_2B, and ThO_2 to be present in the sample.

X-ray examination of mixtures of W_2B and ThO_2 fired to 1800°C showed only W_2B and ThO_2.

$ThWB_4$ was found to be inert to ThO_2 at a temperature of 2100°C.

During this investigation pure ThB_4 and ThB_6 were prepared. The preparation of ThB_4 by firing powder compacts of the elements was found to be mainly a problem of obtaining equilibrium. This was achieved by regrinding and refiring the sample. In the case of ThB_6, boron was lost when the reaction became strongly exothermic at 1050°-1150°C. To compensate for the loss of boron in the resultant ThB_6-ThB_4 mixture, a calculated amount of B was added to convert all the samples to ThB_6 on refiring at 1800°C. The calculations were based on a calibration curve obtained with the x-ray diffractometer from known mixtures of the two compounds. The impurities of the synthesized ThB_4 and ThB_6 were those of the elemental starting materials although substantially reduced by the vacuum firing. The amount of ThO_2 which was the main impurity in the Th has been practically eliminated. The spectrographic analysis of the ThB_4 is included in Table I for comparison.

Acknowledgments

The authors are indebted to Dr. L. Lesensky for his encouragement and helpful discussion during the course of this investigation. They also wish to acknowledge the efforts of Dr. L. E. Alexander who took and interpreted the precession photographs of the ternary phase and Mr. N. J. Aubert and Mr. W. Y. Tye for their skilled assistance.

Manuscript received Aug. 21, 1959. Portions of this paper have been presented at the Nineteenth Annual Conference on Physical Electronics held at the Massachusetts Institute of Technology on March 26-28, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

Theory of Faradaic Distortion

K. B. Oldham

King's College, University of Durham, Newcastle upon Tyne, England

ABSTRACT

The passage of a pure a.c. across an electrode gives rise to a cell potential containing sinusoidal components of frequencies which are multiples of the fundamental. The first harmonic is predominant and expressions are here derived for its amplitude and phase angle. The magnitude of the effect is similar to that of faradaic rectification, but its measurement may offer advantages over the latter in the determination of the kinetic parameters of some electrode reactions. The effect of the double layer is considered, and an apparatus is described which enables faradaic admittance, rectification, and distortion to be measured simultaneously.

Two effects of the passage of an alternating current across an electrode have been employed to determine the rates of the two electrode reactions and their dependence on potential. The first of these effects, faradaic admittance (1), is usually exploited by placing the cell[1] in one arm of an a-c bridge: the kinetic parameters are calculated from the magnitudes of the resistance and capacitance which must be inserted into a balancing arm to achieve a null signal across the bridge (2, 3). The second effect, faradaic rectification (4), is assessed by measuring the change in d-c potential which the alternating current produces, either directly (5, 4) or by supplying the cell with an intermittent high-frequency signal, the resultant square-wave potential being nullified by application of an intermittent current (6, 7). A third effect is now described: this too may be employed for the determination of the kinetic parameters of the electrode reaction.

[1] The design of the cell is such that one electrode remains depolarized. One method of achieving this result is to employ two electrodes similar in all respects except area, of which one electrode has incomparably more than the other. The equilibrium potential of such a cell is, of course, zero and therefore if the passage of a current through the cell causes a change v in the potential of the smaller electrode, the cell potential is directly equal to v plus an ohmic potential V_o caused by the passage of the current through the resistance R_s of the cell solution. The potential across a cell having chemically dissimilar electrodes is, however, equal to the sum of three terms, $(v + V_o + V_e)$, V_e being the equilibrium potential of the polarizable electrode versus the reference (depolarized) electrode.

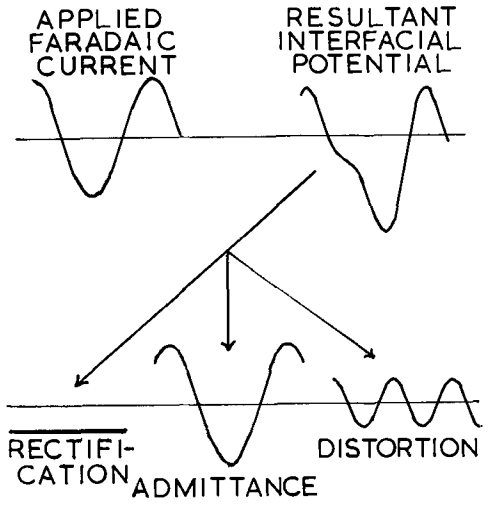

Fig. 1. Wave forms of the applied faradaic current (a pure sine wave) and the resultant interfacial potential. The latter contains three major components having the wave forms shown in the three lower diagrams.

If the instantaneous anodic magnitude of the faradaic component of the applied alternating current is $I \cos \omega t$, its effect is to change the electrode potential from its equilibrium value E_e to $(v + E_e)$. It will be shown in the *Mathematical Derivation* below that v has the form

$$v = \Psi + V \cos(\omega t + \theta) + V_2 \cos(2\omega t + \theta_2) + (\text{much smaller terms}) \quad [1]$$

and the unknowns Ψ, V, θ, V_2, and θ_2 in this equation will be evaluated there. The upper two diagrams in Fig. 1 show typical plots of the quantities $I \cos \omega t$ and v against time; the three lower diagrams correspond to the three leading terms on the right hand side of Eq. [1] into which v can be resolved. The d-c potential Ψ, which has been termed the redoxokinetic potential (8), arises from faradaic rectification. The ratio V/I is termed the faradaic impedance of the electrode and since θ turns out to take values between 0 and $-\pi/4$, this impedance is best represented by a pure resistance in series with a Warburg impedance (1). The third term on the right hand side of [1] arises in the same way as Ψ: from the nonlinearity of electrode reaction rate with potential, and it is suggested that the effect giving rise to this harmonic content in v be termed "faradaic distortion." The primary object of the present communication is the derivation of an expression for V_2, the amplitude of the faradaic distortion.

Electrode Reaction

Established expressions for the cathodic and anodic currents associated with the electrode reaction

$$\mathrm{Ox} + ne^- \rightleftharpoons \mathrm{Rd}$$

are

$$\vec{i} = nA\mathbf{F}ka_o \exp\{-\alpha n\mathbf{F}E/RT\} \quad [2]$$

and

$$\overleftarrow{i} = nA\mathbf{F}ka_o' \exp\{(1-\alpha)n\mathbf{F}E/RT\} \quad [3]$$

where a_o and a_o' are the activities of Ox and Rd at the electrode surface. E is the potential of the electrode vs. the standard Ox/Rd electrode and k is a standard rate constant (9), being equal to the actual rates of both forward (cathodic) and reverse reactions at a standard Ox/Rd electrode in equilibrium. The term α denotes the transfer coefficient of the forward reaction.[2]

If equilibrium is established at the electrode, the surface activities will be equal to a and a', the bulk activities of Ox and Rd; moreover, the forward and reverse currents are then equal to each other and to the quantity termed the equilibrium exchange current I_e. Therefore,[3]

$$a \exp\{-\alpha n\mathbf{F}E_e/RT\} = I_e/nA\mathbf{F}k = a' \exp\{(1-\alpha)n\mathbf{F}E_e/RT\} \quad [4]$$

For many purposes I_e is a more convenient kinetic parameter than k, but it must be appreciated that the equilibrium exchange current (unlike the standard rate constant k) is itself a function of the activities of Ox and Rd and, to a lesser extent, is also dependent on the concentrations of other constituents of the solution.

In the next three sections, cases are considered in which Rd is a pure phase of invariant activity. The reaction $Cu^{2+} + 2e^- \rightleftharpoons Cu$ occurring at a copper electrode would be an example: in such situations it is usual to set the invariant activity equal to unity.

The bulk activity a of Ox may be set equal to fC, where C is the concentration (mole cm^{-3}) of Ox in the bulk of the cell solution[4] and f is its activity coefficient.[5] In such cases equation [4] shows that the relationship between I_e and C is $I_e = nA\mathbf{F}k(fC)^{1-\alpha}$.

The section *Soluble Reductant Case*, below, deals with the more general case in which the activity of Rd is not constant. Examples of such reactions include $Fe^{3+} + e^- \rightleftharpoons Fe^{2+}$ and $Cd^{2+} + 2e^- \rightleftharpoons Cd(Hg)$. For such cases Eq. [4] gives $I_e = nA\mathbf{F}k(f'C')^{\alpha}(fC)^{1-\alpha}$, where C' is the bulk concentration and f' the activity coefficient[5] of Rd.

Mathematical Derivation

Let it be supposed that at time $t = 0$ the circuit is made and that for $t > 0$ the faradaic cell current is given by

$$i = I \cos \omega t + (\text{transients important only at small } t) \quad [5]$$

If r represents the dimension normal to the electrode

[2] Equations [2] and [3] may be applied directly only to electrode reactions which take place in a single step. Nevertheless, these equations often apply in cases where the reaction mechanism is complex, although the terms k and α no longer have the simple significances ascribed to them in the text. Approximate expressions for the apparent k and α terms may be deduced by constructing the mechanism's equivalent reaction pair (10).

[3] Note that Eq. [4] also embodies the Nernst equation for the system.

[4] The present theory is limited to cases in which the cell solution is of high ionic strength. Furthermore, if Ox is an ion, C must be much less than the ionic strength. These restrictions are needed to ensure that transport of Ox shall be by diffusion and not by migration. A high concentration of supporting electrolyte is also useful in reducing R_s and in keeping the double layer capacity constant.

[5] The activity coefficient of Ox (and also that of Rd in cases where the latter dissolves in the cell solution) will be effectively constant in a solution of high ionic strength,[4] even though the concentration of Ox is subject to local variation. Moreover, if a series of experiments is conducted in which the bulk concentration C of Ox is varied, it would be natural to maintain the ionic strength constant throughout the series: thus f would be constant from one experiment to the next as well as within any one experiment.

surface,[6] $C(r, t)$ will signify the concentration of Ox at a distance r at time t. It will be assumed that the surface concentration can be represented by the Fourier series

$$C(0, t) = \sum_{j=0}^{\infty} \mu_j \cos j\omega t + \sum_{j=1}^{\infty} \lambda_j \sin j\omega t \qquad [6]$$

where the μ's and λ's are undetermined coefficients.

Fick's second law of diffusion, $\partial C(r, t)/\partial t = D\partial^2 C(r, t)/\partial r^2$, must apply to the system,[4] D being the diffusion coefficient of Ox. Solution of this equation under the boundary condition [6] and the initial condition $C(r, 0) = C = C(\infty, t)$ is[7]

$$C(r, t) = C + \mu_o \operatorname{erfc} [r/2(Dt)^{1/2}]$$

$$+ (2/\pi^{1/2}) \sum_{j=1}^{\infty} \int_{r/2(Dt)^{1/2}}^{\infty} \{\mu_j \cos (j\omega t - j\omega r^2/4Dp^2)$$

$$+ \lambda_j \sin (j\omega t - j\omega r^2/4Dp^2)\} \exp (-p^2)\, dp$$

On differentiation (13), this gives

$$\partial C(r, t)/\partial r = -(\pi Dt)^{-1/2} \exp (-r^2/4Dt) \sum_{j=0}^{\infty} \mu_j$$

$$+ (2/\pi^{1/2}) \sum_{j=1}^{\infty} \int_{r/2(Dt)^{1/2}}^{\infty} (j\omega r/2Dp^2) \cdot \exp (-p^2)$$

$$dp \{\mu_j \sin (j\omega t - j\omega r^2/4Dp^2) - \lambda_j \cos (j\omega t - j\omega r^2/4Dp^2)\} \cdot$$

which may be evaluated for $r = 0$, $t > 0$, since the integral then has a zero lower limit.[8] The expression thus obtained for the surface concentration gradient is

$$\partial C(0, t)/\partial r = -(\pi Dt)^{-1/2} \sum_{j=0}^{\infty} \mu_j$$

$$- \sum_{j=1}^{\infty} (j\omega/2D)^{1/2} \{(\mu_j + \lambda_j) \cos j\omega t - (\mu_j - \lambda_j) \sin j\omega t\}$$

From Fick's first law of diffusion, an expression may now be derived relating the concentration gradient at the electrode surface to the flux of Ox and hence to the anodic faradaic current in the form $i = -nA\mathbf{F}D\, \partial C(0, t)/\partial r$. Comparison of this equation with [5] shows that $\mu_j = 0 = \lambda_j$ for $j = 0$, $j \geq 2$ and that $\mu_1 = \lambda_1 = I/nA\mathbf{F}(2D\omega)^{1/2}$, whence [6] becomes

$$C(0, t) = C(1 + Q \sin \omega t + Q \cos \omega t) \qquad [7]$$

where $Q = I/nA\mathbf{F}C(2D\omega)^{1/2}$. Clearly, since $C(0, t)$ cannot be negative, $Q \leq 2^{-1/2}$; however, it will be convenient to place a more severe restriction on Q, *viz.* $Q \leq 0.1$.

[6] The electrode need not be planar provided its radius of curvature is everywhere large compared with the "diffusion layer thickness" (11). This latter quantity may be taken as the value of r at which the amplitude of the concentration oscillations has fallen to 1% of its surface value. Now, the concentration amplitude can be shown (2-4) to be proportional to $\exp[-r(\omega/2D)^{1/2}]$, and taking $D = 10^{-5}$ cm^2 sec^{-1}, $\omega/2\pi \geq 10$ cps, we see that the diffusion layer cannot exceed 2.5×10^{-3} cm in thickness. A lower limit to the radius of curvature might thus be set at 0.1 mm.

[7] The analogous problem in heat conduction is considered by Carslaw and Jaeger (12).

[8] Rejecting small values of t, the limit may be taken to approach zero before the integrand. The integration is then carried out with the aid of transformations akin to those discussed by Carslaw and Jaeger (14).

The current $I \cos \omega t$ must be equal to the difference $(\overleftarrow{i} - \overrightarrow{i})$ obtained by subtracting Eq. [2] from [3]. Therefore, since a' is equal to unity and f is constant,[5]

$$I \cos \omega t = nA\mathbf{F}k \exp \{(1 - \alpha)n\mathbf{F}(E_e + v)/RT\}$$

$$- nA\mathbf{F}ka[C(0, t)/C] \exp \{-\alpha n\mathbf{F}(E_e + v)/RT\}$$

This equation may be simplified by substituting for $C(0, t)$ from Eq. [7] and for E_e and k from [4]. The result is

$$I \cos \omega t = I_e \exp \{(1 - \alpha)n\mathbf{F}v/RT\}$$

$$-I_e(1 + Q \sin \omega t + Q \cos \omega t) \exp \{-\alpha n\mathbf{F}v/RT\} \qquad [8]$$

It will be convenient to define a new parameter y by $y = I/I_eQ$. This new parameter is dimensionless and can take values between 0 and $+\infty$; it is a measure of the ability of the electrode reaction to keep pace with the alternating electrode potential. At low y values the electrode is able to follow the potential variation, whereas at high values of y this is not possible and $C(0,t)$ assumes an almost constant value; the changeover between these two extremes occurs in the vicinity of $y = 1$.

Provided that $n\mathbf{F}v/RT << 1$, *i.e.*, if the total magnitude of the perturbation v never exceeds a few millivolts, a simplification of the exact Eq. [8] may be achieved by making series expansions of the two exponential terms and rejecting all but the first few members of these series. However, since both faradaic distortion and faradaic rectification are second order effects, the retention of only two terms, *viz.*

$$\exp \{-\alpha n\mathbf{F}v/RT\} \approx 1 - \alpha n\mathbf{F}v/RT \qquad [9a]$$

$$\exp \{(1 - \alpha)n\mathbf{F}v/RT\} \approx 1 + (1 - \alpha)n\mathbf{F}v/RT \qquad [9b]$$

is inadequate to give a reliable expression for v. Nevertheless, as a first approximation, it is instructive to insert the approximations [9] into Eq. [8]. This approach yields[9]

$$n\mathbf{F}v/RT \approx [(y + 1)Q \cos \omega t + Q \sin \omega t](1 + \alpha Q \sin \omega t + \alpha Q \cos \omega t)^{-1}$$

$$\approx [(y + 1)Q \cos \omega t + Q \sin \omega t](1 - \alpha Q \sin \omega t - \alpha Q \cos \omega t)$$

$$\approx (y+1)Q \cos \omega t + Q \sin \omega t - \tfrac{1}{2}\alpha(y+2)Q^2 - \tfrac{1}{2}\alpha yQ^2 \cos 2\omega t - \tfrac{1}{2}\alpha(y+2)Q^2 \sin 2\omega t \qquad [10]$$

Recalling that $Q \leq 0.1$ and that $0 < \alpha < 1$, inspection of Eq. [10] will show that the rms values of the two terms $(y+1)Q \cos \omega t$ and $Q \sin \omega t$ always account for more than 87% of the rms value of $n\mathbf{F}v/RT$. Therefore, approximation [9a] can be vastly improved by adding a third term in which $n\mathbf{F}v/RT$ is replaced by the two most important terms in [10], *i.e.*,

$$\exp \{-\alpha n\mathbf{F}v/RT\} = 1 - \alpha n\mathbf{F}v/RT + \tfrac{1}{2}\alpha^2[(y+1)Q \cos \omega t + Q \sin \omega t]^2$$

[9] It will be noted that the inclusion of additional terms in the binomial expansion of $(1 + \alpha Q \sin \omega t + \alpha Q \cos \omega t)^{-1}$ would have introduced additional harmonics (terms in $\sin 3\omega t$, $\cos 4\omega t$, etc.) of very small amplitude, but would not have affected the magnitude of any of the five final terms in [10] by more than 1%.

A similar improvement may be made to [9b] and if these amended equations are then inserted into expression [8], the following result can be obtained

$$n\mathbf{F}v/RT = (y+1)Q\cos\omega t + Q\sin\omega t$$
$$-\tfrac{1}{2}[(1+y+\tfrac{1}{2}y^2)-\alpha(y+y^2)]Q^2$$
$$+\tfrac{1}{2}[\alpha(y+y^2)-(y+\tfrac{1}{2}y^2)]Q^2\cos 2\omega t$$
$$-\tfrac{1}{2}(1+y-\alpha y)Q^2\sin 2\omega t + \text{terms in } Q^3$$

This expression for v is readily transformed into [1] and the five unknowns in the latter equation are thus found to be

$$\Psi = -(RTQ^2/4n\mathbf{F})(y+z+yz+2)$$
$$V = (RTQ/n\mathbf{F})(y^2+2y+2)^{1/2}$$
$$\theta = -\operatorname{arccot}(1+y)$$
$$V_2 = (RTQ^2/4n\mathbf{F})(y^2+2y+2)^{1/2}(z^2+2z+2)^{1/2}$$
$$\theta_2 = -\operatorname{arccot}\frac{y+z+yz}{y+z+2}$$

where $z = (1-2\alpha)y$.

The expressions given above for V and θ have been derived previously (4). The equation for Ψ is in agreement with that given by Barker, Faircloth, and Gardner (6), but differs from an expression derived earlier by the present author (4), which was in error (15). For fast electrode reactions y approaches zero and therefore $\Psi = -RTQ^2/2n\mathbf{F} = -n\mathbf{F}V^2/4RT$. This last relationship has been experimentally verified for the $Hg_2^{2+} + 2e^- \rightleftharpoons 2Hg$ reaction (4).

Magnitude of the Distortion

It is convenient to express V_2 in terms of the amplitude V of the fundamental interfacial potential. In this form the amplitude of the first harmonic potential (the faradaic distortion) is given by

$$V_2 = \frac{n\mathbf{F}V^2}{4RT}\left(\frac{z^2+2z+2}{y^2+2y+2}\right)^{1/2} \qquad [11]$$

This equation predicts that if $V = 10$ mv, $T = 300°K$, and $n = 2$, then the magnitude of V_2 will lie between 0 and 2 mv, depending on the magnitudes of the parameters k, α, C, f, D, and ω.

For a given system at constant temperature, Eq. [11] shows that V_2 depends on V and ω only, varying directly as V^2 but showing a complicated dependence on frequency. Figure 2 shows how the ratio V_2/V^2 varies with y for various values of α. Since y is proportional to the square-root of ω, a change in y from 0.1 to 10 corresponds to a ten-thousandfold increase in frequency. The shape of the curves in Fig. 2 is seen to be very dependent on α, especially when the latter is greater than 0.5. If the transfer coefficient exceeds 0.64, the curves exhibit minima at characteristic values of y. It will be apparent that I_e and α may readily be determined if a curve of the type shown in Fig. 2 is constructed. An apparatus which enables V_2 to be measured as a function of ω at constant V is described below.

The faradaic distortion method of determining the kinetic parameters of an electrode reaction shares with faradaic rectification the advantage over the classical a-c method (faradaic admittance) that a knowledge of the double-layer capacity is not needed; uncertainties associated with the double-layer often lead to difficulties when a-c studies are made at electrodes other than mercury (3, 16). Faradaic distortion offers two advantages over faradaic rectification in the determination of α and I_e. First, as a comparison of Fig. 2 and 3 shows, curves of V_2 against frequency are far more characteristic of α than the corresponding plots of Ψ. Second, whereas several effects can be envisaged which might cause spurious d-c potentials to exist across the cell, thereby interfering in the measurement of Ψ, only one effect[10] other than faradaic distortion is likely to introduce alternating potentials of frequency ω/π. On the other hand, faradaic rectification does not suffer from the severe limitations which are the subject of the next section.

The close parallelism between faradaic distortion and faradaic rectification is illustrated by a comparison of the values acquired by V_2 and Ψ in the limiting cases $y << 1$ and $y >> 1$. In the former case $V_2 = n\mathbf{F}V^2/4RT = -\Psi$ while in the latter, $\Psi = (2\alpha-1)n\mathbf{F}V^2/4RT = \pm V_2$.

[10] If the double-layer capacity is potential dependent, then the passage of an a.c. across the electrode will introduce harmonic frequencies in the interfacial potential. The first harmonic is the most serious and its amplitude is $(V^2/4c)(\partial c/\partial E)$. This effect is unlikely to interfere in the determination of faradaic distortion except in the vicinity of the electrocapillary maximum, where the double-layer capacity does change appreciably with potential (17).

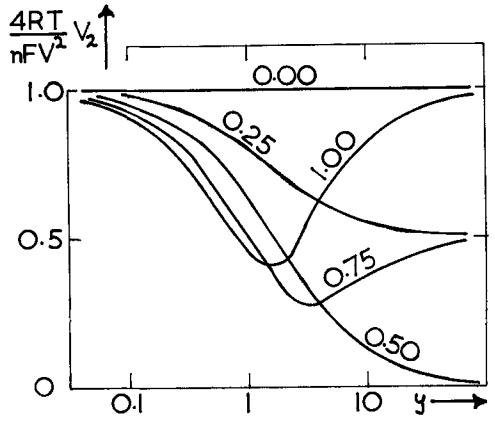

Fig. 2. Dependence of faradaic distortion on the parameter y (proportional to the squore root of frequency) for values of the transfer coefficient α = 0.00, 0.25, 0.50, 0.75, 1.00.

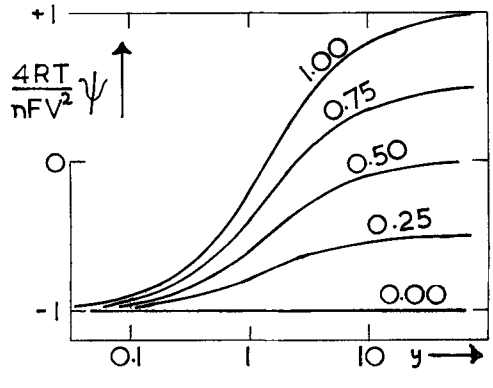

Fig. 3. Dependence of faradaic rectification on the parameter y for values of the transfer coefficient α = 0.00, 0.25, 0.50, 0.75, 1.00.

Effect of the Double Layer

As yet the fact has been ignored that, in addition to the faradaic path, an alternative route, the charging and discharging of the electrical double layer, is accessible to a.c. crossing the electrode/solution interface. Usually this nonfaradaic path is considered as a pure capacity,[11] proportional to electrode area but otherwise constant (19); its capacitance will be equated to cA.

The production by faradaic distortion of an alternating potential of frequency ω/π across the electrode interface will cause a current of the same frequency to flow across the double layer capacity. However, this harmonic current must be shunted back via the faradaic path, as illustrated in Fig. 4, since no harmonic frequencies are present in the current flowing in the external circuit. The presence of this harmonic component in the faradaic current cannot be ignored unless the nonfaradaic impedance is much greater than the faradaic impedance; if this is not the case, the appropriate correction terms must be inserted into Eq. [5] and the entire derivation of V_2 repeated. The result is

$$V_2 = \frac{n\mathbf{F}V^2}{4RT} \cdot \left(\frac{z^2+2z+2}{y^2+2y+2} \right)^{1/2} \cdot \frac{x}{[(y+2^{-1/2})^2+(x+2^{-1/2})^2]^{1/2}} \qquad [12]$$

where $x = n^2\mathbf{F}^2D^{1/2}C/RTc(2\omega)^{1/2}$. Also,

$$\theta_2 = \operatorname{arccot} \frac{(y+2^{-1/2})(y+z+2)-(x+2^{-1/2})(y+z+yz)}{(x+2^{-1/2})(y+z+2)+(y+2^{-1/2})(y+z+yz)}$$

The term x is a measure of the ratio of the nonfaradaic impedance to the faradaic.[12] Therefore, for a sufficiently large x value [12] reduces to Eq. [11]. However, as x becomes small V_2 decreases and this may be interpreted as the shorting out of the faradaic distortion by the decreasing double layer impedance.

[11] However, Bockris and Conway (18) regard the nonfaradaic path as equivalent to a condenser with a relaxing dielectric. In their terms, the present treatment is only valid at frequencies low enough that $1/\omega$ is large compared with the relaxation time of the dielectric.

[12] In fact, $2x$ is the ratio of the reactances of the two paths.

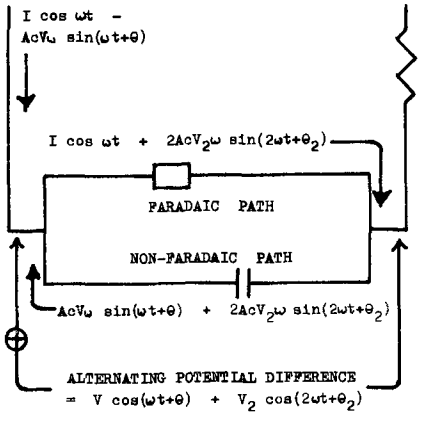

Fig. 4. Distribution of currents between the faradaic and nonfaradaic paths. The resistor shown represents the solution resistance R_s.

Inspection of Fig. 2 shows that $y \leq 10$ covers the region most useful for the determination of kinetic parameters by faradaic distortion. In this region the final fraction in [12] exceeds 0.95 if $x \geq 35$. Taking the following representative values: $T = 298°K$, $c = 39$ μfd. cm^{-2} (20), $n = 2$, and $D = 10^{-5}$ cm^2 sec^{-1}; this restriction becomes $C/\omega^{1/2} \geq 4 \times 10^{-8}$ mole sec$^{1/2}$ cm^{-3}. On the other hand, the final fraction in [12] is less than 0.1 if $x \leq 0.11$ which implies $C/\omega^{1/2} \leq 1.2 \times 10^{-10}$ mole sec$^{1/2}$ cm^{-3}. The practical consequences of these limitations are shown below.

C (mole cm^{-3}):	10^{-9}	10^{-8}	10^{-7}	10^{-6}	10^{-5}	10^{-4}
Double layer effect can be ignored and Eq. [11] is obeyed for frequencies less than	....	...	1.0 cps	100 cps	10 kc/s	1.0 Mc/s
Double layer capacity effectively shorts out all faradaic distortion if the frequency is in excess of	10 cps	1.0 kc/s	100 kc/s	10 Mc/s	....	....

Three conclusions can be drawn immediately. First, faradaic distortion will not interfere in conventional admittance measurements provided low enough concentrations (about 10^{-6} M) are employed: higher concentrations can be tolerated provided a low frequency limit is set at a value greater than 10 cps.[13] Second, since the double layer shorting effect becomes very pronounced at low concentrations, the analytical applications of faradaic rectification (7, 21) are unlikely to be paralleled by similar developments of faradaic distortion. Third, if faradaic distortion is to be employed quantitatively (to measure k or α, for example), the concentration range available will be seen to be severely limited. An audio-frequency bridge has a range of about 10 cps to 10 kc/s and the table shows that full use can be made of this range only for concentrations greater than 10^{-5} mole cm^{-3}. An upper concentration limit (about 0.1 M, i.e., $C = 10^{-4}$) is set by the requirement that the Ox concentration shall be much less than the supporting electrolyte.[4] Taking all factors into consideration it would appear that the faradaic distortion method is a useful one for determining kinetic parameters over a thousandfold range of reaction rates, suitable exchange current densities ranging from about 20 ma cm^{-2} to 20 amp cm^{-2}. Although this range is rather narrow, it does encompass some important electrode reactions: thus the $Cu^{2+} + 2e^- \rightleftharpoons Cu$ reaction is reported to have $I_e/A \approx 2$ amp cm^{-2} at $C = 10^{-5}$ mole cm^{-3} in an acidified KNO_3 solution (22).

Soluble Reductant Case

Cases in which Rd is not a pure phase but is a species soluble in the cell solution (or in the electrode in the case of amalgam electrodes) can be treated in a manner which exactly parallels the method described above under *Mathematical Deri-*

[13] In any case, since V_2 is proportional to V^2, a lower percentage of distortion can always be realized by decreasing the signal across the cell.

vation. Since no new principles are involved it will suffice to present the results; these are

$$\Psi = -(RT/4n\mathbf{F})(Q^2-Q'^2)(Y+Z+YZ+2)$$

$$V = (RT/n\mathbf{F})(Q+Q')(Y^2+2Y+2)^{1/2}$$

$$\theta = -\operatorname{arccot}(1+Y)$$

$$V_2 = (RT/4n\mathbf{F})(Q^2-Q'^2)(Y^2+2Y+2)^{1/2}(Z^2+2Z+2)^{1/2}$$

$$\theta_2 = -\operatorname{arccot}\frac{Y+Z+YZ}{Y+Z+2}$$

where $Q' = I/nA\mathbf{F}C'(2D'\omega)^{1/2}$, $Y = I/I_e(Q+Q')$, and $Z = (1-2\alpha)Y(Q+Q')/(Q-Q')$. Each of these equations reduces to the corresponding equation already given above as Q' tends to zero. The above expression for Ψ differs from that obtained previously by the present author (4) but is in agreement with equations derived by Barker (7) and (for the special case $C = C'$, $D = D'$) by Doss and Agarwal (23, 5). The equations for V and θ are well established (2, 3). The expression for the amplitude of faradaic distortion can be cast into a particularly simple form when $CD^{1/2} = C'(D')^{1/2}$:

$$\pm V_2 = \frac{n\mathbf{F}V^2}{4RT}\cdot\frac{(1-2\alpha)Y}{(Y^2+2Y+2)^{1/2}} = \frac{(1-2\alpha)VI}{4I_e}$$

Moreover, θ_2 then equals θ, showing that the fundamental interfacial potential is perfectly in phase with its first harmonic.

Again, the double layer affects V_2 and θ_2. The equation analogous to [12] is

$$V_2 = \frac{n\mathbf{F}V^2}{4RT}\left(\frac{Z^2+2Z+2}{Y^2+2Y+2}\right)^{1/2}\frac{X}{[(Y+2^{-1/2})^2+(X+2^{-1/2})^2]^{1/2}}$$

and

$$\theta_2 = \operatorname{arccot}\frac{(Y+2^{-1/2})(Y+Z+2)-(X+2^{-1/2})(Y+Z+YZ)}{(X+2^{-1/2})(Y+Z+2)+(Y+2^{-1/2})(Y+Z+YZ)}$$

where $X = n\mathbf{F}I/RTAc(2\omega)(Q+Q')$.

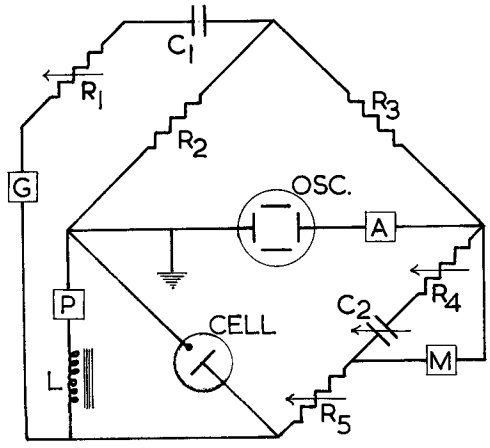

Fig. 5. Circuit for measuring all three faradaic effects. Suitable component values are G: 10 c/s-10 kc/s, 100 v; R_1: 0-100kΩ; C_1: 1 μfd; R_2: 5 kΩ; R_3: 5 kΩ; A: 10000 X; R_4: 0-100Ω; C_2: 0-5 μfd; M: 10 mv f.s.d.; R_5: 0-10Ω; P: to read to 10 μv; L: 10 H.

Measurement

The circuit shown in Fig. 5 permits the amplitude V_2 of faradaic distortion to be measured without the use of filter networks or tuned amplifiers. Faradaic rectification may also be measured with this apparatus and, provided that the double layer capacity is known, the faradaic admittance can be determined as well. Rough measurements with a circuit of this type have confirmed the predicted parallelism between faradaic rectification and distortion.

The pure sinusoidal potential produced by G, a generator of variable frequency and high voltage output, is fed through the high resistance R_1 to produce a pure a.c. of frequency $\omega/2\pi$. Since R_2 and R_3 are equal resistors, if R_4 and C_2 are adjusted[14] so that the impedance of the R_4-C_2-R_5 arm is identical in both phase angle and magnitude to the impedance of the cell, no signal of frequency $\omega/2\pi$ will appear across the amplifier A and cathode ray oscilloscope OSC. However, a signal of the harmonic frequency ω/π remains and if the resistance of R_2 is much greater than the cell impedance, the whole of the distortion voltage V_2 will be developed across the A-OSC arm. V_2 can be calculated from the height of the oscilloscope trace if the gain of A and the sensitivity of OSC are known.

A series of measurements of V_2 at a constant known value of V, the fundamental alternating interfacial potential, but varying frequency can be made by adjusting R_5 to equal the solution resistance R_s. With the bridge balanced the a-c millivoltmeter M then measures V directly and R_1 can be repeatedly adjusted to give any predetermined M reading.

The potentiometer P enables Ψ to be measured, V_e being subtracted if necessary.[1] The choke L restricts the passage of a.c. through P and d.c. is prevented from flowing through the cell by P being balanced and by the presence of the condensers C_1 and C_2.

Symbols

A	area of the electrode, cm²
C,C'	bulk concentrations of Ox and Rd, mole cm⁻³
$C(r,t)$	concentration of Ox at a distance r from the electrode surface at time t, mole cm⁻³
D,D'	diffusion coefficients of Ox and Rd, cm² sec⁻¹
E	potential of the electrode vs. standard Ox/Rd electrode, v
E_e	equilibrium (null) value of E, v
$\mathbf{F}$	the faraday, 9.65 × 10⁴ coulomb equivalent⁻¹
I	amplitude of applied faradaic a.c., amp
I_e	equilibrium exchange current, amp
Ox	an electroreducible species
Q,Q'	dimensionless parameters defined in sections on *Mathematical Deviation* and *Soluble Reductant Case*
R	gas constant, 8.32 joule mole⁻¹ deg⁻¹
Rd	an electroöxidizable species formed by reduction of Ox
R_s	resistance of the cell solution, ohm
T	absolute temperature, °K
V	amplitude of that component of the interfacial potential having the fundamental frequency ($\omega/2\pi$), v
V_2	amplitude of that component of the inter-

[14] Under certain conditions a parallel arrangement of R_4 and C_2 may be more convenient.

	facial potential having the harmonic frequency (ω/π), v
V_e	equilibrium cell potential, v
V_o	potential generated by the passage of current through R_s, v
X,Y,Z	dimensionless parameters defined in section *Soluble Reductant Case.*
a,a'	bulk activities of Ox and Rd, treated as dimensionless
a_o,a_o'	surface activities of Ox and Rd, dimensionless
c	double layer capacity per unit area, farad cm^{-2}
e^-	an electron
f,f'	activity coefficients of Ox and Rd, liter $mole^{-1}$
$\overleftarrow{i}, \overrightarrow{i}$	anodic and cathodic currents resulting from the faradaic reaction at the electrode surface, amp
j	a running index
k	standard rate constant, mole cm^{-2} sec^{-1}
n	number of faradays needed to reduce one mole of Ox, equivalent $mole^{-1}$
p	an integration variable
r	normal distance from the electrode surface, cm
t	time, sec
v	total interfacial potential, v
x,y,z	dimensionless parameters defined in sections *Mathematical Deviation* and *Effect of the Double Layer*
α	transfer coefficient of the cathodic reaction
θ	phase angle by which the fundamental component of the interfacial potential leads the faradaic current
θ_2	phase angle by which the harmonic component of the interfacial potential leads the faradaic current
λ,μ	surface concentration amplitudes, defined by Eq. [6], mole cm^{-3}
Ψ	potential due to faradaic rectification, sometimes termed the redoxokinetic potential, v
ω	angular frequency of the applied current, sec^{-1}

Correction

In the paper by M. P. Korver, R. S. Johnson, and N. C. Cahoon, "Study of the Recuperation Reaction in the Leclanché Dry Cell," which appeared on pp. 587-591 of the July JOURNAL, the line drawings for Figures 1 and 2 on pp. 588 and 589 were reversed. The captions for the figures are correct, however.

The Electrolytic Formation and Dissolution of Oxide Films on Platinum

H. A. Laitinen and C. G. Enke

Noyes Chemical Laboratory, University of Illinois, Urbana, Illinois

ABSTRACT

The extent of surface oxidation of a smooth platinum electrode and the electrode capacitance were measured for various conditions of anodization. The electrolytic formation of the surface platinum oxide is shown to be a highly irreversible reaction. A mechanism which involves a hydroxyl radical intermediate of the oxygen evolution reaction is proposed for the surface oxide formation reaction. This mechanism is supported by the shapes of the anodic and cathodic charging curves on platinum and the interrelationships of the electrode potential, the electrode capacitance, and the extent of surface oxidation. From these same interrelationships it was also concluded that the steady-state evolution of oxygen occurs on a surface which has at least one atom of oxygen per surface platinum atom and that the rate-determining step in the oxygen evolution reaction is the electrolytic discharge of oxygen-containing radicals which are adsorbed on the electrode surface. The surface oxide is reduced at potentials several hundred millivolts cathodic to the potential required to form the oxide. The reduction of the surface oxide is shown to be a first order reaction. The rate of the reduction increases with increasingly cathodic electrode potential.

It has been well substantiated that a surface oxidation occurs on a platinum electrode which is functioning as an anode in water solutions (1-17). The surface oxide thus formed on platinum has the unusual ability to transfer charge from the metal to a reactant in the solution without an appreciable increase in the thickness of the film. The film is electron conducting rather than ion conducting, and therefore does not grow beyond one or two atomic layers. The presence of the surface oxide alters the behavior of platinum indicator electrodes to such an extent that almost all investigators using such electrodes have had to adopt a standard anodic or cathodic pretreatment in order to obtain reproducible results. The formation of the surface oxide layer has been shown to affect considerably the results obtained with platinum indicator electrodes in potentiometry (14), chronopotentiometry (1), polarography (10), and kinetics determinations (18). A knowledge of the chemical nature of the surface oxide as well as the mechanism of its formation is a prerequisite to the understanding of the behavior of platinum indicator electrodes.

Historically, three experimental approaches have been taken in an effort to arrive at a conclusion regarding the composition of the surface oxide on platinum. These are cathodic stripping (3-5, 7-9, 15, 17,), chemical attack (2), and potentiometry 10-12, 16). In the first case, the number of coulombs of electricity required to completely reduce the surface oxide is determined. If the exact electrode area and the number of platinum atoms per square centimeter are known, and if it is assumed that the oxide is a monomolecular film, the oxidation state of the oxidized platinum surface can be calculated. Because of the assumptions required for such calculations, the results are indicative but not conclusive. In the case of the chemical attack the oxide film is dissolved and the solution analyzed spectroscopically for platinum(II) and platinum(IV). Here one must be certain that during the chemical attack the oxidation state of the platinum has not been changed. Finally, the potentials of the plateaus in the anodic and cathodic charging curves have been equated to the thermodynamic standard potentials of Pt-PtO or Pt-PtO_2 to demonstrate the existence of these species on the electrode surface. Giner (8) has discounted all such comparisons by pointing out the physical and chemical differences between a monomolecular layer of PtO on platinum and crystalline platinum(II) oxide [and similarly platinum(IV) oxide]. Such a monolayer may be regarded as identical to a chemisorbed oxygen atom layer. Furthermore, it will be shown here that the reaction of the formation of the surface oxide is so irreversible that it is incapable of determining the potential of the platinum electrode even under conditions of no electrode current.

Cathodic and Anodic Charging Curves

It is worthwhile at this point to make a critical evaluation of the interpretation of the shapes of the cathodic and anodic charging curves on platinum. Typical charging curves for oxygen and hydrogen free solutions are shown in Fig. 1. Potentials in this figure and throughout the paper are referred to the normal hydrogen electrode. A constant anodic current is passed while the potential of the electrode is followed as a function of time (or coulombs). The potential rises slowly (region Ha) until all the hydrogen adsorbed on the electrode has been oxidized. The potential then rises rapidly through region Ca

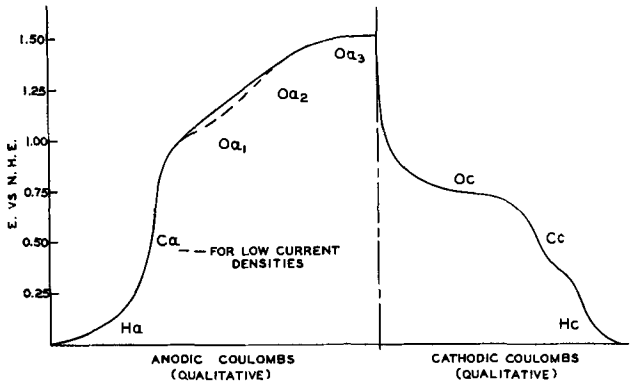

Fig. 1. Anodic and cathodic charging curves

where the only process is the charging of the electrical double layer. At about 0.9 v an anodic process begins and the potential increases more gradually through regions Oa_1 and Oa_2. Eventually the oxygen evolution potential is reached, causing a leveling off of the potential (region Oa_3). If the current is reversed and the electrode thus anodized is now made the cathode, the cathodic charge curve of Fig. 1 is observed. The potential drops very rapidly to about 0.7 v where there is a plateau (region Oc) due to the reduction of the substance formed during regions Oa_1 and Oa_2 of the anodization. When all of the oxidation product has been reduced, the potential drops rapidly again through region Cc and then enters the hydrogen evolution region Hc.

The shapes of the cathodic and anodic charging curves on platinum were one of the first indications of a surface oxidation (5) and they have been of interest to many investigators subsequently (3, 4, 6-9, 11, 15-17). A comparison of the anodic and cathodic charging curves shows that they are not the same shape. If the difference in their shapes were the effect of polarization due to a slow reaction, the curves would become more similar as the current density is decreased. However, very low current density studies (15-17) have shown that the hysteresis is not decreased significantly with decreasing current density. Such an intrinsic hysteresis suggests a reaction which is so irreversible that the oxidation and reduction occur by different mechanisms.

A comparison of the charging curves also shows that the region Oa_1-Oa_2 is always larger than the region Oc indicating that more electricity is used to form the oxide than is required to remove it. Vetter and Berndt (15) who found a ratio of anodic to cathodic coulombs of nearly two postulated the oxidation of water to the oxide during the anodization and the reduction of the oxide to hydrogen peroxide during the cathodization. However, no chemical evidence for the presence of hydrogen peroxide has been reported. Other investigators using slightly different conditions have not observed a ratio of anodic to cathodic coulombs of two. Furthermore, it is unlikely that the oxidation of water to oxide would occur at a higher potential than the reduction of the oxide to peroxide. Another explanation lies in the possibility of a mixed anodic process where a reaction (such as the evolution of oxygen) occurring simultaneously with the oxide formation reaction consumes some of the electricity.

The following mechanism for the electrolytic formation and dissolution of the surface oxide on platinum gives a satisfactory explanation of the shapes of the anodic and cathodic charging curves. When a constant anodic current is applied to the platinum electrode, any hydrogen present at the electrode surface will be oxidized. When the hydrogen has been exhausted the first step in the oxidation of the water occurs. The oxidation product (which is an intermediate in the oxygen evolution reaction) may react with the surface platinum atoms to form a surface oxide, or it may react to evolve oxygen. In this way the unoxidized portion of the electrode surface on which the oxidation of water can occur most readily decreases, causing an increase in the potential due to increased polarization (region Oa_1). When the entire surface of the platinum has reacted with the oxygen evolution intermediate, the oxidation of water must take place on the oxidized platinum surface. The presence of the oxide partially counteracts the positive charge of the platinum thus causing the oxidation of water to occur at a higher electrode potential (region Oa_2). Giner and Lange (19) observed a substantial increase in the work function and a corresponding decrease in the volta potential of platinum when the surface was oxidized, showing that the oxygen imparts a negative charge to the surface. When sufficient intermediate has been formed on the surface of the oxidized platinum, the intermediate will be further oxidized to oxygen and the steady-state oxygen evolution region of the charging curve is reached (region Oa_3). At higher current densities the break between regions Oa_1 and Oa_2 is not observed because the increased polarization overvoltage causes the electrode potential to become sufficient to oxidize the water on portions of the oxide layer before the entire platinum surface has become oxidized.

When the current is reversed making the oxidized electrode the cathode, the potential follows the reduction of the surface oxide and then, when the oxide is exhausted, the potential drops to the hydrogen evolution potential.

Experimental

The cell.—Perchloric acid electrolytes of different concentrations were used exclusively. Perchloric acid was chosen because it was not expected to influence the surface reactions on platinum either by direct chemical interference or by adsorption. If the acid concentration was high enough, the solution was effectively buffered. Unless otherwise stated, the solution was continuously swept with a stream of purified nitrogen in order to keep the solution free from dissolved oxygen and hydrogen. The presence of oxygen is undesirable because it affects the open-circuit potential of an oxidized electrode, and it acts as a depolarizer when treating the electrode cathodically. Hydrogen reacts chemically with the oxygen on the platinum electrode surface and acts as a depolarizer for anodic electrode treatment.

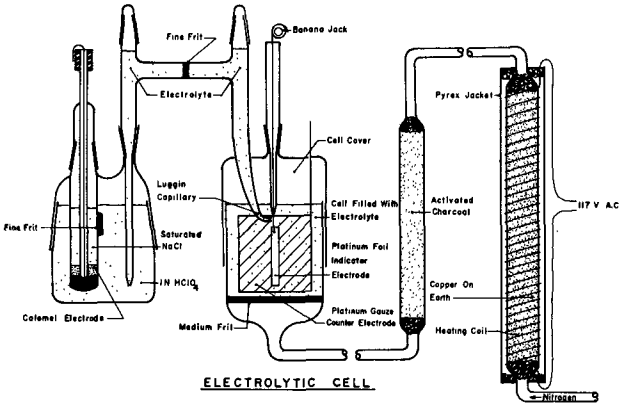

Fig. 2. Electrolytic cell

The cell arrangement is shown in Fig. 2. The cell itself was a filter funnel of 50-ml capacity, provided with a medium porosity glass frit. The indicator electrode was a 36 x 2.5 mm piece of 3 mil platinum foil welded to a 30-ga platinum wire sealed in a soft glass tube. Within the soft glass tube, the platinum wire was silver-soldered to a No. 20 ga copper wire connected to a banana jack.

The platinum foil electrode was cut from a 50-cm^2 piece of previously unused platinum foil. The surface roughness of this foil was determined in the laboratory of Professor Norman Hackerman at the University of Texas by the gas adsorption method (20). Professor Hackerman has perfected an apparatus to work with small areas making this determination economically practical on platinum. The results obtained in his laboratory on the platinum foil indicate a roughness factor of 1.12 within 10% accuracy. The true indicator electrode area was 2.0 cm^2 since both sides of the foil were exposed. The counter electrode was a platinum gauze cylinder placed concentrically around the indicator electrode. The calomel electrode was connected to the cell through an elaborate salt bridge which was designed to prevent any significant diffusion of chloride ions from the calomel compartment into the measurement cell during the course of an experiment. The cell arm of the salt bridge terminated in a luggin capillary which was placed up against the indicator electrode. The other arm of the salt bridge had a drawn-out tip which was immersed in a compartment of 1*N* $HClO_4$. This compartment served to connect the arm of the salt bridge to the frit on the side of the calomel compartment as well as to reduce the concentration gradient of chloride ions between the calomel and the salt bridge. The nitrogen which was bubbled through the cell electrolyte was passed first through a heated column of of copper-on-earth and then through a column of activated charcoal packed with glass wool. The copper-on-earth was prepared in this laboratory by M. S. Chao according to the method of Meyer and Ronge (21).

The equipment.—Figure 3 shows a block diagram of the equipment used in this investigation. A complete description of each piece of equipment and its operation is available (22). The constant current source was used to obtain constant current anodic

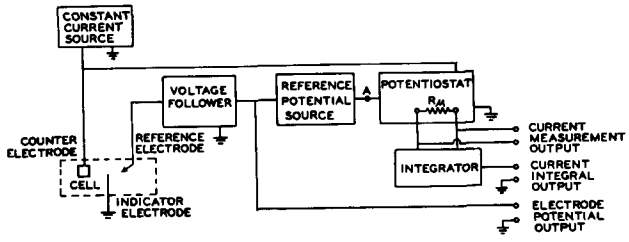

Fig. 3. Complete instrumentation

or cathodic charging curves. The voltage follower allowed the electrode potential to be followed accurately on a recorder or oscilloscope without drawing more than 10^{-10} amp from the indicator electrode. When the potentiostat was turned on, the voltage applied to the counter electrode was such that the potential at point A (Fig. 3) was equal to that of the indicator electrode. Thus the potential between the reference electrode and the indicator electrode was precisely equal and opposite to the potential of the reference potential source. The current required to maintain this electrode potential was measured by measuring the potential across R_m and the time integral of the current was obtained at the output of the integrator. A system of relays was arranged so that when a key was pressed, a signal would trigger the oscilloscope sweep and shortly thereafter the reference potential would change by a preset value of 10 mv. Using a Tektronix Model 502 Dual Beam Oscilloscope, it was possible to observe the number of coulombs necessary to effect this potential change (at the integral output) as well as the shape of the current-time curve. The potentiostat was capable of rising to an output of 50 ma in as little as 50 μ sec.

Surface Oxide Determination by Cathodic Stripping

Chronopotentiometry was used to determine the extent of surface oxidation of the platinum indicator electrode. The indicator electrode was grounded and the saturated calomel reference electrode was connected to either the oscilloscope or the recorder. The constant current source, which was connected between the counter electrode and ground, was turned on and the potential of the indicator electrode was recorded as a function of time. The shape of the curve was that of the cathodic chronopotentiogram shown in Fig. 1. The amount of charge per unit area, Q/A, of oxide on the platinum surface was calculated by multiplying the current density by the time required to reach the middle of region Cc. A current density of 15 $\mu a/cm^2$ was used. This current density was chosen because it was at least one hundred times the current withdrawn by the potential measuring circuit. It is very likely that current densities in the region of 100 $\mu a/cm^2$ would cause the apparent amount of surface oxidation to be decreased due to premature polarization to the hydrogen evolution potential. However, no difference in the quantity of surface oxidation measured was observed between determinations using cathodic current densities of 15 and 30 μa. The cathodic current was turned off as soon as the electrode potential reached the potential of the inflection point of

the region Cc. This procedure avoided the evolution of hydrogen. The discharge of hydrogen on the platinum was observed to have an effect on subsequent anodizations.

If the surface oxidation is thought of as a compound or mixture of compounds obeying the law of small whole numbered ratios of atomic constituents, it is desirable to be able to convert millicoulombs per square centimeter to atoms of oxygen per surface atom of platinum. To make this conversion it is necessary to know the number of surface atoms of platinum per square centimeter. Using the lattice constants in Wyckoff (23) for crystalline platinum one calculates 1.3 x 10^{15} atoms/cm^2 for the 100 plane and 1.5 x 10^{15} atoms/cm^2 for the closest packed 111 plane. If one takes the two-thirds power of the number of platinum atoms per cubic centimeter as calculated from the density of platinum, 1.5 x 10^{15} atoms/cm^2 is obtained. The predominant crystal face on a polycrystalline surface would be the 111. Using 1.5 x 10^{15} atoms/cm^2 it was calculated that about 0.5 millicoulombs/cm^2 are required to provide each surface platinum with an oxygen atom. An accuracy of 10% is all that should be claimed for this number.

Potentiostatic Formation of Surface Oxide

Two methods are available for controlling the anodic treatment given to the electrode: namely, electrolysis at constant anodic current and electrolysis at constant anodic potential. Both methods were tried in this study. It was found that the constant potential anodization yielded a more reproducible quantity of surface oxidation as determined by cathodic chronopotentiometry. If the quantity of oxide on the electrode surface is a function of the anodization potential, the better reproducibility of the constant potential is reasonable. The potential of the electrode follows the shape of the anodic chronopotentiogram, as shown in Fig. 1, during constant current anodization. The steady-state potential of the electrode (region Oa_3) is reached slowly, and therefore only at long times are the two anodization methods equivalent. Another consideration is the shape of the steady-state anodic current-voltage curve. In the region of interest which is negative to the rapid evolution of oxygen, the current increases slowly with increasing potential. It would be difficult then to obtain a reproducible steady-state potential (and thus a reproducible surface oxidation) by applying a constant current.

Constant potential anodization was used throughout this work. With the indicator electrode grounded, the calomel reference electrode was connected to the input of the voltage follower. The reference potential source was connected between the output of the voltage follower and the input of the potentiostat. The potential was established within milliseconds after turning on the potentiostat.

Effect of Varying the Time of Anodization

The quantity of oxide on the surface of the electrode was measured as a function of the time of anodization at a given potential. The purpose of this experiment was to determine how long it takes the surface coverage to come to a constant value at a given applied potential. Before each anodization, the electrode had been freed of oxide by the previous chronopotentiometric determination and then allowed to drift until the open-circuit potential reached a steady value. This potential was between 0.8 and 0.85 v. The cathodic constant current was switched on immediately after the potentiostat was turned off. The quantity of oxide per square centimeter vs. the time of anodization was determined for five potential values. Results are shown in Fig. 4. Each of the curves shown actually has a point on the origin of the graph, but the initial rise is too steep to be shown. The potentiostat could pass 1 millicoulomb in 20 msec, a time very short compared to 1 sec, the shortest time interval plotted.

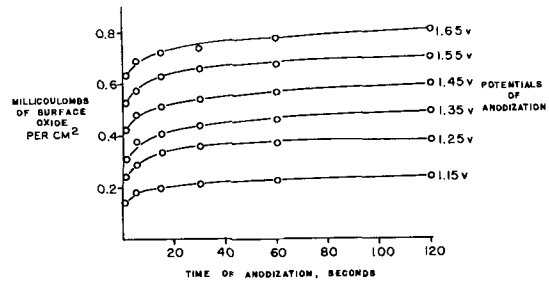

Fig. 4. Variation of amount of surface oxide with time of anodization at constant potential.

The amount of oxide on the surface increased quite rapidly during the first 15 sec of anodization at each potential. The subsequent increase in surface oxide was gradual. Apparently some slow process was causing a slow increase in the oxidation. Since steady-state coverage was not reached within a reasonable time of anodization, an anodization time of 30 or 60 sec was chosen for subsequent experiments. An anodization of 30 sec yielded a coverage which was at least 90% of that for a 2-min anodization.

Post-Anodization Behavior of Electrode

When the potentiostat was turned off after an anodization, the electrode did not remain at the anodization potential. The electrode potential dropped suddenly at first and then decreased slowly to about 0.85-0.95 v. The time required to reach a steady-state open-circuit potential increased with increasing potential of anodization. For an anodization at 0.95 v, steady state was reached in about 10 min. For anodizations at 1.3-1.7 v, over an hour was required to reach steady state. Despite the large drop in potential during an hour, the amount of surface oxide decreased by only about 0.2 millicoulombs/cm^2. Approximately the same amount of oxide was lost during an hour regardless of the anodization potential. The range studied was from 1.15 to 1.75 v. In this case the electrode was anodized for 3 min at each potential.

Experiments were also performed relating the decay of the open-circuit potential and the surface coverage for shorter times. The electrode was anodized for 30 sec at 1.25 v, 1.45 v, or 1.65 v. After the potentiostat had been turned off, the open-circuit

potential was followed for an amount of time t_d. At time t_d the constant cathodic current was applied and the quantity of oxide was determined. Thus the open-circuit potential and the surface coverage were determined for various values of t_d up to 15 min for all the three anodization potentials. The potential fell off rapidly during the first minute of drift. The drop in potential was 0.2 v for the 1.25-v anodization, 0.3 v for the 1.45-v anodization, and 0.35 v for the 1.65-v anodization. A decrease in surface charge was not noticeable for the first minute. At the end of five min, 0.015 millicoulombs had been lost; after 15 min, 0.045 millicoulombs were lost. The absolute value of the oxide loss was the same for all three anodization potentials. If the surface coverage decay is linear at 0.045 millicoulombs/cm^2/15 min, at the end of an hour, the amount lost would be 0.18 millicoulombs/cm^2. This value is in reasonable agreement with the result cited for a 1-hr drifting time. It was thus demonstrated that an electrode may be left at open circuit after the anodization for times up to 1 min without appreciably affecting the amount of surface oxide.

The lack of correlation between oxide loss and potential decay throws considerable doubt on the notion that the post-anodization open-circuit potential is a function of the type or quantity of oxide on the electrode surface. It has been claimed that the potential decay is caused by the decomposition of an unstable surface oxide whose presence affects the open-circuit potential (16). If this were the reason for the potential decay, the rate of loss of the surface oxide would decrease as the quantity of unstable oxide decreases. Furthermore, it seems unlikely that the amount of unstable oxide on the platinum would be independent of the potential of anodization or the quantity of total oxide on the electrode surface.

In the mechanism of the oxide formation suggested in the discussion of the charging curves above, the potential of the electrode during anodization is controlled by the oxygen evolution process and not by a redox couple established between the platinum and the oxide layer. The anodic potential, then, would be dependent on the partial pressure of oxygen. In solutions swept free of oxygen, when the anodization is stopped, the electrode potential will drop rapidly as the oxygen diffuses away from the electrode surface. Eventually the oxygen partial pressure becomes so small that the oxygen-water couple can no longer establish an electrode potential. It is experimentally observed that the open-circuit potential of a platinum electrode, oxidized or reduced, eventually drifts to about 0.8 v. This potential is established by a very slow exchange since it is immediately polarized several tenths of a volt by an applied current density of a half-microampere per square centimeter. This explanation of the potential decay is supported by an experiment reported by Giner (8) who noted that the open-circuit potential of a partially oxidized platinum electrode is increased about 200 mv when the solution is saturated with oxygen. The extent of electrode oxidation was not increased by the presence of the oxygen gas, which shows that the oxidation process requires the passage of an electrical current.

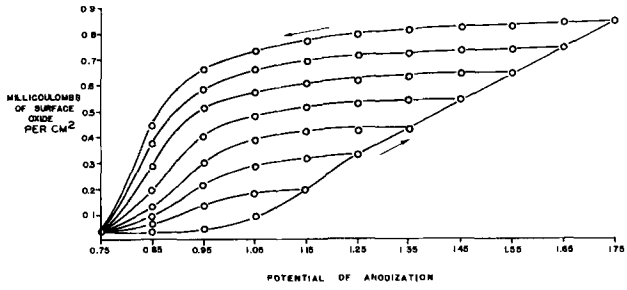

Fig. 5. Variation of amount of surface oxide with potential and direction of potential change.

The slow disappearance of oxide from the electrode surface will be shown later to be due to the diffusion of the oxygen atoms from the electrode surface to the interior of the platinum along grain boundaries. Such a diffusion satisfies the observed conditions of being a potential independent process, of being a process independent of the extent of surface oxidation (once a significant portion of the first oxidation product has formed), and of being a very slow process.

Effect of the Anodization Potential

The electrode was anodized for 30 sec, allowed to remain at open circuit for 30 sec, and then the quantity of surface oxide was determined chronopotentiometrically. The number of millicoulombs of oxygen per square centimeter as a function of the potential of anodization is shown as part of Fig. 5. The quantity of oxide increases with increasing potential of anodization. Between about 1.2 v and 1.75 v the amount of surface oxide increases linearly with potential.

The hysteresis curves of Fig. 5 result from the following experiment. The electrode was anodized for 30 sec and then the electrode potential was reduced to a lower value for 30 sec. The electrode was left at open circuit for 30 sec and then the quantity of oxide was determined. It was found that the quantity of oxide which was present at the first anodization potential remained when the potential was decreased except at potentials below 0.95 v where the surface oxide began to be removed. To determine whether or not this hysteresis might be caused by a slow equilibrium a reduced electrode was put at 1.05 v for 1 hr without obtaining an increase in surface oxide over that shown in Fig. 5. The electrode was also preanodized at 1.45 v for 1.5 min and then put at 1.05 v for 1 hr. The quantity of oxide was only 0.135 millicoulombs less than that shown in Fig. 5 for the same pretreatment with a 30-sec anodization at 1.05 v. The loss of surface oxide at a reduced potential was less than that of an oxidized electrode left at open circuit for the same period.

This hysteresis substantiates several interesting conclusions reached earlier on other bases. (*A*) The electrode potential is not determined by the degree of surface oxidation. (*B*) To reduce a substance on an electrode, electrons must be supplied to the electrode either from an oxidation occurring on the same electrode or from an external current source.

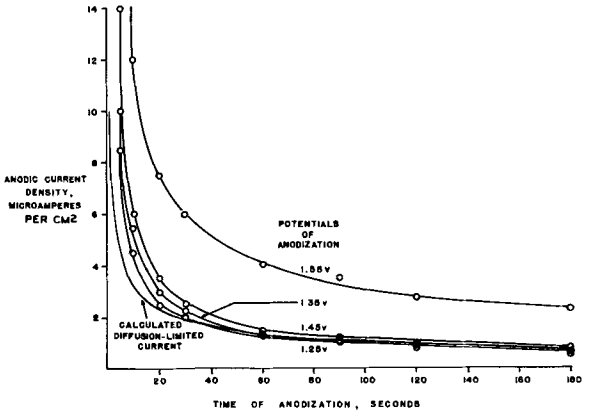

Fig. 6. Anodic current density as function of time

When the surface oxide is not reduced at open circuit, it may be due to the lack of an electron source. When the surface oxide is not reduced when the potentiostat is still connected, it is proof that the oxide is not reduced at the potential applied. (*C*) Since two steps are not observed in the oxide removal curves, that oxidation in excess of one oxygen per platinum is reduced at the same potential and thus probably by the same mechanism as the lower oxide.

Anodic Current as a Function of Anodization Time

When a constant anodic potential was applied to the unoxidized electrode, the current was very large but rapidly decayed to a small value. A plot of the current as a function of the time of anodization is shown in Fig. 6 for four potentials of anodization. Note that the current for the anodizations at 1.25, 1.35, and 1.45 v are almost identical after the first 60 sec of anodization. The current for the anodization at 1.55 v is much higher than that for the other potentials at all times. Apparently the process which requires current at the longer times of anodization is independent of potential. The anodic current at 3 min for anodizations from 1.25 to 1.45 v was also independent of the rate of stirring in the cell as provided by the nitrogen bubbling.

We suggest that an explanation for this behavior may be the diffusion of oxygen atoms into the platinum. Evidence of the penetration of platinum by oxygen has been presented in the literature (9, 24). The diffusion of a surface oxygen atom into the electrode interior would leave a vacancy on the electrode surface which requires current to become refilled. The rate of diffusion would decrease with increasing time of anodization, as was observed. The rate of diffusion would be independent of potential as long as the surface is saturated with oxygen atoms. The greatly increased current at 1.55 v is due to the evolution of oxygen. The solution of Fick's laws for the boundary condition of constant surface concentration is $i = n\mathbf{F}C^\circ \sqrt{D/\pi t}$. A surface concentration of one oxygen per platinum corresponds to a concentration C° of 0.11 moles/cm³. For an observed i equal to 0.8 μa/cm² at t = 180 sec, D is equal to 10^{-18} cm²/sec. This estimate must be regarded as very crude because a linear diffusion model is assumed for what is probably a grain boundary diffusion.

A value for the diffusion coefficient of oxygen in platinum has not been reported previously. The activation energy E for self-diffusion in the platinum lattice has been determined as 68.2 kcal/g-atom (25). The diffusion coefficient D is obtained from the relation $D = D_o \exp(-E/RT)$ where D_o is a constant which can be estimated as 1. Thus the self-diffusion coefficient of platinum at room temperature has a value of about 10^{-49} cm²/sec. The activation energy of self-diffusion along grain boundaries in silver (which has the same crystal structure as Pt) is about 0.45 times the activation energy of lattice diffusion (25). The self-diffusion of Pt along grain boundaries can thus be estimated to be within several orders of magnitude of 10^{-22} cm²/sec. Considering the smaller size of an oxygen atom than a platinum atom the uncertainties in the estimation made above, and the effect of chemical bond formation, the observed value of 10^{-18} cm²/sec for the grain boundary diffusion of oxygen in platinum at room temperature is a reasonable one. The theoretical current due to the replacement of diffused oxygen atoms for D = 10^{-18} cm²/sec is plotted on Fig. 6.

The grain boundary diffusion of oxygen atoms is preferred by the authors over the loss of surface oxygen into the solution for the following reasons: (*A*) The loss of surface oxidation by combination of bonded (chemisorbed) oxygen atoms requires the rupture of platinum-oxygen bonds, a process not likely to be independent of the electrode potential or of the extent of surface oxidation in excess of one oxygen per surface platinum atom. (*B*) Recent photomicrographic evidence (26) indicates preferential attack of grain boundaries upon severe anodic treatment of platinum.

Photographic records were made of oscilloscopic measurements of the electrode current during the first 0.1 sec of anodization at constant potential. The potential was established on the electrode within 2 msec. The area under the current-time curve, expressed as coulombs, was always larger than the amount of surface oxide determined chronopotentiometrically after a 30-sec anodization at that same potential. Anodization potentials from 0.95 to 1.75 v were studied. In some cases the current-time integral was equivalent to as much as twice the quantity of oxide found on the surface after a 30-sec anodization. The ratio would be even greater if the quantities of surface oxide for a 1-sec anodization (Fig. 4) were used.

The fact that considerably more current was used for an anodization than could be accounted for by the amount of oxide formed substantiated the notion that another process occurs while the oxide layer is being formed. At potentials of 1.45 v and lower, the anodization current at long times can all be accounted for by the diffusion of oxygen along the platinum grain boundaries. Therefore, the reaction that occurs during the formation of the surface oxide is inhibited by the formation of the oxide. If the concurrent process is the evolution of oxygen, the overvoltage of oxygen evolution on platinum is thus explained.

Double Layer Capacity as a Function of Potential

The potentiostat was turned on to apply a constant potential to the indicator electrode. The current-integrator was connected, and the step potential was set at 10 mv. The output voltage of the current-integrator was measured on the oscilloscope. Using the second beam of the oscilloscope, the electrode current was also observed. The initiation of the potential step triggered the oscilloscope sweep. No current other than the double layer charging current was observed over the entire potential range except at high anodic and cathodic potentials where oxygen and hydrogen evolution occur, respectively. The step potential was applied in both directions with the same results.

Currents lower than 1 μa could not be observed with the equipment employed because of the noise level of the potentiostat and the voltage follower. For a reaction which is as irreversible as Fig. 5 shows the oxide formation to be, the rate of the reaction would be expected to be too slow for the reaction current to be observed with this equipment. Thus the kinetic parameters of the oxide formation reaction are not obtainable with the potential step apparatus used here. Only the double layer charging current will be integrated by the current-integrator when the integration is performed over very short times (10^{-3} sec).

The double layer capacity was measured by the method described above. The current integrator was calibrated for this purpose using a decade of large standard capacitors. The double layer capacity was shown to be a function of potential, with a distinct hysteresis behavior depending on the direction of potential change. The relationship is shown in Fig. 7. The minimum capacity of the electrode was about 20 μf/cm^2. The capacity rose as the potential increased until a value of about 60 μf was reached at about 1.25 v. The capacity varied between 60 and 55 μf for potentials above 1.25 v. The capacity remained high as the potential was decreased until the potential had reached a value of about 0.95 v. The capacity then rapidly returned to the minimum value. The similarity between the capacity-potential curve (Fig. 7) and the surface oxide-potential curves (Fig. 5) is obvious. It is evident that the presence of the surface charge causes the double layer capacity to increase up to three times its normal value.

It has been postulated by Llopis and Colum (27), who also observed this capacity hysteresis, that the reason for the increase of the electrode capacity of a

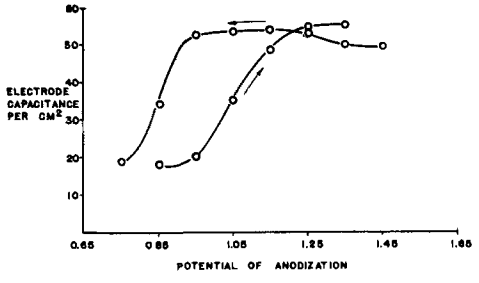

Fig. 7. Hysteresis behavior of electrode capacitance

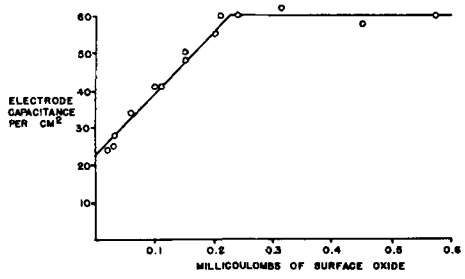

Fig. 8. Relation between electrode capacitance and amount of surface oxide.

platinum electrode at the beginning of surface oxide formation is due to the presence of dipoles such as Pt . . . O at the electrode solution interface. The negative end of the dipole may be adsorbed oxygen or some other intermediate in the oxygen evolution reaction. The capacity across this dipole would be of such a magnitude that the relative effect of the ionic double layer in the solution would be small. Furthermore, a large portion, if not all, of the potential gradient between the electrode and the solution would be developed across the dipole at the electrode surface.

Dependence of Double Layer Capacity on Surface Oxidation

Electrode capacities were again measured for the various conditions of anodizations and preanodization studied in the section above. After each capacity was measured, the current-integrator was disconnected as quickly as possible, the potentiostat was turned off, and the amount of charge on the electrode surface was determined chronopotentiometrically. Figure 8 shows the results of this experiment. The double layer capacity was found to be a linear function of the amount of surface oxide until a capacity value of 55-60 μf was reached. The double layer capacity then remained constant, independent of the amount of surface oxide. The line drawn on Fig. 8 was determined by an analysis by the method of least squares.

On the basis of the explanation advanced above for the increase in the electrode capacity as a result of the electrode oxidation it is possible to account for the capacity vs. surface charge curve (Fig. 8). For an unoxidized electrode in 1*N* perchloric acid at about 0.8 v, the double layer capacity is about 20 μf/cm^2. Highly polar groups, which might be represented as $Pt^+ \ldots O^-$ (27), $Pt^+ \ldots OH$, or $Pt^+ \ldots OH_2^+$ may exist at the metal-solution interface of the "oxidized" metal surface. These dipoles replace the water molecules and ions which form the electrical double layer at the reduced electrode surface. To account for the experimentally observed increase in electrode capacity from 20 to 60 μf/cm^2, a threefold increase in capacity due to the presence of the highly polar groups is required. For a partially covered surface, the total electrode capacity may be thought of as many capacitors in parallel (sites of hydroxyl adsorption and dipole formation) and some of low value (a double layer formed of ions and water molecules). The electrode capacity is thus a linear function of the fraction of the sur-

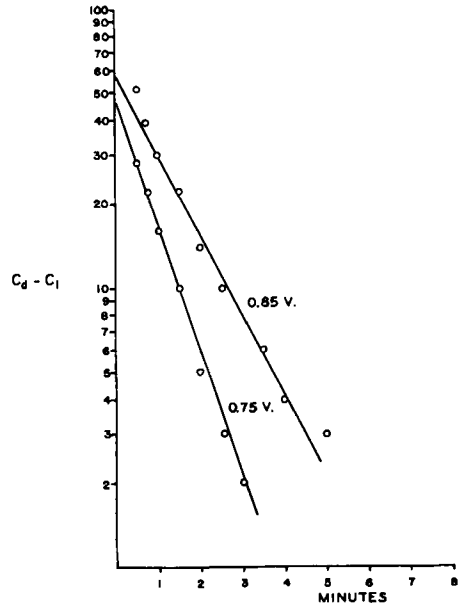

Fig. 9. Decay of surface capacitance in unstable region

face which is covered by the dipoles as demonstrated by Fig. 8.

It can be further postulated that the dipole at the electrode surface is primarily Pt...O, that is, that the electric field across the dipole is largely across the planes of the Pt^+ and O^- atoms, respectively, and is independent of the state of protonation or hydration of the O^- atom. If the surface oxidation continues and the $Pt^+...O^-$ dipole becomes a $Pt^{++}...O^=$ dipole, the capacity will not change. The permittivity of the dipole has a linear dependence on the ratio of the dipole moment to the electric field strength. When the $Pt^+...O^-$ dipole becomes a $Pt^{++}...O^=$ dipole, the dipole moment is doubled, but so is the electric field strength across the dipole. If the permittivity remains unchanged, the capacity will also remain unchanged. This explanation of the electrode capacity accounts for the linearity of capacity with surface oxidation until a surface charge of 0.25 millicoulombs (equivalent of one electron per surface platinum) has been reached as well as the constant electrode capacity observed for higher surface charge.

The postulation of the formation of the polar group as an explanation for the capacity increase is preferred over explanations involving the usual ionic double layer. One reason for this preference is that the capacity is a function of electrode oxidation (Fig. 8), but independent of potential since points on Fig. 8 were taken from both the oxide formation and dissolution curves. There is an electrode potential difference of about 200 mv between equivalent oxidation states on the oxide formation and dissolution curves. The ionic double layer capacity is known to vary with potential and therefore cannot appreciably affect the electrode capacity which is measured for the oxidized surface. The ionic double layer capacity also varies with ionic strength but, as it will be shown later, the electrode capacity of an oxidized electrode is independent of ionic strength.

Rate of Surface Oxide Dissolution

The fact that the double layer capacity is a linear function of the surface coverage was used to advantage to determine the rate of surface oxide dissolution. The electrode was put at 1.25 v until the double layer capacity came to a steady-state value (requiring about 1 min). The electrode potential was then shifted suddenly to 0.85 v and the double layer capacity was followed as a function of time. The capacity jumped to a value higher than that measured at 1.25 v and then dropped off and eventually reached a steady-state value. When the steady-state value of capacity was subtracted from all of the measured capacity values and the logarithm of the difference was plotted against time (Fig. 9), a straight line resulted. The same experiment was repeated using a removal potential of 0.75 v. Another straight line of steeper slope resulted. The conclusions to be drawn from these experiments are that the dissolution reaction is a first order reaction, and that the rate of dissolution increases with increasing cathodic electrode potential. The "half-life" of the oxide is 1 min at an electrode potential of 0.85 v and 2/3 of a minute at 0.75 v.

Effects of Acidity and Ionic Strength

Perchloric acid of 0.01M concentration was used in the cell and salt bridge for some measurements. The surface oxide was measured as a function of potential and the dissolution potential curve for anodization at 1.25 v was made. The results were identical to those shown in Fig. 5 except that the potential axis was shifted 0.12 v in the increasing positive direction. In other words, an anodization of 1.25 v in 0.01M $HClO_4$ corresponds to an anodization of 1.37 v in 1M $HClO_4$.

The double layer capacity measurement at the lower electrolyte concentration was rather difficult to make. The increased solution resistance caused the potentiostat to respond slowly due to the potential drop in the solution between the electrode and the luggin capillary. For this reason the capacity could be measured only roughly. If the experimental error is taken to be 10%, the capacity-potential curve is the same as that for 1M $HClO_4$ (Fig. 7) except for the same potential shift which was noted above for the surface oxide. The capacity-charge relationship observed in 1M $HClO_4$ solutions was also reproduced within 10% for 0.01M $HClO_4$ solutions.

The independence of the electrode capacity over a hundredfold change in ionic strength is another indication that the electrode capacity is not determined by the ionic double layer. The electrode capacity must then arise from the highly polar nature of the adsorbed surface layer.

Conclusions

On the basis of the observed anodic behavior of the platinum electrode, a mechanism for the surface oxidation and oxygen evolution reactions can be proposed. The first step is the formation of an oxygen evolution intermediate which is adsorbed on the electrode surface. The choice of an intermediate

is limited because only one electron is used in its formation from water. Possible intermediates are $\cdot OH$, $\cdot O^-$, $\cdot OH_2^+$. The hydroxyl radical has been chosen to represent the intermediate in the reaction equations.

$$Pt + H_2O \rightleftharpoons Pt...OH + H^+ + e^- \quad [1]$$

The Pt...OH thus formed[1] can further react in either of two ways. First, an oxygen evolution reaction may be written which removes the surface hydroxyl, presumably through the intermediate formation of surface $\cdot OOH$, forming a bare platinum site:

$$Pt...OH + H_2O \rightarrow Pt...OOH + 2H^+ + 2e^-$$

$$Pt...OOH \rightarrow Pt + O_2 + H^+ + e^- \quad [2a]$$

Second, the surface hydroxyl may be converted to a surface oxygen atom which is firmly held

$$Pt...OH \rightarrow PtO + H^+ + e^- \quad [2b]$$

Bare platinum sites produced by reactions [2a] are reoxidized by reaction [1], so that eventually all the surface is covered with firmly held PtO. Subsequently oxygen evolution must occur on the PtO surface, as has been also postulated by Llopis (27). Once again, surface hydroxyl formation may be postulated, with competitive reactions to form oxygen molecules, or to further oxidize the surface.

An important consideration here is the finding of Rosenthal and Veselovskii (13) by isotope experiments that oxides formed at lower potentials (0.8-1.2 v) do not appear in oxygen gas subsequently evolved from the surface. Oxides formed at higher potentials were found to make a partial contribution to oxygen molecules formed at the surface. This finding suggests that the first oxygen atom per surface platinum atom is held more firmly than additional oxygen atoms. Moreover, the oxygen evolution reaction cannot involve combination of oxygen atoms if one of the atoms is of the firmly held type, and the present finding of the stability of even the higher surface oxidation at open-circuit forces the rejection of an atom-combination mechanism for oxygen evolution.

A similar reaction sequence as postulated above for a bare platinum surface may be written for oxygen evolution at a PtO surface, in which the PtO bonds are not disrupted:

$$PtO + H_2O \rightarrow Pt^o...OH + e^- + H^+ \quad [3a]$$

$$Pt^o...OH + H_2O \rightarrow Pt^o...OOH + 2e^- + 2H^+ \quad [3b]$$

$$Pt^o...OOH \rightarrow PtO + H^+ + e^- + O_2 \quad [3c]$$

According to the above mechanism the oxidation of the platinum surface occurs only when oxygen is being evolved concurrently. From the principle of microscopic reversibility it follows that the formation of the oxide is energetically possible at potentials less positive than the potential of oxygen evolution, but it appears that the oxide is not formed at an appreciable rate except in the presence of the oxygen evolution intermediates. In order to dissolve the surface oxide, however, it would be necessary to put the electrode at a potential for which the oxide is unstable. At such a potential, the instantaneous rate of oxide dissolution would be proportional to the instantaneous quantity of oxide on the surface. A first order reduction of the surface oxide was confirmed experimentally. The hysteresis of the potential vs. surface oxidation curve is direct evidence that oxide formed at potentials of 1.2-1.7 v is reduced only at potentials of about 0.95 v and below. The standard potential of the surface oxide formation on platinum would be closer to the reduction potential than to the oxidation potential, that is, about 0.8-0.9 v.

[1] Reaction [1] has been postulated by Bockris and Huq (28) as being the rate-controlling process.

Technical Notes

Electrode Assembly for Electrochemical Measurements

Milton Stern[1] and A. C. Makrides

Metals Research Laboratories, Union Carbide Metals Company,

Division of Union Carbide Corporation, Niagara Falls, New York

The isolation of electrical contacts from the test solution is a common problem in electrochemical measurements. It may be circumvented in some cases by using leads of the same material as the electrode. Such an arrangement, however, produces an ill-defined current density distribution and introduces an extraneous vapor-metal-solution interface.

Electrical connections are masked frequently with tape, wax, or thermosetting plastics. All these substances contaminate the solution to some degree. Wax is probably least objectionable. In corrosive solutions, however, it often causes preferential attack next to the masked surface. Contamination of solution can be avoided with wire electrodes sealed in glass. The method is limited to tungsten and platinum since only these metals give leakproof seals. These difficulties may be eliminated with a demountable electrode assembly in which only glass and a fluorinated plastic (Teflon), besides the electrode, are exposed to solution. The assembly has been used with considerable success for several years in these Laboratories.

A diagram of the assembly is shown in Fig. 1. The electrode is tapped, threaded, and attached to a stainless steel rod through a Teflon washer machined to a narrow edge at the end next to the electrode. The rod is isolated from solution with a heavy-wall glass tube ground at the lower end at an angle of approximately 60°. The assembly is made leakproof by tightening a nut at the top of the steel rod. Sufficient pressure is exerted to produce liquid-tight seals at both the glass-Teflon and Teflon-electrode junctions. A thin Teflon washer is used between the retaining nut and the tube to avoid cracking the glass.

An assembly will remain leakproof for several weeks and has been used in boiling acid solutions. Although Teflon washers can be used more than once, they are deformed to a certain extent after each run and have to be replaced after a few runs. Their life can be extended by remachining the lower edge.

The glass tube is attached eccentrically to a ground glass joint which is inserted, again eccentrically, in a second ground glass joint on the cell (see insert in Fig. 1). The distance between electrode and a Lugin capillary probe can thus be easily adjusted within rather wide limits. Mercury or water-sealed joints are used to avoid contamination from lubricant.

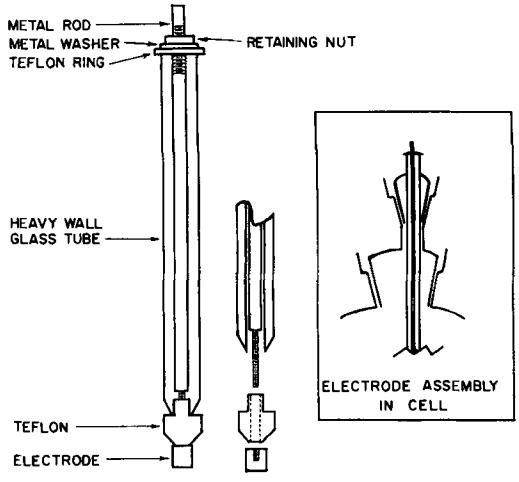

Fig. 1. Electrode assembly

A number of modifications of the basic design have been employed. For example, in experiments with a rotating electrode, a cylindrical sample was secured to the steel rod in the usual way and recessed and threaded at the lower end. A V-shaped Teflon section, which rode in a glass cup fused to the bottom of the cell, was attached at this end. The Teflon bearing minimized eccentric motion of the electrode and isolated the bottom surface of the cylinder from solution. At the top of the assembly, an inverted steel cup rotating in a pool of mercury sealed the system from the atmosphere while providing electrical contact to the electrode.

The basic assembly described above can be used with any metal or semiconductor electrode which can be attached securely to a metal rod. It can be used in practically every common test solution since only glass and Teflon come in contact with solution. Furthermore, it can be cleaned in any of the usual ways, for example, with a saturated chromic-sulfuric acid solution (cleaning solution).

Identification of the Diffusing Species in Uranium Oxidation

J. G. Schnizlein, J. D. Woods,[1] J. D. Bingle, and R. C. Vogel

Chemical Engineering Division, Argonne National Laboratory, Lemont, Illinois

As part of an extensive study of the kinetics of uranium oxidation, experiments have been designed to establish whether uranium or oxygen diffuses through the oxide film during the oxidation reaction at 200°C in 200 mm oxygen. Two distinctly different types of marker experiments have been used to demonstrate the same conclusion.

In the first method, metallographic examination was used to establish whether an inert marker would become buried in the oxide and whether or not two impinging oxide films would fuse together. Other investigators (1-4) have shown that in cases of metal ion diffusion during oxidation, as with copper (1), an inert marker will become buried in the oxide. Similarly, two oxide surfaces growing against one another will fuse into a continuous oxide layer (2). The lack of burial of a wire or lack of fusion of the impinging oxides is generally accepted as indication of the absence of metal-ion diffusion.

The second method used involved an alpha-counting technique to locate a marker of enriched uranium. Although the use of inert markers in metal oxidation studies is common, the use of a radioactive isotope of the metal as a marker is a recent (5), extremely useful innovation. The metal isotope marker is not inert but becomes a part of the oxidation process, thereby avoiding the danger of altering the reaction under examination. In these experiments an enriched uranium film was sputtered onto the surface of normal uranium. The higher percentage of uranium-234 and -235 gives the marker considerably more alpha activity than normal uranium. After oxidation the active marker can be located by direct counting of the surface. The location of the marker indicates whether uranium or oxygen is the diffusing species.

Experimental

The uranium specimens were cubes 1 cm on an edge prepared by the Metallurgy Division of Argonne National Laboratory from high-grade biscuit metal. The metal contained approximately 250 ppm total analyzed impurities. The cubes were β-quenched to assure uniform grain structure and random orientation. The oxidation of the samples was conducted at constant temperature and constant pressure in an apparatus in which the consumption of oxygen was measured volumetrically.

Metallographically determined marker.—Two uranium cubes were polished through 1-μ diamond paste and wired together with 640-μ diameter (22-gauge) Inconel wire with a 25-μ (1-mil) platinum wire separating the cubes near one edge. Thus, a V-shaped space was left between the cubes ranging in width from zero to approximately 30 μ.

[1] Special Scientific Employee in 1957 from Drake University.

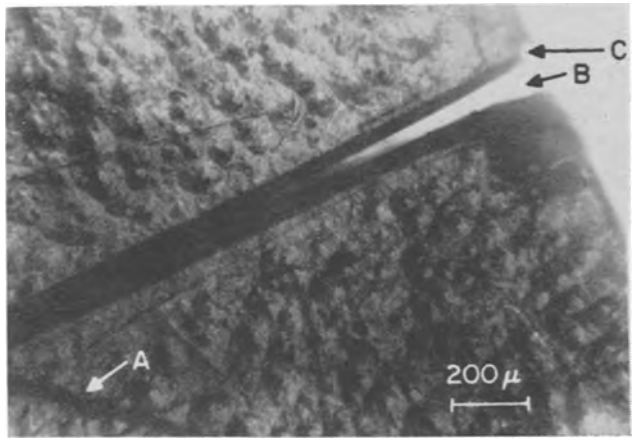

Fig. 1. Open V-shaped space between oxidized uranium cubes. A, 25 μ diameter platinum wire (out of focus); B, V-shaped space still unfilled with oxide; C, notch on edge of oxidized cube.

The sample was then oxidized at 200°C in 200 mm oxygen until the oxygen consumed was equivalent to 5150 μg/cm^2. The study of the kinetics of oxidation (which will be published at a later date) indicates that uranium dioxide is produced under these conditions and that an essentially linear oxidation rate is achieved after a brief, much lower initial rate. After cooling in vacuum, microscopic examination (Fig. 1) showed that the V-shaped space between the cubes was still not closed by oxide. The 25-μ platinum wire (A) can be seen, out of focus, in the corner opposite the open edge (B). The interesting notch (C) in the oxide at the edge of the cube should be noted. This is an indication of the absence of uranium diffusion in the oxidation mechanism (6, 7). Other related uranium oxidation experiments have shown even more clearly than Fig. 1 that the raised surfaces of the oxide are approximately of the same dimensions as those of the original sample, with notches clearly evident at each edge.

An additional oxidation of 12,500 μg/cm^2, to a total of 17,650 μg/cm^2, was completed to close the gap. Examination of the edge of the oxide contact was not satisfactory because of the notch developed on each cube edge. To obtain a cross-section view the sample was mounted in "Scotchcast," a low-temperature thermosetting plastic. After polishing through 600 grit silicon carbide paper, the section was examined.

A view of the cross section showing the platinum wire (A) separating the two cubes and locating the original metal surfaces is presented in Fig. 2. It is obvious that the two oxides have not fused, in fact, the oxide layers (C and D) from the first and second oxidations are distinctly separate. The thickness of these oxide layers is approximately proportional to

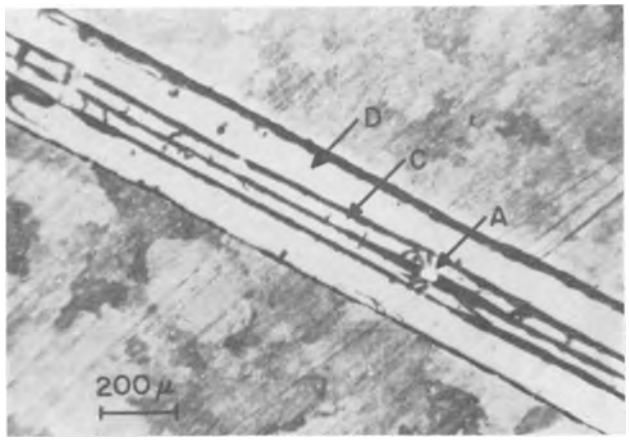

Fig. 2. Cross section of impinging oxide from two uranium cubes. A, cross section platinum wire; C, oxide produced in first oxidation; D, oxide produced in second oxidation.

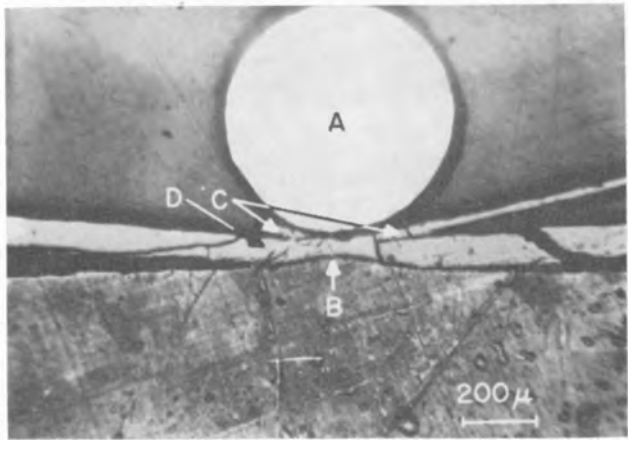

Fig. 3. Cross section of Inconel binding wire on oxidized uranium cube. A, originally 640 μ diameter Inconel wire; B, hump in uranium surface where partial protection is afforded by wire; C, oxide produced in first oxidation; D, oxide produced in second oxidation.

the extent of each oxidation. Two other interesting observations are: (*a*) the metal surfaces are now parallel instead of forming the V-shape of the original assembly, and (*b*) the 25-μ diameter platinum wire (A) has been flattened into an oval cross section approximately 17 x 38 μ. Both of these observations demonstrate the tremendous pressure of the oxide film as the gap was closed.

Figure 3 illustrates the lack of burial of the 640-μ diameter Inconel binding wire (A). It appears that the uranium was partially protected during the oxidation so that a hump (B) is observed in the surface. The oxide produced during the first oxidation (5,150 μg/cm²) becomes diminishingly thin under the wire (C), whereas that produced during the second oxidation (D) (12,500 μg/cm²) is continuous. There is no tendency of the oxide to grow up around the wire.

Radioactive marker.—For the experiments utilizing the marker of enriched uranium, two approaches were used. In the first, the active marker was initially on the exterior of the cube. After oxidation the activity should either remain on the surface or be distributed through the oxide, depending on whether oxygen or uranium was the diffusing species. In the second, the sputtered film of enriched uranium was covered with a film of normal uranium. In this case, if oxygen were diffusing, the activity would remain buried as a thin band, whereas if uranium diffused, the activity would be distributed throughout the oxide.

The normal uranium cubes were polished through 1-μ diamond paste and then electropolished. The sputtering of the enriched uranium marker onto the cubes was accomplished in a vacuum bell-jar with a glow discharge in 25-μ argon pressure using 30 to 50 ma at 2.2-2.6 kv. Although there was not any way of measuring the actual thickness of the sputtered films, previous experiments would indicate that, under the conditions used, the films of enriched uranium were approximately 1 μ thick. In the second approach this 1-μ film of enriched uranium was covered with several microns of normal uranium.

The samples were oxidized at 200°C in 200 mm oxygen. The oxidation was continued to approximately 1000 μg/cm², or a thickness of 8 μ, assuming ideal density and uniform oxidation.

The oxidized samples were hand polished on 2/0 emery paper and one face of the cube was counted with an alpha-beta-gamma proportional counter after successive polishing strokes. Although this polishing technique was only semiquantitative, experience indicated that approximately four strokes removed 1 μ of oxide. The shape of the curve obtained by plotting counts per minute vs. number of strokes (Fig. 4) clearly indicates the location of the marker in each case.

Discussion of Results

Each of two types of marker experiments demonstrate conclusively that oxygen, rather than uranium, diffuses through the oxide layer during the course of oxidation at 200°C in 200 mm oxygen.

In the metallographically determined marker experiment, all of the observations indicate an absence of uranium diffusion through the oxide. The most noteworthy of these observations are: (*a*) the lack of tendency for the oxide to grow up around the Inconel binding wire; (*b*) the lack of fusion of the

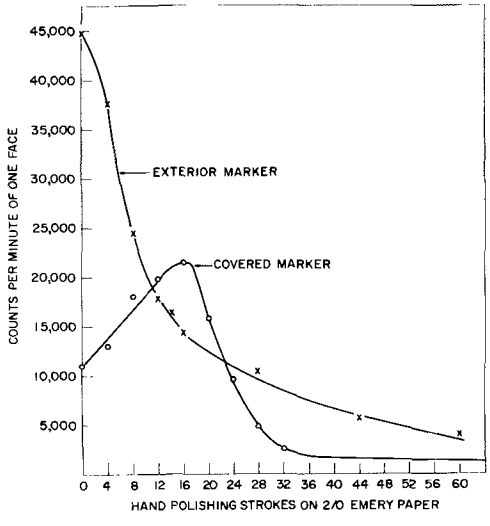

Fig. 4. Activity within the oxide layer: enriched uranium marker experiment.

oxides layers impinging on each other; and (c) the notch in the oxide which occurs at an edge of the cube.

Both approaches to the radioactive marker experiment also demonstrate that oxygen is the diffusing species since uranium diffusion would have caused the active marker to be distributed throughout the exterior oxide. In the first case, the initially exterior enriched uranium marker remained on the outside surface and was readily polished off. In the second case, the covered enriched marker remained covered and in a narrow band. The uniform increase of activity as the sample was polished would be expected as the alpha-absorbing oxide was removed from the enriched marker.

Acknowledgment

The authors wish to express their indebtedness to S. Rothmann of the Metallurgy Division, Argonne National Laboratory, for his aid in the uranium sputtering technique.

Manuscript received Feb. 29, 1960. Work was performed under the auspices of the U. S. Atomic Energy Commission.

Further Studies of Leveling Using Radiotracer Techniques

Seward E. Beacom and Bernard J. Riley

Research Laboratories, General Motors Corporation, Warren, Michigan

In a previous paper (1), it was shown by radiotracer techniques that the organic addition agent, sodium allyl sulfonate, which imparts leveling characteristics to a bright nickel plating solution, is preferentially adsorbed onto the peaks of an irregular surface. This was considered to be verification of a part of leveling theory which assumes that the leveling process is initiated by this preferential adsorption on peaks.

The cathodes, which were machined to exhibit a surface of alternate peaks and valleys, had rather large peak-to-peak separations (0.16 cm) and peak-to-valley heights (0.077 cm). Because of questions which have been raised about making interpretations based on cathodes of these dimensions, it seemed important to determine experimentally the limit to which this concept of preferential adsorption could be extended. Thus, a series of machined cathodes of decreasing surface roughness has been prepared and plated in solutions containing the addition agent tagged with S-35. Within the limits of the techniques available, the results show that the concept of preferential adsorption may be extended to include those surfaces which more nearly approach a microprofile dimension.

To establish further the reliability of the results being reported, it was considered desirable to show that the radioactivity observed in the deposits comes from the pure S-35 isotope only and not from some other radioactive impurity. Also, it seemed necessary to show, by an exchange study, that the observed activity comes directly from the sulfonate part of the tagged addition agent and not indirectly by way of an exchange with the sulfate ions present in the plating bath. The results of the investigation demonstrate that the observed activity is due to the presence of pure S-35 and that it comes directly from the sulfonate group.

Experimental and Results

Radiochemical purity of sodium allyl sulfonate.—Several samples of sodium allyl sulfonate tagged with S-35 were prepared (1) and the chemical purity verified by infrared analysis.

To assure that there was no complicating radiochemical impurity present in the compound, decay measurements were carried out over a period of approximately eight months. The agreement of the experimentally obtained half-life value of 87.4 days with the accepted published value of 87 days indicated that, within the limits of counting statistics, there was no appreciable radioactive impurity present.

As further evidence of the presence of pure S-35, a determination of the energy value of the isotope was obtained using the standard technique of the absorption curve. The average half-thickness corresponded to an energy of 0.172 Mev as calculated from the published range energy value (2). This energy agrees, within experimental error, with the literature value of 0.167 Mev.

Plating cell.—Some trouble with stirring patterns, edge effects, and addition agent depletion had been experienced with the 80 ml cell used previously (1). A new round cell, 13.97 cm in diameter by 8.89 cm high, and holding a liter of plating solution, was constructed from Lucite. To accommodate the anode and cathode, slots 2.54 cm wide by 0.32 cm deep were cut vertically into opposite sides of the cell. When used with a propeller stirrer rotating at 100 rpm, edge effects and stirring patterns have been virtually eliminated, and many plating runs can be made before addition agent depletion becomes serious.

Further work on grooved cathodes.—The surface features of representative machined cathodes, as well as the Precision Reference Specimens of Surface Roughness (3), are recorded in Table I. The sulfa-

to prepare slitted lead foils for examination of the Precision Reference Specimens of Surface Roughness.

Sulfate ion exchange.—Using S-35 tagged sulfate (as H_2SO_4), 1 in.² steel shim stock samples were plated under conditions identical to those used with the S-35 tagged sodium allyl sulfonate. The radioactive H_2SO_4, with a specific activity of 50 mc/ml, was added in increasing amounts to the bright nickel plating bath. The starting concentration of 7.5 x 10^5 cpm/ml of plating solution represented an activity which was close to that used for the S-35 tagged sodium allyl sulfonate experiments. A summary of the results is given in Table IV. At an activity level of 1.5 x 10^6 cpm of the tagged sulfate per milliliter of plating solution, approximately 9 cpm/cm² of sulfate pickup is observed. This is compared with the 5000 cpm/cm² pickup from the tagged sodium allyl sulfonate at the same level of activity. It appears from the small amount of sulfate activity recovered that the exchange reaction, if it occurs at all, must be quite negligible, and that the source of activity found in the deposits comes directly from the sulfonate and not by exchange from the sulfate ions. The very low remaining activity due to sulfate may result from a slight general surface adsorption of sulfate ion.

Discussion

The concept of the preferential adsorption of addition agents on the peaks of irregular surfaces which is verified experimentally in this work is additional support for results previously reported (1). It seems likely that this adsorption produces at least in part the polarization effects, noticed by other investigators, which may lead to the leveling phenomenon.

Experimental work in this laboratory has shown that leveling occurs on surfaces which have an average surface roughness of 125, 50 and 20 μin. If leveling theory is correct, then it seems reasonable to assume that preferential adsorption also occurs on the peaks of these surfaces which possess a more nearly microprofile dimension. It appears that only experimental difficulties have prevented verification of this assumption.

Electrochemiluminescence at a Silicon Anode in Contact with an Electrolyte

Allen Gee

Semiconductor Division, Texas Instruments Inc., Dallas, Texas

In the study of stain films on single-crystal silicon, emission of light has been observed during the anodic oxidation of the film. This film can be formed from the substrate either electrochemically when HF is the electrolyte by the method of Turner (1) or chemically by the method of Archer (2). This note deals principally with the chemically formed film designated as Type I amorphous silicon by Archer because luminescence is more easily observed.

Experimental

A slice of 5 ohm-cm, boron-doped, p-type silicon having 1.2 cm² of its 111 face exposed is sealed with wax to the bottom of a polyethylene cell. Two ohmic contacts to the silicon are made on the under side. After the cell is filled with electrolyte, a platinum electrode and a saturated calomel electrode are inserted from the top. A constant current source is connected between one ohmic contact and the platinum electrode. The voltage between the other ohmic contact and the calomel electrode is fed to a recorder.

Before forming the film, the chemically polished surface of the silicon is treated for a few seconds with a slow etch (10 volumes 70% HNO_3 to 1 volume 49% HF) and then thoroughly rinsed with water. The film is grown by treatment with a 49% HF solution containing about 0.1% HNO_3 until a blue interference color is visible.

Results

With almost any neutral or acid electrolyte, the voltage of the film-covered silicon electrode at constant anodic current increases with time in the manner shown in Fig. 1. The plateau between 0.5 and 1 v represents a region where ready oxidation occurs. Visible light is emitted in the last half to the last fourth of this region, and passivation, indicated by

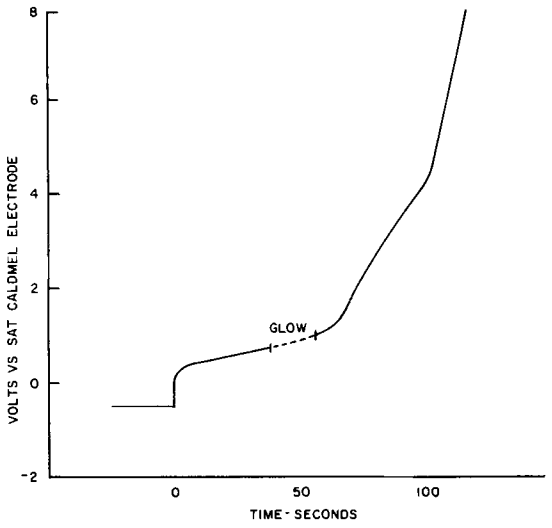

Fig. 1. Voltage of 5 ohm-cm p-type silicon anode coated with Type I film in 1M H_2SO_4. Current density, 1.6 ma/cm² after time zero. Period of luminescence shown on curve.

the sharp voltage rise, always sets in as soon as the luminescence disappears. On the same scale, a film-free silicon electrode gives a near vertical trace.

The faint, reddish glow usually starts at a single point, expands to cover the entire surface, and then contracts to a point away from the area where it started. On some occasions, various areas of the surface glow successively. The luminescence is responsive to short pulses of current, and the pattern of glow is not changed by current interruptions. Color of the emitted light has not been found to vary perceptibly and is not a function of the electrolyte. In subdued lighting, a rather bright flash is seen when the current density is 10 ma/cm². In near darkness, a prolonged glow is detectable at 0.2 ma/cm².

Attempts to obtain quantitative data to correlate with such parameters as the thickness of the film (2) have been disappointing. For many measurements, the entire plateau of Fig. 1 corresponds to the passage of 30-100 millicoulomb/cm². Within such wide limits, the exact procedure for forming the film is not critical.

Luminescence occurs in any indifferent electrolyte such as 1M solutions of KCl, LiCl, H_2SO_4, HNO_3, and acetic acid. Basic solutions (such as 1M NH_4OH), as well as 1M KF, or 20% NH_4HF_2 dissolve the film so that the film-free characteristics are obtained. When the electrolyte is HF, no luminescence or passivation occurs, but light is emitted when the electrolyte is 0.5M KF in acetic acid buffer.

Treatment of the film with most oxidizing agents (dilute solutions of dichromate, permanganate, copper salts; 30% H_2O_2, 70% HNO_3, Br_2 vapor) decreases the amount of oxidizable materials as measured anodically and reduces or eliminates the luminescence. Neutral or acid persulfate and reducing agents in general have little effect. Allowing the film to dry in room air for 16 hr does not alter its properties.

The emission of light accompanies anodic oxidation and is not the result of local heating. By making contact to the film with mercury instead of an electrolyte, current can be passed through the film without evidence of glow. Passage of 25 ma/cm² through the film in either direction for several minutes does not produce any significant change in the subsequent anodic behavior.

The original blue film becomes scarcely visible after anodic treatment. A fresh amorphous silicon film can be grown without etching off the anodized film. When formed in this manner, normal anodic behavior is observed except that the interference colors are now only slightly affected. Unlike the original film, the anodized film seems not to dissolve in dilute bases with evolution of gas even though there is a slight change in appearance.

Passage of cathodic currents until hydrogen evolution is visible has little effect on the original film and does not reduce the anodized film. A p-type semiconductor electrode is known (1, 3) to offer lower resistance to current flow in the anode direction. Application of 60 cycle power instead of d.c. to the silicon electrode produces the same luminescence effect for a comparable level of rectified current.

The amorphous silicon film formed anodically in 49% HF simply by shorting the silicon to a platinum electrode exhibits different and more erratic properties. Luminescence has been detected only at current densities greater than 5 ma/cm² and sometimes not at all.

Luminescence has not been observed on film-covered n-type silicon. Since only a few samples of silicon have been examined, no definite statement relating the phenomenon to the nature of the substrate can yet be made. Further efforts are directed toward locating the region within the film from which light is emitted and toward elucidating the mechanisms involved.

Manuscript received April 29, 1960.

A PNP High-Frequency Silicon Transistor

W. A. Little

Texas Instruments Inc., Dallas, Texas

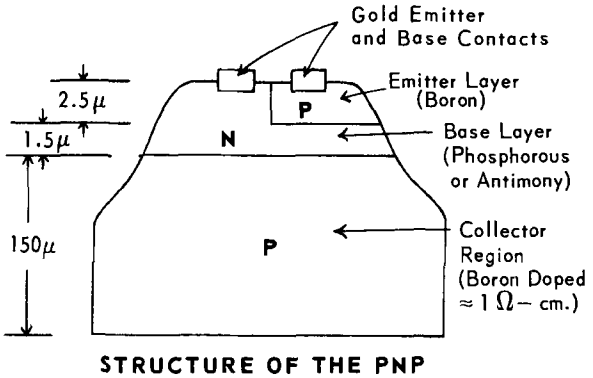
NPN high-frequency silicon transistors were described originally by Tanenbaum and Thomas (1), and more recently a switching transistor was described by Aschner, *et al.* (2). The need for complementary-type switching transistors has led to the development of a PNP silicon double-diffused transistor which is described in this paper. The essential features of this transistor are shown in Fig. 1. Solid-state diffusion techniques are used to obtain the high degree of control required for high-frequency devices. Oxide masking techniques are used to provide exposed emitter and base areas at the surface and to control the emitter geometry. Contact of the exposed regions is obtained by evaporated metal stripes. Electrical characteristics of transistors prepared in this manner are described.

Fabrication

Transistors are fabricated by starting with 1-3 ohm-cm p-type silicon wafers that have been lapped and optically polished flat to provide a uniform surface. An n-type layer with a surface concentration of between 10^{17} and 10^{19} atoms/cm^3 is diffused into the parent p-type material to a depth of 4-5 μ. This is accomplished by an open-tube diffusion process similar to the one described by Frosch and Derick (3). Red phosphorus is used as a diffusant to obtain these values of surface concentration.

This base layer diffusion actually is done in two steps as is shown schematically in the diagram of Fig. 2, which is adapted from Fig. 2 of Aschner, *et al.* (2). First, a thin concentrated n-layer is deposited on the silicon wafer. In the second step, the source of phosphorus is removed from the combustion tube and wet oxygen is used to grow an oxide layer 5000-8000Å thick. During this time, the n-layer is diffused into the wafer to the desired depth.

The purpose of the oxide layer is to provide a mask against the subsequent emitter diffusion on portions of the exposed surface where direct contact to the base region is required. In order to produce the selective mask to accomplish this, a photographic process is used to remove the oxide selectively. This is the same type of process that is used to form the etched wiring of printed circuit boards. A photosensitive liquid, termed the resist, is applied to the surface of the oxidized silicon wafer. Upon drying, this liquid forms a thin photosensitive coating which adheres strongly to the oxide coating of the wafer. The resist coating may then be exposed using ultraviolet light and contact printing, through an ordinary film negative which contains the desired pattern. The resist is then developed in trichloroethylene. The portions of the resist that were protected by the opaque regions of the film negative



STRUCTURE OF THE PNP TRANSISTOR

Fig. 1. Geometry of PNP transistor

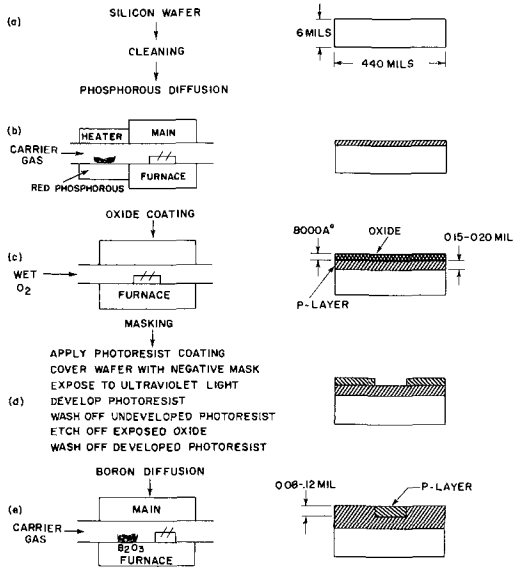


Fig. 2. Detail of diffusion and oxide masking techniques

Fig. 3. Photomicrograph of an oxide masked double-diffused wafer. The junctions have been exposed by bevel lapping and polishing at an angle of about 5° and staining the p regions.

and, hence, were not exposed to the ultraviolet light, are washed away by the developer. The resist pattern thus forms a protective coating over the oxide which limits the attack of etches to those regions not covered by the resist. If the sample is placed in a weak etch, the oxide in these regions will be removed completely down to the silicon substrate. Then the developed resist can be removed easily with an organic solvent, leaving the desired oxide diffusion mask. In addition to producing extremely sharp, well-defined patterns the photo resist process allows a quick and simple method of changing device geometry merely by changing the film negative pattern. In the evaluation units fabricated to date, a simple bar pattern has been used, ultimately leading to a wafer having alternate base and emitter regions exposed.

After the wafer has been prepared with the oxide mask of suitable geometry, a diffused p-type layer 2 μ to 3 μ deep with a surface concentration of approximately 10^{20} atoms/cm^3 is superimposed on the n-layer. This is accomplished by means of an open tube diffusion process in which the source of diffusant (boric acid) was placed in the furnace beside the silicon wafers.

To illustrate the degree of control obtained in this process, a photomicrograph is shown in Fig. 3. This was made by lapping and polishing the wafers at an angle of five degrees to the surface and staining the emitter and collector with a hydrofluoric-nitric acid etch (4) to delineate the junctions clearly. In Fig. 3 it can be seen that the collector and emitter junctions are quite planar. Also, any imperfections are much less than the layer thicknesses. This photograph shows the alternately exposed emitter and base regions produced by oxide masking. Interference microscopy (5) techniques were used in measuring the thickness of the thin diffused layers.

The next step is the metal evaporation of emitter and base stripes through a mask. In order to secure proper placement of the metal stripes, the evaporation mask must be indexed with respect to the negative mask used in preparing the wafers for emitter diffusion. Close control of the vacuum deposition is necessary to secure placement of the stripes on the desired area about 0.5-1 mil from the line marking the boundary between base and emitter.

After alloying the gold emitter and base stripes in an r.f. heater at about 750°-850°C, the squares are ready for mesa masking and etching. The remainder of the fabrication process follows standard procedures for dicing of squares into individual units, bonding the collector to the header, bonding leads to the base and emitter stripes, and encapsulating the units. Figure 4 is a photomicrograph of a completed device showing emitter and base stripes and the bonded leads.

Electrical Characteristics

Electrical characteristics of a PNP silicon high-frequency transistor prepared by the techniques described above are presented here. During fabrication of experimental devices, base widths were deliberately varied from about 1 to 2 μ. The characteristics described below are for an intermediate

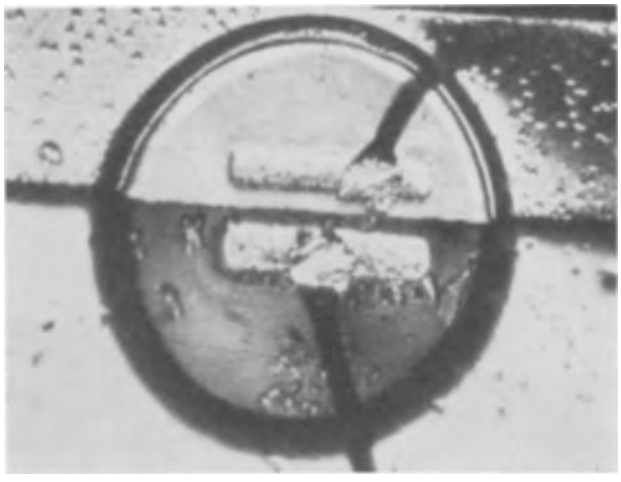

Fig. 4. Photomicrograph of completed unit showing the gold stripes and bonded leads.

base width of 1-½ μ. In such a device, typical collector-base breakdown voltage was of the order of 35 v, while the emitter-base breakdown voltage was 9 v. At a typical d-c bias condition of 10 ma emitter current, with collector-base voltage $V_{CB} = 6$ v, the d-c forward current transfer ratio h_{FE} was 35, and the d-c forward voltage drop V_{BE} was of the order of 0.8 v.

High-frequency characteristics of a typical device are illustrated by Fig. 5. The common-emitter current transfer ratio h_{fe}, shown as a function of frequency, decreases inversely with increasing frequency to a value of 1 at a frequency (f_T) of 200 mc. Common-emitter input resistance $R_e(h_{ie})$, also shown in Fig. 5, decreases with increasing frequency and appears to approach a limiting value of the order of 45 ohms at high frequencies. Hence, this value can be taken as essentially equal to the high-frequency base resistance of the unit. Collector transition capacitance at a reverse bias of 6 v is approximately 3 pf, whereas the emitter transition capacitance (at reverse bias of 3 v) is somewhat larger—3.8 pf. This reflects the fact that, even though the emitter-base area is less than the collector-base area, the emitter-base junction gradient is considerably steeper than that at the collector-base junction.

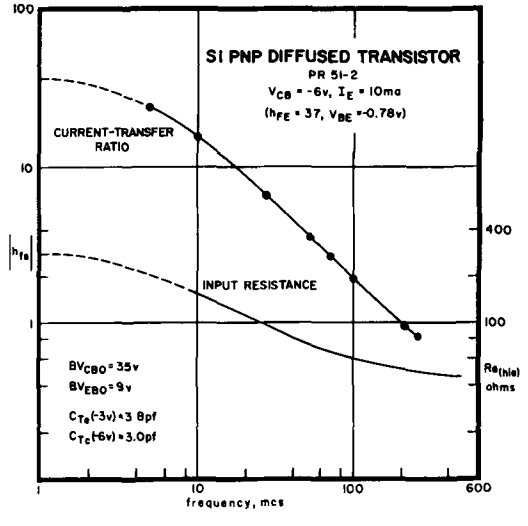

Fig. 5. The current transfer ratio and input resistance vs. frequency for a typical unit.

Acknowledgments

The writer is grateful for the helpful discussions and suggestions of R. L. Pritchard, and wishes to thank Jay W. Lathrop, L. E. Barnes, and R. L. Martin for assistance with experiments. Thanks are also due to George Pierson for measuring the parameters for the experimental transistors.

Manuscript received March 24, 1960. This paper was presented at the Washington, D. C., Meeting of Electron Devices, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

Technical Review

Report of the Chlor-Alkali Committee of the Industrial Electrolytic Division for the Year 1959

Nelson J. Ehlers

Columbia-Southern Chemical Corporation, Pittsburgh, Pennsylvania

Clifford A. Hampel

Skokie, Illinois

Chlorine-Caustic

Production and Sales

Chlorine and caustic soda production in the U. S. was at an all-time high in 1959. With about 4,285,000 ton production of chlorine, the increase above 1958 was nearly 19%. U. S. capacity as reported by The Chlorine Institute was near 14,100 TPD at the end of the year, which means the industry operated at 83% of capacity in 1959. Apparent per capita consumption was 48.2 lb, an all-time high and double that of 1949.

After a substantial chlorine production increase in 1959, it is felt by many that prospects for future growth are good. Recent publicized estimates of growth indicate from 7 to 8.5% per year growth from 1960 to 1970. Another source estimates an increase of 70% in chlorine and 50% in caustic soda during the ten-year period.

Canadian chlorine production in 1959 was about 287,000 tons as compared to 268,000 in 1958. Indications are that about 305,000 tons will be produced in 1960.

Caustic soda production in the U. S. increased 17% above 1958, for a total of about 4,675,000 tons in 1959. The apparent per capita consumption was 50.0 lb, an all-time high, which was nearly twice that of 27.3 in 1949. Lime soda caustic production data are not available, but it is estimated such production was some 300,000 to 325,000 tons for the year.

Even though caustic is being converted to soda ash on a relatively small scale, soda ash continues to be converted to lime soda caustic. Some sources believe that caustic was more in excess during 1959 than in the previous year.

Table I. U.S. sources of chlorine

	1959 (preliminary)		1958	
	Tons	%	Tons	%
Cl_2 equiv. of NaOH	3,997,200	93.3	3,319,042	92.1
Cl_2 equiv. of KOH	58,900	1.4	48,736	1.3
Cl_2 equiv. of Na	172,500	4.0	169,857	4.7
Cl_2 equiv. (others) *	56,400	1.3	66,903	1.9
Cl_2 total gas produced	4,285,000	100.0	3,604,538	100.0

* By difference.

About 75% of the capacity of chlorine in 1959 was in diaphragm cells, 19% was in mercury cells, 5% in sodium cells, and less than 1% in nonelectrolytic processes. Two-thirds of the capacity added in 1959 was in diaphragm cells and one-third in mercury cells.

Estimated sources of chlorine comparing 1959 with 1958 appear in Table I.

New Plants and Expansions

U. S. chlorine capacity increases amounted to about 760 TPD in 1959 as compared to 640 TPD in 1958, and are believed to be as shown on p. 792.

Diamond Alkali completed modernization of facilities at Painesville, Ohio, using Diamond diaphragm cells to replace Tucker-Windecker cells, while Frontier Chemical at Wichita, Kans., completed modernization using Hooker S-3B cells. Chlorine producing plants of Gulf at Port Arthur, Texas, and West Virginia Pulp & Paper at Luke, Md., were shut down in January 1959.

Increased facilities for 1960 and 1961 are believed to be as shown on p. 792.

1959 Increase

Company	Site	Type Cells	Quantity, TPD
Diamond Alkali Co.	Deer Park, Texas	DeNora Mercury Cells	200
Jefferson Chemical Co.	Port Neches, Texas	Hooker S-3B Cells	150
Stauffer Chemical Co.	Niagara Falls, N. Y.	Hooker S-3M Cells	30
Weyerhaeuser Timber Co.	Longview, Wash.	DeNora Mercury Cells	80
Wyandotte Chemicals Corp.	Geismar, La.	Diamond Diaphragm Cells	300

1960-61 Increase

Company	Site	Type Cells	Quantity
Dow Chemical Co.	Plaquemine, La.	—	Expansion
Food Machinery & Chemical Corp.	S. Charleston, W. Va.	Hooker S-3B	Modernization and modest expansion
Hooker Chemical Corp.	Niagara Falls, N. Y.	Uhde Mercury	100 TPD
Kolker Chemical Corp.	Newark, N. J.	Hooker S	50 TPD
Olin Mathieson Chemical Corp.	McIntosh, Ala.	Mathieson (E-11) Mercury	125 TPD
Olin Mathieson Chemical Corp.	Niagara Falls, N .Y.	Mathieson (E-11) Mercury	About 50% increase
Pennsalt Chemicals Corp.	Wyandotte, Mich.	Gibbs	Modernization
Stauffer Chemical Co.	Henderson, Nev.	Hooker S	45 TPD

An estimate of chlorine capacity by companies appeared in the *Chemical & Engineering News,* December 14, 1959, p. 38.

The Canadian capacity at the end of 1959 is estimated by The Chlorine Institute of about 950 TPD. Western Chemicals Ltd., Duvernay, Alta., brought a 20 TPD diaphragm cell expansion on line in 1959. Consolidated Mining & Smelting Co. has announced plans for construction of a $2.6 million chlorine-alkali plant at Trail, B. C. Canadian Industries Ltd. has announced conversion of a number of mercury cells from NaOH to KOH. Pennsalt is apparently firming up its plans for a plant in the Vancouver, B.C., area.

Markets and End-Use Patterns

There does not appear to have been a major change in the end-use patterns for chlorine and caustic during 1959. The use of chlorine dioxide for bleaching in the pulp and paper industry is gaining in importance and is affecting chlorine usage.

The present use of chlorine in the extraction of titanium, zirconium, hafnium, columbium, and tantalum suggests the need for serious consideration of its use in the recovery of other metals. DuPont is using titanium tetrachloride for the production of titanium dioxide at its New Johnsonville, Tenn., plant. The general interest in this use for titanium tetrachloride could lead to a substantial use of chlorine in the future.

Table II. Chlorine—caustic soda end-use pattern*

Chlorine	%	Caustic soda	%
Chemicals	80.7	Chemicals	32.4
Pulp & paper	15.9	Rayon, film	14.9
Sanitation	3.2	Pulp & paper	11.4
Others	0.2	Soap, cleaners	6.0
		Petroleum refining	5.4
		Textiles	5.4
		Net exports	5.3
		Others	19.2
Total	100.0	Total	100.0

* Courtesy of Diamond Alkali Co.

The end-use pattern of caustic remains quite diversified. The alkali industry is watching the nylon-rayon battle for supremacy in the tire industry. Rayon remains the largest single use of caustic soda. The further application of caustic in the pulp and paper industry looks promising.

Table II gives a recent estimated end-use pattern for chlorine and caustic soda in 1959.

Technical Developments

With recent price reductions in power rectification units of silicon and germanium, the trend toward this type of unit will continue, especially where cell amperages are high and circuit voltages are low.

The interest of industry in platinum-titanium anodes for diaphragm and mercury cells continues. Articles of interest appeared in *Chemical Week,* December 12, 1959, p. 67, and *Chemical Week,* December 26, 1959, p. 50. The patent situation is not yet clear. Test installations exist but it is doubtful if any chlorine producer in the U. S., Canada, or England has made a decision at present for a large-scale installation.

For the first time in the U. S., liquid chlorine is being transported from a producer to a consumer in a tank truck (see *Chemical Week,* March 19, 1960, p. 31). Barge shipments of chlorine to large consumers on the Gulf and Atlantic shores, as well as on inland waterways, continue to increase.

The Chlorine Institute, Inc., continues a most aggressive program for the safe handling of chlorine in transportation and in producing and consuming plants.

Monsanto Chemical Co. continues to offer the DeNora cell for recovery of chlorine from hydrochloric acid. Although considerable interest has been shown, it is doubtful if a large-scale installation has been initiated at present.

Among articles of interest appearing recently, which have not otherwise been cited, were: "Chlorine Output Hits New High," *Chemical & Engineering News,* Dec. 14, 1959, p. 38; "Confidence Keys Chlorine Makers Outlook," *Chemical Week,* March 7, 1959, p. 113; "Chemical Forecast—1964," Chemical Market Research Association Report—*Oil,*

Paint & Drug Reporter, Sept. 28, 1959, pp. 44 and 47; "Alkalis and Chlorine Industry—Outlook for 1960 and Review of 1959," *U. S. Dept. of Commerce, BDSA, Chemical & Rubber Div.*, ER-59-86; "Cell Users Get New Fuel for Old Debate," *Chemical Week*, March 5, 1960, p. 95; "Graphitized Anodes in the Electrolysis of Aqueous Chloride Solutions," V. V. Stender and O. S. Ksenzhek, *J. Applied Chem., USSR*, **32** (1), 111 (1959);[1] "Influence of Electrolyte Composition on the Distribution of Current Inside a Graphite Anode and on Its Internal Wear," B. M. Bulygin, *J. Applied Chem., USSR*, **32** (1), 122 (1959).[1]

Among U. S. patents of interest which issued recently are: 2,868,711, electrolytic cell; 2,870,074, electrolysis of alkali metal chloride brine; 2,872,291, process and apparatus for the decomposition of alkali metal amalgams; 2,872,403, electrolytic cell; 2,884,-310, production of alkali metal hydroxides by ion exchange; 2,887,448, fused salt cell; 2,898,284, mercury cathode chlorine cell; 2,919,238, fused salt electrolytic cells.

Soda Ash

The U. S. production of soda ash increased about 13% from 1958 to 5,611,600 tons in 1959, thus reversing the downward trend since 1956. The only year of higher production was in 1956. The apparent per capita consumption was 61.6 lb for 1959, which was equal to the average of the years 1949 to 1959 inclusive. It is evident the per capita consumption of soda ash has not changed since the early 1940's. The U. S. industry operated at about 80% capacity in 1959; 12.7 % of the production was "natural soda" and 87.3% was "synthetic."

Diamond Alkali is engaged in a modernization program of its soda ash producing facilities at Painesville, Ohio. Dow Chemical Co. continues to operate its plant at Freeport, Texas, converting electrolytic caustic to soda ash. Dow is reported to be studying the possibility of increasing its capacity to produce soda ash. Considerable interest in the trona deposits in Wyoming has been indicated by several producers and potential producers of soda ash. Food Machinery & Chemical Corp. continues to expand in soda ash in Wyoming, and capacity is now in the 550,000 ton per year range.

Miscellaneous Chemicals

Potassium hydroxide.—Production of KOH (88-92%) increased about 21%, from 76,870 tons in 1958 to 92,869 tons in 1959. The trend toward high-purity KOH from mercury cells continues.

Chlorates.—The American Potash and Chemical Corp. began an expansion of its sodium chlorate facilities at Aberdeen, Miss., which will increase capacity to 25,000 tons per year. Hooker Chemical Corp. placed an additional circuit on line at its Columbus, Miss., plant, bringing capacity there to over 24,000 tons per year. Pennsalt Chemicals Corp. announced plans to expand its Portland, Oreg., sodium chlorate plant by 25%. The formation of the Penn-Olin Chemical Corp. was announced with the intent to construct a 25,000 ton per year sodium chlorate plant at Calvert, Ky. The new plant of Standard Chemical Ltd. at Beauharnois, Que., was placed in operation during late 1959. A review of markets for chlorates and perchlorates during 1958 and 1959 was published in *Chemical and Rubber*, August 1959.

Sodium chlorate production in 1959 was 87,665 tons, which was an increase of about 30% above the 67,249 ton production in 1958. Production has more than doubled since 1954.

Perchlorates. —Continued interest in solid-fueled missiles and the use of ammonium perchlorate as an oxidizer led to the announcement of plans by Pennsalt Chemicals Corp. to expand its plant at Portland, Oreg., by several thousand tons per year. During 1960, the Navy declared the ammonium perchlorate plant at Henderson, Nev., which is operated by the American Potash and Chemical Corp., as surplus to its needs, and arrangements are being made for disposal.

Miscellaneous Metals

Aluminum.—The production of aluminum in this country continues to grow. The primary production in 1959 of 1,953,000 tons set a new record; it was 25% above 1958 and 16% above 1956, the previous peak year for aluminum. Canada showed a decrease of 46,000 tons, or 7% less than 1958 production, during the past year.

At the end of 1959, total domestic capacity amounted to 2.4 million tons. New production facilities in 1959 included: (*a*) Ormet Corp. started its fifth and last pot line at its 180,000 ton per year plant at Clarington, Ohio; (*b*) Kaiser Aluminum & Chemical Corp. installed two new lines to complete its 145,000 ton per year plant at Ravenswood, W. Va.; and (c) Reynolds Metals Co. completed three lines at its new plant at Massena, N. Y., each having a capacity of 33,000 tons per year.

New aluminum prices established in December are 26¢ per lb for pig and 28.1¢ per lb for ingot.

Magnesium.—Consumption of primary magnesium reached about 44,000 tons in 1959, an increase of some 25% over 1958. While primary production of magnesium has been increasing steadily since 1958, the production rate of some 3,000 tons per month at the end of the year is still less than the consumption rate, although this production rate will be increased during 1960.

Alabama Metallurgical Corp., a new producer, began production of magnesium by the ferrosilicon reduction of dolomite last fall. This year, it should reach its anticipated capacity of 6 to 7,000 tons per year. The company is jointly owned by Calumet & Hecla and Brooks & Perkins.

The brightest possibility for significant expansion of the nonmilitary use of magnesium lies in its use in the engines of the lightweight automobiles. Expectations are that total consumption of primary magnesium will reach 45-50,000 tons in 1960, but the automotive die-casting outlet may cause an increase above this figure.

Sodium.—The production of sodium reached 112,-019 tons in 1959, only slightly more than the 1958 output and still much less than the 133,000 tons made in 1957. It is evident that with the production

[1] Reference pages of the English translation.

capacity at about 200,000 tons per year, the sodium industry faces for some time to come the problem of idle plant capacity.

Titanium.—During the first half of 1959, production and consumption of titanium sponge were at rates slightly greater than the 1958 average annual rate. In the second half of 1959, the steel strike cut the consumption of titanium sponge, and the production rate dropped accordingly. Imports of titanium sponge were about three quarters of the 1958 rate. In spite of the handicap of the steel strike, production of mill products increased. According to BDSA, in the near future consumption of titanium mill products will be reduced because of the cancellation of some defense aircraft programs which would have consumed substantial quantities of mill products. The growing use of titanium in construction of civilian aircraft, in missiles, and in the chemical process industries will only partly compensate for this loss. Therefore, consumption and production of titanium mill products in 1960 may be lower than in 1959. Growth in these uses and in other civilian applications is confidently expected in the future. Recently, ICI mentioned growth in the use of titanium in surgical implants, and suggests the use of titanium in nuclear applications because of the rapid dissipation of radioactivity which is formed when titanium is exposed to intense radiation. The development of new titanium alloys with improved qualities continues at a high rate.

An article of interest appears in *Chemical Engineering,* Feb. 22, 1960, p. 66

The Bureau of Mines and the Business and Defense Services Administration report the following figures:

	Sponge			Mill Products
	Production tons	Imports tons	Consumption tons	Shipments tons
1955	7,398	567	4,145 (est.)	1,898
1956	14,595	2,048	10,936	5,166
1957	17,249	3,532	8,221	5,658
1958	4,585	2,072	4,147	2,594
1959*	3,898	1,563	3,953	3,211

* Based on estimate, 10 months.

Zirconium.—The three companies, Carborundum Metals Co., Mallory-Sharon Metals Corp., and Columbia-National Corp., continue to supply zirconium sponge to the Atomic Energy Commission under contract. Columbia-National temporarily discontinued operations in December, 1959, because of a sponge quality problem with the AEC. The production of these three producers remains a little above 2,200,000 lb per year, and no future expansion of sponge producing facilities is planned at the present time.

Manganese.—The consumption of manganese metal derived by the electrolytic process amounted to 12,732 tons in 1959. This quantity would have been greater but for the long steel strike which began in July. At that time, the consumption had reached about 9,000 tons. Over 80% of this metal is used in the preparation of steel ingots, chiefly of the stainless variety.

Lithium.—The drastic cutback in the preparation of boron high-energy fuels caused the cessation in the production of lithium, as intermediate in the process, at the Olin Mathieson Chemical Corp. plant at Model City, N. Y. This plant had sufficient capacity to be a major producer of lithium by the electrolysis of fused lithium chloride admixed with potassium chloride in Downs type cells.

Beryllium.—Pure beryllium metal is made in the United States by the reduction of beryllium fluoride with magnesium. Both producers, Brush Beryllium Co. and Beryllium Corp., reported higher production of the metal in 1959 over 1958. It is estimated that production reached about 150,000 lb in 1959, compared with 50,000 lb in 1958, and it is expected that the figure will approach 300,000 lb in 1960 (*Chemical Week,* Feb. 20, 1960). Chief outlets for beryllium are in nuclear and space applications.

Chromium.—The electrolysis of ammonium chromium sulfate solution continues to be the premier source of the highest purity chromium metal. Production in 1959 probably reached about 2,000 tons, the reported capacity of the Union Carbide Metals Co.'s Marietta, Ohio plant.

Tantalum and columbium.—Tantalum production was estimated to be well over 300,000 lb in 1959, a sizable increase over the 1958 figure. Most of the metal is obtained either by the electrolysis of fused potassium fluotantalate or by sodium reduction of this and other tantalum compounds. Most of the metal is consumed in electronic applications, chiefly as capacitors. The production and use of columbium, found in all tantalum ores, are still small, probably around 60,000 lb in 1959.

Prices for tantalum were cut toward the end of the year. Capacitor grade powder dropped to $49.80 per lb from $58.60, and sheet tantalum is priced at $59.16 per lb.

Separation of the Defect Concentration and Diffusion Coefficient in Diffusion-Limited Scaling Reactions[1]

Arthur J. Rosenburg[2]

Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts

ABSTRACT

In diffusion-limited scaling reactions the rate constant is proportional to the quantity DC_0, where D and C_0 are the diffusion coefficient and the solubility of the defect whose motion through the growing scale is essential to continued reaction. In order to separate D and C_0, recourse is usually made to an independent measurement of one or the other, which is a difficult and frequently unreliable procedure. A new technique is proposed which permits the accurate and simultaneous determination of D and C_0 from reaction rates alone. The method is based on the controlled interruption of a scaling reaction and possesses a rigorous internal check. It is applicable in principle to any such reaction, and the necessary mathematical formulation is presented in a convenient analytical form. Conventional experimental techniques can be used when $C_0 >> 10^{17}$ cm^{-3}. The treatment is illustrated for the oxidation of InSb.

In diffusion-limited scaling reactions, of which the oxidation of metals provides the most familiar examples, direct contact of the reactants is prevented by the formation of a protective scale at the reaction interface. Once such a scale is formed, continued reaction is made possible by the motion of atomic defects through it. Thus, in the oxidation of a metal surface

$$yM + \frac{z}{2} O_2 = M_yO_z \qquad [1]$$

the formation of a nonporous film of M_yO_z on the surface prevents direct access of the oxygen to the underlying metal, but the diffusion of metal or oxygen defects, interstitial atoms or lattice vacancies, charged or uncharged, through the film lets the reaction proceed. One such defect predominates in a given oxide, and the rate at which the film continues to grow is given by (1, 2)

$$dX/dt = k\,X^{-1} \quad k = \Omega D(C_0 - C_1) \qquad [2]$$

where C_0 is the equilibrium concentration of the defect at the interface where it originates, and C_1 is the equilibrium concentration at the interface where the reaction is completed. D is the diffusion coefficient of the defect and is assumed to be independent of concentration. X is the film thickness, and Ω is the increase in the volume of the film which occurs when one defect completes its reaction.[3] Equation [2] assumes that space-charge effects at the boundaries of the oxide can be neglected. This is always the case for uncharged defects, and holds for charged defects when $X >> (\kappa\, kT/8\pi e^2 C_0)^{1/2}$ where κ is the dielectric constant of the oxide (usually ≈ 10), e is the electronic charge, and the other symbols have their usual meanings.

Upon integration Eq. [2] gives the familiar parabolic growth law

$$X^2 = 2kt \qquad [3]$$

It applies in principle to all reactions which are controlled by the diffusion of defects through a scale which deposits at the interface between the reactants. The reactants may be solids, liquids, or gases, and the scale may be solid or liquid, but solid scales at gas-solid, gas-liquid, liquid-solid, or liquid-liquid interfaces are most frequently encountered.

Since C_0 is generally much larger than C_1, and Ω is usually known, measurements of the parabolic rate constant k give the product DC_0 directly. By itself, however, this quantity is of little theoretical value. In order to separate D and C_0, which have fundamental significance, independent measurements of D or C_0 are required. These measurements are not only very difficult to make but are inconclusive unless differences in sample structure and purity are demonstrably negligible.

It is the purpose of this article to discuss a simple experimental method for simultaneously determining the quantities D and C_0. The method uses reaction rate measurements only and is applicable in principle to any scaling reaction described by Eq. [2].

Theory of Interrupted Kinetics of Diffusion-Controlled Scale Formation

We shall consider the generalized reaction

$$aA + bB = S \qquad [4]$$

where the product S forms a flat, nonporous scale which separates the reservoirs containing A and B. It is assumed that a defect enters the A/S interface ($x = 0$) and diffuses to the S/B interface ($x = X$) where it completes the reaction with B causing an increase, Ω, in the volume of the scale. Since the

[1] The work reported in this paper was performed at Lincoln Laboratory, a center for research operated by Massachusetts Institute of Technology with the joint support of the U. S. Army, Navy, and Air Force.

[2] Present address: Materials Research Division, TYCO Incorporated, Waltham, Mass.

[3] If, for instance, the defect is a metal atom, Ω is $1/y$ times the volume of an M_yO_z molecule.

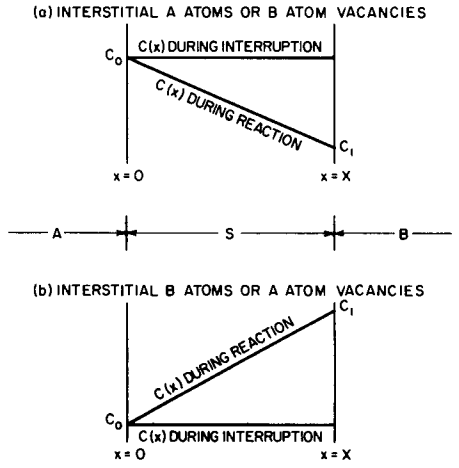

Fig. 1. Concentration of defects in a scale (S) interposed between A and B during the reaction $aA + bB = S$. In each case it is assumed that the supply of B can be interrupted while that of A is held constant.

diffusion of the defect controls the over-all rate, the reaction at each surface goes to equilibrium. The equilibrium concentration of the defect at $x = 0$ is C_0 while that at $x = X$ is C_1 (Fig. 1a). At intermediate positions in the scale the concentration is $C(x)$; if the diffusion coefficient of the defects is independent of $C(x)$, the latter is a linear function of x as shown in Fig. 1a.

Assume that the film has reached a thickness, X, and that its rate of growth is given by Eq. [2]. Let the concentration of B in its reservoir be reduced to a concentration which puts reaction [4] at equilibrium. (In a metal oxidation this would correspond to reducing the oxygen pressure to the dissociation pressure of the oxide.) The defects continue to enter the film at $x = 0$ but are no longer removed at $x = X$. Their concentration approaches C_0 throughout the film, and the reaction stops (Fig. 1a).

If the concentration of B is now suddenly raised to its value prior to the interruption, the flow of defects is resumed and the original concentration distribution is re-established. If C_0X is large enough, the restoration of the concentration gradient should resolve itself as a relatively fast initial uptake of B followed by a gradual return to the rate observed prior to the interruption.

Mathematically, the rate after the interruption can be treated as follows. In addition to requiring that D is independent of $C(x)$ and that the surface is flat, it is assumed that $X >> \Omega\, C_0$ (so the increase of X during this phase of reaction is negligible), and that defects can be created or destroyed only at $x = 0$ and $x = X$. Then at a given temperature,

$$\frac{\partial C(x)}{\partial t} = D\frac{\partial^2 C(x)}{\partial x^2} \qquad [5]$$

with the boundary conditions that

$$\left.\begin{aligned} &C(x) = C_0 \text{ for all } x && \text{when } t = 0\\ &C(x) = C_0 \text{ at } x = 0\\ \text{and}\quad &C(x) = C_1 \text{ at } x = X \end{aligned}\right\} \quad \text{when } t > 0 \qquad [6]$$

where t is measured from the readmission of B to the system. The equation is readily solved by standard techniques (3) giving

$$C(x) = C_0 - \frac{(C_0 - C_1)x}{X} + \frac{2}{\pi}\sum_1^\infty \frac{C_1\cos n\pi - C_0}{n}$$

$$\sin\frac{n\pi x}{X}\, e^{-D'n^2t} + \frac{4C_0}{\pi}\sum_0^\infty \frac{1}{2m+1}\sin(2m+1)$$

$$\pi\frac{x}{X}\, e^{-D'(2m+1)^2t} \qquad [7]$$

where $D' = D\pi^2/X^2$.

By taking the derivative of $C(x)$ with respect to x, evaluating it at $x = X$, and integrating from $t = 0$ to $t = t$, one obtains an expression for Δ, the number of defects crossing unit area at $x = X$ in time t.

$$\Delta = D\int_0^t \left(\frac{\partial C}{\partial x}\right)_{x=X} dt = \frac{D(C_1 - C_0)t}{X}$$

$$-\frac{2X}{\pi^2}\sum_1^\infty [C_1 - C_0(-1)^n]\left[\frac{1}{n^2}\right]$$

$$[e^{-D'n^2t} - 1] + \frac{4C_0X}{\pi^2}\sum_0^\infty \frac{1}{(2m+1)^2}[e^{-D'(2m+1)^2t} - 1] \qquad [8]$$

For most practical purposes $C_1 >> C_0$ and Eq. [8] reduces to

$$\frac{\pi^2\Delta}{XC_0} = 2\sum_1^\infty \frac{(-1)^n}{n^2} - 4\sum_0^\infty \frac{1}{(2m+1)^2}$$

$$- D't + 2\sum_1^\infty \frac{(-1)^n}{n^2}\, e^{-n^2D't}$$

$$+ 4\sum_0^\infty \frac{1}{(2m+1)^2}\, e^{-(2m+1)^2D't} \qquad [9]$$

Equation [9] has been solved numerically with the results given in Table I. The equation has two simple limiting forms. At the beginning of the reaction

$$\Delta = Bt^{1/2} \quad (t << X^2/D) \qquad [10]$$

where

$$B = 1.12\, D^{1/2}\, C_0 \qquad [10a]$$

Later in the reaction

$$\Delta = Q + Rt \quad (t > X^2/2D) \qquad [11]$$

where

$$Q = XC_0/3 \qquad [11a]$$

and

$$R = DC_0/X \qquad [11b]$$

Therefore, while direct rate measurements can at best give the product DC_0/X (Eq. [2] or [11b]) the

interrupted rate measurements give additional expressions for $D^{1/2}C_0$ (Eq. [10a]) and XC_0 (Eq. [11a]). A separation of D and C_0 is thus effected; in terms of the parameters in Eq. [10] and [11] one obtains

$$C_0 = \frac{0.8}{X}\frac{B^2}{R} \qquad [12]$$

$$C_0 = 3Q/X \qquad [13]$$

$$D = 1.25\left(\frac{RX}{B}\right)^2 \qquad [14]$$

It is clear from Eq. [12] and [13] that the parent Eq. [9] is overdetermined, since three independently measurable experimental quantities, B, Q, and R, must be quantitatively described with only two adjustable parameters, D/X^2 and XC_0. The entire formalism thus possesses the rare and wondrous quality of a rigorous internal check.

Experimental Procedure

The use of interruption kinetics depends on the feasibility (i) of reducing the concentration of B to its equilibrium value, and (ii) of measuring the arrival of defects at the S/B interface. Both are quite easily accomplished.

(i) The supply of B to the B reservoir can simply be cut off. The reaction then automatically proceeds to equilibrium, the scale acting as a sink for the residual B. If the reservoir is large, it may be evacuated or flushed with inert gas or liquid (depending on the system) and then closed off. The scale then acts as a source of B (by partial decomposition) and the concentration again adjusts to the equilibrium value. In most cases the latter is small enough so that the required decomposition is negligible.

(ii) When a defect reaches the outer interface it immediately reacts with a stoichiometric number of B atoms. The two kinds of atomic defects which can originate at $x = 0$ are interstitial A atoms or B atom vacancies. When the former reach $x = X$ they will combine with $\frac{b}{a}$ atoms (cf. Eq. [4]) while the latter will combine with one B atom. In either case the depletion of B atoms from the freshly filled B reservoir gives a direct measure of the arrival of defects at $x = X$. Δ_B, the total depletion of B atoms from the B reservoir after time, t, thus gives a direct measure of Δ, the quantity in Eq. [9]-[11]. It should be noted that one may determine Δ by measuring the increase in X, but this will generally be very difficult.

The question naturally arises as to what procedure should be used to measure Δ if the defects originate at the S/B surface, but, as before, the B concentration is the only quantity which can be varied and measured. The defects which can arise at the S/B interface are B interstitial atoms or A atom vacancies. Their concentration distribution before and after the interruption of the supply of B is compared in Fig. 1 with the case where the defects originate at the A/S interface. The obvious difference lies in the relative magnitudes of C_0 and C_1.

It turns out, however, that Eq. [9] is completely symmetrical and, with suitable changes in sign, describes each of the four cases equally well. Procedures (i) and (ii) are thus applicable regardless of the defect type, and the measurement of Δ_B again gives a direct measure of Δ. In order to make the treatment entirely general we shall redefine C_0 in Eq. [9]-[13] to mean the equilibrium concentration of the mobile defect at the interface where it originates when the reaction is proceeding normally. This may or may not correspond to the concentration during the interruption.

Since Δ_B is the quantity which is actually measured, it is convenient to use it directly. If Δ_B is substituted for Δ in Eq. [9], [10], and [11], then, instead of obtaining C_0 from Eq. [12] and [13], one obtains C_0^B whose relation to C_0 is summarized in Table II. The value of D is entirely independent of the units of Δ.

Use of Eq. [9]-[14]

The most convenient way to use Eq. [9]-[14] will be illustrated with recent data obtained on the oxidation of the intermetallic compound InSb where a thin protective scale of In_2O_3 is formed (4). A monocrystalline specimen exposing 4.0 cm^2 of flat surfaces was oxidized at 342°C and 0.3 mm oxygen until the total oxygen uptake was 5.76 x 10^{17} atoms cm^{-2}. The sample enclosure was evacuated and

Table II. Relation between C_0 and C_0^B in the reaction $aA + bB = S$

Defects originating at A/S interface	
1. Interstitial A atoms	$C_0 = \frac{a}{b} C_0^B$
2. B atom vacancies	$C_0 = C_0^B$
Defects originating at S/B interface	
3. Interstitial B atoms	$C_0 = C_0^B$
4. A atom vacancies	$C_0 = \frac{a}{b} C_0^B$

closed off for 15 hr without changing the temperature. Oxygen was then readmitted and the uptake measured by following the small pressure change at constant volume with a thermistor manometer. The results are plotted vs. $t^{1/2}$ and t in Fig. 2a and 2b.

As expected Fig. 2a is linear at small times, while Fig. 2b becomes linear at the longer times, and the rate approaches the value observed just prior to the interruption. The intercept of Fig. 2a is not zero. The value of the intercept, designated Z, can be treated as an additive constant for which a correction must be made in any expression containing Δ_B.

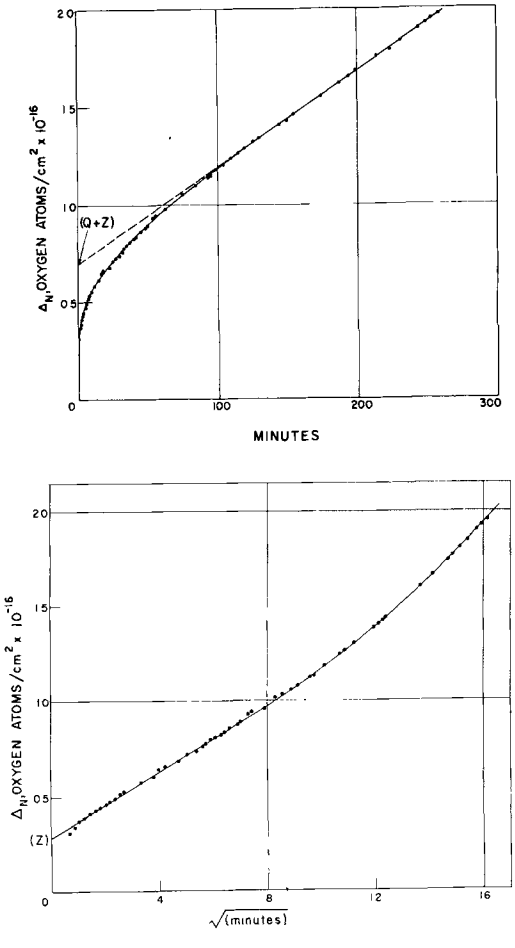

Fig. 2a (top), Fig. 2b (bottom). Interrupted oxidation of InSb. The uptake of oxygen was measured after a 15-hr interruption of the reaction at 342°C, p_{O_2} = 0.3 mm, and X ~1.24 x 10^{-5} cm. The time is measured from readmission of oxygen. The solid curves represent the solution of Eq. [9], modified by the inclusion of the additive constant, Z (see text).

From Fig. 2a and 2b one finds B, the slope of Fig. 2a to be 8.60 x 10^{14} oxygen atoms cm^{-2} min$^{-1/2}$; R, the slope of Fig. 2b to be 4.92 x 10^{13} oxygen atoms cm^{-2} min^{-1}, and Q, the intercept of Fig. 2b minus Z, to be 4.04 x 10^{15} oxygen atoms cm^{-2}. From Eq. [14] one obtains D/X^2 = 4.09 x 10^{-3} min^{-1}. From Eq. [13] one obtains XC_0^B = 1.212 x 10^{16} oxygen atoms cm^{-1}. From Eq. [12] one obtains XC_0^B = 1.202 x 10^{16} oxygen atoms cm^{-1}. The close agreement of the two independent values of XC_0^B provides the most important confirmation of the diffusion mechanism, and presages an excellent over-all description of the data by Eq. [9].

Substituting the value of D/X^2 and the average value of XC_0^B into the column headings of Table I, one obtains values of Δ_B vs. t and $t^{1/2}$ for the entire range of t. Adding Z to these values of Δ_B, plotting the results, and drawing a smooth curve through the points, gives the solid curves in Fig. 2a and 2b. The applicability of Eq. [9] is clearly verified in this case.

Values of D/X^2 and XC_0^B are thus obtained without reference to the chemistry or the thickness of the scale. Knowing X, one can obtain D directly. In order to determine C_0, however, one must know both X and the identity of the defect. The quantity X may be determined independently, or by using the total oxygen uptake combined with the stoichiometry of the scale and its molecular volume. For In_2O_3 the uptake of 5.8 x 10^{17} oxygen atoms cm^{-2} corresponds accordingly to *ca.* 1.24 x 10^{-5} cm.[4]

For reasons which are described elsewhere (4) it is believed that the mobile defects are interstitial In^{+3} cations arising at the $InSb/In_2O_3$ interface. Thus $C_0 = \frac{2}{3} C_0^B$. One obtains, accordingly[3] D = 1.04 x 10^{-14} cm^2 sec^{-1}, C_0^B = 1.22 x 10^{21} oxygen atoms cm^{-3}, C_0 = 8.1 x 10^{20} In^{+3} ions cm^{-3}.

Practical Considerations

(i) The length of time for which the reaction is interrupted must exceed X^2/D if the equilibrium concentration is to be attained throughout the film.

(ii) The quantity $Q^B = XC_0^B/3$ must be considerably larger than the sensitivity limit of the analytical technique. For gaseous reactions the sensitivity of microgravimetric methods is usually about 10^{15} atoms, while standard low-pressure manometric techniques (thermistor or Pirani gauge) permit measurements of 10^{14} atoms. For practical film thicknesses (< 10 μ) and surface areas (< 10 cm^2), C_0^B must exceed *ca.* 10^{17} cm^{-3}. The use of larger areas, thicker films, or very low-pressure techniques, although less convenient, would extend the practical limit of C_0^B to substantially lower values. For practical reasons it is also evident that $DC_0^B t_{min}$ must be smaller than $XC_0^B/3$ where t_{min} is the minimum time before which a measurement can be made after the readmission of B to the system.

(iii) When $XC_0^B/3$ is less than 10^{15} atoms cm^{-2},

[4] The geometric surface area to which the data is normalized is a factor, F, ("roughness factor") less than the true area. If $F \approx 1.3$ as is believed to be the case for chemically polished InSb, the corrected values of X, D, C_0^B, and C_0 are 9.5 x 10^{-6} cm, 6.15 x 10^{-15} cm^2 sec^{-1}, 1.57 x 10^{21} cm^{-3}, and 1.05 x 10^{21} cm^{-3}, respectively.

one may encounter spurious effects due to chemisorption. Since chemisorption usually proceeds much more rapidly than the diffusion reaction described by Eq. [9], it will contribute an additive constant to Δ_B in a manner analogous to that observed in Fig. 2a.[5]

[5] In the case of InSb the effect is not thought to be associated with simple chemisorption of oxygen (4).

The Electrical Properties of Some Natural Waxes

Thomas D. Callinan and Ann M. Parks

International Business Machines Corporation, Yorktown Heights, New York

ABSTRACT

The dielectric constants and dielectric loss factors of Carnauba, Ouricuri, and American Montan wax determined over a temperature range of —60° to 90°C and at frequencies of 0.1, 1, 10, and 100 kc, indicate that the component omega-hydroxy acid esters rotate in the solid state in the temperature region 25°-70°. Furthermore, from dipole measurements, the molecules were found to possess a trans-trans configuration.

Recent advances in dielectric spectroscopy (1) suggested that this might prove a valuable tool in the determination of the nature of waxes. By dielectric spectroscopy is meant the elucidation of certain properties of materials in terms of their molecular and atomic constituents through an analysis of their dielectric constants and dielectric losses over a broad temperature (—100° to 200°C) and broad frequency (dc to 10^{10} cps) range. From the discipline as it now stands, it is possible to establish the presence and magnitude of permanent electric moments in the component molecules and to determine whether association exists. Certain peaks and troughs in the loss spectra may also be related directly to the molecular structure.

Using this technique, it has been found possible to establish the essential molecular structure of such naturally occurring waxes as Carnauba, Ouricuri, and Montan wax and to suggest why they behave the way they do in certain circumstances. In each case, the dielectric constant and dielectric loss factor were determined at frequencies between 100 and 100,000 cps at temperatures in the range —60° to 98°C, and the dipole moments of each were calculated from measurements made on benzene solutions of the waxes.

Materials

The Carnauba wax used in these tests was derived from a genus of palm known as *Copernicia Cerifera Martius*. The wax was obtained from mature leaves and bears the commercial designation "North Country No. 3" and the provincial name "Gordierosa." The solid was a hard, brown material which melted abruptly at 79°C. It has a specific gravity at 25°C of 0.9988. Chemically, Carnauba wax is a mixture of alkyl esters (85%) and uncombined acids, alcohols, lactides, and hydrocarbons. Approximately 40% of the wax consists of omega-hydroxy acid esters having the formula:

$$HO—C_nH_{2n}C(O)O\,C_mH_{2m}+1$$

where n and m may be 18, 20, 22, or 28, (2). No effort was made to separate the components of Carnauba wax as it was the purpose of the work to study the material as a mixture.

Ouricuri wax is derived from the undersurface of the leaves of the palm tree known as *Attalea Excelsa Martisu*. It is a hard, dark brown solid, having a specific gravity at 25°C of 1.06661 and melts at 69°C. The wax is considered to have the following composition: alkyl esters (myricyl cerotate) and hydroxy esters total 61%, free wax acids 11%, resin acids 4%, resinols 15%, hydrocarbons 7%, and residue 2% (2).

Montan wax is a brown-black solid extracted from a California lignite. It has a specific gravity of 1.020 at 25°C and melts at 77°C. It is considered to be composed of esters of wax acids (53%) including hydroxy acids. It resembles, therefore, the Carnauba and Ouricuri waxes, (2).

Some of the properties of these waxes are tabulated in Table I.

Experimental Methods

Each wax was melted and poured into an Elliott cell (3) previously heated in an air oven to 100°C. In actual practice the cell was modified by drilling holes in the base so that dry nitrogen gas could be passed around the electrodes and sample during measurement. This effectively eliminated interference by moisture condensation in the 0°C region. The assembled and filled cell was removed from the oven and allowed to cool to room temperature. Dielectric properties were then determined from

Table I. Select properties of waxes

Acid value	50-55	21-24	3

measurements on the General Radio 1610-A capacitance bridge network. Measurements were made as the samples slowly cooled from 95° to 25°C and as they warmed from −60° to 25°C.

The resistance of each wax sample was measured in the Elliott cell on a General Radio Type 544-B megohm bridge in the temperature range of 25°-95°C. Results are expressed in terms of the volume resistivity of the sample in order to correct for the resistance in the cell itself.

Dipole moments were calculated from measurements on dilute benzene solutions of the waxes. The density of each solution was measured on a Seederer-Kohlbusch density balance and the refractive index measured on a Spencer Refractometer at 24°C. The dielectric constant was measured in a two terminal Balsbaugh cell with a volume of 75 cc, at 24°C and 10,000 cps frequency. This frequency is believed to be above the range of ionic vibrations in the molecules, and the polarization calculated is a result of induced and orientation polarizations. The molar polarization and refraction were calculated according to the Clausius-Mosotti (4) and Debye (5) equations. This method involves use of the relationships

$$P = \frac{\epsilon' - 1}{\epsilon' - 2} \cdot \frac{M_1N_1 + M_2N_2}{d}$$

$$\text{and } R = \frac{n^2 - 1}{n^2 + 2} \cdot \frac{M_1N_1 + M_2N_2}{d}$$

where P is the molar polarization, ϵ' the dielectric constant, d the density, M and N refer to the molecular weights and mole fractions of solute and solvent, R is the molar refraction, and n is the refractive index.

By linear extrapolation of the molar polarization to infinite dilution the dipole moment of the molecules is calculated from the relationship $M = 0.0128 \sqrt{(P-R)\,T}$, where T is expressed in absolute degrees.

Dielectric Properties of Carnauba Wax

The dielectric constants ϵ' and dielectric loss factors ϵ'' of Carnauba wax are listed in Table II and are shown graphically in Fig. 1. At very low temperature, the dielectric constant of Carnauba wax is low (2.16-2.29) and differs only slightly at different frequencies. As the temperature rises the dielectric constant increases at first slowly (0.006/degree) and then more rapidly (0.02/degree) until a temperature is reached at which the dielectric constant passes through a maximum and decreases with further increases in temperature. Concomitant with these changes in dielectric constant, there are changes in dielectric loss factor. All pass through a maximum at different temperatures depending on the frequency.

At higher temperatures the dielectric loss factors show runaway tendencies at low frequencies reaching values greater than the maxima obtained at lower temperatures.

Dielectric Properties of Ouricuri Wax

The dielectric constant ϵ' and dielectric loss factor ϵ'' of Ouricuri wax as a function of frequency and temperature is shown graphically in Fig. 2 based on the data listed in Table III. At low temperatures and all frequencies the dielectric constants and dielectric loss factors are again low.

As was observed above the temperature coefficient of change in dielectric constant changes markedly at about 25°C from 0.003/degree to 0.02/degree. It then passes through a maximum in the vicinity of the melting point of the wax, when determined at frequencies higher than 1 kc. Runaway characteristics are observed above 50°C, but below this temperature the dielectric loss factor curves pass through a maximum at a characteristic temperature for each frequency.

Dielectric Properties of Montan Wax

The dielectric constant ϵ' and dielectric loss factor ϵ'' of American Montan wax are listed in Table IV and are shown graphically in Fig. 3. The dielectric constant remains low and increases only slowly (0.008/°C) on passing from —60° to 25°C. Above this temperature there is a rapid increase resulting in an apparent dielectric constant of 16 at 98°C; this is accompanied by and attributable to very high losses. These losses are so high that they swamp the usual maxima in the dielectric constant at the melting point; the only suggestion of it existing comes from the definite plateau which occurs at 100,000 cps. Again, however, each loss curve passes through a maximum at a definite temperature.

Comparison of Electrical Properties

For the sake of comparison and to interpret the dielectric loss spectra the volume resistivity of each wax as a function of temperature is shown in Fig. 4. In each case the resistance remains constant until the wax begins to melt. At this point the resistance decreases rapidly and levels out again in the liquid.

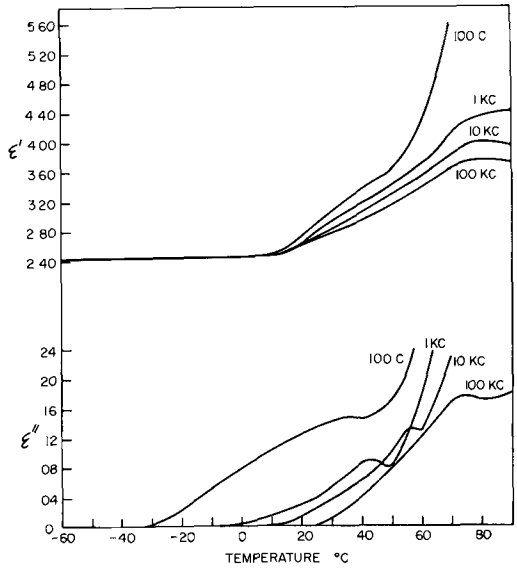

Fig. 3. Variation of the dielectric constant ϵ' and dielectric loss factor ϵ'' of American Montan wax with temperature at 100, 1,000, 10,000, and 100,000 cps.

$M = 920$	1×10^{-5}	2.2772			
	5×10^{-5}	2.2780			
Ouricuri	4×10^{-6}	2.2811	4200	3037	7.5
$M = 848$	9×10^{-6}	2.2803			
	4×10^{-5}	2.2839			
	9×10^{-5}	2.2855			
Montan	1×10^{-5}	2.2763	885	472	4.5
$M = 834$	2×10^{-5}	2.2780			
	1×10^{-4}	2.2800			
	2×10^{-4}	2.2833			

Ouricuri shows less conductivity than Montan and lower dielectric losses. In the solid waxes, however, the order of increasing conductivity is Carnauba, Montan, Ouricuri, but Ouricuri generally shows the lowest losses. Correlation in this region is difficult, however, due to the presence of maxima in the loss curves.

Because of the temperature and frequency dependence of the dielectric constants of the waxes, relatively high dipole moments are indicated. The results of these measurements are shown in Table V. Montan and Carnauba have essentially the same dipole moments, but that of Ouricuri is considerably higher. As was shown above Ouricuri also has the highest dielectric constant at 24°C followed by Montan and Carnauba. Calculation of the theoretical dipole moment for various configurations of a planar omega-hydroxy acid ester such as is present in the waxes leads to the conclusion that these esters must be arranged predominately in a trans-trans configuration. This arrangement is shown in Fig. 5 and predicts a moment of 4. 3D on the basis of known bond moments and angles (6a). The opposite configuration, the cis-cis form in which the hydroxyl hydrogen and the alkyl group of the esters are on the same side of the chain as the carbonyl predicts a moment of only 0.25D. Combination of the *cis* and *trans* forms lead to theoretical moments of 2.65D.

The dielectric properties of the waxes at 25°C are reproduced graphically in Fig. 6. The Ouricuri wax

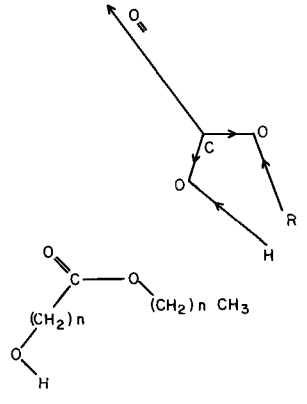

Fig. 5. Vectoral representation of trans-trans omega-hydroxy acid ester.

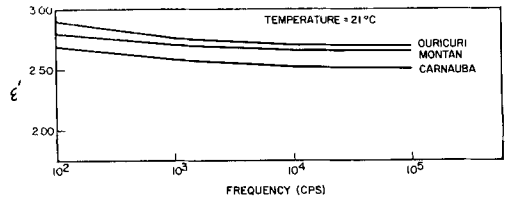

Fig. 6. Comparison of the dielectric constants ϵ' of the waxes

shows the highest ϵ' throughout the frequency range with Montan wax and Carnauba wax placing second and third in that order.

All three natural waxes were found to possess dielectric constants which were highly dependent on temperature and two discrete regions where the temperature coefficient of dielectric constant differed. Both Fitzgerald (7) and Stempel (8) have shown that the waxes remain crystalline to within six degrees of their respective melting points.

Conclusions

In view of the fact that the change in the temperature coefficient of the dielectric constant being discussed occurs well below the melting points of the waxes, a mechanism analogous to that observed on abrupt melting of organic crystals does not apply. This leaves us with the explanation of molecular rotation similar to that found in water and some organic crystals.

Molecular rotation has been also reported to occur in a number of long-chain compounds such as primary alcohols. These compounds are known to exist in alpha and beta forms, and rotation takes place about the axis of the chain in the alpha or high-temperature form (9). That this mechanism also applies to the three waxes under consideration is confirmed by the similarity of their dielectric behavior to that observed in 1-docosanol, a material previously shown to exhibit molecular rotation (6b). In this case the dielectric constant is strongly temperature dependent and shows a fivefold increase in the temperature coefficient of change in dielectric constant at about 26°C, a temperature well below its melting point.

Since the three waxes are composed largely of omega-hydroxy acid esters, the mechanisms of the effects determined dielectrically are interpreted to be as shown in Fig. 7. The molecules tend to align themselves in an orderly fashion. At very low temperatures there is high cohesion between parallel chains and strong head-to-head attraction between hydroxyl groups. As the temperature rises the hydrogen bonding between hydroxyl groups is reduced so that the molecules can rotate around the molecular

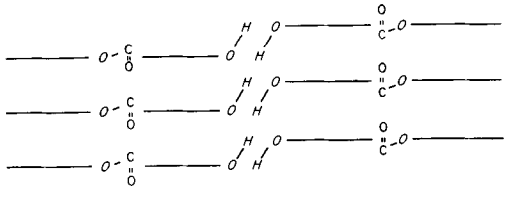

Fig. 7. Molecular arrangement of omega-hydroxy acid esters in wax crystals.

axis but remain in an orderly bundle. At elevated temperatures the cohesion between chains is reduced and the material melts. The noted differences between the three waxes are believed to be caused by differences in the relative amounts of esters and other materials present.

Manuscript received Feb. 15, 1960. This paper was prepared for delivery before the Philadelphia Meeting, May 3-7, 1959.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1961 JOURNAL.

Factors Influencing the Luminescent Emission States of the Rare Earths

L. G. Van Uitert

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

The number of electronic states from which luminescent emission by rare earth ions can be observed is dependent on the extent to which the host lattice perturbs their f-orbital electrons. Among others, perturbing influences may stem from the following sources: (*a*) coulombic affinities of the ions or molecules surrounding the rare earth ions for the electrons they share with the latter; (*b*) concentration effects, i.e., exchange coupling; (c) thermal effects, i.e., vibronic interactions.

Results obtained on metal organic complexes, hydrates, fluorides, and tungstates are compared. The effects on emission of the rare earth ion concentration in the tungstates are compared for europium, terbium, dysprosium, and erbium at room temperature, and the influences of thermally excited interactions on the emission of erbium are demonstrated.

In principle, emission should be observable from all of the excited states of the rare earth ions when they are not influenced by their surroundings. Of course, this condition cannot be fully realized in the solid state. However, different environments have markedly different influences on the rare earths. In the case of europium, for example, the number of states from which emission is observed varies from one in its chelate compounds to four in its oxides (1-3). Even in a given structure, the number of states from which emission is observed can be quite dependent on the rare earth concentration (4, 5) and thermal effects (6). In this paper, the influences of a number of environments on the luminescent emission of several of the rare earths are compared, and the factors which appear to be responsible for the relationships observed are discussed.

Materials

Members of the series $Ca_{1-2x}Na_xRE_xWO_4$, where RE = europium with $x = 3 \times 10^{-5}$, 10^{-4}, 5×10^{-4}, 10^{-2}, 10^{-1}, and 0.50; RE = terbium with $x = 10^{-4}$, 10^{-3}, 10^{-2}, 5×10^{-2}, 0.2, and 0.5; RE = dysprosium with $x = 5 \times 10^{-6}$, 10^{-4}, 10^{-3}, 5×10^{-3}, 10^{-2}, 10^{-1}, 0.25, and 0.50; and RE = erbium with $x = 10^{-5}$, 3×10^{-5}, 10^{-4}, 10^{-3}, 10^{-2}, 3×10^{-2}, 10^{-1}, 0.25, and 0.50, were prepared by crystallization from a $Na_2W_2O_7$ flux, as previously described (7). The crystals obtained by this method are nearly perfect in structure compared to those obtained by sintering techniques and therefore are suitable for making emission intensity comparisons. Emission from samples of a given composition grown at various rates, and hence of quite different crystallite size, compares in intensity to within a few per cent of one another under the measuring conditions employed.

Measurements

Measurements were made employing a Gaertner high dispersion spectrometer with an AMINCO photomultiplier microphotometer which employed a 1P22 photomultiplier tube. The system was calibrated against a tungsten lamp to give relative values of brightness of the emitting surface in units of power per unit wave-length range. Emission was excited by illuminating a sample 1 in. long by ½ in. wide by ¼ in. deep with a 3660Å rich H4 spotlight through a Corning 5874 filter. All of the intensity measurements are relative to 100 for the 5450Å peak of a comparable sample of $Na_{0.5}Tb_{0.5}WO_4$.

Discussion

The number of electronic states from which luminescent emission by rare earth ions can be observed may be expected to depend on the extent to which the host lattice perturbs their electron envelopes. The number of emitting states observed does not appear to be as critically dependent on geometric considerations as the crystal field splitting or the relative strengths of the emission lines. Among others, the perturbing influences may stem from the following sources: (*a*) the coulombic affinities of the ions or molecules surrounding the rare earth ions for the electrons they share with the latter; (*b*) concentration effects, i.e., exchange coupling; (c) thermal effects, i.e., vibronic interactions.

Coulombic Affinities

There is considerable evidence that bond strength, which may be expected to bear directly on perturbing influences, increases with an increase in the affinity of one or both of the bonded atoms for the electrons shared (8, 9). As a first approximation one may consider the electron affinities or ionization potentials of the ions or molecules surrounding the rare earth ions in the several host lattices to provide a measure of the extent to which these surroundings may perturb the f-orbital electrons of the rare earths. A comparison of the values given in Tables I and II shows that the third ionization potential of lanthanum, which may be considered to be representative of the rare earths, is larger than the ionization potentials of H_2O or organic oxygen and is much larger than the electron affinities of fluorine or oxygen. Hence, one cannot ascribe full possession of the electrons about these molecules and ions to themselves when they are bonded to trivalent rare earth ions. Electron diffraction work carried out on beryl ($Be_3Al_2Si_3O_{18}$) by Bragg and West (13) has shown that in the silicates the silicon and oxygen atoms are closer to the Si^{+} and O^{-} ionic states than to the Si^{4+} and O^{2-} states. Hence, one may expect the ionization potential of oxygen to depend on the central cation when it is part of an anionic group such as $WO_4^{=}$.

In a similar manner, the electron affinity of an organic oxygen atom is dependent on the nature of the molecule of which it is part. Coulson (14) has shown that for carbon-carbon bonding one may expect an increase in the electron affinities of the carbon entities as the s-character of their σ bonds increases in the order sp^3 (single bonding), sp^2 (double bonding), and sp (triple bonding). This is a consequence of the fact that the s-orbital lies lower energetically than do the p-orbitals. It may be expected that a similar increase in the multiple bond character of isoelectronic oxygen would result in its having an increased electron affinity. Hence, one may expect a stronger bonding of ketonic oxygen (double bonded to carbon) to the rare earth ions than occurs with ethers or alcohols. Further, one might expect an additional increase in bonding strength to the rare earths through the oxygen atoms of chelating agents such as acetylacetone by the development of resonance structures and a reduction in entropy.

The above considerations, in conjunction with the observations given below, suggest that the following environments diminish in perturbing influence in the order: O—O chelates, ketones and hydrates, fluorides, high central charge anionic groups ($WO_4^{=}$), less covalent oxides. In the case of europium, one emission state (17,300 cm^{-1}) is active in the chelate (1, 15), and an additional state (19,000 cm^{-1}) is observed in the hydrate (1); a third (21,500 cm^{-1}) is apparent in the fluoride (3), and a fourth (24,200 cm^{-1}) in the tungstate (5) and calcium oxide (16). In a like manner, one emission state (20,700 cm^{-1}) is observed for terbium in the chelate, hydrate (1), and fluoride (3); a second is found in the tungstate (4); and there are possibly three or more when terbium is combined with aluminum oxide (4, 17). Erbium does not luminesce in the chelate or hydrate but exhibits two main emission states (15,300 and 18,400 cm^{-1}) in the fluoride (3) and a third (24,500 cm^{-1}) in the tungstates (6) and calcium oxide (16). Parallel patterns are observed for a number of the other rare earths.

Concentration Effects

Increasing the rare earth concentration can produce effects quite comparable to those found on changing the host environments. This is readily observed by comparing members of the series $Ca_{1-2x}Na_xRE_xWO_4$. Figure 1 shows the dependencies of the intensities of emission from the 26,500 and 20,700 cm^{-1} states of terbium on the concentration of terbium in the above tungstates and of the 20,700 cm^{-1} state of terbium when it is substituted totally or in part for yttrium in yttrium hexa-antipyrene tri-iodide (4). These values are represented

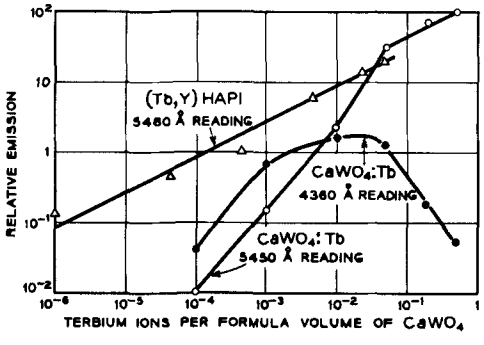

Fig. 1. Relative emission vs. the concentration of terbium

by the intensities measured for the emission peaks at 4360 and 5450Å in the tungstates and 5480Å in the antipyrene complexes, respectively. The metal ions are separated by 14Å in the antipyrene complexes; hence, they can be considered to be isolated from each other. Therefore, it is reasonable to employ the curve for the antipyrene complexes as a reference for the dependence of emission intensity on concentration for strongly bonded terbium ions.

In the dilute materials, the emission from the tungstates is much weaker than that from the antipyrene complexes. However, at high terbium concentrations, the tungstates compare favorably to terbium hexa-antipyrene tri-iodide and take on the emission characteristics of its yttrium substitution series in its intensity dependence on concentration and number of emission states. This is equivalent to a change from a relatively ionic to a more covalent or stronger bonding environment and appears to be related to the development of exchange coupling between the paramagnetic rare earth ions.

Figure 2 shows the dependencies of the intensities of emission from the 24,200, 21,500, 19,000, and 17,000 cm^{-1} states of trivalent europium (represented by the values measured for the peaks at 4312, 5105, 5545, and 6140Å, respectively) on europium concentration. The relationships shown suggest that the emission from 24,200 cm^{-1} is quenched by the pairing of europium ions (they occur in neighboring calcium sites) and emission from 21,500 and 19,000 cm^{-1} is quenched by the association of three or more europium ions (5).

In contrast to the behavior exhibited by europium, the intensities of emission from 24,500, 18,400, and 15,300 cm^{-1} exhibited by erbium vary uniformly (as shown in Fig. 3 which is discussed below) instead of quenching sequentially with increasing concentration. This provides supporting evidence that the quenching observed for terbium and europium is not due to an emission and reabsorption process.

The spectrum of dysprosium in calcium tungstate which is observed in the visible range is due to emission from an electronic state (2, 3) at 21,000 cm^{-1}. The dependence of the intensity of emission from this state (represented by the values measured for the strongest peak which is at 5750Å) on dysprosium content is shown as part of Fig. 4. Dysprosium luminesces a bright yellow at a 1% concentration but is completely quenched in $Na_{0.5}Dy_{0.5}WO_4$. The quenching observed in this case also appears to be due to exchange coupling.

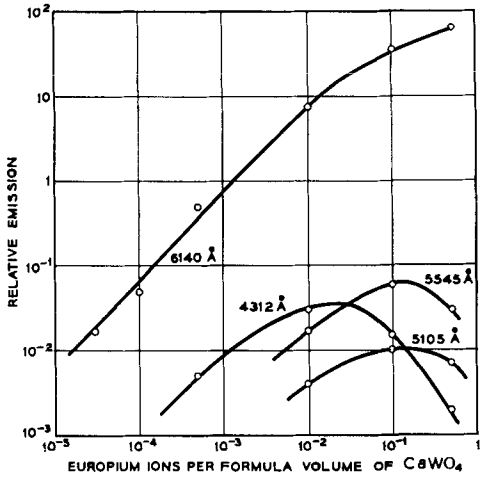

Fig. 2. Relative emission vs. the concentration of europium

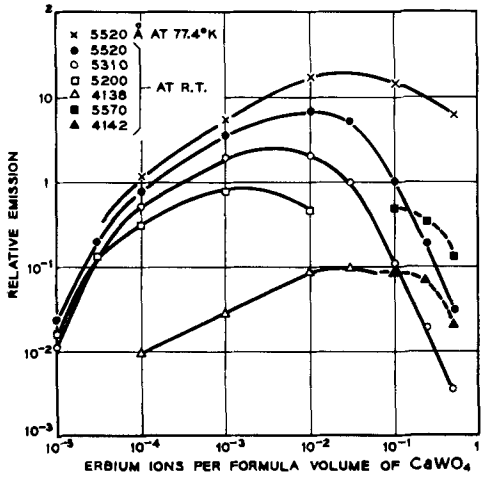

Fig. 3. Relative emission vs. the concentration of erbium

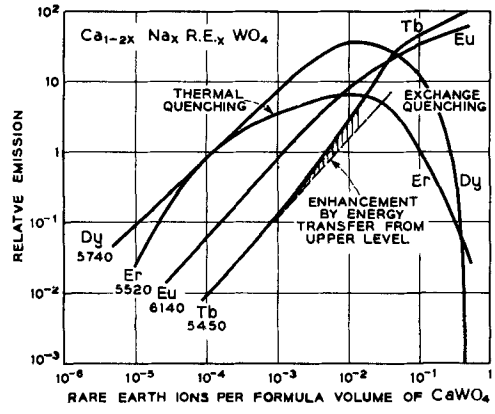

Fig. 4. Relative emission vs. rare earth concentration

Thermal Effects

Thermal effects play an important role in the emission spectra of erbium in the scheelite structure. Besides the three main emission states at 15,300, 18,400, and 24,500 cm^{-1}, erbium shows strong emission from thermally excited levels at 18,830, 19,080, and 19,200 cm^{-1} at room temperature (6). In $Na_{0.5}Er_{0.5}WO_4$, emission from the above states is quenched at room temperature, thus allowing emission from states that are probably just below those at 18,400 and 19,200 cm^{-1} to be seen. At 77°K emission from the thermally excited states is no longer observed, but emission from the high erbium content samples is again very bright (6). Figure 3 shows the dependencies of the intensities of emission from the 18,400, 24,500, 18,830, and 19,200 cm^{-1} levels of erbium (represented by the values measured for the peaks at 5520, 4138, 5310, and 5200Å, respectively) on erbium concentration at room temperature. It also shows the comparable data for levels which are presumed to lie just below those

at 18,400 and 19,200 cm^{-1} (represented by the values measured for the peaks at 5570 and 4142Å, respectively). The comparable data for the peak at 5520Å at 77°K are also given.

The relationships observed show that emission from the thermally excited states of erbium is quenched by increasing the concentration of erbium as well as by lowering the temperature. However, while the emission from the principal excited states is also quenched by increasing the concentration of erbium at room temperature, lowering the temperature reduces the effectiveness of this quenching mechanism and bright emission is obtained from these levels. The effects noted are quite probably due to vibronic interactions and their dependence on temperature. Since the peaks at 5570 and 4142Å do not show the same concentration or thermal dependencies as their close neighbors, they may originate from levels which, while only a few wave numbers below the dominant levels, do not couple thermally to the lattice in the same way.

Comparisons

Figure 4 presents a comparison of the dependencies of emission at room temperature on rare earth concentration for the dominant excited states of the several rare earth ions discussed. The curve for the emission measured for the 6140Å peak of europium appears to be a reliable reference for the following reasons: (*A*) The dilute materials show an almost linear dependence of emission on europium concentration. The deviation observed at high concentration is consistent with the change in environmental conditions discussed in the case of terbium. (*B*) The aggregate emission from the excited states, other than that at 17,000 cm^{-1}, is never more than a few per cent of the latter. Thus, possible emission enhancement due to energy transfer from higher levels as a result of changing environmental conditions would not be significant. (*C*) Emission from the 17,000 cm^{-1} level of europium does not appear to be quenched by concentration or thermal effects in these compositions.

The curve for dysprosium shows the same linear dependence as the one for europium at low concentrations. The rapid decrease in emission as the dysprosium concentration increased above 10^{-2} provides an excellent example of concentration quenching. This effect, as well as the quenching of emission from the higher energy states of terbium and europium, is not altered by reducing the temperature to 77°K.

Concentration quenching of emission from the higher of two energy states can occur so as to permit energy transfer to the lower, thus enhancing emission from it. The data for terbium provide an example of such a transfer. Figure 1 shows that at low terbium concentrations the emission from 26,500 cm^{-1} (as indicated by the data for the peak at 4360Å) is about three times as bright as that from 20,700 cm^{-1} (represented by the data for the peak at 5450Å). As the terbium concentration is increased from 10^{-3} to 5×10^{-2}, both curves deviate from linearity, the curve for the peak at 4360Å in a direction which indicates a relative loss in brightness and the curve for the peak at 5450Å in a direction which indicates a relative gain in brightness. The latter curve is readily compared to the curve for the 6140Å peak of europium in Fig. 4. The arithmetic sum of the two terbium emission curves provides a resultant curve that is symmetrical with that for the 6140Å peak of europium.

The curve in Fig. 4 for the emission at room temperature for the erbium peak at 5520Å shows the effects of a quenching process which has a strong thermal dependence. This curve deviates strongly from linearity at concentrations of erbium as low as 10^{-4}, in addition to showing strong quenching effects above 10^{-2}, as do the curves for dysprosium and the higher emitting states of terbium and europium.

Electroluminescence—A Disorder Phenomenon

D. W. G. Ballentyne

Harlow Research Laboratories, Associated Electrical Industries Limited, Harlow, Essex, England

ABSTRACT

In general, electroluminescence is considered to occur at a junction between a semiconducting crystal and a metal or electron rich material. The present work indicates that electroluminescence only occurs in zinc sulfide powders containing both sphalerite and wurtzite. This observation suggests that electroluminescence is a disorder phenomenon associated with stacking faults in the crystal.

Two types of electroluminescence have been observed. Certain substances (e.g., SiC, GaP, etc.) (1) emit light when subjected to a direct electric field applied between electrodes in contact with the surface of the crystal. This emission, carrier injection electroluminescence, is simply explained by the recombination of injected carriers at p-n junctions. The second type of electroluminescence, intrinsic electroluminescence (2), gives rise to the sustained emission of light on the application of an alternating field to the phosphor suspended in a dielectric. In this case, carrier injection is not possible, and the effect has been explained by the acceleration of carriers in an exhaustion barrier in the phosphor, say zinc sulfide activated with copper, at an interface with an electron rich layer of copper sulfide. Such a mechanism does not explain fully certain observations. Many workers have observed that light can be emitted internally from a crystal (2, 3). Steward, *et al.* (4) showed that the electroluminescent emission from a ZnS platelet occurred in bands parallel to birefringent-colorless bands denoting regions of wurtzite and sphalerite. Ultraviolet emission occurred throughout the crystal, and it was concluded that the emission in this case was associated with stacking faults in the c-direction. McKeag and Steward (5) reported a new method of preparing a zinc sulfide phosphor, which consisted of prefiring ZnS at 1200°C, activating with copper at 700°C. The material was electroluminescent throughout the body of the crystal. The copper necessary for the activation entered the crystal most effectively at the refiring stage which was the temperature where the transformation from the hexagonal to cubic zinc sulfide occurred most readily. There existed a correlation between electroluminescence and disorder.

In the present work (6) it is intended to show that in all cases investigated electroluminescent phosphors consist of mixtures of sphalerite and wurtzite. This structure is associated with a redistribution of trapping levels with the removal of the deep traps. An electroluminescent phosphor has been prepared without the addition of a substance capable of forming an electron rich layer. This phosphor also has a disordered structure.

Experimental Results

Two types of general electroluminescent phosphors were prepared. One type of phosphor was prepared according to the Froelich (7) method at 1100°C, while the other group was prepared according to the Butler (8) method at 800°C. Various activators, copper, silver, and manganese, and various coactivators, aluminum, gallium, indium, and thallium, were added. The crystal structure of the phosphors was determined using a 9 cm Unican Powder camera in conjunction with a Raymax 60 x-ray set.

In Fig. 1 the diffraction photographs of a series of phosphors fired at 1100°C in wet H_2S are given. The phosphors A, B, and C containing less than 10^{-4} g Cu/1 g ZnS are totally hexagonal in structure and are not electroluminescent. Phosphors D and E containing copper in excess of 10^{-3} g Cu/1 g ZnS contain both cubic and hexagonal zinc sulfide. These phosphors are electroluminescent. In the actual case

A, 1 g ZnS 1 x 10^{-6} g Cu 1 x 10^{-4} g Al; B, 1 g ZnS 1 x 10^{-5} g Cu 1 x 10^{-4} g Al; C, 1 g ZnS 1 x 10^{-4} g Cu 1 x 10^{-4} g Al; D, 1 g ZnS 1 x 10^{-3} g Cu 1 x 10^{-4} g Al; E, 1 g ZnS 1 x 10^{-2} g Cu 1 x 10^{-4} g Al.

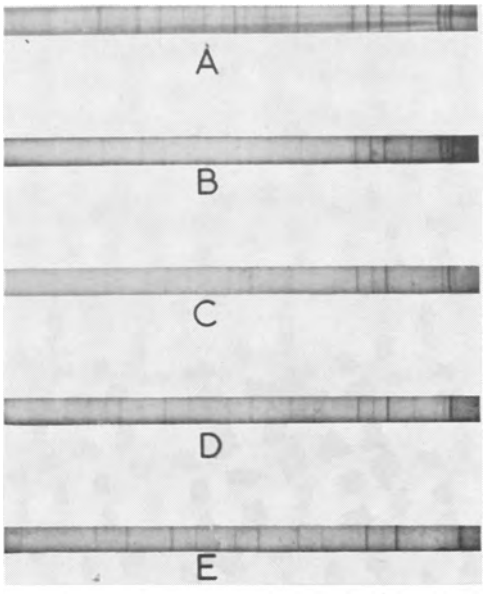

Fig. 2. X-ray powder photograph of a series of phosphors fired at 1100°C in wet H_2S. A, 1 g ZnS 2 x 10^{-4} g Cu 1 x 10^{-4} g Al; B, 1 g ZnS 4 x 10^{-4} g Cu 1 x 10^{-4} g Al; C, 1 g ZnS 6 x 10^{-4} g Cu 1 x 10^{-4} g Al; D, 1 g ZnS 8 x 10^{-4} g Cu 1 x 10^{-4} g Al; E, 1 g ZnS 1 x 10^{-3} g Cu 1 x 10^{-4} g Al.

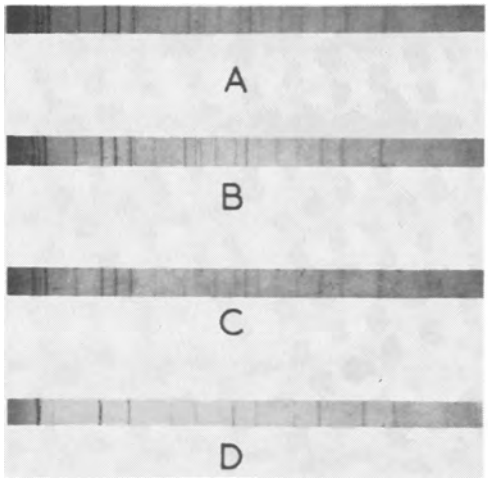

Fig. 3. X-ray powder photograph of a series of phosphors fired at 1100°C in wet H_2S. A, 1 g ZnS 1 x 10^{-5} g Ag 1 x 10^{-4} g Al; B, 1 g ZnS 1 x 10^{-4} g Ag 1 x 10^{-4} g Al; C, 1 g ZnS 1 x 10^{-3} g Ag 1 x 10^{-4} g Al; D, 1 g ZnS 1 x 10^{-2} g Ag 1 x 10^{-4} g Al.

given the concentration of aluminum coactivator was 10^{-4} g Al/1 g ZnS. The same result is obtained for aluminum concentrations varying between 10^{-2} g Al to 10^{-6} g Al/1 g ZnS. The replacement of aluminum by gallium or indium gives similar results. In Fig. 2 the diffraction photographs for a series of phosphors with copper concentrations between C and D in Fig. 1 are given. Up to a concentration of 6 x 10^{-4} g Cu/1 g ZnS the material is hexagonal, above this concentration it consists of a mixture of two phases and only in these cases are the phosphors electroluminescent. It was thought that the correlation between electroluminescence and crystal structure might be fortuitous as copper sulfide precipitation onto the crystallites occurs at approximately the same concentrations. A study of silver phosphors indicates that this is not the case. The

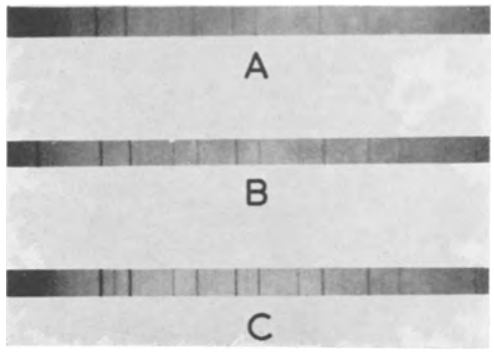

Fig. 4. X-ray powder diffraction photograph of a series of phosphors fired in argon at 800°C. A, 1 g ZnS 1 x 10^{-3} g Cu 1 x 10^{-3} g KCl; B, 1 g ZnS 1 x 10^{-3} g Cu 1 x 10^{-3} g NH_4Cl; C, 1 g ZnS 1 x 10^{-3} g Cu 1 x 10^{-3} g NH_4Cl 1 x 10^{-2} g Pb.

body color of a series of phosphors whose diffraction patterns are shown in Fig. 3 indicates that silver precipitation occurs at 10^{-4} g Ag/1 g ZnS. The mixed phases only occur in the phosphor containing 10^{-2} g Ag/1 g ZnS, and only this phosphor is electroluminescent. There was a further possibility that electroluminescence was a property of cubic zinc sulfide, and that it was the appearance of this phase rather than the formation of a mixture which caused the emission in the cases considered above.

Figure 4 shows the diffraction photographs of three typical so-called cubic zinc sulfide electroluminescent phosphors prepared below the transition point (1024°C). The best of these phosphors is C, and inspection shows that this phosphor has the most clearly defined hexagonal phase. It may be concluded, therefore, that in the so-called cubic electroluminescent zinc sulfide phosphors two phases are necessary for the emission, and the addition of the various substances during the preparation facilitates the growth of the hexagonal phase in the sphalerite temperature range.

Thermoluminescence experiments show that the appearance of electroluminescence and disorder in zinc sulfide is accompanied by a major change in the trapping states in the phosphor. Figure 5A gives the glow curves for the phosphors whose diffraction patterns are given in Fig. 1. It can be seen that the nonelectroluminescent phosphors containing less than 10^{-4} g Cu/1 g ZnS have trapping levels which cause a maximum in the glow curve at −100°C and a "tail" which extends to room temperature. The electroluminescent phosphors, on the other hand, have much shallower traps and the deeper traps have disappeared or no longer give rise to radiative transitions. This trend is shown more clearly in Fig. 5B for phosphors containing the same copper concentration (10^{-6} g-10^{-2} g) but with 10^{-2} g Al instead of 10^{-4} g Al/1 g ZnS. In this case the photoluminescent phosphors have a glow curve consisting of two peaks, one at −100°C, and one nearer room temperature at approximately −40°C. The electroluminescent phosphors again have a much narrower glow curve peak with a maximum between −120°C and −140°C.

Similar results have been obtained for all the other phosphors investigated, although the position

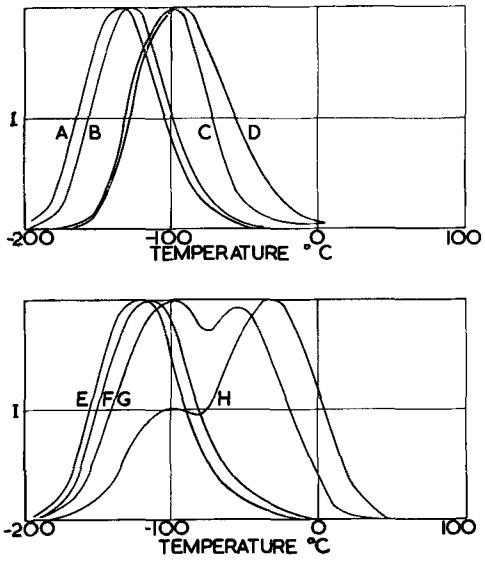

Fig. 5. Thermoluminescence curves of phosphors containing between 10^{-5} and 10^{-2} g Cu (D→A and H→E) with 10^{-4} and 10^{-2} g Al, respectively.

of the glow curve maximum does not appear to be so important as the absence of traps which extend the glow curve to room temperature.

These results appear to indicate, therefore, that electroluminescence occurs in crystals in which there are regions of both wurtzite and sphalerite. It may, therefore, be a property of the disordered region between the two types of crystal. If this is the case, then it should be possible to prepare an electroluminescent phosphor by disordering zinc sulfide by some other means than adding excess copper sulfide. Such a phosphor is described below.

During investigations into thallium-activated phosphors 10% TlCl was added to zinc sulfide and the phosphor was fired at 800°C in a stream of wet H_2S. The resulting phosphors were shown by spectroscopic means to contain no thallium ion; at the temperature of the experiment it had all sublimed. This phosphor was brilliantly photoluminescent and moderately electroluminescent in the green due presumably to vacancies. Exhaustive analysis did not indicate the presence of copper or thallium. The body color, off-white, also showed that an excess of electron-rich material which hitherto had been thought to be necessary for electroluminescence was not present. Figure 6 shows that the crystals of phosphor consisted of a mixture of hexagonal and cubic zinc sulfide. That this phosphor is electroluminescent is shown by the brightness against voltage and frequency curves. The brightness variation may be expressed by the usual relation

$$B = A_o \sqrt{F} \exp\left(-b/\sqrt{v}\right)$$

Discussion

Conventional electroluminescent phosphors have been shown to consist in all cases of the two phases of zinc sulfide, wurtzite, and sphalerite. It would appear possible that electroluminescence can occur without the addition to the phosphor of a material that could act as an electron source.

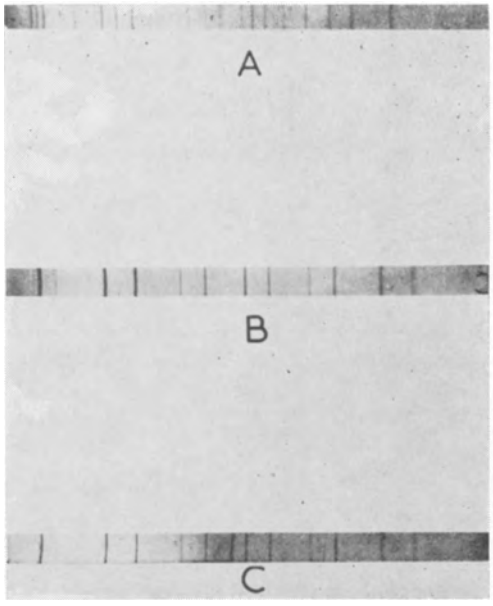

Fig. 6. X-ray powder photograph of: A, hexagonal zinc sulfide; B, 0.9 g ZnS 0.1 g TlCl fired at 800°C in H_2S; C, cubic zinc sulfide.

It is difficult to see, however, where the field for the acceleration of the electrons sufficient to ionize the luminescent centers can arise in such a system. The band gap energy between the two forms of zinc sulfide is small (0.01 ev), but Merz considers that the impurities may cause the band gap to widen to 0.1 ev. The observation of high photovoltages in zinc sulfide single crystals (9) shows experimentally that high fields must exist in these crystals, although the mechanism is obscure. In view, however, of these results, it may not be amiss to suggest the possibility that electroluminescence is a recombination effect at what is essentially a p-n junction. The original objections to this approach, the low threshold and the minority carrier being a hole, is not now important. The threshold of electroluminescence has been shown to depend on the method of detection of the light emitted, and Destriau has been able to go down to levels 0.01 of that visible to the dark adapted eye and still detect light. Wood's (10) observation of p-type conduction in cadmium sulfide doped with copper shows that p-type conduction in the II-VI compounds is not so unlikely as has been hitherto thought.

However, it must be admitted that no explanation of the biphase effect in electroluminescence is satisfactory, and at present the experimental results only are reported.

On the Mechanism of Chemically Etching Germanium and Silicon

D. R. Turner

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

The electrode potential of germanium or silicon in a chemical etching solution is a function of solution pH, rate of etching, physical condition of the surface, conductivity type, and resistivity. The results suggest that excess holes and electrons are produced at the surface of the semiconductor during chemical etching. Holes are injected at cathode sites, but only a portion of these holes are consumed at anode sites since the anode reaction involves current multiplication.

Semiconductors such as Ge or Si are chemically etched in aqueous solutions containing an oxidizing agent such as nitric acid and an anion such as F^- which is capable of forming water-soluble complexes with the semiconductor. The etching process is actually electrochemical in its action, that is, there are anode and cathode sites on the surface of the semiconductor with local cell currents flowing between them. Semiconductor material goes into solution at the anodic sites while the oxidizing agent is reduced at the cathodic areas. The rate of chemical etching is determined by the magnitude of the corrosion current. If the etching process is nonpreferential and material is removed uniformly, any given area on the surface of the semiconductor must continually alternate between being anode and cathode. When one spot is anodic much more than it is cathodic, an etch pit will form at that point. Experience has shown that this is most likely to occur at grain boundaries and dislocations at the surface of the single crystal. Conversely, hillocks are formed on areas that are cathodic more than they are anodic.

The average current density between local anode and cathode areas during chemical etching can be estimated from the rate of etching. Assuming that the surface while etching is half anode and half cathode and that Ge or Si goes into solution with a valence of 4, the average corrosion current density in amp/cm^2 is given by:

$$i = 2\Delta\epsilon d \qquad [1]$$

where Δ is the etch rate in cm/sec, ϵ is the electrochemical equivalent in coulombs/g, and d is the density of the semiconductor in g/cm^3. The rate of chemically etching n-type Si in HF-HNO_3 mixtures has been determined by Robbins and Schwartz (1). A plot of some of their data along with the equivalent corrosion current density derived from Eq. [1] is shown in Fig. 1. Similar results should be obtained for p-type Si specimens. The etch rate can be converted into inches per minute by multiplying by the factor 2.36 x 10^{-3}. The maximum rate of etching occurs when the ratio of HNO_3 to HF in the solution is 1 to 4.5. Klein (2) has studied the rate of chemically etching silicon in HNO_3-HF mixtures under carefully controlled conditions of temperature and stirring. He also found that maximum etching rate occurred when the HNO_3/HF mole ratio was about 1 to 4.5. The significance of this ratio will be discussed later. The maximum Si etch rate is about 28 μ/sec which corresponds to about 190 amp/cm^2 average corrosion c.d. This is a tremendous current density, but even more amazing is the fact that an n-type silicon electrode biased anodically in a suitable electroetching solution will pass just a few μa/

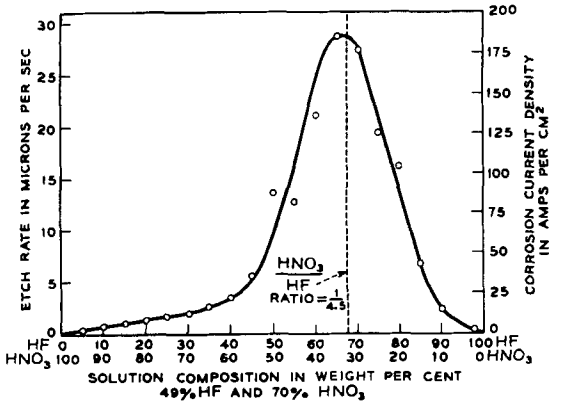

Fig. 1. Rate of chemical etching Si and equivalent corrosion C.D. vs. solution composition, HF + HNO_3 mixtures. Etch rate vs. solution composition data from Robbins and Schwartz (1).

cm^2. This means the maximum chemical etch rate is higher by a factor of 10^8 than the maximum electrolytic etch rate. In order to obtain a better understanding of this phenomenon, potential measurements were made on Ge and Si electrodes in etching and nonetching solutions.

Potential measurements always require two electrodes. If the second electrode is a standard reference electrode, i.e., its potential is known and is constant during the experiment, then the single electrode potential of a semiconductor can be determined from the measured cell voltage. Semiconductor electrodes differ from metal electrodes in that an appreciable part of the single electrode potential may be located inside the semiconductor. In analyzing the potential measurements made on Ge and Si it will be necessary to consider the potential within the semiconductor as well as that at the semiconductor-solution interface.

Experimental Studies on Electrode Potentials

Bars of n- and p-type Ge and Si were used as electrodes. The size, geometry, and surface orientation of the electrodes did not affect the measured potentials within the limit of experimental reproducibility—about ± 0.005 v. Ohmic contacts were made to the Ge by abrading one end, tinning and soft soldering it to a Cu wire. The Si electrodes were abraded at one end and then coated with nickel by the "electroless process" (3) before soldering to the Cu wire. Prior to the potential measurement, each electrode was bright etched in C.P.-4 etching solution (for Si the bromine is omitted), rinsed in deionized water, and blotted dry with filter paper. The electrodes were held vertically during a measurement so that only the tip end of the semiconductor was immersed. Unless otherwise indicated, the solutions were unstirred and initially at room temperature. All potential measurements were made against a saturated KCl calomel reference electrode, hereafter referred to as S.C.E.

Since many of the electrolytes used contained HF or strong alkali, polyethylene containers were used instead of glass. The electrolyte was separated from the saturated KCl solution and the reference electrode by a polyethylene syphon fitted with a filter paper plug. Electrode potential measurements were made with either a Millivac Type MV-17C d-c voltmeter, a L&N X-Y recorder, or a Sanborn Type 151 recorder depending on the experiment and the kind of data desired.

Single electrode potential measurements were made in a variety of solutions, some etching and others nonetching. The results of potential measurements in some of the solutions are shown in Fig. 2. The solutions listed are arranged in their approximate order of increasing *p*H from left to right: (A) conc. (16*N*) HNO_3, (B) CP-4 without Br, (C) 32% conc. HNO_3 + 68% (48%) HF, (D) Landgren's etch (4) — 3% $KMnO_4$ + 97% conc. HNO_3,[1] (E) 48% HF, (F) sat. KCl, and (G) 1N KOH. All per cent compositions in this paper are weight per cent values. The potentials of n- and p-type Ge electrodes are indicated by the small letters while the capital letters are for Si electrodes. These are average values of measurements made on 3 to 5 different electrodes. The spread of the data is indicated where it is more than ±0.02 v. Whenever the electrode potential was photosensitive, the cell was shielded from room light.

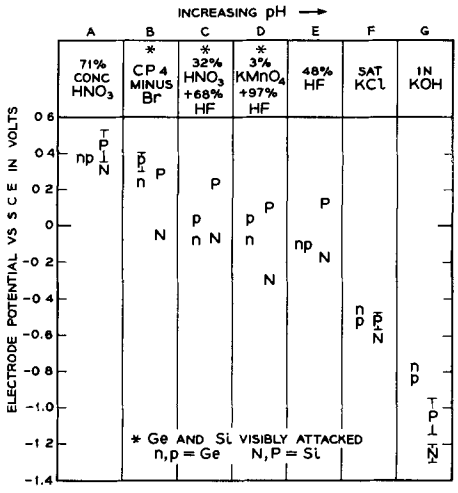

Fig. 2. Electrode potentials of n- and p-type Ge and Si in various etching and non-etching solutions. Unstirred at room temperature.

Figure 2 shows three things: (*a*) increasing *p*H shifts the electrode potential in the negative direction; (*b*) an appreciable potential difference is observed between n and p-type Ge and Si when the solution rapidly corrodes the semiconductor; and (c) p-type Ge or Si is always positive in potential with respect to n-type when a potential difference does exist. The effect of *p*H on the electrode potential of Ge has been observed many times before (5, 6). Cretella and Gatos (7) have observed n-type Ge to be positive in potential with respect to p-type Ge in nitric acid solutions more dilute than 6*N*. This effect cannot always be duplicated. The surface pretreatment appears to be more of a factor than the nitric acid solution. In rapidly etching solutions, however, the results are reproducible and p-type Ge is positive relative to n-type Ge. In etching solutions where the rate of corrosion is controlled by the mass transfer of one of the reacting species to or from the surface stirring increases the etch rate and it also may shift the electrode potential. The effect of stirring on the electrode potentials of Ge and Si are discussed later. If the solution does not attack the semiconductor at an appreciable rate, there is no potential difference between n- and p-type electrodes of either Ge or Si. Electrolytes B, C, and D in Fig. 2 visibly attack both Ge and Si, as evidenced by gas evolution and rapid electrode dissolution. The potential difference between n- and p-type Si in 48% HF is attributed to a slow corrosion process which is made possible by dissolved oxygen. Solution G (1*N* KOH) also attacks Si but only slowly at room temperature. When the electrolyte corrodes the semiconductor at a sufficiently rapid rate, light has no effect on the measured electrode potentials. The potential of Ge and Si in etching solutions is

[1] Solution rapidly etches p-type portions of a silicon single crystal containing p- and n-regions with little effect on n-type regions.

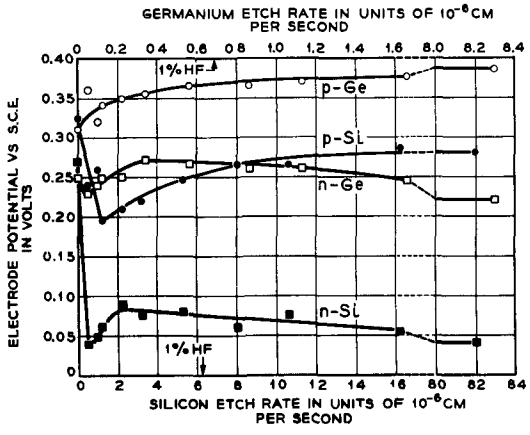

Fig. 3. Effect of etch rate on the electrode potentials of n- and p-type Ge and Si in HF-HNO_3 mixtures. Rate of etching increased by adding HF to HNO_3.

also a function of the equilibrium hole density in the semiconductor, as is shown later.

A fresh solution of concentrated HNO_3 does not chemically etch Ge or Si at an appreciable rate. The etch rates increase rapidly with additions of HF as shown by Cretella and Gatos (7) for Ge and Robbins and Schwartz' for Si (see Fig. 1). It is of interest to observe the change in the single electrode potential of a semiconductor when the electrolyte changes from an essentially nonetching solution to an etching one. This experiment was carried out by measuring the electrode potentials of 0.8 ohm cm n- and 3.5 ohm cm p-type Ge and 0.7 ohm cm n- and 1.2 ohm cm p-type Si first in concentrated HNO_3 and then with various additions of HF. In concentrated HNO_3 alone the electrode potentials are extremely light-sensitive. For this reason, all light was excluded from the cell. Instead of plotting electrode potential against the amount of HF added, it is more meaningful to show the relation between the electrode potential and the rate of etching as given in Fig. 3. The etch rate for a solution composition 1% (49%) HF + 99% concentrated HNO_3 is indicated for both Ge and Si. The etch rate for Ge in conc. HNO_3 solutions containing from 0 to 10% (49%) HF was determined experimentally from weight loss measurements with four specimens, two n-type and two p-type. Robbins and Schwartz's[1] data, Fig. 1, was used for Si. Note that Si etches about ten times faster than Ge in comparable HF-HNO_3 mixtures. One drop (~ 0.04 cc) of 49% HF produces a large shift in the potential of n- and p-type Si and n-type Ge toward the negative direction. p-Type Ge changes slightly in the positive direction. As the etch rate increases with more HF, the electrode potentials of n-type Ge and Si rise and then decrease again while the potentials of p-type Ge and Si increase. The electrode potentials of all the electrodes reach relatively stable values in solutions containing about 10% HF + 90% HNO_3, where the etch rate is 63 x 10^{-6} cm/sec on Si and 6.7 x 10^{-6} cm/sec on Ge. At this rate of etching the photovoltaic effect is completely absent.

Another interesting experiment was to abrade the surface of semiconductor electrodes and record the change in potential with time as the damaged surface layer was chemically etched away. This was done with 1.3 ohm cm n- and 1.2 ohm cm p-type Si electrodes. The surfaces were abraded by lapping on a glass plate with No. 600 silicon carbide and water. Typical electrode potential-time curves after immersion in 10% (49%) HF + 90% concentrated HNO_3 are shown in Fig. 4. Initially the electrode potentials of abraded n- and p-type Si are about the same. As the damaged surface layer is etched away, the potentials drift apart. The largest potential change occurs with the n-type Si electrode. p-Type Si reaches a stable potential in about 30 sec while the potential of n-type Si becomes stable after 6 min. A potential measurement of this kind may be useful in determining when all the abraded surface material has been removed by etching.

Single electrode potentials of n- and p-type Ge and Si in HNO_3 + HF acid mixtures were also measured as a function of material resistivity. To get reproducible results it was necessary to use freshly prepared solutions. The electrode potentials against the resistivity, ρ, and the equilibrium bulk hole density, p, at 300°K, are shown on a semilog plot in Fig. 5 and 6. The p values were determined from the resistivities using the relation:

$$\frac{1}{\rho} = q\mu_n n + q\mu_p p$$

where q is the charge on the electron, μ_n is the electron mobility, n is the equilibrium bulk electron

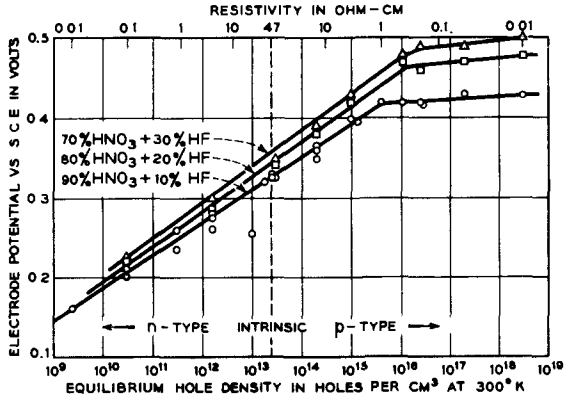

Fig. 5. Electrode potentials of Ge in HNO_3-HF mixtures vs. resistivity and equilibrium hole density.

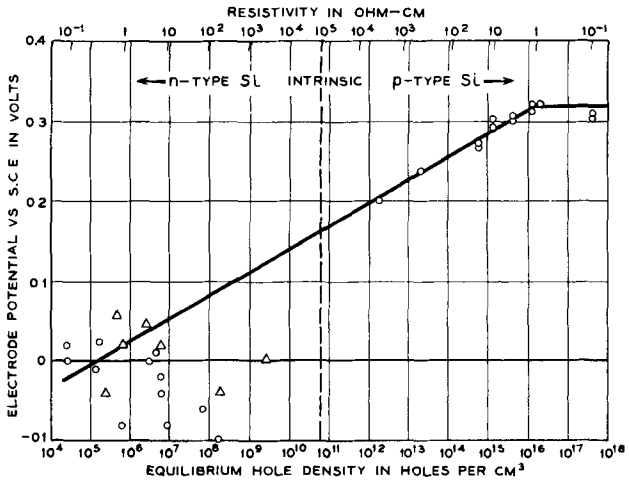

Fig. 6. Electrode potentials of Si in 90% conc. HNO_3 + 10% conc. HF vs. resistivity and equilibrium hole density.

density, and μ_p is the hole mobility. Electron and hole mobilities were obtained from Prince's (8) data and n was derived from the relations: $np = 6.25 \times 10^{26}/cm^6$ at 300°K for Ge and $np = 4.6 \times 10^{21}/cm^6$ at 300°K for Si.

Electrode potentials of Ge were measured in 90% HNO_3 + 10% HF, 80% HNO_3 + 20% HF, and 70% HNO_3 + 30% HF. The measured potentials were fairly stable in freshly prepared 90% HNO_3 + 10% HF, but in the other solutions, where the rate of etching was more rapid, the potentials fluctuated probably because of the stirring effect produced by a greater rate of gas evolution. Most of the data show a linear relation between the electrode potential and the logarithm of the equilibrium hole density with a slope of 0.04 up to about $p \sim 10^{16}$ holes/cm^3. Above 10^{16} holes/cm^3, the electrode potential becomes almost constant. The reason for this limiting potential effect is discussed later. Although there is some difficulty in obtaining a reasonably accurate potential measurement at the higher etching rates, it is clear that at a given equilibrium hole density the electrode potential increases with the etching rate. The difference is most apparent in the region where the potential levels off.

The variation of the electrode potential of Si with p in 90% HNO_3 + 10% HF is different from the Ge results in some respects, as can be seen in Fig. 6. The data obtained with p-type Si electrodes have the same form as p-type Ge except that the slope of the best straight line through the points is about 0.03 instead of 0.04. The results with n-type Si are quite different from those of n-type Ge. The points are widely scattered and there does not appear to be a consistent relation between E_{Si} and p. It was thought at first that perhaps minority carrier lifetime was an important factor. Several uncompensated Si specimens were obtained with reasonably good lifetimes for the resistivity. These results are the triangular points in Fig. 6 and are also widely scattered. An extrapolation of the line from the p-side to the n-side shows the extent of deviation and that there are a few points near the line.

Discussion

An interpretation of the electrode potential measurements on Ge and Si in etching and nonetching solutions should aid in elaborating the mechanism of chemical etching Ge and Si. It will be convenient to discuss the three parts of the measured electrode potentials: (a) the contact potential between the copper wire attached to the semiconductor by means of an ohmic contact and the semiconductor bulk (E_I), (the contact potential is defined as the potential difference in the work functions of the metal and the semiconductor), (b) the potential drop across the space-charge layer between the semiconductor bulk and the surface (E_{II}) (this is called the surface potential, Ψ_s, by physicists), and (c) the potential across the semiconductor-electrolyte interface (E_{III}).

The contact potential E_I between the copper and the semiconductor varies with the position of the Fermi level in the semiconductor bulk; that is, the nature of the doping. The contact potential can be considered to be constant in the electrode potential measurements on a given semiconductor specimen at room temperature. In nonetching solutions, that is, when there is essentially no charge transfer across the semiconductor-electrolyte interface and the semiconductor is at equilibrium, $E_I + E_{II}$ is also a constant regardless of the conductivity type and semiconductor resistivity. This is due to the fact that the Fermi level at the surface of a semiconductor in solutions is determined not by the bulk charge carrier density but by the charge density at the surface. This is illustrated in Fig. 7. The Fermi level at the surface is at a fixed position relative to the valence and conduction bands, that is, Φ_s is independent of the bulk properties of the semiconductor (9, 10). This means that the potential difference ΔE_{II} between n- and p-type material is exactly equal but opposite in sign to the contact potential difference ΔE_I. In nonetching solutions, therefore, changes in the measured electrode poten-

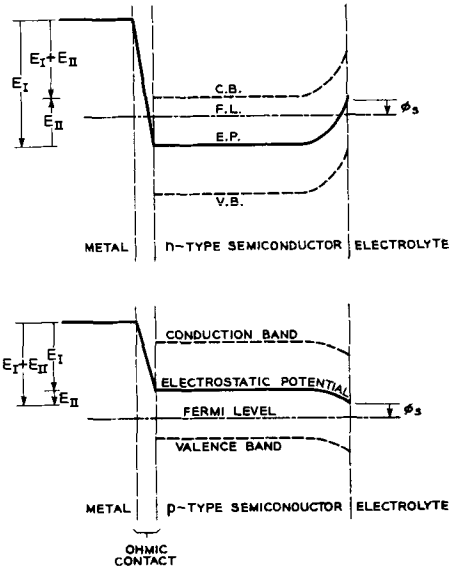

Fig. 7. Energy level diagrams for an n- and p-type semiconductor in contact with a metal and an electrolyte.

tial can be due only to changes in the interfacial potential (E_{III}).

Potential differences between n- and p-type Ge or n- and p-type Si are observed when the electrodes immersed in a nonetching electrolyte are illuminated with light or when they are immersed in a chemical etching solution without light. Under these conditions the surface region of the semiconductor is not at equilibrium. The photovoltaic effect of semiconductor electrodes in solutions has been observed many times (11, 12). It is attributed to hole-electron pairs produced by light energy in the surface region. These extra hole-electron pairs change the Fermi level at the surface of the semiconductor with respect to that of the bulk, that is, E_{II} changes. The measured electrode potential of semiconductors changes when illuminated with light (11, 13). The sign and magnitude of the potential differences between n- and p-type electrodes in etching solutions as shown in Fig. 5 and 6 are essentially the same as those obtained in the photovoltaic effect. This suggests that holes and electrons are produced at the surface of the semiconductor during chemical etching. Several other observations tend to support this interpretation: (*a*) the photovoltaic effect disappears even at moderate rates of chemical etching; (*b*) the rectifying characteristic of a broad-area p-n junction is completely eliminated if either side of the junction is exposed to an etching solution; (c) a Ge or Si diode, with masked leads, generates a considerable amount of power (~ 0.3 milliwatt/cm of exposed junction length) when immersed in C.P.-4 solution; and (*d*) the saturation current density of n-type Ge or Si made anodic in a chemical etching solution increases in proportion to the rate of etching (14). These effects can be explained satisfactorily only by assuming that large numbers of holes and electrons are produced at the surface of semiconductors during chemical etching.

The mechanism of chemically etching Ge and Si must include a source of excess holes and electrons. As stated earlier, chemical etching of semiconductors is an electrochemical process with local anode and cathode areas. Semiconductor dissolution takes place at the anode sites, while the oxidizing agent is reduced at the cathode areas. It has been well established that the anodic dissolution reaction at Ge and Si electrodes consumes holes (11). Brattain and Garrett (11) also found that when they anodically biased an n-type Ge electrode to the saturation current region and then injected holes with light, the total dissolution current increased between 1.4 to 1.8 times the current due to hole injection. Turner (15) has suggested that the mechanism for the anodic dissolution of Ge involves the diffusion of two holes to the surface with a return flow of two electrons for each atom dissolving. This would give a current multiplication factor of 2. Beck and Gerischer (9), however, have found that the current multiplication factor is near 2 only when holes are consumed as fast as they arrive at the anode surface. If holes can diffuse to the surface or holes are injected into the surface region faster than they are consumed in the anode reaction, then the current multiplication factor may be less than 2.

If a semiconductor such as Si is chemically etched in a HNO_3-HF acid mixture, the reaction at the anode sites is the dissolution of silicon as follows:

$$Si + 2H_2O + ne^+ \rightarrow SiO_2 + 4H^+ + (4-n)\,e^- \qquad \xrightarrow{6HF} \quad H_2SiF_6 + 2H_2O \quad [2]$$

where e^+ represents a hole and n is the average number of holes required to dissolve 1 Si atom; n may range from 2 to 4 depending on the current multiplication factor. A Si dissolution valence of four is assumed for the process which is probably correct for HNO_3-rich solutions. In HF-rich solutions, there is evidence that Si dissolution is divalent (12, 16, 17). It is also assumed that Si dissolves by first forming an oxide which then reacts with HF to form the water-soluble silicofluoride complex.

The main function of the oxidizing agent in the chemical etching solution is not to oxidize the semiconductor as is sometimes proposed (1) (Ge and Si are readily oxidized in most oxygen-containing systems) but to provide an easily reduced material for the cathode reaction. In the absence of an oxidizing agent (including oxygen) and metal ions more noble than the semiconductor, the only cathode reaction possible is the discharge of hydrogen ions. The hydrogen discharge reaction can only proceed at a very slow rate, however, because of hydrogen overvoltage. This limits the chemical etching rate to a negligible value.

Oxidizing agents do more than provide an easily reduced material at semiconductor electrodes. They modify the distribution of mobile charge carriers in the surface region so that the Fermi level at the surface is nearer the valence band than it is the conduction band. This is illustrated in Fig. 7. The electron transfer process in the reduction of the oxidizing agent involves the transfer of an electron from the valence band to the ion being reduced. It is equivalent to hole injection. This concept was formulated independently by Gerischer and Beck (9, 18) and Dewald (10). Both have obtained experimental evidence in support of this mechanism. Pleskov (19), using a novel technique of working both sides of a Ge electrode electrochemically, has confirmed their observations.

The reduction of HNO_3 is a complicated reaction involving several steps (20, 21). Cretella and Gatos (7) have shown that the mechanism proposed by Vetter (20) for the cathodic reduction of HNO_3 on a Pt electrode also applies to Ge. The over-all reaction can be written as follows:

$$HNO_3 + 2H^+ \rightarrow HNO_2 + H_2O + 2e^+ \qquad [3]$$
