The Influence of the Active Surface on the Cathodic Reduction of MnO_2

N. C. Cahoon[1] and M. P. Korver

Research Laboratory, Union Carbide Consumer Products Company, Division of Union Carbide Corporation, Parma, Ohio

ABSTRACT

The surface area of samples of manganese dioxide is shown to be an important factor in influencing its behavior. Four samples of MnO_2 of widely different origins, electrolytic, activated, natural ore, and synthetic pyrolusite, with total surface area values of 52.8, 50.5, 7.4, and 1.6 m^2/g, respectively, are used as examples. The rates of the recuperation reaction at temperatures of 21°-50°C are shown to be related to the total surface area of the oxides by a complex relation, dependent on temperature and other factors. The product of the reaction MnOOH develops on the surface and in the pores of the original MnO_2 particle, thus increasing the diameter and resulting in reduced pore volume, respectively. The MnOOH made under these conditions, from all four starting materials, appears as rod-shaped units in electron micrographs.

A survey of the literature on manganese dioxide and its cathodic operation indicates that the field has received considerable attention and is well defined. However, the technologist in this area soon finds that he cannot consistently apply this background to correlate the properties of a particular sample of MnO_2 with actual electrochemical performance in a battery. Each technological advance aids in understanding the over-all problems involved, but in itself provides only a part of the solution. Studies of manganese dioxide by chemical methods (1), *p*H-potential measurements (2), utilization test (3), and reaction rate determinations (4) when combined with electrolyte studies (5) provide the major portion of the answer to the problem from the electrochemical and chemical viewpoints. The physical properties of manganese dioxide have been studied by many methods (6) including x-ray diffraction (7) to determine the significance of the various allotropic forms and their crystallinity. The size and shape of the MnO_2 particle have been studied for many years, most recently by the electron microscope (8). A previously little-recognized property, the surface area of the material, is now shown to be an important factor in correlating the performance of various MnO_2 samples used as battery cathodes.

Experimental

The sample of electrolytic MnO_2 used in this work was prepared by the electrolysis of a manganous sulfate solution as previously described (9). The activated MnO_2 was prepared by leaching Mn_2O_3, from thermal reduction of MnO_2 ore, in sulfuric acid solution (10). The ore sample was typical of that obtained from West Africa (Ghana) and generally available to the battery industry. The synthetic pyrolusite was obtained some time ago and was prepared by the thermal decomposition of manganous nitrate (11). Portions of these same samples were used in the recuperation reaction rate study previously described (4).

Chemical analyses of the four samples were made in the usual manner. Particle size distribution curves were obtained by subjecting the portion of the sample which passed a 200 mesh sieve to the micromerograph (12). Particle surface area values were calculated from these data using a method recommended by the makers of the instrument. Total surface area values were obtained with a conventional BET nitrogen sorption apparatus (13). Pore spectra on the various samples were made using the same apparatus and the method described by Barrett, Joyner, and Halenda (14).

Compositions and properties of these four samples are given in Table I.

Discussion

It has been established that the cathode reduction in the Leclanché dry cell can occur through a stepwise series of reactions (15). The first step is electrochemical in which Mn^{IV} is reduced to Mn^{II} as in reaction [1]. The second step is chemical and may follow one or both of the directions given in reactions [2] and [3[.

$$MnO_2 + 2NH_4^+ + 2NH_4Cl + 2ZnCl_2 + 2e \rightarrow MnCl_2 + 2ZnCl_2 \cdot 2NH_3 + 2H_2O \quad [1]$$

$$MnO_2 + Mn^{++} + 2(OH)^- \rightarrow 2MnOOH \quad [2]$$

$$MnO_2 + Mn^{++} + 4(OH)^- + Zn^{++} \rightarrow ZnO \cdot Mn_2O_3 + 2H_2O \quad [3]$$

Some years ago, it became increasingly clear that chemical reactions [2] and [3] were sufficiently slow to limit seriously the output of the Leclanché cell on many of the shorter time tests and heavy

The electrolytic sample contains a small amount of graphite.

drain applications. A concerted study of the conditions governing the chemical or recuperation reactions was, therefore, undertaken. The general findings and data obtained for specific examples were presented in a recent paper (4). The most important finding was that the synthetic MnO_2 samples, which give better battery performance than the natural ores, show this superiority in their characteristically greater recuperation rate. Since there has been a considerable amount of speculation as to why the synthetic oxides are so much more active, this paper offers an experimental analysis and a partial explanation for this situation.

In any chemical reaction between a solid and a salt dissolved in a medium in which the solid is suspended, there are a number of important considerations which influence the reaction rate. A number of these factors, such as temperature and electrolyte pH, was discussed previously (4). One important physical property of the solid particles must also be considered, namely, the area of the particle which is in contact with the reaction solution. Preliminary studies in this direction involved the calculation of what we have termed the particle surface area (PSA) from the particle size spectrum. The latter is determined by sieving and by measurements of the subsieve portions with the micromerograph. A comparison of the particle surface area values and the reaction rate at the half life of the reaction is given in Table II for the four typical samples of manganese dioxide previously described. Compositions and properties of the manganese samples are shown in Table I.

Table II. Relationship between the particle surface area of four samples of MnO_2 and the experimentally determined reaction rate

Sample	Particle sample area, m^2/g	Reaction rate: Log $\left\{\left[\frac{dz}{dt}\right]_{t=0.5} \times 10^5\right\}$ at pH 6.50 and 21°C
Electrolytic	0.47	2.130
Activated	0.40	2.380
African ore	0.18	0.660
Synthetic pyrolusite	0.47	0.013

Table III. Comparison of the total and particle surface area of four representative MnO_2 samples

Sample	Total surface area BET determination, m^2/g	Particle surface area sizing determination, m^2/g
Electrolytic	52.8	0.47
Activated	50.5	0.40
African ore	7.4	0.18
Synthetic pyrolusite	1.58	0.47

It is clear from the data in Table II that no simple relationship exists between the particle surface area data and the rate of the recuperation reaction for these specific samples. Since the particle surface area is calculated on the assumption that all the particles are spherical, it is apparent that some error would be introduced by the shape factor of the particle; however, the error is not large enough to influence this conclusion.

The MnO_2 samples differ in other respects besides particle shape and size. They differ in crystal type and, most importantly, they differ in their total surface area as determined by the BET method. Measurements of total surface area on the above four samples are compared with the particle surface area in Table III.

Surface Area of MnO_2 Samples

Previous authors (16-19) have noted differences in the BET surface area of various samples of MnO_2. The concept of increasing the surface area of a sample of MnO_2 by grinding the particles to smaller and smaller diameters has often been proposed. The effect of such treatment can be calculated by assuming that only solid spherical particles are produced by the grinding process. Figure 1 shows the relation

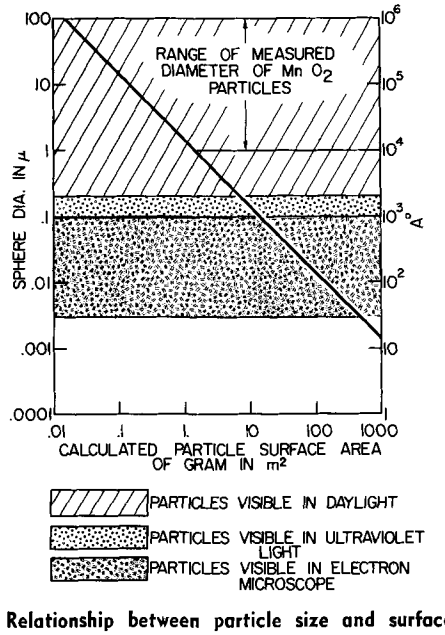

Fig. 1. Relationship between particle size and surface area.

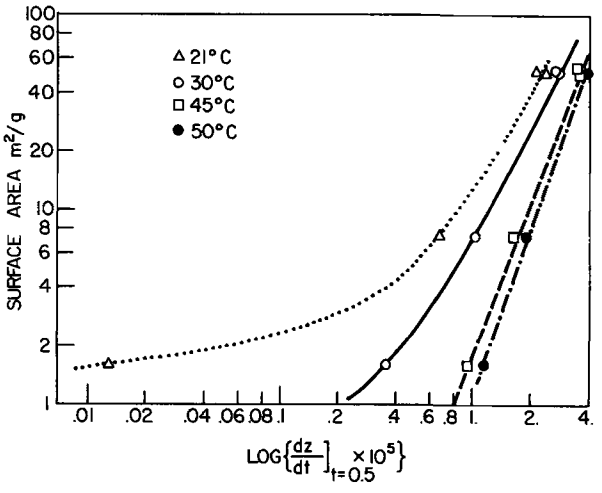

Fig. 2. Relationship between recuperation reaction rate and total surface area of four manganese oxides at pH 6.5 at a variety of temperatures.

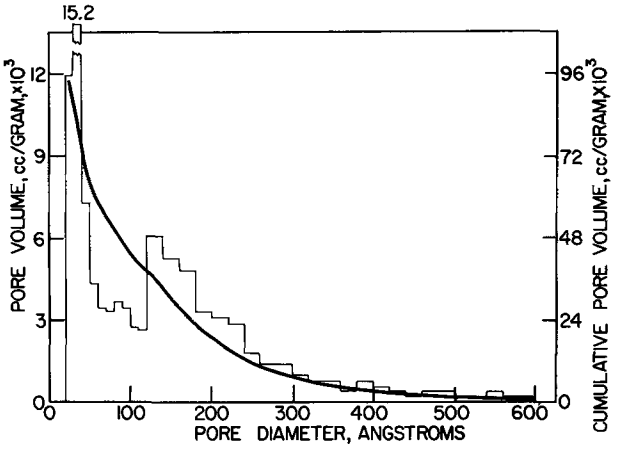

Fig. 3. Pore spectrum of electrolytic manganese dioxide.

between the particle diameter and the calculated surface area of a sample of MnO_2, assuming a real density of 4.54. From this chart, particles of MnO_2 of 200 mesh size (74μ diameter) are shown to have 0.019 m^2/g, and those of 325 mesh (44μ diameter) to have 0.033 m^2/g. Although these areas are considerably larger than those possessed by larger particles, on a unit weight basis, they fall far short of the actual measured surface areas given in Table III. Thus, a nominal 200 mesh ore which contains a considerable amount of finer material is found to have a total surface area of 7.4 m^2/g, of which 0.18 m^2 or about 2.4% represents the area present on the surface of the particles. Since the particle diameter and the total surface area are known, we must conclude that the difference in surface area between the total and calculated values resides in that area which is present in cracks, crevices, and pores in the MnO_2 particles. It is the surface area of this labyrinth that is effectively measured by the BET method. The alternative of grinding the MnO_2 to a particle size to produce a particle surface area 7.4 m^2/g is shown by Fig. 1 to require a particle diameter of 1900Å (0.19μ) or just about the limit of visibility with white light. Obviously, this particle size is not obtained nor is this method a practical or an economical procedure for commercial grinding operation.

Reaction rate values for a variety of temperatures from 21° to 50°C have been calculated from previous results (4). The relation of the total surface area to the reaction rates of the four MnO_2 samples at pH 6.5 at the above temperatures is shown in Fig. 2. A straight line relates the logarithm of the reaction rate to the logarithm of the total surface area at 45° and at 50°C. At other temperatures this relation departs significantly from a straight line. The change at the lower temperatures is caused by a large decrease in rate for the samples of lowest surface area. One important factor that should be considered is that the total surface values as measured on the individual samples of MnO_2 represent the combined surfaces of the MnO_2 itself, the Mn_2O_3, and the inert ingredients present. Since the latter can represent as much as 20% of the total weight of the sample (as may be seen from Table I), their contribution to the total surface area may be quite significant. Therefore, it is not surprising that the relation between the recuperation reaction rate and the surface area of the four samples is so complex. In view of the complexity, it appears impractical to attempt a direct correlation with actual battery test data.

Pore Spectrum of MnO_2 *Samples*

Having shown that some relationship exists between the total surface area of a depolarizer and reaction rate, it seems important to look for the reasons why. One attractive direction of study is to examine the dimensions of the pores in the MnO_2 particles which are responsible for the surface area. The pore structure of a sample of MnO_2 can be determined by established methods. The bar graph in Fig. 3 gives the distribution of the pores in a sample of electrolytic MnO_2 throughout the range of 20-600Å diameter, while the curve presents the cumulative pore volume present. When a sample of MnO_2 is exposed to a solution containing Mn^{++} under conditions where reaction [2] can occur, there is always the question as to how extensively does the reaction operate on the inside surfaces of the pores. The answer depends on many factors, including the availability of both the reaction Mn^{++} and the MnO_2 at the point of contact. One approach to this problem is to consider 1g of electrolytic MnO_2 with a total surface area of 52.8 m^2/g. If this were present as a thin flat plate of 26.4 m^2 area, its thickness could be calculated as 0.84×10^{-6} cm or 84Å. Each square centimeter of such a plate would weigh 3.78×10^{-6}g and, neglecting the minute area of the edge, it would have an exposed surface of 2 cm^2. According to reaction [2], 3.78×10^{-6}g MnO_2 would unite with 2.39×10^{-6}g Mn^{++} for complete conversion to MnOOH. This amount of Mn^{++} would be contained in a volume of 43.5×10^{-6} cc of a 1M solution which would be present in a layer 21.7×10^{-6} cm or 2170Å thick and 2 cm^2 in cross section. This rather involved calculation can be considered only a first and probably very rough approximation of the conditions present at the interface at which the MnO_2 contacts the electrolyte containing Mn^{++}. However, the result serves to emphasize one important fact. Since it requires a layer of electrolyte 2170Å thick to supply

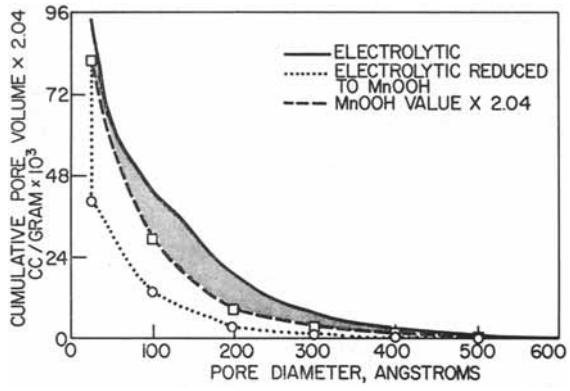

Fig. 4. Comparison of the cumulative pore volume of MnOOH and of the electrolytic manganese dioxide from which it was prepared.

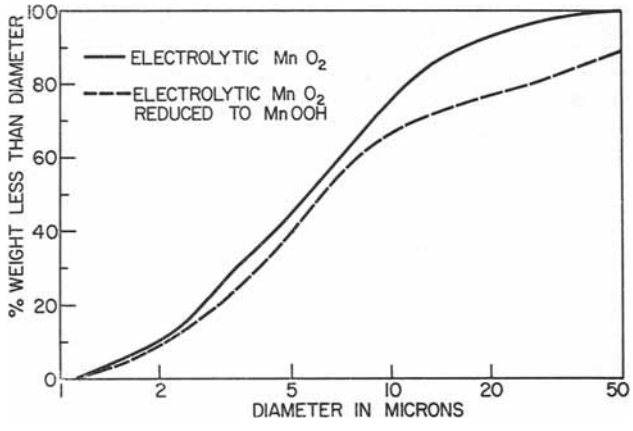

Fig. 5. Comparison of the particle size of MnOOH and of the electrolytic manganese dioxide from which it was prepared.

Mn^{++} at the initial 1M concentration to each square centimeter of MnO_2 plate or 2 cm^2 of MnO_2 surface area, it appears quite impossible to visualize any such complete reaction within the pores in the MnO_2 particle, since the pores are mostly below 400Å in diameter, and, therefore, cannot contain sufficient Mn^{++} in the initial solution absorbed for complete reduction of the MnO_2. Thus, we are forced to one or both of two conclusions: 1. the reaction between MnO_2 and Mn^{++} is initiated primarily on the outside of the particle, and 2, the reaction may occur in the pores of the MnO_2, but the replenishment of the Mn^{++} must be dependent on diffusion into the pores from the bulk of the electrolyte.

Pore Spectrum Measurements of MnOOH

To aid in assigning the proper significance to the above possibilities, some interesting evidence is provided by pore spectra determination data on electrolytic MnO_2 and on MnOOH prepared from it by the recuperation reaction. The initial value of 52.8 m^2/g obtained on the electrolytic MnO_2 is reduced to 27.4 m^2/g in a particular experimental run. According to reaction [2], 1g of the original MnO_2 thus provides 2.04g of the reaction product. Thus, the values on the cumulative pore volume curve obtained on 2.04g MnOOH should be compared with corresponding values obtained on 1g of the electrolytic MnO_2. These curves are shown in Fig. 4. The shaded area in this figure indicates the extent of the pore volume in the initial material that becomes filled with reaction product during the reduction. In the pore diameter range of 100-400Å, and even larger, from 1/3 to 1/2 of the original pore volume is filled, in general accord with the decrease in surface area cited above. This finding proves that the solution of Mn^{++} did diffuse into the pores of the MnO_2 particle to a considerable degree and deposit MnOOH therein. Microscopic examination of carefully sized particles showed that they increased in diameter during a recuperation reaction run. Particle size values were obtained on electrolytic MnO_2 and on MnOOH formed by the chemical reduction of this oxide in a recuperation test at a *p*H of 5.4 and a temperature of 43.95°C. The particle diameter distribution curves of the two materials are given in Fig. 5. From these data, it is apparent that the MnOOH particles are larger in diameter than those of electrolytic MnO_2 by an

amount varying from 0.5 to 40μ depending on the particle size fraction being considered. This finding emphatically indicates the formation of MnOOH on the external surface of the particle.

For many years, samples of cathode mix after reduction during battery discharge have been examined by all available means. Almost without exception the electron microscope pictures showed no significant characteristics that could be associated with the MnOOH present. The experiments described in this paper offered the opportunity to examine MnOOH prepared under conditions simulating battery discharge but without the carbon black present. Figures 6 and 7 show a comparison of the electron micrographs of two representative original MnO_2 samples and the MnOOH prepared from each. The electrolytic and activated MnO_2 samples (the latter not shown) were almost completely converted to MnOOH, i.e., 94.5 and 93.8%, respectively. The electron micrographs of the product from the electrolytic show in Fig. 6 characteristic rod-type particles approximately 0.4-0.6μ in length by 0.02μ in diameter. The African ore, which was reacted to only 50%, also shows in Fig. 7 the development of these rods of MnOOH on the surface of the lump is evident. In the case of the synthetic pyrolusite (not shown), which was reacted to the extent of 17% of its capacity, the beginnings of the rod formation on the MnO_2 particles are reasonably clear. The presence of the MnOOH in each of these products has been confirmed by both x-ray and electron diffraction.

Mechanism of the Recuperation Reaction

The mechanism of the recuperation reaction can now be visualized in the following manner. Under the conditions of the recuperation test the external surface of the MnO_2 particle is continually exposed to the solution of Mn^{++}. Furthermore, this solution probably enters most of the pores in the particle. The initial reaction must occur at the interface where MnO_2 and Mn^{++} meet, with the result that the product MnOOH forms at this point. Further reaction of Mn^{++} in the solution with the unreacted core of the MnO_2 particle probably occurs as the solution of Mn^{++} diffuses through the coating of MnOOH already formed on the external and pore surfaces. As shown in the electron micrographs, this layer consists of rod-shaped particles which adhere together to form a brush-heap type of layer. Since this is apparently quite porous, it probably does not slow down the diffusion process as much as though a solid barrier layer had formed. The reaction continues to proceed by diffusion of the solution of Mn^{++} through the MnOOH layer already formed with the result that the particle increases somewhat in size. In the course of this process a part of the pores in the initial particle becomes filled with MnOOH, thus reducing the internal surface area and establishing that diffusion does carry Mn^{++} into the pores of the MnO_2 particle to a considerable degree. Although the layer of MnOOH on the outside of the particle appears to consist of a myriad of rods of measurable size, the surface area actually found on the MnOOH product is considerably smaller (27.4 m^2/g) than that calculated for the equivalent amount of rods (48.4 m^2/g). Thus the interior of the MnOOH particle must be of a considerably denser structure than the external surface. We recognize that these conditions are analogous to, yet distinctly different, from those found in Leclanché cells during discharge. On this account, it becomes difficult to apply these findings more than a limited extent to practical applications.

Conclusions

From the data presented, it is apparent that the surface area of the sample of manganese dioxide, in the range studied, plays an important role in controlling the reaction rate between MnO_2 and Mn^{++}. It also appears significant that the recuperation rate of manganese dioxide samples of four different allotropic forms can be correlated with the surface areas which they possess. These findings suggest that some of the previous ideas on the importance of crystal structure may be explained, at least in part, by the surface area properties.

The pore structures of powdered samples of manganese dioxide and MnOOH are introduced in an effort to explore further the mechanism of the reaction between the solid MnO_2 and dissolved Mn^{++} to give a solid MnOOH product. The finding that the pore volume of the original MnO_2 particles is reduced to approximately half this level by conversion to MnOOH is supported by the observed reduction in the pore volume of approximately 1/3 to 1/2 in the pore diameter range of 100-400Å. This observation establishes that the recuperation

reaction occurred within these pores and proves that diffusion of electrolyte containing Mn^{++} is of considerable importance. Of equal significance is that the particles increase in size, and the product formed on the external surface is rod-shaped units of MnOOH. Thus the reaction site encompasses both the external surface of the particle and a considerable amount of the internal area of the pores.

The reaction conditions used in this work simulate those in a Leclanché cell during discharge but they differ in important aspects, *e.g.*, the concentration of the Mn^{++} used. On this account, these results should not be applied to battery problems without due consideration being given to the differences present.

Hydrogen Absorption by Zircaloy-2 and Some Other Alloys during Corrosion in Steam

B. Cox

Chemistry Division, United Kingdom Atomic Energy Authority, Atomic Energy Research Establishment, Harwell, Didcot, Berkshire, England

ABSTRACT

Results for hydrogen uptake by Zircaloy-2 during corrosion in steam are presented. The hydrogen absorption curve consists of three regions: in the first, covering the growth of the interference-color oxide film, about 30-50% of the hydrogen released by the corrosion reaction is absorbed; in the second, hydrogen absorption falls to a low value; and in the third, following the transition in the oxidation kinetics, it rises to 80-100% of the hydrogen released by the corrosion reaction during this period. A mechanism for the hydrogen absorption is offered based on the differing oxidation mechanisms in these three periods. The hydrogen absorption behavior of other alloys is similar for those alloys which show oxidation kinetics similar to Zircaloy-2.

It is known (1) that zirconium and its alloys absorb hydrogen during corrosion in water and steam. The amount of hydrogen absorbed usually is expressed as a fraction of the hydrogen released by the corrosion reaction (2-7). To assess the possibility of embrittlement of the metal by this hydrogen, it is the over-all hydrogen concentration in the metal which is important. In most instances the proposed service life is much longer than the longest experiments, and in order to extrapolate from these experiments the rate of hydrogen absorption, and not the integrated hydrogen content, is required. Data presented as the fraction of the corrosion hydrogen which has been absorbed at any point conceal variations in the instantaneous rate of absorption which may occur during the corrosion process.

Some recent results have been presented as the increase in weight of oxygen per unit area of surface versus the concentration of hydrogen in the

reaction occurred within these pores and proves that diffusion of electrolyte containing Mn^{++} is of considerable importance. Of equal significance is that the particles increase in size, and the product formed on the external surface is rod-shaped units of MnOOH. Thus the reaction site encompasses both the external surface of the particle and a considerable amount of the internal area of the pores.

The reaction conditions used in this work simulate those in a Leclanché cell during discharge but they differ in important aspects, *e.g.*, the concentration of the Mn^{++} used. On this account, these results should not be applied to battery problems without due consideration being given to the differences present.

specimen, and apparently lie on a straight line passing through the origin (8). This method of presentation is only valid where all the data are obtained on specimens of identical size. A preferable method is to plot both oxygen and hydrogen absorption as weight increases per unit area of surface. On such a plot the rate of hydrogen absorption can be assessed readily. When existing information (4) is plotted in this form the rate of hydrogen absorption in steam shows a sharp increase near the transition in the oxidation kinetics. The failure of other investigators to observe this appears to have been due only partly to the method of presenting results; the low total corrosion of specimens in some of the other studies probably has contributed also.

In the present work the hydrogen absorption curve for Zircaloy-2 is studied in greater detail, and an explanation of its features is proposed.

Experimental

Work was restricted initially to one billet of Zircaloy-2 (Z8006), available as sheet of 0.030 and 0.100 in. thickness. Its analysis is given in Table I. Specimens from the 0.030 in. sheet were used primarily to minimize the analytical scatter at low hydrogen contents. The blank hydrogen content was obtained on unoxidized corrosion specimens.

The specimens, approximately 3 x 1 cm, were abraded to 3/0 emery and pickled in nitric/hydrofluoric acid. They were corroded in steam at 1 atm pressure and 300°-600°C. The oxidation was carried out in the circulating steam loops described previously (9). The steam flow was maintained at a rate which prevented diffusion of air or hydrogen from the corrosion reaction back into the reaction chamber.

A further atmospheric pressure steam loop was built in which gases could be added to the steam on the inlet side of the furnace. The flow of these gases was determined at room temperature, using a "Rotameter." The steam flow rate was measured by the syphoning time of a known volume of condensate in the return arm of the loop. The values of these flow rates were adjusted to give approximately 50% by volume of the added gas at the temperature of the specimens. Additions of oxygen, air, nitrogen, ozonized air, hydrogen and nitric acid vapor were made at 500°C. Because of the short lifetime of O_3 at 500°C, ozonized air also was used at 350°C.

Some experiments, in water vapor at 1 cm pressure, on Sartorius "electrono" vacuum microbalances are reported, where the specimens subsequently have been analyzed for hydrogen content.

Hydrogen analyses were performed initially on specimens from which the oxide film had been removed. Difficulties in calculating the weight of the residual metal core in specimens showing high weight gains dictated a change to an analysis of specimens which still bore their oxide film. No change in the hydrogen uptake curves at high weight gains resulted from this change in procedure.

Results

The oxidation data from experiments in 1 atm steam are shown in Fig. 1-3. Hydrogen uptake by these specimens is shown in Fig. 4 and 5. The experimental weight gains in Fig. 1-3 have been corrected for the weight of hydrogen in the specimen before plotting in Fig. 4 and 5. The effect on the oxidation of Zircaloy-2 of gases added to the steam is shown in Fig. 6, and the hydrogen absorbed during these experiments in Fig. 7. Results obtained at 1 cm pressure are shown in Fig. 8 and 10 and the corresponding hydrogen contents in Fig. 9. Results for hydrogen uptake by Zircaloy-3 and a Zr-2% Nb-0.5% Sn alloy are shown in Fig. 11-13.

Discussion

The oxidation kinetics of Zircaloy-2 (billet Z8006) agree well with other work (11) and with our own work on other Zircaloy-2 billets. At temperatures of 500°C and above this billet shows shorter times to transition than some other billets. The signifi-

cance of such small differences and of those between samples from the 0.030 and 0.100 in. sheets are not discussed here.

The curve for hydrogen uptake by Zircaloy-2 (Fig. 5) can be divided into three regions:

1. Region A covers the initial oxidation up to a weight gain of 8-10 mg/dm², where the oxide film is still showing interference colors;

2. Region B covers the oxidation from the end of region A up to the transition in the oxidation kinetics, during which a plateau in the hydrogen absorption curve is found;

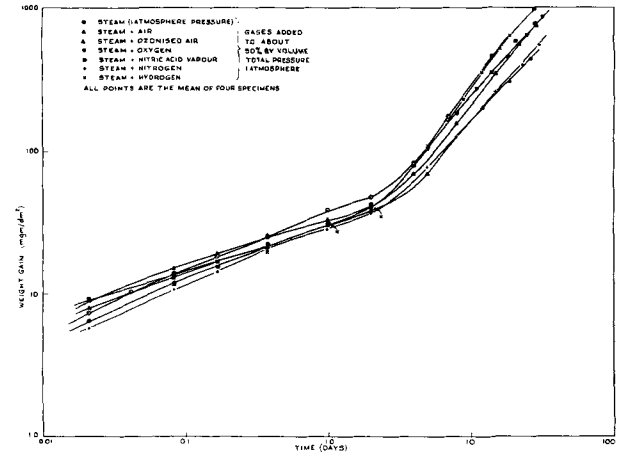

Fig. 6. Effect of added gases on the corrosion of Zircaloy-2 (billet Z8006) in steam.

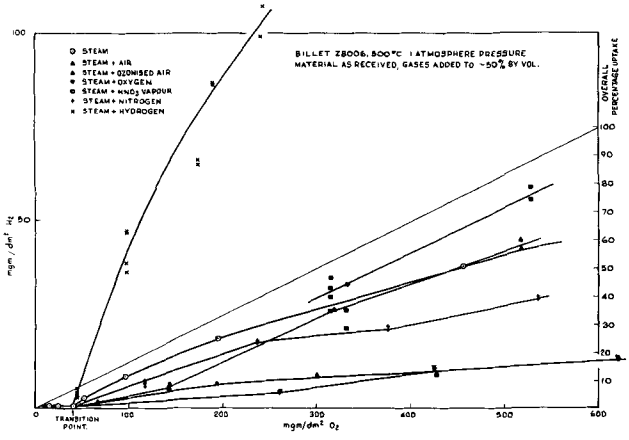

Fig. 7. Hydrogen uptake in steam plus added gases

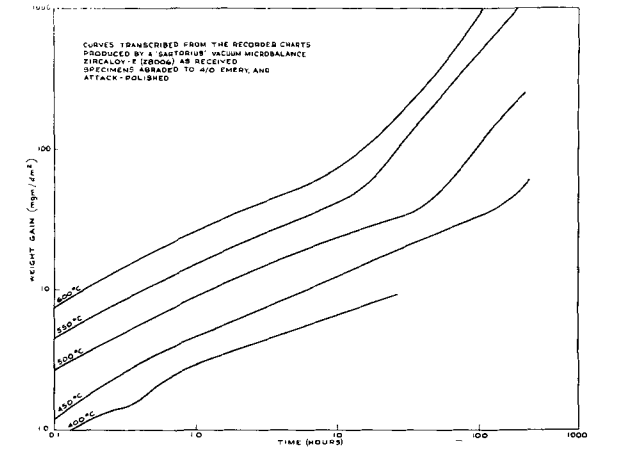

Fig. 8. Oxidation curves for Zircaloy-2 (Z8006) at 1.5 cm pressure in water vapor.

3. Region C commences near the transition in the oxidation kinetics and is marked by a rate of uptake close to 100%, in the early stages, falling to around 50% at high weight gains.

Oxidation Mechanism

Since the rate of hydrogen absorption changes along the oxidation curve, some knowledge of the oxidation mechanism in the above regions is needed before any interpretation of the hydrogen uptake curve is possible. The mechanisms, proposed in

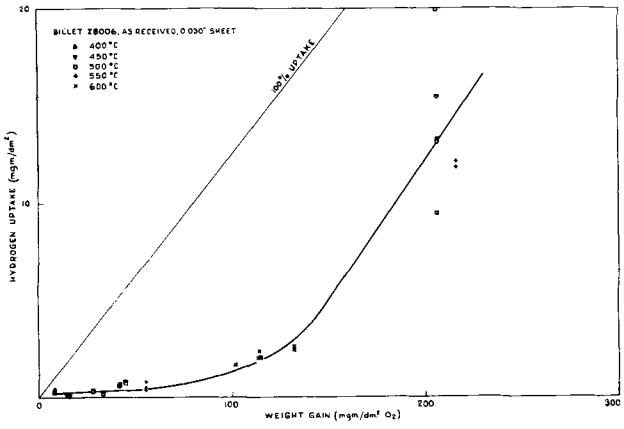

Fig. 9. Hydrogen uptake during oxidation in water vapor at 1.5 cm pressure.

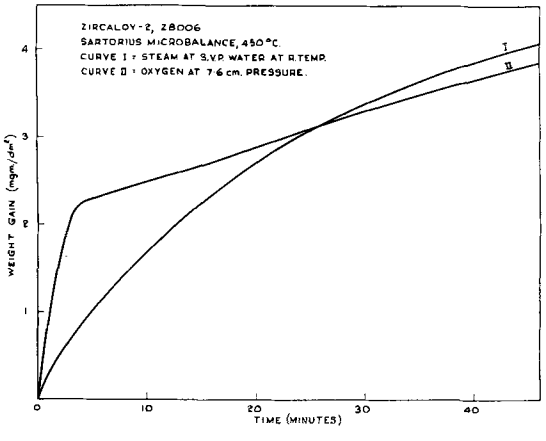

Fig. 10. Initial oxidation rates in steam and oxygen

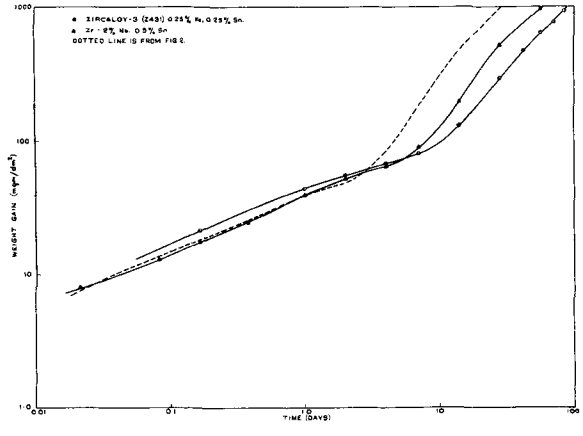

Fig. 11. Oxidation of Zircaloy-3 and Zr-2% Nb-1% Sn in steam at 500°C, 1 atm.

earlier reports, to explain these regions are recapitulated briefly:

1. Region A covers the growth of the interference-color oxide film which is thought to grow by transport of reactants down the potential gradient in the thin film, rather than by diffusion of reactants down a vacancy gradient. The rate law obeyed in the initial stages was thought to be logarithmic (12, 14).

2. Region B commences close to the point where the electric field has decreased until growth by the above mechanism is negligible. The transport of reactants by diffusion down easy paths in the oxide is thought to provide the principal method for film

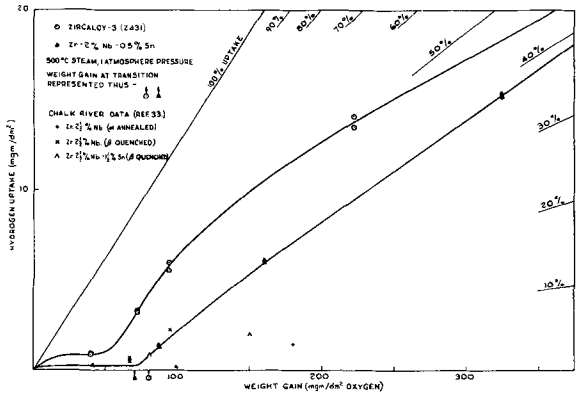

Fig. 12. Hydrogen uptake by Zircaloy-3 and Zr-2% Nb-0.5% Sn at low weight gains.

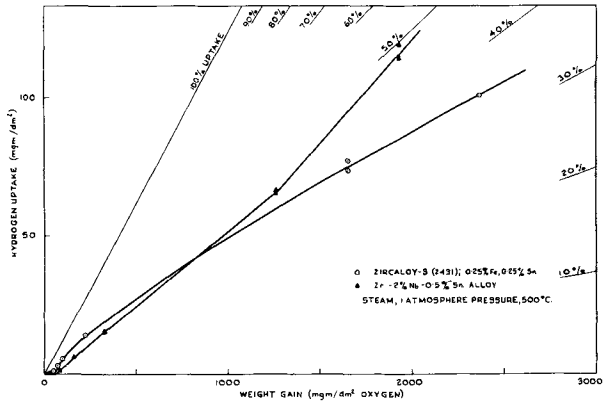

Fig. 13. Hydrogen uptake by Zircaloy-3 and Zr-2% Nb-0.5% Sn at high weight gains.

growth here. Transport through the uniform film continues in parallel with this mechanism. In Zircaloy-2 the easy paths for transport of reactant are distributed relatively uniformly and are thought to be associated with the oxidation of the intermetallic particles in the alloy and with grain boundaries in the metal. During this period the oxide film formed in region A persists as a surface layer (15) and the black film formed in region B grows underneath it.

3. Region C corresponds to the post-transition period of oxidation, where the black oxide film, formed in region B, is thought to have cracked due to stresses set up during its growth (13, 14). A decrease in the incidence of cracking (visible on the electron microscope), with increasing temperature of oxidation (16), suggests that cracking of the oxide film may be an effect of porosity, generated in some other manner, rather than its cause.

Hydrogen Uptake in Region A

If the rate of growth of the thin oxide film is determined by the electric field set up, then the process may be analogous to the growth of an anodic oxide film. The driving force would be provided by the chemical affinity of zirconium for oxygen. The rapid increase in the thickness of the anodic film, formed at a constant potential, with increasing temperature above 200°C (20) makes possible the growth of oxide films several thousand Ångstroms thick at the low potential available. Possible mechanisms by which hydrogen can pass through such a film are: (*a*) by the transport of OH′ ions through

the oxide under the influence of the applied field; and (*b*) by diffusion of the hydrogen down pores in the oxide film.

If the first mechanism applies then the hydrogen uptake should be approximately 50% of the theoretical yield, and higher values should not be possible. If the second mechanism holds, then hydrogen absorption in this region would not be restricted to 50% of that theoretically available, and addition of excess hydrogen to the system should result in increases in the rate of uptake. We have little knowledge of the physical nature of these thin films formed at high temperatures; however, it is known that anodic oxide films show variable porosity depending on the conditions of formation and on alloy composition (21-26).

Our results show that no points occur above the 50% line in this region (Fig. 5), and that no increase in uptake results from the addition of hydrogen to the steam (prior to the transition in the oxidation kinetics). These results support mechanism (*a*) and differences in the initial oxidation rates in oxygen and water vapor provide possible additional evidence for this mechanism for hydrogen uptake in region A (Fig. 10).

In water containing oxygen, with and without the addition of copper sulfate (4, 19), and in copper and cadmium sulfate solutions not containing oxygen (27), zero hydrogen uptake has been observed in this region. This may be evidence for the second mechanism, although it is possible that the reaction in sulfate solutions is with adsorbed sulfate ion and not with adsorbed water molecules. Variations with pressure in the amount of hydrogen absorbed in region A (Fig. 5 and 9) also suggest that microporosity in the oxide film may be partly responsible for hydrogen uptake here.

Specimens anodized at room temperature in N-H_2SO_4, N-$NaHSO_4$, and N-NaOH showed no increase in hydrogen content and did not resolve the above difference. Boyle and Kisiel's results in high-pressure steam plus hydrogen (37) support mechanism (*a*) for the uptake of hydrogen in this region, and it is considered that this mechanism is responsible for most of the hydrogen which enters the metal. Varying porosity of the oxide film, under varying conditions of formation, probably accounts for the apparent discrepancy between results obtained in steam and in water.

Hydrogen Uptake in Region B

In the previous section we have concluded that, in steam, access of hydrogen to the metal via porosity in the oxide film is unimportant. Capacitance measurements show that the oxide film or Zircaloy-2 is apparently porous before the transition point is reached. It seems probable, therefore, that there are some pores present in the oxide film during region B. Since the amount of hydrogen absorbed by the metal is unaffected by additions to the gas phase, these pores do not influence the absorption of hydrogen, prior to the transition in the oxidation kinetics.

During region B the electric field in the oxide is insufficient to transport ions through the film at a significant rate, and diffusion is the rate-controlling process. The hydrogen released in the oxidation reaction will probably be liberated first at surface sites. The probability of its recombining and being released as molecular hydrogen, before it can diffuse down the pores present is likely to be high. The observation of a plateau in the hydrogen uptake curve during region B, and the failure of oxygen and hydrogen additions to the gas to affect uptake prior to transition, can probably be explained on this basis.

In water there is some evidence, from the preceding section, that porosity in the oxide film plays a more significant part in the hydrogen uptake process. That high hydrogen uptakes, in water with added hydrogen, and the converse, with added oxygen, are found in region B (19) as well as in region A therefore is not surprising. There is no evidence for a threshold weight gain for increased hydrogen uptake, but there are indications of a threshold hydrogen concentration for increased absorption (19). The apparent discrepancy between Westinghouse data, in water containing a high concentration of hydrogen (1, 2, 29), and results obtained elsewhere (7, 36), with lower concentrations of hydrogen in solution, may be explained on this basis.

Hydrogen Uptake in Region C

In this region the oxide film is almost certainly porous, although at temperatures above 500°C it is not visibly cracked. The high percentage uptake is probably due to the release of the hydrogen at the bottoms of the pores. The hydrogen then may be unable to diffuse out of the pore, against the flow of the incoming reactants, before being absorbed by the metal. An initial rate of absorption, apparently greater than 100%, is not thought to result from hydrogen accumulating in the gas stream, but remains unexplained.

If the above mechanism for hydrogen absorption applies in region C, then a variation in the experimental conditions which increases the lifetime of the hydrogen atom at the bottom of the pore should increase the proportion of the available hydrogen which is absorbed by the metal. Adsorption on surfaces sites is a necessary preliminary to absorption by the metal, and the lifetime in such a state might be changed by the addition of gases to the steam which would compete for the surface sites. Additions of hydrogen to the steam would be expected to give increased absorption under these conditions, and additions of oxygen (either by surface recombination with the hydrogen or by competition) should reduce the amount of hydrogen absorbed. This is found to be the case (Fig. 7). The effect of nitrogen additions to the steam suggests that both recombination on the surface and competition for the surface sites are participating in the process. Additions of air, ozonized air, and nitric acid vapor result in hydrogen uptake curves not inconsistent with the above hypothesis.

In water vapor at 1 cm pressure the rate of hydrogen absorption, after the transition in the oxidation rate, is lower than at atmospheric pressure (Fig. 9), although it eventually rises to a rate of about 100%. The effect of pressure on the behavior in re-

gion C may result from a decrease with pressure in the ease of adsorption of hydrogen on surface sites.

Other Alloys

Data on other alloys are generally not sufficient to permit a treatment similar to that above. Discussion of the effect of alloying additions on hydrogen uptake, based on the over-all percentage, uptake at different points in the oxidation curve, is obviously invalid. In only a few instances is it possible to draw any conclusions.

Low-nickel alloys.—Hydrogen uptake by the low-nickel alloys, derived from Zircaloy-2 by removing the nickel (Zircaloy-4) and replacing it with the equivalent amount of iron (iron-replaced Zircaloy-4), has been reported (8, 30). The results were presented as the weight increase of oxygen versus the concentration of hydrogen. In other reports a low over-all percentage hydrogen uptake is quoted for alloys of the same type (31, 32). The highest weight gains in these experiments were not large, compared with the weight gain at the transition point, and any change in the rate of hydrogen absorption at the transition point may have been obscured.

Our results for Zircaloy-3 (0.25% Fe, 0.25% Sn, low-nickel) are illustrated in Fig. 11-13 and show an increased rate of hydrogen absorption following the transition in the oxidation kinetics. The maximum rate of absorption in region C is 70%, falling to about 30% at high weight gains. Thus estimates of the total hydrogen absorbed by low-nickel alloys, based on extrapolation of the results for regions A and B, are likely to be seriously in error.

Low-niobium zirconium-based alloys.—Zirconium alloys, containing 1-5 w/o Nb, are also reported to show low over-all percentage uptakes (33-35). Replotting some of these data (33) (Fig. 12) reveals evidence for an increase in the rate of uptake near the transition point in the oxidation curve. Results obtained here on a Zr-2% Nb-0.5% Sn alloy show that the rate of hydrogen absorption (in region C) is about 50% for this alloy (Fig. 11-13). Hence, extrapolation of the hydrogen content, on the basis of the low hydrogen uptake in regions A and B, would again lead to serious errors.

The relative merits of these alloys, for service in steam, may be assessed from the total hydrogen absorbed after corrosion for a given time. In Fig. 14 the hydrogen uptake by Zircaloy-2, Zircaloy-3, and the

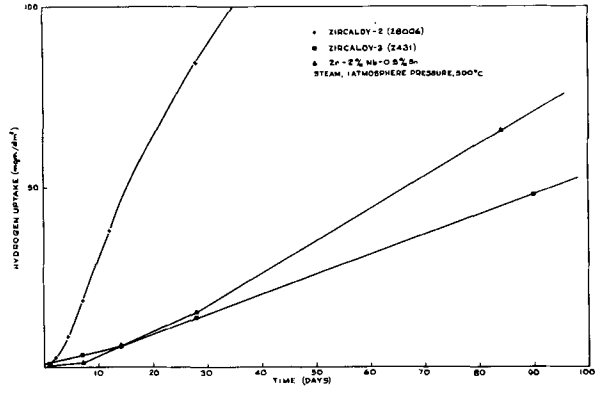

Fig. 14. Comparison of hydrogen absorbed by Zircaloy-2, Zircaloy-3, and Zr-2% Nb-0.5% Sn vs. time.

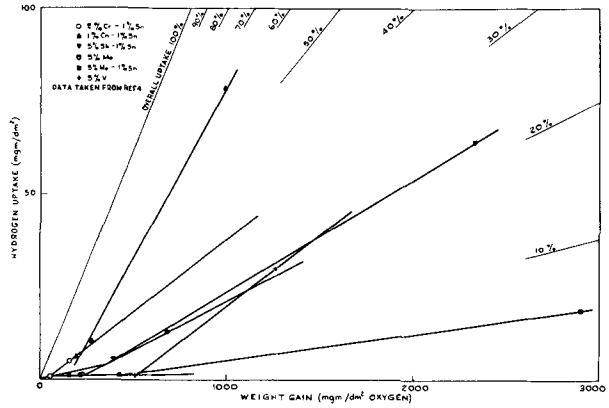

Fig. 15. Hydrogen uptake by some miscellaneous zirconium alloys

Zr-2% Nb-0.5% Sn alloy is plotted against time. Zircaloy-2 is seen to be inferior to the other two alloys (by a factor of ~7); and Zircaloy-3 is superior to the niobium alloy at long times The hydrogen contents of all three alloys at any time (in region C) will be higher than those calculated by the extrapolation of the pretransition data. Since, in practice, most calculations have used the (supposedly) conservative figure of 100% hydrogen uptake in estimating the service life of zirconium alloy components the conclusions reached in them are not invalidated by the work reported here.

Some earlier results (4) for other alloy systems have been replotted in Fig. 15. These show that insofar as a comparison of data obtained under different conditions is valid, increases in the rate of hydrogen absorption in region C are general. The final rates of absorption vary considerably with the alloying addition.

Conclusions

From this study of hydrogen-absorption by Zircaloy-2 it is concluded that the mechanism of absorption changes during the course of oxidation in steam. The processes taking place can be explained by considering the behavior in three regions of the oxidation curve:

1. Region A terminates with the disappearance of the interference-color oxide film. During this period transport of OH' ions through the oxide, under the influence of the electric field, provides the mechanism for the entry of hydrogen. Hydrogen absorption greater than 50% of that theoretically possible is not observed in steam. In water, variations in the porosity of the oxide film may influence the amount of hydrogen absorbed.

2. Region B extends from the point at which the interference colors disappear up to the transition in the kinetics of oxidation. The low percentage of hydrogen absorbed in this region is probably due to the release of hydrogen atoms at surface sites. These atoms recombine to form molecular hydrogen more rapidly than they can diffuse into the oxide.

3. Region C starts near the transition in the oxidation kinetics and is marked by a sharp increase in the rate of hydrogen absorption. In this region the hydrogen released by the corrosion reaction is liberated at the bottoms of pores, rather than at the outer surface of the oxide. Thus it has an increased change of diffusing through the film at the base of

the pore, before it can recombine and diffuse out of the oxide. The addition of oxygen to the steam suppresses the increase in the rate of uptake in region C; addition of hydrogen enhances it. The accelerated uptake following hydrogen additions is not evident during the previous periods, however. Other addition to the steam give results intermediate between those given by oxygen additions and those obtained with steam alone.

The shape of the hydrogen absorption curve, observed with Zircaloy-2, is found to hold for Zircaloy-3, and a Zr-2% Nb-0.5% Sn alloy and is probably general for zirconium alloys which follow oxidation curves in steam of similar form to that of Zircaloy-2. The rate of hydrogen uptake in the post-transition region (C) varies widely with alloying addition.

Electrical Properties of Evaporated Aluminum Oxide Films

E. M. DaSilva and P. White

Thomas J. Watson Research Center, International Business Machines Corporation, Yorktown Heights, New York

ABSTRACT

Insulating films of aluminum oxide have been prepared by evaporation of aluminum in a partial pressure of 10^{-3} mm Hg of oxygen. On exposure to air both dielectric constant and dissipation factor increase to values similar to those observed for anodized films on bulk aluminum. The results can be understood if the initial insulating film is a suboxide similar to the postulated AlO which is normally unstable at room temperature in air or oxygen, decomposing to Al_2O_3.

In recent years anodic oxidation of metal surfaces has been a popular method of preparing thin film capacitors, and the techniques of anodizing various metals have been extensively investigated (1). The oxide dielectric films formed by these methods are generally in the thickness range of 200-500Å and appear to have comparatively high breakdown voltages.

More recently, a tantalum oxide capacitor has been prepared by sputtering tantalum in an inert

the pore, before it can recombine and diffuse out of the oxide. The addition of oxygen to the steam suppresses the increase in the rate of uptake in region C; addition of hydrogen enhances it. The accelerated uptake following hydrogen additions is not evident during the previous periods, however. Other addition to the steam give results intermediate between those given by oxygen additions and those obtained with steam alone.

The shape of the hydrogen absorption curve, observed with Zircaloy-2, is found to hold for Zircaloy-3, and a Zr-2% Nb-0.5% Sn alloy and is probably general for zirconium alloys which follow oxidation curves in steam of similar form to that of Zircaloy-2. The rate of hydrogen uptake in the post-transition region (C) varies widely with alloying addition.

ABSTRACT

Insulating films of aluminum oxide have been prepared by evaporation of aluminum in a partial pressure of 10^{-3} mm Hg of oxygen. On exposure to air both dielectric constant and dissipation factor increase to values similar to those observed for anodized films on bulk aluminum. The results can be understood if the initial insulating film is a suboxide similar to the postulated AlO which is normally unstable at room temperature in air or oxygen, decomposing to Al_2O_3.

In recent years anodic oxidation of metal surfaces has been a popular method of preparing thin film capacitors, and the techniques of anodizing various metals have been extensively investigated (1). The oxide dielectric films formed by these methods are generally in the thickness range of 200-500Å and appear to have comparatively high breakdown voltages.

More recently, a tantalum oxide capacitor has been prepared by sputtering tantalum in an inert

gas atmosphere containing partial pressures of oxygen in the 1μ range (2). These capacitors have similar physical properties to those prepared by anodization. Attempts have been made to prepare metal oxide coatings by evaporating metals in pressures of oxygen in the 10-0.1μ range (3). These coatings are reported to have high mechanical strength and excellent optical properties, but no data exist on the electrical properties of oxides prepared in this manner.

This paper describes the preparation and electrical characteristics of aluminum oxide capacitors made up of thin films of aluminum oxide which were deposited between aluminum electrodes by evaporation techniques. The oxide dielectric was prepared by evaporation of aluminum in an oxygen atmosphere. The values of dielectric constant and dissipation factor of these films have been measured under a variety of conditions and are compared with the electrical properties of aluminum oxide films formed by anodization.

Experimental

There are two possible methods of preparing oxide films using evaporation techniques. The first of these, the direct evaporation of the bulk oxide, is difficult. Most metal oxides require relatively high temperatures for evaporation and often dissociate at or below this temperature. Products of this dissociation can then result in the contamination of the deposited layer. This method was not attempted. The second method is the evaporation of the metal in an oxygen atmosphere. Three possible mechanisms have been postulated for the oxide formation: (a) oxidation of the newly formed metal layer; (b) gas phase collisions between metal vapor and oxygen molecules; and (c) the formation of a suboxide on the source which, if sufficiently volatile, may evaporate. It has been reported (3) that tantalum oxide can be evaporated by mechanism (c). The films used in this study were prepared by the second method, but it was not determined which of the three mechanisms of oxide was operative.

Initially, experiments were performed to determine the resistivity of films evaporated from an aluminum source in various partial pressures of oxygen in the range 10^{-3} to 10^{-5} mm Hg. The pressure was controlled to $\pm 10\%$ by bleeding oxygen into the system through a needle valve and was measured on an ionization gauge mounted on the base plate of the belljar. In addition to controlling oxygen pressure in the system it was desirable to control the evaporation rate of the aluminum. This was not always possible since the presence of oxygen gas caused partial oxidation of the source. In general, three distinct types of film were obtained depending on the oxygen pressure and the evaporation rate of aluminum. Films deposited in an oxygen pressure range of 10^{-5} mm Hg were essentially metallic in appearance and had a low resistance. As the evaporation rate was decreased and the oxygen pressure increased, the resistivity of the film increased. Films deposited in an oxygen pressure of 1×10^{-3} mm Hg at a rate of 1-5 Å/sec exhibited the characteristics of an insulator having a resistivity of about 10^{14} ohm cm. Experimental results are summarized in Table I. The dielectric films for the capacitors discussed in this paper were prepared at low evaporation rates, 1-5 Å/sec, in an oxygen pressure of about 1×10^{-3} mm Hg.

All evaporations were carried out in an oil diffusion pumped high-vacuum belljar system capable of ultimate pressures in the low 10^{-5} mm Hg range. Inside the belljar, provision was made for two sources, each with a separate shutter for preliminary outgassing, arranged so that there was no contamination of one source by the other. Figure 1 illustrates this arrangement. Capacitors were made on a microscope slide by positioning a mask of the appropriate configuration in front of the slide for each of the three evaporations; first metal electrode, dielectric, and second metal electrode. Figure 2 shows the typical configuration of capacitors prepared. The metal electrodes were evaporated in a pattern such that contact was made with a silver painted area on the microscope slide. Copper wires previously soldered to these silvered areas were brought through the base plate of the belljar system and allowed the capacitor to be tested in vacuum in the belljar immediately after preparation.

Sinusoidal shaped sources constructed from stranded tungsten wire were used for evaporation of both pure metal and oxide dielectric. Two separate evaporations were required from the source used for preparation of the metal electrodes. Therefore, a large quantity of aluminum, approximately 0.5g, was

Table I. Resistivity of aluminum films deposited in various partial pressures of oxygen

Film No.	Average deposition rate, Å/sec	Pressure, mm Hg	Resistivity, ohm-cm	Appearance
7	50	4×10^{-5}	2.6×10^{-4}	Bright Metal

distributed among the loops of the source. To achieve the evaporation rate control necessary for the preparation of the oxide dielectric, only one loop of the source was loaded with approximately 0.1g of aluminum. In this way the current input to the source was more stable, since deterioration of the filament was limited to the single loop containing the charge.

The preheat procedure for raising the aluminum charge to evaporating temperature was the same for each source. The temperature of the tungsten wire support was gradually increased within a 15-20 min period to 900°C in order to achieve some outgassing of the charge prior to the filament wetting. At this temperature aluminum was deposited at 15-20 Å/sec on a substrate placed 6.5 cm from the source. (During the preheat procedure the pressure increased from 1 x 10^{-5} to 6 x 10^{-5} mm Hg.) In this manner, metal electrodes, 5000Å thick, were deposited on the substrate.

The oxide dielectric film was prepared by raising the source temperature to 900°C and opening the oxygen leak valve to increase the pressure in the belljar from 6 x 10^{-5} to 1 x 10^{-3} mm Hg. At all times the pressure was maintained above 8 x 10^{-4} mm Hg. Under these conditions the source life was 8-10 min. Using this procedure, the rate of deposition of oxide film was between 0.5 and 1.0 Å/sec with a source-to-substrate distance of 17 cm.

Measurements of capacitance and dissipation factor of the test devices were made at 0.6, 1, and 2 kc, using a G.R. 716-C capacitance bridge. A signal of 1.5 v could be applied to the films at room temperature without adverse effects. Capacitance measurements were accurate to ±1% while dissipation factor varied within ±5% over the range 0.05-0.20. Measurements were made on the film immediately after preparation in the belljar at room temperature, after exposure to air at room temperature, at 78° and at 4.2°K.

Film thicknesses were measured by an optical interferometric method with an accuracy of ±100Å.

Results

The values of dielectric constant and dissipation factor measured immediately after preparation in vacuum and after exposure to air are shown in Table II for a number of aluminum oxide dielectric films. The large percentage change in dielectric constant on exposure to air seems to be about the same for each sample within experimental error. Figure 3 shows in a little more detail the behavior of a series of films. The changes in dielectric constant and dissipation factor are expressed as percentage changes of the values measured, in 10^{-5} mm Hg, immediately after preparation of the second metal layer. The capacitors were stored in the belljar for 24 hr at 10^{-3} mm Hg of oxygen and measured again. Immediately following this, measurements were made with film exposed to 1 atm pressure of nitrogen at 23°C and then with the film exposed to 1 atm pressure of oxygen at 23°C. There appears to be good reproducibility between the measurements on the different slides. The dielectric constant changes only slightly on being stored in vacuum, remains constant on admission of nitrogen to the sample, but increases considerably on subsequent exposure to air or oxygen. This change on admission of oxygen is not as rapid as that which takes place when the film has not been exposed to nitrogen; nevertheless the final values are about the same, *i.e.*, about twice the value of the film measured in vacuum. The values of dissipation factor on the other hand initially decrease on being stored in vacuum (10^{-3} mm Hg), remain constant on admission of nitrogen and then increase by a very large factor on admission of oxygen. The final values of dissipation factor were approximately the same as in the case when nitrogen was not admitted to the belljar prior to admission of oxygen.

The temperature dependence of both dielectric constant and dissipation factor of these films are shown in Fig. 4.

Table II. Values of dielectric constant and dissipation factor measured in vacuum and in air at room temperature

Discussion

After the aluminum oxide capacitor has been exposed to air, the values of dielectric constant at 1 kc and the values of the temperature variation of dielectric constant are similar to values which have been reported for anodized layers of aluminum (4). In spite of the difference between measured values of dissipation factor, it appears likely that the evaporated oxide after exposure to air is similar to bulk aluminum oxide, which has been reported to have a dielectric constant of about 11 (5). The insulating film formed by evaporation of aluminum in 10^{-8} mm Hg pressure of oxygen has a dielectric constant of about six and is apparently different from the bulk oxide.

A condition now exists in which the initial insulating film formed by evaporation in 10^{-8} mm Hg of oxygen is converted by exposure to 1 atm of oxygen gas into an insulating film having similar properties to those of the bulk oxide Al_2O_3. It may be inferred, therefore, that the film, as prepared, is a highly oxidized aluminum film with insufficient oxygen to form Al_2O_3, but which can react with excess oxygen to form a stable oxide similar to Al_2O_3. This type of behavior has been reported previously in the literature for aluminum oxide films prepared by thermal evaporation of aluminum oxide. (6). Both dielectric constant and dissipation factor of the suboxide are lower than the corresponding values of Al_2O_3. Two distinct interactions can be distinguished between oxygen and the suboxide as seen in Fig. 3: (*a*) exposure of the suboxide to pressures of 10^{-8} mm Hg of oxygen for a period of 24 hr accompanied by a slow increase in dielectric constant and a slow decrease in dissipation factor, and (*b*) exposure of the suboxide to 1 atm of oxygen accompanied by a sudden increase in both dielectric constant and dissipation factor.

The first of these is perhaps understandable in terms of an oxygen sorption mechanism. Table I shows that as the partial pressure of oxygen in the system was increased the resistance of the evaporated film increased, which was probably due to incorporation of oxygen in the aluminum lattice. Exposure of one of these films to a greater partial pressure of oxygen than that in which it was prepared, would undoubtedly lead to sorption of more oxygen with an accompanying increase in resistance similar to that observed in Table I.

If it is assumed that the change in dissipation factor caused by changes in polarization due to oxygen sorption is small, then the comparatively large decrease in dissipation factor may be related to an increase in resistivity of the suboxide. This increase in resistivity on sorption of oxygen is what might be anticipated as a result of the above discussion. Obviously, there must be a limit to this process.

It is well known that a variety of suboxides of aluminum are capable of existence, but all are unstable at room temperature in the presence of air or oxygen forming Al_2O_3. If, then, evaporation of aluminum in oxygen produces a suboxide, it might be expected that variation of oxygen pressure over a small range would cause a change similar to that observed above, but on exposure to air or oxygen a decomposition to Al_2O_3 should occur. The rate at which the decomposition takes place would be limited in this particular case by the geometry of the system since the aluminum oxide layer is covered almost completely by the aluminum electrodes.

Tin-Activated Magnesium Barium Pyrophosphate Phosphors

R. C. Ropp

Chemical and Metallurgical Division, Sylvania Electric Products Inc., Towanda, Pennsylvania

ABSTRACT

Although $Mg_2P_2O_7$ cannot be activated by tin, combination with $Ba_2P_2O_7$ (Ba <25 mole %) produces a very efficient phosphor, $(Mg,Ba)_2P_2O_7$:Sn, emitting at 3970Å. This last phase, combined with δ-$Ba_2P_2O_7$, forms a solid solution of limited stability, $(Ba,Mg)_2P_2O_7$:Sn, whose emission band appears at 5120Å when excited by 2537Å. A ternary phase can be formed $(Mg_{1.5}Ba_{0.5-x}Sr_x)P_2O_7$:Sn, whose ultraviolet emission peak changes with composition.

Many investigations have centered on the tin-activated orthophosphates (1, 2) and pyrophosphates (3) containing calcium, strontium, and barium, alone, or in combination. However, no tin-activated magnesium phosphate phosphors have been reported. The present work describes the preparation of the tin-activated magnesium barium pyrophosphates, their spectral characteristics, and the relationships among the members of the system. This study was part of a generic survey of phosphors emitting in the ultraviolet region of the spectrum.

Experimental Method

In general, methods of preparation and measurement of the phosphors were those described in a previous work (3). Ignition of $BaHPO_4$ and

Discussion

After the aluminum oxide capacitor has been exposed to air, the values of dielectric constant at 1 kc and the values of the temperature variation of dielectric constant are similar to values which have been reported for anodized layers of aluminum (4). Tin-Activated Magnesium Barium Pyrophosphate Phosphors

R. C. Ropp

Chemical and Metallurgical Division, Sylvania Electric Products Inc., Towanda, Pennsylvania

ABSTRACT

Although $Mg_2P_2O_7$ cannot be activated by tin, combination with $Ba_2P_2O_7$ (Ba <25 mole %) produces a very efficient phosphor, $(Mg,Ba)_2P_2O_7$:Sn, emitting at 3970Å. This last phase, combined with δ-$Ba_2P_2O_7$, forms a solid solution of limited stability, $(Ba,Mg)_2P_2O_7$:Sn, whose emission band appears at 5120Å when excited by 2537Å. A ternary phase can be formed $(Mg_{1.5}Ba_{0.5-x}Sr_x)P_2O_7$:Sn, whose ultraviolet emission peak changes with composition.

Many investigations have centered on the tin-activated orthophosphates (1, 2) and pyrophosphates (3) containing calcium, strontium, and barium, alone, or in combination. However, no tin-activated magnesium phosphate phosphors have been reported. The present work describes the preparation of the tin-activated magnesium barium pyrophosphates, their spectral characteristics, and the relationships among the members of the system. This study was part of a generic survey of phosphors emitting in the ultraviolet region of the spectrum.

Experimental Method

In general, methods of preparation and measurement of the phosphors were those described in a previous work (3). Ignition of $BaHPO_4$ and

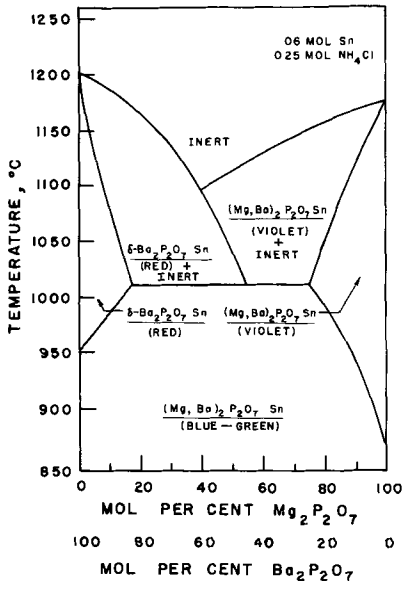

Fig. 1. Diagram of the tin-activated magnesium-barium pyrophosphate system.

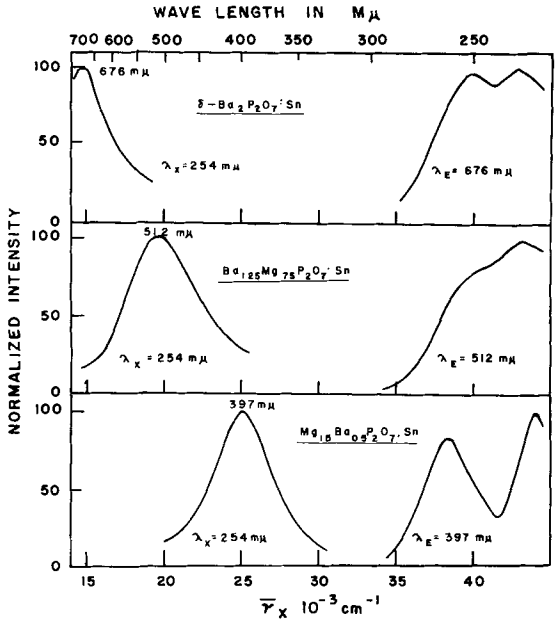

Fig. 2. Excitation-emission properties of the magnesium-barium pyrophosphates.

$MgNH_4PO_4 \cdot H_2O$ readily gave $Ba_2P_2O_7$ and $Mg_2P_2O_7$, respectively, although it was found in some cases that much brighter phosphors were obtained by utilizing the reaction:

$$2MgO + 2(NH_4)_2HPO_4 \rightarrow Mg_2P_2O_7 + 4NH_3 + 3H_2O$$

Precipitation of $BaHPO_4$ was accomplished by the addition of an aqueous solution of $(NH_4)_2HPO_4$ to a solution containing $Ba(NO_3)_2$. Both solutes were of high purity as was the solvent, water. The precipitation of $MgNH_4PO_4 \cdot H_2O$ followed the standard analytical procedure (4). In many cases, the use of NH_4Cl as a flux was found advantageous. Crystal structures were identified by x-ray powder diffraction patterns. The activator was added as SnO and concentrations between 0.01 mole Sn and 0.10 mole Sn per mole pyrophosphate did not change the luminescent properties.

Since tin functions as an activator in the reduced state, considered to be Sn^{+2}, formation of tin-activated phosphors must involve firing in a reducing atmosphere as part of the preparation process. Because excessive reduction can occur as well as undesired re-oxidation, control of the atmosphere during firing and cooling is vital.

Experimental Results

In order to define the luminescent phases present as a function of both firing temperature and composition, it was necessary to control the time of firing closely. An optimum firing time of 135 min gave maximum luminescence in most cases, as well as a single luminescent phase at a given composition.

A diagram is given in Fig. 1 outlining the regions of temperature and composition in which the luminescent phases discovered were stable. Three luminescent phases were found: a red-emitting phase whose x-ray diffraction pattern was similar to δ-$Ba_2P_2O_7$:Sn (5), a blue-green-emitting phase, $(Ba,Mg)_2P_2O_7$:Sn, whose x-ray diffraction pattern was in some respects comparable to α-$Ba_2P_2O_7$:Sn, and a violet-emitting phase, $(Mg,Ba)_2P_2O_7$:Sn. (The formulas are written so that the cation appearing first indicates that of greatest mole per cent composition.)

It was difficult to obtain a completely homogeneous blue-green-emitting phase in the presence of NH_4Cl flux unless the firing conditions were carefully controlled. Therefore, the preferred method of preparation for the blue-green phase involved prefiring in air and refiring in a reducing atmosphere (nitrogen-5% hydrogen). The red- and violet-emitting phases were more easily prepared in the presence of NH_4Cl (0.25 mole per mole pyrophosphate), which served as a flux, as well as a protective atmosphere, during firing. In the absence of flux, much higher temperatures were required to obtain the red- or violet-emitting phases.

The spectral properties of the three phases are given in Fig. 2 and are discussed below. X-ray diffraction powder patterns were employed for identification. Table I shows the *d* spacings and intensities measured for the three main lines and the innermost lines of all the phases discovered.

Table I. X-ray powder diffraction patterns of the magnesium-barium pyrophosphates

Phase	*d* spacings in A			
	Innermost	1	2	3
δ-$Ba_2P_2O_7$:Sn	5.29	3.88	2.81	2.10

0.75	1.25	56	39
0.50	1.50	49	33

Barium-rich phases.—Only δ-$Ba_2P_2O_7$:Sn was found in barium-rich compositions when fired at 950°C or above, the minimum temperature depending on the amount of magnesium present. The luminescent properties described previously (3) include an emission band at 6760Å and excitation peaks at 2330Å and 2500Å. Although the magnesium was presumably incorporated within the lattice, as estimated by absence of lines due to MgO, $MgCO_3$ or $Mg_2P_2O_7$ in the x-ray diffraction pattern, magnesium apparently contributes little to the luminescent properties of the red-emitting phase.

The complexity of the diffraction patterns does not allow nor preclude the identification of $Mg_2P_2O_7$ as a separate phase.

The blue-green-emitting phase was stable over a wide range of composition below the critical temperature of 1010°C (see Fig. 1). The plaque response as compared to a standard phosphor is given in Table II.

The efficiency of the blue-green-emitting phase exceeded that of the low-temperature from α-$Ba_2P_2O_7$:Sn, by several-fold.

As shown in Fig. 2, $(Ba,Mg)_2P_2O_7$:Sn emits at 5120Å and has excitation peaks at 2320Å and 2520Å.

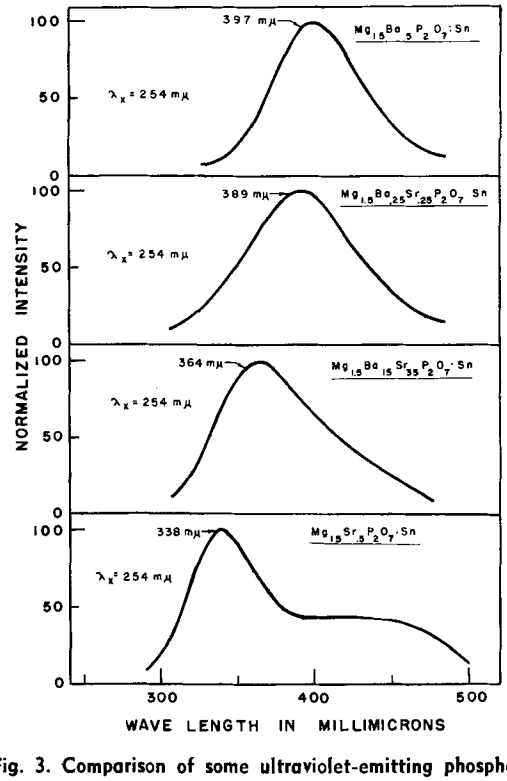

Fig. 3. Comparison of some ultraviolet-emitting phosphors

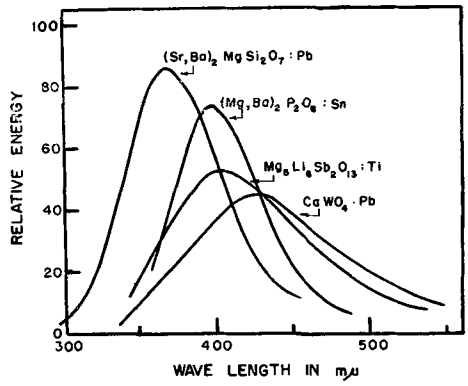

Fig. 4. Luminescent spectra of some ternary alkaline earth pyrophosphates.

The low-temperature form, α-$Ba_2P_2O_7$:Sn, which emits at 5050Å when excited by 2537Å radiation (3), is stabilized by the incorporation of magnesium, and the blue-green-emitting phase, $(Ba,Mg)_2P_2O_7$:Sn, is obtained at firing temperatures far in excess of those requisite for the low-temperature form, α-$Ba_2P_2O_7$:Sn. No difference in luminescent properties was noted between phosphors having the compositions $Ba_{1.25}Mg_{0.75}P_2O_7$:Sn and $Ba_{0.75}Mg_{1.25}P_2O_7$:Sn. However, the blue-green-emitting phase is unstable above 1010°C, and attempts to prepare the phosphor at higher temperatures always resulted in either the red-emitting phase, δ-$Ba_2P_2O_7$:Sn or the violet-emitting phase, $(Mg,Ba)_2P_2O_7$:Sn, depending on composition.

Magnesium-rich phases.—At the higher magnesium ratios, the violet-emitting phosphor was obtained. This phase emits at 3970Å, while two excitation peaks are found at 2270Å and 2600Å (see Fig. 2). In contrast, $Mg_2P_2O_7$ itself is not activated by Sn.

A comparison of the peak height response of four ultraviolet and blue-emitting phosphors to 2537Å irradiation is given in Fig. 3. The peak height of the violet-emitting phosphor is comparable to other more well-known phosphors (6, 7).

Tin content affected the emission peak only in intensity.

Ternary pyrophosphates.—The addition of Sr to the violet phosphor forms a homologous series of phosphors $Mg_{1.5}Ba_{0.5-x}Sr_xP_2O_7$:Sn, whose emission peaks change with the composition as shown in Fig. 4. Only single emission bands were found as the barium content approached zero, and no evidence for multiplicity was seen until the composition $Mg_{1.5}Sr_{0.5}P_2O_7$:Sn was reached. The emission at this point was then composed of an ultraviolet and a blue peak (3). The system $(Mg,Ba,Ca)_2P_2O_7$:Sn in contrast, shows no such effect, and only the violet emission due to $(Mg,Ba)_2P_2O_7$:Sn was seen.

Discussion

The emission colors noted in the tin-activated barium pyrophosphate-magnesium pyrophosphate system depend on the phase which is stable under the conditions of preparation. Considering each separately, it is difficult to relate one to another. The situation is further complicated by the fact that one of the end-members ($Mg_2P_2O_7$) is not activated by

tin. However, a satisfactory explanation may be given in terms of phase relationships.

The data in Fig. 1 represent a nonequilibrium diagram in which the colors and domains of stability of the phosphors are specified in terms of the optimum firing temperature and composition. However, the resemblance to a binary phase system which forms a solid solution over a limited range of composition is striking. In this case, the two phases are δ-$Ba_2P_2O_7$:Sn and $(Mg,Ba)_2P_2O_7$:Sn, which are red and violet emitters, respectively. They form a phase of limited temperature stability, $(Ba,Mg)_2P_2O_7$:Sn, whose emission lies between either parent. This phase seems to be the stable phase in the system at the lower firing temperature, but is not stable above 1010°C, decomposing to give one or the other of the parent phosphors, depending on composition. The inert or nonluminescent phase is probably a mixture of pyrophosphates, but no differences could be ascertained other than a lack of response to excitation, since the system as a whole was not at equilibrium in regard to phases present.

The violet phase is by far the most efficient of those found in the magnesium-barium pyrophosphate system. It has a single emission band in contrast to other binary tin-activated systems where in most cases two bands were found (3), and forms a ternary pyrophosphate phase whose peak emission changes with composition.

Of the known tin-activated systems, the violet phase, $(Mg,Ba)_2P_2O_7$:Sn, is the only one which emits in the 4000Å region. Strontium orthophosphate emits at 3700Å, but the intensity is low, whereas the violet phase possesses high efficiency.

Cathodoluminescent Characteristics of Mn-Activated $KMgF_3$

R. J. Kurtz[1]

Research Department, Westinghouse Electric Corporation, Bloomfield, New Jersey

ABSTRACT

The brightness, persistence, and maintenance of light output during life of cathode-ray excited $KMgF_3$:Mn phosphors were studied as a function of (*a*) Mn concentration, (*b*) K:Mg ratio, (*c*) ZnF_2 addition, and (*d*) firing conditions. The emission spectra and brightness-voltage and brightness-current characteristics of these samples are discussed. A cursory investigation of the cathodoluminescent characteristics of some other Mn-activated complex fluorides is also discussed.

Manganese-activated fluorides of zinc, magnesium, and zinc-magnesium have been investigated in the past from both practical and theoretical viewpoints. Because these fluorides are relatively long-persistence phosphors, they have been used in cathode-ray tubes for applications such as radar and loran display devices (1, 2). These phosphors have also been used by Williams (3-6) and his co-workers in the formulation of basic concepts of the luminescence process.

Other Mn-activated fluorides have, however, received scant attention. Fluorides of the alkali metals were found by Smith (7) to be poor phosphors, probably because in such phosphors there is a lack of suitable sites at which the manganese ions can function as activators. Smith further reported that attempts to prepare Mn-activated fluorides of strontium, barium, and cadmium resulted in nonluminescent samples of the first two and a weakly luminescent sample of the last. It is probable that the cations of these matrices are much too large to be replaced effectively by manganese.

Klasens (8) and his co-workers and Smith (7) have however reported on the preparation of a series of fairly efficient Mn-activated fluoride phosphors. These materials were all of the perovskite type structure. This family of phosphors has been reported (8) to have decay characteristics closely approximating those of ZnF_2:Mn and $(Zn,Mg)F_2$:Mn. Manganese-activated fluoride phosphors, however, in general display one notable disadvantage when compared to other cathodoluminescent phosphors, *i.e.*, they tend to deteriorate rapidly or "burn" during electron bombardment (9). Some of these phosphors have quite recently been found to be suitable for use in the form of transparent films for cathodolumines-

cent applications. This study of Mn-activated $KMgF_3$ is an outgrowth of work done to prepare better films of this material from the standpoint of brightness, persistence, and maintenance of light output during life.

Experimental Results

Three series of samples were prepared in order to determine the relationships between activator concentration and matrix composition and the following parameters: (*a*) brightness, (*b*) persistence, (*c*) maintenance of light output during life, (*d*) emission spectrum, (*e*) brightness-voltage characteristics, and (*f*) brightness-current characteristics. Series A samples were those in which the Mn concentration was varied, for a constant matrix composition. Series B samples were those into which small additions of ZnF_2 were introduced, at a fixed Mn concentration and at a fixed K:Mg ratio. Series C samples explored the effects of varying the K:Mg ratio for fixed Mn and ZnF_2 concentrations. (The manganese concentration, as may be noted later, is expressed in atoms Mn/atom Mg. Activator concentration expressed in this manner is probably more meaningful than weight % or mole %, for this type of compound, since manganese, in all likelihood, enters the lattice substitutionally at a Mg site.) Two additional series were also prepared to determine the effects of firing time and temperature on the aforementioned parameters.

For the preparation of each phosphor, the required quantities of the components, in the form of carbonates or fluorides, were mixed with hydrofluoric acid in platinum crucibles. The simple fluorides were then evaporated to dryness and fired in quartz tubes in a nitrogen atmosphere. For all series A, B, and C samples, firing was accomplished at 875°C for 1 hr. Following firing, each sample was ground lightly with a mortar and pestle. Preparation of the samples for examination in a demountable cathode-ray tube was done by settling a slurry of the phosphor powder onto 2 x 1 in. glass slides.

In measuring the brightness of each sample, data were taken at beam voltages from 4 to 12 kv, with

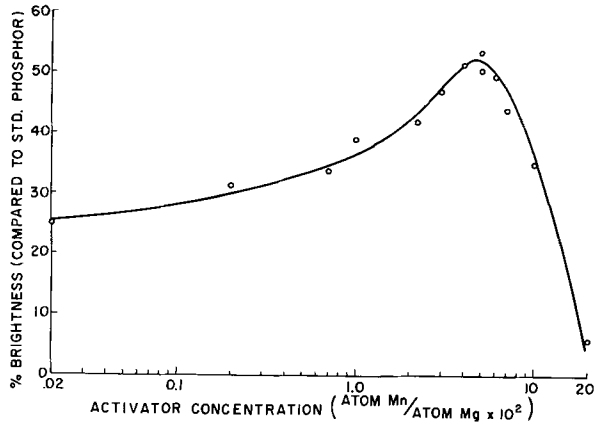

Fig. 5. Brightness as a function of Mn concentration (K:Mg = 0.79, no ZnF_2 added).

the current density ranging from 0.25-2.0 $\mu a/cm^2$. All data obtained are based on bombarded-side brightness. A commercial $KMgF_3$:Mn phosphor[2] was employed as a standard sample for brightness measurements. Brightness-voltage curves were obtained for series A, B, and C samples and also for the standard sample. Brightness-voltage relationships for the standard sample and some representative series C samples are shown in Fig. 1 and 2. Although not shown, similar curves were obtained for series A and B samples. It can be seen that for each series (and for the standard sample) the same characteristic linear relationship exists between brightness and beam voltage, except for a small "dead" voltage. From these curves we can conclude that changes in the phosphor composition do not have any effect on the screen charging properties of this material up to 12 kv. Isolated measurements up to 15 kv have also been made with no evidence of screen charging occurring.

Figures 3 and 4 show typical brightness-current density relationships obtained in measurements made on the standard sample and representative series A samples. Once again, similar relationships were observed for series B and C samples. Here it can be seen that in each series luminescence is proportional to the current density with no saturation effects observable; departure from linearity is observed, however, between zero and 0.25 $\mu a/cm^2$ and may be due to some type of current leakage in the demountable system itself.

Figure 5 presents a plot of the brightness as a function of the Mn concentration. For this series of samples no ZnF_2 was added. It is seen that the brightness reaches a maximum at 0.05 atoms Mn/atom Mg (or approximately 5 mole % with respect to $KMgF_3$) while quenching of the emission becomes pronounced at concentrations greater than 0.10 atoms Mn/atom Mg. It is interesting to note that previous investigation (10) has shown that this molar Mn concentration is close to the optimum for Mn-activated ZnS and ZnSe. Optimum brightness, however, for the other Mn-activated fluoride phosphors (10), such as ZnF_2 and MgF_2, has been found at 0.6 mole %. This apparent anomaly may be due to the fact that the lattice structure of $KMgF_3$ very closely

resembles the cubic form of ZnS and ZnSe, while the other fluorides mentioned have tetragonal structures.

Figure 6 shows the effect on brightness of addition of ZnF_2 to the phosphor. The addition of this component to $KMgF_3$ in small quantities had been reported in the literature (11) as being beneficial in increasing the persistence. While this will be shown later to be so, here it is seen that a significant improvement in brightness also occurs as a result of such addition. The effect is marked even at low concentrations of ZnF_2, as evidenced by a substantial increase in brightness when as little as 0.25 w/o is added. The best brightness is obtained, however, in the region of 9-10 w/o. It should be noted that, although the curve in Fig. 6 displays a rather peculiar shape, the four check points plotted indicate the data to be fairly reproducible.

In Fig. 7 the effect of matrix composition on brightness is shown for a fixed Mn concentration and ZnF_2 concentration. It can be seen that maximum brightness occurs at a K:Mg ratio of zero, which, of course, corresponds to Mn-activated MgF_2. The brightness drops steadily to 43% of its maximum value at K:Mg = 1.0, remains constant at 15% for $1.1 \leq$ K:Mg ≤ 1.8, and then falls to 6% of maximum at K:Mg = 2.0. X-ray diffraction analysis of this series of samples shows the existence of $KMgF_3$ and MgF_2 in samples with molar K:Mg ratios of 0.5-1.0 and the presence of $KMgF_3$ and K_2MgF_4 at mole ratios from 1.1-2.0. Thus it seems that incorporation of Mn into an MgF_2 matrix results in more

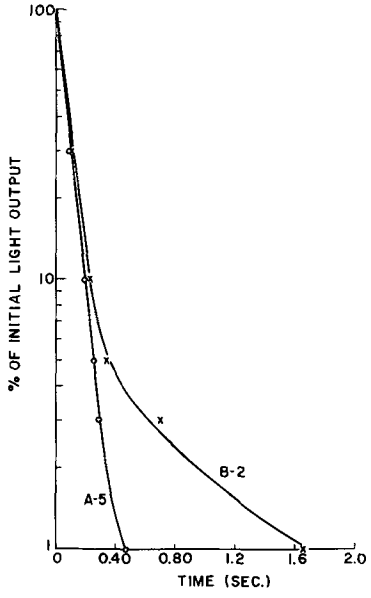

Fig. 8. Effect of ZnF_2 addition on persistence characteristics of $KMgF_3$:Mn (K:Mg = 0.79, Mn:Mg = 0.026).

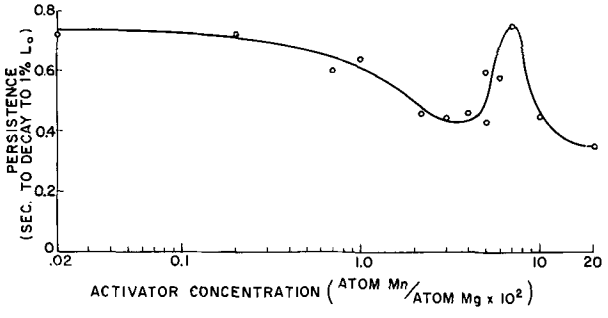

Fig. 9. Persistence characteristic as a function of Mn concentration (K:Mg = 0.79, no ZnF_2 added).

efficient luminescence than in $KMgF_3$, while incorporation of the Mn into K_2MgF_4 is far less efficient.

The phosphors in each series all exhibit a two-component type of decay; that is, initially the luminescence decays exponentially, then changes to a power-law type of decay. While the initial stages of the decay do not exhibit any clearly defined relationships as a result of variation of either activator concentration or matrix composition, very definite differences are discernible in the decay-tail region.

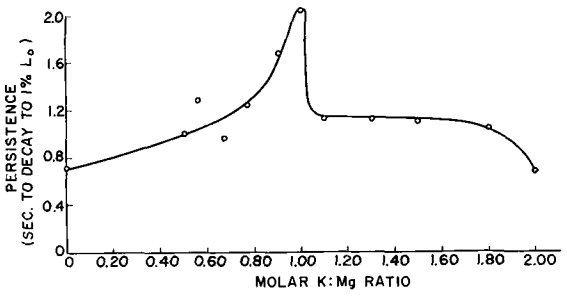

Fig. 11. Persistence characteristic as a function of K:Mg ratio (Mn:Mg = 0.026, 2.0 w/o ZnF_2 added).

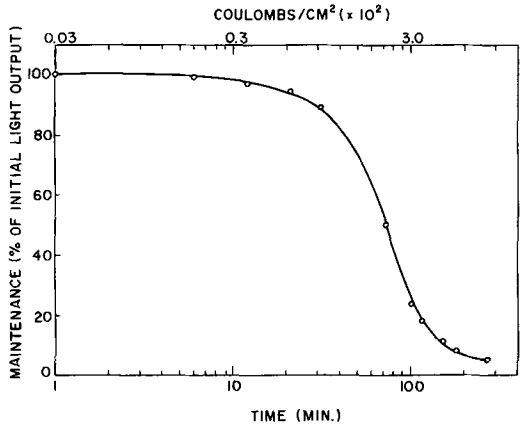

Fig. 12. Typical maintenance of light output curve for a $KMgF_3$:Mn phosphor (current density = 5.0 $\mu a/cm^2$).

The most significant difference is noted on addition of even a small per cent of ZnF_2 to the phosphor. In Fig. 8 this difference in the decay-tail characteristic of two samples is shown. Both samples have identical Mn concentration and K:Mg ratio. Sample B-2 has, however, in addition 2.8 w/o ZnF_2. Figure 9 shows the effect on the decay tail characteristic as a function of Mn concentration. Measuring the persistence as the time to decay to 1% of the initial light output, it was found that a maximum value is obtained at 0.07 atoms Mn/atom Mg. From the next curve (Fig. 10) it can be seen that an over-all improvement of the decay-tail characteristic occurs as a result of addition of varying amounts of ZnF_2 to the $KMgF_3$ matrix (11). The greatest improvement, however, occurs in the range of 0.5-6 w/o addition.

The decay-tail persistence as a function of K:Mg ratio is shown in Fig. 11. For these samples both the Mn and Zn concentrations have been held constant. Here it is seen that the persistence increases steadily to a maximum as the molar K:Mg ratio is increased from zero to 1.0. As the ratio is further increased, however, this decay-tail characteristic drops sharply and is essentially constant in the range of 1.1-1.8. A further decrease is noted as the ratio is further increased to 2.0.

Measurements of maintenance-of-light-output during life were obtained during sustained excitation of the samples in the demountable cathode-ray tube for periods of 2-3 hr at 5 $\mu a/cm^2$. The maintenance curve of a typical sample measured under these conditions is shown in Fig. 12. It seemed reasonable to use as a standard of comparison the per cent of initial light output reached after a given period of time, taking care to keep out of the regions near 0%

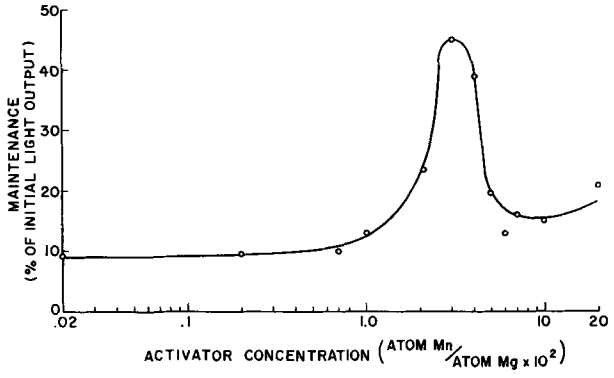

Fig. 13. Maintenance as a function of Mn concentration (K:Mg = 0.79, no ZnF_2 added).

and 100% of initial output. The figure of 100 min, which is equivalent to a charge of 3×10^{-2} coulombs/cm^2, was therefore selected.

This figure of merit for maintenance characteristics is plotted in Fig. 13 as a function of Mn concentration. Here a maximum is obtained in the region of 0.03 atoms Mn/atom Mg. Figure 14 shows that when this characteristic is plotted as a function of w/o ZnF_2 added, a somewhat ill-defined curve is obtained, similar in appearance to the curve in Fig. 6; the four checkpoints, however display the degree of reproducibility of the data. Highest maintenance is obtained in the region of 8-10 w/o ZnF_2. When this maintenance characteristic is plotted as a function of K:Mg ratio (Fig. 15), a series of scattered points results which might be interpreted as indicating an optimum ratio of 0.76.

The maintenance data plotted on these figures do not, however, represent the true maintenance of the material if measured in a sealed-off, well-evacuated cathode-ray tube. Pfahnl (12) has shown that maintenance is considerably poorer when measured in a demountable cathode-ray tube, in all probability as a result of increased ion damage to the phosphor. We have also found this to be true in our investigations. Measurement of a standard $KMgF_3$ phosphor in both a sealed-off tube and a demountable tube shows that the total charge necessary to reduce the light output to 50% of its initial value in the two cases differs by a factor of 10. It was also found, however, that as a result of always measuring the samples in the same demountable, at the same conditions of vacuum, fairly reproducible results could be obtained. Thus it appears that while the actual numbers obtained in demountable maintenance measurements are of no consequence themselves, the information obtained is still quite useful as a relative figure of merit.

Emission spectra were determined for all samples in each series. The data obtained show no shift in spectral emission peak and no change in band width as a result of either altering the phosphor composition or varying the beam voltage or current density. An emission spectrum of a typical sample is shown in Fig. 16. The emission peaks for these samples occur at 600 mμ.

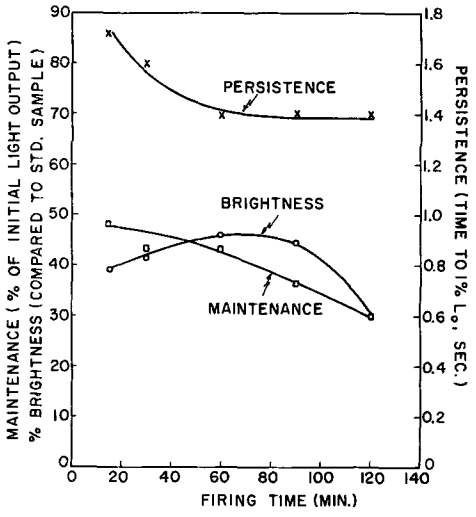

Fig. 18. Effect of firing time on cathodoluminescent characteristics of $KMgF_3$:Mn (firing temperature = 900°C; composition: K:Mg = 1.0, Mn:Mg = 0.02, 2.0 w/o ZnF_2 added).

As an additional part of the investigation, data were obtained to determine the effect of firing conditions on brightness, persistence, and maintenance. In Fig. 17 these characteristics are plotted as a function of firing temperature. The samples in this series were each fired for 1 hr. From the curves it can be seen that relatively little change in brightness occurs over this temperature range, but that persistence is optimum at 875°C, while best maintenance occurs for 900° firing. In Fig. 18 these characteristics are plotted as a function of firing time; all samples here were fired at 900°C. It is found that optimum brightness is obtained for 60-90 min firing, while best maintenance and longest persistence are obtained with a 15 min firing.

Because of the interest developed in $KMgF_3$:Mn as a starting material for the preparation of cathodoluminescent thin films, some additional investigation was done to determine the characteristics of other Mn-activated complex fluoride powder phosphors. While the study of these materials was only cursory, a summary of the characteristics determined seems worthwhile. Only three series of samples were prepared. In the first series Ca, Zn, Sr, or Cd were substituted for Mg in $KMgF_3$:Mn. In the second series, the elements Li, Na, Rb, and Cs were substituted for K in $KMgF_3$:Mn, while in the third series Mn-activated complex flourides were prepared with Zn as the divalent cation and either Li, Na, Rb, or Cs as the monovalent constituent. Control samples of $KMgF_3$:Mn were prepared with each series. For each sample the ratio of univalent cation:divalent cation was kept at 1.0, while the Mn concentration was held constant at 0.02 atom Mn/atom divalent cation. All samples were fired at 900°C for 1 hr. A summary of the brightness, persistence, maintenance, and spectral emission characteristics is shown in Table I. While not shown in Table I, the brightness-voltage and brightness-current characteristics were also measured and found to be linear for all samples (within the limits 4-15 kv and 0.25-2.0 $\mu a/cm^2$). The most promising of the materials investigated are $KCdF_3$ and LiF + ZnF_2, for brightness, and $RbZnF_3$ and $RbMgF_3$, for maintenance. Wherever brightness data for this series of samples could be compared with that compiled by Smith (7) or Klasens and his co-workers (8), it was found that best agreement was achieved with the results reported by the former.

Summary

While no attempt has been made to explain the results obtained, it can be seen that variation of phosphor composition in Mn-activated $KMgF_3$ can lead to materials with considerably improved maintenance characteristics (which of course is the strongest detriment of this class of materials). Improvement of brightness and persistence can also be made by composition change, but there appears to be no single optimum composition to encompass the best of all three characteristics.

An initial attempt to improve further on the cathodoluminescent characteristics of Mn-activated $KMgF_3$ by substitution of some Group IA, IIA, and IIB elements has resulted in some materials which show improved maintenance and brightness. Based

Preparation, Stability, and Luminescence of Gallium Nitride

M. R. Lorenz and B. B. Binkowski

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

Gallium nitride has been prepared from gallium oxide and ammonia at temperatures from 600° to 1100°C. The emission of various preparations under cathode ray excitation has been investigated. Dissociation studies indicate the thermal instability of GaN at temperatures as low as 600°C. Observed emission spectra are discussed in terms of preparation temperature and dissociation.

In the search for new photo-, cathodo-, and electroluminescent phosphors, attention has been given recently to the higher band gap compounds of group III and V elements. The phosphides and nitrides of gallium, aluminum, and boron have been of particular interest, since their band gap would predict emissions in the visible or of shorter wavelength. The present investigation is concerned with methods of preparation, stability, and cathodoluminescence of GaN.

The preparation of GaN has been effected in a variety of ways using NH_3 as a common reactant (1-6). It is notable that direct nitriding with N_2 has been unsuccessful. GaN prepared at low temperatures (1), *i.e.*, in the range 350°-500°C, has been activated by incorporation of suitable impurities and yielded luminescent materials. The emission intensities are markedly affected by the annealing temperature except when activated with Li (1).

More recently, Addamiano (7) prepared GaN from GaAs and GaP. The reactions appeared attractive since both GaP and GaAs can be obtained with high purity.

Preparation.—Attempts at preparing GaN from the reaction of Ga with NH_3 at 1000°-1160°C resulted in a heterogeneous product exhibiting wide color variation. Preparation of the nitride from GaP as suggested by Addamiano (7) was unsatisfactory due to the difficulty in achieving quantitative conversion and the high temperatures involved, > 1000°C.

It was observed, however, that GaP crystals, partially hydrolyzed by grinding in moist air with resultant evolution of PH_3, rapidly reacted with NH_3 to yield GaN. This suggested the use of Ga_2O_3 as starting material and the reaction

$$Ga_2O_3 + 2NH_3 \rightarrow 2GaN + 3H_2O \qquad [1]$$

was studied as a function of preparation temperature. High-purity Ga_2O_3 (99.99%, Varlacoid Chemical Company) was heated in a stream of anhydrous NH_3 (purity > 99.99%, Matheson Company) at controlled temperatures. The products were checked by x-ray diffraction and chemical analysis. Table I shows the pertinent data where the length of reaction time indicated is not necessarily the minimum time required for complete conversion to GaN.

Dissociation.—On several occasions when GaN was heated to 1150°C in previously evacuated and sealed quartz tubes, explosions occurred. Since the quartz tubes were of relatively small diameters

Table I

Sample identification	Reaction temp, °C	Reaction time, hr	X-ray identification	Body* color
A	480	16	Ga_2O_3	Nearly white
B	550	4	Ga_2O_3	Yellowish white
C	600	24	GaN	Light yellow
D	700	16	GaN	Deep yellow
E	800	15	GaN	Yellow
F	1000	3	GaN	Tan yellow
G	1090	3	GaN	Light gray

* Pure Ga_2O_3 is white.

(⅜-¾ in.), pressures of several atmospheres would be necessary to cause explosions. This is particularly intriguing since GaN was prepared from Ga and NH_3 at temperatures as high as 1160°C at an ammonia flow pressure of 1 atm. Accordingly, the thermal stability of GaN was investigated.

GaN prepared by reaction [1] at 1000°C was placed in a graphite crucible and heated in a vacuum system. The samples could be isolated in a constant volume of approximately 600 cm^3 where any pressure buildup or decrease could be observed with a McLeod gauge and a mercury manometer. Samples were heated under pumped vacuum to various temperatures, then isolated and the pressure monitored as a function of time at a controlled temperature. Very slow rates of dissociation were observed which necessitated the introduction of N_2 pressure from an external source in order to show a pressure dependence of the dissociation rate. The effect of hydrogen on the dissociation rate was also investigated.

In Fig. 1 the observed pressure changes are plotted as a function of time. At 412°C no measurable dissociation occurs, but at 616°C, N_2 is generated slowly at a constant rate. With increasing temperature the rate of N_2 evolution increases. The dissociation at 812°C was monitored for 85 hr without observing any deviation in the rate of N_2 formation over the pressure range from less than 10^{-3} to 15 mm Hg pressure. At higher temperatures slight curvature is noted especially at low pressures. After N_2 is added to the system, note curves G and H, a lower rate is observed, but appears nearly constant over the measured pressure interval. The addition of H_2 does not alter the rate as evidenced in Fig. 1 by comparison of curve E to that of D at equivalent total pressures.

The results clearly indicate the thermal instability of GaN at temperatures as low as 600°C. The effect of this instability on the properties of GaN is discussed in detail later.

Cathodoluminescence.—The emission properties of GaN were studied with cathode-ray excitation. A demountable cathode-ray tube was used which included an attachment to permit sample excitation from 25°C to liquid N_2 temperatures. A grating spectrometer and a 1P21 photomultiplier detector completed the assembly. Samples were excited with 15 kv electrons at current densities of 1-4 $\mu a/cm^2$. The emission spectra at liquid N_2 temperature of various preparations and partially dissociated GaN are shown in Fig. 2. The spectra are corrected for the spectral sensitivity of the spectrometer. At low preparation temperatures, weak luminescence occurs with a peak at about 5200Å. With increasing preparation temperature the intensity of the broad 5200Å band decreases, going to zero, while a relatively sharp band centered at 3600Å appears. The relative intensity of this band rises sharply and reaches a maximum for the sample prepared at the highest temperature. It is interesting to compare the spectra of samples C and E. Both samples were prepared at 1000°C from Ga_2O_3 and C corresponds to this preparation. Part of it was heated in vacuum at 950°C and is listed as E. The nearly complete dis-

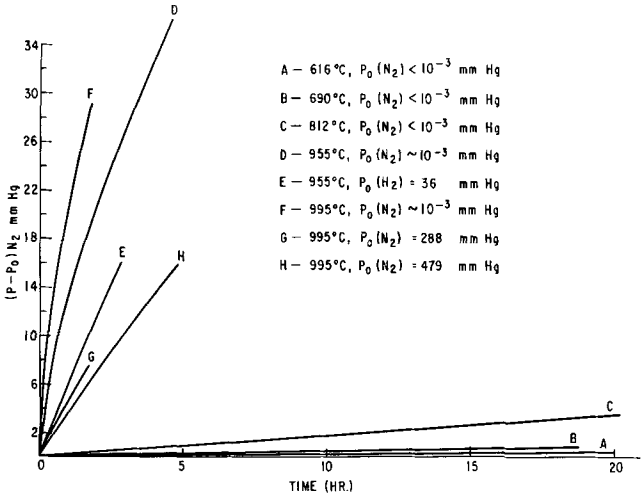

Fig. 1. Rates of GaN dissociation

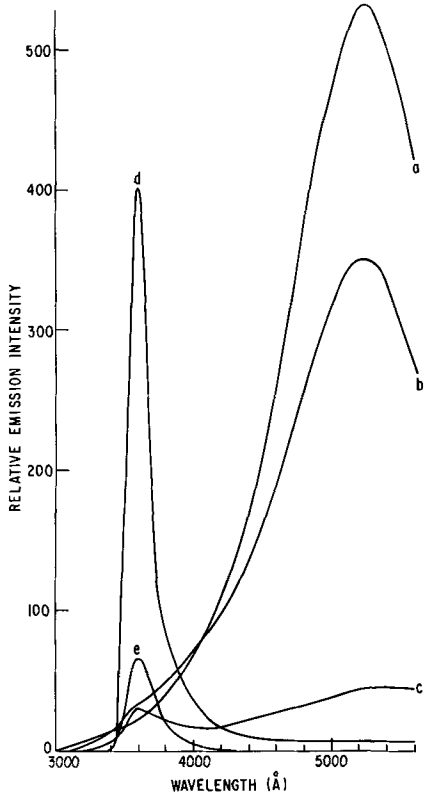

Fig. 2. Cathodoluminescence of GaN prepared at various temperatures, a, 800°; b, 900°; c, 1000°; d, 1090°; e, subjected to vacuum heating at 950°C. Intensities of a and b are reduced by a factor of 100 and c by a factor of 10, relative to d and e. Emission intensities are corrected for the spectral sensitivity of the spectrometer.

appearance of the 5200Å band and sharp rise in the 3600Å band are noteworthy.

Emission at 25°C is always weaker compared to low-temperature emission. A 50Å shift in the high energy peak position to longer wavelengths is observed, which correlates well with the expected band gap shift with temperature.

Discussion

It has been shown that GaN can be prepared from Ga_2O_3 at relatively low temperatures. However, all preparations in the range 600°-1100°C have some yellow body color with the products of the higher preparation temperature tending toward gray. According to Fig. 2, the fundamental absorption edge at 25°C would be expected near 3650Å or at an even shorter wavelength; therefore, the pure material should be white in appearance. The occurrence of discolored products can now be correlated with the thermal stability and cathodoluminescence studies.

The thermal dissociation of GaN proceeds in vacuum at temperatures as low as 600°C, as evident from Fig. 1. It also appears that at 1000°C GaN would dissociate completely in 1 atm of N_2 if given sufficient time. The slow and apparently constant rate suggests a diffusion-controlled dissociation process. Since the rate of dissociation is so low, reliable equilibrium pressures could not be obtained. However, the results explain the problems encountered in the preparation of pure GaN. It is apparent that two reactions are of concern, *i.e.*,

$$GaX + NH_3 \xrightarrow{k_1} GaN + \ldots \quad [2]$$

and

$$2GaN \xrightarrow{k_2} 2Ga + N_2 \quad [3]$$

where GaX may be metallic gallium or some of its compounds and k is the reaction rate constant. It is unnecessary to consider the back reaction of the latter equation since GaN could not be formed from Ga and N_2 at any temperature. From the dissociation studies it is evident that k_2 is relatively small; therefore, if k_1 is larger than k_2, GaN is produced. Since k_2 is not negligible, the products are always partially dissociated. The higher the preparation temperature, the greater the proportion of excess Ga, leading to gray material. This is in accord with the expected increase in the magnitude of k_2 with increasing reaction temperatures.

It is interesting to note that the only white GaN reported in the literature (1) was prepared at about 350°C, which is in agreement with the thermal stability reported here, *i.e.*, no measurable dissociation below 412°C.

The problem of instability also explains why crystal growth of GaN has been essentially unsuccessful. The preparation of the material at higher temperature is indeed possible only if the reaction leading to GaN is rapid. Under these conditions crystal growth is most unfavorable.

GaN prepared from the oxide at low temperatures shows weak luminescence in a broad band peaking at about 5200Å. With increasing preparation temperature this band disappears while at the same time a sharp band at 3600Å appears. The origin of the long wavelength band is uncertain. The only impurities found by emission spectroscopy were minute traces of Si and Fe. Although these may be responsible for the 5200Å band, it is felt that residual oxygen substitutions at nitrogen sites or interstitially are a more likely possibility. This is supported by the disappearance of the long wavelength band at higher preparation temperature or under vacuum heating. Either case enhances the out diffusion of oxygen, whereas it seems unlikely that Si and Fe are readily removed under these conditions. As the centers responsible for the 5200Å band are removed, the emission shifts to the 3600Å band. The latter has been observed by Grimmeis and Koelmans (2) and interpreted as edge emission.

It has been reported that GaN prepared and activated with various impurities below 600°C is luminescent (1). Annealing at temperatures of 600°C and above leads to a sharp decrease in luminescence intensity and eventually the material is nonluminescent when the annealing temperature reaches about 1000°C. The simultaneous decrease in luminescence with the onset of dissociation is more than accidental, and it is suggested that this decrease is indeed caused by the thermal instability of GaN. The mechanism by which the luminescence is quenched cannot be extracted with certainty from the present data, but is most probably a consequence of the formation of interstitial Ga or nitrogen vacancies.

In summary, it may be seen that the potential of GaN with regard to photo-, cathodo-, and electroluminescence is handicapped by its thermal instability at temperatures above 600°C. Accordingly, any effort in materials preparation and impurity activation should therefore be more fruitful at temperatures below 600°C.

Acknowledgment

The authors are indebted to Miss G. P. Lloyd for obtaining the emission spectra reported here and to Dr. J. S. Prener for valuable discussions.

X-Ray Diffraction Microscopy Study of Imperfections in Silicon Single Crystals

G. H. Schwuttke

General Telephone and Electronics Laboratories Incorporated, Bayside, New York

ABSTRACT

The application of x-ray diffraction microscopy to the study and control of crystal perfection of silicon is discussed. The major significance of this technique in establishing standards by which the validity of other methods, such as etch-pit counting and decoration techniques, can be gauged is pointed out. The method previously used only for the mapping of dislocations in single crystals is now applied for the detection of impurities, segregation effects, cluster formation, and second phases. Segregation effects are studied in crystals containing oxygen. It is shown that, due to microsegregation of oxygen, the silicon lattice can become strongly anisotropic. The influence of such a lattice on the diffusion properties is shown. Precipitation effects are investigated in crystals containing copper precipitates. The results are verified by infrared microscopy. Experimental details of a method unique for the investigation of large crystal wafers are given.

It is impossible to characterize semiconductor crystals adequately without a fairly good knowledge of the imperfections present. The existence of as yet unexplained bulk variations encountered in semiconductors indicates the need for more complete studies. In view of the importance of such investigations, it seemed worthwhile to investigate the potentialities of x-ray diffraction microscopy techniques as recently developed for the mapping of dislocations in single crystals by Borrmann (1), Barth and Hosemann (2), Newkirk (3), and Lang (4) for imperfection studies in semiconductor single crystals.

In this paper we shall discuss x-ray diffraction microscopy by extinction contrast for the study and control of crystal perfection in silicon. Its major significance in establishing standards by which the validity of other methods, such as etch pit counting and decoration techniques, can be gauged will be pointed out, and its special importance in the detection of impurities, segregation effects, cluster formation, and second phases will be discussed. X-ray diffraction microscopy by anomalous transmission of x-rays will be covered in a separate paper.

Experimental

Technique.—The experimental technique selected to conduct our experiments is the transmission method as introduced by Lang (4). Silicon is almost ideal for transmission diffraction microscopic work. For hard radiation like Mo and Ag, the absorption coefficient is small, so that relatively thick wafers can be investigated. The optimum contrast can be determined by the thumb rule: the product of linear absorption coefficient and slice thickness is approximately equal to the order of unity; thus in the case of silicon, 1 to 2 mm in thickness can be tolerated.

No experimental details unique for the investigation of large crystal wafers have been published previously elsewhere;therefore they are given here. The experimental set-up, as sketched in Fig. 1, consists of an x-ray source and a diffractometer. The x-ray source, a standard diffraction tube, is placed at least 600 mm from the specimen with its line focus in the vertical position. A slit system in front of the anode is used to limit the effective source size as necessary.

The crystal wafer is mounted on a goniometer head on a diffractometer equipped with a Geiger counter to facilitate orientation for diffraction from various sets of diffracting planes. The slit S_1 in front of the specimen determines the effective beam width. A second slit S_2 behind the crystal wafer is adjusted so that the diffracted beam is allowed to pass while the direct beam is cut off. Slit S_1 consists of two metal plates, 25 x 25 mm in size, held at right distance by placing two metal foils between them. The photographic plate is placed close to the specimen behind S_2. The diffraction micrographs are recorded by moving the crystal wafer and photographic plate together while S_1 and S_2 are stationary.

Ilford x-ray film and Ilford nuclear plates, emulsion G-5, emulsion thickness 50μ, 100μ, and 200μ are used. For a slit width S_1 of 0.1 mm and a scanning width of 25 mm which corresponds to a recorded crystal area of 25 mm x 25 mm the exposure times are as follows: Mo radiation at 50 kv and 20 ma:

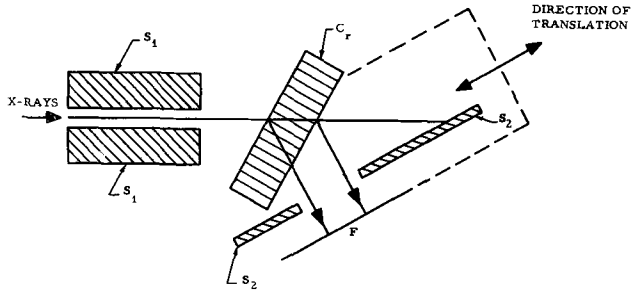

Fig. 1. Sketch of experimental setup: S_1 and S_2, slits; C_r crystal; F, photographic plate.

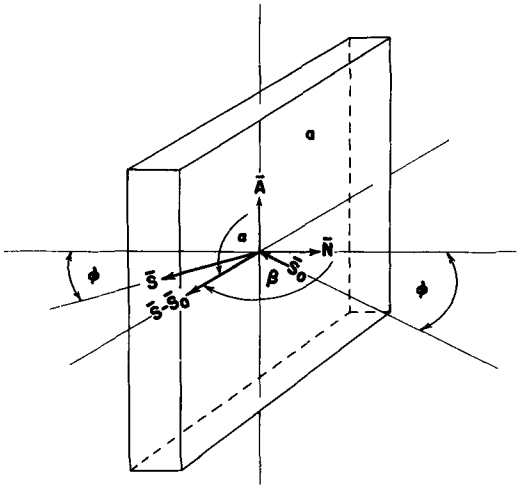

Fig. 2. Orientation of crystal wafer relative to x-ray beam and definitions of α and β.

Ilford x-ray film, 1-2 hr; Ilford nuclear plates 50μ, 10-14 hr; Ilford nuclear plates 100μ, 5-7 hr; Ilford nuclear plates 200μ, 2-4 hr.

Better resolution is obtained by using nuclear plates, but for many cases x-ray film is quite sufficient.

The nuclear plates are processed as follows: (*a*) soak in distilled water for 20 min at 20°C; (*b*) develop in Kodak Developer D 19 for 30 min; (*c*) transfer to 1% acetic acid as stop-bath at 20°C for 10 min, then remove surface fog by rubbing gently with cotton wool; (*d*) fix in 30% plain hypo for 50% longer than clearing time, then wash in running water, 50μ for 30 min, 100μ for 2 hr, 200μ for 4 hr.

It is expedient to describe different orientations of the crystal wafer with respect to the x-ray beam by introducing the angles α and β as shown in Fig. 2. According to this figure the largest lateral crystal face of the wafer is a, the main axis of the wafer is $\overline{A}$, and the normal to the crystal face a is called $\overline{N}$. If the direction of the incident beam is $\overline{S}_o$ and the direction of the diffracted beam $\overline{S}$, α is the angle between the diffraction vector $(\overline{S}-\overline{S}_o)$ and $\overline{A}$ and β is the angle between $(\overline{S}-\overline{S}_o)$ and $\overline{N}$. In our experiments the planes including $\overline{A}$ and $(\overline{S}-\overline{S}_o)$, respectively, $\overline{N}$ and $(\overline{S}-\overline{S}_o)$ are kept orthogonal to each other. Figure 2 is drawn for α and β equal to 90°.

Our experimental setup is such that the Bragg angle ϕ can be controlled with an accuracy of 1 sec of arc and the angle α with an accuracy of 1 min of arc. The photographic plate is placed perpendicular to the diffracted beam. All x-ray micrographs presented in this paper are taken on nuclear plates with the exception of Fig. 8, which is on x-ray film.

Specimen preparation.—Crystal wafers approximately 1.2 mm thick were cut from the bulk material. The lateral face (a in Fig. 2) is a low-index face such as (111), (110), (112), and is oriented optically better than one degree of arc (5). After cutting and lapping, the wafer is etched in a solution of 5 parts HNO_3, 3 parts HF, and 5 parts acetic acid for approximately 5 min to remove the surface layer. After etching the crystal thickness is approximately 1 mm.

General Observations

Diffraction microscopy of dislocations.—Figure 3 is a diffraction micrograph taken using (220) type planes; it shows dislocations lying in a (111) slip plane. Figure 4 explains how the wafer was cut from the bulk crystal. The slice is a 1.2 mm thick cut from a crystal grown in the [111] direction parallel to one of the three octahedral planes that make an angle of 19½° with the [111] growth direction. In cooling

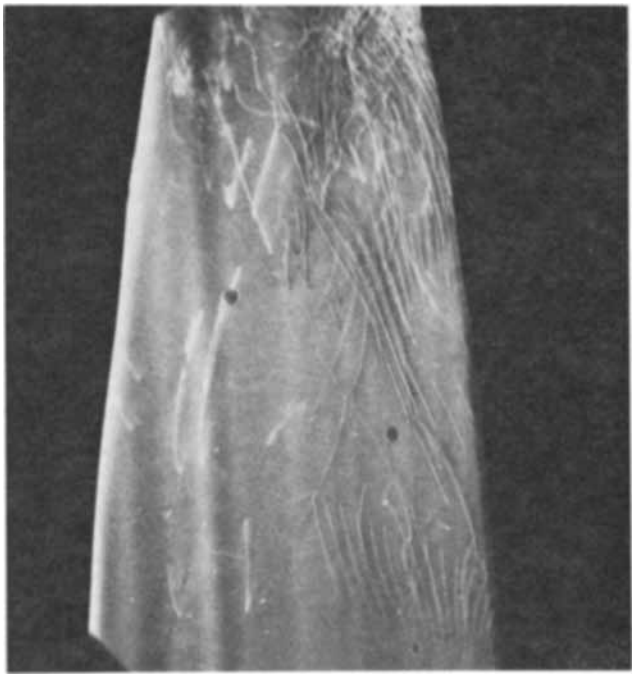

Fig. 5. Dislocations propagated by growth and dislocations introduced by plastic deformation; α = 90; β = 90. Magnification, 7X.

the crystal during growth, slip occurred in the octahedral planes introducing the dislocations seen in the micrograph.

Disclocations propagated by growth from the seed into the crystal (the seed was near the smaller end) are seen in Fig. 5. The wafer is a 1.2 mm thick cut parallel to a (112) plane containing the [111] growth axis as shown in Fig. 4a. The dislocations introduced through the seed grow out with the growing crystal. Some edge-type dislocation, generated by plastic deformation are also seen in the micrograph. The picture is a result of using (220) type planes for the reflection of x-rays.

The visibility of individual dislocation lines in the diffraction micrograph is determined by dislocation density and orientation of the dislocation line relative to the reflecting net plane. Dislocation lines are recorded photographically as lines of enhanced intensity. This is a consequence of the difference in the integrated intensity reflected by a "perfect" and an "imperfect" crystal area. Therefore the dislocation density must be low enough for these lines to be individually distinguishable, and low enough so that the regions between dislocations are sufficiently perfect to approximate the conditions of diffraction by a perfect crystal.

It has been found experimentally that for a dislocation density of 10^4 lines/cm^2 the imperfect region around a dislocation has a diameter of approximately 10μ (4). Bonse has calculated that the strain field around a single dislocation may even extend $50\text{-}80\mu$ (6). However, the extension of the strain field seems to depend on the dislocation density and decreases somewhat with increasing dislocation numbers. The maximum value for which single lines can still be recognized is approximately 10^5 to 10^6 lines/cm^2. For higher numbers the imperfect areas in the crystal begin to overlap. The photomicrograph shown in Fig. 6 is an x-ray transmission image of a crystal with a dislocation density of approximately 10^6 lines/cm^2.

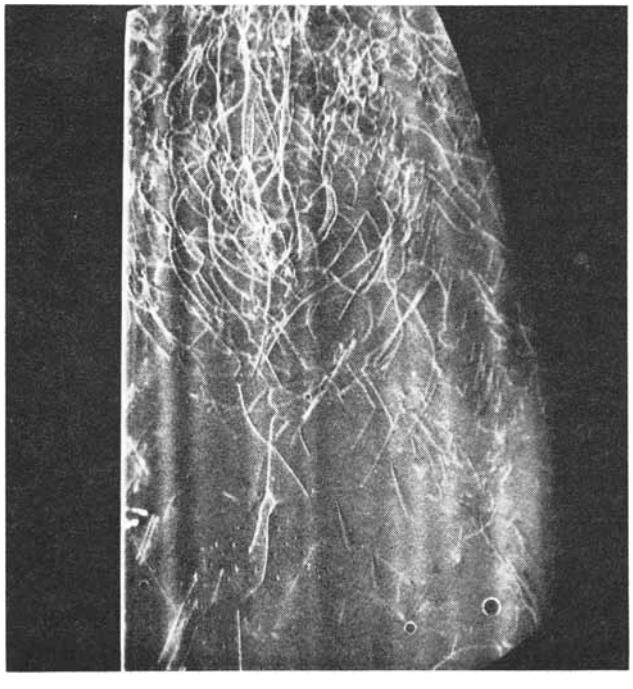

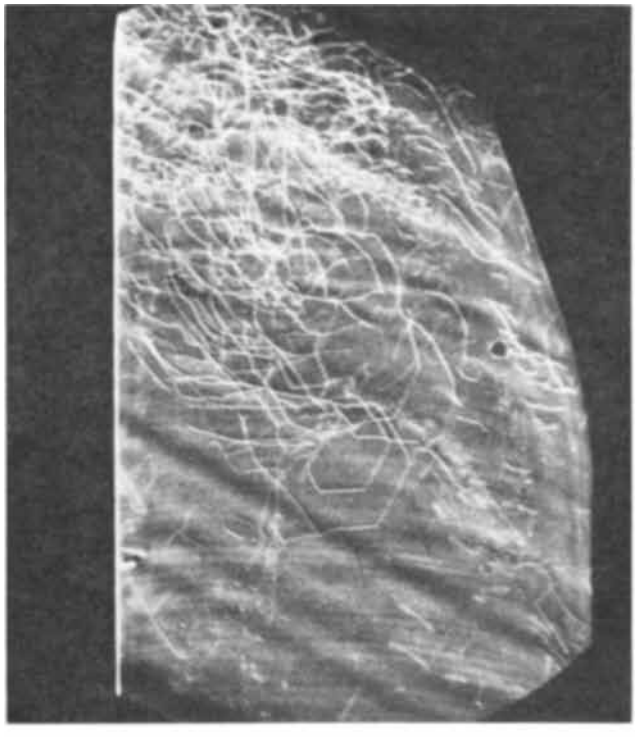

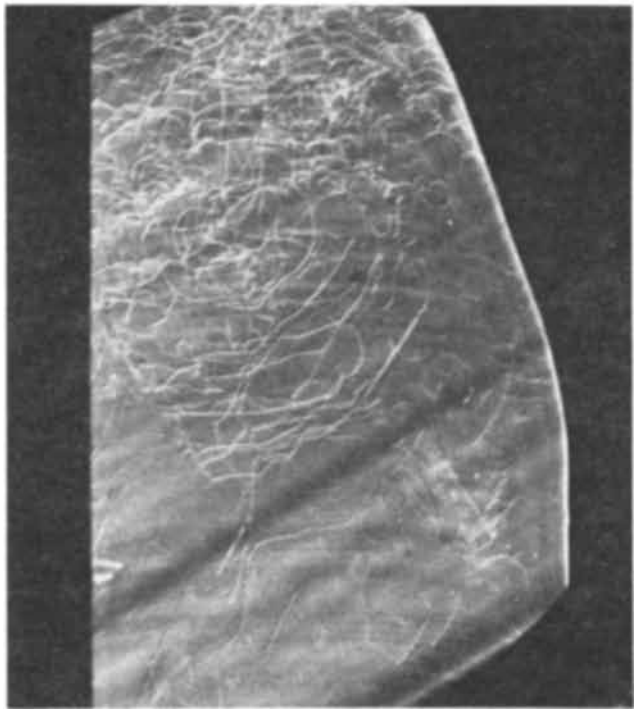

Fig. 7. Visibility of dislocation depending on different reflection: (a) (left) $\alpha = 90$; $\beta = 90$; (b) (top) $\alpha = 150$; $\beta = 90$; (c) (bottom) $\alpha = 210$; $\beta = 90$. Magnification, 7X.

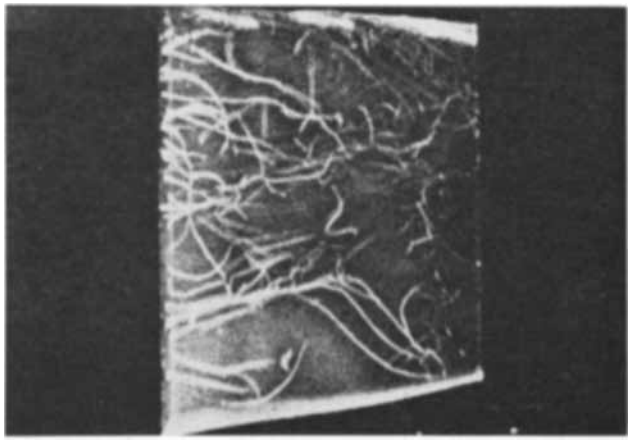

Fig. 8. Etch pits and dislocations: $\alpha = 90$; $\beta = 90$. On Ilford x-ray film. Magnification, 10X.

The slice was cut in accordance with Fig. 4c. In this picture sub-boundary formation is noticed. Formation of such dislocation arrays in silicon has been observed for dislocation densities larger than 10^5 lines/cm^2. The effective interaction distance between dislocations necessary to form such arrays can therefore be estimated to be approximately 10μ, correct to one order of magnitude, which is in good agreement with the radius of the strain field around dislocations as given in (4) and (6).

Dislocations produce a maximum of enhanced intensity in the x-ray image when the latter arises from Bragg reflection against a plane perpendicular to the Burger's vector (4). If the Burger's vector is parallel to the reflecting net-plane, the line is invisible or only very slightly visible in the image. In many cases one reflection is completely sufficient to determine the true dislocation density in a wafer. In cases of doubt a second or third reflection will provide enough evidence to obtain sufficient clarity. This is shown in Fig. 7 which represents three different {220} reflections of a silicon wafer cut in accordance with Fig. 4b. The change in contrast is especially distinct for the dislocation loops in the lower halves of the pictures. The spots are due to defects in the prints.

X-ray diffraction microscopy results are determined by changes in diffraction power due to disturbances in the crystal lattice; therefore, they can be used as standards to establish the validity of measurements obtained by indirect techniques. The x-ray micrograph shown in Fig. 8 is that of a 1-mm thick crystal wafer, cut as explained in Fig. 4a. The crystal thickness can be distinguished very clearly, especially on the left-hand side of the photograph where most of the dislocation lines are found to terminate in the plane of the side face. Before taking the x-ray picture, the wafer was slightly etched for dislocations. It can be seen that the ends of the dislocations at the left consist of small areas of enhanced contrast, similar to white specks. Each white speck represents a tiny etch pit, resulting in a one-to-one correspondence between etch pits and dislocation lines. The dislocation density can be counted easily. We discern approximately 32 dislocations counting those ending at the left-hand side of the wafer. Since the crystal is approximately 1 cm wide and 1 mm thick, we obtain 320 dislocations per cm^2. Another point is illustrated quite readily. Since most of the dislocation lines run from right to left in the picture, a cut through the crystal in this direction, for the purpose of etching the cut face for dislocations, would reveal considerably fewer dislocations. Etch pit counts at low dislocation densities can easily lead to wrong conclusions about crystal imperfection.

Previous investigations with silicon have shown that dislocation counts by decoration of dislocations with copper in general are quite accurate. Experiments with pure silicon crystals of 2000 ohm-cm resistivity and of low resistivity crystals containing varying concentration of oxygen impurities lead to the conclusion that accuracy in determining dislocation numbers is not influenced by the oxygen content of the crystal, which is contrary to results obtained by etching (7). If in addition to oxygen other impurities are present, interference with the copper decoration process may occur. Complicated solid-state reactions in such crystals have been observed (8). In the decoration of more than 100 silicon crystals we have found crystals that did not decorate in the usual way. The photomicrograph in Fig. 5 shows such a crystal. By evidence of this x-ray picture the wafer contains a relatively high dislocation density, especially close to the seed end. An inspection using the infrared microscope after decoration revealed dislocations only very faintly decorated and in addition precipitation, homogeneously distributed throughout the wafer. Due to the weak precipitation along the dislocation lines it was not possible to decide with certainty whether all lines visible in the x-ray image had been successfully decorated. It seems likely that the copper reacted with an unknown impurity in the crystal, thus the usual strong precipitation along the dislocation lines was not formed.

Diffraction microscopy of segregation and precipitation.—So far the use of x-ray microscopy has been reported only for the detection of dislocations. Another important application, which should be very useful for investigating semiconductor crystals, is the detection of segregation and precipitation in the lattice. In general, one expects that any change in lattice periodicity in a crystal will disturb the coherence of multiple reflections. Thus all localized imperfections will act as regions of imperfect crystal

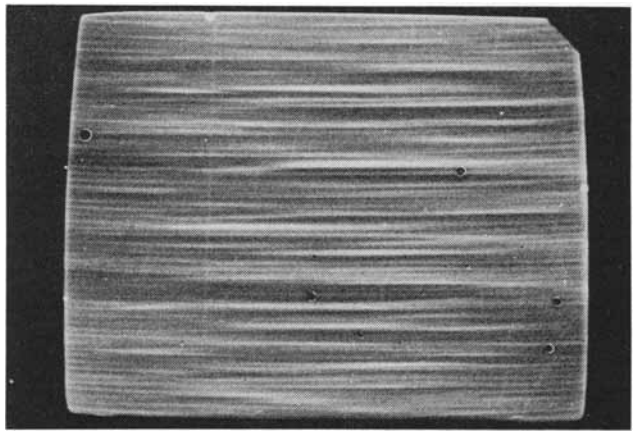

Fig. 9. Oxygen segregation in silicon: $\alpha = 180$; $\beta = 90$. Magnification, 7X.

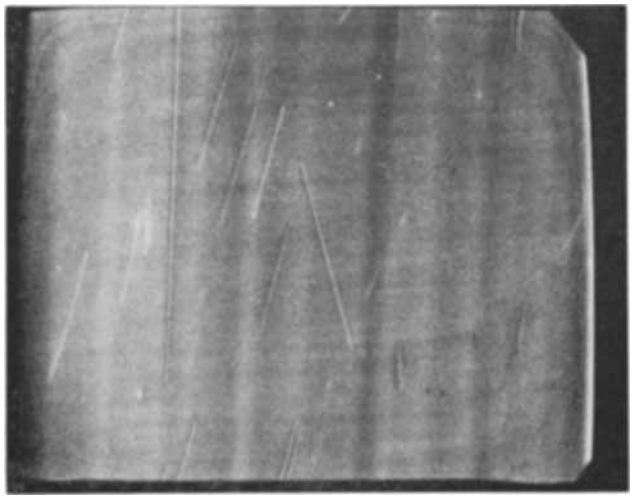

Fig. 10. Oxygen segregation in silicon, same wafer as Fig. 9 for $\alpha = 90$; $\beta = 90$. Magnification, 7X.

and, consequently, lead to an enhancement of diffracted intensity. The region of high strain surrounding areas of microsegregation and areas around precipitates fulfill the requirement for enhancement of diffracted intensity just as in the case of dislocations. Thus certain Bragg reflections can be used to record such imperfections in the same way that dislocations are recorded.

Segregation effects were studied in silicon crystals rotation-grown in a quartz crucible. These crystals are known to exhibit microsegregation of oxygen. The oxygen segregates perpendicular to the growth direction (9). It was found that microsegregation of oxygen can produce strong variations in the diffraction power and, accordingly, can be detected quite readily in the diffraction image (10). The sensitivity of this method is comparable to that of the 9-μ absorption method (11). Variations in oxygen concentration, computed from the absorption coefficient, of about 5 x 10^{16} cm^{-3} have been recorded in the x-ray image. The oxygen can be detected in crystals before and after heat treatment at 1000°C. The diffraction photomicrograph in Fig. 9 is a crystal wafer cut according to Fig. 3a, showing microsegregation of oxygen. The image was obtained by reflecting the x-rays from (111) net planes perpendicular to the growth direction. Figure 10 is a diffraction image of the same slice, but this time (220) type net planes containing the growth axis were used. It is interesting to observe that for the (220) type reflection the segregation stripes are only faintly visible. Several edge dislocation lines barely visible in the (111) reflection, show up much stronger in this picture because their Burger's vector is parallel to the (111) plane and perpendicular to the (110) plane used in these reflections.

For any other reflection, for instance (220) with $\alpha = 30$, $\beta = 90$, the segregation stripes appear stronger than in the (220) with $\alpha = 90$, $\beta = 90$. Maximum contrast was obtained for the reflection perpendicular to the growth direction. From this variation of contrast in the x-ray image with the type of reflection, one can conclude that, due to the segregation of oxygen, the silicon lattice has become strongly anisotropic. The influence of such a lattice on the diffusion properties is shown in the infrared photomicrograph, Fig. 11, which shows a silicon wafer containing oxygen segregation after copper was diffused. The copper is found to segregate and precipitate in the oxygen areas.

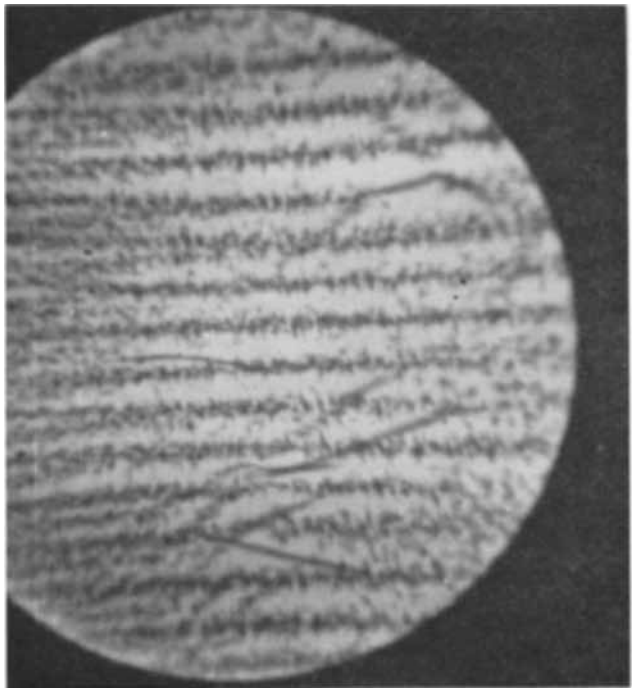

Fig. 11. Infrared micrograph showing copper precipitates in areas of oxygen segregation. Magnification, 25X.

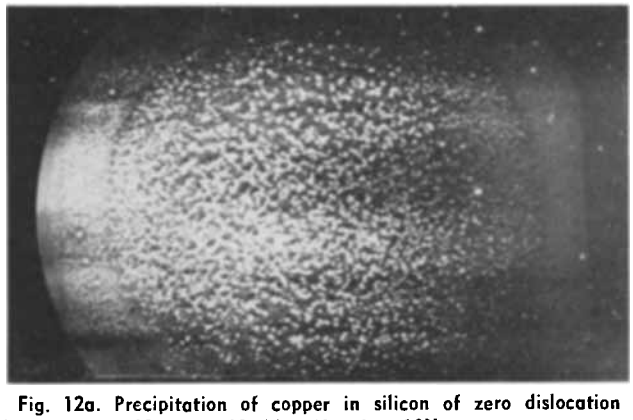

Fig. 12a. Precipitation of copper in silicon of zero dislocation density: $\alpha = 90$; $\beta = 90$. Magnification, 10X.

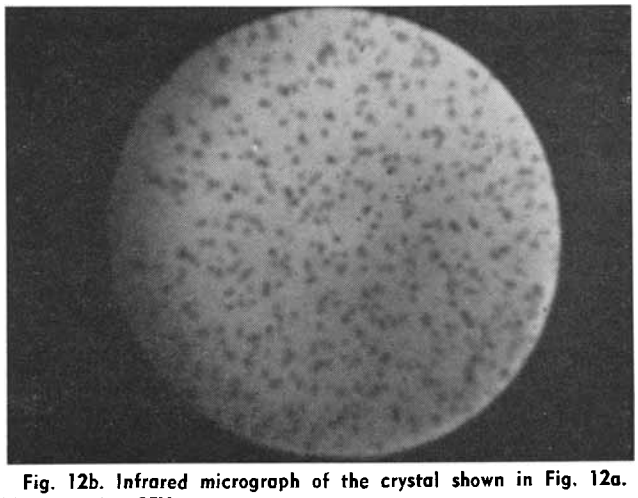

Fig. 12b. Infrared micrograph of the crystal shown in Fig. 12a. Magnification, 25X.

To investigate precipitation effects we selected silicon containing copper precipitates. For this case the x-ray results can be verified directly by infrared microscopy. The x-ray micrograph in Fig. 12a represents a silicon wafer having zero dislocation density. Copper was diffused into this wafer at 900°C for 15 min and then the sample was quenched to room temperature. The solubility of copper in silicon at 900°C is about 10^{17} atoms/cm^3 (12). Since no care was taken to obtain saturation, the concentration of copper in this sample is probably smaller than 10^{17} atoms/cm^3. Figure 12b is an infrared picture of the same wafer for comparison. Random precipitation is easily recognizable in both figures.

Another example of precipitation is shown in Fig. 13. This sample contains approximately 10^{18} atoms of copper/cm^3. The picture reveals a number of interesting details such as random precipitation, decorated dislocation lines, and decorated areas of oxygen precipitation. The precipitation is rather heavy, but the details revealed in the x-ray image in Fig. 13a are remarkably clear and sharp if compared with the infrared picture of the same wafer shown in Fig. 13b. For demonstrating this we chose a relatively large copper concentration. However, the method is sensitive enough to make precipitates directly visible if they are a few microns in size, or indirectly visible if they are much smaller than 1μ and are present in clusters or in clouds. The method is capable of trace analysis, and we have presented evidence that it is possible to find impurities in semiconductors even if their concentration is as small as 10^{15} atoms/cm^3 (13, 14).

Conclusions

X-ray diffraction microscopy by extinction contrast is a very useful technique for the investigation of structure defects in semiconductor crystals. An important feature of this method is its nondestructiveness to the sample. A correlation of electrical properties and imperfections for the same wafer is therefore possible. The methods can provide direct evidence for such crystal defects as dislocations, segregation, and precipitation effects. It should be a powerful tool for the investigation of such problems as the study of preferential segregation of impurities, which may lead to considerable resistivity changes due to core formation (15), the study of diffusion of impurities along dislocation lines and their subsequent precipitation (16), or the formation of metal precipitates in junctions (17). The method is applicable to all semiconductor materials if x-ray radiation of the proper wavelength is selected. The mass absorption coefficient of semiconductors is such that conveniently thick wafers can be investigated in transmission either by the K_α radiation of Mo or W. We have used the method successfully for studies of Ge, Si, GaAs.

Etching Ge with Mixtures of $HF-H_2O_2-H_2O$

J. Bloem and J. C. van Vessem

Semiconductor Development Laboratory, N. V. Philips' Gloeilampenfabrieken, Nijmegen, Holland

ABSTRACT

Etch rate *vs.* composition of the etchant ($HF-H_2O_2-H_2O$) was studied, together with the surface structures after etching Ge single crystals. Conclusions concerning the orientation dependence and the kinetics of the etching process are given. The ratio of the etch rate on different faces depends on the value of C_{H_2O}/C_{HF} in the etchant independent of the H_2O_2 concentration, whereas visible oxide films are formed for a $C_{H_2O_2}/C_{HF}$ ratio smaller than the stoichiometric ratio given by the over-all reaction:

$$Ge + 2H_2O_2 + 6HF \leftrightharpoons H_2GeF_6 + 4H_2O$$

Much work has already been done on the etching of Ge single crystals with mixtures of $HF-H_2O_2$ and H_2O (1-9). This work has been extended by studying the etch rates on (111) oriented Ge crystals at room temperature as a function of etchant composition and by a study of the surface structures after etching.

The Ge pellets used (dimensions 3 x 3 x 0.25 mm, 2-3 ohm-cm N-type) were cut along (111) planes to within 0.5 degree, the surfaces were polished with No. 500 carborundum abrasive powder. Etching was performed in a polyethylene vessel, rotating in a constant temperature bath (25°C). The vessel was inclined in order to be sure of adequate stirring. About 50 crystals at a time were etched in 250 cc of etchant.

After etching the etchant was quenched with water and poured off After washing and drying the thickness of the pellets was measured to within 1μ. Etching times were used to give a total decrease in thickness of about 100μ in each case. This procedure essentially follows that during fabrication, and the influence of damaged surface layers on the etch rate is small. The etch rate has been defined as that on a single surface in μ/min, thus half the decrease in thickness per unit time.

Etch Rates

The results are plotted in a tri-axial diagram (Fig. 1), where the basic components in the three corners correspond to pure water, concentrated HF (50%), and H_2O_2 (30%), respectively. The concentrations are expressed volume percent. Each composition corresponds to a certain point in the diagram to which in turn the appropriate etch rate can be attached. In Fig. 1 contour lines of equal etch rates, at room temperature, on a single Ge surface are given.

Maximum etch rates are found for about equal volume parts of HF and H_2O_2; on dilution with water the etch rate decreases. As the HF contains 28.8 moles HF/l and the H_2O_2 used 9.8 moles/l, equal volume parts of both compose a nearly stoichiometric etchant according to the over-all reaction:

$$Ge + 2H_2O_2 + 6HF \leftrightharpoons H_2GeF_6 + 4H_2O \qquad [1]$$

Figure 1 also shows that for low H_2O_2 or HF concentrations the etch rates vary proportional to this H_2O_2 or HF content.

The etch rates are strongly temperature dependent; a plot of log R over $1/T$ shows that for the stoichiometric etchants a variation in etch rate of about 6% per degree at room temperature is found (activation energy of 10.7 kcal/mole). It is quite possible that with less H_2O_2 or HF another activation energy is obtained, as other reaction steps may then become rate limiting. The experimental results at room temperature can be described by the following empirical formula

$$R = \frac{C_1C_2}{2.4C_1 + 1.0C_2 + 0.2C_3}\ \mu/\text{min}$$

where R is the etch rate in μ/min on a single (111) oriented surface, and C_1, C_2 and C_3 the concentrations of H_2O_2, HF, and H_2O, respectively, in volume per cents of the added reagents. For the higher etch rates (greater than 10-15 μ/min on a single surface) an exponential increase appears over the calculated values, even with good stirring, due to an inevitable temperature rise at the reacting surfaces.

Surface Structures

As to the surface structures after etching, in most cases the (111) surface is covered with small tri-

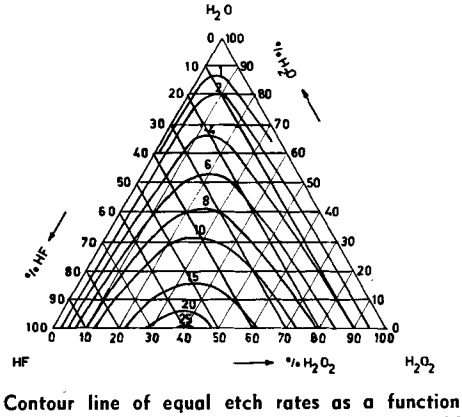

Fig. 1. Contour line of equal etch rates as a function of the composition of the etchant (volume parts of 50% HF, 30% H_2O_2, and water). The numbers in the figure refer to etch rates on a single surface of the crystal in μ/min.

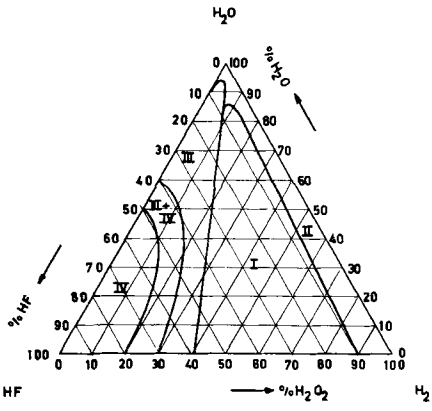

Fig. 2. Regions of different surface structures after etching: I, shiny surface with etch triangles; II, dull surface with etch triangles; III, thin oxide layer under which there are etch triangles; IV, thick oxide layer on top of amorphous surface structure.

angular etch figures. These figures are not related to the presence of dislocations, but arise from the original surface roughness (2, 3).

The surface structures after etching are indicated in Fig. 2. Four regions can be distinguished: (I) the etch triangles are well developed, the crystals having a shiny appearance; (II) the HF deficiency gives rise to somewhat dull surfaces in which the triangular pits are still present; (III) after etching a slight oxide film becomes visible (2). This film is readily soluble in H_2O_2; underneath the film small etch triangles are present; (IV) gives thicker oxide layers after etching, also soluble in H_2O_2. Underneath this film etch triangles can no longer be found, the surface is dull (1).

Growth of etch pits.—In the regions where etch triangles are found the growth rate of these triangles on prolonged etching also depends on the etchant composition. In general, the greater the water content the greater the size of the pits for the same decrease in thickness. For a number of etchants the growth of the pits was followed as a function of the decrease in thickness; initially the whole surface was covered with tiny pits; on prolonged etching the pits grow and overlapping occurs. Some results are

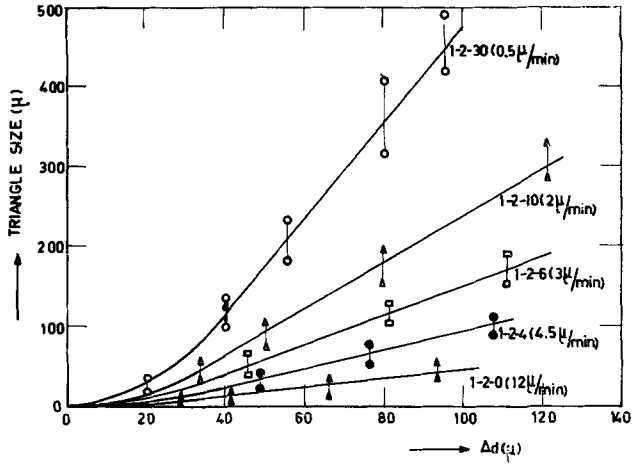

Fig. 3. Growth of the sides of etch triangles vs. decrease in thickness during etching. The greater growth rates are found for the slower etchants (e.g., the composition 1-2-30 indicates the number of volume parts of HF-H_2O_2 and H_2O in the etchant, respectively).

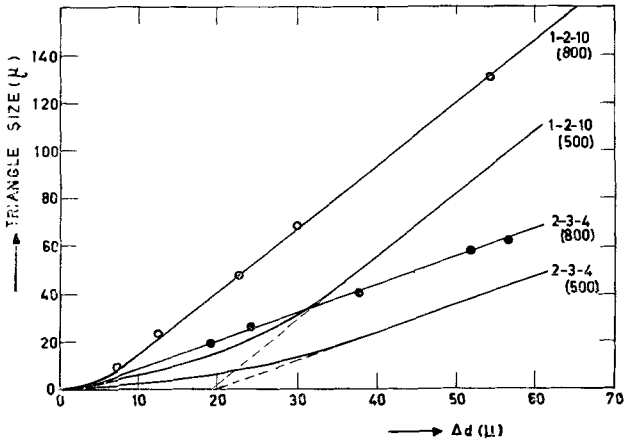

Fig. 4. Growth of etch triangles for Ge crystals lapped with No. 500 and No. 800 carborundum powder (mean grain size 32 and 14μ, respectively). The ultimate slopes are the same, the initial part, *i.e.*, the thickness of the worked layer, is different.

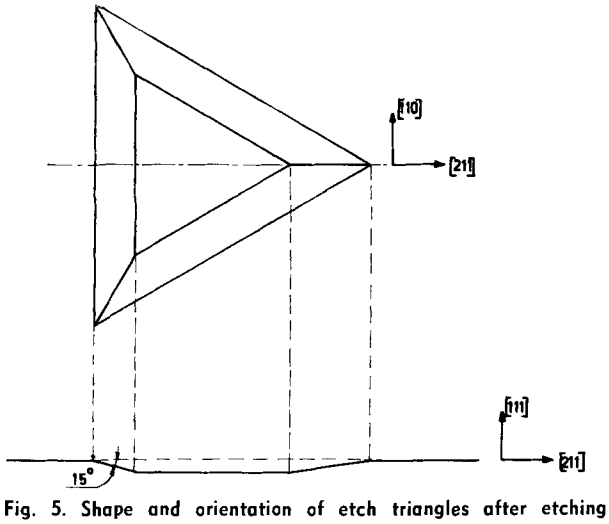

Fig. 5. Shape and orientation of etch triangles after etching (111) oriented Ge crystals.

given in Fig. 3 and 4. After an initial period in which the lapped layer is removed, the triangles begin to grow, the faster the lower the etch rate. Closer inspection of the etch figures (Fig. 5) reveals that the bottom of the pits is formed by a (111) plane, the sides of the pits making an angle of about 15° with the (111) surface. These sides are close to (322) planes. According to Battermann (3) this has to be expected as this orientation shows a relative maximum in etch rate compared with neighboring orientations in the (110) zone. As pointed out in ref. (3) the pits originate from the original surface roughness, as on the concave parts of the surface the slow etching (111) face is exposed, forming the bottom of the pits, whereas on the convex parts of the surface the fast etching (322) facets are stable, giving the sides of the etch triangles.[1]

Etch rates on (111) and (322) faces.—Since the sides of the pits consist of fast etching (322) planes

[1] Similar arguments can be used to explain why on wetting and alloying, e.g., In on Ge, alloy pits are found which tend to be triangular with an orientation different from those of the etch triangles. In this case the first rapid dissolution of Ge in the In pellet does not show any orientation dependency (10), and a hollow shaped cavity is formed. With prolonged alloying the rate of attack decreases because of the higher Ge content of the In; now the orientation begins to show its influence. As the pit already has a concave shape only the slow dissolving (111) faces are exposed, giving the pit a semi-triangular pattern which is rotated 60° if compared with the etch triangles on the same surface, bounded by (322) facets. The difference between normal alloy pits and etch triangles thus is found in the sides of the pits originating from a different mode of attack.

Table I. Etch rates (R), growth rate of etch triangles vs. decrease in thickness (exp. slopes) and the calculated value of the ratio of the etch rates on the sides and on the bottom of the pits (R_s/R_{111}) for various etchants

Etchant (HF-H_2O_2-H_2O)	R (μ/min)	Exp. slope	R_s/R_{111} (calc.)
1-2-0	12	0.60	1.06
1-2-2	6.5	0.85	1.09
1-2-4	4.5	1.2	1.14
1-2-6	3.2	1.9	1.24
1-2-10	2.0	3.0	1.40
1-2-30	0.5	6.0	1.86
1-6-0	5.0	0.60	1.06
1-6-3	3.5	0.90	1.10
1-6-13	1.7	3.0	1.40
1-6-23	1.0	4.5	1.63
2-1-0	25	0.9	1.10
2-1-10	2.0	1.9	1.24
2-1-30	0.55	4.0	1.56
1-1-0	20	0.50	1.03
1-1-2	7.5	1.12	1.13
1-1-4	4	1.75	1.22
1-1-8	1.6	2.3	1.30
1-1-18	0.6	3.8	1.54
1-1-28	0.3	5.4	1.77

and the bottom of the slow etching (111) plane, the growth of the pits *vs.* the decrease in thickness of the (111) oriented crystal is a function of the ratio of the etch rate on the (322) and (111) faces (R_s/R_{111}). The ratio R_s/R_{111} was calculated from the slopes of experimental curves given in Fig. 3 (see appendix A). Some examples are given in Table I.

Battermann (3) experimentally found a ratio $R_s/R_{111} = 1.2$ for an 1-1-4 etchant which value has to be compared with the calculated value of 1.22 given in Table I. From Table I it can be seen that in general a greater water content (low etch rate) will give values of R_s/R_{111} near to 2; for rapid etchants this ratio is about 1. Apart from this general trend a closer analysis shows that actually the ratio of the water and the HF content determines this value of R_s/R_{111}, independent of the peroxide concentration. Figure 6 shows this empirical relationship[2] which can be expressed as follows

$$\frac{R_s}{R_{111}} = 1 + 0.014\,\frac{C_{H_2O}}{C_{HF}} \text{ (concentration in moles/l)} \quad [2]$$

Discussion

From the relations found in the preceding section some conclusions can be drawn regarding the kinetics of the orientation dependent etching. In general (322) and (110) faces etch fast, while (100) and (111) are slower (1, 3). It has been shown above that such differences may disappear for higher etch rates (high HF and low H_2O content). By way of explanation it is worth noting that the fast and the slow etching faces have characteristic differences in atomic surface structures (Fig. 7). The former [(110) type] have surface atoms (bearing unsaturated "dangling" bonds) bonded directly to other surface atoms whereas the latter [(111) type] have Ge surface atoms bonded only to deeper lying "normal" Ge atoms.

[2] As the added H_2O_2 and HF also contain water, in Fig. 6 the ratio C_{H_2O}/C_{HF} is not determined from the amount of added reagents, but the total amount of H_2O and HF is expressed in moles per liter.

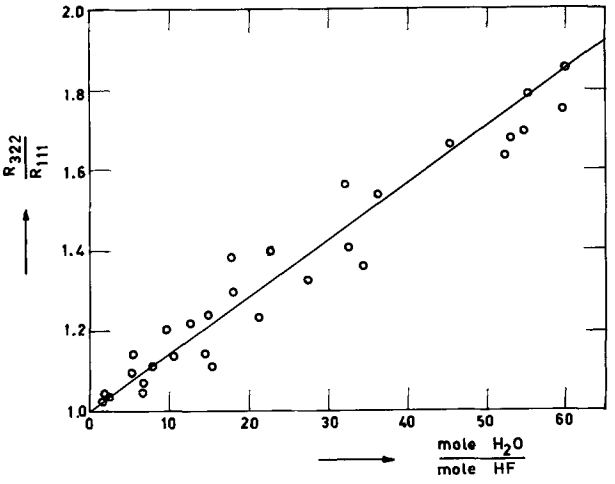

Fig. 6. The ratio of etch rates on the sides and bottom of the etch pits (R_{322}/R_{111}) for various etchants, plotted vs. the ratio of water and HF content in the etchant used, e.g., the higher the water content the faster the growth rate of the etch pits.

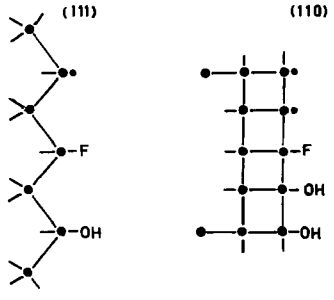

Fig. 7. Two types of surface structures, the (111)-type has surface atoms bonded only to deeper lying normal atoms; for the fast etching (110)-type the surface atoms are interconnected mutually.

It is postulated now that the Ge-Ge- bond of the slow etching (111) faces can be broken readily by H_2O_2 only if the surface atom carries the strongly electronegative F atom; the reaction rate is appreciably smaller if an OH group is attached to this surface atom. For the fast etching orientations of the (110) type this difference will be smaller as on each side of the bond the surface atoms carry electronegative atoms or groups (see Fig. 7).

The first reactions of the dangling bonds with the etchant will lead to the formation of [GeF]- and [GeOH]- groups (11). An "equilibrium"

$$[GeOH] + HF \leftrightharpoons [GeF] + H_2O$$

could be present giving

$$\frac{N_{OH}}{N_F} = K \cdot \frac{C_{H_2O}}{C_{HF}} \quad [3]$$

where N_{OH} and N_F denote the number of surface sites per unit area carrying an OH group or F atom, respectively. If this step is rate determining, which is possible for small HF and large H_2O concentrations, then the orientation dependent reaction rate could be proportional to the number of sites where the first H_2O_2 attack can be effectuated successfully, hence:

$$\frac{R'}{R''} = \frac{k'(N'_F + K'N'_{OH})}{k''(N''_F + K''N''_{OH})} \quad ; \quad (K'' << K' < 1) \quad [4]$$

Here a single prime indicates a property of the (110) and (322) type of surface and a double prime indi-

cates a (111) or (100) property. For the (111) type it is assumed that reactions at (OH) sites are much slower than on (F) sites; thus $K'' << N''_F/N''_{OH}$ then:

$$\frac{R'}{R''} = \frac{k'}{k''}\left(\frac{N'_F + K'N'_{OH}}{N''_F}\right)$$

With Eq. [3] this leads to

$$\frac{R'}{R''} = \frac{k'}{k''}\left(\frac{N'_F}{N''_F} + K'K\frac{N'_F}{N''_F}\cdot\frac{C_{H_2O}}{C_{HF}}\right)$$

$$= \frac{k'N'_F}{k''N''_F}\left(1 + K'K\frac{C_{H_2O}}{C_{HF}}\right) \quad [5]$$

Comparison with [2] shows that the observed relationship could be explained with the additional assumption that $k'N'_F \sim k''N''_F$, which means that the reaction rates on (F) sites for both the (110) and (111) type of surface are about the same.[3]

Conclusion

It seems reasonable to assume that in regions where the etch triangles are formed the orientation dependent etch rates are governed by the first steps in the reaction mechanism where the ratio C_{H_2O}/C_{HF} determines the differences in reaction rate on various crystal faces. This ratio will influence the amount of OH groups and F atoms bonded to the surface Ge atoms. This gives a slow etching (111) or (100) face if only Ge atoms carrying a F group can be oxidized easily on this type of surface. This is in contrast to the (110) and (322) type of surface where oxidation can be successful on Ge atoms bonded to OH or F radicals.

This will be the case especially for the lower etch rates where the water content is relatively high. For the more concentrated, faster etching mixtures the orientation dependence vanishes and a diffusion limited reaction rate could be predominant eventually.

Also for a low peroxide concentration no orientation dependence is found, and visible oxide films are present after etching. In this case it is possible that the oxidation potential near the Ge surface is so low that the oxidation of surface atoms from the divalent to the tetravalent state becomes more difficult, leading to the intermediate formation of GeO films.

[3] The reviewer of this paper has drawn the author's attention to an interesting comparison of the derived and empirical equations. Since $KK' = 0.014$ and $K' < 1$ (according to the hypothesis), then K must be fairly large (~ 1), i.e., the ratio $N_{OH}/N_F \sim C_{H_2O}/C_{HF}$.

Manuscript received July 14, 1961; revised manuscript received Sept. 1, 1961. This paper was prepared for delivery before the Houston Meeting, Oct. 9-13, 1960.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

APPENDIX A

It can be shown that on etching the outward displacement p of the side of an etch pit per unit time is given by

$$p = \frac{R_s/\cos\alpha - R_{111}}{\tan\alpha}$$

where R_{111} is the etch rate on the original (111) surface, R_s the etch rate on the side of the etch pit, and α the angle between (111) and side of the pit (about 15°). Thus the triangle widens as $R_s/\cos\alpha > R_{111}$ with a rate of p μ/min. The increase in size of the edges of the triangle then is given by $2\sqrt{3}\ p$ μ/min. The ratio of the increase in size of the edges to the decrease in thickness can be given as

$$\frac{r}{\Delta d} = \frac{2\sqrt{3}\ (R_s/\cos\alpha - R_{111})t}{2R_{111}\tan\alpha\cdot t}$$

$$= 1.72\left(\frac{R_s}{R_{111}\cos\alpha} - 1\right)\cot\tan\alpha$$

A mean value for α of 15° gives

$$\frac{r}{\Delta d} = 6.4\left(\frac{R_s}{0.96R_{111}} - 1\right)$$

In Fig. 3, $r/\Delta d$ is found as the slope of the experimental curves for $\Delta d > 20\mu$.

Controlled Etching of Silicon in the HF-HNO_3 System

D. L. Klein and D. J. D'Stefan

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

Some of the important factors that affect the degree of reproducibility of desired dimensions, flatness, and surface finish of chemically etched silicon have been investigated. The etching rate of single crystal silicon in hydrofluoric and nitric acids was studied as a function of the ratio of the concentrated acids, temperature, and stirring rate. These variables were found to be related to the etching rates over the ranges studied. No difference in etch rate was observed for n, p and n-p junction silicon, ranging in resistivity from 0.05 to 78 ohm-cm. The etch rate appears to be dependent on the diffusion of the fluoride species to the silicon surface in the nitric acid-rich region. The controlled etching technique has been applied to the etch-cutting of wafers from selectively masked silicon slices. Preliminary investigation has shown that this method is applicable for the preparation of slices for diffusion processing.

With the more sophisticated semiconductor devices now under development, dimensional control is becoming increasingly important. Regulation of the flatness and surface finish as well as the size of wafers and mesas require close dimensional control.

Silicon shaping processes now generally employ abrasive cutting and polishing techniques which are known to introduce surface damage. Therefore, devices must be etched following abrasive shaping to remove this damage. Final control of dimensions must then logically lie in the regulation of the etching process. Direct etch-cutting makes it possible to produce devices with surfaces approaching the degree of perfection inherent in the bulk material.

In order to achieve control of chemical etching, it is necessary to understand the important variables involved and their effects on the kinetics of silicon dissolution. The variables investigated and reported in this paper include etch composition, temperature, and stirring as they were observed on n, p, and junction-containing material over wide resistivity ranges. Additionally, some factors which affect the degree of roughness and the flatness of surfaces were examined.

The most commonly employed etches for silicon contain nitric and hydrofluoric acids together with one or more additives, such as acetic acid, bromine, iodine, and silver or mercuric nitrates (1). These additives are employed to modify the rate of reaction, the finish of the etched surface, or to cause preferential etching of certain crystallographic planes. However, to simplify the kinetics, the present study was limited to the concentrated hydrofluoric-nitric acid system.

Experimental Procedure

The etching was carried out in a specially constructed apparatus. This apparatus provided a close control of the etchant temperature as well as a means for stirring the solution and rotating the silicon samples at a constant rate. The etching solution was contained in a 400 ml polyethylene beaker sealed into a metal water jacket. Water was circulated through this jacket from an external constant temperature bath to control the temperature of the contents of the beaker to within $\pm 0.5°C$.

The samples to be etched were held in a slotted Teflon post by means of a Teflon set-screw. This post was fastened in the center of a flat Teflon disk surrounded by four Teflon blades which served as stirring paddles. The plastic disk assembly was held above the etching beaker by a movable bracket on which the stirring motor was also mounted. This movable bracket permitted the assembly to be lowered into and raised from the etching beaker. An electrical braking system stopped the stirring motor whenever the assembly was withdrawn from the beaker. In this manner the reaction could be quenched safely in less than 2 sec after withdrawal from the etch by immersing the assembly in a beaker of deionized water. Motor speeds were varied between 11 and 88 rpm.

The silicon used in this experiment was cut from single crystal ingots. The n- and p-type samples were cut perpendicular to the <111> and the n-p grown-junction samples were cut parallel to the <100>. All of the samples were cut so that their final dimensions were approximately 0.76 mm thick by 6.3 mm wide with lengths between 1.2 and 4 cm. The bulk resistivity of the material used was: n-type, 0.05-8.0 ohm-cm; p-type, 12.0-78.0; and the n-p samples averaged 0.3 ohm-cm on the n-side while the p-side averaged 5.0 ohm-cm.

Reagent grade nitric acid (69.9% assay) and reagent grade hydrofluoric acid (49.2% assay) were used for all mixtures reported herein as volume percentages.

Some consideration was given to the effects that long time storage might have on the reproducibility of prepared etches. No difference was observed in etch rate between batches of etch used within ½ hr of mixing and batches stored for as long as three months.

Etch rates, reported in microns per minute, were derived from weight loss measurements. Weight

losses were at least ten times the sensitivity of the balance (±0.2 mg).

Changes in thickness of all the samples were also determined directly with a micrometer having a vernier capable of being read to 0.0001 in. to verify the results of the weight loss method.

The flatness of several typical surfaces was determined by measuring differences of thickness across the width of the samples with a dial micrometer gauge. The accuracy of the gauge used was ±0.0001 in. Values for surface roughness were obtained by means of a Brush Surface Analyzer, Model BL103.

Results and Discussion

The rate of silicon dissolution in the HF-HNO_3 system has been examined over the entire composition range. In the concentration interval from 2 to about 65% HF the etch rate was found to increase with HF content. Between 65 and 70% HF the etch rate was observed to reach a maximum. Beyond the maximum, the rate was found to decrease until the dissolution reaction ceased in pure HF. The curve representing these data is shown as an insert in Fig. 1.

Staining of the silicon samples was encountered in etches containing less than 30% HNO_3 (2). Due to the stains, rate measurements based on weight loss or the change in thickness were difficult to make with a high degree of precision. In addition, the HF-rich portion of the system has a higher etch-rate dependence on the minority component than is found in the HNO_3-rich region. From a practical standpoint, therefore, etch-rate control is best achieved in etches containing less than 65% HF. For these reasons, only the nitric acid-rich region of the binary system was studied in detail.

Between 10 and 50% HF, the logarithm of the etch rate was found to be related linearly to the HF concentration while below 10% HF the rate was found to be directly proportional to the HF concentration. This observed change in the rate dependence below 10% HF possibly may result from an association of the HF with HNO_3. Association could reduce the effective concentration or the mobility of the reactive fluoride species required for the dissolution process.

Temperature.—The effect of temperature on the reaction rate was determined between 0 and 60°C for several etch compositions. Essentially, over this small temperature interval and for etch compositions containing between 2 and 50% HF, the reaction rates were found to increase linearly with temperature. When the data were plotted in a form suitable for the application of the Arrhenius equation ($1/T$ in degrees K *vs.* log reaction rate), the curves were found to have the same slope. This suggests that despite the change in the reaction rate slope at 10% HF (Fig. 1), the activation energy remains constant from 2 to at least 30% HF, the highest composition studied in determining this value. Using the Arrhenius equation, the activation energy was found to be 3.9 kcal/mole. This value compares favorably with the value of 4.1 kcal/mole reported by Schwartz and Robbins (3). Activation energies of this order of magnitude are recognized as indicating that the rate-determining step of the system is diffusion dependent. This point is considered in detail in a later section.

From a technological standpoint, the temperature dependence of the reaction rate is most important whenever a high degree of dimensional control must be considered. An illustration of the importance of temperature control was demonstrated when a sample of 10 cm^2 area was placed in 25 ml of a 30% HF-70% HNO_3 etch contained in a Teflon beaker. A wax-coated thermocouple placed within the beaker indicated a temperature rise of 70°C in 10 min. Within this period of time the reaction rate had more than doubled due to the temperature rise. Thus, with moderately fast etches, operating under essentially adiabatic conditions, there is little chance for good control of the etching rate due to thermal runaway. By employing large volumes of slow-acting etches (etches low in HF concentration) with constant agitation, however, the system can be operated under essentially isothermal conditions. In this way it has

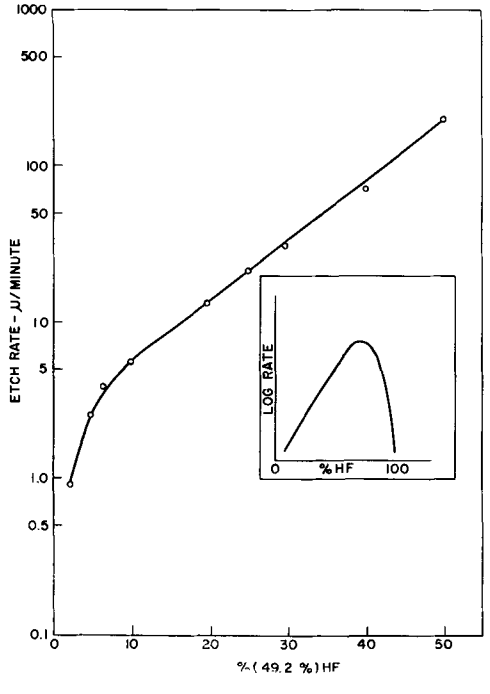

Fig. 1. Rate of reaction with respect to etch composition. Each experimental point is the mean of the values determined for n- and p-type samples; temperature 30°C; rotation, 88 rpm.

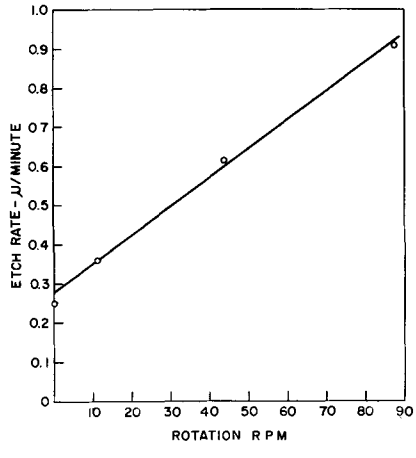

Fig. 2. Effect of rotation on etch rate. Temperature, 30°C; etch composition, 2% (49%) HF—98% (70%) HNO_3.

been found possible, with a slow etch, to limit the maximum temperature rise in an unthermostated system to 3°C in an etching bath operating at an ambient temperature of 25°C.

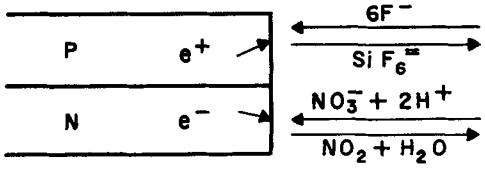
Rotation.—The rate of reaction was found to be directly related to the speed of sample rotation at constant temperature for etch compositions between 2 and 50% HF. A typical curve is shown in Fig. 2. An interesting relationship exists between the etch rate at various speeds of rotation and the HF concentration of the etch. If a plot is made of

$$\log r = Ra/Rb \qquad [1]$$

where r is the coefficient of rotation, Ra the etch rate at 88 rpm, and Rb the etch rate at 0 rpm with respect to the etch composition, a linear dependence was obtained as shown in Fig. 3. The increase in rotation-rate dependence with decreasing HF concentration will be used later to show that the dissolution of silicon is diffusion dependent with respect to HF in HNO_3-rich etches. Based on practical considerations, it might be thought that etch compositions in the range of the maximum etch rate (about 65% HF) might be advantageous since there is so little rotation dependence. Unfortunately, this apparent advantage is of no real value since the reaction rates are so fast that a high degree of control would be extremely difficult to achieve. In addition, rotation is important in order to prevent convection stirring of the etchant. Convection stirring will cause local temperature differentials to develop across the surface of the sample and will result in an increase in the average surface roughness. This is due to the increased etch rates on those areas of higher temperature.

Dissolution mechanisms.—According to Turner (4), the dissolution of silicon in HF-HNO_3 may be thought of as an electrolytic action wherein local anodic and cathodic sites develop on the surfaces of the semiconductor. Feuillade, Marette, and Dumontier (5) have also proposed an electrolytic mechanism for the corrosion of silicon. In addition to the electrolytic attack, they also have suggested that a localized consecutive chemical reaction can take place on the surface of the semiconductor.

The electrolytic attack described by Feuillade, Marette, and Dumontier may be shown diagrammatically:



and written:

$$4e^+ + Si + 6F^- \rightarrow SiF_6^= \qquad [2]$$

$$4e^- + 8H^+ + 4NO_3^- \rightarrow 4NO_2 + 4H_2O \qquad [3]$$

This type of reaction would preferentially remove p-type sites. The local chemical attack is a reduction-oxidation reaction followed by the dissolution of the silicon dioxide formed. These reactions can be written

$$Si + 4HNO_3 \rightarrow SiO_2 + 4NO_2 + 2H_2O \qquad [4]$$

$$SiO_2 + 6HF \rightarrow H_2SiF_6 + 2H_2O \qquad [5]$$

Although NO_2 must be formed in the etching process as evidenced by the appearance of the brown fumes of the NO_2 dimer, N_2O_4, it is possible that NO also results from the reduction of the nitric acid according to the reaction

$$3e^- + 3H^+ + HNO_3 \rightarrow NO + 2H_2O \qquad [6]$$

Turner (4) has pointed out that the ratio $[HF]/[HNO_3] = 4.5$, corresponding to the stoichiometry of the reaction

$$3Si + 4HNO_3 + 18HF \rightarrow 3H_2SiF_6 + 4NO + 8H_2O \qquad [7]$$

is very close to the ratio of the molar acid concentrations that occur at the maximum etch rate observed in the HF-HNO_3 system. This is cited as support for the formation of NO as the major reduction product of HNO_3.

If, in the absence of a junction, the etching of silicon proceeds through a stepwise process, the etch rate might be expected to be diffusion controlled except when $[HF]/[HNO_3]$ approaches 4.5. It should be understood that the molar ratio $[HF]/[HNO_3] = 4.5$ is significant in supporting a diffusion-controlled mechanism only if the diffusion and temperature coefficients of the active species of both the hydrofluoric and nitric acid are the same. Since these active species have not yet been identified, the values of the coefficients have not been determined. It is further assumed for this argument that both the molecular oxidation to SiO_2 and the molecular reaction of SiO_2 to form H_2SiF_6 are essentially instantaneous. For etches low in HF, the surface of the silicon will be covered with an oxide film, probably SiO_2, whenever the reactive fluoride species arrives at the etch-semiconductor interface, due to abundance of the oxidizing agent. Under this condition the rate of silicon removal will be rate-dependent on the arrival of HF at the SiO_2 surface. If the HF is consumed immediately at this surface by reaction [5], the surface concentration of HF will be zero. In this manner, a concentration gradient of HF will develop from the silicon interface back into the bulk of solution. For a given HF concentration, the rate of arrival of HF at the interface will be directly related to the thick-

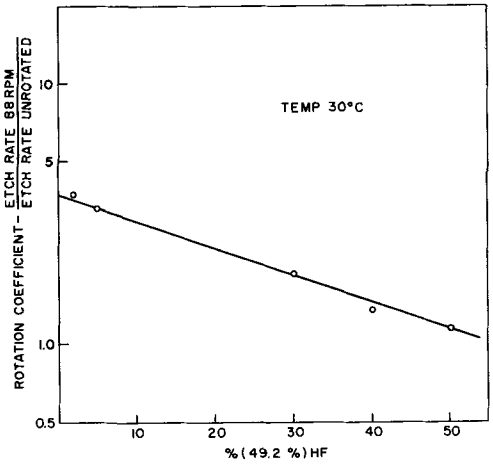


Fig. 3. Decrease in etch rate dependence on the rotation velocity with increasing HF content of the etchant; temperature 30°C.

ness of the diffusion layer. The thickness of diffusion layers of this type is known to be related inversely to the velocity of the interface with respect to the bulk of the solution (6). Thus, with increased rotation of the surface under attack, the thickness of the concentration gradient will decrease so that the diffusion time for an HF molecule to traverse this gradient will become smaller. This effect, that the etch rate does increase with increasing speed of rotation of the sample, has been observed as shown in Fig. 2. As expected, when the HF concentration in the etch was increased, the dependence of etch rate with rotation speed did become smaller (Fig. 3). The extrapolated value of about 60% HF, where the etch-rate dependence on rotation vanished, corresponds closely to the $[HF]/[HNO_3] = 4.5$ value expected. As mentioned previously, the relatively small activation energy of 3.9 kcal/mole measured for the dissolution process supports the contention that the reaction is diffusion controlled in the nitric acid-rich portion of the system.

The electrolytic attack proposed by Feuillade, Marette, and Dumontier should also show diffusion dependence with respect to the minority acid species present in the etch. In this situation, because of the necessity of charge balance, the concurrent oxidation-reduction reaction can occur at a rate no faster than the arrival at the surface of the minority reactant.

The electrolytic mechanism of silicon corrosion was clearly observed when p-n grown junction samples were etched. At distances greater than about 0.025 mm from the junction, the etch-rate was found to proceed at the same rate on the p- and on the n-sides of the junction. At these points, the reaction is believed to proceed through the nondifferentiating consecutive-type of local chemical attack. However, in the immediate vicinity of a junction with a large built-in electric field, the reaction changes abruptly to include an electrolytic attack which produces preferential etching of the p-side of the junction. This effect is shown for a typical sample in Fig. 4. In this case the etch rate in the immediate vicinity of the p-side of the junction was found to be about 60% greater than the remainder of the surface. The n-type silicon close to the junction exhibited a decrease in etch rate of the same magnitude. On the

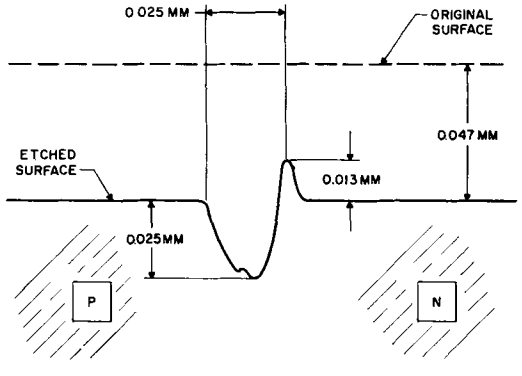

Fig. 4. A cross-section profile of a grown p-n junction after etching. The actual junction probably occurs close to the bottom of the trough. Temperature, 20°C; rotation, 88 rpm; etch composition, 2% (49.2%) HF-98% (70%) HNO_3. (Drawn to scale).

p-side, Eq. [2] is applicable and silicon is removed as H_2SiF_6. On the n-side, the cathodic reduction of the HNO_3 must take place. This reaction does not involve the corrosion of silicon and, therefore, the unattacked silicon is left as a small raised portion on the surface of the n-side of the junction.

For samples of single conductivity, the etch rate was found to be constant and reproducible (±5%), independent of the conductivity type and resistivity (0.05-78 ohm-cm) in etches containing between 2 and 50% HF. Also, no difference was observed between samples cut perpendicular to the <111> axis and those cut parallel to the <100> axis.

The absence of any detectable difference in etch rate between p- and n-type samples in nitric acid-rich etches suggests that the consecutive-type reaction, described in Eq. [4], [5], and [7] takes place. According to Dewald (7), the dissolution of germanium involves the diffusion of 2 electrons away from and 2 holes toward the interface. For silicon this type of reaction can be written

$$Si + 2e^+ \rightarrow Si^{+4} + 2e^- \qquad [8]$$

In the HF-HNO_3 system, the nitric acid serves as the electron acceptor. The holes must be supplied from the bulk of the silicon sample. So long as the electron acceptor, nitric acid, is present in large excess and the diffusion time for the HF to reach the interface is greater than the time necessary for either holes or electrons to diffuse to the surface, the etch rate will be independent of the conductivity type of the silicon. In etches of low HF content, the diffusion velocity of holes or electrons to the silicon surfaces can be expected to be faster than the diffusion of the fluoride species through the solution. As long as the reaction rate is diffusion dependent on the supply of HF to the surface, no differentiation of the etch rate will be observed between n- and p-type samples. With etch rates close to the maximum that occurs at about 65% HF this condition may not be satisfied, and it is possible that the etch rate of p-type material will be higher than n-type silicon.

Surface roughness and flatness.—A mechanically worked surface will etch at a faster rate than the undamaged body of a sample (8). This effect is due, in part, to the increased area of an abraded surface compared to a polished surface. Additionally, the faster rate probably is brought about by the formation of sites whose potential is markedly different from the average crystal value. The relative difference in potential between these sites and the adjacent surface would permit the electrolytic mode of corrosion to occur. As this mode probably operates at a generally higher etch rate than the local consecutive chemical attack, the surface will be consumed at a faster rate than would be observed for a surface with uniform potential.

For the critical removal of small amounts of silicon from samples which were previously lapped, some knowledge of the accelerated etch rate due to mechanical damage would be required. The rate of etching of the damaged surface produced by an 1800 mesh Al_2O_3 lap, after 0.5 min was determined to be about 3 times the steady-state etch rate of the sample. From the data, the average depth of damage appears

to correspond to approximately half of the diameter of the particle size of the abrasive. For 1800 mesh Al_2O_3 this is equivalent to 6μ of damaged material. This agrees closely with the value previously reported by Buck (8). In practice, when the amount of silicon to be removed is an order of magnitude greater than the depth of damage, the initially faster etch rate is of little importance.

The flatness of several typical surfaces was determined by measuring differences of thickness across the width of the samples. In 5 vol. % HF, it was observed on unrotated samples that edges were attacked faster than the faces and resulted in rounded edges of approximately 0.6 mm radius. In the same HF concentration, rotation of the samples increased the radius of curvature of leading diagonally opposite edges to approximately 0.9 mm, due to streaming of the etchant. The faces of the samples that had been rotated were found to be planar to within $\pm 12\mu$.

Surface roughness was determined by means of a Brush surface analyzer. The original surface of the lapped samples had an average roughness of 2.2μ. The average surface roughness after removal of 50μ of material from the surface with nitric acid-rich etches was found to be 0.40μ. The 5% HF etch consistently yielded the lowest surface roughness (0.29μ average). This does not seem to be due to the slowness of the etch since 2% HF etches always yielded rougher surfaces (0.45μ average).

During the course of repeated etching of a sample, it was observed that the surface roughness increased with each additional etch. Samples etched to a given depth in a single etching operation were found to have an average surface roughness one-third that of samples etched and quenched 15 times, with the same amount of silicon removed in each case. Careful observation showed that small droplets of the etch adhered to the samples after withdrawal from the etch container. The slight depressions etched into the surface, during the 1-2 sec before quenching, became preferential sites for droplets of the etch the next time the sample was withdrawn from solution. This progressive roughening of the surface could be eliminated if the etching reaction was quenched by dilution of the etch with either water or nitric acid, instead of quenching the reaction after withdrawal of the samples.

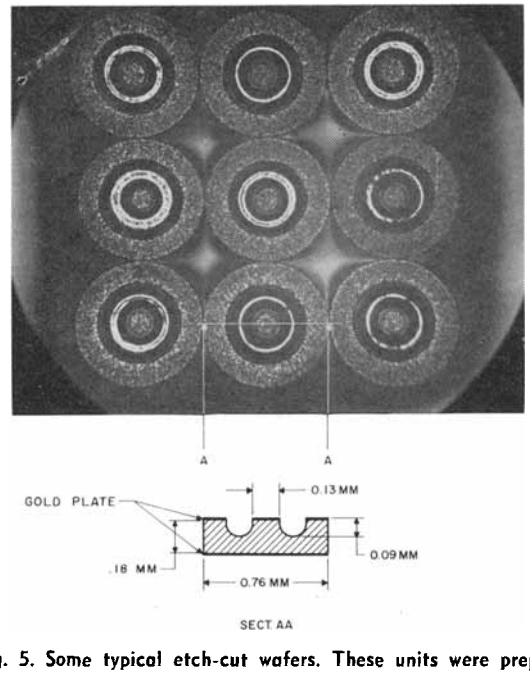

Fig. 5. Some typical etch-cut wafers. These units were prepared in a single operation which produced the mesas and separated the wafers simultaneously. The distortion of the diameters noticeable in all but the center sample is caused by photographic abberation.

Etch-cutting.—Controlled etching by this technique has been applied to the cutting of devices from slices of semiconductor material. The slices to be etched were contained in a platinum mesh basket supported and rotated in the experimental apparatus. Figure 5 shows a group of typical devices produced by this method. These wafers were produced from slices of silicon whose surfaces were masked by selective patterns of electrodeposited gold. The gold served as a mask while the slices were etched. In addition to serving as a mask, the gold provided a direct ohmic contact for the completed devices. Many geometries have been produced by this method. Several thousand devices of 0.76 $\pm$0.064 mm OD containing 0.13 mm diameter mesas have been made. Electrical characteristics of these have been equal to those made by ultrasonic grinding, diamond sawing, scribing and etching, and scribing and breaking processes which were followed by chemical etching.

A major advantage of etch cutting over abrasive techniques is the freedom from damage introduced into the semiconductor material by abrasive cutting action. Since this damage is generally undesirable the usual procedure is to remove it by chemical etching. Direct chemical etch cutting eliminates the damage producing step and greatly simplifies the cutting procedure.

The etching techniques were also evaluated by observing the electrical characteristics of devices made from slices of zone-leveled and pulled-single crystal silicon. These slices were approximately 2.5 cm in diameter and had been lapped with 1800 mesh Al_2O_3. The basic data gathered using small-size silicon samples appear to be completely applicable to the larger surface area slices which are often used for diffusion processing. The reproducibility in final thickness after removing approximately 0.185 mm from one surface of the slices was found to be better than $\pm$5%. The electrical characteristics of PNPN switching devices made from this material have equaled or exceeded the characteristics of similar units prepared by utilizing abrasive operations. The average saturation current of these units was found to be an order of magnitude lower than the control samples prepared by mechanical polishing.

Preliminary investigations indicate that slices of silicon can be controllably etched to thicknesses of less than 0.025 mm. To do this both sides must be etched to remove the mechanical strains introduced by the lapping process.

Summary

By employing nitric acid-rich HF-HNO_3 etches, together with temperature and rotation control, the dimensions of silicon samples can be etched reproducibly to within $\pm$5% of those desired. The applica-

tion of low rate and controlled etches has been used to etch cut complete devices from slices of silicon. In particular, the technique has been successfully employed in the preparation of several thousand mesa diodes of small dimensions. The major advantages gained by employing this technique are the simplicity of the method and the elimination of the damage produced in semiconductors by mechanical cutting.

The degree of control of thickness and surface finish achieved by this method has resulted in etch-polished slices which were found to equal or exceed the requirements for diffusion-doped devices.

Manuscript received June 5, 1961; revised manuscript received Aug. 19, 1961. This paper was prepared for delivery before the Chicago Meeting, May 1-5, 1960.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

The Effect of Organic Molecules on the Adsorptive Properties of Platinum Electrodes

M. W. Breiter

Research Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

The effect of the addition of organic substances (amyl alcohol, caprylic acid, and diphenyl amine) to 1M $HClO_4$ on hydrogen and oxygen adsorption and in the double layer region of smooth platinum was studied by impedance measurements and quasistationary potentiostatic current potential curves in the potential range between hydrogen and oxygen evolution. Hydrogen adsorption is inhibited. The double layer capacity decreases with increasing amyl alcohol concentration between +0.3 and +1.5v. The degree of coverage with molecules was computed between +0.3 and +1.2v from the capacity decrease. An oxidation of the organic substance occurs at potentials where the oxygen coverage is formed simultaneously. Amyl alcohol molecules are adsorbed before the oxidation. Their oxidation goes over an intermediate and takes place to a large extent on surface sites free of oxygen.

The adsorption of organic molecules and ions has been studied mainly on mercury electrodes because mercury behaves like an ideally polarizable electrode in a wide potential range and has an easily reproducible surface of known size. Little work has been done on solid electrodes. Borisova, Ershler, and Frumkin (1) observed a capacity peak, which is characteristic for the desorption of organic molecules or ions on mercury, on a zinc electrode in 1*N* KCl if amyl alcohol was added. Kheifets and Krasikov (2) found capacity peaks on smooth platinum in the presence of caprylic acid and diphenyl amine in 2*N* H_2SO_4 and of sodium caprylite in 0.5*N* Na_2SO_4 and in 0.5*N* NaOH in the potential range between hydrogen and oxygen evolution. Franklin and Sothern (3) investigated the adsorption of different nitrides in 2*N* H_2SO_4 on platinized platinum at the potential of the hydrogen electrode. They assumed that the observed decrease of the amount of adsorbed hydrogen is due solely to a replacement of hydrogen atoms by nitride molecules.

As is well known, three distinct regions can be distinguished for the platinum electrode in the potential range between hydrogen and oxygen evolution. In perchloric acid hydrogen is adsorbed between 0 and +0.4v, the potential being measured against a hydrogen electrode in the same solution. Neither hydrogen nor oxygen is adsorbed between +0.4 and +0.8v in the so-called double layer region where platinum behaves as an ideally polarizable electrode. The chemisorption of oxygen takes place between +0.8 and +1.6v. In the present paper the influence of organic molecules on the adsorptive properties of the platinum electrode in the three regions was studied. Extensive measurements at room temperature were made in 1M $HClO_4$ with addition of amyl alcohol. A few experiments were run in 1M $HClO_4$ with caprylic acid and diphenyl amine. The capacity of the interphase smooth platinum/electrolyte was determined as a function of potential, frequency (5-105 cps) and time in 1M $HClO_4$ with different amounts of amyl alcohol (0.01-0.1M). Quasistationary current potential curves were obtained on smooth platinum in 1M $HClO_4$ with different amounts of amyl alcohol, in 1M $HClO_4$ with 10^{-3} or 10^{-4}M caprylic acid and in 1M $HClO_4$ with 10^{-5}M diphenyl amine by applying potentiostatically a potential which changed periodically and linearily with

time between +0.05 and +1.6v. The current potential curves were measured at different voltage speed.

Experimental

Figure 1 shows a schematic diagram of the circuit for the impedance measurements. The platinum wire with 0.03 cm ϕ was in the axis of a palladium wire spiral which formed a cylindrical counter electrode. The palladium wire with 0.1 cm ϕ was kept at the potential of the α- β-phase transition (ca + 0.05v). The surface of the counter electrode was about ten times larger than that of the test electrode. The impedance of a palladium electrode at the said potential is very small (4). The potential of the platinum electrode was changed with the aid of the potentiometer P and measured against a hydrogen electrode in 1M $HClO_4$. As the measurements were made in solutions saturated with nitrogen by intensive bubbling, the potential of the palladium electrode remained practically constant during the experiments. The resistor between A and B was a suitable one of a set of standard resistors. The a-c signal across the cell never exceeded 5 mv. The a-c voltage across AB was applied to the input of one of the two differential amplifiers of the dual beam oscilloscope Tektronix 502, the a-c voltage across CD to the other. The sweep was adjusted according to the frequency. A photograph was taken. The amplitudes of the two voltages and their phase shift were determined from enlargements of the photographs, and the impedance of the interphase was computed. This method allows fast measurements with an accuracy of 3-5%. It has the advantage that the d-c circuit need not be separated from the a-c circuit by an inductance in the low-frequency range used here.

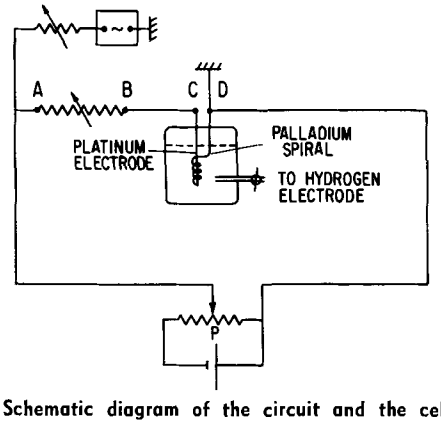

Fig. 1. Schematic diagram of the circuit and the cell for impedance measurements.

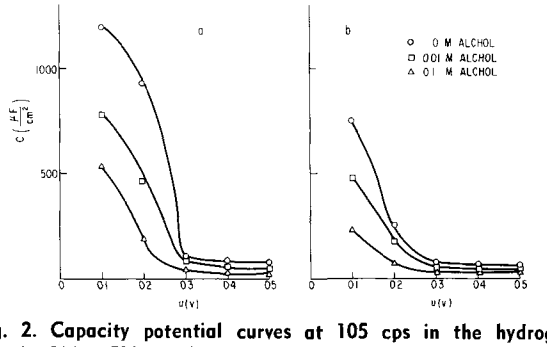

Fig. 2. Capacity potential curves at 105 cps in the hydrogen region in 1M $HClO_4$ with different amounts of amyl alcohol: a, after 2 min of polarization at constant potential; b, after 30 min of polarization at constant potential.

To measure the quasistationary current potential curves the circuit between A and C was connected to the electronic potentiostat and triangular wave generator described and used by Will and Knorr (5). The sine wave generator and the potentiometer P were disconnected. The reference electrode (hydrogen electrode in 1M $HClO_4$) was in a compartment separated from the test vessel by a closed stop cork, as with the impedance measurements. The palladium spiral served as counter electrode. The measurements were made in a resting solution, saturated with nitrogen by intensive bubbling before the experiments.

Preliminary runs showed that the a-c impedance of the platinum electrode changed with time. So the measurements were made in the following way to obtain comparable initial values. The platinum electrode was cleaned in chromic acid, rinsed with distilled water, and pretreated intermittently, cathodically and anodically in 1M $HClO_4$ in another vessel before any run in the test vessel. Then the electrode was transferred to the test vessel and the capacity was determined at constant potential as a function of time for 30 min in the frequency range 5-105 cps. The capacity became nearly time-independent after 30 min. The platinum electrode was subjected to the same pretreatment before taking any current potential curve.

Experimental Results

The capacity of the interface platinum/solution is plotted in Fig. 2a and 2b for different solutions as a function of potential in the region of hydrogen adsorption and in part of the double layer region. The interface was considered as a series circuit of a resistor and a capacitor C. As the measurements at frequencies between 5 and 105 cps yielded the same form of the capacity potential curves, only the curves at 105 cps are plotted in Fig. 2a and 2b. Figure 2a represents the values measured after 2 min of immersion and polarization in the test solution at a given potential. Figure 2b shows the capacity obtained at the same potential after 30 min of uninterrupted polarization.

Capacity potential curves for different solutions are plotted in Fig. 3a and 3b in the double layer region and in the region of oxygen chemisorption. The values in Fig. 3a correspond to 2 min, the values in Fig. 3b to 30 min of polarization at constant potential.

Quasistationary current potential curves in 1M $HClO_4$ with different amounts of amyl alcohol are

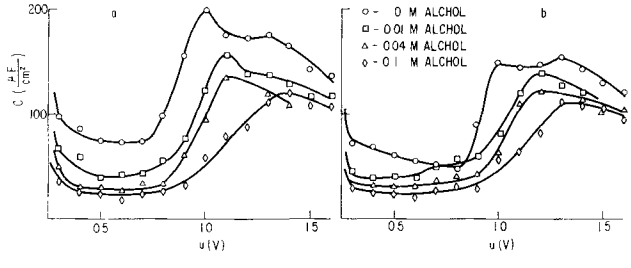

Fig. 3. Capacity potential curves at 105 cps in the region of the double layer and of the oxygen coverage in 1M $HClO_4$ with different amounts of amyl alcohol: a, after 2 min of polarization at constant potential; b, after 30 min of polarization at constant potential.

shown in Fig. 4a, 4b, and 4c. The concentration of amyl alcohol increases in the order of the lettering a, b, c, d, e and is given in the figure caption. The curves in Fig. 4a were measured at 0.2 v/sec, in 4b at 1 v/sec and in 4c at 10 v/sec. No time dependence of the current potential curves was observed within 15 min of observation if the applied potential

changed periodically between +0.05 and +1.6v. If the periodic potential sweep covered the range +0.05-+0.5v only, the current at the same potential decreased strongly with time in accordance with the time dependence of the capacity in the region of hydrogen adsorption.

Current potential curves in 1M $HClO_4$ with 10^{-4} caprylic acid are plotted in Fig. 5a and 5b. The voltage speed was 0.6 v/sec for Fig. 5a and 6 v/sec for Fig. 5b. The time dependence was similar to the one observed during the experiments in 1M $HClO_4$ with amyl alcohol.

Discussion

Capacity measurements in 1M $HClO_4$ *with amyl alcohol in the region of hydrogen adsorption.*—The capacity potential curve in 1M $HClO_4$ has the characteristic form described and discussed in earlier papers (6-8). The capacity increases with decreasing potential due to the adsorption of hydrogen atoms. The fine structure of the capacity potential curve (7, 8) in the hydrogen region cannot be seen from Fig. 2a because there are too few points.

The addition of amyl alcohol to 1M $HClO_4$ leads to a decrease of the capacity with increasing alcohol concentration at a given potential in the whole range. The surface area which is available for the adsorption of hydrogen atoms becomes smaller with increasing concentration of alcohol. A large part of this effect is due to the adsorption of organic molecules at surface sites which are covered with hydrogen atoms in 1M $HClO_4$. The beginning of hydrogen adsorption is shifted toward less positive potentials with increasing alcohol concentration. Specifically adsorbed anions have a similar effect on the hydrogen adsorption (9-11).

A computation of the number of adsorbed organic molecules in the case of simultaneous adsorption of hydrogen atoms and molecules from the capacity decrease in the hydrogen region is difficult because little is known about the interaction between the two types of adsorbed particles. The basic assumption of Franklin and Sothern (3), that hydrogen atoms are replaced quantitatively by molecules, *i.e.*, according to a linear relationship between the decrease of the amount of adsorbed hydrogen and the number of adsorbed molecules, requires an experimental verification.

The comparison between Fig. 2a and 2b shows a marked decrease of capacity with time in the hydrogen region. It cannot be said that this decrease is solely due to a slow displacement of hydrogen atoms by organic molecules, since the capacity also decreases with time at constant potential in 1M $HClO_4$. The decrease in 1M $HClO_4$ could be attributed to a decrease of the surface roughness within the first 20 min after the anodic pretreatment (11). Therefore, at least two effects overlap, and conclusions should only be deduced from the results in Fig. 2a and 3a where the time effect is small.

Capacity measurements in 1M $HClO_4$ *with amyl alcohol in the region of the double layer and of oxygen adsorption.*—The capacity potential curve in 1M $HClO_4$ (see Fig. 3a) has a characteristic form which was described in earlier papers (12-15). The measured capacity represents the double layer capacity in this region. It remains practically independent of potential in the double layer region and begins to increase with potential between +0.7 and +1.0v when the formation of a chemisorbed oxygen layer starts. There is a peak at +1.05v and a second one at +1.3v. The form of the capacity potential curve and the location of the peaks depends strongly on the composition of the electrolyte (12). The curves differ in 1*N* $HClO_4$ and 2*N* H_2SO_4. This suggests that the increase of the capacity is due to an increase of the Helmholtz capacity of the double layer with oxygen coverage. Llopis and Colum (15) and Laitinen and Enke (14) interpret the capacity increase as resulting from surface dipoles (polarized oxygen atoms or other intermediates). Generally the capacity of the ionic double is in series with the capacity of the oxide layer in such a model. Thus a decrease of the measured capacity is expected as found by Vermilyea (16) during the formation of an oxide film on tantalum. A decrease in capacity was observed before attainment of a monolayer. Based on this model of the interface, the observed capacity increase on platinum can be better interpreted by an increase of the capacity of the Helmholtz layer. The interpretation of Llopis and Colum (15) and of Laitinen and Enke (14) implies that the capacity of the ionic double layer is considerably larger than the measured value (20 to 60μF/cm^2 for Laitinen and Enke, 75-200 μ/Fcm^2 in the present work). A value of 00 to 600 μF/cm^2 or 750-2000 μF/cm^2, respectively, for the ionic double layer appears too high. Another possible interpretation is that the capacity increase is due to a kinetic effect such as with the desorption peaks of organic ions and molecules (17). The latter possibility may be ruled out because the reduction and formation of the oxygen layer are too irreversible for any contribution.

Figure 3a and 3b show that the capacity decreases with increasing concentration of amyl alcohol at constant potential in the whole range. The intersection of the curve for 0.04M and 0.1M alcohol at +1.4v in Fig. 3a may be due to a different effectiveness of the pretreatment. The capacity decreases with time at constant potential. The capacity potential curves for 0.04M and 0.1M alcohol in Fig. 3a are very close in the double layer region. This suggests that the surface is covered with a monolayer of adsorbed molecules. The form of all the curves is similar in the region of oxygen chemisorption. A simultaneous adsorption of molecules and oxygen takes place. The oxygen coverage grows more slowly with anodic potential if the concentration of alcohol increases. The capacity at +1.6v differs only slightly in all solutions. This indicates that the organic molecules are desorbed to a large extent from the surface when the evolution of molecular oxygen starts. The same conclusion cannot be made for the beginning of hydrogen evolution (see Fig. 2a). Capacity peaks which are due to the desorption of the organic particles in a small potential range, such as on mercury, were not found for amyl alcohol on platinum. The capacity potential curves indicate a gradual desorption of the alcohol on both sides of the double layer region.

An approximate computation of the degree of coverage θ with organic molecules was carried out for

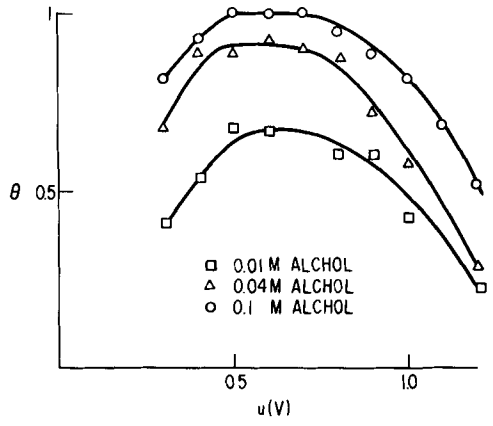

Fig. 6. Degree of coverage θ as a function of the potential and the concentration of amyl alcohol in 1M $HClO_4$ as basic electrolyte.

the potential range +0.3-+1.2v on the basis of Frumkin's model (18) of the double layer

$$C = C_{\theta=1} \cdot \theta + C_{\theta=0} (1 - \theta) \qquad [1]$$

The measured double layer capacity is assumed to be composed additively of a part due to the completely covered surface and a part due to the free surface. $C_{\theta=1}$ is the differential capacity of the surface completely covered with molecules at a given potential, $C_{\theta=0}$ is the capacity of the surface free of molecules at the same potential. An investigation of the adsorption of amyl alcohol on mercury showed that formula [1] is a satisfactory approximation at potentials between the adsorption peaks (19). As platinum behaves as an ideally polarizable electrode in the potential range +0.3-+1.2v with respect to impedance measurements and as no desorption peaks are observed, the application of formula [1] should give approximate θ values. It is possible that the range for the applicability of formula [1] extends anodically only to +1.0v where the oxygen coverage is still moderate. The θ values at +1.2v may be linked with a higher error.

Figure 6 shows the coverage as a function of potential and alcohol concentration. The values in Fig. 3a were used for the computation of θ with the aid of Eq. [1]. $C_{\theta=1}$ was taken equal to 24 μF/cm^2, the value of the double layer capacity in 1M $HClO_4$ + 0.1M amyl alcohol in the double layer region. It was assumed that $C_{\theta=1}$ is nearly independent of the potential at potentials more positive than +0.8v. The error made with this assumption cannot be too large as a look at the capacity potential curve in Fig. 3a shows. $C_{\theta=0}$ was set equal to the capacity in 1M $HClO_4$. The curves in Fig. 6 are similar to the respective curves on mercury (19). The coverage decreases on both sides of the double layer region. It is nearly independent of potential in the double layer region. The capacity potential curves indicate that the decrease of coverage in the cathodic direction is continued at a slower rate with decreasing potential in the hydrogen region than between +0.5v and +0.3v. The experiments on platinum suggest that the cause for the desorption of amyl alcohol is different on mercury and platinum. The potential drop across the interphase mercury/solution finally becomes so great on both sides of the electrocapillary maximum that organic molecules are replaced by water molecules (18, 20). On platinum the desorption is obviously caused by the formation of an oxygen layer at the positive side of the double layer region and probably by the adsorption of hydrogen atoms on the negative side. The coverage potential curves in Fig. 6 represent the behavior of an electrode with the same history of the surface. Therefore the θ values cannot be used for a quantitative kinetic discussion of the current potential curves in Fig. 4a, 4b, and 4c. However, the general tendency of the platinum electrode for the adsorption of amyl alcohol is given by them.

Current potential curves in 1M $HClO_4$ *with amyl alcohol.*—The impedance measurements yield information about the adsorption of the organic molecules in the three potential regions on a platinum electrode. They do not indicate if the molecules undergo oxidation. Therefore current potential curves were taken in the way described previously.

Curves a in Fig. 4a, 4b, and 4c were obtained on platinum in 1M $HClO_4$ at different voltage speeds. The curves show the typical form discussed by Will and Knorr (5) in detail. The three potential regions are clearly recognizable. The current potential curves are practically symmetrical to the abscissa in the hydrogen region during the anodic and cathodic sweep. The ionization and formation of adsorbed H-atoms occurs with a very small hindrance. The current is small in the double layer region. It increases between +0.8 and +1.0v and remains nearly constant between +1.0 and +1.5v during the anodic sweep when an oxygen layer is formed. The reduction of the oxygen layer is an irreversible process and takes place at less positive potentials than the formation.

If amyl alcohol is present, the current potential curves have a different form. The form depends on the alcohol concentration and the voltage speed. Current potential curves at 0.2 v/sec are plotted for different alcohol concentrations in Fig. 4a. The hydrogen adsorption is reduced with increasing alcohol concentration. The two current peaks which show the existence of two types of surface sites with different heat of adsorption for hydrogen (11, 21) disappear. The current is larger in the presence than in the absence of alcohol in the region of oxygen coverage during the anodic sweep. The current peak which is characteristic for the reduction of the oxygen layer is recognizable in all curves during the cathodic sweep. Curves b and c show practically no flow of current between +1.5 and +1.0v; curves d and e exhibit a small anodic current there. The curves have an additional anodic peak in the double layer region during the cathodic sweep. The height of this peak increased if the solution was stirred by nitrogen bubbling. Curves b, c, and d have two humps between +0.8 and +1.6v during the anodic sweep.

It can be concluded from results in Fig. 4a that the molecules of amyl alcohol undergo an anodic oxidation in the potential region where the oxygen layer is formed simultaneously. A large portion of the current is used for the oxidation of the alcohol in this range. The appearance of the anodic current peak in the double layer region during the cathodic sweep

can be interpreted as the oxidation of an intermediate which was formed during the preceding anodic sweep. The intermediate is oxidized at a less positive potential than the alcohol. Such a situation is often observed for the oxidation of an alcohol and the respective aldehyde. The oxidation of the intermediate requires a surface free of chemisorbed oxygen. The reduction of the oxygen coverage and the oxidation of the intermediate overlap. The effect of stirring and the investigations of the coverage show that the intermediate comes from the solution. Obviously part of the intermediate diffuses away after the anodic formation and diffuses back to the surface during the cathodic sweep. The decrease of the anodic current after the peak at about +1.3v is obviously produced by the increasing oxygen coverage which is paralleled by a decreasing coverage with molecules (compare Fig. 6). This suggests that the oxidation occurs on the oxygen-free surface only. The lack of an essential anodic current between +1.5 and +1.0v during the cathodic sweep supports this view. The small bump at about +0.95v of curves b, c, and d disappears at the highest concentration of alcohol. It is probably connected with a reaction between molecules and adsorbed oxygen and does not appear in curve e because the oxygen coverage at +1.0v is small in that case. The current of curve e starts to rise during the anodic sweep at a potential where the surface is practically covered with a monolayer of molecules. It is concluded from this result that the molecules are adsorbed before their oxidation.

An increase in voltage speed changes the ratio of the partial currents which are used for the oxidation of the alcohol and the formation of the oxygen layer in favor of the surface oxidation (see Fig. 4b and 4c). This is probably the reason why the oxidation of the intermediate is no longer strongly pronounced in the curves of Fig. 4b and disappears in Fig. 4c. In general the form of a curve in Fig. 4b is similar to that of the curve at the same alcohol concentration in Fig. 4a. The curves at a relatively high voltage speed of 10 v/sec in Fig. 4c exhibit new phenomena. The two characteristic current peaks in the region of hydrogen adsorption appear in curve b and c. The voltage speed is sufficiently large that the surface area for hydrogen adsorption is not diminished by blocking sites through molecules at the two lower concentrations of amyl alcohol. The average current efficiency for the oxidation of amyl alcohol is 45% for curve b and 60% for curve c under the plausible assumption that the integration of the cathodic current potential curves between +1.5 and +0.4v yields the electricity for the reduction of the oxygen coverage. Curves d and e indicate that the oxygen coverage is not completed to a monolayer at the large alcohol concentrations and high voltage speed. Part of the surface remains covered with molecules during the anodic and cathodic cycle under these conditions, so the area for hydrogen adsorption is reduced. The average current efficiency for the alcohol oxidation increases to 83% for curve d and 88% for curve e. It is difficult to give a more detailed picture of the oxidation mechanism on the basis of the results of this paper.

Current potential curves in 1M $HClO_4$ *with caprylic acid.*—A comparison between curve a in Fig. 5 and curve a in Fig. 4a or 4b shows that oxidation of the caprylic acid occurs at the low voltage speed during the anodic cycle. Oxidation and formation of the oxygen coverage takes place simultaneously. At the higher speed oxidation is not observed (see curve b). The current of the anodic curve b is nearly independent of the potential between +1.0 and +1.5v while this "plateau" is not present in curve a. The current potential curves in 1M $HClO_4$ + 10^{-5}M caprylic acid have a similar form. The characteristic shape of the curves in the hydrogen region is maintained at voltage speeds between 0.2 and 10 v/sec for a concentration of 10^{-5} and 10^{-4}M caprylic acid. However, the amount of hydrogen adsorbed between +0.05 and +0.4v is somewhat smaller in the presence (2.10^{-4} to 3.10^{-4} coul/cm^2) than in the absence (4.10^{-4} coul/cm^2) of caprylic acid. If the applied potential changes periodically between +0.05 and +0.5v only, a decrease of the current at the same potential with time is observed. The relative decrease in 5 min is 20% in 1M $HClO_4$ + 10^{-4}M caprylic acid and 25% in 1M $HClO_4$ + 10^{-5}M. These effects indicate that caprylic acid is adsorbed simultaneously with hydrogen atoms. On the whole the effect of caprylic acid on the adsorptive properties of platinum is small.

Kheifets and Krasikov (2) reported a capacity potential curve on platinum at 50 cps in 2*N* H_2SO_4 + 5.10^{-5}M caprylic acid with a peak at +1.3v and one at +0.2v (measured against a hydrogen electrode in the same solution). The double layer capacity between the two peaks is lower than the capacity in 2*N* H_2SO_4 within the same potential range. Their curves indicate that the hydrogen adsorption in the presence of caprylic acid does not start at a potential more positive than the potential of the hydrogen electrode. The capacity values in the vicinity of the peak at +1.3v are larger in 2*N* H_2SO_4 with caprylic acid than without. Otherwise the capacity potential curve in 2N H_2SO_4 + 5.10^{-5}M caprylic acid lies below that in 2*N* H_2SO_4 in the region of oxygen coverage. The latter effect is peculiar as the capacity potential curves on mercury in the presence of organic molecules used to be above the curve in the absence of molecules at potentials more positive than the left capacity peak.

The results of Kheifets and Krasikov (2) are not in agreement with the results of Fig. 5. If a strong influence of caprylic acid exists, it should be pronounced in the current potential curves of Fig. 5, too. An explanation of the discrepancy is difficult as Kheifets and Krasikov do not give information on the pretreatment of the platinum electrode, the sequence of the measurements, and the time effect.

Current potential curves in 1M $HClO_4$ *with* 10^{-3}M *diphenylamine.*—The current potential curves in 1M $HClO_4$ + 10^{-3}M diphenylamine are not shown in this paper. A current peak in the region of oxygen adsorption and a change of the curves in the hydrogen region were observed if platinum was polarized periodically between +0.05 and +1.5 v/sec. at 1.5 v/sec. The peak changed very much with time. The peak current was too large to attribute it to changes

of the doubler layer capacity. It is caused by the oxidation of diphenylamine. Kheifets and Krasikov (2) used a diphenylamine concentration which was 100 times smaller. The one capacity peak in the presence of diphenylamine was observed by Kheifets and Krasikov at the potential of the current peak of the current potential curves. Therefore it is suggested that the capacity peak is due to the oxidation of the diphenylamine. Owing to the small concentration of diphenylamine, Kheifets and Krasikov found Faradaic a-c currents of the magnitude of capacitive currents.

Manuscript received June 6, 1961. This paper was prepared for delivery before the Indianapolis Meeting, April 30-May 3, 1961. The experimental work was carried out in the Institute of Physical Chemistry and Electrochemistry of the Technical University, Munich, and supported by Dechema and Deutsche Forschungsgemeinschaft.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

Electrodeposition of Gallium on Liquid and Solid Gallium Electrodes in Alkaline Solutions

J. O'M. Bockris and M. Enyo

John Harrison Laboratory of Chemistry, University of Pennsylvania, Philadelphia, Pennsylvania

ABSTRACT

A galvanostatic short time transient method has been used to examine deposition and dissolution on gallium electrodes in alkaline solutions of gallic chloride. The cathodic metal deposition current was distinguished from the total current by current efficiency determinations in steady state.

Behavior on the liquid electrode is consistent with a charge-transfer controlled mechanism in all current density regions, and the rate-determining step is probably $H_2GaO_3^- + e^- \rightarrow HGaO_2^- + OH^-$.

On the solid electrode, the rate constants of the transfer reaction are nearly those of the liquid electrode. However, the behavior in the low current density regions is qualitatively different from that on the liquid. Analysis of phenomena in this region suggests that surface diffusion begins to control the rate of the over-all deposition process on the solid cathode. Rate constants of the surface diffusion process evaluated from the low current density region are semiquantitatively applicable to deviations from the Tafel equation which occur on the solid at high current densities (surface diffusion controlled limiting current). The results provide support for the existence of rate-controlling surface diffusion in metal deposition and dissolution reactions.

In studies on the kinetics of the deposition and dissolution of monolayers of metals in aqueous solutions, it has been shown that the most important partial reactions which determine the rate of the over-all processes are charge transfer and the surface diffusion of adions on the electrode surface (1-6). There exists, however, a quantitative disagreement on the relative importance of these partial reactions in determining the over-all rate. Thus, according to the work of Mehl and Bockris (1), in the deposition and dissolution of Ag in $AgClO_4$ + $HClO_4$ solution, the charge transfer process becomes rate determining at higher current densities [cf. Despic and Bockris (2)]. According to other authors

(3-5), however, the charge transfer process is less important than the crystal building process in rate control for metal deposition and dissolution. It is desirable therefore to devise experiments in which crystal building steps (including surface diffusion) in metal deposition can be tuned out of the possibilities concerning rate control and the current-potential characteristics examined in the absence and presence of possible crystal building rate controlling steps.

A possible approach to this problem is by means of measurements on amalgams. There exist, however, difficulties in inferring the rate of charge transfer on the corresponding solid electrodes from measurements with amalgams. Thus, it is easy to show that

$$\frac{i_{o,\mathrm{am}}}{i_{o,\mathrm{solid}}} = \frac{k_1'}{k_1}\alpha_c/z \qquad [1]$$

where i_o is the exchange current density, [M] the concentration of the amalgam, k_1' and k_1 are the forward rate constants for the transfer reaction on the amalgams and on the solid, respectively, α_c the cathodic transfer coefficient, and z the ionic charge of the metal ion concerned.

If $k_1 = k_1'$, Eq. [1] shows that the charge transfer i_o value for a solid metal should be much greater than that observed experimentally on amalgam electrodes. Such conclusions cannot be made, however, because k_1' may differ greatly from k_1.

In comparison of k_1 and k_1', it is only necessary to consider the potential energy of the final state in the forward transfer reaction. The determining factors are the work function of Hg, and of the metal concerned, and the "heat of sublimation" of the metal atom from its own lattice or from that of the amalgam. If the latter is considerably increased in the amalgam compared with that of the pure substance, then k_1' may be much greater than k_1. These matters indicate the difficulties of inferences from amalgams.

Measurements on solid and liquid Hg are not suited to a comparison of deposition rates on solids and liquid because the temperature of fusion demands either nonaqueous or very concentrated aqueous solutions, and the i_o values for metal exchange involving Hg are very high and thus difficult to determine. Hence, the electrodeposition process of gallium from an alkaline gallate solution onto both solid and liquid electrodes was studied.

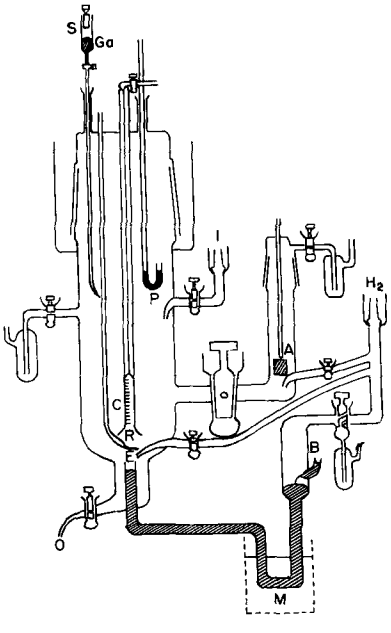

Fig. 1. Experimental cell used for studies on the gallium deposition. A, anode (Pt); B, Pt contact to Ga; C, glass tube to measure volume of hydrogen evolved; E, test electrode (Ga); I, solution inlet; M, cooling mixture (ice water); O, solution outlet; P, pre-electrolysis electrode (Ga); R, reference electrode (Pt); S, supply of Ga metal.

Experimental

Electrode construction and cell.—A cup-type electrode with a Pt wire contact was unsatisfactory, since the solution frequently contacted the wire. This type was employed therefore only for pre-electrolysis. The arrangement used is shown in Fig. 1. The temperature was controlled to ±0.5°C.

Reagents.—Gallium metal was 99.999% and gallic chloride 99.95% pure.

Procedure.—A solution of NaOH was prepared by the amalgam method (7), and the concentration was determined before mixing with $GaCl_3$. Hydrogen gas was purified using heated platinized asbestos (6, 8), charcoal traps (liquid air temperature), etc. Water was prepared by distilling conductance water into the cell in an atmosphere of hydrogen.

The cell was cleaned (8), and the system set up, including the container of NaOH solution already prepared. Air was removed by hydrogen flow, and 5 ml of NaOH solution taken into the cell. $GaCl_3$ then was distilled from I (Fig. 1) in a hydrogen [or helium similarly purified (8)] atmosphere by a weak torch flame (approximately half of the original amount was used). A further amount of NaOH solution was added to make up the final solution to 50 ml. Finally, gallium metal in S (Fig. 1) was taken through a thin glass capillary (9) into the U-tube portion, and the meniscus at E adjusted by hydrogen pressure in B, so that it came about 3 mm below the top of the tube at E. The gallate concentration was determined after the experiment (10).

Pre-electrolysis.—The solution was pre-electrolyzed at 3 ma cm^{-2} for 12-18 hr.

Measurements.—(*a*) *Current efficiency.*—The current efficiency was determined by collecting H_2 in the 1 ml pipette tube over the electrode (C in Fig. 1). The volume of the gas observed was of the order of a few hundredths of a milliliter. The current efficiency measurements were tested by measuring the H_2 produced on Pt electrodes in alkaline solution previously saturated with hydrogen. The result was 100 ±2%.

(*b*) *Polarization.*—The galvanostatic transient method was used (6). To compensate for the static potential difference between the test and counter electrodes, which caused difficulty in obtaining a suitable galvanostatic condition, an auxiliary potentiometer circuit was used between the pulse generator and the cell. The duration of the pulse was 3 msec-1 sec, with current densities of 10^{-5}-10^{-2} amp cm^{-2}. Measurements were mostly cathodic. Anodic dissolution produced films when the galvanostatic pulses were sufficiently long.

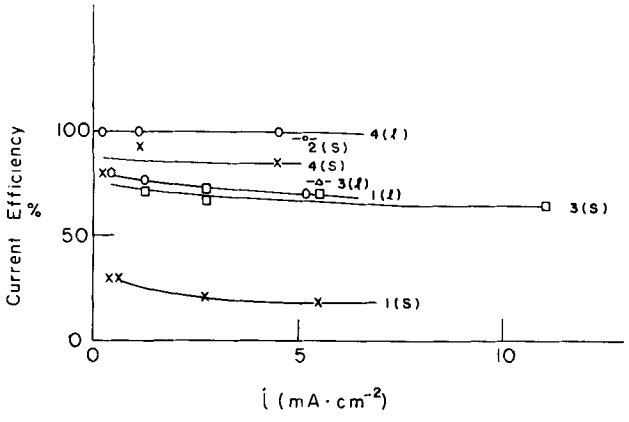

Fig. 2. Current efficiency as a function of current density; l, liquid electrode; s, solid electrode.

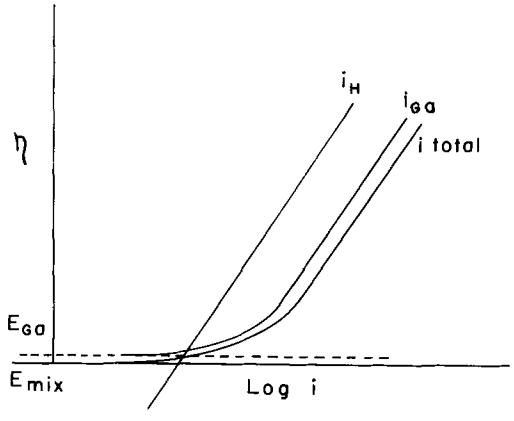

Fig. 3. Current efficiency corrections for gallium deposition (schematic). i_{total}, total current; i_H, hydrogen evolution current estimated from i_{total} and current efficiency; i_{Ga}, gallium deposition current $= i_{total} - i_H$; E_{mix}, mixed potential; E_{Ga}, equilibrium potential of Ga electrode, after correction of i_H.

Fusion and solidification of gallium.—Gallium has a tendency to supercool (11), and solidification occurred below 10°C, if the metal was not agitated. To ascertain whether the gallium is solid or liquid, a cathodic current was applied for a few seconds and the surface observed. For the liquid, the current causes slight deformation of the electrode due to electrocapillary effects.

Results

Current efficiency.—Current efficiencies (C.E.) are summarized in Fig. 2. C.E. decreases with increasing i, and is smaller on solid than on liquid electrodes. The apparently anomalous values from the system "1s" (Fig. 2) would cause, if corrected to the mean of the other C.E. values, a shift in the η-log i relation by about 0.3 log i units to increasing log i values (Fig. 3).[1]

Current efficiency corrections.—Overpotential was measured in the minutes-long polarizations used in the C.E. determinations. Values were in agreement (±10 mv) with those of the transient method for $[GaCl_3] > 0.1$ mole/l, and 30-50 mv higher at lower concentrations. The overpotentials from transient and steady-state methods gave linear Tafel lines.

[1] There is no critical current density below which no hydrogen ions discharge. Even at more anodic potential (downward in Fig. 3) than E_{mix}, there should be a finite amount of i_H, though it is negligible.

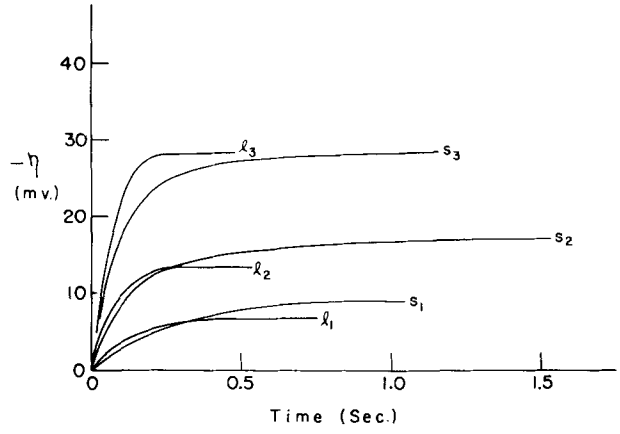

Fig. 4. Typical cathodic —t transients; l, liquid electrode; s, solid electrode.

The gallium deposition current, i_{Ga}, was obtained from

$$(i_{Ga})_\eta = (i_{total})_\eta - (i_H)_\eta \qquad [2]$$

For low overpotentials, i_H was calculated from the extrapolated Tafel line for the hydrogen evolution reaction.

The potential at the intersection of the linear η-log i_H line and the η-log i_{total} line, whose $i_{Ga} = 0$, corresponds to the reversible potential of the gallium electrode process and amounted expectedly to 2-10 mv more negative than the experimental corrosion potential.

Current efficiency corrections were usually less than 0.1 unit in the log i scale. Their reproducibility was ±3%.

Overpotential-time transient.—The rise-time of the η-t transient was 3-4 times longer on the solid than on the liquid electrodes at low current densities (Fig. 4).

The transients on the solid electrodes at low current densities were analyzed by the theory of surface diffusion of adions,[2] by a method already described (1, 2). The results on the equilibrium surface diffusion flux, $v_{ad,o}$, are shown in Fig. 5 as a function of current density. The equilibrium adion concentration was independent of the concentration of the solution or of the current density and the mean value was 5 (±2) x 10^{-11} mole cm^{-2}, which corresponds to 1-2% of the electrode surface coverage, assuming (8, 9) a roughness factor of 1.6.

Steady-state overpotential.—Clear cathodic Tafel relations were obtained on liquid electrodes (b = 130 mv). On solid electrodes, the lines were steeper, and the linearity less clear (Fig. 6 and 7, Table I). At low current densities, the rates of deposition at the same potential were much smaller on the solid than on the liquid electrodes.

[2] In the analysis of the $\eta - t$ transients on solid electrodes, the amount of electricity, Q_x, required to change the concentration of the intermediate state of the charge-transfer controlled mechanism, $HGaO_2^-$ (*cf.* Discussion part), from that at equilibrium to that at certain overpotential is neglected because: (i) The time at which the above-mentioned current appears on liquid electrode is much shorter than the time region concerned in the following analysis (by 10 times at low overpotentials). (ii) Q_x (~10^{-5} coulomb cm^{-2} at low cathodic overpotentials) (8) is much smaller than the variation in c_{ad} values, which is given by

$$(c_{ad} - c_{ad,o})/c_{ad,o} = (-i)/zFv_{ad,o} \text{ (cf. Eq. [18])}$$

and approximate value is $10c_{ad,o}$ at $i = 5 \times 10^{-4}$ amp cm^{-2}, or the numerical value is 10^{-4} coulomb cm^{-2}.

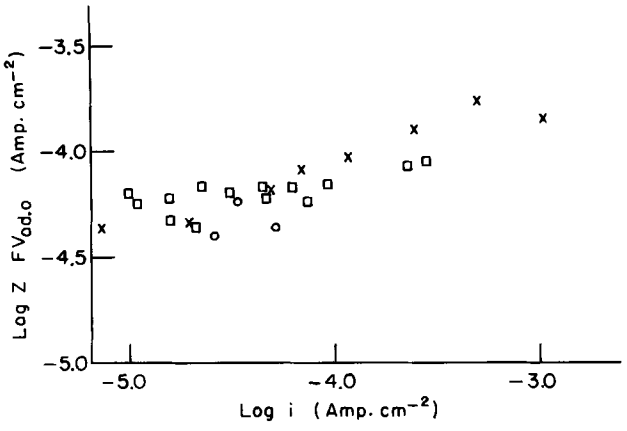

Fig. 5. $V_{ad,o}$ as a function of current density on solid electrode. □, X, ○ = different electrodes.

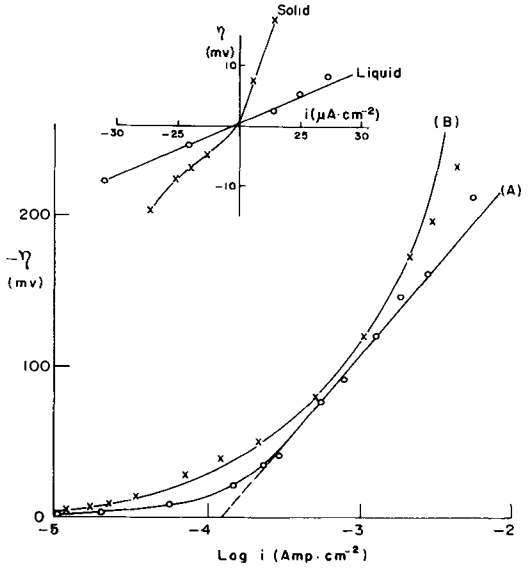

Fig. 6. Typical η vs. log *i* curves (cathodic). X, solid electrode, 28°C; ○, liquid electrode, 30°C; A, theoretical curve for charge transfer only; B, theoretical curve for Eq. [19].

Concentration dependence of exchange current density.—d log i_o/d log [$H_2GaO_3^-$] was about 0.7 ±0.2 (Fig. 8).

Discussion

Current efficiency corrections do not affect the values of log $i_{o,Ga}$ by more than about 0.1 unit. In agreement with the validity of i_{Ga} values is the fact that $i_{o,Ga}$ increases with increase of [$GaCl_3$]; $i_{o,H}$ would be expected to behave conversely (8).

Nonsteady State

Overpotential-time transient on solid electrodes.—In Fig. 5, the equilibrium surface diffusion flux, $v_{ad,o}$ is seen to be almost independent of the current density. [The slight increase indicated at high current density concerns a region for which $-\eta > RT/F$, and the surface diffusion equations from which $v_{ad,o}$ is calculated become inaccurate (1, 2).] Recently a model has been developed (12) in which the relation between $v_{ad,o}$ and the dependence of the density of active growth sites upon current density has been evaluated. The constancy of $v_{ad,o}$ recorded in Fig. 5 implies that the density of active growth sites does not increase significantly with current density on solid gallium. Since the experimental temperature

(B) [4] [5] and [6]	$-RT/(1+\beta)F$	$RT/(2-\beta)F$	3
(C) [4] [5] and [7]	$-RT/\beta F$	$RT/(2-\beta)F$	2
(D) [4] [5] and [8]	$-RT/\beta F$	RT/F	$1+\beta$

* Rate-determining step is underlined. β is the cathodic symmetry factor of the rate-determining elementary step with one-electron transfer (here it is assumed to be 0.5).

was close to the melting point, the metal would be in a well annealed state, *i.e.*, would have a relatively small number of surface dislocations, and hence a large portion of the dislocations are already "active" even at low current densities. [For $N_{active}/N_{total} = \exp(-k N_{total})$, where N is the number of surface dislocations and k a constant, k would be smaller on solid gallium than on Cu or Ag, because of the much lower surface tension values of Ga compared with these metals (12).]

Steady State

Mechanism of charge transfer process.—The clear Tafel lines observed on liquid electrodes may be interpreted only in terms of a charge-transfer controlled mechanism. The stable ionic species of trivalent gallium in an alkaline solution (13) is $H_2GaO_3^-$. The over-all deposition reaction will be

$$H_2GaO_3^- + H_2O + 3e_o^- = Ga + 4\,OH^- \quad [3]$$

The following steps may be considered

$$H_2GaO_3^- + e_o^- \rightarrow HGaO_2^- + OH^- \quad [4]$$

followed by

$$HGaO_2^- + e_o^- \rightarrow GaO^- + OH^- \quad [5]$$

and

$$GaO^- + H_2O + e_o^- \rightarrow Ga + 2\,OH^- \quad [6]$$

Or, since univalent gallium ion is unstable with respect to decomposition into trivalent gallium and metallic gallium (13)

$$3GaO^- + 2H_2O \rightarrow 2Ga + H_2GaO_3^- + 2\,OH^- \quad [7]$$

or

$$HGaO_2^- + GaO^- + H_2O \rightarrow Ga + H_2GaO_3^- + OH^- \quad [8]$$

Tafel slopes expected for various rate determining steps involving the above reactions are given in Table II.

According to the experimental results, $d\eta/d \log i_c = 130$ mv and $d\eta/d \log i_a = 45$-55 mv. (A) and (B) are not admissable; since the experimental conditions were such that there could not be anodic passivation during short time polarization, the observed anodic value is too largely different to be consistent with (A) (which requires 24 mv at 30°C assuming the cathodic symmetry factor, β, to be 0.5), (B) is not consistent with the cathodic value. Mechanism (D) is preferred over mechanism (C) because:

1. Reaction [7] in (C) is likely to involve reaction [8] in (D), and [8] is more probable than [7], since the concentration of the divalent state, $HGaO_2^-$, would be much higher than that of the univalent state, GaO^-.

2. A closer fit of $i_{o,c}$ and the corresponding i_o, $\eta \rightarrow 0$ is obtained if, in calculating the latter, the value of $\alpha_c + \alpha_a$ used is 1.5 [cf. (D) in Table II].

3. Better agreement between experimental and calculated overpotential was obtained in the non-linear Tafel region on the liquid electrode with $\alpha_c + \alpha_a = 1.5$ than if it is taken as 2.

Adding [5] and [8], the mechanism (D) can be rewritten as

$$H_2GaO_3^- + e_o^- \rightarrow HGaO_2^- + OH^- \text{ (slow)} \quad [4]$$

$$2HGaO_2^- + e_o^- + H_2O \rightleftharpoons Ga + H_2GaO_3^- + 2\,OH^- \text{ (fast)} \quad [9]$$

Thus, the cathodic partial current density is

$$i_c = -k_1 [H_2GaO_3^-] \exp[-\beta FV/RT] \quad [10]$$

and the anodic one

$$i_a = k_2 [HGaO_2^-]_V \exp[(1-\beta)FV/RT] \quad [11]$$

where V is the electrode potential measured from a suitable reference point. From [9]

$$[HGaO_2^-]_V = k_3 [H_2GaO_3^-]^{1/2} \exp(FV/2RT) \quad [12]$$

The final equation for i is ($\eta = V - V_R$)

$$i = i_o \left[\exp\left(\frac{\left(\frac{3}{2} - \beta\right) F\eta}{RT} \right) - \exp\left(-\frac{\beta F\eta}{RT} \right) \right] \quad [13]$$

The over-all reaction [3] is obtained from [4] and [9] . The reversible potential, V_R, can be obtained as follows. From [10], [11], and [12] at equilibrium

$$i_o = k_1 [H_2GaO_3^-] \exp\left(-\frac{\beta FV_R}{RT} \right)$$

$$= k_4 [H_2GaO_3^-]^{1/2} \exp\left(\frac{\left(\frac{3}{2} - \beta\right) FV_R}{RT} \right) \quad [14]$$

which gives

$$V_R = V_{R,o} + \frac{RT}{3F} \ln [H_2GaO_3^-] \quad [15]$$

in agreement with [3].

Rate of deposition on liquid gallium electrode.—Using $\beta = 0.5$, the η-log i relation can be calculated and may be compared with the experimental values. In the cathodic region [Fig. 6 line (A)] the agreement over the entire overpotential region is satisfactory. In the anodic region [Fig. 7 line (A)], the experi-

mental values are lower than those calculated at high current densities. This may be due to an increased concentration of the Ga^+ state at high anodic overpotentials, which would shift the mechanism from (D) to (C), whereupon α_a becomes 1.5 instead of 1.0, *i.e.*, the slope would tend to decrease from 60 to 40 mv.

Concentration dependence of exchange current density on liquid gallium electrode.—Substitution of [15] into [14] gives

$$\frac{d \ln i_o}{d \ln [H_2GaO_3^-]} = 1 - \frac{\beta}{3} = 0.83 \left(\beta = \frac{1}{2}\right) \quad [16]$$

Agreement with experimental value (0.7 ± 0.2, Fig. 8) is fair.

Overpotentials on solid gallium electrode.—The deviations between the cathodic Tafel lines on liquid and solid can be discussed in terms of the surface diffusion of adions.

The rate expression, when the changes in the adion coverage is taken into account for both cathodic and anodic partial currents, may be written as

$$i = i_o \left[\frac{c_{ad}}{c_{ad,o}} \exp\left(\frac{\alpha_a F \eta}{RT}\right) - \frac{G - c_{ad}}{G - c_{ad,o}} \exp\left(-\frac{\alpha_c F \eta}{Rt}\right)\right] \quad [17]$$

where G is the total number of metal atoms on the surface (mole cm^{-2}). At the steady state (1, 2)

$$\frac{c_{ad}}{c_{ad,o}} = 1 + \frac{(-i)}{zFv_{ad,o}} \quad [18]$$

[17] and [18] give

$$i = \frac{i_o \left[\exp\left(\frac{\alpha_a F \eta}{RT}\right) - \exp\left(-\frac{\alpha_c F \eta}{RT}\right)\right]}{1 + r \exp\left(\frac{\alpha_a F \eta}{RT}\right) + \theta' r \exp\left(-\frac{\alpha_c F \eta}{RT}\right)} \quad [19]$$

where

$$r = i_o / zFv_{ad.o} \quad [20]$$

and

$$\theta' = c_{ad,o}/(G - c_{ad.o}) \quad [21]$$

Approximate forms of [19] for various conditions of overpotentials can be obtained using the following numerical values (cathodic region).

$$i_o = 1.4 \times 10^{-4} \text{ amp cm}^{-2} \quad \text{(Fig. 6)}$$

$$zFv_{ad,o} = 5.5 \times 10^{-5} \text{ amp cm}^{-2} \quad \text{(Fig. 5)}$$

$$c_{ad,o} = 5 \times 10^{-11} \text{ mole cm}^{-2}$$

and

$$G = 4 \times 10^{-9} \text{ mole cm}^{-2} \text{ (roughness factor 1.6[9])}$$

thus

$$r = 2.5 \qquad \theta' = 0.013 \quad [22]$$

1. $-\eta << RT/F$ [19] and [20] give

$$\eta = \frac{RT}{(\alpha_c + \alpha_a)} \frac{i}{F} \left[\frac{1}{i_o} + \frac{1}{zFv_{ad,o}}\right] \quad [23]$$

using the above numerical values, and $(\alpha_c + \alpha_a) = 1.5$, the slope of the $\eta - i$ plot, $(d\eta/di)_{\eta \to o}$, is about 410 ohms cm^2, which is in fair agreement with the average experimental value, about 300 ohms cm^2.

2. $-\eta \simeq RT/F$

$$i = i_o \exp\left(-\frac{\alpha_c F \eta}{RT}\right) \Big/ \left[1 + r \exp\left(\frac{\alpha_c F \eta}{RT}\right)\right] \quad [24]$$

where $r \exp(\alpha_a F\eta/RT)$ is of the order of 0.1, *i.e.*, the relation between i and η is fairly close to that expected from the charge-transfer controlled mechanism.

3. $-\eta >> RT/F$

$$i = i_o \exp\left(-\frac{\alpha_c F \eta}{RT}\right) \Big/ \left[1 + \theta' r \exp\left(-\frac{\alpha_c F \eta}{RT}\right)\right] \quad [25]$$

This tends to yield a limiting current under the condition

$$1 << \theta' r \exp\left(-\frac{\alpha_c F \eta}{RT}\right) \quad [26]$$

which may be expected at $-\eta > 300$ mv according to [25], with the numerical value of the limiting current of [cf. (22)]

$$i_{lim} \simeq \frac{zFV_{ad,o}}{\theta'} \simeq 4 \times 10^{-3} \text{ amp cm}^{-2} \quad [27]$$

if there is no increase of $zFv_{ad,o}$ with i (but see Fig. 5 and 6).

For test of Eq. [19], i values are calculated at various values of η using the numerical values of [22]. The agreement is fairly satisfactory in the cathodic region [Fig. 6 line (B)].

In the anodic region, the value of $zFv_{ad,o}$ obtained from transients was less well reproduced, as it was not in good accord with that from cathodic experiments (10 times larger). The $\eta - i$ relation was calculated from [19] using this larger value and i_o of 8×10^{-5} amp cm^{-2} [Fig. 7, line (B)]. The experimental values deviate from the calculated line at high overpotentials, but the qualitative shape and the quantitative agreement at low overpotentials are acceptable. Thus, the concave shape of the η-log i curve on the solid gallium electrode is consistent with the development of a limiting current density due to surface diffusion control. The rate constant for this behavior is consistent with that obtained from the interpretation of the deviation from a charge-transfer controlled mechanism at very low current densities. The deviation of the experimental curve from that calculated at very high overpotentials is probably due to a small increase in the number of active growth sites, arising by the mechanism discussed (12).

Acknowledgments

The authors are indebted to the American Electroplaters Society for financial support and to the Supervising Committee of this Society's Project 16 for stimulating discussion. They wish to thank Mr. H. Kita for carrying out a number of confirmatory calculations with the material. One of them (M. E.) is grateful to Professor J. Horiuti for permission to take study leave to carry out this work.

Manuscript received April 25, 1961; revised manuscript received July 19, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

Unit Cell Volume Effects in Some Isomorphous Ferroelectric Systems

Thomas G. Dunne and Gerald Burns

Research Center, International Business Machines Corporation, Yorktown, New York

ABSTRACT

By examining published data, a linear relationship between unit cell volume and ferroelectric Curie point is found for a number of isomorphous systems. The meaning of this is discussed, and for the KH_2PO_4 system it is shown how one can extend Slater's theory qualitatively so that this relationship and the deuteration effect can be understood simultaneously. Several other systems of isomorphous compounds are discussed.

There are few adequate microscopic model theories of ferroelectrics. Often, new mechanisms are proposed when a new group of ferroelectric compounds is discovered. Phenomenological theories have met wider success.

In this paper a relationship between unit cell volume and Curie point is pointed out. This relationship seems to occur generally within isomorphous groups of ferroelectrics. It is not implied that volume itself is the important parameter that determines the ferroelectric behavior. For example, if electronic polarizability is the important parameter, a large electronic polarizability normally will mean larger ionic size, which means larger volume, or if hydrogen bond lengths are the important parameters, then again volume will be the convenient measurable parameter. It is hoped consideration of the relationships pointed out here will help make the transition from phenomenological to model theories and extend model theory. In the case of the KH_2PO_4(KDP) series of ferroelectrics, it is shown how one can extend Slater's model theory qualitatively so that alkali substitution effects and deuteration effects can be understood.

Perovskite System

Merz[1] originally pointed out that the decrease in the Curie temperature T_c of $BaTiO_3$ with increasing pressure is similar to the decrease in T_c as the unit cell volume decreases on substitution of Sr^{+2} in place of Ba^{+2}. Using recent data for T_c *vs.* composition in the (Ba, Sr) TiO_3 system (2) and elastic constants of $BaTiO_3$ (3), one obtains $\Delta T_c/\Delta V = +115°C/A^3$ for compression and $\Delta T_c/\Delta V = +70°C/A^3$ for Sr^{+2} substitution. The fact that these slopes should have similar values has been given some theoretical justification by Triebwasser (4). However, $PbTiO_3$ with a smaller unit cell and higher Curie point doesn't fit the relationship found for (Ba, Sr)TiO_3 (5). This may be due to the fact that

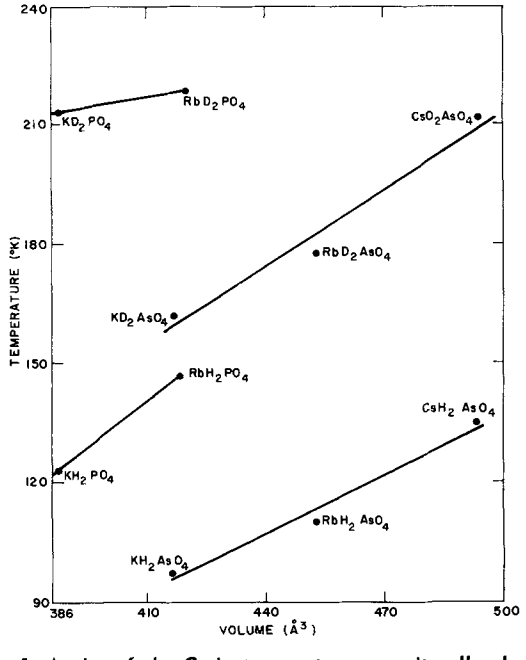

Fig. 1. A plot of the Curie temperature vs. unit cell volume for KDP-type compounds.

Pb is in a different group of the periodic table and tends to bond differently. In this paper hydrogen bonded systems are discussed.

KDP Systems

Using published data (6, 7) and lattice constants of RbH_2AsO_4 and CsH_2AsO_4 determined by Stemple (8), T_c *vs.* volume is plotted in Fig. 1. It is seen that both addition of a larger alkali ion and deuteration increases T_c.

One can connect these effects qualitatively by extending Slater's model (9). Slater derives the expression $\epsilon = k\ T_c \ln 2$ where ϵ is the energy difference between two configurations of the $(H_2PO_4)^-$ group, the lower energy configuration occurring when the protons associated with the PO_4^{-3} group are arranged so that the dipole moment μ of the $(H_2PO_4)^-$ group is parallel to the ferroelectric c axis. One can understand then the effects noted in Fig. 1 by the following reasoning:

1. O-O (the distance between the hydrogen bonded oxygen atoms) increases on substitution of a larger alkali ion. This is a reasonable assumption to make since all the macroscopic dimensions increase on substitution of a larger alkali ion.
2. O-H (the shortest hydrogen bond distance) decreases as O-O increases. This is what one finds in general for hydrogen bonding (10).
3. The decrease of the O-H distance will cause an increase in the induced dipole moment of the PO_4^{-3} group. This change in the dipole moment will further increase the energy difference between the two configurations.

Thus, as one increases the size of the alkali ion, O-O will increase causing O-H to decrease, causing the induced μ to increase, causing ϵ to increase. From Slater's theory T_c should then increase which is what occurs (see Fig. 1). This reasoning also explains the deuteration effect since, on deuteration, one generally observes that the O-O increases (11), which again would cause an increase in T_c, as observed.

Spontaneous polarization data, available for but a few KDP isomorphs, indicate that this quantity is fairly independent of unit cell volume.

Guanidine Aluminum Sulfate Series

The compounds of this isomorphous series are ferroelectric up to the temperature region in which decomposition takes place, so the volume dependence of the transition temperature cannot be investigated. However, the spontaneous polarization does show a consistent increase as the cell volume is increased by isomorphous substitution (12-15) as can be seen in Fig. 2.

The volume effect caused by compression has been obtained using published pressure and elastic constant data (16, 17). It is seen that in this case, spontaneous polarization increases with decreasing volume in contrast to the opposite effect in isomorphous substitution. However, one must be careful in comparing the two because the shape of the unit cell is changed in a different way by hydrostatic compression than by isomorphous substitution. This is well illustrated by comparing the ratio of lattice

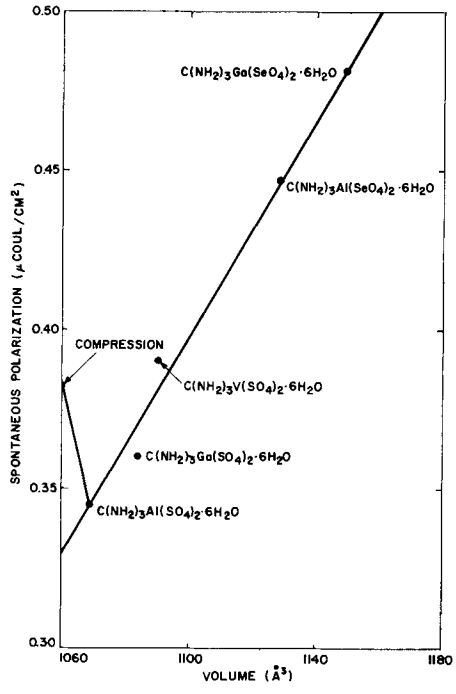

Fig. 2. A plot of the room temperature spontaneous polarization *vs.* unit cell volume for GASH-type compounds. Results of a compression experiment are also included.

constant increments, $\Delta c/\Delta a$ for the two processes. For compression $\Delta c/\Delta a \cong 4$ for GAlSH, GAlSeH, G GaSH, and G Ga SeH. However, in the case of isomorphous substitution, $\Delta c/\Delta a = 4.52$, 2.61, 0.44, and 0.36 for the substitution of Ga^{+3} for Al^{+3} in GAlSH, Ga^{+3} for Al^{+3} in GAlSeH, SeO_4^{-2} for SO_4^{-2} in GAlSH, and SeO_4^{-2} for SO_4^{-2} in G GaSH, respectively. Thus, compression and substitution change the lattice constants in a different way, and it is not surprising that the two processes have different effects on the spontaneous polarization.

However, in the tryglycine sulfate and isomorphous compounds, rough unit cell data (18, 19) indicate that the pressure effect (20) is in the same direction as the isomorphous substitution.

Alums

Ferroelectric behavior in a large number of the cubic alums has been observed (21, 22). In the series (listed in order of increasing unit cell volume) $NH_4M(SO_4)_2 \cdot 12H_2O$ where M= Al, Ga (23), Cr, Fe, V, and In the transition temperature increases approximately linearly with volume. Also for the three compounds with the larger volumes, Fe, V, and In, the transition is to a ferroelectric phase. While for the compounds with the smaller volume, Al, Ga, and Cr, the transition is to another paraelectric phase. Yet the transition temperature of both types fit on the same T_c *vs.* volume line. Also, the spontaneous polarization P is approximately the same ($\sim$ 0.1 μcoul./cm^2) for the two compounds of largest volume (M = In and V). For M = Fe, the compound with the lowest ferroelectric transition temperature, P is considerably smaller ($\sim$ 0.03 μcoul./cm^2).

For the $CH_3NH_3M(SO_4)_2 \cdot 12\ H_2O$ alums (where M stands for the same ions as in the previous case) T_c and P have values of approximately 170°K and

0.1 μcoul./cm^2, respectively, and are roughly independent of volume.

Thus, one often observes a relationship between the ferroelectric properties and the unit cell volume. This relationship can be extended sometimes to include compression experiments and, in the case of KDP systems, it is shown how one can qualitatively extend the present model theory to account for the observed effects.

Ionic Transport Entropy in Nonisothermal Molten Silver Chloride Cells

S. Senderoff and R. I. Bretz

Parma Research Laboratory, Union Carbide Corporation, Parma, Ohio

ABSTRACT

The determination of the emf of the nonisothermal cells Ag/AgCl(1)/Ag and Cl_2/AgCl(1)/Cl_2 is used to estimate the magnitude of the transport entropy terms in the general equation for thermogalvanic potentials. The emf's were determined over the temperature range 500°-900°C with temperature differentials ranging from 40° to 400°C. The limits of accuracy of the measurement are established by reference to accurately known reversible thermodynamic quantities; the irreversible quantities are demonstrated to be small, but not negligible as they were reported to be in solid electrolyte cells; and the Seebeck coefficient's independence of the transport numbers in the system was experimentally confirmed.

When a temperature difference exists between the electrodes of a chemically symmetrical cell (*i.e.*, electrode | electrolyte | electrode in which the two electrodes are identical), an emf is developed which has frequently been called a thermogalvanic potential, or more briefly, a thermopotential. The nonisothermal cell which produces this emf is usually called a thermocell, and its emf is a special case of the very general thermoelectric effect which is associated with the contacts between dissimilar electrical conductors in a thermal gradient. By analogy with the metallic thermocouple, the electrodes represent one conductor, the electrolyte the second conductor, and the two electrode-electrolyte interfaces the hot and cold junctions. Figure 1 shows this analogy pictorially, and the theoretical equivalence of these systems has been discussed by Wagner (1), Lange (2), and others.

When considering the details of the general theory, however, an important difference between the thermocell and the metallic thermocouple emerges. In the latter only electrons flow in the circuit with no net transfer of material, while in the former, matter is transferred from one electrode to the other as a result of the electrochemical reactions at the junctions and ionic transport in the electrolyte. Consequently, the detailed theoretical treatment of these systems includes chemical entropies of classical thermodynamics and entropies of transport of ions.

Eastman (3) and Wagner (1) have presented a detailed theory of thermocells, and in recent years the methods of the thermodynamics of irreversible processes have been applied with great effectiveness to this subject by Holtan (4), Mazur (5), de Groot (6), and others. Excellent reviews of the subject

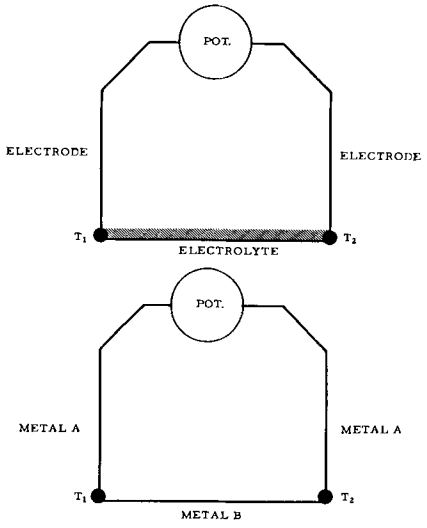

Fig. 1. Pictorial representation of thermocell as thermocouple

have been published by de Bethune (7) and by Agar (8).

Theory

The derivation of the general equations for thermocells has been presented frequently and adequately elsewhere (5-8) and will not be repeated here. Following Holtan (4), one may start with the expression for the emf of the thermocell,

$$\mathbf{F}(dE/dT) = -\sum_{k=1}^{n}(t_k/z_k)\overline{\overline{S}}_k - \overline{\overline{S}}_{el} - \Delta S + \sum_{k=1}^{n}(t_k/z_k)\overline{S}_k + \overline{S}_{el} \quad [1]$$

where $\mathbf{F}$ is the Faraday constant, dE/dT the Seebeck coefficient or thermopotential per degree of temperature difference between the electrodes (v/degree), t_k the transport number of substance, k, z_k the valence of substance, k (sign included), $\overline{\overline{S}}_k$[1] the transported entropy of k, $\overline{S}_k$ the partial molar entropy of k, $\overline{\overline{S}}_{el}$ the transported entropy of an electron in the electrode, $\overline{S}_{el}$ the partial molar entropy of an electron in the electrode, and ΔS the entropy change per equivalent associated with the electrochemical reaction at the electrodes.

It should be noted that all terms of the general equation associated with concentration gradients in the cell have been omitted since concentration gradients cannot exist when the electrolyte is a pure binary salt, molten or solid.

Again following Holtan, Eq. [1] may be separated into a part containing entropies of classical thermodynamics (or thermostatics) and a part containing the transported entropies. Properties of single ions appear only in the latter part. Thus,

$$\mathbf{F}(dE/dT) = \mathbf{F}(dE/dT)_c - \sum_{k=1}^{n}(t_k/z_k)\overline{\overline{S}}_k - \overline{\overline{S}}_{el} \quad [2]$$

where

$$\mathbf{F}(dE/dT)_c = -\Delta S + \sum_{k=1}^{n}(t_k/z_k)\overline{S}_k + \overline{S}_{el} \quad [3]$$

[1] The symbol and definitions used are those of Agar (8). $\bar{\bar{S}}_i \equiv S_i^*$, the latter being the symbol used by Holtan and others of the de Groot school. They define this as "entropy of transfer of i." S_i^* as used by Agar has another meaning. $\bar{\bar{S}}_i = Q_i/T^* + \bar{S}_i$ where Q_i^* is the heat of transfer of i.

It will be seen below that this separation was unfortunate when applied to the study of single binary electrolytes because it obscured the fact that with such an electrolyte the Seebeck coefficient is independent of the transport number. Nevertheless, in studying a large number of cells with solid electrolytes, Holtan made the discovery that in all cases $dE/dT = (dE/dT)_c$ within experimental error; or stated differently, there was no experimental evidence that the sum of the terms involving the transported entropy and single ion quantities was anything but negligible.

Holtan also investigated some solutions and molten salts and found in a number of cases that $dE/dT \neq (dE/dT)_c$, but this did not unambiguously establish that the sum of the transported entropy terms was not negligible since he did not know transport numbers in some cases and could not identify the significant species, *i.e.*, hydrate, complex ion, etc., in any case, as pointed out by Mazur (5) and by Holtan himself. As will be seen below, molten silver chloride is a particularly suitable substance to study to remove this ambiguity.

Silver chloride is also a particularly suitable substance for a measurement which establishes the limits of accuracy of the measured Seebeck coefficient with great certainty and, thus, the magnitude of the inequality, $dE/dT \neq (dE/dT)_c$, necessary to be considered as significant. Consider the thermocells:

$$\mathrm{M}|\mathrm{MX}|\mathrm{M} \qquad \text{I}$$

$$\text{graphite, } \mathrm{X_2}|\mathrm{MX}|\mathrm{X_2}\text{, graphite} \qquad \text{II}$$

and the isothermal cell:

$$\mathrm{M}|\mathrm{MX}|\mathrm{X_2}\text{, graphite} \qquad \text{III}$$

It can be shown that (5)

$$(dE/dT)_{II} - (dE/dT)_{I} = (dE/dT)_{III} - \epsilon_{M,\ graphite} \quad [4]$$

where $\epsilon_{M,\ graphite}$ is the Seebeck coefficient of the M, graphite thermocouple.

Since $(dE/dT)_{III}$ can be measured with considerable accuracy either directly by an emf determination or indirectly by a determination of the entropy of formation of MX, and since $\epsilon_{M,\ graphite}$ is usually less than 1% of $(dE/dT)_{III}$ when MX is a molten salt, a means is provided for checking the measured Seebeck coefficient of the thermocells without complication by the transport entropy

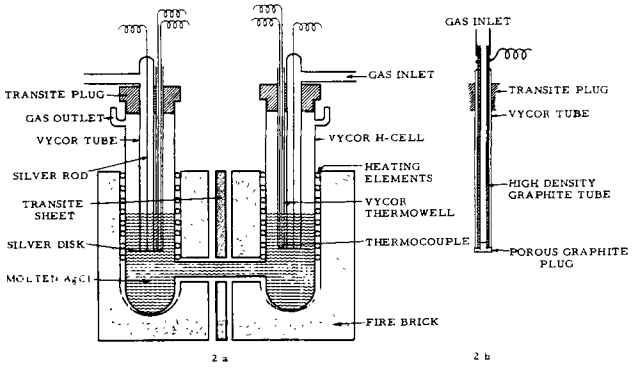

Fig. 2. Apparatus for determination of Seebeck coefficient: a, arrangement with silver electrodes for measurements on cell I; b, Chlorine electrode assembly for measurements on cell II.

and single ion quantities. In the case of silver chloride, cell III has been measured by a number of workers with good agreement, and cells I and II, involving highly reversible electrodes, are amenable to reasonably accurate measurements.

Experimental

The experimental arrangement of measuring the Seebeck coefficients of cells I and II is shown in Fig. 2. In Fig. 2a, the cell is shown with silver electrodes for the measurements on cell I. Measurements on cell II are made by removing the silver electrode assembly from each leg and replacing it with the chlorine electrode assembly shown in Fig. 2b. Two semicylindrical heating elements (Hevi Duty No. 7H-KS) are placed each around a leg of a Vycor H-cell and the assembly is insulated with a few layers of suitably shaped fire brick.

The H-cell is made by joining two Vycor test tubes (12 in. in length, 25 mm in diameter) with a 3 in. length of 13 mm Vycor tubing, the join being about ½ in. above the bottom of the test tubes. Two small tubes were attached near the top of the test tubes to serve as gas outlets.

When the cell is in place a piece of transite is interposed between the legs of the H-cell to maximize the thermal insulation of one leg from the other. The temperature of each of the legs is individually controlled with a controlling pyrometer fed by a Chromel-Alumel thermocouple in the electrolyte in each leg. The temperature of each leg is measured with the same two thermocouples by putting their output across an L&N thermocouple potentiometer (Catalog No. 8657-C).

Electrodes for the measurement of cell I are made by welding a silver disk, ⅝ in. diameter and 0.01 in. thick, to a ⅛ in. silver rod so that the disk is in a horizontal position in the melt. The rod is sheathed with a 9 mm Vycor tube which extends down to the disk. A slow stream of purified argon passing through the Vycor sheath keeps the electrolyte out of contact with the rod so that the emf is characteristic of the temperature of the horizontal disk. Since it is rather difficult to maintain a large isothermal region vertically in nonisothermal cells such as these, but much simpler to maintain a thin isothermal wafer, placement of a thermocouple in a Vycor thermowell as nearly as possible (within 2 mm) in contact with the horizontal disk was sufficient to give satisfactory temperature measurements.

Electrodes for the measurement of cell II were made by sealing a plug of porous graphite (National Carbon grade No. 60) 6 mm in diameter and ¼ in. thick to the end of a high density graphite tube, and purifying the electrode by heating to 2400°C, holding at temperature for 1 hr, and cooling, all in a chlorine atmosphere. The electrode was covered with a tightly fitting Vycor sheath with only the flat surface of the porous plug at the bottom and a few inches at the top to make electrical contact exposed. A seal of carbonaceous cement (National Carbon grade C-9) at the bottom effectively kept the electrolyte out of contact with the tube except at the face of the porous plug. Chlorine gas was passed through a drying tower, down the tube and out through the

submerged porous plug. The thermocouple in its Vycor sheath was within 2 mm of the plug.

The cell was charged by adding enough reagent grade silver chloride to both legs to give a depth of about 2 in. when molten. The liquid was passed back and forth through the bridge to eliminate entrapped gas bubbles, by applying slight gas pressure to one of the outlets at the top of the H-cell.

Well-fitting transite plugs with holes to accommodate the electrode sheath and thermowell were placed on top of the two legs of the H-cell, gas lines were connected to the electrode (cell II) or a sidearm on the sheath of the electrode (cell I), and electrical leads were drawn from the electrodes to a Rubicon potentiometer (Catalog No. 2780). Thermocouples were inserted in the thermowells and con-

nected to the two controlling pyrometers, which were set at the desired temperature for each leg. When the temperatures became steady, the emf of the cell and of each of the thermocouples was measured at the same time, and the controllers reset for other temperatures. These measurements were made at temperatures between 500° and 900°C and temperature differentials ranging from 40° to 400°C. The temperatures of both cold and hot legs were varied widely within this range.

Results

The results of the measurements of the emf of cell I are shown in Fig. 3 and of cell II in Fig. 4. The emf is plotted against the temperature difference between the electrodes for various cold leg temperatures. A least squares straight line through the points in each yields a value of the Seebeck coefficient for cell I (Ag|AgCl|Ag) of −0.375 with a standard deviation of ±0.01 mv/C° and a value for cell II (graphite, Cl_2|AgCl|Cl_2, graphite) of −0.664 with a standard deviation of ±0.02 mv/C°. The negative sign indicates that the hot electrode is the negative pole of the cell. It will be noted that there is no significant variation of the Seebeck coefficient with either the mean temperature or the temperature difference in the range studied.

The accuracy of the Seebeck coefficients can now be estimated by application of Eq. [4]. In Table I are shown the values from various sources for the Seebeck coefficient of the two thermocells, and for the temperature coefficient of the emf of the isothermal cell, Ag|AgCl|Cl_2, graphite. By substituting, in turn, the three values of $(dE/dT)_I$ and the value of $(dE/dT)_{II}$ in Eq. [4], the calculated values of $(dE/dT)_{III}$ are 0.289, 0.264, and 0.244 mv/C°. These may be compared with the measured values of 0.26 and 0.289. Although there is reason to believe that the value of 0.42 for $(dE/dT)_I$ and that of 0.23 for $(dE/dT)_{III}$ are the least reliable of those cited and one would be justified in ignoring them, if no values are rejected and the mean of the three $(dE/dT)_I$ values, 0.398, is used in Eq. [4], the $(dE/dT)_{III}$ thus calculated, 0.266, agrees with the mean of the four values of $(dE/dT)_{III}$, 0.268. It has, thus, been demonstrated that the values of the Seebeck coefficients determined from the data in Fig. 3 and 4 are probably not in error by more than 0.02 to 0.03 mv/C°, equivalent to approximately 0.5 entropy unit.

Table II. Molar entropies at 1000°K (cal/ deg)

Ag	18.00
Cl_2	63.74
AgCl	43.30

These values may now be used to estimate the magnitude of the terms in Eq. [1] which contain transport entropy and single ion quantities. If one defines[2] $\tau \equiv \sum_{k=1}^{n} (t_k/z_k)\overline{\overline{S}}_k + \overline{\overline{S}}_{el}$, Eq. [2] becomes for a cell with a molten silver chloride electrolyte:

$$\mathbf{F}(dE/dT) = -\tau - \Delta S + t_+\overline{S}_{Ag^+} - (1 - t_+)\overline{S}_{Cl^-} + \overline{S}_{el} \quad [5]$$

since in a binary electrolyte $(t_-) + (t_+) = 1$.

The electrode reaction of cell I, $Ag \rightarrow Ag^+ + e$, involves an entropy change,

$$\Delta S = S_{Ag^+} - S_{Ag} + S_{el} \quad [6]$$

Substituting Eq. [6] into [5] gives:

$$\mathbf{F}(dE/dT)_I = -(t_-)S_{AgCl} + S_{Ag0} - \tau \quad [7]$$

and rearranging yields,

$$\tau = -\mathbf{F}(dE/dT)_I + S_{Ag0} - (t_-)S_{AgCl} \quad [8]$$

Similarly, the entropy change for the electrode reaction of cell II:

$$Cl^- \rightarrow \tfrac{1}{2}\, Cl_2 + e$$

$$\Delta S = \tfrac{1}{2}\, S_{Cl_2} + S_{el} - S_{Cl^-} \quad [9]$$

is substituted into Eq. [5] to obtain on rearrangement:

$$\tau = -\mathbf{F}(dE/dT)_{II} - \tfrac{1}{2}\, S_{Cl_2} + (t_+)S_{AgCl} \quad [10]$$

Table II gives the values of the molar entropies at 1000°K (14) required in Eq. [8] and [10]. Substituting these values, together with the Seebeck coefficients from Fig. 3 and 4, into Eq. [8] and [10] yields, respectively,

$$\tau = 23.07 \times 0.375 + 18.0 - 43.3\,(t_-)$$

or

$$\tau = 26.7 - 43.3\,(t_-) \quad [11]$$

and

$$\tau = 23.07 \times 0.664 - 31.87 + 43.3\,(t_+)$$

or

$$\tau = -16.6 + 43.3\,(t_+) \quad [12]$$

A plot of Eq. [12] is shown in Fig. 5.

[2] τ is not exactly the same for cells I and II, since $\overline{\overline{S}}_{el}$ refers to the electron in silver for cell I and in graphite for cell II. $\tau_{II} - \tau_I = \epsilon_{Ag,\,graphite}$, and since τ is the same order of magnitude as the Seebeck coefficients of the thermocells (as will be seen below) ϵ is less than 1% of this value and will be ignored.

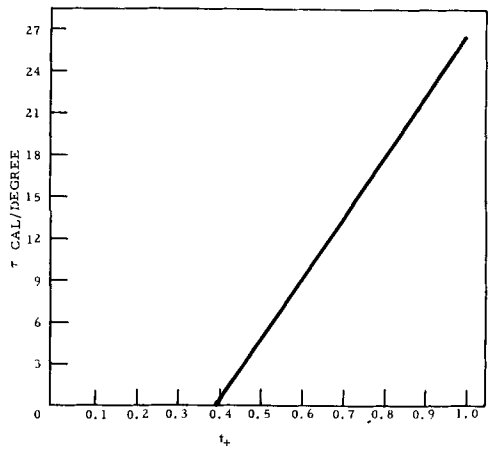

Fig. 5. τ as a function of transport number

Discussion

It is immediately obvious that τ, the sum of terms involving the transported entropies and single ion quantities, must be different from zero. For $\tau = 0$, the chloride ion must carry most of the current (*i.e.*, $t_+ = 0.384$). However, in the solid state, the silver ion is the only carrier ($t_+ = 1$), and measurements of the transference number in molten AgCl indicate that at 850°C t_+ is 0.83 (15), corresponding to $\tau = 19.4$ cal/deg. Even if t_+ were as low as predicted by the radius ratio calculation (16), *i.e.*, 0.59, τ would still be 8.9 cal/deg, and there is reason to believe that the radius ratio calculation is not applicable here.

Having established in the case of molten silver chloride that the transported entropy and single ion terms are not negligible, there remains only to demonstrate that there is little or no ambiguity of the components as in the case of other liquids.

Since in a pure molten salt there is no solvation or reaction with other components, one need only consider self-complexing as represented by $[Ag_2Cl]^+$, $[AgCl_2]^-$, etc. It is unlikely that any appreciable concentration of such clusters exists in molten AgCl at temperatures up to 900°C because silver ion, when it does form complexes, almost always has a coordination number of two and forms linear complexes based on the sp hybrid orbital, a notably weak bonding type. A number of investigations involving thermodynamic measurements such as emf (11, 17, 18) of mixtures of AgCl with other alkali halides show that in all cases the solutions are ideal or very nearly so. The largest reported departures are those in LiCl-AgCl mixtures in which the activity coefficient at 0.585 mole fraction AgCl is 1.10 and at 0.0286 mole fraction AgCl the activity coefficient is 2.23. These very small deviations from ideality with such a large disparity in cation sizes would preclude appreciable self-complexing in molten silver chloride. The high conductivity of molten silver chloride compared with other molten salts (4.5 compared with 2.6 ohm^{-1} cm^{-1} for KCl at 1000°K) also indicates little probability of clustering into large ions with consequent reduction in the number and mobility of carriers.

In view of the special character and well-known properties of silver chloride one can, with confidence, conclude that the sum of terms involving the transported entropies and single ion quantities is not only of the same order as, but larger than $(dE/dT)_c$, the sum of terms involving only classical thermodynamic entropies. Using the value of $t_+ = 0.83$, for which $\tau = 19.4$ cal/deg, $(dE/dT)_c$ for cells I and II are, respectively, 10.7 and 4.1 cal/deg.

Although the quantities τ and $(dE/dT)_c$ in which Holtan was interested depend on the transport number, the Seebeck coefficient of the thermocell is independent of transport number when the electrolyte is a single binary salt, as shown by Pitzer's (19) equation:

$$\mathbf{F}(dE/dT)_{\mathrm{I}} = S_{\mathrm{Ag}} - \overline{\overline{S}}_{\mathrm{Ag^+}} - \overline{\overline{S}}_{\mathrm{el}} \qquad [13]$$

If one separates some of the $\overline{\overline{S}}_k$ terms of Eq. [7] into their components, $\overline{S}_k + Q^*_k/T$, and writes it in the form:

$$\mathbf{F}(dE/dT)_{\mathrm{I}} = -(t_-)S_{\mathrm{AgCl}} + S_{\mathrm{Ag}} - \overline{\overline{S}}_{\mathrm{Ag^+}} + (t_-)(\overline{S}_{\mathrm{Ag^+}} + \overline{S}_{\mathrm{Cl^-}}) + (t_-)\frac{Q^*_{\mathrm{Ag^+}} + Q^*_{\mathrm{Cl^-}}}{T} - \overline{\overline{S}}_{\mathrm{el}} \qquad [14]$$

one notes that since $\overline{S}_{\mathrm{Ag^+}} + \overline{S}_{\mathrm{Cl^-}} = S_{\mathrm{AgCl}}$ Eq. [14] reduces to Eq. [13] if $\dfrac{Q^*_{\mathrm{Ag^+}} + Q^*_{\mathrm{Cl^-}}}{T} = \dfrac{Q^*_{\mathrm{AgCl}}}{T} = 0$. Pitzer asserts that $(Q^*_{\mathrm{Ag^+}} + Q^*_{\mathrm{Cl^-}})$ is, indeed, zero, since the process to which it refers is the bulk displacement of the liquid.

An equation similar to Eq. [13] may be written for cell II, *viz.*

$$\mathbf{F}(dE/dT)_{\mathrm{II}} = -\tfrac{1}{2}\,S_{\mathrm{Cl_2}} + \overline{\overline{S}}_{\mathrm{Cl^-}} - \overline{\overline{S}}_{\mathrm{el}} \qquad [15]$$

With the values of Table II in Eq. [13] and [15] and ignoring[3] (as previously) $\overline{\overline{S}}_{\mathrm{el}}$, one directly obtains the values of the transported entropies of the ions at 1000°K, $\overline{\overline{S}}_{\mathrm{Ag^+}} = 26.7$ eu and $\overline{\overline{S}}_{\mathrm{Cl^-}} = 16.6$ eu, and their sum, 43.3 eu, is seen to be identical with the absolute entropy of AgCl, 43.3 eu, thus confirming that within experimental error $(Q^*_{\mathrm{Ag^+}} + Q^*_{\mathrm{Cl^-}}) = 0$. It is interesting to note that previous workers (4, 20) have assumed transport numbers of unity when dealing with single binary electrolytes. This assumption is not necessary since Eq. [13] and [15] are independent of transport number. The terms in the general equation containing transport numbers cancel out without assumptions regarding transport mechanism.

If one takes an approximate value of the partial molar entropy of a single ion obtained from (19) $\overline{S}_A = 1/2(S_{AB} + 3/2\,R \ln M_A/M_B)$, where M is the atomic weight, one calculates the following values of the partial molar entropies and entropies of transfer for Ag^+ and Cl^- in AgCl at 1000°K.

Cl^-	Ag^+	
20.0	23.3	$\overline{S}$ (eu)
−3.4	3.4	Q^*/T (eu)

Since the entropy of transfer is small compared to the partial molar entropy of the ion, $(dE/dT)_{\mathrm{II}}$ should not differ very much when the electrolyte of the thermocell is any chloride whose absolute entropy is not very different from that of AgCl. CuCl is one such salt, its absolute entropy at 1000°K differing from that of AgCl by only 1 eu. In a recent study

[3] $\overline{\overline{S}}_{\mathrm{el}}$ in copper has been estimated to be approximately 0.1 eu at 800°K (20) and in silver about 0.03 eu at 400°K (21).

of molten cuprous chloride thermocells (20), cell II could not be measured because of the oxidation of CuCl by Cl_2 at the temperature of interest. However, $(dE/dT)_{II}$ was calculated from measurements of $(dE/dT)_{I}$, and extrapolated thermal data for the isothermal cell III. The agreement between the values of the Seebeck coefficient for cell II in the CuCl (calculated) and AgCl (measured) system, 0.65 mv/°C and 0.664 mv/°C, respectively, is remarkable.

Another interesting comparison can be made between the entropy of transfer, 3.4 eu, and the entropy of activation for conduction in molten AgCl. A small extrapolation of the conductivity measurements of Spooner and Wetmore (22) gives an entropy of activation at 1000°K of 1.3 eu. Considering the many approximations, this can be considered confirmation of the suggestion of Pitzer that the entropy of transfer should be of the order of the entropy of activation for conduction.

Technical Notes

The Electrodeposition of Iridium

E. L. MacNamara

Research and Development Group, United States Army Ordnance Arsenal, Frankford, Philadelphia, Pennsylvania

Interest in the development of protective coatings which are stable at high temperature has focused attention on the platinum group metals. Iridium is of particular interest because it is a very hard, dense metal having a high melting point (2454°C) and excellent resistance to high-temperature oxidation.

Examination of the literature revealed that iridium had not been of particular interest to the electrochemist. A few electrochemical constants were published before 1935 (1-8). Several patents (9-13) covering deposition methods for platinum metals included iridium in the claims. Through the early fifties theoretical studies pertinent to iridium deposition began to appear together with the reported attempts at deposition (19). Withers and Ritt (20) were able to deposit a uniform, adherent coating of iridium from a fused cyanide bath. Further studies on suitable electrolytes (21-22) especially those for depositing protective coatings of iridium on molybdenum were reported (23-24). A satisfactory method for the deposition of iridium from aqueous solution had not been developed.

Experimental

An aqueous solution of chloriridic acid[1] was chosen for study in our work. A compound contain-

[1] Available from J. H. Bishop Co., Platinum Works, Malvern, Pa.

ing 48% iridium was used. Present as impurities were 0.3% platinum and 0.15% each of palladium and rhodium. Readily soluble in water, chloroiridic acid ionizes as $H^+ + (IrCl_6)^=$, the resultant solutions being very acid.

Initial experiments were conducted in 50 ml volumes using copper wire cathodes, 0.040 in. in diameter and anodes of perforated platinum sheet, 1 × 3/16 in. The cathode area used for the electrolysis was approximately twice the area of the platinum anode. The anode was not soluble.

In the preliminary studies, the concentration of iridium in the electrolyte ranged from 1-5 g/l, and the solutions were at room temperature. Although there was some evidence of reaction at the electrodes there were no metallic deposits. The iridium concentration was increased to 120 g/l. Dark films were obtained over a current density range of 0.02-2.2 amp/dm², from room temperature to 50°C. When the temperature was increased to 90°C, a black metallic deposit was obtained at a current density of 4.4 amp/dm². Rinsing of the electrodes had diluted the bath at this point enough to decrease the metal concentration to 90 g/l. By increasing the current density to 6.6 amp/dm², a silvery-white deposit was produced. Bright, adherent, metallic deposits were identified spectrographically as iridium containing trace amounts of platinum, rhodium and palladium.

During the course of the work, deposits were obtained throughout a concentration range of 1-120g of metal per liter, within the range of current density of 2.2-10.8 amp/dm². However, as is shown in Table I, the deposition is temperature dependent. At a current density of 3.3 amp/dm² only the solution containing 10g of metal per liter produced a deposit at room temperature. Using the same current density, solutions containing approximately 40 g/l or more required minimum temperatures of 40°C while the solution containing 5 g/l did not produce a coating below 50°C. The lowest concentration (1.4 g/l) required a temperature of 70°C before deposition occurred.

Depending on the temperature, current density showed a marked effect on the appearance of the deposits produced from a bath of a metal content of 10 g/l. At room temperature and current density of 2.2 amp/dm², the cathode area was not completely covered; at 11 amp/dm², the coating was bright but nonuniform. The best appearing coating at room temperature was produced at 6.6 amp/dm².

Table I. Temperature concentration dependence
current density, 3.3 amp/dm²

Concentration, g/l	Temperature, °C						
	30	40	50	60	70	80	90
1.4	-	-	-	-	*	*	*
5.0	-	-	*	*	*	*	*
10.0	*	*	*	*	*	*	*
44.0	-	*	*	*	*	*	*
73.0	-	*	*	*	*	*	*

* Deposition occurred.
\- Deposition did not occur.

Table II. Cathode efficiency, %

Current density, amp/dm²	20°C	60°C
2.2	3	14
6.6	2	6
8.8	1	2

At 60°C, a current density of 2.2 amp/dm² produced a coating of slight nonuniformity while satisfactory coatings were produced at 6.6 amp/dm² and above. At 90°C no difference could be detected in the coatings produced at various current densities. The optimum conditions based on the data obtained from the various experimental baths appeared to be a metal content of the bath of 10 g/l, bath temperature, 60°C, and current density 6.6 amp/dm². The *p*H of the solution was approximately 2. These conditions did not produce the highest cathode efficiency, however. At the stated temperature, but at lower current density, 2.2 amp/dm², the cathode efficiency is 14% (see Table II). It decreased to 2% when the current density was increased to 8.8 amp/dm². It was consistently lower at lower temperature.

Deposits were obtained from sodium and potassium chloroiridates and bromoiridates as well as from chloriridic acid, but could not be obtained from the trichloride and tetrachloride or the tri- and tetrabromides of iridium.[2] The platinum-anode-copper cathode system was used predominantly in the experimental work. However, other materials which served suitably as cathodes were nickel, low carbon steel flash coated with electroless nickel, and polished molybdenum which was first etched in a solution of potassium ferricyanide and potassium hydroxide. There were no deleterious effects when carbon anodes were used.

Iridium, in either +3 or +4 valence state, forms many stable complex ions in solution. The tetravalent iridium complexes are extremely stable. The electrolytes from which iridium was deposited experimentally were aqueous solutions of complexes containing tetravalent iridium. These complexes, similar to those of other platinum metals, are of the inner orbital type, having octahedral configuration, with iridium in the ion having a net negative charge. Inner orbital complexes of most other metals possess such a high energy of coordination that the metal complex is more difficult to discharge than the hydrogen ion in aqueous solution. As has been indicated by Lyons (24), the platinum group metals generally do not follow this, and some of the platinum metals have been deposited with low cathode efficiency from complexes of this type.

The results so far support the premise that iridium (IV) complexes are necessary for successful deposition from aqueous solution. Further studies, using other iridium complexes, are being carried out, to determine the effect of the net charge of the iridium complex on deposition.

Junction Delineation in Silicon

Harry Robbins[1]

Hughes Semiconductors, Newport Beach, California

Junction delineation techniques are based on the fact that a surface chemical reaction can be influenced by the nature of the doping in the bulk of the semiconductor. In the presence of a p-n junction, differences in the rate of the reaction on the opposite conductivity types of the semiconductor may manifest themselves visually as a stain or deposit of metal that extends on one conductivity type up to the position of the junction. However, the reactions involved are often erratic and nonreproducible. It is often found that the reaction is difficult to induce. The reaction may also proceed preferentially on either of the conductivity types, thus making uncertain the identification of the conductivity type even in instances where the junction is sharply delineated. Situations are also encountered where the reaction takes place promiscuously over the entire surface and gives no indication of the location of the junction.

It has been found that one can achieve better control over the reaction in the presence of strong illumination. Under these conditions, Iles and Coppen (1) have postulated that an electrolytic cell is set up, powered by the conversion of the incident light into a photovoltage of such polarity that the n-side of the junction is the cathode, and the discharge of cations from the solution then proceeds selectively on the n-side of the junction. The results of Whoriskey (2), who found that the stain appeared on the p-side of the junction under the influence of light, are consistent with this theory, since the stain is probably caused by the oxidation of the semiconductor, and this reaction should take place on the anode of the electrolytic cell.

The author has found that it is also possible to obtain reproducible delineation in the absence of strong illumination, provided the reactions are carried out in the presence of strong HF. In the absence of substantial amounts of HF, it is possible that an oxide film on the surface may interfere with the reaction. This is indicated by the fact that most investigators employed relatively concentrated solutions of cations in their delineation work. For example, Iles and Coppen (1) used a solution of AgF that was 10% of saturated, which is approximately 18.0 g/l, and Silverman and Benn (3) used solutions containing 10 g/l of $KAg(CN)_2$. On the other hand, we have found that in a solution containing 30 vol. % HF (30 ml conc. HF diluted to 100 ml), concentrations of gold chloride in excess of 2 mg/ml produced indiscriminate plating on both sides of the junction, whereas lesser concentrations produced selective plating, fairly adherent, and invariably on the p-side of the junction. Similar results were obtained with other cations. The threshold concentration for chloroplatinic acid was found to be in the range of 2 mg/ml of 30 vol. % HF; for copper chloride, 0.25 mg/ml of concentrated HF; for silver acetate, 0.25 mg/ml of concentrated HF; and for palladium chloride, 2 mg/ml of 30 vol. % HF. In all instances plating was selective on the p-side of the junction. The threshold concentration

[1] Present address: Bell & Howell Research Center, 360 Sierra Madre Villa, Pasadena, California.

of cation necessary for selective plating varies with the amount of HF in the solution, since we have found that a concentration of less than 1 mg/ml of gold chloride in concentrated HF often gives nonselective plating.

In view of the above, it seems that the two mechanisms postulated by Iles and Coppen (1), namely, the electrolytic mechanism and the displacement mechanism, are oppositely directed. The electrolytic mechanism is directed so that the n-side of the junction is the cathode, whereas the displacement reaction in strong HF is preferential on the p-side. In the absence of strong HF (Iles and Coppen used solutions containing only one drop of HF to 5 ml of solution) the displacement reaction may possibly be influenced by the state of the surface as well as by the underlying bulk properties. This is indicated by the large concentration of cations necessary in the absence of HF and by the erratic preferentiality observed. The role of the surface is further indicated by the fact that Silverman and Benn (3) found it necessary to abrade their surfaces in order to obtain good delineation, and Turner (4) has found that it is possible to get delineation between abraded and nonabraded semiconductor of the same conductivity type.

The opposite directivity of the two mechanisms suggest the desirability of selecting conditions so as to suppress one or the other of these mechanisms. Iles and Coppen (1) have done this by reducing the concentration of AgF when they employed strong illumination, and Whoriskey (5) has done the same by deleting HNO_3 from the staining solution. The staining reaction of Fuller and Ditzenberger (6) may be looked on as a displacement of hydrogen ions by silicon, which causes the liberation of hydrogen selectively on the p-side, and results in the oxidation of the silicon to an insoluble, transparent film which is rendered visible and colored by optical interference. The growth of this film may be observed by noting the change in color through the spectrum, and several orders of interference may be observed. The role of the nitric acid may be either to participate in the selective oxidation of the silicon, or perhaps to act as a depolarizer to remove the hydrogen that is formed. Whereas Whoriskey (5) has found that the electrolytic reaction can be favored by deleting the nitric acid, we have found that the displacement reaction can be enhanced by the use of a trace of sodium nitrite, which catalyzes the oxidation of the silicon. A preferred method is to add oxides of nitrogen in the form of red fuming HNO_3, and a recommended formula is 1-2 drops of red fuming HNO_3 to 10 ml of concentrated HF. We have found that by this technique the reliability of the method has been considerably improved.

Manuscript received Dec. 27, 1960; revised manuscript received Sept. 16, 1961.

Problems Associated with Distribution Coefficient and Solid Solubility Determinations Using Crystal Growth Techniques

W. Bardsley, D. T. J. Hurle, and J. B. Mullin

Ministry of Aviation, Royal Radar Establishment, Great Malvern, Worcestershire, England

In a recent paper, Trumbore *et al.* (1) have described the use of a solvent evaporation technique (2) to grow single crystals of silicon from melts heavily doped with antimony. From measurements made on these crystals, they have calculated the distribution coefficient (k) at various temperatures and levels of doping. The possibility that {111} facets may have developed on the solid-liquid interface of the crystals during growth and modified the solute incorporation [the "facet effect" (3, 4)] and, hence, the measured value of k was considered. They concluded that their measured values of k were near the equilibrium values: in particular they obtained substantial agreement between values of k determined for growth in the three directions <111>, <110>, and <100>.

It is the purpose of this note to point out some of the conditions related to the solvent evaporation technique, under which the solid-liquid interface can become faceted and which can occur for any growth orientation. One such condition is the presence of a gradient of solute concentration in the melt ahead of the interface which, unless the temperature gradient in the melt is appropriately steep, gives rise to constitutional supercooling of the melt (5). Expressions have been derived (6) for the onset of constitutional supercooling and the magnitude of the supercooling when it exists, in a stirred melt. Work in this laboratory has shown (7-9) that, under conditions of constitutional supercooling, the solid-liquid interfaces of germanium and indium antimonide crystals are cellular, the

cells being made up of small {111} facets. This is likely to be the case for all diamond cubic and zinc blende-type semiconductors including silicon.

The laminar interface structure shown in Fig. 1a of ref. (1) is very similar in appearance to the cellular structure seen on the interfaces of [110] oriented germanium or indium antimonide single crystals grown under conditions of constitutional supercooling, where the cells are elongated in the $[1\bar{1}0]$ direction in the plane of the interface (7, 9). The principal faces of the cells are the two {111} planes inclined at 35° 16' to the plane of the interface. In general, the cellular morphology is determined by the direction of growth, the faces of the cells being composed of the {111} planes nearest the plane of the interface.

In the presence of a cellular interface there are three known effects which can result in a solute concentration in the solid which is different from that where the interface is not cellular or faceted:

(i) The facet effect (3, 4), *i.e.*, a difference in the interface distribution coefficient k^* (4) on and off a facet of magnitude appropriate to the particular system. In the case of indium antimonide grown from an indium rich melt, in such a way that constitutional supercooling occurs, the {111} facets which develop show this change in k^* when tellurium is present in the melt (9).

(ii) The lateral component of diffusion produced by segregation at the cell faces leads to an enhanced ($k < 1$) or depleted ($k > 1$) solute concentration at the re-entrant corners formed by the cells. The solute concentration in the re-entrant corners can, in some circumstances, exceed the solubility limit resulting in the precipitation of a second phase (8, 9).

(iii) Evidence has been obtained (8) which indicates that, when the crystal is rotated, the formation of the first cells on the solid-liquid interface produces turbulent flow over the whole interface which modifies the cellular morphology and hence the solute incorporation.

There are other conditions under which growth can be faceted, such as growth into a thermally supercooled melt when, in the absence of the appropriate twin planes, the crystal assumes a polyhedral form bounded by {111} planes (10, 11), or growth with a {111} plane tangential to the melt isotherm (3).

In general, thermal supercooling leads to a few large facets while constitutional supercooling leads to a large number of small facets. However, in both cases, the indications are that a facet, however formed, will show the facet effect. In the case of constitutional supercooling there is the additional inhomogeneity due to the intercellular segregation.

The determination of equilibrium distribution coefficients by growing crystals from heavily doped melts requires a very slow growth rate and a steep temperature gradient in the melt. The problem with the Czochralski technique is that, to promote growth at constant crystal diameter, the power supplied to the melt must be periodically lowered because the accumulation or depletion of solute in the melt ($k \leftrightharpoons 1$, respectively) continually lowers the liquidus temperature of the melt. These power changes cause transient increases in growth rate and lead to the transient formation of a cellular structure with its consequent inhomogeneities. This effect becomes very pronounced at the slowest growth rates (8). The advantage of the solvent evaporation technique in this respect is that the power supplied to the melt is kept constant and no mechanical pulling is employed. Its disadvantage is that it is a nearly isothermal process, *i.e.*, the temperature gradient in the melt is small, and hence constitutional supercooling of the melt readily occurs. To utilize the advantages of the technique a steep temperature gradient in the melt is required.

Trumbore and Porbansky (2) claim the isothermal nature of the process to be its chief advantage since it should yield homogeneous material. While, at present, little is known about the factors controlling cell size it may be possible to grow crystals by the isothermal process under conditions of constitutional supercooling in such a way that the crystal itself forms a "single cell" and the interface is bounded by a single set of low index planes with no re-entrant corners. In this case the material should be homogeneous although its impurity content will depend on the magnitude of k^* on the facets.

The above comments are not intended as a serious criticism of the experimental results of Trumbore *et al.* (1). The consistency of their results indicates that the influence of the effects described above was probably small in their experiments. However, in those alloy systems which exhibit a large facet effect, determination of the equilibrium distribution coefficients cannot be accomplished by the use of an isothermal process.

This note is published by permission of the Controller, H.B.M. Stationery Office.

Unusual Ternary Behavior of Transition Metal Borides

J. M. Leitnaker, N. H. Krikorian, and M. C. Krupka

University of California, Los Alamos Scientific Laboratory, Los Alamos, New Mexico

During the course of a variety of experimental work on transition metal borides (1-3), unusual behavior was found in heated mixtures of the Group IVa metal diborides with tungsten and molybdenum. [Experimental methods are described in detail in ref. (1).]

All three of the diborides were found to behave differently when mixed with tungsten powder and heated. TiB_2 formed what appeared to be a ternary compound with W (at roughly 50-50 mole %). The compound could be indexed in orthorhombic symmetry, by its close analogy to TaB, and had lattice parameters of $a_o = 3.180 \pm 0.008$Å, $b_o = 8.462 \pm 0.006$Å, and $c_o = 3.071 \pm 0.003$Å. HfB_2, when heated with tungsten powder, does not easily attain equilibrium, or at least the quenched samples when examined by x-ray never indicated that equilibrium had been attained. A ternary compound appeared to form, however, but was either of low symmetry or the sample contained a mixture of two ternary phases.

In contrast, ZrB_2 forms no intermediate phases with tungsten. A 3-day heating of an intimate mixture of ZrB_2 and W at 2100°C showed only the sharpening of x-ray lines in the film and elimination of faint impurity lines. Heatings at lower temperatures with about 1% iron as a sintering aid also produced no extra phases.

All three diborides react with molybdenum. X-ray films of quenched samples of ZrB_2-Mo and HfB_2-Mo showed nearly identical patterns with those of HfB_2-W. The behavior of TiB_2 with Mo is nearly identical with the TiB_2-W reaction. Lattice parameters for the orthorhombic phase were $a_o = 3.185 \pm 0.007$Å, $b_o = 8.475 \pm 0.010$Å, and $c_o = 3.075 \pm 0.003$Å.

The ternary compound of TiB_2 with Mo was found to form as low as 1600°C. Steinitz (4) has shown that MoB has a high-temperature modification which is isomorphous with TaB. Hence, instead of a ternary compound, the intermediate one-phase region can be viewed possibly as a solution of TiB in β-MoB with a consequent lowering of the β-MoB transition temperature. The situation with the TiB_2-W system is similar. Whether the high-temperature MoB (or WB) phase can be stabilized down to room temperature is, of course, uncertain.

Examination of the six pseudobinary systems has been only cursory. It would seem that the unusual behavior is of more than passing interest and certainly deserves more attention.

Floating Zone Refining of Boron Using Electron Beam Melting

C. B. Hood and M. O. Thurston

Electron Device Laboratory, The Ohio State University, Columbus, Ohio

The use of electron beam zone refining in the purification of refractory metals was discussed by Davis, Calverley, and Lever (1). The advantages they found in this technique made it attractive for use with boron. They had, however, mentioned difficulties with high resistivity materials, and there was thus a question whether the high resistance of a boron rod near room temperature would permit sufficient beam current to flow at a reasonable voltage for the beam to melt a zone.

In practice it was found that the resistance of the rod is almost immaterial. The current flow in the rod is very slight, the predominant current being the secondary electron emission current from the bombarded zone. The secondary electrons complete the circuit by flowing to the grounded case of the vacuum furnace. The bombardment process could be started with the boron rod cold, and the zone could be brought to the melting point in a minute or less. This contrasts with the r.f. induction heating method, in which a boron rod must be preheated in order to reduce its resistivity sufficiently to allow effective electrical coupling to the heating coil.

Some of the details of the preparation of the materials, the operation of the equipment, and preliminary results obtained are described next. More complete studies of the electrical properties of boron are in progress and will be reported later.

Experimental Techniques

The boron rods used in these experiments were prepared by the reduction of boron trichloride on a 25μ diameter heated tantalum filament, suspended horizontally in a reaction chamber consisting of a Vycor tube with water-cooled copper end flanges and electrodes. Reaction temperatures varied from 1350° to 1450°C as measured with an optical pyrometer. The reaction chamber was connected to a Pyrex gas supply system as shown in Fig. 1. The vapor pressure of boron trichloride at the ice point is such that a stream of hydrogen passed through the liquid at this temperature gave an approximately stoichiometric mixture to feed to the reaction chamber. The spent gas from the chamber passed to the condenser, where unreacted boron trichloride was condensed and recycled. The feed gas was regulated in such a way that only 25-30% reduction took place, thus maintaining fairly uniform concentrations throughout the reaction chamber, giving rods of fairly uniform diameter. The system was operated at atmospheric pressure.

The rods obtained in this process were dark gray, with a fine-grained crystalline appearance, and were quite dense. Approximately 2½ hr were required to grow a rod 6 mm in diameter, which is the largest obtainable with our present power supply. The yield of boron was about 75% of theoretical. All the rods showed evidence of strains by undergoing some cracking when cooled through the 900°-1100°C range. The least amount of cracking seemed to take place when the rods were cooled rapidly by merely shutting off the heater current. By this means, pieces 7-15 cm long (with no apparent cracks) were obtained.

High-purity boron trichloride, obtained from the American Potash and Chemical Company, was used for this preparation. The impurity content, calculated from their analysis, assuming all the impurities entered the rod, is as follows:

Carbon	0.055%
Silicon	0.002%
Tantalum	0.015%
Total	0.072% by weight

The electron beam zone refiner is similar to the one described by Davis (1). It was constructed with a stationary filament assembly, through which the sample rod, supported on a frame, can be moved vertically. There was no provision for rotation of the sample. The entire filament and frame assembly was hung inside a water-cooled vacuum chamber, with an external gear-driven lifting mechanism to provide the vertical motion. The filament arrangement consisted of a tungsten strip 3/32 in. wide by 0.003 in. thick, formed to a 3-cm circle, surrounding the boron rod. Tantalum focusing plates, with 2.5-cm holes in them, were placed about 6 mm above and below the filament. This arrangement gave a molten zone about 6 mm in width. The electron beam current was about 0.15 to 0.20 amp at 3000v. Vertical motion of the rod was 12-18 cm/hr.

The emission of boron vapor from the molten zone was very slight, as evidenced by film formation on the chamber window. However, it was sufficient to contaminate the tungsten filament, reducing its emission, and distorting its shape. This difficulty, which limits the filament life to about 1 hr, seems to be the principal limitation of the filament structure described. An electron gun design in which the filament was not directly exposed to the boron might be expected to minimize this difficulty.

Experimental Results

Although no single crystal rods have been obtained, the zone refined specimens contain crystals 2-3 mm in size, as determined by observations on etched slices.

The electron beam furnace was also used to prepare doped samples of boron by fusing short sections of rod with impurities inserted. Rods were doped with nickel and carbon by this method.

Resistance measurements were made on the various samples of boron over a wide range of temperature. Electrical connections were made to the samples with tungsten wire, using a small amount of platinum as an alloying or bonding agent. The contacts were tested on an oscilloscope and found to be ohmic. The boron samples were not precisely cut, but were of such dimensions that the resistance values are numerically within 3-7 times the absolute resistivity in ohm centimeters.

Figure 2 shows resistance as a function of reciprocal temperature for freshly prepared boron, zone refined samples, and doped samples. Apparent band gaps, calculated for these samples from the average slopes of the curves at the higher temperatures, are as follows: zone refined sample (3 passes), 1.35 ev; unmelted samples, 1.2 ev; nickel doped sample, 1.2 ev; carbon doped sample, 1.2 ev.

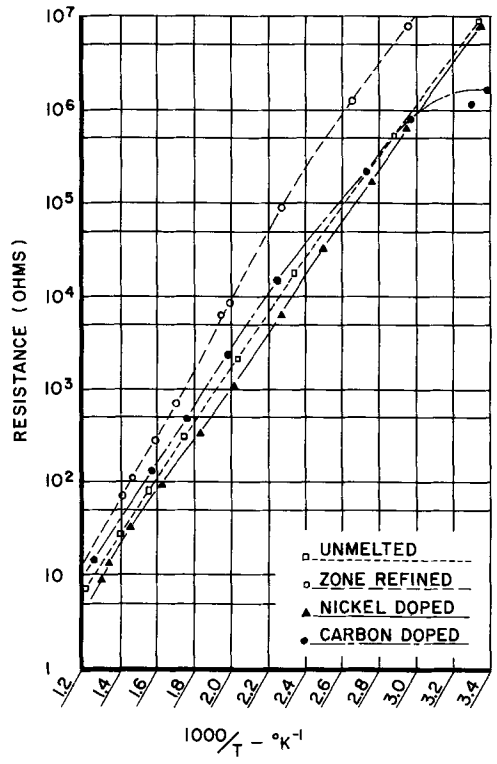

Fig. 2. Resistance of various boron samples as functions of the reciprocal of the absolute temperature.

The band gap, measured by this method, has been reported by various investigators (2-6), giving values ranging from 0.30 to 1.60 ev. Our values agree most closely with those of Greiner and Gutowski (5). These authors (6) also reported reduced resistivity with phosphorus doping, but of the two dopants selected by us, only carbon shows indication of reduced resistivity at room temperature.

Measurements at lower temperatures would be required to determine the energy level structure for impurities, but could not be made with the equipment available for these first tests.

The zone refining produces a definitely measurable increase in slope at the higher temperatures, but not necessarily an increase in resistivity over the entire temperature range.

Thermoelectric power measurements on all the samples studied so far indicate that they are p-type, although one might expect the carbon doped sample to be n-type due to the extra electrons in the lattice contributed by the carbon atoms.

Acknowledgment

The authors wish to acknowledge the cooperation and technical help provided by Mr. C. Powell and Mr. J. M. Blocher of Battelle Memorial Institute in connection with the preparation of boron rods for this work. This work was sponsored by the Air Force Office of Scientific Research of the Air Research and Development Command under Contract AF49(638)-424.

Brief Communications

An Electrochemical Method for the Preparation of AuSn and Its Possible Application to Other Intermetallic Compounds

T. Granville Carver and Henry Leidheiser, Jr.

Virginia Institute for Scientific Research, Richmond, Virginia

The purpose of this communication is to describe a simple electrochemical method for the preparation of the intermetallic compound AuSn and to suggest its applicability to other intermetallic compounds.

When gold electrodes were polarized in boiling 2M HCl containing 0.001M Sn(II) to potentials 10-100 mv more noble than that of tin in the same medium, a uniform deposit formed very rapidly on the gold.[1] The resulting deposit, as identified by electron and x-ray diffraction analysis, was AuSn(3). In a typical experiment in which the gold was polarized to a potential approximately 15 mv more noble than the potential of tin in this medium (−605 mv *vs.* the saturated calomel electrode), 8.7 mg

[1] Deposits on gold samples in contact with tin in solutions containing Sn(II) were reported as early as 1873 by Raoult (1). Later workers, such as Tammann and Wiederholt (2) studied the rate of change of potential of electrodes when polarized in the presence of less noble metal cations.

of AuSn was formed in 1000 min on a gold cylinder exposing approximately 2 cm^2 of surface.

Similar experiments carried out using evaporated gold films approximately 200Å in thickness resulted in the apparent complete transformation within 15 min of gold to AuSn on those fragments of the film which adhered to the glass substrate and remained in electrical contact with the polarization source. This conclusion was based on transmission electron diffraction studies.

In the majority of experiments, a single plateau was observed in the potential-time curve when the polarizing potential was removed. This plateau was approximately 150 mv more noble than the potential of tin in solutions containing 0.0001, 0.001, 0.01, and 0.1M Sn(II). In experiments carried out for long times in solutions 0.1M in Sn(II) and in experiments in which the gold electrode was charged briefly to a potential sufficient to electrodeposit tin, a second plateau was observed at a potential approximately 80 mv more noble than the potential of tin in these solutions. Attempts to identify the compound responsible for the second plateau by diffraction analysis were unsuccessful. It is suggested that this compound may be either $AuSn_2$ or $AuSn_4$ on the basis of the phase diagram for the Au-Sn system.

When a palladium electrode, exposing a surface area of 1.5 cm^2, was polarized in boiling 2M HCl containing 0.001M Sn(II) to a potential several mv more noble than the corrosion potential of tin, a deposit weighing 6 mg formed on the palladium in 24 hr. X-ray diffraction analysis indicated that the major constituent was $PdSn_4$.[2] The potential decay curve exhibited a plateau lasting 15 min at a potential approximately 25 mv more noble than that of tin in the same medium. Two smaller plateaus were also observed at more noble potentials.

Based on the results reported above and preliminary studies on other systems, it appears that intermetallic compounds of tin, lead, and cadmium with noble metals may be prepared by a reaction of the type, $xM + yM'^{+z} + yz\ e^- \longrightarrow M_xM'_y$, where M is the noble and M' is tin, lead, or cadmium.

Niobium Solid Electrolyte Capacitors

H. W. Ling and T. L. Kolski

Pigments Department, E. I. du Pont de Nemours & Company, Wilmington, Delaware

Use of niobium as an anode material for solid electrolyte capacitors is arousing considerable interest. Previous reports (1-3) have indicated the feasibility of preparing niobium solid electrolyte capacitors with satisfactory life under load up to 20v. However, these same reports have shown that fabrication of devices of the 35-v class was unsuccessful because of total failure during life tests. This communication contains test results on 35-v niobium solid electrolyte capacitors which were shown to last longer than 1000 hr when tested at 85°C.

In an earlier communication (4) we indicated the means whereby niobium sintered pellets could be anodized to 200v. Briefly, the conditions involved forming at room temperature in 0.01% aqueous H_3PO_4 electrolyte at a current density of 50 ma/g, and maintaining at formation voltage for 2 hr to allow healing of the anodic film. Porous pellets weighing approximately 0.5g were anodized in this manner, and a counter electrode of MnO_2, graphite, and metal was applied to each using the conventional art. A cathode lead wire was attached to the metal coating of each device, but the units were not hermetically sealed or otherwise isolated from the atmosphere.

With no prior curing period under load, leakage current was measured after 5 min of electrification, using an RCA WV-48B ultrasensitive d-c microammeter. Potential was increased to 35v within a period less than 45 sec; the electrical leakage measured 5 min after reaching 35v was about 25% lower than the 2-min value. Capacitance and dissipation factor were measured on a General Radio Type 1611-B Capacitance Bridge at 35v d-c bias using a 120 cps, 1v a-c signal. After initial characterization, low impedance life testing was carried out at 85°C using wet cells as the d-c source.

A summary of the results is presented in Table I. Comparison of post-life test properties with initial dry properties shows that in the majority of cases capacitance and equivalent series resistance decreased, yielding lower dissipation factors. Absolute electrical leakage increased in most specimens. In general, variations in initial capacitance reflect the use of powders varying in particle size distribution, whereas differences in initial electrical leakage result from differing purity among several powder batches employed.

In previous publications (1, 3), it was stated that partial crystallization of the oxide film during for-

mation limited the voltage ratings of niobium solid electrolyte capacitors. Further, it was proposed that successful formation to voltages higher than 100-125v would have to await a niobium powder of higher purity and/or a more suitable electrolyte for anodization than those used previously. We agree that the feasibility of 35v niobium solid electrolyte capacitors demonstrated by the present data results from the ability to anodize to 200v and higher, which in turn depends on use of a high-purity niobium powder and dilute aqueous H_3PO_4 as an appropriate electrolyte.

Epitaxial Silicon-Germanium Alloy Films on Silicon Substrates

K. J. Miller and M. J. Grieco

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

Silicon-germanium alloys with up to 30 at. % germanium have been deposited epitaxially on silicon substrates by the simultaneous vapor phase reduction of $SiCl_4$ and $GeCl_4$. Silicon has also been epitaxially deposited on these alloys.

The method of deposition used was similar to that reported (1) for deposition of silicon films on silicon substrates. Hydrogen carrier gas was bubbled through a thermostated solution of $SiCl_4GeCl_4$ and carried these halides to the R.F. heated sample in a quartz reaction chamber. The temperatures of deposition were kept close to the alloy melting points. Different epitaxial alloy film compositions were obtained by varying the proportions of $SiCl_4$ and $GeCl_4$ in the solution with resulting variation of their vapor pressures in the reaction chamber. For example, at a 1200°C temperature of deposition a 25 at. % germanium alloy film required partial pressures of 1.3 mm for $GeCl_4$ and 5 mm for $SiCl_4$. Films were analyzed for germanium by x-ray fluorescence after a calibration curve was obtained. Epitaxy was established by Laue back-reflection x-ray diffraction and by electron diffraction which indicated the films had a high degree of crystal perfection.

Surfaces of alloy deposits appear macroscopically to be highly reflective and were smooth and of uniform thickness. Alloy films etched with the Dash etch (2) have surfaces which appear microscopically to have an incomplete triangle dislocation array when deposited on (111) and (110) silicon substrates, and on (100) substrates these films frequently have an incomplete square dislocation array. The (111) films have surfaces which appear microscopically as striae, presumably caused by microscopic variation of germanium composition in the film. The striae are especially evident on films deposited on highly doped substrates, such as the

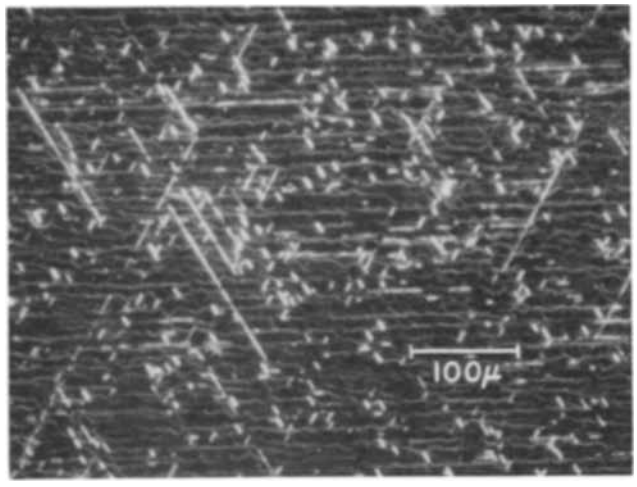

Fig. 1. Etched surface of epitaxial 14 at. % germanium, silicon-germanium alloy film deposited on (111) silicon substrate.

$10^{19}/cm^3$ phosphorus-doped substrate on which the film shown in Fig. 1 was deposited. The striae are fine, parallel lines at low germanium content and become broader and wavy in appearance with increasing germanium content. Figure 1 shows the surface of a 14 at. % germanium film after etching with the Dash etch, showing the striae and the triangular dislocation pattern. Goss *et al.* (3) have noted a similar striae pattern for a (111) 6 at. % silicon, germanium-silicon alloy grown from the melt. Films deposited on (100) and (110) substrates did not have a striae pattern over the entire composition range to 30 at. % germanium. Films of 13 at. % germanium composition, deposited on (110), (111), and (100) substrates had an average random dislocation etch pit density of $5 \times 10^6/cm^3 - 10^7/cm^3$ as revealed by a silver dislocation etch (4). Alloy films with compositions above approximately 30 at. % germanium were usually two-phase and inhomogeneous. Surfaces of epitaxial silicon films deposited on silicon-germanium alloy films appear the same as silicon single crystal film deposits on silicon substrates.

This method of silicon-germanium alloy preparation is simple and provides a means of preparing semiconductor material with properties which can be varied by changing the material composition.

Oxidation of Silicon by High-Pressure Steam

Joseph R. Ligenza

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

ABSTRACT

The oxidation of silicon by high-pressure steam was studied at temperatures between 773° and 1123°K and pressures from 25 to 500 atm. Within a certain range of pressure and temperature a uniform film of amorphous silicon dioxide forms. At moderate pressures the film growth is linear in time and directly proportional to the steam pressure. At higher pressures the kinetics for film formation are complicated by the volatility of silica in steam, and, above a certain large pressure for any temperature, no film will grow. In the linear range, the rate depends on the orientation of the silicon surface and is greater for silicon that is phosphorus doped near the degenerate range than for high-purity material.

There is much current interest in passivating the surface of silicon devices by means of thick silica films grown at moderate temperatures in high-pressure steam (1). It is the purpose of this study to investigate the conditions of steam pressure and temperature which lead to the formation of amorphous silica films on high-purity silicon crystals and to determine the time dependency for film formation. A rather narrow temperature range was selected for study, and particular emphasis was placed on those pressures which would not cause the silica to volatilize. The silicon was oxidized in small bombs, and oxide film thicknesses were determined gravimetrically. Oxidation kinetics for film formation and the factors affecting the oxidation rate are discussed in terms of a model for the oxidation process based on the present experiments and others which have been presented in earlier papers.

Experimental Methods

The procedure followed in an oxidation run was to place a number of bombs, each containing a silicon specimen and water, into a hot furnace, in some sequence. A bomb will reach the furnace temperature in about 5 min during which time all of the water has passed into the gas phase. After the oxidation, the bombs are removed from the furnace, and the oxide film thickness is calculated from the weight of the oxide film. The growth of the films with time, at any fixed temperature and pressure, was found by using ten bombs, each of which was kept in the furnace for a different time. Runs at different temperatures and pressures provided the necessary data to evaluate the dependency of the oxidation rate on these parameters.

The silicon specimens were cut from n- and p-type single crystals of resistivities ranging from 0.5 to 10 ohm-cm, in the form of wafers with a geometric area of 1 cm^2. No attempt was made in the present study to use specimens of known orientation. The wafers were lightly etched in a 10-1 HNO_3-HF mixture to produce a mirror smooth surface. Prior to an oxidation the silicon and bombs were cleaned by boiling in nitric acid followed by at least three rinses in boiling water. All water used in rinsing and in oxidation was prepared by a double distillation in a silica still.

The bombs were made of Inconel X and the interiors were lined with gold. They were designed to support a pressure of 5000 atm at room temperature and 100 atm at 1123°K. The bombs are cylinders 6.5 cm long, 1.5 cm in diameter with a wall thickness of 0.3 cm, and an internal volume of about 0.6 cm^3. They were sealed by means of a screw cap which bore on a plug and compressed a gasket of heavy gold foil to the gold lining. The amount of water placed in the bomb for any desired temperature and pressure was calculated from PVT data for water above the critical temperature and was delivered to the bomb by means of a pipette with an accuracy of 0.5%. The furnace core consists of a nichrome cube, heated on each of its sides by independently controlled flat heating elements. This cube has ten holes located circumferentially on a radius into which the bombs are put. By placing thermocouples at the six faces of the cube, and one in its interior, the block can be easily kept at a uniform temperature of ±1° at any temperature up to 1223°K when the appropriate individual power adjustments are made with the six heating elements. The bomb volumes are known, at the oxidizing temperature, to 0.2% Accordingly, the pressure in the bomb is known to 1%. The drop in steam pressure in the bomb due to reaction with silicon is negligible when compared to the accuracy with which the pressure is known for most of the film thicknesses formed in this study.

A quartz microbalance was used to determine the oxide film thickness. The silicon was weighed before and after oxidation and after removing the film with aqueous HF. The geometric areas of the silicon specimens averaged 1 cm^2, and the balance sensitivity was 8.63×10^{-7}g. Thus the film thickness could be calculated to a precision of ±50Å by

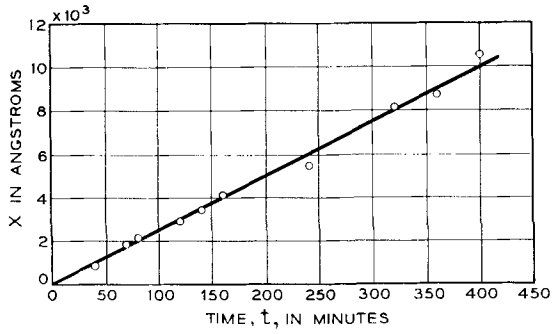

Fig. 1. Oxidation of silicon by steam to form amorphous SiO_2 at 923°K and 50 atm. The oxidation rate is 25.7 ± 0.8 Å/min.

using a weight of 7.85 × 10^{-8}g SiO_2/cm^2 for 3.57Å of the oxide. The latter values were calculated from an oxide density of 2.20 g/cm^3 for amorphous silica. Independent measurements of the film thickness by optical techniques and by capacitance measurements agreed with the gravimetric values within 5%. Electron diffraction reflection studies of the oxide have yielded no evidence of any crystallinity: the oxide films are amorphous SiO_2. When checking the film thickness optically and by capacity measurements, the values used for the refractive index and dielectric constant were those of silica.

Experiments and Results

The growth of silica films on silicon in high-pressure steam proceeds linearly in time. Figure 1 shows the results of an oxidation at 923°K and 50 atm. The line drawn through the experimental points has a slope which is the average value calculated from the points. The rate of growth here is constant to 10,000Å. Other experiments demonstrated that the growth is linear up to 70,000Å at this temperature and pressure. Experiments at temperatures from 773° to 1123°K and pressures from 25 to 400 atm, for times ranging from ½ to 8 hr all gave linear kinetics.

The rate of film formation is directly proportional to the steam pressure. The constant $dx/dt \cdot 1/P$ (Å min^{-1} atm^{-1}) is given in Table I where the results of all the experiments are presented. An average of ten different pressures was used to obtain the results in this table.

Film growth under conditions of relatively high pressure for long periods occurs at rates that are nonlinear. Furthermore, these rates are always smaller than those found at the lower pressures or for short time oxidations at the high pressures. This behavior is due to the "solubility" of the oxide in the steam (2). It has been known for some time that steam at pressures of 100 atm and above can dissolve the various forms of silicon dioxide. Booth and Bidwell (3) give solubility values for silica and quartz at a variety of pressures, but at temperatures lower than those used here. The over-all trend is that the solubility increases with temperature and pressure and that silica is more soluble than quartz. No data were given for the rates of solution. No precise statements can be made at present about the conditions that cause a departure from linearity. With the bomb volumes used here (0.6 cm^3) smaller rates occur at 923°K and 120 atm at times greater than 3 hr. At temperatures greater than 923°K deviations from linearity will occur at pressures above 75 atm and times greater than 2 hr. Less work has been done at temperatures below 923°K, but here pressures of 300 atm and periods up to 8 hr can be used without going outside the range of linearity.

Above certain pressures, the silica film does not grow. This effect results in an etching of silicon to produce a surface approximating the appearance of a lapped surface. This etching has been found to occur at a definite pressure at a given temperature. A number of experiments were done to determine just what these minimum pressures for etching were. The results of these experiments are given in Table II. Supporting evidence for the solubility of silica in steam is provided by the observation that the bomb interiors were uniformly coated with a white deposit after experiments at and above the pressures in Table II. This material must have precipitated from the gas phase when the bomb was cooled.

Although no detailed attention has been paid in this study to the role of silicon orientation on the rates of oxidation, the following effect was observed. A twinned crystal of 200 ohm-cm resistivity was oxidized at 923°K and 105 atm for 1 hr. The resulting film was divided into two regions of different thicknesses, one 2500Å thick, the other 3500Å thick. These regions corresponded to two different orientations resulting from the twinned growth. An analysis of the surface orientation of the bar by electron diffraction disclosed a 610 type plane 1° from the surface (100-type plane 10° from surface) under the 2500Å film and a 541-type plane 2° from the surface (110-type plane 14° from the surface) under the 3500Å film. The difference in rate between the two regions is 35%. Work is being carried on currently to measure the kinetics as a function of orientation. The results to date are consistent with those obtained on the twinned crystal.

Table I. Rate of silica film formation on silicon in high-pressure steam at various temperatures

T, °K	Pressure range, atm	$dx/dt \cdot 1/P$, A min^{-1} atm^{-1}
773	100-400	0.039 ± 0.014
848	50-400	0.19 ± 0.03
923	50-300	0.19 ± 0.04
973	25-80	1.14 ± 0.03
1123	20-60	4.00 ± 1.10

Table II. Steam pressures P_m and temperatures at which only etching of silicon will occur

T, °K	P_m ±50, atm
773	500
848	500
923	400
1023	200
1123	150

Another factor which can influence the rates to an even greater extent than the orientation is the doping level in the silicon. A piece of silicon which had been phosphorus diffused to a surface concentration of 10^{21} P atoms/cm^3 was oxidized at 923°K and 120 atm for about 1 hr. The film thickness was 20,000Å. Under the same conditions, only 3500Å would have grown on high resistivity material. This film was also amorphous. Subsequent oxidations of similar silicon specimens have yielded equivalent results.

Discussion

The rate-limiting step in the oxidation of silicon by high-pressure steam has been found by Ligenza and Spitzer (4) to occur at the interface between the silica and silicon. Films were prepared using O^{16} and O^{18} water and infrared absorption measurements of oxides prepared by successive isotropic oxidations showed that oxygen exchange took place. If, for example, a 7000A SiO_2^{16} film, grown either in oxygen or steam, is oxidized in 90% O^{18} steam at 923°K and 120 atm for 10 min, the O^{18} oxygen in the resulting oxide is found to be distributed uniformly throughout the thickness of the oxide. The conversion amounted, in this case, to 30%, uniformly distributed, although only 500Å of additional oxide was formed. Such results can be accounted for by assuming that a mobile oxygen species, having a very large diffusion constant, diffuses into the film from the silica-gas interface and distributes itself uniformly in the oxide film during the oxidation, while exchanging with the silica oxygens at a rate slower than it diffuses. Spitzer and Ligenza (5) also made a study of the exchange of oxygen between high-pressure steam and silica and found that the rate of exchange is directly proportional to the steam pressure. It was concluded that the diffusing oxygen species responsible for the exchange is interstitial water, the water in the silica film in equilibrium with water in the gas phase. The mechanism postulated for the exchange was a rapid reaction between the interstitial water molecules and a silicon-oxygen bridge to form a pair of silanol groups (Si—O^{16}H + HO^{18}—Si), followed by a slow condensation reaction by the pair to reform an interstitial water molecule and a silicon-oxygen bridge with exchanged oxygens.

On the basis of these experiments, the mechanism for the linear growth of silica films on silicon by oxidation in high-pressure steam is assumed to be the following. At high pressures and moderate temperatures water dissolves in the silica film. The diffusion constant for water in silica is sufficiently large[1] for the water to be uniformly distributed throughout the oxide film during oxidation. The interstitial water in the film is then in equilibrium with water in the gas phase, and the concentration of water in the film depends only on temperature and steam pressure. We shall assume that the oxidation step is the reaction between a water molecule in the silica phase and a silicon-silicon bond at the oxide-silicon interface to form a silicon-oxygen bridge and a hydrogen molecule. The reaction is

$$H_2O_i\ (SiO_2) + Si - Si \xrightarrow[N]{} \overset{HOH}{Si - Si} \rightarrow Si - O - Si + H_2\ (SiO_2) \quad [1]$$

where C_i is the concentration of water molecules in the oxide in molecules/cm^3 and N is the concentration of silicon bonds in bonds/cm^2. The oxidation rate is

$$\Omega \frac{dx}{dt} = kC_i N e^{\frac{\Delta E}{RT}} \quad [2]$$

where Ω is a conversion factor, k is the rate constant for oxidation, and ΔE is the activation energy for oxidation. If we assume the water in the film obeys Henry's law, the concentration of water in the silica film will be

$$C_i = \frac{PN_o}{RT} e^{\frac{\Delta S}{R}} e^{-\frac{\Delta H}{RT}}$$

where N_o is Avagadro's number, R is the gas constant, and ΔS and ΔH are the entropy and enthalpy of solution of water in silica, respectively. The final equation for the oxidation rate is

$$\Omega \frac{dx}{dt} = \frac{kN_o e^{\frac{\Delta S}{R}}}{R} \cdot \frac{PN}{T} e^{-\frac{(\Delta H + \Delta E)}{RT}} \quad [3a]$$

$$\frac{dx}{dt} = k' \frac{PN}{T} e^{-\frac{(\Delta H + \Delta E)}{RT}} \quad [3b]$$

where $k' = kN_o e^{\frac{\Delta S}{R}}/\Omega R$. The form of Eq. [3b] is in agreement with the experimental data. The oxidation rate is constant in time, proportional to the pressure, and is dependent on the orientation through the parameter N.

The parameter N will in general be determined by the bond density, the specific configuration of the silicon bonds at the interface, and by the fact that the effective diameter of the water molecule is large enough when in reacting position on a silicon bond to preclude reaction on adjacent bonds. The greater the available bond density, the larger the oxidation rate, provided that the activation energy ΔE for the different orientations remains unchanged. A detailed analysis of this effect, along with the appropriate experiments, will be published at a later date (6).

The values of the pre-exponential constant $k'N$ and the apparent activation energy $(\Delta H + \Delta E)$ for the data presented here can be determined by applying Eq. [3b] to the experimental rates given in Table I. However, these values will be of questionable accuracy since no attempt was made, while cutting the specimens from the crystals, to obtain but one surface orientation. Undoubtedly, more than one orientation has been used, and this will affect the precision as well as the accuracy of the

[1] Preliminary results on the diffusion of water into silica have been obtained by Ligenza and Spitzer. The diffusion constant appears to be independent of pressure in the range of 35 to 120 atm, and has a value of 1.0×10^{-9} cm^2/sec at 923°K.

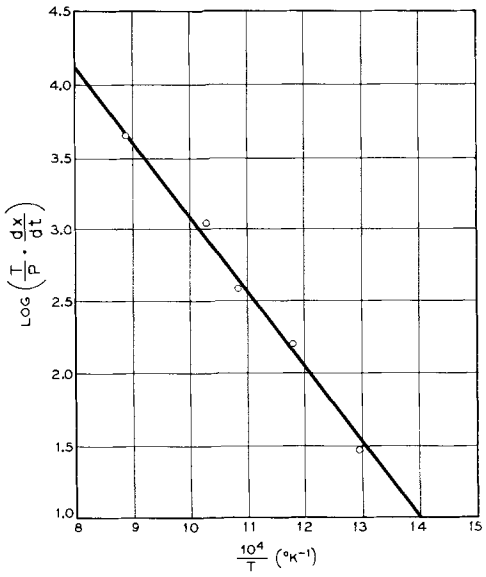

Fig. 2. Arrhenius plot of the steam oxidation data. The slope is the apparent activation energy $(\Delta H + \Delta E)/2.303R$, with $\Delta H + \Delta E = 23{,}800 \pm 920$ cal/mole. The intercept is log $k'N$ with $k'N = 1.90 \times 10^9$ Å °K min^{-1} atm^{-1}.

results. The parameters $k'N$ and $(\Delta H + \Delta E)$ are obtained by plotting $\log\left(\frac{T}{P} \cdot \frac{dx}{dt}\right)$ *vs.* $\frac{1}{T}$. The plot is shown in Fig. 2. The apparent activation energy is $\Delta H + \Delta E = 23{,}800 \pm 900$ cal/mole and $k'N$ is 1.9×10^9 Å °K min^{-1} atm^{-1}.

Acknowledgments

The author wishes to express his appreciation to Miss R. E. Cox for doing the measurements and to the late B. J. McNally who constructed the bombs and furnace.

The Electrochemical Behavior of Uranium

John W. Ward and James T. Waber

University of California, Los Alamos Scientific Laboratory, Los Alamos, New Mexico

ABSTRACT

The potential behavior of uranium was studied in both oxidizing and non-oxidizing media. A low critical anodic current and a very high critical potential for passivity were observed. In the presence of oxygen especially interesting behavior was noted. Oxygen, while passivating the corroding electrode, was reduced to form hydrogen peroxide. At steady state the potential of the passive electrode was found to be slightly more active than that for the reversible oxygen-peroxide couple. Under these conditions, changing the partial pressure of oxygen caused potential shifts in accordance with the Nernst equation.

Stern (1-3) has described in both general and specific terms the mechanism for passivation. An interesting special case is the electrochemical behavior of uranium, which may be adequately interpreted by using the concepts developed by Stern. Since uranium appears to react by anionic diffusion (4), even the "active state" involves what must be considered a protective film, and results must be viewed with the realization that no measurable quantity of uranium ever enters solution. Most of the potentials recorded in this study were open-circuit values in neutral solution, and, as such, relate to the spontaneous corrosion behavior of uranium.

General Concepts

Uranium exhibits active-passive behavior similar to that of stainless steel and titanium. A typical anodic polarization curve for this type of behavior is shown in Fig. 1. Such a curve is obtained by holding the potential constant and measuring the current, and will describe the anodic polarization and passivation of an originally active metal. Stern (1) has shown that the addition of passivating inhibitors (oxidizing agents) produces a mixed potential dependent on the redox potential, exchange current, Tafel slope, and limiting diffusion current of the oxidizing inhibitor. This behavior is attributed to the production of a local-action current which acts to polarize the metal anodically. Whether or not passivity is attained will then depend on parameters exhibited by the metal, primarily the critical anodic current and the critical potential for passivity.

The general behavior of the composite system is shown in Fig. 2. Oxidizing inhibitor A is not present in sufficient concentration to passivate the metal.

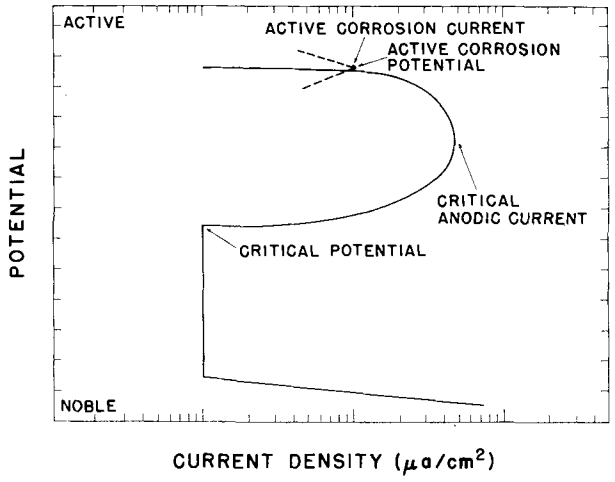

Fig. 1. Anodic polarization curve for a metal exhibiting active-passive behavior.

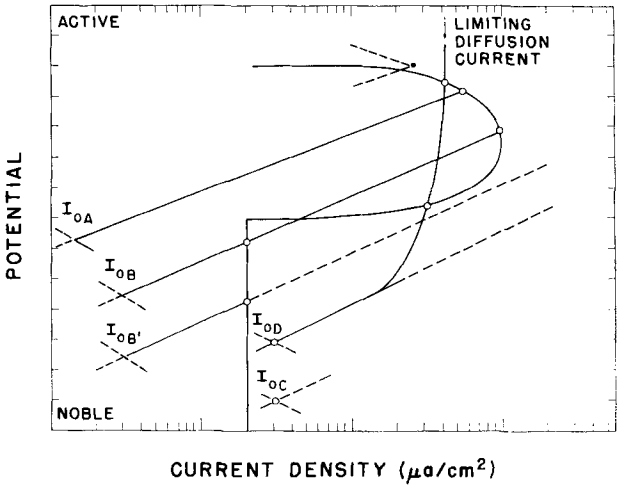

Fig. 2. Anodic polarization diagram, showing mixed potential produced by the addition of oxidizing agents of various concentrations and redox exchange currents.

Inhibitor B produces a situation whereby two possible potentials may exist, one active and one passive. Under these conditions it is possible for the metal to oscillate between active and passive states. Inhibitor B′ (at a higher concentration than B) produces stable passivity. Inhibitor C, whose redox exchange current I_{oD} is greater than the passive corrosion current, produces a mixed potential slightly more active than the reversible redox potential of the inhibitor. The value for this mixed potential will be related to the current that is produced through reduction of the inhibitor, and which is equal to the sum of the currents produced due to oxidation of the metal and oxidation of the reduced form of the inhibitor. Finally, inhibitor D, normally capable of passivating the metal, exhibits concentration polarization under certain experimental conditions as, for example, when the concentration of D is low, and the limiting diffusion current can bring the mixed potential into a non-passive region. Figure 2 was constructed to illustrate the manner in which high concentrations of an inhibitor and high redox exchange currents both favor passivity.

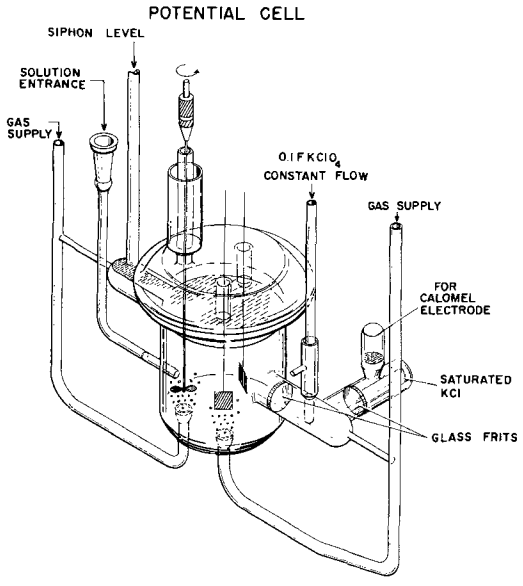

Fig. 3. Sketch of the potential cell used

It will be shown that uranium, under appropriate experimental conditions, will exhibit electrochemical behavior interpretable by the situations A through D described above.

Experimental

Apparatus.—The apparatus, shown in Fig. 3, consisted essentially of a glass vessel, 90 mm in diameter, with a ball joint cap through which the electrodes were suspended. Gas was bubbled into the solution through frits in the bottom of the chamber. By rotating the cap, the electrodes could be placed directly over the gas stream, or removed a distance from it. It was found, however, that stirring the solution by use of an impeller, rather than bubbling the gas directly past the specimen as was done in earlier work, improved the reproducibility immensely and also shifted the observed potential with oxygen in the noble direction. One explanation for this effect is that a surface partially covered by bubbles is not homogeneous; another is that under these conditions the supply of oxygen to the surface is not constant. Stirring should in general provide a more constant thickness of the stagnant layer.

Operation of the cell should be evident from Fig. 3. Since chloride ion was found to affect the study adversely, the 0.1F $KClO_4$ compartment was interposed between the saturated KCl electrode compartment and the main chamber. The siphon arrangement connected to the main chamber was used to maintain a constant level of solution, as a small amount of evaporation occurred during several days run time. The cell was immersed in a large thermostatically controlled bath, maintained at 35° ± 0.01°C.

Potentials were measured against a saturated calomel electrode, by using a Rubicon No. 2780 potentiometer in conjunction with a L&N 2430-D galvanometer having a sensitivity of 0.00045 μa/mm. Currents were measured with a Brown No. 15038G electrometer and strip-chart recorder.

Materials.—Carbon electrodes were made according to a technique outlined by Berl (5).

Solutions of electrolytes were prepared and stored in glass-stoppered volumetric flasks. Distilled water (specific conductivity 0.5 micromhos) was produced by means of a Comroe Laboratories, Inc. "Quikpure" ion-exchange water purifier and was used in making up all solutions. The pH of this water was 7.0.

Six different gases were used: pure oxygen, air, and four argon-oxygen mixtures having oxygen concentrations from 10 to 0.1 v/o (volume per cent). These mixtures were made by diluting commercially pure oxygen with welding grade argon. It had been found in other work that satisfactory mixing could be achieved in large cylinders by first admitting the diluent gas to the cylinder in high-pressure spurts to cause turbulence, and then heating a lower edge of the inclined cylinder. For the present work the oxygen mixtures were made up in H-size cylinders, and mass spectrographic analysis confirmed the accuracies of compositions. The concentration of dissolved oxygen at each partial pressure was calculated from studies by MacArthur (6) and the work of Shirley, Pachucki, and Lobos (7).

Procedure.—A given solution was admitted to the cell, and the gas (either pure argon, or an oxygen mixture, depending on the experiment) was then bubbled through the frits. The impeller was turned on and the cell was then maintained in this manner for 4 hr before the electrodes were immersed in the solution and measurements made. Because of the design of the cell, the equilibrium pressure over the solution was always 1 Los Alamos atmosphere (~590 mm). Atmospheric pressure was noted before, during, and after each experiment. A fixed flow rate, used for all studies, was achieved by using a Brooks Rotameter.

Uranium electrodes were prepared as follows: 1.6 x 1.9 cm depleted uranium specimens were polished through 600 grit paper and then spot-welded to a uranium wire that had been polished in similar fashion. This uranium wire was in turn spot-welded to a platinum wire which passed through the cell cap. Quick-setting epoxy resin was used to mask the wire to below solution level. All of the above operations were performed in an argon atmosphere. The electrodes were then inserted into the cell, which was already at bath temperature, and saturated with gas of the given composition. Potential recording was begun immediately. Steady-state potentials were usually achieved within 12 hr (with several exceptions, which will be noted). A potential value was accepted after five identical readings were obtained over a 2-hr period. Most of the work was done in 0.1F $KClO_4$, which was chosen as a noncomplexing neutral salt.

Behavior in Oxygen-Free Water

Uranium is an electropositive metal capable of releasing hydrogen from water. In boiling H_2O the net reaction is

$$U + 2H_2O \rightarrow UO_2 + 2H_2\uparrow \qquad [1]$$

It was assumed in this study that essentially the same reaction occurs at room temperature, although the amount of corrosion is too small to allow measurement of the evolved hydrogen in the apparatus used for these studies. The reasons for this assumption will become evident.

The first potential observation taken after the electrodes were immersed in the argon-saturated water gave a value of about −0.3v *vs.* SCE. The potential rose quickly at first to more active values and over a 3-hr period attained a steady value of −1.1012v *vs.* SCE. This potential was observed for both distilled water and 0.1F $KClO_4$. The value was not changed by using basic or acidic salts, but adding larger amounts of H^+ or OH^- ions caused competing side reactions to occur.

No pH change was observed during this corrosion reaction even after several days of exposure. Therefore it was assumed, as indicated above, that the primary reaction results in the evolution of hydrogen.

An adherent film was formed on the electrode and was dull gray-black in appearance. Broad x-ray diffraction peaks indicated that the film had a fine-grained structure. Under microscopic examination the oxide appeared dense and granular. The film could not be removed from the electrode by rubbing with a cloth.

The very active potential value reached by the electrode certainly indicates that the metal was in the active state although corrosion was limited or controlled by anionic diffusion through the oxide layer. The large rise in potential indicates the production of a powerful reducing agent in the oxide film, which is logically tri-positive uranium in some form. A likely oxidation reaction for the active region is the metal first going to the positive three state, in line with Stern's suggestion (1) that a metal corroding in the active state produces ions of lower valence than the same metal does when passivated.

$$U + H_2O \rightarrow UO^+ + H_2 + e^- \text{ (fast step)} \qquad [2]$$

$$UO^+ + H_2O \rightarrow UO_2 + H_2 - e^- \text{ (slow step)} \qquad [3]$$

$$U + 2H_2O \rightarrow UO_2 + 2H_2 \text{ (net equation)}$$

This set of equations predicts the existence of an excess of the tri-positive state at any given instant, as well as pH independence. Both predictions agree with the experimental observations. Since only UO_2 is found by x-ray analysis, the excess must be small, and therefore the electrode should be passivated easily.

Anodic polarization does passivate the electrode quickly, as does the addition of certain oxidizing inhibitors. Both these situations will be discussed. Under anodic polarization the oxide gradually becomes glossy, and thereafter the electrode apparently cannot easily return to the active state. This suggests that the oxide formed under active conditions (oxidation in oxygen-free water) may be somewhat porous.

Behavior with Inhibitors

The addition of oxidizing agents to the solution caused changes in behavior that were dependent on the concentration, redox potential, and exchange

Table I. Effect of various oxidizing agents on the corrosion potential of an active uranium electrode

Oxidizing agent	Formal concentration	Final potential, v
None	(0.1F $KClO_4$)	—1.1012
$NaNO_2$	0.0005	—1.04
$NaNO_2$	0.005	—0.94
$NaNO_2$	0.05	—0.54
$NaNO_2$	0.5	—0.11
$NaNO_3$	0.1	+0.03
Na_2CrO_4	0.066	—0.66
Na_2MoO_4	0.001	—0.84
Na_2WO_4	0.001	—0.82

current, as illustrated in Fig. 2. Results are presented in Table I.

Figure 4 shows the potential-time behavior of the nitrite and nitrate solutions. The 0.0005F $NaNO_2$ curve is suggestive of case A of Fig. 2. The potential was shifted only slightly in the noble direction. With 0.005F and 0.05F $NaNO_2$ note the uncertainties exhibited by the potentials, and indeed the violent oscillation between active and passive values with the 0.005F concentration before a steady but still active potential was reached. These two curves aptly illustrate case B. Case B′ is shown in the curve for 0.5F $NaNO_2$; after an initial small rise, the potential falls to a steady passive value. The behavior of 0.1F $NaNO_3$ is also similar to case B′.

Surprisingly, nitrate ion appears to be a better inhibitor for uranium than does nitrite ion. Also, the molybdate and tungstate solutions are not as dramatically effective with uranium as they appear to be with titanium and iron. The addition of oxygen to any of the solutions listed in Table I produced immediate passivity.

Addition of salts with complexing anions (Cl^-, Br^-, CNS^-, etc.) caused destruction of the protective film and rapid corrosion of the specimen. This behavior was actually accentuated by the addition of oxygen.

Behavior with Oxygen

Nature of the reaction.—By far the most interesting results of this study were obtained while using 0.1F $KClO_4$ solutions saturated with oxygen and oxygen mixtures of various concentrations. The

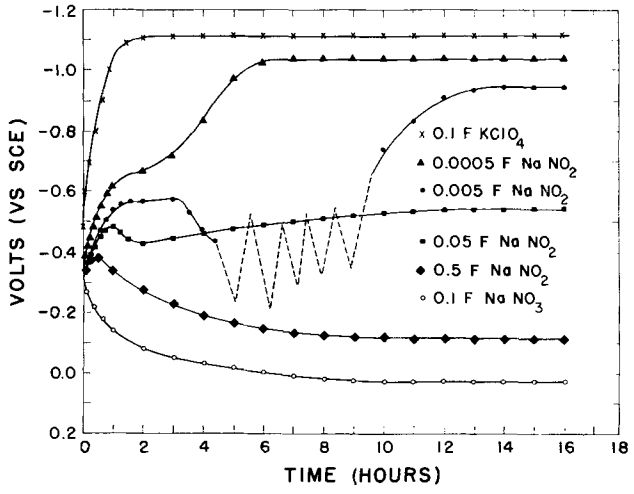

Fig. 4. Potential-time behavior of a uranium electrode in sodium nitrite and sodium nitrate solutions.

oxide that was formed in the presence of oxygen and oxidizing agents, which produced passivation, exhibited bright interference colors. X-ray diffraction patterns of the oxide were sharp, and microscopic examination showed that it had a smooth, nongranular surface.

The potential of the electrode in oxygen-saturated solution decreased over a period of about 6 hr to a steady value of + 0.1432 ± .0002v *vs.* SCE. Solution samples taken after this steady-state potential was reached gave a positive PbS test for hydrogen peroxide, indicating an equilibrium concentration of 1×10^{-6} moles per liter or greater. The *pH remained* at 7.0. The potential of an active carbon electrode in this solution was + 0.145v *vs.* SCE, indicating that the uranium electrode was about 2 mv more active than the reversible oxygen-peroxide redox couple in this solution. From the concentration of oxygen, the *p*H, and the observed potential, the equilibrium concentration of peroxide was calculated by means of the Nernst equation. A value of 9×10^{-6} moles per liter was obtained, which agrees well with the qualitative result of the PbS test.

The behavior of the uranium electrode with oxygen is a good example of case C in Fig. 2. The redox exchange current, I_{oc}, is evidently somewhat greater than the passive corrosion current, and the metal potential is slightly more active than the reversible redox potential. It is also clear that the uranium-uranium oxide electrode must exhibit a surface on which the oxygen-peroxide exchange current is relatively high, and that the catalytic decomposition of peroxide is not effected (or is effected very slowly) on this surface.

Delahay (8) has pointed out that the reduction of oxygen to water is usually easier than the reduction of oxygen to hydrogen peroxide, but that under irreversible conditions this conclusion may not hold. Churchill (9) has shown that hydrogen peroxide is formed during the corrosion of a number of metals (Zn, Sn, Pb, Ag, Hg, Cu, Al); furthermore, he reported that freshly abraded specimens gave a strong Russell effect, but that well-aged specimens did not. Of special interest was his observation that the process was cathodic and probably involved direct oxidation of atomic hydrogen by O_2. Such a process could produce the result observed with the uranium electrode (H_2O_2 production with no *p*H change) since atomic hydrogen must be formed at the oxide-solution interface before released as molecular hydrogen. If this is the actual mechanism, then hydrogen peroxide is formed, both from the O—+3 step (Eq. [2]) and the +3—+4 step (Eq. [3]), as hydrogen is released during the corrosion of uranium. A *p*H-independent net equation could then be written as

$$U + 2H_2O + 2\ O_2 \rightarrow UO_2 + 2H_2O_2 \qquad [4]$$

Under these conditions the basic corrosion mechanism might still be the reaction of uranium with water, with no direct intervention by oxygen. The formation of the entirely different passive film in the presence of oxygen is not so easily explained, however. The film normally formed by reaction

with water is clearly healed in some unspecified manner.

Effect of oxygen concentration.—Equilibrium potentials were measured for pure oxygen, air, and four mixtures of oxygen and argon: 10, 3, 1, and 0.1 v/o oxygen. It was found that the values for air, 10, and 3 v/o oxygen were as reproducible as that for pure oxygen (± 0.2 mv), but that deviations were somewhat larger for the 1 and 0.1 v/o oxygen mixtures. It is thought that this result was due, at least partly, to the slow approach to equilibrium. The more dilute the oxygen mixture, the longer was the time necessary to achieve a steady-state potential. Whereas 6 hr was sufficient time for pure oxygen, almost 30 hr were needed for the 1 v/o mixture. With both the 1 and the 0.1 v/o mixtures the potential began to rise to active values when the fresh electrode was inserted, unless the electrode was first exposed for several hours to a higher oxygen concentration to establish the passive film. Once this film was established, a steady value in (or close to) the passive region could be achieved. It is clear, however, that the passive-type film must be present.

Changing oxygen mixtures after an electrode had reached a steady value produced interesting results. Switching to higher oxygen concentrations caused fairly rapid shifts (~2 hr) to the potential associated with the higher value. Changing to a lower oxygen concentration, however, caused only a very slow shift toward the potential associated with that mixture. Indeed, the shift from the 1 v/o value to that for 0.1 v/o would probably have taken several days to effect, but the supply of mixed gas was not sufficient for such a long-term study.

Stern (1) has pointed out that, when the potential is in the passive region, changing the concentration of oxidizing agent should cause the reversible redox potential to shift according to the Nernst equation. At equilibrium, the current produced by oxidation of uranium and oxidation of peroxide is equal to the current produced due to the reduction of oxygen. If it is assumed that a steady-state concentration of peroxide, which is a function of the corrosion rate of uranium, exists under these conditions, the potential shift due to a change in the oxygen concentration may be calculated. Subtracting the Nernst equations for two different oxygen concentrations, we get

$$\Delta E = RT/n\mathbf{F} \ln(O_2)_1/(O_2)_2 \qquad [5]$$

where T is 308°K, and n, the number of electrons transferred, is 2.

The potentials measured for the several gas mixtures at 590 mm Hg, along with the values calculated for these concentrations (Eq. [5]),are listed in Table II. The first potential used for the calculations was + 0.1432v, the value for pure oxygen. The other calculated values were then obtained from this starting value.

The data of Table II are plotted in Fig. 5. As can be seen, the calculated values closely approximate the measured values from pure oxygen through the 3 v/o mixture. The slight variations are probably due to errors in estimating solubilities. Deviations become noticeable, however, for the 1 v/o mixture and become large with the 0.1 v/o mix. It is believed that these deviations are due to concentration polarization. This situation, then, is similar to case D of Fig. 2, where the limiting diffusion current due to the starved oxygen supply at the surface produces a potential more active than is expected.

Table II. Potentials as a function of the concentration of oxygen in 0.1F $KClO_4$

Composition of gas mixture	Oxygen concentration, g/l	Observed potential,* v	Calculated potential,* v
Pure O_2	2.455×10^{-2}	0.1432	0.1432†
Air	5.2×10^{-3}	0.1230	0.1227
10 v/o O_2	2.455×10^{-3}	0.1127	0.1127
3 v/o O_2	7.365×10^{-4}	0.0962	0.0974
1 v/o O_2	2.455×10^{-4}	0.0793	0.0822

* Potentials referred to a SCE at 35°C.
† Base value.

Other Measurements

Anodic polarization measurements were made on the active electrode in 0.1F $KClO_4$ saturated with argon. As indicated earlier, a small amount of anodic current brought the electrode into the passive region. Since no potentiostatic equipment was available, only an "orthodox" polarization measurement could be made. The critical current break occurred at only 2.2 $\mu a/cm^2$.

The first potential observed when a uranium electrode was immersed in a particular solution was close to −0.3v *vs.* SCE. This value was observed regardless of the solution media. Potentials then either rose to more active values, or fell to passive values from this −0.3v point, depending on the media. Therefore, −0.3v was chosen as a reasonable estimate of the critical anodic potential.

In the situation with oxygen present, addition of judiciously small concentrations of H^+, OH^-, and H_2O_2 produced potential shifts qualitatively in accordance with the Nernst equation. Addition of much larger quantities, however, caused drastic potential changes, formation of uranium peroxide, etc. It was concluded that the existence of the rever-

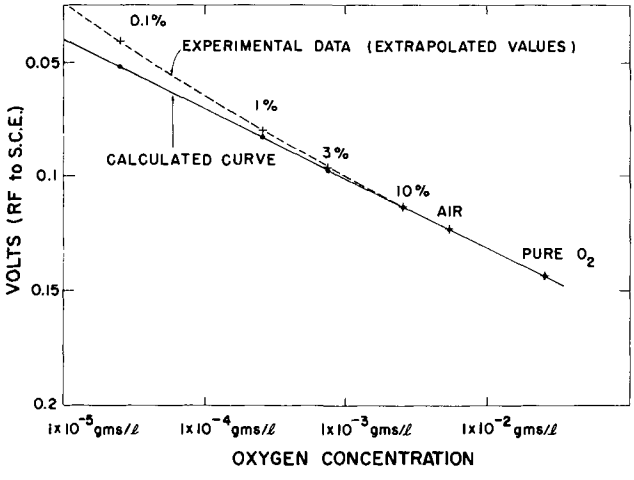

Fig. 5. Comparison of measured potentials with values calculated using the Nernst equation.

sible oxygen-peroxide couple on the uranium electrode is a delicately balanced situation.

Conclusions

Uranium has been shown to exhibit active-passive corrosion behavior similar to that observed with stainless steel and titanium. The uranium surface presents a low exchange current for establishing the redox potentials of a number of oxidizing agents, the most interesting of which is the oxygen-peroxide system. A value of −0.3v *vs.* SCE was estimated for the critical anodic potential, and a value of 2.2 μa/cm^2 was obtained for the critical current.

The electrochemical behavior of uranium in the presence of oxidizing agents and with oxygen illustrates many of the general points made by Stern (1). Data that show the production of a lower valence state during active corrosion have been cited, and examples have been given which illustrate the effect of oxidizing agents of different concentrations and redox exchange currents on the anodic polarization curve of uranium.

The corrosion of uranium in the presence of oxygen has been shown to generate hydrogen peroxide. The resulting equilibria that were established produced an electrode reversible with respect to oxygen concentration, reproducible, and predictable with respect to the Nernst equation, over a fair concentration range.

Because uranium reacts by anionic diffusion, the interesting situation has been observed whereby both the active and passive states involve the build-up of adherent UO_2 films, which are of entirely different natures. It has been shown that the passive film, once formed, is extremely stable, and furthermore, that this film must be present in order for passive potentials to occur.

Of interest is the absence of a *p*H shift for the spontaneous process, both at oxygen-free and oxygen-saturated electrodes, and the possible clue this gives to the generation of peroxide. The vigorous corrosion produced by complexing anions, especially in the presence of oxygen, was also noted.

Manuscript received Dec. 29, 1959; revised manuscript received Sept. 30, 1961. This paper was prepared for delivery before the Columbus Meeting, Oct. 18-22, 1959. The work on this paper was performed under the auspices of the U. S. Atomic Energy Commission.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

Anodic Polarization Studies in Neutral and Alkaline Solutions Containing Corrosion Inhibitors

I. NaOH-NaCl System

K. S. Rajagopalan, K. Venu, and K. Balakrishnan

Central Electrochemical Research Institute, Karaikudi, India

ABSTRACT

In neutral and alkaline solutions containing both inhibitive and corrosive constituents corrosion becomes localized and weight loss measurements are of little value in finding out when solution becomes corrosive. Points of attack also vary considerably at border line concentrations. An elegant method of finding out at what concentration of corrosive constituents such solutions become corrosive is described. The method is based on anodic polarization measurements over as short a period as 5 min and takes into account the mechanism of passivation of metal surfaces in such solutions.

Anodic polarization studies by galvanostatic and potentiostatic methods in acid solutions have been shown to be a powerful tool for elucidating the mechanism of passivation of metal surfaces (1-3). Their application to the behavior of neutral and alkaline solutions containing corrosion inhibitors as well as corrosive constituents is lacking. Mayne and Hancock (4) have recently shown that the corrosive or inhibitive character of neutral and alkaline solution containing corrosion inhibitors can be predicted by anodic polarization measurements involving application of a fixed current and following the changes in potential with time. They have studied several systems containing inhibitive and corrosive constituents by anodic polarization measurements at a fixed current density of 10 μa/cm^2. A detailed investigation into the applicability of Mayne's method with NaOH—NaCl system reveals that Mayne's choice of 10 μa/cm^2 is arbitrary and that a rise in potential to the passivation potential on application of this current cannot be a sufficiently reliable criterion for the inhibitive character of a

solution. A more elegant and sensitive method is presented. The present study is of considerable practical importance in relation to the understanding of the corrosion behavior of steel embedded in concrete.

Experimental

Metal: 1.25 cm diameter m.s. rods from the same stock were used in all the tests. The rods were cut into 5 cm pieces, scale and rust removed on grinding machine, and a smooth finish given by abrasion with 120 emery wheel. This was followed by solvent cleaning in trichloroethylene. A thin stem was screwed to the rod, and the joint was insulated from solution by fixing a glass sleeve and sealing the joint with a thin film of paraffin wax.

Solutions: NaOH solution in the normality range 0.0001-0.1*N* and containing varying concentrations of sodium chloride were used. The solutions were aerated before test.

Procedure: The test solution was taken in a 600 ml beaker, the specimen suspended in the solution and made anode. A mild steel sheet cut into the form of a cylinder and lining the wall of the container was made cathode. Current was applied to the cell from a battery source and the potential measured by null method, with reference to a saturated calomel electrode connected to the test solution with a saturated KCl-agar bridge. All experiments were carried out at 35°C ± 0.5°C.

Results

Potential time curves of NaOH—NaCl *solutions at 12 μa/cm².*—In his experiments Mayne (4) considered various current densities in the range 5-100 μa/cm² and concluded that 10 μa/cm² was a suitable current density to be applied to the system. Potential-time curves of test specimens immersed in 0.04*N* NaOH containing seven concentrations of chloride and 12 μa/cm² applied after 24 hr immersion in the test solution are given in Fig. 1. There is considerable similarity between these curves and

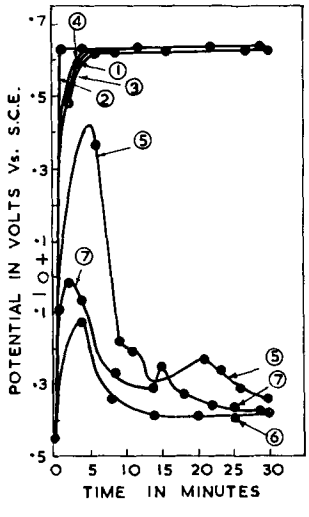

Fig. 1. Potential time curves of mild steel in NaOH-NaCl solutions when anodically polarized at 12 μa/cm². Concentration of NaOH 0.04*N* and concentrations of NaCl: 1, 0.001%; 2, 0.01%; 3, 0.02%; 4, 0.03%; 5, 0.05%; 6, 0.07%; and 7, 0.1%. Polarization carried out 1 day after immersion.

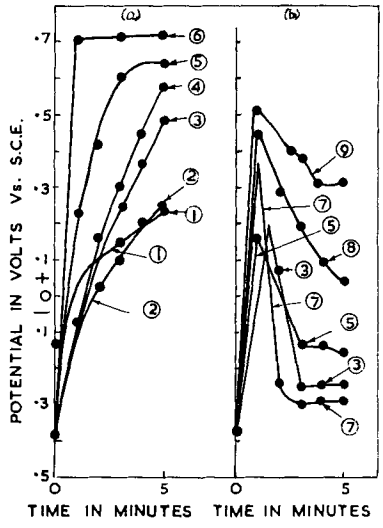

Fig. 2. Effect of current density on potential-time curves in 0.04*N* NaOH containing (a) 0.001% and (b) 0.05% NaCl. Current densities are: 1, 4.8; 2, 9.6; 3, 14.4; 4, 19; 5, 24; 6, 290; 7, 33.6; 8, 2156; and 9, 4800 μa/cm². Polarization carried out immediately after immersion.

those obtained by Mayne, and it is also seen that when a concentration of 0.05% NaCl is reached the potential-time curve first rises followed by a steep fall, while at lower concentrations the potential rises to a steady value of +0.65v (*vs.* SCE) at which oxygen evolution can take place in this medium. The rise in potential diminishes to a negligibly small value at the highest chloride concentration employed.

Potential-time curves at six different current densities in 0.04N NaOH *containing 0.001% and 0.05%* NaCl, *respectively.*—Unlike the potential-time curves given in Fig. 1, the curves given in Fig. 2 were obtained immediately after immersion of the test specimen in the medium which condition was presumably also employed by Mayne. It is now seen that the potential rises slowly at most of the current densities, and a steep rise is observed only at the highest current density (290 μa/cm²) in the case of 0.001% NaCl solution. The potential of oxygen evolution is obtained within 5 min at this current density. The curves in 0.05% NaCl solution are quite different from the curves in 0.001% NaCl solution. In 0.05% solution all the curves show a rapid fall after rising. The potential rises above +0.3v, the potential to which rise should take place according to Mayne, at the higher current densities. The potential values, in fact, show considerable variation at such high applied current density values.

Applied current density vs. NaCl *concentration.*—The data given in Fig. 1 and 2 show that with some of the solutions the potential rises steeply to the potential of oxygen evolution and remains steady there, while in some other solutions, although the potential rises initially, it falls subsequently. It is also seen that the value of applied current decides how quickly the potential of oxygen evolution is reached in different solutions. In every solution, as has been observed, it is possible to reach a given potential at sufficiently high current densities within the duration of test, namely, 5 min. It is also seen that at

Table I. Current density required to raise the potential of M.S. Rod in 0.04N NaOH-NaCl solutions to (a) + 0.3v (SCE) and (b) + 0.6v (SCE) in the course of 5 min when anodically polarized

NaCl concentration, %	Applied current density (ma/cm²)			
	Immediately after immersion		48 hr after immersion	
	(a)	(b)	(a)	(b)
0.001	0.014	0.024	0.007	0.019
0.01	0.014	0.024	0.0096	0.014
0.03	9.6	14.4	9.6	12.0
0.05	4.8	9.6	4.8	9.6
0.1	14.4	19.2	9.6	9.6
0.5	33.6	48.0	14.4	19.2

the same current density and in the same solution the potential rises steeply in the case of the specimen exposed to solution for 24 hr, but this does not take place immediately after immersion (compare Fig. 1 and 2).

The current densities at which the potential rises to +0.3 and +0.6v immediately after immersion in the solution and when polarized 48 hr after immersion are given in Table I. It is seen from the table that the current density decreases in the case of specimen polarized 48 hr after immersion as compared to specimens polarized immediately after immersion. Similarly the current density to raise the potential to +0.6v is always higher than the current density to raise it to +0.3v. In Fig. 3, the log current density is plotted against log NaCl concentration in all cases. It is seen from the figure that a S-shaped curve is obtained for both +0.3v and +0.6v, the range of potential over which the passivation of metal surface is likely to take place, and the two curves coincide. The curves also show that the current at which a jump in potential above +0.3v will take place shows a steep rise after a certain chloride concentration is reached. The chloride concentration and current density corresponding to the middle point appear to divide the solutions as well as the current densities into two broadly distinguishable groups, one in which the current density requirement is low and the other in which the current density requirement is very much higher. Practically the same values are obtained for the current density and the NaCl concentration for the curves relating to

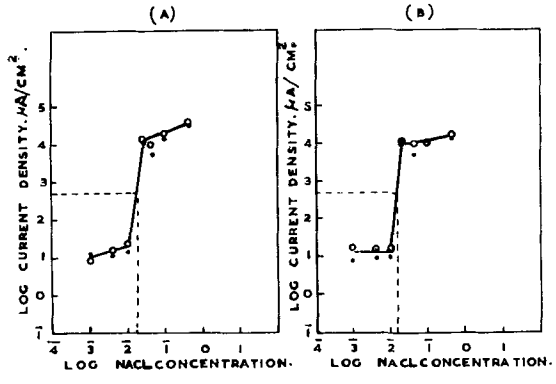

Fig. 3. Applied anodic current density vs. sodium chloride concentration: (A) immediately after immersion of specimen to get +0.3v (SCE) (●—●—●—●) and +0.6v (SCE) (O—O—O—O); (B) 48 hr after immersion in solution to get +0.3v and +0.6v (SCE).

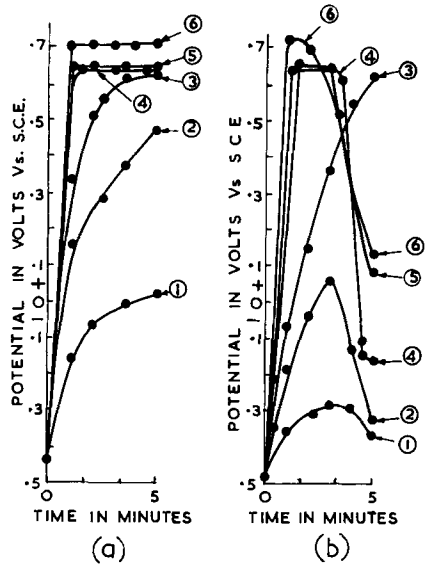

Fig. 4. Potential-time curves of mild steel in 0.04N NaOH containing (a) 0.02% and (b) 0.03% at various applied current densities: 1, 2.4; 2, 12; 3, 24; 4, 72; 5, 144; and 6, 290 μa/cm².

specimens polarized immediately after immersion and those polarized after immersion in solution for 48 hr. The current density and the NaCl concentration corresponding to the middle point are 290 μa/cm² and 0.02% NaCl, respectively. Since the local cell current that can be generated in the absence of applied anodic current will be only of the order of the current densities indicated in the first portion of the curve, it may also be concluded that chloride concentrations below that corresponding to the middle point perhaps do not make the solution corrosive. The current density corresponding to the middle point is then the appropriate current density to apply for distinguishing the two types of solutions. In Fig. 4 the potential-time curves for two solutions on either side of the middle point are considered at various current densities. The interesting observation is made that the solution above the concentration corresponding to the middle point always shows a fall of potential within the duration of the test, and the solution having a concentration below the middle point does not show such a fall. This seems to be a characteristic difference between the two types of solutions. Further, at the current density corresponding to the middle point and at some lower current densities, the rise of potential takes place very steeply in both types of solutions. Hence, the two solutions cannot be distinguished on the basis of whether the potential rises to a given value within the duration of the test. On the other hand, at very low current densities the potential does not rise appreciably in both solutions. Subsequent behavior after the rise, therefore, seems to be more important than the initial change, and the subsequent behavior is brought out in an unambiguous manner by application of the current density corresponding to the middle point.

Anodic polarization behavior at 290 μa/cm² of solutions containing varying ratios of NaOH *and* NaCl. —In Fig. 5, the NaOH concentration is maintained at 0.04*N* and NaCl concentration is changed. It is seen from the figure that solutions having NaCl concen-

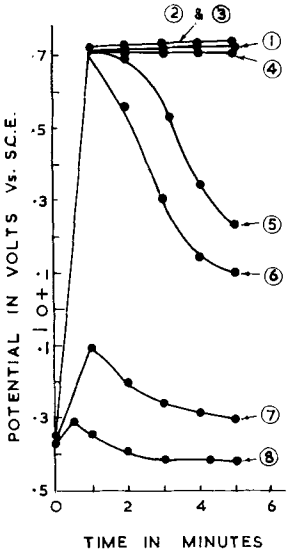

Fig. 5. Potential-time curves of mild steel in 0.04*N* NaOH containing: 1, 0.001%; 2, 0.005%; 3, 0.01%; 4, 0.02%; 5, 0.03%; 6, 0.05%; 7, 0.1%; and 8, 0.5% NaCl when anodically polarized at 290 $\mu a/cm^2$.

tration above 0.02% show the characteristic fall referred to earlier, while at this concentration and below the fall is not observed. These observations confirm the conclusions earlier arrived at from Fig. 3. In Fig. 6, the chloride concentration is kept constant at 0.02%, but normality of NaOH solution varies. It is observed that only in one solution containing 0.1*N* NaOH the potential rises to +0.65v (SCE) and remains constant there. In Fig. 7, both NaOH and NaCl concentrations vary. It is now observed that only one solution is able to show behavior similar to what is observed in 0.04*N* NaOH at NaCl concentration below the middle point of Fig. 3.

Effect of stirring and deaeration during the test on the polarization behavior at 290 $\mu a/cm^2$.— It was shown earlier that in a 0.04*N* NaOH solution containing 0.02% NaCl, the potential rises steeply to +0.6-0.7v and remains constant. The experiment was repeated after deaerating the solution by bubbling nitrogen before and during test. It is seen that no important difference is observed between the two conditions (Fig. 8). The effect of stirring the medium on the behavior of 3 solutions containing 0.02%, 0.03%, and 0.04% NaCl, respectively, are also considered in this figure. It is seen that when the solution is stirred the fall in potential is not observed in 0.03% within the duration of the test, but this was observed at 0.04% NaCl. Apparently the increased availability of oxygen brought about by stirring appears to have some effect, although variation should have been observed on deaeration also in that case.

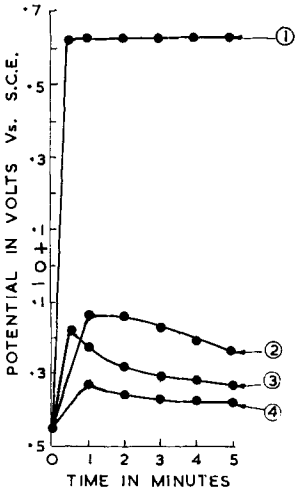

Fig. 6. Potential-time curves of mild steel in 0.02% NaCl containing: 1, *N*/10; 2, *N*/100; 3, *N*/1000; and 4, *N*/10000 NaOH anodically polarized at 290 $\mu a/cm^2$.

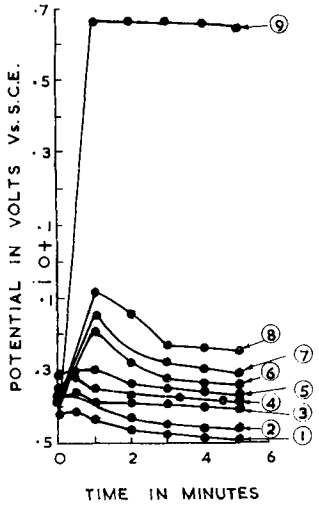

Fig. 7. Potential-time curves of mild steel when anodically polarized at 290 $\mu a/cm^2$ in the following solutions:

	NaOH	NaCl
1.	0.01*N*	0.09*N*
2.	0.02*N*	0.08*N*
3.	0.03*N*	0.07*N*
4.	0.04*N*	0.06*N*
5.	0.05*N*	0.05*N*
6.	0.06*N*	0.04*N*
7.	0.07*N*	0.03*N*
8.	0.08*N*	0.02*N*
9.	0.09*N*	0.01*N*

All the experiments mentioned earlier have been confined to a test period of 5 min. It is of interest to consider the behavior over longer periods although, from the point of view of application as test method, shorter test periods will be preferred. Potential-time curves for two concentrations of NaCl in 0.04*N* NaOH are given in Fig. 9. It is seen that even in solutions below 0.03% NaCl, the potential falls after a sufficiently long period. But it is also observed that this time appears to increase exponentially. It is, therefore, concluded that, for all practical purposes, it will be justified to carry out the experiments for a period of 5 min.

Discussion

Kabanov and Leikis (5, 6) showed that if iron previously reduced in hydrogen atmosphere was subjected to anodic polarization in 2*N* NaOH solutions, three arrests were obtained which were characteristic of ferrous hydroxide formation, ferric hydroxide or oxide formation, and oxygen evolution, respectively. Mayne, Menter, and Pryor (7) found that these arrests were not observed in the case of iron carrying an oxide film formed during exposure to air. They, therefore, observed a sharp rise in anodic polarization at a current density of 15 $\mu a/cm^2$ to the potential of oxygen evolution. Subsequently

Mayne and Hancock (8) showed that the current density at which the potential rose to the potential of oxygen evolution varied depending on the nature of the anion present. They showed that corrosion inhibitive anions such as acetate, benzoate, borate, etc., polarize the metal surface to the oxygen evolution potential at low current densities while the current density was very much higher in the case of sulfate and perchlorate solutions. They could not polarize in chloride solutions. On the basis of the detailed analysis of the polarization curve obtained with iron from which the air-formed oxide film was completely removed, as was done by Kabanov and Leikis, they concluded that the significant potential is the potential at which the second arrest correspond to the reaction:

$$2Fe + 6\,OH^- \rightarrow Fe_2O_3 + 3H_2O + 6e$$

is observed.

A solution which requires a very high current density in order to reach such a potential at which the dissolution reaction will give place to the reaction leading to film formation is obviously not likely to generate sufficient current in the corrosion process itself to reach the state of passive film formation. It is apparently from this point of view that the current density of 10 μa/cm^2 is employed in Mayne's studies. On comparing Fig. 1 and 2, it is seen that the same current density causes much less change on a freshly immersed specimen as compared to the specimen which had been left in solution for 24 hr. It is also readily seen from the typical S-shaped curves which are obtained in anodic polarization studies with metals which form passive films that the current density required to maintain the passive state is much smaller than the initial current to reach the passive state. Therefore, it is concluded that a corroding system must, if the analogy is correct, generate in the first instance sufficient current to reach the potential at which oxide film formation takes place. This potential is also referred to as "flade-potential" (9, 10) although flade-potential originally meant the resting potential before film breakdown occurred.

It is seen from Fig. 2 that in two different solutions like (*a*) 0.04*N* NaOH + 0.001% NaCl and (*b*) 0.04*N* NaOH +0.05% NaCl steel can be polarized to the potential of oxygen evolution within a few minutes by choosing the appropriate current density. If the time of measurement is increased, the current density may perhaps be reduced in the case of solution (*a*), but this is immaterial in the present discussion. It is, therefore, possible to find out, for the same time of measurement, at which current densities the different solutions containing increasing concentration of chloride are polarized to reach either the potential of oxide film formation or of oxygen evolution. When this was done and the log current density was plotted against chloride concentration, the curve shown in Fig. 3 is obtained. Despite the different conditions considered in Fig. 3, it is seen that a characteristic behavior is also indicated in Fig. 3, namely, in all cases the current density makes a jump after a particular chloride concentration is reached. Further, the current density and chloride concentration corresponding to the middle point are practically the same in all cases. Application of such a current density corresponding to the middle point should distinguish between a corrosive and inhibitive solution. Apparently, the jump should indicate the vast change in the current requirement for passivation to be brought about after a certain chloride concentration is reached. Solutions having

higher chloride concentration could not be polarized by the current density corresponding to the middle point. But solutions having chloride concentration corresponding to the region before the jump could be quickly polarized because they show this behavior at lesser current densities also.

The polarization behavior of the two solutions on both sides of the chloride concentration corresponding to the middle point are given in Fig. 4. As already pointed out, the time over which a certain potential is reached is a function of the current density. It is seen from the figure relating to a chloride concentration on the high side of the middle point that, although the potential rises to start with, there is a subsequent fall which is not observed in the case of the curves corresponding to the chloride concentration on the low side of the middle point. This is significant. When the metal is made positive, the field produced attracts the chloride ions to the metal surface. Adsorption of Cl^- on the metal-oxide film is facilitated by such conditions. If the chloride concentration is such that the rate of breakdown of the oxide film is higher than the rate of formation of the oxide film, then passive conditions will not be maintained. In this sense, the absence of a fall of potential may be said to be more characteristic of the inhibitive system than the rise to the particular potential. However, at the instant at which current is applied, in view of the well-known affinity of OH^- for metal surface and the presence of OH^- in much larger concentration at the vicinity of the electrode, conditions may be favorable for the potential to rise as is observed in Fig. 4 in both cases. However, when the field is maintained, adsorption of Cl^- will be facilitated, and the chloride concentration should not be such as to breakdown the oxide film. In a system in which no external current is applied, the same situation is expected to arise over a longer period of time.

The polarization curves for various chloride concentrations in Fig. 5 show that below a certain concentration the potential is maintained constant after the initial rise, but at higher concentrations the potential falls back. The highest concentration at which the potential remains constant and the lowest concentration at which the potential begins to fall are on the two sides of the middle point, as is to be expected. When the concentration of OH^- is changed, this behavior is also changed, which is to be expected. At concentrations lower than 0.01*N*, 0.02% NaCl cannot be tolerated. The method is also helpful in picking out the inhibitive system when both NaOH concentration and chloride concentration are varied. It is seen from Fig. 7 that out of the 9 concentrations only one is able to maintain the potential after the initial rise. In Fig. 9, the implications of such an approach are examined. On increasing the duration over which the observations are made, we get the interesting results that at concentrations of chloride lower than that corresponding to the middle point, there appears to be an exponential increase in the time over which the fall can be observed. The exact relationship, however, requires further study. If the corrosion current is considered to be less than 10 $\mu a/cm^2$, application of 290 $\mu a/cm^2$ may be said to accelerate the test more than 30 times.

Table II. Changes in potential with time in the absence of applied current of steel specimen immersed in 0.04*N* NaOH-NaCl solution

Concentration of NaCl, %	Potential in millivolts *vs.* SCE					
	1 hr	2 hr	3 hr	4 hr	1 day	2 days
0.001	—243	—237	—228	—231	—380	—460
0.01	—250	—250	—245	—250	—302	—302

The experiments with deaerated solutions shows that the extent of variation is not critical with regard to present study. Similarly, stirring appears to bring about only a minor change in the results obtained.

A comparison of the potential measurements in the absence of applied current with the polarization experiments can be made with the help of Table II.

It is seen from the table that in all cases the potential tends to become more negative with time. Further, as the chloride concentration is increased, the potential becomes more negative. These can hardly be useful criteria for distinguishing between the two types of solutions. It was earlier put forward (11) in connection with the potential changes following pretreatment of the metal surface that the potential will not change when both anodic and cathodic areas are increased or diminished and that diminution of the cathodic area as well as increase of anodic area can shift the potential in negative direction. Thus the

0.001	—	Unattacked
0.005	—	Unattacked
0.01	12th day	A tiny spot of rust formed at the top corner of one specimen. One spot at the edge of the second specimen; otherwise unattacked.
0.02	6th day	One elongated patch of rust on one side of one specimen. Three spots of rust on edge, one at the corner and suspension hole on the second specimen. Otherwise unaffected.
0.03	6th day	3 elongated patches of rust on the one specimen; and one elongated patch on the second specimen, otherwise unaffected.
0.05	1 day	Several elongated patches on both specimens.
0.1	4 hr	Widely attacked.
0.5	4 hr	Widely attacked covering almost the whole surface.

interpretation of changes in potential in the negative direction does not lend itself to an unambiguous explanation. It is not unlikely that with exposure to the medium the oxide film undergoes a certain amount of thickening in the inhibitive solutions which reduces the area over which cathodic reduction can take place and that the fall in potential is not indicative of corrosive conditions introduced. The visual observations made in direct corrosion tests for a period of two months, Table III, confirms this view.

Only at a concentration above 0.01% does the surface of the metal become susceptible to attack. The shift in potential in the negative direction in these cases is presumably due to the product of anodic areas where attack can take place.

Conclusions

The corrosive or inhibitive character of the neutral and alkaline solutions containing both corrosive and inhibitive constituents can be evaluated quickly by anodic polarization measurements at fixed current density. The criterion on which the current density should be chosen is indicated. The corrosive character is brought about by not maintaining the potential of the metal so that only reactions which do not involve dissolution can take place. It is likely that this method lends itself for application in the case of other systems where anodic inhibition takes place.

Dissolution of Zirconium in HCl-Methanol

J. R. Aylward and E. M. Whitener

Atomic Energy Division, Phillips Petroleum Company, Idaho Falls, Idaho

ABSTRACT

The dissolution of zirconium in HCl-methanol was studied potentiostatically as a function of HCl concentration and temperature. At low overvoltages the reaction is activation controlled and the rate independent of HCl concentration. In this region preferential grain boundary attack results in etching and separation from the electrode of finely divided particles of α-zirconium. At overvoltages above 0.5v a limiting current density is observed and the metal surface electropolished at HCl concentrations above 1.5M. The current for electropolishing decreases with increasing HCl concentration. The energy of activation at overvoltages of 0.0 and 1.0v (corrosion and electropolishing reactions) was found to be 16.5 and 7.7 kcal/mole, respectively.

The need to reprocess nuclear reactor fuel elements has given impetus to the study of the dissolution of zirconium, aluminum, and stainless steel. The present paper is concerned with the dissolution of zirconium, one of the more chemically resistant fuel element materials. The chemical inertness of zirconium is due to its strong affinity for oxygen and the resulting formation of protective oxide films. Of the anions, only fluoride forms a stronger bond with zirconium than oxygen, so that in aqueous systems zirconium readily dissolves in hydrofluoric acid. Because of the undesirable properties of this reagent in subsequent reprocessing steps, other media not containing fluoride were investigated.

Since the affinity of zirconium for anions decreases in the order $F^- > O^= > Cl^-$, a chloride system appeared to be the logical alternate. The formation of soluble zirconium compounds with chloride may be effected in two ways; (*a*), by changing the potential across the metal/solution interface; (*b*), by using nonaqueous systems. A preliminary investigation indicated that electrolytic dissolution in HCl-methanol [a combination of (*a*) and (*b*)] showed promise for dissolving zirconium as well as other reactor fuel element materials.

Potentiostatic determinations of the potential-current density relationship for zirconium in HCl-methanol solutions were undertaken to define the factors affecting the dissolution, the reactions taking place, and their mechanisms.

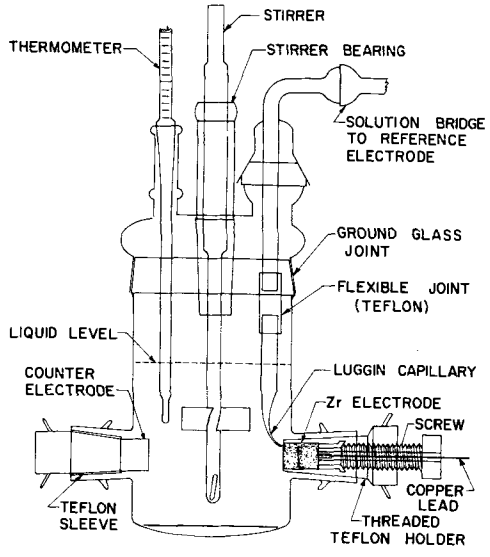

Fig. 1. Electrolysis cell

Experimental

The cell and electrode design used in this work are shown in Fig. 1. Vacuum annealed reactor grade zirconium rod was machined to fit tightly in the Teflon holder so that 1 cm² of electrode surface would be exposed to the solution. A 12-gauge copper wire was inserted into a nipple on the zirconium and crimped. In all cases the resistance from the electrode surface to the end of the copper lead was less than 0.002 ohm. A stainless steel screw mechanism facilitated removal of the zirconium from the Teflon holder on completion of an experiment. The holder was cut with a 19/38 standard taper (T) and provided with stainless steel hooks to give a leak proof fit in the polished T 19/22 glass joint of the cell. The counter electrode was machined from Hastelloy C (Ni 54.6%, Mo 16.0%, Cr 15.5%, Fe 5.5%, W 3.8%, Co 2.5%, Si and Mn 1.0%) to fit the other T 19/22 polished glass joint and a tapered Teflon sleeve used to prevent leaking. A solution bridge with a Luggin capillary connected the cell to a saturated calomel reference electrode (S.C.E.). The absence of appreciable error from IR drop and shielding effects with this capillary was confirmed by the use of interrupter techniques.

The solutions were freshly prepared by saturating absolute methyl alcohol with anhydrous hydrogen chloride gas at 15°C and diluting this with methanol to the desired concentration. Solution concentrations were determined by titration with sodium hydroxide. No attempt was made to eliminate atmospheric gases from the cell because any current resulting from the reduction of dissolved oxygen would be negligible compared to the lowest current density investigated (10^{-4} amp/cm²).

During a given experiment the solution temperature was controlled to within ± 1°C and the stirring speed maintained at 140 ± 10 rpm. Prior to each experiment, the exposed surface of the zirconium electrode was refaced by machining under an argon atmosphere. The resulting work-hardened surface was removed by dissolution at a high current density in an HCl-methanol solution of the same concentration as used in the ensuing experiment.

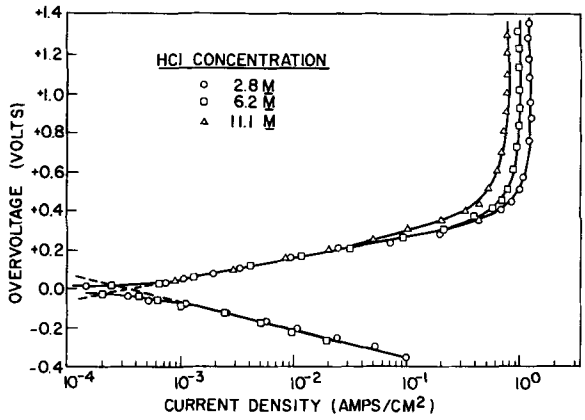

Fig. 2. Overvoltage at a zirconium electrode as a function of HCl concentration at 20°C.

An electronic potentiostat was used to obtain the potential-current density curves. Measurements were initiated at the steady-state mixed potential (approximately −0.54v with respect to the S.C.E.). The potential was increased in 50 mv increments to +1.0v, then decreased stepwise back to the steady-state mixed potential. The cathodic potential-current density curve was measured after completion of the anodic measurements.

This procedure was repeated three times for each run, and the current found to be reproducible to within ±10%. Duplicate experiments were also carried out for each temperature and HCl concentration to check the over-all reliability of the data.

Results

The anodic and cathodic overvoltage[1]-current density relationships for a zirconium electrode in HCl-methanol solutions are shown in Fig. 2 as a function of HCl concentration at 20°C. At low overvoltage values a Tafel relationship is obtained indicating that both the anodic and cathodic reactions are activation controlled. The Tafel slopes at 20°C are 0.115 and 0.15v, respectively. It can be seen that the current density at constant overvoltage in this region is independent of HCl concentration. The corrosion rate, as given by the intersection of the Tafel lines extrapolated to zero overvoltage, is also independent of HCl concentration within the limits of reproducibility (3 to 5×10^{-4} amp/cm²). The reproducibility of the steady-state mixed potential (−0.54v *vs.* S.C.E. for 6.0M HCl) was in the order of ± 10 mv. Because of this, it was difficult to determine with any accuracy the variation of the steady-state mixed potential as a function of solution composition. However, there appeared to be a trend toward more positive values with increasing HCl concentration (30 mv in going from 1M to 10M HCl).

Zirconium dissolution in the Tafel region (from zero to approximately +0.4v) results in an etched surface and is accompanied by the separation of a finely divided black residue from the electrode

[1] Overvoltage is defined in this case as the difference between the potential at any current density and the steady-state mixed potential.

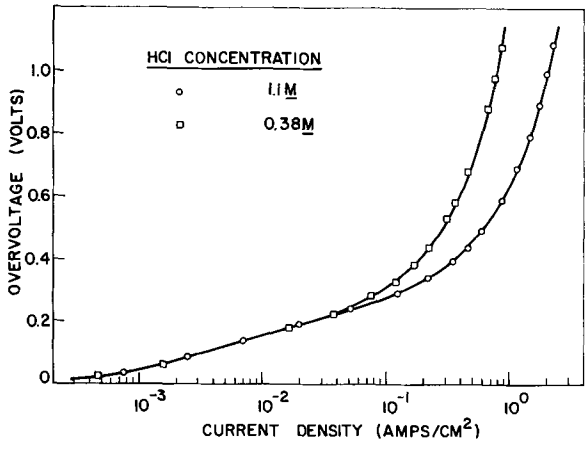

Fig. 3. Anodic overvoltage of a zirconium electrode in dilute HCl-methanol solutions at 20°C.

which is pyrophoric and gives an x-ray pattern corresponding to alpha-zirconium. This zirconium residue is quite passive in HCl-methanol solutions in contrast to bulk zirconium which corrodes at a rate of 3.4×10^{-4} amp/cm². The amount of residue formed decreases with increasing overvoltage.

At high anodic overvoltages ($> +0.5$v) the current density is independent of potential, and the value of this limiting current density decreases with increasing HCl concentration. Also, in this region, the zirconium surface is electropolished and complete dissolution is attained (no undissolved residue).

As shown in Fig. 3, the anodic behavior of zirconium in more dilute HCl-methanol solutions (<1.5M) is different at high overvoltages in that the limiting current density is not well defined and its value at constant overvoltage decreases with decreasing HCl concentration. In this case the surface at high overvoltages is etched (as opposed to electropolished), but the over-all surface is brighter than the etched surface obtained at low overvoltages.

A comparison of the different surface features obtained under the various dissolution conditions mentioned above is shown in Fig. 4. In A and B

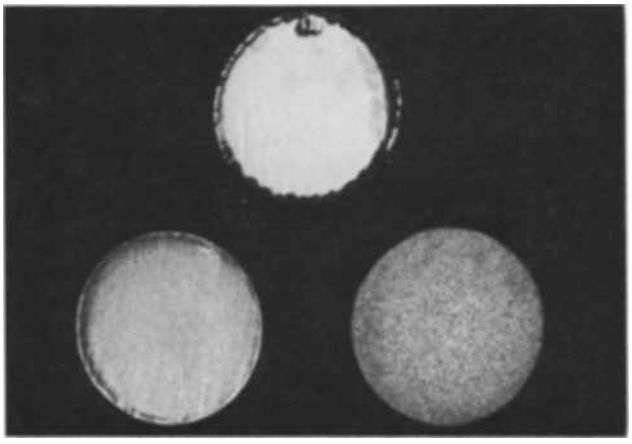

Fig. 4. Electrode surface obtained under various dissolution conditions: A. (top) 6.0M HCl, +0.8v overvoltage, ≈1 amp/cm²; B. (left) 1.0M HCl, +0.8v overvoltage, ≈1 amp/cm²; C. (right) 6.0M HCl, +0.3v overvoltage, ≈100 ma/cm².

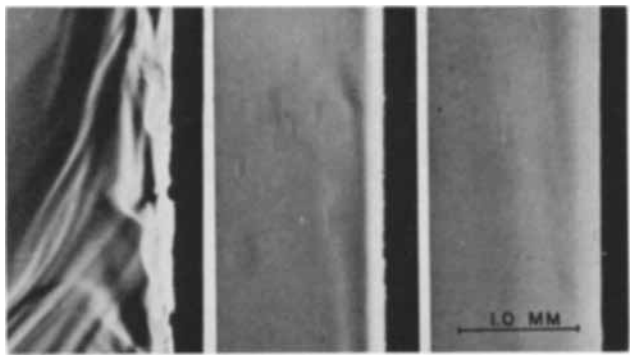

Fig. 5. Schlieren photographs of metal/solution interface during dissolution in HCl-methanol: A (left), 6.0M HCl, 1 amp/cm²; B (center) 1.0M HCl, 1 amp/cm²; C (right) 6.0M HCl, 100 ma/cm².

of Fig. 4 the effect can be seen of a higher dissolution rate at the electrode boundary. This is due to the presence of a considerable product concentration gradient which plays a predominant role in controlling the reaction rate in the limiting current density region. The fact that the gradient is larger at the electrode edge results in a higher dissolution rate at this point. In the region where the reaction is activation controlled an even dissolution rate is observed over the whole surface (electrode C of Fig. 4). Schlieren photographs of the metal/solution interface under conditions corresponding to A, B, and C of Fig. 4 are shown in Fig. 5A, B, and C, respectively. The light areas represent regions of higher refractive index (dissolution product concentration). In Fig. 5A the streaming off of the viscous layer is characteristic of electropolishing, while in B a quiescent concentration gradient typical of concentration polarization is evident. Both A and B were taken at the same current density (≈1 amp/cm²). Figure 5C obtained at approximately 100 ma/cm² (activation-controlled region) shows no significant concentration gradient.

Figure 6 shows the effect of temperature on the anodic overvoltage curves in 6.0M HCl-methanol. As is to be expected, the reaction rate in the activation and electropolishing region increases as the temperature is raised. From these data the energy of activation at overvoltages of zero and 1.0v corresponding to the corrosion and electropolishing

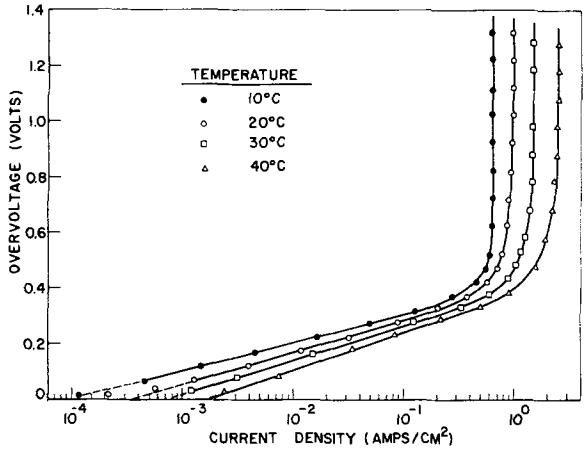

Fig. 6. Effect of temperature on the anodic overvoltage of zirconium in 6.0M HCl-methanol.

reactions was calculated to be 16.5 and 7.7 kcal/mole, respectively.

Discussion

When zirconium is placed in an HCl-methanol solution, dissolution of the metal takes place at a very slow rate to give as products hydrogen gas and a mixture of the various chlorozirconium methoxides. This over-all reaction is shown in [1] where x has values from 0 to 4.

$$Zr + (4-x)HCl + xCH_3OH \rightarrow ZrCl_{(4-x)}(OCH_3)_x + 2H_2 \quad [1]$$

Evidence for this reaction is supported by the identical optical spectra of dissolver solutions and solutions prepared by adding zirconium tetrachloride to methanol. Reaction [1] is believed to take place in two principal steps. First, zirconium reacts with hydrogen chloride to form zirconium tetrachloride and hydrogen gas at the metal/solution interface.

$$Zr + 4HCl \rightarrow ZrCl_4 + 2H_2 \quad [2]$$

The next step [3] takes place primarily in the bulk of the solution (at HCl concentrations >1M) and has little if any effect on the dissolution rate.

$$ZrCl_4 + xCH_3OH \overset{K_x}{\rightleftharpoons} ZrCl_{(4-x)}(OCH_3)_x + xHCl \quad [3]$$

At low HCl concentrations (<1M) and high overvoltage there is some indication that chlorozirconium methoxides may be formed directly at the metal/solution interface. This possibility will be discussed later.

The equilibrium constants K_x for reaction [3] were determined by Simmons and Hansen (1), ($pk_1 = 1.62$, $pk_2 = 5.18$, $pk_3 = 10.4$, and $pk_4 = 18.2$). From these data it is obvious that $ZrCl_4$ and $ZrCl_3OCH_3$ are the main species in solution.

Reaction [2] can be divided into two half reactions; one representing an oxidation [4] and the other a reduction [5]

$$Zr + 4Cl^- \rightarrow ZrCl_4 + 4e \quad [4]$$

$$4H^+ + 4e \rightarrow 2H_2 \quad [5]$$

In reaction [4] it is not to be construed that the reactive species is the chloride ion as such because molecular HCl is present at a higher concentration and may serve just as well. However, if the equilibration $HCl \rightleftharpoons H^+ + Cl^-$ is rapid the two would be kinetically equivalent.

When reactions [4] and [5] are activation controlled their respective rates i_a and i_c expressed in terms of current density are given by

$$i_a = i_0' \exp\left(\frac{1}{b_a}\eta\right) \quad [6]$$

and

$$i_c = i_0' \exp\left(-\frac{1}{b_c}\eta\right) \quad [7]$$

where η is the overvoltage, b_a and b_c constants, and i_0' the reaction rate at zero overvoltage. At zero overvoltage the anodic [4] and cathodic [5] rates are equal and, therefore, i_0' is the corrosion rate (reaction [2]). The cell current density, I, will be given by the difference in the rates of reaction [4] and [5]. Thus,

$$I = i_a - i_c = i_0'\left[\exp\left(\frac{1}{b_a}\eta\right) - \exp\left(-\frac{1}{b_c}\eta\right)\right] \quad [8]$$

This particular form of the equation gives negative values for the cell current when zirconium is the cell cathode and positive when it is the anode.[2]

Under circumstances where a limiting current density is observed, *e.g.*, in the electropolishing region, it can be shown (2, 3) that the equation expressing the current density as a function of overvoltage takes the form

$$I = \frac{i_a - i_c}{1 + i_a/i_l} = \frac{i_0'\left[\exp\left(\frac{1}{b_a}\eta\right) - \exp\left(-\frac{1}{b_c}\eta\right)\right]}{1 + i_0'/i_l \exp\left(\frac{1}{b_a}\eta\right)} \quad [9]$$

where i_l is the limiting current density for electropolishing. From the experimental data the corrosion current and the limiting current density (for electropolishing) are given by

$$i_0' = \exp\left[\, 20.09 - \Delta H_0^+/RT\right] \quad [10]$$

$$i_l = C^{-0.462} \exp\left[\, 14.02 - \Delta H_l^+/RT\right] \quad [11]$$

where C = HCl concentration, $\Delta H_0^+ = 16.5$ kcal/mole and $\Delta H_l^+ = 7.7$ kcal/mole. Equation [9] reduces to the usual Tafel relationship when $\eta > \pm 50$ mv and $i_a \leqq i_l/10$.

The stoichiometric number ν for the anodic reaction can be calculated from the equation

$$\nu = \frac{b_a n\mathbf{F}}{2RT} \quad [12]$$

where n is the number of electrons transferred during one act of the over-all process (equal to four from reaction [4]) and the other terms have their usual significance. Equation [12] assumes a symmetrical energy barrier. The stoichiometric number calculated from the average experimental anodic Tafel slope ($2.3\ b_a = 0.115 \pm 0.005$v) and Eq. [12] is 3.96 ± 0.16. From this it is concluded that the rate-determining step in the activation-controlled region for the anodic process represented by Eq. [4] must take place four times for each act of the over-all reaction. However, the behavior of the steady-state mixed potential and the corrosion rate with changing HCl concentration cannot easily be associated with any simple sequence of reaction steps for the over-all process. The change in the steady-state mixed potential of approximately 30 mv in going from 1*M* to 10*M* HCl is not of real significance because of possible changes in the liquid junction potential (HCl methanol | | KCl

[2] In Fig. 2 this sign convention is disregarded.

aqueous) with HCl concentration. Unfortunately, the Ag, Ag_2Cl_2 electrode was found to be unsuitable as a reference in concentrated HCl-methanol because of the high solubility of Ag_2Cl_2.

The independence of the corrosion rate on HCl concentration can possibly be explained by assuming complete coverage of the zirconium surface with specifically adsorbed Cl^-. This adsorption step could be rapid at the potentials and HCl concentrations involved (4). The next step would then result in the formation of a positively charged zirconium chloride species which could react further with chloride ion or methanol in the double layer to form a soluble product. Thus, the reaction may be divided into three parts:

$$M\text{-}Zr + pCl^- \rightarrow M\text{-}ZrCl_p^{-p} \quad [13a]$$

$$M\text{-}ZrCl_p^{-p} \rightarrow M\text{-}ZrCl_p^{+(4-p)} + 4e \quad [13b]$$

$$M\text{-}ZrCl_p^{+(4-p)} + (4-p)Cl^- \rightarrow M + ZrCl_4 \quad [13c]$$

The stoichiometric number of four indicates that the rate-determining step may be associated with the formation of the zirconium chloride species of [13b].

Under conditions of electropolishing it is generally believed that a solid film is formed on the metal surface which in the steady state is dissolving as fast as it is formed (5, 6). The rate-determining step is, in this case, the "physical" dissolution of the film and, therefore, independent of electrode potential. Increasing the potential merely increases the steady-state film thickness. Since the film is the controlling factor in the dissolution, the differing rates of removal of cations from the metal lattice due to their special positions within the lattice are no longer of significance. On the other hand, in the nonelectropolishing region preferential attack at grain boundaries, etc., results in etching and the separation of small bits of metal from the surface. (The reason for the passivity of this undissolved residue in HCl-methanol solutions is not apparent.) Fedot'ev and Grilikhes (6) attribute electropolishing to the formation of oxide films rather than salt films. This may be true for the most part in aqueous systems, but we do not believe it to be the general case in nonaqueous solutions. It is difficult to see how increasing the HCl concentration would decrease the dissolution rate of an oxide film (see Fig. 2), but this effect is conceivable if the film were a chloride of zirconium.

At low HCl concentrations and high current densities the transport of HCl to the electrode surface becomes rate determining (concentration polarization), and the value of the limiting current density decreases as the HCl concentration is decreased (see Fig. 3). Under these conditions the electrode surface cannot be completely covered with adsorbed Cl^- so that it becomes possible for the solvent (methanol) to play a direct part in the dissolution mechanism with the resulting formation of chlorozirconium methoxides at the metal/solution interface. This, combined with the fact that the rate of transport of Cl^- to the metal surface would increase with increasing potential (in the absence of supporting electrolyte), may explain the ill-defined limiting current density observed at low HCl concentrations.

Effect of Partial Dissolution of the Oxide Film on the Aqueous Corrosion Resistance of Zircaloy-2

S. Kass and D. B. Scott

Bettis Atomic Power Laboratory,[1] Pittsburgh, Pennsylvania

ABSTRACT

The aqueous corrosion resistance of corrosion-tested Zircaloy-2 was found to decrease markedly after vacuum heating to dissolve the oxide film partially. Although a complete explanation of the accelerated corrosion is not proposed, several possible mechanisms are presented.

During the fabrication of Zircaloy-2 components for pressurized water reactors, it is occasionally desirable to remove the oxide film formed by various corrosion tests to ascertain that the corrosion resistance has not been reduced by processing methods. A potential method for accomplishing this utilizes zirconium's high affinity for oxygen. The components are vacuum annealed for sufficient time to dissolve the oxide film into the metal completely and to minimize the oxygen gradient in the vicinity of the surface. Although the feasibility of the process has been demonstrated (1), the work described herein was performed to determine the corrosion resistance of previously corrosion tested Zircaloy-2 which was improperly vacuum annealed and produced only partial dissolution of the oxide film.

Experimental

Specimens of Zircaloy-2,[2] measuring 1.5 x 0.5 x 0.1 in. prepared from one section of strip, were corrosion tested for 3 or 14 days in 360°C water using techniques and precautions previously noted (2). After the weight change measurements were recorded, specimens were annealed in vacuum (dynamic system, less than 0.1μ Hg pressure) for 40 or 60 min at 590°C or for 60 or 80 min at 700°C. All specimens were then returned for corrosion testing in 360°C water. Weight gains were determined periodically during the final corrosion exposure. The corrosion product was not removed after the vacuum treatment or during the subsequent corrosion exposure.

Vacuum annealing times and temperatures were selected in accordance with ref. (1) to produce incompletely dissolved oxide films.

Results

Corrosion test results depicted graphically in Fig. 1 and 2, show that Zircaloy-2 corrodes at an accelerated rate when the oxide film formed during the initial corrosion exposure is partially dissolved in the base metal by thermal treatment. Re-examination of the data when plotted in the conventional manner on logarithmic scales (Fig. 3) shows the influences of annealing times and temperature. Coupons annealed at 590°C after the initial corrosion test showed little or no variation of weight gain with variation in annealing time. Similarly, little or no dependence of corrosion kinetics on annealing time is noted for coupons treated at 700°C. Large differences in the corrosion behavior as functions of annealing temperature, however, are apparent. Coupons which were tested for 3 days at 360°C and subsequently annealed at 590°C showed weight gains of 9-12 mg/dm^2 in the first 3 days of re-exposure. In comparison, coupons which were not vacuum annealed showed weight gains of only 4 mg/dm^2 after 3 days of re-exposure. The same general trends are noted for specimens tested for 14 days, vacuum annealed at 700°C, and re-cor-

rosion tested. Treated specimens showed weight gains of 41-45 mg/dm^2 after 3 days of re-exposure, while those not treated showed gains of only 1-2 mg/dm^2.

Corrosion films on the coupons tested for 3 days and treated at 590°C were black throughout the test; those treated at 700°C were gray-black. No evidences of spalling or flaking were observed. It should be noted that the weight changes of the specimens not vacuum annealed agree with previously reported Zircaloy-2 curves (2-4).

Discussion

It is not believed that the heating alone causing modifications in the material microstructures produced the higher corrosion rates as it has been shown that the corrosion resistance of Zircaloy-2 does not vary with heat treatment provided temperatures are maintained below 815°C (5).

Chirigos and Thomas observed that the oxide grows by the inward diffusion of oxygen ions through the film and that new oxide is produced at the metal-oxide interface (5). The corrosion initially follows a quasi-cubic relationship with time, and the rate decreases as the oxide film thickens. As vacuum-annealing treatments reduce the oxide film thickness through the mechanisms of oxygen diffusion into the metal (6), the oxygen uptake rate during subsequent corrosion should increase. This explanation appears to be an oversimplification of the phenomena observed if Fig. 2 is re-examined. During the first 14 days of corrosion, where the specimens were initially in the bright etched condition (unoxidized surfaces), an average weight gain of 18 mg/dm^2 was obtained. Three days of corrosion exposure after heating the oxidized samples in vacuum produced an additional weight gain of 44 mg/dm^2, a value far in excess of what would be expected if complete oxide film dissolution was caused by the thermal treatment.

Another factor which must be considered is the oxygen enrichment of the metal at the metal-oxide interface. Calculations of the oxygen uptake and gradient in the metal produced by the treatments have shown the 700°C specimens to contain in excess of (2 w/o) oxygen at the interface and for some distance below, while values for the 590°C specimens approximate 0.1 w/o. Since Rubenstein and co-workers have shown that oxygen enriched Zircaloy-2 corrodes more rapidly than normal material (7), it is suggested that after subsequent corrosion exposure the vacuum annealed specimens should initially corrode more rapidly than specimens not containing an oxygen-rich area at the interface. This explanation is untenable if the growth of the oxide film is controlled by the diffusion of oxygen through the film. The explanation is reasonable (*a*) if marked changes in film characteristics occurred during the vacuum anneal, or (*b*) if the growth of the oxide film is controlled by other factors in addition to simple diffusion.

The suggested change in kinetics and accelerated corrosion rates may be explicable on the basis of the memory effect noted by Thomas and Kass (4) in experiments where Zircaloy-2 was initially tested in steam at 400°C and then transferred to water at 360°F. Specimens showed a peculiar tendency for the corrosion rate characteristics of the high temperature to persist for considerable times after transfer to the lower temperature. The memory phenomenon appeared to be explicable on the basis of anion diffusion as the oxide film is believed to grow by the diffusion of ions via oxygen ion vacancies from the water/oxide interface to the metal/oxide interface. It was expected that an oxide film of a given thickness formed at a higher temperature would have a greater oxygen ion vacancy gradient than when formed at a lower temperature. It was not surprising, then, that on returning the specimens to the lower temperature an initially higher corrosion rate operated until the excess anion vacancy gradient was removed. Analogous behavior is noted here. In the case of the 3-day test (Fig. 1) it is seen that the untreated specimens gained about 4 mg/dm^2 (an increase of 36%) while the 60 min, 590°C treatment produced weight gains of 11 mg/dm^2 (an increase of 100%) after the return to corrosion test. The accelerated corrosion rate associated with the excess vacancy gradient must also result in a continued rapid rate in the generation of vacancies. Thus the passage of many vacancies is required before the corrosion rate decays to normal. It is noted in Fig. 1 and 2 that times in excess of 84 days are required before the corrosion rate of the heat-treated specimens approaches the rate of the untreated specimens.

The authors agree with Misch and Gunzel (6) who studied the effects of vacuum heating and electrical conductivity of the oxide films formed on zirconium that more evidence concerning the ZrO_2 structure, diffusion rates, and electrical properties is desirable.

Physical and Dielectric Properties of the Metal-Silicon Dioxide-Silicon System

J. L. Sprague, J. A. Minahan, and O. J. Wied

Research Laboratories, Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

Thin film capacitors using silicon dioxide as the dielectric material have been prepared by the thermal oxidation of silicon. The physical and optical characteristics of the oxide dielectric are given, and the permittivity and loss tangent of the capacitors are shown as functions of a-c frequency and d-c bias. The dielectric properties are seen to be functions of the conductivity type and resistivity of the substrate silicon.

It is possible to fabricate a capacitive device with silicon dioxide as the dielectric material by thermally oxidizing silicon at high temperatures. This paper describes the results of physical measurements made on the dielectric film, presents new dielectric measurements on the metal-silicon dioxide-silicon system, and gives a qualitative explanation for the shape of the observed dielectric curves.

The measured capacitance *vs.* applied d-c bias curves are similar to those reported by Moll (1), except that at low frequencies we have observed a unique capacitance minimum in many cases. Such a minimum was found by Brown (2) in measurements of the differential surface capacitance of a germanium sample, and predicted by Pfann and Garrett (3) for the more general case of the metal-insulator-semiconductor system. In each of these studies a change in the character of a space-charge region at the semiconductor surface was given as the reason for the observed capacitance variations. This mechanism is similar to that described by Uhlir (4) to explain the operation of the nonlinear p-n junction capacitor. In addition to the variation of capacitance with d-c bias, we have observed distinct dispersion effects in the frequency range studied. These effects are due, it is believed, to charge exchange between the bulk of the silicon and surface states or an inversion region at the surface of the semiconductor. Such charge exchange has been discussed by Lehovec (5).

Experimental Techniques and Results

Physical characteristics of the silicon dioxide film.—All measurements were made on films formed by the thermal oxidation of silicon at 950°C. Disks, 0.6 cm diameter, of single crystalline, noncompensated silicon were first cleaned by briefly etching them in a hydrofluoric acid-nitric acid solution followed by a series of recirculating hot deionized water, cold deionized water, and methyl alcohol rinses. The disks were then oxidized in a furnace in which steam was introduced at atmospheric pressure by passing argon through a heated deionized water bubbler.

The dielectric constant of the films was determined as follows. First, the capacitance of a parallel-plate capacitor consisting of optically polished low resistivity n-type silicon as one electrode, the thermally grown silicon dioxide film as the dielectric, and an evaporated metal plate as the counter-electrode was measured. Then the oxide thickness was determined by multiple-beam interferometry, and the permittivity of the silicon dioxide layer calculated using the standard parallel-plate capacitance formula. By this method, a relative permittivity of 3.82 $\pm$ 0.02 was found. For comparison, Von Hippel (6) found a value of 3.78 for several different samples of fused silica and quartz.

Silicon dioxide films were stripped from the silicon substrate by etching with hydrogen bromide (7). This method is similar to one described by Tannenbaum (8), except that the bromide is used as the etching agent rather than chlorine. The films showed an absence of crystalline structure when studied by means of x-ray diffraction and optical microscopy and gave an infrared absorption spectra identical to that of fused silica. The absorption spectra, in the u.v. and visible regions, of films which had been irradiated with u.v. light, high energy x-rays, and gamma rays were also studied. These spectra showed an absence of anion vacancy absorption, indicating that, as expected, the films were of very high purity.

Finally, the index of refraction of the films was found to be equal to 1.458 by matching them *vs.* different solutions of normal-amyl-phthalate and carbon disulfide. Comparing with other forms of noncrystalline silicon dioxide, opaline silica ($SiO_2 \cdot X\ H_2O$) has an n = 1.40 — 1.46 which increases

with decreasing hydration, while lechatelierite, a natural glassy form of silica, has an index of refraction of 1.458—1.462. Therefore, we conclude that the thermal oxide film formed was a high-purity form of amorphous or glassy silica, similar to "dry" opal or lechatelierite.

Dielectric properties of the metal-silicon dioxide-silicon system.—Dielectric measurements were made on a standard General Radio 716-C Schering bridge with a Rhode and Schwarz Tunable Detector and Dumont Type 347 Oscillator. Included in the bridge circuit was a network which permitted a known d-c voltage to be applied across the sample. The capacitors measured were constructed as follows: 0.6 cm diameter disks of single crystalline noncompensated silicon were oxidized for 5 hr at 950°C by the method outlined above. This gave an oxide film thickness of around 1.14 x 10^{-4} cm. Then the oxide was removed from one side of each disk by lapping or sandblasting and metal plates were evaporated, one directly onto the silicon as an ohmic contact and one onto the oxide film as a counter electrode. The capacitive area of the devices was determined by the area of the metal plates which was 0.178 cm^2.

Figures 1 and 2 show the frequency dependence of capacitance and loss angle, measured at zero d-c bias, for n- and p-type capacitors, respectively. The capacitance of n-type capacitors is seen to be frequency invariant while the loss angle increases with increasing resistivity indicating that there is an ohmic contribution due to the bulk silicon. The reason why the 1 ohm-cm and 20 ohm-cm loss angle curves in Fig. 1 cross is not clearly understood, but this may be due to different resistance values for the ohmic contacts on the two samples. The p-type units, on the other hand, show a strong

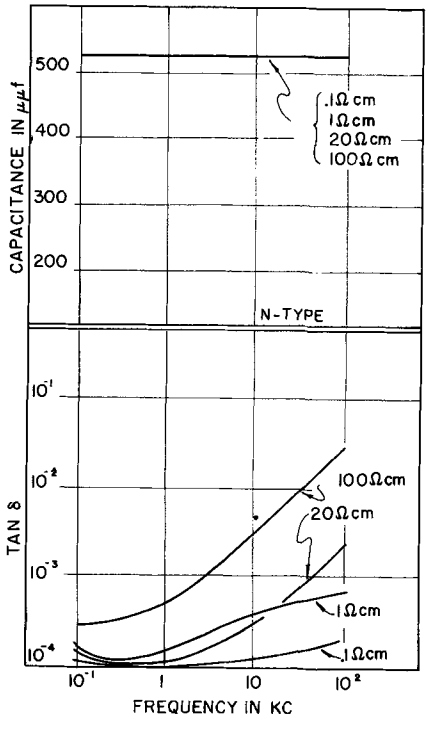

Fig. 1. Frequency dependence of capacitance and loss angle, at zero bias, of n-type capacitors.

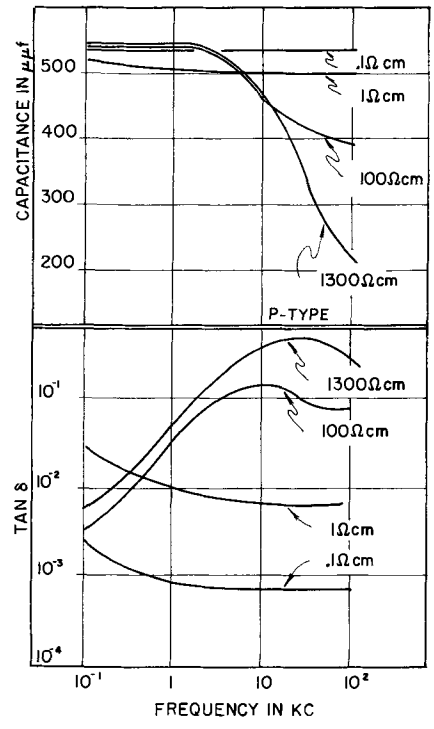

Fig. 2. Frequency dependence of capacitance and loss angle, at zero bias, of p-type capacitors.

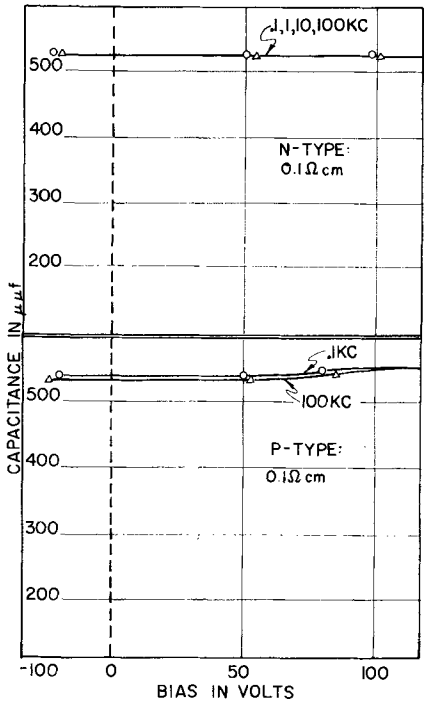

Fig. 3. Bias and frequency dependence of capacitance of 0.1 ohm-cm capacitors.

capacitance variation, particularly with the higher resistivity material, and the over-all dielectric response indicates a relaxation type phenomenon. It appears, in Fig. 2, that the relaxation frequencies for the 0.1 ohm-cm and 1 ohm-cm material are lower than the lowest measured frequency of 10^{-1} kc. This would account for the intersection of the 100 and 1300 ohm-cm curves with those for the 0.1 and 1 ohm-cm material.

Figure 3 shows the bias and frequency dependence of capacitance for capacitors made from 0.1

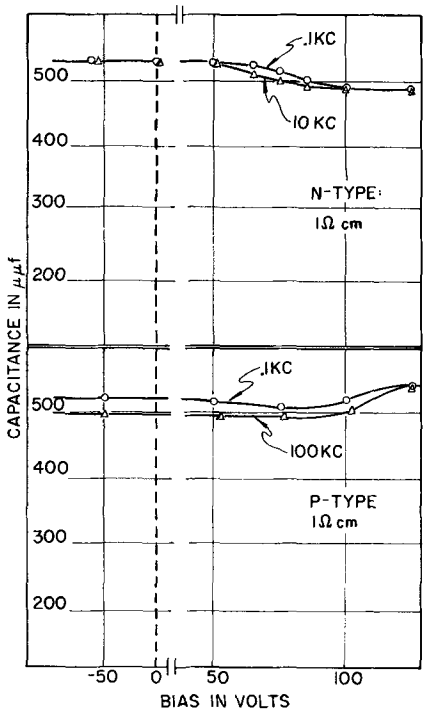

Fig. 4. Bias and frequency dependence of capacitance of 1 ohm-cm capacitors.

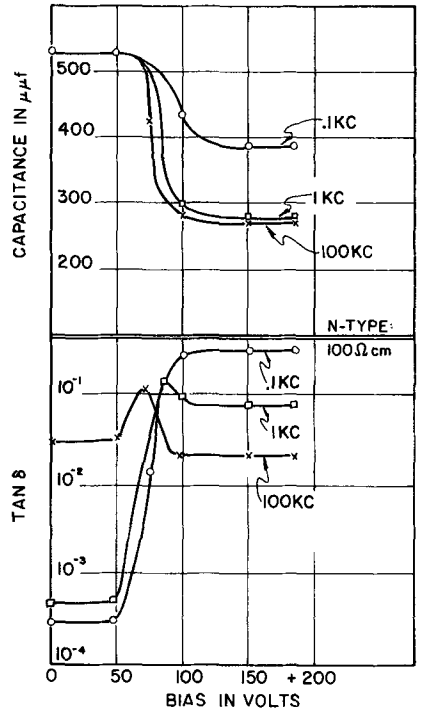

Fig. 5. Bias and frequency dependence of capacitance and loss angle for 100 ohm-cm n-type capacitors.

ohm-cm silicon. The sign of the potential indicates the polarity of the d-c voltage applied to the ohmic silicon contact. As is seen, with n-type silicon capacitance is bias and frequency independent, while with the p-type material there is a slight frequency dispersion and increase in capacitance starting around 70v. As Fig. 4 shows, these effects are amplified with 1 ohm-cm material, both types of capacitors demonstrating a bias and frequency dependence. However, whereas the capacitance of n-type units decreases with increasing bias, that of p-type capacitors increases at high positive bias.

Figures 5 and 6 show the bias effects on capacitance and tangent δ for 100 ohm-cm material, n- and p-type, respectively. Here the bias and frequency sensitivity is considerable, and there is evident a certain mirror-image symmetry between the two types of capacitors. While no capacitance minimum was observed with these particular n-type units, others have shown such a minimum in the lower frequency curves (see Fig. 8B). The loss

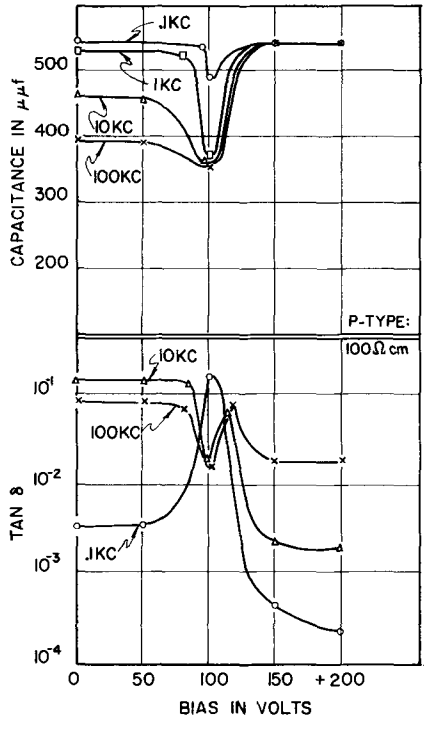

Fig. 6. Bias and frequency dependence of capacitance and loss angle for 100 ohm-cm p-type capacitors.

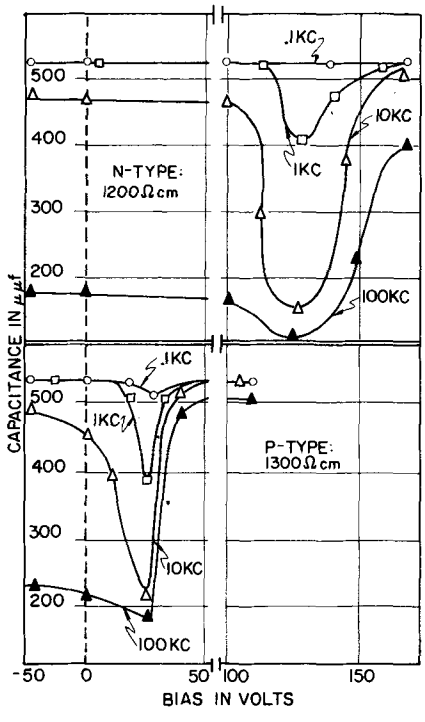

Fig. 7. Bias and frequency dependence of capacitance of 1000 ohm-cm capacitors.

angle curves are seen to be exceedingly complex, and the exact cause of these complexities is not clearly understood at this time, as is pointed out below.

As would be expected, these effects are even greater with 1000 ohm-cm material. This is seen clearly in Fig. 7. Interestingly, however, the 1200 ohm-cm n-type curve shows that this material has been converted to p-type during the oxidation process. This was possibly due to the introduction of boron into the system from Pyrex glassware associated with the quartz furnace tube. This phenomena has been encountered by Law (9) during his studies on the surface properties of vacuum cleaned silicon.

Theoretical Discussion

The capacitance *vs.* d-c bias p-type curves at high frequencies and the corresponding n-type curves which have been discussed so far are similar to those of Moll (1). That is, they show an increasing or decreasing capacitance, respectively, as bias is increased and the absence or near absence of a capacitance minimum. On the other hand, the lower frequency p-type curves all show a definite capacitance minimum, as was encountered in the work of Brown (2) and predicted by Pfann and Garrett (3). It is evident, therefore, that the dielectric response of the metal-silicon dioxide-silicon system is strongly dependent on the measurement frequency, and this fact must be taken into consideration in evolving any theoretical model for the system.

Figure 8A shows a theoretical curve, after Garrett and Brattain (10), of capacitance *vs.* surface potential for an oxide capacitance of 287 $\mu\mu$f in series with the space charge capacitance of 100 ohm-cm n-type silicon. Figure 8B shows, for comparison, experimental curves of capacitance *vs.* bias for the metal-silicon dioxide-silicon system in which the oxide capacitance is also 287 $\mu\mu$f, and the bulk starting material was 100 ohm-cm n-type silicon. These latter curves differ from the experimental n-type curves in Fig. 5 only in that the oxidation time was longer (19 hr) and therefore the oxide formed thicker (2.06×10^{-4} cm), and that here a capacitance minimum was observed. The theoretical and lower frequency experimental curves are seen to be similar in shape.

The shape of the theoretical curve is due to the fact that, with n-type silicon, as one goes from a strongly positive to strongly negative surface potential the space charge at the surface of the semiconductor goes from an accumulation to a depletion and finally into an inversion region. The capacitance minimum is caused by decreasing accumulation and depletion capacitances followed by an increasing inversion capacitance as Y goes from strongly positive to strongly negative. The expressions used in calculating the theoretical curve are given in the appendix at the end of the paper.

Figure 9 shows a proposed equivalent circuit for the metal-silicon dioxide-silicon system. In it, C_o is the oxide capacitance, C_d is the depletion region capacitance, C_a is the accumulation region capacitance, r_{si} is the bulk silicon resistance, and Σ is a

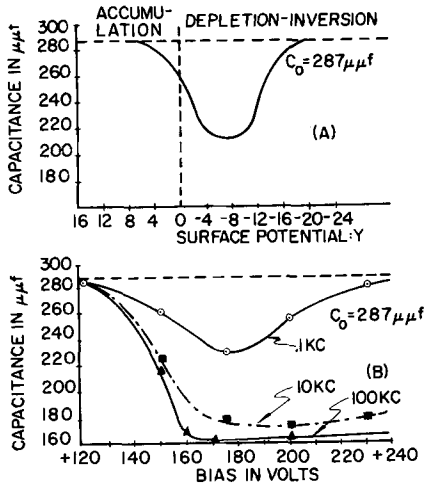

Fig. 8A. Theoretical curve of capacitance vs. surface potential for oxide capacitance in series with space charge capacitance for 100 ohm-cm n-type silicon.

Fig. 8B. Bias and frequency dependence of capacitance of metal-silicon dioxide-silicon (100 ohm-cm, n-type) system.

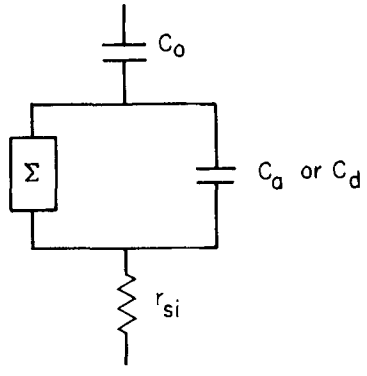

Fig. 9. Equivalent circuit for metal-silicon dioxide-silicon system

complex admittance. Σ has contributions from an inversion region capacitance, from charge leakage through the space charge region, and from charge exchange between the semiconductor bulk and surface states at the silicon-silicon dioxide interface or an inversion region at the silicon surface. Using this equivalent circuit, one can explain the shape of the curves in Fig. 8B as follows. It is postulated that there is sufficient positive charge, at zero bias, in donor type surface states to cause an accumulation region on the semiconductor surface. At very low frequencies one approaches a bias independent capacitance corresponding essentially to C_o. This is due to the fact that the impedance of Σ is much less than that of C_d or C_a at these frequencies and they are essentially shunted by it. At higher frequencies, for example at 0.1 kc, one observes a curve with a capacitance minimum similar in shape to the theoretical curve. Here as one increases the potential on the silicon, the space charge goes from an accumulation to a depletion to an inversion region. Finally, at high frequencies, one sees only the series combination of C_o and C_d or C_a due to the high relative impedance of Σ. In the experimental n-type curves where a capacitance minimum has not been observed (for example, Fig. 4 and 5) apparently there was insufficient d-c potential to form an inversion region.

With p-type silicon the effect is reversed. Here the positively charged surface states cause an inversion region to be formed on the semiconductor, and increasing the potential on the silicon causes the space charge region to go from inversion to depletion and finally to accumulation. Thus, the mirror symmetry between n- and p-type capacitors.

The decreasing amount of capacitance change with bias as the silicon resistivity decreases is readily explained by the fact that as bulk doping increases, C_a and C_d increase also. At a high enough doping level they become so large that one only observes the series oxide capacitance. On the other hand, the position of the capacitance minimum is determined by the charge density in the donor-type surface states. The complex form of the loss angle curves and frequency dispersion of capacitance are due to Σ. The exact form of Σ is presently not completely understood. It is believed, however, that the frequency dispersion in the inversion capacity region is due to the relaxation effects involved in minority carrier exchange between the inversion layer and bulk of the semiconductor through the depletion region, while dispersion in the depletion or accumulation region is due to minority and majority carrier exchange through the space charge region between the bulk silicon and surface states at the silicon-silicon oxide interface. A complete understanding of Σ should make it possible to interrelate curves of capacitance *vs.* total charge and *vs.* space charge in a similar manner to the way in which conductance change and charge are related in field effect studies. In the present studies, if one assumes that at high frequencies only an accumulation or depletion capacitance is observed in series with C_o, then from the curves in Fig. 8 one can calculate the surface state charge as a function of Y for the accumulation and depletion conditions. Such calculations have been made by Lehovec for 100 ohm-cm n-type silicon (5). Ultimately, simultaneous capacitance and field effect measurements should serve as the best check of the model.

Conclusions

The dielectric response of the metal-silicon dioxide-silicon system is strongly dependent on the resistivity and conductivity type of the substrate silicon. This is due to the presence of a space charge region at the surface of the semiconductor underneath the oxide. When low resistivity silicon (0.1 ohm-cm n-type or lower resistivity p-type) is used, the observed dielectric response is essentially that of the silicon dioxide film. Capacitors made using such material exhibit the excellent dielectric properties of high-purity amorphous silica: bias and frequency insensitivity, high insulation resistance, high power factor, low temperature coefficient, radiation resistance, and high stability. On the other hand, as the resistivity of the silicon is increased one observes an increasing dielectric contribution due to the space charge region in the silicon. When high resistivity material, such as 100 ohm-cm, is used, considerable capacitance change with both bias and frequency is observed. The present difficulty in using such capacitors in varactor applications is in reproducibly controlling the charges in the silicon surface states and therefore controlling the position of the capacitance minimum. This problem is probably not insolvable, however.

When the exact relationships between dielectric response and the nature of the silicon surface are understood, measurements of the type described in this paper should become a valuable tool in studying silicon surfaces.

Properties of Evaporated Film Capacitors

F. S. Maddocks and R. E. Thun

IBM Command Control Center, Federal Systems Division, Kingston, New York

ABSTRACT

The preparation of film capacitors by evaporation is described utilizing the following dielectric materials: silicon monoxide, silicon dioxide, magnesium fluoride, lanthanum fluoride, cerium fluoride, cerium dioxide, and zinc sulfide. The dielectric constants and loss tangents of these materials are presented as functions of the deposition parameters, and the contribution of the lead and condenser plate losses to the apparent loss tangents is shown. The necessary evaporation conditions are discussed for optimizing the dielectric properties of the chosen insulator material. For cerium fluoride, a deposition method utilizing a controlled partial decomposition is described yielding dielectric constants up to $\epsilon/\epsilon_0 = 300$ without an undue increase of the capacitor losses.

In the field of microelectronics, development of component and interconnector networks produced by the vacuum evaporation of metals, dielectrics and, to a more limited degree, semiconductors has made rapid progress during recent years. Dielectrics serve two purposes in these "thin film" circuits: they are used as insulating layers between crossing or superimposed conductor patterns and as capacitor dielectrics. In both cases, uniformity, good adhesion to substrates and other film materials, high electric breakdown strength, and low dielectric losses are desirable. The requirements regarding the permittivity, however, differ to a certain extent: a low dielectric constant is preferable for insulation films, a high dielectric constant for capacitor dielectrics.

The choice of dielectric film materials is usually limited to inorganic compounds, since dielectric films are often deposited jointly with materials requiring high deposition or annealing temperatures. The selection of suitable dielectric materials has been hampered, however, by the lack of data on the electrical and mechanical properties of most inorganics evaporable without decomposition. In view of this situation, this study was aimed at the compilation of data on the electrical and mechanical properties of the most common dielectric film materials and the development of a suitable capacitor dielectric of high permittivity, *e.g.*, $\epsilon/\epsilon_0 \geq 100$.

Deposition Techniques

A New York Air Brake vacuum system of the type R2H with an 18-in. glass bell jar was used for film deposition. Its 6-in. diffusion pump yields a vacuum of 1×10^{-5} torr or better in less than 1 hr. The depositions were performed between 10^{-6} and 10^{-5} torr.

Dielectric film thickness was monitored during deposition by recording the change of optical reflectance at a wavelength of 4358Å with an optical densitometer (Welch Densichron) coupled to a L&N millivolt recorder. Metal capacitor plate and land thicknesses were controlled by monitoring their resistance. Tolansky's multiple interference method was used to obtain the accurate film thickness after removal of the samples from the bell jar.

The coating chamber was equipped with a mask changer to permit deposition of the capacitor array shown in Fig. 1 without breaking the vacuum. In this mask changer (Fig. 2), two 1×3-in. substrates are positioned over a rotatable disk with apertures for four masks. Two masks yield the upper and

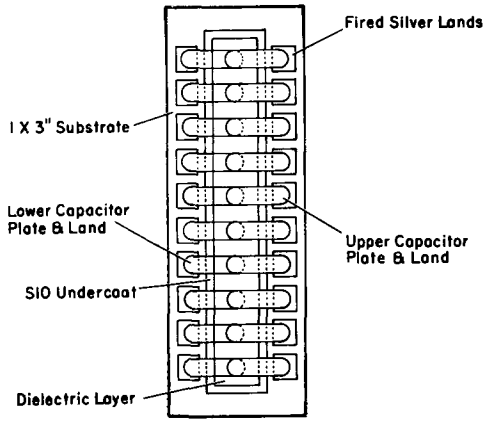

Fig. 1. Evaporated capacitor array

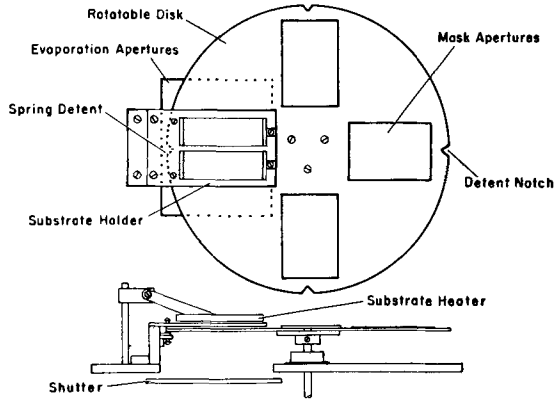

Fig. 2. Mask changer

lower metal capacitor plates, one a silicon monoxide undercoat and a protective top layer, and the fourth the dielectric film to be studied. The geometric registration is accurate to ±0.002-in. The substrate can be heated to a temperature of 400°C, measured by thermocouple. A source changer permits evaporation of the different layers from a single source location for a more uniform thickness distribution. It consists of a turntable with outside drive and rubber-sealed feedthrough.

Graphite crucibles have been used successfully for the evaporation of aluminum, but better results were obtained with boron nitride-titanium diboride crucibles made by the National Carbon Company. The dielectrics have been evaporated from a number of different source arrangements. Except as noted later, best results were achieved with a high-purity aluminum oxide crucible (Morganite "Triangle RR"[1] recrystallized alumina) covered with an aluminum oxide aperture plate with an orifice diameter of 0.25 in. The installation of such an aperture plate creates a space of more nearly saturated vapor over the evaporating surface and reduces thereby the decomposition of the evaporant. The crucible is heated by radiation from an enclosing graphite crucible, which in turn is induction heated. The source temperature was monitored by an optical pyrometer.

Substrate Requirements

Early attempts to evaporate capacitors on cleaned, but otherwise unprepared microscope slides yielded a large number of film pinholes, accompanied by electrical shorts between the capacitor plates. Microscopic examination of the glass slides showed extended areas of increased surface roughness which probably represented recrystallization zones. By applying an undercoat of silicon monoxide, however, a sufficiently smooth surface could be obtained to eliminate pinhole formation.

The yield of short-free capacitors was further increased by a proper choice of the metal used for the capacitor plates. Metals of high evaporation temperature such as chromium, nickel, germanium, and iron resulted in a higher percentage of failures, probably due to penetration of the dielectric by the highly energized metal atoms. Gold, an obvious choice because of its low evaporation temperature and high conductivity, also gave poor results. Its high mobility may have caused shorts by grain-boundary diffusion. Of all metals investigated, aluminum yielded the fewest shorts. This can probably be explained by its low evaporation temperature combined with a decreased surface mobility caused by the affinity of aluminum for oxide bonds. Copper, another obvious choice, was not investigated due to the known poor adherence of copper films when not backed by thin chromium layers. With aluminum plates and lands, a 95-100% yield of short-free capacitors could be obtained with most dielectrics investigated. In all cases, the same substrate cleaning procedure was followed, using detergent, water, and alcohol washes under ultrasonic agitation.

[1] Trademark of Morganite, Incorporated.

Electrical Measurements

The dielectric constants and loss tangents of the capacitor samples were measured in the frequency range from 120 cps to 5 mc on two different commercial capacitor bridges. At 120 cps, 1 kc and 10 kc, an ESI Universal Impedance Bridge with adaptors gave capacitance and loss tangent directly. From 30 kc to 5 mc, a Wayne-Kerr 601 Bridge, using a Rhode and Schwarz SBF Signal Generator and USVH Null Detector, yielded the capacitance and the effective parallel resistance, from which the loss tangent was calculated. The dielectric constant was calculated from the capacitor plate area and the thickness of the dielectric without correcting for edge effects, which are small compared to the experimental error.

Film Structure Determination

The crystallographic investigation of the film structures was performed by electron diffraction and x-ray diffraction. Samples for electron diffraction and electron microscopy were prepared on freshly cleaved rock salt substrates which were first coated with a thin amorphous silicon monoxide layer to prevent a preferential crystal growth of the dielectric films.

The optical constants n (refractive index) and k (absorption coefficient) were obtained from reflectance and transmittance measurements of separately prepared dielectric samples on a Beckman DK-2 spectrophotometer, covering the wavelength region from 3000 to 10,000Å.

In cases where the purity of the deposited dielectric films was questionable, samples were submitted to an analysis by x-ray fluorescence and emission spectroscopy.

Dielectric Losses at High Frequencies

The dielectric constant and loss tangent values were measured on layers forming the dielectric of vacuum deposited capacitors. To separate the ohmic lead and plate losses from the true dielectric losses, the electric resistance of leads and plates must either be kept negligible or be independently determinable. In the study of dielectric films, no completely satisfactory experimental solution exists for either approach.

Attempts to obtain low-resistance capacitor plates were not successful. On test capacitors consisting of an optically flat copper electrode coated with the dielectric and a second electrode in contact with the first, the remaining surface irregularities often caused electrical shorts. In addition, the air film at the second dielectric-metal interface caused errors in the electrical measurements. Increasing the thickness of evaporated capacitor plates and leads by electroplating was also unsuccessful, since the surface roughness of thick platings resulted in electrical shorts.

Better results were obtained by determining lead and plate losses with a method given by McLean

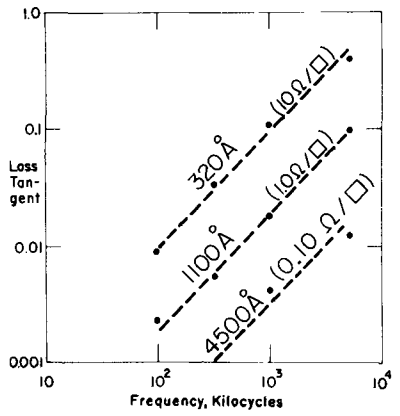

Fig. 3. Loss tangent vs. frequency for evaporated capacitor plates and leads of various thickness in series with a loss-free 1000 pfd air capacitor. The "ohm per square" values given indicate the resistivities of the films, whose dimensions were ⅛ x ⅜ in. (3 squares).

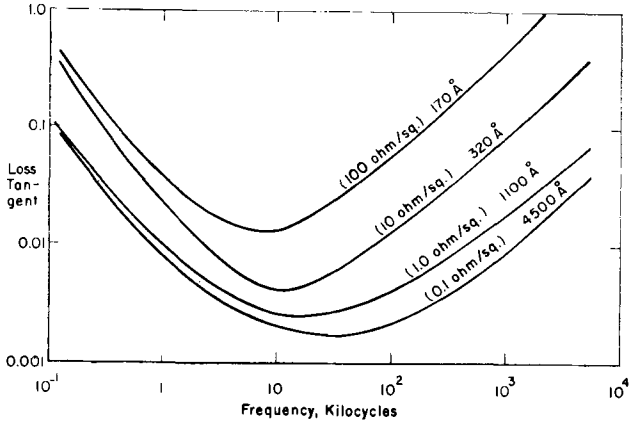

Fig. 4. Loss tangent vs. frequency for an evaporated magnesium fluoride 1000 pfd capacitor with plates and leads of various thicknesses.

(1). The loss tangent of a series capacitance-resistance network is given by

$$\tan \delta = \omega C \, (R_s + R'_s) \qquad [1]$$

where R_s is the "effective series resistance" of the dielectric, and R'_s is the ohmic resistance of the leads and plates. At high frequencies, R_s becomes small against the ohmic resistance R'_s, and the slope of the loss tangent curve approaches 45° in a log log plot. This has been shown by placing evaporated leads and plates, with no dielectric layer, in series with a loss-free air capacitor and comparing the loss tangent curve obtained (Fig. 3) with the one obtained using identical leads and plates containing an evaporated magnesium fluoride dielectric layer (Fig. 4). Figures 3 and 4 also show the dependence of the capacitor losses on the thickness of the leads and plates.

Equation [1] can be solved simultaneously at two points on the 45° slope of the loss tangent curve yielding R'_s, since it can be assumed that $\omega C R_s$ is approximately constant over this interval. With the R'_s values obtained, the loss tangent curve is then corrected point by point to yield the loss tangent of the dielectric itself as a function of frequency. The dielectric losses given in Fig. 6 have been obtained by this method.

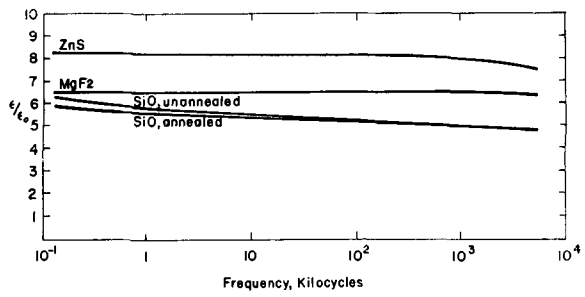

Fig. 5. Dielectric constant vs. frequency for evaporated dielectric materials.

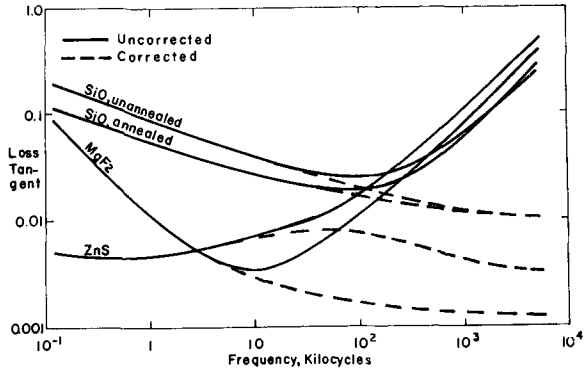

Fig. 6. Loss tangent vs. frequency for 1000 pfd evaporated capacitors. The solid line indicates the loss tangent measured on the evaporated capacitors, the dashed line the corrected loss tangent of the dielectric obtained by the method outlined in the text.

Experimental Results

Dielectrics of low dielectric constant.—The following dielectric materials have been studied: cerium dioxide, cerium fluoride, lanthanum fluoride, magnesium fluoride, silicon dioxide, silicon monoxide, and zinc sulfide.

Several of these materials were found to be unsatisfactory as capacitor dielectrics. Cerium dioxide decomposed strongly when evaporated from aluminum oxide crucibles. Its behavior when evaporated from metal crucibles will be discussed later. Lanthanum fluoride and silicon dioxide films were hygroscopic. These silicon dioxide films were produced by evaporating silicon monoxide in oxygen at a pressure of 5×10^{-4} torr.

The remaining materials all were satisfactory to a greater or lesser extent. Their dielectric constants as a function of frequency are shown in Fig. 5, and their loss tangents as a function of frequency in Fig. 6. Silicon monoxide has been previously used as a capacitor dielectric (2). Its dielectric constant of 6.0 could be reproduced only to about ±10%, due to the strong dependence of the film composition on the deposition parameters. However, its d-c breakdown strength of 2×10^6 v/cm is excellent, even exceeding that of mica (4×10^5 v/cm). This fact and the low dielectric constant make silicon monoxide an excellent choice for an insulation material.

Zinc sulfide yielded the comparatively high dielectric constant of 8.2, good reproducibility (± 5%), and small low-frequency losses when deposited from an aperture source. However, its d-c

breakdown strength of 2×10^5 v/cm is an order of magnitude lower than that of silicon monoxide.

Magnesium fluoride, with a dielectric constant of 6.5, good reproducibility, excellent d-c breakdown strength (2×10^6 v/cm), and very low d-c leakage current (less than 1 μa at 2×10^6 v/cm) exhibited the best dielectric properties of the materials tested. These values were achieved with films evaporated on room temperature substrates. The films were hard and durable, even in thicknesses up to 2μ.

A limited amount of accelerated life test data is available for one of these materials, silicon monoxide. These data indicate that the dielectric material itself is unaffected by thermal stress (—55° to 100°C), relative humidity (20-95%), and power dissipation (0 to 10 w/in.^{2}). However, corrosion of the metal plates and leads causes failure if not protected against excess humidity in combination with the other stresses.

Dielectrics of high dielectric constant.—In a certain range of deposition conditions, cerium dioxide, cerium fluoride, and lanthanum fluoride yielded films exhibiting a thickness dependent dielectric constant much higher than normal. Because of the ease of preparation, cerium fluoride was the most extensively investigated of these compounds. When evaporated from a tantalum crucible at 1450°C, cerium fluoride films have an apparent dielectric constant at 1 kc varying from $\epsilon/\epsilon_0 = 52$ at 1100Å to $\epsilon/\epsilon_0 = 280$ at 5900Å, as shown in Fig. 7. Powder x-ray diffraction measurements made from these films show the structure of bulk cerium fluoride, and measurements of the refractive index yield, in agreement with previously published data (3), a value for the dielectric constant of 2.7 at optical frequencies. Cerium fluoride films evaporated from aluminum oxide crucibles under otherwise identical conditions exhibit a nonthickness dependent dielectric constant of 8.2 at 1 kc.

Careful x-ray diffraction measurements obtained directly from the evaporated films show that films evaporated from oxide crucibles are amorphous, while the metal crucibles yield polycrystalline films, with the c-axis oriented in the plane of the substrate, and the a- and b-axes randomly oriented. Cerium fluoride has a hexagonal cell (a = 7.112Å, c = 1.279Å). Since no significant change in the degree of orientation could be observed with increasing film thickness, the thickness behavior of the dielectric constant cannot be explained by assumptions based on crystalline anisotropy. Ferroelectricity is also ruled out, since it too does not explain the observed thickness dependence of the dielectric constant.

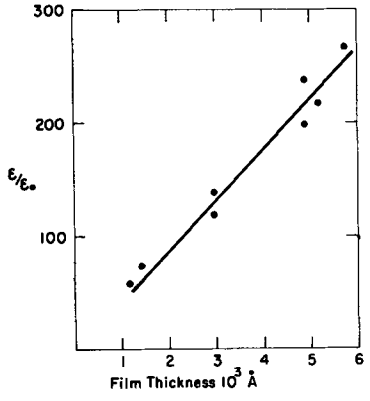

Fig. 7. Apparent dielectric constant vs. dielectric thickness at 1 kc for cerium fluoride evaporated from refractory metal crucibles.

A decomposition of the deposit leading to the formation of metallic grains imbedded in the dielectric could yield a high dielectric constant (4). However, in order to explain the large effect observed, the percentage of conducting material would have to be so high that the films would be optically opaque, and insulation would almost certainly not be achieved. For a 5900Å film having an apparent dielectric constant of 280 at 1 kc, the equivalent dielectric thickness would be 150Å and conductor thickness 5750Å.

As a mechanism for this thickness dependence, the possibility of the presence of Schottky barrier layers at the metal-dielectric interfaces was therefore investigated. Parker and Wasilik (5) have found the presence of barrier layers at the electrode-crystal interfaces of a single crystal of rutile and could thereby explain the high, thickness-dependent dielectric constant at low frequencies.

The Schottky barrier layer is formed at the interface of materials of different surface work functions. Equalization of the Fermi levels of the two interface materials results in a carrier depletion in the slightly semiconducting dielectric, forming the barrier layer. The depth of the layer D is determined by the difference in work functions θ, by the applied voltage V, and the carrier density N:

$$D = \left[\frac{2\epsilon(\theta - V)}{eN}\right]^{1/2} \qquad [1]$$

ϵ being the static dielectric constant of the semiconducting dielectric and e the electron charge.

A slight catalytic decomposition of the cerium fluoride at the metal crucible walls is probably causing the formation of charge carriers necessary to obtain the proposed barrier layers in the investigated rare earth compounds.

The equivalent circuit of an evaporated capacitor having barrier layers at the electrode-dielectric interfaces is shown in Fig. 8. C_1, R_1 and C_3, R_3 represent the capacitance and resistance of the barrier layers, and C_2, R_2 that of the dielectric layer. When a voltage is applied in a forward direction for the barrier layer (C_3, R_3), the resistance R_1 becomes much larger than R_2 and R_3, and the capacitance is given by:

$$C_1 = \epsilon A/D_1 \qquad [2]$$

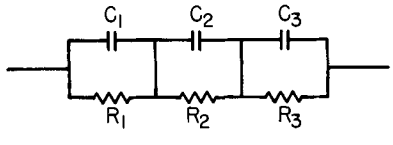

Fig. 8. Equivalent circuit of a capacitor having barrier layers at electrode-dielectric interfaces.

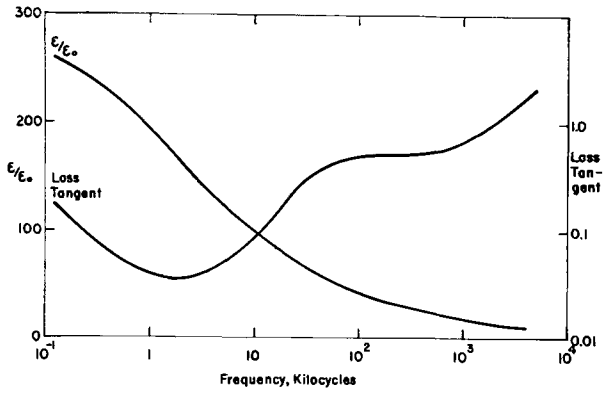

Fig. 9. Apparent dielectric constant and loss tangent vs. frequency for a 2300Å cerium fluoride capacitor.

where D_1 is the thickness of the barrier layer C_1, R_1. The capacitance of this condenser, at low frequencies, is therefore independent of the dielectric thickness and is determined solely by the area and the barrier layer thickness. Using the value for ϵ of 7.2×10^{-11} farad per m measured on amorphous cerium fluoride films, a barrier layer thickness of about 150Å is indicated.

As a further proof of the presence of barrier layers, a capacitor was made having a silicon monoxide layer at one metal-dielectric interface about 200Å thick. Ohmic contact was not achieved, but the barrier layer characteristics were changed so that rectification occurred. Although the resistance was very high ($> 10^6$ ohms) a front-to-back ratio of about 5-to-1 was observed.

As would be expected, losses are associated with such as mechanism, Fig. 9 shows the loss tangent and apparent dielectric constant of a 2300Å cerium fluoride film with respect to frequency. The dielectric constant remains high throughout the audio frequency range. The loss tangent at 1 kc is lower than that of silicon monoxide and remains acceptably low in the audio frequency range.

In spite of the small barrier layer thickness, the breakdown voltages of 20-30v and leakage resistances of the order of 10^6 ohms or higher make these capacitors well suited for applications in evaporated circuits. Storage of unprotected capacitors in air at room temperature for over a year has not altered their electrical properties.

Manuscript received July 17, 1961; revised manuscript received Sept. 28, 1961. This paper was prepared for delivery before the Indianapolis Meeting, April 30-May 3, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

Some Effects of the Electric Contact in Films of Electroluminescent ZnS:Cu,Cl

W. J. Harper

Electronics Department, Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

A low-conductivity layer placed between a conducting electrode and a film of evaporated electroluminescent ZnS:Cu,Cl phosphor has a pronounced effect on the properties of the cell. The logarithm of the integrated brightness varies inversely as the voltage or as the square root of the voltage, or their combination, depending on the electric contact and on the conditions of excitation. Three brightness peaks may be obtained in each half cycle of alternating voltage, one substantially in phase, the other two delayed. The in-phase brightness peak is accompanied by some rectification of current. The direction of greater current is determined by the nature of the contact and the conditions of excitation.

In the electroluminescence (EL) of ZnS phosphor powders embedded in a dielectric the nature of the electrode plays a minor role (1-3). Greater attention has been given to the electric contact in the EL of single crystals where some correlation has been reported between different electrode metals, the method of applying them, and the resulting cell properties (4-11). For EL thin films Halsted and Koller (12) used an evaporated metal while Koller (13) applied a thin nonconductor prior to the metal. Vlasenko and Popkov (14) observed some effects of an insulating film on a ZnS:Mn phosphor, while Thornton (15) evaporated Al directly on phosphor films with various activators.

The dependence of EL brightness on voltage may be represented by

$$L = L_o \exp(-a/V) \quad [1]$$

or by

$$L = L_o \exp(-b/V^{1/2}) \quad [2]$$

where L is the brightness, V the voltage, and L_o, a, b are constants. These relationships, among

others, have been proposed by earlier authors. Most EL cells of phosphor powders and of films follow [2] quite well, although Lehmann (16) found that [1] represented results for some single particles and selected thin films of ZnS:Cu,Cl.

Generally, the brightness-voltage and the brightness-frequency relationships have not been correlated with the electric contact by previous authors. In the work reported here it was found that the nature of the electric contact to ZnS:Cu,Cl EL phosphor films has a pronounced effect on the brightness and its relationship to voltage, frequency, and efficiency.

Experimental Results

Electric contact.—The films were prepared by evaporating a phosphor onto a glass coated with tin oxide and were then heat treated. They are substantially similar to those reported by Thornton (15). The tin oxide on glass forms one electric contact and also the transparent electrode. A variation in the properties of EL is obtained by varying the other electric contact, which is usually an evaporated metal with or without a film of insulating material between the phosphor and the metal. In this report only electric fields normal to the plane of the phosphor are considered. The phosphor thickness is 1-3μ and appears to be a single-crystal thickness with the diameter of the crystals about the same dimension as the thickness of the film. The layer of low-conductivity material applied between the phosphor and the metal will be referred to as an insulator although in very thin layers it may conduct current appreciably.

It was found that if the metal electrode is evaporated directly on to the phosphor layer, EL may be obtained with the metals Al and Mg, but not at all or very poorly with some other metals such as Ag, Cu, In, Zn, Sn, Fe, Pt. The latter metals directly on the phosphor give a low resistance contact and a substantially ohmic current-voltage relationship for the cell. Thus the tin oxide apparently also forms a low resistance contact. However, all the metals give a high resistance contact and EL from ZnS:Cu,Cl films when excited by an alternating voltage if an insulating layer is placed between the metal and the phosphor. The thickness of the insulator required depends on the identity of the metal and the insulator. Occasionally any metal alone may give EL, but it is thought that in such instances effective insulating layers may be produced by the mechanical or chemical treatment of the ZnS surface or by some interaction between the phosphor and the metal. This conclusion is reached because the properties of the resulting cells are similar to those obtained with Al or Mg electrodes. However, there are additional factors involved since some metals such as Au, Pd, Ni, Bi, Pb yield luminescence and cell properties somewhat different from those obtained with Al.

This paper describes the type of properties obtained with Al electrodes with and without an insulator. The Al is evaporated from a tungsten filament at a pressure greater than 10^{-5} mm Hg. It is believed that the Al oxidizes on exposure to the atmosphere. There may also be some effect due to electrical forming since usually an initially higher voltage and current must be applied to Al and Mg contacts before EL can be obtained at lower voltages.

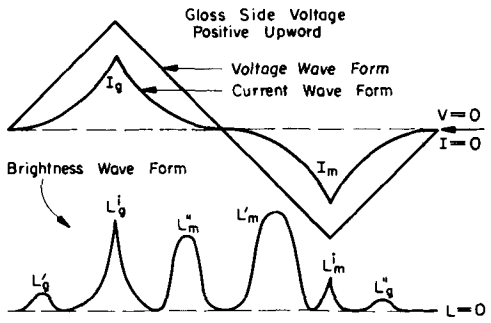

Fig. 1. Schematic diagram of the voltage, current, and brightness wave forms. Symbols shown for current and brightness are used to identify the peaks and also as their maximum amplitude.

Brightness wave form.—The brightness wave form of EL films forms a convenient reference for explaining and correlating other properties. Three brightness peaks are usually obtained in each half-cycle of sine or triangular voltage. In the films described here the brightness peaks in one half-cycle of voltage are much greater than those in the other half. Of the three peaks, one is substantially in phase with the voltage and the other two are delayed. Figure 1 shows a schematic diagram of the brightness and current wave forms obtained with a triangular voltage wave form. A triangular rather than a sine voltage is used in order to distinguish the in-phase peaks more readily. The brightness peak is denoted by subscript "g" (or "m") if it begins when the glass (or metal) side electrode is going positive. Superscripts "i," double prime, and prime are used for the in-phase, secondary, and primary peaks, respectively. Sometimes there are small peaks which cannot be identified as one of the above six. Figure 2 shows voltage, brightness and current wave forms for an evaporated Al electrode with and without a 10 mμ insulating layer of SiO_2. Brightness values given in this and the following figures should be considered as approximations.

The magnitude of the in-phase peaks, L_g^i and L_m^i, depend on the amount and type of low-conductivity material between the metal electrode and the phosphor and on the conductivity of the phosphor itself. Frequently, L_m^i is about equal to L_g^i, but because it is often overlapped by L_m', it does not appear prominently. Both peaks are absent if the metal electrode is insulated sufficiently. The amplitude of these peaks at low-frequency alternating voltage is about the same as for the equivalent direct voltage. With a-c excitation the maximum of the in-phase peaks follows the voltage and current maxima by an interval of about a millisecond. The interval decreases as the voltage or frequency is increased.

Narrow band optical filters indicate that the in-phase peaks L_g^i and L_m^i have a strong blue compo-

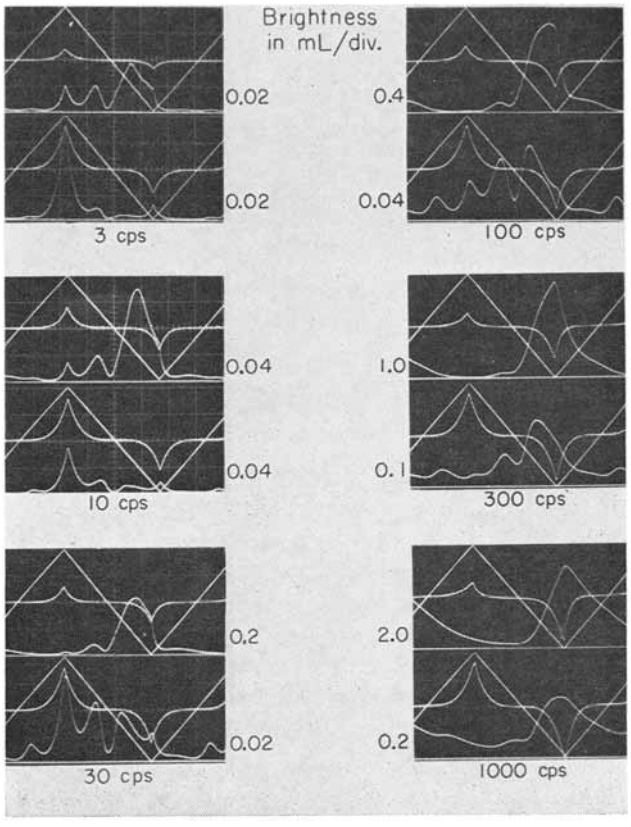

Fig. 2. Voltage, current, and brightness wave forms from an EL ZnS:Cu,Cl layer of thickness 1.5μ at six frequencies. The top half of each photograph is for a cell area with an Al electrode on 10 mμ of SiO_2; the bottom half is for another area of the same specimen with Al alone. The triangular voltage was held constant at 20v peak. Positive voltage on the glass side is to the top of the picture. Brightness zero is shown at the bottom of the picture. The brightness magnitude is given in millilamberts per division (major). The current magnitude is 25 ma/cm^2 per division. The phosphor layer is one of comparatively low conductivity.

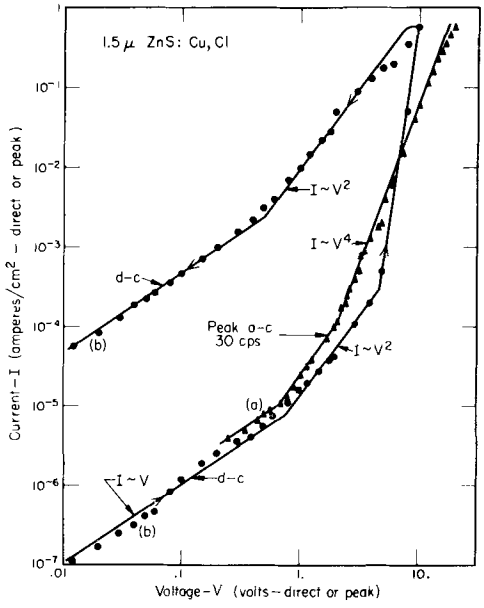

Fig. 3(a). Peak current variation with peak triangular voltage at 30 cps. Fig. 3(b). Steady-state d.c. with the Al electrode negative for increasing voltages starting with a de-excited phosphor, and for decreasing voltages.

nent. The peaks L_m' and L_m'' are of the same quality green at frequencies of 1-10 cps, but possess a more blue characteristic at 100-1000 cps.

A buildup in the initial several cycles, well known in EL powders, occurs in the peaks L_m' and L_m'', but the in-phase peaks do not have a buildup.

Current relations.—The current wave forms are also affected by the nature of the electric contact. With thick insulators the capacitive property of the cell dominates the current wave form. If high resistance Mg or Al contacts are used, the instantaneous current I varies approximately as the square of the voltage, V, as may be seen in Fig. 2. If prominent in-phase peaks are present, the current may be somewhat rectified. The direction of greater current is usually the glass side positive at low voltages, low frequencies, and high temperatures. If the small differences due to current rectification are neglected, the amplitude of the current peaks at low frequencies varies roughly as the second to the fourth power of the voltage [Fig. 3(a)].

If a direct voltage, V, is applied in steps to a cell with an Al contact and the current, I, is allowed about 1 min to reach a steady state, the current is proportional to V up to about 0.5v, varies as V^2 from about 1 to 8v and approximately as V^4 or a higher power up to breakdown. At voltages above about 8v the current must be limited to prevent destruction of the cell. The polarity of the applied voltage or whether it is being increased or decreased does not change the shape of the I-V relationship greatly. However, the history of the cell and other unknown factors often have large effects on the magnitude of the current at low voltages. For example, as shown in Fig. 3(b), the initial current through a de-excited phosphor layer is much lower than in the same cell after it has been recently excited.

Effect of voltage.—The dependence of integrated brightness on voltage for a ZnS:Cu,Cl layer may range from Eq. [1] to Eq. [2], depending on the electric contact, frequency of excitation, temperature, and the conductivity of the phosphor. Equation [2] is favored by phosphor films with high conductivity, with very thin insulators, and at low frequencies. With more insulation, Eq. [1] is followed quite well in the audio frequency range. Combination of the two forms are usually obtained. Frequently, at very low voltages, the fit is not good to either of the equations.

Whether Eq. [1] or [2] is followed by the variation of integrated L with V is determined by the dominant brightness wave forms. The amplitude of the peaks L_g', L_m', and L_m'' follow [2]; the peaks L_m' follow [1] fairly well. When the logarithms of L_g' and L_m'' are plotted against $V^{-1/2}$, the slopes of the lines are approximately equal as shown in Fig. 4. In all the figures showing amplitude of brightness peaks, the maximum was measured from zero brightness, and no correction has been made for overlap of peaks. The relative magnitude of the brightness peaks depends on the resistance of the contact, preparation of the phosphor, and conditions of excitation.

The peak L_m' may consist of two superposed peaks, suggested by the following evidence. At high voltages its amplitude may become greater or less than that given by [1], and this is accompanied by the narrowing or broadening of the peak. At high volt-

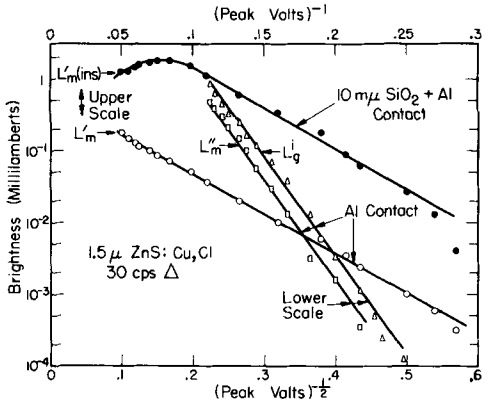

Fig. 4. Amplitude of brightness peaks as a function of voltage

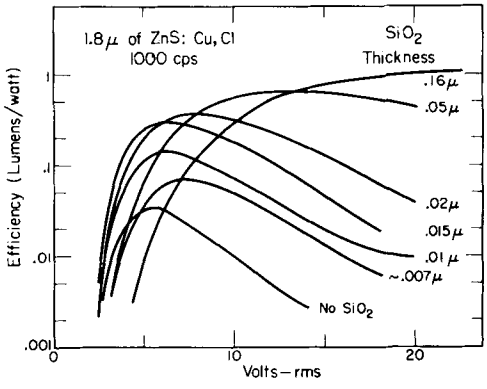

Fig. 6. EL efficiency for different thicknesses of silica insulator as a function of voltage.

ages and with high positive bias on the metal electrode, L_m' may develop two overlapping peaks. In the first few cycles after a voltage is applied, the amplitude sometimes decreases while the width broadens. These properties of L_m' occur even when L_m^i and L_m'' are distinctly separated from it. However, in this report, L_m' will be treated as a single peak.

The voltage relationship between the three peaks may also be shown by adding a small direct voltage, positive on the glass side, to an alternating voltage. Peaks L_g^i and L_m'' increase approximately the same amount, while peak L_m' remains unchanged. This indicates that L_m' depends more on the peak-to-peak voltage than on either of the two peak voltages.

Effect of thickness of insulator.—As the thickness of the insulating layer between the metal contact and the phosphor is increased beyond about 5 mμ, the conductance of the cell is decreased, while the brightness at moderate voltages and frequencies is increased. Thus the efficiency is increased substantially by the use of the insulating layer.

Figure 5 shows how the brightness-voltage relationship is affected by increasing the thickness of SiO_2 under Al electrodes. Up to a point the slope remains constant while the brightness increases. Then, as more insulation is added, the slope increases by pivoting on a point of constant L_o. The latter property is similar to that found for cells of phosphor powders embedded in a dielectric.

For the phosphor layer used, the optimum brightness at a given voltage corresponds to an SiO_2 layer of about 10 mμ. Optimum efficiency is obtained with greater thicknesses of insulation. Figure 6 shows how the efficiency varies with voltage as the SiO_2 layer is increased in thickness. At 1000 cps and moderate voltages the equivalent parallel capacitance of the contact 'C' in Fig. 5 is about 10 nf/cm^2 and the a-c conductance is 100 μmhos/cm^2.

Effect of frequency.—The nature of the electric contact also determines the relation of brightness to frequency. Again, a correlation with the brightness wave form is possible. The amplitude of the peaks L_g^i and L_m^i is almost independent of frequency. The base of the in-phase peaks retains the same fraction of each cycle as the frequency is varied. Thus the integrated brightness of the in-phase peaks is almost independent of frequency up to about 500 cps. Beyond this frequency the amplitude of the peaks diminishes and their identity is lost. An example is shown in Fig. 7. At room temperature the in-phase peaks dominate the total brightness up to frequencies of about 3 cps. The films described were prepared for a-c excitation. Films may be prepared to have the in-phase peaks dominant to higher frequencies. Such films are more suitable for d-c excitation.

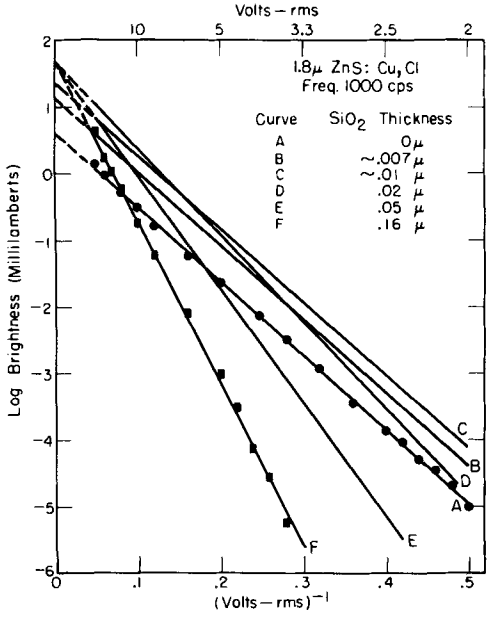

Fig. 5. Dependence of integrated brightness on thickness of silica insulator under an evaporated Al metal electrode as a function of voltage.

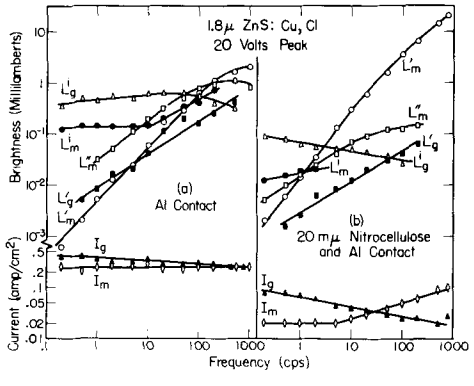

Fig. 7. The variation with frequency of the amplitude of brightness and current peaks, (a) with an Al contact, (b) with 20 mμ nitrocellulose under the Al. No correction is made for the overlap of brightness peaks. The phosphor layer is relatively more conducting than the specimen in Fig. 2.

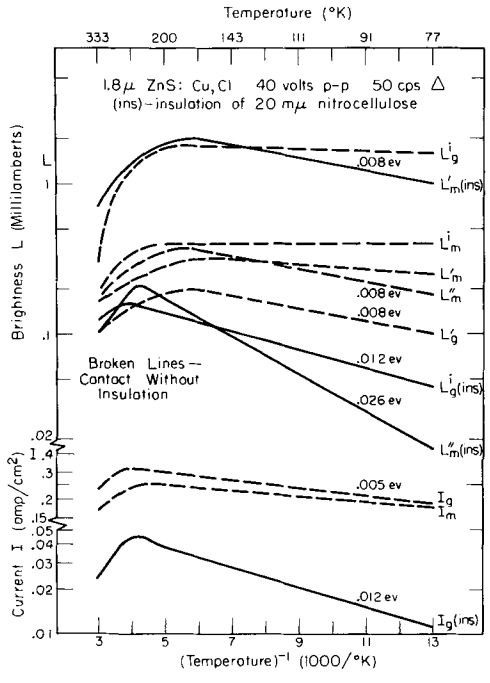

Fig. 8. Amplitude of brightness and current peaks as a function of temperature. The slope of the straight line portions of the curves is indicated in terms of electron volts.

The amplitude of peaks L' and L'' increases with frequency and hence the integrated light does also, if the delayed peaks dominate the brightness wave form. In the films described here the integrated light at moderate voltages is constant up to a frequency of about 3 cps, then increases with frequency up to about 5000 cps where it levels off.

Effect of temperature.—Each of the brightness peaks is affected by temperature somewhat differently. Figure 8 shows the amplitude of some peaks for a layer with 20 mμ of nitrocellulose plus Al and the corresponding peaks for the same phosphor with Al contacts only. In the figure it may be noted that curve L_m'', rather than L_m', for the Al-contact peak has the same slope as the peak L_m'(ins) for the insulated contact. This correlation occurs quite frequently. The range of temperature where these two curves are parallel seems to decrease with decreasing voltage and frequency. The magnitude of the brightness peaks and their dependence on temperature vary considerably for specimens which are substantially alike so that the values given in the example cannot be considered representative of the phosphor.

The integrated brightness curves for layers with insulated contacts have the same slope as those for the corresponding amplitudes of L_m'. In the specimens examined activation energies of 0.005-0.03 ev were obtained. The integrated brightness for layers with Al contact only is usually flat from 77°K to about 250°-300°K where it drops off rapidly.

Discussion

A common interpretation of EL in ZnS is that a barrier provides a high field region which may give rise to collision processes. An exhaustion layer of the Mott-Schottky type has been proposed by Piper and Williams (17). An insulator at the barrier contact has been considered by Zalm (18) and suggested by others (19, 20). Froelich (21) deduced from experimental observations that Al_2O_3 is associated with the formation of barriers in EL Zn(Al)S:Cu phosphor powders. Larach and Shrader (22) showed that a surface phase of CuZnS plays an important role in the EL of ZnS powders.

The results of the present work indicate that a low conductivity layer at an electrode is one method of inducing EL in single-layer thin films of ZnS:Cu,Cl when the voltage is applied normally to the plane of the films.

It is believed that the contact of the metal electrode and the insulating layer results in the accumulation of electrons in the insulator. Skinner (23) has shown that such an accumulation in depth occurs for a suitable choice of metal and insulator. The contact between the insulator and the phosphor probably results in a depletion or exhaustion layer in the phosphor, thus providing a high resistance and a local high field. Harrick (24) has shown that an insulator of thickness about 10 mμ facilitates charge injection and extraction. In the present work it was found that, with favorable conditions, about 5 mμ of SiO_2 plus a high-resistance Al evaporated electrode resulted in greater current at moderate voltages than with silica thickness somewhat greater or none at all. Charge carriers penetrating the insulating layer provide current for the in-phase peaks. When the insulator is thicker, an accumulation of electrons at the interface between the phosphor and the insulator may provide electrons for the delayed peaks. When the glass side electrode is positive, electrons from the insulator or, if the latter is thin enough, from the metal electrode are accelerated and may produce excited and ionized luminescent centers. Some of the electrons are trapped in the phosphor, forming a space charge. A field resulting from the space charge accelerates electrons toward the metal electrode. As the field due to the applied voltage is reduced, electrons thermally released could recombine with empty activator centers and produce the secondary peak L_m''. If a thick insulator is present, the latter action is subdued. As the field due to the external voltage reverses, electrons released from traps and the injected electrons are transported into the region of the crystal having ionized centers and the primary peak L_m' results. The peak L_m' may be due to the field resulting from the superposition of an external voltage and the space charge or polarization voltage. The effect of a small bias voltage mentioned above is used to support this interpretation. The presence of a polarization voltage has been previously reviewed and described by Haake (25).

The asymmetry of the brightness peaks L_m' and L_m'' with respect to the halves of the voltage cycle indicates that they depend on the barrier or junction at the metal electrode. The substantial symmetry of the in-phase peaks indicates that they are not very sensitive to the nature of the contacts. Changing the voltage, temperature, or frequency can reverse the direction of the current rectification and the relative intensity of the peaks, L_m^1 and L_g^1. Since both peaks have similar blue components in their spectrum, the peak L_m^1 does not depend on the "blue" centers created in the previous half cycle. It is concluded

that, in each half cycle, the in-phase peaks are due either to the electrons ionizing "blue" centers with which other electrons later combine, or the current results in the capture of holes by luminescent centers by some other process. Hole injection may be a part of the latter, but seems unlikely in view of the asymmetry of the electric contacts.

If the direct voltage I-V relationship of Fig. 3 is used with the space-charge-limited current relations developed by Lampert (26) and others (27, 28), what may be interpreted as the trap-filled-limit voltage leads to a calculated defect density of 10^{16} cm^{-3}. This appears to be another example of the type of compensation reported by Allen (29).

The dependence of emission intensity on the applied voltage has been reviewed by several authors (5, 16, 30). In particular, Zalm (18) has calculated that the L-V relationship [2] can be due either to the excitation probability or to the supply of primary electrons. If L_m'' were determined by the supply of electrons, then, when it is suppressed and presumably the released electrons are available to L_m', the $L_m'' - V$ characteristic should be superposed on L_m'. There is a little evidence at high voltages in some specimens of such superposition. Since both L_m' and L_m'' depend on the excitation when the metal electrode is negative, their difference in voltage relationship must depend on the conditions during recombination. Using relations developed by Rose (31), Alfrey and Taylor (32) associated single depth traps with Eq. [2] and trapping states distributed in energy with [1]. The present work gives some support to their suggestion since the field release of electrons may be predominantly from deeper trapping states distributed in energy.

The following may pertain to the form of the L-V relationship for the different peaks. During the emission of peaks L^1 and L'', the field within the crystal is the resultant of two opposing fields, one due to a space charge, the other due to a potential applied externally. During the emission of L', the external voltage reinforces the potential due to space charge in the portion of the crystal where emission takes place. The position and density with respect to time of the two space charge layers, one at the insulator and the other in the phosphor near the glass electrode, would determine the degree of validity of this interpretation.

The increase of efficiency with thickness of the insulating layer indicates that EL is more efficient when charge carriers move only within the crystal and much less efficient when they pass through the crystal. It may also indicate a greater accumulation of charge as the insulation thickness is increased.

The frequency effect is also related to the transport of carriers. The in-phase peaks are due to carriers passing through the crystal and hence do not vary with frequency. The delayed peaks are due to carriers oscillating within the crystal, so that, if the same charge transfer prevails for each cycle, their brightness increases with frequency.

The effect of temperature on the brightness peaks indicates that thermally released electrons from shallow traps are made use of by the peak L_m'' when the insulating layer is very thin, but by the peak L_m' when the insulating layer is thicker. With a thick insulator, the peak L_m'' is reduced, and a small peak often appears approximately where L_g'' would be expected. This evidence also suggests that the peak L_m' arises from two sources. The dependence of the peaks L_m^1 and L_g' on temperature, shown in Fig. 8, is not well established since there was considerable variation in them in the specimens examined. The activation energies (0.005-0.03 ev) obtained from the slopes of the curves of primary peaks are similar in magnitude to those obtained by Haake (33) for powders.

Variations in current amplitude with temperature, frequency, and voltage may be partly due to the nature of the conduction at the metal-insulator contact as explained by Fisher and Giaever (34). Two competing processes, the electrons tunnelling through the barrier and those passing over the potential barrier, could cause reversals in the direction of greater current.

Acknowledgments

The author is indebted to Dr. W. A. Thornton for the method of preparing EL films and for much fruitful association, to Dr. H. L. Cox for the design of a low-frequency amplifier, and to G. D. Ondo and K. A. Rumon for a great deal of the experimental work.

Manuscript received Aug. 21, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

Luminescence of Copper-Activated Orthophosphates of the Type $ABPO_4$ (A = Ca, Sr, or Ba and B = Li, Na, or K)

W. L. Wanmaker and H. L. Spier

Light Division, N. V. Philips' Gloeilampenfabrieken, Eindhoven, Netherlands

ABSTRACT

Activation of orthophosphates of the type $ABPO_4$ with copper gives an efficient phosphor in some cases. The brightest phosphors found are $SrLiPO_4$-Cu and $BaLiPO_4$-Cu, with an emission peak (with 2537Å excitation) at 4150 and 4600Å, respectively. The properties of orthophosphates of the type $ABPO_4$ with two kinds of alkali earth or alkali metal ions, respectively, were also studied. X-ray diagrams of the compounds investigated are given.

During the past few years several papers concerning copper-activated phosphors have been published. Uehara, Kobuke, and Masuda (1) described the preparation and luminescent properties of copper-activated calcium orthophosphates and related phosphors, and Wanmaker and Bakker (2) investigated modified strontium orthophosphates. The properties of copper- and tin-activated halophosphates were given in a paper published by Hunt and McKeag (3).

Thorium phosphate activated with copper shows a yellow-orange emission when excited by 2537Å radiation (4). In a subsequent patent the application of this phosphor in low-pressure mercury discharge lamps is given, with the addition of diammonium phosphate or phosphoric acid (5).

Moreover, some papers were published concerning the more fundamental properties of this kind of phosphor. The configurational coordinate curve for the copper center in calcium orthophosphate was reported by Maeda (6). Uehara (7) has given a quantitative interpretation of the luminescent properties of the same phosphor.

The quantum efficiency of many copper-activated phosphors is high, *e.g.*, we found a quantum efficiency of 0.87 for strontium magnesium orthophosphate. Uehara and co-workers give a value of 0.91 for β-$Ca_3(PO_4)_2$-Cu with 2537Å excitation (8).

In this paper we deal with the preparation and luminescent properties of a new type of copper-activated phosphors, $ABPO_4$, in which A = Ca, Sr, or Ba and B = Li, Na, or K. Although we did not succeed in obtaining as high a quantum efficiency as that of the modified strontium orthophosphates, some phosphors of rather good efficiency were made, *e.g.*, $SrLiPO_4$-Cu with an emission peak at 4150Å and $BaLiPO_4$-Cu with an emission peak at 4600Å, both with 2537Å excitation.

Several phosphors with this type of host crystal have already been mentioned in the literature. Kröger (9) reports the luminescence of manganese-activated $CaLiPO_4$, $MgLiPO_4$, $ZnLiPO_4$, and $CdLiPO_4$. More recently Smith (10) studied manganese luminescence in the system $Zn_3(PO_4)_2$-Li_3PO_4 or Na_3PO_4 and $Cd_3(PO_4)_2$-Li_3PO_4 or Na_3PO_4. In the first system, formation of $ZnLiPO_4$ and $ZnNaPO_4$ was found, whereas in the second system more complicated structures are formed. Activation with cerium renders an u.v. emission (11) with very short decay time (smaller than 0.1 μsec.). From this group of phosphors $BaNaPO_4$-Ce (emission peak at 3600Å with cathode-ray excitation) may be used for excitation of other phosphors in order to determine their decay times (12).

The quantum efficiency of the cerium-activated phosphors, studied by Kröger, decreases in the sequence B = Li, Na, K. The highest values were obtained with $SrLiPO_4$-Ce (0.88) and $CaLiPO_4$-Ce (0.81). The copper-activated phosphors studied by us showed a similar difference in brightness with variation of the alkali ions.

Concerning other activator ions, a faint green emission (u.v. excitation) is reported for $MgNaPO_4$-U (13). $CaKPO_4$-Tl, excited with 2537Å radiation, gives an emission peak at 3150Å and was studied by Clapp and Ginther in connection with its possible use in sun-tan lamps (14).

Method of Phosphor Preparation

The ingredients used in the firing mixtures were reagent grade $CaHPO_4$, $SrHPO_4$, $BaHPO_4$, Na_2CO_3, Li_2CO_3, K_2CO_3, $(NH_4)_2HPO_4$, $CuSO_4$, Al_2O_3, and $MnNH_4PO_4$. The required amounts of the dry materials were thoroughly mixed and subsequently fired in a way already described (2). In some cases a prefiring in air at about 1100°C was carried out, followed by a second firing in a slightly reducing atmosphere at about 700°C. This procedure often gives a more homogeneous product.

Chemical Composition

In nearly all phosphors the brightness generally depends strongly on the ratio between the basic and the acidic constituents of the compound, the optimum brightness being found mostly at the stoichiometrical composition. In the phosphors investigated in this paper, however, we found the optimum brightness with a slight excess of cations, *e.g.*, in $SrLiPO_4$-Cu the optimum brightness is reached with a molar ratio $Me/P_2O_5 = 3.05$ (Me being $A^{II}O + B^{I}_2O$). The molar ratios are derived from the added amounts of ingredients, so the actual molar ratio of the fired phosphors may be different; *e.g.*, it may be possible that part of the alkali or earth alkali carbonate added does not react with the phosphate added, giving rise to an actual Me/P_2O_5 ratio being lower than the molar ratio derived from the added amounts of ingredients.

As regards the ratio of the alkali earth metal ions to the alkali metal ions, an optimum brightness was found with an excess of alkali ions of about 5 mole %.

In accordance with our previous results, we found that simultaneous addition of Cu and Al enhances the brightness of the phosphors prepared. This effect is probably due to a facilitation of the incorporation of Cu^+ in the $A^{II}B^{I}PO_4$ lattice, two A^{II} ions being substituted by a Cu^+ and an Al^{3+} ion.

A minimum amount of copper is necessary in order to absorb the u.v. radiation. With a high amount of copper added, however, in most cases a certain percentage of this copper is not incorporated into the crystal lattice, and the resulting copper-oxides give rise to grayish colored products with a low brightness.

With $SrLiPO_4$-Cu we achieved the best results with the following composition: $P_2O_5 = 1$; $SrO + Li_2O = 3.05$; $Li_2O = 1.05$; $CuO = 0.01$; $Al_2O_3 = 0.04$. It will be clear that this optimum composition is also a function of the firing conditions and the primary ingredients used.

Fluorescence of Copper-Activated Orthophosphates of the Type $ABPO_4$

In this survey only the luminescence with 2537Å excitation is considered, as the quantum efficiency with long wavelength u.v. excitation is very low.

A = Ca.—$CaLiPO_4$-Cu shows an u.v. emission with a peak at 3600Å. Moreover, a blue emission is observed in many cases at 4800Å, as may be seen from Fig. 1. The relative intensity of the two bands varies with the firing conditions, the u.v. peak being more pronounced at a lower firing temperature.

Several explanations for the occurrence of two emission bands in $CaLiPO_4$-Cu are possible; *e.g.*, one may suppose that two crystal forms are present. X-ray diffraction analysis, however, showed that the unactivated $CaLiPO_4$ has the same crystal structure at firing temperatures ranging from 500° to 1300°C. Because at a firing temperature below 900°C the primary ingredients will not react completely, these preparations were made by refiring the product prepared at a temperature of 900°C at the required lower temperatures. $CaLiPO_4$-Cu has the olivine structure, this structure possessing two kinds of cation sites (15, 16). According to Dachille (17) the olivine (Mg_2SiO_4) structure is built of SiO_4 tetrahedra joined together by O-Mg-O bands. One half of the Mg^{2+} is in a position of symmetry between two tetrahedra, the other half sharing oxygen of four tetrahedra, although all Mg^{2+} ions are surrounded by six oxygens. It is questionable whether the occurrence of these two kinds of cation sites explains the presence of two emission bands in $CaLiPO_4$-Cu.

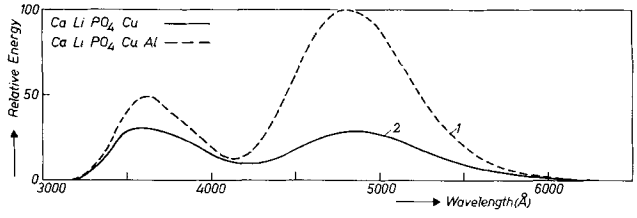

Fig. 1. Spectral energy distribution curves of the emission of $CaLiPO_4$-Cu, with Al added (curve 1) and without Al (curve 2). $Cu/P_2O_5 = 0.01$ (curve 1) and 0.015 (curve 2). $Al/P_2O_5 = 0.08$ (curve 1).

Perhaps the explanation of the problem may be found in the following direction. One cannot know for certain where the copper ions (ionic radius of Cu^+ — 0.96Å) are to be found, on a Ca^{2+} (ionic radius 1.06Å) or on a Li^+ site (ionic radius 0.78Å). On increasing the amount of aluminum, however, one would expect a tendency for the Cu^+ to occupy a Ca^{2+} site (two Ca^{2+} ions being replaced by a Cu^+ and an Al^{3+} ion). Comparing the spectral energy distribution curves of these types of phosphors, the actual amount of Cu^+ and Al^{3+} in the phosphors should be known, as in many cases a rather large proportion of the copper added is not incorporated into the host crystal lattice (as follows from the grayish body color of the fired products). Comparing phosphors with about the same body color, we found that increasing the amount of Al increases the relative intensity of the blue emission peak as illustrated in Figure 1.

One might conclude therefore that a Cu^+ ion on a Li^+ site gives the u.v. emission band and on a Ca^{2+} site the blue emission band. More work is required to elucidate this interesting problem, *e.g.*, investigating the effect of quenching on the intensities of the two peaks, and the effect of the firing atmosphere, as there are some indications that the hydrogen pressure also influences the relative intensity of the two emission peaks of $CaLiPO_4$-Cu.

Normally, copper-activated phosphors have a rather narrow emission peak. With the type of phosphors studied by us, we found in some cases a broader emission band, *viz.*, with $CaNaPO_4$-Cu, $CaKPO_4$-Cu, $SrNaPO_4$-Cu, $BaNaPO_4$-Cu, and $BaKPO_4$-Cu.

Probably these emission bands are caused by the simultaneous occurrence of two crystal forms, as it is known from the literature (18, 19) that several compounds investigated occur in two crystal forms. *E.g.*, we found, from x-ray diffraction analysis the high- and low-temperature form of $CaNaPO_4$-Cu, which phosphor has a broad emission peak located at 4400Å (Fig. 2). Although it was not possible to judge from x-ray analysis whether the $CaKPO_4$-Cu sample investigated contains both the α- and β-form (due to the small difference in the x-ray diagram of the two forms), we do conclude from the spectral distribution curve that the two crystal forms are present (Fig. 2). The emission peak of the second crystal

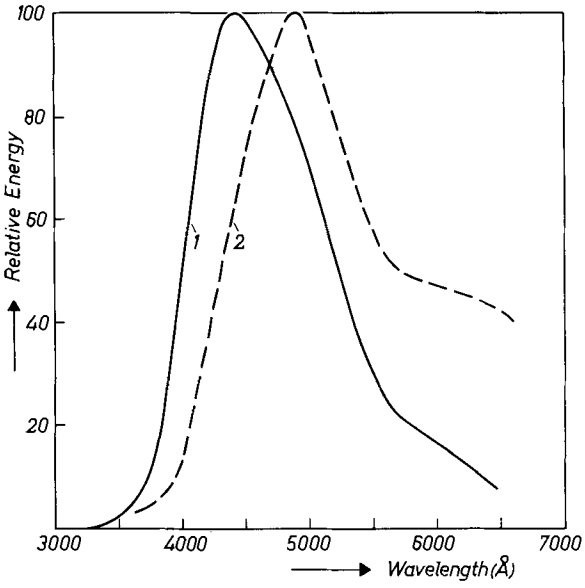

Fig. 2. Spectral energy distribution curves of the emission of $CaNaPO_4$-Cu (curve 1) and of $CaKPO_4$-Cu (curve 2). Cu/P_2O_5 = 0.01 and Al/P_2O_5 = 0.08.

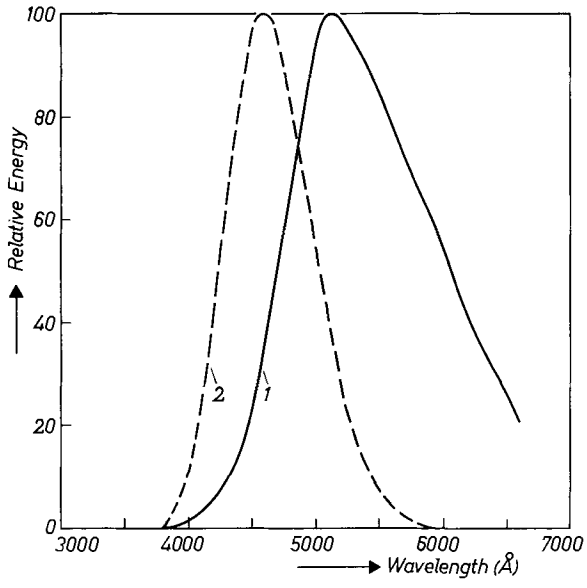

Fig. 4. Spectral energy distribution curves of the emission of $SrNaPO_4$-Cu (curve 1) and of $BaLiPO_4$-Cu (curve 2). Cu/P_2O_5 = 0.01 (curve 1) and 0.016 (curve 2). Al/P_2O_5 = 0.08 (curve 1) and 0.016 (curve 2).

structure can be found at a wavelength of about 5400-5700Å. Perhaps broadness may be due to a situation similar to the one proposed for $CaLiPO_4$, the two peaks lying close together.

A = Sr.—From Fig. 3 and 4 it may be seen that the emission peaks of $SrLiPO_4$-Cu and $SrNaPO_4$-Cu are to be found at 4100Å and at 5150Å, respectively. In $SrLiPO_4$-Cu addition of Al has only a small influence on the location of the emission peak. With the introduction of manganese, a second emission peak arises at 6100Å, as illustrated in Fig. 3. $SrLiPO_4$-Cu has a rather high brightness and is of potential interest for the application in blue-printing lamps, as the emission curve of this phosphor fits closely to the absorption curve of widely used types of diazotype papers. $SrNaPO_4$ shows a broad emission band with a maximum at 5000-5250Å (see Fig. 4, curve 1). As already discussed, $SrNaPO_4$-Cu probably contains two crystal forms. So, according to expectation, it was found that chemical composition and firing temperature have an influence on the position of the emission peak. Probably Al promotes the formation of the high-temperature form, because both with an increase of the Al content and with a higher firing temperature, the emission peak broadens, the high-temperature emission peak lying at about 5600Å. $SrKPO_4$-Cu gives a narrow emission peak of a low intensity, located at 4600Å.

A = Ba.—The emission peak of $BaLiPO_4$-Cu lies at 4600Å, as illustrated in Fig. 4. $BaNaPO_4$-Cu and $BaKPO_4$-Cu give an emission at about 4600 and 4900Å, respectively.

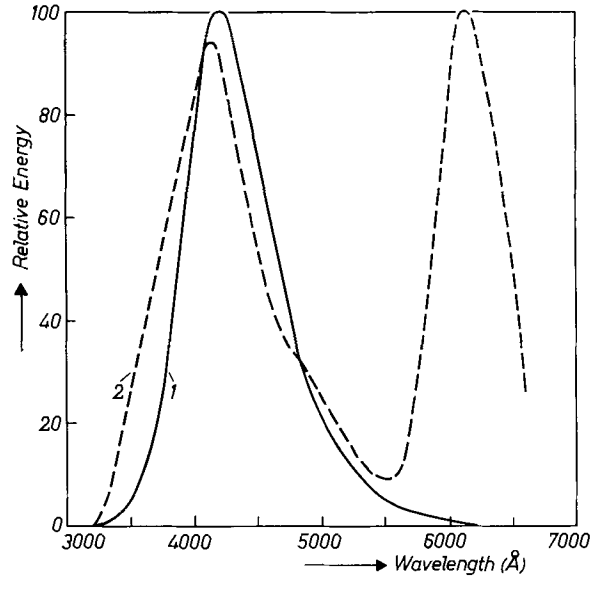

Fig. 3. Spectral energy distribution curves of the emission of $SrLiPO_4$-Cu (curve 1) and of $SrLiPO_4$-Cu.Mn (curve 2). Cu/P_2O_5 = 0.01, Al/P_2O_5 = 0.08, and Mn/P_2O_5 = 0.04 (curve 2).

Ternary Orthophosphates

Next to the binary orthophosphates of the type $ABPO_4$, described in the foregoing, some ternary orthophosphates were prepared with two kinds of alkali or earth alkali ions. Probably due to the fact that several binary orthophosphates have two crystal structures, the change in emission colors of the substituted orthophosphates is complicated.

Substituting sodium for lithium in $CaLiPO_4$-Cu causes the visible emission to shift gradually from 4800 to 4400Å, whereas the u.v. emission disappears when equal amounts of Na and Li are added. Although $SrLiPO_4$-Cu gives a single emission band only, a small amount of sodium gives a green emission band (5100Å) next to the deep blue emission band of the pure $SrLiPO_4$. On increasing the amount of Na, both bands move to shorter wave lengths, until at a high percentage of sodium the broad emission band of $SrNaPO_4$ appears at 5100Å. The location of the emission peaks in $Sr(Li,Na)PO_4$ are illustrated in Fig. 5.

Substitution of the earth alkali ions in the orthophosphates of the type $ABPO_4$ also gives rise to shifts in the location of the emission peak, as may be seen

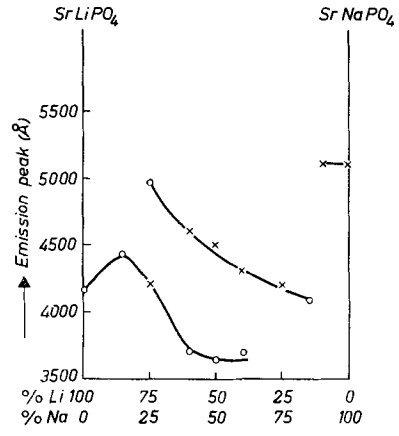

Fig. 5. Location of the emission peaks in Sr(Li,Na)PO_4-Cu. Cu/P_2O_5 = 0.01; Al/P_2O_5 = 0.08. o, main peak; x, secondary peak.

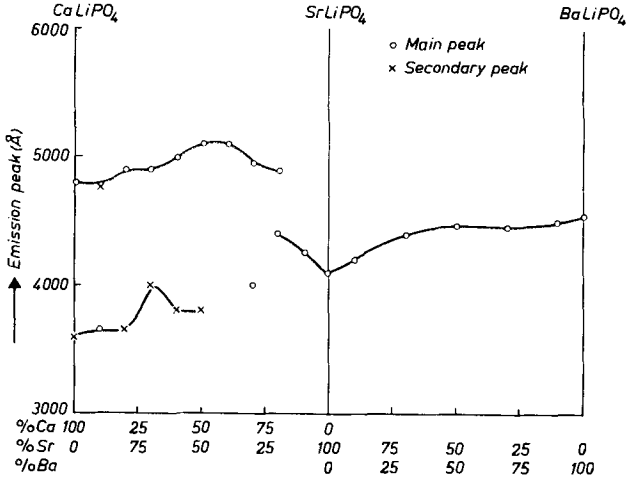

Fig. 6. Location of the emission peaks in (Ca,Sr)$LiPO_4$-Cu and (Sr,Ba)$LiPO_4$-Cu. Cu/P_2O_5 = 0.016; Al/P_2O_5 = 0.016.

from Fig. 6. Substituting Sr for Ca in $CaLiPO_4$-Cu shifts the blue emission peak to longer wavelengths, until a peak is obtained at 5100Å with equimolar amounts of Ca and Sr. With a still higher proportion of Sr this peak is moved to shorter wavelengths, and finally above about 75% of $SrLiPO_4$, the emission peak of $SrLiPO_4$-Cu is gradually reached. The u.v. peak of $CaLiPO_4$-Cu disappears with about 50% of the Ca being replaced by Sr. Substituting Ba for Sr in $SrLiPO_4$-Cu the emission peak shifts gradually from 4100 to 4600Å, as may be seen from Fig. 6.

Reflection and Excitation Spectra

Figure 7 shows the reflection spectra of the most important phosphors investigated, *viz.*, $SrLiPO_4$-Cu and $BaLiPO_4$-Cu. In order to determine the influence of the copper addition, the reflection spectra of the unactivated compounds are also given. It may be seen that the introduction of the copper ions produces an increase in absorption of the u.v. radiation. In the visible region of the spectrum an appreciable absorption still takes place, probably due to a certain amount of metallic copper or copper-oxides produced during the firing process. It is superfluous to say that this absorption decreases the brightness of the phosphors considerably.

The excitation spectra of $SrLiPO_4$-Cu and $BaLiPO_4$-Cu may be found in Fig. 8. From this figure

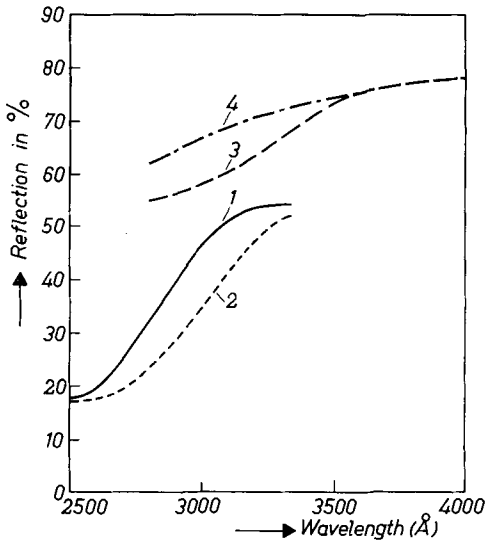

Fig. 7. Reflection spectra of $SrLiPO_4$-Cu (curve 1), $BaLiPO_4$-Cu (curve 2), $SrLiPO_4$ (curve 3) and $BaLiPO_4$ (curve 4). Cu/P_2O_5 = 0.01; Al/P_2O_5 = 0.08; Li_2/P_2O_5 = 1.05. Me (= earth alkali metal + alkali metal)/P_2O_5 = 2.90.

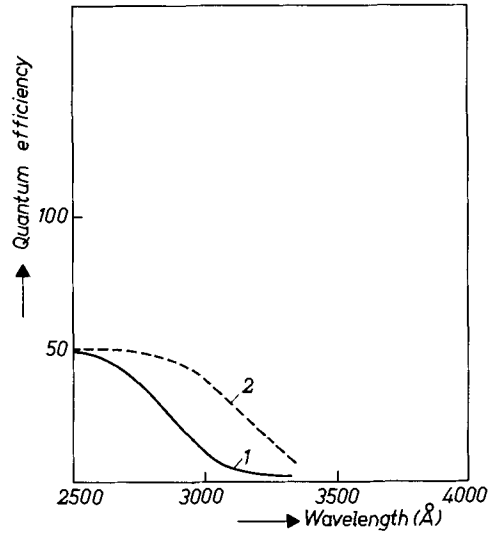

Fig. 8. Excitation spectra of $SrLiPO_4$-Cu (curve 1) and of $BaLiPO_4$-Cu (curve 2). Molar ratios as given in Fig. 7.

it may be seen that the phosphors investigated have a quantum efficiency of about 0.50 by excitation with the 2537Å mercury resonance line. Thus this new type of phosphor might be suitable for use in low-pressure mercury discharge lamps, were it not for the difficulties encountered with the application of these phosphors, as already reported in a previous paper (2).

X-ray Analysis

In our investigation, the x-ray diffraction of the phosphors was determined by conventional x-ray diffraction techniques using CuKα radiation from a Philips Norelco Unit.

The x-ray diffraction data of the compounds investigated are given in Tables I and II. The samples investigated have the theoretical chemical composition and are double fired for 3 hr at 900°C. No copper and aluminum were added in order to avoid any influence of these ions on the crystal structure, although we did not find a difference in the x-ray

diagram between activated and unactivated phosphors.

According to Thilo (15) $CaLiPO_4$ should be isotypical with Monticellite $CaMgSiO_4$, both having the olivine (Mg_2SiO_4) crystal structure. The crystal structure of $CaNaPO_4$, $SrNaPO_4$, and $BaNaPO_4$ and of the corresponding potassium compounds were given by Klement and Steckenreiter (18). Bredig described in more detail the crystal structures of the α and β form of $CaNaPO_4$ and $CaKPO_4$ (19). We found no references concerning the crystal structure of $SrLiPO_4$ and $BaLiPO_4$.

Bragg and Brown (16) described the olivine structure extensively. According to these authors the oxygen atoms are hexagonal, closed packed, whereas the magnesium is octohedrically and the silicon tetrahedrically surrounded by oxygen.

Concerning $CaNaPO_4$, Bredig found two crystal structures with a transition temperature of 680°C. As may be seen from Table I, our unactivated sample is a mixture of the α and β structure, the amount of β being greater than that of α. This may explain the broad emission band observed in $CaNaPO_4$-Cu.

According to Bredig $\alpha CaKPO_4$ is transformed into $\beta CaKPO_4$ at a temperature of 705°C, the α-form hav-

ing a hexagonal structure [glaserite type = $(K,Na)_2SO_4$] and the β-form being rhombic with a pseudohexagonal cell. From Table I it may be seen that our figures fit closely with those of Bredig. As the d-values of α and $\beta CaKPO_4$ differ only when d is greater than about 1.60Å, and the differences are very small, moreover, it cannot be concluded from our figures whether α or $\beta CaKPO_4$ are present. From the spectral energy distribution of the phosphors, however, it follows that presumably two crystal forms are present. Our x-ray data of $SrNaPO_4$, $SrKPO_4$, $BaNaPO_4$, and $BaKPO_4$ correspond to the low-temperature form of the figures given by Klement and Steckenreiter.

Acknowledgments

The authors wish to express their thanks to Dr. A. Bril for the measurements of the quantum efficiency, the reflection, the emission and the excitation spectra of the phosphors; to Mr. J. G. Verlijsdonk and Mr. A. A. L. Sleutjes for preparing the phosphors; and to Mr. W. Parchen for carrying out the x-ray analysis.

Manuscript received July 3, 1961; revised manuscript received Oct. 17, 1961. This paper was prepared for delivery before the Indianapolis Meeting, April 30-May 3, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

Surface Concentration of Indium in Germanium from Gaseous Diffusion

Karl M. Busen, Earl L. Meeks, and George A. Shirn

Sprague Electric Company, North Adams, Massachusetts

ABSTRACT

In order to measure surface concentrations C_o of indium, indiffused from the vapor phase into germanium, a new closed system was designed. Numerical values for C_o as a function of the diffusion temperature and the temperature of the liquid source, which is in equilibrium with its vapor, are given. The surface concentration, which depends mostly on the concentration of the indium vapor, is proportional to the concentration of the indium vapor with a "segregation coefficient" of about 10^{-7}.

Electrical devices made from semiconductive single crystals usually require the formation of p- and n-type regions within that crystal. One technique to obtain such regions is gaseous diffusion. It is performed by exposing, at an elevated temperature, the surface of a semiconductor doped homogeneously with an impurity to the vapor of a second impurity of opposite conductivity type.

After completion of the diffusion process a concentration distribution of the second impurity has been formed which extends from the surface toward the inner part of the semiconductor.

Where the concentration of the second impurity becomes equal to the concentration C_B of the first impurity, a boundary or junction between p-type and n-type regions is formed. The distance, x_j, of this junction from the surface and the concentration of the indiffused impurity at the surface, C_o, are important parameters for device design and fabrication. C_o is one of the parameters determining the junction depth; it also determines the "base" resistance of a graded base transistor. For mesa-type transistors where the emitter is plated and micro-alloyed on the surface, C_o is the impurity concentration adjacent to the emitter which is of great significance for the emitter capacitance and emitter breakdown voltage.

It is the purpose of this paper to discuss the surface concentration of indium resulting from indiffusion into antimony doped germanium. In the following, the apparatus which was used for the experiments is

described, and the surface concentrations resulting from the experiments are presented. A discussion of the results concludes the paper.

Apparatus Design and Experimental Procedures

A general method for diffusion of an impurity into a semiconductor is to expose the solid semiconductor to the vapor of the diffusing impurity. The temperature of the semiconductor and the vapor pressure of the diffusing impurity must be well controlled to obtain reproducible concentration distributions. One way to control the vapor pressure is to have equilibrium conditions between vapor and liquid phase of the diffusing impurity in a closed system. The pressure will then depend on the temperature of the liquid phase provided that the liquid phase is at the lowest temperature of the closed system. This requirement imposes the condition that, if the system has a closure, this closure must be at or above the temperature of the liquid phase. If the vapor pressure of the impurity is relatively low (in the order of 10^{-6} mm Hg) it is convenient to evacuate the system prior to the evaporation of the impurity. This means that the closure must have the properties of a high vacuum valve. If, furthermore, the liquid phase is at a relatively high temperature (over 500°C), most of the known vacuum valves will not perform satisfactorily.

A popular solution to this problem is to seal the impurity and germanium in an evacuated quartz tube and to introduce this tube into a two zone furnace. There are several disadvantages to this method: the necessity of a glass-blower to seal off for each run; introduction of impurities from the quartz in sealing the tubes; use of new quartz for each run which introduces an additional parameter to be taken into consideration in the evaluation of results. There are several other solutions known which overcome the problem of the valve. For convenience and best possible control of the vapor pressure a new apparatus was designed which is shown in Fig. 1.

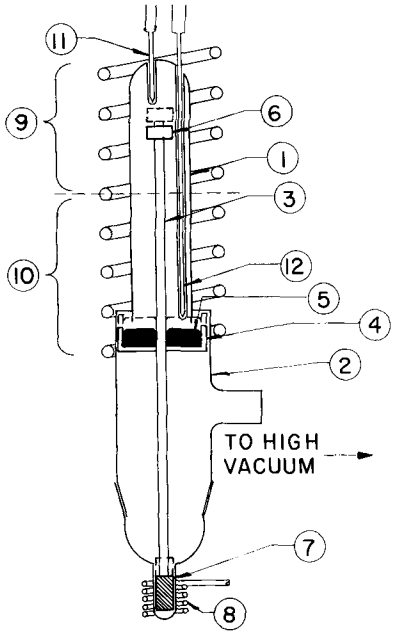

Fig. 1. Apparatus used for the diffusion experiments

This apparatus requires no glass blowing after initial construction and may be used repeatedly for many runs. It may also be cleaned and baked out under high vacuum at temperatures in excess of temperatures intended for the experimental work. This eliminates the aforementioned disadvantages of the sealed quartz tube. The apparatus consists of two vertical quartz tubes, 1 and 2, of different diameter which are concentrically arranged. A part of the upper quartz tube is inserted into the lower one and both quartz tubes are sealed together. Through the opening of the lower quartz tube a quartz rod, 3, is introduced which bears a trough, 4, for the impurity, 5, and a holder, 6, for the semiconductor. An iron slug, 7, is connected to the end of the quartz rod. The slug, together with the rod, can be moved up and down by means of an electromagnet, 8. The quartz tubes are surrounded by two independently controlled furnaces, 9 and 10. Two thermocouples, 11 and 12, are inside the upper quartz tube. For an experiment the trough, 4, is filled with indium, 5, and the holder, 6, is loaded with germanium. The rod, 3, is in its lowest position. First the quartz system is pumped down to a pressure of about 10^{-6} mm Hg. Then the two furnaces are heated. The upper furnace, 9, heats the germanium and determines the diffusion temperature. The lower furnace, 10, heats the indium, which is liquified. As long as the furnaces are not on their predetermined temperature care is taken that the germanium always has a higher temperature than the indium in order to prevent condensation of indium on the germanium. When both furnaces have the right temperature, the rod is lifted by means of the magnet, 8, into a position (see dotted line) such that the rim of the upper quartz tube is immersed into the liquid indium, which acts now as a valve against the pumping system. This indium valve at the same time acts as a source which builds up a saturation vapor pressure corresponding to the temperature of the liquid indium. The moment the indium valve is closed, the diffusion process starts. When the diffusion is to be terminated, the rod is lowered by means of the magnet, thus opening the indium valve. The pressure of the indium vapor drops and the diffusion process is stopped. Care was taken that the cooling time of the furnace was short compared to the diffusion time. Therefore, no correction was necessary.

Methods of Evaluation for the Experiments

The surface concentration, C_o, of indium, indiffused into germanium, has been obtained by the following measurements: (*a*) measurements by four-point-probe; (*b*) measurement of the absorption of infrared light; (*c*) measurement of junction depth: (i) by copper plating, (ii) by dielectric powder deposition, (iii) by thermoelectric probe.

Measurements by the four-point probe.—For the evaluation of the surface concentration, C_o, four-probe measurements (1) were made on the diffused samples. C_o was determined from

$$\rho_o = \frac{V}{I}\lambda\frac{\pi^{1/2}}{\ln 2} = \frac{V}{I}\lambda \times 2.56 \text{ ohm-cm} \qquad [1]$$

where $\lambda = 2(Dt)^{1/2}$ and V/I was measured by the

four-probe. The formula is derived from the relation (2, 3)

$$G = \bar{\sigma} x_j = e \int_0^{x_j} \mu(C) \left[C_o \operatorname{erfc} \frac{x}{\lambda} - C_B \right] dx \quad [2]$$

where x_j is the junction depth, G is the total conductance between surface and junction, $\bar{\sigma}$ is the average conductivity, C is the concentration and C_o the surface concentration of the indiffused impurity, C_B is the concentration of the n-type impurity (background concentration), and e is the electronic charge. With the assumptions that

$$\left.\begin{aligned} &\mu(C) = \mu(C_o) = \text{constant} \\ &\int_{x_j}^{\infty} \operatorname{erfc} \frac{x}{\lambda} dx \approx 0 \\ &C_B << C_o \end{aligned}\right\} \quad [3]$$

Eq. [2] yields

$$\bar{\sigma}^* = \lambda \frac{e\mu(C_o)}{x_j} \frac{1}{\pi^{1/2}} C_o \quad [4]$$

If the space between the probes is much larger than the junction depth and if the junction area is considered as a nonconducting bottom, the sheet conductivity of the diffused layer is given by (4)

$$\bar{\sigma} = \frac{\ln 2}{\pi x_j} \frac{I}{V} \quad [5]$$

Defining $\bar{\sigma} = g\,\bar{\sigma}^*$, combining Eq. [4] and [5] and observing $C_o = 1/e\rho_o\mu(C_o)$ results in

$$\rho_o = g \frac{V}{I} \lambda \frac{\pi^{1/2}}{\ln 2} \quad [6]$$

The functional relation between ρ_o and C_o as given by Hunter (5) is

$$C_o = \frac{3.47 \times 10^{15}}{\rho_o} \text{ for } 10 > \rho_o > 1 \text{ ohm-cm}$$

$$C_o = \frac{3.47 \times 10^{15}}{(1 + 0.33 \log \rho_o)} \text{ for } \rho_o \leq 1 \text{ ohm-cm}$$

This relation, which is in agreement with Prince (6) and Trumbore and Tartaglia (7) enables the evaluation of Eq. [6].

For our measurements, g was chosen unity. The error introduced by this choice and by the assumptions [3] was determined by comparison of the two surface concentrations C_o^* and C_o which were derived from the conductances G^* (where $\mu = \mu(C_o) = \text{const.}$ and $g = 1$) and G(where $\mu = \mu(C)$ and $g = \bar{\sigma}/\bar{\sigma}^*$). The conductances were obtained from graphical integration with the assumption that $C_B = 10^{15}$ and $x_j/\lambda = 2$. A comparison of C_o^* and C_o shows that the surface concentrations differ (in only a few cases) at the most by a factor of 1.4. This is well within the experimental error and can therefore be disregarded. The values for the diffusion coefficient D used in the calculations were taken from a paper by Bösenberg (8). When the concentration distribution, C, the diffusion coefficient, D, and the time, t, are known, the total number of atoms diffused into a sample after time t is given by

$$s = q \int_0^{\infty} C dx \text{ total number of atoms} \quad [7]$$

Dividing both sides of Eq. [7] by q, the cross section through which the diffusion took place gives

$$\frac{s}{q} = \int_0^{\infty} C dx \text{ atoms/cm}^2$$

If $C = C_o \operatorname{erfc} x/\lambda$, then $\int_0^{\infty} C dx = C_o\lambda/(\pi)^{1/2}$ so that

$$\frac{s}{q} = C_o \frac{\lambda}{(\pi)^{1/2}} \quad [8]$$

By determining C_o by the four-probe s/q can be easily derived by means of Eq. [8].

Infrared absorption measurements.—The method is described by several papers (9-11). The set-up for the absorption measurements is shown in Fig. 2. The quartz plate together with the n-type germanium act as a filter which passes a band of light with wave lengths between 2 and 4μ. When d is the thickness of the specimen, α is the coefficient of absorption, I_o is the intensity of the incident light beam, and R is the fraction which is reflected (for germanium $R = 0.36$), then taking into account all transmitted components and the absorption, the transmitted radiation can be obtained as

$$I_t = I_o \frac{(1 - R)^2 \exp[-\alpha d]}{1 - R^2 \exp[-2\alpha d]} \quad [9]$$

By means of the thermocouple the voltages for the combinations:

1. filter and specimen (intensity of transmission), V_1
2. filter without specimen (intensity of the incident light beam), V_2, are measured. Because the voltage is proportional to the intensity,

$$\frac{V_1}{V_2} = \frac{I_t}{I_o} = \frac{(1 - R)^2 \exp[-\alpha d]}{1 - R^2 \exp[-2\alpha d]}$$

From a calibration curve, where I_t/I_o is plotted *vs.* αd, α can be obtained when d is measured. Because α is proportional to the number of holes per cm^3 (9) it can be written $\alpha = AC$, $\alpha d = A \int_0^d C dx$, or

$$\frac{\alpha d}{A} \approx \int_0^{\infty} C dx \text{ number of atoms/cm}^2 \quad [10]$$

where A is a constant. For the measurements reported here the constant A was determined to be

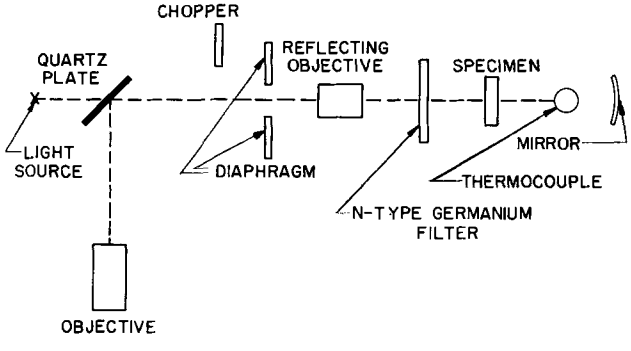

Fig. 2. Schematic diagram of the apparatus setup for infrared absorption.

$A = 1.124 \times 10^{-16}$ cm²/atoms. Furthermore, the expression $R^2 \exp[-2\alpha d]$ was neglected against 1. Thus the number of holes per cm² is obtained simply by dividing the determined expression αd by the constant A.

Measurements of junction depths.—Evaluations of surface concentrations from junction depth measurements require knowledge of the concentration distribution of the indium, the net ionized antimony concentration, and the diffusion coefficient. Difficulties were encountered when values had to be assigned to the net ionized antimony concentration. A detailed discussion of this problem is presented below. In order to be sure that the junction depths determined by junction delineations were reliable in several cases, three different delineation procedures were applied to the same sample.

The first procedure, described, for example, by Bond and Smits (12) and Glang (13) consisted of plating copper on the p-type area of a lapped bevel. After plating, an interference picture was taken in order to obtain the junction depth by counting the interference fringes. Figure 3 shows a typical sample which has been copper plated. Another junction delineation procedure was the dielectric powder deposition. The technique is described by Valdes and Smith (14), for example. The powder used consisted of $BaTiO_3$ which was ground in a mortar. The powder was suspended in trichlorethylene, and the suspension was regarded as satisfactory when it stayed cloudy for several hours after shaking. The thermoelectric probe (12) was applied as a final procedure. The probe was run over a bevel which made a 1° angle with the original surface. The place where p-type changed to n-type was an indication of the junction.

Discussion and Conclusions

The temperatures investigated were: 775°, 837°, and 900°C for the germanium, and 600°, 650°, 700°, and 750°C for the indium. The surface concentrations obtained from these experiments are based on four-probe measurements and are shown in Fig. 4.

The three different germanium temperatures give three sets for the number pair: absolute temperature of the indium, surface concentration. If for a set the log of the surface concentration is plotted *vs.* the inverse absolute temperature of the indium source, the graph through these points can be approximated rather well by a straight line which may be described by the equation

$$C_o = \exp\left[-\frac{m}{T} + p\right] \qquad [11]$$

Figure 4 shows the three straight lines a, b, and c which have been obtained from the application of the method of least squares to the sets of points which belong to the germanium temperatures 900°, 837°, and 775°C, respectively.

The numerical values for the constants m and p, as determined from the lines a, b, and c are listed in Table I. The spreading of the points around line b is indicated by line segments. The numbers on top of these segments give the numbers of points measured at the corresponding temperature. The spreading of points for lines a and c is similar to the spreading for line b. For the benefit of clearness no line segments are given for a and c.

The dashed line gives the log of the concentration of indium vapor in (atoms/cm³) x 10^7. The factor 10^7 was applied to the actual values in order to place the line in the vicinity of the other three. The concentration of the indium vapor was obtained from vapor pressure data (15).

From Fig. 4 it can be seen that the lines a, b, c are close together and nearly parallel to each other. This shows that the surface concentrations depend mostly on the concentration of the indium vapor and are less dependent on the temperature of the germanium. The slope of line a differs most from the slope of the indium vapor line. We think that this does not in-

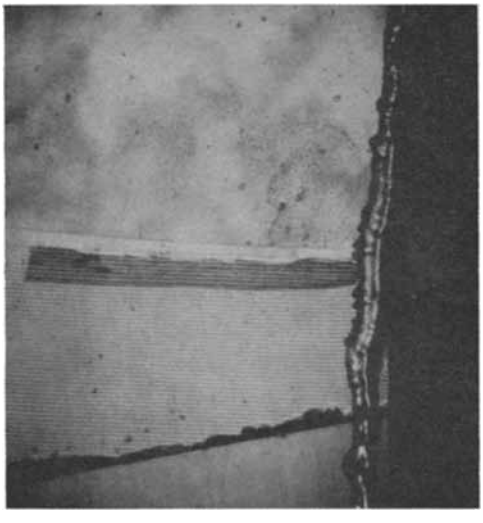

Fig. 3. A junction delineated by copper plating

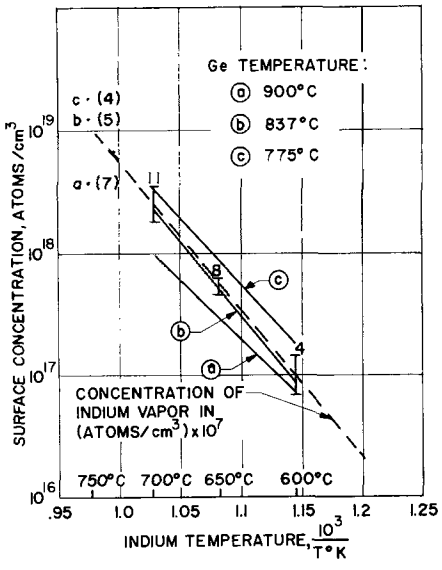

Fig. 4. Surface concentration *vs.* indium temperature for germanium temperatures of 775°, 837°, and 900°C.

Table I. Constants for Eq. [11]

Ge temp, °C	m	p
775	2.50×10^4	68.3
837	2.77×10^4	70.8
900	2.25×10^4	69.4

Table II. Impact rate of indium atoms at different temperatures

Ge temp, °C	In temp, °C	Indium vapor pressure, mm Hg	Impact rate, atoms/sec cm²
900	600	2.0×10^{-6}	1.91×10^{14}
	650	7.0×10^{-6}	6.70×10^{14}
	700	3.3×10^{-5}	3.15×10^{15}
837	600	2.0×10^{-6}	1.96×10^{14}
	650	7.0×10^{-6}	6.85×10^{14}
	700	3.3×10^{-5}	3.23×10^{15}
775	600	2.0×10^{-6}	2.02×10^{14}
	650	7.0×10^{-6}	7.07×10^{14}
	700	3.3×10^{-5}	3.34×10^{15}

dicate a special phenomenon but that the slope comes from two points which we did not want to omit but which were off from the bulk of the other points. While the rate of impacts of indium atoms on the germanium sample decreases with increasing temperatures at the same vapor pressure, the variation of the surface concentration with the germanium temperature is much stronger and cannot be explained by this effect. Table II lists numerical data which were obtained from the formula $\nu = 3.513 \times 10^{22}\ (P/(MT)^{1/2})$, where P is the vapor pressure of the indium in mm Hg, M is the molecular weight of indium, and T is the temperature of the germanium (16).

The lines a, b, and c in Fig. 4 are nearly parallel to the dashed line. Therefore, the quotient: indium vapor concentration ÷ surface concentration is nearly constant and about 10^{-7}, which may be named the distribution coefficient of indium between solid germanium and indium vapor.

For the establishment of the lines a, b, c it was observed that points were used where the limit of solid solubility of indium in germanium was not exceeded. The values for the solid solubilities were taken from Trumbore (17) and are listed in Table III. Thus, one should expect that according to Table III and line a in Fig. 4 for a germanium temperature of, for example, 900°C, the solid solubility limit is exceeded when the indium temperature is higher than 740°C. It was interesting to note that for all germanium temperatures the surface concentrations, which were derived from four-probe measurements, continue rather smoothly into a range where the solid solubility is exceeded. This is demonstrated in Fig. 4 where the three single points a, b, c at 750°C represent centers of gravity for 7, 5, and 4 points, measured at germanium temperatures of 900°, 837°, and 775°C, respectively.

Special experiments were carried out to confirm that the surface concentration is independent of diffusion time. Indium being at 600° and 650°C was indiffused into germanium at 837°C for different times. Table IV shows that the surface concentration is constant with time within tolerable limits.

Table III. Solid solubilities for indium in germanium (17)

Temperature, °C	Solid solubility, atoms/cm³
775	4.0×10^{18}
837	3.5×10^{18}
900	2.0×10^{18}

Table IV. Time dependence of the surface concentration of indium (indiffused at 837°C)

Temp of the indium source, °C	Diffusion time, hr	Surface concentration by four-point-probe, atoms/cm³
600	9.0	8.0×10^{16}
	16.0	9.5×10^{16}
650	2.5	4.0×10^{17}
	10.5	5.5×10^{17}
	16.0	3.5×10^{17}
	22.0	4.6×10^{17}

Table V. Comparison between four-probe and infrared absorption measurements

Sample No.	Ge temp, °C	In temp, °C	No. of indiffused indium atoms, atoms/cm² four-point probe	infrared absorption
1	775	750	2.4×10^{15}	2.5×10^{15}
2	775	750	2.4×10^{15}	1.6×10^{15}
3	775	750	2.4×10^{15}	2.4×10^{15}
4	837	750	1.8×10^{15}	1.9×10^{15}
5	837	750	5.6×10^{14}	8.1×10^{14}
6	900	700	1.8×10^{15}	1.8×10^{15}
7	900	725	7.6×10^{14}	6.3×10^{14}
8	900	750	1.5×10^{15}	1.9×10^{15}

The evaluations of four-probe and of infrared absorption measurements both lead to the number of p-type carriers/cm² indiffused into the germanium. Making measurements by both methods on some samples and using Eq. [1], [8], and [10] for the evaluation of s/q, the data of Table V result. The good agreement between the s/q values of this table indicates the reliability of the four-probe measurements.

All samples to which the four-point-probe method was applied underwent a junction delineation, which has already been described. However, in early experiments it was found that the surface concentrations derived from the junction depths scattered considerably in spite of the fact that the various delineation methods were in good agreement. Junction depths obtained from copper plating and dielectric powder deposition for the same sample were in nearly all of the cases within an error of about 0.25μ. Similar results were obtained by the thermoelectric probe. But because of the probe width the limits of error were greater.

For the evaluation from junction depth measurements, the value of the net ionized antimony concentration must be known because the surface concentration is given by

$$C_o = \frac{C(x_j,t)}{\operatorname{erfc} \frac{x_j}{\lambda}} \qquad [12]$$

where $C(x_j,t)$ is the net ionized antimony concentration at the junction.

The initial concentration, C_B, of the antimony is determined by the doping and is uniform throughout the whole piece of germanium. During the experiment outdiffusion and thermal conversion can take place. Outdiffusion would lead to concentrations near the surface which are smaller than C_B, and thermal

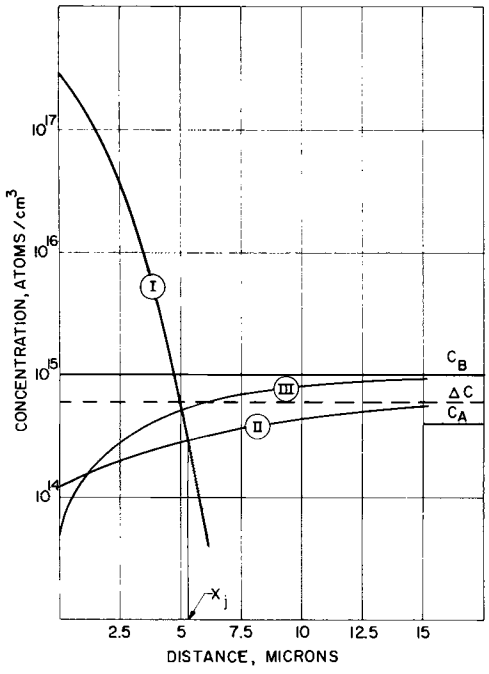

Fig. 5. Typical p- and n-type concentration distributions

conversion would result in a uniform bulk concentration C_A which is smaller than C_B. The concentration distribution after an outdiffusion time of t seconds is given by (18)

$$C_{out} = C_B \left\{ \operatorname{erf} \frac{x}{2(Dt)^{1/2}} + \exp\left[K\frac{x}{D} + K^2\frac{t}{D} \right] \operatorname{erfc}\left[K\left(\frac{t}{D}\right)^{1/2} + \frac{x}{2(Dt)^{1/2}} \right] \right\} \quad [13]$$

where D is the diffusion coefficient for antimony in solid germanium and K is a constant, the surface evaporation velocity.

The above-mentioned concentration distributions are shown in Fig. 5. The curves shown here are typical for many samples.

The concentration of the indiffused indium is plotted *vs.* the distance from the surface and is represented by curve I, which is a graph of $C = C_o \operatorname{erfc} x/\lambda$. Curves II and III are graphs of Eq. [13] and show the concentration distribution of the antimony (for $t = 16$ hr and $T = 837°C$) after the experiment has been completed. For both curves II and III the values of K are from a paper of Miller and Smits (19). The value for the diffusion coefficient of curve II has been taken from Bösenberg (8) and for the diffusion coefficient of curve III from Blakeslee (20).

After each experiment 25μ were lapped off the nonpolished side of the sample, and the bulk resistivity was measured with the four-probe. A change from C_B to C_A due to thermal conversion could be observed for almost all of the samples. The difference $C_B - C_A = \Delta C$ is equivalent to p-type centers introduced by thermal conversion and therefore represents a p-type level. For each sample it was tried to determine the net ionized antimony concentration $C(x_j,t)$ in such a way that the concentration profile I, which met $C(x_j,t)$ at x_j matched a surface concentration which was close to the surface concentration observed from four-probe measurements. Several possible cases were considered for the determination of $C(x_j,t)$:

1. $C(x_j,t) = C_A$
2. $C(x_j,t) = C_{out,II}$
3. $C(x_j,t) = C_{out,II} - \Delta C$
4. $C(x_j,t) = C_{out,III}$
5. $C(x_j,t) = C_{out,III} - \Delta C$

The best result was found for case 2, for which nearly half of the surface concentrations were within a factor of 3 or less in agreement with the surface concentrations from the four-probe measurements.

This led us temporarily to the assumption that thermal conversion measured for the bulk is negligible for a thin surface layer. In the light of new findings for the value of the diffusion coefficient of antimony in germanium (20) however, cases 4 and 5 have to be considered. Case 4 offers no good agreement, whereas case 5 gives a good fit for nearly a third of the samples. The other cases lead to inconclusive results. Therefore, for the present time we have no explanation why the junction delineations are so far off. For a better understanding of the whole situation it would be important to determine the net ionized antimony concentration at the junction by direct measurements, *e.g.*, by capacitance measurements.

It was observed that at higher indium temperatures the surface concentrations derived from junction depth measurements were higher by a factor of 10-10^3. The possibility that field-aided diffusion (21) was responsible for the inconclusive results could be excluded because the condition that the intrinsic carrier concentration was much smaller than the surface concentration was not fulfilled in any run. It seems as if the large disagreement between the surface concentrations from resistivity measurements and junction delineation starts when solid solubility values, given by Trumbore (17), are exceeded. This indicates that the assumed error-function distribution no longer holds. It is, therefore, surprising enough that the resistivity measurements still give consistent values (see points a, b, and c in Fig. 4).

Summary

1. Numerical values for the surface concentration of indium diffused into germanium at 775°, 837°, and 900°C are given.

2. The surface concentrations depend mostly on the concentration of the indium vapor and only to a small extent on the germanium temperature.

3. The surface concentrations are proportional to the concentration of the indium vapor phase with a "distribution coefficient" of about 10^{-7}.

4. Resistivity measurements, which are in good agreement with infrared absorption measurements, give the most consistent values for surface concentrations.

Acknowledgment

The authors want to thank Dr. Kurt Lehovec for helpful discussions and advice and Dr. Hans Reinheimmer for the infrared absorption measurements.

The Chemical Polishing of Germanium

B. A. Irving

Research Laboratory, Associated Electrical Industries, Aldermaston Court, Aldermaston, Berkshire, England

ABSTRACT

The mode of action of the components of the polishing solution CP4 has been elucidated. The initiation of dissolution is dependent on the state of the germanium surface and the concentration of bromine. The final etch rate is limited by the diffusion of hydrofluoric acid to the germanium surface and even though the oxidizing agent, nitric acid, is in excess, the surface is free of detectable oxide. A difference in reactivity between ground and chemically polished surfaces has been demonstrated. Certain observations relevant to the practice of etching are made.

An important step in the manufacture of devices such as diodes and transistors from germanium single crystals is the chemical polishing of cut slices, usually with C.P.4[1] to produce clean surfaces free from cutting damage to which alloy contacts can subsequently be made. A similar treatment is used in the assessment of crystal quality and in the preparation of crystals for electrical measurements such as the lifetime of minority carriers. In the present investigation the chemical significance of each component of the polish was determined.

Experimental

The surfaces of the crystals were prepared by grinding (600 grade carborundum paper) and in some cases followed by chemical polishing. Etch rates were determined from the weight loss of slices etched for a measured time. Weight losses were determined for several different times in the same etchant so that any change of rate in the course of etching became apparent. The surface area of the slices was estimated from their weight and thickness (determined with a micrometer) and did not change significantly during the course of several etch rate measurements. Results were calculated in terms of weight loss (mgm) per square centimeter, and this quantity was plotted against time. The slope of the plots gives the etch rate. Slices of several crystals were used, but when a specific comparison was required, for instance between a ground surface and a chemically polished surface, adjacent slices of the same crystal were used.

The following etching technique was employed and gave reasonable reproducibility (about ±5%). A ring of polythene was cut from a 1/16 in. sheet so that it was somewhat smaller in internal diameter than the width of a slice. The ring was put round the slice so that the latter rested in a polythene beaker at about 45° to the horizontal. Both sides were thus attacked simultaneously when the slice was covered with etchant. After a measured time the etching was stopped by flooding with a large quantity of distilled water (at least 10 times the capacity of the beaker) poured through a polythene funnel which dipped into the etchant. A fresh portion of etchant was used for each measurement.

The potential differences between ground and chemically polished surfaces under etching and non-etching conditions were measured with the aid of a recording millivoltmeter. For these, a slice of germanium was ground on one side and gold plated with a standard cyanide solution using a brush plating

[1] The recipe for C.P.4 is: 25 ml nitric acid (conc); 15 ml hydrofluoric acid (conc); 15 ml acetic acid (glacial); 0.3 ml bromine. The bromine is first dissolved in the acetic acid and the other acids added. C.P. 8 is C.P.4 without bromine.

technique. The slice was cut in two and each half had a wire fixed to the gold plating with silver paste. The joint was cemented with epoxy resin and the specimen, except for the front face, was sealed into polythene. The faces of both specimens were ground and one was chemically polished.

Etchants were made up from Analar reagents. A stock solution of 5% bromine in acetic acid was used to prepare etchants with intermediate bromine concentration. For some experiments nitric acid was freed from lower nitrogen oxides by refluxing in a stream of nitrogen already saturated with nitric acid fully oxidized by ceric nitrate. Urea was added to an etchant by dissolving a small quantity (~¼g) in the acetic acid used.

Results

The following experiments were performed. The etch rate of previously polished germanium surfaces was determined in both C.P.4 and C.P.8 immediately after these had been made up and at 15-min intervals. Results are given in Table I. In addition a slice showed the same rate when etched with a C.P.8 mixture used immediately or stored in a closed polythene bottle for 5 days.

The variation in etch rate during the course of etching was measured for both ground and polished surfaces in C.P.4 and in C.P.8. Results are given in Tables II and III and are plotted in Fig. 1. This variation was further examined for a series of etchants

with intermediate bromine concentrations (0.01, 0.04, and 0.1% approx.), and Table IV gives the results. A considerably reduced bromine concentration gave more uniform attack on ground surfaces. A small quantity of hydrobromic acid (equivalent to about 0.5% Br_2) was added to a C.P.8 etchant. This, used immediately, behaved as normal C.P.8 on a polished surface and as C.P.4. on ground surfaces; neither surface showed an accelerating period. However, the etchant oxidized the hydrobromic acid to bromine. Bromine in acetic acid solution was injected into a beaker containing a slice being etched by C.P.8. It did not affect the weight loss or the apparent course of the reaction: bromine must therefore be present before the etching starts if it is to show its characteristic effects.

The etch rate of polished surfaces was determined for a series of etchants in which the amount of hydrofluoric acid was varied. The compositions of the etchants and the results are listed in Table V. A similar series in which the nitric acid concentration was varied was carried out and the compositions and results are given in Table VI and Fig. 2. A few experiments were performed in which the acidity was increased by using perchloric acid in place of acetic and/or nitric acid. Rates were similar to those with high nitric acid concentration, *i.e.*, replacing 5 ml of acetic acid by perchloric acid had similar effect to adding 5 ml of nitric acid in place of acetic acid.

A C.P.8 etchant made up with purified nitric acid gave the same etch rate as etchant with the usual nitric acid, demonstrating that the initial presence of nitrous acid is not essential for avoiding the accelerating period.

4 min					11.7	6.4	
6 min						10.1	
Final mean rate/min		~9.4	7.9	7.5	3.0	1.6	

The rate with an etchant containing urea was considerably lower than the normal rate. Urea reduces the nitrous acid available during etching.

A C.P.8 etchant already used for polishing germanium until a brown color due to reaction products persisted behaved as C.P.4. on a ground slice.

The potential difference between ground and polished surfaces of between 25 and 30 mv (ground surface more active) was recorded in an etchant made up with perchloric acid in place of nitric acid. In C.P.8. the difference in mixed potential decayed in about 1 min. Reversing the crystal preparations gave similar results, which could therefore be directly attributed to surface preparation.

Discussion

The results of the above experiments established certain facts which are summarized as follows.

There is no ageing effect with C.P.4. or C.P.8.

The etch rate of C.P.4. on a polished surface and C.P.8 on a ground surface builds up for about 1 min. The rate eventually reached is the same as that observed immediately for C.P.4 on a ground surface and C.P.8 on a polished surface.

The accelerating period is absent on a ground surface even when the bromine concentration is as low as 0.01%. At reduced concentrations of bromine on a polished surface the accelerating period is reduced, but is still nearly ½ min at 0.01% bromine.

The addition of hydrobromic acid to C.P.8 did not alter its etching characteristics provided it was used immediately after making up. The etchant slowly oxidized hydrobromic acid to bromine.

At hydrofluoric acid concentration lower than in C.P.8 etch rates on a polished surface were reduced, but were constant with time. At increased hydrofluoric acid concentration, etch rates increased as etching proceeded.

At reduced nitric acid concentration, etch rates on a polished surface were likewise reduced. Increased nitric acid concentration increased the etch rate only slightly, but caused considerable increase in bubbling.

Nitric acid free from lower oxides did not alter the etching of polished surfaces.

Etchants containing urea had lower rate on polished surfaces.

The presence of reaction products removed the accelerating period of C.P.8 on ground surfaces.

Potential measurements indicate that a ground surface is more reactive than a polished one.

The above facts conform to the following interpretation. The results at intermediate bromine concentration indicate that evaporation of bromine from C.P.4 is responsible for the alleged "ageing" of the etchant. These results also indicate that bromine adsorbs strongly onto polished surfaces and inhibits dissolution at low etch rate.

The constant rate exhibited by both C.P.4 and C.P.8 indicates that the rate of reaction is limited by the diffusion of hydrofluoric acid to the surface. The results of the experiments in which hydrofluoric acid and nitric acid concentrations were varied confirm this. The rates at high nitric acid concentration or when perchloric acid was added were rather more variable than most results, and this is attributed to the change in reduction product normally encountered with nitric acid. This produced excessive bubbling and turbulence and resulted in uneven surfaces. (Nitric acid can be reduced by metals or other reducing agents to nitric oxide or nitrogen dioxide depending on its concentration.)

This conclusion is in some ways surprising. The oxidizing agent, nitric acid, is in excess, but the surface produced by etching is free from any appreciable oxide layer. Holmes and Newman (1) failed to detect any oxide on chemically polished germanium by an electron diffraction method which could detect down to a monolayer. No visible oxide film was formed even at the lowest hydrofluoric acid concentration used. It would seem that the hydrofluoric acid participates in the oxidation reaction although it is not itself an oxidizing agent. (The situation is similar to that in some electropolishing processes. The rate of reaction is controlled by the diffusion of a reactant, although the anodic potential is theoretically great enough to cause extensive oxidation. A frequent, although by no means entirely satisfactory, explanation invokes a solid layer on the electrode surface in addition to the diffusion layer in the electrolyte.)

The oxidation of germanium by nitric acid has been investigated by Cretella and Gatos (2). The present etchant results are in substantial agreement with the mechanism they propose. However, their autocatalytic factors would seem unimportant in many instances, and a constant etch rate is established very quickly even though the nitric acid used in the etchant is free from lower oxides. The reduced rate in the presence of urea (which reacts with nitrous acid but not nitric acid $2HNO_2 + CO(NH_2)_2 \rightarrow 2N_2 + CO_2 + 3H_2O$) indicates the importance of nitrous acid to the etching. It is not certain that the urea removed all the nitrous acid produced by the reaction, but the rate of reaction of germanium with undissociated nitric acid must be appreciable. Usually a high surface concentration of nitrous acid is rapidly established by reduction of nitric acid, and the rate is then limited by the availability of hydrofluoric acid. The action of bromine is best understood in terms of the difference between ground and polished surfaces. The potential measurements indicate that the ground surface is more active and the value of 25-30 mv is quite large enough to change the reduction product of nitric acid from nitrous acid to nitric oxide (3). Nitric oxide and bromine react in the presence of water to give nitrous acid and bromide ion. Therefore bromine can promote the autocatalysis, due to nitrous acid, even though the ground surface produces only nitric oxide. In addition it was observed that bromide is oxidized to bromine by the etchant or at least the nitric acid it contains. Therefore bromine is regenerated and has its effect even though present in very small quantity.

In addition, the behavior of bromine-containing etchants on already polished surfaces suggests that it is adsorbed onto the surface. The adsorption increases the availability of bromine at the surface for reaction with nitric oxide. It also inhibits attack, and this can give rise to uneven attack at high bromine concentration even on ground surfaces. The absence of an accelerating period with C.P.8 containing reaction products, including nitrous acid, on ground surfaces is also in accord with this scheme.

Certain observations and deductions relevant to the practice of etching have emerged from this work. (*A*) Provided care is taken to avoid loss of bromine and hydrofluoric acid this type of chemical polish is stable and free from ageing effects. (*B*) The quantity of bromine in C.P.4 etchant can be reduced to about 1/50 that normally recommended to give a more even initial attack. (*C*) Bromine can be added more conveniently in the form of hydrobromic acid. The etchant oxidizes this to bromine. (*D*) Chemical polishing at a reduced rate takes place at lower hydrofluoric acid concentrations and produces a good surface. This modified etch would be useful for controlled thinning of specimens.

The Stabilization of Germanium Surfaces by Ethylation

I. Chemical Treatment

G. W. Cullen, J. A. Amick, and D. Gerlich

RCA Laboratories, Radio Corporation of America, Princeton, New Jersey

ABSTRACT

It is proposed that the termination of each germanium surface atom in a (111) plane with an ethyl group should provide stabilization of the chemical composition of the surface, chemical stabilization being a prerequisite for the stabilization of electrical properties. The germanium surface is first activated with hydrogen chloride and chlorine gases and then ethylated by exposure to ethyl magnesium bromide. Evaluation by various methods indicates that ethyl groups are reproducibly and strongly bound to the surface in a ratio very close to one ethyl group for each surface atom. Details of the electrical and chemical evaluation are included in the following two papers.

The objective of the work described in this series of papers has been to gain further insight into the relationship between the electrical characteristics of a semiconductor surface and the chemical constituents bonded directly to the surface, and thus to learn better how to deal with the problems of control and stabilization of semiconductor surface properties.

The most common approach to surface stabilization has been to inhibit interaction between the surface and the ambient by application of a barrier over an etched surface. The chemical nature of such surfaces is not sufficiently well controlled to provide information on the relationship between the chemical and electrical nature of the surface since the species present subsequent to the inherently irreproducible etching processes are variable, and the nature of bonding at the surface is not defined.

Growth of oxide layers on silicon surfaces has provided more control over the species present on the surface (1), but the type of bonding at the surface is not clear cut since the substrate is crystalline while the oxide covering is amorphous (2).

It should be possible to prepare a chemically well-defined surface by choosing a material as a surface covering which bonds to each surface atom independently without imposing the requirements of a crystalline structure. These considerations have led to the proposal to terminate each surface atom with a saturated carbon chain. The preparation and evaluation described here is specifically concerned with the termination of each germanium surface atom in a (111) plane by an ethyl group. Ideally such a surface should exhibit the following characteristics:

1. A relatively nonabrupt transition from substrate to protective surface layer: The bonding in germanium is similar to that in carbon, thus the Ge-C bond at the interface should resemble the Ge-Ge bonds of the substrate and the C-C bond of the barrier. This should provide a more gradual transition of bond character than that, for instance, at the germanium-germanium oxide interface.

2. Termination of all the surface germanium atoms: Each carbon chain extending from a germanium surface atom is essentially independent of the carbon chain on the adjacent germanium atom; the cross section of the ethyl group is large enough to fill nearly the entire surface, but small enough to permit termination of each surface atom.

3. Chemical inertness: Germanium tetraethyl is an extremely stable compound which is not hydrolyzed by moist air. This stability indicates that the Ge-ethyl bond is strong and suggests that the ethylated surface should not be attacked by ambient constituents.

4. Insulating surface covering: Germanium tetraethyl is transparent to visible light and nonconducting. One may infer from this that the alkyl groups on the surface should also be nonconducting and thus should inhibit surface channeling.

Preparative Procedure

Ethylation of germanium surfaces is achieved by carrying out reactions at the surface which are analogous to well-known bulk reactions. The surface is activated by reacting the (hydrated) germanium oxide layer on the surface with hydrogen chloride and by reacting the underlying germanium with chlorine. The chlorinated surface is then exposed to ethyl magnesium bromide (a Grignard reagent) which replaces the chlorine atoms at the surface with ethyl groups in a manner analogous to the reaction

$$GeCl_4 + 4C_2H_5MgBr \rightarrow Ge(C_2H_5)_4 + 4MgBrCl$$

Very nearly quantitative yields have been realized in the preparation of tetraethyl germane by this procedure (3).

The ethylation process is described in the following sections. The treatment is designed to offer the greatest assurance of obtaining the desired surface,

and the complexity of the preparative procedure is of secondary importance.

In order to provide the greatest possible latitude in the initial preparative techniques, the stabilization of simple wafers, rather than of devices, was attempted. In particular, the (111) surfaces of both n- and p-type germanium were ethylated.

Sizing and cleaning of the sample.—The sample is cut from a single crystal and ground on a 240 grit wheel. Approximately 3 mils of material are removed from each surface by lapping with AO-305[1] abrasive. At least an additional 2 mils are removed from each surface with a fast etch ($2HNO_3$:1HF) to remove the mechanically worked layer left by the lapping operation.

It is essential to avoid the presence on the surface of strongly adsorbed ions which might interfere with subsequent steps in the reaction sequence. Fluoride ions are therefore carefully excluded from the surface at this point. If fluoride ions remain on the surface throughout the surface treatment, they may strongly influence the electrical characteristics of the final surface. For this purpose an etch free of hydrogen fluoride is used subsequent to the fast etch to act as a surface cleaning agent. The cleaning etch consists of 30% hydrogen peroxide saturated with oxalic acid dihydrate. The acid is added because it has been found that, in hydrogen peroxide solutions, the rate of dissolution of germanium increases rapidly with a decrease in *p*H below 5 (4). Oxalic acid, which is one of the strongest organic acids ($K_1 = 6.5 \times 10^{-2}$), provides a means of lowering the *p*H of the solution without adding ions which are diffcult to remove later. Oxalic acid is readily removed from the germanium surface following the etch, since it is decomposed by heat (186°C) or hot hydrogen peroxide into carbon dioxide and water, and it sublimes at 100°C. This treatment removes approximately 0.3 mil of material from the surface which carries with it strongly adsorbed contaminants remaining from the HNO_3-HF etch. Mass spectrometric data (5) show that, on heating, less gaseous material is released from a hydrogen peroxide-oxalic acid etched germanium surface than is released from germanium surfaces treated with other etching mixtures. The quantity of the gases evolved is taken as an indication of the total amount of material adsorbed on the surface.

Activation of the germanium surface.—The sample is activated and ethylated in the apparatus pictured in Fig. 2. The germanium is mounted in a glass clip on the end of a Trubore[2] rod which serves to center the specimen in the heating tube and provides for the rapid transfer of the sample into the various temperature zones. The two zones A and B are maintained at the proper temperatures with automatic controllers.

The sample is exposed for 15 min to pure argon at 144°-147°C and 1 atm pressure to drive off adsorbed moisture. The argon is first passed through type 5A Molecular Sieve[3] cooled to −78°C. The

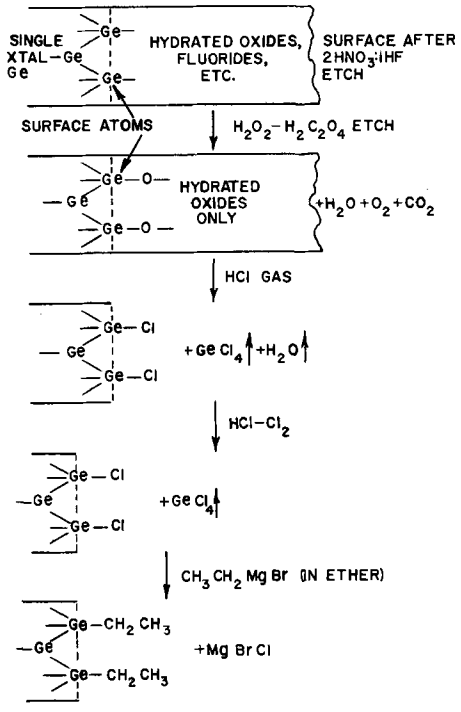

Fig. 1. Alkylation procedure, sequence of steps

sample is then exposed to hydrogen chloride gas at 144°-147°C for 20 min to remove all hydrous germanium oxide present. The water and germanium tetrachloride [bp 83.1 (6)] which form are volatile at this temperature.

The sample is lowered into zone B where the temperature is maintained at 87°-90°C, and an equal amount of chlorine (by volume) is then added to the HCl gas stream. The lower temperature is employed because above 100°C, in the presence of chlorine, an unidentified haze often forms on the germanium surface. At 87°-90°C in 20 min the chlorine removes approximately 0.2μ (by weight loss) from the surface. By removal of a small amount of germanium all impurities should be purged from the surface and each surface atom should then be occupied with a chlorine atom. Both tank gases and gases generated *in situ* (and dried with calcium sulfate and concentrated sulfuric

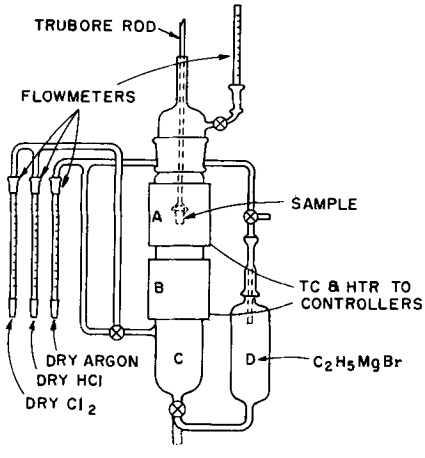

Fig. 2. Alkylation apparatus

acid) have been employed. The source of the gases does not appear to affect the final surface characteristics.

Ethylation.—The chlorine-hydrogen chloride gas mixture is flushed from the apparatus with dry argon, and the sample is lowered into zone C which is at room temperature. Ethyl magnesium bromide which has been prepared and stored in chamber D is forced into the reaction chamber. A stream of argon is allowed to flow into the apparatus at all times to maintain a positive pressure. The sample is allowed to remain immersed in the ethyl magnesium bromide for 15 min although radio tracer studies show that the surface alkylation reaction is essentially instantaneous (7). The excess ethyl magnesium bromide is then forced back into the storage chamber. When the sample is exposed to the atmosphere the ethyl magnesium bromide clinging to the surface immediately hydrolizes. The alkaline hydrolysis products are removed with slightly acidic aqueous ammonium chloride solution followed by distilled water. At this time the germanium surface is strongly hydrophobic.

Preparation of the ethyl magnesium bromide.—The ethyl magnesium bromide is prepared by reaction of ethyl bromide with magnesium turnings in dry ether. Details of the preparation may be found in organic texts (8). The reagent is made as concentrated as possible while avoiding solidification (approximately 5M at room temperature). Moisture and carbon dioxide are rigorously excluded during preparation of the reagent by carrying out the reaction in flamed glassware under an atmosphere of dry argon. The reagent is transferred to the storage chamber D in a completely closed system under argon.

Results and Discussion

The preparative procedure outlined above was developed from more primitive techniques in accordance with results from radio tracer analyses and electrical measurements. The procedure was modified, using these measurements as a control, until reproducibility and complete monolayer coverage with strongly bonded ethyl groups was achieved. These measurements are discussed in detail in the following two papers of this series.

The two major preparative uncertainties are the completeness of surface coverage and the effect of reagent impurities. Unfortunately, both of these factors may be only approximately evaluated by macroscopic chemical analysis due to the minute amount of material associated with a surface monolayer. More explicit information must be inferred from the surface electrical characteristics. A strong surface inversion layer (approx. 4 kT) is observed on ethylated n-type germanium. This may be an unanticipated characteristic of a completely ethylated surface or it may be associated with either of the preparative uncertainties mentioned above.

Occupation of a surface atom with an ethyl group may affect the chemical reactivity of adjacent surface atoms, and steric hindrance at a chlorinated atom surrounded by ethylated atoms may also play a role in the degree of surface coverage. It has been observed, however, that exposure of a chlorinated surface to lithium ethyl, which is an even more vigorous alkylating agent than ethyl magnesium bromide (9, 10), yields a surface with essentially the same electrical characteristics as that achieved with the ethyl magnesium bromide. If low reactivity of a partially ethylated surface were an important factor, one would anticipate that the use of ethylating agents of different reactivity would yield surfaces having different electrical properties.

The above observation also suggests that one may rule out the possibility that the surface electrical properties are strongly affected by adsorbed magnesium and lithium ions. It is anticipated that magnesium ions would have a different influence on the electrical properties than lithium ions.

Every effort has been made to exclude contaminants from the system prior to ethylation. The purity of the chlorine and hydrogen chloride gases is probably the most difficult factor to control. It was found that surface electrical properties were not altered if tank gases rather than gases generated in an all-glass apparatus with pure reagents were employed in the chlorination step. Moisture traps were used for the tank gases, the vapor pressure of the possible metal chlorides from tank gases is very low at room temperature, and surface adsorption of such contaminants as carbon dioxide or monoxide would be prevented by the more reactive major constituents. It is therefore assumed that the chlorination step does not introduce unknown impurities.

Since the electrical characteristics of an ethylated surface are essentially independent of the alkylating agent used and the source of the hydrogen chloride and chlorine gases, the origin of the surface inversion layer is not clear. This, as well as other questions presented in the subsequent papers, will be the subject of further investigation. All measurements available at this time, however, indicate that the procedure outlined above is effective in reproducibly preparing a surface essentially completely occupied with strongly held ethyl groups.

Acknowledgment

The authors are grateful to J. Baglio and J. Bacskai for their assistance in the preparation of the ethylated surfaces.

Manuscript received May 31, 1961; revised manuscript received Oct. 26, 1961. This paper was prepared for delivery before the Indianapolis Meeting, April 30-May 3, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

The Stabilization of Germanium Surfaces by Ethylation

II. Chemical Analysis

J. A. Amick, G. W. Cullen, and D. Gerlich

RCA Laboratories, Radio Corporation of America, Princeton, New Jersey

ABSTRACT

Radiotracer techniques and mass spectrometry have been employed in analyzing ethylated germanium surfaces; the results from these two analytical techniques are in good agreement. The number of ethyl fragments on a treated (111) germanium surface is the same as the number of surface germanium atoms, within experimental error. The surfaces are stable at temperatures below 200°C in vacuum and in air, but begin evolving C_1 and C_2 fragments above 200°C. At higher temperatures, additional hydrocarbon fragments are seen mass spectrometrically. Using wafers having labelled ethyl groups, it has been found that the treated surfaces are stable to immersion in common chemical solvents.

As a result of research on the preparation of stable and reproducible semiconductor surfaces, a chemical treatment has been developed for germanium which is designed to bond ethyl groups to all surface atoms (1). Electrical measurements made on these surfaces show that they are unusually stable and insensitive to ambients (2).

To confirm the presence of ethyl groups on the treated surfaces and to enable a correlation of the electrical properties of the surface with its chemical composition to be made, suitable analytical techniques were required. For wafers of a few cm^2 total area, the number of surface fragments will be no greater than about 10^{15} for monolayer coverage. Both radiotracer studies and mass spectrometry were used in this investigation since they possess the required sensitivity, and since the two techniques give complementary information.

Radiotracer Studies

(111) wafers of germanium having labelled ethyl groups were first prepared by procedures more primitive than that described in the first report of this series (1). For the synthesis of the Grignard reagent, tritium labelled ethyl bromide was employed. The activity of the treated surfaces was used as a guide for modifying the treatment, leading finally to an ethylation procedure giving reproducible results and monolayer coverage. The consequences of exposing these treated surfaces to heat and to chemical solvents was then determined.

Materials and Equipment

The Grignard reagent used in preparing the ethylated surfaces, was synthesized from labelled ethyl bromide supplied by New England Nuclear Corporation. Tritium, rather than carbon, was chosen as the labelling atom since it can be obtained in much higher specific activity and can therefore be detected at lower concentrations than can C^{14}. With a half life of 12 years, the activity is essentially constant over a period of one or two months. Standard precautions were followed in the preparation and handling of Grignard reagent.

The apparatus used in the ethylation of germanium surfaces, was essentially a duplicate of that described earlier (1). Samples were counted in a 2π windowless gas flow counter[1] whose efficiency was found to be 0.670 using tritium labelled stearic acid films deposited on polished copper surfaces (3).

Concentration of Ethyl Groups on the Surface

The radio-ethyl bromide was supplied as Ethyl-1-H^3 Bromide in sealed vials containing 40 mg each, with a specific activity given as 27.7 millicuries per millimole. Each vial was specified to contain 10 millicuries. Before use, this material was diluted 1:100 with inactive ethyl bromide, making the ratio of labelled to unlabelled molecules 9.19×10^{-6}.

Corrections for back scattering and for counter efficiency were made on raw data. A factor of two correction is required because the counter detects radiation over only a 2π rather than a 4π solid angle. The number of ethyl groups on a treated surface can thus be calculated from:

$$N = \frac{C\,(1\text{-}0.275)\,(2)}{0.672\,A\,\lambda\,R}$$

where N is the number of ethyl groups per cm^2; C is the activity of the sample in counts per minute; 0.275 is the fraction of the radiation back scattered; 0.672 is the counter efficiency; A is the area of the sample in cm^2 = 0.816 cm^2; λ is the disintegration constant for tritium = 1.09×10^{-7} min^{-1}; R is the ratio of active to inactive ethyl bromide molecules.

Table I.

Sample	Average net cpm	Ethyl groups/cm² (±5% estimated)	Number of ethyl groups per surface Ge atom
1	117.8	3.12×10^{14}	0.43
2	105.9	3.1	0.43
3	134	4.08	0.56
4	29	0.75	0.10
5	212	5.62	0.77
6	211	5.59	0.77
7	234	6.20	0.85
8	234	6.20	0.85
9	254	6.73	0.92
10	282	7.47	1.0

The number of surface germanium atoms per cm² (111 plane) is given by Handler (4) as 7.3×10^{14}/cm².

Influence of Ethylation Procedure on Ethyl Group Concentration

The steps in the original ethylation procedure consisted of (*a*) an etch in CP-8 (HF-HNO_3) to remove any mechanically worked surface, (*b*) an oxalic acid hydrogen peroxide etch to remove undesirable ions from the surfaces (1), (*c*) chlorination in an HCl/Cl_2 mixture at 85°C, (*d*) without exposure to air, immersion in Grignard reagent for a few minutes, (*e*) rinsing with saturated ammonium chloride solution, then with water, and, finally, (*f*) drying in air at room temperature.

The influence of modifying the procedure may be seen in Table I. Samples 1 and 2 were treated according to the steps outlined above. Samples 3 and 4 were treated similarly except that the chlorination step (c) was omitted. Sample 3 has a reasonably large concentration of ethyl groups, but subsequent heat treatment showed that the surface was no longer heat stable. The concentration of ethyl groups on sample 4 is seen to be only 10% of that on sample 10. From this it is inferred that chlorination is an essential step in the surface treatment procedure. Samples 5 and 6 were heated in nitrogen at 120°C for 1½ hr following chlorination and preceding Grignard treatment. Samples 7 and 8 were similarly heated in nitrogen both preceding and following chlorination. Samples 9 and 10 were cycled three times between nitrogen heat treatments at 120°C and chlorination at 85°C prior to Grignard treatment.

With the cyclic treatments in nitrogen and HCl/Cl_2 mixtures, the number of ethyl groups on the surface was increased, presumably due to more complete chlorination of the germanium surface prior to Grignard treatment. Subsequent work has shown that equivalent results can be obtained by treatment in pure HCl at 144°-147°C and this has been incorporated into the standard ethylation procedure (1).

Sample 5 was allowed to stand in contact with the Grignard reagent overnight [step (*d*)]. The surface concentration of ethyl groups is seen to be about the same as for sample 6 which was in contact with the Grignard reagent for only a few minutes. Reaction of the chlorinated germanium surface is therefore presumed to be nearly instantaneous.

Following ethylation, the number of ethyl groups present on the germanium surface is seen to be very nearly one for each surface germanium atom (Table I, samples 9, 10). This is the ratio which would be expected using the simple conceptual model of a germanium surface in which each surface atom has a bond directed outward (normal to the surface) to which an ethyl group is covalently attached. Although the calculation assumes an atomically smooth surface, the statement would still be true, within experimental error, as long as the number of surface atoms is not increased by more than a few per cent because of surface roughness. For the germanium wafers used in this work, this seems a reasonable hypothesis.

If a thick hydrated oxide surface layer were "esterified" by this treatment, and if the structure were sufficiently porous to allow penetration of reagents into the layer, it is anticipated that more than one ethyl group would be present for each surface germanium atom. If ethane or some other hydrocarbon molecule were physically adsorbed on the surface, it would be surprising if exactly one molecule were present for each surface germanium atom.

Results of Exposure to Heat and Ambient

The Grignard treated surfaces appear stable to heating in air to about 200°C. Above this temperature they decompose and the radioactivity present on the surface decreases rapidly. This behavior may be seen in Fig. 1 where the activity on the surface, in counts per minute, is plotted as a function of time for sample 5 held at 335°C and for sample 6 held at 200°C. At 335°C the activity drops more than an order of magnitude in the first hour. After 4 hr at 200°C the activity has dropped to only about ½ the initial value. In Fig. 2, similar data for sample 9 (improved treatment) is presented. At 200°C the activity drops by about 10% and then remains constant during a 2-hr heat treatment during which the temperature is allowed to rise to 230°C. When the temperature is subsequently raised to 260°C the activity immediately begins to decrease. No loss in activity is observed for a sample kept in a vacuum for periods up to a day at room temperature, for a sample heated in a vacuum at 100° for 18 hr, or for a sample heated in a vacuum at 147°C for 5 hr.

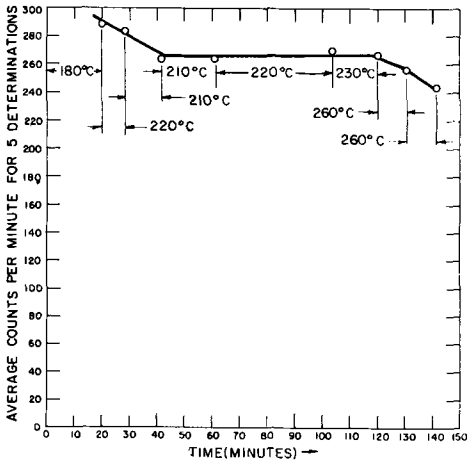

Fig. 2. Loss of radioactivity from an ethylated germanium surface during heating in air. Surface has one monolayer of ethyl groups, within experimental error. Ethyl groups labelled with tritium.

Results of Immersion in Common Chemical Reagents

The effect on the treated surface of immersion in some of the more common chemical reagents was determined in the following manner. A tritium labelled ethylated wafer was first placed in a beaker containing the reagent, and the solution was mechanically stirred for 3-5 min. The wafer was then removed, rinsed in water, dried, and counted. Results of these tests are shown in Table II. It will be noted that the surface is unaffected by immersion in the organic solvents tested, that small changes are observed when the surface is immersed in dilute acids, but that concentrated acids, and bases in all strengths, remove most of the activity from the treated surface.

From these experiments it is concluded that the labelled atoms are not present in molecules adsorbed on the surface. Adsorbed molecules should desorb in one or more of the solvents listed in the first column of Table II and should also desorb when the surface is heated moderately in vacuo.

Mass Spectrometry

To obtain analyses of the surface composition by mass spectrometry, it is first necessary to remove fragments from the surface. This has been done for the ethylated germanium surfaces by two techniques: (*a*) by sputtering with rare gas ions and (*b*) by heating *in vacuo*. The sputtering technique has the advantage that the temperature of the sample can be kept low and therefore rearrangement of fragments on the surface is minimized. The rare gas ions, however, introduce strong peaks of their own at the parent mass and at submultiples of the parent mass. This makes the detection of other radicals having masses in these regions difficult. Direct heating of the surface *in vacuo* is a very simple way of producing desorption of surface fragments. The surface may act as a catalyst at higher temperatures, however, and form new species not present originally. The interpretation of the spectra must therefore be made with caution.

Table II.

No change (within statistical error) (±3%)	Small changes (<10% removed)	Large changes (>10% removed)

Spectra Obtained by Heating the Ethylated Surface

For analysis of the fragments desorbed by simple heating, a Diatron[2] 20 mass spectrometer was available. This instrument has several major advantages: The total volume is small. Thus, the absolute amount of gas needed for an analysis is a minimum and the sensitivity is high. The resolution is about 20; thus mass 20 is completely resolved from mass 21. The useful m/e range is 1-50 which is satisfactory for the present work. The instrument has been modified so that it is completely bakeable (5), which allows background pressures of 10^{-9} mm Hg to be obtained readily.

For the present work, the instrument was modified in two ways. A quartz sample tube wrapped with a heating tape was connected to the mass spectrometer through a Granville-Phillips[3] high vacuum valve. Secondly, a flap valve was included between the mass spectrometer and the diffusion pump. The fragments desorbed from the germanium surface are thus retained in the mass spectrometer chamber and their concentration increases as the heating proceeds. The temperature of the sample was monitored with an iron constantan thermocouple and a K-3 potentiometer.[4]

The entire system, including the quartz sample tube and the mass spectrometer, is first baked out at 350°C for several hours. After cooling, base pressures of 10^{-8} mm Hg are usually obtained. The mass spectrometer is then closed off from the sample area by means of the high vacuum valve. The sample tube is next cracked open and the sample is inserted. The sample tube is then sealed back onto the system, and the quartz section only is baked out at 500°C while the sample is kept in the Pyrex portion of the system at room temperature.[5] After a week of pumping the pressure is usually down to about 3×10^{-9} mm Hg.

In beginning a run, the ion gauge is turned off to prevent the pumping of fragments released by the surface, the flap valve is closed and a background spectrum is taken. The sample is then heated slowly until the surface begins to release hydrocarbon frag-

[2] Consolidated Electrodynamics Corp., Pasadena, California.

[3] Granville-Phillips Company, Pullman, Wash.

[4] Leeds and Northrup Co., Philadelphia, Pa.

[5] Initially, the sample tube was removed and resealed using a gas/oxygen flame. A test experiment showed, however, that during this sealing process, methane, carbon dioxide, carbon monoxide, and water were adsorbed on a clean, de-ethylated germanium sample, *i.e.*, one which had been baked out in the mass spectrometer at 400°C overnight. A new sample tube was consequently designed which would permit resealing without exposing the inner walls of the sample tube to the hot flame gases (Fig. 3). Hydrogen/oxygen flames were also used in order to minimize the presence of hydrocarbon impurities. With these precautions, impurities were reduced by an order of magnitude, but were not completely eliminated.

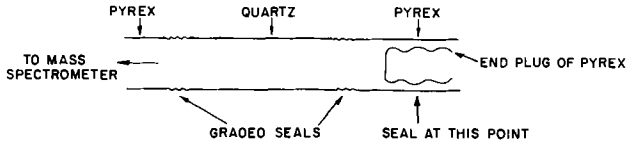

Fig. 3. Sample tube used for the thermal desorption of fragments from an ethylated germanium surface, showing the shape of the plug used for sealing the sample wafer into the system.

ments. Spectra are recorded continuously, each spectrum (m/e 12 through 44) requiring about 8 min. The current through the heating tape was usually increased stepwise in such a way that the temperature of the quartz tube approached 150°, 225°, and 400°C in sequence, spectra being recorded during each step.

Results

Typical spectra obtained from an ethylated germanium surface are shown in Fig. 4 and 5. The first spectrum Fig. 4a, corresponds to the background fragments which appear even when the sample is kept at room temperature. The major peak is 28 and consists of both CO and N_2. Also present are water, carbon dioxide, and methane. This background spectrum was obtained with the quartz sample tube at 163°C.

The ethylated sample was inserted in the heated tube, and after a 10-min interval the second spectrum, Fig. 4b, was taken. The C_1 peaks have continued to increase as have the CO/N_2 and water peaks. Peaks in the C_2 region at 25, 26, and 30 are just becoming detectable.

When the quartz sample tube is heated to 211°C, the C_2 peak heights rise by almost two orders of magnitude while the C_1 and water peaks remain almost unchanged, Fig. 4c. As the heating of the sample to

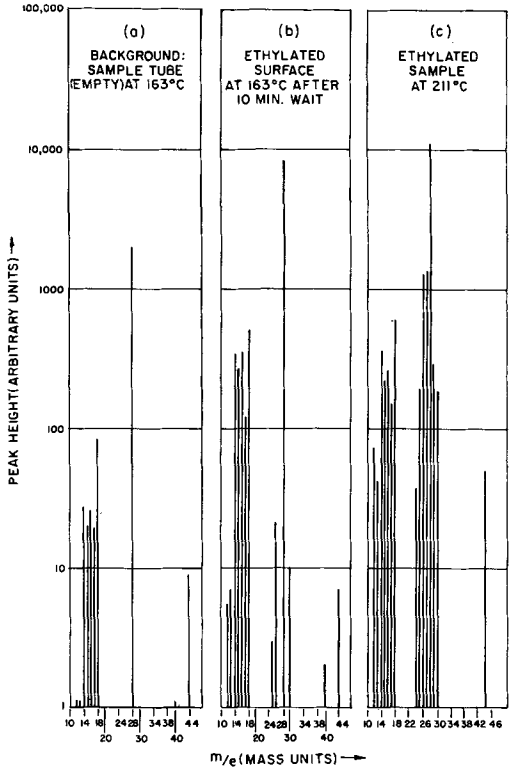

Fig. 4. Mass spectra of the fragments released from ethylated germanium surfaces by heating.

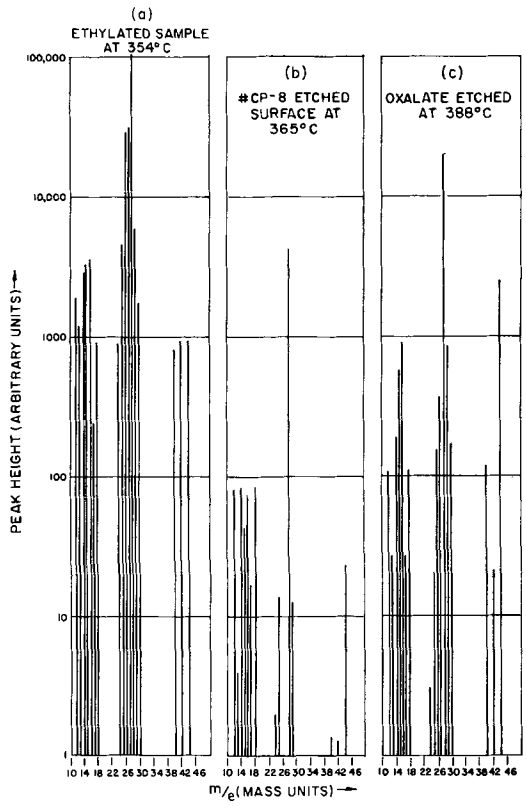

Fig. 5. Mass spectra of the fragments released from the germanium surfaces by heating. (a) ethylated surface at 354°C, (b) CP-8 etched surface, (c) oxalate etched surface.

successively higher temperatures continues, the pressure finally rises to the point where abnormal spectra having very broad peaks are obtained. This is apparently due to a continuous discharge occurring within the mass spectrometer. At this point, therefore, the temperature is held constant while the flap valve is opened for ½ to 1 min to pump out the accumulated gases. The valve is then closed and the heating continued.

Finally, the sample is heated to 354°C and the spectrum shown in Fig. 5a is obtained. The C_2 peak heights are much larger than in Fig. 4c, and new peaks, corresponding to C_3 fragments, are observed.

For comparison, the spectra obtained from a CP-8 etched wafer and from an oxalic acid-hydrogen peroxide etched wafer are also included in Fig. 5. These were obtained at temperatures greater than 350°C since it is only at these high temperatures that reasonable peak heights can be obtained. The CP-8 etched sample contains almost no C_2 or C_3 fragments. At temperatures up to 300°C, no C_2 or C_3 fragments can be detected on the oxalate etched wafer either. Even at the high temperatures, however, the C_2 peak heights are 100 times less intense than those obtained from an ethylated surface. It can thus be concluded that the C_2 peaks in the spectra of the ethylated surfaces are due to molecular fragments present on these surfaces before insertion into the mass spectrometer.

With the help of standard spectra taken under nearly equivalent conditions (6), it is possible to determine the composition of the gases resulting from vacuum heating. These are ethane, ethylene, acetylene, and methane, all of which would be expected

in the spectra of ethylated germanium surfaces. The ethane probably results from rearrangement of fragments on the hot quartz walls surrounding the sample.

Although no observation of the mass 1 or mass 2 peaks for hydrogen was made, an analysis of the average hydrogen to carbon ratio for the observed hydrocarbons was carried out. This ratio was 2.7 for the sample heated at 211°C, 2.3 for the sample heated at 354°C. If all of the hydrocarbons originated from ethyl groups on the surface, and if the desorption of hydrogen as H or H_2 were negligible, the ratio should be 2.5. This analysis is therefore consistent with the hypothesis of an ethylated germanium surface.

The stability of the surface at temperatures below about 200°C is also in agreement with the observations made on the tritium labelled surfaces, as is the occurrence of decomposition above 200°C. When an ethylated sample is heated to a given temperature, say 250°C, for the first time, and then pumped at that temperature for a period of several hours, the evolution of gas gradually ceases. If the sample is now heated above this temperature, say to 300°C, rapid evolution begins with the spectra having peaks at the same masses as obtained at the lower temperature. This behavior is characteristic of chemisorption where the binding energy of the groups on the surface depends on coverage.

Concentration of Surface Groups

The number of surface groups originally present on an ethylated surface can be estimated from (*a*) the surface area of the wafer, (*b*) the volume of the mass spectrometer and sample chamber, and (*c*) the pressure reached after most of the fragments have been removed from the surface. This estimate is only approximate because of the crudeness of the measurements involved, but should be good to within a factor of 10.

The ion gauge cannot be used directly to measure the pressure because of its strong pumping action for the hydrocarbon fragments. Although the reasons are not understood, this action is much less pronounced for water vapor and for nitrogen. The deflection of the chart recorder pen can thus be calibrated against the ion gauge during a background run where only water and nitrogen appear. Higher pressures of hydrocarbons can then be estimated using this calibration.

The total pressure can be estimated as the sum of the partial pressures of the major components present in the spectrum. In a spectrum such as Fig. 5a, the major peaks are 26, 27, and 28. Assuming that these are C_2 fragments which originated from ethyl groups on the surface, the total deflection can be taken as the sum of the individual deflections for these three masses only. For a typical spectrum, this leads to a surface concentration of ethyl groups of 10^{15} per cm^2, estimated accurate to within a factor of 10. This figure is in good agreement with the number of surface atoms per cm^2 in the (111) plane of germanium, 7.3×10^{14}. This calculation is thus in agreement with the radiotracer results which indicate that ethyl groups are present, within experimental error, in the ratio one for each surface germanium atom, and indicates that contaminating hydrocarbon layers, *e.g.*, of grease, are absent.

Although the sensitivity of the mass spectrometric technique is extremely high, no unusual impurities were detected. If fluorine or HF were present in small quantities (from the etching step), they would probably react rapidly with the quartz or the glass and would not appear in the mass spectrometer. Fragments which are not volatile, *e.g.*, Na or K ions, would not appear either and could only be detected in sputtering experiments. No oxygen containing fragments are observed except CO and CO_2 which are probably due to background. The only fragments which might be considered impurities are the higher hydrocarbon fragments, *e.g.*, C_3,C_4. These might be present in the original ethyl bromide in the concentrations observed on the surface, or they may result from rearrangement on the surface.

Spectra Obtained by Sputtering the Ethylated Surface

With a larger, higher resolving power mass spectrometer having a suitable sputtering source (7), several ethylated germanium wafers have been examined. In this instrument, the germanium wafer is mounted inside the ionization chamber of the mass spectrometer so that fragments released from the surface immediately become part of the ion beam. Rearrangement and loss of the fragments on the walls are therefore avoided. Although the argon ions are accelerated to 400v, the sputtering current is so low that the sample temperature is not perceptibly above room temperature.

Those fragments released from the surface as positive ions are recorded in Table III. Those fragments released from the surface as neutrals and ionized subsequently with an electron beam are recorded in Table IV.

Since the surface is partially decomposed during alignment of the source, it is not possible to obtain quantitative estimates of the species present. It is

Table III. Bombardment of ethylated germanium wafer by A^+ ions (400 ev): positive ions released from surface

(m/e = 30 not seen)

Because of ionization of argon in the electron beam, interference in the m/e = 40 region is severe. Peaks above m/e = 45 are too weak to be detected.

significant, however, that fragments consisting of an ethyl group attached to a germanium atom are observed, (Table III) whereas fragments consisting of an ethyl group, a germanium atom, and an oxygen atom are not observed. Further, $C_2H_5^+$ appears with a reasonably high intensity whereas $C_2H_5O^+$ is entirely absent. Since the oxygen containing fragments GeOH and Ge_2O do appear,[5] it can be deduced that the number of C_2H_5 groups bonded to the surface via an oxygen "bridge" is less than a few per cent of the number of C_2H_5 groups present. This observation is supported by the very weak intensity of the O^- peak seen in the spectrum of negatively ionized fragments released from the surface (8). Since no mass 30 peak is observed in the spectrum, the C_2H_5 groups cannot be present as adsorbed ethane. These observations therefore confirm the hypothesis that ethyl groups are bonded directly to germanium atoms in the surface. They also rule out such alternative possibilities as that the C_2H_5 groups are present as adsorbed ethane or ethyl alcohol or that an "ethyl germanate" surface results from the ethylation procedure.

Although the primary peaks for chlorine, 35 mass unit region, are masked by argon, no fragments consisting of a germanium atom or an ethyl group bonded to a chlorine are observed. The absence of chlorine containing fragments is taken as evidence that the reaction between the Grignard reagent and the chlorinated germanium surface is essentially complete.

Summary

Estimates of the number of surface groups per unit area, as obtained from the mass spectrometric data, agree well with the number obtained from radiotracer studies. This number corresponds, within experimental error, to one ethyl group for each surface germanium atom in a (111) plane. Ethyl groups are seen in the mass spectra of fragments sputtered from the surface, but no ethane is observed. Fragments consisting of ethyl groups attached to a germanium atom are also observed in these spectra, but no fragments containing chlorine and no fragments consisting of a germanium atom, a carbon atom, and an oxygen are detected.

Mass spectrometric analyses and radiotracer studies show that ethylated surfaces are stable in air and in vacuum below about 200°C. They are also stable to immersion in common organic solvents and in water. This supports the hypothesis that the surface layer consists of groups chemically bound to the surface rather than molecules adsorbed on the surface.

From these observations it is concluded that the treatment described in the first report of this series results in a (111) germanium surface in which an ethyl group is chemically bonded to each of the surface germanium atoms.

[5] The Ge-OH and Ge_2O peaks probably result from reaction of the bombarded germanium surface with background water. These peaks are relatively strong because reaction occurs continuously during sputtering, whereas the surface hydrocarbon monolayer is rapidly removed and is not regenerated. These peaks are in the same intensity ratio to the primary germanium peak (74) as for a bombardment cleaned (unethylated) germanium surface.

Acknowledgment

The radiotracer data on the ethylated germanium surfaces were obtained by Mrs. M. Tiner under the supervision of Dr. D. A. Ross at the Industrial Reactor Laboratories, Plainsboro, New Jersey. The mass spectrometric data on the sputtered germanium surfaces were obtained by Dr. R. E. Honig who also kindly made available the Diatron 20 mass spectrometer for the thermal desorption studies. The authors would also like to acknowledge the technical assistance of Mrs. J. Bacskai and Mr. J. Baglio.

Manuscript received May 31, 1961; revised manuscript received Oct. 26, 1961. This paper was prepared for delivery before the Indianapolis Meeting, April 30-May 3, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

The Stabilization of Germanium Surfaces by Ethylation

III. Electrical Measurements

D. Gerlich, G. W. Cullen, and J. A. Amick

RCA Laboratories, Radio Corporation of America, Princeton, New Jersey

ABSTRACT

Measurements of both the trapped charge density in the fast states and the surface recombination velocity as a function of the surface potential are reported for ethylated germanium surfaces. Measurements have been made at room temperature on n- and p-type wafers. The surface potential was varied over a range of 0.15v by the application of an a-c electric field normal to the surface. In the region of surface potentials examined, the charge distribution can be approximated by two discrete sets of surface states. The surface formed by ethylation have a concentration of fast states of the order of 5 x 10^{11} cm^{-2}. On n-type material a strong p-type inversion layer is formed; on p-type material the bands are nearly flat at the surface. Ethylated samples have also been examined by the large signal surface photovoltage technique and by observation of the slow states conductivity relaxation. Measurements on several samples and repeated measurements on the same sample in a series of different gaseous ambients show the surface structure to be reproducible, stable, and insensitive to ambients.

Extensive research has been carried out during the last several years on the electrical properties of germanium surfaces (1), and a fairly good concept of the electrical structure of these surfaces has evolved as a result of these investigations. Most of this work, however, has been done on germanium surfaces etched in CP-4 or some similar etch containing hydrofluoric acid. The chemical and structural features of the surfaces prepared in this manner are ill-defined, and it is therefore difficult to correlate the electrical properties of these surfaces with their chemical composition. It is desirable, therefore, to prepare a surface by a well-defined chemical treatment and correlate its electrical properties to its chemical composition.

At this laboratory, the approach to this problem was to create an active surface free of mechanical damage as far as possible on a germanium wafer and to react this surface with a chemical reagent which would bond ethyl groups to each surface atom (2). To monitor changes in the chemical procedure and to determine the influence which the chemical treatment has on the electrical properties of the wafer, electrical measurements were carried out on these surfaces. These included measurements of the large signal field effect, surface recombination velocity, large signal surface photovoltage and slow states conductivity relaxation on a number of different samples and in a series of different gaseous ambients. These measurements furnish information about the surface potential and the electronic structure of the surface states on the treated samples. Thus, hopefully, one will be able to correlate the chemical composition of these surfaces with their electronic structure.

Experimental Method

The germanium samples used in all measurements except the surface photovoltage were in the form of right parallelopipeds with the approximate dimensions of 0.03 x 0.4 x 1.2 cm^3, with ohmic tin contacts soldered to their ends. These were placed between two metal sheets which served as electrodes for the applied electric field, two Mylar[1] sheets of 0.0005 in. thickness serving as insulating spacers. The total capacity between the plates and germanium sample was of the order of 60 $\mu\mu$F. The quantities actually measured were the filament lifetime, τ_f, and the filament resistance, R_f, as a function of a 60 cps electric field which varied in amplitude from zero to a few hundred volts. The frequency was chosen so as to eliminate the relaxation effects of the slow states, while still being low compared to the response of the fast states (3-5).

τ_f was measured by means of a double bridge described in detail elsewhere (6, 7). The bulk lifetime of all the samples investigated was high enough (several hundred microseconds or more) so that effectively only surface recombination was active in the annihilation of the excess minority carriers. Thus the surface recombination velocity s could be determined directly from τ_f (8). R_f was measured by a modified Montgomery and Brown circuit (9). The changes in the measured R_f values are used to evaluate the changes in the surface conductance, and from these the surface potential ϕ_s is determined, ϕ_s being defined as $E_F - E_i$ where E_F is the Fermi level, E_i the intrinsic Fermi level at the surface. This is done by matching the observed and theoretical minimum of the surface conductance [as this minimum is independent of the surface states configuration, being determined solely by E_F (10)]. A modified Schrieffer correction for the surface mobility (11, 12) was used for computing the theoretical surface conductance *vs.* ϕ_s curve. s is thus determined at each ϕ_s value. Fin-

[1] DuPont registered trade mark.

ally from the voltage and the known capacity between the electrodes and the germanium sample, the total induced charge density can be determined. Subtracting from the latter the space charge density estimated theoretically (10-13), the trapped charge density in the fast states, Q_{fs}, is obtained.

The surface photovoltage was determined in a set up equivalent to that described by Johnson (14). The samples were in form of circular plates, about 1 cm in diameter and 3-4 mm thick. The back surface of each wafer was sandblasted after the chemical treatment, the photovoltage being measured on the front surface under high intensity light injection.

The slow states conductivity relaxation was measured with the same apparatus and on the same samples used for field effect studies. The only difference is that the applied field is d.c., and the off balance signal is followed with a recording potentiometer instead of an oscilloscope.

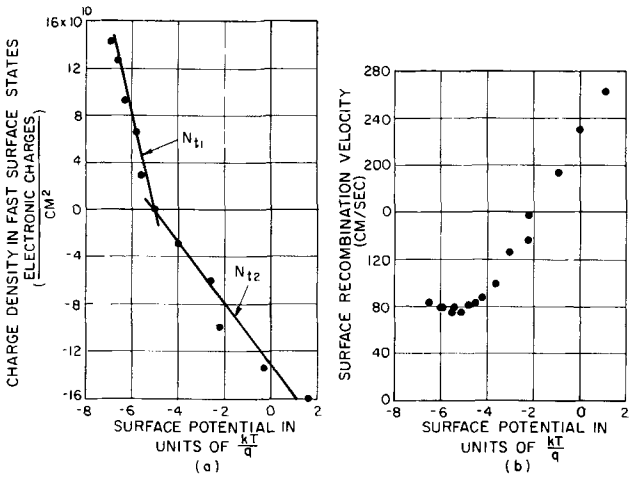

Fig. 1. Trapped charge density (a) and surface recombination velocity (b) *vs.* surface potential for an ethylated surface of an n-type sample, 15 ohm-cm resistivity in dry nitrogen (run 5 in Table I).

Results

Repeated runs of Q_{fs} and s *vs.* $q\phi_s/kT$ (q being the electronic charge) at room temperature were taken in a series of gaseous ambients over a period of several weeks. Usually the surface was exposed at least 24 hr to the ambient before making the measurement.

Figure 1 shows typical results for an n-type sample, resistivity 15 ohm-cm, (111) crystallographic plane, 6 days after ethylation, the sample having been kept in dry nitrogen all the time (run 5 in Table I). The circles in Fig. 1(a) represent the measured values of Q_{fs} *vs.* $q\phi_s/kT$. (Actually, Q_{fs} is the excess charge over and above the charge in the fast states at the quiescent surface potential, *i.e.*, the surface potential at zero applied field). The ultimate aim of the analysis of such results is to determine the energy E_t and concentration N_t of the fast states giving rise to this distribution. In principle this can be done by fitting the experimental curve with a Fermi distribution of the form

$$Q_{fs} = N_t \{1 + (1/2) \exp [(E_t - E_i - q\phi_s)/kT]\}^{-1} \quad [1]$$

or a sum of such terms, N_t and E_t are treated as parameters to be determined by the best fit, and the states are assumed to be spin degenerate. But since such a fit is not completely unambiguous (7), only an approximate analysis is carried out here. The experimental curve is approximated by two straight line segments, each of them attributed to a discrete fast state. The slope of the straight line determines the concentration of the state, being equal to $\frac{2}{9} N_t$ while the range in ϕ_s over which the particular segment extends determines the range in which E_t is to be found. Analyzing the curve in Fig. 1(a) in this manner, one can distinguish two states in these results; one closer to the valence band with a concentration N_{t1} of 4.0 x 10^{11} cm^{-2} and an energy $E_{t1} - E_i < -5kT$; the second state is closer to the conduction band with a concentration N_{t2} of 1.3 x 10^{11} cm^{-2} and an energy $E_{t2} - E_i > -5kT$. Another fact revealed by Fig. 1(a) is that the quiescent surface potential ϕ_{so} is about $-5kT/q$, *i.e.*, a strong p-type inversion layer of about 0.12v is formed on the ethylated surface, in contrast to CP-4 etched surfaces which usually tend toward forming an accumulation layer.

Figure 1(b) shows the complementary results of s *vs.* $q\phi_s/kT$ which were measured simultaneously with the field effect. As a result of the limited swing in ϕ_s due to the high concentration of the fast states and the strong inversion layer only a limited part of the extreme left branch of the $s(\phi_s)$ curve could be covered, and very little information can be drawn from it. Figure 2 shows similar results on the same filament, but in a gaseous ambient of dry oxygen (run 6 in Table I). The analysis is carried out in a completely analogous manner to

the previous case. The Q_{fs} results show also in this case the presence of two states with concentrations $N_{t1} = 4.8 \times 10^{11}$ cm^{-2} and $N_{t2} = 1.3 \times 10^{11}$ cm^{-2}, and energies $E_{t1} - E_i < -5.5kT$ and $E_{t2} - E_i > -5.5kT$, respectively. Also here the surface exhibits a strong p-type inversion layer, and the $s(\phi_s)$ curve is similar in shape to that obtained with the nitrogen ambient.

Figures 1 and 2 are typical examples of a large number of runs on the same sample from immediately after ethylation to 11 days later. These runs are summarized in Table I, where the energies E_{t1} and E_{t2}, the concentrations N_{t1} and N_{t2} of the two states, as well as the quiescent surface potential $q\phi_{so}/kT$ are given. The column "time" shows the number of days during which the surface was exposed to the same ambient, while the numbers in parenthesis show the time elapsed since ethylation. The most striking feature of Table I is the stability and insensitivity of the ethylated surface structure to the different ambients, as contrasted to etched surfaces. The changes from run to run are well within the experimental error which is rather large due to the high concentration of fast states, the limited swing in surface potential, and the difficulty of using the $s(\phi_s)$ curves for the analysis of the surface structure. The quiescent surface potential is virtually clamped at -4 to $-5kT/q$ during the whole cycle, which shows that the Brattain-Bardeen gaseous cycle could not possibly have been used in the investigation of these surfaces.

4	4(4)	6.4	<-5	1.3	>-5	-5.2

Table II gives similar results for an n-type sample of 30 ohm-cm resistivity and (111) crystallographic plane, the sample having been kept in dry nitrogen during the whole course of the measurements. Table III shows similar results for an n-type sample, resistivity 16 ohm-cm, (111) crystallographic plane, the sample having been exposed to room atmosphere all the time. The results presented in both Tables II and III are extremely similar to those given in Table I, which shows that the ethylation forms a reproducible electronic structure which is very insensitive to changes in ambients ranging from dry nitrogen through dry oxygen to room atmosphere.

In order to check whether this particular surface structure is determined by the ethylation process or is due to some other factor, the same measurements were carried out on an n-type sample, resistivity 31 ohm-cm crystallographic plane (111) which has undergone only the oxalate etching process (2), and not the chlorination and ethylation steps. The results are shown in Fig. 3. As is readily seen, the structure which results is completely different from that of the ethylated surfaces. The undisturbed surface shows an accumulation layer, and the character of the $s(\phi_s)$ curve is completely different from the case of the alkylated surfaces.

Similar measurements have also been carried out on p-type material. Figure 4 shows typical results of Q_{fs} *vs.* $q\phi_s/kT$ for a p-type sample, 22 ohm-cm resistivity, (111) crystallographic plane, immediately after ethylation, the surface being exposed to dry nitrogen (run 1 in Table IV). It is evident that

Table IV. Values of characteristic fast states parameters for an ethylated surface on p-type material, resistivity 22 ohm-cm in different gaseous ambients

Run	Ambient	Time, days	$N_{t1} \times 10^{-11}$ cm^{-2}	$\frac{E_{t1} - E_i}{kT}$	$N_{t2} \times 10^{-11}$ cm^{-2}	$\frac{E_{t2} - E_i}{kT}$	$\frac{q\phi_{so}}{kT}$
1	dry N_2	0(0)	10	<-3	3.0	>-3	-2.5
2	dry N_2	1(1)	8.4	<-2	4.7	>-2	-1.9
3	dry N_2	4(4)	8.2	<-3	4.1	>-3	-2.7
4	dry N_2	5(5)	10	<-3	4.6	>-3	-2.5
5	dry O_2	1(6)	7.0	<-2	3.8	>-2	-1.4
6	dry O_2	3(8)	7.2	<-2	3.4	>-2	-1.6
7	dry O_2	7(12)	?	?	3.2	>-2	-1.3
8	wet N_2	1(13)	3.2	<3	7.0	>3	2.9
9	wet N_2	3(15)	?	?	5.8	>3	3.3
10	dry N_2	0(15)	5.6	<-1	4.8	>-1	-0.4
11	dry N_2	3(18)	8.6	<-2	3.3	>-2	-1.8
12	dry N_2	4(19)	6.3	<-2	3.1	>-2	

the essential characteristics of the surface structure are the same as in the case of n-type material. The Q_{fs} results presented in Fig. 4 can also be explained by the presence of two levels, one closer to the valence band with a concentration $N_{t1} = 1.0 \times 10^{12}$ cm^{-2} and energy $E_{t1} - E_i < -3kT$, the second closer to the conduction band with a concentration $N_{t1} = 3.0 \times 10^{11}$ cm^{-2} and energy $E_{t1} - E_i > -3kT$. In this case the quiescent surface potential is close to the flat band position.

Table IV summarizes the results of a whole series of runs in different ambients on the sample described previously during a period of three weeks. Again one notes the similarity with the results for n-type material. Neither the fast states densities nor the quiescent surface potential changes appreciably in the different dry ambients. There is a change in these quantities in the measurements performed in wet nitrogen (100% relative humidity), a point which will be taken up later.

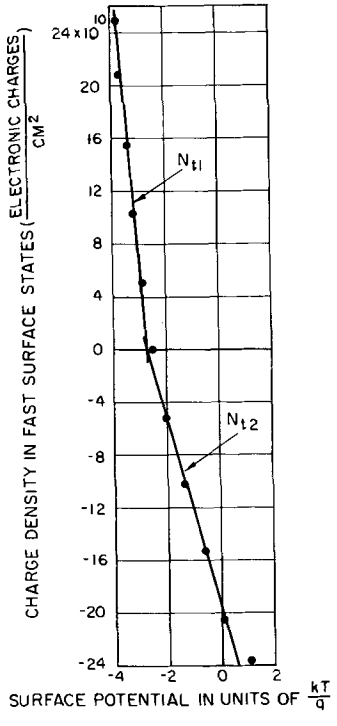

Fig. 4. Trapped charge density vs. surface potential for an ethylated surface of a p-type sample, 22 ohm-cm resistivity in dry nitrogen (run 1 in Table IV).

Preliminary measurements of the slow states conductivity relaxation were also carried out on the ethylated surfaces. Usually a d-c field of ± 800v was switched on and off, the conductivity variation being recorded continuously as a function of time. These relaxations are usually very long, of the order of hours. Apparently a highly insulating film has formed on the surface which slows down appreciably the leakage of charge from the space charge region and the fast states to the slow states. However, the surface relaxes back to its original state if one waits long enough, *i.e.*, all the charge initially induced in the fast states has looked to the slow states indicating that the latter are much more numerous than the fast states, and that there has been no permanent chemical change affecting the fast states during the cycle. Since the temperature stability of the system over extended periods was not good enough, no qualitative results concerning the slow states could be deduced.

Photovoltage measurements on ethylated wafers were carried out for both n- and p-type material. Table V lists the results of the photovoltage in units of kT/q (0.025 volts at room temperature) for an n-type sample, 15 ohm-cm resistivity, (111) crystallographic plane, in a series of gaseous ambients.

Table VI presents similar results for a p-type sample, 22 ohm-cm resistivity, (111) crystallographic plane. The measured photovoltage is given as such. It has been shown (14) that for complete saturation, the photovoltage is equal to $\phi_s - \phi_b$, where $\phi_b = E_F - E_i$ in the bulk, E_F being the Fermi level. Since in our case complete saturation has not been reached, the measured photovoltages are somewhat smaller than $\phi_s - \phi_b$. However, the meas-

Table V. Photovoltage for an ethylated surface on an n-type material, 15 ohm-cm resistivity in different gaseous ambients

8	dry N_2	0(5)	−0.5	p

urements are in agreement with the observation made with the field effect technique. Furthermore, these measurements show that the quiescent surface potential is not affected even by wet ambients; it remains essentially unchanged during the whole cycle of different ambients.

Discussion

Several conclusions concerning the ethylated surfaces can be drawn from the results presented above. The surfaces produced by this treatment are reproducible; completely different crystals yield essentially the same surface structure after ethylation. The quiescent surface potential is not affected appreciably by the whole gaseous cycle ranging from dry oxygen to wet nitrogen. This strongly suggests that the slow states on these surfaces are quite inert, being unable to absorb or desorb chemical species from or to the ambient. The character of the $Q_{fs}(\phi_s)$ and $s(\phi_s)$ curves is essentially the same for the different gaseous ambients, which indicates that the fast state structure stays constant. It can therefore be inferred that the ethylation treatment yields a reproducible and stable surface, one which does not change chemically in various gaseous ambients.

In contrast, for CP-4 etched surfaces, the quiescent surface potential will usually change over a range of 12 kT/q during the gaseous cycle (15-17), some changes in the fast states structure will occur due to exposure to different gaseous ambients (7, 18), and slow states conductivity relaxation is of the order of minutes (19).

The discrepancy between the photovoltage and the field effect measurements for the case of the wet ambients is probably due to irreversible changes caused by the action of the high electric fields on the surface in the presence of the wet ambient, on the surface. Such effects on etched surfaces have also been reported by other investigations (20-22) and might be due to ionic movement in a water film on the surface.

A puzzling feature of the ethylation treatment is the high concentration of fast states and the strong p-type inversion layer formed on n-type material. If one assumes that all the dangling bonds at the surface are occupied by ethyl groups, an assumption which is corroborated by tracer analysis and mass spectroscopy (23), then such a structure should, conceptually, be nearly electrically neutral. It is therefore difficult to conceive where the states observed on the ethylated surfaces can arise. On the other hand, the number of "dangling bonds" on a (111) germanium surface is of the order of 10^{14} cm^{-2} (24) so that, if only 1% were not saturated, they could account for the concentrations of the fast states appearing in our experiment. Incidentally the density of the fast states on ethylated surfaces is of the same order of magnitude as the density of fast states for etched surfaces (7, 9, 18). It is also possible that the fast states appearing on these surfaces are associated with distortions of the bonds connecting the ethyl groups to the germanium atoms, or with structural defects in the germanium layer beneath the ethyl groups, defects which have not been removed by etching prior to ethylation. Another possibility is that other groups besides ethyl are bound to the surface in small quantities during the treatment, and that these are responsible for the appearance of the fast states.

All these questions require further investigation before a complete understanding of the surface ethylation treatment can be achieved.

Acknowledgment

The authors wish to thank Mr. E. Margerum for his technical assistance and Mr. J. Baglio for his help in the ethylation treatment.

Method for Analyzing Volatile Silicon Compounds

W. J. McAleer, M. A. Kozlowski, P. I. Pollak, and R. G. Denkewalter

Electronic Chemicals Research Department, Research Laboratories, Merck Sharp & Dohme, Rahway, New Jersey

ABSTRACT

A technique has been developed for the detection of donor impurities in volatile silicon compounds. The method consists of depositing a thin layer of elemental silicon from the silicon-containing vapor on to a single crystal wafer of high-resistivity silicon. Electrical measurements on the freshly deposited layer yield information about the effective concentration of total donor or acceptor impurities present in the volatile compound. The method is sensitive to at least 1 ppb of contaminating substance.

The use of Si in solid state electronic devices has produced the need for Si of an unusually high degree of purity. Many of the methods currently in use for producing ultrapure Si involve thermal or reductive decomposition of volatile Si compounds. It is important therefore to develop means of preparing the Si compounds in a highly purified state and to have an analytical method of extreme sensitivity for detecting electrically active impurities in the volatile semiconductor precursors. This work describes such an analytical technique based on the electrical behavior of impurities in the semiconductor itself.

The method developed in our laboratory consists of the deposition of a thin layer of Si from a vapor containing the volatile Si compound to be analyzed onto a single crystal wafer of high-purity Si. Examination of the type and resistivity of the freshly deposited layer can in an empirical manner reveal the type and quantity of the electrically active impurities present in the volatile compound.

It is important to note that, since the measurement employed shows only the final resistivity state of the Si, an integrated or net n- or p-concentration is determined. Thus, if the freshly deposited layer is found to be low resistivity, n-type Si, the volatile precursor compound contains a significant concentration of donor impurities. Conversely, if the volatile compound was contaminated with high levels of acceptor impurities, a p-layer of low resistivity would be formed. When lower levels of donors or acceptors are present, higher resistivity layers will result.

Analyses described here were carried out on trichlorosilane; however, the method is equally applicable to other volatile Si compounds and in principle could be used to analyze the volatile precursors of any semiconductor material.

Apparatus

The apparatus consists of a quartz reaction tube 18 mm in diameter and 30 cm long. The bottom (inlet) is tapered to receive 5 mm (ID) polyethylene tubing, and the top terminates in a 24/40 standard tapered quartz joint. A 24/40 ground glass (Pyrex) adapter is inserted in the top and extends, via Tygon tubing, to an oil bath bubbler through which the exiting gases are discharged into a fume hood. The gases are introduced into the reactor at the bottom through the vapor train sketched in Fig. 1.

The interior assembly consists of a quartz disk with a handle on top and a small hook on the bottom. The disk is of a diameter large enough to rest on indentations in the quartz reactor inserted just below the quartz joint. Suspended from the hook is a thin quartz rod (2 mm diameter and 12 cm long) on which the single crystal Si substrate is mounted horizontally. The Si is then virtually free of contact with the reactor.

An RF coil is fitted rather snugly around the wall of the quartz reactor to provide for the heating of the Si wafer. The coil, issuing from the RF generator on flexible leads, is mounted on a laboratory jack which permits easy raising and lowering of the coil in the vicinity of the wafer. RF heating is preferred since it allows the walls of the reactor to be cooler than the Si substrate, effectively eliminating deposi-

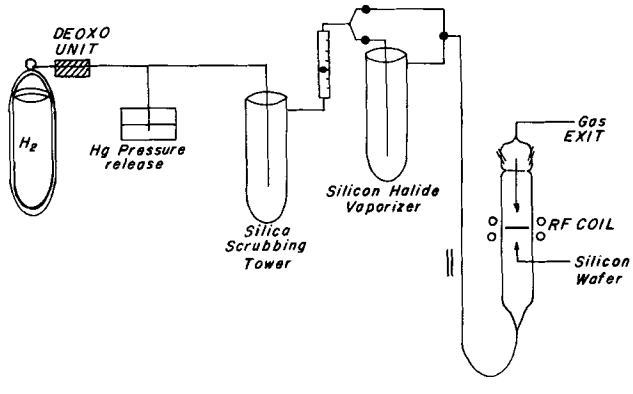

Fig. 1. Diagram of vapor train

tion of Si on the walls and decreasing the transfer of impurities from quartz to Si.

Operation

Silicon wafers 16 x 14 x 2 mm are cut from high-resistivity,[1] uncompensated (~1000 ohm-cm), zone-refined single crystals, and a 3 mm hole is drilled just off-center of the wafer. The Si piece is suspended from the thin quartz rod (described above) by slipping it over the hook at the top and sliding it down until it rests on a bead at the bottom. The wafer must lie approximately horizontally in the reactor to provide sufficient surface for RF coupling. If the crystal hangs perpendicularly, insufficient coupling occurs and the wafer cannot be raised to the proper temperature when an induction heater with a capacity of 5 kw operating at 4 megacycles is used.

The wafer, suspended on the quartz rod, is etched in 30 ml of warm (60°C) 50% potassium hydroxide solution for 5 min. High-resistivity (≧16 megohm) water is poured into the beaker to produce a more dilute solution (3:1), and the wafer is treated for an additional 15 min in this solution. The wafer is removed from the bath and washed copiously with the high-resistivity water. Finally, the piece is sprayed with reagent grade acetone and air dried.

The rod and wafer are attached to the inner assembly and the whole inserted into the reaction tube from above. The Pyrex adapter is fixed in place and a stream of hydrogen passed through the reactor for 15 min, at 0.8 liter/min, to purge it of air. The vaporizer line is also purged with hydrogen to insure complete removal of oxygen from all parts of the assembly before the Si wafer is heated. The total free volume in the system is approximately 250 cc; thus, at a plug flow rate of 0.8 l/min, the time required to displace the air with hydrogen is approximately 20 sec.

To effect RF coupling to the high-resistivity Si (which will not couple at room temperature) the wafer is heated to a red glow by warming the reactor wall immediately around the wafer with a hand torch burning a gas-oxygen mixture. As the Si piece glows red, torch heating is discontinued, and the RF coil, which has been held several inches below the wafer region, is cranked into place and the RF generator turned on to activate the coil. Coupling occurs immediately, and the wafer is brought to 1150°C (unconnected) by adjusting the power control on the RF generator to the proper setting. An optical pyrometer, accurate to ±2.5% in this temperature range, is used to check the temperature of the wafer.

When the desired temperature has been established, the hydrogen flow is continued for approximately ½ hr to effect a final *in situ* removal of SiO_2 from the substrate surface before deposition of Si is begun (1). The hydrogen stream is then diverted to pass through the vaporizer line and carry the trichlorosilane into the reactor. The hydrogen flow is held at 500 cc/min, and the trichlorosilane is at room temperature. Vaporization is carried out for 30 sec, and the stream of hydrogen is readjusted immediately by means of the two-way stopcock to allow pure hydrogen to pass through the reactor, purging it of residual trichlorosilane. Finally, the RF generator is turned off and the wafer allowed to cool to room temperature in a stream of hydrogen. Blank runs are carried out in identical fashion with the trichlorosilane step omitted.

[1] Although high resistivity Si was used throughout this work, lower resistivity material could be used since the requirement of nonconducting surfaces (cf. Measurement Section) is provided by the p-n junction.

Measurements

The thickness of the deposited n-layers is determined by angle lapping. The specimen is lapped in a jig of the sort described by Fuller (3), thus exposing the junction. The p and n areas are clearly delineated by applying the $HF \cdot HNO_3$ staining etch described by the same authors, and from the angle of a lap and a direct measurement of the exposed n zone the thickness can be calculated from the relationship: $X = d/\sin\theta$, where d is the horizontal distance across the stained surface. Following the deposition conditions given above, layers 1.0 mils in thickness are obtained.

The resistivity of the deposited Si layers is determined with a four-point probe apparatus (2). For a crystal of infinite thickness the resistivity ρ_o is given by the formula $\rho_o = (V/I)\,2\pi S$, where I is the current (amp) supplied to the crystal through the two outer probes, V is the potential difference (v) between the inner two probes, and S is the spacing between the probes (cm) where all spacings are made equal. For a finite geometry (*i.e.*, very thin layer) with nonconducting surfaces the necessary correction to the resistivity formula is given by the function $(\rho/\rho_o) = F(W/S)$, where W is the thickness of the layer and ρ_o the measured resistance. For values of $W/S << 1$ the factor reduces to $(\rho/\rho_o) = 0.72\ W/S$.

In measuring the resistivity of the deposited layers, we have assumed that the p-n junction acts as an insulating plane (3) and that the correction for finite geometry with a nonconducting surface can be applied. The resistivities given in the following tables have been corrected by multiplying the observed resistivities (ρ_o) by $0.72\ W/S$, since W is 0.0025 cm and $S = 0.1$ cm in our system.

A standard curve for the effect of various levels of phosphorus on the freshly deposited layers was ob-

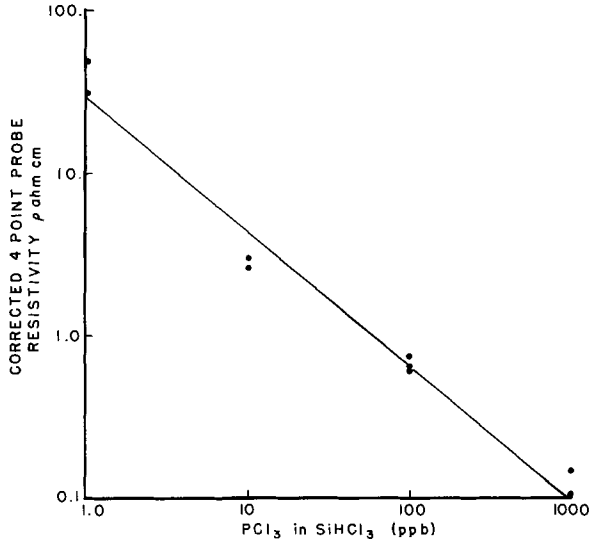

Fig. 2. Plot of resistivity vs. concentration of PCl_3

Table I.

Charge	Observed resistivity,* ohm-cm	Calculated** resistivity	Type
$SiHCl_3$ + 1000 ppb PCl_3	0.10, 0.15	0.22	n
$SiHCl_3$ + 100 ppb PCl_3	0.60, 0.75	2.40	n
$SiHCl_3$ + 10 ppb PCl_3	3.00, 2.60	24.0	n
$SiHCl_3$ + 1 ppb PCl_3	50.0, 32.0	240	n
H_2	00‡		p

* Duplicate runs at the various PCl_3 levels indicated an accuracy of ~25%. The resistivities have been corrected for layer thickness.

** The calculated resistivity values are obtained by assuming 100% cracking and incorporation of phosphorus from the PCl_3. A 10% yield of Si from the trichlorosilane is used in the calculation based on data obtained by Allegretti (4) for the reductive cracking of $SiHCl_3$ in flow system of the type used here. Finally, the mobilities used were from a compilation by Conwall (5).

‡ Wafers heated in hydrogen alone acquire a very thin film of high-resistivity p material. Immediately below this layer one detects the original 1000 ohm-cm Si unchanged.

tained by adding successively higher charges of phosphorus trichloride (from 1 ppb to 1 ppm based on grams of PCl_3 added to grams of $SiHCl_3$) to high-purity trichlorosilane and cracking aliquots of these known solutions on wafers. The results are shown in Table I. A plot of resistivity *vs.* concentration of PCl_3 in $SiHCl_3$ reveals a nearly linear relationship between the added PCl_3 and the observed resistivity of the deposited layer (cf. Fig. 2).

A series of analyses were carried out on samples of commercial trichlorosilane and fractions obtained from several distillations of this material. The results of these analyses are presented in Tables II and III.

Both distillations were carried out in all-quartz stills with quartz ring packing with an efficiency of approximately 14 plates. In the first distillation a reflux ratio of 5 to 1 was used while in the second distillation a 10 to 1 ratio was employed. The distillation covered in Table II was performed on approximately 17 liters of trichlorosilane. A 0.5 liter forerun and 8 cuts of 1.8 liter each were taken, leaving a residue of 2 liters. Analyses were performed on cuts 4 and 5, cut 8, and the residue. The very low resistivities resulting from the distillation residues are evidence of the fact that a donor impurity is concentrated in that fraction; furthermore, the higher resistivities obtained with fractions from the 10 to 1 ratio distillation show that improved distillation conditions can yield higher purity trichlorosilane.

Fitting the data obtained for the commercial trichlorosilane and the distillation cuts derived therefrom to the plot in Fig. 2, one could conclude that the commercial material contains approximately 10 ppb donor impurity. Fractional distillation is capable of reducing this well below the 1 ppb level in the overhead cuts while the concentrations in the residue go up to ~110 ppb. This, of course, assumes that the donor impurity in $SiHCl_3$ is behaving like PCl_3. In any event, it is possible with this method to follow the reduction of electrically active impurities in volatile Si compounds with a sensitivity not available by any other analytical technique.

Measurement of the Depth of Diffused Layers in Silicon by the Grooving Method

B. McDonald and A. Goetzberger

Shockley Transistor, Unit of Clevite Transistor, Palo Alto, California

ABSTRACT

A technique for the determination of the depth of diffused layers presented first by Happ and Shockley in 1956 is evaluated and compared with conventional methods. The process involves cutting a groove of cylindrical shape into a diffused specimen, delineating the junction by standard techniques, and, under magnification, measuring two variables which can be substituted into a simple equation to calculate the thickness of the diffused layer. The regularity of the groove contour is evaluated from measurements with interference fringes. Diffused layers as thin as 0.2μ can be measured with a deviation of $\pm$ 0.04μ over an entire slice.

It is the purpose of this paper to evaluate a technique of junction depth determination described in 1956 by Happ and Shockley (1). The technique discussed here lends itself particularly well to the measurement of very thin diffused layers which are difficult to measure accurately by the commonly used methods such as angle lapping (2) or breaking along crystal planes (3). Since extreme care in sample preparation is not required for this technique, measurements of diffused layers may be made conveniently and with a high degree of accuracy. This technique involves cutting a cylindrical groove into the silicon surface, staining the layers by conventional methods, and, under magnification, without the necessity of interference fringes, making simple linear measurements from which the depth of the diffused layer can be easily calculated.

Sample preparation.—A low melting, readily soluble wax, such as Apiezon wax, is melted on the top of a stainless steel mounting block (labeled 2 in Fig. 1) in a very thin layer. If the sample to be measured is thin, a glass cover plate (5 in Fig. 1) is then placed on the wax to provide a smooth flat surface on which to mount the sample. Additional wax is melted in a thin layer on the cover plate to hold a small piece of silicon broken from a diffused sample. The excess wax is removed and the mounting block is placed as shown in Fig. 1. The grooving cylinder, which may be made from a highly polished cast semisteel such as meehanite,[1] is held in a small lathe. The sample is held against the cylinder by a spring (labeled 4 in Fig. 1), and the cylinder is rotated over the sample by the lathe in the presence of an extremely fine abrasive (such as "Linde B") suspended in a light oil. This process cuts a groove into the silicon. (The accuracy of locating a groove in a particular area of the sample surface is determined by the capabilities of the lathe being used.) The abrasive suspension is cleaned off, and the sample is ready to be stained. It is possible to use any of the conventional methods for diffused layer delineation; however, the staining method which was found to be fastest and most reproducible is that described by Fuller and Ditzenberger (2). This stain consists of ½ H_2O, ½ HF (49%), and 0.1% HNO_3 (67%). A drop of this stain is placed on the groove and, with an illumination of approximately 850 f.c. from a tungsten filament lamp, the diffused layer can be nicely delineated in about 1 min.

Measurement.—The mathematics of the grooving technique are as follows. Figure 2 shows a schematic cross section of a groove in the surface of a silicon sample. X_j represents the depth of the diffused layer, R is the radius of the grooving cylinder, D is the cylinder diameter, and x and y are the distances one would measure looking at the groove from the top.

[1] Product (process) of the Meehanite Corp.

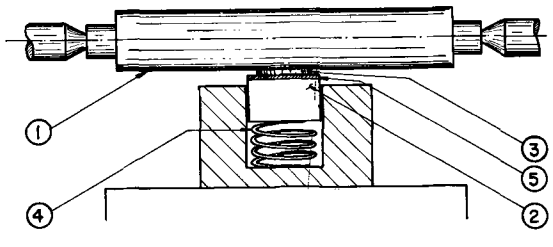

Fig. 1. Grooving apparatus: 1, grooving cylinder; 2, mounting block; 3, silicon slice; 4, spring; 5, glass cover plate.

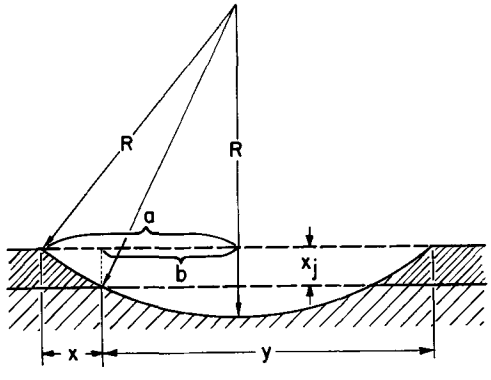

Fig. 2. Groove cross section

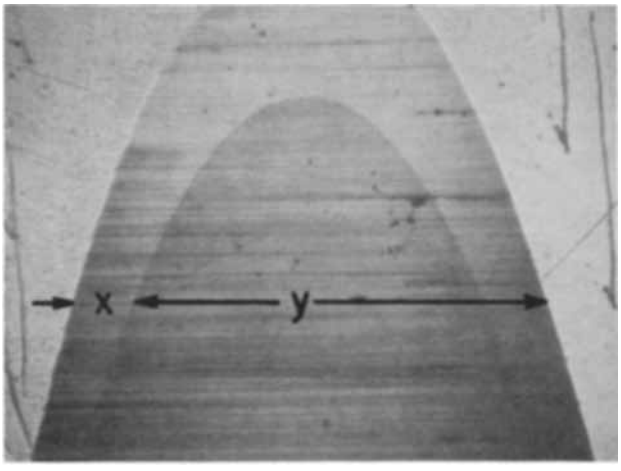

Fig. 3. Diffused n-layer

From Fig. 2,

$$x = a - b,$$

$$y = a + b,$$

and

$$X_j = \sqrt{R^2 - b^2} - \sqrt{R^2 - a^2}$$

$$= R\left[\sqrt{1 - \frac{b^2}{R^2}} - \sqrt{1 - \frac{a^2}{R^2}}\right]$$

When $b << R$

$$X_j \approx R\left[1 - \tfrac{1}{2}\frac{b^2}{R^2} - 1 + \tfrac{1}{2}\frac{a^2}{R^2}\right]$$

$$= \tfrac{1}{2}\frac{a^2 - b^2}{R}$$

$$= \tfrac{1}{2}\frac{(a+b)(a-b)}{R}$$

$$= \tfrac{1}{2}\frac{xy}{R} = \frac{xy}{D}$$

The grooved and stained sample will appear as in Fig. 3, which shows an n + layer delineated. (The surface of the sample is in the plane of the photograph. In this case, the axis of the grooving cylinder was at an angle to the surface). The values x and y are then measured along a continuous straight line, divided by the magnification of the optical system, and the simple calculation is made for X_j.

Evaluation of the Technique.—In order to evaluate the process more fully, several investigations were made, the first being a study of the groove contour. This was done by observing the groove with an interference objective and a filar eyepiece (Fig. 4). The number of fringes were counted between regular increments in the filar eyepiece and the number of fringes plotted against the number of increments to obtain the derivative of the curve. If the contour was of regular curvature, one would expect a plot displaying a straight line, such as is shown in Fig. 5. (These points were taken from the groove shown in Fig. 4.) Proof of a regular contour was obtained on all samples evaluated in this manner.

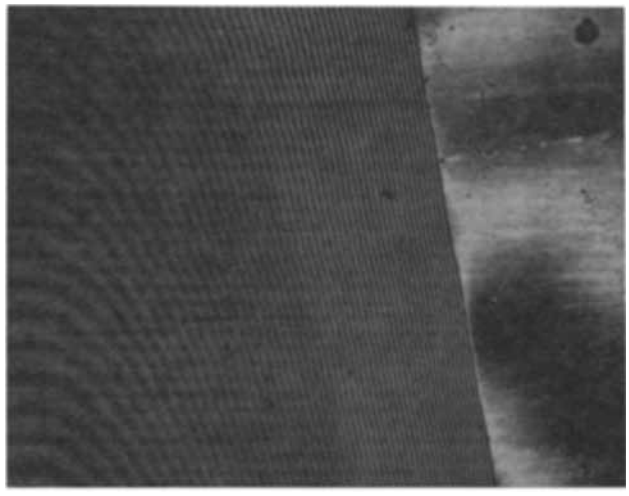

Fig. 4. Groove with interference fringes

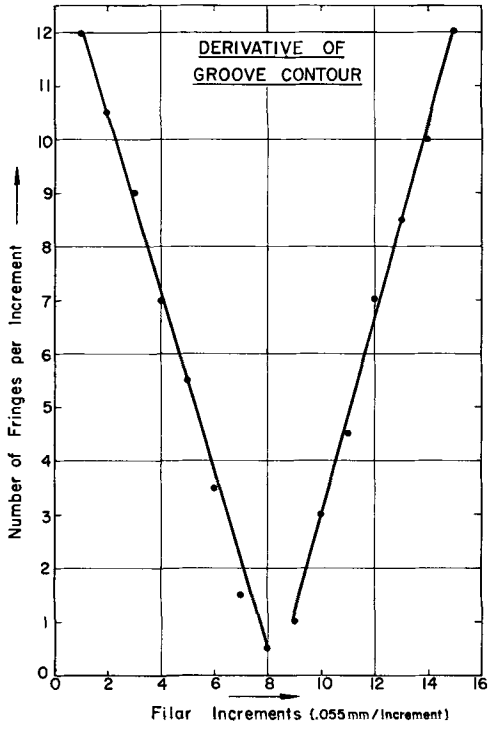

Fig. 5. Derivative of groove contour

The contour produced by the grooving technique has several qualitative advantages over the sloping surface produced by the conventional angle lapping method. For some undetermined reason, the diffused layer can be more easily delineated (using the same staining solution) with greater reproducibility. Since the angle of the silicon surface with respect to the axis of the cylinder is not critical within a few degrees, the sample may be mounted without extreme care, and there is no problem of maintaining the sample in a specific orientation while the operation is being performed. The advantages of the grooving method become particularly apparent when applied to very thin layers. The rounding which occurs at the edge of the lapped angle does not appear at the edge of the groove because the system is maintained securely in position and the abrasive action occurs only in one direction. This eliminates a very large source

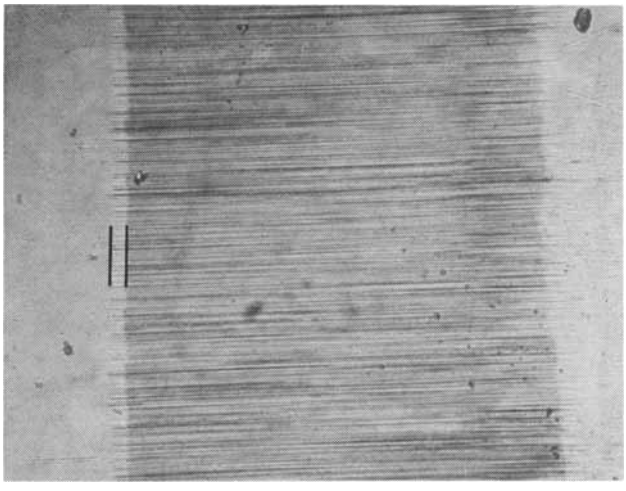

Fig. 6. Thin diffused layer (0.27μ)

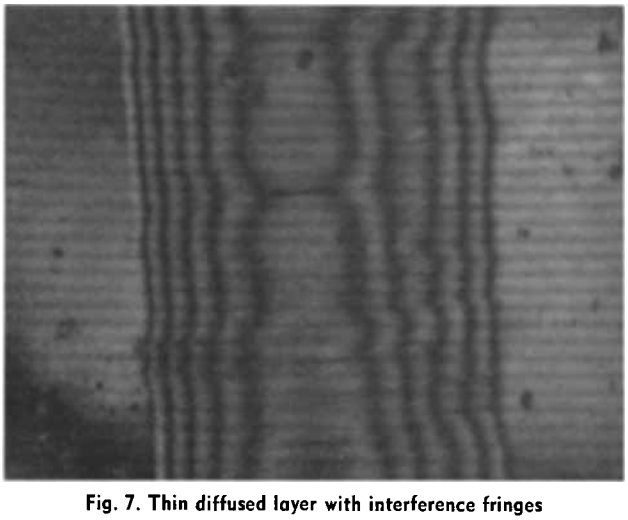

Fig. 7. Thin diffused layer with interference fringes

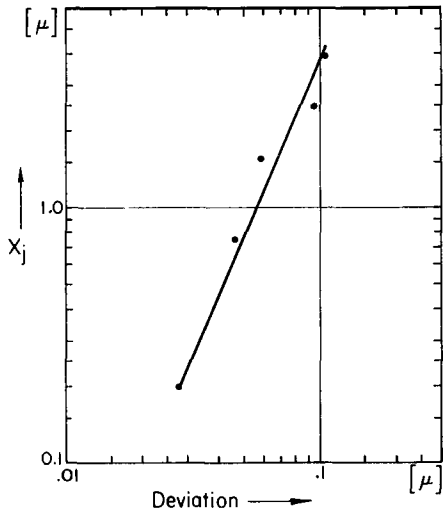

Fig. 8. Layer thickness (X_j) vs. deviation

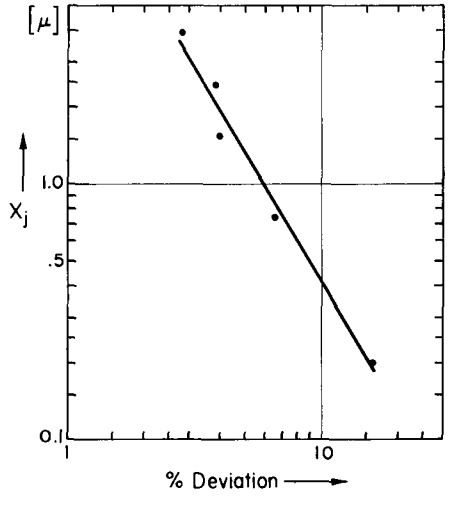

Fig. 9. Layer thickness (X_j) vs. % deviation

of error in measuring thin layers. Another advantage of the grooving method is that it is not necessary to measure a very small angle accurately. The only quantity that has to be known is the diameter of the grooving cylinder.

In measuring the delineated layer by conventional methods, either a probe or an interference objective is generally used. Probing for the depth is an extremely time-consuming and exacting procedure requiring delicate and precise equipment, especially in measuring shallow layers of less than 0.5μ. The estimated accuracy is $\pm$ 0.1μ. The use of an interference objective is also limited in accuracy when applied to extremely shallow layers, an example of which is shown in Fig. 6 and 7. Figure 6 shows a layer in a grooved sample which, measured by employing the technique previously described, was found to have a depth of 0.27μ. Figure 7 shows the same layer under illumination from a sodium vapor lamp with the fringe plates of an interference objective in contact with the sample. The edge of the delineated layer lies somewhere under the first fringe and cannot be seen at all. Even with a deep layer, as in Fig. 4, the interfringe distance with sodium vapor is 0.2945μ. The measurement can at best be approximated to $\pm$ 0.1μ. In contrast, measurements of diffused layers can be made down to depths as shallow as the order of 0.2μ, using the grooving technique, with an accuracy of $\pm$ 0.04μ.

In order to evaluate the reproducibility of the grooving technique, measurements were made on several grooves in the same specimen. This was repeated for specimens having diffused layer thicknesses between 0.195 and 3.92μ. The deviation of the measurements, which was taken as the average of the difference between the mean and measured values, and the per cent deviation are shown plotted against the diffusion depth in Figures 8 and 9. These results indicate a high degree of reproducibility and also point out that, while the absolute deviation increases with increasing layer thickness, the relative deviation decreases.

As a final check on the accuracy of this method, samples were sectioned anodically (4, 5) until the junction was reached. In all cases evaluated in this manner, the sum of the thicknesses removed down to the junction came with 200Å of the layer depth as measured by the grooving method.

Conclusion

The grooving technique described in this paper offers a convenient and accurate method for determining the depth of diffused layers in silicon. In this laboratory, the technique has been found to be

indispensable when it is necessary to determine accurately the depth of a very shallow layer.

Vapor Pressure of Gallium, Stability of Gallium Suboxide Vapor, and Equilibria of Some Reactions Producing Gallium Suboxide Vapor

C. N. Cochran and L. M. Foster

Alcoa Research Laboratories, Physical Chemistry Division, Aluminum Company of America, New Kensington, Pennsylvania

ABSTRACT

Vapor pressures of gallium in the literature are too high because $Ga_2O(v)$ formed in the reaction of gallium with the quartz effusion cells used for the measurements. Gallium was found to be less reactive with alumina than with quartz. Measurements in an alumina effusion cell gave vapor pressures for gallium that obey the expression

$$\log P \text{ (atm)} = -14{,}900/T - 0.515 \log T + 7.34$$

Values for $\Delta H_{f\,298[Ga_2O(v)]}$ of -17.4 ± 0.7 and -19.7 ± 0.7 kcal/mole were found for the reaction of gallium with quartz and magnesium oxide, respectively. The latter value was employed to calculate the equilibria in forming $Ga_2O(v)$ from the following pairs of reactants: gallium-gallia, graphite-gallia, tin-gallia, gallium-alumina, and gallium-water vapor. The vapor pressures of silver and tin were determined and compared with literature values to check the constants of the system.

Previous measurements (1, 2) of the vapor pressure of gallium employed the Knudsen method with quartz effusion cells. However, a mass spectroscopic study of Antkiw and Dibeler (3) showed that considerable concentrations of $Ga_2O_{(v)}$ formed from reaction of gallium with a quartz crucible at 865°-1025°C. This indicates that the reported vapor pressure data for gallium are too high.

In the present work an alumina effusion cell was used to measure the vapor pressure of gallium. Additions of quartz or magnesium oxide were made to the gallium in the cell to form gallium suboxide. The differences in the effusion rates with and without quartz or magnesium oxide are used to derive the heat of formation of gallium suboxide vapor.

Experimental

A single sintered alumina (99+% pure) effusion cell, 15 mm ID, 30 mm deep, with an orifice 0.90 mm in diameter and 0.37 mm thick, was employed in obtaining all of the data. Reactions between the charge materials and the alumina cell were negligible. The weight loss of the cell in an effusion experiment was always considerably less than 1% of the total weight loss. A cell constant of 0.00098 and a Clausing factor of 0.71 were calculated for the orifice.

In two experiments where silver was employed in the cell, the orifice was covered with a tight fitting cover of sintered alumina. By comparing the loss in this case with that when the orifice was uncovered, $46 \pm 5\%$ of the total loss with the orifice uncovered was found to occur through the lapped seal between the removable cover and the body of the cell. With this "leakage" taken into account, the following relationship between pressure and effusion losses from the cell was obtained

$$\text{Pressure}_{(atm)} = \frac{0.00075 \text{ (effusion rate in g/hr)} T^{1/2}}{\text{(molecular weight vapor)}^{1/2}}$$

The rates of weight loss were determined with an automatic, recording, vacuum analytical balance, modeled after the microbalance described elsewhere (4). Only data from the linear portions of the weight loss-time plots were used. This practice eliminated errors in effusion rate determination caused by outgassing of the cell and its contents as steady-state conditions were approached. Usually, steady-state conditions were reached within ½ hr after reaching temperature.

Temperatures were regulated to within ±1°C by a Foxboro Recorder-Controller, Model 8253-201R, with the control thermocouple located between windings of the furnace element at a position corresponding to the midpoint of the cell. The relationship between the temperature of the control couple and the

* Effusion of $Ga_2O_{(v)}$ and $Ga_{(v)}$ from cell treated as being entirely $Ga_{(v)}$.

cell was determined with a second thermocouple in a separate experiment.

Materials

Alcoa GA-6 grade, 99.9999+% pure gallium, Tadanac Brand (Consolidated Mining and Smelting Company of Canada, Ltd., Trail, B. C.) 99.9999% silver, and Fisher Scientific Company's 99.97% tin were employed in this work. In the Ga-SiO_2 and Ga-MgO experiments, the gallium was covered with a bed of 4 to 8-mesh chips of ordinary fused quartz, and pellets (⅛ in. in diameter and ⅛-¼ in. long) of Fisher Scientific Company's 99.93% magnesium oxide, respectively.

Vapor Pressure of Gallium

Vapor pressures calculated from the effusion data for gallium are given in Table I and compared with literature values in Fig. 1. The values from the present work range from fourfold lower at 1100°C to fivefold lower at 900°C than the values selected by Stull and Sinke (5) from previously published data.

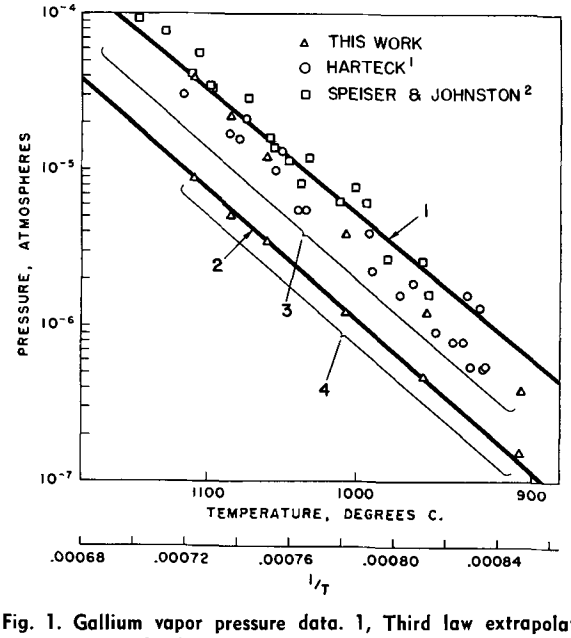

Fig. 1. Gallium vapor pressure data. 1, Third law extrapolation of previous data by Stull and Sinke (5), $\Delta H°_{v\,298}$ = 65.00 kcal/mole; 2, third law extrapolation of data from this work, $\Delta H°_{v\,298}$ = 68.96 kcal/mole; 3, measured in presence of quartz; 4, measured in an alumina effusion cell.

With the vapor considered as being monatomic, as indicated in mass spectroscopic studies (3,6), log $P = -14,900/T - 0.515 \log T + 7.34$, $\Delta H°_{v\,298} = 68.96 \pm 0.19$ kcal, and the boiling point is 2676°K. Stull and Sinke (5) chose $\Delta H°_{v\,298}$ = 65.00 kcal and a boiling point of 2510°K.

Drowart and Honig (6) found the heat of vaporization of gallium from beryllia and graphite crucibles to be 59 ± 4 kcal/mole by second law treatment of ion intensities in a mass spectroscopic study. It is recognized that their procedure might give only approximate results.

Apparent monatomic gallium pressures were calculated from the gallium-quartz effusion data and also plotted in Fig. 1. These data were found to fall within the band of pressures reported by the previous workers who vaporized gallium from quartz. These values show the same systematic deviation from the third law extrapolation line of Stull and Sinke (5) as do the data of the previous workers. This deviation is another proof, as noted by Drowart and Honig (6), that these data cannot be represented simply by vaporization of monatomic gallium.

Stability of Ga_2O Vapor

Before information on the stability of $Ga_2O_{(v)}$ could be obtained from the effusion data with quartz or magnesium oxide added to the gallium, the most favorable of the possible reactions had to be determined. This was accomplished in each case by finding the reaction that resulted in the least negative value of $\Delta H°_{f\,298[Ga_2O_{(v)}]}$ and that showed no systematic deviation of this quantity with temperature. Using these criteria, the steady-state reaction between quartz and gallium is

$$2Ga_{(l)} + SiO_{2(c)} \rightleftarrows SiO_{(v)} + Ga_2O_{(v)} \qquad [1]$$

However, calculations showed that the initial reaction of quartz with gallium produces silicon (reaction [2])

$$4Ga_{(l)} + SiO_{2(c)} \rightleftarrows Si_{(in\ Ga)} + 2Ga_2O_{(v)} \qquad [2]$$

This dissolves in the gallium until its activity is large enough that any further silicon produced will react with the quartz to produce $SiO_{(v)}$ (reaction [3]) and give the same over-all reaction as [1].

Table II. Calculation of ΔH°_{298} for the reactions and $\Delta H^\circ_{f\,298}$ for $Ga_2O_{(v)}$

$2Ga_{(l)} + SiO_{2(c)} \rightleftarrows SiO_{(v)} + Ga_2O_{(v)}$

										Avg. ΔH°_{298} =	159,310 ± 680

At 298°K, $\Delta H^\circ_{f\,Ga_2O} = \Delta H^\circ_{reaction} + \Delta H^\circ_{f\,MgO_{(c)}} - \Delta H^\circ_{f\,Mg_{(v)}} = 159{,}310 - 143{,}700 - 35{,}330 = -19{,}720 \pm 680$ cal/mole

$$Si_{(in\ Ga)} + SiO_{2(c)} \rightleftarrows 2SiO_{(v)} \quad [3]$$

Similar calculations show that the steady-state reaction of gallium with magnesium oxide is

$$2Ga_{(l)} + MgO_{(c)} \rightleftarrows Mg_{(v)} + Ga_2O_{(v)} \quad [4]$$

Gallium saturates rapidly with magnesium from the reaction to achieve a steady-state condition.

The effusion data from experiments where quartz and magnesium oxide were added are listed in Table II. After correcting the effusion losses for metal vaporization, the remaining weight losses were divided stoichiometrically between the gaseous products according to the reaction equations. Partial pressures and equilibrium constants were calculated and converted to free energy changes. These in turn were converted to values of ΔH°_{298} with the aid of free energy function data discussed in a later section. Values of ΔH°_{298} were used together with values of $\Delta H^\circ_{f\,298}$ for the other reactants and products to calculate values of −17.4 ± 0.7 and −19.7 ± 0.7 kcal/mole for $\Delta H^\circ_{f\,298[Ga_2O_{(v)}]}$ from the quartz and magnesium oxide reactions, respectively.

2. $2Ga_{(l)} + MgO_{(c)} \rightleftarrows Mg_{(v)} + Ga_2O_{(v)}$, ΔH°_{298} = 159.3 kcal
3. $4Ga_{(l)} + SiO_{2(c)} \rightleftarrows Si_{(c)} + 2Ga_2O_{(v)}$, ΔH°_{298} = 175.1 kcal

Other workers have found evidence recently that the presently accepted heat of formation for silica used in this work may be too positive. Taylor (7) and co-workers believe that the error in this value may be about 4.5 kcal/mole. A tentative calculation by Good (8) places the error at between 6-8 kcal/mole. If all of the difference in the values of $\Delta H^\circ_{f\,298[Ga_2O_{(v)}]}$ obtained from the quartz and magnesium oxide experiments in this work is assigned to an error in $\Delta H^\circ_{f\,298[SiO_2]}$, the error becomes 2 x 2.3 = 4.6 kcal/mole. (The difference of 2.3 kcal is multiplied by two because the heat of formation of SiO that is employed will become 2.3 kcal more negative at the same time.) The value of $\Delta H^\circ_{f\,298[Ga_2O_{(v)}]}$ calculated from the gallium-magnesium oxide experiments will be employed in all further calculations because of the good agreement between the 4.6 kcal/mole error in the value of $\Delta H^\circ_{f\,298[SiO_{2(c)}]}$ that we calculated using it and the 4.5 kcal/mole that Taylor and co-workers calculated.

The fit of all of the effusion data to the third law extrapolation of these data is shown in Fig. 2. The equilibrium constants for reaction [2], are also shown in Fig. 2. These equilibrium constants are the

same whether they are calculated from the uncorrected heat of formation of quartz and the heat of formation of gallium suboxide from the gallium-quartz experiments or from the corrected value for quartz and the value for gallium suboxide from the gallium -magnesium oxide experiments.

Equilibria of Some Other Reactions Producing $Ga_2O_{(v)}$

Calculated equilibrium constants are shown in Fig. 3 for a number of other reactions that produce $Ga_2O_{(v)}$. The small equilibrium constants calculated for the reaction of gallium with alumina are substantiated by the low reactivity between gallium and alumina found in this work. The equilibria of the reaction of gallium with water vapor will be employed along with the equilibria of the quartz-gallium reactions in the following paper dealing with implications of these reactions in the synthesis of gallium arsenide in quartz systems.

The reactions of tin, graphite, and gallium with gallia, shown in Fig. 3, were employed in other attempts to measure the stability of $Ga_2O_{(v)}$. However, equilibrium was not achieved in these cases. The apparent equilibrium constants that were obtained from the effusion rates were always less than the corresponding equilibrium constants calculated with the $\Delta H^\circ_{f\,298[Ga_2O_{(v)}]}$ from the magnesium oxide-gallium experiments.

The chief cause of poor approach to equilibrium in these cases is evident from the effusion data. The

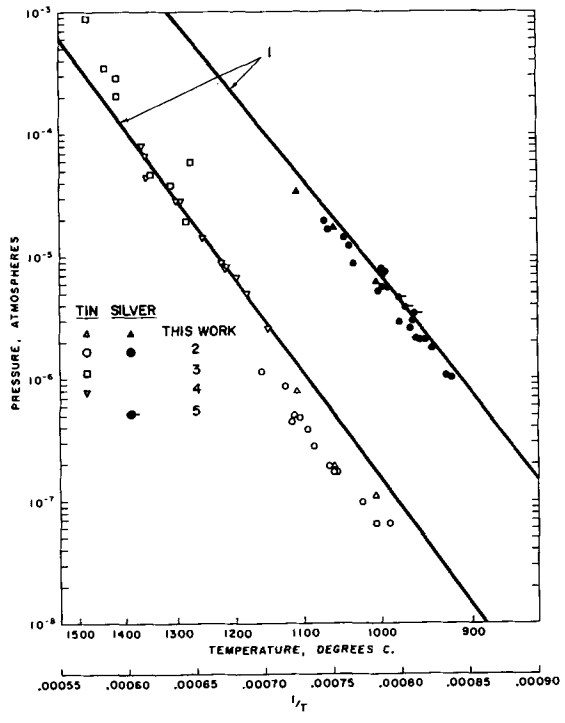

Fig. 4. Vapor pressures of silver and tin. 1, Third law extrapolations of previous data by Stull and Sinke (5); 2, Harteck (1); 3, L. Brewer and R. F. Porter, *J. Chem. Phys.*, 21, 2012 (1953); 4, A. W. Searcy and R. D. Freeman, *J. Am. Chem. Soc.*, 76, 5229 (1954); 5, C. L. McCabe and C. E. Birchenall, *AIME Trans.*, 197, 707 (1953).

average increases in the effusion rates on adding gallia to tin, gallium, and graphite were, respectively, 150-fold, 2000-fold, and an undetermined large factor. These compare to average increases of two to fourfold on adding quartz and magnesium oxide to gallium. If the reaction between the oxide and the metal involves mainly metal vapor rather than liquid metal, the ease of achieving equilibrium in the effusion cell will be related to the ratio of the equilibrium pressure from the reaction to the equilibrium metal vapor pressure. If this ratio is large, equilibrium will be difficult to achieve, especially as this ratio approaches the ratio of the metal surface area to the area of the effusion hole.

Reaction between metal vapor and the oxide would be expected to be the predominant reaction in the effusion cells because gaseous products formed at submerged sites where the liquid metal and oxide are in contact would have difficulty in escaping from under the head of molten metal at these low pressures. With the quartz and magnesium oxide added to the gallium, the increase in pressure was small enough that the gases in the effusion cell were probably at equilibrium.

Gershenzon and Mikulyak (9) reported that Frosch and Thurmond of Bell Telephone Laboratories, Inc. of Murray Hill, New Jersey, have measured gallium suboxide pressures of 0.2 mm at 800°C

and 10 mm at 1000°C for a 4-1M mixture of gallium and gallium suboxide. From Curve 3 in Fig. 3, the corresponding pressures calculated for this reaction are 0.091 mm and 8.6 mm. This good agreement supports the choice of −19.7 kcal/mole for the value of $\Delta H^\circ_{f\,298[Ga_2O_{(v)}]}$.

Vapor Pressures of Silver and Tin

In order to obtain an independent check on the effusion cell constants employed in this work, the vapor pressures of silver and tin were determined. These are given in Table III and are compared with literature values in Fig. 4. There is good agreement with the results of Harteck (1) who employed quartz cells. These values average 22% to 46% lower than the values chosen by Stull and Sinke (5) from data obtained mostly in graphite cells. It appears that diffusion through graphite cell walls was not considered in most of the earlier work.[1]

Sources of Thermodynamic Data

Except for the free energy functions for liquid and gaseous Ag, Sn, and Ga which were obtained from Stull and Sinke (5), all of the free energy functions and heats of formation employed are listed with their sources in Table IV.

Estimated values of the free energy functions for $Ga_2O_{(v)}$ are also listed in Table IV. This quantity is a function of heat capacities alone and, therefore, can be estimated for gases quite accurately from heat capacity data for molecules of similar structure and molecular weight. A value of 69.54 was estimated for $S^\circ_{298[Ga_2O_{(v)}]}$ from a correlation of molecular weights with values of S°_{298} for other triatomic gaseous molecules. Heat capacities for $Ga_2O_{(v)}$ above 298°K were taken to be the same as for $CTeS_{(v)}$ from the Bureau of Mines Bulletin 584 (13).

The described free energy functions were used to calculate the free energy function changes for the reaction at 100°K intervals. Free energy function changes for the desired temperatures were obtained by graphical interpolation.

[1] Fujishiro and Gokcen (10) found that the amount of titanium vapor permeating the walls of a cell made from a very dense, impervious graphite ranged from 45 to 77% of the total effusate in the 2383°-2593°K range.

Manuscript received June 28, 1961.

Reactions of Gallium with Quartz and with Water Vapor, with Implications in the Synthesis of Gallium Arsenide

C. N. Cochran and L. M. Foster

Alcoa Research Laboratories, Physical Chemistry Division, Aluminum Company of America, New Kensington, Pennsylvania

ABSTRACT

The reaction of gallium with quartz to produce gallium suboxide, Ga_2O, and silicon is shown by equilibrium calculations to be a mechanism by which gallium arsenide can become contaminated with silicon, and possibly oxygen, when synthesized in quartz systems. The contamination of gallium arsenide with silicon by this reaction is governed by the rate at which the gallium suboxide vapor is removed. The silicon content commonly observed in GaAs (up to a few ppm) can be accounted for by this mechanism. Suggestions for minimizing the attack are given. The apparent transport of GaAs in a system containing traces of water vapor can be explained by reaction of water with gallium in the hot zone to form Ga_2O and hydrogen, which react with arsenic in the cold zone to produce GaAs and regenerate the water.

A current problem in the production of gallium arsenide for use in semiconducting devices is contamination of the product with silicon. This silicon is thought to be formed by the reaction of gallium with its container during synthesis, which is carried out in a quartz boat or crucible contained in a sealed quartz envelope. In this operation, some part of the quartz envelope contains solid arsenic at about 610°C in equilibrium with arsenic vapor at 1 atm pressure. This is slightly greater than the arsenic decomposition pressure of 0.9 atm from gallium arsenide at the melting point (1237°C) (1, 2).

A mass spectroscopic study (3) had shown the presence of significant quantities of Ga_2O vapor when gallium was heated with quartz at 865°-1025°C. This Ga_2O vapor was formed in the same reaction that produces the silicon that contaminates the gallium or gallium arsenide; thus,

$$4Ga_{(l \text{ or from GaAs})} + SiO_{2(c)} \rightleftarrows Si_{(\text{in Ga or GaAs})} + 2Ga_2O_{(v)} \quad [1]$$

Knudsen effusion studies were employed by the authors to determine the equilibria of the reactions of gallium with quartz and gallium with magnesium oxide in the 900°- 1100°C range (4). A reaction heat of 175.1 kcal at 25°C for reaction [1] was used from this work to calculate the equilibrium of reaction [1] at 1250°C, the temperature of synthesis of GaAs.

Gallium Activity in Gallium Arsenide

The activity of gallium in gallium arsenide at 1250°C in 1 atm of arsenic vapor must be known before the equilibria of the reactions with quartz can be calculated. The arsenic decomposition pressure at the melting point of gallium arsenide reveals nothing about the gallium activity without additional information about the stability of GaAs.

Drowart and Goldfinger (5), in a combined Knudsen effusion-mass spectroscopic experiment, measured the decomposition pressures and identified the vapor species from gallium arsenide at temperatures from 758° to 863°C. The phase diagram of the gallium-arsenic system (6) shows that the gallium content of the gallium-rich liquid phase produced in decomposition over this temperature range would increase from 91 to 94 at. %. These compositions would correspond in the simple ideal case to gallium activities ranging from 0.82 to 0.88, since GaAs is the only compound in the system. Presumably, Drowart and Goldfinger took this into account when they calculated the median values of $\Delta F°_f$ and $S°$ for gallium arsenide at 808°C (1081°K) given on the following page, although this was not made clear in their paper. (If they assumed instead that the liquid dissociation product was pure gallium with unit activity, the value of $\Delta F°_{f\,1081}$ would be only 0.3-0.4 kcal more positive.)

$$\Delta F°_{f1081} = -15.34 \text{ kcal (calculated from the } As_2 \text{ component of the vapor)}$$

$$S°_{1081} = 34.4 \text{ cal/deg}$$

Using Stull and Sinke's (7) heat capacity data for diatomic arsenic vapor and liquid gallium, and assuming that $C_P = 12$ for gallium arsenide and the $\Delta F_{\text{fusion }1523} = 0$, ($\Delta F$ is actually zero at the fusion temperature of 1510°K), the free energy change and equilibrium constant for formation from $As_{2(v)}$ and Ga were calculated for molten gallium arsenide as follows:

$$Ga_{(l)} + \tfrac{1}{2}\, As_{2(v)} \rightleftarrows GaAs_{(l)} \quad [2]$$

$$\Delta F°_{f\,1523} = -5.40 \text{ kcal}$$

$$\log K_{1523} = \frac{5{,}400}{(4.576)(1523)} = +0.77$$

$$= -\log a_{Ga} - \tfrac{1}{2} \log P_{As_{2(v)}}$$

For self-consistency, Drowart and Goldfinger's value for the heat of dissociation of arsenic tetramers to dimers ($\Delta H°_{298}$ = 71.8 kcal) was employed to calculate the partial pressure of $As_{2(v)}$ in 1 atm of arsenic vapor at 1250°C. Using free energy function data for $As_{2(v)}$ and $As_{4(v)}$ from Stull and Sinke, the equilibrium constant for the dissociation of arsenic tetramers (reaction [3]) at 1250°C (1523°K) was calculated:

$$As_{4(v)} \rightleftarrows 2As_{2(v)} \qquad [3]$$

$$\frac{\Delta F°}{T} = 2\left[\frac{F° - H°_{298}}{T}\right]_{As_{2(v)}} - \left[\frac{F° - H°_{298}}{T}\right]_{As_{4(v)}} + \frac{\Delta H°_{298}}{T}$$

$$\log K_{1523} = \frac{-9.35}{4.576} = -2.044$$

$$K_{1523} = 0.0090 = \frac{(P_{As_2})^2}{P_{As_4}}$$

$P_{As_2} = 0.090$ atm when $P_{As_4} = (1\text{-}0.090) = 0.91$ atm

With an $As_{2(v)}$ pressure of 0.090 atm substituted in the expression for the equilibrium constant for reaction [2], the gallium activity in gallium arsenide at 1250°C is 0.56.

The activity of gallium in gallium arsenide in equilibrium with 1 atm of arsenic vapor must also be known at lower temperatures for some of the calculations to be made later in this paper. The activity at 808°C is calculated to provide a basis for obtaining the activities at temperatures between 808° and 1250°C, by graphical interpolation. The As_2 pressure in 1 atm of arsenic vapor becomes 0.00084 atm at 808°C, and the corresponding gallium activity in gallium arsenide in equilibrium with 1 atm of arsenic vapor becomes 0.027.

Course of the Reaction of Gallium with Quartz

According to calculations in the preceding paper (4), gallium and quartz can react in two ways, the favored reaction depending on the silicon content of the gallium. If the gallium or gallium arsenide contains no silicon initially, Eq. [1] is favored. The silicon activities vs. Ga_2O pressures from this reaction, using log K_{1523} = −9.24 from that paper, are shown in Fig. 1 for pure gallium (curve I) and for gallium arsenide (curve II). As the silicon activity increases in the gallium or gallium arsenide, the equilibrium Ga_2O pressure decreases.

As reaction [1] proceeds, silicon monoxide, $SiO_{(v)}$, is simultaneously produced from the reaction of quartz with the silicon product, thus

$$Si_{(\text{in Ga or GaAs})} + SiO_{2(c)} \rightleftarrows 2SiO_{(v)} \qquad [4]$$

and its pressure increases with increasing silicon activity in the gallium or gallium arsenide. For reaction [4], log $K_{1523} = -5.82$, by combination of the equilibrium constant of reaction [1] and that of [5], below [see preceding paper (4)]. The silicon activity from reaction [1] increases eventually to a point where the SiO pressure from reaction [4] equals the Ga_2O pressure from reaction [1].

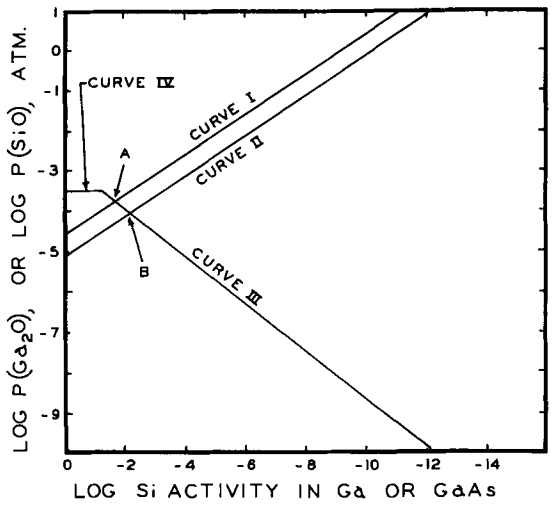

Fig. 1. Equilibrium partial pressures of $Ga_2O_{(v)}$ and $SiO_{(v)}$ from reaction of gallium with quartz at 1250°C; point A, where reactions for curve I and curve III occur concurrently, a_{Si} = 0.019; point B, where reactions for curve II and curve III occur concurrently, a_{Si} = 0.0061.

Curve I
$4Ga_{(l)} + SiO_{2(c)} \rightleftarrows Si_{(\text{in Ga})} + 2Ga_2O_{(v)}$
Curve II
$4Ga_{(\text{in GaAs})} + SiO_{2(c)} \rightleftarrows Si_{(\text{in GaAs})} + 2Ga_2O_{(v)}$
Curve III
$Si_{(\text{in Ga or GaAs})} + SiO_{2(c)} \rightleftarrows 2SiO_{(v)}$
Curve IV
$Si_{(\text{in Ga or GaAs})} + SiO_{2(c)} \rightleftarrows 2SiO_{(c)}$

Further reaction of gallium with quartz will not produce additional silicon but only $Ga_2O_{(v)}$ and $SiO_{(v)}$ by the composite reaction [5].

$$2Ga_{(l \text{ or from GaAs})} + SiO_{2(c)} \rightleftarrows Ga_2O_{(v)} + SiO_{(v)} \qquad [5]$$

Log $K_{1523} = -7.53$ for reaction [5] from the preceding paper (4).

The silicon activity that has been attained when reaction [5] takes over is 0.019 for the reaction of pure gallium and 0.0061 for the reaction of gallium arsenide (obtained as the intersection of curve III with curves I or II).

Removal of Reaction Products

Once the high-temperature zone containing the reacting gallium and quartz has been saturated with the equilibrium partial pressures of the gaseous products, the contamination reaction can proceed further only if the vapors are removed. Removal can occur by $Ga_2O_{(v)}$ dissolving in the gallium arsenide or diffusing to a colder zone where it can react with arsenic vapor, as follows

$$3Ga_2O_{(v)} + 2As_{2(v)} \text{ (or } As_{4(v)}) \rightleftarrows Ga_2O_{3(c)} + 4GaAs_{(c)} \qquad [6]$$

The solubility of gallium suboxide in gallium arsenide is unknown, and therefore only removal of vapors by diffusion (the case that results in the minimum amount of contamination) will be considered.[1]

The temperatures at which reaction [6] occurs to deposit crystalline GaAs and Ga_2O_3 are shown in

[1] Removal of $Ga_2O_{(v)}$ by dissolving in the quartz or by reacting with the quartz to form gallium silicate are two additional possibilities which, however, cannot be treated.

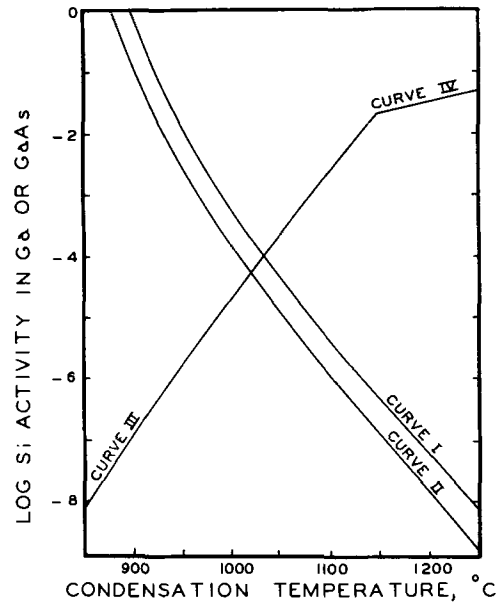

Fig. 2. Condensation temperatures of gaseous products from reaction of gallium with quartz at 1250°C in 1 atm of arsenic vapor.

Curve I
$3Ga_2O_{(v)}$ (from Ga + SiO_2) + $As_{(v)} \rightleftarrows Ga_2O_{3(c)} + 4GaAs_{(c)}$
Curve II
$3Ga_2O_{(v)}$ (from GaAs + SiO_2) + $As_{(v)} \rightleftarrows Ga_2O_{3(c)} + 4GaAs_{(c)}$
Curve III
$2SiO_{(v)} \rightleftarrows Si_{(c)} + SiO_{2(c)}$
Curve IV
$SiO_{(v)} \rightleftarrows SiO_{(c)}$

Fig. 2. These calculations employed the previously calculated activities of gallium in gallium arsenide in 1 atm of arsenic vapor, together with equilibrium constant data for the disproportionation of gallium suboxide to gallium and gallia from the preceding paper (4).

The reaction zone will also be saturated with the equilibrium partial pressure of silicon monoxide. Further transfer of silicon can occur only if there is diffusion of the silicon monoxide to a colder region where it can condense. Figure 2 also shows the temperatures at which the SiO vapors will deposit by disproportionation for different silicon activities in the Ga or GaAs. At silicon activities near one tenth (the break in the SiO curve), the SiO pressure becomes large enough for it to condense without disproportionation, according to the free energy of vaporization data given by Schick, (8) as follows:

$$\Delta F_{\text{vaporization}} = 77{,}530 - 34.94T$$

$$\log P_{SiO} = -\frac{77{,}530}{4.576T} + \frac{34.94}{4.576} = -\frac{16{,}950}{T} + 7.639$$

This expression was used to correct the $SiO_{(v)}$ curves of Fig. 1 and 2 for formation of condensed SiO at high silicon activities.

Klemm (9) reported a condensed phase from gallium suboxide vapors that contained no gallium by x-ray diffraction and only traces of gallia. However, this phase is probably unstable with respect to gallium and gallia at any of the temperatures of this work.

Rate of Silicon Formation

Assuming that the actual reaction of gallium with quartz is not rate-determining, the rate at which the silicon activity approaches the limiting activities shown in Fig. 1 ($a_{Si} = 0.019$ from reaction of pure gallium, and $a_{Si} = 0.0061$ from reaction of GaAs, determined by the point at which reaction [5] takes over to maintain the constant silicon level) will depend on the rate of removal of the gaseous products from the reaction zone.

Nothing is known about the solubility or rate of solution of $GaO_{(v)}$ in the gallium arsenide, but the rate of diffusion of $Ga_2O_{(v)}$ from the 1250°C zone can be considered. This rate will likely be proportional to the $Ga_2O_{(v)}$ pressure which, in turn, varies inversely as the square root of the silicon activity (from the equilibrium constant expression for reaction [1]). As a result, the rate of silicon production should decrease continually as the reaction proceeds and become zero at the limiting silicon contents given by the intersection of the curves in Fig. 1.

The rate of $Ga_2O_{(v)}$ removal in vacuum can be rapid, particularly in the proximity of a cold condensing surface, and relatively large quantities of silicon can be introduced. Figure 3 shows, at two magnifications, silicon single crystals deposited on a quartz vessel that had contained high-purity gallium at 1100°C for ½ hr in a vacuum of better than 10^{-5} mm. The gallium was heated inductively and was covered by a cold quartz condenser situated about 1 cm above the surface.

Figure 4 illustrates the attack of gallium on the surface of a quartz beaker heated to 1175°C for 3½ hr in vacuum below 5 x 10^{-6} mm. The curved border between the etched and unetched areas corresponds to the outer periphery of the gallium globule that rested on the quartz. Attack of the quartz underneath the gallium was negligible because the first Ga_2O vapor formed was slow in escaping from this area. However, gallium vapor

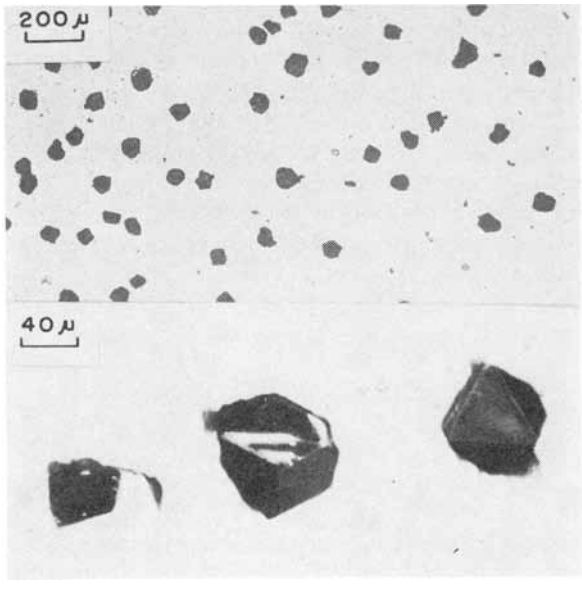

Fig. 3. Silicon crystals from reaction of gallium and quartz, growing on quartz surface.

Fig. 4. Micrograph showing vapor vs. liquid phase attack of gallium on quartz.

from the globule etched the quartz beside the globule because the $Ga_2O_{(v)}$ that formed there was free to escape into the vacuum.

The silicon contamination of the gallium can easily go undetected in such experiments unless great care is taken in sampling. Silicon is completely insoluble in gallium at room temperature, and it precipitates out and adheres to the quartz as shown, or floats to the top of the metal. In the experiments shown in Fig. 3, the quartz container lost 0.03g.

Heating of gallium in the presence of quartz at high temperature in high vacuum is certainly to be avoided. In the presence of the atmosphere of arsenic vapor employed during the synthesis of GaAS, the diffusion of gaseous products from the reaction zone will be much slower than in vacuum.

If the solubility of $Ga_2O_{(v)}$ in GaAs should prove to be insignificant, it should be possible to suppress the gallium-quartz reaction by saturating the 1250°C zone with a sufficiently high $Ga_2O_{(v)}$ pressure from the reaction of gallium with gallia or with water vapor. This presupposes that oxygen contamination is not a problem, however, and one would hesitate to recommend the deliberate addition of oxygen-containing species.

Clearly, if the gallium could be contained in a completely nonreactive boat, the entire situation would be changed. There would be no need to maintain the free volume around the gallium at 1250°C since there would be no volatile products that would condense at lower temperatures. In fact, it would be desirable in this case to maintain the entire quartz envelope just above the condensation temperature of arsenic, and heat only the gallium to 1250°C.

Examples of Contamination

The information that has been obtained can be used to estimate the extent of contamination by silicon under various circumstances. The relationship for making this estimate is derived as follows.

The equation for curve I of Fig. 1 is

$$\log P_{Ga_2O_{(v)}} = -\tfrac{1}{2} \log a_{Si \text{ in } Ga} - 4.62 \qquad [7]$$

Assuming an ideal solution of silicon in gallium, the activity of silicon in the dilute range is given by the following expression:

$$a_{Si} = \frac{M_{Ga}}{M_{Si}} W \qquad [8]$$

where M is the atomic weight and W is the weight fraction of silicon.

Since two molecules of gallium suboxide are produced for each atom of silicon formed, the partial pressure of suboxide, $P_{Ga_2O_{(v)}}$, can be expressed in terms of W and V, the ratio of the free volume in the 1250°C zone to the volume of gallium using a value of 6 g/ml for the density of liquid gallium.

$$P_{Ga_2O_{(v)}} = \frac{53{,}500W}{V} \qquad [9]$$

The weight fraction of silicon is solved for by combining Eq. [7], [8], and [9] to give

$$\log W = -6.365 + 2/3 \log V$$

The corresponding expression for GaAs is

$$\log W = -6.701 + 2/3 \log V$$

It can be seen that, in the case of the reaction of arsenic-free gallium and quartz, if the free volume of the 1250°C zone is five times the volume of the gallium in the boat, the silicon content of the gallium will reach 1.3 ppm (or 0.6 ppm based on the final GaAs) just in saturating this zone with Ga_2O vapor. If the free volume of the hot zone is ten times the volume of the gallium, the silicon content will reach 2.0 ppm (or 1.0 ppm based on the final GaAs). Somewhat lower silicon contents would result if the equilibria shown by curve II of Fig. 1 were determining.

Reaction at the Quartz Envelope

Thus far, only reaction at the gallium-containing boat has been considered. Gallium could also react with the quartz envelope to produce gaseous products that could diffuse back to the boat and be a source of contamination. Reaction [5] would predominate, since there is no gallium sink in which the silicon would dissolve at low activity.

In an atmosphere of arsenic vapor, the equilibrium gallium activity in the gas phase is the same as that in gallium arsenide ($a_{Ga} = 0.56$ at 1250°C, from an earlier section). In early stages of the synthesis, reaction of gallium vapor with the quartz envelope will be suppressed by the high pressure of Ga_2O that is more easily produced by reaction of unreacted gallium (or gallium-arsenic solutions) in contact with the quartz boat. Ultimately, when synthesis is complete, the equilibrium will

be the same whether the reaction is with the boat or the walls.

Solubilities and Activities

The activity coefficients of silicon in gallium and gallium arsenide are not known and are assumed to be unity for purposes of the present calculations. The usual concepts of solid solubilities and activities undoubtedly do not hold in the extremely dilute ranges that are of interest in semiconductor applications. The activity coefficient of silicon on cation sites in gallium arsenide might be different from that when it is on anion sites, for example.

The activity of silicon in more concentrated ranges can be predicted qualitatively from information obtained from phase diagrams of the Ga-As (5), Ga-Si (10, 11), and Si-As (12) systems. The high solubility (40 w/o) of silicon in gallium at 1250°C, with no compound formation, and the close correspondence between the measured heat of solution of silicon in gallium and the known heat of fusion of silicon both indicate that the activity coefficient of silicon in gallium at 1250°C may be near unity.

Two compounds, SiAs and $SiAs_2$, have been reported, and the activity coefficient of silicon in molten GaAs might be considerably less than unity.

The solid solubility limit of Si in GaAs at high temperatures has not been reported. If it is low, there exists the possibility that a silicon-rich phase could precipitate and become occluded in the GaAs during cooling. This has not been considered in the calculations.

The observed amounts of silicon contaminating the gallium arsenide that is currently being produced are of the same order of magnitude as the values predicted in this work for saturating the 1250°C zone with Ga_2O vapor.

Other Factors which May Affect the Reaction of Gallium with Quartz

Effect of oxide films.—Workers in other organizations, as well as in these Laboratories, have noted that etching of the quartz is promoted if the gallium is not initially heated in vacuum or flowing inert gas at low temperatures (600°-700°C). This treatment removes gallia films and their adsorbed water, or water of hydration, in the form of gallium suboxide, water, and hydrogen. A frequent observation is that if the gallium is not thus treated there might be general etching of the quartz but preferential attack at quartz-gallium interfaces where oxide films were known to be trapped.

This action is difficult to understand because the reaction of gallium with gallia or water vapor in these areas should form sufficient pressures of $Ga_2O_{(v)}$ to suppress the gallium-quartz reaction in the early stages of the attack. Apparently the quartz surface is sensitized in some manner, perhaps as a result of etching by the vapor species, so that it is more susceptible to further attack.

Effect of water vapor.—Frosch and Derick (13) demonstrated that about one hundred times more gallium was transported in flowing wet hydrogen at 950°C than in dry hydrogen. They explained that the water reacts with the gallium to form gallium suboxide and hydrogen. Weisberg (14) has observed the "distillation" of large quantities of GaAs with traces of water vapor.

In a test of these reactions at the authors' Laboratories, each of two identical quartz boats, 12 mm wide and 45 mm long, was placed near one end of separate, 15 cm long 37 ml volume, quartz tubes. One of the tubes with its boat was outgassed for 16 hr at 1000°C in a pressure of about 10^{-6} mm Hg. Vacuum was broken with argon and 6g of 99.9999+% gallium, weighed to ±0.05 mg, was added to each boat. The tubes were re-evacuated, and the tube that had been carefully outgassed was heated again to approximately 1000°C in high vacuum. A pressure of 19 mm of dry argon was admitted to this tube before sealing it off. A quantity of 0.0008g of water was introduced into the second tube before it was sealed off. These quantities of water and argon were such that the total pressure would be the same in both tubes at temperature.

The sealed tubes were placed side by side in a furnace in such a position that there was a temperature gradient along their length. The temperature at the end of the tubes containing the gallium was 1060°C. The temperature at the other end was 1020°C. Heating was continued for 48 hr.

In the tube containing argon, 0.0034g of gallium distilled to the ends, compared to 0.3259g, or 96 times as much, that distilled to the ends of the tube containing added water vapor. Nearly all of this gallium distilled to the end nearest the boat, even though this end was probably no more than 5° cooler than the gallium in the boat, whereas the other end, 7 in. away, was 40° colder.

The equilibrium constant derived for the reaction of gallium with water (4) becomes less favorable as the temperature is lowered so that gallium suboxide and hydrogen formed at one temperature will back-react partially to liquid gallium and water vapor at a lower temperature, other conditions remaining constant. The same water vapor can then diffuse back to the gallium at the higher temperature to form gallium suboxide and hydrogen, which can repeat the action.

If the water pressure is too high, some gallia will form in the distillate. This will not occur if the initial pressure of water vapor is reduced to the point where the pressure of gallium suboxide vapor forming at the higher temperature is too low for gallia to form by disproportionation at the lower temperature.

In principle, the transport of gallium from the hot to the cold end of the two tubes could be calculated from information on the equilibria between gallia, gallium, hydrogen, and water given in the previous paper (4). An approximate calculation showed that about a thousandfold difference in transport would be predicted for the two cases if vapor transport were accomplished by convection alone, one tube were completely free of moisture, and the temperature of the condenser were exactly

known. This is about tenfold greater than the observed ratio. However, diffusion transport may be of equal or greater importance, and the temperature of the actual site of condensation was not determined. Moreover, it is not possible to prevent accumulation of some trace of water vapor in a heated closed quartz tube even after careful outgassing.

Because of these uncertainties detailed treatment of the data is not warranted. A refined experiment would yield much interesting information about this transport process.

Distillation of gallium from gallium arsenide could also occur by the same transport mechanism, with the arsenic recombining with the gallium at a colder zone. This would seem to have interesting implications in the epitaxial growth of gallium arsenide, since there is no apparent mechanism for the transport of GaAs, *per se*.

Recommendations

It is interesting to speculate on modifications of the conventional horizontal GaAs synthesis apparatus that should lessen the attack on quartz and thus reduce the silicon contamination in the product.

An obvious precaution to observe is to separate any cold surface as far as possible from the reaction zone, *i.e.*, extend the 1250°C zone as near as possible to the arsenic boiler. Although extending the hot zone might enhance undesirable diffusion of gaseous products out of the reaction zone, such diffusion would be impeded by the countercurrent diffusion of arsenic into the reaction zone. This could be accentuated by reducing the diameter of the quartz tubing that joins the 1250°C zone to the 610°C zone. In the limiting case, this connection might even be a capillary tube.

The volume of "free space" in the 1250°C zone should be as small as possible, since this space will be filled with the gaseous reaction products whether or not there is a cold surface available.

Figure 5 is a sketch of the conventional apparatus and a suggested system that incorporates these recommendations. These recommendations might be met also in the conventional synthesis system by encapsulating the gallium in a quartz ampoule with a small hole at one end to admit the arsenic vapor. Such arrangements have not actually been employed in the synthesis of gallium arsenide to our knowledge.

Crucible synthesis and crystal pulling by the Czochralski technique seems to incorporate a number of undesirable features in the light of our present knowledge. The free space around the crucible is large in this case and, since induction heating is generally employed, a large area of cold condensing surface is close at hand. These features combine to present the worst situation from the standpoint of sustained reaction with the quartz. The

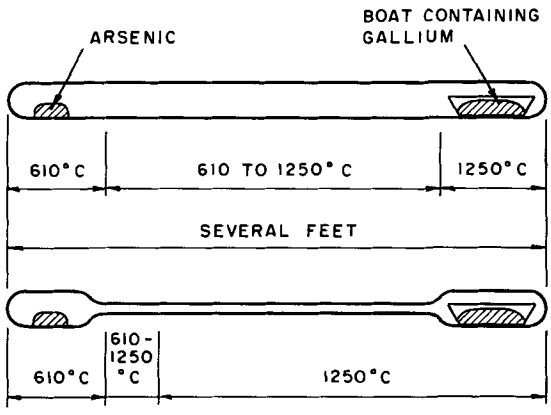

Fig. 5. Conventional top, and suggested, bottom of synthesis systems for GaAs.

fact that the carrier mobility in Czochralski grown GaAs is generally lower than in boat grown material, in spite of greater crystal perfection, seems to bear this out. Clearly the situation would be reversed if a completely nonreactive crucible material were available. In this case, the outer quartz envelope should be kept as near the arsenic condensation point as possible.

Only equilibrium calculations have been attempted here. Obviously, if the attainment of equilibrium can be delayed or prevented, lesser contamination should result. Carrying out the synthesis in the shortest possible time and at the lowest possible temperature are indicated.

Electrochemical and Adsorption Measurements on Single Crystals: The Germanium-Iodide Solution System

W. W. Harvey, W. J. LaFleur, and H. C. Gatos

Lincoln Laboratory,[1] Massachusetts Institute of Technology, Lexington, Massachusetts

ABSTRACT

An apparatus for simultaneous electrochemical and adsorption studies on single crystals is described. The electrode surface can be cleaned and characterized after mounting in position, the composition of the electrolyte can be altered, and repeated adsorption measurements can be made without removing the electrode. By employing the radioactive tracer I^{131} the adsorption of iodide was determined as a function of electrode potential and orientation in 0.1*N* Na_2SO_4 solutions of various *p*H containing small amounts of KI (5.0×10^{-6} to 2.5×10^{-4}*N*). Reversible multilayer adsorption on the {111} surface was observed, with a distinct maximum near the rest potential. Desorption of iodide occurred at strongly anodic and cathodic potentials. In addition to reversible adsorption of iodide, incorporation of iodide into an anodically formed surface compound was observed in the case of the {100} surface over a limited range of *p*H and iodide concentration.

Direct measurements of adsorption on solids from liquids can be made by tagging the adsorbing species with a radioactive tracer and determining the radioactivity on the surface. In such measurements the solid is usually removed from the liquid and freed from the mechanically adhering liquid before counting. The extent of adsorption on smooth electrodes can also be determined from the decrease in radioactivity in the solution, provided one employs extremely low adsorbate concentrations (1). If powders of large surface area are to be studied, direct adsorption measurements can be carried out by monitoring the adsorbate concentration in the liquid (2). A method has been reported for the continuous measurement of monolayer adsorption from solutions, using a thin film of the solid evaporated onto the window of a Geiger tube (3).

The methods outlined above are not generally suitable for performing simultaneous and continuous electrochemical and adsorption measurements on solids; they are particularly unsuited for single-crystal electrodes and relatively high concentrations of adsorbate. In order to overcome some of these limitations, an apparatus was developed recently and submitted to preliminary evaluation (4). This apparatus has been extensively modified for the present study and employed in an investigation of the adsorption of iodide ions onto germanium single crystals at controlled electrode potentials.

The adsorption of iodide on germanium has not been measured hitherto. However, the maxima observed in the rate of germanium dissolution in oxygen-saturated solutions as a function of Cl^-, Br^-, or I^- concentration were attributed to specific adsorption of the anion with charge transfer (5). Recently, it was reported (6, 7) that the limiting anodic current of n-type germanium in 0.1*N* HCl was increased by the presence of 0.1*N* KI. In contrast to the behavior of oxalate ion, which similarly increased the limiting anodic current, iodide ion was not oxidized at the n-type germanium anode. It was postulated that iodide is oxidized in an intermediate step of the anodic process, "injecting" electrons into the germanium, and that the iodine formed is subsequently reduced electrochemically with the injection of holes. Whether or not this explanation is correct, sufficient interest is attached to the system Ge-I^-(aq.) to warrant a direct study of the adsorption characteristics.

[1] Operated with support from the U. S. Army, Navy, and Air Force.

Experimental Techniques

Apparatus.—Details of the present shielding and counting arrangement are shown in Fig. 1. The ad-

Fig. 1. Adsorption cell and counting arrangement. A, Teflon gasket; B, electrode; C, gold foil for electrical contact; D, polyethylene insulator; E, steel plate for transmitting pressure (side arms prevent shearing); F, pressure applying screw; G, scintillation crystal; H, light source; I, photomultiplier tube; J, cell support; K, lead shield; L, brass fastening plate; M, lead cover; N, brass plate; O, reference vial; and P, lead plug.

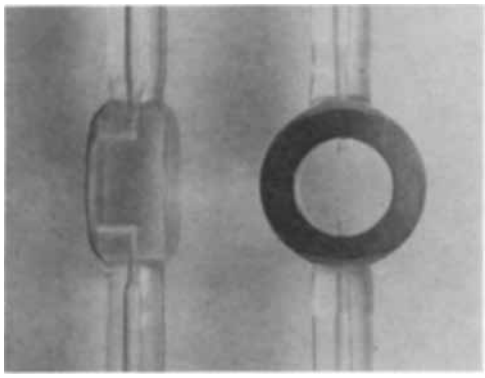

Fig. 2. Side and top view of Pyrex adsorption cell; Teflon coating is shown; diameter of recess 1.13 cm; diameter of capillary bore 1 mm.

sorption cell (Fig. 2) is of the same construction as that originally reported, except that a coating of Teflon replaces the Teflon gasket shown in Fig. 1; the coating has proved completely reliable in preventing leakage of radioactive solution out of the cell. Additional shielding within the lead pig and the use of a smaller scintillation crystal essentially restrict detection of radioactivity to that contained in the cell recess and in the immediately adjacent portions of the side arms. Illumination of the electrode surface is provided by a small lamp located between the cell and the scintillation crystal. More efficient circulation of the solution has resulted from replacing the thermal convection arrangement with a gas lift (Fig. 3); further modifications in the glass apparatus are evident on comparison of Fig. 3 with Fig. 1 of ref. (4).

The adsorption cell (capacity 0.05 ml) employed in this study has a recess 0.05 cm deep and 1.13 cm in diameter, allowing an exposed electrode area equal to 1.00 cm^2. With radioactive solution circulating through the cell, it was found that the counting rate, exclusive of that due to adsorption, corresponds to 0.10 ml of solution, *i.e.*, a factor of two greater than the volume of solution in the cell recess. Considering the large volume of solution contained in the glass apparatus, (approximately 130 ml, not including any solution in the reservoir) it is evident that the shielding arrangement is very effective, making for optimum sensitivity. The upper limit of radioactive solute concentration reported earlier (4), namely 10^{-4}M, applies to the detection of monolayer coverage; at this concentration the counting rate of the solution corresponds to 6 x 10^{15} atoms of the adsorbed species, or roughly six monolayer equivalents. At lower concentrations, small fractions of a monolayer equivalent can be detected.

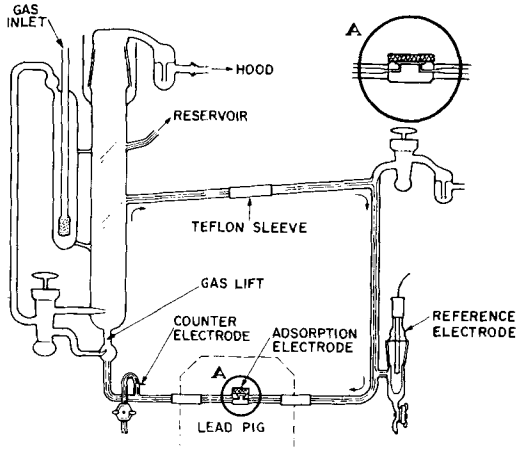

Fig. 3. Apparatus for radiotracer adsorption and electrochemical studies on single crystals.

Adsorption measurements.—The adsorbed activity is measured through a thin layer of solution in contact with the electrode and through some thickness of glass. Thus, the chemical species whose adsorption behavior is to be studied is tagged preferably with a gamma-emitting isotope, in this case I^{131} (half-life 8.14 days).

The contribution of the solution to the total observed counting rate is most conveniently established by comparing the counting rate of a 1.00-ml aliquot of the solution, contained in a suitable positioned vial (see Fig. 1), with that of the solution in the cell; for this measurement the specific activity of the adsorbing species is made so low that the adsorbed radioactivity is completely negligible. The ratio of solution counting rate (r_{soln}) to vial counting rate (r_{vial}) is a constant (R_{soln}) for a particular cell and counting arrangement. Once this "geometry" factor has been determined, the contribution of the solution in the apparatus to the observed counting rate is readily ascertained in an actual run by inserting the vial and measuring the increase in counting rate.

The difference between the observed counting rate, corrected for background, and the counting rate due to the solution in the apparatus is the counting rate of the adsorbed species. To proceed from this quantity to the amount of material adsorbed, use is again made of the counting rate of 1.00 ml of the test solution in the vial as follows: in a separate experiment the counting rate (r_{surf}) of a given quantity of radioactive material deposited on the surface of the electrode is compared with the counting rate (r_{vial}) of the same quantity of radioactive material contained in 1.00 ml of solution in the vial. The ratio $R_{surf} = r_{surf}/r_{vial}$, like the ratio R_{soln}, is a constant for the geometry employed. Having performed the necessary calibration, it becomes possible to evaluate the amount of material adsorbed from the observed counting rate, r_{obs} (corrected for background), the counting rate of the vial, r_{vial}, and the adsorbate concentration in the solution in contact with the electrode. Thus, for example, the number of adsorbed iodide ions $(I^-)_{ads}$ is given by:

$$(I^-)_{ads} = \frac{r_{obs} - R_{soln}\, r_{vial}}{R_{surf}\, r_{vial}} [I^-] \qquad [1]$$

where $[I^-]$ is the number of I^- ions per ml of solution. A distinct advantage in counting an aliquot of the solution is the fact that no explicit correction for radioactive decay need be made. Furthermore, this technique does not necessitate a determination of the absolute specific activity of the tagged species.

Characterization of the germanium electrodes.—Two types of electrochemical characterization were employed: (*a*) charging curves (8, 9), *i.e.*, plots of electrode potential *vs.* time (or number of coulombs) with a constant current passing through the cell, and (*b*) current-potential curves. An electronic con-

stant-current source having an equivalent source voltage of 500v was used for the charging curves; an apparent current density of 0.02 ma/cm² was generally employed. Current-potential characteristics were obtained by employing a potentiostat. Generally, the current employed did not exceed 0.1 ma. The varying efficiency of circulation in different parts of the recess posed no problem for the measurements reported here since the solutions used did not attack the electrode and since relatively long times were required for counting.

A limitation inherent in the method of counting adsorbed activity through a thin layer of solution is that the current density is not entirely uniform over the exposed surface of the electrode; in particular, the current density is greatest at the portions of the surface opposite the capillary orifices of the cell as revealed by prolonged anodic etching. In the present apparatus, a portion of the cell current flows in the direction of circulation (Fig. 3), so that a small IR drop is included in the potential of the adsorption electrode measured *vs.* the saturated calomel electrode. The virtual elimination of this small extraneous voltage is largely a matter of redesigning parts of the glass apparatus. Finally, it should be pointed out that the formation of gaseous reaction products on the electrode surface is to be avoided, since even very small bubbles constitute an appreciable fraction of the volume of the recess and are, moreover, difficult to dislodge.

Preparation of electrodes.—The electrodes were cut to the desired orientation from p-type germanium single crystals (resistivity about 10 ohm-cm) and had the nominal dimensions 2 x 2 x 0.8 cm. The large faces were ground precisely parallel and were chemically polished before mounting. Preliminary rinsing with distilled water circulating through the cell was followed by electrolytic cleaning in the solution to be studied (but containing no radioactivity); *i.e.*, the electrode was charged alternately anodically and cathodically until the characteristics of the charging curves did not change with time. Whenever some contaminant was present on the surface, it was readily detected as shown, for example, by the anodic portion of the initial charging curves in Fig. 4. Such contamination could be removed in a short time by the procedure described. A second portion of inert solution was employed for the electrochemical characterization of the electrode-solution system, both by charging curves and by current-potential curves. The characterization was repeated in the radioactive solution to insure that no chemical contamination was introduced along with the radioactivity. Occasionally, contamination was detected at this stage, and it was necessary to repeat the entire experiment. Electrochemical characterization, where applicable, is clearly an essential preliminary to reliable adsorption measurements.

Preparation of solutions.—All of the solutions employed in this study were 0.1*N* Na_2SO_4 containing various concentrations of H_2SO_4 and KI. Reagent grade anhydrous Na_2SO_4 was used to prepare a large volume of 1.0*N* stock solution; stock solutions of H_2SO_4 were prepared from Acculute volumetric standards. Since iodide in acid solutions is slowly oxidized by free oxygen, special consideration was given to the preparation of the KI solutions. First, weighed quantities of reagent grade KI were added to a dry volumetric flask containing a magnetic stirring bar. The air in the flask was then displaced by purified nitrogen; subsequently, the nitrogen in the flask was displaced by thoroughly deoxygenated distilled water, which was allowed to fill the flask to the brim. The solution in the completely filled and stoppered flask was then stirred magnetically. This stock KI solution was added last in making up Na_2SO_4/H_2SO_4/KI solution in the reservoir and only after oxygen had been removed from the solution by bubbling purified nitrogen.

The usual commercial form of carrier-free I^{131}, obtained from fission products, is in the form of NaI in alkaline sulfite solution. Since, however, sulfite participates in germanium electrode processes, sulfite-free solutions were specially procured from the Oak Ridge National Laboratory. Occasionally, these solutions contained peroxide and could not be used for adsorption measurements (see Fig. 4).

Results and Discussion

Current-potential characteristics. — Current-potential curves were obtained at various pH values and iodide concentrations. Some results are shown in Fig. 5 and 6. It is seen (Fig. 5) that in acid solutions of $10^{-4}N$ KI with 0.1*N* Na_2SO_4 supporting electrolyte,

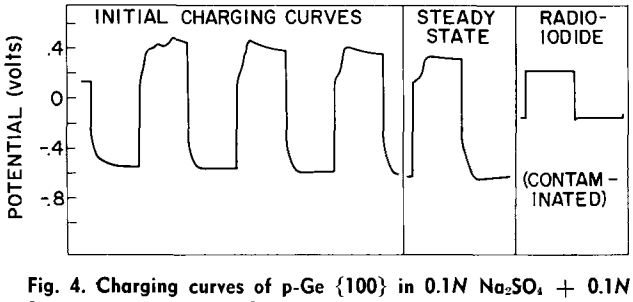

Fig. 4. Charging curves of p-Ge {100} in 0.1*N* Na_2SO_4 + 0.1*N* H_2SO_4 containing 5 x $10^{-6}N$ KI, showing removal of surface contamination present and detection of peroxide contamination in the radioiodide. Apparent current density 0.020 ma/cm²; charging intervals 60 sec.

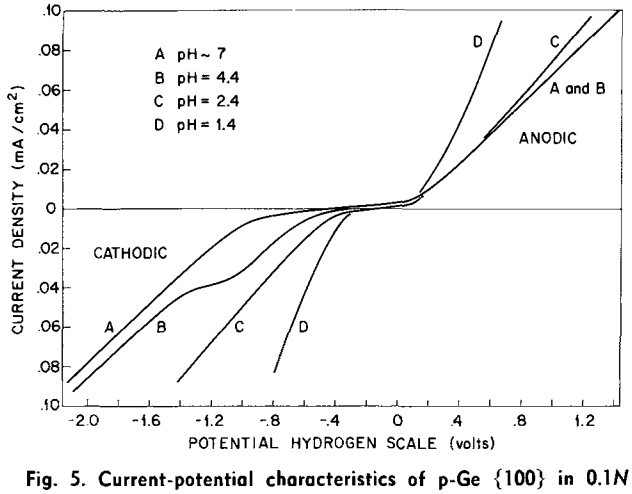

Fig. 5. Current-potential characteristics of p-Ge {100} in 0.1*N* Na_2SO_4 containing $10^{-4}N$ KI plus H_2SO_4 as follows: A, zero; B, $10^{-4}N$; C, $10^{-2}N$; D, $10^{-1}N$. Figure also shows convention used throughout this paper in plotting cathodic and anodic currents; 24°C.

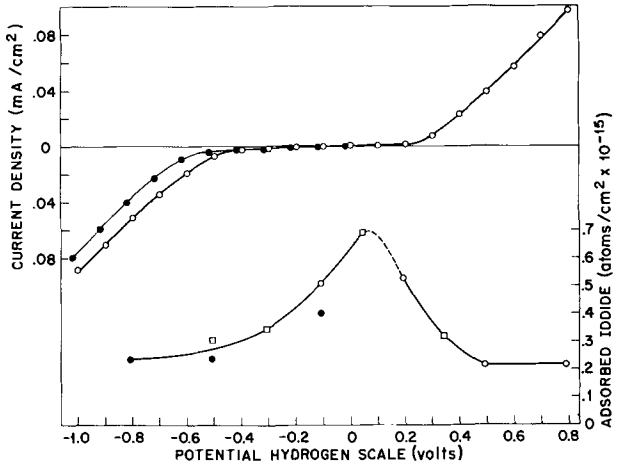

Fig. 7. Current-potential curves and iodide adsorption on {111} p-Ge from 0.1*N* Na_2SO_4 + 0.1*N* H_2SO_4 containing I^{131}-tagged 5 x 10^{-6}*N* KI. Measurements made with increasing (o) and decreasing (•) potential. Squares show adsorption measurements made on a subsequent day; 24°C.

both the germanium dissolution reaction (anodic branch) and the hydrogen ion discharge reaction (cathodic branch) become increasingly polarized with increasing pH. Since the primary interest in the present study is in adsorption behavior, and since the current density distribution is not entirely uniform, as pointed out earlier, a detailed discussion of these curves will not be attempted. It should be stated, however, that the inflection in the cathodic portion of curve B is reproducible; it may indicate the advent of strong iodide adsorption as the germanium electrode potential is changed in the positive direction. In the nearly neutral solution, current-potential characteristics at various lower KI concentrations were virtually superposable on curve A. This result is attributable to the fact that appreciable concentrations of hydroxide ion inhibit the adsorption of iodide, direct evidence for which will be presented later.

At pH 1.4, the hydrogen overvoltage on the {111} surface increases with iodide concentration (Fig. 6). By contrast, the {100} surface is characterized by an appreciably lower hydrogen overpotential at the highest iodide concentration and, in the same concentration range, iodide decreases the hydrogen overpotential. The latter effect is small, however, and is not shown in the figure. Evidently, no generalization can be made concerning the effect of iodide on the hydrogen overpotential on a germanium electrode. As is shown below, the {111} and {100} surfaces also differ considerably in their adsorption behavior.

Adsorption measurements.—The most characteristic feature of the adsorption data is the occurrence of a sharp adsorption maximum at the rest potential or at somewhat more positive potentials. Figure 7 shows the results obtained with the {111} electrode at the lowest KI concentration studied. Assuming a roughness factor of 1.5, the unit 10^{15} cm^{-2} approximates the calculated number of iodide ions in 1 cm^2 of a close-packed monolayer. Results obtained with increasing and decreasing potential are also shown in the figure. The data are somewhat atypical in that (*a*) the cathodic polarization curves taken with increasing and decreasing potential do not more nearly coincide, and (*b*) the calculated amount of adsorbed iodide does not fall to zero on either side of the maximum. The general features of the adsorption behavior, however, were duplicated at iodide concentrations up to 2.5 x 10^{-4}*N* KI. The data are summarized in Table I.

It is seen from the table that iodide is desorbed at potentials more positive than 0.4v. This behavior is consistent with the fact that the steady-state anodic reaction in these solutions is germanium dissolution. On the other hand, the ready removal of adsorbed iodide by cathodic polarization contrasts with earlier results obtained by Kolotyrkin (1), who estimated that adsorption of iodide on silver and lead begins at potentials near −1.0v. The contrast is even greater than it appears since a substantial portion of an applied cathodic potential may reside in the space charge region of a p-type germanium electrode (10, 11).

At potentials close to maximum adsorption, the amount of adsorbed iodide increases with iodide concentration over the entire range investigated. The adsorption isotherm taken at −0.11v, *i.e.*, approximately at the rest potential, shows no sign of leveling off even though the adsorption attained very high values, *e.g.*, 25 x 10^{15} atoms/cm^2 for the 2.5 x 10^{-4}*N* KI solution. Comparably large iodide adsorption was measured by Balashova (12) on smooth platinum. In

our case, autoradiograms showed no evidence of accumulation of iodide at active sites such as at the termination of dislocations, and the adsorption appeared to be uniform over small regions of the surface. Adsorption to the extent of many monolayer-equivalents cannot reasonably be described as specific adsorption, since contact with the surface is not possible for the majority of adsorbed atoms. Moreover, there must be coadsorption of cations in order to provide counter charges in sufficient numbers. A convenient alkali metal iodide for studying coadsorption might be RbI tagged with Rb^{86}; by measuring adsorption of both I^- and Rb^+, it could be determined whether HI is adsorbed in significant amounts.

The data of Fig. 7 and Table I were obtained with the same electrode by displacing a given solution with one containing a higher concentration of iodide. Repeated treatment of the electrode was unnecessary since the adsorption was completely reversible, *i.e.*, adsorbed activity was removed (by exchange) when the radioactive solution was replaced by a solution of inert (nonradioactive) iodide. The adsorbed activity could also be removed by circulating water or an iodide-free solution through the apparatus. A time-dependent irreversible adsorption as found, for example, by Balashova (12) for iodide on platinum was not observed in the present system. No attempt was made in our experiments to measure rates of exchange of iodide between surface and solution, although such measurements can be carried out with the present apparatus provided the times involved are not too short.

In some instances illumination effects were looked for, but no significant changes in the amount of adsorbed iodide were noted. However, for the electrodes and solution compositions employed, the photopotentials were not large. In order to observe photoadsorption and desorption on germanium, one would need to employ an electrode having bulk electrical properties such as to result in a large permanent photopotential (13) in the given electrolyte solution and in a region of electrode potential where the amount of adsorption depends strongly on potential.

Orientation effects.—Polarization and adsorption characteristics for the {111} and the {100} surfaces are compared in Fig. 8 for $10^{-4}N$ KI in $0.1N$ Na_2SO_4 + $0.1N$ H_2SO_4. It is seen from Fig. 8 that, in addition to the smaller anodic and cathodic overvoltages on the {100} surface (see also Fig. 6), iodide ions are adsorbed on the {100} surface to a much smaller extent than on the {111} surface. For the {100} surface, the amount of iodide adsorbed at the maximum, near zero volts on the hydrogen scale, is close to that observed for the {111} surface at the same potential, but at one twentieth of the iodide concentration (Fig. 7).

Another significant feature of the adsorption behavior of the {100} surface in the solution of Fig. 8 is the appearance of a second and larger adsorption maximum at a potential more positive than that of the first. Unlike the reversibly adsorbed iodide, the iodide in this case is associated with an anodically formed surface compound. Effects related to the presence of an anodically formed compound containing iodide are transient except within a fairly narrow range of solution composition as discussed below. An example of a transient effect of this nature is shown in Fig. 9 (lower curve). The hysteresis indicated by the dashed line was recorded by using the inert solution, but was not found subsequently by using the radioactive solution; otherwise, the curves for the two solutions are identical. The principal significance of Fig. 9 is a comparison of iodide adsorption at low and high pH. The extent of adsorption at the maximum is smaller by a factor of seventeen in the alkaline solution in which the concentration of hydroxide ion exceeds that of iodide ion by a factor of forty.

For the {100} electrode, effects associated with an anodic film (surface compound) were observed repeatedly in $10^{-4}N$ KI + $10^{-3}N$ H_2SO_4 + $0.1N$ Na_2SO_4, *i.e.*, at the same pH as for Fig. 9, but at a higher KI concentration. Thus, following anodic polarization, an extended step appeared in the cathodic charging curve, as shown in Fig. 10. By allowing various times to elapse between anodic and cathodic charging (see Fig. 10), it was determined that at least two hours are required for the complete dissolution (without external polarization) of the anodically formed sur-

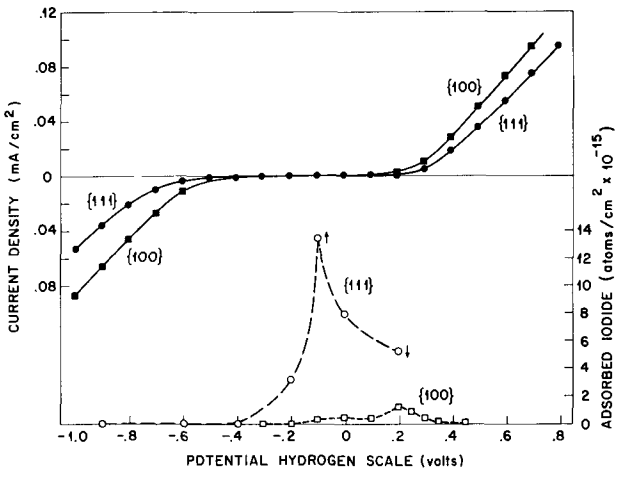

Fig. 8. Comparison of polarization and iodide adsorption characteristics of the {111} and {100} surfaces of p-Ge in $0.1N$ Na_2SO_4 + $0.1N$ H_2SO_4 containing $10^{-4}N$ KI; 23°C.

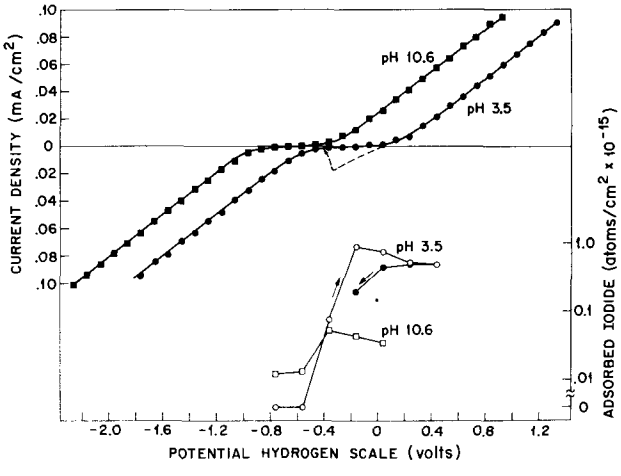

Fig. 9. Effect of pH on the polarization and iodide adsorption characteristics of {100} surface of p-Ge in $0.1N$ Na_2SO_4 containing 1 x $10^{-5}N$ KI + $10^{-3}N$ NaOH (pH 10.6, 26°C) or $10^{-3}N$ H_2SO_4 (pH 3.5, 24°C).

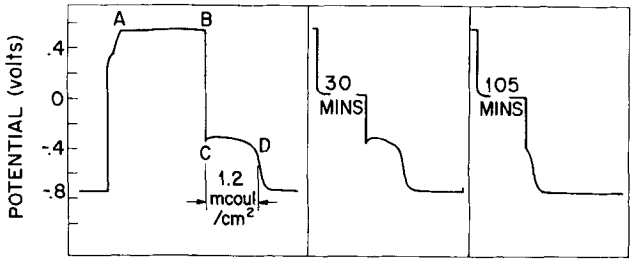

Fig. 10. Charging curves for {100} p-Ge in 0.1*N* Na_2SO_4 + 10^{-3} H_2SO_4 containing $10^{-4}N$ KI; apparent current 0.020 ma/cm².

face layer. For short anodic charging times, the width of the cathodic step $\overline{CD}$ is approximately equal to the length of the horizontal portion $\overline{AB}$ of the anodic curve. The thickness of the anodically formed layer does not increase indefinitely, however; if, for example, $\overline{AB}$ is made twice as great as for Fig. 10, $\overline{CD}$ is increased by about 40%. The steady-state anodic reaction, in other words, is still germanium dissolution. The steady-state thickness of the anodic surface layer at a current density of 20 μa/cm² is about 11 monolayer-equivalents, assuming that 10^{15} atoms/cm² constitutes one monolayer-equivalent and that one electron is transferred for each atom incorporated into the surface film. On the other hand, adsorption measurements revealed that 17 monolayer-equivalents of iodide present in the anodically formed surface layer are removed cathodically (Fig. 11). This observation is significant with regard to the chemical composition of the film in that it indicates that not all of the incorporated iodide is in good electrical contact with the substrate.

In the solution of Fig. 10 and 11, a pronounced hysteresis occurred in the current-potential curves when measurements were made fairly rapidly. However, the cathodic potential at which the anodically formed surface compound appears to be suddenly reduced is not critical, but depends on the rapidity of the measurements. In taking the adsorption data, roughly 20 min elapsed between settings of the electrode potential; consequently, although the current density followed the hysteresis curve for a time, the abrupt removal of the surface film occurred at a potential more positive by 0.54v (compare upper and lower parts of Fig. 11).

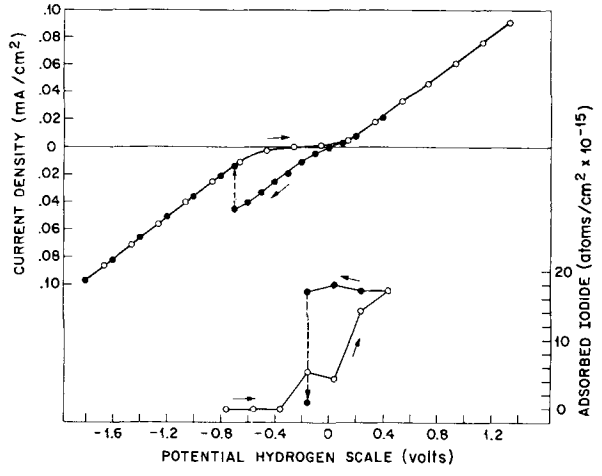

Fig. 11. Hysteresis in the polarization and adsorption behavior of the {100} surface of p-Ge resulting from the anodic formation of a surface compound. Solution composition as in Fig. 10; 25°C.

The adsorption data of Fig. 11 may be compared to those for the {100} electrode in Fig. 8. As a result of increasing the *p*H by two units, the amount of iodide adsorbed from $10^{-4}N$ KI solution was increased from 0.43 to 5.5, and the amount of iodide incorporated into the anodically formed surface layer was increased from 1.2 to 17.2, in units of 10^{15} cm⁻². However, there is reason to believe that at still higher *p*H's the amount of adsorbed iodide will decrease as for the $10^{-5}N$ KI solution (Fig. 9).

Summary

The capabilities and limitations of the apparatus and technique for the simultaneous measurement of adsorption and electrochemical properties of single-crystal electrodes were assessed in a study of the system germanium-iodide solution. In the absence of a significant amount of irreversible adsorption, the same electrode can be used repeatedly, without intermediate treatment of the surface. Electrochemical characterization (charging curves as well as current-potential curves) proved indispensable both as an aid in interpreting the adsorption data and as a sensitive means of detecting contamination of the surface or of the solution.

The practical upper limit of adsorbate concentration (about $10^{-4}N$ for monolayer adsorption) is orders of magnitude higher than that attainable by other techniques using solid electrodes and determining adsorption *in situ* by differences in radioactivity of the solution. In the case of multilayer adsorption, as observed in the present work, correspondingly higher adsorbate concentrations can be investigated. Owing to the necessity of counting through a thin layer of solution, IR drops in the solution result in nonuniform current distribution over the surface, with attendant uncertainties in the significance of the potentials measured. It was partly for this reason that relatively low current densities were employed in this work.

Iodide ion is reversibly adsorbed on the {111} surface of germanium, leading to an increase in the hydrogen overpotential. The adsorption exhibits a maximum near the rest potential; virtually complete desorption can be accomplished both by cathodic and anodic polarization at readily attainable potentials. At *p*H 1.4, the extent of adsorption increases with concentration in the range 5 x $10^{-6}N$ to 2.5 x $10^{-4}N$ KI, reaching many monolayer-equivalents in the more concentrated solutions. The nature of the observed multilayer adsorption must be such as to involve the coadsorption of cations; alternatively, the adsorbed species may be HI. Evidently it will be necessary to look for specific adsorption of iodide ions at KI concentrations well below 5 x $10^{-6}N$.

The {100} surface of germanium differs from the {111} surface in its polarization and adsorption behavior. The effect of iodide on the hydrogen overpotential is smaller than for the {111} surface and is in the opposite direction. Where comparisons were made at the same solution composition, the amount of reversibly adsorbed iodide was found to be an order of magnitude less on the {100} surface. In addi-

tion, in certain solutions the charging and current-potential characteristics revealed the anodic formation and cathodic removal of a surface compound containing substantial amounts of iodide as shown by adsorption measurements.

In a 0.1*N* Na_2SO_4 supporting electrolyte containing $10^{-4}N$ KI, reversibly adsorbed iodide on the {100} surface amounted to 0.4 and 5.5 monolayer-equivalents when the solution was made 0.1 and $10^{-3}N$, respectively, in H_2SO_4. At higher *p*H's the trend is reversed, and adsorption of iodide is small in alkaline solutions. The anodic surface compound is formed within fairly well-defined composition limits. Thus, aside from transient effects, evidence for its formation in 0.1*N* Na_2SO_4 containing $10^{-4}N$ KI was obtained at *p*H 3.4, but not at *p*H 2.4, and also not at *p*H 3.4 when the KI concentration was decreased to $10^{-5}N$.

In conclusion, it can be stated that the apparatus described previously and modified for the present work is admirably suited for extensive adsorption and polarization studies carried out *in situ* using solid electrodes. The capabilities of the technique with respect to electrochemical characterization and absolute measurements of adsorption have been demonstrated in a study of germanium electrodes in contact with solutions containing iodide ion.

Acknowledgment

The authors are pleased to acknowledge helpful discussions with Mr. J. A. Kafalas in developing the procedure for the calibration of the adsorption cell and his assistance with instrumentation.

Manuscript received Aug. 9, 1961. This paper was prepared for delivery before the Indianapolis Meeting, April 30-May 3, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

Transient Potentials of the Mercury-Aqueous Solution Interface

Carl D. Spear,[1] Melvin A. Cook, and Milton E. Wadsworth

Department of Metallurgy, Institute of Metals and Explosives Research, University of Utah, Salt Lake City, Utah

ABSTRACT

Methods of studying transient electrode potentials produced by expanding a mercury-aqueous KCl solution interface at constant rate are described and results obtained in studies of the expanding mercury electrode-aqueous chloride ion system presented. Correlations with available potential, overpotential, and electrocapillarity data for this system permit one to determine the variables which control the transient potentials for such a system. The transient potential produced by expansion of this metal-aqueous solution interface is thereby shown to be associated with a finite rate of reformation of the diffuse part of the electrical double layer.

Studies of strain potential transients of metals were stimulated by the development of the electrolytic theory of corrosion. Andrews (1) in 1894 investigated the potential between cold-worked and annealed steels. Researchers who have more recently studied the effect of stress on electrode potentials for solid metals are Nikitin (2), Zaretskii (3), Gautam and Jha (4), Coffin and Simon (5), McFadden (6), Dudley, Elliot, McFadden, and Shemilt (7), Fryxell and Nachtrieb (8), Coffin and Tingley (9), and Wernick (10).

More recently, Eyring *et al.* made experimental studies of strain induced electrode potentials as a function of electrode material, *p*H, nature and concentration of electrolyte, dissolved gases, etc. (11-14) using as the reference of potential the corresponding unstrained electrode. A model based on electrode kinetics was proposed (11) in which the electrode strain potentials were explained in terms of reactions that transfer charge across the electrical double-layer.

Also early investigators (2) ascribed transient potentials of stretching wires to heat produced by internal strain; however, more recent ones have indicated that surface reactions are responsible (3, 8, 11).

In order to demonstrate experimentally whether or not internal strain is necessary for the development of transient potentials of this sort the liquid metal mercury was chosen because its surface can

[1] Present address: Research and Development Division, Corning Glass Works, Corning, New York.

be expanded without developing internal strain and surface irregularities. For this purpose a cell and pump system was designed which permitted the mercury-aqueous solution interface to be expanded at a constant rate analogous to elongating a metal wire in contact with an aqueous solution at a constant rate.

Further advantages of mercury for studying transient potentials are that the extensive information concerning the electrical double-layer given by electrocapillarity and overpotential studies, and the large volume of standard electrode potential data permit one to establish a quantitatively steady-state potential ($dV/dt = 0$) as functions of the appropriate independent solution and variables.

Apparatus and Procedures

The equipment consisted of two parts: (a) a pump for the liquid mercury suitable for pumping the mercury at a constant rate into a cell permitting the mercury surface to expand the mercury-aqueous solution interface at a constant rate; and (b) an electronic device to measure and record automatically the voltages produced.

The mercury pump was constructed from a 100 ml hypodermic syringe and a screw and nut system which drove a plunger into the syringe cylinder. The screw was driven by an electric motor with a low rpm gear box and pulleys so that various expansion rates of the interface from 1.0 cm²/sec to 5.2 cm²/sec were achieved.

In determining the cell geometry it was necessary to design the cell so that the mercury-solution interface expanded at a constant rate when a constant volume of mercury was pumped into the cell $(dV/da) = k$.

The cell was constructed from three sheets of ¼-in. thick plexiglas cemented together with a plastic cement. It was connected to the pump with stainless steel tubing (2 mm ID) with a joint as shown in Fig. 1.

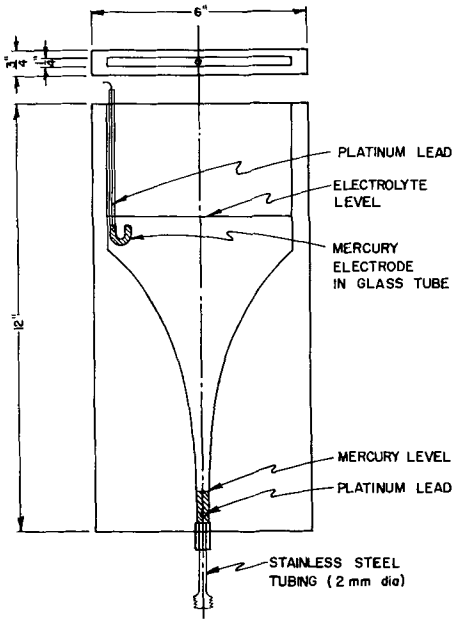

Fig. 1. Mercury cell which gives constant expanding interface between mercury and electrolyte.

The electrodes used to measure the potential developed in the cell are also shown in Fig. 1. The electrode for the expanding surface was simply a platinum wire passing through the cell wall into the mercury at the bottom of the cell. Either a saturated calomel cell or mercury itself was used as the reference electrode. The mercury electrode was made of a glass tube (3 mm ID) with a U bend situated just above the limiting position that the expanding mercury surface was capable of reaching. The U bend was filled with mercury and a platinum electrode placed in contact with the mercury. The two electrodes were connected to a high impedance L&N No. 7664 *p*H indicator for amplification. The output from the *p*H amplifier was modified by a variable voltage divider to actuate a Varian strip-chart potentiometer G11A recorder. A calibration voltage was displayed on the chart by means of the standardization control on the *p*H indicator.

The electrolyte was deaerated with N_2. The flow of gas was measured with a flowmeter which measured the pressure difference across a capillary constriction. A cellophane tape lid, with openings for the reference electrode and gas bubbler, maintained the desired gas composition. The bubbler with a sintered glass bottom was made using simply a glass rod long enough to reach to the bottom of the cell. A pyrogallol-sodium hydroxide solution trap was introduced into the nitrogen line to remove traces of oxygen, and a water trap kept the dry gases from depleting the water in the cell and changing the electrolyte concentration.

The spent mercury was first cleaned in a mercury oxifier. The clean mercury was then distilled in a Cenco vacuum mercury still. Fresh mercury prepared in this manner was used in each separate run.

In carrying out a run the hypodermic syringe (the pump) was first filled with mercury and connected to the cell by a coupling through a stainless steel tube. The mercury was then brought to a certain fixed level at the bottom of the cell, and a platinum wire in contact with the mercury at this point served as the lead for the expanding mercury electrode. The electrolyte was then poured into the cell and a mercury electrode or a saturated calomel reference electrode placed in it. The leads from the expanding mercury electrode and reference electrode were connected to the *p*H millivoltmeter. To remove dissolved oxygen the electrolyte was then deaerated with nitrogen. After deaeration for about 1 hr, the glass tube was removed and the pump motor switched on. The transient potential began to rise the instant the mercury surface started to expand.

Experimental Results

The potential-transient traces shown in Fig. 2 are typical of the results obtained with an inert electrolyte such as potassium chloride. Initially the potential rose sharply to a maximum and then remained essentially constant except for a slight dip in the curve caused by a tendency toward over-

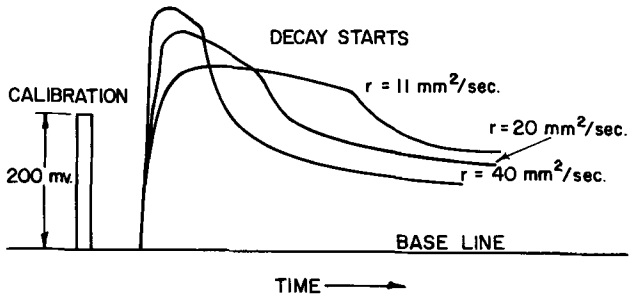

Fig. 2. Varian recorder trace in Hg-1M KCl system

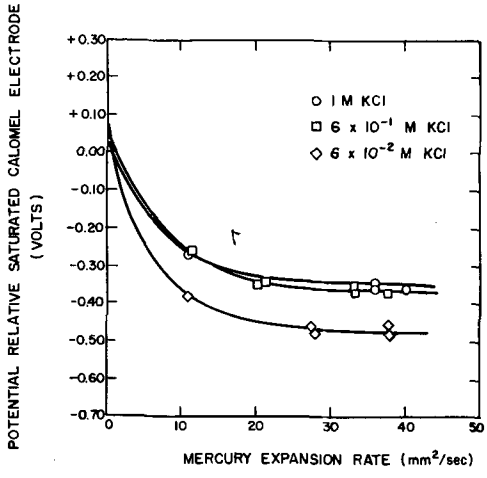

Fig. 3. Expansion rate vs. potential developed for KCl system in the absence of O_2.

shoot. When expansion was stopped the potential underwent characteristic exponential type decay. As may be seen from Fig. 2 the fastest expansion rate produced the greatest potential and the most rapid decay when expansion was stopped.

Figure 3 presents plots of the steady-state potential (maximum potential, $dV/dt = 0$) against the rate of expansion r for solutions of three different concentrations. For a given concentration of electrolyte the voltage approached a plateau as the expansion rate increased. Figure 4 presents graphically the steady-state potentials against electrolyte concentration for various expansion rates. The potential was linear in log $[Cl^-]$ at high concentrations. At 6×10^{-2}M KCl, the potential-concentration curves reached the most negative value. Significantly, this corresponds to the point where the potential of the expanding electrode reached the potential of the electrocapillary maximum. The potential then followed the electrocapillary maximum curve which varies with the concentration of the electrolyte. This occurred because the expanding interface was then essentially depleted of its charge. The dropping mercury electrode confirms this since its steady-state voltage is coincident with the electrocapillary maximum. The curves in Fig. 4 also show that at a given concentration the potential approached the electrocapillary maximum more and more as the expansion rate was increased.

For concentrations lower than 6×10^{-2}M KCl the voltages were nonreproducible. A probable reason for this was the presence of impurities in the electrolyte. While these impurities were always present their effects were negligible at high chloride ion concentrations. Hence, only the average values are shown in Fig. 4. The standard deviation was about 70 mv at potentials of 400 mv in this region, corresponding to an experimental error of about ±20%. This is contrasted with the high concentration region where the experiments were reproducible to within ±5%.

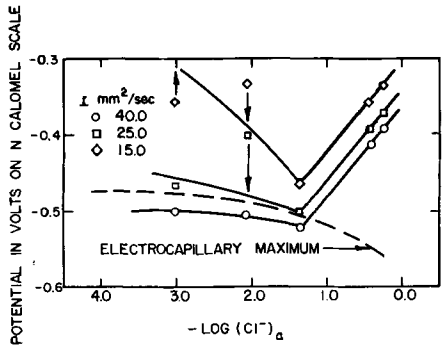

Fig. 4. Log $[Cl^-]_a$ vs. potential of an expanding mercury electrode for oxygen free electrolytes.

The logarithm of the expansion rate against potential plot was linear as shown in Fig. 5.

Discussion

The expanding mercury surface gave essentially the same type of potential-time trace described previously for elongating metal wires (see Fig. 2). The fact that the potential-time traces for mercury and the ones for metal wires were closely analogous indicates that the generation of active surface sites by internal strain may not be necessary for the development of transient potentials of stretching or expanding metals in aqueous solutions. The similarity of the traces cannot, of course, exclude the possibility that active surface sites play a role in transient potential phenomena for solid metal wires. However it appears that the important considerations are: when a metal is strained, interfacial conditions are disrupted and surface reactions result which tend to restore the wire-aqueous solution interface to its original condition. The reactions cause charge to flow into or from the electrical double-layer or possibly in some cases of chemical reaction to cross it, depending on the nature of the electrode and its environment.

Because of the practically ideal polarization characteristics of mercury in contact with aqueous

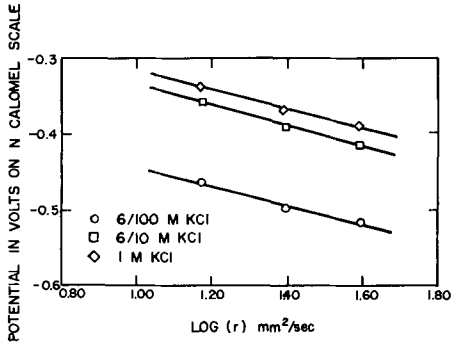

Fig. 5. Log (r) vs. potential of an expanding mercury electrode for oxygen free KCl electrolytes.

potassium chloride it is necessary only to account for the flow of ions into the reforming electrical double-layer following exposure of new surface in order to account for the transient potential developed when the electrode expands. The following reaction is postulated for the absorption of Cl^- at the mercury-aqueous chloride solution interface.

$$| \text{Hg} + \text{Cl}^- \rightarrow | \text{Hg Cl}^- \qquad [1]$$

Letting θ equal the fraction of the surface covered with adsorbed chloride ions and $(1-\theta)$ the fraction of uncovered mercury surface | Hg, the velocity of the chloride ion adsorption on the surface might be expected to be proportional to $(1-\theta)$, to the activity of the chloride ions $(Cl^-)_a$, and to the rate k_1 of reaction [1] in the forward direction. The rate k_1 is a function of the potential across the metal-solution interface and therefore a relationship of the following form can be written (1):

$$k_1 = k'_1 e^{\frac{\pm Z_i \alpha_i e V}{kT}} \qquad [2]$$

where V is the potential difference between electrode and solution and k'_1 the rate at zero potential or charge. The parameter α_i is usually considered to be a fraction which depends on the symmetry of the energy barrier. In a symmetrical barrier $\alpha_i = 1/2$. The sign of the exponential factor is either positive or negative depending on whether the reaction is anodic or cathodic, respectively. Here $e = 4.80 \times 10^{-10}$ esu and the number of electronic charges transported by a single ith process is Z_i. The rate of loss of chloride ions from the mercury surface is proportional to θ and to the rate k_2 of the desorption reaction, which for a freshly expanded surface might be expected to be negligible relative to the reformation of the electrical double-layer. It would not be negligible as the equilibrium conditions are again approached. Also, expansion decreases the surface coverage. Hence, the uncovered surface changes with time as follows:

$$\frac{d(1-\theta)}{dt} = \beta r - (1-\theta)\,[\text{Cl}^-]_a\, k'_1\, e^{\frac{-\alpha VF}{RT}} + \theta k'_2 e^{\frac{\alpha' VF}{RT}} \qquad [3]$$

where, as above r is the expansion rate and β is a proportionality constant. If θ is small, which is the case when the potential is approaching the electrocapillary maximum or the point of zero charge, and if the rate k_2 for chloride ions leaving the mercury-aqueous solution interface is small compared to the expansion rate, the term $\theta k'_2 e^{\alpha' VF/RT}$ may be neglected. At the maximum voltage the slope of the potential-time curve (see Fig. 2) is zero. The change in the uncovered interface with time will then also be zero because the amount of the interface covered with charge determines the potential at any given time. Hence $[d(1-\theta)/dt = 0]$ and Eq. [3] becomes

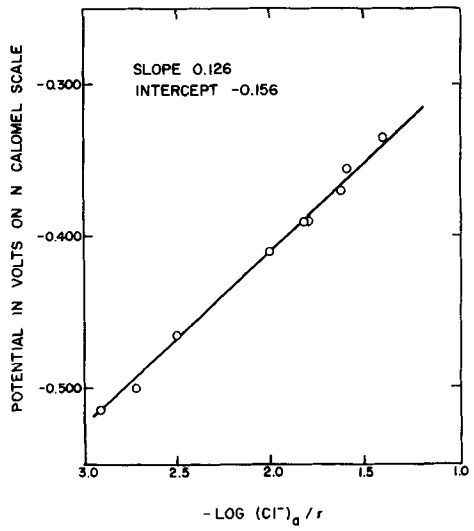

Fig. 6. Correlation of chloride ion concentration and the expansion rate r of the mercury with the steady-state potentials developed for an expanding mercury electrode.

$$\beta r - (1-\theta)\,[\text{Cl}^-]_a\, k'_1 e^{\frac{-\alpha VF}{RT}} = 0 \qquad [4]$$

Solving for V results in the expression

$$V = -\frac{RT}{\alpha \mathbf{F}} \ln \frac{\beta r}{(1-\theta)\,[\text{Cl}^-]_a\, k'_1} \qquad [5]$$

Now it is assumed that the fraction θ is proportional to the charge q on the interface divided by the total charge that occupies the interface ($\theta \sim q/Q$) when it is fully covered. Thus, q is small because, as the mercury surface is expanded, the potential approaches the point of zero charge and therefore $\theta << 1$. Equation [5] then becomes

$$V = 2.303 \frac{RT}{\alpha \mathbf{F}} \log \frac{[\text{Cl}^-]_a}{r} + 2.303 \frac{RT}{\alpha \mathbf{F}} \log \frac{k'_1}{\beta} \qquad [6]$$

In Fig. 6 $\log [(Cl^-)_a/r]$ is plotted against the potential. Note the good correlation of the data. Moreover, from the observed slope (0.126) one obtains for α the value 0.43 which is in good agreement with theoretical value 0.5 based on symmetry of the reaction barrier.

Summary

1. Based on results obtained with mercury, it may be concluded that internal strain or the production of active sites by the generation of dislocations in a metal is not requisite for the development of transient potentials for an expanding metal-aqueous solution interface.

2. Considering the variables which control the transient potentials of an expanding mercury-aqueous solution interface under the conditions approaching perfect polarization the transient potential was found to obey the equation

$$V = 2.303 \frac{RT}{\alpha \mathbf{F}} \log \frac{[\text{Cl}^-]}{r} + \text{K}$$

in the case of aqueous potassium chloride. The correlation held until the transient potentials reached

the electrocapillary maximum or point of zero surface charge. Then the potential followed that of the electrocapillarity maximum.

Technical Notes

Birefringence Studies in Electroluminescent Zinc Sulfide

F. J. Baum and F. J. Darnell

Central Research Department, E. I. du Pont de Nemours and Company, Wilmington, Delaware

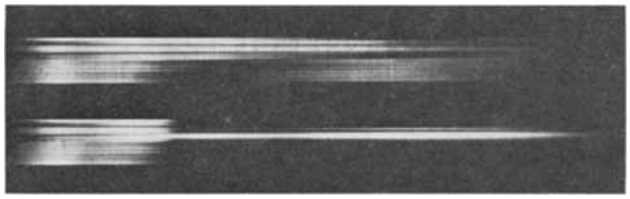
Several investigators have found correlation between electroluminescent activity in ZnS crystals and the extent of stacking disorder as evidenced by x-rays (1, 2) and optical birefringence (3-5). Microbeam x-ray studies (50μ diameter beam) on ZnS crystals in these laboratories have also shown electroluminescent activity to occur predominantly in regions of mixed hexagonal and cubic structure, with little activity in perfect cubic or perfect hexagonal regions. The majority of our crystals, which were grown from the vapor (6), appear in the form of prisms containing both wurtzite and sphalerite with the hexagonal [00·1] and cubic [111] directions along the prism axis. Stacking faults of planes perpendicular to this axis give rise to layered regions of differing structure. Electroluminescence, viewed normal to the axis, occurs in streaks parallel to these layers (6), in agreement with observations of others (3-5, 7, 8). The present experiments make use of birefringence to study the layered structure on a scale smaller than is possible with x-rays, and to correlate structure with electroluminescent activity.

The optical method involves the fact that ZnS in the sphalerite structure exhibits a single index of refraction, while in the wurtzite or other noncubic structures it has different indices for light polarized normal or parallel to the hexagonal axis. The amount of hexagonal structure in an element of a zinc sulfide crystal can then be determined by the degree of birefringence provided stacking sequences are regular, *i.e.*, definite polytypes exist, for distances along the prism axis comparable to the light wavelengths. There exists also the possibility that one-atom layer displacements of the type postulated by Strock (9) will lead to changes in birefringence.

A crystal to be examined was placed on a microscope stage between crossed polaroids with the axis of the crystal perpendicular to the microscope optic axis and at 45° to the polarizing direction of each polaroid. The magnified image of the crystal, made visible in high order colors, was projected onto the slit of a medium Hilger spectrograph equipped with glass optics. Interference between the ordinary and extraordinary rays created channel spectra which could then be photographed. Measurement of the wavelengths λ_i at which extinctions occurred, together with measurement of the crystal thickness, d, then allowed determination of the birefringence from the relation (10)

$$\Delta n \equiv n_o - n_E = \frac{1}{d} \frac{\Delta N}{\left(\frac{1}{\lambda_1} - \frac{1}{\lambda_2}\right)}$$

where ΔN is the difference in extinction orders which take place at wavelengths λ_1 and λ_2. Correlation of electroluminescence with the birefringence so observed was accomplished by exciting electro-



Photograph of birefringence channel spectra and electroluminescence in the visible region. Horizontal axis is wavelength, and vertical axis is 28μ distance along [00·1] direction of ZnS crystal. Upper image is birefringence only; lower image shows same birefringence filtered to pass only the red end of the spectrum, with electroluminescent image superposed. Birefringence exposure 3 sec; electroluminescence exposure 40 hr.

luminescence in the crystal as mounted and projecting this through the spectrograph onto the same photographic plate to make a double exposure. Since the intensity of the electroluminescence was low, 16-40 hr exposures with ASA film speed of about 2000 were necessary. A typical photograph of birefringence and electroluminescence is shown in Fig. 1. The superposed spectra, arising in one case from localized occurrences of electroluminescence and in the other from the varying magnitudes of birefringence, permitted a structurally sensitive characterization of those regions exhibiting electroluminescence.

All crystals were found to have a layered structure with layers lying perpendicular to the hexagonal c axis (prism axis). From the spectrographic plates, the birefringence of regions as small as 5μ in dimension along the crystal axis could be determined; regions as small as 1μ could be differentiated, but not accurately measured.

Many individual regions were characterized by discrete birefringence values ranging from zero to 0.036 at a mean wavelength of 5000Å, while other regions showed continuous variations. A few absolute values of birefringence were checked with an eight-order Babinet eyepiece-compensator, in order to check the largest value in this region of the spectrum. The zero value corresponds to cubic structure, the intermediate values presumably to polytypes (11-13) or faulted structures, and the maximum value to perfect hexagonal structure. Birefringences from 0.003 to 0.028 have been reported by Strock, Brophy, and Peters (5), with wavelength unspecified, but probably for Na D light. Careful measurements of the two indices of refraction as functions of wavelength on three ZnS single crystals have been made by Piper, Marple, and Johnson (14), who find a broad birefringence maximum in the visible region. Their largest value is $\Delta n = 0.024$. According to Smith (13), a detailed x-ray study of natural zinc sulfide mineral yielded no crystals possessing perfectly hexagonal structure. It is possible that the present narrow layers having the highest birefringence correspond to perfect hexagonal structure.

It was found that electroluminescent activity occurred only in crystal volumes that were characterized by varying structure. No structure in which electroluminescence occurred persisted for more than 2μ. The resolution of the technique unfortunately was not sufficient to determine whether activity occurred in regions of a fixed structure or in the transition plane between structures. There was no indication of a relation between occurrence of electroluminescence and any particular value of birefringence.

Junction Delineation in GaSb by Differential Chemical Etch Rate

S. J. Silverman

Research Laboratory, General Electric Company, Schenectady, New York

Etching to delineate p-n junctions in semiconductors is a useful tool in detecting impurity striations incorporated during the course of crystal growing and also in revealing single or multiple junctions produced by various device processing techniques. There is extensive literature on the subject concerning elemental semiconductors such as Ge or Si, a few examples of which are given in the bibliography (1, 2). Less information is available on III-V compounds. Whereas Cunnell (3), Schell (4), and more recently Haisty (5) refer to several such etches to detect junctions in GaAs, little has been recorded about GaSb other than Detwieler's (6) unspecified concentration ratio for the

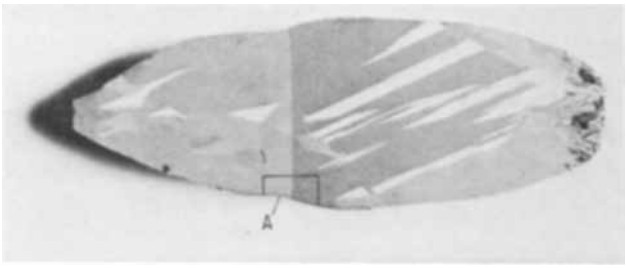

Fig. 1. GaSb ingot etched 12% HF:25% HNO_3:60% H_2O to delineate grain boundaries as well as the p-n junction; p-type, left; n-type, right. Magnification approximately 1½X.

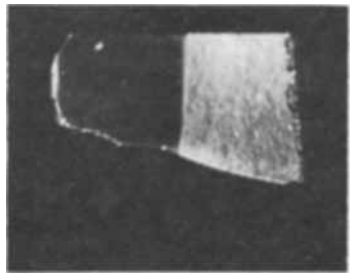

Fig. 2. Single crystal section cut from area (A) of ingot in Fig. 1 and etched in 15% HF:35% HNO_3:50% H_2O; p-type, left; n-type, right. Magnification 5X.

$HCl:HNO_3$ system. This paper deals with the HF: HNO_3:H_2O system and its successful application to the delineation of n-p junctions in GaSb.

Experimental

T. J. Soltys, of this Laboratory, in the course of growing GaSb by the Czochralski technique, produced a grown junction by doping the melt with Te. The resultant ingot, J-75, was cut longitudinally along the growth axis. Single crystal bars taken from the Te-doped section were investigated at room temperature by Hall, resistivity, and mobility measurements. The results of these measurements indicated a net carrier concentration of 2×10^{17}/cc, n-type and a Hall mobility of 3000 cm^2/v sec. The undoped p-type region was similarly studied and found to contain 2×10^{17} carriers/cc with a Hall mobility of 500 cm^2/v sec. The position of the junction was determined independently by obtaining resistivity and thermal emf profiles along the length of the ingot. The ingot was then prepared for etching to show that the position of the junction could be correlated with the previous measurements as well as the observations on the doping during crystal growth, as indicated by an abrupt change in crystal diameter seen in Fig. 1.

From a preliminary study it was soon realized that the etch composition was primarily instrumental in the success or failure of junction detection. Consequently a series of etches with different ratios of the components was evaluated to determine optimum compositions required. The same specimen was used by freshly preparing the surface prior to each exposure to a new solution. The surface preparation involved lapping with 600 mesh carborundum, thorough rinsing in running H_2O, and air drying. The specimen was then placed in a 25 cc polyethylene container. Care was taken not to contaminate the surface by improper handling techniques, which might otherwise lead to spurious patterns. The solution for each etch was freshly prepared immediately prior to use, and in each case was 10 cc in volume. The etching period was standardized to a 2-min exposure for each solution. At the end of this period the excess acid was decanted, leaving a smaller amount which still covered the specimen but which could be quickly flushed with running water from the tap. In this manner the formation of oxide films was minimized.

Some of the compositions were equally effective in portraying grain boundaries as well as a junction, as seen in Fig. 1. A single crystal section containing the junction was cut from the original ingot to eliminate the possibility of any competing differential etching action at the grain boundaries. An example of the junction delineation on such a single crystal region is shown in Fig. 2.

A summary of the compositions and their effects is given in Table I. If one were to average the compositions of solutions 1 and 2, then the etch having 15% HF:35%HNO_3:50%H_2O would be typical of a fast reaction solution, producing moderate gas evolution. Under these conditions a disk of GaAs having a diameter of 0.4-in. and thickness of 40 mils had an etch rate of 2 mil/min. This action resulted in a differential etching rate at the junction, leaving the p-type side with a smoother, more lustrous surface than the n-type side, as seen in Fig. 2. From microscopic observation at 100X, it was estimated that the p-type side was about 10μ lower than the n-type side. This action is analogous to that for a Si n-p junction where the p-type side etches faster than the n-type side in either an alkaline solution or a 3%K MnO_4:95% HNO_3 solution. The mechanism of this etching action appears to be similar to that discussed by Turner (7) who describes the etching phenomenon for Si or Ge in the HF-HNO_3-H_2O system as being electrochemical in nature. Semiconductor material goes into solution by forming water soluble complexes with the

Table I. Comparison of etch compositions and the effects on GaSb junctions

Solution	Composition in vol %			Effect
	HF	HNO_3	H_2O	
1	10	40	50	(a) moderate gas evolution (b) rapid junction delineation by differential etch rate
2	20	30	50	(c) p-type surface shiny
3	19	19	62	(a) little gas evolution (b) slow delineation by differentially reflected light
4	12	29	59	(a) little gas evolution
5	13	20	67	(b) rapid delineation by differentially reflected light
6	6	31	63	(a) no gas evolution (b) complete surface blackening
7	31	6	63	No apparent reaction

F^- anion on the anodic p-type side while the oxidizing agent, HNO_3, is reduced on the cathodic n-type side of the junction.

The etch rate could be significantly reduced with increased water dilution. Solutions 4, 5, and 6 were typical of the slower reaction rate which was accompanied by very little gas evolution. A difference in the reflected light intensities on either side of the junction was observed within the specified etching period. In this connection the apparent variation in reflected light intensity was reminiscent of the stain etch described by Fuller (8) and the Au chemiplating (9) on Si p-n junction discussed by the author, in which a photovoltaic effect was attributed to the differential staining or plating action. Fresh solutions similar to 4 through 6 were used to etch the specimen under the light of a 60-w tungsten source as well as in the dark. Under both conditions the junctions were reproducibly delineated so that this effect was not considered to be significant in this case. The present case is not to be confused with a stain which has been attributed to the presence of an oxide layer on the p-type side of the junction in Si (7). Furthermore, when a Si specimen so stained is viewed under a low-power microscope using oblique light, the apparent color contrast remains invariant with specimen rotation. This is not the case for GaSb etched in slowly reacting solutions such as 4 to 6. Upon rotating the specimen the contrast in the light intensity can be obliterated or reversed depending on the angle of incidence of the light as well as the angle in the plane of specimen rotation. This is exactly similar to the differential reflectivity from different facets on an abraded single crystal or from different grain orientations on polycrystalline specimens. However, in this case the crystal orientation is the same, but the impurity content is different.

The contrast in reflected light intensities from the specimen surface was enhanced as one increased the ratio of HNO_3 to HF, producing an easily delineated junction as seen in Fig. 1 until one approached conditions in solution 6 where a blackening of the entire surface, presumably due to oxidation by excessive HNO_3 and H_2O, completely obscured the junction. Reversing this ratio to a high concentration of HF, as in solution 7, leads to a condition of no apparent reaction.

It is of interest to note that in contrast to solution 5, if one substitutes glacial acetic acid for water as the diluent, rapid etching occurs, and the entire surface is left with a shiny luster which reveals neither junctions nor grain boundaries.

Conclusion

From the foregoing discussion, it can be seen that GaSb p-n junctions can be revealed readily by two different rates of differential chemical attack. The first is a rapid differential etch rate in which the p-type region etches faster than the n-type region. A representative composition is 15% HF: 35% HNO_3: 50% H_2O. For applications where the etch rate is very small, but differential reflectivity is desired, a typical composition 12% HF: 25% HNO_3: 63% H_2O will suffice.

It has been shown that by a judicious choice of the composition of the HF: HNO_3: H_2O system, n-p junctions and differently oriented grains in polycrystalline specimens can be revealed and delineated by a simple, straightforward etching technique.

Polarization Capacitance Determinations of Surface Roughness[1]

M. R. Turpin and M. K. Testerman

Graduate Institute of Technology, University of Arkansas, Little Rock, Arkansas

Experimental measurements of the polarization capacitance of the electrical double layer at a metallic surface in a nonaqueous electrolytic solution were undertaken at this laboratory as a part of an evaluation survey of various methods of measuring irregularities in metallic surfaces. Results from tests using potassium iodide as the electrolyte and formamide as the nonaqueous solvent (0.25M KI-$HCONH_2$) suggest that this system could be employed, with some modification in technique, to determine roughness factors for metallic surfaces.

The polarization capacitance was measured as an impedance, using a modification of Grahame's bridge circuit (1). The electrolytic medium, 0.25M-KI-$HCONH_2$, was prepared from reagent grade chemicals and subsequently flushed with helium for 24

[1] A detailed report of these experiments is available from the University of Arkansas Technology Campus, Little Rock, in report number WADC-TR-60-97.

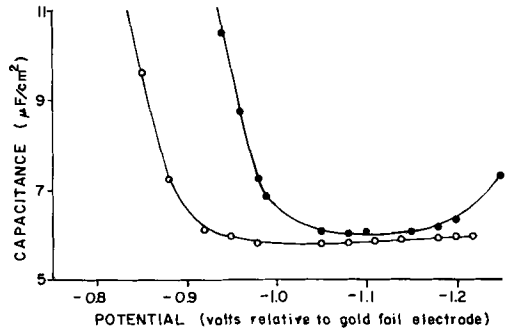

Fig. 1. Mercury and amalgamated copper polarization capacitance: solid circle, mercury; open circle, amalgamated copper.

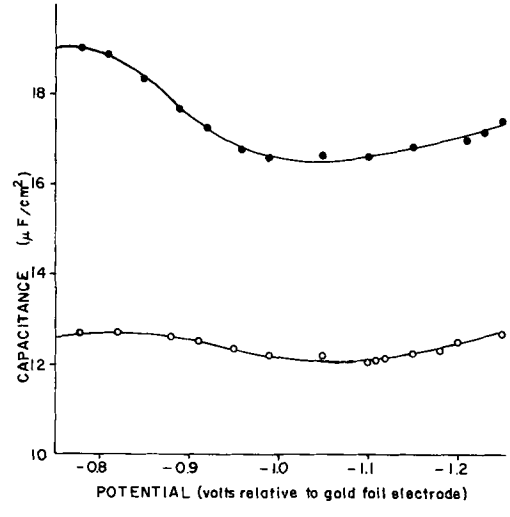

Fig. 3. Stainless steel polarization capacitance: solid circle, "rough" electrode; open circle, "smooth" electrode.

hr preceding polarization experiments. A helium atmosphere was maintained in the 300 ml Pyrex test cell during experiments. A large-area gold-foil cylinder was employed as a nonpolarizable electrode. All voltages were read relative to this gold-foil electrode.

The metals used in these tests were mercury, amalgamated copper, copper, stainless steel, aluminum, and titanium. The design of the mercury pool electrode holder was similar to that described by McMullen and Hackerman (2), consisting of a

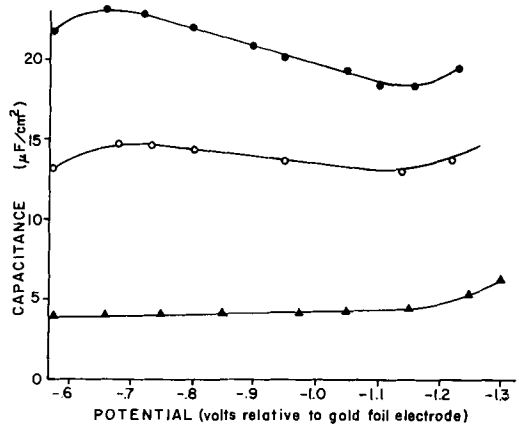

Fig. 4. Aluminum polarization capacitance: solid circle, "rough" pretreated electrode; open circle, "smooth" pretreated electrode; triangle, untreated electrode. (Note: Differences in polarization capacitance between "rough" and "smooth" untreated electrodes were too small to show on graph.)

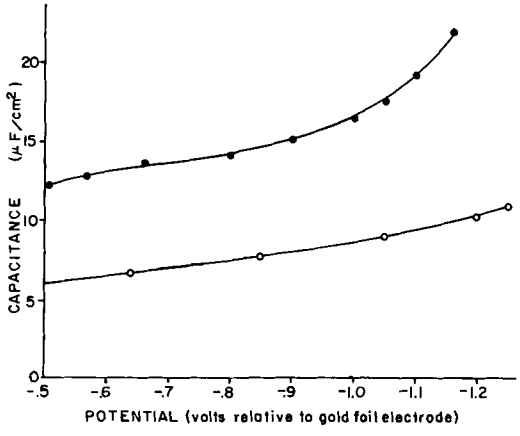

Fig. 5. Titanium polarization capacitance: solid circle, "rough" pretreated electrode; open circle, "rough" untreated electrode.

Teflon cup attached to a length of Pyrex tubing. The amalgamated copper electrode was prepared by first electroplating mercury on copper and then dipping into metallic mercury. The solid metal electrodes consisted of small cylinders, each sealed to a Pyrex tube whose outer diameter equalled that of the metal cylinder. For each solid metal, two electrodes were prepared, one of which was abraded with 320-grit sandpaper for a "rough" surface and the other with 800-grit sandpaper for a relatively "smooth" surface. The surfaces were rinsed with doubly distilled water to remove any foreign particles present after the abrasion process. The apparent surface area of each electrode was 1 cm². Figures 1-5 show typical polarization capacitance curves using these electrodes.

Surfaces of aluminum and certain other metals (*e.g.*, tantalum, titanium) are normally covered by a naturally occurring oxide film. This film is considered to be the cause of the abnormally low polarization capacitance usually exhibited by these metals. Various film removal methods have been attempted with some success, but they have proved to be largely unreproducible. A 10% trisodium phosphate bath immediately before polarization in the formamide solution will deoxidize an aluminum surface sufficiently to give reproducible polarization

capacitance readings of the same order of magnitude as those of the other metals tested (Fig. 4). In this treatment the aluminum is: (*a*) immersed in a hot (65°C) bath of Na_3PO_4 until effervescence of hydrogen infolds the surface completely; (*b*) transferred to an acetone bath until gas evolution is complete; (*c*) rinsed in doubly distilled water to displace any residual Na_3PO_4; (*d*) rinsed again in a separate solution of the electrolyte before being placed in the polarization cell. Reoxidation-pretreatment-polarization cycles were repeated several times with the aluminum electrodes. Capacitance readings were consistently within ± 0.05 $\mu F/cm^2$ of the initial values obtained using this method.

A titanium electrode pretreated in this same manner responded with a rise in capacitance (Fig. 5).

The results of these experiments indicate that this system offers a reliable and comparatively simple method of obtaining relative roughness factors for metallic surfaces.

Brief Communication

The Effective Duration of a Linear Slow-Cool

Daniel Richard Killoran

Michigan State University, East Lansing, Michigan

In the diffusion of impurities into low-quality semiconductor material, annealing is often practiced to avoid the undesirable effects of thermal shock. When the annealing is done at a constant temperature, the effective duration is simple to calculate, but if the temperature is allowed to vary, trial and error methods have been relied upon. This paper examines the popular method of allowing the temperature to fall linearly with time. In particular we wish to find what length of time, at the initial temperature, will produce the same diffusion as an indefinitely prolonged slow-cool.

Given the diffusion equation

$$\frac{\partial C}{\partial t} = D\{\theta\}\frac{\partial^2 C}{\partial x^2} \qquad [1]$$

where C is the impurity concentration, θ is the temperature, t is the actual physical time, x is the distance from the surface, and D is the diffusion constant, we define a new variable (τ) by the relation

$$d\tau = D(\theta\{t\})\, dt \qquad [2]$$

We shall assume linear dependence of temperature on time.

$$\theta_o - \theta = Rt \qquad [3]$$

where (θ_o) is the initial temperature, and R is the rate at which temperature is falling with time.

For most diffusion processes

$$D = D_o \exp\{-k/\theta\} \qquad [4]$$

where k and D_o are constants.

Inserting [3] and [4] into [2] and integrating

$$\tau = \int_o^t D_o \exp\left\{-\frac{k}{\theta_o - Rs}\right\} ds \qquad [5]$$

where s is used as the integration variable.

Letting

$$x = \frac{k}{\theta_o - Rs} \qquad [6]$$

we have

$$\tau = \frac{k D_o}{R}\left[\int_{k/\theta_o}^{\infty} \frac{e^{-x}}{x^2}\, dx - \int_{k/(\theta_o - Rt)}^{\infty} \frac{e^{-x}}{x^2}\, dx\right] \qquad [7]$$

Now define

$$K(y) = \int_y^{\infty} \frac{e^{-x}}{x^2}\, dx \qquad [8]$$

Integrating [8] by parts, we have

$$K(y) = \frac{e^{-y}}{y^2} + Ei(-y) \qquad [9]$$

where $Ei\{-y\}$ is the well-known exponential integral function. (See the Handbook of Chemistry and Physics for tables).

For a long slow-cool, the second term in [7] is small, so we have approximately

$$\tau \approx \frac{k D_o}{R} K\left(\frac{k}{\theta_o}\right) \qquad [10]$$

However, the exponential integral is not commonly tabulated for the range of values of the argument in which we are interested, so we integrate [8] by parts and obtain

$$K(x) = \frac{e^{-x}}{x^2}\left\{1 - \frac{1\cdot 2}{x} + \frac{1\cdot 2\cdot 3}{x^2} - + \cdots\right\} \quad [11]$$

Using a more convenient form for the exponential,

$$K(x) = \frac{1 - 2/x + 6/x^2 - + \cdots}{x^2 \text{ antilog}_{10}(0, 43\ x)} \quad [12]$$

In the special case of seeking the effective time at the initial temperature, the exponential cancels when we insert [4] into [10] and we have simply

$$t_{\theta_o} = \frac{\theta_o^2}{k\,R}\left\{1 - 2\left(\frac{\theta_o}{k}\right) + 6\left(\frac{\theta_o}{k}\right)^2 - + \cdots\right\} \quad [13]$$

Example: Boron is diffused into silicon for 5 hr at 1200°C. Then the temperature is decreased at a rate of 2°/min to room temperature.

If the diffusion were to be done at a constant temperature of 1200° instead of slow-cooling it, how long a diffusion is needed?

Solution: We are given $R = 2°/\text{min}$, $\theta_o = 1200°\text{C} + 273 = 1473°\text{K}$. And for boron in silicon, $k = 40{,}800°\text{K}$.

Therefore

$$t_{\theta_o} \cong \frac{\theta_o^2}{k\,R} = \frac{(1473)^2}{2 \times 40{,}800}\ \text{min} = 27\ \text{min}$$

is the effective length of the slow cool, with an error of less than 10%.

Consequently, to obtain the same diffusion we must leave the silicon at 1200°C for 5 hr + 27 min = 5.45 hr.

The AgO-Ag_2O Electrode in Alkaline Solution

Thedford P. Dirkse

Department of Chemistry, Calvin College, Grand Rapids, Michigan

ABSTRACT

The standard potential of the $AgO/Ag_2O/OH^-$ electrode has been found by direct measurement against a hydrogen electrode to be 0.599 ± 0.001v at 25°C. The value appears to vary slightly with KOH concentration. Furthermore, dE/dT values appear to change with KOH concentration as well as with temperature. Voltages measured with pellets of AgO and Ag_2O show that the voltage is determined by the materials present at the grid.

It became evident while doing a literature search on silver(II)oxide that very little work has been done to determine the standard electrode potential of the silver(I)oxide-silver(II)oxide couple in alkaline solutions. Some careful work has been done with the Ag^{++}-Ag^+ couple in acid solutions (1), but the literature shows nothing corresponding to this in alkaline solutions. Nor is there much thermodynamic data from which the potential of this couple could be calculated.

Some of the earliest work in this area was that of Luther and Pokorny (2). They followed the oxidation of silver in 1*N* NaOH and measured the potential difference between that electrode and a $HgO/Hg/OH^-$ electrode in the same solution. Their results give the potential of this couple on the hydrogen electrode scale as 0.57v, and they suggested that this value was independent of OH^- concentration. They observed also that the difference between the potential of the $AgO/Ag_2O/OH^-$ and the $Ag/Ag_2O/OH^-$ couples was 0.23v. These results were confirmed by others (3).

Later Hickling and Taylor (4) measured the potential of the $AgO/Ag_2O/OH^-$ couple in 1*N* NaOH against a calomel electrode and obtained a value of 0.63v instead of the value reported by Luther and Pokorny. Hickling and Taylor prepared their electrode by making a slurry of the two oxides. Electrical contact was made by means of a platinum wire dipped into the mixture. This matter of the construction of the electrode may be significant as will be pointed out later.

Still other results on the potential of this couple were reported (5), but in only one case has an attempt been made to determine E° for this couple (6). Bonk and Garrett found this E° value to be 0.604v by measuring the voltage of the cell

$$Pt, Ag_2O(s), Ag(s) \,|1M\ NaOH|\, AgO(s), Ag_2O(s), Pt$$

They also measured dE/dT for this cell and from this calculated various thermodynamic values for AgO. Previous to this, the only thermodynamic data determined independently was that of Jirsa *et al.* (7), who measured the heat of reaction of AgO with hydrazine and the heat of solution of AgO both in perchloric acid and in nitric acid. From this they concluded that the heat of formation of Ag_2O_2 is close to 5400 cal/mole. This corresponds to 2700 cal/mole using the more generally accepted formula, AgO.

There are several difficulties to be overcome in making emf measurements with the AgO/Ag_2O couple. There is, *e.g.*, the matter of the preparation of the electrode. It was found in our work that when a slurry of AgO and Ag_2O was prepared and a platinum wire was used to make electrical contact, the measured emf was fairly steady, but it gave a value of about 0.4v on the hydrogen electrode scale. Other workers, however, have been more successful with this type of electrode (6). Using only a slurry of AgO, a somewhat lower value was obtained. A similar difficulty has been pointed out with respect to the Ag/Ag_2O couple (8). For this latter couple the difficulty was resolved by insuring intimate contact between the two solid phases in the electrode.

Another possible difficulty arises from the fact that not all methods suggested for the preparation of silver(II)oxide yield the same product (9). This work of Schwab and Hartmann raises some question about the oxide produced by anodizing a silver nitrate solution between platinum electrodes and then boiling the product with water. The AgO used by Hickling and Taylor (4) was prepared in this manner.

The purpose of this work was to determine the standard potential of the $AgO/Ag_2O/OH^-$ electrode by direct measurement against the hydrogen electrode.

Experimental

The cell used in this work can be represented as follows

$$Pt, H_2(g) \,|KOH(aq)|\, AgO(s), Ag_2O(s), Pt$$

The construction of the cell, the method of preparing and storing the electrolyte, the procedure used in making a run, the method for analyzing the electrolyte, and the train used to purify the hydrogen have all been described previously (10). A new hydrogen electrode was prepared for each run.

Several methods were used to prepare the AgO/Ag_2O electrodes. Some were prepared by pasting moist AgO on a Pt screen about 1 cm^2 and folded

* NaOH was used as the electrolyte in this cell.

to make a trough. The AgO used was that commercially available from Merck and Co. and also from the M. Ames Chemical Works. These electrodes were allowed to stand in water and in a dilute KOH solution for several weeks to age them and to produce a film of Ag_2O on the surface (11). The results obtained with two such electrodes are given in Table I, and the results obtained by using a third one are shown on Fig. 1.

Another electrode was prepared by pasting an aqueous slurry of Ag_2O on a 40 mesh nickel screen and then treating this anodically for 24 hr in a KOH solution. After making a series of measurements with this electrode, shown on Fig. 1, it was placed in a 14% KOH solution and kept in the dark for a week. Then this KOH solution was boiled, with the electrode still in it, for 15 min and set aside for another day, at which time another series of measurements was made with this electrode. These last results agreed within a millivolt with those determined earlier for this same electrode. This was done to get an estimate of the stability of the electrode.

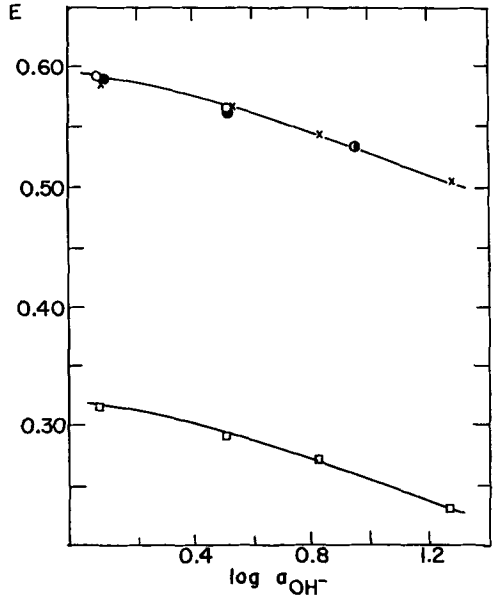

Fig. 1. Electrode potential of silver oxide electrodes vs. the hydrogen electrode: ○, electrolytically prepared AgO on nickel screen grid; ●, chemically prepared AgO on Pt screen grid; X, $AgO_{1.5}$ on Pt screen grid; □, Ag/Ag_2O electrode on Pt screen grid.

A third type of electrode was prepared by pasting an aqueous slurry of Ag_2O on a 40 mesh Pt screen. This was reduced thermally to Ag and then the electrode was treated anodically at a constant potential, about 350 mv above the reversible Ag/Ag_2O/OH^- potential, in a 21% KOH solution for 7 weeks. It was then soaked in distilled water, dried in a stream of N_2 at room temperature, and placed in a desiccator for at least a day. Assuming the weight gained by this electrode to be due solely to oxygen added during the oxidation process, this electrode had a composition that can be represented as $AgO_{1.5}$. Measurements with this electrode gave values that were in agreement with those of the other electrodes, Fig. 1. The x-ray diffraction pattern of this electrode had peaks identical to those obtained from AgO.

Figure 1 shows that the electrodes prepared by these various methods all have the same electrode potential value.

The cell was immersed in a constant-temperature bath kept at 25° ± 0.05°C. This was measured with a thermometer which had been calibrated by the National Bureau of Standards. A Rubicon portable potentiometer was used to make the voltage readings. It was checked from time to time against a National Bureau of Standards calibrated standard cell, and could be read to 0.1 mv. A run was considered acceptable only if the total variation of cell voltage readings was less than 0.5 mv over a 3-hr period. Furthermore, the results were rejected if there was a constant although small drift in voltage during this time. Little difficulty was experienced in getting a stable H_2 electrode. In one case cell voltages were constant within a millivolt for 48 hr. Some cells were also run at 45° ± 0.2° and 0° ± 1°C.

Results

The reaction for the Ag/Ag_2O/OH^- electrode is given in Eq. [1].

$$Ag_2O + H_2O + 2e = 2Ag + 2\ OH^- \qquad [1]$$

The variation of the potential of this couple with OH^- and solvent activity is the same as that of the AgO/Ag_2O/OH^- electrode in the same solution, Fig. 1. This indicates that the contribution of H_2O and OH^- is the same for both these electrode reactions,

and the reaction of the latter electrode is then taken to be

$$2AgO + H_2O + 2e = Ag_2O + 2\ OH^- \quad [2]$$

Table I lists the results of cell voltage measurements and the analysis of the solutions in the electrode compartments. The electrode reactions were assumed to be Eq. [2] and [3].

$$H_2 + 2\ OH^- = 2H_2O + 2e \quad [3]$$

The equilibrium electrode potentials for each of these reactions as written is, at 25°C,

$$E_{Ag} = E^\circ_{AgO/Ag_2O} - 0.05916 \log a_{OH^-} + 0.02958 \log a_{H_2O} \quad [4]$$

$$E_H = 0.8282 - 0.05916 \log a_{H_2O} + 0.05916 \log a_{OH^-} + 0.02958 \log a_{H_2} \quad [5]$$

The activity of the OH^- ions was calculated from the data of Akerlof and Bender (12). The activity of the solvent at 25°C was calculated from this same work while the values at 0° and 45°C were calculated using the treatment described by Lewis and Randall (13). The a_{H_2} was taken to be equal to

$$(P_{bar}\ mm - a_{H_2O} \cdot 23.76\ mm)/760\ mm \quad [6]$$

As a first approximation, the cell voltage at equilibrium is

$$E_{cell} = E_{Ag} + E_H \quad [7]$$

This assumes no junction potential. Table I shows that in some instances the solutions in the two electrode compartments did not have exactly the same composition. Consequently, the possibility of a junction potential must be considered. Since the solutions in the electrode compartments differed only in concentration, the junction potential may be considered as due to the transfer of ions across the junction. Its value then is given by Eq. [8].

$$E_j = (2t^- - 1) \cdot 0.05916 \log a_{OH^-_{Ag}}/a_{OH^-_H} \quad [8]$$

where $a_{OH^-_{Ag}}$ and $a_{OH^-_H}$ refer to the hydroxide ion activities in the silver and hydrogen electrode compartments, respectively. To estimate the maximum value of this junction potential t^-, the transference number of the OH^- ions, is assumed to be unity. Equation [8] then becomes

$$E_{j\,max} = 0.05916 \log a_{OH^-_{Ag}}/a_{OH^-_H} \quad [9]$$

Equation [9] has been used to calculate the $E_{j\,max}$ values given in Table I.

The E°_{AgO/Ag_2O} values in Table I are calculated from Eq. [4], [5], and [6] and are based on the assumption of zero junction potential. A summary of the maximum uncertainties introduced into these calculated E° values by the various experimental operations is given in Table II.

Table II. Maximum uncertainties introduced into E°_{calc} of Table I

	mv
Potentiometer reading	±0.2
Activity of solute	±0.1
Activity of solvent	±0.02
Activity of hydrogen	±0.05
Total	±0.37

The E° value of 0.599v is larger than that given by Latimer (14) based on the work of Luther and Pokorny (2), but smaller than that found by Bonk and Garrett (6). Using the value 0.599v, ΔF°_{298} for reaction [2] is −27.63 kcal. From this and other accepted free energy values (8, 15) ΔF°_{298} for the formation of AgO is 3200 cal/mole.

The value of 0.604 for E° of the AgO/Ag_2O/OH^- couple reported by Bonk and Garrett (6) was determined by measuring the difference in potential between this couple and the Ag/Ag_2O/OH^- couple in the same solution. This difference was 0.262v, and E° for the latter couple was taken to be 0.342v. The difference between the E° reported in this paper (0.599) and that reported earlier (10) for the Ag/Ag_2O/OH^- couple by direct measurement *vs.* a hydrogen electrode (0.338) is 0.261v, practically the same as the difference reported by Bonk and Garrett.

There seems to be some dependence of this E° value on the electrolyte concentration, Fig. 2. The lower values at the low concentrations are not due to permanent changes in or damage to the electrode. Each of these low values was obtained with a different electrode. One of these electrodes was later used in more concentrated KOH solutions and then gave the higher voltage value obtained with other electrodes in such solutions. It appears that these low voltage values are associated with the strength of the alkali solution, and this may indicate a change in electrode reaction or mechanism. If the two lowest points on Fig. 2 are excluded, then E° for the AgO/Ag_2O/OH^- electrode at 25°C is 0.5994 ± 0.0003v.

To obtain further thermodynamic data, the temperature coefficient of the electrode potential for reaction [2] was measured. Figure 3 shows the temperature variation of this potential. Three different temperatures were used. From these data a plot of E *vs.* T can be made for various OH^- activities, Fig. 4. The temperatures are too far apart to permit a determination of dE/dT values at a specific temperature. The results do suggest that dE/dT varies with KOH concentration as well as with temperature. This also may indicate that the electrode reaction or mechanism is not the same under all the conditions described here. The possibility

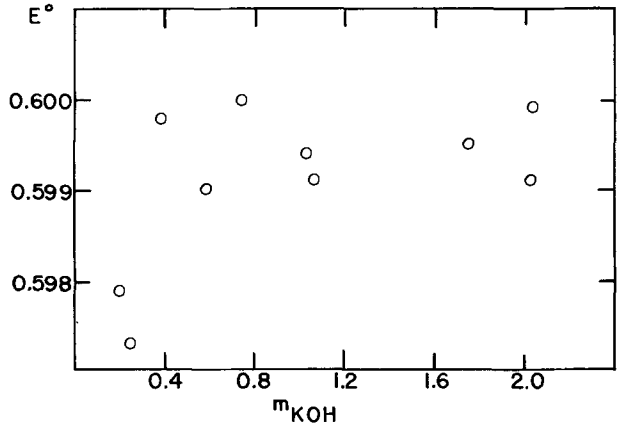

Fig. 2. Variation of E° for the AgO/Ag_2O/OH^- electrode with KOH concentration.

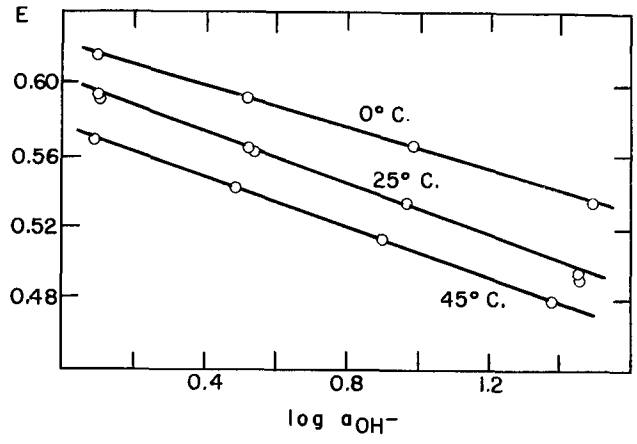

Fig. 3. Potential of the $AgO/Ag_2O/OH^-$ vs. the hydrogen electrode as a function of temperature and OH^- activity.

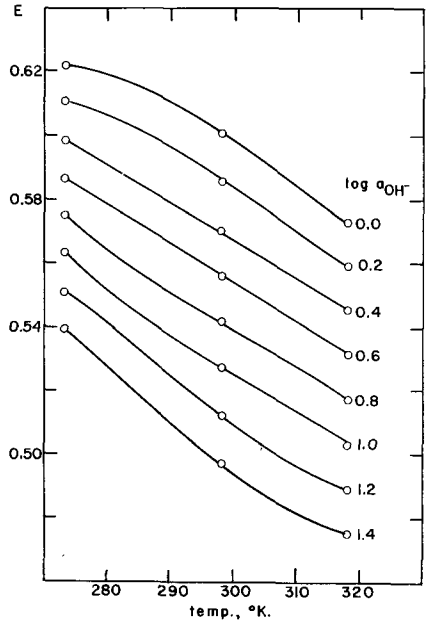

Fig. 4. Variation of the potential of the $AgO/Ag_2O/OH^-$ electrode vs. the hydrogen electrode at various OH^- ion activities.

of a mixed potential seems to be ruled out because only two solid species are present, AgO and Ag_2O.

Bedwell (16) found difficulty in getting reproducible voltage values above 30°C for a cell similar to that used by Bonk and Garrett (6). However, she did not attribute these difficulties to either electrode as against the other. Her voltage values for this cell from 0 to 25°C were linear and fairly reproducible. Assuming that the values on Fig. 4 are linear from 0 to 25°C, then they are in agreement with those of Bedwell as far as comparisons can be made.

An attempt was made to relate the values reported here to the silver-zinc-alkali cell. The open-circuit voltages (ocv) of this system are usually 1.85 and 1.60v, corresponding, it is believed, to the presence of the AgO/Ag_2O and the Ag/Ag_2O couple, respectively. These are about the values expected assuming E° values of 0.599 and 0.338, respectively, for these two couples in alkaline solutions.

To check this, pellets of Ag_2O and AgO were prepared and used in a cell described previously (17). The pellets were 2.5 cm in diameter and about 1

Table III. Open-circuit voltages of silver oxide pellets

Electrode pellet	Metal backing	Open-circuit voltage vs. zinc: At start	After charge	After discharge
Ag_2O	Ag	1.80	1.95 1.89	1.67 1.82
Ag_2O	Pt	1.89	2.18 1.96	1.66
AgO	Ag	2.13 1.79	1.95	1.67
AgO	Pt	2.05 1.93	1.95	1.66

mm thick. They were made from commercially available material and were pressed at 5000 lb. The opening between the pellet and the electrolyte was 6 mm diameter. The electrolyte was 30% KOH to which a small amount of ZnO had been added. The ocv's were measured by a General Radio d-c electrometer having an input resistance of 10^{10} ohms. The output from this electrometer was fed into a recorder. A sheet of zinc served as the negative electrode. Electrical contact to the pellets of silver oxide was made by means of a platinum or silver foil clamped against the pellet.

The ocv was measured over a period of several hours. Then the electrode was charged at 10 ma for about 30 min, and the ocv was again measured for an hour. Finally the electrode was discharged at 10 ma for an hour or more, and the ocv was again measured over a period of an hour or so. Results are shown in Table III. "Metal backing" refers to the metal foil used to make electrical contact with the pellet, and the multiple values refer to the fact that the ocv varied from the first to the second during the time the measurements were being made.

The ocv of the fresh pellets does not correspond to the potential for either reaction [1] or [2]. The ocv of the fresh Ag_2O pellet was steady but considerably higher than that of the Ag_2O/Ag electrode even when Ag foil was used as the backing. These ocv's are likely those of a nonequilibrium system and/or those of a solid-electrolyte interface even though they approximate the values associated with the presence of AgO.

The ocv of the fresh AgO pellets was unsteady, starting at a high voltage and falling rapidly at first. With the Ag foil as backing no steady ocv was obtained. Probably the AgO reacts with the electrolyte to form Ag_2O (11) so that Ag_2O and AgO are present at the Ag foil. This may give a mixed potential or it may prevent attainment of equilibrium. With Pt foil as backing the reaction of AgO with the electrolyte produces Ag_2O giving an AgO/Ag_2O electrode on a Pt surface. This decomposition takes place rapidly. The ocv then corresponds to that of the $AgO/Ag_2O/OH^-$ electrode and is 1.93v in the 30% KOH. This is substantially the same as the ocv obtained after the Ag_2O pellet had been charged on a Pt foil backing. In the case of the AgO pellets, the small charge did not oxidize all the Ag_2O that had been formed previously on stand so that the ocv after charge was still that of the $AgO/Ag_2O/OH^-$ electrode.

The ocv corresponding to the Ag/Ag_2O electrode is obviously 1.67v under these conditions, as seen from the last column in Table III. The reduction of

the Ag_2O pellet on a Ag foil backing gave an ocv of 1.67v, but this later increased to 1.82v. This no doubt is due to reactions at the Ag foil which could have resulted from the dissolving of some Ag_2O in the electrolyte, or some change in contact of the backing with the pellet.

With the partial discharge of the AgO pellets only a small amount of reduction could take place because of the small quantity of current withdrawn. At the end of this discharge the pellet was largely AgO. What discharge there was appeared to have taken place at the backing. Spots of reduced Ag were observed there and only there. It appears then that the potential of the electrode is determined solely by the materials present at the grid and not by the bulk composition of the pellet. Here the ocv corresponded to that of Ag_2O/Ag even though the bulk of the pellet was AgO.

These results show, among other things, that ocv's of silver-zinc cells in the neighborhood of 1.66v correspond to the presence of the $Ag/Ag_2O/OH^-$ system in the silver electrode, and those near 1.93v correspond to the presence of the $AgO/Ag_2O/OH^-$ system. However, the ocv's are determined by the materials present at the backing and give no indication of the composition of the electrode active material.

Intermediate potentials or voltages have been observed (18), and these probably are mixed potentials due to the presence of AgO, Ag_2O, and Ag. This is likely also true of ocv values in the neighborhood of 1.85v.

Electrode Potentials and Thermal Decomposition of Alpha- and Beta-PbO_2

R. T. Angstadt, C. J. Venuto, and P. Rüetschi

The Carl F. Norberg Research Center, The Electric Storage Battery Company, Yardley, Pennsylvania

ABSTRACT

Electrode potentials of α- and β-PbO_2 were measured in solutions containing fixed amounts of SO_4^{--} ions or ClO_4^- ions, as a function of pH. Oxygen overvoltage and ease of electrochemical reduction are correlated with anion adsorption and true surface area of the two oxide modifications. A method for synthesis of α-PbO_2 by chemical means is described. Differences in the solid-state properties between α- and β-PbO_2 are revealed by thermal degradation to the intermediate oxide PbO_x, with $1.42 < x < 1.58$. The unit cell of PbO_x was determined to be orthorhombic with $a_0 = 7.76$Å, $b_0 = 10.98$Å, and $c_0 = 15.31$Å.

The electrochemical and solid-state properties of lead dioxide have been studied extensively in recent years, with particular emphasis on the polymorphism of the substance (1-19). Both modifications, the orthorhombic α-PbO_2 and the tetragonal β-PbO_2, are good conductors of electricity (20-23), but until recently little quantitative data were available on their physical properties. Results with nuclear and electron resonance techniques (24-26) are consistent with the concept that PbO_2 behaves

as a metal. The Knight shift in the PbO_2 resonance is dependent on the density of conduction electrons near the top of the Fermi distribution and is therefore a qualitative measure of conductivity. From the relative chemical shifts of α- and β-PbO_2 (0.48 for α and 0.62 for β), it appears that α-PbO_2 might be a slightly better conductor. The conductivity of both modifications seems to be due to a nonstoichiometry, related to the oxygen deficiency. The α modification often tends to show a lower oxygen content.

If the oxygen content of β-PbO_2 is decreased by thermal decomposition below $PbO_{1.94}$, a new chemical compound starts to appear in the reaction product (2,27-29); a compound with the composition PbO_x with $x \cong 1.5$, is formed. The corresponding N M R absorption (25) indicates an increase in the Knight shift relative to the metal which corresponds to a decrease in conductivity.

The present paper presents new results of electrochemical and solid-state measurements with α- and β-PbO_2. In particular, thermal decomposition was studied with improved techniques and with special consideration of the polymorphism of PbO_2.

Although a large amount of work has been done on thermal degradation of PbO_2 by earlier investigators, a lot of previous results are inconclusive and in disagreement with each other. This is in part due to the fact that earlier investigators did not know of the polymorphism of PbO_2. The decomposition products reported by these investigators range from Pb_3O_4, Pb_2O_3, Pb_5O_8, Pb_7O_{11}, to intermediate oxides with variable oxygen content, called PbO_x. The crystal structures reported for these compounds range from face-centered cubic (28) to tetragonal (28) to orthorhombic (27) to monoclinic (27). In the present paper the decomposition products were analyzed chemically and by x-ray techniques.

Equilibrium electrode potential studies and kinetic measurements on oxygen evolution and electrochemical reduction to $PbSO_4$ were performed with improved experimental techniques and with particular emphasis on the influence of the lattice polymorphism on these electrochemical parameters.

Experimental

Electrode potentials of α- and β-PbO_2 were measured using a new type of electrode construction, illustrated in Fig. 1. A thin platinum wire was sealed into a U-shaped glass tube forming an open cup at one end (electrode to the left). The platinum wire extending into the cup was electroplated with the particular modification of PbO_2 to be studied (electrode in the middle). The plating procedures for α- and β-PbO_2 have been reported earlier (3). By plating tht platinum wires, the exposure of any platinum to the electrolyte was prevented, and by surrounding the plated wires with powdered PbO_2 a very high degree of stability of electrode potentials could be achieved. The cup was subsequently filled with powdered PbO_2 of the same modification as electroplated (electrode to the right).

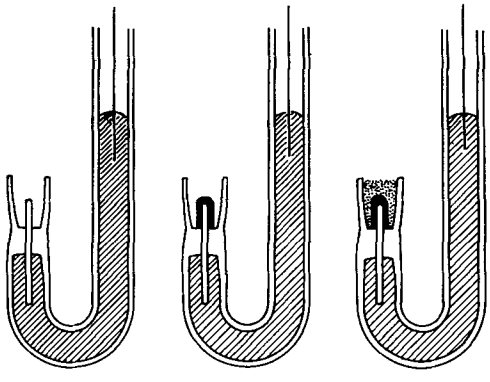

Fig. 1. Powder-type PbO_2 electrodes for potential measurements. At the left the Pt-wire seal into the glass cup is illustrated. In the middle, the Pt-wire extending into the cup is shown electroplated with PbO_2. At the right, the cup is filled with powdered PbO_2.

The α-PbO_2 powder was synthesized by ammonium persulfate oxidation of lead acetate in a strongly ammoniacal solution of ammonium acetate (1), according to the reaction

$$4NH_4OH + PbAc_2 + (NH_4)_2S_2O_8 \rightarrow \alpha PbO_2 +$$

$$2NH_4Ac + 2(NH_4)_2SO_4 + 2H_2O$$

A quantity of 250g $(NH_4)_2S_2O_8$ was added to 250 cc of water and 1 liter of saturated ammonium acetate solution; a saturated solution of 325g of $PbAc_2$ in water was then added slowly, simultaneously with 300 cc of 58% NH_4OH. The reaction proceeded at a very low rate. After 6 hr an additional amount of 50g $(NH_4)_2S_2O_8$ was added. The mixture was stirred for 24 hr and then heated to 70°C to drive off excess NH_3 and to dissolve any divalent lead compounds. The precipitate was filtered on a Buchner filter, washed with NH_4Ac and distilled water, and dried at room temperature.

The β-PbO_2 powder was reagent grade Merck PbO_2 whose crystal structure was confirmed by x-ray diffraction.

Electrode potentials were measured as a function of pH in solutions containing constant amounts of either SO_4^{--} or ClO_4^- ions. In solutions containing SO_4^{--} ions, the electrode potentials were measured with Hg/Hg_2SO_4 reference electrodes up to pH 4, and with Hg/HgO electrodes above pH 10. These solutions were saturated with $PbSO_4$. The potentials were checked also against hydrogen electrodes. For these checks lead sulfate saturation was omitted in the hydrogen electrode cells to prevent poisoning of the hydrogen electrodes. Several thousand measurements were made on several hundred different electrodes of the type shown in Fig. 1 over a period of two years.

In solutions containing ClO_4^-, a constant lead ion concentration of 1/1000M was maintained for all experiments. In this system, the electrode potentials were measured against a hydrogen electrode in a separate compartment, containing the same electrolyte, but without the lead ions being present. The reference electrode compartment was separated by a microporous plug.

Kinetic measurements were performed with electroplated rod-shaped electrodes, 20 mm long and 1.3 mm in diameter. The electrodes were prepared according to the procedure described earlier (3). Smooth, adherent deposits about 1 mm in thickness were obtained using a plating current of 1 ma/cm^2 for 168 hr, at 30°C.

These electrodes were transferred to 4.00M H_2SO_4 solution and anodized at 10 μa at 30°C over extended periods of time, prior to taking measurements.

For all electrochemical measurements the solutions were prepared with triple distilled water. Equilibrium electrode potentials were measured with a Minneapolis-Honeywell/Rubicon-Instrument Potentiometer, Model No. 2780S and galvanometer.

For the kinetic measurements constant current was obtained with electronic instrumentation described previously (1). Changes in electrode potential were followed using a Keithley model 610 electrometer, with an input impedance of better than 10^{14} ohm, driving a ¼ sec Minneapolis-Honeywell recorder. In this manner electrode potentials were measured with a precision of 1 mv and with a response of better than 1 mv in 20 msec (30).

All the electrochemical measurements were made in Pyrex glass vessels, thermostated to ± 0.02°C using an infrared lamp as a heater, controlled by a mercury contact-thermometer, and an electronic relay.

For the thermal decomposition experiments the starting materials were α-PbO_2 prepared by the persulfate oxidation method described in the experimental part, and β-PbO_2 in the form of reagent grade Merck PbO_2. Samples of 1g were placed in 8 mm Pyrex tubes, 70 cm long, and inserted in a tube furnace at constant temperature for 23 hr. The temperature was controlled by setting a regulated (0.25%) a-c voltage with a Variac. Two samples in separate tubes were heated simultaneously. One tube was maintained at 47 mm pressure of O_2, and the other at 2280 mm O_2 pressure. At the end of the 23-hr period the tubes were removed from the furnace, air cooled, and samples subjected to x-ray diffraction, and analyzed iodometrically for active oxygen content.

The 47 mm O_2 pressure regulation during thermal decomposition was achieved by a mercury-glass check valve simliar to the one described by Smith *et al.* (31). The sample tube was attached to the high-pressure side of a fritted glass disk, which was barely immersed on the opposite side into a mercury pool. The low-pressure side was attached to a vacuum pump. The regulation of the oxygen pressure to 2280 mm Hg was achieved by a special regulator valve on an oxygen tank and a controlled leak. The latter was necessary because of the oxygen generated by the thermal degradation reaction.

The decomposition products were analyzed with x-ray techniques using nickel-filtered copper radiation. The diffraction unit was a GE-XRD-5. Slow and fast scanning was used and the reflections were indexed by analytical methods.

Results

Electrode potentials measured with cup-type electrodes in solutions 1M and 1/10M in SO_4^{--} ions at 30°C are shown in Fig. 2 and 3. The variation in *p*H at constant SO_4^{--} ion concentration was achieved by mixing appropriate amounts of NaOH and H_2SO_4 (except the first point at negative *p*H,

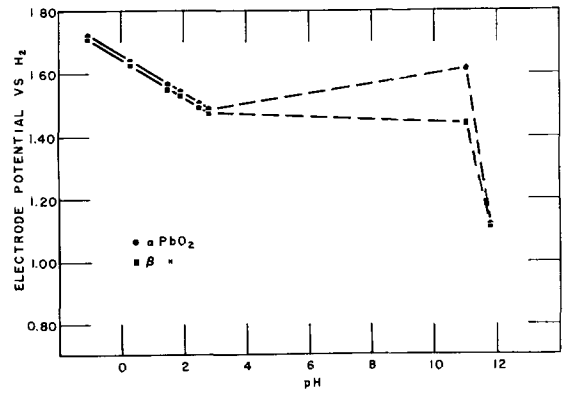

Fig. 2. Electrode potentials (vs. H_2 in the same solution) of α- and β-PbO_2 electrodes in solutions containing SO_4^{--} ions at 1 mole/liter as a function of *p*H at 30°C.

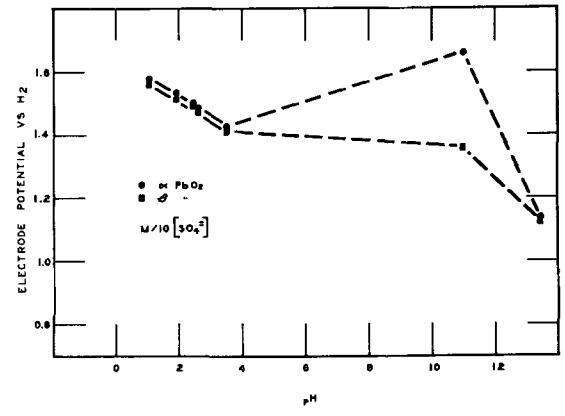

Fig. 3. Electrode potentials (vs. H_2 in the same solution) of α- and β-PbO_2 electrodes in solutions containing SO_4^{--} ions at 1/10 mole/liter as a function of *p*H at 30°C.

which was obtained in 4M H_2SO_4). Each point is an average of about 100 measurements on several different electrodes. At low *p*H values the electrode potential followed the theoretically expected behavior, changing about 60 *mv* per *p*H unit (*vs.* H_2 in the same solution). At *p*H values above 4, the potentials tended to become independent of *p*H. In this region the electrode did not readily establish stable values. Very long time periods, up to many days, were required to approach steady potentials, and the measurements were quite tedious.

The electrolyte system H_2SO_4-Na_2SO_4 is naturally a very poor buffer at *p*H values above about 4. Because of our interest in relating our studies to phenomena in lead-acid batteries, we preferred not to introduce an anion of a weaker acid and not to buffer the system between *p*H 4 and 10, but rather to measure the potentials as accurately as possible in the SO_4^{--} system.

It must be pointed out that the important *p*H region with regard to conclusions on lead-acid batteries is the one at low *p*H values. The striking result here is that both the α- and β-PbO_2 electrode show the thermodynamically expected response to the hydrogen ion concentration. This confirms that also the α-PbO_2 electrode is able to establish an electrochemical equilibrium in acid solution (3, 8).

One can calculate (32) that in solutions containing SO_4^{--} ions of activity 1, $PbSO_4$ should be the stable divalent lead phase up to *p*H 8.4, monobasic

lead sulfate between 8.4 and 9.6, tribasic sulfate between 9.6 and 14.7, and PbO above this value. In solutions containing SO_4^{--} ions of activity 10^{-4} only, the $PbSO_4$ phase is stable up to *p*H 6.4, then between *p*H 6.4 and 7.4 monobasic lead sulfate is stable and above 7.4 tribasic lead sulfate, and finally above *p*H 12.7 lead oxide. As long as a solid divalent phase of some kind is present, the electrode potentials in these regions are due to couples between PbO_2 and the corresponding basic sulfates or PbO.

The slopes of potential-*p*H plots should therefore decrease successively from 0.059 to zero toward the higher *p*H ranges, if the potentials are measured *vs.* hydrogen in the same solution. Delahay, Pourbaix, and Rysselberghe, in their *p*H-potential diagram, neglected the presence of solid basic lead sulfates and concluded that independence of *p*H begins at *p*H 9 if the electrode potential is measured against a hydrogen electrode in the same solution. Experimentally, it was found here that the potentials tended to become *p*H-independent at considerably lower *p*H values.

As pointed out, the hydrogen ion concentration was not stabilized above *p*H 4. Nevertheless, several thousand measurements on over 100 different electrodes were made above this *p*H value. Although reproducibility was not as good as in the low *p*H region, it must be pointed out that these measurements gave consistently higher electrode potential values than one would have expected theoretically. The average values of the observed potentials are indicated with dotted lines in Fig. 2 and 3.

The result that the α-PbO_2 electrode in acid solution has an electrode potential 7-10 mv higher than the β-PbO_2 electrode (2, 3, 12) is strongly corroborated in Fig. 2 and 3. On the other hand, these new results do now show the crossover of electrode potentials between *p*H 1 and 2, as reported earlier (3). The apparently reproducible crossover was observed with rod-shaped electrodes of very limited surface area. The present measurements with powder-type electrodes are considerably more accurate.

While Fig. 2 and 3 show potentials at constant SO_4^{--} ion concentration, Fig. 4 shows the *p*H dependence of the PbO_2 electrode at constant ClO_4^- ion (1/10M) and constant lead ion (1/1000M) concentration. The results show that also in this system, the potential of the α-PbO_2 electrode is higher than that of the β-PbO_2 electrode. Again, there is a region of ill-defined *p*H in which the potentials appear independent of *p*H. In the acid region the potential dependence confirms the expected behavior, the slope being just slightly higher than theoretical.

The temperature dependence of the α- and β-PbO_2 electrode potentials in 3.90M (4.62M) H_2SO_4 is illustrated in Fig. 5. It is interesting to note that the α-PbO_2 potential decreases more rapidly with temperature than the β-PbO_2 potential. A crossover is observed at about 50°C. It seems that above this point α-PbO_2 becomes the more stable modification.

From the equations defining the electrochemical equilibria

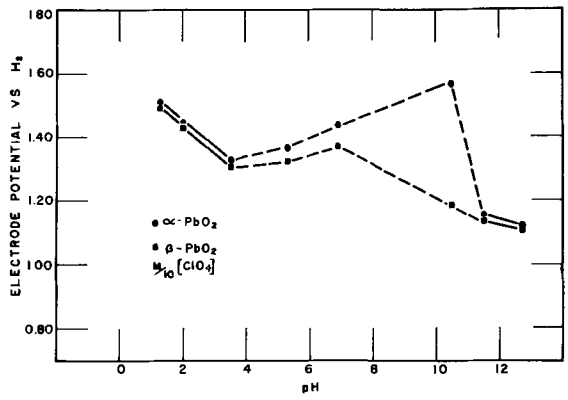

Fig. 4. Electrode potentials (vs. H_2 in the same solution) of α- and β-PbO_2 electrodes in solutions containing 1/10 mole/liter of ClO_4^- ions and 1/1000 mole/liter of divalent lead, as a function of *p*H at 30°C.

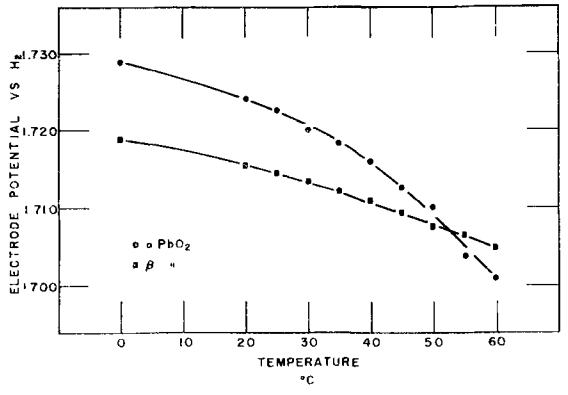

Fig. 5. Electrode potentials of α- and β-PbO_2 in H_2SO_4 (3.90 moles/liter) as a function of temperature.

$$\beta\text{-}PbO_2 + H_2\ (1\ atm) + H_2SO_4\ (4.62M) \rightleftarrows PbSO_4 + 2H_2O\ (\text{in. } 4.62M\ H_2SO_4)\quad E = 1.713 \text{ at } 25°C \quad [1]$$

$$\alpha\text{-}PbO_2 + H_2\ (1\ atm) + H_2SO_4\ (4.62M) \rightleftarrows PbSO_4 + 2\,H_2O\ (\text{in. } 4.62M\ H_2SO_4)\quad E = 1.722 \text{ at } 25°C \quad [2]$$

with the corresponding free enthalpy equations $\Delta G_\beta = -nFE_\beta$, and $\Delta G_\alpha = -nFE_\alpha$ one obtains for the free enthalpy difference between α- and β-PbO_2 at 25°C

$$\alpha\text{-}PbO_2 \rightleftarrows \beta\text{-}PbO_2 \qquad \Delta G = -0.4 \text{ kcal}$$

The data of Fig. 5 are the most precise ones obtained to date for α- and β-PbO_2 electrodes in sulfuric acid. Earlier results for electrode potentials of the two modifications were obtained with electroplated rod-type electrodes (3), which had a limited surface area. The present results for both modifications are 5 to 6 mv higher than the values reported earlier (3). From the data of Hamer (33) one obtains, for an acid concentration of 4.62*M* at 25°C, a potential of 1.707v, while from Fig. 5 the corresponding value for β-PbO_2 is 1.713v. The temperature dependence of the electrode potential for β-PbO_2 checks very accurately with the values of Hamer:

$$\alpha\text{-}PbO_2 : \left(\frac{\partial E\alpha}{\partial T}\right)_p =$$

-0.36 mv/°C at 25°C, 4.62*M* H_2SO_4

$$\beta\text{-}PbO_2 : \left(\frac{\partial E\beta}{\partial T}\right)_p =$$

-0.20 mv/°C at 25°C, 4.62M H_2SO_4

$$PbO_2 \text{ Hamer (33)} : \left(\frac{\partial E}{\partial T}\right)_p =$$

-0.20 mv/°C at 25°C, 4.62M H_2SO_4

These temperature dependences of the electrode potentials of α- and β-PbO_2 permit a calculation of the enthalpy difference between the two modifications at 25°C. With

$$\Delta H_\beta = -nFE_\beta + nFT\left(\frac{\partial E\beta}{\partial T}\right)_p$$

$$\Delta H_\alpha = -nFE_\alpha + nFT\left(\frac{\partial E\alpha}{\partial T}\right)_p$$

for Eq. [1] and [2] one obtains for the difference of the ΔH's between α- and β-PbO_2

$$\alpha\text{-}PbO_2 \rightleftarrows \beta\text{-}PbO_2 \qquad \Delta H = -2.6 \text{ kcal at } 25°C$$

Kinetic studies on α- and β-PbO_2 electrodes were performed with electroplated rod-type electrodes of reproducible surface area, prepared by electroplating under identical conditions of current density, temperature, electrolyte composition, and mass transport (3). Figures 6 and 7 show buildup of oxygen overvoltage at constant current in 4.00M H_2SO_4 on α- and β-PbO_2, respectively. Charging currents as indicated were switched on only after prolonged (several days) anodization at 10 μa/cm² in order to prevent the presence of $PbSO_4$ and changes in surface area. The charging curves are linear with time initially. From the slopes one can conclude that α-PbO_2 had a larger adsorption capacity per total electrode surface. From unpublished work in this laboratory, indications are that α-PbO_2 also has a larger "specific" capacity (per unit of "true" surface area). The "true" total surface area of the α-PbO_2 electrodes was smaller than that for the β-PbO_2 electrodes. In general, α-PbO_2 tends to develop larger crystals than β-PbO_2 (9).

The Tafel slopes for the oxygen evolution on the two modifications, obtained from the steady-state oxygen overvoltage values of Fig. 6 and 7, agree well with the data reported earlier (3). It appears that the difference in Tafel slopes can be best interpreted as follows. On electrodes of β-PbO_2, SO_4^{--} ions are adsorbed to a larger degree and contribute to the charge of the double layer. This increase of the double layer charge, due to SO_4^{--} ions, increases the electrode potential for a given current, or a given number of reacting oxygen species on the surface. The Tafel slope of the α-PbO_2 electrode, however, would possibly be characteristic for an oxygen evolving electrode with decreased adsorption of these SO_4^{--} species.

To study the difference in the kinetics of the discharge reaction between α- and β-PbO_2

$$2e + PbO_2 + 4H^+ + SO_4^{--} \rightarrow PbSO_4 + 2H_2O \quad [3]$$

about 30 electrodes of each type described in ref. (3) were discharged in 1M H_2SO_4 solution. The discharge curves at 1 ma/cm² are shown in Fig. 8 (β-PbO_2) and Fig. 9 (α-PbO_2). The discharge time for the β-PbO_2 electrodes average 2000 sec, while the average time for α-PbO_2 electrodes was about 800 sec. The remarkable difference must be

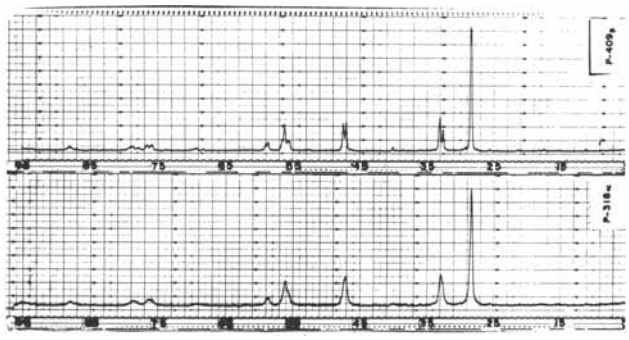

Fig. 12. Typical fast-scan x-ray patterns for α- and β-PbO_x materials. The chart marked P 318 α was obtained with a sample produced at 318°C from α-PbO_2 at 2280 mm O_2 pressure. The chart marked P 409 is for a sample produced at 409°C at the same pressure from β-PbO_2.

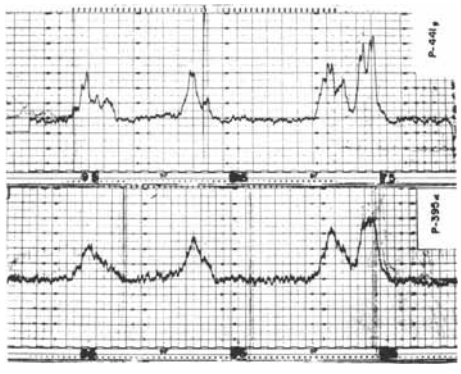

Fig. 13. Typical slow-scan x-ray patterns α- and β-PbO_x. The α-PbO_x (P 395 α) was obtained at 395°C from α-PbO_2 at 2280 mm O_2 pressure, the β-PbO_x (P441 β) is for a sample produced from β-PbO_2 at 441°C at the same pressure.

attributed largely to difference in the true surface area. The apparent areas were identical. Only a very thin surface layer of PbO_2 reacted on both electrodes, with a depth in the order of 10^{-4} cm in agreement with Ikari *et al.* (15).

The results of the behavior of α- and β-PbO_2 during thermal decomposition are illustrated in Fig. 10 to 13. In Fig. 10 and 11 the lead to oxygen ratios determined iodometrically are plotted *vs.* the decomposition temperature for two different partial oxygen pressures. The regions of appearance of different reaction products, as determined by x-ray diffraction (shown by the hatched areas), correlate well with the plateaus of the chemical analysis data.

At 2280 mm partial oxygen pressure (Fig. 10) three plateaus are observed. The three plateaus correspond to PbO_2, PbO_x (with $x = 1.52$ to 1.58) and Pb_3O_4. The PbO_x materials seem to have a somewhat variable oxygen content. The decomposition of α-PbO_2 to PbO_x occurs at a lower temperature than that of β-PbO_2. The PbO_x compounds produced from α- and β-PbO_2 are called here α- and β-PbO_x, respectively.

At 47 mm partial oxygen pressure (Fig. 11) the plateau corresponding to the PbO_x materials is still apparent. However, the Pb_3O_4 plateau has disappeared, although some Pb_3O_4 was detected by x-ray analysis of the reaction products formed between 415° and 485°C. Above 490°C, PbO (tetr.) is the sole reaction product. A comparison of Fig. 10 and Fig. 11 reveals the drastic influence of the partial oxygen pressure on the stability of Pb_3O_4 at temperatures above 400°C. A further transition, not shown in Fig. 11, was observed at approximately 610°C from tetragonal to orthorhombic PbO.

Since considerable discrepancies concerning the PbO_x materials exist in the literature, it was decided to study the crystallography of these compounds in greater detail with x-ray techniques. A comparison of fast scan x-ray charts of α- and β-PbO_x illustrates a close similarity of the crystal structure of these two lead oxides (Fig. 12). The well resolved multiple peaks in the β-PbO_x pattern have their counterparts in the α-PbO_x pattern, where they appear as more diffuse, single peaks. The diffuse composite single peaks of α-PbO_2 occur at the same average 2θ values as the equivalent double peaks of β-PbO_x.

Detailed slow scans, as shown in Fig. 13, of the two PbO_x materials substantiate and emphasize the similarity of the two patterns. It can be seen that the broad diffuse peaks in the α-PbO_x pattern have their well-defined equivalents in the β-PbO_x pattern at the same 2θ angles. The x-ray data obtained for α- and β-PbO_x with slow scanning are summarized in Tables I and II.

The reflections were indexed by analytical methods using the $\sin^2\theta$ relationship for the orthorhombic system.

Table III. Lattice constants for α- and β-PbO_x

α-PbO_x, Å	β-PbO_x, Å
$a_0 = 7.72$	$a_0 = 7.76$
$b_0 = 10.98$	$b_0 = 10.98$
$c_0 = 15.31$	$c_0 = 15.31$

$$\sin^2\theta_{hkl} = h^2\frac{\lambda^2}{4a^2} + k^2\frac{\lambda^2}{4b^2} + l^2\frac{\lambda^2}{4c^2}$$

where θ is the diffraction angle, hkl are the indexes of the reflecting plane, λ is the wavelength (copper radiation), and *abc* are the dimensions of the unit cell. All the observed reflections were indexed. Table III presents the data for the unit cell of α- and β-PbO_x; both unit cells were determined to be orthorhombic.

It is concluded from the similarity of the x-ray powder patterns and the unit cell dimensions that α- and β-PbO_x are identical materials. It appears that β-PbO_x is simply a more perfectly ordered structural equivalent of α-PbO_x. This accounts for the well-defined multiple peaks in the β pattern, and some smaller peaks, not observed in the α pattern.

These crystallographic results agree well with the data of Bystrom (27). The two sets of data are compared in Table IV. The agreement is particularly good for the β-PbO_x pattern. The unit cell turned out to be a multiple of Bystrom's cell. With the unit cell chosen here, it was possible to *index satisfactorily all the observed reflections of both the α- and β-PbO_x materials.* It should be pointed out that Bystrom prepared the PbO_x materials differently, "α-PbO_x" by thermal decomposition of β-PbO_2 at 400°C for 11 hr, or by hydrothermal treatment with NaOH at 290°C; β-PbO_x by thermal decomposition of β-PbO_2 at 400°C for 37 hr. Bystrom suggests for α-PbO_x a monoclinic unit cell with $\beta = 88.68°$, $a_0 = 7.72$Å, $b_0 = 10.81$Å, $c_0 = 11.48$Å. However, he expresses some concern about the purity of his α-PbO_x sample and admits that his data may not be accurate due to the very diffuse nature of the reflections at the high angles. Also, his value of $\beta = 88.68°$ is so close to 90° (and the orthorhombic system) that no conclusive distinction can be made on the basis of powder data. The same conclusion was recently reached by Reuter (29).

Table IV. Comparison between Bystrom's data (27) and results of the present paper (ESB)

α-PbO_x Bystrom	β-PbO_x Bystrom, Å	β-PbO_x Multiple Bystrom, Å	β-PbO_x ESB, Å
7.72Å	3.89	7.78	7.76
10.81Å	5.49	10.98	10.98
11.48Å	3.82	15.28	15.31
β-88.68°			

Manuscript received May 1, 1961; revised manuscript received Oct. 24, 1961. This paper was prepared for delivery before the Houston Meeting, Oct. 9-13, 1960.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

Oxide Films on Aluminum

I. Ionic Conduction and Structure

Michael J. Dignam[1]

Aluminium Laboratories Ltd., Kingston, Ontario, Canada

ABSTRACT

Films formed on superpurity aluminum and certain of its binary alloys were studied employing anodic polarization and electron transmission microscopy. Specimens were prepared by electropolishing followed by either oxidation in dry oxygen, anodic oxidation, or anodic oxidation followed by high-temperature annealing. The nucleation and growth of gamma alumina crystallites during oxidation at 450°C and the inhibiting effect of copper and particularly silicon on this process was explained by assuming that an 0.001% magnesium impurity was responsible for the nucleation. The change in ionic conduction of anodic oxide films on annealing was interpreted as arising primarily from a decrease in the number of aluminum ions which can become current carriers, rather than a change in activation energy or activation distance. Annealed anodic films and "amorphous" films formed in dry oxygen could not be distinguished. The observations in general, are consistent with Wilsdorf's model for the "amorphous" oxide films, randomly oriented "molecular" groups.

It has been known for some time that films formed on aluminum in dry oxygen above about 500°C exhibit the structure of gamma alumina, whereas for films formed below about 500°C x-ray diffraction analysis yields only diffuse halos characteristic of either amorphous material or material composed of extremely small crystals (1-9). From an examination of the literature (10-12) it can be concluded that anodic oxide films formed at room temperature and low current densities in a nonsolvent electrolyte also give rise to diffuse halo x-ray diffraction patterns.[2] The original reason for undertaking this investigation was to compare the ionic conduction of films formed in dry oxygen with that of films formed by anodic oxidation. This information was desired in order to adapt an electrometric method developed by Hunter and Fowle (13) for determining anodic oxide film thicknesses, to the measurement of thicknesses of oxide films formed in dry oxygen. The completed investigation, however, was more general in scope. It provides information concerning the nature of the so called "amorphous" films, the difference in properties between anodic oxide films and those formed in oxygen at elevated temperatures, and the nucleation process associated with the appearance of gamma alumina crystallites in the oxide film.

[1] Present address: Department of Chemistry, University of Toronto, Toronto, Ontario, Canada.

[2] Stirland and Bicknell (11) imply that the applied voltage is the fundamental parameter which determines whether the film is "amorphous" or crystalline. It is more likely, however, that the anodic current density (or field strength) is the fundamental parameter (10), the voltage, for fixed cell and circuit geometry, merely limiting the maximum current obtained.

The bulk of the data was obtained from anodic polarization measurements made in an aqueous boric acid solution on aluminum and aluminum alloy specimens. These specimens were treated previously by anodizing, by anodizing followed by annealing in helium at temperatures of 250° and 450°C, and by exposure to dry oxygen at temperatures of 250°, 350°, and 450°C. In addition electron transmission micrographs were taken of films stripped from certain aluminum specimens in order to elucidate oxide crystallization effects.

Apparatus

The vacuum furnace assembly was designed to permit the simultaneous thermal treatment of a number of specimens. Samples could be moved by a magnetic counterweight arrangement from the furnace zone proper into a water-cooled head piece while the apparatus was under vacuum (or controlled atmosphere).

The cylindrical resistance furnace had three windings controlled by two independent thermocouple activated pyrometric controllers. The temperature was maintained uniform and constant to ±0.5°C over at least 14 in. of the furnace. (Specimens never exceeded 6 in. in length.) Specimens required about 10 min to reach thermal equilibrium when lowered into the furnace in 5 mm Hg pressure of helium and, on removal, cooled from 350° to 300°C in 30 sec and from 300° to 250°C in 60 sec.

The vacuum system was of conventional design. A liquid air trap was placed between the specimens and the rest of the system to prevent mercury

contamination. Helium was purified, as required, by passage through a bright metallic sodium column. Oxygen was purified by passing it through Ascarite, phosphorus pentoxide, then distilling it from a liquid air trap retaining the middle fraction in a storage volume.

Experimental Procedure

Materials.—Experiments were carried out on 0.020 gauge sheet rolled from ingot of superpurity and superpurity base binary alloys containing 0.19% Ga; 0.01 or 0.06% Fe; 0.24 or 1.78% Si; 0.53 or 2.20% Mn; 0.08, 0.19, 1.51 or 6.0% Cu. The major impurities in the superpurity metal were 0.003% Fe, 0.001% Cu, 0.001% Mg, and 0.001% Si.

Sample preparation.—Samples 0.25 × 8 in. were cut from the 0.020 gauge sheets and formed into symmetrical "hair pin" shapes. After vacuum annealing for 1 hr at 543°C (this temperature was chosen as the highest safe temperature for annealing Al + 6% Cu), the samples were electropolished for 1 min at about 15°C and 17v (~ 0.5 amp/cm^2) in a bath containing 1 part 71% perchloric acid to 5 parts anhydrous methanol by volume. Immediately after polishing, a sample was rinsed 15 sec in absolute methanol, 45 sec in a jet of distilled water, then dried in a clean, dry, air blast and stored in a desiccator over activated alumina.

Oxide formation.—To form high-temperature oxide films, the electropolished samples were placed on the furnace sample holder and the system evacuated and kept at $< 10^{-6}$ mm Hg pressure for about 20 hr with the furnace at temperature and the samples in the cold furnace head. The samples were then lowered into the hot zone in 5 mm Hg pressure of helium. After 0.5 hr, 0.2 atm of purified oxygen was introduced. When the desired oxidation period had elapsed, the samples were raised into the cold furnace head, allowed to cool, removed, and stored in a dry desiccator until required.

Anodic oxide annealing.—Certain electropolished superpurity samples were anodized to various voltages at a constant current density of about 70 μa/cm^2. This was achieved by increasing the voltage at a steady rate of 1.75 v/min. The anodizing bath consisted of an aqueous ammonium bicarbonate solution (40 g/l, pH ≃ 7.5) held at 30°C. Sets of anodized samples were evacuated 20 hr in the cold furnace head as above then annealed in purified helium for the desired period, cooled, removed, and stored in a dry desiccator until required. Ammonium bicarbonate was used so that any of the salt which might remain on the samples would largely be removed during the subsequent vacuum treatment.

Electron micrographs.—Electron transmission micrographs were made of certain of the oxide films formed during high-temperature oxidation. The films were isolated by dissolving the metal in a 2% bromine-methanol solution.

Polarization measurements.—Polarization measurements were made employing one half a "hair pin" sample as anode suspended within a cylindrical wire gauze platinum cathode (surface area ~ 40 cm^2). The electrolyte, which was maintained at 30.0°C, consisted of an aqueous solution, 0.67M in boric acid and neutralized to pH 6 with ammonia. The cell was supplied with a d-c potential increasing steadily at the rate of 1.75 v/min, the selection of this rate being arbitrary to a large extent. The cell current was recorded with a strip chart recorder.

Providing that the cathodic overpotential and iR drop in the electrolyte and external circuit can be neglected, it is apparent that the anodic overpotential, V, is given by $V = V' + E$ where E is the reversible emf for the cell reaction, $2Al + 3H_2O = Al_2O_3 + 3H_2$ and V' is the applied potential (all terms taken as positive). In the present case, for anodic current densities up to 11 μa/cm^2 or more, both these terms were found to be less than 10 mv and hence negligible. The voltage values reported, therefore, are $V = V' + E$, where E was calculated to be 1.42v from the thermodynamic data compiled by Thompson (14). Provided that space charges at the metal-oxide and oxide-electrolyte interface are small, for current densities less than about 11 μa/cm^2, V will represent within about 10 mv the voltage drop across the oxide film.

Experimental Results

Polarization curves.—Figures 1 to 6 are a selection of tracings from the original polarization curves. The curves were quite reproducible in shape, although the peak heights and steady-state currents were reproducible only to about 10% because of lack of careful control of the sample area exposed during measurement.

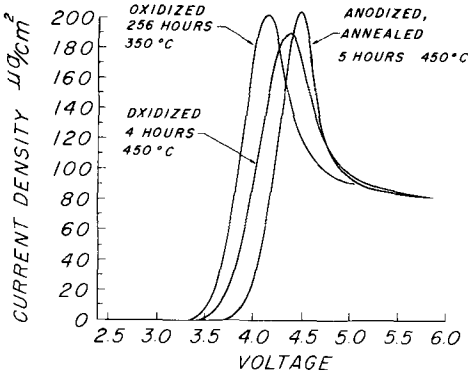

Fig. 3. Comparison of polarization curves for superpurity treated by anodic oxidation and annealing, with those for superpurity treated by oxidation in oxygen.

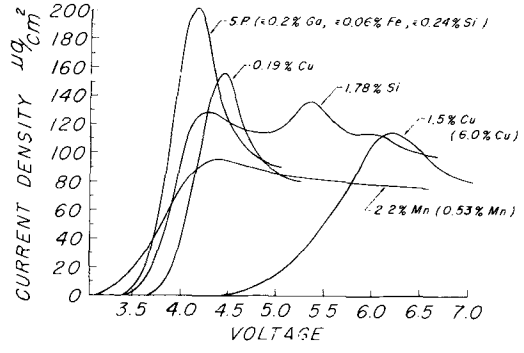

Fig. 4. Influence of alloying additions on the polarization curve for specimens oxidized 256 hr at 350°C. (Alloys with the compositions shown in brackets have polarization curves the same as the one illustrated.)

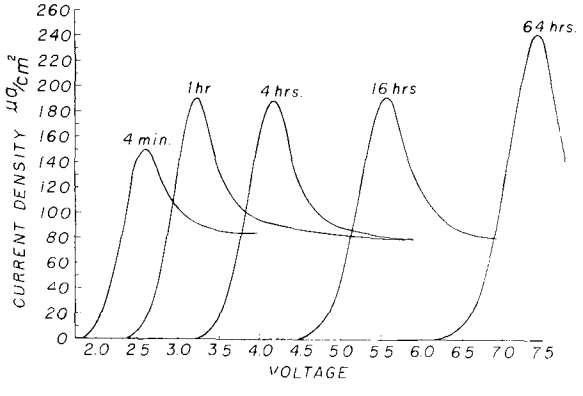

Fig. 5. Influence of oxidation time at 450°C on the polarization curve for superpurity + 0.24% silicon.

Electron transmission micrographs.—Figure 7 represents a selection of the micrographs obtained for electropolished samples oxidized in 0.2 atm of oxygen.

Annealing results.—The results obtained from polarization measurements on the anodized samples and the annealed anodized samples are presented in Fig. 8. The "barrier voltage" values are anodic overpotentials obtained in the following way. For a sample anodized to about 1 v, the potential was read at a point on the polarization curve corresponding to a current density of about 1 $\mu a/cm^2$, those anodized to 6v, at 6 $\mu a/cm^2$, and so on. This procedure was adopted in anticipation of the interpretation of the results. The slopes of the resulting straight lines in barrier volts per anodizing volt

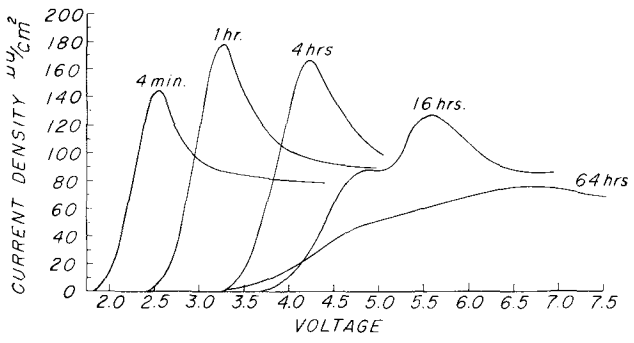

Fig. 6. Influence of oxidation time at 450°C on the polarization curve for superpurity.

are 0.83 for freshly anodized samples, 1.08 and 1.11 for samples annealed 1.5 and 5 hr at 250°C, and 1.18 and 1.20 for samples annealed 0.5 and 5 hr at 450°C.

Interpretation of Results

Oxide nucleation phenomena.—From electron transmission micrographs, conduction measurements, and weight gain data, it is apparent that the oxide film on superpurity aluminum undergoes a discontinuous change in properties during oxida-

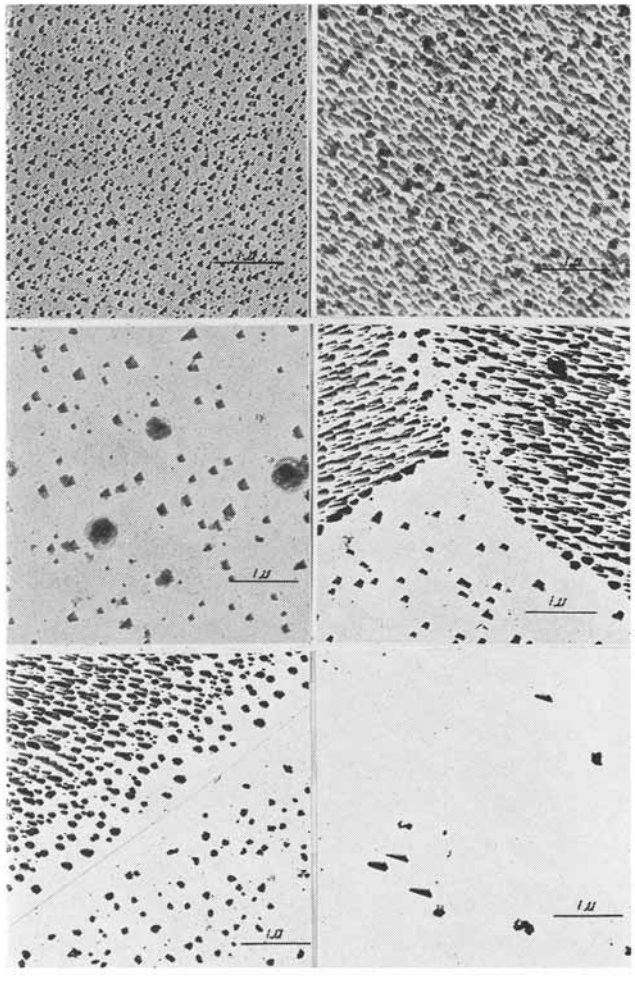

Fig. 7. Electron transmission micrographs of oxide films formed on aluminum at 450°C. (a) (top left) superpurity oxidized 16 hr, (b) (top right) and (c) (center left) superpurity oxidized 64 hr, (d) (center right) superpurity + 0.06% Fe, oxidized 64 hr, (e) (bottom left) superpurity + 0.53% Mn, oxidized 64 hr, and (f) (bottom right) superpurity + 0.24% Si, oxidized 64 hr.

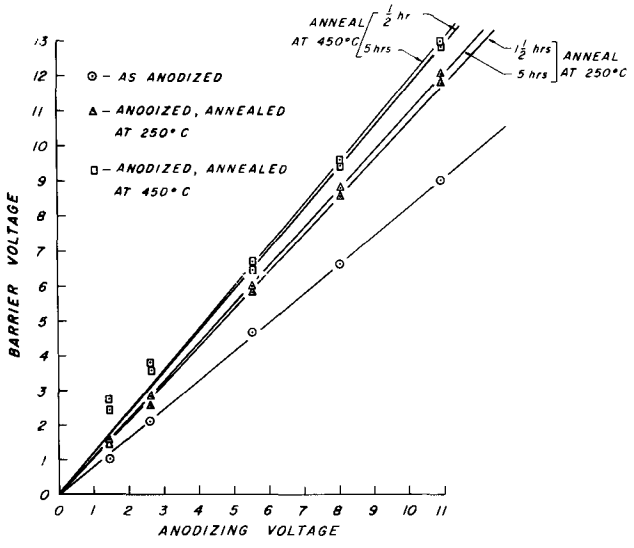

Fig. 8. Influence of annealing on the "barrier voltage" values for anodic films.

tion in pure oxygen at 450°C. Between 4 and 16 hr at 450°C, the oxidation rate is found to increase somewhat, falling off once again beyond 16 hr (15). Polarization curves for superpurity samples oxidized at 450°C for 16 or 64 hr show distinct anomalies not present for samples oxidized for 4 hr or less (Fig. 6) or oxidized at lower temperatures (Fig. 2). It is known (1-9) that sufficiently prolonged oxidation of aluminum at a temperature of about 450°C will lead to the formation of gamma alumina; x-ray diffraction measurements on films formed at appreciably lower temperatures or for sufficiently short oxidation periods yield only diffuse patterns. There is little doubt, therefore, that the decorations apparent in the transmission micrographs (Fig. 7a, b, and c) represent crystallites of gamma alumina which have nucleated from the thin base "amorphous" film. No evidence of these crystallites could be found for oxidation periods of 4 hr or less at 450°C, or for oxidation periods up to 256 hr at 350°C or 600 hr at 250°C. A surface discoloration was observed to accompany the formation of these crystallites, a bluish haze or bloom, which varied in shading from one metal grain to the next.

The regular orientation of the oxide crystallites within a metal grain and the change in orientation across a grain boundary (Fig. 7) suggest an epitaxial relationship between the crystallites and the metal. Although such a relationship is by no means certain, the postulate is strengthened by evidence that nucleation of the crystallites takes place near the metal-amorphous oxide interface. This evidence is provided by the observed variation from grain to grain of the surface concentration of the crystallites, implying preferred metal planes for nucleation. The above observations are only consistent with nucleation near the metal oxide interface, unless long range order in the amorphous film, a contradiction of terms, is assumed. (The amorphous films are ~ 40Å thick). Crystal nucleation at the metal-oxide interface was found by Vermilyea (10) during high field anodizing of tantalum.

The nucleation sites do not appear to be related to general impurities, since additions of 0.53% Mn, 0.06% Fe, or 0.2% Ga cause no observable change in the nucleation behavior. The presence of copper, and to a greater extent silicon, was found, however, to have a very appreciable affect on the induction period for crystal nucleation during oxidation at 450°C. From a series of polarization curves (curves not shown) the induction periods were estimated to be about 7 hr for superpurity, and 10 hr and 20 hr for the 0.2 and 1.5% Cu alloys, respectively. Copper was also found to affect the conduction properties and rate of growth of the amorphous oxide film; this effect will be discussed later. The presence of 0.24% silicon, however, appears to have no appreciable effect on the amorphous oxide or oxidation behavior except to increase the induction period for crystal nucleation. From Fig. 7f, and on comparing Fig. 5 and 6, it is apparent that little or no crystal nucleation has taken place on this alloy after 64 hr oxidation at 450°C.

It has been observed by Brouckère (1) that addition of magnesium to aluminum decreases the temperature at which gamma alumina first becomes apparent on oxidation in dry oxygen. That the presence of magnesium should promote nucleation of gamma alumina is not at all surprising, since gamma alumina is isomorphous with spinel, $MgAl_2O_4$ (16). It is reasonable to suggest, therefore, that in the present experiments the nucleation sites are in some way related to the 0.001% magnesium impurity. The observations may be explained qualitatively if it is assumed that clusters of magnesium atoms trapped by vacancy-like defects at the metal-oxide interface form the nucleation sites. The attraction of the grain boundaries for vacancies and impurities would tend to deplete the areas adjacent to the grain boundaries of such nucleation sites, which agrees with the observations (see particularly Fig. 7e). Preferred planes for nucleation would of course be expected. Again, soluble impurities which could compete with the trapping sites for magnesium atoms would be expected to reduce the probability of formation of a nucleation site. Thus the influence of copper and silicon can be explained. The attraction of copper and magnesium atoms for one another would be expected since copper atoms are smaller, while magnesium atoms are larger than the host atoms, aluminum. The greater influence of silicon can be attributed to weak chemical bonding between magnesium and silicon atoms. (Magnesium silicide is a moderately stable intermetallic compound.)

Ionic Conduction—General

The most striking feature of the polarization curves (Fig. 1 to 6) is the high current peak which occurs for all films formed or annealed at high temperatures. Polarization curves for identically anodized samples, as anodized, and annealed at 250° and 450°C, respectively, are compared in Fig. 1. Annealed samples exhibit a current peak, and the "barrier voltage" is increased over that for an unannealed sample. For polarizing potentials greater than about 12v, the current densities for the samples

illustrated in Fig. 1 become the same within experimental error. Also, the total charge passed in the three cases (determined by integration under the curves) on anodizing to say 12v, is very nearly the same. The suggestion is, therefore, that the change brought about in the film by annealing is reversed by further anodizing. Although some such effect would be predicted by the theory of transient ionic conductivity proposed by Bean, Fisher, and Vermilyea (17), the very long observed decay times for the transients (> 1 min) is far more consistent with the postulate of a more major change in the film, perhaps a rearrangement of the amorphous film structure.

A comparison of polarization curves for samples with films of about the same thickness formed by oxidation at 250°, 350°, and 450°C is presented in Fig. 2. The three curves are, within experimental error, identical in shape. A similar comparison for films formed by oxidation at 350° and 450°C, and by anodizing and annealing at 450°C is presented in Fig. 3. Again, the three curves are nearly identical in shape. The conduction properties and hence film structure are therefore apparently the same for samples oxidized in the range 250°-450°C and for samples anodically oxidized and annealed at 450°C. Anodic films annealed for 5 hr at 250°C do not exhibit quite the same conduction properties as the above group. It is possible, however, that on prolonged annealing, agreement would be obtained, since films formed by oxidation at 250°C conform to this group.

It has been suggested to the author that annealing anodic films results in the loss of water which is assumed to have been incorporated into the oxide structure during the formation of the film. This explanation for the observed change in conduction properties on annealing, however, appears rather unlikely. This is so because on further anodizing an annealed sample, the conduction properties of the film return to those of a freshly anodized sample, implying a re-hydration of the anhydrous film if the postulate mentioned is accepted. It is difficult to conceive of a mechanism by which this re-hydration could take place during anodizing in a few minutes at room temperature. The transport number for the hydroxyl ion would be expected to be insignificant compared to that for the aluminum ion, and protons would hardly diffuse against a potential gradient of about 10^7 v/cm, the field strength present in the film during anodizing. It has been assumed, therefore, that these anodic oxide films are essentially anhydrous, differing only slightly from films formed in dry oxygen.

Figure 4 illustrates the effect of certain alloying additions on the polarization curves. Small additions of Ga, Fe, Si, or Cu appear to have little or no effect on the conduction properties of the film formed during oxidation. The effects observed for the 1.78% Si alloy and the manganese alloys are probably due to the presence in the metal of a substantial second phase, rather than a change in the film properties. This view is supported in the case of the 0.54% Mn alloy by the fact that weight gain data for oxidation of this alloy at 450°C does not differ from that for superpurity aluminum (15). On the other hand there is little doubt that copper effects a pronounced change in the conduction properties of the oxide films. In the following paper (15) it is concluded from a comparison of weight gain and barrier voltage data for the oxidation at 450°C of superpurity and superpurity plus 1.5% Cu that the ratio of film thickness to barrier voltage for the 1.5% Cu alloy is about 2.5 times that for superpurity aluminum. This indicates that the specific ionic conductivity for the amorphous film on this alloy is substantially greater than that for the amorphous film on superpurity. Such an effect would be expected providing ionic conduction through the amorphous film can be considered as involving an interstitial cation (or pseudo interstitial cation) transport mechanism. The substitution of divalent copper for trivalent aluminum ions in the oxide would then lead to an increase in the equilibrium concentration of interstitial cations. It is of interest to note that, of the alloying elements studied, only copper gives rise to an ion of radius close to that for aluminum, but differing from it in valency.

A comparison of the polarization curves for samples of superpurity and superpurity + 0.24% Si oxidized at 450°C is of interest. At 16 or 64 hr oxidation, the superpurity samples have developed oxide crystallites, whereas those of superpurity + 0.24% Si have not to any appreciable extent. The first current peak for the superpurity sample oxidized 16 hr is very likely due, therefore, to conduction through the crystallites. The second peak, falling in the same position as that for the 0.24% Si alloy, is undoubtedly due to conduction through the remaining amorphous film. After 64 hr oxidation, this second peak is very much reduced in agreement with the observed reduction in the proportion of the original amorphous film remaining (*cf.* a and b, Fig. 7).

Accepting the above interpretation it follows that the specific ionic conductivity of the crystallites is considerably higher than that for the amorphous film. (Electronic contribution to the measured current was shown experimentally to be small.) The fact that the crystallites grow to a greater thickness than does the amorphous film (see Fig. 7) also suggests a higher ionic transport coefficient for the crystallites.

According to the views of Ervin (18), the structure of gamma alumina in all its modifications differs from spinel, $MgAl_2O_4$, only in that 8 cations must be distributed among sites occupied by 9 cations in the spinel lattice. These various crystal modifications, resulting from different cation distributions, would not be expected to have greatly differing cationic diffusivities or conductivities. Also the observed effect of copper on the ionic conductivity of the amorphous film can only be expected if ionic conductance in the film is by interstitial cations. Ionic conductance in gamma alumina would be expected to be by cation vacancies, since it possesses as an essential part of its structure one vacancy per 9 cation sites. It seems unlikely, therefore, that the amorphous oxide has a proper gamma

alumina type structure. A high cationic transport coefficient for gamma alumina is to be expected because of the high vacancy concentration. It is, however, difficult to conceive a crystalline structure, metastable with respect to gamma alumina, yet having a much lower transport coefficient. Perhaps this difficulty can be resolved by considering the amorphous film to be made up of randomly oriented "molecular" units, as suggested by Wilsdorf (9).[3]

Ionic Conduction—Interpretation of Annealing Effects

The interpretation of the results illustrated in Fig. 8 has been based on the high field ionic conductance theory of Bean *et al.* (17) as this theory appears to provide the best explanation for ionic conductance effects in amorphous films on tantalum and aluminum (19). Only an outline of the development given by Dewald (19) is presented here. It is assumed that during anodic oxidation, metal ions are the mobile species and that the rate-controlling step is the passage of ions through the film. In the bulk of the film, every lattice ion[4] is a potential source of an ion-vacancy pair, the rate of production of ion-vacancy pairs being given by

$$\frac{dn^+}{dt} = \frac{dm^+}{dt} = (N_o - m)\nu \exp - (W - E\lambda q)/kT \qquad [1]$$

where n is the carrier concentration, m vacancy concentration, N_o concentration of lattice sites, ν frequency of atomic vibration, 10^{12} sec^{-1}, W activation energy for the creation of an ion-vacancy pair, λ the distance from the equilibrium to the position of the maximum in the potential energy diagram of an ion around a lattice site, q charge of the interstitial ion, E electric field in the film, k Boltzmann constant, and T absolute temperature.

It is further assumed that whenever an interstitial ion passes within an area, σ, in the vicinity of an immobile vacancy, it will be captured by that vacancy; the rate of annihilation of ion-vacancy pairs is therefore given by

$$\frac{dn^-}{dt} = \frac{dm^-}{dt} = \frac{i'\sigma m}{q} \qquad [2]$$

where i' is the current density in the oxide film. The conduction through the film is assumed to depend exponentially on the field strength according to Eq. [3]

$$i' = 2qa\nu n \exp - (U - Eaq)/kT \qquad [3]$$

where U is the activation energy for diffusion of an ion through the oxide, and a is the activation distance associated with U.

Neglecting space charge in the film and current associated with charging the electrolyte-oxide-metal capacitor, and assuming $n \cong m < No$, Eq. [1], [2], and [3] become

$$\frac{dn}{dt} = N_o \nu \exp - (W - E\lambda q)/kT - i\sigma n/q \qquad [4]$$

and

$$i = 2qa\nu n \exp - (U - Eaq)/kT \qquad [5]$$

where i is the external, observed current density.

The solution of Eq. [4] and [5] for the case of a linearly increasing applied voltage (the conditions obtaining during a polarization measurement) is very complicated; a useful solution can be obtained, however, for certain limiting conditions. For amorphous films either formed or annealed at high temperatures, the concentration of interstitial ions and vacancies will be small due to the high recombination rate caused by thermal diffusion of the ions within the film. During the early stages of a polarization measurement, the rate of annihilation of ion-vacancy pairs may therefore be neglected by comparison with their rate of formation, giving:

$$\frac{dn}{dt} = N_o\nu \exp - (W - E\lambda q)/kt \qquad [6]$$

Substituting $E = V/\delta$ and $t = V/R$ (where V is the voltage across the film, δ the film thickness, and R the rate of voltage rise, a constant) and integrating assuming δ independent of time (which is a good approximation provided that the total charge passed is small compared to the film thickness) the following equation is obtained:

$$n - n_o = \frac{N_o \nu kT\delta}{R\lambda q}(\exp - W/kT)\left(\exp\frac{V\lambda q}{\delta kT} - 1\right) \qquad [7]$$

where n_o is the concentration of interstitial ions at $t = V = 0$. As soon as an appreciable current is flowing, n will be $> n_o$, and $\exp V\lambda q/\delta\, kT >>> 1$. To a first approximation, therefore, n is given by:

$$n = \frac{N_o \nu kT\delta}{R\lambda q}\exp - (W - V\lambda q/\delta)/kT \qquad [8]$$

Substituting this value for n into Eq. [5], the following relation is obtained:

$$V = \frac{kT\delta}{(\lambda + a)q}\ln\left(\frac{R\lambda \exp (W + U)/kT}{2a\nu^2 N_o kT}\frac{i}{\delta}\right) \qquad [9]$$

The logarithm term has a value of about 100; a factor of 10 error in the value of n resulting say from the use of Eq. [8], will therefore cause an error of only about 2.5% in V, calculated using Eq. [9]. It should be emphasized that Eq. [9] will be valid only for the initial current rise portion of polarization curves for samples with amorphous films formed or annealed at high temperatures. It predicts a linear relationship between the barrier voltage, V, and the film thickness, δ, where the voltage measurements are made at current densities

[3] Such a postulate does not preclude the possibility that the "intermolecular" order in the amorphous film is essentially the same as the short range order in gamma alumina. It would be expected that inter atomic forces within sufficiently small "crystals" would differ considerably from those within macro crystals.

[4] Dewald (19) defines, for an amorphous solid, a lattice cation as a cation whose charge is locally compensated, an interstitial cation as one whose charge is not locally compensated, and a cation vacancy as a region of negative charge which is not locally compensated.

such as to maintain (i/δ) approximately constant. This is in agreement with the experimental dependence shown in Fig. 8, since the film thickness is proportional to the anodizing voltage (20). (It is believed that the high barrier voltage values for the samples anodized to 2.5v and less and annealed at 450°C were caused by oxidation during annealing, arising from the presence of adsorbed oxygen or water.) Provided annealing is carried out under such conditions as to reduce n sufficiently (*i.e.*, make n_o sufficiently small) Eq. [9] clearly predicts the barrier voltage *vs.* thickness curves to be independent of annealing conditions, which is contrary to the experimental results.

Vermilyea (21) concludes from conduction measurements on tantalum oxide films annealed under various conditions that the conductance theory by Bean *et al.* is inadequate. Dewald (19), however, studying transient conduction effects during anodic oxidation of tantalum at 25°C and over a moderate range of current densities, obtained excellent confirmation of the theory. It appears to be reasonable to assume, with Vermilyea, that the structure of the oxide film modifies on annealing. Dewald's results, however, suggest that the theory of Bean *et al.* is applicable, providing the measurements are made on films all of which have the same structure. Some support for this notion is also provided by the results in Fig. 8. The variation in the observed slopes (Fig. 8) for samples annealed at different temperatures can perhaps be explained, therefore, in terms of a difference in structure of the oxide films and hence different values for the parameters of Eq. [9]. In the following calculation an attempt is made to determine which of the parameters is primarily responsible for the change in conduction properties observed on annealing.

Re-arranging Eq. [9], the following is obtained:

$$q(\lambda + a)/2 = \frac{\delta}{V}\frac{kT}{2}\ln\frac{R(i/\delta)\lambda}{kT/2\,\nu^2 a N_o} + \frac{\delta}{V}\frac{(W+U)}{2} \qquad [10]$$

For films annealed 5 hr at 450°C, δ/V is calculated from the value 12.7 Å/v (22) for converting barrier voltage to film thickness for the as-anodized samples and from the slopes obtained from Fig. 8. Thus $\delta/V = 12.7 \times 0.83/1.20 = 8.8$ Å/v. $kT = 0.0261$ ev at 30°C, the temperature at which polarization measurements were made. $R = 2.92 \times 10^{-2}$ v/sec, and $i/\delta = 1.0$ μa/cm^2 per anodizing volt $= 7 \times 10^{19}$ electrons cm^{-3} sec^{-1}, the current density to film thickness ratio used to obtain the barrier voltage values, $(W + U)/2 = 1.76$ ev, from kinetic measurements on the oxidation of aluminum in the temperature range 250°-450°C (15). The use of this value appears to be justified, first, because the air oxidation kinetics are in agreement with Eq. [4] and [5], and second, because the conduction properties of annealed anodic and high temperature air-formed films appear identical, as discussed earlier. $\Omega\nu(2N_o\, a/\sigma)^{1/2} = 7.5 \times 10^{-2}$ cm-sec^{-1}, from kinetics of air oxidation (15). Ω is the volume per metal ion in the oxide and is 2.34×10^{-23} cm^3 for Al_2O_3 of density 3.6g cm^{-3}. $\sigma/\lambda = 10^{-7}$ cm, a value estimated from the results of Dewald (19) and Vermilyea (21) on tantalum and aluminum. An error of a factor of 10 in this estimate will introduce an error of less than 2.5% in the calculated value of $q(\lambda + a)/2$.

On making the above substitutions, the result $q(\lambda + a)/2 = 11.3$ eÅ is obtained.

In order to make a similar calculation for $q(\lambda + a)/2$ for the as-anodized films, a somewhat different expression must be used, since the assumptions made in deriving Eq. [10] are not applicable in this case. The solution of Eq. [4] and [5] for steady state conditions (*i.e.*, $dn/dt = 0$) can be written as follows:

$$q(\lambda + a)/2 = \frac{kT}{2E}\ln\left(\frac{i^2(\sigma/a)}{q^2\nu^2 2N_o}\right) + \frac{W+U}{2E} \qquad [11]$$

During the formation of the anodic films under discussion, steady state conditions prevailed, permitting the use of Eq. [11]. The samples were anodized at a constant current density of about 7×10^{-5} amp/cm$^2 = i$. By comparing the voltage to which the samples were anodized with the corresponding barrier voltage (Fig. 8) and employing the value 12.7Å per barrier volt, one obtains $1/E = \delta/V = 0.83 \times 12.7 = 10.5$ Å/v. Since the activation energy for anodic oxidation of aluminum determined by Charlesby (20), 1.6-1.8 ev, is the same within experimental error as the value for high-temperature oxidation, the value $(W + U)/2 = 1.76$ ev was used for this calculation as well. Setting $N_o = 4.27 \times 10^{22}$, the concentration of aluminum ions in Al_2O_3 of density 3.6 g/cm^2, $\sigma/a = 10^{-7}$ cm (an estimate), $\nu = 10^{12}$ and $kT = 0.026$ ev, one obtains $q(\lambda + a)/2 = 10.5$ eÅ.

Vermilyea (21) obtained values of $q(\lambda + a)/2$ for aluminum oxide formed by anodizing. His film thickness measurements were based on a dielectric constant for the oxide films of 10. Since the present film thickness measurements are based on the results of van Geel and Schellen (22) (*i.e.*, their value 12.7 Å/barrier volt was employed) before comparing the present values with those of Vermilyea, his results were recalculated using van Geel and Schellen's value for the dielectric constant, 8.7. Vermilyea's results then become $q(\lambda + a)/2 = 9.2$ eÅ and 10.5 eÅ for films formed at current densities of about 2 and 0.2 ma/cm^2, respectively, as compared to the present values of 10.5 eÅ for films formed at 0.07 ma/cm^2, and 11.3 eÅ for films annealed at 450°C. The agreement between these results is quite amazing and probably somewhat fortuitous. In addition to the values for films formed at low current densities agreeing so well, the trend of increasing $q(\lambda + a)/2$ for increasing order in the film structure is preserved. (It is assumed that films formed at high current densities would be the most disordered, those formed at low current densities the next, and annealed films the most ordered.) From the results of Bernard and Cook (23), obtained from room temperature anodic oxidation measurements, one can calculate a mean value for $q(\lambda + a)/2$ of 12.5 eÅ ± 7%. Comparing

this value with the value of 12.2 Å/v obtained from their results for films formed at 0.07 ma/cm², it can be seen that the ratio of these numbers is in excellent agreement with the ratio of the corresponding values reported herein (*i.e.*, 10.5 eÅ and 10.5 Å/v at 0.07 ma/cm²), indicating once again excellent agreement apart from the scale of thickness.

From these calculations most of the change in conduction properties which accompany the annealing of anodic oxide films on aluminum can be ascribed to the pre-exponential factor, rather than to either the effective activation energy, $(W + U)/2$ or the effective activation distance $(\lambda + a)/2$. For films formed by anodizing at 0.07 ma/cm², No appears to be nearly equal to the total number of aluminum ions in the film, that is about 4×10^{22} ions/cm³. On the other hand for the annealed films N_o is equal to about 10^{11} ions/cm³ (from $\Omega\nu(2N_oa/\sigma)^{1/2} = 7.3 \times 10^{-2}$ cm sec). Annealing, therefore, appears to reduce greatly the number of lattice sites which are potential sources of ion-vacancy pairs, or more generally, it appears to decrease the conductivity of the film by reducing the number of potential current carriers. It can be shown that this conclusion is substantially independent of the particular conduction mechanism assumed.

Wilsdorf's model for the amorphous oxide can once again provide an explanation of the results. In a randomly oriented molecular array one would expect certain cations to be in relatively high potential energy sites. It would be these ions, presumably, that could be excited into interstitial positions, leading to cationic conductivity. On annealing the film, some ordering of the molecular groups could take place, causing a reduction in the number of cations in high potential energy sites, hence a reduction in the number of cations which can become current carriers, in agreement with the interpretation of the results. The high ionic current imposed during re-anodizing of an annealed sample could cause, initially, rearrangement of the molecular groups, leading to an increase in the concentration of ions in high potential energy sites. This, in turn, would lead to an increase in the conduction ion concentration and hence to a current overshoot during a polarization measurement. Ultimately, the properties of the film would be expected to return to those of a freshly anodized sample, as observed. A more quantitative appraisal of these ideas is at the moment not possible.

Manuscript received Nov. 7, 1960; revised manuscript received June 5, 1961. This paper was prepared, in part, for delivery before the Ottawa Meeting, Sept. 8-Oct. 2, 1958.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

Oxide Films on Aluminum

II. Kinetics of Formation in Oxygen

Michael J. Dignam[1]

Aluminium Laboratories Ltd., Kingston, Ontario, Canada

ABSTRACT

The reaction rates in oxygen of electropolished samples of superpurity aluminum and certain of its binary alloys were investigated in the temperature range 250°-450°C, employing anodic polarization[2] and weight gain measurements. The rate of formation of "amorphous" oxide was not affected by small alloying additions of Fe, Mn, or Ga, and was found to be in good accord with the Cabrera-Mott[3] theory for the formation of very thin films. A modified version of this theory is preferred, however, since the rate appears to be controlled within the film, rather than at the metal-oxide interface. At 450°C and presumably above, the nucleation and initial growth of gamma alumina crystallites was found to coincide with a region of approximately constant oxidation rate, providing a qualitative explanation for the latter. The presence of copper was found to have an appreciable effect on the oxidation behavior. This effect can be explained by assuming that the presence of copper ions in the oxide film increases the concentration of conducting aluminum ions substantially.

The kinetics of formation of the oxide film on aluminum and its alloys at low temperatures where a so-called limiting oxide film thickness is obtained has not been studied in any detail. The data of Hass (3), Gulbransen and Wysong (4), Smeltzer (5), and Aylmore, Gregg, and Jepson (6) indicate that a limiting oxide film thickness is obtained on aluminum for oxidation below about 400°C, and, while the results of Obrist (7) and Cabrera and Hamon (8) indicate a somewhat lower temperature, anodic polarization studies of Hunter and Fowle (9) tend to confirm this value. It might reasonably be expected, and indeed the present results show, that the rate of oxidation of aluminum in this low-temperature range is of the form predicted by Cabrera and Mott (2) for the growth of very thin oxide films on metals.

Most of the data consist of "barrier voltage" values determined using a modification of the anodic polarization measurement technique employed by Hunter and Fowle (10), although some weight gain data were also obtained. Samples oxidized for various times at temperatures of 250°, 350°, and 450°C were anodically polarized and the barrier voltage determined as described in the foregoing paper. For superpurity aluminum the film thickness may then be taken to be proportional to the barrier voltage. Until the present work, the validity of this method had only been demonstrated for the case of nonporous anodic films (10). In the foregoing paper, however, it was shown that for superpurity the barrier voltage is proportional to film thickness for annealed anodic films; also, the room temperature ionic conduction properties of films formed by oxidation at 250°, 350°, or 450°C could not be distinguished from those of anodic films annealed at 450°C; it appears likely, therefore, that for films formed on superpurity aluminum by oxidation in the range 250°-450°C, the barrier voltage is proportional to the oxide thickness, the value of the proportionality constant being the same as that for anodic films annealed at 450°C, namely, 8.8 Å/v (1).

The main advantages in this method of film thickness determination are the following. First, the barrier voltage is independent of sample area to a first approximation, in contrast to weight gain or capacitance measurements. For example, a roughness factor of 2, if not taken into account, will lead to an error in the film thickness calculated from the barrier voltage of less than 1% (cf. Eq. [9], (1)). Second, absolute film thickness can in principle be obtained from polarization measurements, whereas only changes of film thickness can be obtained from weight gain measurements. Finally, the barrier voltage value is not affected appreciably by flaws or fissures in the oxide film, in contrast to the film capacitance. The main disadvantage of the method is that it is by no means absolute, requiring, therefore, careful calibration. Its application depends on the properties of the particular oxide-metal system in question. The same relation between barrier voltage and film thickness cannot be assumed, *a priori*, for samples other than those with identical oxide-metal interface and identical oxide form. Techniques for obtaining the thickness of films on aluminum, similar to the one employed herein, have been used by some workers rather indiscriminately, without experimental or theoretical justification for its application to the system under study.

The present investigation was undertaken to determine the oxidation mechanism of aluminum and the effect of small alloying additions of gallium, iron, manganese, silicon, and copper on the oxidation behavior. Alloy additions were kept small in

[1] Present address: Department of Chemistry, University of Toronto, Toronto, Ontario, Canada.

[2] See ref. (1).

[3] See ref. (2).

order to avoid having to consider the oxidation properties of phases rich in alloying element, where such phases existed. The above alloys were included in an attempt to further elucidate the oxidation mechanism of pure aluminum. Certain of the alloys studied are heterogeneous at one or more of the oxidation temperatures. However, copper was the only alloying addition found to have an observable effect on the growth rate of the amorphous oxide film on an aluminum rich phase. Alloy heterogeneity is of consequence therefore only in the case of the data for oxidation of the 1.5% Cu alloy at 350° and 250°C, where the solubility limit is about 0.8% and 0.3%, respectively. As other limitations of these data exist, very little weight is attached to them. Accordingly, conclusions concerning the effect of copper are based on the behavior of the 1.5% copper alloy at 450°C, where it is homogeneous, and on the behavior of alloys containing less than 0.3% Cu.

All the alloys studied except the alloy containing 1.5% Cu have been shown to exhibit oxidation kinetics consistent with the Cabrera-Mott theory of oxidation. A modified version of this theory is preferred, however, since the rate appears to be controlled within the film rather than at the metal-oxide interface. In contrast, the results for the 1.5% Cu alloy suggest that the rate-determining step in this case could very well be controlled at the metal-oxide interface. The results for this alloy for oxidation at 450°C are in accordance with a direct logarithmic law.

Experimental Procedure

Samples of superpurity aluminum and superpurity base binary alloys of composition, purity, and dimensions given in the foregoing paper, were oxidized in 0.2 atm of purified oxygen at temperatures of 250°, 350°, and 450°C, as previously described (1). Polarization measurements were then made on the samples from which "barrier voltage" values were obtained (1). A new set of samples was used for each oxidation period, since a polarization measurement changes the thickness and conduction properties of the oxide film (1). Comparison of the behavior of different alloys was of primary interest; one sample of each alloy was therefore oxidized in the multiple sample furnace at one time in order that random variations of the furnace temperature might influence the oxidation rate of all alloys equally. Each sample permitted duplicate determinations of the barrier voltage to be made.

Weight gain measurements for oxidation at 450°C were made on superpurity and superpurity base binary alloys containing 0.01% Fe, 0.24% Si, 0.54% Mn, or 1.51% Cu. Samples 1 × 12 in. were cut from the 0.020 in. thick sheets, and vacuum annealed for 1 hr at 543°C. They were then electropolished for 30 min at 30v (~ 25 ma/cm²) in a bath at about 10°C containing 27.7% by volume of 71% perchloric acid, 8.3% by volume of water, and 64.0% by volume of acetic anhydride. The perchloric acid-methanol electropolishing bath (1) could not be used for these large samples because of the high currents that would have been required. The samples were rinsed 30 sec in absolute methanol and 1 min in running distilled water, then dried in a clean, dry air jet. They were then folded over a quartz hook and suspended from the furnace sample holder. The degassing and oxidation procedure was the same as that described previously (1). The samples were weighed on a Mettler chemical microbalance, correcting the observed weighings for atmospheric conditions. After weighing, the samples were returned to the furnace for further oxidation.

Experimental Results

The results obtained from polarization and weight gain measurements are presented in Tables I and II, respectively. The barrier voltage values are reported with reference to the hypothetical reversible aluminum electrode (1). Each voltage entry is the result of averaging duplicate determinations, which agreed in general to about 0.04v. The accuracy of the weight gain measurements was estimated to be about ± 4 μg.

Interpretation of Results

Examination of the results in Tables I and II indicates that, within experimental error, all of the alloys except the copper bearing alloys oxidize at the same rate at temperatures of 250°C, 350°C and for oxidation periods up to 4 hr at 450°C.[4] Oxidation results for the aluminum copper alloys are therefore treated separately, those for the remaining alloys being treated as a unit.

Figure 1 illustrates the effect of silicon on the oxidation of aluminum at 450°C. The weight gain data was converted to oxide thickness, expressed in barrier voltage units, by choosing the value of the initial weight of the film and the relation between film weight and barrier voltage (25.8 μg/dm² per barrier volt) which gave the best agreement between the two sets of data. The agreement between the two measurement techniques is considered quite good for the 0.24% Si alloy, and for oxidation periods up to 4 hr or so for superpurity as well. Choosing a value for the oxide density of 3.6 g/cm³ and using the value 8.8Å per barrier volt for the conversion factor, 25.8 μg/cm² per barrier volt implies a roughness factor for the weight gain samples of 1.65. This is considered a reasonable value since these samples, although bright after electropolishing, were not smooth on a macro scale.

The divergence of the weight gain and barrier voltage data for superpurity after 4-16 hr oxidation at 450°C is undoubtedly caused by the onset of crystal nucleation in the oxide film in accordance with the results and discussion of the foregoing paper.

If the rate-determining step for the oxidation of aluminum were controlled at the metal-oxide interface, as assumed by Cabrera and Mott, it would be expected that the oxidation rate would vary considerably from one sample to the next because of variations in the nature of the interface which are bound to exist. To an even greater extent, one would expect large impurity concentrations in the metal to affect the oxidation rate. However, the polarization data fall on smooth curves (see Fig. 1 and 2) indicating consistency, since each point is obtained from a separate sample. Also, with the exception of the high copper bearing alloys, the polarization and weight gain data indicate little influence of alloying conditions on the oxidation rate of aluminum. In addition, the electron transmission micrographs of the foregoing publication (1) show no variation in the thickness of the amorphous film with metal grain orientation. It seems probable, therefore, that the rate-determining step is controlled in the bulk of the oxide rather than at the oxide-metal interface.

The 0.24% Si alloy behaves the same at all temperatures as superpurity except for the oxide crystallization phenomenon at 450°C; this alloy rather than superpurity, therefore, was used to test the modified Cabrera-Mott theory, since it provides more data for calculation.

Oxidation of superpurity + 0.24% silicon.—The barrier voltage and weight gain data for this alloy are illustrated in Fig. 2.

The Cabrera-Mott theory of oxide film growth in the very thin film region is based on the assumption that equilibration of electrons between the metal and the adsorbed oxygen is established in a time short compared with that required for ions to be transported across the oxide film. The resulting constant voltage, V, established across the film causes the metal ions to be transported across a barrier which is assumed to be at the metal oxide interface, the rate of transport depending exponentially on the field strength. In interpreting the present data, this theory was modified by assuming

[4] This conclusion may be reached from the barrier voltage data as well as from the weight gain data despite the fact that barrier voltage values were calibrated in terms of film thickness only in the case of superpurity aluminum. This is so since the only alternative conclusion is extremely improbable, namely, that the film thicknesses are different for these alloys, but that the conduction properties of the films also differ in just such a way as to give the same barrier voltage values for oxidation at all three temperatures.

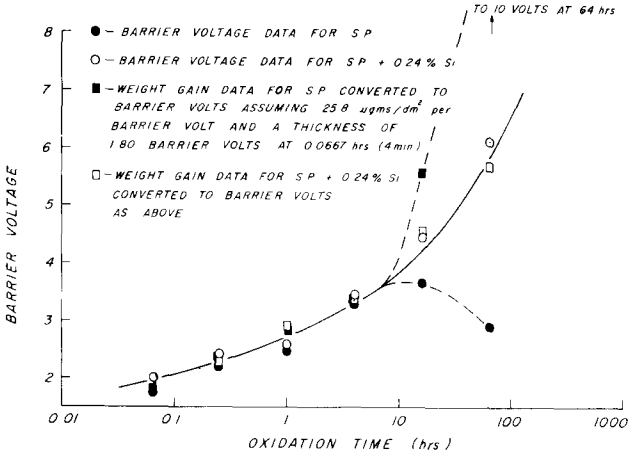

Fig. 1. Influence of silicon on the oxidation of aluminum at 450°C.

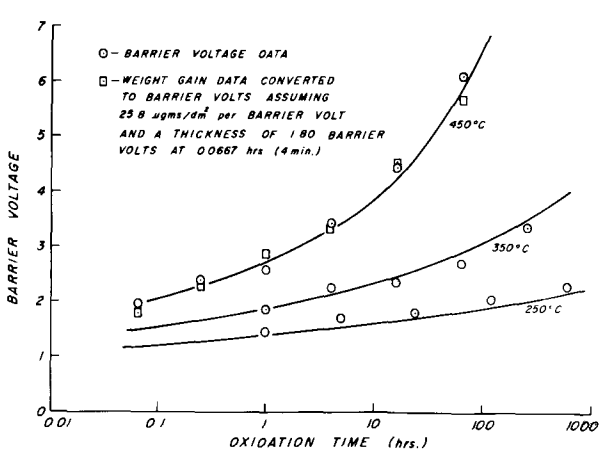

Fig. 2. Influence of temperature on the oxidation of superpurity aluminum + 0.24% silicon.

the rate-controlling process to be site to site diffusion of the metal ions within the oxide film in accordance with the ionic conductance theory of Bean *et al.* (1, 11).

From the 450°C oxidation results, at 4 min, the oxidation rate (or oxidation current) changes by less than 0.4% per sec. At longer oxidation times, or lower temperatures, the rate of change is much slower, being, for example, 0.05% per sec at 15 min at 450°C. From this, it can reasonably be concluded that for oxidation times of 4 min or more at 450°C or less, transient effects will be of only secondary importance. The steady-state relation between current density and field strength is obtained from Eq. [4] and [5] of the foregoing paper (1) by eliminating n for the condition that $dn/dt = 0$. The resulting equation is:

$$\frac{d\delta}{dt} = \Omega\nu\left(\frac{2N_o a}{\sigma}\right)^{1/2} \exp - \left[\frac{W+U}{2} - \frac{Vq(\lambda+a)}{2\delta}\right]/kT \quad [1]$$

where the field strength, E, has been replaced by V/δ, δ being the film thickness, and the units have been changed from current density to rate of growth of film thickness, Ω being the volume per metal ion in the oxide. This equation is formally the same as that by Cabrera and Mott.

Equilibration of electrons between the metal and the adsorbed oxygen, which is assumed to establish the potential V across the film, can only take place if the electrons can pass freely through the film. Vermilyea (12), in discussing this problem, concludes that for a film 100Å thick and a concentration of electrons in the conduction band of the oxide of only 10^8 cm^{-3}, a potential difference of the order of a volt would be established across the oxide in 1 sec. Since the films presently being discussed were not more than 55Å thick, it seems likely that essentially the full equilibrium potential would be established, particularly in view of the extremely slow rate of growth of the thicker films.

The following method was used to fit the barrier voltage data to Eq. [1], which can be written

$$\frac{d\delta}{dt} = A \exp B/\delta \quad [2]$$

where A and B, constants for a given temperature, are given by $A = \Omega\nu(2N_o a/\sigma)^{1/2} \exp - (W+U)/2kT$, and $B = Vq(\lambda+a)/2kT$. The integrated form of Eq. [2] can be written

$$\ln t/\delta^2 = -B f(B/\delta)/\delta - \ln AB \quad [3]$$

where $f(B/\delta)$, a function of B/δ only, approaches unity for large values of B/δ. $f(B/\delta)$ was calculated as a function of B/δ by comparing Eq. [3] with the following integrated form of Eq. [2]

$$\frac{At}{B} = \int_o^{\delta/B} \exp - B/\delta \, d(\delta/B) \quad [4]$$

and from numerical values of the above integral.

An approximate value for B at 450°C, B_3, was obtained by plotting log t/δ^2 *vs.* $1/\delta$, the slope of the resulting straight line being approximately $-B_3/2.303$. The data for the three temperatures were then plotted for several assumed values of B_3 (which settled the values for B at 350° and 250°C, B_2 and B_1, since $B_1 : B_2 : B_3 : : 1/T_1 : 1/T_2 : 1/T_3$) plotting log t/δ^2 *vs.* $f(B/\delta)/\delta$ and drawing the best straight lines of slopes B_1, B_2, and B_3 with intercepts approximately linear in $1/T$ (since $-\log AB = -\log[\Omega\nu(2N_o a/\sigma)^{1/2} \; Vq(\lambda+a)/2kT] + (W+U)/4.606kT$). The term $Vq(\lambda+a)/2$ was then calculated from the best value for B_3. From the values of the intercepts and of B, log A was plotted against $1/T$, and $(W+U)/2$ and $\Omega\nu(2N_o a/\sigma)^{1/2}$ obtained from the resulting slope and intercept. The values of the parameters obtained in this way for the oxidation of the 0.24% Si alloy are:

$$\Omega\nu(2Noa/\sigma)^{1/2} = 3.0 \times 10^9 \text{ (barrier volts) hr}^{-1} = 7.3 \times 10^{-2} \text{ cm sec}^{-1}$$

$$(W+U)/2 = 1.76 \text{ ev}$$

$$Vq(\lambda+a)/2 = 0.935\, e\text{(barrier volts)} = 8.2 \text{ eÅ v}$$

The solid curves in Fig. 2 were calculated using the above values. Although the average deviation of the points from the lines is only about ±0.13v (or ±1.2Å), there does appear to be a small systematic deviation of the experimental points from the best fit calculated curves. It can be shown that this systematic deviation could have arisen as a result of small variations with temperature and film thickness of V, in accordance with the theory presented by Grimley (13). Small differences in the conduction properties of the oxide films formed at the different temperatures might also have been responsible. This discrepancy, however, is not considered to be very significant.

The value for the activation energy, 1.76 ev, compares favorably with the values 1.6 and 1.8 ev calculated by Charlesby (14) from steady-state anodic oxidation measurements on aluminum. From $\Omega\nu(2N_o a/\sigma)^{1/2} = 7.3 \times 10^{-2}$ cm sec^{-1} and setting $\Omega = 2.34 \times 10^{23}$ cm^{-3}, $\nu = 10^{12}$ sec^{-1}, $a = 10^{-8}$ cm, and $\sigma = 10^{-15}$ cm^2, the result $N_o = 5 \times 10^{11}$ cm^{-3} is obtained which is to be compared with a value of about 4×10^{22} cm^{-3} for the concentration of aluminum ions in the oxide lattice. An interpretation of this result would be that of the aluminum ions in the oxide lattice, only 1 in 10^{11} is a potential source of an ion-vacancy pair for films formed by oxidizing between 250° and 450°C. This phenomenon has been discussed in the foregoing paper.

By making the very reasonable assumption that the mechanism of air oxidation and anodic oxidation are the same for samples with the same film structure, it is possible to calculate the value of the voltage, V, established across the film during oxidation. From the foregoing paper, a study of ionic conduction through films with apparently the same conduction properties are those formed during air oxidation led to the value $q(\lambda+a)/2 = 11.3$ eÅ. Comparing this with the present results, $Vq(\lambda+a)/2 = 8.2$ eÅ, the result $V = 0.73$v is obtained. This compares favorably with the value 0.7v estimated by Vermilyea (12) for the oxidation of tantalum between 50° and 300°C.

In the light of the present results and those presented in the foregoing paper, it is of interest to investigate the results obtained by Smeltzer (5), and more recently by Aylmore, Gregg, and Jepson (6), on the oxidation of aluminum between 400° and 650°C. Both these sets of data were obtained from weight gain measurements on samples of superpurity abraded with emery. A typical curve of weight gain *vs.* time can be divided, for purposes of discussion, into three regions; an initial region in which the rate falls off rapidly, an intermediate region of nearly constant oxidation rate, and a final region in which the rate decreases once again. The present data for oxidation of superpurity at 450°C, when plotted on a linear time scale, indicate an initial region in which the rate decreases rapidly with time. This region persists somewhat beyond 4 hr. Between 4 and 16 hr oxidation, during which time crystallites of gamma alumina are known to be forming (1), the oxidation rate actually increases, falling off once again from about 16 hr to 64 hr oxidation or more. The general features of this curve, although not the same as those obtained by Smeltzer and by Aylmore *et al.*, strongly suggest that their initial region is associated with the formation of amorphous oxide in accordance with the mechanism proposed herein, the second approximately linear region with the nucleation and rapid initial growth of gamma alumina crystallites, and the final region with the coalescence of the crystallites and continued growth of a film composed entirely of such crystallites. Smeltzer's data at 450°C exhibits a linear oxidation rate between about 2 and 16 hr oxidation, confirming the above thesis. In other areas of comparison, however, the data of Smeltzer and of Aylmore *et al.* do not agree with the present results. Thus for oxidation at 450°C of samples possessing films formed at room temperature the weight gains per unit area reported by Aylmore *et al.* are higher than those presented herein by factors of about 22, 13, and 4 for oxidation periods of 64, 4, and 0.25 hr, respectively. Some of this enormous discrepancy could perhaps be explained by a difference in roughness factor, but the major difference almost certainly arises because of the different methods employed for preparing the surface.

An emery abraded surface will most probably be rough on a very fine scale, giving rise to cracking and buckling of the oxide film during oxidation, exposing fresh metal, and leading to excessively high weight gains. This oxide cracking must take place if the surface roughness is on a small enough scale such that the radii of curvature of peaks and edges on the surface are of the same order of magnitude as the thickness of the oxide film formed. Under these conditions, as oxidation proceeds, it can be demonstrated that the surface area of the metal will decrease appreciably in the neighborhood of the sharp edges and peaks in much the same fashion as occurs during the electropolishing of metals (15). Since the oxide grows by transport of aluminum through the film, however, the surface area of the oxide in contact with the metal will not change, leading eventually to rupture of the oxide film.

In addition to this roughness effect it has been demonstrated by Aziz (16) that emery abrasion leaves a very high concentration of emery particles in the surface of the metal. The abrading material is revealed after metallographic polishing of the abraded surface.

In the study of any surface reaction, the type of surface treatment used is all important. Although no type of surface treatment is without fault, it is felt that abrasion is a poor choice in many instances. The state of emery abraded surfaces is ill defined, and consequently results pertaining to such surfaces, although undoubtedly of practical interest, may often be of little theoretical consequence in respect to the elucidation of the basic reaction mechanisms.

The effect of vacuum annealing in reducing the subsequent oxidation rate, as observed by Smeltzer and by Aylmore *et al.* can be explained either by one of several hypothesis arising from the foregoing discussion, or from a consideration of the process of nucleation of gamma alumina. It is not considered worthwhile at present to discuss this in detail.

In contrast to the poor correlation with results obtained from abraded samples, the present results are in quite good agreement with those obtained by Hass (3) on evaporated aluminum films. For oxidation periods of 2 hr at 20°, 150°, 300°, 400°, and 450°C Hass obtained total film thickness values of 10, 12, 17, 25, and 42Å, respectively. From the present results, total film thicknesses corresponding to these same oxidation conditions were calculated to be 7.5, 10, 14.5, 21, and 26Å, respectively. Excluding the values at 450°C, the two sets agree very well, differing by a constant factor of about 1.2. The lack of such good agreement for oxidation at 450°C is probably related to the phenomenon of oxide crystallization.

Oxidation of superpurity-copper alloys.—The influence of copper on the barrier voltage values for the oxidation of aluminum is illustrated in Fig. 3. The data indicate an increase in barrier voltage for increasing copper content. The influence is minor, however, for copper additions up to 0.2%. The data for these alloys can still be represented, within experimental error, by the Cabrera-Mott theory, whereas those for the 1.5% Cu alloy cannot. The change in oxidation behavior on adding 0.2% copper to superpurity aluminum can be explained equally well, within experimental error, by a change in the

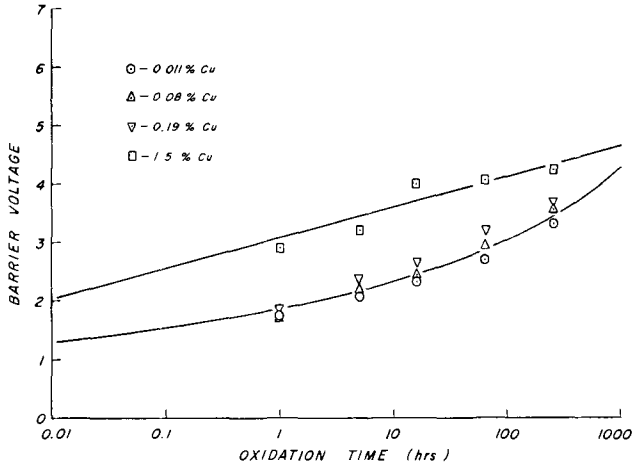

Fig. 3. Influence of copper on the barrier voltage values for the oxidation of aluminum at 350°C.

pre-exponential factor, activation energy, or activation distance. Thus the addition of 0.2% Cu could cause a factor of 6.3 ±1.6 increase in N_o, or a (12 ± 4) % increase in $V(\lambda + a)$, or a decrease in the activation energy, $(W + U)/2$, of 0.05 ± 0.004 *eV*, or some combination of all three changes.

There is no doubt that the addition of 1.5% copper causes a fundamental change in the reaction mechanism. The weight gain data for the oxidation of this alloy at 450°C indicate adherence to a direct logarithmic oxidation law (δ linear in log t), and are quite inconsistent with the Cabrera-Mott theory. A relation between weight gain and barrier voltage change for the oxidation at 450°C of this alloy can be obtained in the same way as was that for the 0.24% silicon alloy. The ratio 52.6 $\mu g/dm^2$ per barrier volt obtained for this alloy is to be compared with the result 25.8 $\mu g/dm^2$ per barrier volt obtained for superpurity and the other superpurity base alloys. Assuming the same roughness factors for these alloys, the relation between barrier voltage and film thickness, 21.3Å/barrier volt, may be deduced. It is doubtful, however, that this value also applies to the films formed on this alloy at 350° and 250°C, since there is no very convincing evidence that the films formed at the three temperatures have the same conduction properties.

Assuming copper increases the ionic conductivity of the amorphous film by introducing interstitial aluminum ions into the oxide (1), it is of interest to consider what effect this might have on the kinetics of air oxidation. If the equilibrium concentration of aluminum ions is not too large, but large compared to the concentration of ion-vacancy pairs, it can be shown that oxidation will still proceed in accordance with an equation of the same form as Eq. [1], although with somewhat different parameters. This is apparently not the case for the 1.5% Cu alloy. If the interstitial aluminum ion concentration is increased sufficiently, it is entirely possible that the rate-controlling process will no longer be the transport of aluminum ions through the film, but rather the transport of aluminum ions, or perhaps electrons, across the metal-oxide interface. Some evidence to support the supposition that the oxidation rate of the 1.5% Cu alloy is controlled at the metal-oxide interface is found in the lack of reproducibility of the polarization data for this alloy as compared to that for superpurity. Also, some results obtained for the oxidation of a 6% Cu alloy at 450°C (in which a second phase would be present) were highly erratic, although conforming more or less to those for the 1.5% Cu alloy.

Uhlig (17) has derived a rate equation, assuming the rate-controlling process to be transport of electrons across a rectifying metal-oxide interface. The process is assumed to be aided by the "apparent positive potential at the metal surface created by the growing oxide," and hindered by the opposing field arising from a uniform concentration of negative space charge in the film. A major difficulty presented by the application of Uhlig's theory to the 1.5% Cu alloy is that it requires that the metal work function be greater than the electron affinity of the adsorbed oxygen, whereas the Cabrera-Mott theory, or its modification, requires the opposite. It is very difficult to understand how the introduction of copper could cause such a large change in these properties.

As an alternative to Uhlig's theory, it is possible to obtain a direct logarithmic oxidation law of the same form from the Cabrera-Mott (2) theory for the formation of very thin oxide films, by including the possibility of space charge in the oxide. If the rate-controlling process has shifted from metal ion transport within the film to transport across the interface, in the manner proposed, it can be shown that under steady-state conditions a negative space charge must be present near the metal-oxide interface. If beyond this negative space charge region, a positive space charge region is assumed to exist, such that the total negative space charge in the film decreases linearly with film thickness, the desired oxidation law will result. Although the application of this theory to the results does not lead to any obvious contradictions, the space charge concentrations required are very high indeed ($\sim 10^{20}$ e/cm^3). Also, in common with Uhlig's theory, it is difficult to account entirely for the space charge distributions required. Further experimental investigation must be made before a definite conclusion can be reached.

General Discussion

In conjunction with those results of the foregoing paper pertaining to oxide crystallization, the present results provide a reasonable explanation for the oxidation behavior of aluminum in dry oxygen. Below about 450°C, and initially at higher temperatures, a very thin, amorphous film is formed. The observed kinetics are in agreement with a mechanism in which a nearly constant potential difference of 0.73v is established across the film by means of electron transport from the metal to oxide surface levels. The resulting field causes metal ion transport through the film in accordance with an exponential field strength relationship. The rate of formation of this film appears to be unaffected by metal grain orientation in conformity with the above mechanism.

After a suitable induction period, for oxidation temperatures above about 450°C, nucleii of crystalline gamma alumina form and initially grow rapidly. The weight gain data for this region conform approximately to a linear oxidation law. The induction period is effected by impurities, and the surface concentration of crystal nucleii by metal grain orientation; each of these factors would therefore be expected to have considerable influence on the film growth during this period of oxide crystallization, and perhaps also on the subsequent growth of the all-crystalline film, as they might influence the distribution of crystal orientation in the final polycrystalline film.

It is not possible, on the basis of the data presented herein, to suggest a mechanism for the growth of the crystalline oxide; it is apparent, however, that the rate does decrease with increasing film thickness. In view of the fact that the crystalline film is nucleated at the metal-oxide interface, its rate of growth is probably dependent on the orientation of the underlying metal, irrespective of whether the oxidation

rate is controlled at the metal-oxide interface or within the film.

The effect of impurities, both surface and bulk, on the general oxidation behavior is of interest. On the basis of the interpretation presented herein, only those impurities which can introduce defects into the oxide film would be expected to affect the rate of formation of the amorphous film, and then only if the concentration of defects introduced is of the same order of magnitude or larger than the concentration of defects assumed to be introduced by the electric field, in accordance with the theory of Bean *et al.* It appears likely, therefore, that the rate of formation of amorphous oxide for ultra high-purity aluminum would not differ from that for superpurity reported herein. It is apparent, however, that very small traces of impurities could have a profound effect on the nucleation of gamma alumina, and consequently on the subsequent oxidation rate. The time and temperature required to initiate growth of gamma alumina may be affected by trace impurities whether or not these appear in the film itself.

Fission Fragment Recoil Effects on Zirconium Oxidation

W. C. Yee and G. H. Jenks

Oak Ridge National Laboratory, Oak Ridge, Tennessee,
Operated by the Union Carbide Nuclear Company for the United States Atomic Energy Commission

and E. E. Stansbury

University of Tennessee, Knoxville, Tennessee

ABSTRACT

Fission fragment recoil effects on zirconium oxidation in pure oxygen were studied at 1 atm pressure and 250°C. Specimens were oxidized under the following conditions: (*a*) reactor radiations including recoils, (*b*) reactor radiations in the absence of recoils, and (c) no radiation. Irradiation experiments were conducted in a maximum thermal neutron flux of 8.5 x 10^{11} neutrons/cm^2-sec. Specimen surfaces subject to fission fragments were exposed to an estimated average recoil intensity of 6 x 10^8 particles/cm^2-sec, the average particle energy being about 32 Mev or ~40% of the initial energy. It was concluded from electron and optical microscopy studies of the specimens that the normal oxide film on surfaces exposed to recoils had undergone a phase transformation with fine particle size, although the possibility that the normal oxide had developed a fine particle size of random orientation could not be ruled out. From estimates of oxide thickness based on interference colors and from a limited amount of weight gain data, it was concluded that the oxide film on surfaces exposed to fission fragments was thicker than surfaces exposed to reactor radiation alone. The amount of corrosion as indicated by the oxide thickness and weight data was at least a factor of ten less than that expected in a solution of uranyl sulfate producing an equivalent recoil intensity. However, the data obtained do not provide sufficient information to establish the mechanism of the effects of fission fragment recoils on zirconium oxidation.

It has been shown that under radiation the corrosion rate of Zircaloy-2 and zirconium in uranyl sulfate solutions is appreciably greater than in similar control experiments run in the absence of radiation. Jenks (1, 2) has summarized the results of these experiments to date.

Several mechanisms have been proposed to explain this increase in corrosion rate. These involve

the effects of irradiation on (*a*) the dilute uranyl sulfate solution, and (*b*) the metal and/or its oxide film. For aqueous solutions, it has been reported (3) that the initial products of irradiation are hydrogen peroxide and the free radicals H and OH. Although these provide a possible means of influencing the corrosive properties of the liquid, Jenks (1) has reported that the results of radiation studies of Zircaloy-2 and zirconium in uranyl sulfate solutions have indicated that the increased corrosion rate is not directly due to changes in the solution itself.

The alternate interpretation proposes that the damage is due to fission fragment recoil effects on the metal and/or its oxide film. Mechanisms which have been advanced to explain the loss in protective qualities of the oxide film include (*a*) increased rate of solution of the oxide exposed in aqueous environments (1), (*b*) production of easy diffusion paths along the tracks of the fission fragments (4, 5), and (*c*) conversion of the oxide film to a different phase (monoclinic to cubic) (6).

Another approach considers the consequences of fission fragment recoils on the metal itself. This model proposes (2) that recoils produce defects within the metal which increases its activity. For zirconium, in particular, it has been suggested (7) that the normal oxidation reaction occurs at the metal-oxide interface. Because of these defects in the metal, the rate of reaction at the interface is increased.

Since the study of the aqueous corrosion of zirconium under irradiation involves the resolution of several variables, it was thought that experimental data on the effects of fission fragment recoils on the gaseous oxidation of zirconium would be of aid in interpreting the aqueous radiation corrosion results. Specifically, this information might be helpful in separating the effects in the oxide and/or metal due to radiation *per se* from those due to changes in the aqueous environment.

Equipment

The experiments were designed to provide for the gaseous oxidation of zirconium under the following conditions: (*a*) reactor radiation including fission fragment recoils, (*b*) reactor radiation in the absence of fission fragment recoils, and (*c*) no radiation.

Each of the experiments was conducted in an especially designed autoclave unit which had three main components: (*a*) a water-cooled stainless steel holder containing the fission fragment recoil source, (*b*) a hollow cylindrical heater unit, and (*c*) a specimen holder. The source was placed in one end of the hollow cylinder. Inserted in the other end was the holder containing specifically located zirconium specimens. Figure 1 is a schematic diagram which locates the specimens and source within the autoclave unit. The components of the autoclave are shown in Fig. 2.

The recoil source was prepared by powder metallurgy techniques (8). A binary powdered mixture of enriched uranium dioxide (93.2% U-235) and stainless steel, 36 w/o UO_2, was sintered and

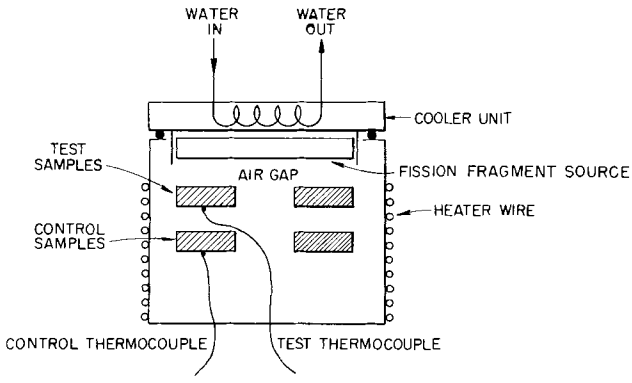

Fig. 1. Schematic diagram of assembled autoclave unit

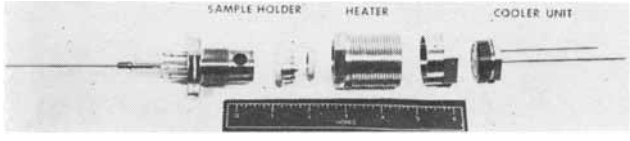

Fig. 2. Components of autoclave

then bonded to a cooler unit to dissipate heat generated by uranium fission.

The specimen holder held four zirconium specimens in position. One pair was placed approximately 1 mm away from the recoil source thus permitting one surface of each specimen to be exposed to recoil bombardment. These specimens, designated as test specimens, were maintained at 250°C by the heater unit. The remaining two specimens, the control specimens, were located in back of the test specimens, and except for the fission fragment recoils, were exposed in approximately the same radiation and oxidation environment. The control specimens operated at about 265°C.

The temperatures were measured by attaching 30-gauge iron-constantan thermocouples to the back side of one of the test and one of the control specimens. From the symmetrical arrangement of the specimens and their essentially identical mass, it was assumed that the experimental conditions for the weighed specimen were identical to the conditions for the matching specimen to which the thermocouple had been attached. This experimental arrangement was chosen to provide a means whereby the temperature of the test and control samples could be accurately established and still permit a reasonable evaluation of the magnitude of weight changes.

A third thermocouple was peened to the exterior wall of the heater section. This served as a detector for temperature control.

At the conclusion of the series of experiments, a comparison of the test and control specimens, both irradiated and nonirradiated, was made on the basis of weight change and individual surface characteristics.

Experimental

The zirconium specimens were made from crystal bar stock furnished in the form of a cold-rolled sheet, 0.025-in. thick. This metal had the following nominal spectrographic analysis: 100 ppm hafnium, 200-500 ppm iron, 200 ppm nickel, and less than 100 ppm each of titanium, aluminum, and silicon.

Samples in the form of half disks were machined from this sheet. Each specimen weighed approximately 0.4g and each side of the half-disk had a surface area of 1.2 cm^2.

The surfaces of all zirconium specimens were chemically polished in a solution of 50% distilled water, 45% concentrated nitric acid, and 5% hydrofluoric acid (48%). Each disk was alternately put into polish solution for 1 or 2 min and then in distilled water until the surfaces appeared visually to be smooth and bright. In order to achieve uniform polishing, the specimen had to be manually agitated even though the polish solution was magnetically stirred. Quick transfer of the disk to vigorously boiling distilled water removed trace quantities of polishing solution. This was followed by successive rinses in ethyl alcohol, ethyl ether, and petroleum ether. After shaking off excess solvent, the remaining thin film on the surface was evaporated rapidly by a jet of oxygen.

Each assembled autoclave unit, including zirconium specimens, was oxidized in an oxygen atmosphere at 250°C for 48 hr as part of a reliability test prior to irradiation.

Four irradiation experiments (Table I) were performed in Hole 16 of the ORNL Graphite Reactor where the maximum thermal neutron flux is 8.5 x 10^{11} nv. Three of these experiments contained a fission fragment source; one was exposed for two weeks and two were exposed for one week. The fourth in-pile test, exposed for one week, contained no source in order to establish any effects on the specimens due to fast neutron flux alone. Another test was a control experiment run out-of-pile for two weeks.

Table I. Experimental summary

Run	Time, weeks	Conditions
Z-5	1	Source—irradiated
Z-6	1	Source—irradiated
Z-8	2	Source—irradiated
Z-7	1	No source—irradiated
Z-9	2	Source—out-of-pile

Irradiated experiments: Hole 16 of ORNL graphite reactor
$\phi_{th\,max} = 8.5 \times 10^{11}$ neutrons/cm^2-sec

Table II. Nuclear conditions—irradiated experiments

	Average of 3 exps. with source	One exp.—no source
Thermal flux—Zr samples (neutrons/cm^2-sec)	4.7×10^{11}	4.9×10^{11}
Thermal flux—Source (neutrons/cm^2-sec)	$\sim 4.2 \times 10^{11}$	
Calc'd fission fragment intensity at Zr sample surface (particles/cm^2-sec)	5.9×10^8	
Fast flux—2 Mev energy—at Zr samples (neutrons/cm^2-sec)	2×10^{14}*	$\sim 10^{11}$ (>2 Mev)

* Calculated Zr atomic displacement rate due to recoils expressed in terms of fast flux.

An estimate of the fission fragment intensity impinging on the exposed test sample surfaces was obtained (9) from the prevailing thermal neutron flux conditions (Table II). The actual thermal neutron flux in the vicinity of the zirconium samples and source was determined experimentally by activation analysis of the exposed specimens themselves. For the geometry of this experiment, it was estimated that the flux in the source was depressed to about 90% of this value due to its high thermal neutron absorption cross section. From this flux in the source, a fission rate was approximated for a depth equal to the fission fragment range in the UO_2-stainless steel mixture (7μ). The number and total energy of fission fragments bombarding the exposed sample surface were calculated to be 25% and 10% of the number and total energy generated in the 7μ layer. For the nuclear conditions of these experiments, the fission fragment intensity at the sample was estimated to be 6 x 10^8 particles/cm^2-sec.

The potential damage rate at the fission fragment irradiation intensity can be estimated (9) to be several orders of magnitude greater than that of the prevailing fast neutron flux by comparing the atomic displacement rate due to recoil absorption in a thin surface layer of zirconium with the fast neutron flux (2 Mev neutrons) which would cause an equivalent displacement rate. Assumptions made for this comparison included (*a*) Ozeroff's calculated value (10) of 10^5 displacements in uranium per 80 Mev fission fragment applies in zirconium, and (*b*) although a spectrum of fission fragment energies exists in the incident particle flux on the specimen, 10^5 displacements occurred for each 80 Mev of energy in these particles.

The volume of zirconium considered for this comparison was 2 x 10^{19} atoms/cm^2 or a thickness of about 60% of the maximum range of recoils in zirconium. Calculations indicate that the potential damage rate by recoils could have been 2 x 10^{13} zirconium atoms displaced/cm^2-sec. The data of Kinchin and Pease (11) were employed to find a fast neutron flux which could approximate this rate of damage. They estimated that, after exposing copper to an integrated neutron dose of 10^{19} $(nvt)_{fast}$, about 10% of these atoms are displaced. Assuming these estimates apply also to zirconium, it was found, by proportion, that a fast neutron flux of about 2 x 10^{14} nv would cause an atomic displacement rate equivalent to that for the estimated fission recoil intensity.

The actual flux of neutrons with energies greater than 2 Mev was approximately 10^{11} nv for these experiments, about 10% of the thermal flux. Thus the probable rate of production of atomic displacements by neutrons in this experiment was about a factor of 10^2-10^3 less than that due to fission recoils.

Results

At the conclusion of each run, the zirconium specimens were studied by a number of techniques. Listed according to explicitness of result, these were microscopic examination of the surfaces at both high and low magnification using normal and

polarized light, low angle electron diffraction studies for possible identification of the structure of the oxide film on the surface seeing fission fragment recoils, study of surface topography of replicas of sample surfaces by electron microscopy, and visual comparison of surface interference colors. Weight change data were obtained also whenever possible.

Visually, almost a whole range of interference colors was seen on surfaces subject to recoils. All surfaces not subject to recoils had more uniformly colored surfaces. Figure 3 shows the scheme used to identify the various specimen surfaces. Unfortunately it is not possible to produce photographs which would show, satisfactorily, the detailed characteristics of the surface. However, some of the gross features are shown in Fig. 4, which compares the surfaces of specimens irradiated for two weeks in-pile with a source to those irradiated one week in-pile without a source, an out-of-pile oxidized specimen and a chemically polished specimen.

Microscopic examination of the specimens under bright field illumination showed a consistent difference between those surfaces facing the fission fragment source and those exposed to neutron flux only. As shown in Fig. 5, the recoil effects were particularly evident on comparison of the protected edge (due to the shoulder of a metal ring holding the specimen in place) and the unprotected center of the test specimen surface facing the source. Assuming the blue blotches appearing at the shielded edge result from first order interference, it was possible to observe the entire second order interference color band and finally a mixture of gold and red-purple of third order on the main surface. The oxide thickness of the directly exposed area was estimated (9) to be 2500-3000Å.

No other surface exhibited this feature along its periphery. The opposite surface of the test specimen was a uniform yellow field intermixed with blue and reddish purple (1500-1600Å). Test sample surfaces of run Z-7, which involved no recoils, had a uniform array of similar interference colors while run Z-9, which was out-of-pile, had a blue field with light yellow and purple spots (700-800Å).

Microscopic examination of the specimens under polarized light showed pronounced differences between surfaces that were exposed to fission fragment recoils and all other surfaces examined. Only the surfaces seeing recoils were inactive to polarized light. All of the other specimen surfaces, when examined, were responsive to polarized light as the specimen was rotated 180°. Figure 6 shows again the periphery of the same surface exposed to fission fragment recoils as in Fig. 5, but this time under polarized light. A line of demarcation divides the surface into two distinct regions: the featureless region corresponds to the surface area that saw fission fragment recoils while the contrasting region is the surface area that was shielded from recoils by the metal ring holder. Figure 7 is a picture of the opposite surface of the same specimen. Here, resolvable areas are uniformly distributed over the whole surface area exactly as under the shielded edge in Fig. 6.

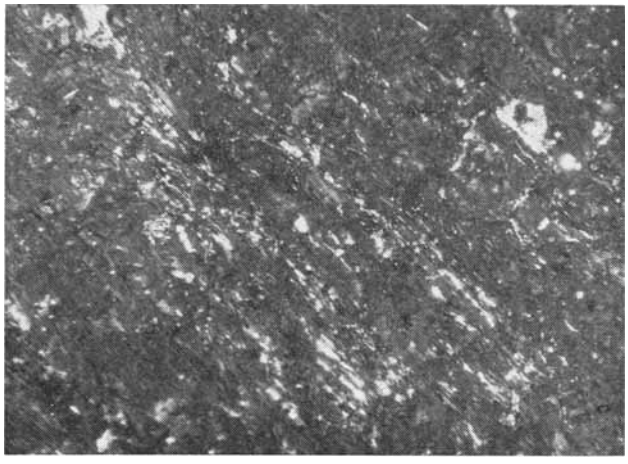

Fig. 7. Periphery of zirconium test specimen surface opposite to side seeing fission fragment recoils (exposed in neutron flux only), polarized light.

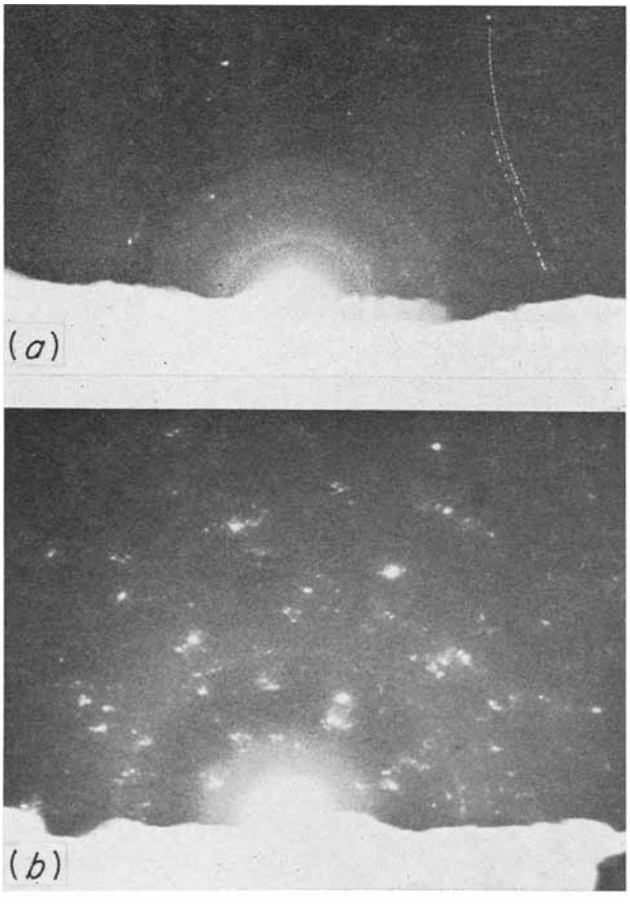

Fig. 8. Low angle electron diffraction patterns of each surface of a zirconium test specimen: (a) surface facing fission fragment recoil surface; (b) surface opposite to side facing fission fragment recoil surface.

Low angle electron diffraction patterns of the side exposed to fission fragment recoils appeared to be composed of very diffuse rings. In contrast, the opposite surface showed a pattern of a relatively large number of spotty rings. The two types of patterns described are shown in Fig. 8.

Palladium shadowed carbon replicas were made of the surfaces of all specimens used in this series of experiments. Fifteen areas were photographed on the surfaces seeing fission fragment recoils. These electron micrographs in all but two cases indicated a rough mottled surface, an example of which is shown in Fig. 9. The size of the mounds seen in the figure was in the order of 0.5μ. The surfaces not seeing fission fragment recoils were consistently much smoother as shown in Fig. 10. The size of the pebbles observed was about an order of magnitude smaller than the mounds seen in Fig. 9.

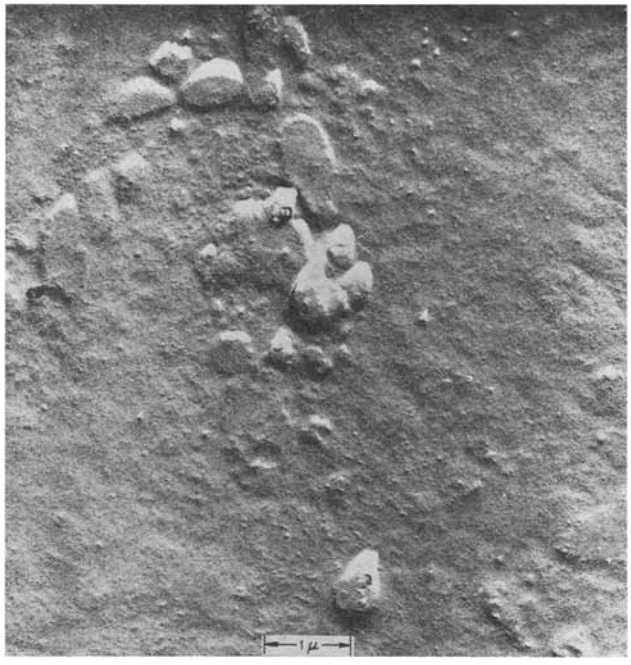

Fig. 9. Surface of zirconium test specimen exposed to fission fragment recoils (Pd shadowed carbon replica).

Unfortunately it was not possible to obtain weight change data on all of the samples. From the data available, however, it was possible to observe a trend which was not inconsistent with the other results. For the single experiment exposed in-pile for two weeks, the weight gain of the test and control sample was 0.10 and 0.11 mg, respectively. For the single experiment run out-of-pile for two weeks, the corresponding increases in sample weights were 0.02 and 0.04 mg, respectively. A comparison of these data indicate that (*a*) the weight gain of the in-pile samples was significantly greater than the out-of-pile samples, and (*b*) both samples of the in-pile experiment gained about the same amount of weight.

The latter observation suggests that the fission fragment recoils had no effect on the weight gains. However, it was observed that the control sample was at 265°C which compares to 250°C for the test sample. Thus, it is possible that a fission recoil effect was masked by the difference in temperature.

Sample surface studies under bright field illumination of the two week in-pile experiment lend support to this possibility. As estimated from observed interference colors, the test sample surface exposed to fission fragments had an oxide film thickness of about twice (2500-3000Å) that of the unexposed surface (1500-1600Å), while both surfaces of the control sample had about the same film thickness (2100-2200Å). The calculated weight gains, equivalent to the estimated oxide thicknesses, were

Fig. 10. Surface of zirconium test specimen opposite to side seeing fission fragment recoils (exposed in neutron flux only; Pd shadowed carbon replica).

found to be about 0.07-0.09 mg for both the test and control samples, which compares favorably with the corresponding measured weight gains.

Discussion and Conclusions

Polarized light and electron microscopy studies show that surfaces exposed to fission fragments either (*a*) had undergone a phase transformation or (*b*) had developed a fine particle size. Based on recently published information, the authors are more inclined toward the first possibility. Wittels and Sherrill (12, 13) have found that pure monoclinic ZrO_2 is stable to an integrated neutron flux of $\sim 10^{20}$ $(nvt)_{fast}$, but transforms to the cubic phase under the action of fission fragments at a rate of $\sim 10^{8}$ transformations per fission recoil. Adam and Cox (14, 15) have reported that the oxide on certain alloys of zirconium exposed to 10^{19} $(nvt)_{fast}$ will either partially or completely change to the cubic phase when there is uranium impurity in the presence of fission fragments. Based on the data of Wittels and Sherrill, the exposure time for the zirconium specimens ($\sim 10^{6}$ sec) was $\sim 10^{2}$ sec greater than that needed for complete transformation of the oxide to the cubic phase. This estimate assumes a fission fragment intensity of 6×10^{8} particles/cm^2-sec and an oxide film thckness of about 4000Å or less. An appreciable transformation would also be expected on the basis of the findings of Dawson *et al.* (4) for oxide on a Zr-5% V alloy under fission recoil irradiation.

Although retaining their optical activity to polarized light, surfaces exposed to reactor radiation, but not to fission fragments, appeared to have an oxide thickness intermediate between that formed on surfaces oxidized out-of-pile and surfaces exposed to recoils. Film thickness estimates, based on interference colors, in radiation run Z-8 and out-of-pile run Z-9 are typical of the data obtained. For run Z-8, the test sample surface, controlled at 250°C and not exposed to recoils, had an oxide thickness of 1500-1600Å. This is a factor of about two greater than that observed on out-of-pile oxidized surfaces (700-800Å) and a factor of two less than surfaces exposed to recoils (2500-3000Å). Irradiated control specimens in run Z-8, operating at 265°C, had an oxide thickness of 2100-2200Å, about a factor of two greater than corresponding specimens oxidized out-of-pile (1100Å). Thus it appears that test sample surfaces exposed to recoils had an oxide film three to four times as thick as the corresponding out-of-pile test sample, but only twice as thick as surfaces exposed to reactor radiation only. The corrosion of the surface exposed to recoils, as indicated by the oxide thickness, was at least a factor of ten less than that expected in uranyl sulfate solution at the same recoil intensity as that assumed in this report (this is equivalent to a solution fission power density of about 12 watts/ml) (2).

There is evidence that some oxide was lost from the recoil irradiated surfaces and, as a consequence, the actual corrosion may have been greater than that estimated from oxide thicknesses and sample weights. This is based on a subsequent experiment, not reported here, in which zirconium samples were irradiated for one week at 300°C in the presence of a fission recoil source. Spectrographic analysis of surface scrapings from the exposed source gave qualitative evidence of zirconium being present. Unfortunately, surfaces of the sources reported in this paper were not analyzed for the presence of zirconium. Hence, the magnitude of an error that might be introduced in this way is not known.

From the experimental results and the above discussion the following conclusions can be stated:

1. The oxide film of the surfaces that saw fission fragment recoils did not show optical anisotropy as determined by examination under polarized light with the microscope employed (750X). This indicates that these oxide films either underwent a phase transformation or developed randomly oriented grains of a size too small to resolve the optical activity with an optical microscope. All other oxide surfaces remained highly oriented and showed resolvable areas of optically active oxide.

2. The low angle electron diffraction study revealed that the surface subjected to recoil bombardment had a structure which produced a diffuse ring pattern while the opposite surface, exposed to a neutron flux only, produced a pattern of relatively large numbers of spotty rings. Since the diffuse rings could not be interpreted in terms of a crystal structure, it is not possible to state whether or not the fine particles are those of a transformed oxide or merely fine particles of the normal oxide.

3. It was found from interference color-oxide thickness estimates and a limited amount of weight gain data that the oxide film of surfaces exposed to fission fragments was thicker than surfaces exposed to reactor radiation in the absence of fission fragments. In turn, the oxide film of these latter

surfaces was thicker than surfaces oxidized out-of-pile. Thus it is concluded that fission fragment recoils do, in fact, have an effect on the oxidation rate. However, the amount of corrosion as indicated by the oxide thickness and weight data was at least a factor of ten less than that expected in a solution of uranyl sulfate producing an equivalent recoil intensity.

4. The electron micrographs gave evidence of a difference in the surface that had been subjected to recoil bombardment. Most of the photographs of these surfaces showed mounds on the surface in the order of 0.5μ in size. In comparison, most of the other surfaces that were either in a neutron flux or were oxidized out of radiation revealed a pebbly surface with the size of each pebble being about an order of magnitude smaller than the mounds.

5. The data obtained do not provide sufficient information to establish the mechanism of the effects of fission fragment recoils on the oxidation of zirconium.

6. The experimental technique that has been developed is one which can be effectively used to study the fission fragment recoil effects on other metals or alloys.

Acknowledgment

The authors wish to express their appreciation to J. V. Cathcart and M. L. Picklesimer for the helpful discussions on the interpretation of the results; to E. L. Long, Jr. and W. H. Bridges and their groups for the detailed optical and electron microscopy studies of the specimen surfaces; and to A. R. Olsen and his group for the remote disassembly of each radioactive experiment.

Oxidation of Zirconium and Zirconium-Oxygen Alloys at 800°C

K. Östhagen and P. Kofstad

Central Institute for Industrial Research, Blindern, Oslo, Norway

ABSTRACT

Oxidation of zirconium and zirconium-oxygen alloys in oxygen at 800°C has been studied. The studies include gravimetric oxidation rate measurements and metallographic and x-ray diffraction studies of oxidized specimens. The initial oxidation conforms with an approximate cubic oxidation rate, after which a breakaway oxidation is observed. The initial cubic period becomes shorter and the rate of breakaway oxidation becomes faster with increasing oxygen concentration up to 12-15 at. % oxygen. The oxidation is interpreted in terms of simultaneous oxide formation and oxygen dissolution in the metal.

Oxidation of zirconium constitutes oxide scale formation and oxygen dissolution in the metal (1-9). In the temperature range 300°-900°C the rate data of the initial oxidation of zirconium in oxygen appear to be best fitted by an approximately cubic oxidation rate (3, 5, 8). After an initial period, alterations in the kinetics have been observed, and for alloys this has in many cases been found to result in a "breakaway" oxidation (7, 8). This change in kinetics has been suggested to be a result of a mechanical breakdown of the scale, a change in ZrO_2 modification or to be associated with the oxygen dissolution in the metal. So far no clear correlation appears to have been established. In general there appears to be no satisfactory interpretation of the oxidation mechanism of zirconium.

Oxidation of metals which may dissolve relatively large amounts of oxygen appear to have several fea-

tures in common (7, 9-12). Depending on the temperature the oxidation of titanium, niobium, and tantalum involves initial stages which are to a large extent associated with oxygen dissolution in the metal. These initial stages are followed by a more rapid rate of oxidation, a "breakaway" oxidation, which primarily involves heavy oxide formation (9-12). For titanium the change in kinetics has been found to take place when the oxygen concentration in an outer layer of the metal reaches a composition of approximately $TiO_{0.85}$ (11). It does not appear unreasonable that similar considerations may apply for zirconium. At any rate, for an understanding of the oxidation mechanism of zirconium the relative importance of and the interplay between oxide formation and oxygen dissolution have to be considered. In the present work the effect of dissolved oxygen on the oxidation of zirconium at 800°C has been studied.

Materials and Methods

Zirconium metal in the form of rolled plates of 0.5 mm thickness was obtained from Johnson, Matthey & Co. Ltd., England. Spectrographic analysis of impurities gave the following estimates of metallic impurities: Al, 0.01%; Mn, Pb, Si, Mg, and Fe, each 0.001%. Neutron activation analysis showed that 2.4% Hf was also present in the material. Metallographic examinations of the as-received material indicated zirconium carbide inclusions in the metal. No analysis was made of the carbon content or of gaseous impurities in the metal. The hardness of the as-received cold-rolled plates was 197 VHN (10 kg).

The zirconium metal was cut into specimens with dimensions 10 x 20 x 0.5 mm. Specimens with varying concentrations of oxygen were prepared by oxidation at 1200°C at oxygen pressures $<10^{-1}$ torr and with subsequent high-vacuum anneal at 1200°C in high vacuum for 18 hr. Microhardness indentation studies indicated no oxygen gradient in the specimens after this treatment. The zirconium was oxidized in commercial oxygen dried over phosphorus pentoxide.

The rate of oxidation was measured gravimetrically by means of a quartz helix type apparatus. Prior to start of each run the apparatus was evacuated overnight to a pressure of 10^{-5} torr. A more detailed description of both the apparatus and the procedure employed has been given elsewhere (13).

Experimental Results

Oxidation rate measurements.—The results of oxidation of as-received zirconium at 800°C in oxygen at atmospheric pressure are shown in Fig. 1, where the weight gain is plotted *vs.* time and $(\text{time})^{1/3}$. As seen, the oxidation conforms with an approximate cubic rate during the first 300 min, after which an increase in the rate of oxidation is observed. Annealing of the as-received material in high-vacuum at 1200°C for 1 hr did not change the kinetics of the oxidation. The results were reproducible to within 5%.

Zirconium specimens containing from 2 to 17 at. % oxygen were oxidized under the same conditions. The results of these studies are shown in Fig. 2 where the weight gain is plotted as a function of time. During the very initial oxidation all specimens oxidized at approximately the same rate. In later stages, however, the rate of oxidation increased with increasing oxygen concentration. Above approximately 12-15 at. % oxygen there was no increase in oxidation rate with oxygen concentration. Furthermore, the time period until the transition to a faster breakaway oxidation became shorter with increasing oxygen concentration.

X-ray diffraction and metallographic studies of oxidized specimens.—X-ray diffraction studies of the oxide scale after various lengths of oxidation showed that the oxide in all cases consisted of monoclinic ZrO_2. Micrographs of metallographic cross sections of oxidized specimens of unalloyed zirconium suggested the presence of a single oxide layer on the surface. During initial periods the oxide scale had an even thickness, while with increased oxidation a more uneven attack of the metal surface was observed. The results suggest a more localized oxidation associated

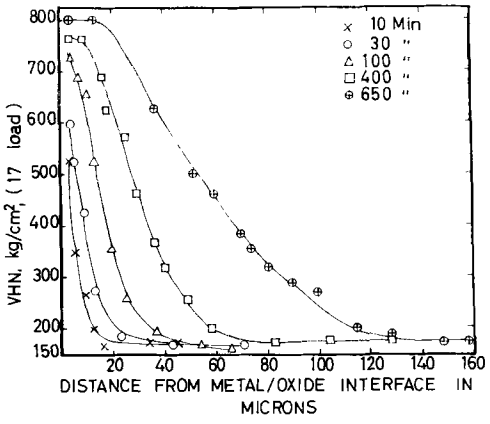

Fig. 3. Microindentation hardness studies on zirconium specimens oxidized for various lengths of time at 800°C and 1 atm oxygen.

with the individual grains in the metal. In addition the micrographs also showed evidence of an oxygen-enriched zone in the metal beneath the surface oxide.

Microindentation hardness studies on specimens of unalloyed zirconium oxidized for various lengths of time clearly showed an increased oxygen penetration into the metal with time. These measurements are shown in Fig. 3. Assuming that the hardness increases with increasing oxygen concentration, the results suggest that the oxygen in an outer layer of the metal reaches a "saturation" value.

Examinations of metallographic cross sections of oxidized zirconium-oxygen alloy specimens showed an uneven oxidation of the metal surface after the breakaway oxidation. Specimens containing relatively large concentrations of oxygen also exhibited an appreciable grain growth during oxidation.

Discussion

The present results confirm that the oxidation of zirconium involves both oxygen dissolution and oxide scale formation. Furthermore, the rate and kinetics of oxidation have been shown to be greatly dependent on the oxygen concentration in the metal.

From the present study it is difficult to calculate accurately the relative importance of oxygen dissolution in the metal. Estimates of the oxide thickness from metallographic cross sections suggest that approximately 10 and 20% of the reacted oxygen has dissolved in the zirconium metal after 100 and 300 min of oxidation, respectively.

Assuming a diffusion-controlled oxygen dissolution in the metal, an estimate of the amount of dissolved oxygen may also be made from the diffusion coefficient and the appropriate diffusion equation (22). Taking $D = 5.2 \exp(-51000/RT)$ (6) and assuming the oxygen concentration in the metal at the surface to be 29 at. % (solubility limit), the amount of dissolved oxygen after 300 min at 800°C is calculated to about 1 mg/cm². As seen from Fig. 1 this is about 25% of the observed weight gain. The calculation of course neglects oxide scale formation.

The results clearly suggest that the cubic oxidation rate reflects a combined result of oxygen dissolution and oxide scale formation. A resultant, approximate cubic oxidation may be a result of two-part processes obeying approximate logarithmic and parabolic time dependences, respectively. However, at present any considerations of the mechanism of the cubic oxidation may be only speculative due to the lack of detailed knowledge as to the part processes and their interplay. It is commonly assumed, possibly partly by analogy with TiO_2, that ZrO_2 is an n-type semiconductor and that its defect structure involves oxygen vacancies (3, 14, 15). However, the only studies known to the authors of the electrical conductivity of ZrO_2 as a function of oxygen pressure at high temperature (900°-1000°C) show that the electrical conductivity is approximately proportional to $p_{O_2}^{+1/5.2}$ (16). This relationship suggests that ZrO_2 is a p-type conductor and possibly that the defect structure involves interstitial oxygen ions.

With regard to oxygen dissolution in the metal, studies of oxygen diffusion in zirconium indicate that grain boundary diffusion predominates at 800°C and lower temperature (17), and that volume diffusion only becomes appreciable at about 1000°C. Grain boundary diffusion would result in a different time dependence than for the parabolic volume diffusion. According to Fisher's (18) model for grain boundary diffusion, the amount of oxygen dissolved would in this case be proportional to $t^{1/4}$.

From the above considerations it is evident that further studies of the relative importance and interplay of oxygen dissolution and oxide formation and studies of the defect structures of ZrO_2 are needed for an elucidation of the mechanism of the cubic oxidation of zirconium.

Studies of oxidation of zirconium and zirconium alloys by Porte *et al.* (8) indicate no change to a faster oxidation rate during the initial 400 min of oxidation at 800°C and an oxygen pressure of 200 torr. In the present case such a change is observed after approximately 300 min of oxidation. This may possibly be affected by presence of carbon impurities, as such have been shown to increase the tendency for breakaway oxidation (8). However, the present results also clearly demonstrate the effect of dissolved oxygen on the oxidation behavior of zirconium. The rate of oxidation is found to increase with increasing oxygen content up to 12-15 at. % above which no further increase in oxidation rate is observed. Furthermore, the time periods until the change in kinetics become shorter with increasing oxygen content up to 12-15 at. %.

If one assumes, as is suggested for titanium (11), that heavy oxide formation (breakaway oxidation) begins to take place after the oxygen concentration in an outer layer of the metal reaches a "saturation" value, the time lag until the change in kinetics occurs will be shorter the higher the oxygen concentration in the starting material. This is in accord with the present results. The fact that the time lag decreases until the oxygen concentration of the Zr-O alloys reaches 12-15 at. % may suggest that the "saturation" limit corresponds to this concentration range. Zirconium may dissolve up to 29 at. % oxygen, and it is not altogether clear why the "'saturation" value does not correspond to this solubility limit. A possible explanation may be that relatively large structural changes take place in zirconium-oxygen solid solutions at concentration of oxygen of 12-15 at. %. Such changes may affect the rate of oxygen dissolu-

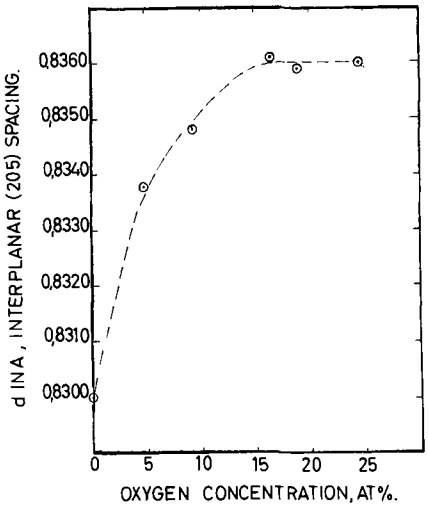

Fig. 4. The d-value of the interplanar (205) spacing as a function of oxygen content in zirconium-oxygen solid solutions.

tion, and further dissolution of oxygen may lead to large stresses and strains which partly results in cracking of this layer, and with a subsequent more rapid oxidation. Titanium solid solutions corresponding to approximately Ti_6O (14.3 at. % oxygen) have been found remarkably volatile possibly because of the relative large stability of individual Ti_6O octahedra (19-21). Corresponding effects may be found in zirconium-oxygen solid solutions. To study this, samples of zirconium oxygen-solid solutions were prepared by argon arc melting of mixtures of Zr and ZrO_2 and subsequently studied by x-ray diffraction. The results are given in Fig. 4, which shows the interplanar (205) spacing as a function of oxygen concentration. As seen, a transition in the effect of the oxygen content on the interplanar spacing is at approximately 15 at. % oxygen, in agreement with the arguments presented above.

The increased rate of oxidation with oxygen content is suggested to reflect a competition and interplay between oxygen dissolution and oxide formation. As proposed for oxidation of titanium, niobium, and tantalum (10-12), the rate of oxide formation is suggested to be governed by the rate of nucleation and rate of growth of oxide nuclei during breakaway oxidation.

An additional or alternative interpretation may be made in terms of considerations of the zirconium-oxygen phase diagram (23). Zirconium-oxygen alloys prepared at 1200°C containing less than 4 at. % oxygen will be homogeneous beta alloys; alloys containing between 4 and 12 at. % are in the alpha-plus-beta region; and alloys above 12 at. % are homogeneous solid solutions of the alpha alloy. The rapid increase in the oxidation rate in the region between 4 and 5 at. % may be due to the presence of grains of alpha alloy. Alloys above 12 at. % oxygen consist entirely of alpha alloy and this may give rise to an apparent "saturation" limit. Metallographic studies of oxidized alloy specimens showed a mixture of two phases up to about 10 at. % oxygen, while above this value only one phase was observed.

The present study clearly establishes the great importance of oxygen dissolution and dissolved oxygen on the oxidation of zirconium. For an elucidation of the mechanism of oxidation of zirconium further studies of the relative importance and interplay between oxide formation and oxygen dissolution are needed. This will form the subject of future studies of oxidation of zirconium in this laboratory.

Solution and Diffusion of Corrosion Oxide Film in Zircaloy

R. M. Treco

United Nuclear Corporation, New Haven, Connecticut

ABSTRACT

In Zircaloy-2 processing, an oxide surface film is formed during the water corrosion test. Removal by vacuum annealing is an economical and rapid method. The effects of heating on the distribution of oxygen in the Zircaloy were reviewed, and it is shown that subsequent pickling is desirable to remove the surface layer of diffused oxygen.

During the fabrication of Zircaloy-2 for reactor cores, a corrosion test is required which forms a black oxide film on the surface. Since the Zircaloy-2 is further processed, it becomes necessary to remove the tightly adherent film. The oxide film is not readily removed by the usual chemical methods, and its elimination poses a problem.

One method which has been used successfully has been to anneal at a sufficiently high temperature to dissolve the oxide film in the Zircaloy. This method is most desirable from the economic standpoint since it involves few processing steps and the annealing treatment involved is required for other reasons as well. Removal of the film by annealing has been objected to because the dissolved oxygen adversely affects the mechanical properties, particularly in relation to surface crack susceptibility. However, it is usual to pickle the surface at a subsequent step of the process, and this has been thought sufficient to remove most of the dissolved oxygen. Pickling removes from 0.001 to 0.002 in. of the surface. A second method of removing the film is mechanical, involving sand or vapor blasting. This method has the disadvantages that the thin film is difficult to remove evenly thereby maintaining the dimensional tolerance requirements, and it is an additional step requiring additional equipment.

Since experimental data were available for the purpose, an analysis has also been made of the contribution of the corrosion film in adding oxygen to the Zircaloy. A further analysis has been made of the annealing process and its effect on the oxygen concentration in the Zircaloy-2. The losses due to these processes have been compared with the losses due to pickling.

Zirconium Oxide Corrosion Film Formation

The rate of oxide film formation on Zircaloy-2 has been well established. For the case involved, namely, 3 days in 680°F water, the weight gain in mg/dm^2 is found from the equation,

$$\log \Delta m = 0.76 + 0.38 \log t \qquad [1]$$

where t is in days. Thus the weight gain in 3 days at 680°F is 8.7 or 9 mg/dm^2. Corresponding values are 15.7 mg/dm^2 for 14 days at 680°F and 29.3 mg/dm^2 for 14 days in 750°F steam.

The oxide film consists of monoclinic zirconium oxide ZrO_2, having a density of 5.6 g/cc and consisting of 26 w/o oxygen. From this it is easily shown that a weight gain after 3 days of 0.09 mg/cm^2 is equivalent to a film thickness on one surface of the Zircaloy of 62 x 10^{-6} cm or 24 x 10^{-6} in. The corrosion film thickness is based on the assumption that all of the oxygen weight gain stays on the surface, an assumption which is shown to be justified in a later section where the diffusion rate of oxygen in the corrosion test is examined.

Diffusion Constants for Oxygen in Alpha Zirconium

To study the effect of surface oxide solution, it is necessary to establish the diffusion rate of oxygen in alpha zirconium. Experimental work has established three separate equations for the diffusion of oxygen in zirconium as a function of temperature.
These equations are summarized below.

1. Pemsler (3), for the temperature range, T = 400° — 585°C:

$$D = 9.4 \exp (-51{,}780 \pm 220/RT) \qquad [2]$$

2. Misch (2), for the temperature range, T = 450° — 600°C:

$$D = A \exp (-43{,}500/RT) \qquad [3]$$

3. Mallett, Albrecht, and Wilson (4) for the temperature range, T = 1000° — 1500°C:

$$D = 0.196 \exp (-41{,}000 \pm 1500/RT) \qquad [4]$$

where D is the diffusion constant in cm^2/sec, R the universal gas constant, and T the temperature in degrees Kelvin. Of the three values given, the first two, those of Pemsler and Misch, were determined by studies of the dissolution rate of the oxide in the metal. The third equation was determined as a study of the rate of diffusion of oxygen in alpha and beta zirconium in the alpha solid solution range of the phase diagram. It will be apparent that the activation energies given by Eq. [3] and [4] are in reasonably good agreement and somewhat lower than the value determined by Pemsler (Eq. [2]). Despite this fact there appears to be little significant difference in the choice of the diffusion equation. Since Misch did not put his values in the form of a specific diffusion constant, the values of Pemsler and Mallet *et al.* were used. The temperature of interest for film dissolution in this study is 750°C, a temperature not covered specifically by either of these investigators. It was therefore necessary to extrapolate upward in the case of the Eq. [2] constant and downward in the

case of Eq. [4]. A comparison of the two values at 750°C shows that, if the higher limit of activation energy is used in Eq. [4], the diffusion rate from this relation will be in the ratio of approximately 2 to 1 to the diffusion constant according to the Pemsler relation. Thus the respective values for the diffusion constant at 750°C are D (Eq. [2]) = 8.07×10^{-11} and D (Eq. [4]) = 16.42×10^{-11} cm²/sec. In determining the oxygen gradient as a function of time during the 750°C anneal, an average value for the diffusion constant based on Eq. [2] and [4] was used, as follows:

$$D_{ave} = 12.24 \times 10^{-11} \text{ cm}^2/\text{sec} \quad (T = 750°\text{C})$$

In considering diffusion at temperatures lower than 585°C the Pemsler values were used. In particular, for the corrosion temperature of 680°F (360°C), the diffusion constant according to Eq. [2] is equal to 11.41×10^{-18} cm²/sec.

All values of the diffusion constant have been determined for oxygen in zirconium. It is assumed that the same values may be applied to Zircaloy-2 without substantially altering the conclusions, since it is known that oxygen reactions with Zircaloy-2 are almost identical with those of zirconium.

Solution of Corrosion Film in Zircaloy-2

Quantity of Oxygen.—From Eq. [1] it was shown that the weight gain in corrosion after 3 days at 680°F in water is 0.09 mg/cm². It is interesting to calculate the thickness of the oxide film from the oxygen weight gain and the following relation:

$$L = \frac{\Delta m}{(\rho \times \text{w/o } O_2)_{ZrO_2}} \qquad [5]$$

where Δm is weight gain in mg/dm² and ρ the density of ZrO_2 in mg/dm³. From this it can be shown that the thickness of the film is equivalent to 6180Å or 24.3×10^{-6} in. In view of the small value of L, the diffusion calculations have been made with no allowance for film thickness in the penetration curve.

If the entire weight gain of the oxygen in the film were to be dissolved and diffused uniformly throughout the Zircaloy-2, it would increase the average oxygen concentration by 270 ppm. Since the average oxygen level in wrought Zircaloy is approximately 1000 ppm, the total oxygen becomes about 1300 ppm. However, the oxygen does not diffuse in this way under normal conditions, and it is necessary to consider further, not the over-all average oxygen, but the maximum concentration at any particular point in the Zircaloy. In other words, it is necessary to examine the diffusion penetration curve.

Diffusion penetration during corrosion.—The possibility of oxygen diffusion from the film during the time of the corrosion test must be considered since, if the additional oxygen supplied by the film diffuses inward appreciably, it will have an effect on the concentration gradient after annealing. To examine this effect the Pemsler diffusion constant value was used rather than the average constant used at higher temperatures. Referring to Fig. 1, we have a representative diagram of the cross section of a corrosion coupon showing the ZrO_2 film. Since the diffusion constant does not take into account the physical phenomena involved in the dissociation of ZrO_2 which

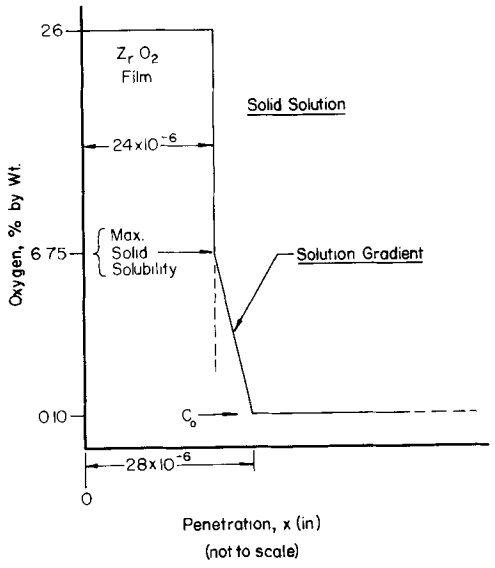

Fig. 1. Distribution of oxygen in Zircaloy-2 after 3 days in 680°F water.

supplies oxygen atoms for diffusion, the oxygen differential which is the driving force for the diffusion, *i.e.*, the boundary conditions, must be established. The maximum concentration of oxygen C_s is the maximum solid solubility of oxygen in Zircaloy and is equal to 6.75 w/o. Initial oxygen content C_o was taken equal to 1000 ppm, corrosion conditions are 3 days at 680°F (360°C), and the diffusion constant for this temperature equals 11.41×10^{-18} cm²/sec. Under these conditions the expression for concentration *vs.* distance penetrated is given by Darken and Gurry as

$$(C - C_o)/(C_s - C_o) = 1 - \text{erf } (X/2\sqrt{Dt}) \qquad [6]$$

where C is O_2 concentration after time t, C_o is initial concentration of O_2, C_s is max solid solubility of O_2 in Zircaloy-2, erf is error function, D is diffusion constant, t is time (sec), and X is penetration (in.). In this case it is sufficient to determine the depth of penetration at which the oxygen concentration is reduced to the initial level of the material. From Eq. [6] it can be shown that the quantity $(X/2\sqrt{Dt})$ equals 6.0, from which the penetration, X, can be calculated as 4.05×10^{-6} in. This amount of penetration is negligible and is therefore ignored in the later calculation of diffusion during the annealing at 750°C. Figure 1 shows the distribution of oxygen after the corrosion test.

Solution of the corrosion film.—The time required for complete solution of the film is obtained by using the proper boundary conditions in the following relation adapted from Barrer:

$$C_f - C_o = \frac{Q}{(\sqrt{\pi D_T t})\rho_{solv}} \quad \text{for } X = 0 \qquad [7]$$

To determine the time required for the film to be completely dissolved and uniformly distributed throughout the Zircaloy-2, the boundary conditions are:

$$C_f = 1270 \text{ ppm}$$
$$C_o = 1000 \text{ ppm}$$
$$Q = 9 \times 10^{-5} \text{ g/cm}^2$$
$$D_T = (D_{ave})\ 750°\text{C} = 12.24 \times 10^{-11} \text{ cm}^2/\text{sec}$$
$$\rho_{solv} = 6.55 \text{ g/cc}$$

Substituting and rearranging,

$$t = \frac{(9 \times 10^{-5})^2}{\pi(12.24\times10^{-11})[(1270-1000)(10^{-6})]^2(6.55)^2}$$

from which $t = 1.87 \times 10^2$ hr $= 7.8$ days. It is apparent that this time is much too long to be economical. It is therefore of more significance to determine the annealing time required to make the corrosion film just disappear from the surface. In this case, and using the same relation, the boundary conditions are $C_f = 0.0675$ (*i.e.*, maximum solid solubility) and $C_o = 1000$ ppm as before. Substituting in Eq. [7] and solving, the time required for the oxide film to just disappear is 0.03 hr or 1.8 min. Laboratory tests under ideal conditions have confirmed that this short time is correct for film disappearance. Since this time is shorter than the normal process anneal of 4 hr, it is apparent that further diffusion of the oxygen will take place. However, if only film disappearance is required, an anneal of 20-30 min is indicated.

Diffusion penetration during process anneal.—As noted previously, a common process anneal is 4 hr at 750°C *in vacuo*. During this annealing the oxide film disappears from the surface of the Zircaloy and is distributed by diffusion. The distribution of oxygen after the 4-hr anneal requires that the diffusion equation be solved for the condition where the surface concentration does not remain constant, but decreases with time. The following equation has been adapted from Barrer to fit the conditions for Zircaloy-2 during annealing and the appropriate boundary conditions:

$$C - C_o = \left(\frac{Q}{\rho_{solv}\sqrt{\pi D_T t}}\right) \exp(-X^2/4D_T t) \quad [8]$$

where Q is the quantity of oxygen dissolving (g/cm^2),

$$\rho_{solv} = 6.55 \text{ g/cc}$$

$$D_T = (D_{ave})750°C = 12.24 \times 10^{-11} \text{ cm}^2/\text{sec}$$

t is time (sec), and X is penetration (cm). Substituting appropriate values, the concentration as a function of time and penetration at 750°C is then

$$C - C_o = \left(\frac{0.7}{\sqrt{X}}\right) \exp(-1.32 \times 10^{+10} X^2_{in}/t) \quad [9]$$

For an annealing time of 4 hr

$$C - C_o = 5.83 \times 10^{-3} \exp(-9.16 \times 10^{+5} X^2_{in.}) \quad [10]$$

Solving for $(C - C_o)$ from Eq. [10] for various appropriate values of X, results in the following values:

X, in.	C, ppm
0	6830
1.5×10^{-4}	6710
5.0×10^{-4}	5640
1.0×10^{-3}	3300
1.25×10^{-3}	2394
1.5×10^{-3}	1780
2.0×10^{-3}	1150
3.0×10^{-3}	1002
4.0×10^{-3}	1000

The diffusion gradient thus obtained has been plotted in Fig. 2 (solid curve). It is apparent that in order to reduce the surface oxygen to a value equivalent to that of the Zircaloy, it is necessary to remove

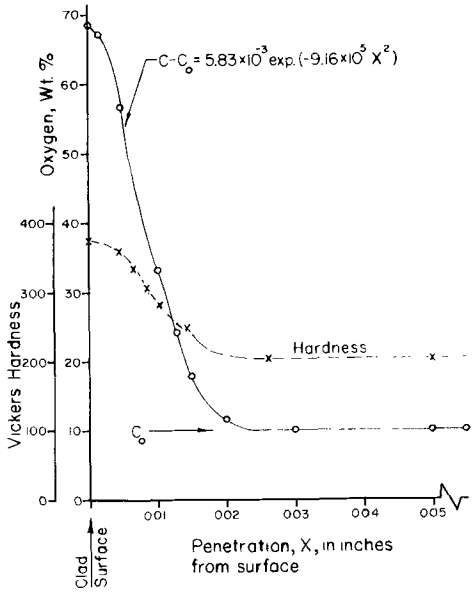

Fig. 2. Diffusion gradient after annealing 4.0 hr at 750°C

0.002 in. from the surface. If a lesser amount of metal is removed, it is then necessary to consider the effect of the residual surface oxygen on the Zircaloy properties. For example, if only 0.001 in. is removed, there will be approximately 0.33 w/o of oxygen in solution at the surface of the Zircaloy. However, it is apparent that all of the oxygen added by solution and diffusion of the 3-day corrosion film can be removed by pickling 0.002 in. from the surface.

Recorrosion Testing

Occasionally it becomes necessary to submit Zircaloy to a second corrosion test. In this case the Zircaloy must be prepared so as to have a clean surface for recorrosion testing. To do this, the initial corrosion film from the first test must be completely removed. While the film can be removed by mechanical means, it is often more convenient to dissolve the film by vacuum annealing as described above. A simple and obvious procedure for preparing the surface is to anneal the Zircaloy at 750°C for just the amount of time required to dissolve the film completely. It has been shown above that the dissolution time is 1.8 min at this temperature. Assuming that a 30-min anneal is used for convenience, we must consider how deep the oxygen penetrates in this time. Knowing the penetration, a decision can be made as to how much to pickle from the surface in order to restore the Zircaloy to its initial condition. To determine the concentration gradient curve, the same boundary conditions are used as those for the 4 hr anneal with the exception that the time is now reduced to 30 min. The diffusion equation is then

$$C - C_o = 0.0165 \exp(-7.33 \times 10^{+6} X^2) \quad [11]$$

where X is in inches. Values for total oxygen as a function of distance penetrated are shown below.

Penetration, X, in.	Total O_2, ppm
1×10^{-6}	17,500
1×10^{-5}	17,500
1×10^{-4}	16,350
5×10^{-4}	3,640
1×10^{-3}	1,011

The results of this calculation show that the total oxygen concentration is reduced to the residual value of the Zircaloy at a penetration of 0.001 in. It is therefore apparent that in order to restore the Zircaloy to its original condition after a 3-day, 680°F water corrosion test, the Zircaloy should be annealed *in vacuo* at 750°C for 30 min followed by a pickling operation to remove 0.001 in. per surface. This may be done as many times as required, subject to maintaining final dimensions. If less than 0.001 in. per surface is removed, consideration must be given to the retained oxygen. For example, removal of only 0.0005 in. per surface leaves approximately 3600 ppm at the surface in solution.

Conclusions

It has been shown above that the oxygen film accumulated during a 3-day, 680°F water test diffuses into the Zircaloy-2 during the process anneal at 750°C. The effect of this additional oxygen is primarily one of increasing hardness although other properties are also affected (8). The hardening effect of oxygen in Zircaloy-2 has been discussed by Rubenstein (9), and it can be shown that the Vickers hardness is a function of oxygen concentration as follows:

$$\text{VHN} = 333(\text{w/o O}_2)^{1/2} + 97.5 \qquad [12]$$

A hardness-penetration curve has been plotted from this relation in Fig. 2 (dashed line) from which it may be seen that the hardness is almost doubled at the surface after the 4-hr anneal. It is apparent that the removal of 0.0015-0.002 in. by pickling is sufficient to reduce the hardness to an acceptable level. Furthermore, the hardening effect is considerably reduced at elevated temperatures and in addition the notch sensitivity of Zircaloy-2 has been shown by fatigue tests to be very low. These factors substantiate the original assumptions that the Zircaloy is not damaged by the solution treatment to remove oxide if the surface is subsequently pickled.

Manuscript received Aug. 14, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

An Electron Optical Study of the Effect of Temperature and Environment on the Growth of Oxide Whiskers on Cold-Rolled and Annealed Copper

William R. Lasko and Warren K. Tice

Research Laboratories, United Aircraft Corporation, East Hartford, Connecticut

ABSTRACT

A systematic electron microscope study comparing the effect of temperature and environment on the formation of oxide crystal growths on high-purity, cold-rolled, and preannealed copper sheet is presented. Changes in size, shape, and rate of whisker growth in environments of dry air and oxygen occurred only during critical temperature intervals, clearly differentiating the phenomena of whisker-type growth from simple oxide film thickening. Whisker growth examinations of the preannealed copper specimens at some temperatures, both in air and oxygen, revealed increased whisker growth over that exhibited by specimens which were initially cold-rolled. Generally, the oxide crystal growths obtained on the preannealed material were longer and thinner than those observed on the preworked material.

In recent years a great deal of emphasis has been given to the propagation of oxide whiskers on metal surfaces (1-3). The formation of oxide whiskers is unique in itself, but still of greater interest is the relationship between whisker growth and metallic oxidation (4). The latter point of view has not received the attention it deserves in the past literature. This was one of the reasons for the comprehensive research effort undertaken to determine the effect of temperature and environment on the growth of oxide whiskers with particular attention being directed at determining the relationship between whisker growth and oxidation.

Despite the large amount of work performed (5-7) on the oxidation behavior of copper, little is still known at what critical temperatures oxide whisker growth is initiated in environments such as air and oxygen and the effect of these localized growths on

the kinetics of oxidation. Recent work by Gulbransen, Copan, and Andrew (8) has indicated that whisker growths, although of interest as a natural phenomena, do not have an appreciable effect on the oxidation kinetics. However, information is still lacking concerning the effects of deformation and subsequent annealing on the crystal nature of oxide whiskers and the correlation of these growth effects with current concepts on dislocation density changes during annealing. The purpose of this paper is to present the results of a careful and precise electron microscope investigation of the effects of temperature, treatment, and environment on the crystal habit of copper oxide whiskers. The ultimate goal is to arrive at a better understanding of the mechanism of whisker formation and its ultimate relationship to various metallurgical processes and phenomena such as cold-rolling, annealing, and oxidation.

Experimental Procedure

High-purity (99.999%) copper rod[1] was cold-rolled to a sheet thickness of 0.003 cm, and 0.3 cm disks with a V-slot were punched out using a special jig. The disks were slotted in order to make an area near the center of the disk which would be parallel to the electron beam so that the nature and shape of the outgrowths emanating from the slotted area could be directly observed. After punching, the V-slot disks were degreased, hand polished using conventional techniques, and immediately subjected to environmental study to avoid the buildup of contamination. Annealed specimens were prepared by heat treating the cleaned V-slotted disks in argon at 450°C for 4 hr. These are referred to as condition B specimens to differentiate them from the nonannealed (cold-rolled) or condition A specimens. This differentiation was made since it was realized that, once the specimens were exposed to temperature during growth, they could no longer be strictly referred to as cold-rolled or annealed.

Reaction environments studied included dry air and laboratory pure (99.995%) oxygen. The gases were passed through a drying chamber containing Drierite (anhydrous calcium sulfate) and glass wool prior to flowing over the samples supported in porcelain boats. A tubular furnace was designed and equipped with a chromel-alumel thermocouple element to monitor the temperature within ±2°C. A reaction time of 1 hr at 100°C intervals was employed for temperature ranges from 100° to 800°C.

The Hitachi HU-11 electron microscope was used to examine the surface growths. Normal bright-field images, using the 75-kv electron beam were taken at 3000X and enlarged optically to 6000X.[2] In specific instances, especially at the higher temperatures, where the growths were extensive, the magnification was reduced to accommodate the whole field. Specimens were examined in all phases of growth, but only selected micrographs necessary for clarity are illustrated.

Both x-ray and selected area diffraction techniques were applied to a number of the A and B specimens to determine changes in structure brought about by the environment. Under the conditions studied gross oxide formation (whiskers and base oxide) were identified by x-ray diffraction methods to be a mixture of $Cu_2O + CuO$, while selected area diffraction analysis of individual whiskers alone showed CuO. No differences in structure between the A and B specimens could be detected in either air or oxygen.

Whisker length measurements and density counts were taken from the original negatives of the various samples. Both determinations were made directly on the viewing glass window of a Jones and Lamson comparator by enlarging the negatives from 3000X to 30,000X employing a 10X objective. Whenever possible approximately 50 whiskers were measured to ensure obtaining a good statistical average. To aid in obtaining accurate whisker determinations, a grid network consisting of small squares was drawn on the comparator viewing window, and the ends and lengths of the whiskers located in each square for a designated vertical and horizontal area were counted and measured. As a further precautionary measure, to ensure obtaining counts and length measurements representing a random distribution of the whiskers, the determinations were made in arbitrary areas of the negatives for each of the samples.

Results

A summary of the observations which were made is presented in Table I. Since it is extremely difficult to describe quantitatively or measure each of the specimens with respect to such salient features as whisker shape, density, length, width, etc., particularly at the higher whisker densities, the descriptions given in Table I are semiquantitative estimations of the average whisker length and density for the conditions indicated. As a result, in the descriptions of the electron micrographs to follow, the discussions are confined primarily to revealing gross changes in growth rather than to describing particulars.

Table I. Summary of observations on whisker growth

Temp, °C	Condition*	Environment and time of exposure** Dry air—1 hr Fig. 1-2 Avg. density/cm²	Length-μ	Oxygen—1 hr Fig. 3-4 Avg. density/cm²	Length-μ

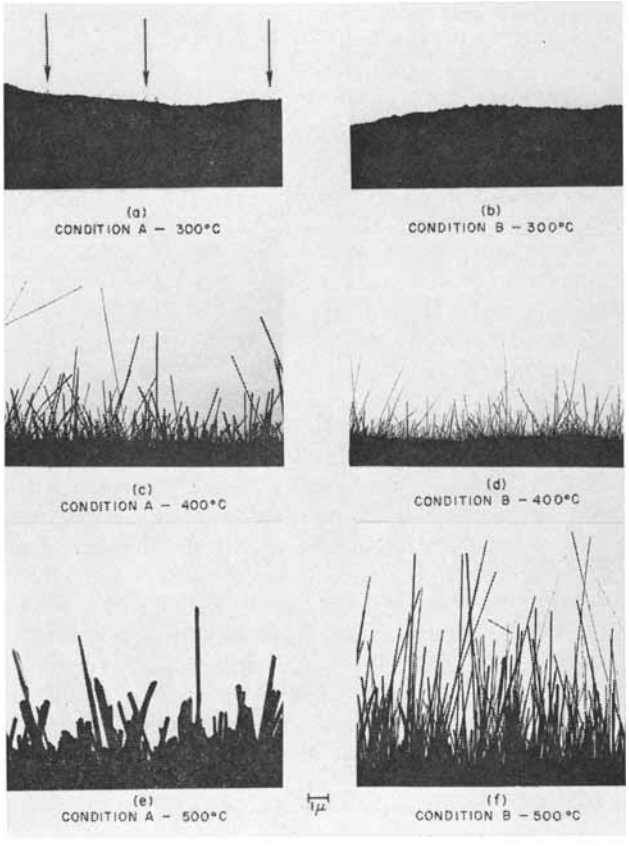

Fig. 1. Effect of temperature on the growth of oxide whiskers on pretreated copper in dry air. Magnification approx. 3000X.

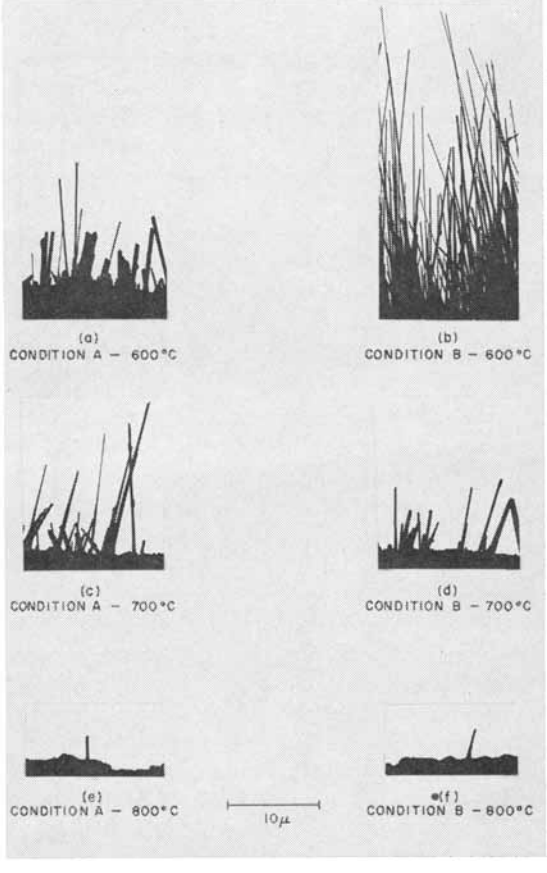

Fig. 2. Effect of temperature on the growth of oxide whiskers on pretreated copper in dry air. Magnification 1300X.

Dry air.—Some whisker-type growths (shown by arrows on Fig. 1a) were observed after exposure for 1 hr at 300°C for condition A (cold-rolled) specimens and at a slightly higher temperature for condition B (annealed) specimens. At higher temperatures more whiskers were formed on both the A and B specimens, but in general, thinner, longer and a higher density of whiskers formed on B specimens than on A specimens treated under identical conditions. Whisker growths reached a maximum at about 600°C. As the temperature was increased to 700°C, the differences in whisker growth between the pretreated specimens (cold-rolled and annealed) were less pronounced. At 800°C whisker growth had virtually ceased; no differences could be detected between the A and B specimens, but a general surface roughening had occurred.

Oxygen.—Whisker growth began at about 300°C. At this temperature, more thin whiskers apparently formed on the A specimen than on the B specimen. At 400° and 500°C, the same pattern was observed as for those specimens treated in air, namely, more thin long whiskers on the B disks than on the A disks. Comparing the micrograph of Fig. 3 with that of Fig. 1, it is also apparent that whisker growth is greater in oxygen than in air. The same trend of more thin whiskers on the B specimen than on the preworked or A specimens persisted to the highest reaction temperature studied, but as the temperature was raised, the whiskers became coarser and as a result, the density was decreased. In an oxygen atmosphere, whisker formation did not completely cease at the highest temperature (800°C) as it did on those specimens exposed to air (compare Fig. 2e and f with Fig. 4e and f).

Observations

The pertinent trends which have been observed from these experiments on copper disks can be summarized as follows:

1. At the lowest whisker formation temperature in dry atmospheres (300°C), whiskers occur more profusely on the specimens which were initially cold-worked (A specimens) than on the preannealed samples (B specimens) (Fig. 1a *vs.* 1b, 3a *vs.* 3b).
2. In direct contrast to the previous observation for the initiation of growth, at the higher temperatures the whiskers which form on the preannealed specimens appear to be more profuse, longer, and thinner than on the specimens which were initially in the cold-rolled condition.
3. In an air environment, there was a temperature at which growth reached a maximum. This temperature was always in the neighborhood of 500° or 600°C. At temperatures much in excess of this, no whisker formation was observed.
4. Oxygen enrichment of the reacting atmosphere accentuated whisker growth.
5. In general, whisker formations on the specimens which were initially cold-rolled were coarser than those observed on the preannealed specimens.

Discussion

It has been found from these experiments that many variables (reaction temperature and time, atmospheric composition, pretreatment, etc.) affect the

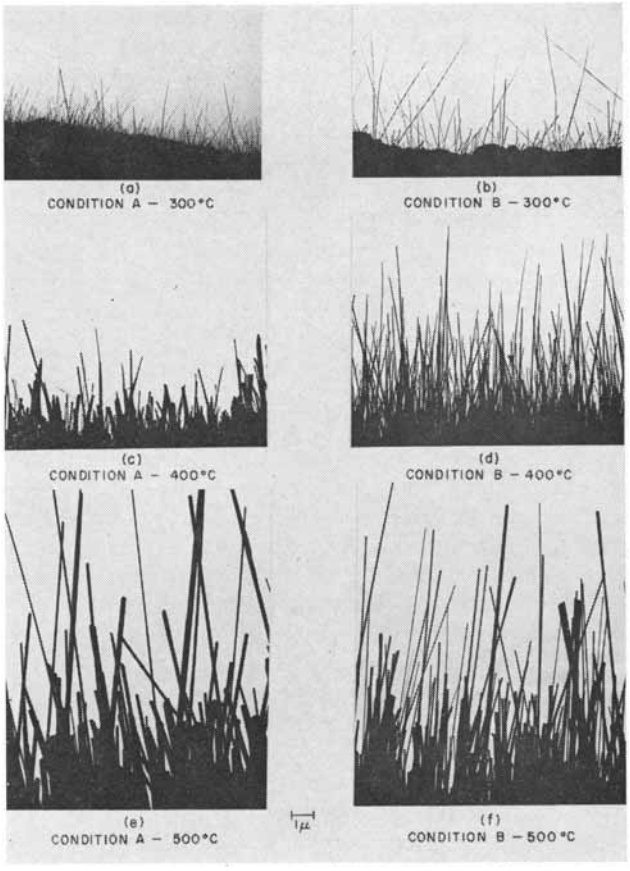

Fig. 3. Effect of temperature on the growth of oxide whiskers on pretreated copper in dry oxygen. Magnification approx. 3000X.

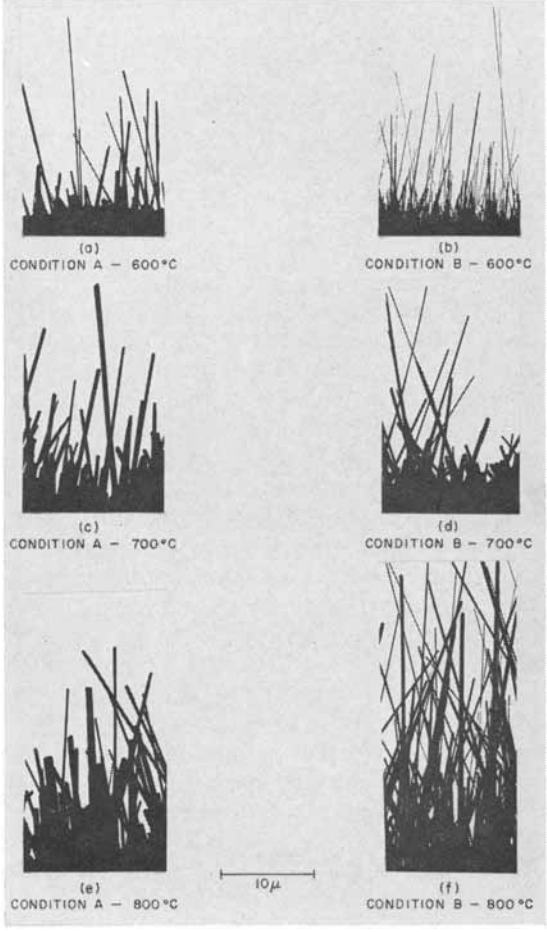

Fig. 4. Effect of temperature on the growth of oxide whiskers on pretreated copper in dry oxygen. Magnification 1300X.

formation of whiskers and that many parameters (number, length, width, shape, crystallography, etc.) are required to describe a whisker formation. It is apparent that any theory of whisker formation in air or oxygen must account for the observations given in this paper. Many of the concepts (3, 9) on oxide whisker growth have revealed that whiskers originate from a defect site such as a screw dislocation and that the energy required to form the whisker is supplied by surface oxidation. Two theories have been developed to establish the rate at which whiskers grow, namely, by diffusion of material at the whisker base (growth from the base) or by surface diffusion to the growth step at the whisker tip (growth from the tip). Undoubtedly, the development of whisker growth is a common phenomena, but the exact mechanism whereby this growth occurs is still quite obscure. Nevertheless, it is believed that valid rationalizations can be made on some of the features of whisker growth based on the relative ease of dislocation mobility and surface diffusion. It is on this basis that an attempt will be made to account for the differences in growth behavior obtained under the experimental conditions reported herein. The whisker density would then be related to the number of dislocations which have penetrated the oxide layer, while whisker growth would be associated with the rate of surface diffusion of material to a spiral growth step at the whisker tip.

In comparing the gross changes in whisker density between the cold rolled and preannealed samples in air and oxygen from Table I, it is apparent that the whisker density counts are generally greater for whiskers grown on the preannealed material than for those grown on the cold worked samples. A possible explanation for this difference is that the dislocations in the cold-rolled samples are restricted in movement by opposing dislocation stress fields and barriers instituted by the cold rolling process. On the preannealed samples the stress fields have been sufficiently reduced to permit the remaining dislocations to move more readily which would account for the increased whisker density. The effect of the cold-rolling process is also delineated in the whisker shape. Broader whiskers were obtained on the cold-rolled than on the preannealed samples, indicating a rearrangement or elongation of the initial growth sites by the cold-rolling process.

A strong dependency of whisker growth on temperature is indicated for both the cold-rolled and preannealed samples in air and oxygen. The temperature dependency may be considered on the basis of the rate of material diffusion, that is, an increase in temperature results in an increase in the rate of diffusion accounting for the increase in whisker growth length observed at the higher temperatures. The effect of temperature on whisker density is not clearly delineated, but may be partially explained on the basis of stress relieving and metal purity. At temperatures below 300°C, it would appear that the dislocations are still quite immobile and difficult to move accounting for the lack of whisker growth. At a temperature of 300°C and above, it would be reasonable to assume that the dislocation stress fields and lattice faults induced by the cold-rolling process

have been sufficiently reduced, in the case of the cold-rolled sample, to permit the dislocations to move more easily, accounting for the growth. The lack of any gross changes in whisker density, after 300°C indicates that the metal is of high purity. Only in impure metals would it be reasonable to expect a gross variation in whisker density at a critical temperature range resulting from a sudden release of dislocations where barriers of the Cottrell type are released by impurity atoms. The reduction in whisker densities obtained at the highest temperature studied (800°C) has been previously explained by other workers on the basis of sintering of the surface oxide layer.

The increase in whisker lengths obtained in an oxygen environment over that typified in air may be explained on the basis of increased availability of oxygen for surface reaction, perhaps by the process of surface diffusion to the spiral dislocation growth step at the whisker tip. Undoubtedly, the explanations described herein are not without some limitations, and close inspection will reveal some inherent discrepancies, particularly the observation that an oxide whisker emerges from a defect site such as a dislocation. To date, this observation has not been rigorously demonstrated. However, it is believed that, through the use of thin foils subjected to controlled oxidation, the role of specific dislocations could be unambiguously correlated with whisker formations. In particular this would apply in establishing a correlation between the nature of the growth site and the points at which dislocations emerge. It is further believed that application of this technique should clarify the effect of environment and pretreatment on the shape of the growth site. Further emphasis using this approach is underway.

Cell and Thermoelectric Effects of Tantalum Electrolytic Capacitors

Jack M. Law[1] and William C. Richards

Fansteel Metallurgical Corporation, North Chicago, Illinois

ABSTRACT

A voltage is normally present across the terminals of electrically isolated electrolytic tantalum capacitors. The magnitude, cause, and source impedance of this voltage were investigated. Wet-electrolyte units generate a small, high-impedance, cell emf between the tantalum anode and the silver case. This emf increases with film thickness to a maximum of 3v at elevated temperatures. Solid-electrolyte units generate a small, high-impedance emf, apparently thermoelectrically, normally not exceeding a few millivolts, but on some units, reaching a few hundred millivolts. Larger voltages are generally due to a residual charge from previous electrification, either from a slow decay rate or from dielectric hysteresis.

A voltage, although it may be small, is normally found to be present when an electrically isolated tantalum capacitor is tested with a voltmeter having a high internal impedance. In some applications for which tantalum capacitors are used, the magnitude of this voltage and its variation with temperature are important design considerations.

This paper reports the investigation that was made of the emf at the terminals and the causes for it. The two types of tantalum capacitors tested were solid electrolyte and wet electrolyte, both containing porous anodes of large surface area covered with a dielectric film of Ta_2O_5. The solid-electrolyte type has a layer of thermally decomposed MnO_2 covering the Ta_2O_5 film. The MnO_2 is electrically connected to the case and the cathode lead through a layer of graphite, silver paint, and solder. In the wet-electrolyte type, the anode is immersed in a liquid electrolyte which is contained in a sealed silver case. The cathode lead is soldered to the case.

The possible causes for the voltage were thought to be (*a*) an internally generated voltage such as a cell emf or a thermoelectric output, (*b*) an undecayed charge from previous electrification, (*c*) dielectric hysteresis, or (*d*) an electrostatic or electromagnetic charge. That wet-electrolyte electrolytic capacitors have a cell emf with a very large internal impedance was reported by Guntherschulze (1), but no values were given for tantalum.

[1] Present address: Rheem Semiconductor Corporation, Mountain View, California.

Several papers have reported cell potentials for tantalum (2, 3), but the measurements are not directly applicable to a commercial-type tantalum capacitor, where a formed anode and a silver case are the electrodes.

Dielectric hysteresis of aluminum electrolytic capacitors was investigated by van Geel and Pistorius (4), and the amount of dielectric hysteresis was found to increase with temperature and with the thickness of the oxide layer.

Methods of Testing

Voltages were measured with a 10-megohm meter (SIE Model R-2) and a 10^{11} ohm electrometer using a chopper and an a-c amplifier (Brown Recording Electrometer).

For d-c leakage measurements, the voltage drop across a 100-ohm series resistor was measured (the conventional manner of testing). However, unusual results were obtained under certain conditions of testing if the leakage current was less than 1 μa. When a d-c amplifier-type electrometer was used in combination with a d-c supply containing some ripple, a reversed voltage reading was obtained, indicating a negative leakage current, as though the capacitor was generating a larger voltage than the applied working voltage. The reversed voltage reading was not taken to be a true reading because a normal reading was obtained under the same conditions using the chopper-type a-c amplifier electrometer. Therefore, the latter meter and a lead battery voltage supply were used for all d-c leakage measurements.

For dielectric hysteresis tests, the working voltage was applied for 15 min, after which the unit was shorted through a 100-ohm resistor for 5 sec. The open-circuit terminal voltage was then measured at suitable intervals.

Wet-Electrolyte Capacitors

Voltages at room temperature were measured at the terminals of a number of wet-electrolyte capacitors. To minimize the possibility of a residual charge being present, a group of capacitors was used that had been at room ambient temperature and had not been electrified for six months or longer. The temperature was then increased in increments. Because of the extremely slow charge decay rate usually present in these capacitors, precautions were taken that the voltage at a given temperature was not affected by a residual charge from a previous temperature where the voltage had been higher. This was done by short circuiting the anode and cathode leads together for 1 min. The voltage at each temperature was found to be unstable at first, slowly changing, but normally reaching equilibrium within 4 hr. The voltage readings were recorded after equilibrium was reached.

Figure 1 shows the average terminal emf readings for several of these units over the temperature range of −55° to 125°C. The emf from −55° to +25°C is a few millivolts, changing from slightly negative to positive within this temperature range.

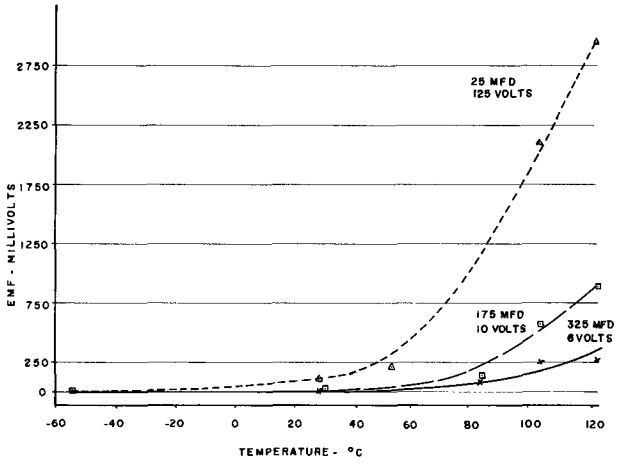

Fig. 1. Change of emf with temperature of wet-electrolyte capacitors. Values are for equilibrium conditions.

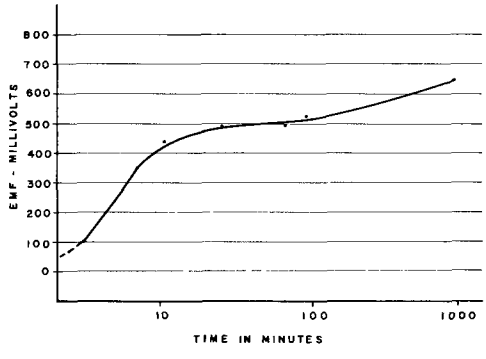

Fig. 2. Change in emf with time of a wet-electrolyte 25 μf/125v capacitor heated from 25° to 125°C, as measured on a voltage recorder.

Above room temperature the voltage increases to a maximum at 125°C. The emf reaches the highest value, 3v, on the 25 μf/125v units with the thickest film (and largest voltage rating).

To determine if the results would be similar if the temperature was increased immediately to 125°C instead of stepwise as in the preceding test, the voltage was recorded on a 25 μf/125v unit as it was placed in a 125°C oven, Fig. 2. The voltage increases fairly rapidly during the first 10 min and then levels off. No violent fluctuations or reversals in voltage are noted.

The small emf on the terminals of the capacitors shown in Fig. 1 and 2 are assumed to be due to a cell effect. To investigate the cell emf further, a capacitor was fabricated with an unformed tantalum anode, a silver case, and 40% sulfuric acid electrolyte. Figure 3 shows how the emf varies with temperature and reaches −190 mv at 125°C in contrast to the formed anodes that had a positive voltage. That the presence of an oxide causes tantalum to become more electropositive in oxidation-reduction potential was noted by Vermilyea (5). The unfilmed anode has a thin oxide film from contact with air that gives a potential different than that obtained with pure tantalum. If the half-cell potential of tantalum is more negative than the silver, Ta_2O_5 tends to form and the tantalum electrode is negative. If a film of Ta_2O_5 is present and the half-cell potential is more positive, silver tends

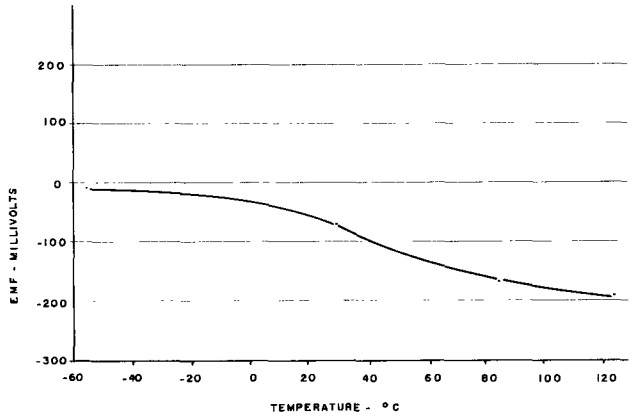

Fig. 3. The change of emf with temperature of wet-electrolyte capacitors containing an unformed tantalum anode. Average values for two units for equilibrium conditions.

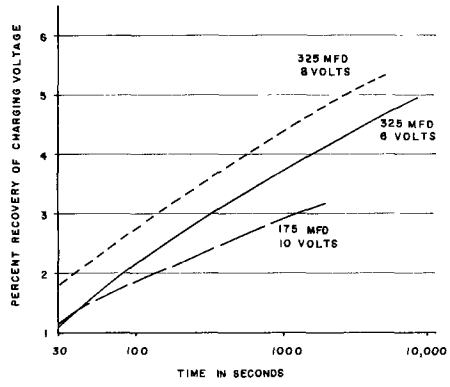

Fig. 4. Dielectric hysteresis of low-voltage wet-electrolyte capacitors, measurements at 25°C.

to dissolve and the silver electrode is negative. Some of the possible half-cell reactions are:

$$5H_2O + 2Ta = Ta_2O_5 + 10H^+ + 10e^- \quad E^\circ = -0.81v \qquad [1]$$

$$Ag = Ag^+ + e^- \quad E^\circ = 0.7991v \qquad [2]$$

$$2Ag + SO_4^{--} = Ag_2SO_4 + 2e^- \quad E^\circ = 0.653v \qquad [3]$$

There are many variables that can affect the cell potential of a tantalum capacitor including the activities of the various ions in the electrolyte and the thickness of the Ta_2O_5 film, and the emf can undoubtedly vary from one type to another.

The internal impedance was measured using a 1-megohm load to determine if these capacitors are a good source of emf. The impedance was determined by taking the open-circuited emf (no load) minus the emf with the load, and dividing by the current flowing through the load.

$$Z = \frac{E_{NL} - E_L}{I_L} \qquad [4]$$

The results are shown in Table I. The currents were extremely small, varying from 2 to 7 mμa. It will be noted that the internal impedance increases as the thickness of the tantalum oxide film increases. The computed resistivity of Ta_2O_5 based on a thickness of 18.5 Å/v (6) compares with previously reported values of 10^{12} to 10^{15} ohm-cm (7-9). The internal impedance is due, therefore, primarily to the resistivity of the Ta_2O_5.

Because the available current is in the milli-microampere range and the voltage is a few millivolts with a 1-megohm load, these devices are not too practical as batteries.

Voltages from External Sources

A voltage on a capacitor can be due to dielectric hysteresis from prior electrification (4) even though the capacitor has been completely discharged at one time. For example, Fig. 4 shows three capacitors that were charged to their working voltage and then discharged according to the procedure previously outlined. After 3 hr the terminal voltage of one 325 μf/6v capacitor is 5% of the charging voltage and is still increasing. The emf from dielectric adsorption could be mistaken for an internally generated voltage, particularly if the capacitor has a very slow decay rate.

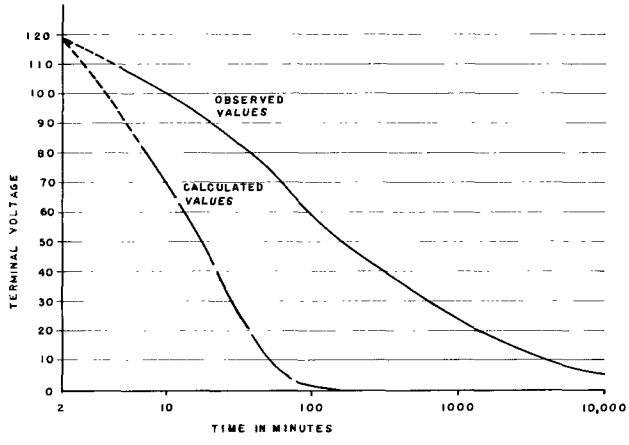

Fig. 5. Decay in charge on a high-voltage wet-electrolyte capacitor after the removal of the working voltage compared to the theoretical, (25 μf/125v capacitor); measurements were made at 25°C.

To determine how long a charge can be held if a capacitor is not discharged after the working voltage is applied for 15 min, voltage readings were taken at intervals on a 25 μf/125v capacitor as shown in Fig. 5. Internal leakage paths which are responsible for d-c leakage when a steady voltage is applied would also be the discharge paths for a charged capacitor. The resistance of the internal leakage paths can be approximated from

Table I. Internal impedance of wet-electrolyte capacitors as cells

Capacitor rating	Temperature of test, °C	No load emf, mv	emf with load, mv	Current with load, mμa	Internal impedance, megohms	Thickness of Ta_2O_5, Å	Resistivity of Ta_2O_5, ohm-cm
325 μf/6v	85	56	2	2	27	185	5×10^{15}
175 μf/15v	85	161	2	2	80	425	7×10^{15}
25 μf/125v	125	2100	7	7	300	3700	3×10^{15}

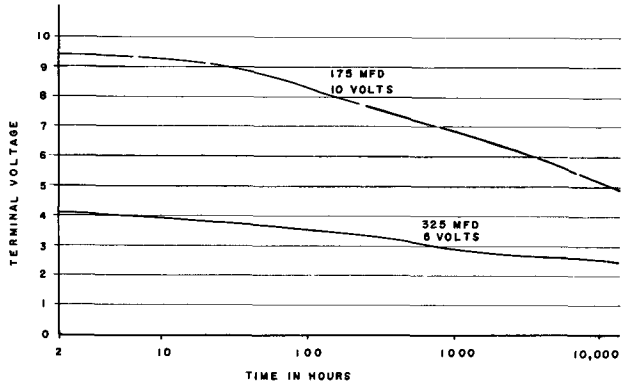

Fig. 6. Decay in charge on low-voltage wet-electrolyte capacitors after removal of the charging voltage, (10v and 4.3v); measurements were made at 25°C.

the d-c leakage current. The discharge rate should follow the formula for an R-C combination:

$$E = E_o e^{\frac{-T}{RC}} \qquad [5]$$

where E is the voltage at time, T, in seconds, E_o is the initial charging voltage, RC is the time constant, R is the resistance in megohms, and C is the capacitance in microfarads. The theoretical values do not agree too well with the observed values. The calculated internal resistance is 62.5 megohms, but the apparent resistance during discharge from 125 to 46v (which is 37%, or $1/e$, of 125v) is ten times greater (640 megohms). The apparent resistance from 46v to 17v shows a further increase by a factor of eight (5100 megohms). Therefore, it is evident that the internal resistance increases as the voltage decays.

Figure 6 shows the observed decay rates for two low-voltage units. The 325 μf/6v capacitor had been charged to 4.3v initially and the 175 μf/10v capacitor had been charged to 10v. After 18 months, the 6v part still has 57% of the initial charge and the 10v capacitor, 48.5%.

The exact explanation for the retention of such a large charge for such a long time is not known. That a cell emf causes the voltage does not seem likely; uncharged units have not been found to approach these values. The effective internal resistance, which has been shown to increase with a decay in voltage, might reach a sufficiently large magnitude in thin film units to cause the very slow decay rate.

Several factors can contribute to an increase in effective internal resistance. The resistivity of the Ta_2O_5 film can vary with a change in space charge and also with the direction of current flow. The current flow caused by cell action in a capacitor is opposite in direction to the current flow due to a decay in charge. The current that is flowing due to cell action with the tantalum positive is such that the electrons flow internally from the tantalum through the Ta_2O_5. The current that is flowing when an isolated capacitor is discharging internally is such that the electrons flow through the Ta_2O_5 to the tantalum. The resistance of Ta_2O_5 is known to be considerably less for the former case than for the latter. This might be the reason for the difference in the internal impedance calculated for the capacitors as cells in Table I as compared to the higher effective internal resistance shown by the charge decay rate. In the latter case, the resistivity of Ta_2O_5 might be considerably greater than 10^{15} ohm-cm.

The effective internal resistance of liquid-electrolyte capacitors can also be increased by the presence of double layers at both the Ta_2O_5 and the silver case surfaces, which would add series resistance. Gaseous layers causing an overvoltage can also have an effect on the retaining of a charge. A comparison of a thick-film, 125v capacitor in Fig. 5 with the thin-film capacitors in Fig. 6 shows that the former does not hold a charge as efficiently as the latter. The 125v capacitor continued to discharge at a faster rate and reached lower voltages than the thin-film capacitors. Young (10) has found evidence that the buildup of thicker Ta_2O_5 films on rough tantalum surfaces tends to create stresses as the tantalum is used up from protuberances under the film. Finally the Ta_2O_5 cracks, forming fissures down to the tantalum metal. Such fissures would result in more imperfections in thicker Ta_2O_5 films and would help to explain why such capacitors do not hold a charge as well as thin-film units.

Solid-Electrolyte Capacitors

The voltage present on a solid-electrolyte capacitor can be expected to be different than a wet-electrolyte capacitor. The solid electrolyte does not conduct current by ions. Therefore no cell emf should be present. Two semiconductors, MnO_2 and Ta_2O_5, are present. These capacitors appeared to be more sensitive to electrostatic charge pick-up than the wet units, and particular care was taken to keep them electrically insulated during testing, especially from contact with the hands. Even approaching the units with the hands can cause widely fluctuating electrometer readings, which subside upon withdrawing the hands.

The emf at the terminals of several typical 68 μf/10v capacitors over a temperature range is shown in Fig. 7. When the temperature was changed, the capacitors were discharged by shorting the leads together for 5 min to eliminate any residual charge. The results are similar to the wet

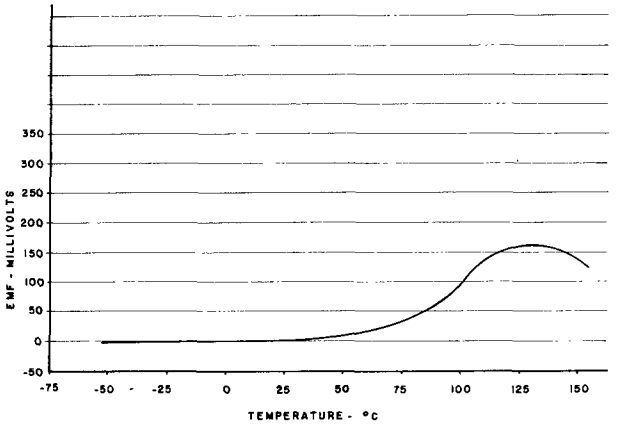

Fig. 7. Change of emf with temperature of 68 μf/10v solid-electrolyte capacitors. Values are for equilibrium conditions.

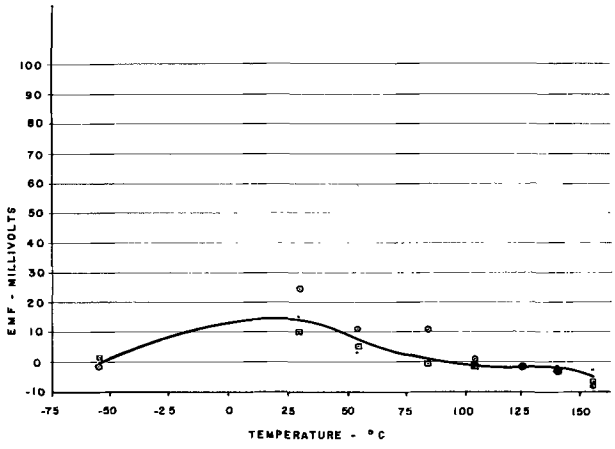

Fig. 8. Change of emf with temperature for 22 μf/35v solid-electrolyte capacitors. Values are for equilibrium conditions.

units except that the voltage decreases at higher temperatures (over 130°C). The explanation for this is presumed to be the decrease in internal resistance above the maximum operating temperature and the bleeding off of the charge.

The voltage-temperature relationship for three 22 μf/35v units is shown in Fig. 8. The emf drops to values between zero and —10 mv. The emf stayed in this region when the units were annealed at 155°C for days. Figure 9 shows the results on three smaller-size capacitors. The 6-volt units show a decrease above 130°C, as was previously noted for 68 μf/10v units. The two units with higher voltage ratings are similar to each other, both being slightly negative over the entire temperature range. Figure 10 shows the emf for two large intermediate-voltage units. Here, the 15-volt unit shows a continuous increase in voltage at higher temperatures, whereas the 20-volt unit shows very little output over the entire temperature range.

Figure 11 shows the daily variation in emf on capacitors of three different voltage ratings and sizes at 155°C. The two groups with higher voltage ratings have an emf close to zero, particularly the 100 μf/20v units. The 6-volt units have a somewhat more negative voltage, but are quite stable.

Figure 12 shows the effect on open-circuit terminal voltage of placing a room-temperature 68

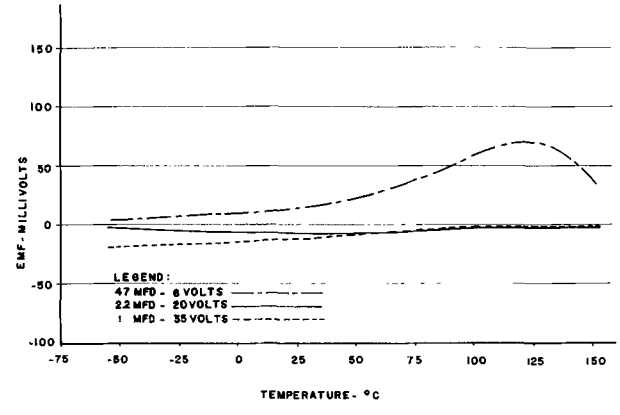

Fig. 9. Change of emf with temperature for three ratings of small solid-electrolyte capacitors. Values are for equilibrium conditions.

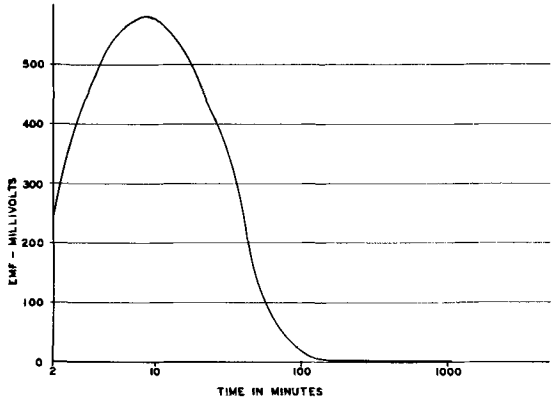

Fig. 12. Change of emf with time of a solid-electrolyte 68 μf/10v capacitor heated from 25° to 155°C, as measured on a voltage recorder.

μf/10v unit in a 155°C oven. Here again, the capacitor was shorted for 5 min before being placed in the oven. The emf reaches 580 mv after 8 min, then gradually decreases to zero at about 1000 min. This curve shows evidence of what appears to be a thermoelectric effect due to the thermal gradient between the inside and outside of the device during the short time required to reach thermal equilibrium. Such an emf could leave a residual voltage on a capacitor.

Mechanisms for the internal voltage generation were investigated by assembling various combinations of the elements normally found in a solid unit. For example, the MnO_2 electrolyte was placed over the surface of an unfilmed tantalum anode and a cathode contact was made with solder. No

emf reading was detected. A graphite coating was placed over the MnO_2 with no change. A conductive silver coating was placed over the graphite, making a complete capacitor except for the Ta_2O_5 film. No emf can be detected from any combination of components as long as unfilmed tantalum is used. That is, there appears to be no thermoelectric or Seebeck effects in action as long as the temperature is held constant. When graphite was placed directly over a 90v tantalum oxide film with no MnO_2 present, an emf of about —12 mv was noted over a 22-day series of measurements at 155°C. No emf was detectable at 145°C or below. Thus, apparently the presence of the MnO_2 is not necessary for such voltage, but the tantalum oxide is required.

The internal impedance of a number of solid-electrolyte capacitors was measured. On groups of 68 μf/10v and 22 μf/35v units, the voltage decreased to such low values (less than 10 μv) that it was very difficult to obtain measurements having any real meaning. It can only be said that the internal impedance appears to be extremely high on these devices.

Voltages from External Sources

Dielectric hysteresis was investigated on these units. Figure 13 shows the curve for a typical 22 μf/35v unit. The voltage reaches a peak of 1.2% of the original applied voltage 3 min after the shunt is removed and then decreases very rapidly. A 68 μf/10v unit reached the peak of 3% of the applied voltage also in 3 min and decreased rapidly after that. Thus, it appears that dielectric hysteresis in the solid capacitor contributes very little to any terminal emf.

Charge decay rates were also investigated for solid units. They were found to be much more rapid than for the wet devices. Figure 14 shows the calculated and observed decay rates for a 120 μf/10v unit. The internal resistance is 23.8 megohms, computed from the d-c leakage at 10v. The apparent internal resistance for a decay in voltage to 3.68v (1/e) is 360 megohms, as calculated from the actual decay rate. The apparent internal resistance for a further decrease to 1.33v is 1470 megohms, showing that the apparent internal resistance again increases as a charge decays, as it did for the wet devices, probably due to a change in resistance of the Ta_2O_5 with a change in space charge. Figure 15

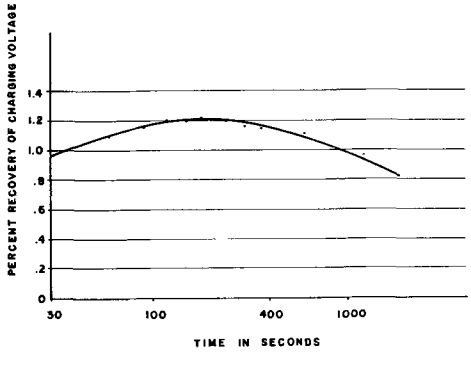

Fig. 13. Dielectric hysteresis of a 22 μf/35v solid-electrolyte capacitor, measurements at 25°C.

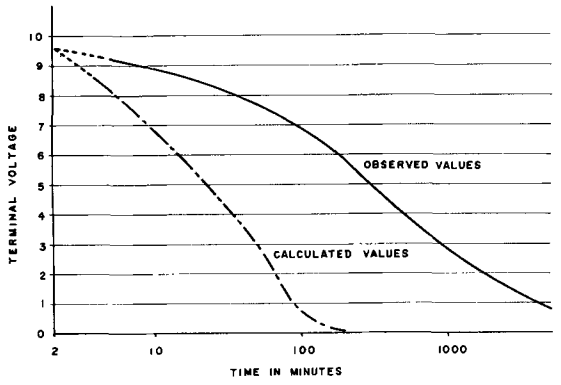

Fig. 14. Decay in charge on a 120 μf/10v solid-electrolyte capacitor after the removal of the working voltage compared to the theoretical; measurements were made at 25°C.

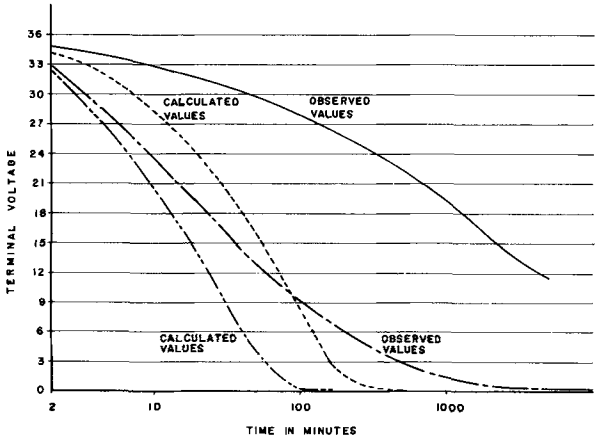

Fig. 15. Decay in charge for two 22 μf/35v solid-electrolyte capacitors after the removal of the working voltage compared to the theoretical; measurements were made at 25°C.

shows the observed and theoretical curves for two 22 μf/35v units. Again, the decay rate is much slower than if the apparent internal resistance at the operating voltage, as determined by the leakage current, holds constant. The apparent internal resistance for a voltage decay to 1/e of 35v (13v) is 10,000 megohms, which is substantially higher than the previous low-voltage unit.

The internal resistance paths, both series and parallel, of solid-electrolyte capacitors are undoubtedly a very important factor in determining what emf values can be sustained and how fast these will decay. Variations in these resistances probably account for a considerable part of the differences noted in the observed open-circuit emf's.

Conclusions

A high-impedance cell emf can be present across the terminals of an open-circuited wet-electrolyte tantalum capacitor and can be as high as 3v on a 25 μf/125v unit at 125°C. Other ratings are generally found to have only a few hundred millivolts.

An emf can also be present on the terminals of solid-electrolyte tantalum capacitors. These are generally only a few millivolts, but can be as high as a few hundred millivolts.

No forward current flow is found for either wet- or dry-electrolyte units when measuring d-c leak-

age using a series resistor if a proper d-c source and voltage-sensing instrument are used.

Voltages remaining due to the extremely slow charge decay rates of tantalum capacitors can be readily mistaken for internally generated voltages.

Gas Permeation Study and Imperfection Detection of Thermally Grown and Deposited Thin Silicon Dioxide Films

S. W. Ing, Jr., R. E. Morrison, and J. E. Sandor[1]

Semiconductor Products Department, General Electric Company, Syracuse, New York

ABSTRACT

Methods have been developed to measure gas permeation through thin thermally grown and deposited silicon dioxide films. From the data collected it is shown that pores and microchannels (orders of magnitude smaller than pores) are formed in these films, and permeation through them is the main diffusion mechanism involved. The existence of imperfections in the oxides is demonstrated by using a chlorine etching technique. An important result from this work is that insufficient surface cleaning is an important factor in the production of relatively large pores in the oxide. Channel size approaching atomic dimensions could be obtained in these films by being extremely careful in the preoxidation or predeposition cleaning of the silicon. Some oxide films show the presence of crystalline structures considered to be caused by a nucleation phenomena due to the presence of foreign particles on the silicon surface.

Measurements of the permeation rate of gases through thin films (10,000-40,000Å) of thermally grown and pyrolytically formed silicon dioxide have been made to determine quantitatively the imperfections existing in these films. Moreover, the procedures and techniques developed may be applied to permeation measurements of thin films of other materials.

A survey of the techniques used for permeation studies of glasses and crystalline material indicates that most classical approaches are not adaptable for studying very thin films, and in particular, most methods require large areas of material. The early permeation studies for silica and glasses, done by Urry (1, 2), Barrer (3), Rayleigh (4, 5) and others (6), utilize a form of double-bulb cell in which the inner bulb is blown from the material being studied. More recent techniques developed for permeation studies of sheet organic polymers (7, 8) satisfy the requirements for this investigation more closely; however, many modifications are still necessary due to the extreme fragility of the silica films and the limited size attainable.

From the existing published permeation studies reviewed, the device and procedures used by Park (7) seemed to satisfy thin film requirements provided gas permeation rate through the film is comparatively high. The device measures the volume of the permeated gas under conditions of constant pressure and temperature while a pressure difference is maintained across the film.

Park obtained ±5% accuracy with this procedure and could measure a flow rate of 2.3×10^{-3} cm³/min (permeation constant of 1×10^{-9} cc-cm/sec-cm²-cm Hg) with excellent reproducibility.

Initial permeability studies were begun by employing this volume change procedure, but as some permeability constants of below 1×10^{-14} cc-cm/sec-cm²-cm Hg were anticipated for these silicon dioxide films, ultimate values were expected to be obtained by using mass spectrometer. However, the semimicro film holder and volume increase measurement procedure proves an excellent method for screening films and collecting information.

Apparatus and Procedure

Semimicro film holder and volume increase measurement procedure.—The film holder, which is a slight modification of Park's device, is shown in Fig. 1. It is constructed of brass with an aluminum tightening ring. The high-pressure side is constructed with a set-screw-ball and socket valve to flush air from the upstream side prior to testing.

[1] Present address: Fairchild Semiconductor Corporation, Palo Alto, California.

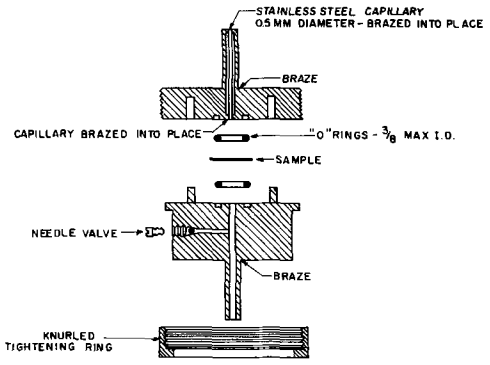

Fig. 1. Cross-sectional view of film holder for permeability measurement.

The volume on the low-pressure half of the device is minimized by brazing a 0.5 mm stainless steel capillary into place. Rubber "O" rings, recessed into the face of the device, provide a gastight seal with the sample when the unit is assembled and the tightening ring is applied. To insure against torsional tearing forces on the sample, three positioning pins are placed on the device halves.

The silicon dioxide films tested range in thickness from 10,000 to 40,000Å. These films are extremely fragile, and it would be impossible, as it is with plastic materials, to simply place the sheet between the device "O" rings and tighten. The film must be mounted or supported on a rigid frame, which will bear all the pressure of the "O" ring contact, and yet the film must lie completely flat on this support surface and adhere tightly about the periphery of the hole drilled into the support.

Many attempts were made to float a stripped silica film onto a polished quartz plate that had a hole of known diameter. Water, alcohol, and acetone were used; however, in most cases the film either wrinkled or would lift around the periphery of the hole creating possible error in the area considered for permeation study. Some success was attained by heat-sealing a sheet of film between two sheets of polyvinyl chloride containing drilled windows. However, this method proved unfeasible as the film cracked readily in most cases due to differences between the thermal properties of the film and the polymer.

Eventually, two satisfactory methods were developed for rigidly mounting the films for testing,

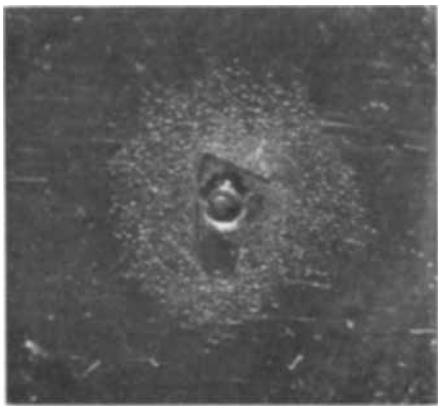

Fig. 2. Stripped film glass-brass sandwich; film 15,000Å

the oxide window method and the stripped film sandwich (see Fig. 2).

For the oxide window method a silicon wafer (3 cm^2) is completely oxidized on both sides. The surfaces are then completely masked with wax except for a circular area on one side of approximately 1 mm diameter. The silica is removed from this nonmasked area by etching with HF; the surface is washed with distilled water, and all wax removed with solvent. The wafer is then placed-silicon exposed side up–in a dry chlorine gas stream at 900°C for 2 min. In this period a neat vertical channel is cut through the silicon substrate, with very little horizontal undercutting, until the silica film on the opposite side of the wafer is reached. In this method, the silicon itself acts as support for the "O" ring contact, and the permeation area can be measured accurately as the film lies flat over the window area and is, of course, tightly adhered to the silicon substrate.

The stripped-film sandwich method was also used many times with success. Here, a silicon wafer covered with oxide is completely masked on one side with wax. All oxide on the opposite side is etched off with HF leaving the silicon clean and exposed. The wax is removed with solvent, and the wafer is placed silicon side up in a dry chlorine gas stream at 900°C for 10 min. In this period, all the silicon reacts and volatilizes leaving a flat transparent sheet of silicon dioxide.

This film is laid down on a clean, mechanically polished piece of brass which has a drilled hole of known diameter. A very light coating of silicone grease provides a tight seal. Next, a lightly greased glass plate with a matching hole, slightly larger in diameter, is placed on top of the silica-brass making a glass-silica-brass sandwich. "O" ring contact on this assembly gave a tight seal when pressure was applied on the permeation device with the tightening ring. The stripped film sandwich had the advantages of ease of handling and less film breakage; however, if the film does wrinkle or lift from the brass plate, an error is introduced into the assumed area measurement for permeation.

Both methods, however, provide a good film support for insertion into the permeation device.

In operation, the supported silicon dioxide film is placed horizontally on one half of the film holder. The holder is assembled and tightened as hard as possible with hand pressure. The film holder, is then placed between two three-way-stopcocks held flush with the holder with Tygon tubing. The test gas is slowly applied until a constant pressure is reached on the manometer. The entrapped air on the upstream side of the film holder is bled off several times through a needle valve.

A glass capillary containing an approximate 2 mm slug of methyl isobutyl ketone is next attached flush to a stopcock with Tygon tubing. A millimeter scale is adjusted to measure accurately the progression of the slug with volume increase.

During a run, the gas pressure is fixed and the rate of displacement of the organic capillary slug

Table I. Experimental results

Film No.	Gas used	Film mounting method	Film thickness, Å	Means of measurement	P, cm³ cm / sec-cm²-cm Hg
1	Air	PVC* sandwich	16,000	Volume displacement	8.5×10^{-8}
1	Air	PVC sandwich	16,000	Volume displacement	8.9×10^{-8}

* Polyvinyl chloride.

is noted over a set 3 cm distance. Repeated determinations on the same piece of film are made by one closing stopcock and gently sucking the slug back to the starting position, again observing the time intervals required to progress the successive sections of the 3 cm distance.

In general, with an exposed film area of approximately 0.01 cm², a range of gas pressure difference across the film can be used without puncturing the film varying from 200 mm Hg for 5000Å thickness to well over 760 mm Hg for 15,000Å.

Since the capillary slug movement is affected by changes in ambient temperature, as much care as possible should be taken to provide a constant ambient temperature.

Mass spectrometer measurement apparatus.— Both oxide window and stripped silicon dioxide films are used. The film is mounted between the polished ends of two capillary glass tubes, 1 mm bore, and is sealed tightly with apiazon wax. The assembly is then incorporated into the mass spectrometer vacuum system. A fraction of a millimeter Hg gas pressure differential is generally applied across the film. The film temperature can be varied by using a heater placed around the film assembly.

Results

For all films investigated, there was no evidence of an initial induction period. In the case of volume change permeation measurements, the rate of displacement of the liquid slug seemed to reach a steady state very readily after the start of each run.

The experimental results of permeation of various gases through different silicon dioxide films are presented in Table I. All films were thermally formed by steam oxidation with the exception of film No. 5, which was formed with oxygen bubbling through a room temperature water supply. *P*, the permeability, is defined as the cc of gas at normal temperature and pressure passing through a film 1 cm thick, per second, per cm² area with 1 cm Hg pressure difference across the film.

Discussion of Permeation Results

As can be seen from the tabulated data, the permeation constants for these thin silicon dioxide films not only vary using the same gas, e.g., air, 2.18×10^{-7} to $< 10^{-10}$ and argon 3×10^{-4} to $< 10^{-10}$, but also the lower values obtained are several orders of magnitude higher than those anticipated (9).

From the spread of permeation results, a proposed spectrum of values is suggested according to the degree of imperfections within the silicon dioxide films. Breaking the values down into permeation ranges, one might categorize the results as follows for a gas like argon or oxygen.

A. 10^{-3} to 10^{-5} — Flow through microcracks, pores, and crystalline portion boundaries.

B. 10^{-7} to 10^{-10} — Flow through micro-channels.

C. $\sim 10^{-15}$ — True diffusion and permeation (9).

If a film contains a crack due to handling or insertion into the film holder, it is readily detected by the rapid progression of the capillary slug. On microscopic examination the crack can usually be observed.

The higher rates of 10^{-4} and 10^{-5} are obtained on films in which many fine crystal-like growths appear. These crystals very closely resemble those described by other authors (10) and are probably also cristobalite. The average diameter of these crystals vary from 4×10^{-4} cm to 3.3×10^{-3} cm (see Fig. 3). It is noted sporadically that this phenomenon occurs independent of the oxidation technique although the standard preoxidation cleaning treatment is used. In advanced stages this "crystallization" can give a milky cast to the oxide, even while still on its silicon substrate, and often after etching away such a film, the silicon surface is noticeably pitted in regions where these "crystals" were observed. This phenomenon seems to be pre-

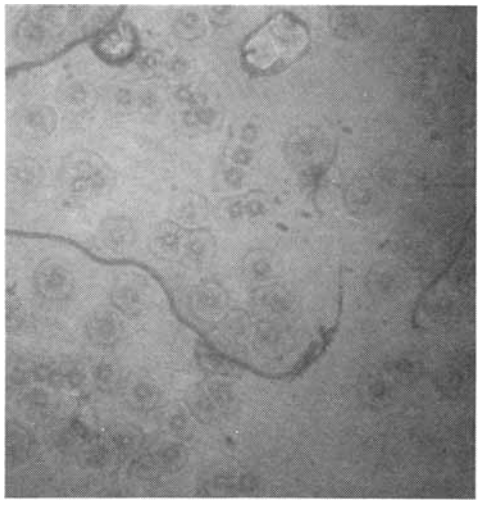

Fig. 3. "Crystalline" growth in stripped thermal oxide film. Magnification 150X.

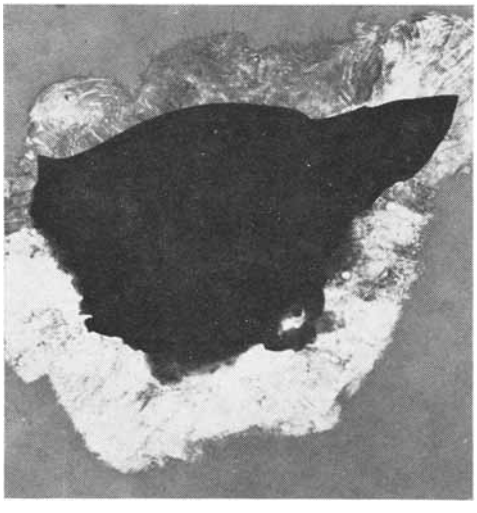

Fig. 4. SiO_2 crystallization around foreign particle; note: produced during electron microscope observation.

dominant in cases in which the amorphous silica can nucleate about a foreign material such as might be found on an insufficiently cleaned silicon surface. Figure 4 illustrates this crystallization phenomenon. This transition occurred while scanning a stripped silica film under the electron microscope. While the photographed area was being observed, some unknown foreign material landed on the silica, and immediately the surrounding silica crystallized.

The bulk of the results fall into the 10^{-7}-10^{-10} permeation range. It is felt that this range indicates permeation through microchannels rather than through the membrane by solubility for several reasons. First, a steady-state flow is immediately observed on starting a run either by mass spectrometer or by volume displacement. Solubility type of permeation should show an initial time lag. Second, mass spectrometer measurement shows H_2 and He are about equal in rate, and H_2 should be approximately 1/10 the rate of that of He for fused silica (9). Third, the temperature dependence is not found to be exponential. Argon was used in the mass spectrometer with a pressure differential of 6 mm Hg. Permeation measurements were made at 29° and 59°C, and the rates were found to be approximately the same with, perhaps, a 3% higher rate for the higher temperature. As a rough approximation with a P of 5×10^{-10} for oxygen it is estimated that using a test area of 3×10^{-2} cm^2 the total "channel area" would be 3.65×10^{-10} cm^2. If this entire area is assumed to be one pore, this would correspond to a pinhole of approximately 2×10^{-5} cm in diameter in a test area of 0.2 cm diameter. The electron microscope failed to detect any pores in several films over the limited field observed, even with a resolution down to 50Å, so channels should be numerous and extremely small in size.

The rates obtained with hydrogen and helium (see Table I) approach the values found by other authors using fused silica (11) by one or two orders of magnitude. Leiby and Chen (12) studied the permeation of various gases through Vycor glass, and report permeation constants in the range of 10^{-10} to 10^{-11} cm^3-cm/sec-cm^2-cm Hg for He at room temperature, which is again one or two orders lower than is found with the least permeable thermally grown oxide. The permeation constant of He in Vycor glass was found to be both a square root and an exponential function of temperature. The square root temperature dependence was considered to indicate the existence of a molecular streaming process through extremely small voids and/or channels of near molecular dimension. If this is the case, then the channels existing in some of these thermally grown oxide films also could not be too much larger than molecular size.

The runs which gave values below 10^{-10} were obtained by the volume displacement method, but this value is certainly the extreme upper limit measurable by this procedure due to time factor and effects of external surroundings such as temperature. For values less than 10^{-9} mass spectrometer is the most accurate and most sensitive method, for with the present system, a permeability for oxygen in the order of 10^{-15} could have been detected if these films were free of imperfections and if permeation occurred through the silica by solubility.

Detection of Film Imperfections

Basically, the films studied for imperfection detection are prepared by either of three methods: (*a*) thermal oxidation of silicon with oxygen, (*b*) thermal oxidation of silicon with steam, and (*c*) pyrolytic decomposition of an organic-oxy-silane onto a silicon crystal surface. The state of the surface prior to oxidation or deposition appears to affect the quality of the resulting film greatly, as undesirable foreign materials on the silicon surface will produce a poor oxide. In general, few physical differences are noted in the oxides prepared by these three methods. All are amorphous by x-ray and electron diffraction. The films deposited pyrolytically, however, appear to be under considerably more stress than the thermally oxidized films, so an annealing step must be introduced to get them to lie flat and continuous (see Fig. 5). Of course, the reaction kinetics and the preparation tempera-

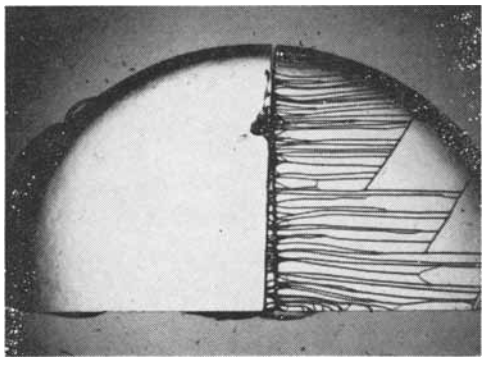

Fig. 5. Effect of annealing on pyrolytic film; left, annealed; right, unannealed; both after 1 min Cl_2 at 900°C.

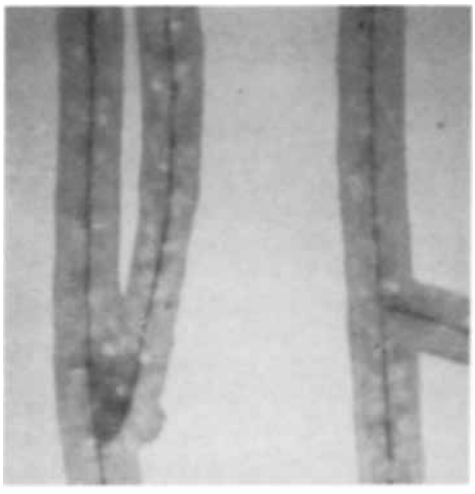

Fig. 6. Unannealed pyrolytic film cracking defined by chlorine etching. Original oxide crack and chlorine channel shown. Magnification 100X.

tures of these three preparation methods are quite different.

A method is developed by which films and silicon preoxidation cleaning processes could be evaluated qualitatively in relation to the imperfections introduced into the silicon dioxide film. Chlorine etching proves to be a very effective method for qualitatively screening films for cracks and pores. A test oxide must still be on its silicon substrate, whether thermally grown or deposited, and the silicon must be completely covered including its edges. Gross film imperfections, even those not visible with the eye, are easily detected after placing the sample in a dry Cl_2 stream at 900°C for 1-2 min. If the sample oxide contains large visible cracks, this time will be almost sufficient to attack the silicon completely, leaving fragments of oxide film.

A 2-min, 900°C Cl_2 etch finely brings out microcracks in oxide films as the chlorine attacks through the discontinuities and slowly undercuts along into the silicon (see Fig. 6). Microscopic examination of the etched areas always discloses the crack in the oxide.

However, to reveal some of the pores previously discussed, at least 30 minutes in Cl_2 at 900°C are required to undercut the silicon sufficiently for observation.

Chlorine etching tends to indicate that there is little difference in the three preparation methods

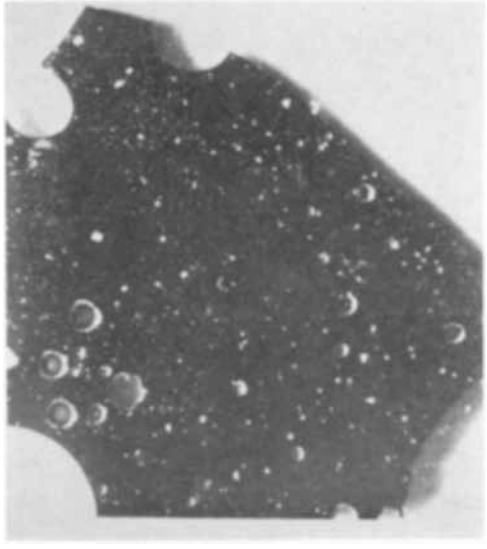

Fig. 7. Effect on oxide by chlorine etching insufficiently cleaned silicon; 10,000Å oxide by dry O_2 at 1200°C.

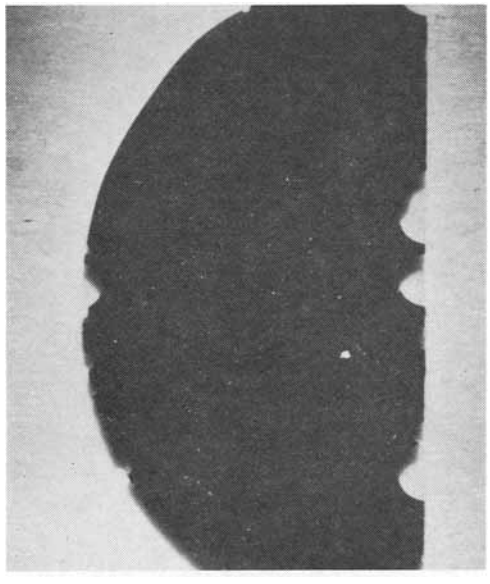

Fig. 8. Effect on oxide by chlorine etching chemically cleaned silicon; 6000Å oxide by steam at 1200°C.

in their relative susceptibility to film imperfections. All are basically equivalent in regard to number of pinholes; however, unannealed pyrolytically deposited oxides do tend to crack more readily in thicknesses over 15,000Å. The factor which appears most critical for imperfection reduction is silicon pretreatment and cleanliness prior to oxidation or deposition (see Fig. 7 and 8).

Conclusions

Methods have been developed to measure gas permeation through thin silicon dioxide films. From the data collected it is shown that pores and microchannels (orders of magnitude smaller than pores) are formed in these films, and permeation through them is the main diffusion mechanism involved.

The existence of imperfections in the oxides is demonstrated by using a chlorine etching technique.

An important result from this work is that surface contamination is an important factor in the production of pores in the oxide. Channel size ap-

proaching atomic dimensions could be obtained in these films by being extremely careful in the preoxidation cleaning of the silicon.

Some oxide films show the presence of crystalline structures considered to be caused by a nucleation phenomena due to the presence of foreign particles on the silicon surface.

Acknowledgments

The authors wish to express their appreciation to Dr. Frank J. Norton, General Electric Research Laboratory, Schenectady, for making mass spectrometer measurements and also to Dr. William C. Dash, General Electric Research Laboratory, Schenectady, for electron microscope photography.

Preparation of Solid Solutions of GaP and GaAs by a Gas Phase Reaction

Frank A. Pizzarello

Chemical Physics Department, Semiconductor Materials Section, Hughes Research Laboratories, Newport Beach, California

ABSTRACT

Homogeneous solid solutions of gallium phosphide and gallium arsenide were synthesized. The synthesis involves the transport of the constituents of the solid solution to a cool substrate by means of a complex reaction with iodine under near-equilibrium conditions. The homogeneity of the samples prepared was demonstrated by x-ray, microscopic, and optical absorption measurements.

Among the first to describe the synthesis of the III-V compounds by a gas phase reaction were Antell and Effer (1). These workers demonstrated that GaAs, GaP, and InP can be successfully synthesized from a mixture of a group III halide and an element of group V. At present, a great deal of work is being devoted to the epitaxial growth of silicon (2) and germanium (3). In these epitaxial growth systems transport of silicon and germanium halides to a substrate occurs either by mixing with a flowing gas or under the influence of a thermal gradient. The substrate temperature is so fixed that deposition takes place by the disproportionation of the silicon and germanium halides.

The technique described in this paper uses the general approach of transport of halides by means of a thermal gradient. The principle advantages of this method of synthesis is that high temperatures, high pressures, and long periods of equilibration are not required to form homogeneous solid solutions.

A mechanical mixture of gallium arsenide and gallium phosphide, together with a measured quantity of iodine, is sealed in a quartz tube that is heated in a furnace of a known temperature gradient. The gallium phosphide-gallium arsenide mixture is placed in the high-temperature zone of the furnace. Material is transported to the cooler zone and deposits on the quartz wall of the reaction vessel as a homogeneous solid solution of gallium phosphide-gallium arsenide. Microscopic examination, x-ray analysis, and optical measurements were made to verify the homogeneous nature of the deposited material.

The net chemical reactions involved in the process can be represented by the following equations:

High-temperature region: Source material

$$4GaP\ (S) + 2I_2\ (g) \rightarrow 4GaI\ (g) + P_4\ (g) \quad [a]$$

$$4GaAs\ (S) + 2I_2\ (g) \rightarrow 4GaI\ (g) + As_4\ (g) \quad [b]$$

Cooler temperature region: substrate

$$4GaI\ (g) + (1-x)P_4\ (g) + (x)As_4\ (g) \rightarrow 4GaAs_xP_{(1-x)}\ (S) + 2I_2\ (g) \quad [c]$$

Reactions [a] and [b] occur at the high source temperature. The gallium iodide, phosphorus, and arsenic formed are transported to the cooler region of the tube by thermal convection. In the cooler region $GaAs_xP_{(1-x)}$ deposits on the walls of the tube as indicated by reaction [c].

Experimental

Mechanical mixtures are prepared by grinding measured quantities of gallium phosphide and gal-

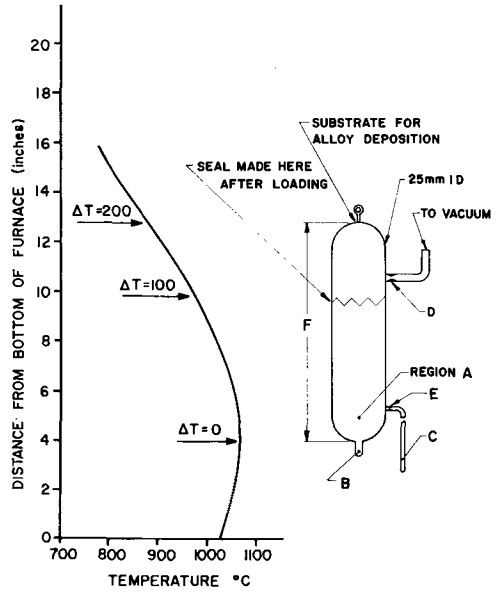

Fig. 1. Composite view of the quartz apparatus and the thermal gradient used in these experiments.

lium arsenide together in an agate mortar. Two grams of the desired mixture are placed in region A of the quartz reaction tube shown in Fig. 1.

One tenth of a gram of iodine is placed in tubulation B. The assembly is evacuated to 10^{-6} mm Hg. In earlier experiments, the tubulation B was immersed in liquid nitrogen during evacuation to avoid loss of iodine. It was found, however, that small quantities of water introduced into the system by this procedure produced undesirable effects. This contamination is avoided through use of cuprous iodide, placed in tubulation C, as an iodine source. The system is evacuated and thoroughly degassed at 100°C. The cuprous iodide is then decomposed at approximately 400°C and the liberated iodine condensed at B. The quartz tube is degassed by heating with an oxygen-hydrogen torch, and then sealed off at the constriction D. This is followed by sealing off tubulation C at constriction E.

The assembly is placed in a vertical furnace with the thermal distribution shown in Fig. 1. Any desired temperature difference, t, can be imposed on the system by adjusting the length, F, of the quartz tube. In these experiments, the temperature differences used were 100° and 200°C.

Results

Figure 2 illustrates a typical gallium phosphide-gallium arsenide deposit. These deposits are densely packed, adherent masses of crystallites, ranging in size from 1 mm to 10^{-2} mm on an edge. The largest crystallites are found in the center portion of the deposit. Microscopic examination reveals well-formed tetrahedral outcroppings, indicating preferential growth on (111) faces.

X-ray powder patterns show the deposits to be homogeneous solid solutions with a crystal structure of the zinc-blende type. A plot of the lattice parameter *vs.* mole fraction of gallium arsenide is given in Fig. 3. This plot shows that Vegard's law is approximated, a result which is in agreement with that of Flicker and Herkart (3). The scatter in the data shown in Fig. 4 is due, in part, to the inaccuracy of

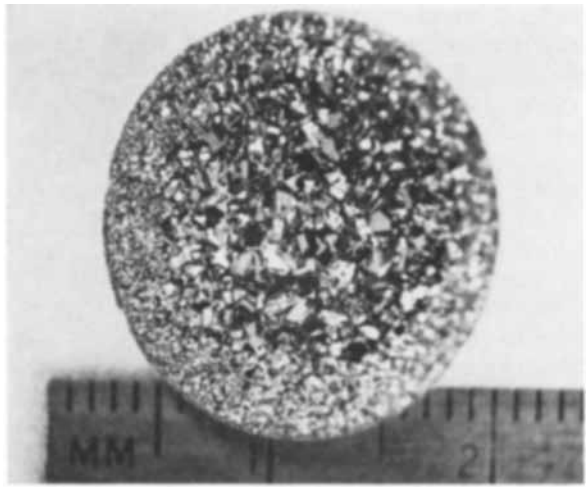

Fig. 2. Photograph of a typical solid solution deposition

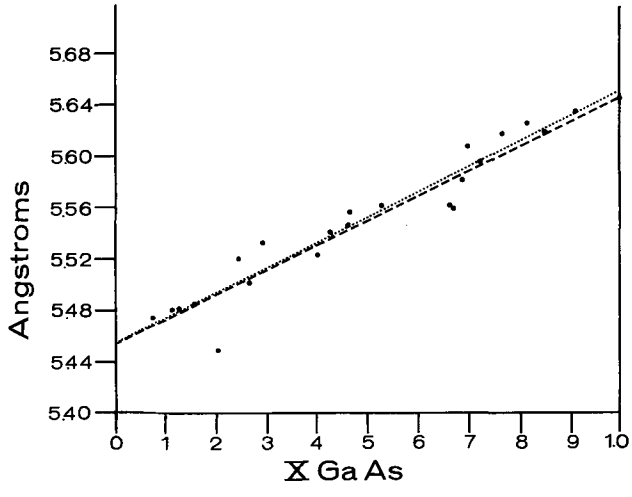

Fig. 3. Lattice parameter *vs.* mole fraction of gallium arsenide

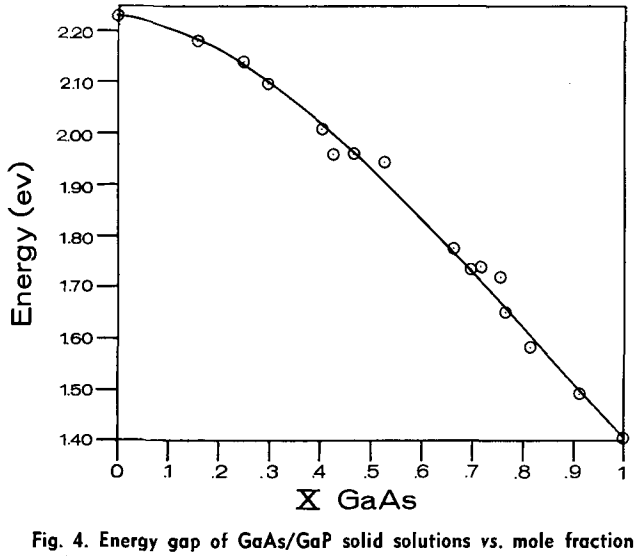

Fig. 4. Energy gap of GaAs/GaP solid solutions *vs.* mole fraction of gallium arsenide.

the analytical chemical technique used for the determination of concentration. The accuracy of the chemical analysis technique used was determined to be 6%. X-ray and microscopic examinations revealed the inclusion of a second phase in the deposition. An x-ray powder pattern of this material was identified as $Ga(PO_4)$. The amount of this material was reduced below the level of detection by microscopic and x-ray

techniques by using the cuprous iodide thermal decomposition technique, which assured the exclusion of oxygen and water from the system.

Optical absorption measurements on polished polycrystalline samples of gallium phosphide-gallium arsenide solid solutions were performed. Results are given in Fig. 4. Values of energy gap were determined from a plot of transmission *vs.* energy at a point on the energy axis where the transmission is 30% of the maximum transmission. Comparison of this optical data with similar data published by Folberth (4) shows agreement within a maximum deviation of 6%. Optical samples containing less than 0.50 mole fraction of gallium arsenide are transparent to visible light. Visual and microscopic examination of these samples revealed uniformly colored material containing a random mosaic pattern of crystallites. Samples not prepared by the cuprous iodide technique show a maximum transmission less than that calculated from reflectance data. This effect is probably due to the presence of occluded gallium phosphate acting as light scattering sites.

Since the nature of this system is such that many factors may have an effect, the four parameters, concentration of the mechanical mixture of gallium phosphide-gallium arsenide, temperature difference between source and substrate, pressure of arsenic, and pressure of phosphorus, were independently varied. A composite graph of the experimental results is given in Fig. 5. The term "excess pressure" used in the legend of Fig. 5 refers to the partial pressure of phosphorus or arsenic developed at the temperature of deposition in excess of the pressure developed by the decomposition of the gallium arsenide or gallium phosphide. This excess pressure is determined by the quantity of phosphorus or arsenic added to the mechanical mixture. Curve a (no excess phosphorus or arsenic used) shows a simple proportional relation between mechanical mixture concentration and deposition concentration. Curves b and c, 0.25 atm excess pressure of arsenic and 0.48 atm excess of phosphorus respectively, show a more complicated relationship between the mechanical mixture concentration and deposition concentration at the end portions of the curves. An interesting consequence of the study is that a wide range of concentrations was synthesized by using mixtures of gallium arsenide-red phosphorus and gallium phosphide-arsenic. Figure 6 shows the variation of concentration of deposition with excess phosphorus pressure when gallium arsenide-red phosphorus mixtures are used.

Discussion

The Gibbs free energy of the net equilibrium reaction

$$4\,GaI(g) + (1-x)\,P_4(g) + X\,As_4(g) \rightarrow 4\,GaAs_x\,P_{(1-x)}\,(s) + 2I_2(g)$$

is given by

$$\Delta F_1 = -RT_1 \ln \frac{P^2_{I_2}}{P^4_{GaI}\,P_{P_4}^{1-x}\,P^x_{As_4}} \qquad [1]$$

where P_{I_2} is the total iodine pressure, P_{GaI} is the total gallium iodide pressure, P_{P_4} is the total phosphorus pressure, P_{As_4} is the total arsenic pressure, T_1 is the substrate temperature, and x is the mole fraction of gallium arsenide. Rearranging terms Eq. [1] can be put in the form.

$$x = \frac{\frac{\Delta F_1}{RT_1} + 2\ln P_{I_2} - 4\ln P_{GaI} - \ln P_{P_4}}{\ln P_{As_4} - \ln P_{P_4}} \qquad [2]$$

At the source region of the system, the net chemical equilibrium reactions postulated are:

$$4GaAs\ (S) + 2I_2\ (g) \rightarrow 4GaI\ (g) + As_4\ (g)$$
$$4GaP\ \ (S) + 2I_2\ (g) \rightarrow 4GaI\ (g) + P_4\ \ (g)$$

The Gibbs free energy for these reactions are:

$$F_2 = -RT_2 \ln \frac{P^4_{GaI}\,P_{As_4}}{P^2_{I_2}} \qquad [3]$$

$$F_3 = -RT_2 \ln \frac{P^4_{GaI}\,P_{P_4}}{P^2_{I_2}} \qquad [4]$$

where T_2 is the source temperature.

From Eq. [3] and [4] it can be seen that for a given temperature, T_2, the total pressures of arsenic, phosphorus, gallium iodide, and iodine in the closed system are independent of the relative proportions of GaAs and GaP in the solid phase. Consequently one expects x, as given by Eq. [2], to be single valued when the substrate and source temperatures are fixed. This conclusion is in direct contradiction to the data shown in Fig. 5 where it is seen that the alloy composition is varied by changes of mixture composition at the source region. No exact mechanism has been devised to explain the observed data. This anomaly, however, is resolved by postulating a complex solid phase reaction between GaAs and GaP at the source temperature which forms gallium arsenide-gallium phosphide solid solutions of composition dependent on the concentration of the mechanical mixture introduced. This postulate is partially supported by the observation that GaAs is preferentially transferred to the substrate when GaAs and GaP is used as the source in an unmixed state.

Acknowledgments

The author wishes to thank Mr. J. Vuoto for his support in the experimental work, Mr. D. Thrasher for the performance of the chemical analysis, and Dr. J. B. Bryden for the x-ray work needed.

Study of Aluminum Fusion into Silicon

Tchang-Il Chung

Semiconductor Division, Hughes Aircraft Company, Newport Beach, California

ABSTRACT

The wettability of silicon by aluminum, the spreading diameter of aluminum on silicon, and the depth of penetration of aluminum into silicon are analytically and experimentally studied as a function of the fusion temperature, the fusion time, and the aluminum spherical diameter. Graphs are provided to estimate these factors quantitatively during the fusion process and to predetermine the configuration of an alloyed junction. A method is also derived to calculate the penetration depth of aluminum in silicon.

In the manufacture of some semiconductor devices, the p-n junctions are prepared by alloying acceptor-type material such as aluminum to a homogeneous silicon crystal. The formation of alloy junctions is principally determined by the wetting of the silicon by the aluminum and subsequent solubility of the silicon into the aluminum. In order to increase the reproducibility of the process, it is often necessary to understand the causes which affect the values of diode parameters.

The purpose of this paper is to study, in detail, the phenomena occurring during the fusion of semiconductor devices.

Wettability of Silicon by Aluminum

On heating in an inert atmosphere, aluminum will wet the silicon and spread out to the shape of a section of a sphere. The wetting is dependent, in part, on the surface tension of the molten aluminum and affects the junction shape. The degree of wettability (1) of silicon by an aluminum liquid is characterized by the contact or wetting angle θ and the spreading diameter of the aluminum as indicated (2, 3) in Fig. 1, where γ_{SG} is the interfacial tension of the solid silicon-gas, γ_{SL} is the interfacial tension of solid silicon-liquid aluminum, γ_{LG} is the interfacial tension of liquid aluminum gas, and D_s is the spreading diameter of the aluminum. These interfacial tensions can also be represented as force vectors as shown in Fig. 2.

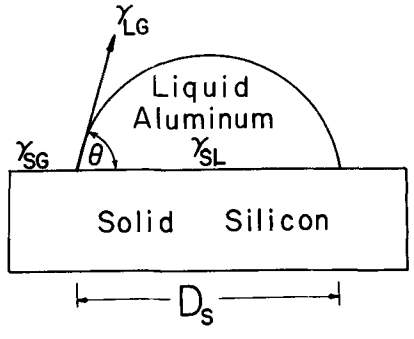

Fig. 1. Angle of contact θ of a liquid aluminum with a solid silicon surface, considered in terms of interfacial tensions.

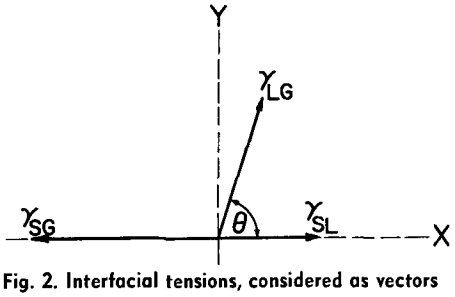

Fig. 2. Interfacial tensions, considered as vectors

For the equilibrium along the contact line, these three forces must balance each other. This gives when the gravitation is neglected

$$\gamma_{SG} = \gamma_{SL} + \gamma_{LG} \cos\theta \quad [1]$$

therefore,

$$\cos\theta = \frac{\gamma_{SG} - \gamma_{SL}}{\gamma_{LG}} \quad [2]$$

From this expression it is noted that the contact angle varies directly as the tension at the liquid aluminum-gas interface and the tension at the solid silicon-liquid aluminum interface.

For most materials, however, the surface tension of liquid decreases approximately linearly from very low temperature to a few degrees below the critical temperature where it becomes almost zero. If γ_L is surface tension of the liquid at the temperature T, its value is approximately given by (3)

$$\gamma_L = \gamma_o \left(1 - \frac{T}{T_c}\right)^{11/9} \quad [3]$$

where T_c is the critical temperature and γ_o is a quantity independent of temperature but characteristic for every substance.

According to Eq. [2] and [3] the contact angle θ is a function of temperature. The contact angle depends on the fusion temperature, time, and the gaseous medium in which the wetting occurs. It should be noted (1), however, that when aluminum is fused into silicon, the silicon is not only wetted but also dissolves in the aluminum and when the fusion temperature increases, the composition of the wetting liquid varies.

Penetration Depth of Aluminum into Silicon

The depth of penetration is determined by the solubility of silicon into the aluminum, and it depends on the fusion temperature, time, and the relative weight of the alloyed components (4). The aluminum-silicon phase diagram (5) (Fig. 3) is one way of describing the solubility of one component in another as a function of temperature. When the fusion temperature increases (6), the silicon concentration in the melt increases and the liquid will penetrate into the interior of the silicon slowly, gradually approximating an equilibrium value.

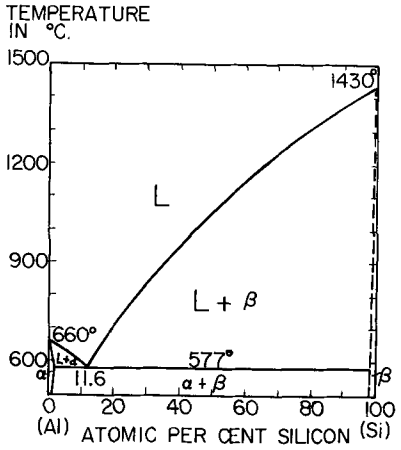

Fig. 3. Aluminum-silicon phase diagram

To calculate (6) the penetration depth of aluminum into silicon, let the ratio of silicon atoms to the total number of atoms in a melt at certain temperature be S. Then

$$V_{Si} = V_{Al} \frac{S}{1-S} \frac{\text{Density of Aluminum}}{\text{Density of Silicon}} \frac{\text{Atomic Weight of Silicon}}{\text{Atomic Weight of Aluminum}} \quad [4]$$

Since S is a function of temperature as given by the aluminum-silicon phase diagram, this can be rewritten as (6)

$$V_{Si} = F(T)\, V_{Al} \quad [5]$$

where $F(T)$ is a function of temperature and is plotted against temperature in Fig. 4. This figure has been prepared from the aluminum-silicon phase diagram shown in Fig. 3. When a small amount of aluminum sphere is heated on a flat silicon surface, it (6) will wet the silicon and spread out to the shape of a spherical segment, and at the same time it dissolves some silicon in a limited volume. The dissolved silicon volume is assumed to be in the shape of the frustum of a cone, one of whose base area is that of the contact area of the aluminum and the other is the area of transition and whose height x is the depth of penetration (see Fig. 5).

Substituting the aluminum and silicon dissolved volumes in Eq. [5],

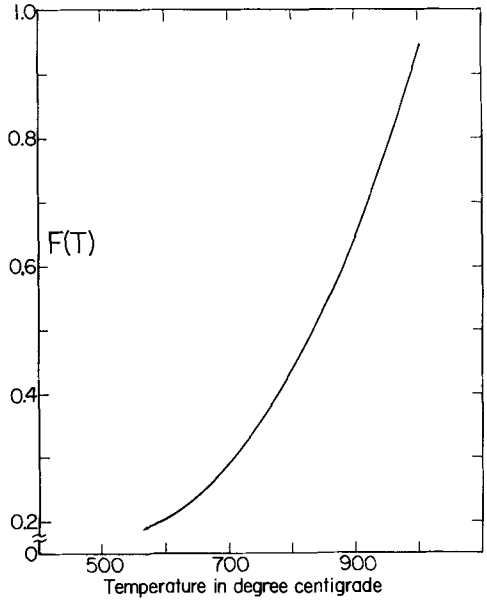

Fig. 4. Volume solubility of silicon in aluminum *vs.* temperature

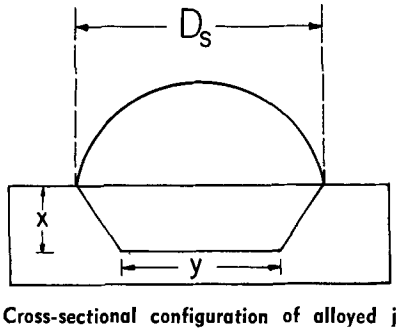

Fig. 5. Cross-sectional configuration of alloyed junction

$$\frac{\pi}{12} x(D_s^2 + D_s y + y^2) = F(T) \frac{\pi}{6} D^3$$

$$x = F(T) \frac{2D^3}{D_s^2 + D_s y + y^2} \qquad [6]$$

This is the general equation to calculate penetration depth of alloying, x, as a function of temperature, $F(T)$, diameter of aluminum sphere, D, spreading diameter, D_s, and diameter of transition, y.

Fusion Technique (1, 7)

A pure aluminum sphere is fused to the silicon dice cut from the slices of crystal to form a rectifying junction.

The procedure is to place a controlled amount of pure aluminum sphere on the surface of silicon dice and heat the crystal above the silicon-aluminum eutectic point which is 577°C in an inert atmosphere. The aluminum first melts, allows the alloy to wet the surface and dissolve some silicon in a limited area. When the silicon-aluminum liquid solution becomes saturated at fusion temperature, the fusion comes to attain an equilibrium position. However, the aluminum atoms are still diffusing into the solid silicon at the interface and convert the immediately adjacent region to p-type. If we now cool the sample under controlled cooling conditions, the saturated silicon-aluminum liquid solution, which has become p-type, regrows on the original crystal, as a continuation of the single crystal, to form the rectifying p-n junction. Both the diffusion converted and the regrown region play important factors in the device properties. The remaining aluminum liquid crystallized to form an ohmic contact to the p-region.

The entire heating and cooling cycles take place while the crystals are in an inert atmosphere, so that all the possibilities of any contamination of active elements during the fusion operation have been eliminated.

Experimental and Discussion

A fusion study was made on n-type silicon. Silicon slices were first ground using carborundum No. 280. Ground samples were polished in a mixture of hydrofluoric, nitric, and acetic acids, taken in the ratio of 1:1:1 for 6 sec at 30°C. The semipolished surface, with no scratches, dust or grease on it, was fused as described in fusion technique. Resistivity of silicon varied from 7 to 15 ohm-cm.

Contact angle.—The dependence of the contact angle on the wetting of silicon by aluminum was investigated in the temperature range of 700°-960°C. The results are shown in Fig. 6. It is evident that the contact angle decreases rapidly up to a temperature of 800°C as expected, then decreases very slowly up to a temperature of 900°C, and remains almost constant with an increase in the temperatures. The results are also illustrated by the photographs of cross sections in Fig. 7. As predicted in the theory, the surface tension of the fused aluminum decreases with an increase in the temperature. Besides, depending on the temperature, the contact angle must depend on the fusion time. In order to investigate this dependence, a fusion time of from 18 to 180 sec at the peak temperature was used. The time was measured from the instant at which the specimen reaches the preheated peak temperature. As can be seen in Fig. 8, the contact angle decreases as the fusion time at the peak temperature of 800°C increases. The result is also illustrated by the photographs of cross sections in Fig. 9.

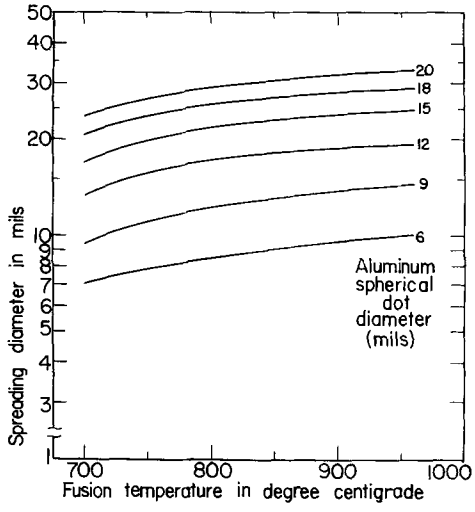

Fig. 10. Spreading diameter of the aluminum on fusion temperature and aluminum dot size (fusion time, 180 sec).

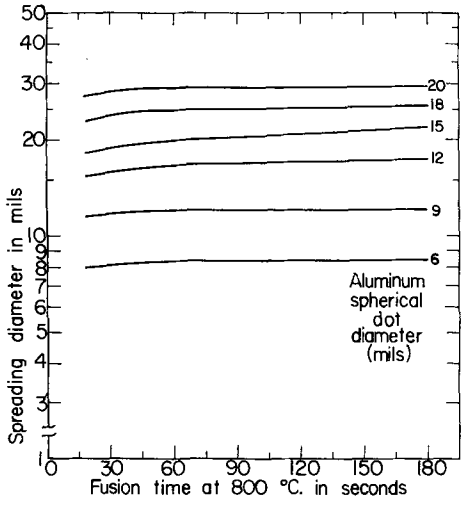

Fig. 11. Spreading diameter of the aluminum on fusion time at 800°C and aluminum dot size.

Spreading diameter.—The dependence of the spreading diameter for the wetting of silicon by aluminum was investigated in range 700°-960°C. The results are shown in Fig. 10. The spreading diameter of the aluminum dot increases rapidly up to a temperature of 800°C, and then increases slowly as the temperature increases. The spreading diameter (D_s in Fig. 1) was also investigated on the fusion time at 800°C as shown graphically in Fig. 11. The spreading diameter attains its equilibrium value during a period of 60-90 sec and remains constant for further heating. The wetting can be accelerated by exerting mechanical pressure on the aluminum liquid during alloying which helps overcome the surface tension. This method aids particularly a uniform penetration of the alloy junction area. Further wetting during alloying can be prevented by tight jig construction around the aluminum liquid.

Depth of penetration.—The dependence of the depth of penetration of aluminum into silicon was investigated in the temperature range 700°-960°C. The results on the temperature dependence of the depth of penetration of aluminum into silicon are shown in Fig. 12. The limit of the alloying depth is closely dependent on the solidus curve in the silicon-aluminum phase diagram in Fig. 3. Elementary considerations indicate that the higher the temperature, the greater will be the penetration. The depth of penetration is a function of temperature, as predicted in the theory, and also depends linearly on the relative amount of aluminum or aluminum spherical diameter. The rate of penetration will be essentially characteristic of pure aluminum dissolving pure silicon at the fusion temperature. If there is little aluminum,

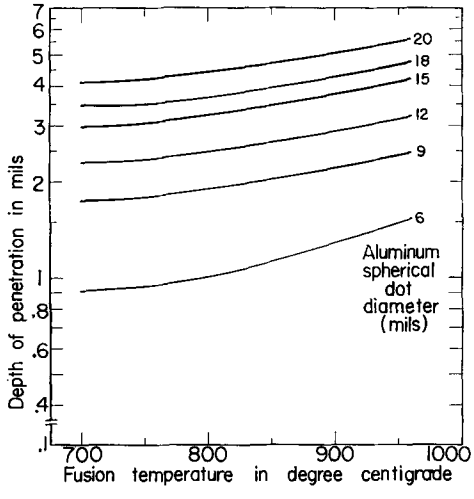

Fig. 12. Depth of penetration on fusion temperature and aluminum dot size (fusion time, 180 sec).

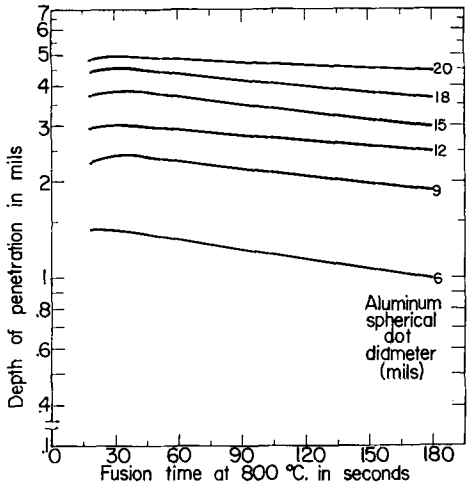

Fig. 13. Depth of penetration on fusion time at 800°C and aluminum dot size.

the silicon will saturate the aluminum rapidly and the rate of penetration must decrease rapidly. The depth of penetration of aluminum into silicon on temperature and aluminum spherical diameter, which is shown in Fig. 12, was obtained experimentally for the constant period of fusion time at peak temperature in question. In this regard, the dependence of the depth of penetration on the fusion time was also investigated and, as obtained at a temperature of 800°C, is shown in Fig. 13. The rate of penetration increases up to a fusion time of 30 sec and decreases as increasing the fusion time. It is the author's opinion that, when heated in 30 sec, the depth of penetration attains its equilibrium value on cooling. When heated beyond 30 sec, however, the aluminum melt spreads rapidly; this is caused by decreasing liquid surface tension before the depth of penetration attains its equilibrium value. The depth of penetration is determined by the temperature, aluminum spherical diameter, and time; therefore, when aluminum is fused into silicon it is not practical to prolong the heating process beyond 30-40 sec. It is also not practical to limit the fusion time to less than 20-30 sec.

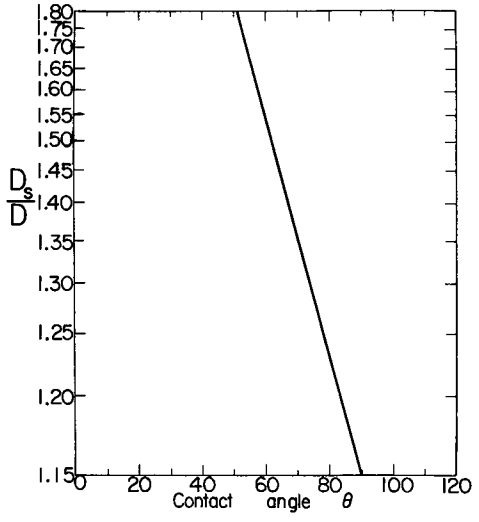

Fig. 14. Contact angle vs. spreading ratio

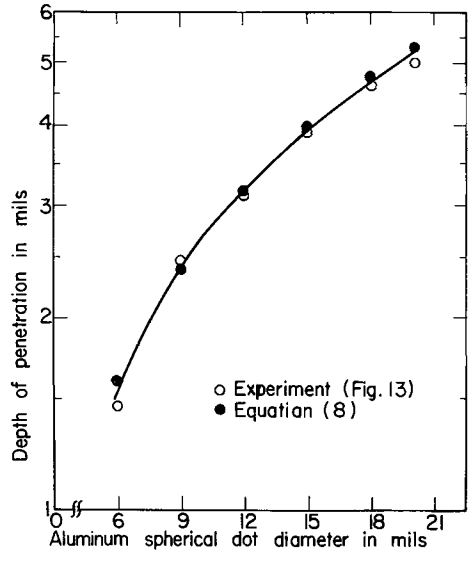

Fig. 15. Depth of penetration on aluminum dot size at 800°C for 30 sec.

Throughout this experiment, it was observed that the contact angle is closely related to the spreading diameter, since both relate to the surface tensions. This relationship gives the curve of Fig. 14 in which D_s/D is called the spreading ratio. As the result of this experiment, it has been found that $D_s/D = 1.4$ as a median value for pure aluminum fusion into the clean silicon in an argon atmosphere. Substituting the value of $D_s/D = 1.4$ into Eq. [6]

$$x = F(T)\frac{2D^3}{1.96D^2 + 1.4Dy + y^2} \qquad [7]$$

Let us suppose that $y = \frac{2}{3}D$, Eq. [7] becomes

$$x = F(T)\ (0.6\,D) \qquad [8]$$

This equation was then used in preparing the curve of Fig. 15, which has closely agreed with experimental values in Fig. 13. Equation [8] is applicable only for the calculation of maximum depth of penetration at given temperature. The value of spreading ratio, $D_s/D = 1.4$, is not always to be expected, since the spreading diameter of aluminum, D_s, has a tendency to spread beyond the value of $D_s/D = 1.4$ for the prolonged fusion time beyond 30 sec.

When an aluminum sphere 12 mils in diameter, for example, is heated on a pure silicon surface at 800°C, the cross-sectional configuration of fused junction can be predicted, as shown in Fig. 16.

Shape of the p-n transition.—The typical shapes of the transitions which were observed in this experiment are shown in Fig. 17. Figure 18 shows the approximate locations of photographs in Fig. 17. The "isosceles" effect on triangle is due to slight polishing angle.

Since silicon is normally grown in the direction (111) and dice used for making devices are cut from the crystal at right-angles to the growth axis, the author was interested mainly in the revealing of fusions on the (111) plane. However, he also studied plane (100), shown in Fig. 19. Figure 20 shows the approximate locations of photographs in Fig. 19. The

$F(T) = F(800°C) = 0.44$ (Fig. 4)

maximum penetration depth:
$x = (0.6)(12)(0.44) = 3.17$ mils (Eq. 8)

median spreading diameter:
$D_s = 1.4D = 16.8$ mils (Fig. 14)

minimum transition diameter:
$y = \frac{2}{3}D = 8$ mils

median high of aluminum melt:
$V_{al} = \frac{\pi}{6}D^3 = \frac{\pi}{6}(h^3 + \frac{3}{4}D^2h)$
$\therefore h = 6.73$ mils

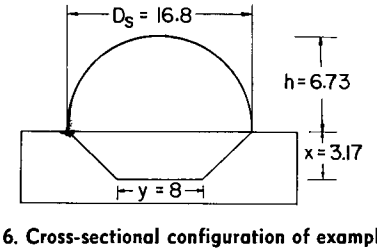

Fig. 16. Cross-sectional configuration of example

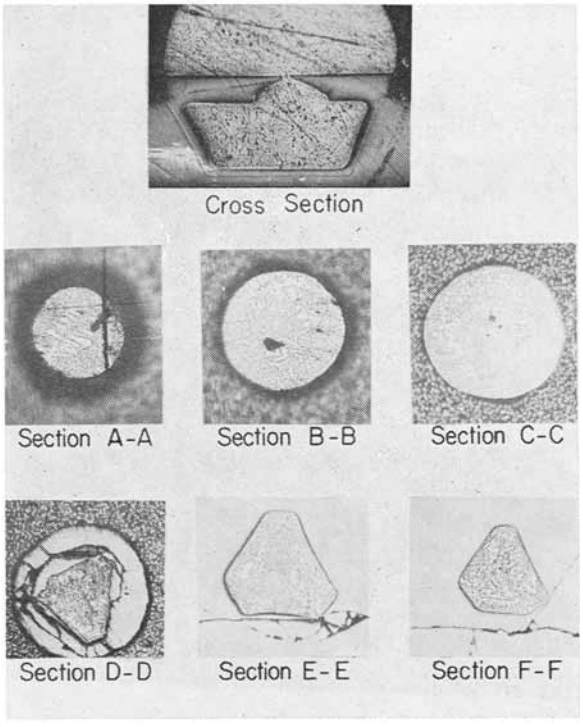

Fig. 17. Photographs illustrating planes parallel to crystal 1-1-1 plane (see Fig. 18 for sections).

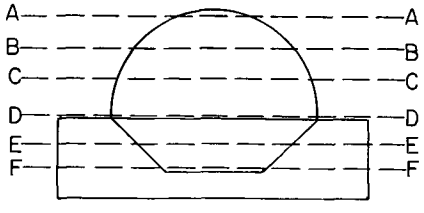

Fig. 18. Approximate locations of photographs in Fig. 17

trapezoidal effect noted in sections "E-E" and "F-F" is due to a slight polishing angle. At the tip "G-G", the p-n transition tends to approach a spherical shape.

Conclusions

The work described in this paper has been concerned with an investigation, analytically and experimentally, of the influence of fusion temperature, time, and aluminum sphere dot size on aluminum fusion into silicon. For calculating the depth of penetration of aluminum into silicon, Eq. [8] is analytically derived and verified by the experiment in Fig. 15. Figures 12 and 13 are prepared to predetermine the penetration depth of aluminum into silicon for various aluminum spheres, fusion temperatures, and time. Control of all phases of the process would make very uniform junction formation. The amount of aluminum and the heating and cooling cycles affect the junction area and the penetration of regrown region; therefore, its capacitance and the forward characteristics. Moreover, the perfection of junction formation affect on the over-all characteristics of device.

The Average Conductivity and Hall Effect of Diffused Layers on Silicon

O. N. Tufte

Honeywell Research Center, Hopkins, Minnesota

ABSTRACT

The relation between the average conductivity and Hall coefficient of a diffused layer on silicon and the surface concentration of the layer has been calculated for a complementary error function impurity distribution. The results show that the Hall coefficient is almost completely determined by the surface concentration of the layer and is only a very weak function of the mobility values used in the calculation. An experimental comparison of the surface concentration values obtained by the two methods is made.

The mathematical form of the impurity distribution in a diffused layer is determined by the boundary conditions of the diffusion process. If the mathematical form of the impurity distribution is known, the diffused layer may be completely described by a knowledge of the surface concentration and the concentration of impurities at a given distance from the surface. By knowing the concentration of electrically active impurities in the silicon before diffusion and by diffusing in electrically active impurities of the opposite conductivity type, the concentration of impurities at a given depth can be determined by measuring the location of the resulting p-n junction. Also, the p-n junction electrically isolates the diffused layer from the base silicon and allows electrical measurements to be made on the diffused layer. The general problem in the evaluation of diffused layers by this method is to relate some electrical property of the diffused layer to the surface concentration. It has previously been shown that for silicon (1, 2) and germanium (3-5) the surface concentration can be obtained by measuring the average conductivity of a diffused layer if the impurity distribution and the carrier mobilities are known for all concentrations of impurities found in the layer. Recently, Hall coefficient measurements have also been used by Subashchiev and Poltinnikov (6) to determine values of surface concentration.

In the present work, a calculation of the relation between the average conductivity and Hall coefficient of a diffused layer and the surface concentration is given for a complementary error function distribution of impurities. The results for several values of the impurity concentration in the base silicon are shown graphically. An experimental comparison of the values of surface concentration obtained by the two methods is made for n- and p-type layers on silicon.

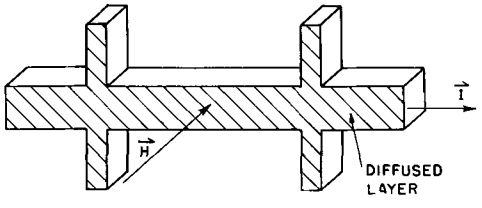

Fig. 1. Arrangement considered in the calculation of the average Hall coefficient of a diffused layer.

Method of Calculation

The arrangement considered here for the measurement of the Hall coefficient has the magnetic field perpendicular to the surface of the diffused layer as shown in Fig. 1. This arrangement has the advantage that the deflection of the carriers by the magnetic field is in a plane parallel to the surface of the layer so that the carriers are not deflected to regions of different mobility. Also, this method allows the use of the side-arm technique for making Hall effect contacts to the sample.

For the arrangement shown in Fig. 1, the expressions for the average conductivity and Hall coefficient of a surface layer in which the carrier concentration and mobility vary continuously with x, the distance from the surface area, are (7)

$$\sigma = \frac{|e|}{x_o} \int_0^{x_o} n(x)\, \mu(x)\, dx \qquad [1]$$

and

$$R = \frac{e x_o \int_0^{x_o} n(x)\, \mu^2(x)\, dx}{[|e| \int_0^{x_o} n(x)\, \mu(x)\, dx]^2} \qquad [2]$$

In these expressions $n(x)$ is the density of charge carriers at position x, $\mu(x)$ is the mobility of these carriers, e the charge of the carriers, and x_o the thickness of the layer. In Eq. [2] the assumption is made that the Hall mobility is equal to the drift mobility. It is also assumed that the diffused surface layer is completely isolated from the bulk so that the bulk is neglected in the calculation. Thus the layer thickness x_o is equal to the measured pn junction depth. Only one type of charge carrier is assumed to be present in the diffused layer. This assumption is questionable near the pn junction, but for the cases discussed here, the contribution to the integrals from the region near the pn junction is very small so that no significant error results.

For the complementary error function impurity distribution, the $n(x)$ in Eq. [1] and [2] is replaced by

$$n(x) = N_s \left(1 - \operatorname{erf} \frac{x}{2\sqrt{Dt}}\right) - N_o \qquad [3]$$

where N_o is the bulk impurity concentration of the base silicon, N_s the surface concentration, x the distance from the surface, and Dt the diffusion coefficient-time product. The values of the carrier mobilities used by Backenstoss (1) are used here. His relations for n-type silicon are

$$\mu_n = 300(19\text{-}\log N) \quad \text{for } 10^{16} < N < 5 \times 10^{18} \text{ cm}^{-3}$$
$$\mu_n = 80 \quad \text{for } 5 \times 10^{18} < N < 10^{21} \text{ cm}^{-3} \quad [4]$$

and for p-type silicon,

$$\mu_p = 180(18.2\text{-}\log N) \quad \text{for } 10^{16} < N < 8 \times 10^{17} \text{ cm}^{-3}$$
$$\mu_p = 40 \quad \text{for } 8 \times 10^{17} < N < 10^{21} \text{ cm}^{-3} \quad [5]$$

where N is the concentration of donor or acceptor atoms. For impurity concentrations of less than 10^{16}, the nearly constant mobilities appropriate to lightly doped silicon were used. The mobilities given in Eq. [4] and [5] are effective mobilities defined by

$$\mu = \frac{1}{e\rho N}$$

where ρ is the resistivity. This takes into account the incomplete ionization which occurs in doped silicon.

By making use of Eq. [3] one can rewrite Eq. [1] as

$$\sigma = \frac{|e|}{x_o} \int_o^{x_o} \mu(N) \left[N_s \left(1 - \text{erf} \frac{x}{2\sqrt{Dt}} \right) - N_o \right] dx \quad [6]$$

where $\mu(N)$ is given by Eq. [4] or [5]. At this point it is convenient to make a change of variable in Eq. [6] by letting $x = ax_o$, where a is a number between 0 and 1 and $w = x_o/2\sqrt{Dt}$. Equation [6] may then be written

$$\sigma = |e| \int_o^1 \mu(N) \left[N_s(1 - \text{erf } wa) - N_o \right] da \quad [7]$$

By making the same substitutions for the Hall coefficient in Eq. [2], one finds that

$$R = \frac{e \int_o^1 \left[N_s(1 - \text{erf } aw) - N_o \right] \mu^2(N)\, da}{\left[|e| \int_o^1 \left[N_s(1 - \text{erf } aw) - N_o \right] \mu(N)\, da \right]^2} \quad [8]$$

The expression in the denominator of Eq. [8] is the conductivity given by Eq. [7] and thus, if the conductivity for a given set of conditions has been calculated, only the numerator of Eq. [8] must be calculated to determine the Hall coefficient.

The value of w in Eq. [7] and [8] is determined by the values of N_s and N_o used in the calculation. Since intrinsic carriers are neglected when a is unity, $n(a)$ must be zero so that

$$w = \text{erf}^{-1} \left(1 - \frac{N_o}{N_s} \right)$$

The value of w depends only on N_o and N_s and not on the diffusion coefficient or time.

The integrals in Eq. [7] and [8] were evaluated numerically using Simpson's rule.

Results and Discussion

The results of this calculation for n- and p-type layers are shown in Fig. 2 through 5. The various curves in each figure are for different values of N_o, the impurity concentration in the base silicon. Three

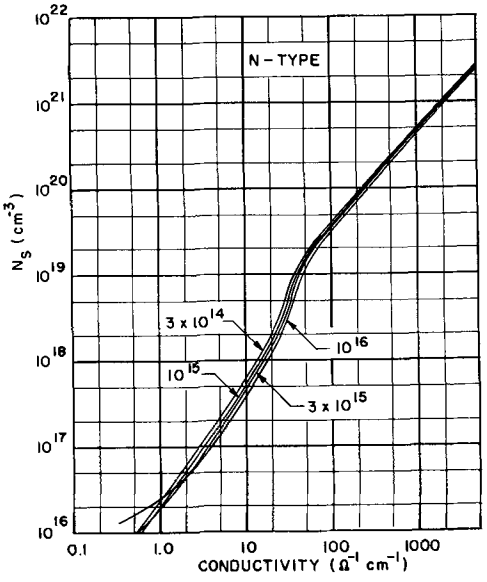

Fig. 2. Surface concentration N_s vs. average conductivity for an n-type diffused layer on silicon.

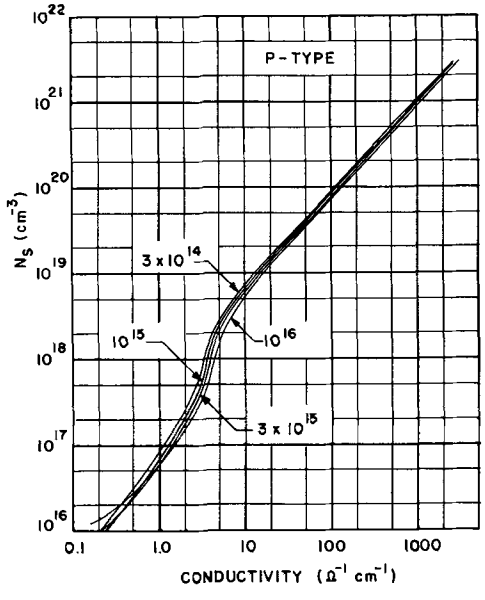

Fig. 3. Surface concentration N_s vs. average conductivity for a p-type diffused layer on silicon.

points per decade were used for each curve. The conductivity curves shown in Fig. 2 and 3 compare very well with the ones given by Backenstoss (1) for surface concentrations below 10^{18} cm^{-3}. However, for conductivities corresponding to concentrations above about 10^{18} cm^{-3}, the present curves give surface concentration values between two and three times larger due to a systematic error present in Backenstoss' curves.

The Hall effect curves for n- and p-type layers shown in Fig. 4 and 5 are very nearly identical. To show this better the curves for n- and p-type layers on silicon having a bulk impurity concentration of 3×10^{14} cm^{-3} are replotted in Fig. 6. Also shown in this figure is the Hall coefficient curve obtained by assuming the mobility is independent of impurity concentration, *i.e.*, $R = 1/\overline{N}e$ where $\overline{N}$ is the average impurity concentration. The curves in Fig. 6 show that the Hall coefficient in both n- and p-type dif-

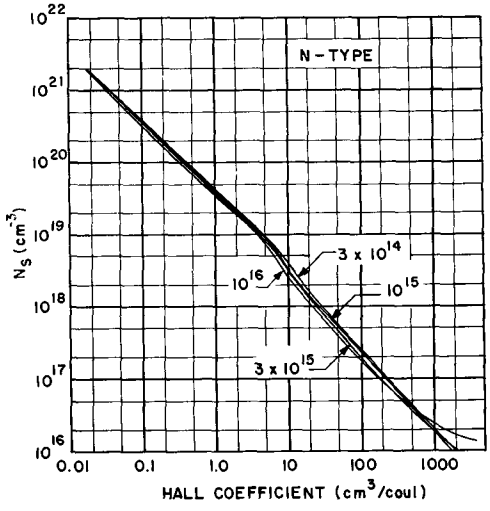

Fig. 4. Surface concentration N_s vs. average Hall coefficient for an n-type diffused layer on silicon.

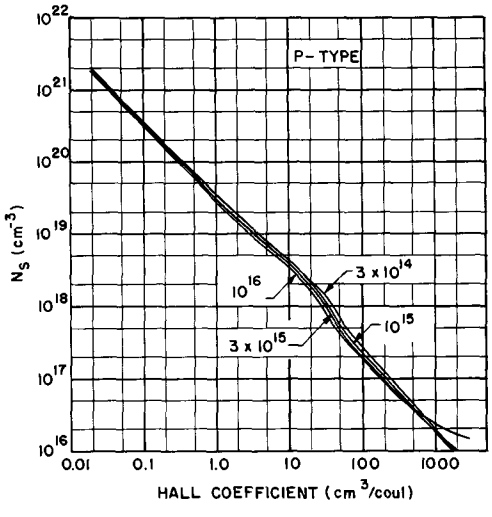

Fig. 5. Surface concentration N_s vs. average Hall coefficient for a p-type diffused layer on silicon.

fused silicon layers is very nearly a measure of the average carrier density and only a weak function of the mobility. Thus the accuracy of the surface concentration values obtained by the Hall effect method can be much greater than the accuracy to which the mobility values are known. This would make the Hall effect method especially useful for diffusion studies on less well-known semiconductor materials.

Comparison of surface concentration values obtained by average conductivity and Hall effect measurements.—Hall effect and conductivity measurements were made on diffused silicon layers to compare the values of surface concentration obtained by the two methods. Samples having two sets of side arms for Hall and conductivity measurements were ultrasonically cut from high resistivity (~300 ohm-cm) silicon. Both a pn junction and high resistivity base material were used to minimize leakage of current from the diffused layer. The samples were placed in an open-tube diffusion apparatus, and a diffused layer was formed on all sides of the samples. The thickness of the diffused layer was measured by angle lapping and staining (8) a monitor sample to determine the pn junction depth. The diffused layer is made sufficiently thick that the resistance of the

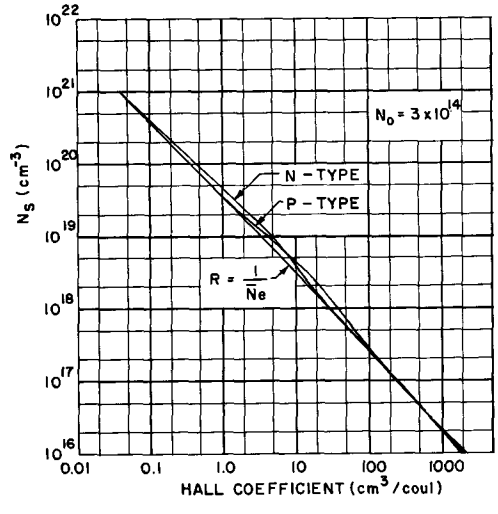

Fig. 6. Comparison of the surface concentration N_s vs. average Hall coefficient curves for n- and p-type diffused layers on silicon along with the mobility independent Hall coefficient curve.

layer is less than 2% of the resistance of the silicon in parallel with it. On one sample, the sides were etched after diffusion leaving a diffused layer only on the front and back surfaces such as shown in Fig. 1. The measured conductivity and Hall coefficient were the same before and after etching, indicating that the diffused layer on the sides of the sample is not introducing any spurious effects. Boron or gallium were used for p-type layers, and phosphorus or antimony were used for n-type layers.

The results for several n- and p-type layers having a wide range of surface concentrations are given in Table I. The agreement between the surface concentration values obtained by the two methods is very good at the higher concentrations. The largest discrepancies occur at the lower surface concentrations and can be attributed mostly to the insensitivity of the conductivity to surface concentration at concentrations near 10^{18} cm^{-3}. In this region a variation of ±10% (the accuracy of the layer thickness measurement) in the conductivity will result in a change of a factor of two in the surface concentration. Also, the uncertainty in the mobility values used in the calculation of the conductivity and deviations of the impurity distribution from a complementary error function can lead to a variation in the surface concentration values measured by the two methods. Conductivity values are corrected for incomplete ionization of the impurities by means of the mobility values used in the calculation. Since the calculated Hall coefficient values are nearly independent of the

Table I. Results for several n- and p-type layers

	Sample	N_s (conductivity) cm^{-3}	N_s (Hall coefficient) cm^{-3}
p-type	251A	2.0×10^{21}	2.0×10^{21}
	254A	7.0×10^{20}	7.7×10^{20}
	1021A7	2.7×10^{20}	2.4×10^{20}
	C595	6.6×10^{19}	5.9×10^{19}
	C593	1.3×10^{19}	0.7×10^{19}
	C594	3.5×10^{18}	5.6×10^{18}
n-type	3153	3.2×10^{20}	3.8×10^{20}
	KG1	3.0×10^{19}	5.2×10^{19}
	3151	1.8×10^{18}	0.8×10^{18}

mobility, these values are not corrected for incomplete ionization. However, for the impurities used, this correction is significant only in p-type layers and at an impurity concentration near 10^{18} cm^{-3}. Experimentally, the Hall effect method does not give consistently lower surface concentration values. This indicates that any errors due to incomplete ionization are smaller than the discrepancy between the surface concentration values obtained by the two methods.

Effects of Copper on Fast Surface States of Etched Germanium

D. R. Frankl

General Telephone & Electronics Laboratories, Inc., Bayside, New York

ABSTRACT

Copper contamination is found to influence the fast surface states of Ge. The nature of the effect depends on the previous surface treatment: (*a*) on an etched surface, which is hydrophobic, the copper has little immediate effect, but enhances the growth of the density of recombination centers in oxidizing atmospheres; (*b*) on a KOH-treated surface, which is hydrophilic, the copper immediately produces a large concentration of recombination centers. In general, there is no apparent correlation between surface recombination and charge trapping in fast states.

In recent years there have been a number of studies (1-9) of the influence of the preparation and treatment procedures on the resulting fast surface states on germanium surfaces. One of the primary objectives of such studies has been to associate the surface states with specific physicochemical entities existing at or near the surface. In further pursuit of this objective, the present work deals with the effects of a deliberately added contaminant, copper, on the fast states of germanium, both freshly etched and aged in various gases. Copper was chosen for this study because of its known activity in the bulk and because it had already been shown (8) to influence certain surface properties.

Experimental Procedures

Measurements of the large-amplitude a-c field effect in the dark and under illumination were made on samples cut to the shape illustrated in Fig. 1. This geometry obviates the necessity of masking the contacts during etching, since the sample is dipped into the etchant only about half way up the legs. Thus, there is no possibility of contamination of the surface by matter dissolved from the masking material.

Figure 1 also shows the arrangement of the two field plates (one transparent) and mylar spacers. An important feature is that, in contrast with the usual arrangement, the spacers are cut out over the active portion of the sample. This promotes uniformity of the surface in two ways: (*a*) the ambient gas has free access to all portions of the surface; and (*b*) the capacitance variations arising from surface roughness are minimized. It is true that the applied field is limited by breakdown to about 10^6 v/cm, which is only about one-tenth as large as can be applied with a full dielectric spacer, so that the accessible range of surface potential is reduced by several kT/e. However, since the work of Rzhanov *et al.* (4), as well as some preliminary experiments in this laboratory, have shown that higher a-c fields can significantly increase the fast state density, it is not certain that this restriction is a serious one.

Most of the measurements were made on a 10.8 ohm-cm p-type germanium sample about 8 mils thick with surfaces parallel to [111] planes. The bulk lifetime was not known precisely, but was certainly >150

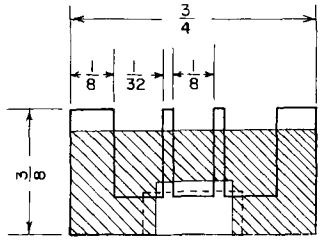

Fig. 1. Sample geometry. Heavy outline = die-cut Ge sample, dimensions in inches; hatched area = 1 mil mylar spacers; dashed outline = field plates, one transparent. The sample thickness is ~ 0.010 in.

μsec, so that the recombination was nearly always strongly dominated by the surface.

Two types of etchant were principally employed: (*a*) a "standard etchant" (600 cc HNO_3, 1200 cc acetic acid, 100 cc HF, 25 mg KI) that gave slow uniform dissolution, and (*b*) HF followed by hot KOH. The reasons for the use of the latter rather unconventional treatment will be given later. After etching, the sample was quickly plunged into a large volume of deionized water, rinsed copiously in flowing water (about 1 megohm-cm), rinsed again in recirculating water (5 to 10 megohm-cm), and dried with absolute ethanol. When copper was to be applied, the sample was dipped in a 1 ppm $Cu(NO_3)_2$ solution before the ethanol.

The prepared sample was mounted in a holder with field plates and spacers, the latter being swabbed with cotton dampened with trichloroethylene to remove dust. This usually assured that the capacitances to the two field plates agreed within 2 or 3%. The total time for preparation, mounting, and capacitance measurement amounted to about 10 min. Thereafter, the assembly was kept under controlled conditions in a copper box immersed in a water bath thermostatted to 27.00° ± 0.01°C. Nitrogen or oxygen, dried with "molecular sieve" or bubbled through water, was circulated through the box at about 0.1 liter/min after passing through a long copper coil in the water bath, and was taken out through a dew-point apparatus and a silicone oil trap. Dew points of the dried gases were usually below −75°C. The nitrogen was first de-oxygenated with a vanadyl sulfate solution (10). The oxygen could be ozonized by sparking with a Tesla coil.

Measurements were begun as soon as the temperature was stabilized, using the circuit shown in Fig. 2. The bridge is first balanced with switch SW open, adjusting R_G and the C_1's to obtain a single horizontal trace on the X-Y oscilloscope. Then, with SW closed and with light chopped at a nonsynchronous frequency, directed onto the sample through the transparent field plate, the oscilloscope displays both the "light" and "dark" field-effect curves. Auxiliary zero-field measurements of dark resistance and lifetime provide the factors necessary to obtain surface potential and trapped charge in fast states as usual (11) from the "dark" curve, and surface recombination velocity from the vertical difference between the two curves.

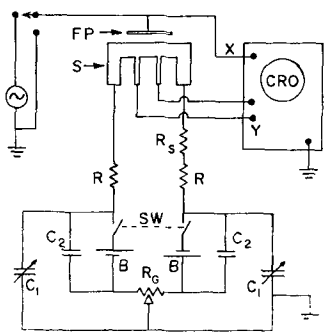

Fig. 2. Circuit diagram. S = sample; FP = field plates, one each side, one transparent; R = 300 kΩ; R_s = 1 kΩ standard resistor for measurement of sample current; B = 45-v battery; C_2 = 1 mfd; C_1 = 6-100 pf; R_G = 20 kΩ; SW = DPDT switch.

Several precautions are necessary to obtain valid results with this method. First, the sample current must be small enough to prevent sweepout of minority carriers when inversion layers are present. This requires $t_{tr} >> \tau$, where t_{tr} is the transit time of minority carriers across the region between probes, and τ the sample lifetime. Thus, the current was limited to about 0.15 ma, and a sensitive preamplifier (Tektronix Type 53/54G) used in the oscilloscope. Second, as discussed by several authors (13, 14) the light intensity must be low enough to produce little shift in the surface potential yet (necessarily) large enough to obtain measurable photoconductance. In the present work it was sometimes impossible to satisfy both of these requirements completely, particularly when the lifetime varied widely with field. It is estimated that shifts of as much as $(1/2)kT/e$ may occasionally have occurred under extreme conditions. For the most part, however, they were much smaller, and no attempt was made to correct the data. A third precaution is that the field frequency should be chosen to minimize hysteresis in the curves. In this respect, the present method has the advantage over point-by-point methods (1) that hysteresis, if present, is clearly evident. Two principal types can occur: one, due to the presence of "slow" states with fairly small time constants, can usually be minimized by increasing the frequency; the other, due to a "lifetime" effect (15), can be minimized by decreasing the frequency. Occasionally, due to one or both of these effects, single-valued curves are not obtained. In that event, the mean of the two branches is assumed to represent the correct curve provided the spread is not too large.

Results

Surfaces prepared with standard etchant.—Graphs of the surface recombination velocity s and trapped charge density Σ_{tr} as functions of the normalized surface potential u_s are shown in Fig. 3a and 3b, respectively, for the initial runs following six standard etch preparations, three with and three without copper treatment. The experimental points in these and all subsequent figures were computed without any mobility correction (16) for diffuse surface scattering. The reason for omitting this correction was that some of the oscillograms were, as was also found by Millea and Hall (17), too steep to be accountable by completely diffuse scattering. There are, of course, the possibilities that the surface scattering was partially diffuse and that the degree of diffuseness varied with the preparation and/or aging. Thus, the detailed shapes of the computed curves at extreme u_s values must be regarded as somewhat uncertain.

The s-curves (Fig. 3a) may be compared with the familiar theoretical expression (1) for a single type of recombination center, viz.

$$s = s_M \frac{\cosh(u_s - u_o) + 1}{\cosh(u_t - u_o) + \cosh(u_s - u_o)} \text{ (cm/sec)} \quad [1]$$

where $u_s = (E_F - E_i)/kT$, E_F = Fermi level, E_i = intrinsic Fermi level at the surface. $u_t = (E_t - E_i)/kT$, E_t = energy level of the center. $u_o = 1/2 \ln (C_p/C_n)$; C_p and C_n are the capture probabilities (cm³/sec) of the center for holes and electrons, respectively.

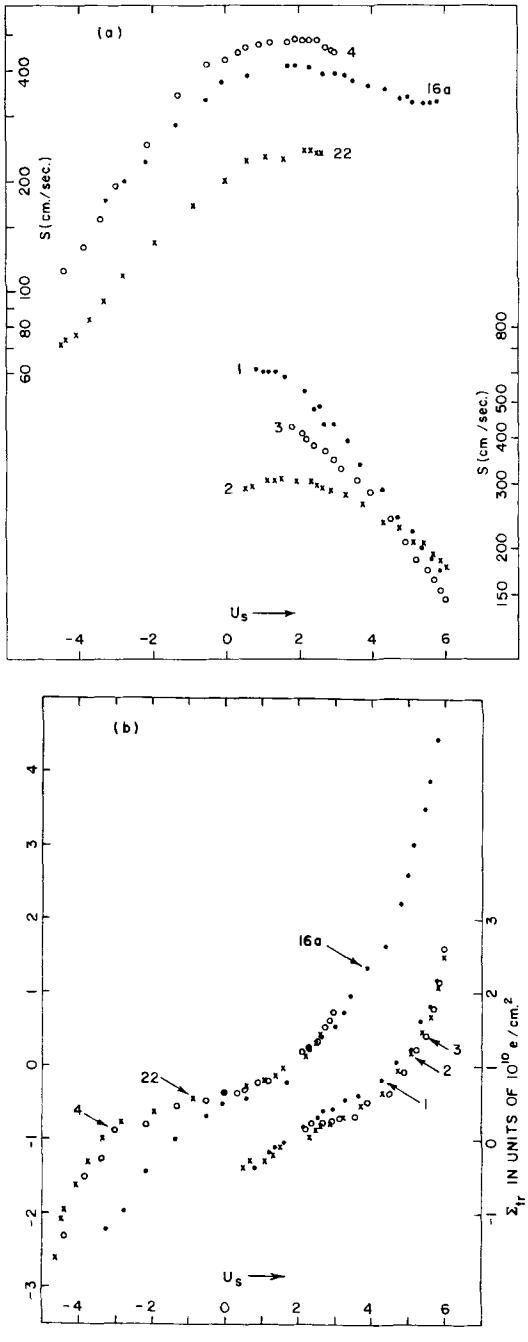

Fig. 3. First measurements after standard etches No. 1, 2, 3 (no copper added) 4, 16a, 22 (copper added). Note shift of ordinate scales.

$$s_M = \frac{N_t (C_p C_n)^{1/2} (n_o + p_o)}{2n_i[\cosh(u_t - u_o) + 1]}$$

$= \text{maximum value of } s$

$N_t = \text{surface density of centers (cm}^{-2})$

The present results are in fair agreement with the commonly observed values (1-7, 9) $u_o \sim 1$ to 2, $u_t \sim 5$, although curves 2 and 16a clearly indicate the presence of additional centers with larger u_o values. However, most striking is the rather large variation of s_M without a corresponding variation in trapped charge density in the range $u_s > 2$. Indeed, the copper treatment appears, if anything, to lower s_M slightly, but roughly to double Σ_{tr}. Thus, there appear to be recombination-ineffective states in the same energy range as the recombination centers. A

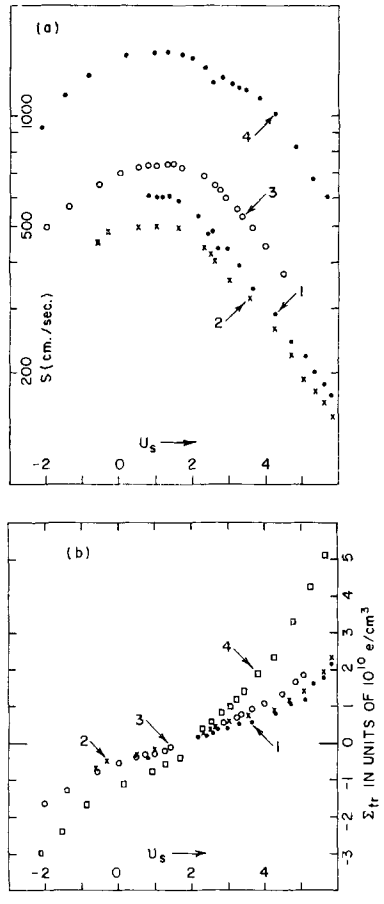

Fig. 4. Aging effects after etch No. 1 (no copper added). 1, initial run after 24 hr in dry N_2 (same data as in Fig. 3). 2, 48 hr in dry N_2. 3, 24 hr in dry O_2. 4, 16 hr in dry O_2 following 15 sec in ozonized O_2.

similar result was found by Arnold (13) on ion-bombarded surfaces, and further examples will be cited below.

As is evident from Fig. 3, the surfaces prepared without copper were quite strongly n-type at zero field. Indeed, initially the n-type bias was so strong that the conductance minimum could not be reached, and it was necessary to wait several hours (24 hr in the case of etch No. 1) while the surface drifted toward p-type. The copper treatment, however, made the surfaces more p-type (8), and measurements were commenced at once.

Some effects of oxygen and of brief (15 sec) exposure to ozone are illustrated in Fig. 4 and 5. The effects of the ozone could only be measured after some hours of "recovery" during which an appreciable hysteresis effect slowly diminished. These treatments increased both s_M and Σ_{tr}, as had been previously found, in whole or in part, by some authors (2, 4, 5, 12).

A new result, however, is the fact that the increases in s_M are considerably greater for the copper-treated than for the untreated surface. Furthermore, although Σ_{tr} at $u_s \sim 5$ changes roughly proportionally to s_M for the untreated surface, there is very little change in this range with copper. This again illustrates the lack of correlation between s_M and Σ_{tr}.

An attempt was made to ascertain whether the aging effects on the untreated surface were connected with accidental copper contamination, by rinsing the

sample in KCN after etching. The surface was then, however, highly sensitive to the a-c field (*i.e.*, the "dark" oscilloscope curve changed markedly, indicating an increase in Σ_{tr}, within a few seconds after applying the field) and no reliable data were obtained.

Surfaces prepared with HF *and* KOH.—In the course of the work described in the preceding section, it became clear that the standard etch procedure suffered two major deficiencies: (*a*) the initial strong n-type bias described above; and (*b*) the initial, familiar (18), strongly hydrophobic character of the surface, which cast doubt on the efficacy of the rinsing procedure.

Accordingly, an extensive series of variations of the preparation procedure was undertaken, with results, in brief, as follows:

1. Careful drying (copious amounts of absolute ethanol) and crude drying (blotting) produced essentially the same results. Hence, the initial n-type bias was not due to residual water, as was first conjectured.

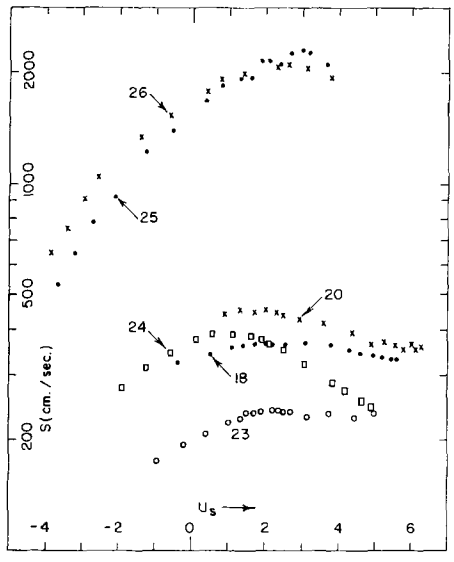

Fig. 6. Initial runs following treatment with 48% HF (1 min) followed by hot KOH (1 min). Nos. 18, 23, 25: 1% KOH; Nos. 20, 24, 26: 0.1% KOH; Nos. 25, 26: copper added. Measurements made about 30 min (in dry N_2) after treatment.

2. HF, alone or followed by acetic acid, produced essentially the same results as the standard etch, though with perhaps slightly higher s_M.

3. On one occasion, dipping the sample in 5% NH_4OH about 4 hr (in dry N_2) after a standard etch immediately removed the n-type bias. This experiment had been prompted by the thought that the bias might be due to an adsorbed layer of protons remaining from the strong acid etchant. The initial result appeared to bear this out, but later it was found that NH_4OH solutions up to 30% concentration applied immediately after etching, either in the standard etchant or in HF, left the surface still strongly n-type. Therefore, it appeared plausible that, if protons were indeed the surface donors giving rise to the n-type bias, they were initially protected from chemical neutralization by a hydrophobic film. The well-known (18) disappearance of the hydrophobicity with time would then account for the observation of neutralization by dilute NH_4OH after some hours.

4. Two of the writer's colleagues, P. Goldberg and D. H. Baird, made the valuable suggestion that the supposed film might be a hydrated oxide of germanium and that it might be soluble in a caustic solution. This treatment proved to reduce both the hydrophobicity and the n-type bias greatly, and the remainder of this paper is devoted to measurements on the resultant surfaces. In detail, the treatment was as follows: 1 min in 48% HF at room temperature; plunge, then rinse copiously in 1 megohm-cm water; 1 min in hot (~90°C) KOH (0.1-10%); rinse as before; rinse in 5-10 megohm-cm water; 15 sec in 1 ppm $Cu(NO_3)_2$ when desired; dry with absolute ethanol.

Figure 6 shows the initial *s* curves after several surface treatments of this type. The copper now greatly increases s_M, presumably by introducing additional recombination centers. If the above hypotheses concerning the hydrophobic film are cor-

rect, then removal of this film by KOH permits the copper ions to interact much more strongly with the germanium surface.

The additional centers due to copper appear either to be of several kinds or to possess several energy levels, since the differences in s between the copper-treated and untreated surfaces cannot be fitted by a single expression of the form (1). Fitting near the maximum indicates $u_o \sim 2.8$, $| u_t - u_o | \sim 3.5$, with additional levels having $u_o < -4$, but these values should be regarded as highly tentative.

The trapped charge curves corresponding to Fig. 6 showed, unfortunately, a great deal of variation, hence will not be discussed in detail. As before, however, there was no apparent correlation between Σ_{tr} and s.

Some preliminary aging results were also obtained following etches 20 and 26. In the former (no copper), s_M increased to about 700 cm/sec in N_2, 800 in O_2 and 1100 after ozone. In the latter, s_M changed relatively little in N_2, but decreased to 1400 cm/sec in O_2 and remained at about that value after ozone. In both cases, Σ_{tr} increased in both O_2 and ozone.

Discussion

The major results of the preceding section may be summarized as follows:

1. Copper (and presumably many other contaminants) influences the fast surface states; the nature of this influence depends on the previous surface treatment.

2. On the hydrophobic surface produced by at least one etchant, the copper effect is relatively slight initially, but the growth in density of recombination centers in oxidizing atmospheres is enhanced.

3. On the hydrophilic surface resulting from hot KOH treatment, the copper immediately produces recombination centers with indications of complex level structure.

4. There is, in general no correlation of s with Σ_{tr}. This means that the recombination center energy level cannot be used validly in the fitting of the Σ_{tr} *vs.* u_s curve by a sum of Fermi functions. It is for this reason that no attempt has been made in the foregoing to deduce trap state energies or concentrations.

A qualitative comparison with previous work may, however, be obtained by comparison of the minimum slopes of the trapping curves. For fresh surfaces, we obtain $(d\Sigma_{tr}/du_s)_{min} \sim 3 \times 10^9$ cm^{-2}, which is comparable to the results of Montgomery and Brown (11), Wallis and Wang (5), Rzhanov *et al.* (2), and Litovchenko and Lyashenko (19). Harnik and Margoninski (6), on the other hand, found minimum slopes about three to ten times greater, comparable with the results on "aged" surfaces of Many and Gerlich (1) and Margoninski and Farnsworth (9) and to those on ozone-treated surfaces of Rzhanov *et al.* (2), Flietner (12), and the present work. Presumably this reflects some subtle difference in surface preparation and may be connected with their finding (6) that s_M was sometimes decreased by ozone treatment, as in the present copper-treated KOH-prepared surfaces.

Another point of comparison concerns the use of HF alone as an etchant. Margoninski (7) finds that this "greatly increases the surface recombination velocity" whereas here little or no change was found. The latter result is the more "desirable" since it permits many repeated etches of the same sample without serious geometrical distortion. The conflicting results, however, strongly emphasize again the sensitivity of surfaces to minute variations in the preparation procedures.

Finally, mention should be made of the very interesting recent work of Boddy and Brattain (20), who found that on germanium surfaces in contact with especially purified electrolytes addition of trace amounts of Cu^{++} to the solution introduces appreciable numbers of surface recombination centers. This again demonstrates that copper can produce quite drastic effects if allowed to come into intimate contact with the surface.

Acknowledgments

Sincere thanks are due to A. Feuersanger for assistance and suggestions in setting up the measurements, and to P. Goldberg and D. H. Baird for extremely helpful discussions.

Manuscript received Oct. 5, 1961. This paper was prepared for delivery before the Detroit Meeting, Oct. 1-5, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

Double Layer Capacities of Single Crystals of Gold in Perchloric Acid Solutions

G. M. Schmid and Norman Hackerman

Department of Chemistry, The University of Texas, Austin, Texas

ABSTRACT

The electrical double layer differential capacity has been measured by single pulse technique on single crystal gold electrodes exposing the (100) and (110) crystal plane in 0.001-1*N* $HClO_4$ between about —0.9v (15 ma/cm² maximum cathodic current) and +1.4v *vs.* SCE. A capacity maximum at +0.9 to +1.3v, depending on concentration, is attributed to "oxygen" adsorption. This showed strong hysteresis, the corresponding desorption peaks being as much as 500 mv more negative. Some evidence for adsorption of a second "oxygen" species is presented. A maximum occurring at +0.4v has been ascribed to slight specific ClO_4^- adsorption. A "hydrogen" adsorption peak is observed only on the (100) electrode at —0.2v. The complete absence of a profile during actual H_2 evolution is taken as evidence that recombination of H atoms is not the rate-determining step. A capacity minimum appears at the (110) electrode in $10^{-3}N$ $HClO_4$ at 0.0v and between two small maxima at the (100) electrode at —0.05v. These minima have been tentatively identified as the zero point of charge. The difference of 50 mv is reflected in an equal difference in the oxygen adsorption peaks. The zero point of charge potentials agrees satisfactorily with values interpolated from work function data.

The metal/electrolyte system is of interest to both the surface chemist and the electrochemist, mainly because it allows variation of the potential drop across the metal/electrolyte interface by applying a bias in an electrochemical cell. According to the theory of electrocapillarity (1), measurements of the interfacial tension as a function of potential permit calculation of the electronic charge on the metal at any potential and the determination of the zero point of charge (2). This information can be used to calculate the amount of cationic and anionic charge adsorbed at the solution side of the interface (1).

Surface tension measurements of the required accuracy are limited to liquid metals, *i.e.*, at room temperature, to mercury, some amalgams, and gallium. High-temperature data on molten metals are available (3). Attempts to replace surface tension by other properties, for example friction (4), repulsion of two wires of equal potential (5), have been made recently with some success in the latter case.

Complementary to surface tension data, and in principle not restricted to liquid metals, are measurements of the interfacial differential capacity, which constitutes the second derivative with respect to potential of the surface tension-potential function. On mercury, excellent agreement was found between properties of the interface calculated from surface tension data and from differential capacity measurements (1).

Differential capacity measurements can be made with an impedance bridge using sine wave alternating current (a.c.) (6), or with charging techniques using square wave currents (7, 8) or single constant current pulses (9, 10). The data are interpreted on the basis of simple circuit analogs, *e.g.*, a capacitor and a resistor in series, or in parallel.

On electrodes other than mercury, electrochemical reactions frequently take place. These find their expression in a more or less pronounced dependence of the capacity on the frequency of the bridge a.c. (11), or in an increasingly curved potential-time function when using a charging technique (7). At least part of the charge supplied to the electrode by the measuring signal flows across the interface, rather than only up to it as in the case of an ideally polarizable electrode (12). For a given electrochemical reaction the charge crosses the interface at a rate which is dependent on the frequency of the a.c., or on the time elapsed after application of the constant current signal. It is only at high frequencies, or at times in the order of microseconds, that this part of the total supplied charge becomes negligible and true double layer capacities are measured. "Pseudocapacities" obtained with low frequency a.c. on nonideally polarized electrodes should be interpreted on the basis of reaction parameters rather than properties of the electrical double layer.

The impedance of a given interface becomes smaller and smaller with increasing frequency of the a-c measuring signal. Thus, the limit of practicality for this type of measurement is set at about 200 kc (13). On the other hand, single pulses of 1 μsec duration are easily available today, corresponding in fundamental frequency to values with which a-c impedance measurements can be made only with difficulty.

Solid electrodes present some special problems. The unknown true area of the electrodes makes un-

certain the absolute magnitude of the parameters of the electrical double layer. Moreover, roughening of the electrode during the experiment should lead to time dependence. The electrode surface cannot be renewed constantly, as in the case of the dropping mercury electrode. Therefore extreme purity has to be achieved and maintained. Due to the difference in work function of single crystal faces (14), a difference in their electrical double layer parameters can be expected (15). In other words, two electrodes of the same material in the same solution may behave quite differently, depending on which crystal plane is predominantly oriented in the surface.

This investigation was undertaken to elucidate the influence of crystal orientation on the capacity of the electrical double layer. Gold was selected because of its availability in single crystals. Perchloric acid solutions were taken as electrolyte, ClO_4^- being the anion with the least likelihood of specific adsorption (1). The capacities were measured with a single pulse technique and equipment recently developed (10). The method is based on a circuit analog for the electrical double layer of a single resistor and capacitor in parallel.

Experimental

Materials.—The single crystals of gold, oriented by x-ray analysis, were obtained from Monocrystals Company, Cleveland, Ohio. They were pressure sealed into short pieces of Kel-F at 200°C, so that the (100) or (110) face was exposed. This method was adopted after attempts to obtain a good seal with Teflon as described by Breiter and Hoffman (16) failed, probably because of the rather irregular surface of the single crystal rods. A threaded brass rod, nut, and Teflon washers allowed the Kel-F mold to press tightly against a Pyrex glass holder, giving a water-proof seal and providing electrical contact with the gold. The apparent electrode area was about 0.09 cm^2. To obtain minimum roughness, electropolishing was tried at first, but had to be abandoned because of preferential attack at the edges. For the experiments reported here, the electrodes were etched in aqua regia, washed in conductivity water, and degreased with acetone in a soxhlet. The roughness factor was estimated to be 1.5.

Solutions, 1 to $10^{-3}N$ $HClO_4$, were made up from stock 70% $HClO_4$ and water from a Barnstead conductivity still ($\sim 2 \times 10^{-7}$ ohm^{-1} cm^{-1}). The solutions were pre-electrolyzed between Pt electrodes for 48 hr at 10-100 ma, and degassed with a steady stream of Grade A He for an additional 12 hr.

Cell and method.—The all-Pyrex glass cell contained a large platinized Pt wire gauze as polarizing electrode. Polarizing current was supplied by the pulse generator, or by a potentiometer and a large SCE whenever the total required current was less than 1 μa (from about $-0.2 + 1.4$v). The potentials were measured with a second SCE and a Haber-Luggin capillary, using a Keithley electrometer. They are reported with respect to SCE. A rapid stream of He served as stirrer and to remove gases evolved during the experiments. The cell had a jacket which contained $K_2Cr_2O_7$ solution, thermostated at 30°C. When connected to ground, the jacket gave an efficient shield for the cell.

The single pulse method and equipment used here has been described elsewhere (10). The differential capacity, C, was calculated with

$$C(t = 0) = \Delta Q'(0)/\Delta e'(0) \qquad [1]$$

[Eq. 10a in ref. (10)], where $\Delta Q'(0) = I_2 - I_1$, with I_1, the current density at time $t < 0$ (before the pulse) and I_2 the current density at $t > 0$ (during the pulse). $\Delta e'(0)$ is the change in slope of the potential-time curve at $t = 0$. A resistor and a capacitor in parallel were taken as the circuit analog for the electrical double layer in this analysis. The potential-time function of the test electrode was displayed on a Tektronix Type 545 oscilloscope using a Type-D preamplifier. The trace was photographed with a Dumont Polaroid oscilloscope camera.

Equation [1] requires obtaining the slope of a curve at one point ($t = 0$). Taking slopes with a ruler involves at least two points, and the measurement becomes more accurate the straighter the portion of the curve between the two points and in the limit of a straight line, the greater the distance between the two points. Therefore, the horizontal sweep of the scope was set so that a linear portion over at least 5 cm was obtained. In most cases, 5 μsec/cm served the purpose, but during H_2 evolution a sweep speed of 1 μsec/cm was necessary. The amplitude of the pulse was selected so that a vertical deflection of 2-4 cm over the horizontal screen width was obtained (1-0.1 ma). The scope amplifiers are linear to within 3% only, thus limiting the precision of the capacity measurement. The agreement between successive runs also was within 3%.

A run was started at about -1.0v (15 ma/cm^2 cathodic for $1M$ $HClO_4$). A capacity measurement was taken 10 min after the potential became steady. The electrode potential was then gradually made more noble, in steps of approximately 50 mv every 10 min. In most cases, the capacities had reached a stable value after 5 min. Experiments in which the time to obtain a final value exceeded 10 min were discarded. At $+1.4$v the direction of the potential change was reversed. Data taken this way were more reproducible than data from runs started at $+1.4$ v.

Results

During H_2 evolution the capacities of both the (100) and the (110) electrode are of the order of 10

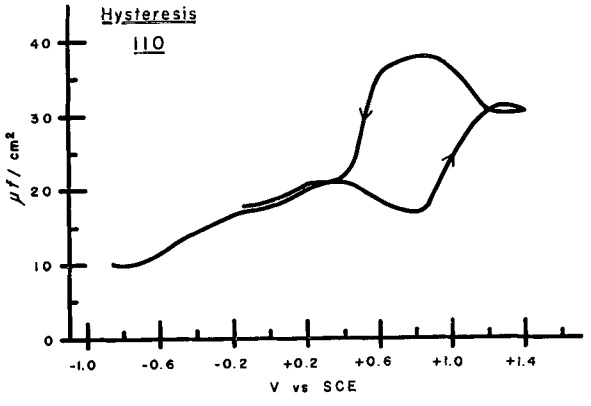

Fig. 4. Differential capacities of a (110) single crystal gold electrode in 1M perchloric acid.

$\mu f/cm^2$ (Fig. 1 and 2). The curves are flat and show no significant variation of capacity with potential between —0.6 and —0.9v (15 ma/cm^2 maximum cathodic current).

At the (110) face (Fig. 1) the capacity begins to increase at less negative potentials leading to a maximum positioned at +0.4v, independent of concentration. In 10^{-3}M $HClO_4$ this increase is interrupted by a minimum at 0.0v. A second maximum, found at +1.3v for 1M solutions, shifts about 200 mv per tenfold concentration decrease to less positive values. There is a third maximum at +1.25v in 10^{-2}M $HClO_4$ and some evidence of a third maximum beyond +1.4v in 1M and 0.1M $HClO_4$. The reproducibility becomes very poor beyond +1.4v, probably due to oxide film formation and a thorough investigation has not been possible.

The (100) electrode (Fig. 2) shows an additional maximum at —0.2v. The minimum that follows is at —0.05v. The maximum at +0.4v did not change position compared to the (110) electrode. The maxima at the far anodic side are 50 mv more negative for the (100) electrode than the corresponding maxima at the (110) electrode (Fig. 3).

Both electrodes show pronounced hysteresis when going from +1.4v to more negative potentials (Fig. 4). The maximum previously found at +0.9-+1.3v is displaced by as much as 500 mv to more active values. The maximum capacities are larger than any of the previous maximum values. The maximum itself is rather flat and drops off sharply toward negative potentials. At about +0.2v the hysteresis disappears.

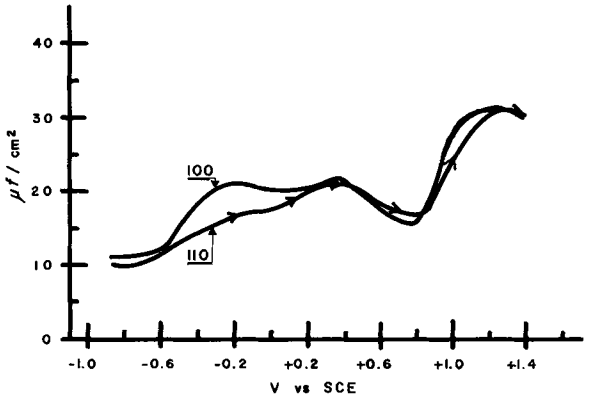

Fig. 3. Differential capacities of a (100) and a (110) single crystal gold electrode in 1M perchloric acid.

Discussion

The differential capacity is defined as (1)

$$C = \delta q/\delta\psi \qquad [2]$$

where q is the electronic charge on the metal side of the interface, and ψ the potential drop across the electrode/electrolyte interface. Thus, the value of the differential capacity gives a measure of the change of electronic charge on the metal with potential. According to the principle of electroneutrality, this change of electronic charge is compensated by an equal change of ionic charge with potential at the solution side of the interface. Thus, at any given potential, the absolute magnitude of the differential capacity gives a direct measure of the change with potential in the amount of adsorbed charged species. It has to be kept in mind, however, that changes in ionic charge density or adsorption of neutral organic molecules also lead to changes in differential capacities. This becomes apparent if the electrical double layer is considered as a plate condenser.

At present there is no clear-cut way to distinguish between the two effects. In the absence of adsorbable neutral organic substances and the presence of maxima and minima in the capacity potential curve we prefer the former view. In this case the occurrence of maxima cannot be explained by changes in ionic charge densities, unless one wants to assume complete saturation of the electrical double layer at the potential of the maximum.

In agreement with this interpretation, the appearance of the maximum at +0.9-+1.3v can be explained as being due to adsorption and/or chemisorption of oxygen (or some oxygen containing species). This explanation is prompted and confirmed by results obtained with a potential sweep method (17) and by cathodic stripping experiments (18). The high overpotential necessary for "oxygen" desorption (400-500 mv) (17) is again pointed out by the pronounced hysteresis in the capacity-potential curves.

Integration of the "oxygen" adsorption peak between +0.8 and +1.4v gives 6 μcoul/cm^2 for the (110) electrode in 1M $HClO_4$, or about 4×10^{13} electronic charges/cm^2. This is equivalent to 4 electronic charges per 100 surface atoms at +1.4v. The

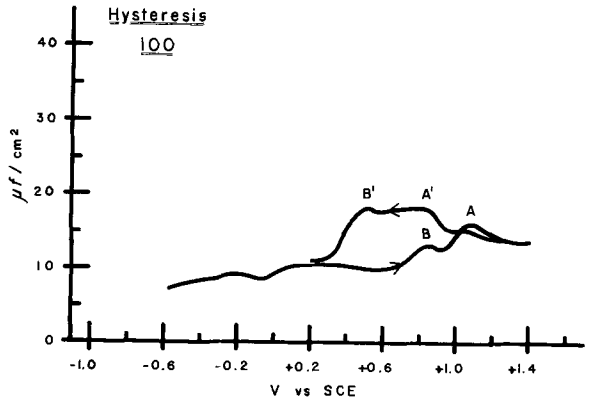

Fig. 5. Differential capacities of a (100) single crystal gold electrode in 10^{-2}M perchloric acid.

integration includes only part of the peak, as may be seen from Fig. 1. The 6 μcoul/cm² found in this way have to be confronted with a coverage equivalent to 800 μcoul/cm² as determined by cathodic stripping experiments (18) and 650 μcoul/cm² as measured with a triangular potential sweep method (17). It must be kept in mind, however, that the 6 μcoul/cm² represents a net charge, the excess of anionic charge over cationic charge. Further analysis, *e.g.*, a separation of positive and negative charges, requires $(\Delta C/\Delta a)_E$ data (a = activity) (19), involving high precision measurements for which our method is not suitable as yet.

Beyond a potential of +1.5v permanent changes seem to take place at the gold electrode. Therefore, no attempt was made to obtain data beyond +1.4v. Some indication for a second "oxygen" adsorption maximum above +1.4v was found, and this becomes apparent in 10^{-2}M $HClO_4$, where the shift with concentration brings this second peak down to about +1.2v (Fig. 5). Here the first "oxygen" adsorption maximum is represented by the little hump at about +0.9v, as can be seen from the hysteresis curve.

Measurements in 10^{-3}M $HClO_4$ could be made only in a narrow potential region. The high solution resistance tends to overdrive the scope amplifier, which leads to erroneous potential time curves.

The appearance of a small capacity maximum at +0.4v may be identified with the occurrence of some slight ClO_4^- adsorption. Evidence for specific adsorption of ClO_4^- on mercury has quite recently been found by Delahay and co-workers (20). The expected shift in position of the maximum by 60 mv/tenfold concentration change was not observed, however. Adsorption of a species like OH^-, on the other hand, should lead to the same shift in the opposite direction. The maximum in question does not shift either way with concentration. This discrepancy has not been solved so far.

The method of electrode preparation used here causes some faceting. The (110) and (100) electrode are therefore surfaces with a predominantly rather than complete (110) or (100) character. Nevertheless, some distinct differences can be detected. A capacity maximum at about −0.2v was found at the (100) face, but not at the (110) face. In view of the potential at which this maximum appears we ascribe this peak to hydrogen adsorption.

At the (100) electrode, the minimum between the maxima at −0.2 and +0.4v is found at −0.05v. At the (110) electrode a minimum appears at 0.0v. These two minima may be tentatively identified with the zero point of charge of the (100) or (110) face of gold, respectively. These zero point of charge potentials agree fairly well with values interpolated from work function data although this amounts only to an estimate at best. According to Frumkin (15), the difference in work function of two metals coincides with the difference in the zero point of charge potentials. Taking 4.5 ev and −0.45v, respectively, for mercury, and 4.9 ev for gold (21), one obtains 0.0v for the zero point of charge of gold. The difference between (110) and (100) of 50 mv is reflected in a difference of 50 mv in the position of the oxygen adsorption peaks of the two electrodes (Fig. 1 and 2). There is, of course, a liquid junction potential between a saturated KCl solution and $HClO_4$ involved.

The present capacity data are considerably lower than the 110 μf/cm² (22), 150 μf/cm² (23), and 200 μf/cm² (17) previously reported for gold in acid. This is probably due to the influence of Faradaic processes in the methods used by these authors. Quite recently, Laitinen and Chao (18) measured the capacity of gold, oriented predominantly with the 111 plane in the surface, in $HClO_4$, using a pulse technique. There is good agreement with our values in position and magnitude of the "oxygen" adsorption maximum (~35 μf/cm² at +1.30v). The agreement is not so good at other potentials (60 *vs.* 22 μf/cm² at +0.40v), although considerably better than with data obtained by others. A Δt of 200 μsec used by Laitinen and Chao may already be too long a time to eliminate the possibility of Faradaic processes completely and cause the capacity values to be too high. Our "oxygen" peaks and hysteresis effects are much more pronounced and seem perhaps more reasonable in view of other available oxygen adsorption data (17). On the other hand, Laitinen and Chao observe a shift of the maximum of 60 mv/pH unit, which is closer to expectations than the 200 mv/tenfold concentration change observed by us.

The magnitude of the capacities found in this work may seem to be too low. Frequently, the metal/electrolyte interface is assumed to have a capacity of 20 μf/cm², especially just before H_2 evolution (24). Apparently this assumption has its roots in the findings on mercury (1). In view of our interpretation, values considerably lower than 20 μf/cm² should be acceptable and, of course, have been found. The complete absence of an adsorption peak during actual H_2 evolution (up to 15 ma/cm²) on the (110) face is remarkable. This suggests that there is no buildup of hydrogen at the surface in this case, and recombination of hydrogen atoms cannot be the rate-determining step.

Summary

Electrical double layer differential capacities have been measured, using a single pulse technique, on

single crystal gold electrodes exposing the (110) or (100) crystal plane. 1*N* to 10^{-3}*N* $HClO_4$ solutions were used as electrolyte. The effectiveness of fast pulse techniques for the measurement of "true" double layer capacities is demonstrated for cathodic current densities up to 15 ma/cm^2.

The observed maxima and minima in the capacity potential curve have been interpreted on the basis of adsorption and desorption processes. Thus, a maximum occurring at +0.9 to +1.3v, depending on $HClO_4$ concentration has been attributed to adsorption of oxygen-containing species. This peak shows strong hysteresis and is displaced on desorption up to 500 mv to more negative values. Some evidence of adsorption of a second oxygen species is presented. A peak at +0.4v has been attributed to slight ClO_4^- adsorption, but does not show the expected concentration dependence. A maximum observed at −0.2v at the (100) electrode only was identified with "hydrogen" adsorption.

The absence of an adsorption peak during actual H_2 evolution up to 15 ma/cm^2 is taken as evidence for the nonexistence of a rate-determining recombination step.

A minimum occurring in dilute solutions at the (110) electrode at 0.0v, and between two slight maxima at the (100) electrode at −0.05v has been tentatively identified as the zero point of charge. The potentials agree fairly well with values obtained by interpolation of work function data. The difference of 50 mv between the crystal faces is reflected by an equal difference in the "oxygen" adsorption peaks.

Preparation of Lanthanide and Actinide Monosulfides by Fused Salt Electrolysis

R. Didchenko[1] and L. M. Litz[2]

Parma Research Center, Union Carbide Corporation, Parma, Ohio

ABSTRACT

The monosulfides of the metals in the lanthanide and actinide series may be prepared by the electrolytic reduction of the higher sulfides in an oxygen-free, fused salt medium that contains the chloride of the metal in question.[3] A detailed description of the preparation of CeS and ThS is given, and possible reaction mechanisms are discussed.

The monosulfides of thorium, uranium, and of the lanthanide elements are highly refractory materials with the NaCl structure. Most of them exhibit high electrical conductivity of the metallic type, but some are semiconductors. The first synthesis by Eastman and Brewer (1, 2) was based on the reaction $2CeH_3 + 2Ce_2S_3 \rightarrow 6CeS + 3H_2$ and required for completion heating above 2000°C at 10^{-4} mm Hg, rather extreme conditions. The method of Flahaut and Attal (3) circumvents the need for CeH_3, which

[1] Parma Research Laboratory of Union Carbide Corporation.

[3] Patent applied for.

is difficult to handle, and instead utilizes aluminum metal as the reducing agent in the reactions

$$9\ Ce_2S_3 + 2\ Al \xrightarrow{1000\text{-}1200^\circ C} 6\ Ce_3S_4 + Al_2S_3$$

$$3\ Ce_2O_2S + 3\ Ce_3S_4 + 2\ Al \xrightarrow{1200^\circ C} 15\ CeS + 2\ Al_2O_3$$

The sulfide and oxide of aluminum are stated to be removed by vacuum distillation at 1500°C and 10^{-2} mm Hg. The evaporating oxide species is most likely Al_2O (4). The reduction of cerium dioxide with sulfur in a hydrogen sulfide atmosphere claimed by Samsonov (5) and coworkers could not be repeated in our Laboratory.

The purpose of this paper is to describe a new method which is particularly suitable for large-scale preparations and which may be applied to synthesize the subsulfides of many other transition metals. It is based on the electrolytic reduction of the sulfide of a metal in its higher oxidation state, suspended in a molten salt bath which may conveniently consist of alkali metal chlorides and the chloride of the metal in question. The reduction is followed by vacuum distillation of the salts and electrolysis by-products at 1000°C. The higher sulfide used as one of the starting materials may be prepared either separately or *in situ*. In the latter case, an alkali sulfide, preferably Na_2S, may be added to the melt containing a calculated excess of the metal chloride beyond the requirements of the electrolytic bath.

Experimental

A typical preparation of CeS and ThS is described in detail to illustrate the experimental procedures based, respectively, on a higher metal sulfide and on an alkali sulfide as one of the starting materials.

Preparation of the starting materials.—1. The NaCl-KCl eutectic (mp 658°C) was prepared by mixing 44 weight % (w/o) NaCl and 56 w/o KCl in a graphite crucible, placing it inside a vertical quartz tube, flushing with purified argon and heating to 800°-850°C. Purified argon was then bubbled through the melt for 1 hr. The last traces of chemically bound water were eliminated most effectively by electrolyzing the melt at 1.8-2.0v with the crucible acting as anode and a graphite rod immersed in the melt as the cathode. Thus, electrolysis was conducted until the current through the melt became constant and very small ($\simeq$ 0.1 amp). The solidified cake was removed from the crucible in a good dry-box and ground to a coarse powder.

2. Cerium sesquisulfide, Ce_2S_3, was prepared by prolonged treatment of cerium dioxide with hydrogen sulfide gas in a graphite crucible at 1000°-1100°C (6).

3. Cerium trichloride, $CeCl_3$, was prepared either from cerium sesquisulfide or from the dioxide. In the first case, dry chlorine was passed over the sulfide while raising the temperature slowly. At around 300°C, a strongly exothermic reaction set in and proceeded very rapidly. In order to achieve complete conversion, it was necessary finally to raise the temperature above the melting point of cerium trichloride (822°C) and to bubble chlorine through the melt. When cerium dioxide was the starting material, it was treated with S_2Cl_2 (7) while slowly increasing the temperature from 400° to 750°C. After the main bulk of the oxide was converted into the chloride, the temperature was raised to 850°C and a chlorine stream charged with S_2Cl_2 bubbled through the melt. A new method for dehydrating commercial cerium and thorium chlorides also was developed in the course of this investigation (8). All these methods gave pure anhydrous cerium trichloride which crystallized from the melt in large, pure white needles that dissolved rapidly in absolute alcohol forming completely clear solutions. The latter is a very sensitive test for the absence of undesirable oxychloride which, when present even in small amounts, produces a cloudy solution. Anhydrous cerium trichloride is extremely hygroscopic and should be handled only in a good dry-box.

4. Anhydrous sodium sulfide is easily prepared in small quantities by elemental synthesis in liquid ammonia (9). For larger scale preparations the method of Koenig (10) based on the reaction $Na_2CO_3 + H_2S \rightleftharpoons Na_2S + CO_2 + H_2O$ was found suitable although tedious.

Electrolytic cell.—The cell is shown in Fig. 1. The crucibles (55 mm OD, 45 mm ID, 90 mm high) were made from ATJ grade graphite (National Carbon Company). Graphite could not be used as the cathode material because it disintegrated during the electrolysis, ostensibly due to the formation of laminar compounds with alkali metals. Therefore, the cathode shaft and paddle were made of molybdenum and were protected from attack by anodically produced chlorine by an alumina sleeve projecting above the melt. Electrical contact to the cathode was made by means of a spring-loaded carbon brush which permitted rotation of the cathode during the electrolysis. Alundum extraction thimbles (Norton, RA 98) 34 mm diameter, 100 mm high, were used as catholyte container and diaphragm.

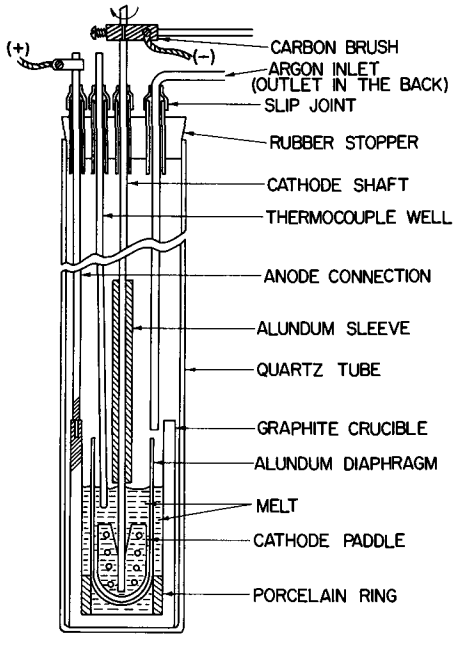

Fig. 1. Electrolytic cell

The electrolysis.—A typical preparation of cerium monosulfide was conducted in the following manner. Cerium sesquisulfide (35g) and cerium trichloride (35g) were mixed together and put into the Alundum diaphragm cup. The NaCl-KCl eutectic prepared as described above was charged loosely into the bottom part of the cell until it covered the porcelain support ring. The Alundum cup then was fitted into the ring and more eutectic charged into the cell with constant tapping to make sure that both anode and cathode compartments were tightly filled with salt. The total charge of the eutectic mixture was 225g. The cell was lowered into the quartz envelope previously flushed with argon and closed (by the rubber stopper) with the cathode in the proper position. All above operations were performed in the dry-box. The cell was then heated electrically to 800°C in a pot furnace while maintaining a slow flow of argon (2-3 l/min) through the tube. The cathode was set in rotation at 60-80 rpm, with the blades 2-3 mm above the bottom of the Alundum cup, centered in such a manner that no scraping of the walls occurred.

For the first 45 min the melt was "pre-electrolyzed" in order to eliminate any moisture and oxygen which may have found their way into the cell during the loading and transfer operations. In the course of this pre-electrolysis the applied voltage ran from 0.6 to 2.1v, which is just below the decomposition voltage of cerium trichloride in these melts (11), and the current fell from 0.3 to below 0.1 amp. The back-emf, *i.e.*, the open-circuit voltage between the cathode and the anode an instant after interrupting the current, reached the value of 2.0v indicating the presence of cerium metal at the cathode. The voltage then was raised to 5.0v and maintained close to this value during the entire electrolysis. The current decreased from a peak value of 6.3 amp to about 5.5 amp after 3 hr while the back-emf remained constant at 2.4v for the first hour, rose to 3.0v within the next 30 min and remained at this value, which corresponds to the decomposition voltage of NaCl, until the end of the electrolysis (Fig. 2). Sixteen ampere-hours of current passed through the cell, *i.e.*, twice the amount needed to produce sufficient cerium metal to convert the sesquisulfide to the monosulfide. After continuing the stirring without current for 1 hr, the cathode was lifted above the melt and the cell allowed to cool under argon. The solidified melt was easily separated from the graphite crucible; the

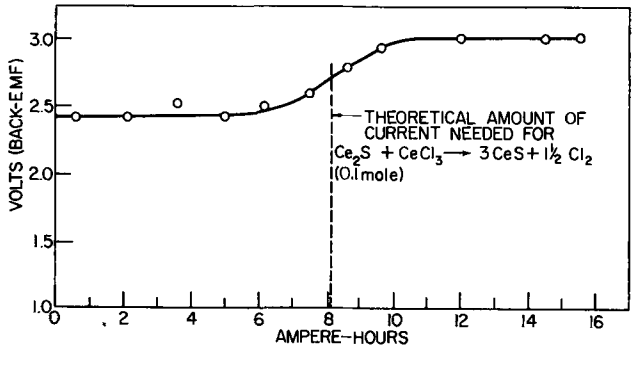

Fig. 2. Plot of back emf *vs.* current passed through the cell

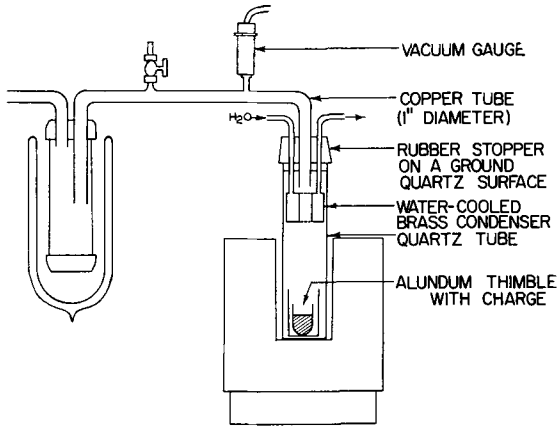

Fig. 3. Vacuum distillation apparatus

thimble was broken exposing at the bottom a large golden-brown button of cerium monosulfide, embedded in the salts.

Vacuum distillation of the salts.—The salts above the cerium monosulfide in the diaphragm thimble were mechanically removed as well as possible. The thimble, inside of a Vycor cup, was then placed in the quartz tube of the distillation apparatus shown in Fig. 3. After repeatedly evacuating and purging the entire assembly with purified argon, the thimble was heated in the course of 2-3 hr to about 1000°C at a few microns pressure. The distilled salt condensed on the cold baffle together with alkali metals and some cerium metal. These finely divided metals reacted immediately after exposure to air, often sparking and flaming. The light-brown cake of CeS, which remained in the thimble, was easily removed and broken up into a crystalline powder of about 200 mesh.

Purification and sintering of cerium monosulfide.—The powder was placed in a molybdenum crucible and heated inductively in a vacuum furnace. Between 1000° and 1500°C, some residual salts and cerium metal distilled off while the pressure decreased from 10^{-3} to 10^{-5} mm Hg. The sulfide was then heated at this pressure to 1800°-1900°C for 15-30 min and cooled, first *in vacuo*, then in purified helium atmosphere. After this treatment, the monosulfide was found to be sintered to a bright golden ingot which weighed 42g. When occasionally the product was contaminated with small amounts of higher sulfides and oxysulfide, these impurities tended to separate on the outside of the ingot as a black skin. They were removed by breaking up the ingot into a coarse powder and heating it again in the vacuum furnace with approximately 5% by weight of cerium metal.

Preparation of thorium monosulfide and other monosulfides.—The only modification in the preparation of ThS was in the original charge. Thus, 37.4g (0.1 mole) of anhydrous thorium tetrachloride and 7.8g (0.1 mole) of anhydrous sodium sulfide were mixed together and put in the diaphragm cup. The cell was then filled with the salt eutectic and assembled as described above. An electrolytic current of 4-6 amp at 4.4-5.0v was passed through the cell for 150 min which amounted to 11.0 amp-hr or twice the theoretical requirement for the reduction

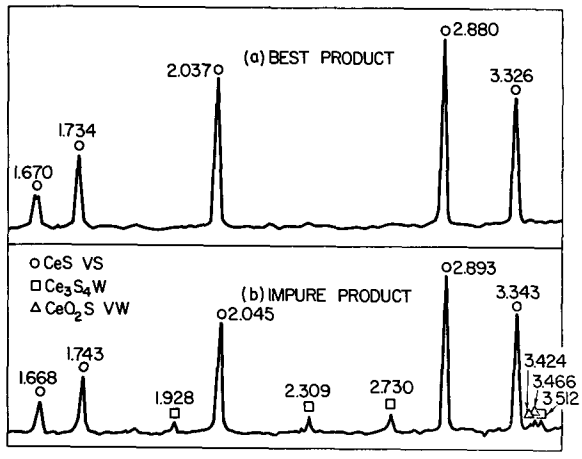

Fig. 4. X-ray patterns of electrolytic CeS

of all the thorium in the melt from tetrapositive to dipositive ion. The product was vacuum-distilled in the same manner as the cerium monosulfide. Twenty-one grams of thorium monosulfide were obtained, a yield of 78% based on the amount of thorium added as the tetrachloride.

The monosulfides of lanthanum, gadolinium, ytterbium, and uranium were prepared in a manner analogous to that described for CeS. It was also possible, starting with "didymium" oxide, converting it to mixed trisulfides and trichlorides and electrolytically reducing the latter, to obtain a mixture of monosulfides of lanthanum, cerium, neodymium, praseodymium, samarium, and other rare earths.

Discussion

The yields of monosulfide varied from 80 to 90% based on the conversion of the sulfur in the original trisulfide. Therefore, the over-all reaction must be: $Ce_2S_3 + CeCl_3 \rightarrow 3\,CeS + 1\frac{1}{2}\,Cl_2$. The back-emf curve shown in Fig. 2 is typical for all electrolyses; it shows a rather abrupt change in voltage at the number of ampere-hours necessary to produce just the amount of cerium metal needed for the reduction of the trisulfide. The back-emf values do not necessarily represent equilibrium potentials at the very high current densities used. It is then reasonable to expect that, along with the cerium metal, alkali metals also are formed to some extent from the onset of electrolysis, contributing to the total polarization voltage of the cell. The break in the curve occurs at a point where the major "depolarization" reaction, *i.e.*, reduction of Ce_2S_3 with cerium metal, is completed.

In further support of this reaction mechanism, it has been shown repeatedly that complete conversion of the trisulfide is greatly facilitated if cerium trichloride is present in the melts at least in 1.5-fold excess over the above stoichiometric equation. Since cerium metal dissolves in the melts containing cerium trichloride (12, 13) its reducing action would thus be enhanced. In this context it is also important that cerium monosulfide can be obtained without the electrolysis by simply adding cerium metal to a suspension of cerium trisulfide in a melt composed of NaCl-KCl eutectic and cerium trichloride and stirring the latter for several hours. Although this heterogeneous reaction appears most straightforward, different homogeneous mechanisms are also possible. The authors have established that cerium trisulfide is slightly soluble in cerium trichloride. Mellors and Senderoff (14) consider likely the existence of the species Ce^{I} $[Ce^{III}\ Cl_4]$ in solutions of cerium metal in cerium trichloride. It seems possible, therefore, that the reduction of the trisulfide in electrolyzed melts also can involve the interaction in solution between Ce^{+} and some species derived from dissolved cerium trisulfide.

The monosulfides obtained by this method are usually metal-rich and analyze $MeS_{0.95-1.00}$. The major impurities are silica and iron if these are present in the starting material (oxide). They occur in total concentrations of up to 1%, but do not seem to affect the properties of the monosulfide in any noticeable manner in contrast to oxygen which easily forms oxysulfides. The oxysulfides form solid solutions with the monosulfides and, even in small quantities, change their golden color to dark brown or black and reduce their melting point considerably. For this reason a rigid exclusion of moisture and oxygen from the electrolytic melt is necessary. The best products obtained by fused salt electrolysis give the x-ray pattern of pure CeS as shown in Fig. 4a. When incompletely reduced and when small amounts of oxysulfide are present, there is obtained a pattern as shown in Fig. 4b. The vacuum treatment with cerium converts pattern b into pattern a due to the reduction of Ce_3S_4 to CeS, whereas Ce_2O_2S is eliminated by the reaction: $Ce_2O_2S + Ce \rightarrow CeS + 2\,CeO_{(volatile)}$.

Electroosmosis in Cation-Selective Collodion Matrix Membranes of Graded Porosity

Charles W. Carr, Ruth McClintock,[1] and Karl Sollner

Department of Physiological Chemistry, University of Minnesota Medical School, Minneapolis, Minnesota, and Laboratory of Physical Biology, National Institute of Arthritis and Metabolic Diseases, National Institutes of Health, Bethesda, Maryland

ABSTRACT

Electroosmosis was studied in a series of highly charged cation-selective collodion matrix membranes varying in porosity from fairly dense permselective membranes (9% water content) to highly porous membranes (75% water content). In all membranes the amount of water transported per faraday was independent of the current density in the tested range, 0.05-0.80 ma/cm². There was a parallelism between the water content of the membrane and the moles of water transported per faraday. In the presence of KCl the moles of water transported per faraday varied from 3 to 50 for the series of membranes tested, and with LiCl from 6 to 90. With all membranes the values with LiCl were about twice those obtained with KCl. This is in conformity with current theories of the transport process, according to which the water transport is higher the greater the friction between water and the permeating ions. Accordingly, the lower mobility of the lithium ion in the membrane (and in aqueous solution) is associated with a higher transport per faraday across the membrane. Exclusively anion permeable membranes gave analogous results.

The collodion matrix membranes developed in our laboratories (1-5) have recently been used in studies of the relative rates of electromigration of two ions of the same charge across a membrane (6), and of anomalous osmosis (7). In this connection, the electroosmotic behavior of the membranes is of importance. Accordingly, the present report is concerned with the electroosmosis across permselective membranes and across a series of membranes of graded porosity prepared by swelling permselective membranes in various concentrations of ethanol (8).

In our permselective membranes, which in the concentration range explored in these experiments are essentially permeable to ions of one sign only, the current is carried virtually exclusively by the counter ions of the charged (ionic) groups which are located in the pore system of the membrane and constitute an integral part of the latter. Thus the number of counter ions in the membrane is determined by the number of fixed charges on the pore walls and is independent of the concentration of the external solution. For all concentrations in which the membranes are of extreme ionic selectivity one would therefore predict that the ratio of current to rate of water transport is constant. With more porous membranes (as well as with permselective membranes and solutions of rather high concentrations) nonexchange electrolyte enters the pores; its concentration depends on the external concentration. In this case, the nonexchange electrolyte carries a part of the current. Consequently, the number of moles of water transported per faraday under these conditions should depend to some extent on the concentration of the external solution.

Several recent papers are concerned with the electroosmotic transport of water across ionic membranes (9-20), prompted in part by the technical use of such membranes for saline water conversion. Some of the data were obtained under conditions in which the membranes were not exclusively permeable to ions of one sign only and therefore cannot readily be compared with our observations on permselective membranes. Some of the data however are comparable; first, those obtained with truly permselective membranes; second, those obtained with solutions of low concentration in which the transport number of the preferred ion in the membrane is close to unity, the membrane acting almost like a truly permselective membrane; and third, those in which the water transported per ion was obtained by measurement of both the quantities of preferred ion and of water moved. Winger, Ferguson, and Kunin (14) obtained 7.0 ± 1 moles of water per faraday with K^+ and 13.5 ± 1 with Li^+, values which were independent of the electrolyte concentration. For Na^+, Stewart and Graydon (17) reported 4-15 and Oda and Yawataya (13) 8-19 moles per faraday. The latter groups both observed a lower water transfer at higher concentrations and a parallelism between the water content of the membrane and the quantity of water transferred.

Experimental Procedure

Most of the permselective membranes used were cation-selective collodion matrix membranes prepared with different concentrations of polystyrene sulfonic acid (PSSA) to obtain membranes of different resistances (and water contents) (3). Their

Table I. Properties of a series of polystyrene sulfonic acid collodion matrix membranes of graded porosity

Designation of membrane	Concentration potential, 0.1/0.01M KCl, mv	Water content, vol %	Smallest molecule held back
Alc 0	55	≃15	Urea (60)
Alc 80	51	23	Glucose (180)
Alc 90	44	30	Salmine (3000-6000)
Alc 95	28	55	Serum albumin (70,000)
Alc 97	19	75	Edestin (310,000)

resistances in 0.1*M* KCl and their approximate water contents are given below with the experimental results.

Membranes of graded porosity were prepared by swelling permselective membranes in solutions of 80, 90, 95, and 97% ethanol (8). The membranes of this series, including an unswelled one, vary in porosity from a permselective membrane to membranes with porosities corresponding to conventional dialyzing membranes. A membrane swelled in 95% ethanol is designated an Alc 95-Membrane, a membrane that has not been swelled, an Alc 0-Membrane, etc. A summary of the properties of this series of membranes is given in Table I. Column 2 gives the concentration potential in 0.1/0.01*M* KCl, which indicates the degree of ionic selectivity of the membrane (3); column 3 lists the water content in per cent by volume (3,21); column 4 gives the smallest molecule which does not move across the membrane to any significant extent (the molecular weights are given in parentheses) (8).

The apparatus for the measurement of the electroosmotic water transport consisted essentially of a test-tube shaped membrane, 25 x 100 mm, with a similarly shaped electrode on either side, a calibrated tube for measuring the volume change of the solution in the inside compartment, and a beaker for the outside compartment (Fig. 1). The membrane was tied to a glass ring in which was mounted a rubber stopper carrying a three-way stopcock connected with the calibrated tube, made from a 1-ml graduated pipet, and a side-arm for filling. In some experiments with permselective membranes, a 0.1-ml graduated pipet was substituted to facilitate the measurement of small volume changes. The silver screen electrodes were electrolytically coated with thin layers of silver chloride. The entire assembly was mounted in a rubber plate and placed in the beaker. The electrical circuit included a source of direct current, a variable resistance, a milliammeter, and the electroosmosis apparatus.

Currents of 2.5-60 ma were employed, which, with the total membrane area of approximately 50 cm², gave current densities of about 0.05-1.2 ma/cm². The external resistance was adjusted periodically so that the current did not vary by more than ± 2% during an experiment. The volume changes, measured over intervals of about 5-15 min, were 4-40 μl. The experiments were carried out in an air-conditioned room so that volume changes due to fluctuations in temperature were insignificant.

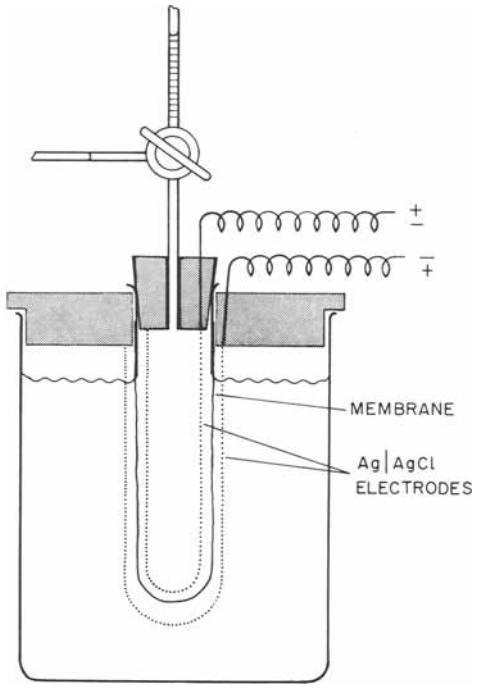

Fig. 1. Apparatus for measuring electroosmosis across test-tube shaped membranes.

Because the height of the solution in the calibrated tube was 20-30 cm above the solution in the beaker, there was a slow downward movement of the meniscus when no current was flowing. The rates of water movement with the current on and with the current off were measured repeatedly. The difference between the average rates was considered as the true rate of electroosmotic water movement; it was independent of the direction of the current. The results were expressed in terms of moles of water transferred per faraday.[2] The reproducibility was ordinarily within ± 10%, except with the very densest membranes, where the error might be somewhat larger.[3]

Results

Measurements made at several current densities with unswelled (permselective) and swelled membranes showed that the water transport per faraday is independent of the current strength, at least at current densities of about 1 ma/cm² or lower. Table II gives representative data for both groups of membranes obtained with 0.02*M* KCl.

[2] With the two densest permselective membranes, the movement of water began slowly with an initial lag after the current was started; it continued, often with a sudden spurt, for a short time after the current was stopped. The final spurt just equalled the initial lag. The curves of water moved *vs.* time were similar to those reported by Oda and Yawataya (13). The values for the rate of electroosmosis were taken from the linear portions of the curves, omitting the small initial and final effects.

[3] Mackay and Meares (20) have recently pointed out that, in determining the rate of electroosmotic flow through a membrane, volume changes occurring at the electrodes should be taken into account. If the cation transport number is unity and one faraday of electricity is passed through the cell, then the increase in volume in the compartment with the cathode, ΔV, is (in the case of a KCl solution)

$$\Delta V = W\bar{V}_{H_2O} + \bar{V}_{KCl} + \bar{V}_{Ag} - \bar{V}_{AgCl} \qquad [1]$$

The $\bar{V}$'s are the partial molal volumes, and W is the number of moles of water transported per faraday. $\bar{V}_{KCl}$ (in 0.2*M* solution) is 27.5, $\bar{V}_{Ag}$ is 10.3 and $\bar{V}_{AgCl}$ is 25.8 so that $W\bar{V}_{H_2O} = \Delta V - 12.0$. The increase in the cathode compartment, which is equal to the decrease in volume in the anode compartment, is 12 ml per faraday or about 0.7 mole per faraday. For LiCl the correction is 0.1 mole per faraday. Such corrections would be insignificant with nearly all the data reported below. Only in the case of the permselective membranes with solutions of KCl (Table III) would they be significant; however, they would not be large enough to change the meaning of our results.

Table II. Electroosmosis across PSSA collodion matrix membranes of different porosities with 0.02M KCl at varying current densities

Designation of membrane	Moles of H_2O transported/faraday 0.05 ma/cm²	0.10 ma/cm²	0.20 ma/cm²	0.40 ma/cm²	0.80 ma/cm²

Alc 90	23.8	23.5	22.4	23.5	20.9
Alc 97	44.7	50.6	47.6	49.9	47.0

Table III. Electroosmosis across permselective PSSA collodion matrix membrane with 0.2M KCl and 0.2M LiCl

Membrane Resistance, ohm-cm²	Water content,* vol %	Moles of H_2O transported/faraday 0.2M KCl	0.2M LiCl
420	9.3	3.2	6.4
140	10.2	3.5	7.4
25	15.0	11.5	16.0

* Estimated from the data of Neihof (3).

Having established that the water transport per faraday is independent of the current strength, we proceed to the influence of (*a*) water content of the membranes; (*b*) nature of the permeating or preferentially permeating ion; and (*c*) concentration of the solutions.

With both groups of membranes the higher the water content the more water moved with each ion through the membrane. Table III gives the results for a group of permselective membranes; Figures 2 and 3 show that at any given concentration the same holds true for a series of membranes of higher porosities.

Likewise, with both groups of membranes more water was transported with Li^+ than with K^+ (Table III and Fig. 2 and 3). Figure 4 shows a direct comparison of the results obtained with solutions of KCl and LiCl as well as with NaCl, for a membrane of high water content, 75% by volume.

The lowest curves in Fig. 2 and 3 show that with low resistance permselective membranes of relatively high water content (15% by volume) there is a variation of about 20% in the quantity of water transportation per faraday over the concentration range 0.001-0.50*M*. It might be added that with permselective membranes of lower water contents the concentration of the solutions has no

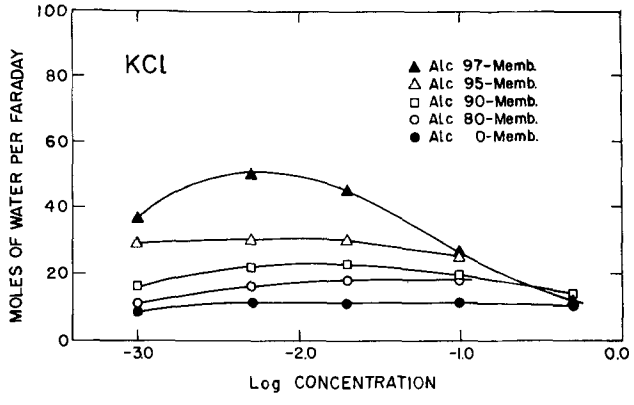

Fig. 2. Electroosmosis across PSSA collodion matrix membranes with KCl solutions.

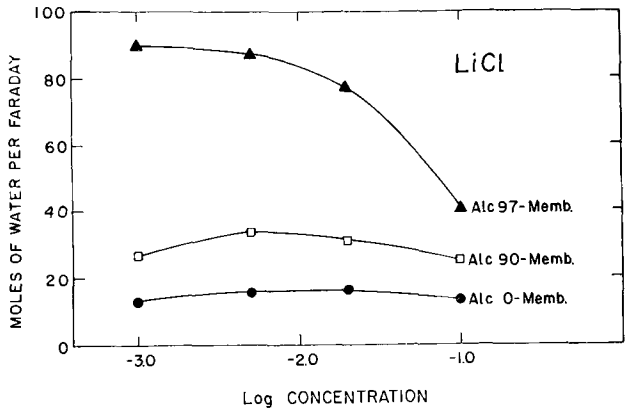

Fig. 3. Electroosmosis across PSSA collodion matrix membranes with LiCl solutions.

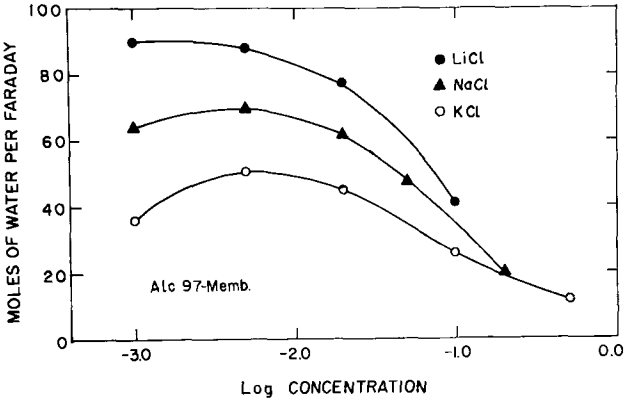

Fig. 4. Electroosmosis across an Alc 97-PSSA collodion matrix membrane with KCl, NaCl, and LiCl solutions.

significant influence on the quantity of water transported. With membranes of higher water content, 23-75% by volume (Alc 80- to Alc 97-Membranes) the influence of the concentration tends to be more pronounced the higher the water content (Fig. 2 to 4).

A few experiments were performed with anion permeable permselective membranes with various concentrations of KCl, KI, and KAc. These membranes are similar in their electroosmotic behavior to the cation permeable ones with respect to the amounts of water transported, to the correlation of water transport with the water content of the membrane, to the dependence on the species of permeating ion, and to the absence of a concentration effect.

Discussion

The values for electroosmotic transport with the permselective collodion matrix membranes (Table III) are in the same range as those obtained by Winger, Ferguson, and Kunin (14) for K^+ and Li^+, and by Stewart and Graydon (17) and Oda and Yawataya (13) for Na^+ with membranes made of ion exchange materials. The electrolyte concentration has little influence on the rate of electroosmotic water transport as anticipated on the basis that in the concentration range studied, (0.001-0.5*M*), the number of movable counter ions in the membrane is practically independent of the concentration of the external solution. This is also in agreement with the observations of Winger, Ferguson, and

Kunin (14) on membranes of sulfonated polystyrene cross-linked with 4-15% divinylbenzene.

In the case of the ethanol-swelled membranes, the most porous of which are similar in porosity to dialyzing membranes, the expected decrease in the electroosmotic water movement at higher concentration is clearly seen (Fig. 2-4). This decrease was also observed by Oda and Yawataya (13) and by Stewart and Graydon (17). Entirely unexpected, however, was the fact that the water transport per faraday is in many instances less at low (0.001*M*) concentration than in an intermediate concentration range. An explanation for this phenomenon, based on the uncoiling of entrapped polyelectrolyte at low ionic strength, has been suggested by Caplan of this laboratory. This topic will be developed in a later publication concerning the preparation of polyacrylic acid collodion matrix membranes (22).

With both the unswelled, permselective membranes and the swelled membranes of graded porosity, the electroosmotic transport parallels the water content, as shown in Table III for permselective membranes and in Fig. 2 and 3 for more porous membranes. For example, the ratio of the water contents (Table I) of the Alc 97- and Alc 0-Membranes in Fig. 2 is 5.0, and the ratio of the moles of water transported electroosmotically at the optimum electrolyte concentration is also about 5. Similarly, for the Alc 90- and Alc 0-Membranes the ratio of water contents is 2.0 while the ratio of the quantities of water transported is 2.2. The correlation is much poorer at higher salt concentrations. The observed parallelism between water content and electroosmotic water transport is in agreement with the data of Oda and Yawataya (13) and Stewart and Graydon (17) obtained with membranes of commercial ion exchange materials. A somewhat different relationship was found by Winger, Ferguson, and Kunin (14) with membranes of different degrees of cross-linking; while the water transported was greater across membranes of higher water content there was not a direct proportionality.

The lowest values we have obtained (3.2 moles of water per faraday for K^+ and 6.4 moles of water per faraday for Li^+) indicate that under these conditions the ions carry only a little more than what is believed to be the tightly held water of hydration. According to a recent review by Bell (23) the most probable hydration numbers are about 1 for K^+ and about 3 for Li^+. Thus, in the denser permselective membranes not more than 2 or 3 water molecules are being swept along electroosmotically.

The ratio of the quantities of water transported electroosmotically per faraday at any given concentration with KCl solutions and with LiCl is fairly independent of the water content of the membranes. For instance, in the two densest membranes with water contents of about 10 v/o (volume per cent), where only a few molecules of water are transported per ion (Table III), the water moved with K^+ is about 50-60% of that transported with Li^+; the same ratio is also found with the Alc 97-Membrane containing 75% water by volume across which up to 90 molecles of water per faraday are transported in LiCl solutions (Fig. 4). It is of interest that the work of Ballou (24) with kaolinite showed that, in an even more open structure than our most porous membranes, lithium is much more effective than other monovalent cations in electroosmotic water transport.

The resistances of ion exchange bodies in general, including ion exchange membranes, are higher when equilibrated with ions of low electrolytic mobility, such as Li^+, than with ions of higher mobility, such as K^+. In fairly open exchangers, such as the resins studied by Heymann and O'Donnell, the ratio of the resistances in the K^+ and Li^+ states, 1:1.86, is nearly the same as that of the reciprocals of the ionic mobilities of these two ions in free solution, 1:1.95 (25). Similar results were reported by Jakubovic, Hills, and Kitchener (26). The resistances of earlier types of low charge density collodion matrix membranes were shown to be 1.3-3.7 times higher in LiCl than in KCl solutions in the concentration range 0.001-0.1*M* (27). Thus it is apparent that the twin factors of higher electroosmotic water transport and higher resistance of the membranes in the lithium form are linked with the lower mobility of the lithium ion in free solution, as compared with the potassium ion.

A clear understanding of these observations emerges from the treatment of membrane transport recently given by Spiegler (19). The balance of forces is evaluated for the steady state of flux, the retarding forces being represented quite generally as simple frictional interactions between the four components: counter-ions, co-ions, water, and solid matrix. No specific structure is postulated for the membrane. A large frictional interaction between an ion and the surrounding water implies a large transference of momentum from the ion to the water. Consequently, such an ion moves more slowly, and drags water along with it more efficiently. The quantitative analysis of this situation with regard to electroosmosis leads to a straightforward relationship between water transport and friction. For the case of a membrane in which the concentration of nonexchange electrolyte is negligibly small, and in which the counter-ion is M^+, this relation can be written:

$$W = H + \frac{1}{\frac{c_{M^+}}{c_{H_2O}} + \frac{X_{H_2O\text{-matrix}}}{X_{M^+\text{-}H_2O}}} \qquad [2]$$

where W represents the total moles of water transported per faraday, H is the counter-ion hydration (moles H_2O/mole M^+), c_{M^+} and c_{H_2O} represent the concentrations of counter-ion and "free" water, respectively, and X denotes a friction coefficient between the components given in the subscripts. From this it is readily seen that, *ceteris paribus*, the higher the friction coefficient $X_{M^+\text{-}H_2O}$ the higher the value of W. Furthermore, the parallelism found between W and c_{H_2O} is obviously to be expected. An additional consequence is that in membranes of increasing porosity, where much of the water is at a distance from the matrix and the friction coefficient $X_{H_2O\text{-matrix}}$ becomes relatively small, W approaches in

value the ratio c_{H_2O}/c_{M^+} (provided the concentration of nonexchange electrolyte remains negligible). This implies that in the limit, when zero friction occurs between water and matrix, the water migrates in the membrane with the same velocity as the counter-ions. For permselective membranes this cannot, of course, be the case.

The concept of uniform migration velocity forms the basis of the classical Helmholtz electrokinetic theory, which is only applicable to membranes having relatively large pore radii, in contact with very dilute solutions. A theory based on a model can be developed which relates the electroosmotic permeability of a membrane and its conductivity, despite the assumptions and simplifications involved. More realistic models than the classical have been proposed by Schmid (28) and Meares (29), although they too assume uniform migration velocity. Schmid considers the space charge due to the counter-ions to be uniformly distributed within the pores, and arrives at the following relation:

$$V = \frac{F^2 A r^3}{8\eta\kappa} \qquad [3]$$

where V is the volume of solution transported per faraday, A the equivalents of fixed charges per unit volume of pore liquid, the latter being taken to have a viscosity η and a conductivity κ, and r is the radius of the pores. Equation [3] is consistent with our conclusions on the basis of Eq. [2] and is also relevant to situations where significant quantities of nonexchange electrolyte enter the membrane. To the extent that nonexchange electrolyte enters the pores (without significant change in viscosity), the conductance of the membrane increases and the quantity of water transported per faraday is decreased accordingly, this effect being most conspicuous with the most porous membranes (Fig. 2-4).

Equation [3] may also be interpreted in terms of the quantity of electrical energy used in the process of electroosmosis. If the resistance of a membrane is doubled by using another electrolyte at the same concentration, twice the voltage is required to obtain the same current; therefore, twice the energy is expended in the work of moving the ions and the water.

Acknowledgment

The authors wish to thank Dr. S. R. Caplan for stimulating discussions which were most helpful in the critical interpretation of the data.

One of the authors (C.W.C.) would like to express his appreciation to the Lalor Foundation for a Summer Fellowship in 1956 during which time part of this work was carried out, and to the National Institute of Health for providing laboratory facilities.

Manuscript received July 3, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

On the Mechanism of the Hydrogen Reaction

A. C. Makrides[1]

Metals Research Laboratory, Union Carbide Metals Company, Niagara Falls, New York

ABSTRACT

Two simple reaction schemes for hydrogen evolution, the Volmer-Tafel and Volmer-Horiuti mechanisms, are discussed. The results are applied to hydrogen evolution on nickel from alkaline solutions.

Criteria for various possible mechanisms for the hydrogen reaction, $2H^+ + 2e^- \rightleftharpoons H_2$, have been discussed in a number of articles (1-6). Of particular interest are the slope of the Tafel line and the stoichiometric number. Characteristic values of these quantities are in dispute (3-6). Some of the controversy involves the interpretation of experimental results for the hydrogen reaction on nickel (7-11). We discuss here two simple reaction schemes, the Volmer-Tafel and Volmer-Horiuti mechanisms, and apply our results to nickel cathodes.

The stoichiometric number was introduced by Horiuti and Ikusima (1). They started from the relation

$$\frac{\vec{i}}{\overleftarrow{i}} = f(\eta) = e^{\lambda\eta} \qquad [1]$$

where $\vec{i}$ and $\overleftarrow{i}$ are the velocities in amperes/cm^2 of $2H^+ \rightarrow H_2$ and $H_2 \rightarrow 2H^+$, η is the overpotential in units of RT/F,[2] and λ a constant. In the current literature the stoichiometric number, $\nu = 2/\lambda$, is used generally.

From Eq. [1] we have by differentiation with respect to η

$$\frac{f'(\eta)}{f(\eta)} = \lambda = 2/\nu \qquad [2]$$

Since $f(o) = 1$, ν is given by

$$\nu = 2/f'(o) \qquad [3]$$

The net cathodic current i_c is given by

$$i_c = \vec{i} - \overleftarrow{i} = \overleftarrow{i}\,[f(\eta) - 1] \qquad [4]$$

Differentiating Eq. [4] and evaluating the derivative at $\eta = 0$ we also find

$$\nu = 2\, i_o/(\partial i_c/\partial\eta)_{\eta=0} \qquad [5]$$

where $i_o = \vec{i} = \overleftarrow{i}$ at $\eta = 0$

An alternative definition of ν has been given by Parsons (3). It is assumed in ref. (3) that the rate of the whole reaction is determined by the rate of some intermediate step. The stoichiometric number is then the number of times the rate-determining step must be repeated for the over-all process to occur once. Parsons also derives Eq. [5] using this definition and the activated complex reaction rate theory.

[1] Present address: Field Research Laboratory, Socony Mobil Oil Company, Dallas, Texas.

[2] We follow Frumkin's convention for the sign of η and consider it positive for cathodic polarization ($\eta = E_o - E$ where E_o is the reversible potential and E the potential at some current i_c).

Reaction Mechanisms

We consider two mechanisms suggested frequently (1-6):

(i) Volmer-Tafel Mechanism		(ii) Volmer-Horiuti Mechanism
$e^- + H^+ \underset{U_2}{\overset{U_1}{\rightleftharpoons}} H_{ads}$	(I)	$e^- + H^+ \underset{U_2}{\overset{U_1}{\rightleftharpoons}} H_{ads}$
$H_{ads} + H_{ads} \underset{U_6}{\overset{U_5}{\rightleftharpoons}} H_2$	(II)	$e^- + H^+ + H_{ads} \underset{U_4}{\overset{U_3}{\rightleftharpoons}} H_2$

[6(i, ii)]

We assume the electrode surface to be homogeneous and neglect any interaction between adsorbed hydrogen atoms. We also neglect the ψ-potential effect. With these assumptions we may write for the rates in a solution of fixed composition (4-6)

$$\begin{aligned} U_1 &= k_1(1-\theta) &&= k_1^{\circ} e^{\alpha_1\eta}(1-\theta) \\ U_2 &= k_2\theta &&= k_2^{\circ} e^{-\beta_1\eta}\theta \\ U_3 &= k_3\theta &&= k_3^{\circ} e^{\alpha_2\eta}\theta \\ U_4 &= k_4(1-\theta) &&= k_4^{\circ} e^{-\beta_2\eta}(1-\theta) \\ U_5 &= k_5\theta^2 &&= k_5^{\circ}\theta^2 \\ U_6 &= k_6(1-\theta)^2 &&= k_6^{\circ}(1-\theta)^2 \end{aligned} \qquad [7(a\text{-}f)]$$

The rate of the over-all reaction is $\vec{R} = -\frac{1}{2}\frac{d[H^+]}{dt} = \frac{d[H_2]}{dt} = \frac{i_c}{2}$. The k's are rate constants in electrical units (amp/cm^2) and θ is the fraction of the electrode surface occupied by adsorbed hydrogen atoms.

Mechanism (i) [Volmer-Tafel].—The rates of the forward and reverse reactions are

$$\vec{i} = \frac{2U_1U_5}{U_2 + 2U_5} \quad \text{and} \quad \overleftarrow{i} = \frac{2U_2U_6}{U_2 + 2U_5} \qquad [8a, b]$$

From Eq. [8] together with ($\alpha + \beta = 1$) we have

$$f(\eta) = \frac{\vec{i}}{\overleftarrow{i}} = \frac{U_1U_5}{U_2U_6} = \frac{k_1^{\circ}k_5^{\circ}}{k_2^{\circ}k_6^{\circ}}\, e^{\eta}\, \frac{\theta}{1-\theta} \qquad [9]$$

and

$$f'(\eta) = f(\eta) + \frac{k_1^{\circ}k_5^{\circ}}{k_2^{\circ}k_6^{\circ}}\, e^{\eta}\, \frac{\partial\theta/\partial\eta}{(1-\theta)^2} \qquad [10]$$

From the steady-state condition, $d\theta/dt = 0$, we find

$$\theta = \frac{K \pm [K^2 - 8(k_6^\circ - k_5^\circ)(k_1^\circ e^{a_1\eta} + 2k_6^\circ)]^{1/2}}{4(k_6^\circ - k_5^\circ)} \quad [11a]$$

with

$$K = k_1^\circ e^{a_1\eta} + k_2^\circ e^{-\beta_1\eta} + 4k_6^\circ \quad [11b]$$

Differentiating Eq. [11], setting $\eta = 0$, and using the relation $(k_2^\circ)^2 k_6^\circ = (k_1^\circ)^2 k_5^\circ$, which can be derived from the conditions of equilibrium ($U_1 = U_2$, $U_5 = U_6$) we find

$$(\partial\theta/\partial\eta)_{\eta=0} = \frac{k_1^\circ k_2^{\circ\,2}}{(k_1^\circ + k_2^\circ)[k_2^\circ(k_1^\circ + k_2^\circ) + 4k_1^\circ k_5^\circ]} \quad [12]$$

Substituting Eq. [12] into Eq. [10] and noting that $(1 - \theta^\circ)^2 = [k_2^\circ/(k_1^\circ + k_2^\circ)]^2$ we find

$$f'(0) = 1 + \frac{k_2^\circ(k_1^\circ + k_2^\circ)}{k_2^\circ(k_1^\circ + k_2^\circ) + 4k_1^\circ k_5^\circ} \quad [13]$$

Designating by $i_{o\mathrm{I}}$ and $i_{o\mathrm{II}}$ the velocities of steps I and II at equilibrium, we have

$$i_{o\mathrm{I}} = k_2^\circ\theta^\circ = k_1^\circ k_2^\circ/(k_1^\circ + k_2^\circ)$$
$$i_{o\mathrm{II}} = 2k_5^\circ(\theta^\circ)^2 = 2(k_1^\circ)^2 k_5^\circ/(k_1^\circ + k_2^\circ)^2$$

Their ratio γ is

$$\gamma = i_{o\mathrm{I}}/i_{o\mathrm{II}} = k_2^\circ(k_1^\circ + k_2^\circ)/2k_1^\circ k_5^\circ \quad [14]$$

Substituting Eq. [14] into [13] and using Eq. [3] we have for the stoichiometric number

$$\nu = \frac{\gamma + 2}{\gamma + 1} \quad [15]$$

The stoichiometric number for this mechanism has the extreme values 1 ($\gamma >> 1$) and 2 ($\gamma << 1$). Thus, when there is a rate-determining step, ν gives the number of times this step must be repeated for the over-all process to occur once. For other values of γ, ν falls between 1 and 2. For example, $\nu = 1.50$ when $\gamma = 1$.

The net cathodic current is

$$i_c = U_1 - U_2 = 2(U_5 - U_6) \quad [16]$$

From Eq. [4], [8], and [9],

$$i_c = \frac{2(1-\theta)k_1^\circ k_5^\circ[k_2^\circ\theta e^{a_1\eta} - k_1^\circ(1-\theta)e^{-\beta_1\eta}]}{k_2^\circ(2k_5^\circ\theta + k_2^\circ e^{-\beta_1\eta})} \quad [17]$$

At $\eta >> 1$ (*i.e.*, where U_2 and U_6 are negligible) Eq. [17] reduces of course to

$$i_c = k_1^\circ(1-\theta)e^{a_1\eta} = 2k_5^\circ\theta^2 \quad [18]$$

where θ is given by Eq. [11].

Mechanism (ii) [Volmer-Horiuti].—The rates of the forward and reverse reactions are (5)

$$\vec{i} = \frac{U_1U_3}{U_2 + U_3} + U_3 \quad \text{and} \quad \overleftarrow{i} = \frac{U_2U_4}{U_2 + U_3} + U_4 \quad [19]$$

From the condition of equilibrium, $k_1^\circ k_3^\circ = k_2^\circ k_4^\circ$. From the steady-state condition ($d\theta/dt = 0$)

$$\theta = \frac{k_1 + k_4}{k_1 + k_2 + k_3 + k_4} \quad [20]$$

Using these relations and Eq. [7] and assuming $\alpha_1 = \alpha_2$, $\beta_1 = \beta_2$, we find[3]

[3] Equations [19], [21] and [24] are given by Frumkin (5).

$$f(\eta) = \frac{2(k_2^\circ/k_3^\circ)e^\eta + 1}{2(k_2^\circ/k_3^\circ)e^{-\eta} + 1} \quad [21]$$

The velocities of steps I and II at equilibrium are given by

$$i_{o\mathrm{I}} = k_2^\circ\theta^\circ = k_1^\circ k_2^\circ/(k_1^\circ + k_2^\circ)$$
$$i_{o\mathrm{II}} = k_3^\circ\theta^\circ = k_1^\circ k_3^\circ/(k_1^\circ + k_2^\circ) \quad [22a, b]$$

and

$$\gamma = i_{o\mathrm{I}}/i_{o\mathrm{II}} = k_2^\circ/k_3^\circ \quad [23]$$

Substituting [23] into [21] we find for $f(\eta)$,

$$f(\eta) = \frac{2\gamma e^\eta + 1}{2\gamma e^{-\eta} + 1} \quad [24]$$

and

$$f'(0) = 4\gamma(1 + 2\gamma)$$

or

$$\nu = 1 + \frac{1}{2\gamma} = 1 + \frac{i_{o\mathrm{II}}}{2i_{o\mathrm{I}}} \quad [25]$$

The stoichiometric number of this mechanism has a bound of 1 for large values of γ, but increases continuously as γ approaches zero. Thus, when the discharge step is much slower than the electrochemical desorption step, ν no longer represents the number of times the rate-determining step must be repeated for the over-all reaction to occur once. We discuss this point below.

The net cathodic current is

$$i_c = \left[\frac{U_2U_4}{U_2 + U_3} + U_4\right]\left[\frac{2\gamma e^\eta + 1}{2\gamma e^{-\eta} + 1} - 1\right] \quad [26]$$

from which, upon substitution for the U's, we find

$$i_c = 2k_1^\circ(1-\theta)e^{a\eta}\frac{1 - e^{-2\eta}}{1 + \gamma e^{-\eta}} \quad [27]$$

Equation [27] reduces at sufficiently large η to

$$i_c = 2k_1^\circ(1-\theta)e^{a\eta} = 2k_3^\circ\theta e^{a\eta} \quad [28]$$

where θ is given by Eq. [20].

General Discussion

The two mechanisms discussed above have been treated by a number of authors (1-5). Frumkin discussed the stoichiometric number of the Volmer-Horiuti mechanism using the method adopted here. Equations [19], [21], and [24] are identical with those given in ref. (5). However, our conclusions on the value of the stoichiometric number differ from those in ref. (5). Frumkin states that ν increases without limit when $i_{o\mathrm{I}} >> i_{o\mathrm{II}}$ in mechanism (ii). The discrepancy arises from an algebraic oversight in substituting for γ in Eq. [11] of ref. (5). If this equation and the discussion in the following paragraph of ref. (5) are modified to take into account this slip, they coincide with ours.

A form of Eq. [27] was derived by Vetter (4) for the case $\theta << 1$ using a different procedure from the one employed here. The assumption $\theta << 1$ at all $|\eta|$ is not applicable to most systems. It is particularly inappropriate when $\gamma \sim 1$ since θ in this case varies by at least an order of magnitude between $\eta = 0$ and $\eta = 10$, *i.e.*, over the range usually accessible in practice. Vetter (4) discusses the stoichiometric numbers for both the Volmer-Tafel and the Volmer-Horiuti mechanisms. His discussion correctly ap-

plies to "apparent stoichiometric numbers" (see below), but not to stoichiometric numbers obtained from Eq. [3].

Bockris and collaborators (6, 8, 12, 13) arrive at different conclusions although they use the same basic set of rate equations, *i.e.*, Eq. (7a-f). Bockris and Mauser (6) assume a rate-determining step and let ν be 1 or 2 corresponding to its happening once or twice in the course of a unit act the over-all reaction. They evaluate ν from Eq. [5] above, obtaining $(\partial i_c/\partial\eta)_{\eta=0}$ from the rate expression and i_o by extrapolation from large $|\eta|$. They find that Eq. [5] yields the assumed ν's.

The argument of Bockris and Mauser (6) follows essentially that of Parsons (4) who introduced this definition and procedure.

The different results of Bockris and Mauser (6) arise from the ambiguous meaning of the term i_o as used in ref. (6). The exchange current which appears in Eq. [5] is the total rate in the forward or reverse direction at equilibrium as is shown by the Horiuti and Ikusima (1) derivation reproduced above (Eq. [1]-[5]). It can be determined, at least in principle, by an isotopic experiment. It has therefore definite operational meaning. This exchange current may or may not coincide with the exchange current determined by extrapolation from large $|\eta|$. We shall denote this last quantity by $(i_o)_{extr}$. We discuss below the Bockris and Mauser (6) procedure in detail. We shall use the Volmer-Horiuti mechanism as an example. The Volmer-Tafel mechanism will be discussed for the hydrogen reaction on nickel.

Apparent stoichiometric numbers.—Frumkin (5) has shown that a variety of ν's can be obtained for the Volmer-Horiuti mechanism if the exchange current is determined by extrapolation.

Let us first consider Eq. [24] and [25]. As noted above, ν can attain any value as i_{oI} becomes negligible in comparison to i_{oII}. This result may seem surprising at first since in other cases, *e.g.*, the Volmer-Tafel mechanism, ν approaches a small integer when one step in the mechanism is rate determining. The lack of an upper bound of ν for $\gamma << 1$ is not inconsistent with its definition by Eq. [1]. The only restrictions imposed by classical thermodynamics on any electrochemical reaction are (14)

$$\frac{\vec{i}}{\overleftarrow{i}} = 1 \text{ at } \eta = 0, \qquad \frac{\vec{i}}{\overleftarrow{i}} > 1 \text{ at } \eta > 0 \qquad [29]$$

If there are no discontinuities in the region of equilibrium, for sufficiently small values of η we have

$$i_c = \vec{i} - \overleftarrow{i} = \lambda i_o \eta \qquad [30]$$

since the net reaction rate, i_c, and η vanish together at equilibrium. Equation [1] satisfies Eq. [29] and [30] for any finite value of λ. A coincidence of λ with the reciprocal of the number of times a rate-determining step is repeated is not necessary and must be examined separately for each mechanism.

Large values of ν in the case of the Volmer-Horiuti mechanism when $\gamma << 1$ are brought about by step II which, at equilibrium yields H_2 independently of step I, but has no influence on the net rate of hydrogen evolution away from equilibrium. In Frumkin's (5) terms, a large (total) exchange current does not insure a small polarizability in this case. This is true of all mechanisms which incorporate the scheme $A \overset{e^-}{\rightleftharpoons} C$, $A + C \overset{e^-}{\rightleftharpoons} P$, where A is the reactant, C an intermediate, and P the product.

To examine the conclusions of Bockris and Mauser (6), we formulate first their procedure in the terms used here. For the sake of simplicity of exposition we restrict our discussion to $\theta << 1$, the case discussed by Vetter (4). Results for the more general case where $(1-\theta)$ is not approximated by 1 are given in the table below.

If $(1-\theta)\sim 1$, Eq. [27] reads

$$i_c = 2k_1^\circ e^{a\eta}\frac{1-e^{-2\eta}}{1+\gamma e^{-\eta}} \qquad [31]$$

The net anodic current is given by $i_a = \overleftarrow{i}\,[1-f(\eta)]$ with the approximation $(1-\theta)\sim 1$. It is:

$$i_a = 2k_1^\circ e^{-\beta\eta}\frac{1-e^{2\eta}}{\gamma+e^{\eta}} \qquad [32]$$

Bockris and Mauser assume that $\gamma << e^\eta$ at all $|\eta|$ and simplify Eq. [31] and [32] to

$$i_c = 2k_1^\circ e^{a\eta}, \qquad i_a = 2k_1^\circ e^{-(1+\beta)\eta} \qquad [33]$$

In this range of $|\eta|$, *i.e.*, for sufficiently positive overpotentials on cathodic polarization and sufficiently negative on anodic, $i_c = \vec{i}$ and $i_a = \overleftarrow{i}$. Bockris and Mauser then extrapolate i_c and i_a to the neighborhood of equilibrium and write for all η

$$\vec{i} = 2k_1^\circ e^{a\eta} \qquad \text{and} \qquad \overleftarrow{i} = 2k_1^\circ e^{-(1+\beta)\eta}$$

from which they derive

$$i_c = 2k_1^\circ e^{a\eta} - 2k_1^\circ e^{-(1+\beta)\eta} \qquad [34]^4$$

and

$$(\partial i_c/\partial\eta)_{\eta=0} = 4k_1^\circ \qquad [35]$$

The exchange current, given by Eq. [33] with $\eta = 0$, is $2k_1^\circ$. With these values substituted in Eq. [5], they find $\nu = 1$.

The crucial difference between the present development and the Bockris and Mauser (6) argument outlined above is in the meaning of the exchange current. The extrapolated current, $(i_o)_{extr} = 2k_1^\circ$, does *not* coincide with $\vec{i}$ at $\eta = 0$. The exchange current is actually given by Eq. [7], [19], and [20] [with the approximation $(1-\theta)\sim 1$] by

$$i_o = \frac{2k_1^\circ + k_4^\circ}{1+\gamma} = \frac{2k_1^\circ(1+\tfrac{1}{2}\gamma)}{1+\gamma} \qquad [36]$$

Since $(\partial i_c/\partial\eta)_{\eta=0} = 4k_1^\circ/(1+\gamma)$, Eq. [36] together with Eq. [5] yield $\nu = 1 + (\tfrac{1}{2}\gamma)$ as before instead of $\nu = 1$. We call the quantity obtained from Eq. [5] when i_o is set equal to the extrapolated exchange current the apparent stoichiometric number and denote it by ν' (5). The apparent stoichiometric number depends on the approximations made in selecting

[4] This step is not justified nor is it valid generally. The net cathodic current is not necessarily the difference between the *extrapolated* cathodic and anodic currents.

Table I. Volmer-Horiuti mechanism

$\gamma = i_{oI}/i_{oII}$
(Extrapolated i_o from cathodic polarization curve)

	γ	ν	ν'	
(Slow electrochemical desorption)	$\gamma >> 1$	1	1	with $(i_o)_{extr}$ from range $\gamma e^{-\eta} >> 1$
			$1 + \gamma$	with $(i_o)_{extr}$ from range $\gamma e^{-\eta} << 1$
—	$\gamma = 1$	1.5	2	
(Slow discharge)	$\gamma << 1$	$1 + (\frac{1}{2}\gamma)$	1	

the linear section of the polarization curve. It also depends on whether the extrapolated exchange current is found from the anodic or cathodic polarization curve. The two extrapolated currents do not always coincide as can be shown easily from Eq. [31] and [32].

The exchange current is generally determined by extrapolation of the cathodic curve in the case of the hydrogen reaction. The apparent stoichiometric number is

$$\gamma' = \gamma \frac{(i_o)_{extr}}{i_o}$$

If $\gamma >> 1$ in the Volmer-Horiuti mechanism, there are two segments of the cathodic polarization curve [log i_c *vs.* η] which approximate a straight line. If a range of η is selected such that $\gamma e^{-\eta} >> 1$, then $(i_o)_{extr} = 2k_1^\circ/\gamma$ and $\nu' = 1$. If, on the other hand, the range of η is chosen for which $\gamma e^{-\eta} << 1$, then $(i_o)_{extr} = 2k_1^\circ$ and $\nu' = 1 + \gamma$. Therefore ν' attains any value as i_{oI} becomes much larger than i_{oII}. This last result was obtained by Vetter (4). Frumkin (5) finds $\nu' = 1$ for $\gamma >> 1$ making the approximation $\gamma e^{-\eta} >> 1$. We summarize our discussion in Table I. The values shown hold also for the general case where $(1 - \theta)$ is *not* approximated by 1.

The hydrogen reaction on nickel.—The mechanism of the hydrogen reaction on nickel is in dispute (8-10). Of particular interest are alkaline solutions where side reactions are negligible. Bockris and Potter (8) concluded that discharge of water is the slow step while Horiuti and collaborators (9) found the combination of two hydrogen atoms to be rate-determining. We have made extensive measurements, to be discussed in a later communication, which suggest that the Volmer-Tafel mechanism is operative. Equations [7] through [18] are applicable therefore, except that in alkaline solution H_2O must be substituted for H^+.

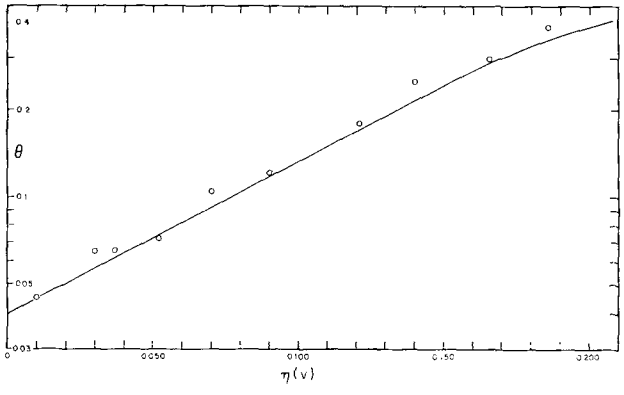

Fig. 1. Fractional surface coverage by adsorbed hydrogen atoms as a function of overpotential for nickel in 2*N* NaOH. The solid line was calculated from Eq. [11] with $k_1^\circ = 1.0 \times 10^{-5}$ amp/cm², $k_3^\circ = 3.15 \times 10^{-3}$ amp/cm², and $\theta^\circ = 0.04$. Circles give the experimental values of Devanathan and Selvaratnam (11).

Devanathan and Selvaratnam (11) recently determined θ on nickel cathodes in 2*N* NaOH. Their analysis suggested to them that discharge from water molecules is the rate-determining step. Their conclusion was based essentially on a value of 2 for the stoichiometric number. The previous controversy (9) also revolved around the proper value for the stoichiometric number. We examine therefore the Devanathan and Selvaratnam results in detail.

If the Volmer-Tafel mechanism is operative, according to Eq. [18] plots of $\log[i_c/(1-\theta)]$ *vs.* η and of i_c *vs.* θ^2 should yield straight lines as found by Devanathan and Selvaratnam. The intercepts of these plots give, respectively,

$$k_1^\circ = 1.0 \times 10^{-5} \text{ amp/cm}^2 \quad [38]$$

and

$$k_5^\circ = 3.15 \times 10^{-3} \text{ amp/cm}^2 \quad [39]$$

The slope of the log $[i_c/(1-\theta)]$ *vs.* η curve gives $\alpha = 0.67$ and, therefore, $\beta = 0.33$.

The value of θ at $\eta = 0$ is according to ref. (11),

$$\theta^\circ = 0.04 \quad [40]$$

From Eq. [7] for $\eta = 0$, we find

$$k_2^\circ = 2.5 \times 10^{-4} \text{ amp/cm}^2 \quad [41]$$

and

$$k_6^\circ = 5.4 \times 10^{-6} \text{ amp/cm}^2 \quad [42]$$

If the Volmer-Tafel mechanism is operative under the assumptions made above, θ should be given as function of η by Eq. [11] with the k°'s given by Eq. [38]-[42]. Figure 1 gives $\theta = \theta(\eta)$ calculated from Eq. [11] together with the experimental values. The agreement between calculated and observed θ is within experimental error.

The exchange currents for step I and II are

$$i_{oI} = k_1^\circ(1 - \theta^\circ) = k_2^\circ\theta^\circ = 1.0 \times 10^{-5} \text{ amp/cm}^2$$

$$i_{oII} = 2k_5^\circ(\theta^\circ)^2 = 2k_6^\circ(1 - \theta^\circ)^2 = 1.0 \times 10^{-5} \text{ amp/cm}^2$$

Consequently

$$\gamma = i_{oI}/i_{oII} = 1.0$$

The stoichiometric number is from Eq. [5] and [15]

$$\nu = 2i_o/(\partial i_c/\partial\eta)_{\eta=0} = 1.50$$

However, the apparent stoichiometric number is given by

$$\nu' = 2(i_o)_{extr}/(\partial i_c/\partial\eta)_{\eta=0}$$

Consequently

$$\nu' = \nu\frac{(i_o)_{extr}}{i_o} = \nu\frac{(i_o)_{extr}}{(i_{oI}/2)} = \nu\frac{(i_o)_{extr}}{5\times10^{-6}}$$

Devanathan and Selvaratnam give no details of their calculation of the stoichiometric number besides stating that it was 2. Data in the range $\eta << 1$ from which $(\partial i_c/\partial\eta)_{\eta=0}$ was presumably calculated are not given. If $(i_o)_{extr}$ is obtained from a plot of log i_c vs. η, then $(i_o)_{extr} = 8\times10^{-6}$ and $\nu' = 2.4$. If $(i_o)_{extr}$ is obtained from a plot of log $[i_c/(1-\theta)]$ *vs.* η, then $(i_o)_{extr} = i_{oI}$ and $\nu' = 3.0$. In any case, a value of ν' in the neighborhood of 2 does not prove that the discharge step is rate determining. Devanathan and Selvaratnam's results actually show that there is no rate-determining step, the exchange currents for discharge and combination being equal.

The calculation of $\theta = \theta(\eta)$ also gives the current at any η via Eq. [17]. To our knowledge, this is the first time that a complete description (including the variation of θ with overpotential) of the experimental cathodic curve for the hydrogen reaction is possible in terms of simple expressions involving only three independent constants. It is surprising that the simple Volmer-Tafel mechanism fits these results so well (see Fig. 1). Both the assumption of a homogeneous surface and the neglect of interactions between adsorbed hydrogen atoms appear *a priori* to be unlikely. However, nickel electrodes subjected to anodic-cathodic cycling, the procedure used in ref. (11), are probably covered by a layer of chemisorbed hydroxyl ions as we show elsewhere (17). Such surfaces should be essentially homogeneous for adsorption of hydrogen. A hydroxyl covered surface, in contrast to a nickel surface, is expected to adsorb hydrogen weakly. This agrees with the small coverage ($\theta^0 = 0.04$) found at equilibrium by Devanathan and Selvaratnam (11). Lateral interactions between adsorbed atoms are predominantly isolated pair interactions at low coverages. They apparently do not contribute significantly to the total heat adsorption for $\theta < 0.4$.

Transport Numbers in Pure Fused Zinc Chloride

Arnold Lundén[1]

Institute for Atomic Research and Department of Chemistry, Iowa State University, Ames, Iowa

ABSTRACT

The radioactive tracer method differs in two aspects from other methods used to determine transport numbers in fused salts. First, four different tracer experiments can be designed: two with cation and two with anion tracer. Second, due to nonideal conditions at the disk separating catholyte and anolyte, there is a tendency that the measured transport numbers are too low. This second property should be most pronounced in salts with low self-diffusion coefficients, such as the zinc halides.

The transport numbers have been measured for both cation and anion in molten zinc chloride. The tendency to give too low values for t^+ and t^- became stronger as the current density increased in the cell. An extrapolation to zero current density, *i.e.*, infinite running time, gives $t^+ = 0.6 \pm 0.1$ for the region from 420° to close to the boiling point. No current transport by complex ions could be detected.

In recent years a number of experiments have been designed for measuring transport numbers in pure molten salts (1). However, the interpretation of the experiments has been questioned, and it has even been stated that the whole concept of transference has little significance in pure molten salts (2). The aim of the present work is to examine

[1] On leave from the Department of Physics, Chalmers Institute of Technology, Gothenburg, Sweden.

critically some factors that might influence the results of the experiments. The general discussion is exemplified by measurements on zinc chloride.

Consider first the general experimental arrangement with two compartments separated by a membrane. Both compartments are at least partly filled with a melt, either a pure salt or a mixture of several components. The membrane can consist of a fritted disk of sufficiently fine porosity (such as in most "transport number" experiments), a separation column (a packed column of some 20 cm length used in isotope enrichment experiments) (3), an electrophoresis strip (4, 5), or some similar arrangement. Transport of salt through the membrane can be due to a hydrostatic pressure gradient, diffusion and, in the presence of an electric field, electroosmosis and transference. The distinction between the two latter entities is obvious if a quasi-lattice model (6-8) for the melt is considered,[2] in which case electroosmosis causes a bulk transport of salt relative to the walls of the capillaries of the membrane, and transference refers to the migration of individual ions in the "lattice." Transference should thus solely be a property of the melt (at the temperature, pressure (9), and chemical composition in question), and it should be independent of external conditions such as the type of material used for the construction of the membrane. For transference, the transport number, *e.g.*, for a cation, can be defined as $t_t^+ = v^+/w^+$, where v^+ is the velocity of the cation measured relative to the "lattice," while w^+ is measured relative to the anions (10). The question arises: Is this theoretically defined transport number t_t identical with, or can it be determined from, the experimentally measured "transport number" t_m?

Of the four entities contributing to the transport through a membrane, the hydrostatic effect can be measured in an arrangement with a sufficient head of the melt on one side of the membrane. Harrington and Sundheim (11) have thus measured leakage rates through membranes of five different types, for which the electrical resistance was also measured in order to determine if the membranes could be useful for transference experiments. It might be mentioned in this connection, that there need not be a close correlation between leakage and resistance, *e.g.*, two membranes should be expected to have nearly the same electrical resistance if the total geometrical cross section of their pores is the same, but if one of these membranes has a great many pores of a small diameter while the other one has a few pores with relatively large diameter, the leakages should, according to Poiseuille's law, be considerably higher in the latter case. The hydrostatic flow through a membrane should increase if an electric current passes through the melt, since local heating is likely to give an appreciable decrease in the viscosity of the melt within the pores. The hydrostatic flow of salt through a membrane might well be disturbed by "stickiness" (12) between the melt and parts of the apparatus, which in turn can be due to surface tension effects or to chemical reactions taking place (giving oxides or other reaction products, which might change the properties of the original surfaces).

The diffusion through a membrane can be estimated, if the self-diffusion coefficient is known for the ion in question, since a "cell constant" can be determined by measuring the electrical resistance. It is, however, worth remembering that studies of aqueous solutions (13) and melts in separation columns (14) have shown that the "electrical free space," calculated from measuring the resistance when the column is filled with a liquid of known conductivity, is of the order of 75% of the "geometrical free space," determined by weighing the packing in the column. There might thus be reason to expect that the cell constants are not identical for diffusion and conductivity.

Electroosmosis and transference are both proportional to the field strength (6), which makes it very difficult to distinguish between these two entities when interpreting "transport number" experiments. It is possible to introduce a formal transport number for electroosmosis, t_{os}, by using the following definition:

$$t_{os} = V_{os}/V_{eq} \qquad [1]$$

V_{eq} is the equivalent volume of a liquid, and V_{os} is the volume transported by electroosmosis through a surface perpendicular to the electrical field if the transported charge is 1 Faraday.[3] If we choose to define V_{os} as positive for transport toward the cathode, the following relations hold:

$$t_m^+ = t_t^+ + t_{os} \qquad [2]$$

$$t_m^- = t_t^- - t_{os} \qquad [3]$$

Thus $t_m^+ + t_m^- = 1$, independent of the magnitude of t_{os}. However, one of the t_m will be > 1 and the other negative, unless

$$-t_t^+ \leqq t_{os} \leqq t_t^- \qquad [4]$$

Sundheim (2) has claimed that t_t can be calculated for each experimental setup from the conservation of momentum within the melt. In this case the experiments actually should give not only t_m but also t_{os}. However, Sundheim has recently modified his theory (15)[4] so that, due to friction within the melt, momentum can be transferred from the melt to the membrane.

It might be mentioned for completeness that the contribution from electroosmosis can change with time if the properties of the surfaces within the membrane change due to chemical reactions between melt and membrane. Such changes might be of importance, *e.g.*, for lithium salts, if the running times are several hours (6, 17).

It is obvious that t_m is the only measurable entity, *e.g.*, in the indicator bubble (18), electrode

[2] A way to picture the situation is to consider the melt as containing minute crystallites or aggregates held in place by the membrane. For our discussion there is no difference between this view and the quasi-lattice model.

[3] In the assumed formalism, V_{os} is proportional to a zeta potential and the dielectric constant of the liquid, and inversely proportional to the viscosity and conductivity of the liquid, *cf*, *e.g.*, F H. MacDougall, "Physical Chemistry," p. 690, MacMillan, New York (1943).

[4] This new theory has not been available for study while preparing this paper, and it is thus not possible to consider it in detail. For this reason it is not clear if there are any contradictions between the results of Sundheim's theory and those of a recent theory by Klemm (16).

displacement (19, 20) and moving boundary (21) experiments, but the situation is not quite the same for the radioactive tracer method (22), since one might say that the movement of individual ions is followed. Thus, if the two electrode compartments were separated by an ideal membrane with a thickness of the same order of magnitude as the average interatomic distance in the melt, *i.e.*, if an ion had to make only a few "jumps" (perhaps only one jump) in the quasi lattice structure in order to pass from one compartment to the other, there would be reason to expect that electroosmosis could be detected even if restriction [4] were fulfilled. However, in all practical arrangements the thickness of the membrane is at least 10^6 times the average interatomic distance, and the measured transport is an average over the displacement of the individual ions, *i.e.*, also in this experiment t_m is the only measurable entity.

So far no experiments with molten salts have given results in contradiction with the limits for t_{os} set in [4]. The situation is different in molten metals, where studies of the Haeffner-effect (isotope effect in electromigration) have shown that the transport number for the metal ions (equivalent to our t_t^+) is of the order of 10^{-4} (23). Klemm (16, 24) has recently found for mercury that the electroosmotic mobility is about 17 times higher than that of transference.

It has usually been assumed for the performed experiments on transport numbers, that the contribution from electroosmosis is negligible in comparison with the transference, *i.e.*, $t_{os} \simeq 0$. This assumption has been supported by the fact that within experimental error, with perhaps one exception, the same transport numbers have been obtained regardless of the membrane material or the method employed. $PbCl_2$ has been studied by the indicator-bubble method with different membranes (18, 25), a moving boundary method (21), and with radioactive tracers (22). For $NaNO_3$, the transport number determined by the volume-change method (26) agrees with what can be calculated from Arnikar's electrophoresis experiments (5, 27), but very careful measurements with the indicator-bubble method (28) seem to show a slight dependence of t_m on the material used for the membrane. The original electrode-displacement method (19) did not give agreement with the indicator-bubble method (18, 12), but after a modification of the former method agreement has been obtained for $AgNO_3$ (20). When considering this indirect evidence for $t_{os} \simeq 0$, it might be worthwhile to remember that electroosmosis of molten mercury is found to be independent of the chosen capillary (glass, Fe, Pt, or Ge) (24). Thus experiments performed with different membranes need not rule out the possibility that t_{os} is of importance in molten salts.

In the above discussion we have assumed that the more or less complete dissociation of the salt has given only simple ions. The situation would be different if complex ions with a long life time were formed. For salts such as alkali halides or nitrates, complete dissociation generally is assumed, but for divalent halides it has been questioned (22, 29) whether the primary dissociation dominates or if complete dissociation takes place. In the case of zinc halides there is much evidence for the presence of complex ions (30, 31) or associations (32). Consider a divalent halide MX_2 where the following reactions take place in the melt:

$$MX_2 \rightleftarrows MX^+ + X^- \quad [5]$$

$$MX^+ \rightleftarrows M^{2+} + X^- \quad [6]$$

$$MX_2 + X^- \rightleftarrows MX_3^- \quad [7]$$

Thus, we have the ions M^{2+}, X^-, MX^+, and MX_3^- to which the transport numbers t^+, t^-, t_c^+, and t_c^- can be ascribed.

Four experiments can be performed with radioactive tracers:

I. Tagged M in the anolyte can pass through the membrane as M^{2+} or MX^+, giving $t^+ + t_c^+$ (see below).

II. Tagged M in the catholyte can pass through the membrane as MX_3^- giving t_c^-.

III. Tagged X in the anolyte can pass through the membrane as MX^+, giving t_c^+.

IV. Tagged X in the catholyte can pass through the membrane as X^- or MX_3^-, giving $t^- + t_c^-$.

As an example of the evaluation consider Experiment I, where Z equivalents of charge are passed through the cell. Thus, t^+Z equivalents of M^{2+} ions and t_c^+Z equivalents of MX^+ ions pass through the membrane toward the cathode, while t^-Z equivalents of X^- ions and t_c^-Z equivalents of MX_3^- ions pass through toward the anode. After the run, the weight of the salt in the anolyte is W_A g, and in the catholyte, W_c g. Depending on the method used for measuring the radioactivity, either the total activity, I_A counts/min, or the specific activity C_A (counts/min)/g, is determined for the anolyte and for the catholyte, I_C and C_C. (The measured activities are corrected for diffusion.) The equivalent weight of the salt MX_2 is M. Because the specific activity is the same in the migrating $(t^+ + t_c^+)Z$ equivalents of salt as in the anolyte, we have

$$\frac{I_C}{(t^+ + t_c^+)Z} = \frac{I_A}{W_A/M}$$

$$t^+ + t_c^+ = \frac{1}{Z}\frac{I_C}{I_A}\frac{W_A}{M} = \frac{1}{Z}\frac{C_C}{C_A}\frac{W_C}{M} = \frac{1}{Z}\frac{I_C}{C_A}\frac{1}{M} \quad [8]$$

since $I_C = C_C W_C$ and $I_A = C_A W_A$.

If there is reason to suspect that complex ions are responsible for part of the current transport, it is necessary to perform at least three experiments, II, III and either I or IV, to determine the transport numbers in a melt. Thus, a complete study requires that suitable tracers are available for both cation and anion.

The question arises if t_t can be determined indirectly from other types of experiments than those discussed above, which all give t_m. In developing a theory for the isotope effect of electromigration in molten salts (and aqueous solutions), Klemm (7, 10) finds that the transport number t_t is a constant of proportionality in the expression for $\Delta w/w$,

the relative difference in velocity for the ions of two isotopes of an element. In Klemm's model there are also a couple of other parameters for which certain assumptions need to be made, if transport numbers are to be calculated from available data on isotope effects. However, it cannot be expected that such estimations made from the measured isotope effects for zinc and lead halides ($ZnCl_2$, $ZnBr_2$, $PbCl_2$, and $PbBr_2$, where all eight isotope effects have been measured) (33), will give more than, at best, very approximate values for t_t. The accuracy would not be good enough to estimate t_{os} from a comparison with t_m.

Experimental

Materials.—Inactive anhydrous zinc chloride was prepared by letting a stream of chlorine gas pass over zinc metal at 500°-750°C and collecting the distilled zinc chloride in tubes that were sealed off from the apparatus. Zinc chloride tagged with radioactive zinc (Zn^{65}, half-life 245 days) was made in the same way as the inactive salt.

For the zinc chloride tagged with radioactive chlorine (Cl^{36}, half-life of 4×10^5 years) another method was needed because the above method would require special arrangements to recover the excess chlorine after it had passed over the zinc metal. The radioactive chlorine was available as a solution of hydrochloric acid from which silver chloride was precipitated. After drying, the silver chloride was mixed with slightly more than twice the equivalent amount of zinc metal (34), and the mixture was slowly heated to about 800°C, whereby zinc chloride was distilled off. Since the product contained considerable amounts of zinc metal, it was purified by redistillation (35).[5] However, for most of the runs with radioactive zinc chloride, this was prepared by letting molten anhydrous zinc chloride flow down into a tube containing a small amount of silver chloride of high specific activity. The salt was kept molten long enough to be sure that the mixture of $ZnCl_2$ and AgCl was homogeneous. The radioactive salt thus obtained contained about 0.3 w/o silver chloride.

Apparatus.—Because $ZnCl_2$ is a very hygroscopic salt, it was considered best to work under a nitrogen atmosphere, and since the salt is fairly volatile at the higher working temperatures the cells were designed as shown in Fig. 1. The cells were made of Pyrex glass or of quartz. The disks were treated as described elsewhere (22, 36) in order to reduce the porosity. In the runs with tagged zinc, the anode consisted of a carbon rod, but when working with tagged chloride, an anode of a droplet of zinc metal was used to prevent liberation of radioactive chlorine gas, which otherwise could penetrate over to the compartment with inactive salt. In all runs at temperatures above 420°C, the melting point of Zn, the metal was merely deposited at a tungsten cathode, but when this cathode was used at lower temperatures, the deposited metal grew as dendrites which punctured the disk, thus short-circuiting the cell. For the lowest temperature region, mercury metal was used as a cathode in the hope that the zinc would form an amalgam at the same rate as it was deposited. For the temperature region 356°-420°C, molten lead was tried as the cathode, but there was little success because the lead-zinc alloy was not formed fast enough to prevent the growth of zinc dendrites.

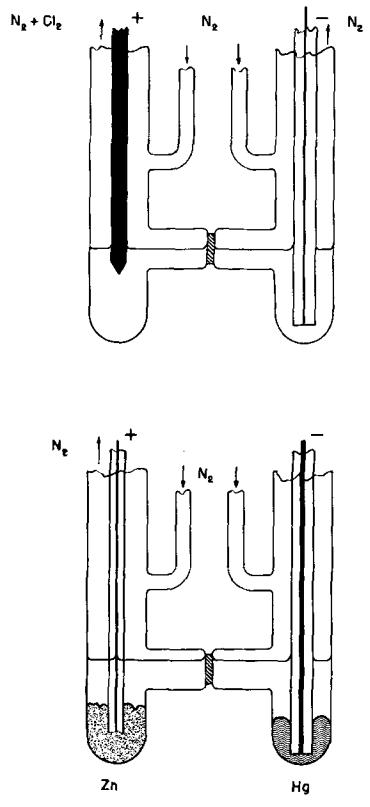

Fig. 1. Designs of cells

The power supply was a rectifier capable of giving up to 500v dc. The transported electrical charge was measured with a silver coulometer.

Runs at temperatures below 420° were performed in a temperature-stabilized salt bath, while the other runs were made in a vertical oven, which also was temperature stabilized. In the latter runs the cell temperature was measured by means of a Pt, Pt-Rh thermocouple, which was wound around the cell as close to the disk as possible.

Procedure.—For each run one batch of inactive and one of radioactive zinc chloride were selected, cut open, and lowered into the hot part of the cell, through which nitrogen gas had been flowing during the entire heating-up period. When the salt had melted, the empty holders were pulled out of the cell and the electrodes were inserted; meanwhile, the temperature of the oven was raised to the desired height. The temperature of the cell was measured before the run, at frequent intervals during the run, and also some ten minutes after the electrolysis current had been shut off. As expected, the heat generated in the disk was sufficient to raise the temperature of the cell some 3°-20°C above the temperature in the oven. Due to the fact that the conductivity of $ZnCl_2$ increases rapidly with temperature (37), the current drifted considerably the first seconds after each adjustment of the applied voltage, but in nearly all runs the current was very steady most of the time. The real exception

[5] This procedure was worked out by J. P. Cook.

to this was in those runs below 420°C, where dendrites of Zn metal penetrated through the disk. Obviously the dendrites were formed and then dissolved or broken at frequent intervals, thus causing current fluctuations. Simultaneous measurements of the current and the voltage across the cell gave an approximate figure for the resistance. The resistance would vary considerably from cell to cell, evidently because the porosity of the individual disk was not the same.

The electrolysis time was chosen such that the transported charge was of the order of 150-200 coulombs in each run. After the run the cells were lifted out of the oven to check whether the melt had been at equal heights on both sides of the disk. The cell was quenched and then divided into two samples, catholyte and anolyte, the disk being included with the part to which the radioactivity had been added.[6] Samples were dissolved and then treated in two slightly different ways depending on whether Zn^{65} or Cl^{36} had been used as tracer.

When working with radioactive zinc the total activity of liquid sample was measured with a scintillation well counter. For the runs with radioactive chlorine, on the other hand, the specific activity was measured for a solid sample of silver chloride (36). The zinc chloride in the samples was determined by an EDTA titration with naphthyl azoxine as indicator (38).

In all runs with a tungsten cathode the deposited zinc was collected and either weighed or determined by an EDTA titration. In this way we had a check on the transported electrical charge as determined with a silver coulometer. As an additional check, the average current was always found to be in agreement with readings during the run.

A couple of auxiliary experiments were also performed. Thus, it was found that a considerable exchange of zinc takes place in the molten state between metal and salt. The effect of a hydrostatic head was studied at 512°C by letting a cell stand for 10 hr with a height difference of about 25 mm between the salt in the two compartments. The leakage was found to be 0.4%. Self-diffusion of zinc ions was measured in a run at 674°C.

[6] In a few cases the disk and part of the horizontal tube formed a third sample, which also was analyzed. The remaining sample from the low activity side (catholyte in type I) had a normal specific activity, which proved that convection flow gave a homogeneous distribution of the activity within each compartment.

Results and Discussion

As seen from the data summarized in Table I, the runs covered a wide range of temperature and current settings. Of the resistances calculated from

Table I. Transport number experiments on molten $ZnCl_2$

Run No.	Temp, °C	Approx. temp increase, °C	Time, sec	Transported charge, coulombs	Mean current, ma	Approx. resistance, ohms	t_+	Remarks
				I. Runs with Zn^{65} in the anolyte				
1	435	30	10800* (2200)	125	11.6 (35)	2100-65 k	0.51

* The resistance was very high during the first part of the run, but it dropped suddenly to a normal value. The run was continued for the time given in parentheses.

the frequent measurements of current and voltage during the runs, either one typical value or the extreme limits are given in Table I. In a few runs (No. 1, 14, 16, 17, and 18) the resistance was very high in the beginning, but after a while there was a sudden change to "normal" conditions. Since this only happened at lower temperatures where the viscosity of zinc chloride is high (39), the plausible explanation is that it took some time before enough salt had penetrated into the disk to establish a good contact between the two compartments. For these runs, Table I gives both the mean current calculated for the whole running time and, in parentheses, an estimated value for the second part of the run.

The current and voltage measurements were also used as a basis for calculating the wattage, which of course varied very much from run to run (and also, in some cases, during a run), with typical values from 0.4-8.3w. (The high-temperature runs in quartz cells used 0.1-1.5w.) We could also make a crude estimation of the total cross section of the "capillaries" in the disk and of the current density in these capillaries, since

$$A_{eff} = L/R\kappa \qquad [9]$$

$$\beta = \frac{L}{f A R\kappa} \qquad [10]$$

and

$$i = I R\kappa/L \qquad [11]$$

where A is the geometrical cross section of membrane, f the fraction of disk covered by the melt, L the length of the "capillaries,"[7] A_{eff} the total cross section of the "capillaries," 100 β the free area, percentage, κ the conductivity of zinc chloride (37), R the resistance in the membrane, approximately equal to total cell resistance, I the current, and i the current density.

All the disks had a diameter of 1 cm, thus A = 0.79 cm^2. Since it is difficult to determine the average path length through the membrane, we found it sufficient merely to use the thickness of the disks, approximately 1.5 mm, as L in our calculations. Since the conductivity of zinc chloride is extremely temperature dependent (37), the calculations are very sensitive to errors in estimating the temperature *in* the capillaries.[8] For this reason the uncertainty in the β and i obtained was considered greatest for the runs at low temperatures or with high currents. Although in one run an extreme value of 1.6% was found for β, the runs with currents less than 30 ma gave values between 0.2 and 0.5%. Further considerations showed that the most likely free area of a disk was 0.3-0.4%. The limits for the current densities in our runs with Pyrex cells were found to be 5 and 25 amp/cm^2. For one of the runs with a quartz cell the current density was found to have been 47 amp/cm^2. For previous work with similarly prepared membranes (22, 36) no measurements of the current density have been reported, but it might have been of the order of 100 amp/cm^2.

The transport numbers were calculated according to Eq. [8] and corresponding equations. For the runs with Zn^{65} in the anolyte (Type I), the activity I_c measured for the catholyte was corrected for the activity in the deposited zinc. The amount of deposited metal was too small to allow any accurate measurement of its activity, but from our exchange experiment (see above) we concluded that the specific activity of the deposited metal could be considered as approximately 0.75 C_c.

The above-mentioned diffusion experiment at 674°C confirmed that the known self-diffusion coefficient for zinc in $ZnBr_2$ could be used in our estimations (40). It was assumed from measurements in other salts (41, 42) that the chlorine and zinc self-diffusion coefficients were of the same order of magnitude. The contribution from self-diffusion was of importance only when calculating the transport numbers at higher temperatures. For the run at 673°C (No. 12), 5-10% of the activity was transported by diffusion.

Of the runs for measuring t_c^- and t_c^+ (Type II and III), the four runs in Pyrex cells showed such a small transport of activity through the membrane that it was difficult to distinguish from the background. Estimations gave the result that self-diffusion alone was more than sufficient to account for the whole transport, and the measured t_c^- (runs 20 and 21) and t_c^+ (runs 23 and 24) are to be considered as upper limits, likely to be at least an order of magnitude too high. The run at 660°C (No. 22) gave an uncorrected value for t_c^- of 0.036, which, however, was due to self-diffusion and a hydrostatic head of about 3 mm. Thus, also in this run t_c^- is very small, and we can conclude that no transport by complex ions has been detected in any part of the investigated temperature range, and that t_c^+ and t_c^- can be neglected in comparison with t^+ and t^- when interpreting the runs of Type I and IV. If complex ions exist in molten $ZnCl_2$, their life time must be considerably less than the time it takes for an ion to traverse the membrane.

Regarding the measured t^+ and t^-, it is obvious that the spread in the obtained results is considerably higher than what can be expected from the statistical error of the chemical, electrical, and radioactivity measurements. Most runs have probable error of about ± 0.02, while the extreme values for t^+ (runs 3 and 8, resp. 4) differ by a factor of 2. The variations from run to run could be suspected to be due to hydrostatic effects, but the head was less than 1 mm for more than half of the runs, and for the remaining runs there was no correlation be-

[7] The pores in the disks consist of a number of cavities connected with each other by small openings. This whole irregular system is for this estimation considered as equivalent to a series of parallel capillaries.

[8] It is obvious that the temperature distribution is very inhomogeneous in the disks, since the heat production is concentrated to the salt-filled "capillaries." The heat is then transported through the disk to the other parts of the cell. The heat conductivity of molten $ZnCl_2$ is not known, but it is possible to make some very crude estimations of existing temperature gradients by assuming that the heat production is homogeneous throughout the disk, and that heat conduction in the axial direction dominates. The heat conductivity of Pyrex glass can be estimated to be approximately 0.015w cm^{-1} degree^{-1}, *cf. e.g.*, Morey, "The Properties of Glass," 2nd ed., p. 220, New York, (1954). The difference in temperature between the center of the disk and the ends would then be 1.6°C for 1w and 13°C for 8.3w dissipated in the disk. Due to the concentration of the heat production to the capillaries the actual temperature differences are likely to be higher. Because of the lack of information on the actual temperatures in the disks, the conductivity at the measured cell temperature was used when calculating β and i. The systematic error introduced in these latter entities by using a low value for η is counteracted by the fact that a low value has been used also for L, see above.

tween t^+ (or t^-) and the occurrence of a head of a couple of millimeters on either side of the disk. Neither would this be expected from a comparison with the above-mentioned check run at 512°C.

The most striking result of the runs is that the t^+ values obtained as $1 - t^-$ from the runs with Cl^{36} do not agree with the t^+ values of the runs with Zn^{65}. The division in two groups is significant, since, in spite of the great spread within both groups, not a single result falls among the data obtained with the other method. The unexpected result that $t_m^+ + t_m^- < 1$ can only be obtained with the radioactive tracer method, while for all other methods $t_m^+ + t_m^- = 1$ by definition. To explain the discrepancy between the runs with Zn^{65} and Cl^{36}, it is to be noticed that there are strong indications that the transport numbers depend on the current or, perhaps rather, the duration of the run. Thus the four highest values for t^+ (runs 3, 8, 10, and 12) were all obtained in 6000 sec runs, and these do not differ more than by the experimental error, since, due to the considerable contribution from self-diffusion at higher temperatures, run 12 has an experimental error of $\pm$ 0.06 instead of $\pm$ 0.02. However, the remaining 6000 sec t^+ run (No. 4) is far off. The shorter runs (1200-4000 sec) show much more of a spread in the obtained t^+. The highest t^- value is obtained in a 6000 sec run. It might be noticed that among the long t^- runs (all runs except No. 28) there is a tendency that t^- increases with temperature, and also that the low-temperature t^+ runs give low transport numbers. (Runs 17-19 are uncertain due to dendrites, but this disturbance did not occur in the runs with a Hg cathode.)

The time-dependent process in the experiments is diffusion, *i.e.*, the exchange of ions due to self-diffusion in the melt. The distribution of concentration by diffusion depends on $(Dt)^{1/2}$, where D is the diffusion coefficient and t the time (43). Thus for $D \approx 10^{-6}$ cm^2/sec and $t \approx 3000$ sec very little material is transported further than 1 mm from the original position. Diffusion should be of importance inside the disk as well as in the surface layer on both sides of the disk. If the disk were to be considered as an ideal membrane with only straight channels open in both ends, the transport would depend only on the electrical field strength, and an ion would traverse the disk in something like 50 sec, *i.e.*, a time that is short compared to our running times. However, in the disks there are many blind channels and other cavities, containing salt which is gradually exchanged by diffusion. Once an ion has been transported through the disk, it might stay a certain time in a thin salt layer close to the surface. Since the field strength outside the disk is roughly 0.3% of what it was in the channels in the disk, a diffusion process should be responsible for the transport of the ion out into the bulk of salt, where, again, transport is rapid, since a considerable convection flow takes place here (as was checked by dividing some cells into three parts, see above). If the tracer concentration is higher in a thin surface layer, which adheres to the disk when the cell is cut apart than it is in the bulk of salt, the obtained transport numbers will be too low. This systematic error should increase with decreasing running time and with decreasing temperature. This seems to be the case in the present experiments.

When discussing the existence of a surface layer through which diffusion is the main mode of transport, it might be worthwhile remembering that, due to the heat dissipation at the high current densities in the disk, the salt within the disk and immediately on its surface will be at a higher temperature than the bulk of salt. Regarding zinc halides, even rather small temperature gradients mean considerable changes in physical properties such as viscosity and conductivity. These differences between individual salt layers will be accentuated with increasing current density in the disk, but we cannot distinguish between current and time effects in the present experiments, since it was necessary to transport about the same charge in each run.

Since there is a tendency for obtaining low values for the transport numbers, it is suitable to make an extrapolation to zero current density, *i.e.*, infinite running time. For both t^+ and t^- the limiting value is close to $t_m^+ = 0.6$. For ideal conditions we can thus expect a transport number of $t^+ = 0.6 \pm 0.1$. This result is in agreement with the very recent experiments by Fischer and Klemm (44), who used a new method. Due to their better precision, they were able to detect a slight dependence on temperature (θ). Thus they found $t^+ = 0.716 - 3.07 \times 10^{-4} \times (\theta - 318)$.

The question arises if the discussed diffusion effects have caused systematic errors in previous measurements with the radioactive tracer method, where only one tracer, Cl^{36}, was used (22, 36). In general, this need not be the case, since the self-diffusion coefficient is higher and much less temperature dependent for $PbCl_2$ and the alkali halides than it is for $ZnCl_2$. For $PbCl_2$ the result is in agreement with what was obtained by other methods. However, for AgCl the radioactive tracer method (45) has given much lower values than another method (25). Thus it seems wise always to check the results by using both anion and cation tracers.

Summarizing, we find that the shortcomings of the radioactive tracer method are accentuated by the rather special properties of the chosen salt, but that even in this case it is possible to use the method if suitable precautions are taken, such as using two tracers. A final valuation of the merits of this method relative to other ones will require further measurements on several salts.

Acknowledgments

The author is much indebted to Professor F. R. Duke and Mr. J. P. Cook for stimulating discussions during the experiments and to the former also for valuable criticism of the manuscript.

Manuscript received Feb. 20, 1961; revised manuscript received Dec. 11, 1961. Work was performed in the Ames Laboratory of the U.S.A.E.C.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

Technical Notes

Vapor-Phase Doping of Silicon with Arsenic Trichloride

E. J. Mehalchick and P. K. Marshall

Chemical and Metallurgical Division, Sylvania Electric Products Inc., Towanda, Pennsylvania

With the advent of Esaki diodes, fast-switching electronic devices, and epitaxial devices, a need for very low resistivity crystals became very important.

Low resistivity silicon monocrystals are available commercially, but methods of production are not reported. Backenstoss (1) has reported values of 0.001 ohm-cm, arsenic-doped, melt-grown silicon crystals. Trumbore (2) gives a solubility limit of arsenic in silicon, most probably by diffusion, of 1.2×10^{21} atoms/cm^3 below 1375°C, corresponding to about 2×10^{-4} ohm-cm. Goorissen and VanRun (3) reported constant resistivities of about 0.01 ohm-cm by gas-phase doping with a phosphine-hydrogen mixture in float-zoned silicon crystals.

An easier method of growing arsenic-doped silicon crystals with uniform resistivity profiles ranging from 1.0×10^{-3} to 5.0×10^{-2} ohm-cm has been developed. The procedure involves passing an arsenic trichloride-helium mixture into a crystal-growing apparatus. Upon reaching the hot zone, the arsenic trichloride is reduced by the molten silicon, producing arsenic and silicon halides. A fraction of the arsenic is dissolved in the silicon. The evaporation rate of arsenic is sufficiently slow that it is possible subsequently to grow the crystal in pure helium and yet maintain a constant displacement of arsenic atoms from the liquid to the solid.

Experimental Details

The silicon used in the experiments was prepared by deposition on a silicon substrate by the hydrogen reduction of silicon tetrachloride. The boron concentration of this material after six passes in a semiautomatic floating-zone refiner was calculated

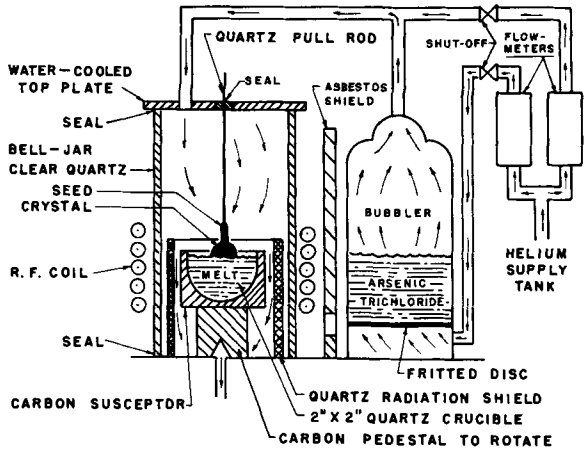

Fig. 1. Crystal puller

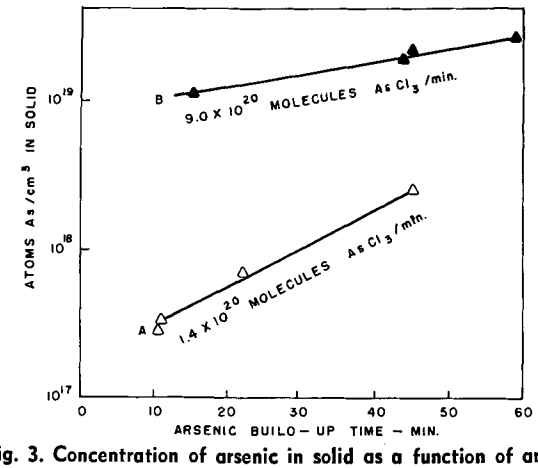

Fig. 3. Concentration of arsenic in solid as a function of arsenic buildup in the melt.

to be 1.1 ppb based on resistivity measurements. All resistivity measurements were made with a two-point probe.

A diagram of the crystal-growing apparatus is shown in Fig. 1. The experimental procedure first involved melting a charge of silicon in a vitreous silica crucible in an atmosphere of pure helium. Arsenic trichloride was introduced by metering a known volume of helium through a saturator containing the arsenic trichloride at 25°C. The exact supply rate was determined by weighing the arsenic trichloride before and after the experiment and by recording the times The gas mixture was then admitted to the crystal-growing apparatus and was allowed to pass over the molten silicon for 45 min, permitting a sufficient quantity of arsenic to be dissolved in the melt. The crystal was then grown in the same gas mixture.

During the crystal-growing operation, the supply rate of arsenic trichloride, the total gas-flow rate, and the growth rate were carefully kept constant to provide a constant supply of impurity atoms to replace those being incorporated into the solid.

Results and Discussion

The feasibility of the method depends on the existence of an equilibrium in which the net number of impurity atoms captured by a unit volume of the liquid per unit time is equal to the net number incorporated into a unit volume of the solid in the same period.

Several arsenic-doped silicon crystals were grown, and the concentration in the solid was found to be a function of the arsenic trichloride supply rate and/or the arsenic build-up in the melt.

The following conditions were held constant in the experiments performed: growth rate, 0.152 cm/min; total gas-flow rate, 66 l/min; pot charge, 150g; crystal diameter, 22-28 mm; pot rotation, 6 rpm; arsenic buildup time, 45 min. The results of these experiments are given in Fig. 2.

Variations in the preceding method were carried out to study the effect of growing in a neutral atmosphere after some initial buildup period in the melt. The lowest possible supply rate of arsenic trichloride (1.4×10^{20} molecules $AsCl_3$ per minute) was kept constant and the buildup period was varied from 11 to 45 min. All other conditions were the same as in the preceding section. The results of these experiments are given in Fig. 3 (curve A).

A series of experiments using a higher arsenic trichloride supply rate (9×10^{20} molecules $AsCl_3$ per minute) with other conditions the same as in the preceding section yielded a maximum arsenic concentration of 2.5×10^{19} atoms/cm³ after 1.0 hr. In all experiments the arsenic carrier density was determined from the resistivity measurements made on the crystal. The results of these experiments are given in Fig. 3 (curve B).

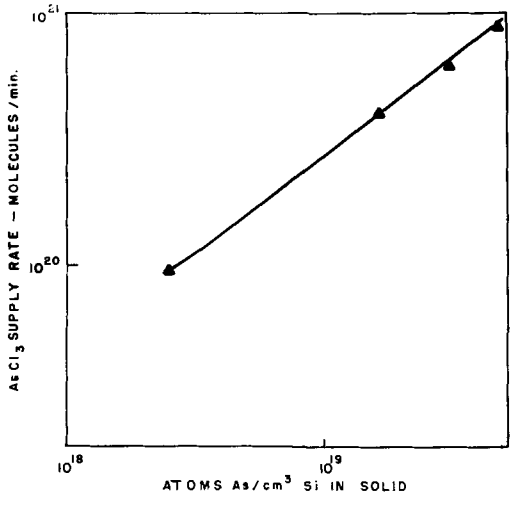

Fig. 2. Concentration of arsenic in solid as a function of $AsCl_3$ supply rate.

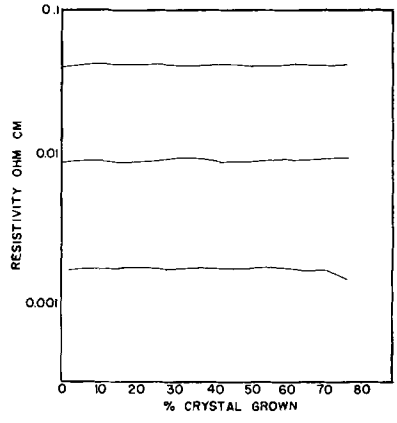

Fig. 4. Axial resistivity distribution obtained by vapor phase doping of silicon.

The axial resistivity profiles of the silicon crystals were quite level. It appears then that the evaporation of arsenic atoms from the liquid is nearly in equilibrium with the number of atoms rejected by the freezing solid. Figure 4 shows some typical plots of resistivity *vs.* the percentage crystal pulled for crystals grown by the vapor-phase technique and doped with arsenic trichloride.

A few experiments using higher arsenic trichloride-supply rates and longer buildup periods of arsenic in the melt, produced crystals with resistivities not lower than 0.0009 ohm-cm. It appears that saturation of arsenic in the melt occurs after 45-60 min, limiting the carrier concentration of arsenic in the crystal to a maximum value of 3×10^{19} atoms/cm^3.

Summary

Arsenic-doped, melt-grown silicon crystals with level resistivity profiles, ranging from 1×10^{-3} to 5×10^{-2} ohm-cm, were obtained by passing an arsenic trichloride-helium mixture into a silicon crystal grower. The desired resistivity could be obtained by varying the arsenic trichloride supply rate and/or by varying the arsenic buildup period in the melt.

Acknowledgments

The authors wish to thank J. M. Demangone and W. S. Shaw, both of this laboratory, for evaluating the crystals.

Manuscript received Sept. 29, 1961.

Controlled Chemical Etching in the Production of Semiconductor Dice

P. J. A. McKeown

Transistor Division, Standard Telephones & Cables Ltd., Footscray, Kent, England

In the production of some kinds of semiconductor device, a key process is the etching of single crystal dice to remove mechanical damage and to clean the surface in preparation for the next operation. It is desirable to remove an appreciable thickness of material and to require the etched dice to have a small spread of thicknesses. An investigation of the process has led to the development of improved means of control. The dice used in this work were 2.25 mm square and were n-type single crystal germanium of {111} orientation.

The main factors which influence the amount removed are: (*a*) lapping damage, since the etching rate of a mechanically damaged surface is higher than that of undamaged material; (*b*) etching time, since this is usually less than a minute and therefore timing errors introduced by an operator can be significant; (*c*) the temperature at which etching takes place. This is made up of two terms, the average temperature of the etchant bath, and the local temperature rise at the semiconductor surface due to the heat of the reaction. The heat of solution of germanium in a typical etchant containing nitric and hydrofluoric acids was measured and found to be about 2000 cal/g. From this it has been calculated that the temperature of an isolated die together with liquid layers 100μ thick, would increase at about 200°C/sec.

Temperature control obviously requires that the local dice temperature should be kept close to that of the bulk etchant. This was achieved by means of an apparatus which used a stationary polythene beaker 7 cm in diameter with a conventional mechanical stirrer near the bottom and a special baffle to provide the necessary flow pattern. The stirring was adjusted so that all dice 150μ thick were kept in suspension in the etchant, and yet the breakage rate for dice 50μ thick was only 0.25% per min.

The temperature of the bulk etchant was controlled by means of a heat exchanger made from 4 mm diameter platinum/rhodium tubing. This was made into a 10 turn spiral 2.1 cm in diameter. The spiral was bent to form almost one complete turn about the stirring shaft. This heat exchanger also acted as the baffle to improve dice agitation. All gaps between beaker, coil, and stirrer were such that dice could not wedge nor be caught between moving parts.

Water at a controlled temperature flowed through the heat exchanger at 18 cc/sec. The temperature was regulated by means of three heaters. The first heater automatically kept the temperature of water leaving it about 4° below the required etchant temperature. Heater No. 2 raised the temperature of the water by an amount such that its effect on the etchant temperature was approximately equal to the heat produced by etching. This heater was switched off a few seconds before etching so that it ceased to influence the etchant temperature just as the etching began. The third heater was controlled by a thermocouple in the etchant and corrected any small errors in temperature.

The bottom of the beaker was perforated by 185 holes each 1.4 mm in diameter, but during etching a solenoid-operated sealing plate prevented loss of etchant. Etching was started by automatic injection of dice, and the reaction was stopped by draining the etchant and at the same time adding a large volume of deionized water. All operations were con-

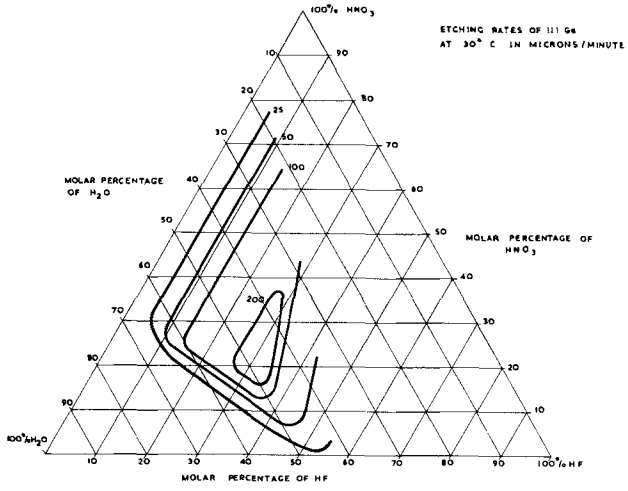

Fig. 1. Etching rates of {111} germanium at 30°C in microns per minute.

trolled by timers and the etching time could be preset with accuracy of ¼ sec.

It was found that 200 dice could be etched at a time so that the mean scatter in thickness introduced by etching was less than 0.3 of a micron. The reproducibility from batch to batch was ± 0.7μ, and thicknesses of etched dice could therefore be predicted.

The machine has also been used for the accurate measurement of etching rates. Figure 1 shows a triangular plot of etching rates for the HNO_3-HF-H_2O system. It refers to 2 ohm-cm dice with a dislocation density of 5000/cm^2. It should be noted that the etching rates plotted differ by factors of 2, and so a wide separation of contour lines indicates an insensitivity to etchant composition. The activation energy of the reaction is 14.5 kcal for solutions containing 15 molar % HF and increases to 40 kcal for solutions in which the molar ratio $HF/HNO_3 = 3$. These values are higher than those reported by Schwartz and Robbins (1) for silicon.

Other factors which have a slight effect on etching rates are dice thickness, resistivity, and dislocation density. For an etchant removing 1.25 μ/sec, the etching rate was found to be a minimum for dice 50μ thick. Thicker dice etched slightly faster because of the increased flow of etchant over their surfaces, and thinner dice did so because their low thermal inertia permitted temperature fluctuations. Resistivity appeared to have little effect on etching rate within the narrow range investigated. Seven ohm-cm material etched about 1% faster than 1 ohm-cm. Dislocation density had more effect, a minimum etching rate being obtained at a dislocation density about 1000/cm^2, 20,000 dislocations/cm^2 increased the rate by about 3%, and in the absence of dislocations the rate increased by 10%. This may be because both dislocations and lattice vacancies promote attack by acting as nuclei.

Some fast etchants have been observed to produce pits at dislocations. This was traced to the etching which occurs during the fraction of a second required to quench by the addition of water. Very rapid quenching such as is obtained with the machine described above keeps this pitting to a minimum.

Alloying to III-V Compound Surfaces

L. Bernstein[1]

Alloys Unlimited, Incorporated, Long Island City, New York

Because of the interest in using the III-V intermetallic semiconductor compounds for making semiconductor devices, it was felt that a greater understanding of the alloying nature of these materials would be helpful. To this end, a program to determine the condition under which the indium and gallium antimonides, arsenides, and phosphides alloy with some of the common bonding materials was instituted.

Alloy bonds may be required either for ohmic contact or p-n junction formation. Impurities in Group II of the periodic chart (Zn and Cd) act as acceptors in the III-V compounds, whereas those in Group VI (S, Se, and Te) act as donors. In addition, however, materials like Ge, Si, Pb, Sn, Cu, or Mn, which may be used in bonding to III-V surfaces, also act as donors or acceptors. Usually, however, they have low doping efficiency compared with the II-VI elements. Small quantities of II or VI group impurities may, therefore, be added when necessary to give the appropriate doping.

The III-V compounds used in this investigation were in the form of dice 0.100 x 0.100 x 0.020 in. thick. All alloying was done on material cleaned using the etchants shown in Table I. Except for a few alloys studied for feasibility in producing p-n junctions, the bulk of this investigation was concerned with large surface area ohmic contact covering the complete die. In the case of Au alloying, the material used was 0.2 to 0.5 mil gold clad material on suitable substrate (1). All other alloys

[1] A portion of this work was done by the author while with Hughes Semiconductor Products.

studied were 0.5 to 1.0 mil foil or clad on the same substrate material.

All of the etchants shown in Table I produced shiny, clean surfaces. The etch was followed by a wash in distilled water and finally an acetone rinse before alloying.

Table II describes the results of some bonding experiments run during this investigation. Approximate eutectic temperatures and preferred bonding temperature ranges are shown. Additional results with other alloys are shown in the body of the report. In addition, the type of doping is indicated with the appropriate literature references.

Thermal expansion measurements on these III-V compounds were reported in a previous publication (1).

Au-Sn *bonding.*—From previous experience in bonding to Si and Ge, it was learned that Au-Sn alloyed to their surfaces at lower temperatures and under much less critical atmosphere conditions than did pure gold. With the III-V compounds, however, this was not the case; therefore, there seems to be no advantage in its use over pure gold, other than those cases where the doping effects of tin are required.

Au-Ge *bonding.*—No eutectic formations were noted in these systems at all. Very little solution of the intermetallic took place as much as 100°C above the melting points of the gold-germanium eutectic, but in all cases good alloy bonds were formed. Much less penetration was noted compared with pure gold. The antimonides are apparently more sensitive to cracking than all the other compounds; therefore, Au-Ge is not recommended for use with them.

Au-Si *bonding.*—Again, no eutectic formations were observed. Similar to the Au-Ge system, solubilities and penetrations were low. In all cases, except for InSb, bonds formed were excellent.

Pb *bonding.*—Alloying with pure lead was very reproducible and simple. No eutectic formation was observed. Solubility and penetration (in most cases approximately 5-10μ) was low at temperatures as high as 300°C above the melting point of Pb. No cracking was observed at all.

Pb-Sn *eutectic bonding.*—Again, no eutectic formation or cracking was observed. At necessary bonding temperatures, however, there was more penetration and solubility than with pure Pb. Small additions of In or Sb had no effect on the wetting properties.

Table I. Etching of III-V compounds

III-V Compound	Etching solution	Etching time in sec
InSb	2HF/1HNO_3 diluted with an equal volume of H_2O	10-15
InAs	Conc. HCl	12-15
InP	Conc. HCl	3-6
GaSb	2HF/1HNO_3 diluted with an equal volume of H_2O	10-15
GaAs	2HF/1HNO_3 diluted with an equal volume of H_2O	10-15
GaP	2HF/1HNO_3	10-15

Sn *bonding.*—No eutectic formation or cracking was observed. Alloying with tin produced the lowest temperature bonds so far possible (see Table II). Small additions of gallium, contrary to results experienced in other systems, inhibited good wetting.

Ni, Cu, *and* Ag *bonding.*—In all these systems eutectic formations were observed. With nickel they were in the 700°-800° range; with copper 350°-500°C; with silver 400°-680°C. No bond was formed to InSb or GaSb with Ni below their melting points (523° and 702°C, respectively). No cracking was observed, except in the case of copper alloying to GaAs, and even in this system, no fracture occurs if the bond is formed above 650°C. The microstructure of bonds made at these elevated temperatures indicates a possible phase transformation to a more ductile form.

Bonding with Al *and* Al/Si *eutectic.*—Bonding to all six intermetallic compounds was accomplished with aluminum below 650°C. However, no eutectic structure was noted. Even in cases where fusions were made as high as 700°C, penetration was extremely shallow, much less than 5μ, indicating low solubility of the compounds in Al. This fact may be used to advantage in making contacts to shallow diffused regions. Al/Si bonds to III-V compounds were unsuccessful.

Cd *and* In *bonding.*—These bonds require temperatures in a range of 600°-800°C. Little if any eutectic formation is noticeable, and the penetration is extremely shallow as compared with other alloy bonds, except aluminum, made in a similar fashion. With Cd, some eutectic seems to form at a very low III-V concentration and only a few degrees below its melting point. Indium bonds with these elements were successfully made to all the intermetallics.

A number of alloys were studied for possible p-n junction formation on the III-V compounds. Binary alloys, where the major alloying element was In, Ag, Sn, Pb, Cd, or Au, were were fused on to all of the III-V surfaces. In a simple-type phase system such as exists in the Al-Si or In-Ge systems, the semiconductor bulk material, which has been dissolved at some elevated temperature, recrystallizes out on its original surface after cooling. These regions are sometimes referred to as regrown regions. They can be delineated by metallographic etching on a cross-section sample. If a pseudobinary phase diagram, using the III-V compound as one component and one of the binary alloys as the other, was of the two-component system type without intermediate compounds or solid solutions (similar to the Al-Si or In-Ge systems), one would expect to see some regrown region crystallizing out on the original III-V surface. Although all of the alloys mentioned, when doped appropriately, exhibited rectification properties after fusion, only the Sn and Au alloys showed any regrown regions. In all the other systems, at least one other unidentified phase was observed to have crystallized out of solution, and no regrown regions were observed. One ternary alloy composed of Sn, Cd, and Zn gave the appearance of a double junction formation when fused

Table II. Temperatures of alloy fusions to III-V surfaces

Kinetics and Mechanism of Nickel-Sulfur Reaction

Lucjan Czerski, Stanislaw Mrowec, and Teodor Werber

Department of General and Coal Chemistry, School of Mining and Metallurgy, Crakow, Poland

ABSTRACT

Kinetics and mechanism of the reaction between nickel and sulfur vapors were investigated in the temperature range 480°-640°C under atmospheric pressure. The sulfurization of nickel has been found to follow, under these conditions, the parabolic rate law. The activation energy of this process amounts to 22 kcal/mole. The examination of x-ray patterns of the scale formed on the surface of the metal has demonstrated that this scale layer is composed almost entirely of NiS. Morphologic investigations show that the scale is composed of two distinct layers. The outer layer, constituting the main part of the whole scale, is compact, polycrystalline, and exhibits an ordered growth texture. The inner layer is porous and does not exhibit any growth texture. The investigations carried out with the aid of the radioactive sulfur isotope ^{35}S have demonstrated that the sulfide scale on nickel is formed exclusively by the outward diffusion of the metal.

The confrontation of experimental data with the results obtained by Dravnieks (1) leads to the assumption that the mechanism of the sulfide scale formation on nickel does not depend on the state of aggregation of the oxidizing medium.

Dravnieks (1) and Wagner and Lichter (2) have demonstrated that the sulfurization of nickel in molten sulfur in the temperature range 205°-445° follows the parabolic rate law. On the other hand Hauffe and Rahmel (3), as well as Pfeiffer (4), stated that if the reaction was carried out in sulfur vapor at 630° under a pressure not exceeding 1 mm Hg the course of the reaction could be described with a linear rate law.

It was thereby stated that the sulfide scale formed on nickel is composed exclusively of the NiS-phase independently of the state of aggregation of the oxidizing medium and of the temperature. The scale is built up of two distinct layers; the outer one is compact, and the other, inner layer, is porous. Arkharov and Blankova (5), Czerski (6), Mrowec and Werber (7), Pfeiffer (4), and Hauffe (3) suppose that the formation of these two layers of the same reaction product can be explained by assuming simultaneous diffusion of both reactants through the scale layer in two opposite directions.

However, according to the opinion of Pines and Tchaikowskij (8), the sulfide scale layer on nickel grows exclusively because of the inward diffusion of sulfur.

From the literature data given above it can be seen that the mechanism of sulfurization of nickel is not yet definitively cleared up and more experimental work must still be done. The aim of the present work was therefore to investigate the kinetics and mechanism of sulfurization of nickel in sulfur vapor under atmospheric pressure in the temperature range 480°-640°C.

Experimental

The measurements were carried out on specimens containing 99.85% Ni. By means of spectral analysis the presence of the following impurities Fe, Mn, Cu, Mg, Si, Co, Al, and traces of Ag, Zn, Ca has been shown. The metal was melted *in vacuo* (10^{-4} mm Hg) and cold rolled to sheets 0.1 cm thick. The sheets were annealed for 100 hr at 750°C in helium atmosphere and subsequently cut into samples of dimensions 3 x 2 x 0.1 cm. The surface of the samples was polished with emery paper (including No. 4/O) and washed with water, acetone, and methanol. The process of sulfurization was carried out in a modified apparatus of Wagner (2) enabling continuous gravimetric measurements of the reactions kinetics (9) (Fig. 1). The apparatus (Fig. 1) consisted of two electrical furnaces into which a quartz tube containing molten sulfur was inserted. The lower furnace controlled the temperature of the molten sulfur at the bottom of the quartz tube and

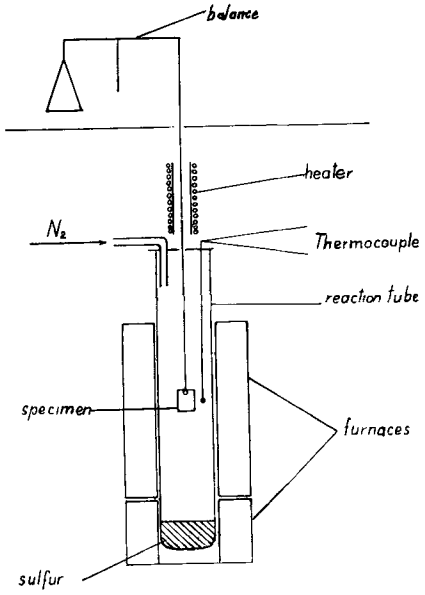

Fig. 1. Apparatus for kinetic measurements of sulfurization of metals in sulfur vapor under atmospheric pressure by the continuous gravimetric method.

the upper furnace controlled the temperature of the sulfur vapor in the reaction chamber. The temperature of sulfur vapor in the reaction tube was controlled automatically by an electronic compensator with an accuracy of ± 3°C. The thermocouple was introduced into the reaction tube on the specimen level at a distance from the tube wall equal to that of the specimen. Purified nitrogen was introduced into the upper, nonheated part of the quartz tube in order to avoid penetration of oxygen into the reaction zone. Traces of sulfur escaping with nitrogen from the reaction tube were directed into a corresponding trap with the aid of an appropriate exhauster. The specimen suspended in the reaction tube was fastened with a nichrome wire to an arm of an analytical balance. The wire was preliminarily oxidized in air at 1000°C for 100 hr to protect it against the attack of sulfur. In order to eliminate the possibility of condensation of sulfur on the wire in the upper, nonheated part of the tube the wire itself was heated to 600°C with an additional heater which maintained its temperature above 450°C. Preliminary investigations have shown that the mass of the wire did not change much during the reaction (the variation amounted to ± 1.0 mg). These variations can be explained by the convection flow of air and sulfur vapor around the wire. The increase in weight of the sulfurized nickel specimens was of the order of 100 mg; the mass of the wire on which the specimen was suspended therefore could be considered to be practically constant. The sulfurization rate could be measured continuously by determining the weight increase of the sample. The investigations were carried out in the temperature range 480°-640°C. This restriction of the temperature range resulted from the necessity of investigating the process at temperatures above the boiling point of sulfur and below the melting point of the eutectic Ni-NiS (645°C). The results of the sulfurization rate measurements are given in Fig. 2 and 3. The figures show the $(\Delta m/q)^2$ values plotted against t where Δm is the weight gain of the sample, q the surface area of the sample, and t the reaction time. Surface area q was assumed to be constant during the sulfurization process and equal to the initial surface area of the metal specimen. It is clear that this surface decreases during the process, but owing to the particular geometric form of specimens used the maximum changes in the surface area of metal did not exceed 2-3% of the initial value in the investigated ranges of temperature and reaction time.

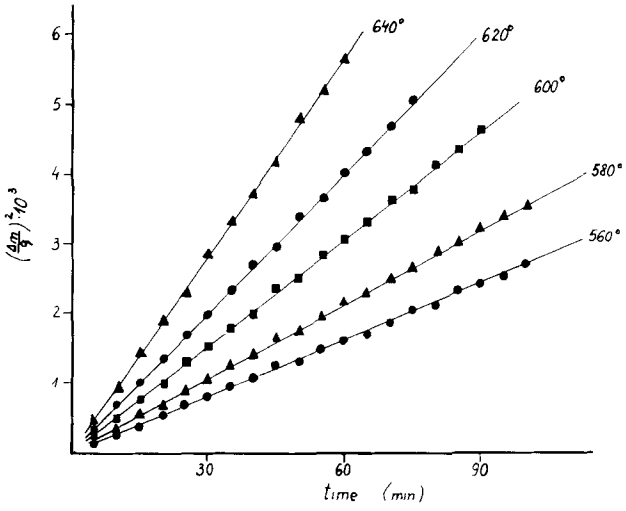

Fig. 3. Weight gain plot for the temperature range 560°-640°C

As can be seen, the experimental data in these coordinates fit a straight line independent of the reaction temperature. This means that in our experimental conditions the scale formation process follows the parabolic rate law:

$$\left(\frac{\Delta m}{q}\right)^2 = k'' \cdot t \qquad [1]$$

where k'' is the parabolic rate constant of the sulfurization process. Measurements of the sulfurization rate could be reproduced with an accuracy of ±5%. Table I contains the parabolic rate constants calculated from our data. The relation between the rate of sulfurization and the reaction temperature is illustrated by Fig. 4 in which log k'' is plotted *vs.* $1/T$. As can be seen from the figure this relation is linear. Activation energy for the sulfurization of nickel as calculated from these figures amounts to **22 kcal.**

9	640	$15.7 \cdot 10^{-7}$

Morphologic investigations have demonstrated that, independent of the reaction temperature, the sulfide scale growing on nickel is composed of two layers. The outer layer, constituting the main part of the scale, is compact, polycrystalline, and exhibits an ordered growth texture (5). The thinner, inner layer is porous and composed of very small crystals of sulfide. In this layer no growth texture could be detected. According to the results of the x-ray analysis both scale layers are built up of the same phase of the reaction product which was identified as the high-temperature form of NiS (stable above 300°C) (10). The mean chemical composition of the scale corresponded to the nonstoichiometric formula $Ni_{0.91-0.92}S$ and was practically independent of the temperature of the reaction.

As proved by detailed microscopic observations the ratio of the thicknesses of the two scale layers depends on the temperature of the sulfurization process and the time of the reaction. The relative mass of the porous inner layer has been found to decrease with increasing reaction temperature. On the other hand, the ratio of thicknesses of both scale layers observed on various samples at the same temperature has been found not to be constant, but to vary with increasing duration of the experiment (the porous inner layer is growing faster). Corresponding photomicrographs of the cross sections through the scale formed at 600°C are shown in Fig. 5. The boundary between the layers of the scale can be seen easily on these micrographs; the growth of the scale is accompanied by a distinct growth of the relative thickness of the porous inner layer. On the micrographs one can also see a thin platinum wire marker wrapped primarily around the metal sample and situated nearly at the boundary between both layers of the scale.

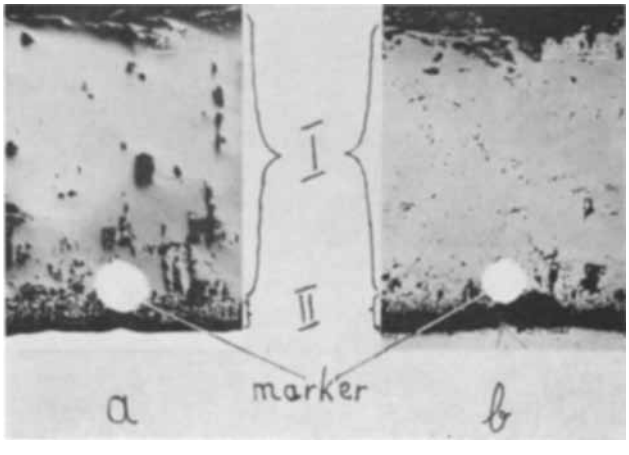

Fig. 5. Cross section through specimens sulfurized at 600°C: a, 1 hr; b, 4 hr. I. The outer layer is compact. The dark regions result from the mechanical process of the metallographic preparation of the scale. II. The inner layer is porous. The platinum wire marker was artificially retouched for greater clarity of the micrograph.

According to the conventional interpretation such position of the marker (11, 12) is taken as proof that the scale grew because of the diffusion of both reactants, nickel and sulfur, migrating simultaneously in two opposite directions. The compact outer layer formed because of the outward diffusion of the metal; the thinner, porous inner layer formed because of the inward diffusion of sulfur.

Recent investigations by two of the present authors (13-15) and Rickert (16) on Cu-S and Ag-S systems have shown however that the position of the marker in the scale does not definitively explain the mechanism of observed double-layer scale formation. Thus, contrary to the results obtained by the marker method, the formation of a double-layer sulfide scale on copper and silver was found not to depend on the diffusion of both reactants in the opposite directions. The scale was formed exclusively because of the outward diffusion of the metal (15, 17). The formation of the porous inner layer is bound up, in this case, with secondary processes occurring within the scale during its growth (17, 18). From the morphologic point of view the structure of the two-layer sulfide scale on nickel is analogous to the structure of the sulfide scale formed on copper and silver. Therefore it can be supposed that the mechanism of both sulfurization processes is also analogous, and the process develops exclusively owing to the outward diffusion of nickel. In order to verify this assumption Brückman, Mrowec, and Werber carried out a new series of measurements (19) using the isotopic method described in previous papers (13, 15). These investigations were carried out at 600°C in an apparatus shown in Fig. 1. Nickel plates of the same dimensions as those in the kinetic investigations were preliminarily sulfurized in a medium not containing the radioactive sulfur isotope until a scale layer was formed thick enough to absorb fully the radiation emitted by the isotope ^{35}S. The radioactive sulfur isotope in the form of a pellet was then introduced into the reaction chamber and the sulfurization was continued. After various periods of time the process was stopped by removing the specimens from the sulfurizing medium and by cooling them in air. The scale layer was separated from the metal and the activity of both scale surfaces was measured with the aid of a G.M. counter.

The inner surface of the scale (which had been in contact with the metal during the sulfurization) was found to be practically inactive independent of the time of the sulfurization carried out in the radioactive medium. The results obtained for different reaction times are given in Table II. It can be seen that the radioactivity at the inner surface does not exceed 2% of the activity measured at the outer surface of the scale. The activity at the inner surface of the scale has been shown not to increase with increasing time of sulfurization in the active

t_1, time of sulfurization in the nonactive medium; t_2, time of sulfurization in the medium containing the radioactive sulfur isotope; A_1, activity of the outer scale surface (which was in contact with the oxidizing agent); and A_2, activity of the inner scale surface (which was in contact with the metal).

medium containing the ^{35}S-isotope. If the inward diffusion of sulfur were to participate in the growth of the scale, an appreciable radioactivity could be expected to appear at the inner scale surface after relatively short periods of sulfurization carried out in the radioactive medium. The results described above can then be considered to prove that the inward diffusion of sulfur does not practically participate in the formation of the sulfide scale on nickel. The insignificant activity revealed at the inner surface of the scale can be explained probably by the inevitable contamination of this surface with traces of the sulfide formed primarily on the outer surface of the scale. The inner surface becomes contaminated during the operations of cutting the fragile scale layer and separating it from the metal.

Discussion

The sulfurization of nickel in the temperature range 480°-640° under atmospheric pressure has been shown to follow the parabolic law. With the aid of the radioactive sulfur isotope it could be found that sulfurization occurs in these conditions exclusively owing to the outward diffusion of the metal. This conclusion concerning the mechanism of nickel sulfurization has been fully confirmed by the recent investigations carried out by Mrowec and Rickert (28) with aid of the well-known Wagner pellet method. On the basis of obtained results it can be stated that the outward diffusion of the metal being the slowest partial process determines the rate of sulfurization of nickel. Taking into account the deviation from the stoichiometric composition in the case of NiS (metal deficit) (10, 20) it can be assumed that the metal, in conformity with the theory given by Wagner (21), diffuses in the form of ions and electrons through the cation vacancies and electron holes in the crystal lattice of NiS.

From the considerations given above it follows that the sulfide scale formed on nickel ought to be compact and composed of a single layer only. It has been found, however, that the scale is built up of two layers of the same reaction product. The formation of the porous inner layer can be explained on the basis of the following assumptions concerning the mechanism of the reaction: during the initial stage of the reaction a thin, compact, and adherent scale layer is formed. Since the scale is formed owing to the outward diffusion of the metal, *i.e.*, at the phase boundary scale/sulfur, the contact between the growing layer of the reaction product and sulfurized metal could be easily cut off if the plastic flow of the scale toward the surface of the metal would not take place. The extent of this plastic flow is limited by the dimensions and the size of the specimen. For geometrical reasons the deformations of the scale are not observed at edges and curved parts of the sample (2, 15, 22, 23). At some critical scale thickness which depends on the temperature of the reaction, on the plasticity of the scale, and on the geometry of the sulfurized metal specimen the decrease in the volume of the metal cannot be further compensated by the plastic flow of the scale; the contact between the scale layer and the metal becomes partially broken and longitudinal cracks are formed. The formation of the cracks begins at the edges of the specimen where the plastic flow of the scale is limited in its extent by geometrical factors.

Before the crack has been formed the gradient of the chemical potential responsible for the outward diffusion of the substrate is distributed in the scale in the following manner.

The chemical potential of the metal attains its highest value at the phase boundary scale/metal. This value is approximately equal to the value calculated for virtual thermodynamic equilibrium between the metal and the scale.

Conditions at the phase boundary scale/sulfur do not deviate very much from the conditions of the thermodynamic equilibrium between NiS and sulfur; in the vicinity of this phase boundary the chemical potential of the metal attains its minimal value.

When the contact between the metal and the scale gets partially broken the chemical potential of the metal in the scale tends to attain at the phase boundary scale/crack a value corresponding to the equilibrium state between sulfur and nickel sulfide. Correspondingly, the sulfur vapor pressure in the void space must increase. At the metal surface the process of secondary NiS formation begins; the pressure of dissociation of the nickel sulfide remaining in contact with the metal is lower than the dissociation pressure of the detached scale consisting of the same phase. The secondary process of the sulfide layer formation at the metal surface results in decreasing the vapor pressure within the crack and in shifting the equilibrium of the system scale/crack: the scale dissociates in order to replace the sulfur deficit in the crack. Nickel ions and electrons formed in this process migrate through the NiS lattice vacancies toward the surface of the scale and recombine there with sulfur. The existing gradient of the sulfur vapor pressure enables the migration of the sulfur molecules toward the surface of the metal or NiS grains adjacent to the metal and participate there in the formation of the porous inner layer of the scale. Owing to this process the contact between the scale and the metal is partially maintained. In accordance with the mechanism described above, formation of the two-layer scale does not involve the diffusion of both reactants through the layer of the reaction product in two opposite directions, but is conditioned by secondary processes which depend on the conditions of the experiment-limited size of sulfurized specimens.

Such a mechanism of the two-layer scale formation was first proposed by Dravnieks and McDonald (24). It was proved experimentally in a recent investigation of Mrowec and Werber who had used the radioactive sulfur isotope in investigations of the mechanism of two-layer scale formation on copper (13, 15, 17) and silver (15, 25).

Rickert, who investigated the mechanism of the sulfurization of copper and silver using a modified Wagner-Tubandt pellet method, came to analogous results (16). An analogous mechanism of the two-layer scale formation on Fe has also been proposed by Birchenall (26).

The rate of sulfurization is considerably influenced by the formation of the porous inner layer. In view of the fact that nickel can be transported only through the volume of the sulfide, the cross section available for diffusion in the porous inner layer is smaller than in the case of the compact outer layer. The fact that the process of sulfurization of nickel can be described in the initial stage of reaction with the parabolic law indicates that, in this case, the porosity of the inner layer is small and remains practically constant in the course of the reaction. This means that the secondary processes mentioned above and resulting in filling the longitudinal cracks between the metal and the compact scale layer occur sufficiently fast to compensate to a considerable degree the loss of the metal. The absolute values of the parabolic rate constants given in Table I must be considered, therefore, regarding the formation of the porous inner layer, to be only approximate values and to characterize the formation of NiS in given conditions only in a rough manner. These values cannot therefore be used for the evaluation of the self-diffusion coefficients with the aid of the well-known Wagner relation (27). Much more reliable results may be obtained with the help of the pellet method (15) enabling the elimination of all secondary processes resulting in the formation of the inner porous layer of the scale (16, 28).

The investigations carried out by Dravnieks (1) have demonstrated that the sulfurization of nickel in molten sulfur can be described also with the parabolic law. The energy of activation calculated for this process from data obtained in the temperature range 324°-444° (when the high-temperature modification of NiS is formed) amounts to 20 kcal. Considering the analogy between processes of sulfurization in molten sulfur and in sulfur vapor and taking into account the equality of energies of activation it can be assumed that the mechanism of this reaction does not depend on the state of aggregation of the oxidizing medium.

On the other hand, investigations carried out by Hauffe and Rahmel (3) and by Pfeiffer (4) proved that the sulfurization of nickel in sulfur vapor at low pressures (<1 mm Hg) and at 600°-630°C can be described with the linear rate law. This shows that it is not the outward diffusion of the metal but the chemical reaction occurring at the phase boundary scale/metal or scale/sulfur which must be considered as a rate-determining step. According to Pfeiffer the transition of nickel in form of ions and electrons through the phase boundary scale/metal is the slowest partial process which determines the rate of sulfurization.

The investigations carried out by the present authors have demonstrated, however, that the sulfurization of nickel carried out at the same temperature but under a higher sulfur vapor pressure can be described with the parabolic rate law. These results indicate that the mechanism of the sulfurization is influenced by the pressure of sulfur vapor.

If the rate of sulfurization were controlled, as postulated by Pfeiffer, by the transition of nickel atoms from the metal in to the scale, this rate should not be dependent on the pressure of sulfur vapor. Such dependence is, however, strongly suggested from the comparison of Hauffe's and Pfeiffer's low-pressure experiments with our high-pressure experiments. According to our opinion it is rather the chemical reaction at the phase boundary scale/sulfur that is the rate-controlling process. Evidently it must be preceded by chemisorption of sulfur at the outer surface at the scale. At low pressures of sulfur and correspondingly low surface concentration of S-atoms or molecules chemical reaction may be slow even in comparison with the solid-state diffusion; at higher pressures of sulfur vapor and higher surface concentrations of adsorbed sulfur the chemical reaction may become faster than the diffusion of nickel.

Summary

The sulfurization of nickel in sulfur vapor under normal pressure at temperatures between 480°-640°C has been found to follow the parabolic law. In the sulfide scale layer formed in these conditions and built up of NiS (with stoichiometric deficiency of the metal) two different sublayers can be clearly distinguished: the outer compact sublayer and the inner porous one.

With the aid of the radioactive tracer method it has been demonstrated that sulfurization can proceed exclusively owing to the outward diffusion of nickel. The porous sublayer, therefore, can be formed exclusively as the result of secondary processes occurring within the layer of the reaction product and consisting of the formation of a "crack" between the scale and the metal in the course of the reaction. This crack becomes filled with fine-crystalline nickel sulfide formed as a result of interaction between the metal and the sulfur supplied to the metal surface by the dissociation of the compact scale layer. Relative thicknesses of these two sublayers depend on the temperature of sulfurization, on the duration of this process, and on the geometry of specimens under investigation.

In view of formation of the porous sublayer, the rate constants, which can be determined experimentally, must be considered to characterize the reaction rate in the Ni-S system in given conditions only in an approximate manner.

Oxidation of Iron-Nickel Alloys

V. Influence of H_2O in Oxidizing Gas

R. T. Foley[1]

General Engineering Laboratory, General Electric Company, Schenectady, New York

ABSTRACT

The oxidation of three iron-nickel alloys nominally 30%, 41%, and 78% Ni was investigated over the temperature range of 600°-1000°C in controlled O_2/N_2 atmospheres with partial pressures of H_2O of 0.32 mm, 5.81 mm, and 26.3 mm. The gross effect of H_2O in the oxidizing atmosphere is to increase the oxidation rate (up to 13-fold for the 30% alloy at 1000°C). In addition, at higher temperatures and higher p_{H_2O}, the rate-determining diffusion process changes from the first half to the second half of the 60-min reaction. The observed rates for the 30% and 41% alloy during the second phase are higher, while the second-phase rate for the 78% alloy is lower. The Arrhenius plots for these alloys are not linear over the 600°-1000°C range. Below 800°C a low apparent activation energy, 30-40 kcal, is calculated, while above 800° a value in the 60 kcal range is obtained.

The results are interpreted in terms of changes in the physical condition of the oxide film as caused by H_2O which enhances surface migration of ions and promotes solid-state reactions.

Several previous reports from this laboratory have dealt with the oxidation of iron-nickel alloys (1-4). Alloys of these two elements have found many engineering applications because of their magnetic properties, their ability to participate in glass-to-metal seals, and their thermal expansion characteristics. Therefore, it is important to know quite completely the behavior of these alloys in various environments such as oxidizing atmospheres at high temperature.

The present investigation is concerned with the oxidation of alloys, nominally 30, 41, and 78% Ni, in the range 600°-1000°C. In an earlier report (3) the kinetics of oxidation in two atmospheres, laboratory air and a 21.7% O_2-78.3% N_2 mixture, was established. An inspection of the rates in the two atmospheres does not allow any good generalization to be made relative to the oxidizing potential of these two atmospheres. The observed reaction rate in the laboratory air was greater, less, or equal to that in the controlled atmosphere depending on the alloy and the reaction temperature. Certain conclusions could be drawn from the rate data however. The first had to do with the precision of the measurements. While two runs made during the same day in laboratory air were quite precise (within 3% of an average value) runs made several weeks or months apart might vary by 60%. The second conclusion was that, while the reaction rate for oxidation in the controlled atmosphere followed the parabolic law quite well, in laboratory air there were real deviations. Moreover, the deviation was not always in the same direction.

[1] Present address: Melpar, Inc., Falls Church, Virginia.

While not the only "contaminant" in the atmosphere it is highly probable that water vapor is the significant one. The k[1] laboratory air is free of exhaust fumes, sulfur oxide gases, and such compounds that have been demonstrated to have an accelerating effect on the corrosion of metals. Thus, to explain these results it was necessary to learn the role of H_2O on the mechanism and kinetics of oxidation.

The role of H_2O in high-temperature oxidation is an extremely important item despite the fact that it has been often overlooked. The development of general principles which would define its part in the oxidation process would be a significant contribution to oxidation theory. Further, knowing the role of H_2O in the oxidation process would help to interpret much of the "practical" oxidation data in the literature in comparison with well-controlled experiments. A final contribution to basic oxidation theory is the over-all objective of this series of papers, the complete description of the kinetics and mechanism of oxidation of iron-nickel alloys.

Experimental

Alloys.—The composition of the alloys, the heat treatment prior to oxidation, and the technique of surface preparation have already been described (2, 3). It has been pointed out that the preferred method of surface preparation involves chemical etching because, following proper etching, electron diffraction patterns of the alloy itself were obtained whereas abrasion and polishing techniques sometimes gave patterns difficult to interpret.

Oxidation studies.—The Chevenard thermobalance employed in this work is capable of operation up to 1050°C. The instrument furnace has a quartz tube liner which allows the introduction of special atmospheres into the oxidation zone. The oxidizing atmospheres flowing at a rate of 263 ml/min consisted of a mixture of 21.7% oxygen and 78.3% nitrogen (by volume) with three different H_2O contents. These atmospheres were: (*a*) the gas mixture without any intentional addition of H_2O with a dewpoint of −20°F [vapor pressure H_2O = 0.32 mm (5)]; (*b*) the gas mixture to which H_2O was added by passing the gas stream through a fritted glass plug and water held at about 0°C. The measured dewpoint of this gas was +38°F [vapor pressure H_2O = 5.81 mm (5)]; (*c*) the gas mixture to which H_2O was added by passing the gas stream through a fritted glass plug and water held at room temperature. The measured dewpoint of this gas was +80°F [vapor pressure H_2O = 26.3 mm (5)].

In each case the dewpoint of the gas was measured with a General Electric Dew Point potentiometer with a precision of ±3°F. At least duplicate experiments were run at 600°, 700°, 800°, 900°, and 1000°C in each atmosphere, each run being of 60 min duration.

Treatment of data.—The oxidation rate for these iron-nickel alloys may be represented by a parabolic rate equation.

$$(\Delta m)^2 = b + k_p t \qquad [1]$$

where Δm is gain in weight in g/cm² of a sample oxidized for t seconds; k_p is the parabolic rate constant ($g^2\ cm^{-4}\ sec^{-1}$); b is a constant (g^2cm^{-4}). The data for certain experiments were represented over the entire run by a linear plot, Eq. [1]. In other cases, notably those at higher temperatures and higher H_2O vapor pressure, the plot was not linear over the whole 60 min duration. These data could be represented in either of two ways. The first would be by using two parabolic equations, one for the early part of the run and a second for the later part of the run. Alternatively the data could be represented over the entire time interval by using an equation wherein the (Δm) exponent fell somewhere between 1.5 and 2.5. On theoretical grounds the use of two parabolic equations for separate time intervals seems more justified.

The temperature dependence for reactions of this type is usually described by an Arrhenius type equation:

$$k_p = Ae^{\frac{-\Delta E^*}{RT}} \qquad [2]$$

in which ΔE^* is termed the apparent energy of activation and A the frequency factor. The exact significance of ΔE^* has not been satisfactorily established insofar as high-temperature oxidation is concerned and can only be considered a guide to the type of oxidation process. Some of the difficulties in the interpretation of ΔE^* have been discussed (3). Further, where the reaction product film is composed of more than one species it would be suspected that ΔE^* would not be constant over an extended temperature range. This was the situation encountered in this study.

Electron diffraction examination of oxide films.—Electron diffraction analyses by the reflection technique were made of the oxide films with a General Electric electron diffraction instrument. This instrument is equipped with a furnace attachment enabling one to study the oxidation products at the temperature of reaction. The detailed description and interpretation of the patterns obtained in these special atmospheres have been reported (4).

Results

The parabolic rate constants, k_p in Eq. [1], for the 30% Ni alloy are listed in Table I. Only average values for the several runs are given, the precision of these data having been discussed (3). The values given for the $p_{H_2O} = 0.32$ mm run were taken from this earlier paper. These data are plotted in Fig. 1. At 600° there is a moderate increase in rate while at 700° the rate constant is insensitive to H_2O additions to the gas stream; at 800° the rate doubles over the p_{H_2O} range investigated here; at 900° and 1000° the rate increases by a factor of 5 and 14, respectively, the "initial" rate being compared in the last two cases. The influence of water vapor in the oxidizing gas has a second effect at 900° and 1000°. At these temperatures it is necessary to use two parabolic equations to represent the experimental data. The first equation holds for the initial 30 min, the second (solid circles on Fig. 1) for the 30-60 min part of the reaction. This in-

Table I. Parabolic rate constants for 30% Ni alloy

t °C	k_p (g² cm⁻⁴ sec⁻¹) p_{H_2O} = 0.32 mm	p_{H_2O} = 5.81 mm	p_{H_2O} = 26.3 mm
600	1.27×10^{-12}	1.74×10^{-12}	2.14×10^{-12}
700	1.46×10^{-11}	1.65×10^{-11}	1.50×10^{-11}
800	8.5×10^{-11}	1.24×10^{-10}	1.85×10^{-10}
900	5.2×10^{-10}	(a) 1.42×10^{-9} (0-30 min)	2.73×10^{-9} (0-30 min)
		(b) 1.75×10^{-9} (30-60 min)	4.28×10^{-9} (30-60 min)
1000	3.3×10^{-9}	(a) 1.10×10^{-8} (0-36 min)	4.48×10^{-8} (0-30 min)
		(b) 1.53×10^{-8} (36-60 min)	10.8×10^{-8} (30-60 min)

crease in rate for the second part of the reaction itself increases with p_{H_2O}. At p_{H_2O} = 5.81 the second parabolic reaction rate constant increases by about 30% over the first, while at p_{H_2O} = 26.3 mm the rate during the second half of the reaction approximately doubles.

The temperature dependence of the reaction is given by the Eq. [2] type of plot in Fig. 2.[2] The curves labeled A and D, B and E, and C and F represent data at 0.32 mm, 5.81 mm, and 26.3 mm vapor pressure H_2O, respectively. The apparent activation energies derived from the slopes of these lines are:

A = 41.2 kcal
B = 41.2
C = 41.5

D = 55.2
E = 60.6
F = 73.7

It is very obvious that a single linear plot does not represent the data over the entire temperature range. Above 800° the slope increases to yield activation energies considerably higher than the "normal" 41,200 cal.

The parabolic rate constants representing the

[2] Note that in Fig. 2, 4, and 6, decreasing rate constants are plotted in the vertical direction.

oxidation kinetics of the 41% alloy in the three different atmospheres are listed in Table II and plotted in Fig. 3. In the oxidation of the 41% Ni alloy the effect of H_2O is evidenced at 600° and 700° with increased rates; at 800° there is practically no effect, and at 900° and 1000° the rates are increased approximately threefold over the p_{H_2O} range studied. The necessity to represent the data by two

Table II. Parabolic rate constants for 41% Ni alloy

t °C	k_p (g² cm⁻⁴ sec⁻¹) p_{H_2O} = 0.32 mm	p_{H_2O} = 5.81 mm	p_{H_2O} = 26.3 mm
600	1.27×10^{-12}	2.20×10^{-12}	2.88×10^{-12}
700	9.8×10^{-12}	1.37×10^{-11}	
800	9.3×10^{-11}*	8.33×10^{-11}	1.18×10^{-10}
900	4.05×10^{-10}	8.92×10^{-10}	(a) 1.10×10^{-9} (0-30 min)
			(b) 1.58×10^{-9} (30-60 min)
1000	3.51×10^{-9}	(a) 6.90×10^{-9} (0-30 min)	(a) 1.20×10^{-8} (0-30 min)
		(b) 8.00×10^{-9} (30-60 min)	(b) 1.71×10^{-8} (30-60 min)

* Corrected from typographic error in (3).

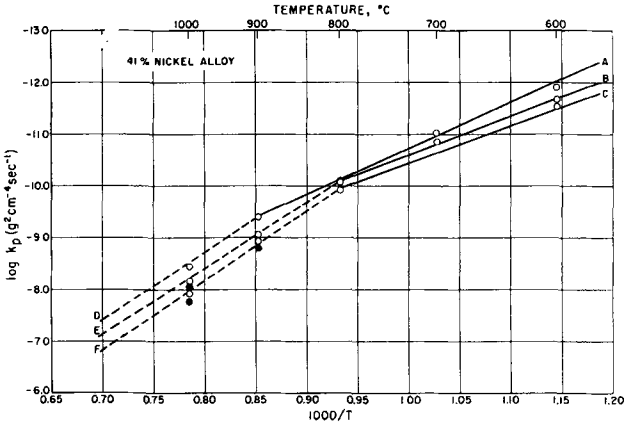

Fig. 4. Temperature dependence of oxidation rate for 41% alloy; A, D, p_{H_2O} = 0.32 mm; B, E, p_{H_2O} = 5.81 mm; C, F, p_{H_2O} = 26.3 mm.

parabolic equations rather than one is observed at 900° in the 26.3 mm p_{H_2O} atmosphere and at 1000° in both the 5.81 mm and the 26.3 mm p_{H_2O} atmospheres. The rate during the second phase of the reaction increases by about 43% over the first half of the reaction.

The temperature dependence of the reaction is given in Fig. 4. Again, the Arrhenius plot is not linear, but deviates because of higher reaction rates above 800°. In each of the three atmospheres, a low apparent activation energy is observed in the 600°-800° range and a high value in the 800°-1000° range. The activation energies corresponding to the slopes are as follows:

A	40.8 kcal
B	33.9
C	32.7
D	59.3
E	58.3
F	61.3

The parabolic rate constants which describe the oxidation behavior of the 78% alloy in the three

	(b) 5.5×10^{-10} (30-60 min)		1.16×10^{-9} (30-60 min)

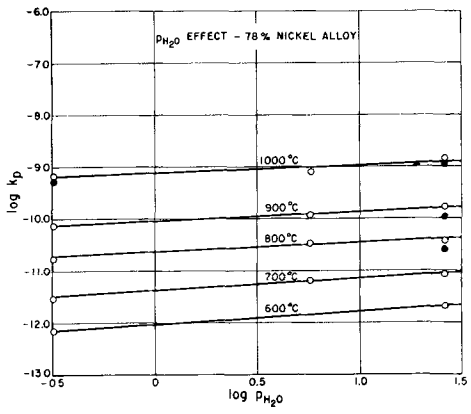

Fig. 5. Oxidation rate of 78% alloy as a function of vapor pressure H_2O. O, 0-30 min kinetics; •, 30-60 min kinetics.

atmospheres are given in Table III and the log k_p — log p_{H_2O} plot in Fig. 5. Here the over-all effect of increased H_2O vapor pressure is one of increased rate. The effect is not as pronounced as is the case with the 30% and 41% alloy, but rather a consistent doubling or tripling over the whole p_{H_2O} range. The other effect observed was seen in the high p_{H_2O} run and in the temperature range of 800°-1000°. Under these experimental conditions the oxidation kinetics is represented by two parabolic rate constants, the second k_p less than the first.

Figure 6 gives the temperature dependence of the rate. The apparent activation energies corresponding to the slopes are as follows:

A	= 35.5
B	= 33.6
C	= 33.4
D	= 66.0
E	= 60.4
F	= 66.0

Discussion

Experimental observations indicate that certain broad conclusions may be drawn as to the influence of moisture in the oxidizing gas on the oxidation kinetics of these alloys. The most conspicuous effect

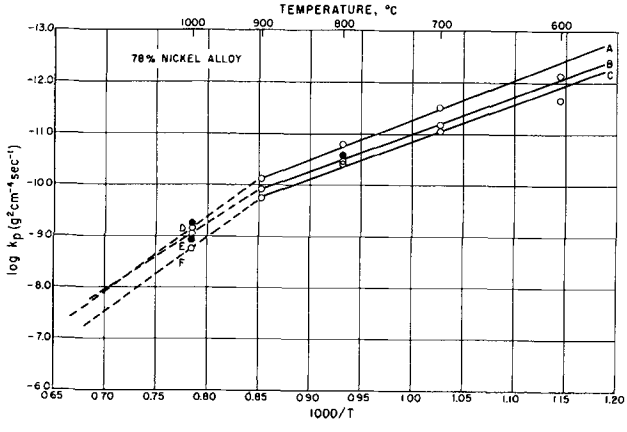

Fig. 6. Temperature dependence of oxidation rate for 78% alloy; A, D, p_{H_2O} = 0.32 mm; B, E, p_{H_2O} = 5.81 mm; C, F, p_{H_2O} = 26.3 mm.

is to increase the rate as expressed by the parabolic rate constants. This holds with few exceptions (700°C with the 30% alloy, 800° with the 41% alloy). With respect to the 30% alloy this increase is considerable, over 13-fold over the p_{H_2O} range considered. The second effect is demonstrated at the higher temperatures and higher partial pressure of H_2O. Under these conditions the oxidation reaction over the 60-min duration must be represented by two parabolic equations rather than a single one. The inference is that different processes operate during different phases of the reaction. In the case of the 30% and 41% alloys the reaction rate accelerates during the second half of the reaction, whereas with the 78% alloy the parabolic rate constant is less. For each of the three systems it is quite obvious that the conventional "Arrhenius" plot is not linear over the entire 600°-1000°C range. This nonlinearity is emphasized with the increase in p_{H_2O}. Recognizing this nonlinearity over the whole temperature range it is still possible to calculate two values of apparent activation energy for each alloy. One value would hold below 800°, and this would be a low activation energy process, 30-40 kcal. A second would hold for experiments above 800°, a high activation energy, of the order of 60 kcal. A final effect of moisture in the oxidizing gas, namely, the production of an enlarged lattice parameter in the oxide product, has already been discussed in connection with the electron diffraction examination (4) of the films formed under these experimental conditions. A major reaction product on alloys containing 30% and 41% Ni is a spinel of the $Ni_xFe_{(3-x)}O_4$ type in which the Ni and Fe content can vary with distance from the metal-oxide interface. $NiFe_2O_4$ has an a_o value of 8.33Å; and usually the a_o value for the spinel formed on this type of alloy falls in the range 8.33-8.40 depending on the Ni content (6). The spinel formed in the higher p_{H_2O} atmospheres had observed a_o values of 8.60Å and 8.58Å for the 30% and 41% alloy, respectively. The structure of the oxide film formed on the 78% alloy apparently was not influenced by H_2O vapor in the oxidizing gas within the limitations of the electron diffraction technique.

Thus the influence of moisture is revealed in both reaction kinetics and oxide film structure with the 30% and 41% alloy and in reaction kinetics with the 78% alloy.

With few exceptions, these occurring at 600° and 700°C, the oxidation rates observed previously in laboratory air (3) can be explained on the basis that the oxidizing atmosphere contained moisture equivalent to a few millimeter partial pressure which varied from day to day. The few exceptions to this semiquantitative explanation are rates that were lower in laboratory air than in the controlled atmosphere. These deviations at the lower temperatures fall almost within experimental error and, as discussed below, the influence of moisture should be more pronounced at the higher temperatures. The present results also explain the need to use two parabolic plots to represent data for the 30% alloy and the 78% alloy in laboratory air at 1000°, accounting for the higher later phase kinetics of the 30% and the lower later phase kinetics of the 78% alloy.

In attempting to explain the observed results the first consideration should be one of the thermodynamics involved. From free energy calculations on Fe-Ni alloys of these compositions it would be concluded that Fe would react with H_2O vapor at these temperatures while Ni would not. Experimentally this appears valid as discussed by Kubaschewski and von Goldbeck (7) who found the Fe-Ni system to be almost ideal. Thus at the start it would be expected that the reactions that take place by moisture additions to the oxidizing atmosphere would involve mainly Fe and the oxides of Fe rather than Ni and NiO. This was confirmed by the only structural changes observed. The 78% alloy contained 3.8% Mo which would be expected to react with H_2O and lead to a higher rate.

Considering the reaction product formed on the 30% and 41% Ni alloy, the interpretation of the enlarged lattice parameter constitutes a critical point as the rate-determining step for oxidation of these alloys is most likely the diffusion of cations through a spinel of variable nickel content. The possibility of this parameter being due to the incorporation of Mn in the lattice was discussed (4), and it was pointed out that Mn in the amount present in our alloys had been observed to have a profound effect on the oxidation rate of heater alloys by Gulbransen *et al.* (8, 9) and actually detected by Yearian and co-workers on chrome steels (10). However, the possibility also exists that the lattice parameter is a measure of the physical condition of the film. Spinels with lattice parameters in the 8.5-8.7Å range were observed by Hickman and Gulbransen (11) in their early oxidation studies, for example, a spinel of a_o = 8.66Å was observed on an 18-8 stainless steel after oxidation at 700°C. These investigators considered this high value as being associated with a stressed condition which in time could lead to cracking. Pande also observed oxide lattice parameters during electron diffraction studies that were 0.60% higher than x-ray measurements and discusses these in terms of the particle size of crystals (12). That water vapor can have a profound effect on nucleation, lateral growth, and morphology of oxide films was clearly demonstrated by Gulbransen and Copan (13) in experiments carried out with pure Fe at 450°C for 48 hr. Fine oxide whiskers grew in a dry O_2 atmosphere (dewpoint −79°C) as contrasted with blades grown in a 10% H_2O-90% argon atmosphere. Their experiments led to the conclusion that H_2O facilitates nucleation, promotes surface diffusion, and expands reaction sites. This would imply that the general effect of moisture in the absence of specific reactions (*e.g.*, hydroxide formation) would be to increase reaction rate, and this would explain the over-all general effect. Thus, while there may exist compositional variation in oxide films formed in atmospheres of varying dewpoint which have gone undetected it seems more logical that the kinetic changes observed reflect changes in the physical condition of the films.

The morphology of the oxide films which would normally be grown on the 30% and 41% alloys would be governed to a large extent by solid-state reactions that would occur as the component oxides attempt to achieve equilibrium structures as established by Brabers and Birchenall (14). These solid-state reactions would be enhanced by the presence of moisture. Reported observations on the kinetics of such reactions and the influence of moisture on the kinetics leads one to conclude that such solid-state reactions must be given consideration in establishing the mechanism of oxidation of binary or ternary alloys that contain more than one oxidizable metal. The reaction between NiO and Fe_2O_3 to form nickel ferrite commences at about 650°C and is rapid above 800°C (15, 16). For example, at 900°C the reaction is over 70% completed in 30 min as shown by Turnbull (16) in his review and interpretation of the kinetics of this reaction. Fe_2O_3 is observed on the surface layers of oxides formed on the 30% and 41% alloys in low dewpoint atmospheres but not in the higher dewpoint runs, suggesting that under the latter conditions cation diffusion occurred to establish a spinel with lower nickel content (less protective). Water vapor has the effect of promoting such solid-state reactions. Wickert and Wiehr (17) observed that water vapor lowered the temperature at which solid-state reactions would occur between CuO and Fe_3O_4 and increased the rate of reaction as compared to that in neutral atmosphere. Bénard (18) concludes from sintering experiments with oxides that in certain situations water vapor increases rate of reaction by promoting surface diffusion of ions. Certainly the possibility of these solid-state reactions occurring exists, and certainly such reactions would alter the morphology of the oxide films, but with the available experimental evidence one can only speculate as to whether these changes would account for the increased rate observed in the three systems.

The nonlinearity of the Arrhenius plot may be explained on the basis of different rate-determining mechanisms holding in the two temperature ranges. It seems reasonable that any change in the rate-determining mechanism would be gradual rather than abrupt, so any discussion of "low temperature activation energy" and "high temperature activation energy" is quite arbitrary. The activation energy value derived for the 30% and 41% alloys in the 600°-800° range is interpreted as representing diffusion through a spinel structure varying in composition from $NiFe_2O_4$ (near the metal-oxide interface) to Fe_3O_4.

This diffusion process is considered to involve an activation energy of about 41.5 kcal, and lower values are interpreted in terms of this diffusion process being enhanced by surface migration as suggested by Bénard. Considering the way in which these activation energies are established, more precise interpretation would be questionable. In the 800°-1000° range the rate is accelerated, but the slope of the Arrhenius plots would indicate a high activation energy, characteristic of some other process. The higher activation energy was common with all three alloys and would support the hypothesis which explained the moisture influence in terms of the physical condition of the film.

There is evidence that would lead one to expect that, if one dealt with an oxidation involving a single diffusion process, and further, if the oxide film remained compact and continuous during the oxidation run, then a linear Arrhenius plot would indeed be observed. Obviously such conditions were not achieved in these experiments, but were by Paidassi (19) who obtained linear temperature dependence plots for the oxidation of iron over the range of 700°-1250°C. His micrographs show a uniform, compact, and continuous oxide film, and his kinetics indicate diffusion through an FeO layer. On the other hand if there was no change in reaction mechanism, but there was change in the physical condition of the film, a nonlinear Arrhenius plot would result. Thus the temperature dependence plots of Gulbransen and Andrew (20) on the oxidation of Ni over the 750°-1050°C range yielded a heat of activation of 41,200 cal below 900°C and 68,300 cal above, with the explanation probably lying in cracking and change in the physical condition of the film. Studies on film structure similar to those conducted by Brabers and Birchenall (14) would be very illuminating here.

Several investigators have employed models which utilize the defect structure of the oxide as altered by the moisture in the oxidizing atmosphere (21). Presumably the decomposition of water vapor at these elevated temperatures would supply hydrogen or oxygen to alter the concentration of defects. It would not appear that such models would apply in view of our experimental conditions. The percentage decomposition of H_2O is low and would alter in a negligible way the total oxidizing potential of the atmosphere.

Manuscript received Sept. 5, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

Oxidation of Refractory Metals as a Function of Pressure, Temperature, and Time: Tungsten in Oxygen

J. N. Ong, Jr.

Research Laboratories, Aeronutronic, A Division of Ford Motor Company, Newport Beach, California

ABSTRACT

By regarding the kinetics of oxidation of tungsten as occurring by the consecutive reactions: $W + O_2 \rightarrow WO_2$; $WO_2 + \frac{1}{2}O_2 \rightarrow WO_{3(s)}$; $WO_{3(s)} \rightarrow 1/n(WO_3)_{n(vap)}$ and by expressing the rate in terms of conventional chemical kinetic quantities, it is shown that the results of three investigations may be correlated in the temperature range 500°-1300°C and pressure range 0.0013-20.8 atm of oxygen. A good approximate form for the rate of attack of metallic tungsten above 700°C is shown to have the form: Rate $= d(m/A)/dt = 5.89 \times 10^6 \exp(-12{,}170/T)\ P^{1/2}$ mg_W/cm^2 hr, where T is expressed in °K and P in atmospheres of oxygen.

Although there has been much work done on the kinetics of oxidation of tungsten as summarized recently (1), the basic understanding of the mechanism of oxidation has not as yet yielded to analysis. This is due in part to the complexity of the chemistry and in part to the fact that an entirely adequate theory for oxidation of metal oxygen systems has not heretofore been available. It has been fairly well established (2) that tungsten in the presence of oxygen reacts first to form a suboxide, which for present purposes may be assumed to be WO_2, according to: $W + O_2 \rightarrow WO_2$, followed by subsequent reaction to form WO_3: $WO_2 + \frac{1}{2}O_2 \rightarrow WO_{3(s)}$. The WO_3 then sublimes according to: $WO_3 \rightarrow 1/n\ (WO_3)_{n(vap)}$. There are minor changes in the stoichiometry of these oxides with temperature and pressure, but these may be considered incidental to the kinetic problem.

It is the purpose of the present paper to demonstrate the utility of a method of treatment of reacting metal-oxygen systems recently developed (3). The method will (*a*) correlate the results of the three principal experimental investigations (2, 4-6), (*b*) introduce the effect of pressure on the rate of oxidation, and (*c*) present the results in a form having practical utility.

Development of Rate Equations

It has been shown (3) that all metal-oxygen reactions are first order complex chain reactions whose rate is described by an equation of the form:

$$\text{Rate} = \frac{d\,m_{O_b}/A}{dt} = k_r C_i = k_r f(P) \qquad [1]$$

where m_{O_b}/A (g/cm²) is the weight change per unit area of a specimen caused by reaction with b atoms of oxygen, k_r is the reaction rate constant, C_i is the concentration of intermediate species controlling the rate of reaction, and $f(P)$ is a complex function of pressure relating pressure to the intermediate species concentration.

When the reaction rate is controlled at a phase boundary Eq. [1] can be written:

$$\text{Rate} = k_s C_{is} \qquad [2]$$

where C_{is} is the concentration of intermediate species at the phase boundary (g/cm²) and k_s is the specific reaction rate constant (sec^{-1}). This has been interpreted (7) as

$$k_s = \frac{kT}{h} \exp(\Delta S^{+}/R) \exp(-\Delta H^{+}/RT) \qquad [3]$$

where k is Boltzmann's constant (ergs/°K), T is absolute temperature (°K), h is Planck's constant (erg-sec), ΔS^{+} the entropy of activation (cal/g mole °K) and ΔH^{+} the enthalpy of activation (cal/g mole).

When the reaction is controlled by diffusion through an oxide phase, the rate equation may be written

$$\frac{d\,m_{O_b}/A}{dt} = \left\{\frac{D\Delta C \rho_{ox} M_{O_b/Me_aO_b}}{2}\right\}^{1/2} \frac{1}{t^{1/2}} \qquad [4]$$

where $\Delta C = C_{i\ o-g} - C_{i\ o-m}$, which is the concentration difference of diffusing species at the oxide-oxygen and oxide-metal interfaces, respectively, (g/cm³), ρ_{ox} is the density of the oxide film (g/cm³), D is the diffusion coefficient (cm²/sec), and M_{O_b/Me_aO_b} is

$$\frac{\text{weight of oxygen consumed } (b/2\ O_2)}{\text{weight of oxide formed } (Me_aO_b)}. \quad (g/g)$$

The diffusion coefficient may be written in its temperature dependent form:

$$D = D_o \exp\left(\frac{-\Delta H^{+}_d}{RT}\right) \qquad [5]$$

where D_o is the diffusion constant and $\Delta H^{\ddagger}_d$ is the enthalpy of activation of a diffusion process.

D_o may be further interpreted by the reaction rate theory of Eyring as (8)

$$D_o = \alpha d^2 q \frac{kT}{h} \cdot \exp\left(\Delta S^{\ddagger}_d / R\right) \qquad [6]$$

where α is a geometrical factor related to the arrangement of sites into which a diffusing species may jump, d is the lattice parameter, q is the number of equivalent diffusion paths and $\Delta S^{\ddagger}_d$ is the entropy of activation of the diffusion step.

For purposes of further analysis the following assumptions are made: (*A*) For every chemical product formed an equation may be written for its rate of formation. (*B*) The rate of formation of the inner oxide (WO_2) is diffusion controlled and Eq. [4] applies. (*C*) The rate of formation of the outer oxide (WO_3) is phase boundary controlled and is given by Eq. [2]. (*D*) The rate of volatilization of (WO_3) is also phase boundary controlled. (*E*) The rate of consumption of tungsten metal is unaffected by the volatility rate of WO_3. (*F*) The functions relating concentration to pressure are of the form of the Langmuir isotherm involving dissociation of oxygen molecules to atoms

$$C_{is} = C^{\circ}_{is}\left\{\frac{\exp(\Delta S_{is}/R)\exp(-\Delta H_{is}/RT)\,P^{1/2}}{1+\exp(\Delta S_{is}/R)\exp(-\Delta H_{is}/RT)\,P^{1/2}}\right\} \qquad [7]$$

where ΔS_{is} and ΔH_{is} are the entropy and enthalpy of adsorption of intermediate species at the phase boundary, and C°_{is} is a conversion factor relating mole fraction of adsorbed species to concentration of adsorbed species (g/cm²) and

$$\Delta C = \Delta C^{\circ}_d\left\{\frac{\exp(\Delta S_d/R)\exp(-\Delta H_d/RT)\,P^{1/2}}{1+\exp(\Delta S_d/R)\exp(-\Delta H_d/RT)\,P^{1/2}}\right\} \qquad [8]$$

where ΔS_d, ΔH_d, and ΔC°_d(g/cm³) are the corresponding quantities of Eq. [7] pertaining to the appropriate intermediate species in the diffusion process. Tentative evidence for this type of pressure dependency may be inferred from the low pressure work of Speiser and St. Pierre (9).

A great source of confusion, resulting in considerable misinterpretation of kinetic data, has arisen from failure to pay careful attention to the meaning of defined rate equations.

The defining equation is in terms of oxygen consumption, Eq. [1]. However, of greater importance in metal oxygen reactions is the rate of metal consumption, given by

$$-\frac{d(m_{Me}/A)}{dt} = \frac{1}{M_{O_b/Me_a}}\frac{d(m_{O_b}/A)}{dt} \text{ (g/cm}^2\text{ sec)} \qquad [9]$$

where M_{O_b/Me_a} is

$$\frac{\text{weight of oxygen consumed } (b/2\ O_2)}{\text{weight of metal reacted } (aMe)} \text{ (g/g)}$$

or

$$\frac{-dX_{Me}}{dt} = \frac{1}{M_{O_b/Me_a}\rho_{Me}}\frac{d(m_{O_b}/A)}{dt} \text{ (cm/sec)} \qquad [10]$$

where X_{Me} and ρ_{Me} are, respectively, the thickness and density of the metal.

Where volatile species are formed during reaction, it is necessary that care be taken that thickness or weight change measurements are properly related to oxygen or metal consumption.

The derivations which follow will be on the basis of oxygen consumption and will be modified to other convenient forms as necessary.

The reaction of tungsten with oxygen has been identified as a consecutive reaction and analyzed by Loriers (10) and Webb, Norton, and Wagner (6).

Using the present formulation, it is found that the rate due to the formation of the first oxide (WO_2) is given by:

$$\frac{d(m_{O_2}/A)}{dt} = \left\{\frac{D_b\,\Delta C_b\,\rho_b\,M_{O_2/WO_2}}{2}\right\}^{1/2}\frac{1}{t^{1/2}} - \frac{1}{M_{O_3/O_2}}k_{s_c}C_{is_c} \qquad [11]$$

where m_{O_2} is weight change due to formation of WO_2 and subscripts b and c pertain to the quantities governing the formation rate of the oxides WO_2 and WO_3, respectively.

$\frac{d(m_{O_2}/A)}{dt}$ becomes zero at

$$t_m = \frac{D_b\,\Delta C_b\,\rho_b\,(M_{O_2/WO_2})\,(M_{O_3/O_2})^2}{2k^2_{s_c}C^2_{is_c}} \qquad [12]$$

The total amount of WO_2 formed can be found by $\int_o^{t_m}\frac{d(m_{O_2}/A)}{dt}$ which has the value:

$$(\Delta m_{O_2}/A)_{max} = \frac{D_b\,\Delta C_b\,\rho_b}{2k_{s_c}C_{is_c}}\cdot M_{O_2/WO_2}M_{O_3/O_2} \qquad [13]$$

The rate of formation of the second oxide, WO_3, is given by

$$\frac{d(m_{O_3}/A)}{dt} = k_{s_c}C_{is_c} \qquad [14]$$

where m_{O_3} is weight gain due to the formation of WO_3.

In graphical form Eq. [11] and [14] appear as represented in Fig. 1. The two processes combined are designated as "sum" in the figure and the arrow designates the value of t_m and $(\Delta m_{O_2}/A)_{max}$.

When the volatility rate becomes appreciable, an appropriate term must be subtracted from the sum of Eq. [11] and [14]. This rate may be represented by

$$\frac{-d(m_{WO_3}/A)}{dt} = k_{s_v}C_{is_v} \qquad [15]$$

where m_{WO_3} is the weight change due to WO_3 volatilization. The subscript v pertains to the quantities governing the weight loss due to the volatilization of WO_3. As illustrated in Fig. 2, the sum of the three terms takes different forms depending on the magnitude of the volatility rate.

A third type of weight change curve is encountered under the conditions where the molar evaporation rate of WO_3 exceeds the molar consumption rate of metal. Under these conditions an experimental weight change measurement represents the sum of oxygen pickup due to the formation of WO_2 and the

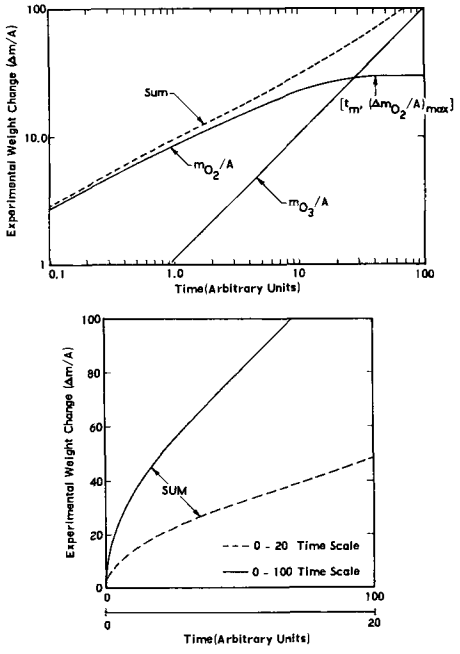

Fig. 1. Experimental weight change due to WO_2 and WO_3 formation, Eq. [11] and [14].

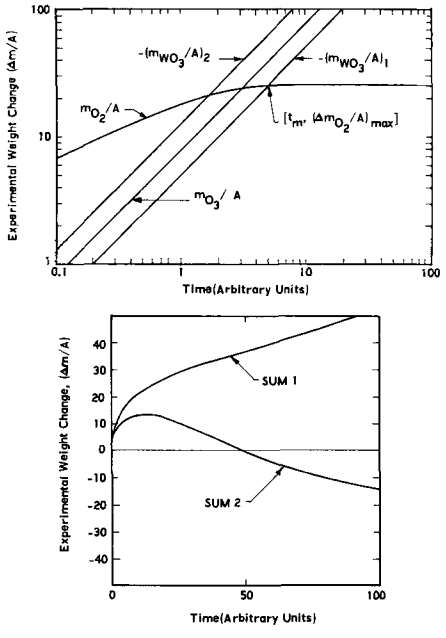

Fig. 2. Experimental weight change due to WO_2 and WO_3 formation and WO_3 volatilization, Eq. [11], [14], and [15].

metal loss due to volatilization of W in the form of $1/n(WO_3)_n$ as shown in Fig. 3. All three types of curves were obtained by Gulbransen in his extensive study (4, 5).

Analysis of Data

Equations [12] and [13] may be solved simultaneously to give the following equations:

$$k_{s_c} C_{t_{s_c}} = \frac{(\Delta m_{O_2}/A)_{max}}{t_m} \cdot M_{O_3/O_2} \qquad [16]$$

$$(D_b \Delta C_b \rho_b M_{O_2/WO_2}) = \frac{(\Delta m_{O_2}/A)^2_{max}}{t_m} \cdot \frac{2}{M_{O_3/O_2}} \qquad [17]$$

An overlay of experimental points was made and compared with a master plot of Eq. [11] and [14].

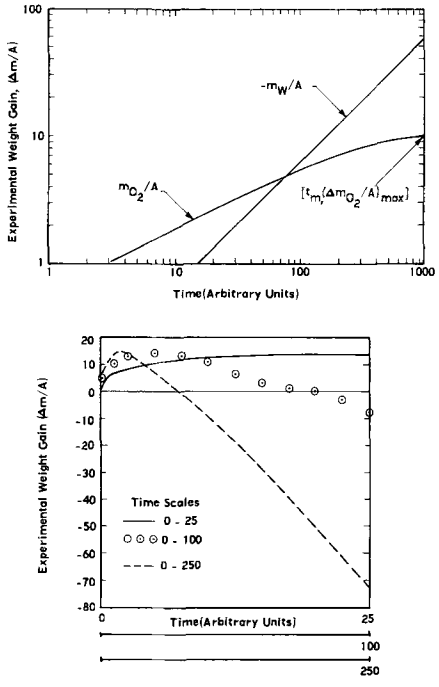

Fig. 3. Experimental weight change due to WO_2 formation and W metal loss, Eq. [11] and [20].

From this, values of t_m and $(\Delta m_{O_2}/A)_{max}$ could be obtained. From Eq. [16] and [17], values of $k_s C_{t_s}$ and $D_b \Delta C_b \rho_b M_{O_2/WO_2}$ could be directly calculated. The logarithm of these values were then plotted *vs.* $1/T$ to determine activation energies and *vs.* log P to determine pressure sensitivities. The results are presented in Fig. 4 through 7. From these plots it was determined that Eq. [7] and [8] represented reasonable pressure functions for both the diffusion controlled and phase boundary controlled reactions. Overheating is obtained at higher rates which accounts for the deviations of experimental points from the theoretical curves.

The simplest form of the equations governing the oxidation rate of tungsten is also the most directly practical, namely, by expressing it in terms of metal consumption.

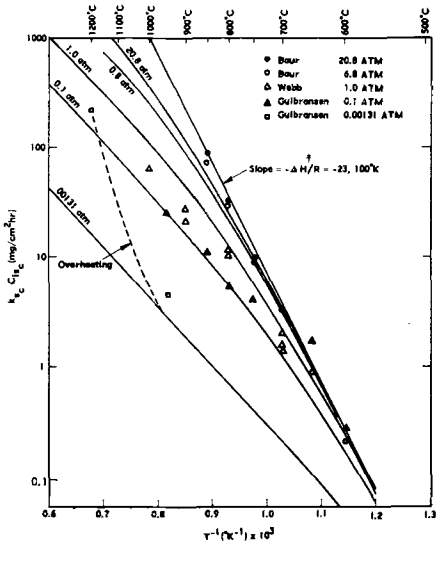

Fig. 4. Arrhenius plot of $k_{s_c} C_{t_{s_c}}$ isobars. Deviations from slope of $-\Delta H^{\ddagger}/R$ indicate pressure sensitivity.

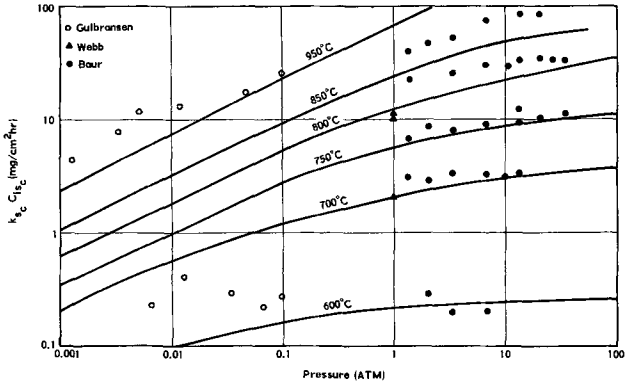

Fig. 5. Plot of $k_{s_c} C_{i_{s_c}}$ isotherms vs. pressure showing pressure dependency at high temperatures and low pressures.

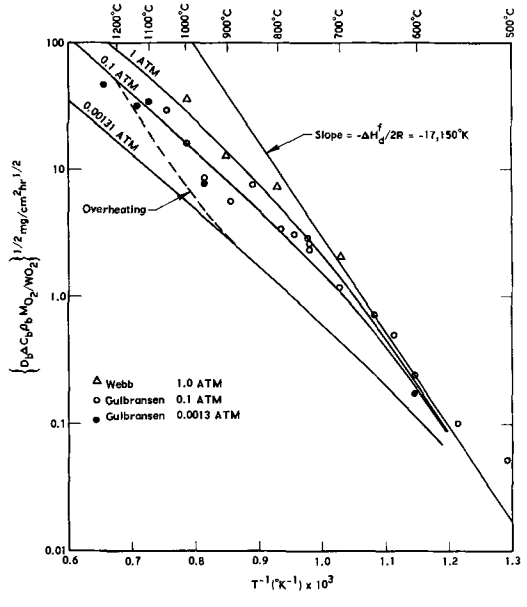

Fig. 6. Arrhenius plot of $\{D_b\ \Delta C_b\ \rho_b M_{O_2/WO_2}\}^{1/2}$ isobars. Deviations from slope of $-\Delta H^{\ddagger}/2R$ indicate pressure sensitivity.

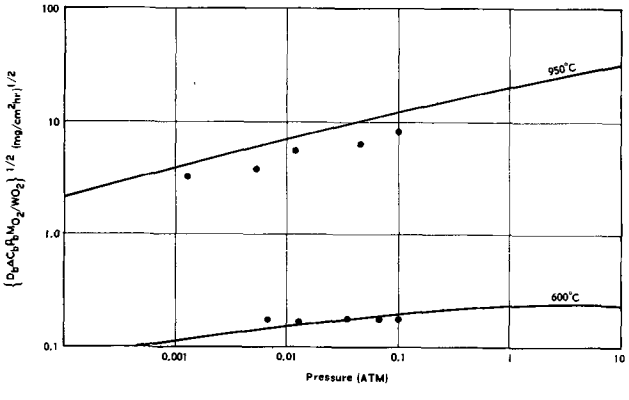

Fig. 7. Plot of $\{D_b\ \Delta C_b\ \rho_b M_{O_2/WO_2}\}^{1/2}$ isotherms vs. pressure for data of Gulbransen showing pressure dependency at high temperatures and low pressures.

The rate of metal loss due to the formation of WO_2 is, from Eq. [11] and [9]

$$\frac{-d(m_w/A)}{dt} = \frac{1}{M_{O_2/W}} \frac{d(m_{O_2}/A)}{dt}$$

$$= \frac{1}{M_{O_2/W}} \left[\left\{ \frac{D_b\ \Delta C_b\ \rho_b\ M_{O_2/WO_2}}{2} \right\}^{1/2} \frac{1}{t^{1/2}} - \frac{1}{M_{O_3/O_2}} k_{s_c} C_{i_{s_c}} \right] (\text{mg/cm}^2\,\text{hr}) \quad [18]$$

or

$$\frac{-dX_W}{dt} = \frac{1}{\rho_W M_{O_2/W}} \left[\left\{ \frac{D_b\ \Delta C_b\ \rho_b\ M_{O_2/WO_2}}{2} \right\}^{1/2} \frac{1}{t^{1/2}} - \frac{1}{M_{O_3/O_2}} \cdot k_{s_c} C_{i_{s_c}} \right] (\text{cm/hr}) \quad [19]$$

where ρ_W is the density of tungsten (g/cm³).

Each equation is to be integrated over the limits 0 to t_m determined by Eq. [12], as before.

The metal consumption rate due to the formation rate of WO_3 is given by

$$\frac{-d(m_W/A)}{dt} = \frac{1}{M_{O_3/W}} \frac{d(m_{O_3}/A)}{dt}$$

$$= \frac{1}{M_{O_3/W}} k_{s_c} C_{i_{s_c}} (\text{mg/cm}^2\,\text{hr}) \quad [20]$$

or

$$\frac{-d\,X_W}{dt} = \frac{1}{\rho_W M_{O_3/W}} k_{s_c} C_{i_{s_c}} (\text{cm/hr}) \quad [21]$$

Since the metal loss due to the formation of WO_3 reaches a limiting value, Eq. [20] and [21] may be used as a satisfactory approximation to describe the oxidation rate.

The values obtained by the above analysis for the appropriate quantities are presented in Table I. When these values are substituted into the appropriate equations, the experimental curves of three investigations (2, 5, 6) are adequately reproduced in the temperature range 500°-1300°C and pressure range 0.0013-20.8 atm.

For purposes of practical application, the rate of consumption of tungsten above 700°C may be expressed by the equations

$$\frac{-d(m_W/A)}{dt} = 5.89 \times 10^6 \exp(-12{,}170/T)\ P^{1/2}\ (\text{mg/cm}^2\,\text{hr}) \quad [22]$$

and

$$\frac{-d\,X_W}{dt} = 3.05 \times 10^2 \exp(-12{,}170/\text{T})\ \text{P}^{1/2}\ (\text{cm/hr}) \quad [23]$$

where T is to be expressed in °K and P in atmospheres of oxygen.

Discussion

Two recent investigations have reported a decrease in rate with temperature above 2000°C (11, 12). Referring to Eq. [12] and [13] and noting that the quantity $D_b\ \Delta C_b\ \rho_b\ M_{O_2/WO_2}$ increases more rapidly than $k_{s_c} C_{i_s}$ with increasing temperature, it is seen that both t_m and $(\Delta m_{O_2}/A)_{max}$, or $(\Delta X_{O_2})_{max}$ where X_{O_2} is the thickness increase due to WO_2 formation, will increase at higher temperatures and also at lower pressures. The resulting weight or thickness change measurements will then take the form of the curves of Fig. 3. Since the absolute weight change and zero time are not known experimentally, an arbitrary straight line through a series of points will give an

Table I. Values for rate equations

Phase boundary process	Diffusion process
$(3.6 \times 10^8) \cdot \frac{kT}{h} \cdot \exp(\Delta S^{\ddagger}/R) C^{\circ}_{ts_c}$	$(3.6 \times 10^9) D_b \rho_b M_{O_2/WO_2} \Delta C_b^{\circ}$

The Effect of Organic Compounds on the Codeposition of Hydrogen with Nickel

Thomas C. Franklin and Jack R. Goodwyn[1]

Chemistry Department, Baylor University, Waco, Texas

ABSTRACT

A coulometric method of analyzing for hydrogen was used to study the effect of a group of organic additives on the amount of hydrogen codeposited with nickel from a Watts-type bath. This technique indicated the presence of one form of hydrogen at the electrodes, and this was indicated to be hydrogen codeposited in the nickel. There was marked correlation between the hydrogen content of the nickel deposits and the current efficiency for the deposition of hydrogen. It was also observed that, in general, the brightest deposits occurred at the minimum in the hydrogen content curves.

Thon (1) studied the codeposition of hydrogen and nickel, but did not study the effect of additives. Yeager and co-workers (2) have also carried out this type of study. Brenner and co-workers (3) studied the effect of additives on this process, but found no definite relationship; however, the technique used in their study analyzed for both free and combined hydrogen in the deposit. The purpose of the work reported in this paper was to reinvestigate the effect of additives on the amount of hydrogen codeposited with nickel using a technique which analyzed only for the free hydrogen to see if there was a systematic variation.

[1] Present address: Texas Eastman Company, Longview, Texas.

At the same time, a study was made of the effect of the organic compounds on the current efficiency for nickel deposition.

Experimental Materials and Methods

Nickel wire electrodes were prepared by sealing 14 gauge nickel wire in glass tubing with 1.2-1.5 cm lengths exposed. The wire electrodes were mechanically polished and plated at a known current density for a definite time, usually 6.96 ma/cm^2 for 12 min. They were plated in a Watts-type plating bath consisting of $NiSO_4 \cdot 6H_2O$, 240 g/l; $NiCl_2 \cdot 6H_2O$, 45 g/l; and H_3BO_3, 30 g/l. After dissolving the components, nickel carbonate was added to raise the pH.

The solution was filtered and the pH lowered to 4.0 by adding dilute hydrochloric or sulfuric acid. Measured amounts of a solution of the organic additive in the Watts bath were added to the plating bath with a graduated pipette.

Hydrogen content studies.—After plating, the electrode was rinsed with distilled water, and the hydrogen was analyzed coulometrically by the procedure used by Franklin and Cooke (4). The electrode was oxidized polarographically in a cell filled with hydrogen-saturated 2*N* sodium hydroxide. The reference cell was mercury, mercuric oxide, 2*N* sodium hydroxide. A Sargent Model XXI polarograph was used to record the current-voltage curves. The area under the curves was used as a measure of the amount of hydrogen in the deposit. Most of the data recorded are differences between results obtained with and results obtained without additives present in the plating bath. Each of the hydrogen analyses was made at least in triplicate, and each complete curve reported was run at least twice. The ethanenitrile study (Fig. 3) was repeated by three different workers on a number of electrodes over a period of two years. Even though the total amount of hydrogen codeposited varied from one experiment to another, the differences using the same basic pretreatment method were the same within ±5%. All connections were standard taper or ball and socket ground glass joints.

The appearance of the deposit was also noted as the additive concentration was varied.

Current efficiency studies.—The apparatus used to determine current efficiencies is shown in Fig. 1. The coil cathode of 14 gauge nickel wire was attached to the iron shaft of the mercury sealed rotating electrode designed after that of Kolthoff and Lingane (5). The length of wire extending into the solution was 28 cm. The iron shaft of the stirrer was coated with ceresin wax. The stirring motor was rotated at 600 rpm, and the anode was made of nickel wire.

In a typical run, 35 ml of the plating solution were placed in the cathode compartment, and enough plating solution was placed in the anode compartment to equalize the liquid levels. The entire apparatus was immersed in a water bath maintained at 25° ± 0.1°C. After making preliminary runs until the amount of hydrogen evolved in a run became constant, measured amounts of a solution of the organic additive in the plating solution were added to the cathode compartment. After each addition, the electrode was plated for 12 min at a current density of 6.96 ma/cm^2. The amount of hydrogen evolved was indicated by the displacement of a drop of butyl phthalate along the capillary tube, the current was measured with a previously calibrated ammeter, and the time was measured with a timer. The current efficiency for nickel deposition or for hydrogen ion discharge was obtained from the number of coulombs passed and the volume of hydrogen evolved. All curves are the average of at least two runs. The same pretreatment technique was used in all experiments. The volumes of hydrogen were reproducible within ±3%.

In all experiments the inorganic chemicals were reagent grade, the water was triply distilled, and the organic chemicals were the purest grades available commercially. (In all cases except one this was either Spectrograde or Eastman White Label. The disodium 2,7-naphthalene disulfonate was technical grade. At a later date this chemical was purified somewhat, but the purification did not alter the general shape of the curve.)

Data and Results

Effect of organic compounds on the hydrogen content of electrodeposited nickel.—Along with this study of Watts nickel an investigation was made of the polarographic oxidation of palladium, black nickel, and iron electrodes. With all of these metals three peaks were observed that could be interpreted as being due to the oxidation of three forms of hydrogen. In the cases of palladium and platinum black all three forms could be observed by bubbling hydrogen over the electrode. However, it was necessary to generate hydrogen electrolytically or codeposit hydrogen with the metal in order to observe all three forms with black nickel and iron. These peaks were not observed unless hydrogen was generated, indicating that they were caused by the oxidation of hydrogen at the electrode. Hydrogen

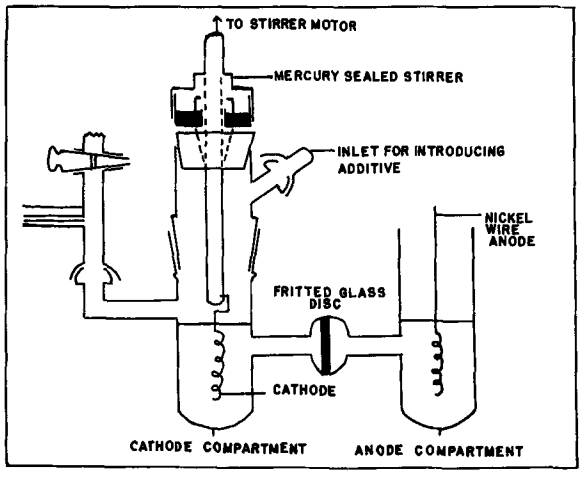

Fig. 1. Apparatus for measuring the hydrogen evolved during the plating process.

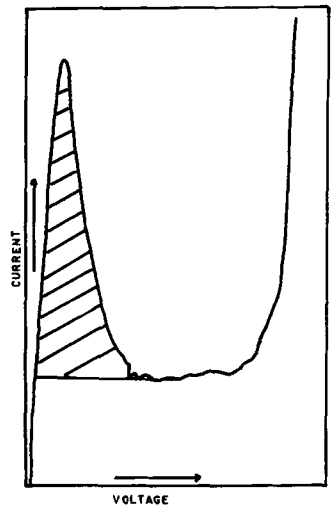

Fig. 2. Current-voltage curve for the oxidation of the hydrogen codeposited with Watts nickel.

was placed on the electrodes in one bath and then the polarograms were run in a hydrogen-free sodium hydroxide solution. This would make it unlikely that solution hydrogen was being oxidized.

Figure 2 shows a typical current voltage curve for the oxidation of the hydrogen present at a nickel electrode which has been plated in a Watts bath.[2] The peak is the middle peak observed in the oxidation of hydrogen on black nickel. Since hydrogen was not appreciably absorbed from solution into nickel it was not possible to make a study similar to that made of platinum (4). However, the hydrogen oxidized to cause this peak was concluded to be hydrogen in the interior of the nickel deposit. This was shown by dipping the freshly plated electrode in 1*N* potassium permanganate in 1*N* sulfuric acid. There was no change in the area under the oxidation curve. With black nickel the two other peaks decreased markedly. In addition when the electrode was plated, mechanically polished, then replated before oxidizing, the area under the curve was higher than the area obtained when the electrode was plated only one time. Both of these experiments indicate that the hydrogen being oxidized is in the interior of the nickel and not on the surface.

Figures 3 and 4 show the variation of the hydrogen content for ethanenitrile, propanenitrile, butanenitrile, and pentanenitrile. The visual appearance of the deposits is also indicated in these figures. Curves similar in shape were obtained for hexanenitrile, 3 hydroxypropanenitrile, butanedinitrile, m-aminophenol, 1 ethylquinolium iodide, and disodium 2,7 naphthalenedisulfonate. As will be noted in the curves there was considerable variation in the initial point. This was probably caused by differences in pretreatment of the electrode. Using the same pretreatment, one obtains results that agree within ±5%. For all of these compounds there was the same marked correlation between the hydrogen content and the appearance of the deposits that is seen in Fig. 3 and 4. The best deposits were always obtained at the minimum in the curve. However, in the cases of m-aminophenol and butanedinitrile the minimum hydrogen content did not correspond to the minimum in the curve as seen, for example, in Fig. 5. Of the compounds investigated only thiourea (Fig. 6) did not give a curve similar to those above. But, even here it can be seen that there

[2] The areas recorded in the figures correspond to the shaded area in Fig. 2. This is not the total hydrogen content since the residual current lies lower than the level portion of the curve. However, it was found that the residual was constant for each electrode; therefore, the total amount of hydrogen would be different, but the shape of the curve would be the same.

is the same correlation between the appearance of the plate and the hydrogen content.

Effect of pressure on hydrogen content.—In a further investigation of the correlation between the appearance of the deposit and the amount of co-deposited hydrogen, a study was made of the effect of pressure on the codeposition of hydrogen and nickel. It was noted that there was a decrease in hydrogen content with a decrease in pressure and that the plates became smoother and more even, but not bright. In addition, it required only a concentration of 3.2 x 10^{-3}M propanenitrile to obtain the brightest deposits at 70 mm pressure compared to 4.5 x 10^{-3}M propanenitrile at atmospheric pressure.

Effect of stirring on hydrogen content curves.—Since some of the experiments were run in stirred solutions and some in nonstirred solutions, a study was made of the effect of stirring on the hydrogen content of the deposits. In the case of the nitriles, stirring had no effect on the hydrogen content curves. Figure 7 shows the effect of stirring on the hydrogen content curves for disodium 2,7 naphthalenedisulfonate. As can be seen, stirring causes a shift in the curve, but does not change the general shape of the curve.

Effect of organic compounds on the current efficiency of hydrogen deposition.—The observed variation of the hydrogen content could be due to variations in the current efficiency of the deposition process or it could be due to variations in the amount of hydrogen adsorbed at the surface of the electrode. In order to distinguish between these two possibilities the current efficiency in the Watts bath for the deposition of hydrogen was measured as a function of the concentration of the organic additive.

Figures 8, 9, and 10 show a definite correlation between the current efficiency for the deposition of hydrogen and of hydrogen content curves for propanenitrile, pentanenitrile, and disodium 2,7 naphthalene disulfonate, indicating that the cause of the variation in hydrogen content is a change in the current efficiency for the deposition process.

In summary, it has been shown that there is a marked correlation between the amount of hydrogen codeposited with nickel from a Watts bath containing various organic additives, the current efficiency for hydrogen deposition, and the appear-

ance of the deposit. All of these quantities vary in the same manner as a function of the concentration of the additive.

Simultaneous Cataphoretic and Electrolytic Deposition of Nickel for Cathode Bases of Reliable Electron Tubes

Peter F. Váradi and Kitty Ettre

The Machlett Laboratories, Incorporated, Springdale, Connecticut

ABSTRACT

The combination of electrolysis and cataphoretic deposition of metal particles was used in the development of a porous nickel matrix layer for electron tube extended interface cathodes. The codeposition phenomenon was studied and the influence of the various parameters (time, temperature, concentration) on the deposited layer structure was shown. The technique may be used for preparing porous layers from metal mixtures and alloys.

The extended interface (matrix) cathode used in high voltage or high power electron tubes was described by Fisk *et al.* (1) and by Field (2). This cathode consists of a nickel base metal, which is coated by a porous nickel layer. This nickel layer is sintered to the base and thereafter the voids are filled with the standard emissive $(BaSrCa)CO_3$ coating material. The main advantages of the use of a porous nickel matrix layer as the base for oxide coated cathodes are: good heat and electrical conductivity, increase in the adherence of the emissive coating to the base metal, decrease in the interface resistance, and finally minimization of the detrimental effect of the high voltage sparking.

On considering the working mechanism of such a nickel matrix cathode, it is evident that the porous nickel matrix must have the following properties: (*A*) Adherence: A very good adherence to the base metal after sintering, to avoid peeling off of the matrix. (*B*) Pore size: The size of the voids must be several times larger than those of the carbonate grains. This means that the pores should be filled easily by the emissive materials. It is recommended, assuming a carbonate size of 2-5μ, to have a pore size of 25-50μ. (*C*) Reproducibility: Height, density, surface properties of the porous layer, and the dimensions and shape of the voids must be reproducible from sample to sample and lot to lot in mass production.

The most important part of this type of electron emitter is the uniformly porous nickel matrix layer. This layer can be prepared as described, utilizing painting (3, 4), spraying (4, 5), or press technique (3). The disadvantages of these methods are: it is difficult to get uniformly porous and reproducible structures, and the layer obtained might readily peel.

In order to develop a method to produce reproducible and reliable porous nickel matrix layers suitable for electron tube cathode purposes, we made experiments with a new process: simultaneous electrolytic and cataphoretic deposition. The two types of deposition can be performed from the same solution simultaneously, resulting in a porous nickel matrix deposit. In the following method, the influence of the various parameters on the layer structure and the mechanism of deposition are described.

Experimental Method

The experimental arrangement is shown in Fig. 1. The glass beaker (B) contained the plating solution with the added nickel metal powder. The

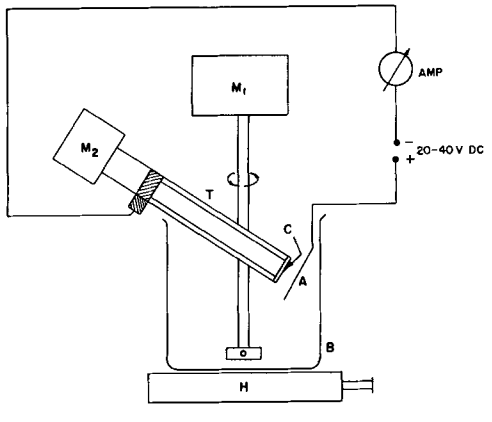

Fig. 1. Schematic drawing of the experimental setup

plating solution was a "hard nickel plating bath" containing 5% $NiSO_4$ and 2.3% $(NH_4)_2SO_4$ in deionized water. Carbonyl nickel powder of 325 mesh was mixed into the solution, and the mixture was agitated thoroughly by a Teflon stirrer (M_1). The sample to be coated (C) was mounted on a holder and was rotated by a slow (10 rpm) motor (M_2), and except for the round flat (0.5 cm^2) target surface, it was protected by a Teflon shield (T). The sample was attached to the negative side of a d-c power supply, while the positive side was attached to a flat nickel anode (A) spaced approximately 8-15 mm from the sample. The temperature of the slurry was maintained by a hot-plate (H) and was controlled in the solution.

The nickel samples to be coated were cleaned carefully before using. The samples were degreased in ether and rinsed in acetone and boiling water. Finally they were rinsed again in acetone and dried in air. After mounting the samples on the holder, the sample was immersed in the slurry, and a voltage of 25v d.c. was switched on. After the time required for obtaining the proper coating thickness had passed, the voltage was switched off, and the sample was removed from the solution and from its holder. It was rinsed in distilled water, then in acetone, and after drying it was examined.

Appearance and Characteristics Data of a Nickel Matrix

The general appearance of a nickel matrix cathode suitable for electron tube application is shown in a schematic drawing, Fig. 2. The drawing shows a cross section of the porous layer. The characteristic data of such a matrix can be defined by the height of the porous layer and by its roughness. The porous nickel layer was scratched with a pin across the center of the coated surface (before sintering). The height of the matrix is defined as the depth of this scratched groove from the bottom (base metal) to the top of the nickel peaks (see Fig. 2A). The roughness of the coating denotes the distance between the peaks and valleys of the matrix (see Fig. 2B). The height and roughness measurements were made with a Zeiss light section microscope. Another characteristic datum of the porous layer is the weight of the deposited nickel. The apparent density of the layer can be calculated from the above data and also the ratio of height/roughness. The ratio of height/roughness is most characteristic on the structure of the matrix layer, and it is affected by the different parameters as described below.

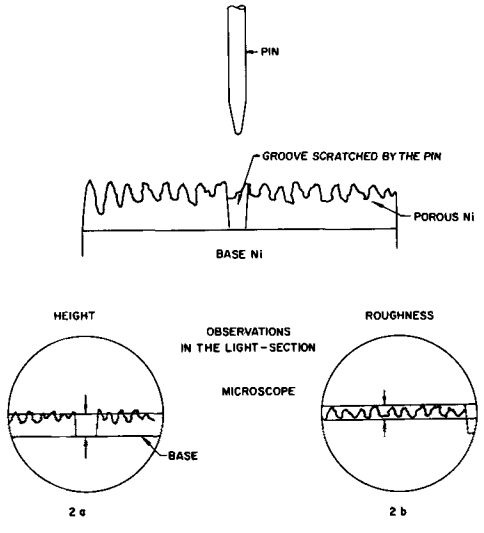

Fig. 2. Schematic drawing of the cross section of a deposited layer

Influence of Several Parameters on the Matrix Surface Structure

The characteristic data of a porous matrix, height, roughness, height/roughness ratio, depend on the following parameters: nickel powder concentration, temperature of the plating solution, coating time. Experiments were made on the influence of these parameters on the structure of a porous matrix layer. The voltage was kept constant at 25v.

Effect of the nickel powder concentration.—The effect of the nickel powder concentration of the solution on the porous layer structure is shown in Fig. 3. The data were taken at 70°C bath temperature and with 12 sec coating time. Two conclusions can be drawn from the experiment: (*a*) Height and roughness values increase with increasing amount of nickel powder and finally they reach a saturation; and (*b*) the ratio of height/roughness decreases considerably with increasing nickel powder concentration. The roughness increases much faster at higher nickel concentration than the height, which

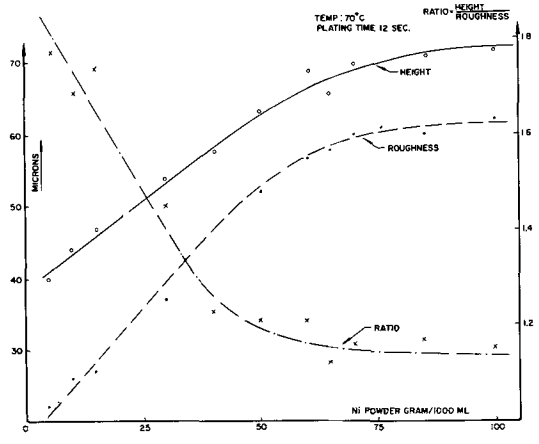

Fig. 3. Effect of the nickel powder concentration on the layer structure.

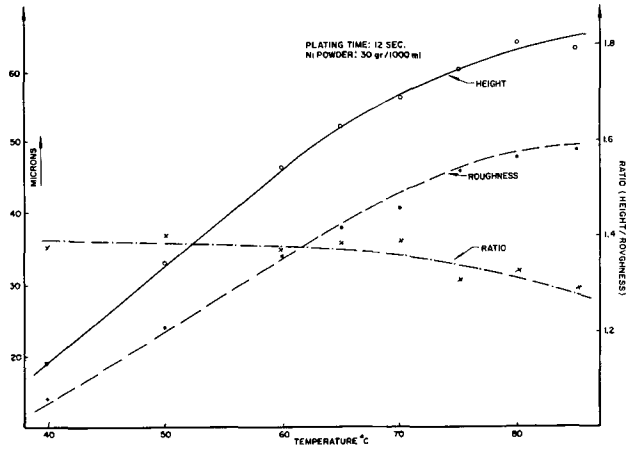

Fig. 4. Effect of the temperature on the layer structure

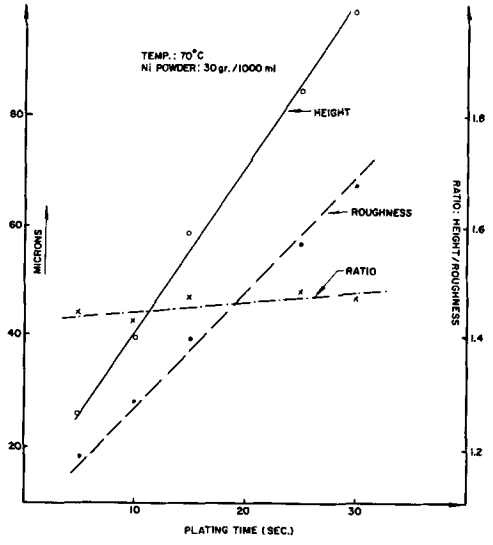

Fig. 5. Effect of the plating time on the layer structure (30 g/1000 ml nickel powder concentration in the solution).

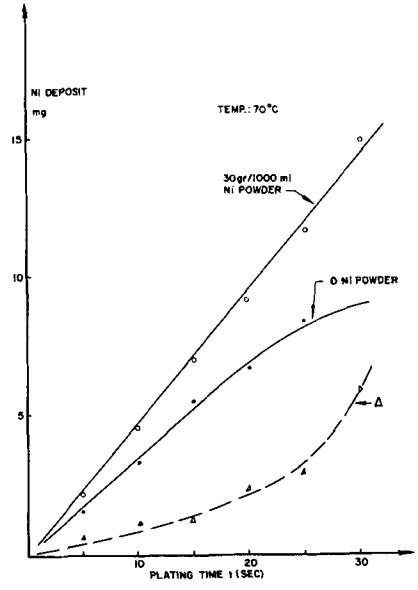

Fig. 6. Effect of the plating time on the deposited nickel quantity

means that the structure of the porous matrix layer changed considerably at higher nickel powder concentration.

Effect of bath temperature.—Figure 4 shows the effect of temperature on the structure of a matrix applying 30 g/1000 ml nickel powder concentration and 12 sec coating time. As can be seen (*A*) the height and roughness values increase with increasing temperature and tend to reach saturation above 75°C; (*B*) the ratio of height/roughness is not much affected by the temperature and it decreases only very slightly wtih increasing temperature.

Effect of coating time.—Figure 5 shows the effect of the coating time on the characteristic data of the matrix at 30 g/1000 ml nickel concentration and 70°C bath temperature. The results show that: (*a*) the height and roughness data increase with increasing coating time; (*b*) the ratio of height/roughness remains practically constant, *e.g.*, the structure of the layer does not change by increasing the coating time.

Simultaneous Electrolytic and Cataphoretic Deposition

The preceding experiments show that the structure of the porous layer is affected considerably only by the change in the nickel powder concentration in the plating solution. It is evident that a combined deposition process takes place: an electrolytic deposition process of nickel on the cathode from the plating solution, and simultaneously a cataphoretic deposition of the nickel particles from the slurry. The nickel quantity deposited purely by electrolysis, having no nickel particles in the solution, was measured, as was also the deposition from the combined process, having 30 g/1000 ml nickel powder concentration in the slurry. We made experiments varying the coating time but keeping the temperature constant at 75°C (Fig. 6). The addition of the nickel powder to the solution causes a considerable increase in the deposited amount indicating that the cataphoretic process also takes place. The deviation from the pure electroplating caused by the addition of nickel powder is indicated also in the figure denoted as Δ.

The current density during our measurements was approximately 4 amp/cm^2; it remained the same when nickel powder was added. There was a slight but definite trend of current increase over the plating period if nickel powder was present, which is normal for cataphoretic depositions. The current, however, remained constant during the plating experiments having no nickel powder in the solution.

From the above experiments we can conclude that by adding nickel powder to a regular nickel plating solution a combined electrolysis-cataphoresis process takes place. The cataphoretically deposited nickel powder is incorporated in the electrolytically deposited layer forming a very rough and highly porous nickel layer which is suitable for the extended interface (matrix) cathode purposes. This procedure can be used for deposition of a rough layer of any metal mixtures.

Deposition of Metal Mixtures

In certain types of electron tubes the emitter contains known amounts of additives in the nickel. This is necessary also for certain types of matrix cathodes. The technique described above is also useful in producing porous nickel matrixes with known amount of additives as magnesium, titanium, tungsten, aluminum, etc.

Metal powder mixtures.—We made experiments on depositing a mixture of nickel and titanium powder. The coating procedure described above was followed, except that a mixture of nickel and titanium (0.5%) powder was used. The resulting layer had the same structure as one without the titanium additive.

Chemical analyses were made on the original nickel and titanium metal powder mixture; the deposited coating was also analyzed. The original metal powder mixture contained 0.5% titanium, and the deposited porous coating contained only 0.26% titanium. These results were reproducible and indicate that metal particles different from nickel also can be deposited this way cataphoret-

ically. The chemical determination of titanium besides excess amount of nickel was performed by a modification of the colorimetric method described in Snell's book (6).

Nickel alloys.—Nickel alloy powder containing 3.6% tungsten was prepared. This powder was used in our experiments. The original powder and also the deposited layer were chemically analyzed. There was 3.5% tungsten in the original, while the tungsten content of the deposited layer was found to be 2.5%. The analysis of the tungsten content of the nickel was performed colorimetrically as described in Snell's book (6).

Sintering

The appearance of the resulting matrix layer, after deposition, is black, and it becomes metallically bright after sintering. The sintering was made in wet hydrogen at 1000°C for 10 min. The adherence of the sintered layer is excellent. Its removal from the base nickel after sintering is not possible.

Reproducibility

The reproducibility of the method (height, roughness values of the matrix layer) depends on how well the different parameters are kept constant during the preparation. With the simple equipment shown in Fig. 1 the values may be kept within ±4% deviation from the mean. By introducing a more advanced setup, this reproducibility can be improved greatly.

Experiments in Electron Tubes

Spraying.—The voids of the porous matrix body are filled with the standard emissive spray material by a "wet" spraying. The void structure of the co-deposited layer is such that no special solution or technique is required to fill the pores with the emissive material.

Electron tubes.—These were prepared utilizing this co-precipitated nickel matrix base cathode procedure. The pumping and processing of tubes with this type of cathode is similar to the standard sprayed oxide coated cathodes. Life and high voltage stability tests of electron tubes in which this type of matrix cathode was incorporated (under the trade name "Phormat cathodes") indicated high reliability and several thousand hour life. These experiments were made (7) in ML-7698 and ML-7815 tubes, tested in a grid-modulated amplifier circuit with a plate voltage of 3000v d.c. In the ML-7815 tube type in a hard tube modulator circuit, the Phormat cathode tubes withstood a field strength of 135 kv/cm. At this field strength standard sprayed cathodes were almost completely destroyed, while the Phormat type cathodes showed only a few arc marks.

Electron-Microscopic Observations of the Structure of Electroplated Nickel

R. Weil and H. C. Cook

Department of Metallurgy, Stevens Institute of Technology, Hoboken, New Jersey

ABSTRACT

Nickel electrodeposits, of various thicknesses, were prepared from Watts' baths containing several addition agents to study the development of the surface structure. By electron-microscopic examinations of replicas, thin films, and electrolytically thinned bulk metal the reasons for the formation of several structural features, previously observed, were found. Selected-area diffraction was found to be the best method of measuring the grain size of the electrodeposits studied. Markings believed to be sites of lattice-included foreign substances were observed.

An earlier paper (1) dealt with the use of electron microscopy in the elucidation of certain structural phenomena observed in nickel electrodeposits from Watts' baths containing a variety of addition agents. The work described below is a continuation of this study. The purposes of the present work are to investigate the causes for the formation of the various structural features, the reasons for the fiber axes observed under certain plating conditions, and the location of the foreign substances known to exist in plated nickel. In order to accomplish these objectives, the growth of different structures was observed with electron microscopy using replicas as well as thin metal films.

Experimental Procedure

To study the effect of addition agents on the growth of electrodeposited nickel as independently

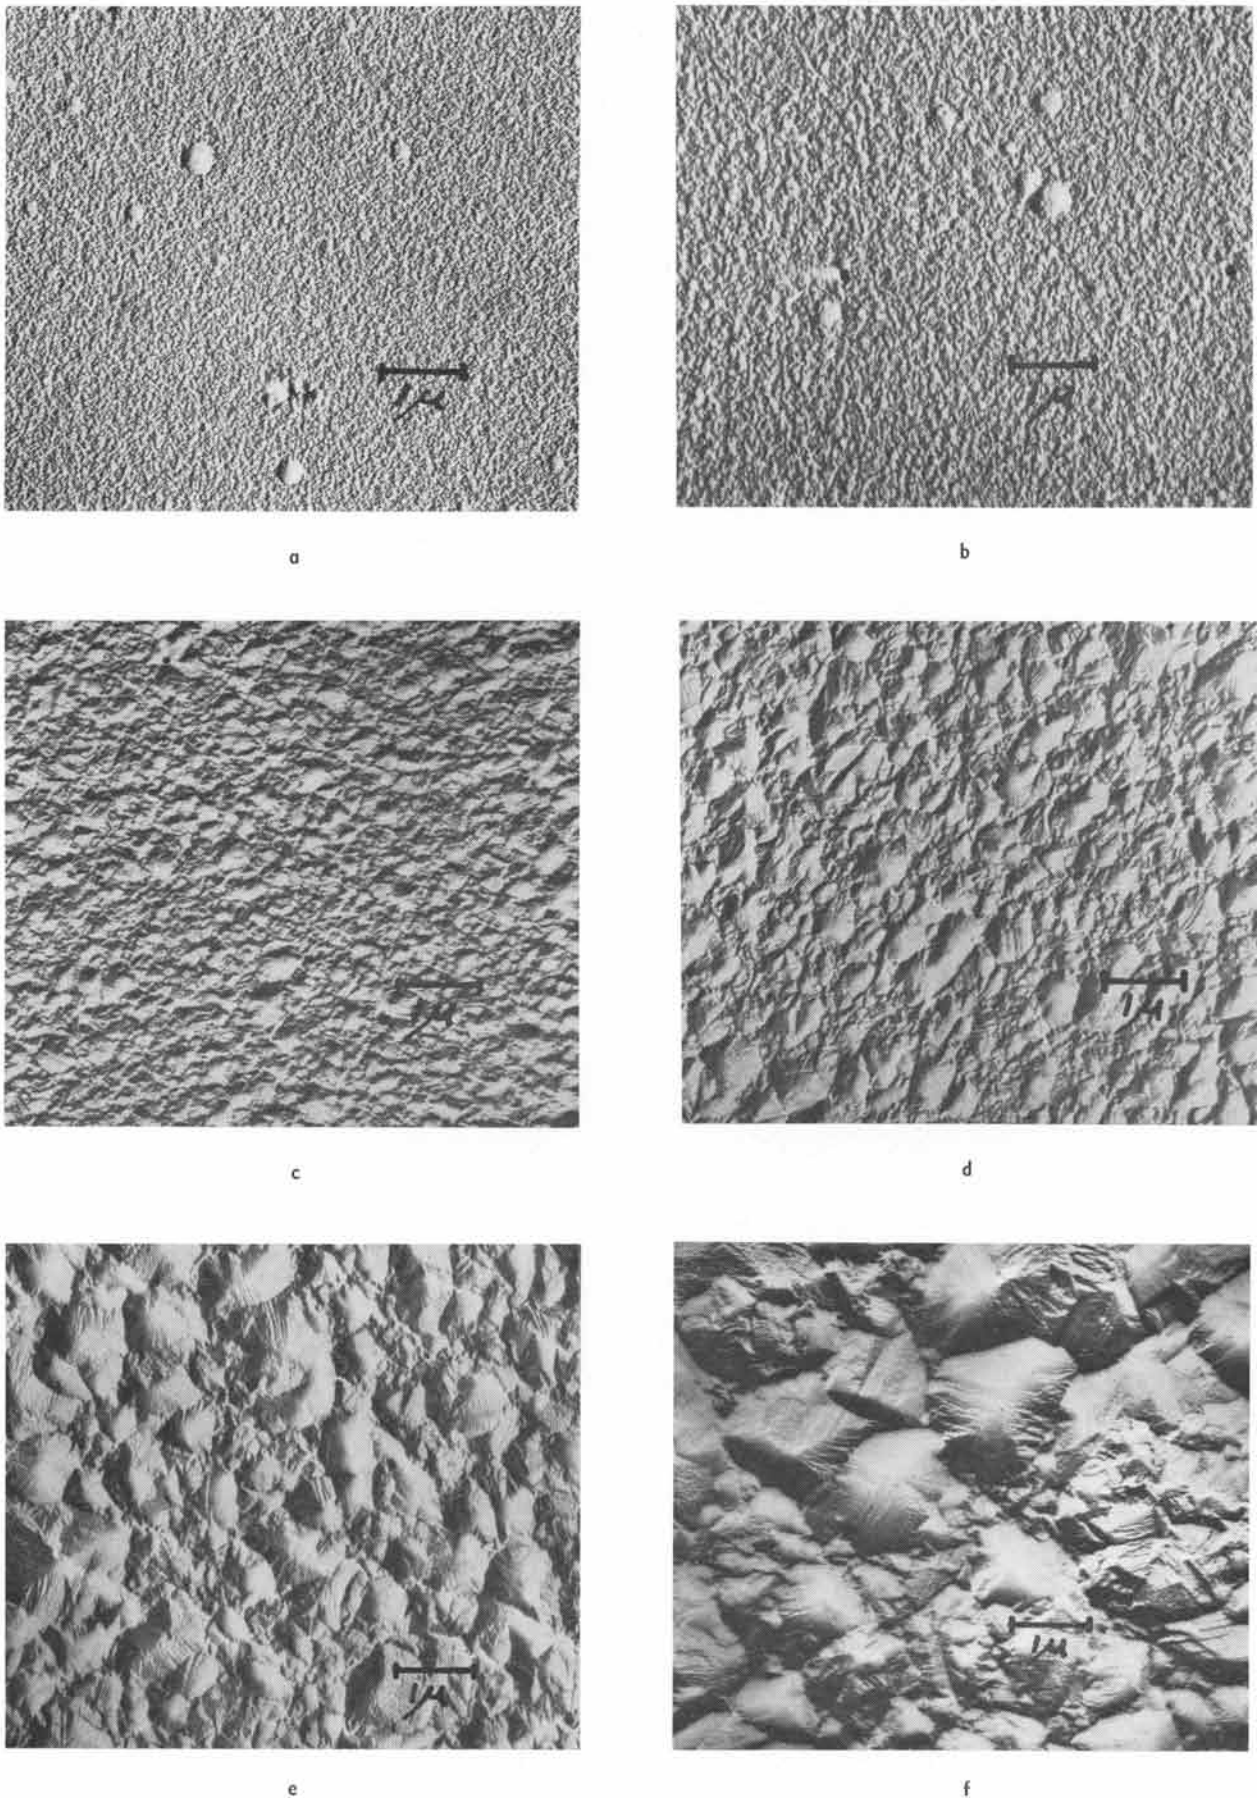

Fig. 1. Negative parlodion replicas of surface structures of nickel from plain Watts' bath plated for (a) 20 sec, (b) 40 sec, (c) 1 min 20 sec, (d) 2 min 40 sec, (e) 5 min 20 sec, (f) 10 min 40 sec.

2. 0.03 g/l Coumarin
3. 0.05 g/l Coumarin
4. 0.1 g/l Coumarin
5. 0.15 g/l Coumarin
6. 0.02 g/l Thiourea
7. 0.07 g/l Thiourea
8. 0.2 g/l Thiourea
9. 0.3 g/l Thiourea
10. 0.25 g/l Aniline
11. 0.6 g/l 1-5 Naphthalene disulfonic acid + 0.2 g/l chloral hydrate

as possible of the substrate, special copper basis metal had to be prepared. This was done by vapor depositing copper on specular nickel or polished glass and then electroforming a piece of sufficient thickness to handle. After stripping, the copper surface which faced the nickel or the glass was specular and consisted of extremely fine, randomly oriented grains. Nickel was deposited on the specular copper from Watts' baths; the composition and plating conditions are listed in Table I. To study the growth, the plating time was increased in a geometric series from 5 sec to 42 min, 40 sec. The area deposited was 0.25 dm², while that of the anode was 0.4 dm². Otherwise the experimental apparatus was as previously (1) described. Thin nickel films were plated over thin copper on half the originally deposited area as in the earlier work.

The surfaces of the deposits were examined electron microscopically with negative parlodion replicas as before. When greater resolution was required, carbon replicas were made by first shadowing the specimen with palladium and then evaporating carbon. The replicas were removed by scoring the specimen to produce squares to fit the electron-microscope holder and then making the specimen anodic in an aqueous solution of 25% by volume H_2SO_4 with a stainless steel cathode. The current was slowly increased until the replica floated off. Thin films were also prepared by electropolishing. First the surface of the nickel was coated with an adherent plastic film. Then the copper basis metal was dissolved. The electropolishing method used was that described by Kelly and Nutting (2). Because of the plastic coating, the thin film came from a region near the surface.

Results and Discussion

The surface structures of the deposits from a plain Watts' bath plated for various times are shown in Fig. 1. Figure 1a shows that after 20 sec of plating a few grains grow faster than the others. There is some evidence from selected-area-diffraction studies of such grains in thin films that they have a (100) plane parallel to the surface. With increasing deposition time, these preferentially oriented grains grow over other grains and some new ones form

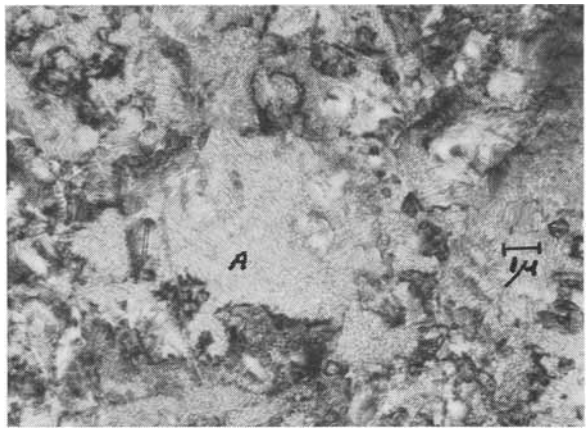

Fig. 2. Thin film of nickel deposit from plain Watts' bath

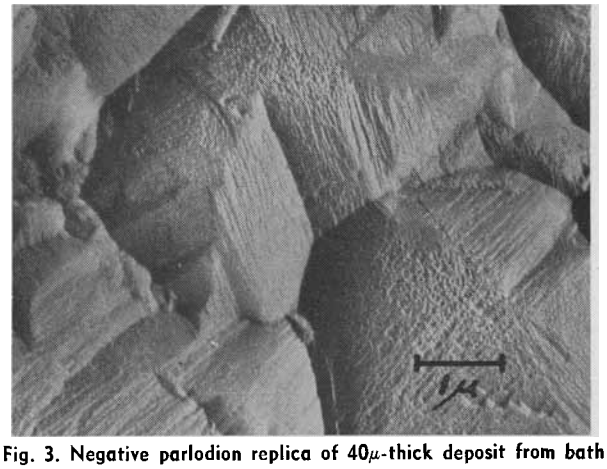

Fig. 3. Negative parlodion replica of 40μ-thick deposit from bath containing 0.03 g/l coumarin.

and start to develop until they occupy almost the entire surface. The growth layers become discernible at an early stage in the deposition and tend to become coarser probably by a bunching mechanism. The layers are not parallel, but inclined to the surface frequently resulting in a pyramid structure. In the thin nickel film, shown in Fig. 2, the growth steps and their orientations can be readily seen. An area such as that marked 'A' has a (100) direction perpendicular to the surface and a single-crystal pattern as determined by selected-area diffraction. It is thus possible to measure the grain size of the film by this method. Similar measurements using electrolytically thinned bulk material showed that the film is representative of the surface of the electrodeposit on which it was plated.

Some addition agents in Watts' baths do not change the fiber axis or decrease the grain size. An example of such a material is coumarin. Figures 3-5 show the effect of increasing coumarin concentrations in the bath on the structure of samples plated for 42 min 40 sec and which were about 40μ thick. Figure 3 represents the surface of a deposit from a solution containing 0.03 g/l coumarin. The difference between this deposit and one from a plain Watts' bath is that the height and distance between successive growth layers has decreased resulting in a flatter surface. The deposit from a bath with 0.05 g/l coumarin shown in Fig. 4 has more platelets growing parallel to each other, resulting in still larger areas which are flat. The degree of preferred

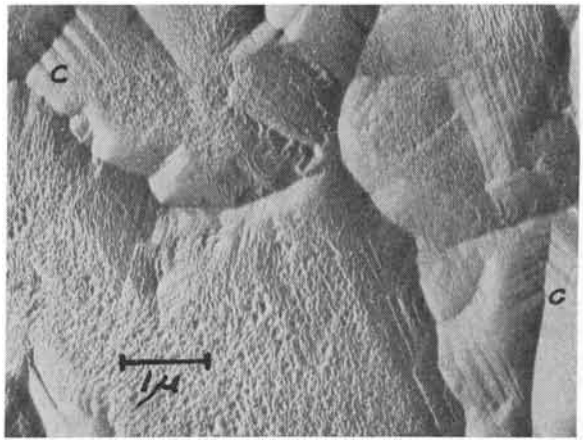

Fig. 4. Negative parlodion replica of 40μ-thick deposit from bath containing 0.05 g/l coumarin.

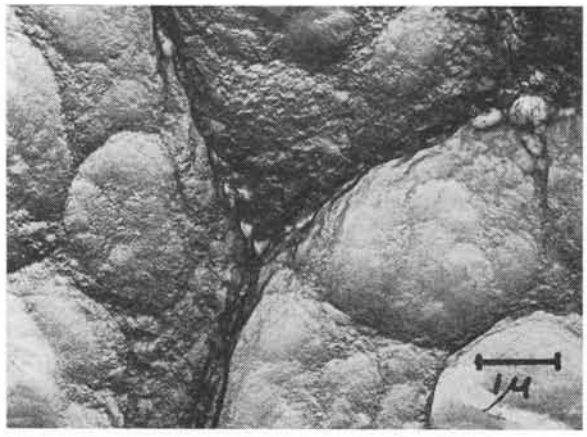

Fig. 6. Negative parlodion replica of 40μ-thick deposit from bath containing 0.02 g/l thiourea.

Fig. 5. Negative parlodion replica of 40μ-thick deposit from bath containing 0.15 g/l coumarin.

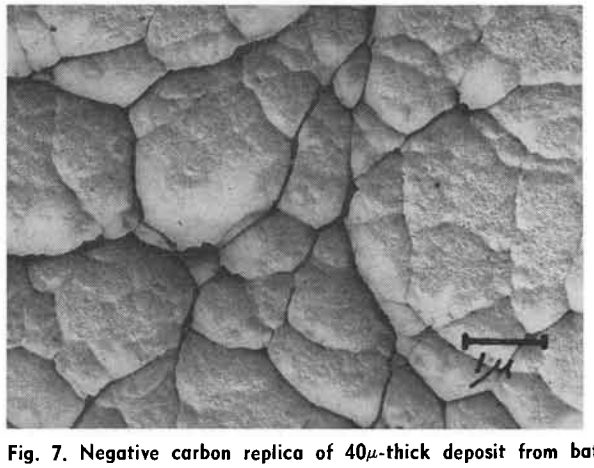

Fig. 7. Negative carbon replica of 40μ-thick deposit from bath containing 0.07 g/l thiourea.

orientation as determined by x-ray diffraction in the way previously (1) described did not change with the concentration of coumarin in the plating bath. The crevices between growth in different directions also have become shallower. It is also noticed that growth occurs simultaneously along two intersecting planes, probably of the same family in the areas marked 'C'. With a concentration of 0.15 g/l coumarin in the plating bath the deposit was quite bright. The reason for this is evident in Fig. 5 which shows very large areas of parallel-growing platelets with a few, relatively shallow crevices. It can thus be seen that one way of getting brighter nickel deposits is to cause growth to proceed along the same directions and to decrease the step height. The same features as were observed in the examination of the replicas were seen in thin films. Selected-area diffraction again showed that almost all grains large enough to give single-crystal patterns had a [100] direction perpendicular to the surface.

Almost specular deposits are obtained in a bath containing 0.6 g/l naphthalene disulfonic acid and 0.2 g/l chloral hydrate because the platelets are fine and only very few crevices or ridges form. As the development of the structure of deposits from such a bath with increasing time is followed, there is practically no coarsening of the platelet size with deposit thickness. The crevices which are present are chiefly due to stacking irregularities of the growth layers. In thin films from these samples, where such irregularities caused the stacking of the platelets to be somewhat coarser than average, the edges of the steps could be seen and were found to be along [100] directions.

An interesting feature observed in many structures is the formation of colonies, *i.e.*, a series of grains surrounded by a relatively deep crevice, which often resembles a grain boundary. Samples from baths containing thiourea and aniline exhibited this structural feature. With a concentration of 0.02 g/l thiourea very large colonies formed as seen in Fig. 6. With increasing thiourea concentrations, the colonies become smaller as do the growth steps. Figure 7 is a photograph of the surface of a deposit from a bath containing 0.07 g/l thiourea. Deposits from a bath containing 0.3 g/l thiourea have no crevices deeper than 0.4μ and are bright.

Examination of the surface structures at various stages in the growth of a deposit from a bath containing 0.07 g/l thiourea showed that they begin as very fine grains which tend to form groups with crevices between them. With increasing thickness, the crevices become deeper, but are not yet continuous as seen in Fig. 8. The actual grain size of the samples, even the one from the bath with 0.02 g/l thiourea, is quite small. This can be seen in Fig. 9 which is a transmission electron micrograph of a

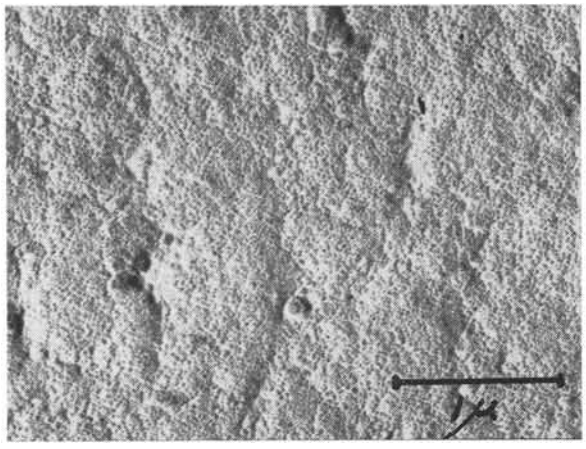

Fig. 8. Negative carbon replica of 1μ-thick deposit from bath containing 0.07 g/l thiourea.

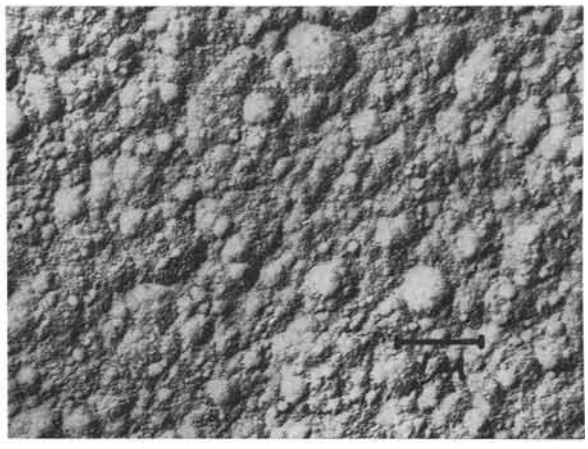

Fig. 10. Negative parlodion replica from 5μ-thick deposit from bath containing 0.25 g/l aniline.

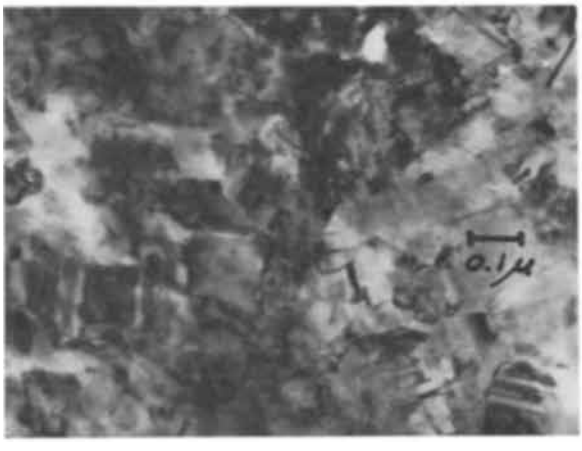

Fig. 9. Transmission micrograph of electrolytically thinned deposit from bath containing 0.02 g/l thiourea.

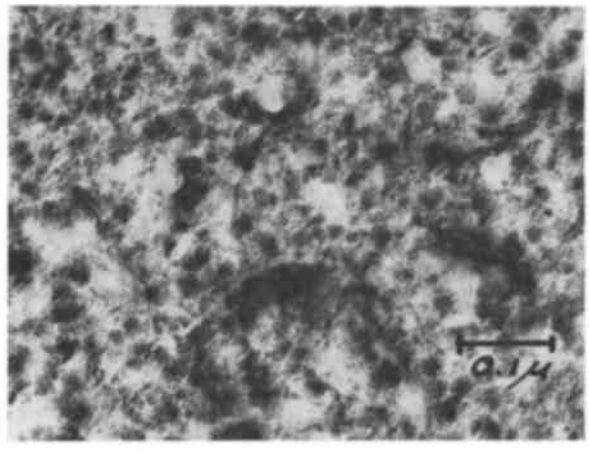

Fig. 11. Thin film of surface shown in Fig. 10

40μ-thick deposit from this bath. The sample was thinned by electropolishing.

The colony size in samples from baths containing other addition agents can be quite small as shown in Fig. 10, an electron micrograph of a replica from a deposit plated for 5 min, 20 sec in bath containing 0.25 g/l aniline. The extremely fine grain size of this sample can be seen from Fig. 11, a photograph of the corresponding thin film. Also with a selected-area-diffraction aperture of 1μ square, the pattern consisted of complete rings. This, plus the presence of all diffraction rings in what appeared to be normal intensities also indicates random orientation, a fact which the very irregularly oriented growth layers corroborates.

The location of codeposited material in electrolytically thinned films of copper deposits has recently been observed by Steinemann and Hintemann (3). Similar structural features were observed in nickel films. In Fig. 12 which represents a thin film from a 2μ-thick deposit from a bath containing 0.10 g/l coumarin, a large number of light markings are seen. These tend to be aligned along definite crystallographic directions. In a fully bright deposit from a proprietory bath shown in Fig. 13 they are more randomly distributed. To determine if these are the sites of codeposited foreign materials, the findings of Beacom and Riley (4) that foreign substances are preferentially codeposited at

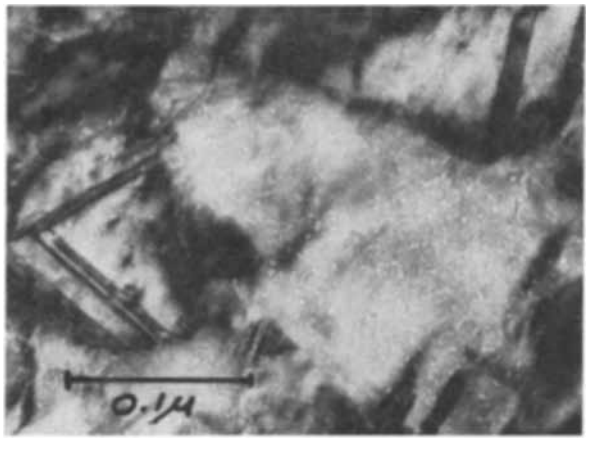

Fig. 12. Thin film showing markings in sample from bath containing 0.10 g/l coumarin.

protrusions in high-levelling baths, were utilized. Copper basis metal was prepared by vapor depositing on bright nickel having fine buffing scratches. The copper, copying the surface, therefore had tiny ridges. A photograph of the thin film plated on this surface and then stripped is shown in Fig. 14. A concentration of the light markings can be seen along the ridge. The plating bath, No. 11 in Table I was of the levelling type because the ridges could no longer be seen in a deposit 0.5μ thick. There is some evidence that the light markings represent sites where material has evaporated, as they tend

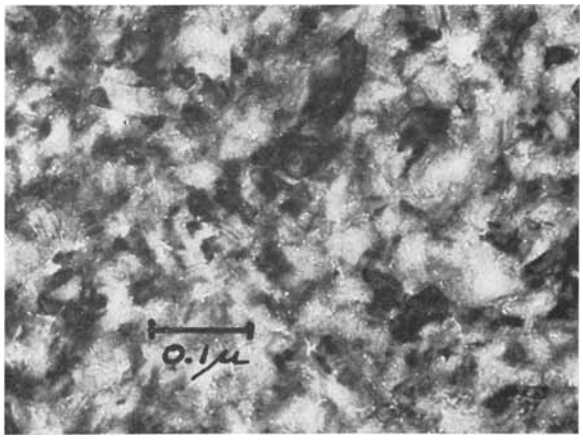

Fig. 13. Thin film showing markings in bright nickel deposit

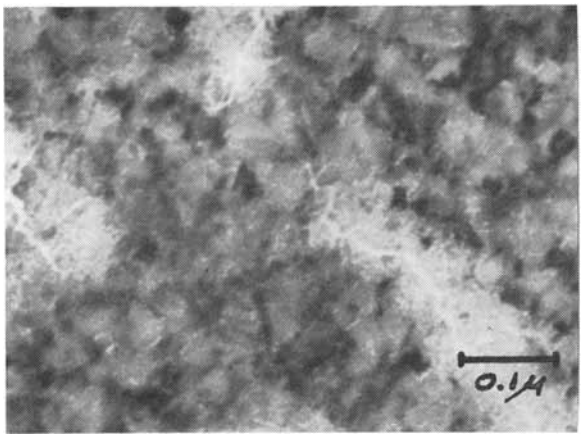

Fig. 14. Thin film showing markings lined up along ridges

to develop as a result of exposure to the electron beam. It is possible that some of the markings are due to electron bombardment. Such markings, however, tend to be randomly distributed and not lined up along certain directions. A few markings may be dislocations. However, in thin films, dislocations tend to extend from the top to the bottom surfaces. Most of the markings shown in the previous figures appear to be in a plane parallel to the surface. None of the markings were observed to move under the electron beam; dislocations often do. In a photograph taken as soon as an area is exposed to the electron beam there are dark markings and black areas lined up along the ridge.

The reasons for the formation of crevices, which have previously (1) been shown to be responsible for haziness in very fine-grained deposits and, depending on their size, can be a cause of dullness in general, have not yet been determined. On the basis of this study it is possible to make some suggestions. As previously indicated, irregularities in the height or spacing of the growth steps can cause crevices when the steps are inclined to the surface. A change in the growth direction of the platelet can result in a ridge or a valley. The crevices surrounding colonies may be caused, at least in part, by surface tension as suggested by the angles at their intersections. No crystallographic reasons have been found for their existence. The same diffraction patterns are observed on either side or on a crevice. Stresses may also cause regions to separate. There is a marked similarity between the dark areas seen on a ridge and crevices in fine-grained deposits which are hazy. This suggests that there may be some local adsorption of foreign material which hinders deposition and thereby causes a crevice. It is noteworthy that Watson and Edwards (5) observed negative levelling at the same concentration of thiourea where the deep crevices were formed. It is quite possible that crevice formation is a normal phenomenon in electroplating. Only under the right conditions for levelling are these crevices prevented from forming to noticeable depths so that a specular deposit results. These optimum conditions need not be the same as those which give best results with the relatively larger crevices used in levelling experiments. It has been shown by Garmon and Leidheiser (6), for example, that levelling is a function of the size and shape of the crevice.

The results of this study also permit further discussions about preferred orientations. Strong fiber axes were observed in samples showing relatively large grains and extended growth layers. It has been found by Pick, Storey, and Vaughan (7) that the surfaces of growth steps are usually low-index crystallographic planes. As the conditions which favor extended growth layers also favor continuation of the substrate orientation, layers will be formed nearly parallel to each other, resulting in large grains. As these grains grow from preferentially oriented nuclei, they tend to be aligned with a common direction of low indices perpendicular to the surface. Under conditions of growth inhibition, the layers are small and tend to be more randomly oriented with respect to one another because there is only a weak tendency to continue the immediate substrate orientation. Thus, fine-grained structures show generally only weak fiber axes or are randomly oriented.

The relative merits of using thin films plated on copper and stripped by removing the latter and those prepared by thinning bulk material became evident from this study. As the measurements of grain size and orientation obtained from both methods were the same, either is suitable for this purpose. For the examination of growth layers, crevices, and surface contours, the as-plated thin films are best suited as these features are no longer visible after electropolishing. Etching effects from the electropolishing solutions often occur in complicated structures. This again favors the first method. A slight etching effect has also been observed in the thin films due to the solution which dissolves the copper. The as-plated films can be made thinner, and they are more uniform in thickness than the thinned films. On the other hand, to study dislocations, subgrain formations, and annealing behavior, the thinned films are preferable. Dislocations are probably introduced in the as-plated thin films. Small changes in the lattice spacing, as occur in going from copper to nickel, can be easily accommodated under conditions of epitaxy by the introduction of dislocations.

Conclusions

Electron microscopy, especially using thin films in conjunction with replicas, has been usefully ap-

plied to the study of the very fine structure of electroplated nickel. Selected-area diffraction appears to be the only satisfactory method of measuring grain size of electrodeposits of the type used in this study as other means do not differentiate between colonies and grains or between microstress and microcrystals. An investigation of the interaction of dislocations with the sites of lattice-included, foreign material should be very helpful in elucidating the reason for the wide range of mechanical properties, as should also be a study of the effect of crevices acting as possible stress raisers.

Aging of Electrodeposited Chromium

I. Deposits from Chromic/Chromous Plating Baths

Kenneth A. Moon and Charles Levy[1]

Ordnance Materials Research Office, Watertown, Massachusetts

ABSTRACT

Deposits from the chromic/chromous plating baths used for the commercial electrowinning process lose about half their hydrogen and gain about 0.06 weight per cent (w/o) oxygen during about 100 days aging. The hydrogen loss does not occur in vacuum and is probably due to oxidation of elementary dissolved hydrogen. The remaining hydrogen is probably in hydrous oxide inclusions. The oxygen gain may be due to absorption in chromous oxide inclusions.

During studies of the nature and behavior of impurities in electrodeposited chromium, we have found that many deposits show pronounced aging effects during storage at room temperature. In this paper we report the results obtained with specimens deposited from chromic/chromous plating baths by the electrowinning process developed by the U.S. Bureau of Mines and the Union Carbide Metals Company (1). Studies of the aging of deposits from chromic acid plating baths are in progress (2) and will be reported later.

Materials and Procedures

Six deposit samples were used in this work. Deposits 1-5 were received from Union Carbide Metals Company in November 1959, and deposit 6 was received from the same source in March 1959. For these deposits, the usual heat-treatment in the plating plant to dry and dehydrogenate the material was omitted. The experimental specimens were given numbers which include the number of the deposit of which they were a portion, and a letter to distinguish between different specimens from the same deposit, *e.g.*, 1A, 1B, 2A, etc.

Dilatometric work was done with a Leitz Type HTV Universal Dilatometer, which produces a photographic curve representing specimen length *vs.* temperature. The slope of this curve, minus the slope of a curve on the same film made with the same specimen after complete annealing, multiplied by the appropriate calibration factors, gives the rate of shrinkage. The dilatometer furnace heating rate was 3°C/min, and the specimens were in an atmosphere of about 1 cm pure hydrogen gas up to about 550°C, and in vacuum thereafter. The purpose of the hydrogen gas was to increase heat transfer.

Hydrogen analyses were performed with a glass vacuum system in which the specimen was heated at 3°/min and the hydrogen evolved was collected in a known volume. Pressure of the hydrogen was measured with an oil manometer containing Dow Corning DC 703 silicone oil, and a Gaertner Scientific Corp. Model M300 cathetometer. To facilitate rate of evolution measurements, which require rapid manipulation, no Toepler pump was used, and the upper boundary of the known volume was the mercury vapor stream in the collector diffusion pump. Since this vapor stream retreats further into the pump as the pressure builds up, the known volume (511-561 cc) had to be calibrated as a function of pressure. It was established experimentally that loss of hydrogen by permeation through the silicone oil or by oxidation by mercury oxide in the pump was negligible, and also that no measurable hydrogen was evolved during the period of pumping which preceded the heating. Spot checks indicated that the gas collected in the known volume was essentially pure hydrogen. A liquid nitrogen trap was used between the specimen and the collector diffusion pump; the term "hydrogen content" as used in this paper does not include any

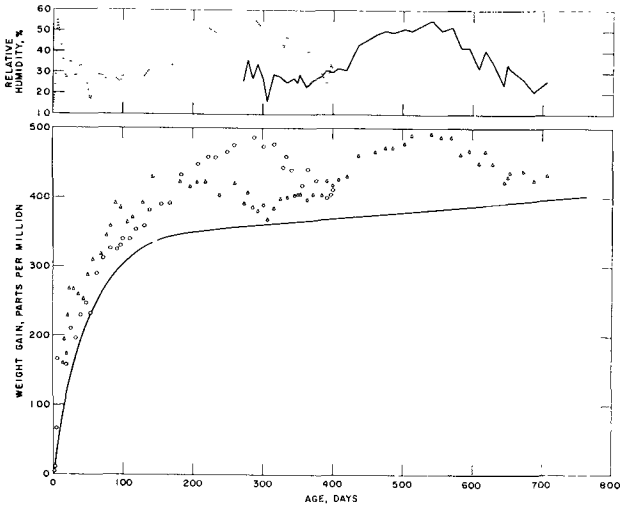

Fig. 1. Effect of age and humidity on the weight of specimens 1B (circles) and 6A (triangles). Weight gain is relative to the weight at age 1.3 days and 15% humidity. The curve represents the effect of age alone. See Fig. 2.

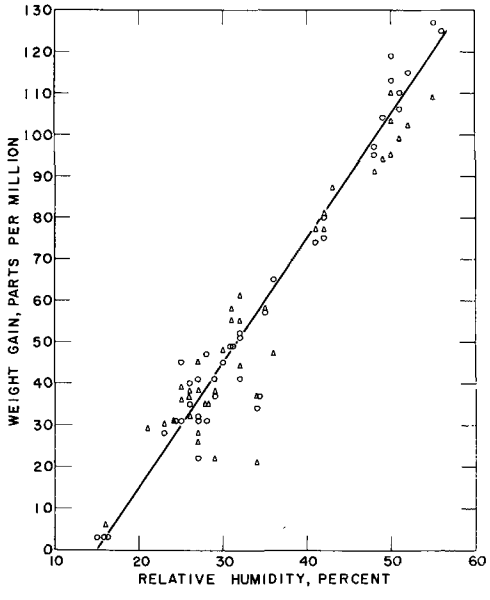

Fig. 2. Effect of humidity on the weight of specimens 1B (circles) and 6A (triangles). The ordinate of each point is the vertical distance between the corresponding point in Fig. 1 and the curve in Fig. 1.

hydrogen evolved from the specimens in the form of water vapor. Hydrogen content was calculated graphically from the rate-of-evolution data. In some cases rate measurements were not made, and hydrogen content could be calculated directly from the pressure/volume data; where cross checks were possible, the two methods gave identical results for hydrogen content.

Oxygen analyses by vacuum fusion and carbon analyses by combustion were performed by the Analytical Chemistry Branch of Watertown Arsenal Laboratories. In some cases we extracted the oxides from annealed specimens and submitted these to the Analytical Chemistry Branch for chromium analysis by standard procedures. The reported chromium content was then multiplied by the factor 48/104 to give the oxygen content. For extraction, a 1g specimen was placed in a solution of 10 ml bromine and 100 ml methanol. When solution of the metal was complete the mixture was filtered and the residue washed thoroughly with a solution containing 7g of ammonium bromide per 100 ml of methanol.

Results

Figure 1 shows how the weight of specimens 1B and 6A changed with age, age being reckoned from the time of removal of the deposit from the plating bath. The first weighing of specimen 1B was at age 1.3 days, and that of 6A, 14 days. To bring the two sets of measurements into conformity, a hypothetical 1.3-day weight was chosen for specimen 6A such that the two sets of data coincided as closely as possible. Spot checks with specimens 1G, 1H, and 1I gave agreement with the data for specimen 1B. The relative humidity of the laboratory atmosphere at the time of weighing is also shown in Fig. 1; for specimen 1B up to age 6 days direct humidity readings were not available, and the values shown were calculated from indoor temperature and outdoor dew point. These calculated values are probably a little low. It is clear that both age and

humidity affect the weight, and the separate effects are shown by the curve in Fig. 1 and the line in Fig. 2.

Figure 3 shows how the hydrogen content changes with age, and Fig. 4 shows how age affects the details of the hydrogen-evolution process. Since aging produces a hydrogen loss but a weight gain, it follows that something is absorbed from the atmosphere during aging. If this material were lost during vacuum treatment, there should be a corresponding trend in the data for age *vs.* weight loss during vacuum treatment; the appropriate data from Table I are plotted in Fig. 5, and we see there is no such trend. When data for oxygen content *vs.* age are examined, however, as in Fig. 5, the correspondence between weight gain and increase in oxygen content is readily apparent. Thus, either oxygen or water vapor is absorbed during aging.

The easy access of oxygen and/or water to the interior of the deposits can be attributed to an inclusion system which forms a finely divided skeleton throughout the entire deposit. Conventional sectioning, polishing, and microscopy do not easily reveal this system, but by dissolving the metal in alcoholic bromine as described above, the skeleton is isolated in the form of a pseudomorph, of composition approximating Cr_2O_3, which under the microscope has a spongelike appearance with an average pore diameter of roughly 1μ. Annealing the specimen slightly (say 3°/min to 300°, which is too slight to give rise to any doubts as to whether the skeleton has been changed appreciably in size or shape by annealing) is necessary to obtain a good

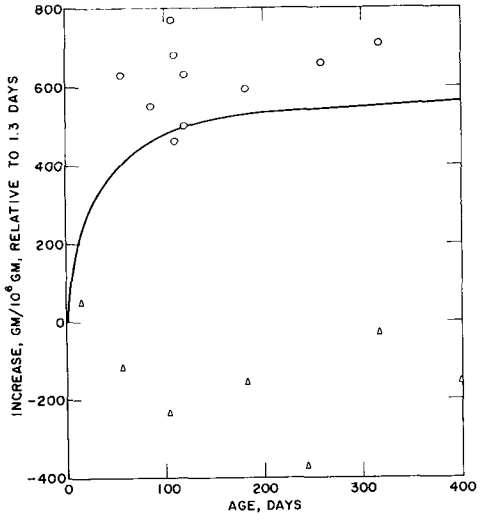

Fig. 5. Effect of age on oxygen content of annealed specimens (circles) and weight loss during annealing (triangles). Weight losses are corrected for hydrogen recovered and for humidity variations. The curve is the sum of weight gain and hydrogen loss, from Fig. 1 and 3. See also the data for specimens 1D and 2P in Table I.

pseudomorph. Very old unannealed specimens also gave good pseudomorphs; slightly aged unannealed specimens gave broken pseudomorphs; and it appears that a very fresh unannealed specimen would yield no pseudomorph at all.

Figure 6 shows the effect of age on the shrinkage characteristics of the deposits. The curves have been slightly idealized to eliminate random variations not related to age. The increase in the 300° peak from age 1.4 days to 60 days could be spurious. The other trends shown in Fig. 6 are qualitatively reliable. Figure 7 compares the observed decrease in length during aging with the observed loss, during aging, of capacity to shrink during annealing. The data for length *vs.* age were obtained by mounting specimen 4A, of length 4.15 cm, in a dial micrometer which could be read with a precision of 5 x 10^{-5} cm. It will be noted that there is a discontinuity at 5 or 6 days, preceded by five points of constant length. We believe that this was caused by sticking of the micrometer, and accordingly are reluctant to place too much reliance on Fig. 7. However, it does provide some indication that the oxygen or water absorbed during aging does not compensate dilatationally for the hydrogen lost during aging.

Some specimens were stored in special atmospheres and weight was followed as a function of time after returning the specimens to the normal atmosphere. Figure 8 shows one set of experiments in which specimens were placed in the special atmospheres at age 4 days and retrieved at some later age as indicated by the dotted lines. Figure 9 shows a second set of experiments in which the beginning of treatment in special atmospheres was at age 46 days. Because of the late start, the experiments in Fig. 9 were made with specimens which had been stored in an evacuated glass capsule from age 4 days to 42 days. With specimen 1E the carbon dioxide atmosphere was provided by storing the specimen in a bottle which was filled by gravity with carbon dioxide and then stoppered; presumably air was also present. In every other case a

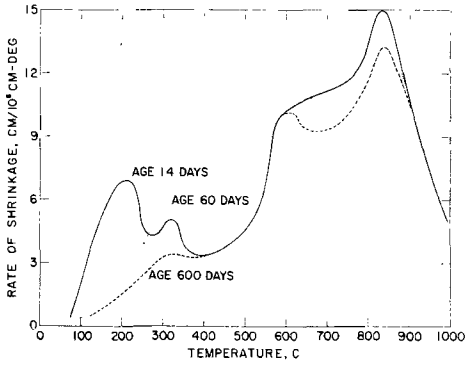

Fig. 6. Effect of age on shrinkage during annealing at 3°/min. Slightly idealized: see text.

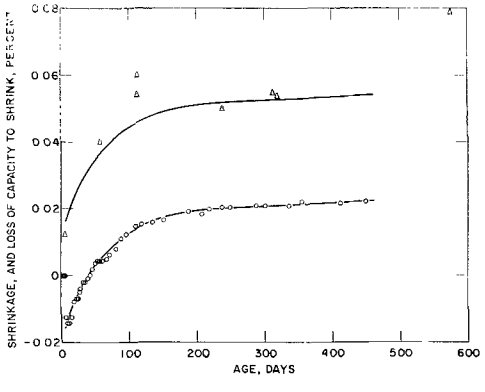

Fig. 7. Effect of age on the length and shrinkage capacity of deposits. Triangles show the loss in linear shrinkage during annealing at 3°/min to 400°, relative to specimen 1J of age 1.4 days. Circles show the loss in length of specimen 4A relative to 1.4 days. The two curves are identical except for vertical displacement.

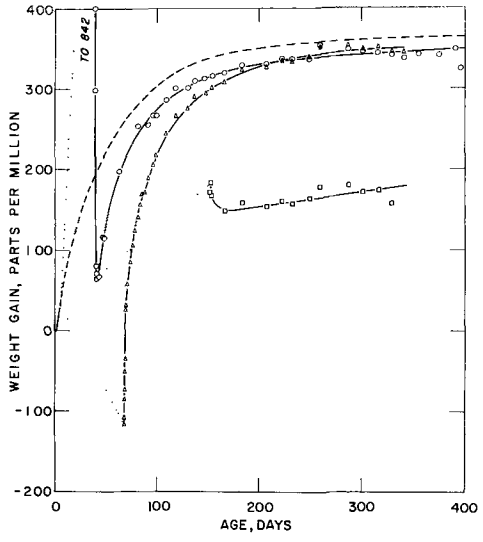

Fig. 8. Effect of storage in special atmospheres on the weight gain relative to age 1.3 days. Specimen 1F (circles) was in pure saturated water vapor from age 4 to 39 days; specimen 2N (triangles) was in an evacuated glass capsule from 4 to 68 days; specimen 1E (squares) was in a mixture of carbon dioxide and air from 4 to 151 days. The dashed line is the curve in Fig. 1. All weighings were corrected for humidity variations.

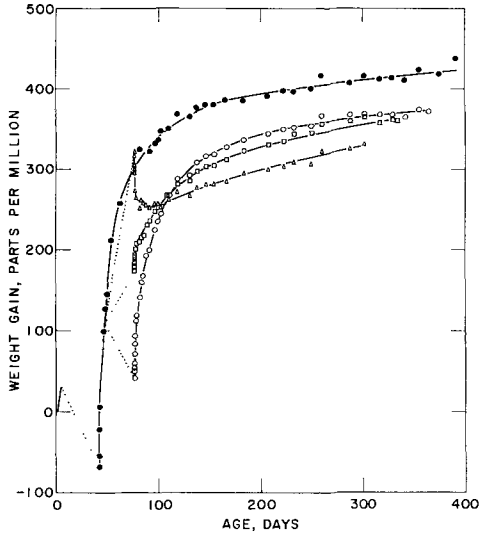

Fig. 9. Effect of storage in special atmospheres on the weight gain relative to age 1.3 days. Up to age 46 days, all four specimens were part of a single piece, which was in an evacuated glass capsule from 4 to 42 days. After the original piece was broken up, specimen 2A (solid circles) was left exposed to normal air; specimen 2K (open circles) was in 0.7 atm pure nitrogen from 46 to 76 days; specimen 2B (squares) was in 0.7 atm pure carbon dioxide from 46 to 76 days; specimen 2L (triangles) was in 0.7 atm pure oxygen from 46 to 76 days. All weighings were corrected for humidity variations.

glass capsule of volume about 100 cc was used, and air was pumped away with a high vacuum system before admitting the special gas and sealing by fusion of a constriction. The duration of pumping before admitting the special atmosphere was 1½ hr for specimens 2B, 2K, and 2L; 17 hr for 2A; and 20 for 2N. Observed weights were corrected for deviation of relative humidity from a standard value by means of the line in Fig. 2. For each specimen the standard value was chosen as the humidity prevailing at the time of opening the capsule, so that no humidity correction would have to be applied to the weight of the freshly retrieved specimen. The use of different standard humidity values for different specimens does not vitiate direct comparison of the curves in Fig. 8 and 9, because each curve is based on a reference weight which was also adjusted to the same standard humidity. The values of the standard humidities were 2L, 25%; 1E, 42; 2B, 25; 2N, 24; 2K, 25; 2A, 30; 1F, 32. The hydrogen content of each specimen was measured immediately after the last weighing shown in Fig. 8 or 9 and is listed in Table I.

The hydrogen content of two specimens was measured after a period of storage in sealed evacuated glass capsules. Specimen 2P was stored from age 4.3 days to 190 days, and its hydrogen content at 190 days was 313 ppm. In addition there was 9 ppm free hydrogen in the capsule. Specimen 1D was stored from 4.2 days to 60.05 days, and at 61.06 days its hydrogen content was 304 ppm.

Discussion

The results with specimens 1D and 2P strongly suggest that the hydrogen loss during aging takes place according to the reaction

$$4H(Cr) + O_2(gas) = 2H_2O(gas) \quad [1]$$

where H(Cr) represents hydrogen dissolved in the metal, presumably stabilized at imperfections or impurity atoms, since the true solubility of hydrogen in chromium is very small (3). Equation [1] is also supported by the experiment in which specimen 2L, after storage in pure dry oxygen, lost weight immediately after being returned to the normal atmosphere, whereas with specimens 2A, 2B, 2K, and 2N there was an initial rapid weight gain, followed in a day or so by a rather abrupt change (not clearly visible in Fig. 8 and 9 because of the small scale) to a slower rate of weight gain. This behavior suggests that the humidity in the capsule containing 2L was higher than that in the laboratory.

That accounts for about half the initial hydrogen content. It is reasonable to assume that the other half is in hydrous form, as a constituent of hydrous oxide inclusions (4). One plausible interpretation of the weight gain during aging and of the shift of hydrogen evolution to higher annealing temperatures as shown in Fig. 4 is based on the hypothesis that some or all of the chromium in the hydrous oxide inclusions is in the divalent state. Then on annealing

$$2CrO + H_2O(oxide) = Cr_2O_3 + H_2(gas) \quad [2]$$

$$2Cr + 3H_2O(oxide) = Cr_2O_3 + 3H_2(gas) \quad [3]$$

and during aging

$$4CrO + O_2(gas) = 2Cr_2O_3 \quad [4]$$

where the symbols CrO and H_2O(oxide) represent constituents of the hydrous oxide inclusions. Reaction [4], which is known to occur at room temperature (5), would account for the weight gain during aging, and perhaps also for the observation that the inclusions become more insoluble in alcoholic bromine as aging proceeds. From Fig. 5, reaction[4] would occur to the extent of 600 ppm oxygen. Thus reaction [2] would occur to the extent of 600 x 4/32 = 75 ppm hydrogen in fresh specimens, but not at all in old specimens. Correspondingly, reaction [3] would increase with aging by 75 ppm hydrogen. This would account for the shift of hydrogen evolution to higher annealing temperatures, as shown in Fig. 4, since reaction [2] is known (6) to occur rapidly in the vicinity of 100°, and reaction [3] probably occurs in the general vicinity of 300° (7). We have been attempting, so far without success, to prepare some hydrous chromous oxide by the method of Lux and Illman, in order to determine its behavior more precisely.

Other possible but less credible interpretations of the aging behavior have been discussed in ref. (2).

A puzzling feature of our results is the effect of carbon dioxide on the weight and hydrogen content of the deposits. The effect is both profound and sensitive to the details of the experimental conditions, perhaps to presence of oxygen or water vapor. These characteristics suggest that further study might prove very instructive. However, because of the difficulty of maintaining a supply of the fresh deposit, we do not at present have any plans for such a study.

Thallium-Activated ZnS Phosphors

A. Wachtel

Research Department, Westinghouse Electric Corporation, Bloomfield, New Jersey

ABSTRACT

Firing of ZnS with Tl_2S + S in sealed tubes results in yellow photoluminescence peaked at 590μ as well as thermoluminescence and infrared-stimulated emission with the same color. In the presence of Cu or Ag, the photoluminescence is red and peaks at 835 mμ. This emission is excited at wavelengths where ZnS:Cu,Cl or ZnS:Ag,Cl, respectively, emit. The thermoluminescence and infrared-stimulated emission, at room temperature, of ZnS:Ag,Tl is yellow; in the case of ZnS:Cu,Tl, the stimulated emission contains yellow and red components.

Recent work in this laboratory has shown that Tl can be incorporated into ZnS. Because of lack of published data on Tl-activated ZnS (1)[1], an attempt was made to correlate the results of the present investigation with data on ZnS:Cu or ZnS:Ag coactivated by Al, Ga, or In (2-7), as well as ZnS activated by In alone (8).

Phosphor Preparation

Thallium salts are known to be quite volatile, and numerous samples of ZnS:Cu,Tl fired at atmospheric pressure indicated at best incomplete incorporation of the added Tl under such firing conditions. Because of the high limit of spectrographic detectability of Tl (100 ppm), it was also considered difficult to obtain accurate analytical data on such phosphors. A more practical approach, therefore, consisted of conducting all firings for 1 hr in sealed, evacuated silica tubes. Additions of Cu or Ag were made from aqueous solutions prior to a preliminary firing in H_2S at atmospheric pressure which, in such cases, is always necessary to enable the proper degassing of the sample during the subsequent evacuation. Quantitative incorporation of the added Tl was not proven, but at least extensive incorporation was assumed on the basis that no separate phase of Tl-sulfide was discernible[2] on the fired phosphors, except after additions as large as 10^{-3} g atoms Tl/mole ZnS. X-ray diffraction analyses showed that both firing temperatures of 950° and 1100°C resulted in essentially cubic phosphors which, moreover, had the same emission spectra. Therefore, the presence of Tl evidently favors the formation of the cubic phase.

All of the phosphors described in this paper were fired in sealed tubes. At this time, it should however be pointed out briefly that, depending on composition and firing schedules, some ZnS:Cu,Tl phosphors fired at atmospheric pressure displayed similar properties. With increasing Cu addition and firing temperature (decreasing Tl retention), green luminescence was obtained, however, without evidence of special properties such as deep traps which could be ascribed to the presence of Tl. For this reason as well as their necessarily uncertain composition,[3] they are not further described until such samples can be duplicated under more controlled conditions.

Results

Table I shows the compositions employed and the visually observed photoluminescence properties. Sample 1 was prepared by firing ZnS with TlCl (in the absence of S) in an effort to obtain Tl^{1+} acceptor centers. This was unsuccessful because the phosphor showed only the characteristics of self-activated

[1] Ballentyne's phosphor (1) was prepared with Tl, but was stated to contain no Tl after firing.

[2] Unavoidable temperature gradients always cause a separate phase with high vapor pressure to segregate in clearly visible form on one side of the tube.

[3] To avoid complete loss of Tl, firing in capped silica tubes was necessary in such cases. This, however, made it impossible to avoid the presence of some oxygen.

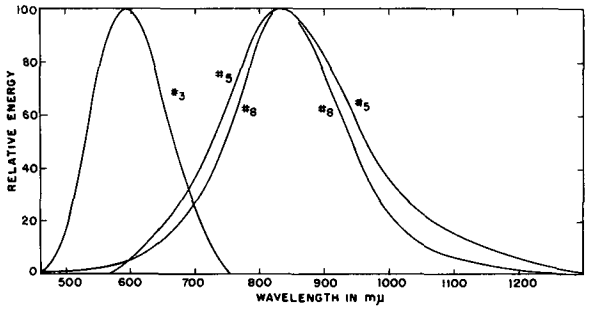

Fig. 1. Room-temperature emission spectra of phosphors. Excitation: 365μ. Perkin-Elmer Model 13-U Spectrometer.

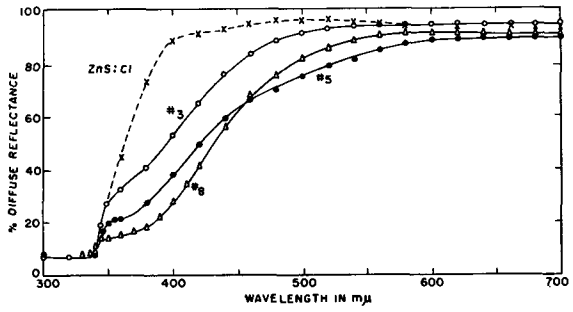

Fig. 3. Diffuse reflectance spectra of Tl-activated phosphors in comparison to ZnS:Cl. Beckman Model DU Spectrophotometer. Measurements relative to MgO.

ZnS:Cl. In all other samples, Tl was added as Tl_2S (absence of Cl) with a small excess of elementary S so as to favor the formation of Tl^{3+} centers. Measurements on sample No. 3 (ZnS:Tl), No. 5 (ZnS:Cu,Tl), and No. 8 (ZnS:Ag,Tl) are shown in Fig. 1 to 4. The numbers in the figures refer to the sample numbers in Table I.

The room temperature emission spectra (Fig. 1) indicate that each phosphor emits a single band. In the case of ZnS:Tl, the emission is peaked at 590 mμ[4] and has a band width of 0.38 ev, *i.e.*, nearly the same as that of the ZnS:Cu,Cl luminescence. The emission bands of ZnS:Cu,Tl and ZnS:Ag,Tl peak at 835 mμ with half widths of 0.43 and 0.33 ev, respectively. The narrower distribution of the latter is made apparent by a deeper red visual appearance of the photoluminescence. The accuracy of the difference between the band widths of the Cu- and the Ag-activated phosphors is questionable because of the low sensitivity of the detector (PbS) which was required to measure the long wavelength emission.

The excitation spectra (Fig. 2) show some interesting features: ZnS:Tl is excited primarily in the fundamental band, and in addition, there is excitation in the neighborhood of 370 and 380 mμ which is the region where excitation of blue ZnS:Cl emission has been noted (9). Excitation of the red emission of ZnS:Cu,Tl and ZnS:Ag,Tl is predominantly in the same bands where ZnS:Cu,Cl and ZnS:Ag,Tl are known to emit. A similar phenomenon has been noted in the excitation spectrum of ZnS:Cu,Li,Ti (10). The diffuse reflectance spectra, as shown in Fig. 3, indicate the presence of absorption in the neighborhood of 370-380 mμ and an additional absorption of the Cu-activated phosphor at longer wavelengths. Despite the poor resolution obtained in this type of measurement, there appears to be general agreement between the observed wavelengths for absorption and excitation. For comparative purposes, Fig. 3 also shows the diffuse reflectance spectrum of a typical blue emitting ZnS:Cl phosphor.

The yellow thermoluminescence of ZnS:Tl is very strong. Its glow curve (Fig. 4) shows two peaks above room temperature which are obtained more clearly by excitation at room temperature (filled points). In contrast, the thermoluminescence of ZnS:Cu,Tl is extremely feeble, and its color could not be observed with certainty. ZnS:Ag,Tl, however, showed a clearly visible yellow thermoluminescence at higher temperatures and in addition, one of the glow peaks (265°K) is also obtained with the Cu-activated phosphor. Unfortunately, agreement of the positions of glow peaks for ZnS:Tl with

[4] By means of sensitive equipment (RCA 7102 photomultiplier), an extremely weak band peaked at 915μ was also observed. This, however, could not be detected with the apparatus used to measure the spectra shown in Fig. 1, and its existence is therefore questionable.

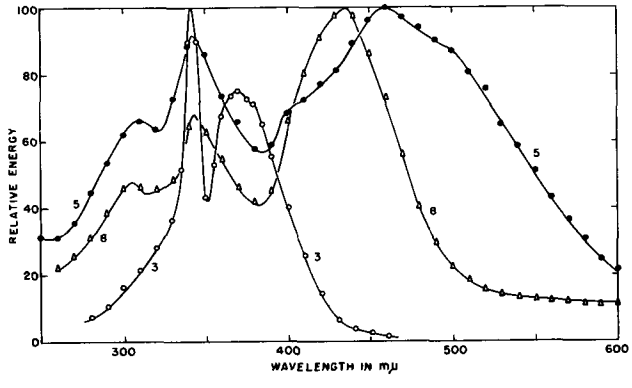

Fig. 2. Excitation spectra, corrected for equal number of quanta of exciting radiation. Thin powder layers, measured on side opposite to excitation. Below 420μ: Xe-lamp and RCA 1P21 photomultiplier. Above 400μ: W-lamp and RCA 7102 photomultiplier. B&L 500 mm Grating Monochromator.

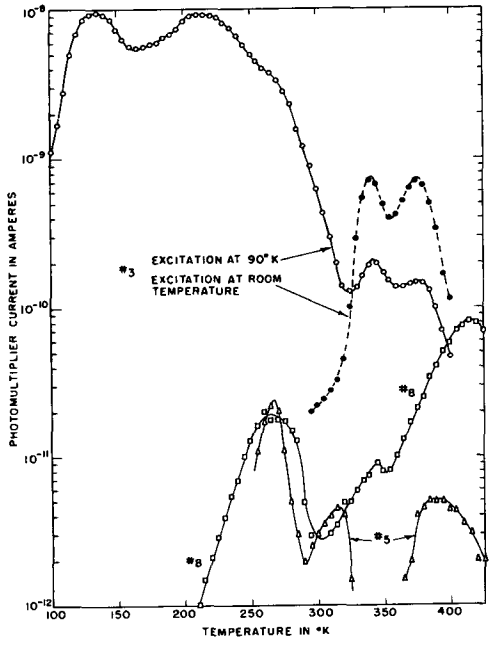

Fig. 4. Glow curves obtained after 365μ excitation and 10 min decay. Detector: RCA 1P22 photomultiplier. Heating rate: 10°/min.

those shown by ZnS:Cu,Tl and ZnS:Ag,Tl is uncertain. The visually observed emission colors, however, seem to be similar for all phosphors.

In this work, only visual observations were taken on infrared-simulated emission (Table I). The source of infrared was an incandescent lamp equipped with a Corning No. 2540 filter. The emission of ZnS:Tl is fairly strong and persistent during infrared irradiation and, at room temperature, of the same color as the ultraviolet-excited fluorescence. This phosphor also shows a persistent yellow phosphorescence. Introduction of 10^{-4} Cu results in decreased yellow and increased red emission, depending on the amount of Tl in the phosphor.[5] The effect of Cu on the emission color is weaker for the stimulated emission than for room temperature photoluminescence. The same holds true for the effect of Tl concentration, as seen in Table I.

Copper also quenches the room temperature phosphorescence and reduces the infrared-stimulated emission to a brief flash. The latter effect seems to differ very slightly for the two emission bands, and consequently, both yellow and red stimulated emission can be discerned side by side. In order to indicate the relative strength of the respective bands, Table I shows only the over-all color impression. It can be seen that it is always less red than that of photoluminescence; if the phosphor is excited simultaneously by ultraviolet and infrared and then the infrared is turned off, a distinct change to a deeper red color can be noted in all ZnS:Cu,Tl samples.

The effect of 10^{-4} Ag on the infrared stimulated emission seems to be less pronounced than that of Cu.[6] The emission is weaker than in ZnS:Tl, but still persistent and appears to contain no red component. The more greenish-yellow color obtained with Ag may be due to a weak blue band whose origin has not been ascertained. It could easily arise from contamination by traces of Cl. ZnS:Ag,Tl also showed no room temperature phosphorescence.

Careful heating of a mixture of CuS and Tl_2S with excess S resulted in a black product whose x-ray diffraction analysis is shown in Table II. The tetragonal structure, $a = 5.58$Å, $c = 11.16$Å ($c/a = 2.0$) is similar to that listed for $CuGaS_2$ (11). The substance is therefore likely to consist of $CuTlS_2$. Continued heating results in loss of S, followed by sublimation of Tl_2S. Therefore, no attempts to prepare phosphors at atmospheric pressure, analogous to ZnS:$CuGaS_2$ (4), seemed worthwhile. Nevertheless, the existence of this compound suggested the possibility of charge compensation of Cu^{1+} by Tl^{3+} in ZnS.

Discussion

Because of the position of Tl in the periodic table, it is tempting to seek an analogy between the present phosphors and the properties of phosphors coactivated by Al, Ga, and In as reported by others. The emission which may be associated with trivalent substituents in Cu-activated phosphors shifts to longer wavelengths with increasing atomic weight of the substituent; therefore, one should expect a further shift in the case of Tl. Figure 1 shows that this is the case. The narrower spectral distribution of the Cu- and Ag-activated phosphor, as compared to that reported for ZnS:Cu,In (7), may be explained by the absence of pronounced subsidiary emission bands such as are clearly shown in measurements reported by Melamed (6).

Table II. X-ray diffraction data for $CuTlS_2$

hkl	CuK_α radiation d (Å)	Intensity
	8.15	5
112	3.22	100
	3.11	3
	3.04	5
004, 200	2.79	15
201, 113	2.72	52
	2.04	4
220, 204	1.973	30
312, 115	1.685	17
224	1.614	5

A further analogy of ZnS:Cu,Tl in comparison to Al, Ga, and In coactivated phosphors may be desirable on the basis of systematically increasing trap depths as reported by Hoogenstraaten (12). Unfortunately in the present system, there is no definite evidence of thermoluminescence either in the long wavelength emission band characteristic for the Cu and Ag activated phosphors, or of green Cu (520μ) or blue Ag (445μ) emission. Therefore, the observed glow peaks may arise from processes which differ from those proposed for Al, Ga, and In coactivated phosphors. The same argument may be advanced with respect to the infrared-simulated emission of ZnS:Ag,Tl. It is felt that conclusions as to the nature of the trapping states in Tl-activated phosphors will require identification of the spectral distributions of thermoluminescence and stimulated emission, as well as measurements of the latter as a function of wavelength of infrared radiation. Further investigations will also be necessary on phosphors prepared with varying amounts of Ag and Cu.

The similarity of the blue luminescence of ZnS:Al and ZnS:Ga (2) with the blue emission band in ZnS:In (8) (470 mμ) suggests that the wavelength for this transition (which is generally associated with a Zn vacancy) is not strongly affected by the atomic weight of the donor. One should therefore expect that "self-activated" emission caused by Tl^{3+} should be similar, which was, however, not observed. The question as to whether the 590 mμ band of ZnS:Tl is caused by transitions proposed either for the 535 mμ band or the 620 mμ band in ZnS:In (8) is much more difficult. At this time, it is felt that the large polarizability of Tl, as well as its ability to exist in an additional (monovalent) state, adds to the complexity of this system.

Summary

The important results obtained in this investigation are: (*A*) The 590 mμ emission of ZnS:Tl which is also visually observed (although not identified) in thermoluminescence and infrared-stimulated

[5] No samples with Cu additions other than 10^{-4} were prepared.

[6] The comparison can be made only with ZnS:10^{-4} Cu, 10^{-4} Tl (sample No. 5). No ZnS:Ag phosphors with more than 10^{-4} Tl were prepared, and the possibility of stimulated red emission in such samples must be left open.

emission of the Cu and Ag activated phosphors. (*B*) The 835 mμ emission which is shown in the photoluminescence of the Cu- or Ag-activated phosphors, while at least in the case of Ag, it does not seem to appear during thermoluminescence of infrared-stimulated emission. (*C*) The fact that the 835 mμ luminescence of the Cu and Ag activated phosphors is at least nearly identical. (*D*) The fact the excitation spectra of the Cu- and Ag-activated phosphors are different and correspond to the emission bands of ZnS:Cu,Cl and ZnS:Ag,Cl, respectively. At present, no mechanism can be proposed to explain all of these observations.

Acknowledgments

The Effect of Li and Ti on ZnS:Cu and ZnS:Ag Phosphors

A. Wachtel

Research Department, Westinghouse Electric Corporation, Bloomfield, New Jersey

ABSTRACT

ZnS:Cu,Li fired in H_2S or H_2 shows blue and green photoluminescence peaked at 443 and 510 mμ, respectively. Addition of Ti quenches this emission and causes red and infrared emission peaked at 730 and 830 mμ, respectively. Infrared radiation stimulates the red emission and also quenches the blue and green bands. ZnS:Ag,Li,Ti emits in the orange with a band peaked at 640 mμ and an infrared band peaked at 810 mμ. In the absence of Ti, ZnS:Ag,Li shows properties essentially similar to those of ZnS:Cu,Li, except for a weak orange-yellow infrared-stimulated emission.

Kröger (1) has shown that Li or Na can form activator centers in ZnS, provided that Cl is present. If the concentration of Cl is decreased sufficiently, the presence of Li then quenches the self-activated (blue) photoluminescence which can otherwise be observed. Recent work in this laboratory has shown that, in the presence of Cu and Li, blue and green photoluminescence is obtained even in the absence of halides. If the phosphor has been fired in H_2S or H_2 (preferably at 1100°C), it also shows a deep red photoluminescence which can be stimulated by infrared radiation either during or after excitation by 365 mμ u.v. (ultraviolet). At the same time, the blue and green emission is quenched. Spectrographic analyses of specimens with more pronounced red emission indicated the presence of Ti which was therefore investigated in more detail.

Phosphor Preparation

The samples were prepared in 10-g lots, fired in small open silica tubes in a current of purified H_2S at 1100°C for 1 hr. The raw materials were ZnS (RCA LM476) and solutions of $Cu(C_2H_3O_2)_2 \cdot H_2O$ or $AgNO_3$, $LiHCO_2 \cdot H_2O$, and Ti $[(CH_3)_2CHO]_4$, hydrolyzed in $(CO_2H)_2$ solution. The activator additions were kept at 3 x 10^{-5} g-atoms Cu or Ag, and 10^{-3} g-atoms Li per mole ZnS.[1] Owing to volatility, the concentration of Li in the fired phosphors was probably much lower, but was not determined. Any free Li_2S formed during the firing in H_2S was removed by washing in dilute acetic acid.

Results

Figure 1 shows room-temperature 365 mμ-excited emission spectra of phosphors prepared with or

[1] Preliminary experiments indicated that for red emission, the optimum Cu concentration is between 1 and 3 × 10^{-5}. The higher concentration was chosen in order to minimize the effect of any unwanted contaminations. The effect of Li addition was less marked; the amount chosen is nominal.

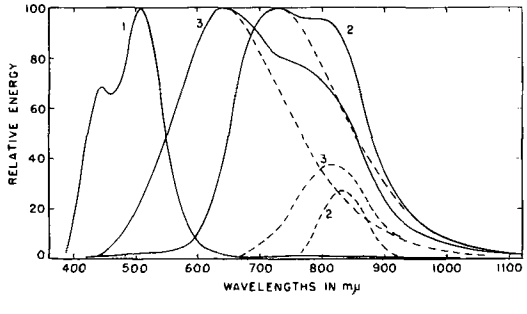

Fig. 1. 365 mμ-excited emission spectra of 1, ZnS:Cu,Li and Zns:Ag,Li; 2, ZnS:Cu,Li, 10^{-5} Ti; 3, ZnS:Ag,Li, 10^{-5} Ti. Perkins-Elmer Model 13-U Spectrometer.

without additions of 10^{-5} Ti. It should be noted that, except for intensity,[2] the spectral distributions of the blue and green emission bands of ZnS:Cu,Li and ZnS:Ag,Li were identical. Only in the presence of Ti did the Ag-activated phosphor show a different emission spectrum, the visual impression of this being orange. Moreover, the same blue and green emission bands remained unchanged in phosphors prepared with the addition of 3 x 10^{-5} Al (as well as Li). Therefore, the possibility that they are due to coactivation by Al (spectrographically detectable in the ZnS raw material) cannot be ruled out. On the other hand, the blue-green emission in ZnS:Cu,Na and ZnS:Cu,K as well as in ZnS:Cu (presumably caused by Al contamination) was much weaker. Samples prepared without Cu or Ag were nonluminescent.

The identity of the emission spectra of ZnS:Cu,Li and ZnS:Ag,Li suggests that the latter emits only by virtue of traces of Cu whose presence can rarely be avoided. This does not explain the absence of a distinct blue band in ZnS:Ag,Li (*i.e.*, different from that of the Cu-activated phosphor), even when fired with additional Al. The absence of any luminescence of ZnS fired only with Li also indicates that no significant contamination by Cu was likely. On the other hand, ZnS fired with Li and 1 x 10^{-6} Cu showed not only weak blue-green photoluminescence, but also a very weak orange (rather than red) IR-stimulated flash, similar to that observed on the 3 x 10^{-5} Ag-activated phosphor.

The excitation spectra for the blue-green emission of ZnS:Cu,Li and ZnS:Ag,Li (Fig. 2 filled points) show the same similarity, except for the shift of the short wavelength band of ZnS:Ag,Li to 325 mμ, corresponding to an energy appreciably more than the band gap of ZnS. No such discrepancy can be noted in the diffuse reflectance spectra as shown in Fig. 3. In all other cases, the fundamental excitation band (peaked at 338 mμ) is shown quite clearly. In the u.v., no additional band due to Ti (long wavelength emission, open points) can be observed; for the most part, the excitation bands for short and for long wavelength emission differ only in relative height. In the visible region, the excitation bands for the red and infrared emission of ZnS:Cu,Li,Ti (open circles) are conspicuous inasmuch as they appear to match the two emission bands (blue and green) of the same phosphor prepared without Ti. To facilitate this comparison, the emission spectrum of ZnS:Cu,Li (from Fig. 1) is reproduced in Fig. 2, dashed line. A similar effect was also noted with ZnS:Cu,Tl and ZnS:Ag,Tl phosphors (2). In the case of the orange and infrared emission of ZnS:Ag,Li,Ti (open triangles), the excitation peak at 415μ cannot be similarly correlated; the concept that it may correspond to a hypothetical distinct blue emission of ZnS:Ag,Li (which was not obtained experimentally) is too speculative to be of serious concern.

The pronounced influence of variations of the concentration of Ti on the blue-green and red photoluminescence of ZnS:Cu,Li,Ti is illustrated in Fig. 4. Addition of 1 x 10^{-6} Ti decreases the blue-green photoluminescence by a factor of 16. The increase in red emission obtained between the additions of zero and 1 x 10^{-6} is indeterminate because of the questionable validity of the point corresponding to "zero Ti", excited without infrared. The par-

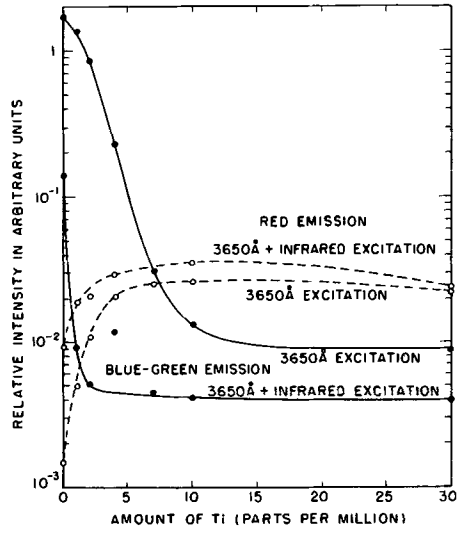

Fig. 4. Relative intensity of 365 mμ-excited photoluminescence of ZnS:Cu,Li,Ti as a function of Ti addition. Infrared obtained by W-lamp with Corning No. 2540 Filter. Measurements with Spectra Brightness Spot meter set on "Blue" and on "Open" with Corning No. 2030 Filter.

[2] The quantum yields under 365 mμ excitation of ZnS:Cu,Li, ZnS:Ag,Li, ZnS:Cu,Li,10^{-5} Ti, and ZnS:Ag,Li,10^{-5} Ti were measured to be 48, 29, 56, and 34%, respectively, of that obtained with ZnS:3 x 10^{-5} Cu,Cl.

ticular sample[3] on which it was measured is the same whose emission spectrum (Fig. 1) shows only a very weak long wavelength band.[4] Therefore, the measured value may incorporate a contribution from the long wavelength tail of the green band. The red flash which can be stimulated by infrared after u.v. excitation of this phosphor is, however, strong and unmistakable. Nevertheless, it is still an open question as to whether this is due to spectrographically undetectable traces of Ti, or an intrinsic property of ZnS:Cu,Li. In connection with Fig. 4, it may be mentioned that phosphors with higher Ti additions were also prepared. It was interesting to observe that with as little as 1 x 10^{-4} Ti, the red emission was appreciably quenched; at higher concentrations, it became very weak. Inasmuch as the same was observed with respect to Cu addition, this seems to be a system requiring unusually low activator concentrations.

Figure 5 shows the 365 mμ-excited intensities of blue-green and red emission of ZnS:Cu,Li as a function of wavelength of infrared radiation simultaneously incident on the phosphor plaque. All points represent differences between the measured intensities with and without u.v. excitation. The latter represents stray light from the monochromator (used as source of infrared) whose intensity was usually equal to or greater than that of the red radiation (open circles) to be measured. These points, therefore, show considerable scatter. Below 830 mμ, the reflected primary radiation from the monochromator dominated, and no meaningful differences could be obtained. In the case of ZnS:Ag,Li, no long wavelength emission could be measured. For blue-green emission, it can be seen that the dependence of the intensity on infrared wavelength shows considerable differences for the Cu- and Ag-activated phosphors.

An attempt was made to determine the influence of Ti by performing similar measurements on ZnS:Cu,Li,4 x 10^{-6} Ti (blue-green emission weak but still measurable). The results (inverted triangles, dashed curves) show that the quenching of blue-green emission (filled points) is shifted from 1150 to 1300 mμ, and that the red emission (open points) is stimulated at all wavelengths below 1700 mμ. Especially toward shorter infrared wavelengths, the interference from stray radiation was considerable, and no attempt was made to extend the curve into that region.

The glow curves or blue-green and red or orange emission are shown in Fig. 6 and 7, respectively. In the case of ZnS:Cu,Li and ZnS:Cu,Li,Ti, excitation was performed not only at 90°K[5] (open circles), but also at room temperature, followed by continued excitation during cooling (filled circles). In the latter case, one usually observes an intensification of the

[3] A selected sample with minimum infrared-stimulated red emission.

[4] The red bands became pronounced at 4 × 10^{-6} Ti. With 7 × 10^{-6} Ti, the peak heights of the green and red bands were equal.

[5] The lowest temperature obtainable with the equipment.

higher temperature glow peaks, as reported by Garlick and Mason for CaS:Bi (3). The present results show this effect especially for the 275°K peak for ZnS:Cu,Li (Fig. 6). This method of excitation of the same phosphor also prevents all red thermoluminescence below room temperature (Fig. 7), although the excitation was continued down to 90°K.

Except for intensity, the glow curve for blue-green emission of ZnS:Ag,Li does not significantly differ from that of ZnS: Cu, Li. The orange thermoluminescence of ZnS: Ag, Li, Ti (Fig. 7) is, however, distinct from the red thermoluminescence of the Cu-activated phosphors.

Particular attention should be drawn to the effect of Al on the glow curve of blue-green emission of ZnS:Cu,Li. It was mentioned earlier that 3×10^{-5} Al had no influence on the emission spectrum of this system. A critical comparison of the glow curve for ZnS:Cu,Li,Al shown in Fig. 6 with that of red emission of ZnS:Cu,Li (or ZnS:Cu,Li,Ti) in Fig. 7 shows that the two characteristic red glow peaks at 217° and 265°K seem to be reproduced, but now represent the short wavelength radiation.

Discussion

The complex nature of the system precludes definite conclusions as to the nature of the activator centers responsible for the phenomena observed. In order to avoid further complications at this time, no attempt has been made to differentiate between the blue and the green emission bands separately, although such investigations have proven to be fruitful in the case of single crystals of ZnS:Cu,Cl (4). Similarly, the infrared emission bands were not detected in the measurements described in Fig. 4 to 7. Therefore, one can only summarize those data which tend to suggest the occurrence of certain processes.

Regardless of which model for the blue and green emission of Cu in ZnS one wishes to accept, the presence of such emission requires the concept of some donor which is capable of compensating the single charge produced by Cu at a Zn site. In the present system, the only possibility seems to be interstitial Li. To support this, it may be pointed out that the sizes of the alkali metal ions are such that Li (strong emission observed), but not Na or K (little emission observed) can enter ZnS interstitially. The Cu-Li emission bands are displaced slightly to shorter wavelengths with respect to accepted values for hex. ZnS:Cu,Cl (5); the difference possibly arises from the influence of the different coactivator. Any simple analogy of this nature fails, however, because of the identical emission spectra observed in Cu-Li and Ag-Li activated phosphors.

Figure 5 shows that the infrared wavelength for maximum quenching of blue-green emission of ZnS:Cu,Li,Ti agrees with the value of 1300 mμ reported by Melamed for ZnS:Cu,Co (6). In the absence of Ti, there is, however, no agreement. Substitution of Cu by Ag causes a shift of one of the bands to longer wavelengths. It can probably be assumed that the mechanism of quenching involves electron capture, from the valence band, by ionized acceptor centers and the creation of a hole in the valence band (7). Inasmuch as the infrared band causing the quenching also stimulates the red emission, the latter evidently depends on the presence of such holes. Among different models which may be proposed, there seems to be none which satisfactorily explains all of the observed phenomena. The fact that the orange ZnS:Ag,Li,Ti emission band peaks at a shorter wavelength than the red ZnS:Cu,Li,Ti band suggests that the long wavelength transitions may occur from the conduction band to ionized Cu or Ag centers which, in association with Li or Ti, would have to occupy positions only 1.6 to 1.9 ev below the conduction band. If one wishes to avoid the concept of acceptor levels in those positions, transitions from highly associated donor levels may be visualized, such as proposed by Apple and Williams for the long wavelength emission in Ga- and In-activated phosphors (8).

It has been shown that in the absence of infrared radiation, efficient red emission depends on small but appreciable concentrations of Ti. The firing conditions (H_2S or H_2) suggest that Ti may be present in trivalent form and therefore acts as a donor, although not independently, *i.e.*, in the absence of Li. Accordingly, it should have no influence on the excitation spectra, as was observed. The shape of the glow curves shown in Fig. 7 indicates that red thermoluminescence originates from sites whose position is quite independent of Ti concentration[6] and may therefore not be associated with Ti. On the other hand, the lack of red thermoluminescence, below room temperature, of ZnS:Cu,Li after room temperature excitation, suggests that the number of electrons available for trapping at these sites was limited, evidently by lack of Ti. The concept of Ti as an auxiliary donor is involved and certainly requires further experimental evidence. Nevertheless, the fact that under simultaneous u.v. and i.r. excitation, the red emission of ZnS:Cu,Li was only 4 times smaller than the maximum obtained with Ti (see Fig. 4) indicates that Ti is not directly involved in this process. Qualitatively, its action rather resembles that of infrared radiation, *i.e.*, it facilitates the thermal filling of acceptor levels from the valence band. The mechanism by which this occurs has not been ascertained.

Fabrication and Characteristics of Phosphorous-Diffused Silicon Solar Cells

J. Mandelkorn, C. McAfee, J. Kesperis, L. Schwartz, and W. Pharo

United States Army Signal Research and Development Laboratory, Fort Monmouth, New Jersey

ABSTRACT

Results of an experimental study of fabrication processes for making phosphorous-diffused silicon solar cells are presented. Solar cells having sheet resistance of 10 ohm/sq, high long-wavelength collection efficiency, and efficiencies above 10% were fabricated by diffusion at 975°C. Diffusions carried out at 875°C for ½ to 1 hr periods resulted in cells having high short- and long-wavelength collection efficiency. Gridded contacts applied to such cells to minimize effects of their comparatively high sheet resistance raised the efficiencies of the cells to values above 10%. Phosphorous-diffused cells in general have superior radiation resistance as compared to boron-diffused cells because of the slower rate of degradation of lifetime of minority carriers in p-type silicon as compared to n-type silicon under bombardment by atomic particles. The high short-wavelength collection efficiency of the 875°C diffused cells results in increased radiation resistance of these cells. Cells having efficiencies above 10% were made from 13-ohm-cm material and found to have higher radiation resistance than cells made from 1-ohm-cm material. Low junction reverse currents and contact resistances of approximately 0.2 ohm have also been achieved.

Until recently commercial silicon solar cells have been made by diffusion of boron into n-type silicon having a resistivity of 0.5 to 1 ohm-cm. Industrial efforts to improve the efficiencies and spectral response of silicon solar cells were concentrated on modification of boron-diffusion processes. A possibility completely overlooked was that phosphorous diffusion could be more successfully adapted to the creation of better solar cells.

The purpose of this paper is to present the results of a 2-yr study of phosphorous-diffused solar cells. The information will be presented in two sections. The first part deals with the diffusion conditions and processing methods that were found to yield phosphorus cells having desirable characteristics. The second part discusses the results obtained and the interrelationship of fabrication processes and solar-cell characteristics. The various characteristics considered are: (*a*) forward current-voltage behavior of the solar-cell diode, (*b*) contact resistance, (c) junction reverse current, (*d*) collection efficiency, (*e*) radiation resistance, and (*f*) temperature behavior.

Experimental

Material preparation.—Single-crystal silicon ingots were grown from transistor grade material, using the Czochralski technique, a necked down seed (1), a rotation rate of 14 rpm, and a pull rate of 4 in./hr. The melt was doped with a master boron-silicon alloy to produce p-type ingots with selected resistivities in the 0.2 to 40-ohm-cm range. Etch pit counts using the Dash etch (2) gave counts below 1000/cm^2 on wafers cut from several ingots. Typical counts were less than 100/cm^2.

Wafers cut from ingots were lapped with No. 1000 silicon-carbide abrasive in a planetary lapping machine and then given a finish lap with No. 3000 aluminum-oxide abrasive. After the wafers were thoroughly degreased and cleaned ultrasonically in organic solvents and distilled water, they were given a 5-min etch in a solution consisting of 20:12:2 parts of acetic acid, nitric acid, and hydrofluoric acid, respectively. Etching time was not found to be critical; however, prolonged etching (greater than 10 min) resulted in poor adhesion of subsequently plated nickel contacts to the surface of the wafers.

Diffusion.—After the wafers were etched, they were rinsed in distilled water, dried, and laid flat on a quartz-slab diffusion boat. The boat was inserted into a high-temperature zone of a laboratory-designed two-zone diffusion furnace, shown in Fig. 1. Dry oxygen, used as a carrier gas, was passed through the quartz diffusion tube at a flow rate of approximately 40 cc/sec. The constancy of wafer boat thermocouple readings indicated that the boat had reached temperature equilibrium. Following the attainment of equilibrium, a hollow quartz boat containing phosphorus pentoxide was moved forward in the source zone to a point that had been precalibrated for a temperature of 220°C. The phosphorous pent-

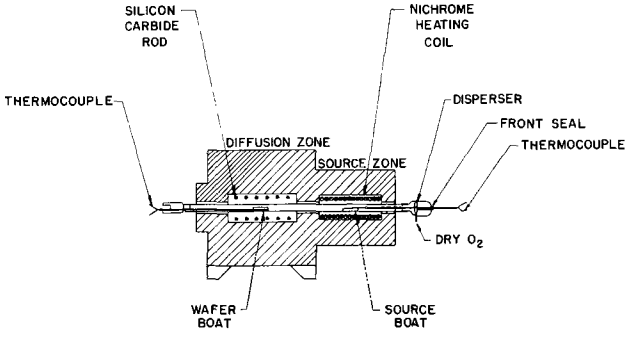

Fig. 1. Phosphorous-diffusion furnace

oxide vapors formed were transported to the diffusion zone by the carrier gas.

The establishment of a proper flow pattern of carrier gas and the degree of dryness of the carrier gas is critical. A silica-gel drying tube followed by two liquid-air traps removed water vapor from the carrier gas. The diffusion tube was sealed at its front end to prevent the entry of water vapor from the external environment. The diffusion process was terminated by withdrawal of the source boat and shutoff of power to the furnace. Carrier-gas flow was continued until the source vapors were removed from the system. The wafers were withdrawn from the furnace after they had cooled to a temperature of 600°C or less.

The process incorporates the following features that establish a flow pattern, yielding solar cells with very good junction characteristics: (*a*) the sequence of introduction of wafers, source vapors, and carrier-gas flow; (*b*) use of a moderate source temperature and a slow rate of carrier-gas flow; (*c*) a special fritted glass carrier-gas disperser, as shown in Fig. 1.

Application of contacts.—When the diffusion process was completed, the bottom surfaces of the wafers (those in contact with the quartz slab) were marked with acid-resistant paint. The surface layers formed on the wafers were removed by a 5-min soak in hydrofluoric acid, a 5-min treatment in boiling aqua regia, and a 1-min cleanup in hydrofluoric acid. The resultant surfaces were clean, without any traces of foreign films or discolorations, and presented a satin-smooth gray appearance.

A photoresist pattern was applied to mask the top surface. Nickel was plated in the form of a thin grid pattern with one wide stripe on the unmasked regions of the wafer by use of the electroless nickel-plating method (3). The bottom surface of the wafer was lapped to remove the nickel plating. The photoresist mask was removed from the top surface and Divco No. 335 Liquid Flux[1] brushed over the nickel-plated pattern on the top surface. The nickel-plated pattern was then covered with solder by dipping the wafer into a molten solder bath. The bottom of the wafer was lapped with No. 600 silicon-carbide abrasive and plated electrolytically with rhodium. Plating-current densities of 3-5 ma/cm^2 have yielded adherent low-resistance contacts.

Edge and surface finish.—The final fabrication steps consisted of dry-lapping the periphery of the wafers, using No. 600 silicon-carbide paper on a belt sander, and applying crystal-clear Krylon[2] over the active top surface to form an antireflective coating. The completed solar-cell structure is shown in Fig. 2.

Results

Diffusion.—A polished "control" wafer was diffused in each run to determine junction depths and sheet resistances. Junction depths were measured by angle lap and stain techniques (4). The estimated error of measurement is $\pm 0.1\mu$. Sheet resistances were calculated from 4-point probe measurements applying appropriate correction factors. Table I presents data typical of the results obtained using various diffusion temperatures and time periods for material of different resistivities.

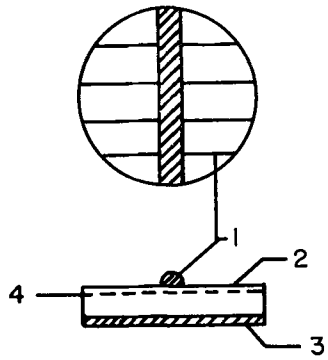

Fig. 2. Phosphorous solar-cell structure, active surface Krylon coated: 1, nickel plate, solder dip contact; 2, diffused layer-phosphorus; 3, contact-rhodium plate; 4, junction, 0.6μ deep.

No significant variation in junction depth with resistivity of material for equal temperatures and time periods of diffusion was detected. Sheet resistances for equal junction depths were found to depend primarily on carrier-gas flow pattern for investigated rates of flow between 10 cc and 40 cc/sec. Turbulent flow patterns introduced wide variation in sheet resistances of wafers diffused in the same run. Turbulence was decreased by use of a slower rate of carrier-gas flow, and better junctions were obtained. However, a flow rate of 40 cc/sec was necessary to achieve sheet resistances of less than 50 ohm/sq for 875°C ½-hr diffusions. The upper limit of 50 ohm/sq of sheet resistance was set by imposing a minimum efficiency requirement of 10% for cells made by the process. The 10 ohm/sq sheet resistance of 975°C diffused cells was sufficiently low to permit attainment of efficiencies above 10% without the use of gridded contacts. However, cells made by 875°C diffusion having sheet resistances above 50 ohm/sq were found to be limited to efficiencies below 10% even with the use of gridded contacts.

Calculations of surface concentrations were not made because of the anomalous characteristics of shallow phosphorous-diffused layers noted in this investigation and by other investigators (5).

Forward-diode characteristic.—The "n" value measurement is a nonconventional solar-cell measurement applied very successfully in this investigation to monitor diffusion processes. The n value as given in the modified ideal diode equation, $I = I_o(e^{qV/nkT} - 1)$, was determined from the slope of the log I *vs.* V plot of the solar-cell diode in the re-

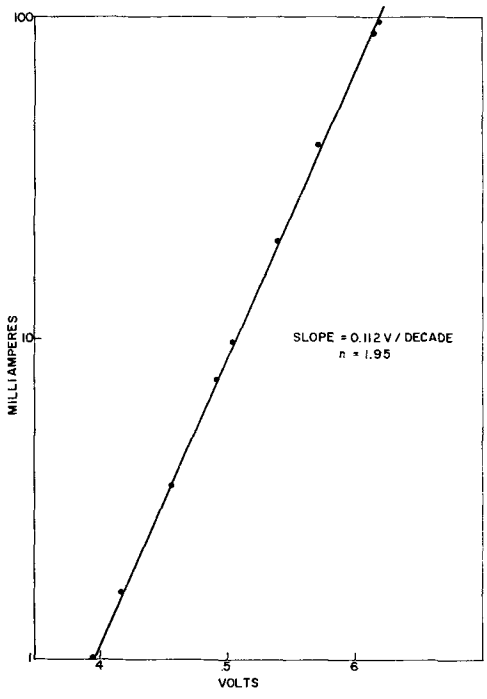

Fig. 3. Typical cell forward characteristic with n value below 2

gion of 1-100 ma of forward current. A typical n value characteristic showing a constant value of n over two decades of current is shown in Fig. 3.

The n value was found to be extremely fabrication dependent and a sensitive parameter for optimizing fabrication processes and controlling them. By the use of the process described, n values below 2 were normally obtained. High n values or increases in n value of cells made in particular runs have been related to the presence of excess water vapor during diffusion or turbulent flow patterns of carrier gas. The n value is directly related to junction reverse current and influences the open-circuit voltage and solar-cell junction impedance (6). Values of n of commercial boron cells and of boron cells made in this investigation (7) are generally well above 2. Often n values cannot be specified for boron-diffused cells because of the nonlinear relationship of log *I vs V* of such cells. The fact that the n value is fabrication dependent was further substantiated by the measurement of three selected boron-diffused cells that had n values below 2 and efficiencies in the range of 13 to 14.5%.

Contact resistance.—The slope of the solar-cell diode characteristic in the range of forward currents of 300-400 ma determines what is commonly referred to as the limiting diode forward resistance (LDFR). The LDFR depends primarily on contact resistance. This measurement was used in the investigation to determine the effects of various plating conditions and surface preparations on contact resistance. Typical values of LDFR presently obtained are in the 0.2-ohm range and this compares with values in the 1-ohm range common to commercial cells.

Instrumentation.—Monitoring of n value, LDFR, and junction reverse current was carried out rapidly by displaying "dark" cell voltage-current curves on the calibrated oscilloscope face of the Tektronix-575 Transistor Curve Tracer. Display of the illuminated solar-cell characteristic curve on the same instrument permitted rapid visual measurement of open-circuit voltage, short-circuit current, and comparative sheet resistance. Precise measurements of voltages and currents with a potentiometer and precision decade resistance box showed that the values obtained from oscilloscope readings are sufficiently accurate for evaluation of cell characteristics.

Where measurements in sunlight are indicated, these were made using a double-barrel narrow aperture system especially designed by the Eppley Laboratories for solar-cell measurements. The solar cell was mounted in one barrel while the incident radiation was monitored by a temperature-compensated thermopile in the other barrel. The system was mounted on an equatorial mount for tracking the sun.

Junction reverse current.—Dark cell reverse currents were measured for 0.6-v reverse bias. Reverse currents of 10-30 μa were commonly obtained. The only periphery treatment given the cells was dry belt sanding. The low junction reverse currents of these cells represent better than an order of magnitude improvement as compared to typical commercial boron-diffused cells and boron cells made in the investigation (7). The three selected boron cells previously mentioned had junction reverse currents of 10-20 μa.

Collection efficiency.—The ability of the process to preserve high values of lifetime in the base region of solar cells is evident from comparison of the integrated long-wavelength collection of the cells, as shown in Table II.

Table II gives the values of short-circuit current/cm^2, I_{sc}/cm^2, obtained by illuminating cells with light passed through a long-wavelength pass filter having a cutoff at 0.65μ. Under these conditions, hole-electron pairs were generated in the base well below the junction, and the integrated collection was an indication of lifetime of minority carriers in the base.

The equivalent collection values obtained for 975° and 875°C diffusions into material of the same resistivity indicated that the process preserved base lifetime equally well for both diffusion temperatures. The more than 10% higher collection obtained for the 13-ohm-cm cells represents a considerable difference in the lifetime in the base of these cells as compared to the lifetime in the base of the high-efficiency 1-ohm-cm cells. The reason for this is that collection

increases slowly with increasing base lifetime for values of lifetime above 1 μsec.

Measurements of diffusion lengths of minority carriers generated in the base by electron bombardment revealed that lifetimes of 10-15 μsec were preserved in the 13-ohm-cm cells, whereas the lifetimes in the 1-ohm-cm cells were 3-5 μsec (8).

Although high long-wavelength collection can be achieved with diffusion temperatures of 975° or 875°C, high short-wavelength collection has only been obtained by 875°C diffusion. This is shown by the plots of relative collection efficiency *vs.* wavelength in Fig. 4. The curves are shown for cells having equal junction depths, and the only difference in fabrication is that the cells with the high "blue" collection were made by an 875°C diffusion. The curve for the 975°C cell (Fig. 4) is similar to that obtained for boron cells having "good blue" collection. High "blue" collection can also be obtained for comparatively deep junction depths (1-hr diffusion at 875°C), as shown in Fig. 5. Measurements of collection efficiency *vs.* wavelength of the USASRDL cells were made at several industrial laboratories, and the results agree with those presented here.

Phosphorous cells Krylon coated; boron cells boron-diffusion coated.

The effects of high base lifetime and high "blue" collection on the short-circuit current of cells are shown in Table III.

Analysis of the data shows that an increase in short-circuit current per sq cm, I_{sc}/cm^2, of approximately 15% was obtained from the improved short-wavelength collection of 875°C diffused cells. An additional increase of 10% in I_{sc}/cm^2 was obtained from the higher long-wavelength collection of the high base lifetime 13-ohm-cm cells. The net increase results in values of I_{sc}/cm^2 of 13-ohm-cm 875°C cells above that obtained for a selected 14.5% boron-diffused cell. The referenced boron cell was the highest efficiency cell ever measured at this Laboratory.

The phosphorous-diffused cells were coated with Krylon, as indicated in Fig. 2. Cells of this type were sent to several industrial laboratories for application of more effective antireflective coatings. The short-circuit currents of the cells after coating with silicon monoxide were 8-10% higher than those obtained with Krylon coatings. The percentage increase in short-circuit current obtained by application of coatings, using the uncoated cell short-circuit current as a reference, is 15-20% for Krylon coatings and 30% for optimized silicon-monoxide coatings.

The efficiencies of the 13-ohm-cm cells were limited by sheet resistance and comparatively lower open-circuit voltages because of Fermi-level considerations. However, the very high short-circuit currents and low n values of these cells decreased their junction impedance, as shown in Fig. 6. The junction impedance is defined as $r_j = dV/dI$ under constant illumination.

Eleven per cent efficiencies were obtained for Krylon-coated high-resistivity cells (Table IV).

Application of optimum antireflective coatings should raise the short-circuit current of the cells by 8-10% and increase the efficiencies. Cells similar in characteristics to those shown in Table IV were made using 10-ohm-cm and 40-ohm-cm material.

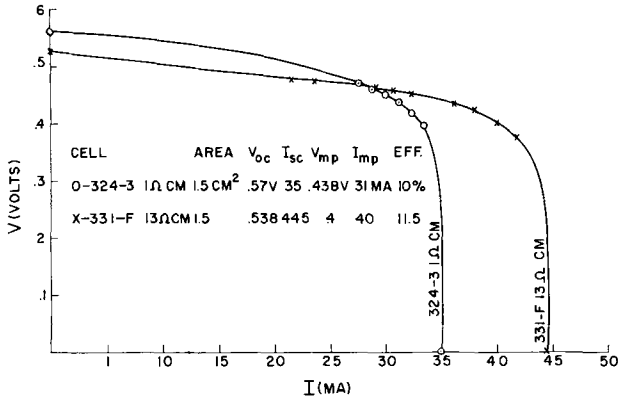

Fig. 6. Output characteristics of a 13 ohm-cm and a 1 ohm-cm cell.

Table V compares the characteristic "limits" of cells made in this investigation from material of several different resistivities.

It is difficult to obtain n values in the range of 2 and high open-circuit voltages in solar cells made from highly doped material. As shown in Table V, both open-circuit voltages and short-circuit currents are comparatively low for cells made from 0.2-ohm-cm material. The listed characteristics of the 1-ohm-cm base cells are similar to those of boron-diffused cells with the exception of the limiting diode forward resistance.

The high short-circuit currents obtained for cells made from high-resistivity material was a result of the high base lifetime and high short-wavelength collection of these cells.

Radiation resistance.—Analysis of collection efficiency *vs.* wavelength curves of solar cells before and after atomic bombardment revealed that the lifetime of minority carriers decreased more slowly in the p-type base material of phosphorous cells than in the n-type base material of boron cells (9-13). Direct measurement of base diffusion length degradation as a function of atomic bombardment was carried out for electron and proton bombardment over a wide range of bombarding particle energies (8). The collected data show that the phosphorous-diffused cell has superior radiation resistance compared to the boron-diffused cell.

Table V. Characteristics vs. resistivity of base material for typical solar cells

Resistivity, ohm-cm	V_{oc}, v	I_{sc}, ma/cm²	LDFR, ohm	Efficiency, %
0.2	<0.56	<22	0.2	<10
1	<0.60	<26	0.2	10-12
13	<0.55	<31	0.2	10-12

All cells measured in sunlight (intensity 88 mw/cm²).

The comparative radiation resistance of cells is also dependent on the short-wavelength collection efficiency. This dependency becomes stronger with increasing integrated bombardment flux. Measurements of absolute collection efficiency *vs.* wavelength showed that after bombardment which reduced the total "sunlight" short-circuit current of cells to 75% of their initial value, the collection at short wavelengths (0.6μ or less) had decreased by less than 5%. Figure 7 illustrates this effect for very heavy bombardment. Since approximately one-third of the short-circuit current of the 875°C phosphorous-diffused cells is obtained from short-wavelength collection, these cells have improved radiation resistance.

Further improvement in radiation resistance was obtained by fabricating cells with high-resistivity base material using 875°C diffusions. Table VI compares the short-circuit current degradation of cells in relation to diffusion temperature and base resistivity.

Although only small quantities of high-efficiency high-resistivity cells were subjected to bombard-

ment, it is significant that good consistency in results was obtained.

Temperature behavior.—The changes in open-circuit voltage, short-circuit current, and efficiency of phosphorous solar cells with increasing temperature in the 25°-125°C temperature range were found to be similar to those of boron-diffused cells (14).

Conclusions

The investigation resulted in a phosphorous-diffusion process that yields solar cells with the following desirable characteristics: 1, efficiencies above 10%; 2, n values of 2 or less; 3, junction reverse currents of 10-30 μa for reverse bias of 0.6v; 4, contact resistances in the range of 0.2 ohm; 5, high short-wavelength collection (1/3 of I_{sc} from short-wavelength collection); 6, very-high long-wavelength collection efficiency for high-resistivity base cells; 7, superior radiation resistance.

The 875°C diffusion process has already been adapted for production of solar cells for use in communications satellites (15). A recent outer space experiment has verified the superior radiation resistance of the phosphorous-diffused solar cell (16).

The most promising approach to further improvement of phosphorous-diffused cells is believed to be the study of effects of electrically inactive impurities in silicon on characteristics of solar cells. Another area requiring research is the interactions of impurities and imperfections in the region of the junction.

Acknowledgments

The authors wish to give special acknowledgment to F. M. Smits and his colleagues at the Bell Telephone Laboratories for their significant work in the study of radiation behavior of solar cells. Acknowledgment is also made to Joseph Wysocki, RCA, David Sarnoff Research Center, Princeton, New Jersey, for collection-efficiency measurements, and to Calvin Davidson and Margaret Palmateer, USASRDL, for preparation of material. Purification of Tellurium by Distillation

Bruce D. Wedlock

Department of Electrical Engineering, Energy Conversion Laboratory, Massachusetts Institute of Technology, Cambridge, Massachusetts

ABSTRACT

A rapid method is described by which tellurium and materials of similar vapor pressures may be separated from less volatile impurities such as antimony and various oxides. The technique consists of multiple distillation under a continuously pumped vacuum. A mechanical arrangement has been devised which employs a reusable crucible, thereby increasing the speed of the operation. Evaluation indicates that one operation will produce tellurium with an electrically active impurity concentration of 4 x 10^{14}/cc from material with considerable surface oxides.

The increasing interest in thermoelectric energy converters during the past few years has resulted in a large research effort in the area of intermetallic semiconducting tellurides, notably bismuth telluride and lead telluride. In addition, mercury telluride, cadmium telluride, and molybdenum telluride also are receiving increased attention. As research in each of these materials progresses, it is necessary to produce crystals of the highest possible perfection, both chemically and crystallographically speaking, if de-

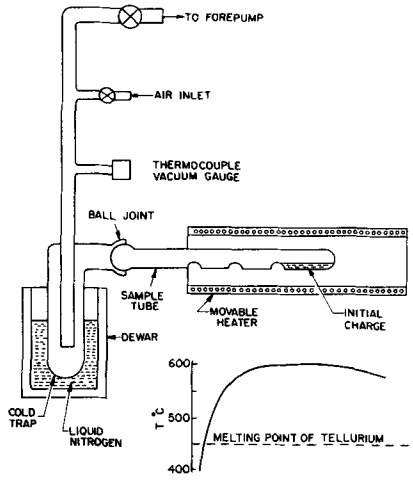

Fig. 1. Tellurium distillation apparatus

tailed experiments on their transport properties and band structure are to yield meaningful results. In an effort to produce such high-quality single crystals by both the Bridgman and Czochralski techniques, it was determined experimentally that the "high-purity" tellurium as commercially supplied[1] required further purification. Accordingly, the scheme of multiple distillation under a continuously pumped vacuum was employed with considerable success.

A system was designed to employ a reusable sample tube. This feature reduced the time required to purify a given sample inasmuch as glass blowing operations associated with individual sample tube preparation have been eliminated. At present, using a 25 mm tube the system has an output capability of approximately 35g of purified tellurium per hour.

System Description

A schematic diagram of the tellurium distillation apparatus is shown in Fig. 1. It consists of a sample tube, surrounded by a moveable heater and connected to a vacuum system by means of a ground-glass ball joint. The sample tube, made entirely of Vycor, consists of three sections formed by semicircular indentations of the tube wall. The tube is sealed at one end and provided with a Vycor ground ball-joint at the other. This ball-joint mates with a Pyrex ball-joint on the vacuum system, thereby eliminating the need for a graded seal. The heater power is controlled by a Variac, and the temperature is monitored by a thermocouple mounted on the inside wall of the heater.

The tellurium to be distilled is placed at the closed end of a clean, dry sample tube. The tube then is connected to the vacuum system and pumped down to a pressure of approximately 1μ. The movable heater is placed so that only the end section of the sample tube will be above the melting point of tellurium. The heater temperature is then brought up to approximately 500°C, whereby the molten tellurium condenses in the center section of the tube. The heater is then moved so that the center section is now included and the temperature raised to approximately 600°C. The tellurium then recondenses in the third section. It is important that a temperature profile similar to that shown in Fig. 1 be maintained along the sample tube. Otherwise, if the temperature of the right-hand section is allowed to drop below that of the center section, back-distillation will take place, with a resulting loss of some of the tellurium. Finally, the condensed tellurium in the third section is melted down by moving the heater to form an ingot, and the tube is cooled rapidly in air by retracting the movable heater. After the tube is cooled, the purified tellurium may be removed without breakage by rotating the tube and sliding the ingot past the last indentation and out through the ball joint. In this way, the tube may be reused.

[1] American Smelting and Refining Co., South Plainfield, N. J.; semiconductor grade, 99.999% pure tellurium.

Experimental Evaluation

In order to obtain some quantitative measure of the effectiveness of this method of purification, an evaluation program was proposed and executed. Considerable information is available (3, 4) on the effects of impurities on electrical conductivity in tellurium. Since these data established that most acceptors are nearly fully ionized down to liquid nitrogen temperature and for impurity concentrations less than 10^{20}/cc the mobility may be assumed constant at a given temperature, it was decided to employ electrical conductivity measurements as a measure of the purity of tellurium. In addition to measurements of improvement on commercially supplied "high-purity" tellurium, the effect on antimony impurity also was investigated.

Sample preparation.—In order to reduce the effect of anisotropy ($\sigma_{||}/\sigma_{\perp} = 2$) (4) in the conductivity measurements, samples were taken from large grain material and the current axis was chosen along the parallel direction. Samples measured approximately 0.2 x 0.2 x 1 cm. Current contacts were soldered with indium solder, and voltage probes were attached by welding fine gold wires. Samples were etched in dilute aqua regia momentarily prior to measurements.

Estimation of carrier concentration.—The dashed line in Fig. 2 represents an experimentally determined curve of hole concentration as a function of electrical conductivity at 167°K ($10^3/T = 6.0$). This relationship will be used to estimate the carrier concentrations quoted in the following sections. We believe that these estimations will be accurate within

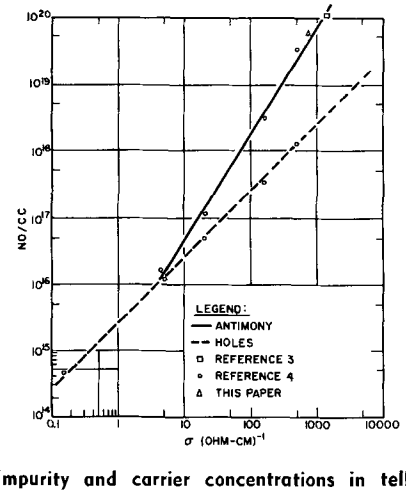

Fig. 2. Impurity and carrier concentrations in tellurium as a function of conductivity at 167°K.

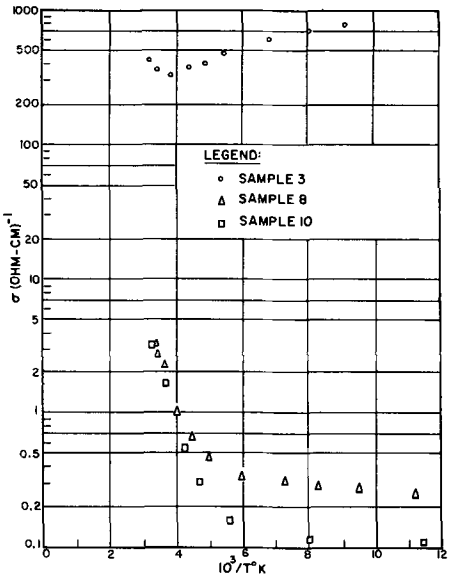

Fig. 3. Effect of distillation on commercial high-purity tellurium

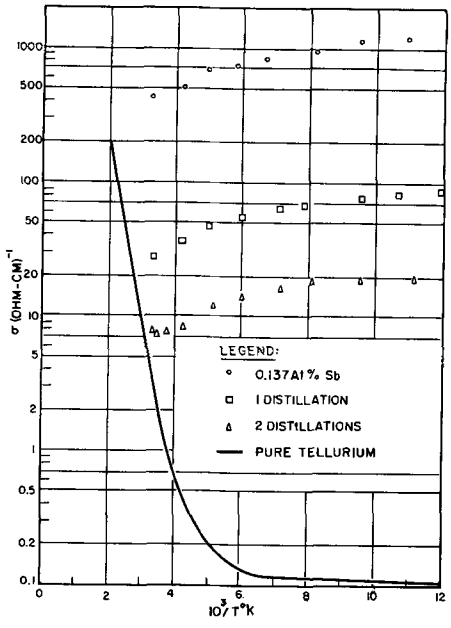

Fig. 4. Effect of distillation on antimony concentration in tellurium.

perhaps a factor of two and hence sufficient for this evaluation program.

Commercial high-purity tellurium.—It has been found that by distillation commercial high-purity tellurium can be further purified. This material as supplied consists of large lumps as well as small pieces and fine powder. Sample 8 was cut from a large piece of tellurium as received. Sample 3 was cut from an ingot produced by melting under vacuum small pieces and powder as received. Even though the tellurium is stored under vacuum, the small pieces and dust absorb a considerable amount of oxygen due to their large surface to volume ratio. From Fig. 2 and 3 we find that in the low-temperature extrinsic range sample 3 exhibits greater than 10^{18} holes/cc compared to 8 x 10^{14} holes/cc for sample 8. Sample 10 was produced by one distillation from a batch of small pieces and dust, special care being taken to keep the oxidized material out of the section where the final product is cooled. As usual, a sizeable quantity of white residue remained in the initial section of the distillation tube. The compositon of this residue is unknown, but certainly contains oxides of tellurium. The hole concentration at 167°K in sample 10 is on the order 4 x 10^{14}/cc. The conductivity curve for sample 10 represents the limit which has been achieved consistently for one distillation of commercial high-purity material. The carrier concentration in sample 10 agrees with the best materials prepared by Kronmuller *et al.* (4) and with tellurium which has been zone refined with 300 passes by Aigrain (1). This limiting value of carrier concentration may represent the best that can be obtained by distillation or zone refining or may be due to the large number of crystal imperfections introduced by even the most careful handling of the material.

Antimony doped tellurium.—Since the conductivity of tellurium is very sensitive to antimony doping and since at 600°C the vapor pressure of antimony is 10^3 less than that of tellurium, it was decided to attempt separation of antimony by distillation. A sample doped with 5 x 10^{19}/cc antimony atoms was distilled successfully and samples prepared. The results of this experiment are presented in Fig. 4. Using Fig. 2 it may be seen that one distillation reduced the antimony concentration to 6 x 10^{17}/cc and two distillations reduced it to 7 x 10^{16}/cc. A third distillation yielded essentially the same result as two distillations, indicating that an equilibrium situation was reached with two operations.

Conclusions

It has been shown that the quality of commercial high-purity tellurium can be improved substantially by a simple vacuum distillation technique. The success of this method has been measured directly by carrier concentration improvement as summarized in Table I, and indirectly by success in growing high quality single crystal material by both the Bridgman and Czochralski techniques. In the case of antimony, a limiting impurity level of 7 x 10^{16} was obtained after two distillations.

Sources of Contamination in GaAs Crystal Growth

L. Ekstrom and L. R. Weisberg

RCA Laboratories, Radio Corporation of America, Princeton, New Jersey

ABSTRACT

Current evidence indicates that the purity of GaAs is now limited by contamination during crystal growth, rather than by the purity of the starting materials. A careful study has been carried out to identify sources of such contamination in the preparation of GaAs. Vacuum baking of gallium at 650°C for several hours in a quartz boat to remove oxides was found to increase the copper content, but not the silicon or other spectrographically detectable impurities. Back diffusion of impurities from a contaminated high vacuum pump was observed to affect properties of GaAs even when pressures of 10^{-6} torr were maintained. Sealing under vacuum of large (20 mm) diameter quartz ampoules introduces significant quantities of silicon and copper onto the inner ampoule walls, which subsequently contaminate arsenic vapor when heated to above 1000°C. During growth, it was found that there is no appreciable diffusion of atmospheric gases through quartz at 1200°C. However, nearly 10^{18} molecules of gas are released due to outgassing of the walls. The most serious contamination, especially with silicon, occurs from the reaction between the GaAs melt and the quartz boat, and the reaction increases rapidly with increasing melt temperature.

The application of GaAs for transistors and transistor-like devices requires a material of extremely high purity in single crystal form. Past efforts to increase the purity of GaAs have centered on the purification of the component elements, gallium and arsenic, because of the existence of impurities that could not readily be removed from GaAs by zone refining. The impurity content of commercially available gallium and arsenic has now been reduced to the point where it is comparable to or below the amount of impurities introduced into GaAs by contamination during its preparation. The following evidence supports this conclusion.

First, emission and mass spectrographic analyses have detected impurities, such as silicon and copper, in GaAs in concentrations greater than that present in the starting materials. Second, series of GaAs crystals produced from the same lots of gallium and arsenic have had widely varying electrical properties. However, variations in the lots of gallium and arsenic have produced only minor changes in the electrical properties of the resulting GaAs. Third, special purification treatments carried out for gallium and arsenic have improved the properties of other compounds such as InAs, but have had little or no effect on the properties of GaAs.

For these reasons, this investigation was carried out to determine the sources of such contamination and thus provide guidance in devising improved methods of preparation. The investigation is specifically concerned with the horizontal Bridgman technique of crystal growth; however, the results are applicable to other methods of crystal growth. The details of the preparation of a GaAs growth ampoule for this growth technique are described in the following section. In subsequent sections each step in this procedure is carefully examined for possible sources of contamination. Throughout this paper, it is implicit that careful precautions were taken to remove the obvious contamination sources such as dust and similar foreign matter, to use gloves where required, etc.

Preparation of GaAs

The arsenic was received in chunks each weighing approximately a gram, sealed in a Pyrex ampoule in 50 or 100 g lots. After being opened, the Pyrex ampoule was stored under vacuum in a larger Pyrex ampoule, sealed by a vacuum stopcock. The gallium is received in a polyethylene bag as a large lump. To remove pieces, the gallium was cooled to liquid nitrogen temperature, placed in "Glassine" paper bags, and cracked by squeezing in a vise. It was subsequently stored in these bags within a closed glass jar inside an air tight cabinet.

The ampoule, shown in Fig. 1, consists of a quartz tube of 20 mm bore with a ball joint at each end and a breakseal dividing it into two chambers. All quartz ware, including the tube, growth boat, and slug for

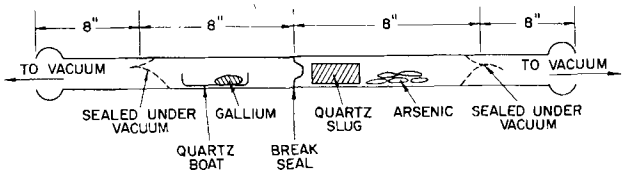

Fig. 1. GaAs growth ampoule

rupturing the breakseal, was cleaned by first washing it in a detergent such as "Alconox", then treating it with aqua regia, then etching with a 1:1 mixture of HF and HNO_3, and finally cleaning in a mixture of triple distilled HNO_3 and HCl. Each step was followed by extensive rinsing in triple distilled water, and after the final rinse, the water was removed using transistor-grade acetone which was drained, and the quartz allowed to dry in air. The quartz slug and the arsenic were loaded in air into one chamber of the tube, and the tube was then connected through a liquid nitrogen trap to a diffusion pump and evacuated. The arsenic was heated in a vacuum of below 10^{-6} torr for 1 hr at 300°C to remove surface oxides and then that section of the ampoule was sealed under vacuum after first collapsing the tube with a broad flame produced by a brass hydrogen-oxygen torch.

Next, the growth boat containing solid gallium was placed in the other chamber of the tube, which was then evacuated before the gallium was melted. A vacuum heat treatment of 3 hr at 650°C was given to remove oxides of gallium as Ga_2O, after which the gallium was refrozen and the ampoule sealed off using the same technique as for the arsenic section. The final ampoule is shown in Fig. 1.

After the breakseal was ruptured by causing the quartz slug to strike it, the GaAs was synthesized and grown into a crystal in a typical two zone horizontal Bridgman furnace (1). In synthesizing the GaAs, the entire system was brought up to the arsenic reservoir temperature of about 600°C, and then the temperature of the reaction zone containing the molten gallium was gradually raised to about 1260°C. The crystal was then grown by moving the entire furnace over the stationary quartz tube at a rate of about 1 cm hr^{-1} for a total period of 16 hr.

Effects of Cleaning and Handling Procedures

It was first determined whether the ordinary rinsing with distilled water is sufficient to remove the acids used for cleaning. This was found by measuring the resistivity of the water after each rinse. A 1:1 mixture of HCl-HNO_3 was placed in a quartz ampoule for 1 hr. This mixture was then discarded and replaced with deionized water, which remained in the ampoule for various times (usually 10 sec). After a number of rinses, the rinse water was also boiled in the ampoule. Typical results are shown in Table I. It can be seen that even ten rinsings with cold deionized water is not sufficient to remove all traces of impurities subsequent to acid cleaning. Instead, it is at least necessary to boil the water for a half hour in the vial.

Experiments were also carried out to determine if the cleaning procedure itself was adequate. Many

15	10 sec	2

variations were tested, such as treating different ampoules with HF only, HF followed by aqua regia, or aqua regia alone, using nondistilled acids, eliminating the acetone rinse, etc. It was noted that a scouring agent such as "Ajax" should be avoided since it is not dissolved by aqua regia. Variations were also attempted in the handling of the elements such as weighing out and transferring gallium as a liquid rather than a solid (2), the use of filter paper instead of "Glassine" paper, and plastic instead of stainless steel forceps. Despite all of these variations, no difference could be seen in the properties of the resulting GaAs. The conclusion can be drawn that the cleaning procedure used for quartz and the handling techniques for the elements are not significant variables compared to contamination sources described in the sections to follow.

Effects of Vacuum Baking and Sealing

During the vacuum annealing of the gallium and arsenic to remove oxides and the subsequent sealing of the evacuated ampoules, there are several ways in which contamination might occur. The three which have been investigated are back diffusion of impurities from the vacuum pump, reaction between gallium and the quartz boat during bakeout, and evolution of material from the quartz while it is being sealed.

Contamination from vacuum pumps.—Both oil and mercury diffusion pumps have been used in the preparation of GaAs ampoules, and no significant difference was noted in the purity of the resulting GaAs. On certain occasions, the vacuum pumps have been cleaned or new vacuum pumps have been used. In general, this has caused no improvement in the properties of the GaAs, except on one occasion (2). In this case, a series of crystals were produced with electron mobilities on the average below 4000 cm^2 v^{-1} sec^{-1}. Many variations were attempted, but the mobilities did not improve until the mercury diffusion pump was dismantled and cleaned. The resulting change in the mobility is shown in Fig. 2. The points with the attached bars indicate crystals of GaAs produced from the same lots of gallium and arsenic. Not all crystals grown are included in the graph, because some were doped or else grown under special conditions. The importance of a clean vacuum

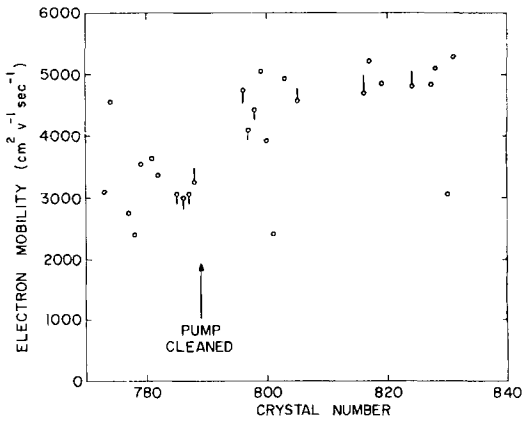

Fig. 2. Electron mobility of GaAs crystals before and after cleaning of the mercury diffusion pump.

system is manifest from these results. However, this result is somewhat surprising since the system was producing vacuums of the order of 10^{-6} torr both before and after the cleaning. At this pressure, the number of residual gas molecules in the ampoule is about 10^{13} while the change in properties corresponds to 10^{17} atoms or more. It would appear that material was continuously diffusing back from the pump through the trap and condensing on the walls.

In further tests of the effects of vacuum systems, the vacuum grease in the ball and socket joints used to attach the cold trap and growth ampoule to the vacuum system was replaced by black vacuum wax. This wax does not have a tendency to flow out of the joint into the system and reportedly has a vapor pressure of only 10^{-8} torr at room temperature. However, this substitution did not improve the purity of GaAs prepared with this vacuum system.

Vacuum baking of gallium.—The next possibility is that gallium might react with the quartz boat during the vacuum anneal and become contaminated, especially with silicon. Gallium is known to react with quartz readily at higher temperatures (3), so there was reason to suspect that this reaction might also be occurring a 650°C to a significant extent. To test this possibility, gallium samples were subjected to the same annealing conditions used in preparing an ampoule, except that the annealing time was increased to 12 hr from the usual 3 hr to exaggerate any effects. Changes in the impurity content of the gallium were determined by emission spectrographic analysis before and after the anneal. In each case, several samples were analyzed, and the reported impurity concentration is the geometric mean of the results. This averaging process was necessary, since the spectrographic analysis was semiquantitative and accurate to within only a factor of three. To differentiate between bulk contamination of the gallium and impurities which collect on, or segregate to the surface of the gallium, two types of samples were taken for analysis. The first consisted of pieces from the interior of a 5g ingot of gallium, obtained by fracturing the ingot. The other type was a piece of gallium small enough to be used directly in the spectrograph, thus including the entire original surface. The samples were treated simultaneously in a suitably compartmented boat. Table II shows the results

Table II. Impurities introduced during the vacuum baking of gallium in quartz

Gallium treatment	Type of sample	No. of samples	Spectrographic impurity content in ppm Si	Mg	Fe	Cu
As received	—	5	<0.1	0.3	2	<1
12 hr at 650°C, pressure of 3×10^{-6} torr	interior	2	<0.1	0.2	1	2
	exterior	3	<0.1	0.3	2	3
12 hr at 650°C, pressure of 5×10^{-5} torr (air leak)	interior	2	1	<0.1	2	<1
	exterior	3	5	0.5	3	1

of such a heat treatment on the gallium using both a tight vacuum system and one with a small air leak. It can be seen that no detectable silicon contamination occurs due to the baking process at 650°C provided there is no oxygen present. However, one of the oxides of gallium apparently attacks quartz at this temperature. It can also be seen that there is no evidence for iron and magnesium contamination, but that the copper content is increased. The copper could be leached from the quartz boat, since quartz is known to contain copper that easily diffuses out (4). Since copper has a small distribution coefficient in GaAs, this source of contamination has little effect on the electrical properties of the grown crystals.

Sealing of the ampoule.—During the sealing of the ampoule the quartz is heated above its softening point. The quartz vaporizes with some decomposition at these temperatures and redeposits in part on cooler portions of the quartz as manifested by the appearance of a rough white film. The decomposition products include oxygen (5) which could enter the ampoule, as could the gases from the oxy-hydrogen flame. Thus, the sealing procedure might first introduce gaseous impurities into the ampoule; second, directly contaminate gallium or arsenic within the ampoule; and third, contaminate the inner ampoule walls and thereby contaminate the arsenic vapor during growth.

The first possibility was investigated by attaching a thermocouple gauge to a quartz ampoule, which was subjected to the same cleaning and vacuum baking process used for growth ampoules. After sealing of the ampoule, the pressure in the ampoule was below the 10^{-3} torr detection limit of the gauge, indicating that a total of less than about 5×10^{15} gas molecules are trapped in the ampoule due to the sealing process. This represents a comparatively negligible amount of contamination in the GaAs crystal, which is usually about 4 cm^3 in volume.

The possibility of direct deposition of decomposition products onto the gallium was investigated by preparing an ampoule containing a compartmented boat with both large and small gallium samples similar to the experiment described in the previous section. After the usual vacuum baking and freezing, the quartz ampoule was sealed at a point beyond the boat and vacuum pump. Thus, if there were a flow of material toward the vacuum pump, it would enhance the effects of deposition. Subsequent to the sealing, the samples were spectrographically analyzed. Results are shown in Table III, which also includes re-

Table III. Impurities introduced during the sealing of an ampoule

Material and treatment	No. and type of sample	Spectrographic impurity content in ppm Si	Mg	Fe	Cu

	3 exterior	<0.1	1	1	1
Arsenic (as received)	3	0.1	<0.1	nd	nd
Arsenic (after vacuum bake and sealing)	3	<0.1	nd	nd	nd

sults for a similar experiment with arsenic. The analysis of the interior samples of gallium indicates that no accidental introduction of impurities occurred during the vacuum baking within the limits of error. It can be concluded, therefore, that direct deposition of impurities onto the elements is not a significant source of contamination.

The third experiment on the sealing of quartz tubing dealt with the possibility of the deposition of impurities on the ampoule walls from the sealing operation with subsequent contamination of the arsenic vapor during crystal growth. The procedure was again designed to duplicate the conditions prevailing in the growth of GaAs. A 20 mm bore quartz ampoule, cleaned in the usual manner, was degassed in vacuum for 2 or 3 hr at 700°C, cooled, and about 0.3g of arsenic was then introduced without breaking the vacuum. This amount of arsenic was calculated to be just sufficient for complete vaporization. After vacuum baking to remove arsenic oxides, the ampoule was sealed under vacuum and placed in a two-zone furnace for periods of about 16 hr with the sealed end held at 1220°C and the opposite end at 600°C. After this treatment, care was taken to cool the ampoule slowly and at the cooler end first. In this manner the arsenic condensed in the form of lumps, rather than as large area thin sheets. The condensed arsenic was recovered by breaking the ampoule. Changes in the impurity content of the arsenic were determined by spectrographic analyses before and after this exposure to quartz. In all cases, the arsenic starting material was found to contain only two impurities: copper at or below the detection limit of 1 ppm, and silicon at or below 0.2 ppm. For each run, four samples of arsenic were analyzed. The reported impurity concentration represents the geometric mean of the four results.

The typical contamination of arsenic that is observed due to the sealing is shown in the first two rows of Table IV for two separate runs. A large increase in both the silicon and copper content of the arsenic can be seen. To try to enhance this effect, several runs were made in which multiple seals were performed on the ampoule, each seal being made closer to the arsenic. The results of one such run using 6 seals is shown in the third row. The absence of a proportional increase in the contamination is probably caused by much of the vaporized material depositing very close to the seal, so that most of the contamination comes from only the last seal.

In the above experiments the possibility existed that the arsenic simply attacked the quartz walls, and the contamination was not related to the sealing process. To test this possibility, ampoules were constructed with the 20-mm bore quartz ampoule terminating with 6-mm bore tubing. Much less heating is required to seal 6-mm bore quartz tubing than 20-mm bore tubing so less quartz is vaporized. As shown in Table IV in the last two rows, this reduces the arsenic contamination to below the limits of detection.

Next, the effect of temperature on the above reaction was investigated. To exaggerate any effects so that they could be easily observable, four to five seals were made on the 20 mm bore tube for each run. The sealed end of the ampoule was held in different runs at 700°, 1000°, and 1220°C while the opposite end was held at 600°C. The improve reliability, separate runs were made two or three times at each temperature. The results in Table V represent geometric averages of 8 or 12 analyses. The usual contamination discussed previously is shown in the first row. It can be seen that reducing the temperature to only 1000°C is not sufficient to remove the contamination completely; and to do so, a temperature as low as 700°C must be employed.

Although contamination due to sealing of quartz has been demonstrated, no unambiguous effect of sealing has been noted on the electrical properties, indicating that other sources of contamination are more important.

Contamination during Crystal Growth

Gaseous impurities from quartz.—In general, it is known that fused quartz can release considerable quantities of gases when heated, and is quite permeable to both helium (6) and hydrogen (7) at elevated temperatures. The latter fact suggests that atmospheric gases might also diffuse through the quartz ampoule at the melting temperature of GaAs. Therefore, the effect of both diffusion through and desorption from quartz has been investigated at temperatures used during GaAs crystal growth.

The literature on the diffusion of gases other than H_2 and He through fused quartz is conflicting, and does not include studies above 1000°C. T'sai and

Table V. Contamination of arsenic at various temperatures due to sealing of 20-mm bore quartz tubing

Hogness (7) report no observable diffusion of air through quartz at 1000°C. Nevertheless, based on Barrer's (8) data, Dushman (9) calculates a permeability rate for N_2 at 1100°C high enough to allow over 10^{19} N_2 molecules to enter an ampoule during a routine crystal growth. However, Barrer's work failed to take account of the outgassing of quartz. In order to distinguish between diffusion and degassing as the source of this gas, experiments were conducted with an apparatus similar to that of T'sai and Hogness (7).

The present apparatus consisted of two fused quartz tubes, one inside the other and so connected that the outer one could be either evacuated or open to the atmosphere. The inner tube was connected to a thermocouple gauge and to a diffusion pump by means of a stopcock. After the inner tube was evacuated with the diffusion pump, the stopcock was closed and the rate at which the pressure increased in the inner tube was measured. Every 12 hr the stopcock was again opened, and the process repeated. In this way the rate at which gas collected in the inner tube was obtained when it was alternately surrounded by air and by vacuum for these 12-hr periods. A temperature of 1200°C was used throughout, because it is the maximum temperature to which an evacuated fused quartz tube can be heated in air for several hours without collapsing.

The typical results of one of these experiments are shown in Fig. 3. The units of the ordinate are chosen to correspond to the maximum area of fused quartz that is heated above the melting point of GaAs in a routine crystal growth. It can be seen that the rate at which gas is collected is independent of whether there is air or vacuum around the tube. Thus, the amount diffusing through the walls is below the detection limit of the experiment, which is estimated to be 2 x 10^{15} molecules hr^{-1}. Furthermore, the fused quartz used in these tests was about ½ as thick as that used in a standard growth ampoule. It is also noteworthy from Fig. 3 that the rate of evolution decreases exponentially with time, which is not to be expected for the general case of the permeation of gases through a wall from a relatively large source

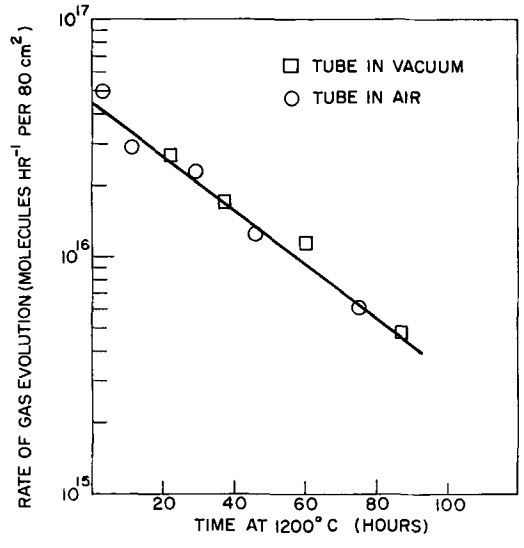

Fig. 3. Time dependence of the rate of gas evolution from fused quartz at 1200°C.

Table VI. Outgassing of quartz for 16 hr at indicated temperatures after various treatments

Prebaking treatment Time, hr	Prebaking treatment Temp, °C	Outgassing Temp, °C	Outgassing Total gas molecules
3	650	1200	7×10^{17}
1	350	650	2×10^{17}
40	1100	1200	3×10^{17}
40	1200	1200	2×10^{17}
80	1200	1200	8×10^{16}
100 hr at 1200°C, exposed to air at 25°C, then 3 hr at 650°C		1200	2×10^{17}

such as the atmosphere. Nevertheless, this type of behavior was always observed. Thus, the diffusion of gases through the quartz walls during crystal growth is not considered an important source of contamination of GaAs.

To determine the number of molecules entering the ampoule during the usual 16-hr growth period due to the desorption, apparatus similar to that previously described was used but with no outer tube. Results are shown in Table VI. In the first line is shown the number of gas molecules desorbed from the section of the ampoule containing the gallium. The second line gives the molecules desorbed from the arsenic end of the ampoule. Therefore, a total of nearly 10^{18} molecules of gases enter the growth ampoule, which could dope a 20g GaAs crystal to a level of roughly 3 x 10^{17} cm^{-3}.

The effect of predegassing at 1100° and 1200°C is shown by the data in the third and fourth lines in Table VI. It can be seen that predegassing is not very effective since the rate of degassing is quite slow, which is also indicated by the data in Fig. 3. As would be expected, predegassing at the higher temperature is always more effective. The fraction of the total degassing that is due to *ad*sorbed gases as compared to *ab*sorbed gases is indicated in the final two lines of Table VI. Prebaking the ampoule at 1200°C for 80 or 100 hr reduces the evolution of absorbed gases to below 10^{17} molecules. Subsequently, a short exposure to the air will introduce 2 x 10^{17} adsorbed molecules, which is a sizable fraction of the total number of molecules desorbed from quartz that has not been prebaked. Therefore, quartz ware that has been prebaked and subsequently exposed to air will still introduce significant contamination during GaAs growth.

A preliminary mass spectrometric analysis of the gases evolved from quartz *in vacuo* has been obtained by Honig (10). His results were reported as percentage of the total gas evolved at 600° and at 1150°C. The analysis at 1150°C was obtained after the quartz had been prebaked in vacuum at 1200°C for about 1 hr. The amount of helium evolved was not investigated. Results are given in Table VII. In accord with these results is the separate observation that most of the gas evolved at 600°C can be condensed at liquid nitrogen temperature, while very little of the gas evolved at 1200°C is thus condensible. Even if one assumes that hydrogen is not harmful to GaAs, there is still a total of 3 x 10^{17} molecules

Table VII. Composition of gases evolved from fused quartz *in Vacuo* at 600° and 1150°C

of water vapor and 7 x 10^{16} molecules of carbon monoxide introduced into the growth ampoule due to the desorption from both its sections. In addition, it has been found that the presence of arsenic in the reaction tube will increase by an order of magnitude the number of molecules of the major species of gaseous molecules found in the growth ampoule (11). To determine the effect of these impurities on the electrical properties, growth procedures must be devised to eliminate this source of contamination so as to provide control samples.

Contamination from the boat.—It has been previously found (1) that silicon is the main donor in GaAs, and tests have shown that the major source of silicon contamination is due to a reaction of molten GaAs with the quartz boat. The type of contamination that occurs is shown in Table VIII. The crystal was grown with a maximum temperature in the range 1265°-1275°C. It is seen that both copper and silicon are introduced; however, the copper segregates to the tail end of the crystal due to its small distribution coefficient. There is also some evidence for a little magnesium contamination.

The contamination shown in Table VIII is not due to the sealing process, since it depends strongly on relatively small variations of the growth temperature. The effect of the maximum temperature to which the melt is heated is shown in Table IX. It can be seen that higher growth temperatures simultaneously increase the electron (or silicon) concentration and decrease the electron mobility. The scatter in the data in Table IX is due in part to the use of nonuniform preparative techniques for all of the crystals. It should be remembered that in these tests 16-hr growth periods were used, so that the melt remained at or near the elevated temperatures for periods of several hours. An extremely rapid change in the stability of quartz at these temperatures is also manifest by the amount of devitrification of the

* Grown at higher speeds.

quartz ampoule. After a 16-hr run at 1270°C, the devitrification is so bad that the quartz becomes opaque; while at 1250°C devitrification causes only slight clouding. It can be concluded that reaction of the GaAs melt with the quartz boat constitutes the major source of contamination.

Conclusions

A study has been carried out of the contamination introduced during the preparation and growth of GaAs by the horizontal Bridgman technique in a quartz ampoule and quartz boat. The major source of contamination, especially with silicon, is due to reaction of the GaAs melt with the boat. Contamination with silicon and copper has also been observed during sealing of the quartz ampoules, with copper during vacuum baking of gallium, and with water vapor and carbon monoxide during growth due to outgassing of quartz. Contamination has also been observed to occur due to back diffusion of impurities from a vacuum system.

Atmospheric gases were not observed to diffuse through quartz at the growth temperature, and the cleaning procedures used for the quartz had no significant effect on the properties of GaAs. No direct reaction of gallium with the boat was observed during vacuum baking at 650°C.

To reduce the contamination of GaAs crystals, it is most important to control the reaction of the melt with the boat. As a first step in this direction, the melt temperature must be maintained as close as possible to the melting point and the crystal grown in a short time. In addition, other boat materials such as BN, AlN, BeO, etc., might prove to be more suitable than quartz if they can be made ultrapure and impervious. To minimize the outgassing of the quartz ampoule, the ampoule should be maintained well below 1000°C by employing heating methods such as r.f. induction. The high vacuum pumps used in processing the ampoules should be cleaned at regular intervals. Finally, alternative growth procedures might be investigated, in which lower temperatures are employed, such a growth from solution, or from the vapor phase.

Polarization Curves of Redox Systems Involving Consecutive Electron-Transfers: Some Theoretical Aspects

R. M. Hurd

Texas Research Associates, Austin, Texas

ABSTRACT

An equation, first worked out by Vetter, describing the complete polarization curves for redox systems involving two consecutive electron transfer steps, has been examined in detail by computer solutions. It is shown that quite wide variations in the values of the individual transfer coefficients have little effect on the shape of the theoretical curves. However, as the ratio of the individual exchange currents approaches 100:1, two definite linear-logarithmic regions appear in one branch of the curve. It is further shown that in many cases the diffusion current masks the true Tafel portion, leaving the "pseudo-Tafel" part as the only observable linear-logarithmic region.

In one of a series of papers (1, 2-9) describing the use of reaction order methods in determining mechanisms of electrode reactions in redox systems, Vetter derived an equation which describes the theoretical polarization curves for a redox system which proceeds by two consecutive electron transfer steps. The conditions and assumptions for the applicability of his equation are the usual constancy of activity coefficients, compression of the double layer to constant and nearly negligible zeta potential, suppression of the transference number of the reacting species, etc. Most of these conditions, it should be noted, are accomplished by addition of a large excess of inert electrolyte to the system. There is, however, one additional assumption in this particular case, *i.e.*, that the actual electrode reactions involve the transfer of only *one* electron between *individual* solution species. For an over-all electrode reaction $A+2e \rightleftarrows C$, the reaction scheme thus can be formulated:

$$A + e \rightleftarrows B \qquad [1]$$

$$B + e \rightleftarrows C \qquad [2]$$

Each of these reactions is characterized by its own transfer coefficient, α_1 or α_2, and by its own exchange current, $i_{o,1}$ or $i_{o,2}$.

This assumption excludes reactions which involve simultaneous electron transfer and molecular combination, such as

$$A + H^+ + e \rightleftarrows HA \qquad [3]$$

It does not exclude purely chemical equilibrium reactions involving any of the substances in Eq. [1] and [2], provided only that they are rapid equilibria. The over-all reaction can thus include other species which do not enter into the actual electron transfer processes. A notable example is the quinone/hydroquinone system, in which the over-all reaction involves hydrogen ion and a two electron transfer, while the electrode reactions, according to Vetter (10), involve single electron transfers in which hydrogen ion does not participate.

For the conditions as stated, then, the equation which describes the complete polarization curves for a system which proceeds by the two consecutive transfer steps 1 and 2 above is given by Vetter as

$$\frac{i}{2} = \frac{\exp(\alpha_1+\alpha_2)\frac{\mathbf{F}\eta}{RT} - \exp\left[-2+(\alpha_1+\alpha_2)\right]\frac{\mathbf{F}\eta}{RT}}{\frac{1}{i_{o,2}}\exp\alpha_1\frac{\mathbf{F}\eta}{RT} + \frac{1}{i_{o,1}}\exp\left[-(1-\alpha_2)\right]\frac{\mathbf{F}\eta}{RT}} \qquad [4]$$

In this equation i is the net external current and η the overvoltage. Both i and η are positive for anodic, negative for cathodic, polarization. It should be noted that the factor 2 (in $i/2$) does not appear in the original article (1), but was introduced as a correction in a subsequent note (11).

Vetter examined this equation in the four simplified forms to which it reduces when one assumes η "large and positive," η "large and negative," when $i_{o,1} = \infty$, and when $i_{o,2} = \infty$. From this examination he has drawn the following three conclusions, which may be used as criteria for the existence of two consecutive electron transfer steps in the reaction mechanism:

1. Since α_1 will not generally be equal to α_2, the slopes of the anodic and cathodic linear-logarithmic regions which occur at high overvoltages will not add up to 1, as they must for a single transfer step $[\alpha + (1 - \alpha) = 1]$.

2. Extrapolation of the linear-logarithmic regions to $\eta = 0$ will give two values of exchange current. Because of the factor 2 mentioned above, the values at the intercept are actually $2i_{o,1}$ from extrapolation of the cathodic branch and $2i_{o,2}$ from extrapolation of the anodic branch.

3. For either exchange current equal to infinity, the linear-logarithmic regions extrapolate to the exchange current characteristic of the slower step, but exhibit slopes which add up to 2 instead of 1.

In a research program designed to extend Vetters' reaction order methods to organic systems somewhat more complicated than the quinone-hydroquinone case, some of the experimental results (which will be presented in subsequent papers) led to the conclusion that an exchange current ratio in the range 1-1000 was a more practical case than a ratio of infinity. As a matter of fact, it seems reasonable that the large majority of electrode systems of this type will involve exchange current ratios up to perhaps only 100, from which it follows that a detailed examination of Eq. [4] in these regions is desirable. With the use of modern computers, such an examination is actually rather straightforward, and can even be extended to the general case of n electron steps with little additional effort.

Solutions of Eq. [4] at Intermediate Exchange Current Ratios

Visual examination of Eq. [4] reveals that, regardless of the magnitudes of the two exchange currents, there exists a value of η sufficiently large and positive to justify neglecting the second term in both numerator and denominator. The same holds true for the first terms for η large and negative. However, it is also apparent that the criterion for η sufficiently large in either direction to justify dropping of terms is dependent on the values of the exchange currents. The same reasoning process holds true for dropping either term in the denominator on the basis of a "sufficiently large" value of either exchange current.

The questions which can be answered, then, by complete solutions of the equation are:

1. For various magnitudes and ratios of the two exchange currents, what values of overvoltage are required to put one in the linear-logarithmic region, i.e., Vetter's limiting cases?

2. What is the character of the polarization curves in the intermediate overvoltage regions (40-300 mv) when the exchange current ratio is large, but not infinite?

A computer program was established to obtain values of i as a function of η as η ran the series 1, 2, 4, 7, 10, 20, 40, . . . *etc.*, mv. Solutions were cut off at 2v. Exchange current densities of various values and various ratios were used through the range 10^{-7} to 10^{-4} amp/cm^2. Transfer coefficients of 0.2, 0.4, 0.5, 0.7, and 0.8 were used in various combinations. Plots were made of log i *vs.* η for the complete polarization curves and of i *vs.* η in low overvoltage ranges (0-50 mv). Although literally dozens of such curves have been obtained (the limiting factor is the time required to plot the data), only the more significant are presented here.

Figure 1 shows the complete polarization curves for $\alpha_1 = \alpha_2 = 0.5$, with $i_{o,2}$ fixed at 10^{-4} amp/cm^2 and $i_{o,1}$ varying. Note that an average value for a diffusion limited current density in well stirred $10^{-2}N$ solutions (conditions used in the experimental work for this program) is about 10^{-2} amp/cm^2, which is indicated by the horizontal dashed line in the figure. The most interesting part of the curve is the progression on the anodic side as the cathodic exchange current decreases. At a ratio of $i_{o,1}/i_{o,2}$ of 100, a well-defined linear-logarithmic region covering nearly two orders of magnitude appears and becomes even more distinct and extended as the ratio increases. This branch of the curve thus contains two linear-logarithmic regions, the true Tafel region at values of overvoltage above about 250 mv, and a "pseudo-Tafel" region at the lower values. For $\alpha_1 = \alpha_2 = 0.5$ the slope of this pseudo-Tafel region varies between about 1.0 at the lowest ratio of exchange currents (50-100) at which it is observable, and 1.5 at the

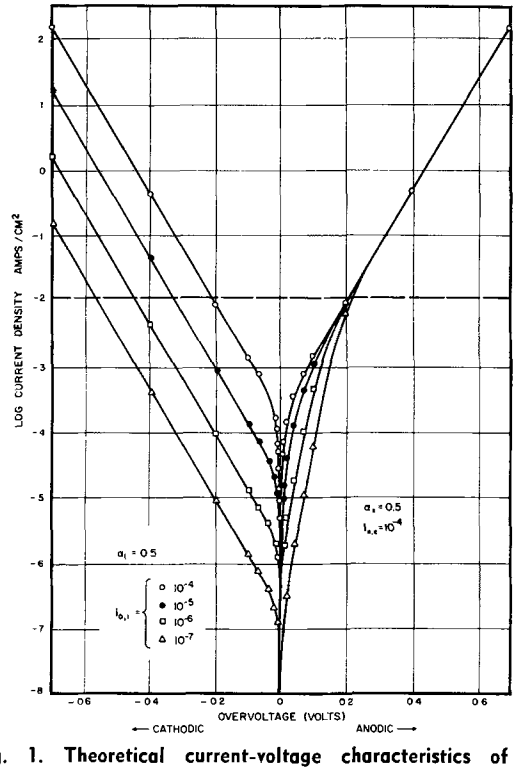

Fig. 1. Theoretical current-voltage characteristics of redox system with two consecutive electron transfers, varying $i_{o,1}$.

limiting case of one exchange current equal to infinity.

The difficulties to which the existence of this "pseudo-Tafel" region can lead are illustrated by Fig. 2 and 3. Figure 2 is a redrawn portion of Fig. 1 with the approaches to the limiting current densities sketched in as would be observed in an actual experiment. It is apparent that the true values of anodic exchange current and anodic transfer coefficient are completely obscured. Figure 3 is an actual experimental curve obtained with platinum electrodes in a 10^{-2}M toluquinone-10^{-2}M toluhydroquinone system. The measured cathodic α from these data is -0.49, an entirely reasonable value, but the measured slope of the well-defined linear-logarithmic region in the anodic curve corresponds to an apparent anodic α of 1.2. The similarity of these curves to the theoretical curves of Fig. 2 is not of itself sufficient proof of the existence of consecutive electron transfers and a "pseudo-Tafel" region. Curves which show *two* well-defined linear-logarithmic regions below the limiting current, plus agreement between the exchange current ratios and transfer coefficients would constitute unequivocal proof.

Curves obtained by using values of α_1 and α_2 other than 0.5 are quite similar to those of Fig. 1, except for the slopes in the true Tafel region. It is interesting to note that if from actual data one true Tafel slope and one exchange current are known, as will usually be the case, a fair prediction of the other exchange current and the other transfer coefficient can be obtained by comparison with the various theoretical curves. The accuracy of such a prediction is markedly dependent on the accuracy of the polarization data in the pseudo-Tafel region.

As in most electrode kinetic studies, additional information about the nature of the electrode reactions can be obtained from data very near the reversible potential. Differentiation of Eq. [4] with respect to η and determination of $(d\eta/di)_{i\to 0}$ yields

$$\frac{4F}{RT}\left(\frac{d\eta}{di}\right)_{i\to 0} = \left(\frac{1}{i_{o,1}} + \frac{1}{i_{o,2}}\right) \qquad [5]$$

Vetter denoted this quantity by $1/i_o$* and used it to check the values of individual exchange currents obtained by extrapolation in his quinone/hydroquinone paper.

Plots of the computer calculations in the low overvoltage regions (+20 to −20 mv) show that the curves pass through the origin at the slopes predicted by Eq. [5], and that variations in α values tend to spread the curves apart somewhat in this region, but probably not enough to make firm determinations of α. Figure 4 is a plot for $i_{o,1} = i_{o,2} = 10^{-4}$ amp/cm^2, and for five different combinations of α_1 and α_2. Figure 5 is a similar plot for $i_{o,1} = 10^{-4}$, $i_{o,2} = 10^{-5}$ amp/cm^2. It is notable that even at this small ratio of exchange currents, the plots possess a definite curvature at the

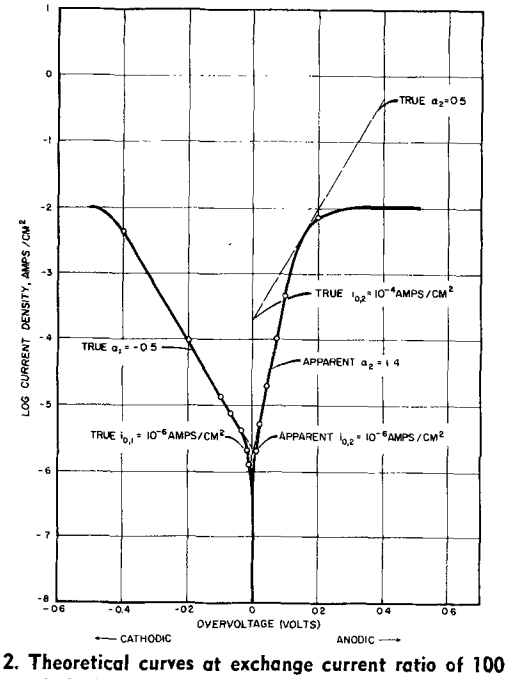

Fig. 2. Theoretical curves at exchange current ratio of 100 (from Fig. 1) with limiting diffusion current of 10^{-2} amp/cm^2 superimposed.

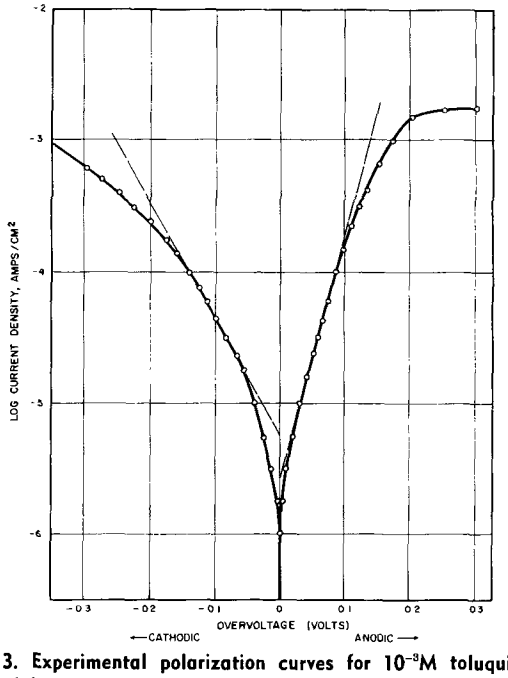

Fig. 3. Experimental polarization curves for 10^{-3}M toluquinone, 10^{-3}M toluhydroquinone.

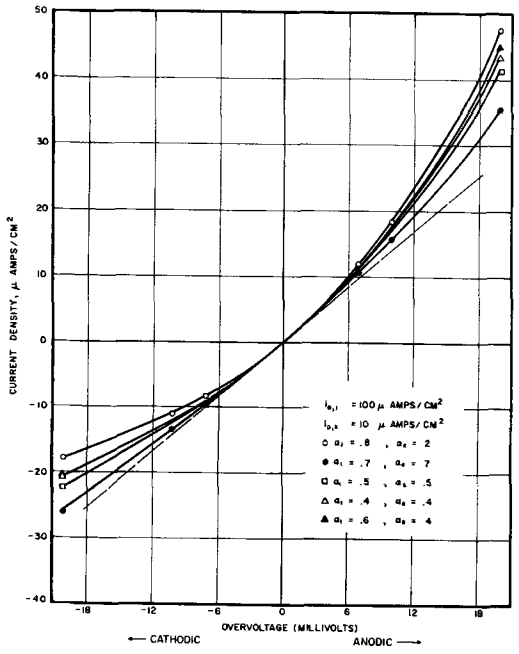

Fig. 5. Theoretical low current density polarization curves, two consecutive electron transfers, exchange current ratio equals ten.

origin, while at $i_{o,1} = i_{o,2}$ they pass through the origin in a straight line. This curvature persists at the higher ratios of exchange currents, but does not become significantly more pronounced. For values of $i_{o,2} > i_{o,1}$, the curvature is an exact mirror image of Fig. 5.

Examination of Eq. [5] reveals that the value of i_o* obtained from the slope at the origin can be obtained by many combinations of perfectly reasonable values of $i_{o,1}$ and $i_{o,2}$. If values of the individual exchange currents as obtained by extrapolation of Tafel regions combine in the manner of Eq. [5] to give close agreement with the measured i_o*, then certainly the extrapolated values merit a greater confidence. However, in those cases where one exchange current is about 100 times larger than the other (the condition, incidentally, which leads to the pseudo-Tafel region of Fig. 1 and 2), the larger exchange current no longer has any influence on i_o*. For cases of this type, the combination of curvature in the low-overvoltage region and a greater than usual slope in the linear-logarithmic region, or, even more convincing, two linear-logarithmic regions in one branch of the curve, will lead one to expect a large ratio of exchange currents. It would then be hoped that further experiments could be designed to ferret out the elusive electrokinetic parameters.

General Solution for *n* Consecutive Steps, with Some Solutions for the Three Electron Case

The solution for the general case of n consecutive electron transfer, represented as

$$S_1 + e \underset{k_2}{\overset{k_1}{\rightleftarrows}} S_2 \text{ - - - - - - with } \alpha_1 \text{ and } i_{o,1}$$

$$\vdots$$

$$S_i + e \underset{k_{2i}}{\overset{k_{2i-1}}{\rightleftarrows}} S_{i+1} \text{ - - - - - with } \alpha_i \text{ and } i_{o,i} \quad [6]$$

is obtained by solving simultaneously a group of equations of the form

$$\frac{i}{n} = k_{2i}\, C_{s_{i+1}} \exp \frac{\alpha_i \mathbf{F}\epsilon}{RT} - k_{2i-1}\, C_{s_i} \exp -\frac{(1-\alpha_i)\mathbf{F}\epsilon}{RT} \quad [7]$$

With the exchange current expression

$$i_{o,i} = k_{2i}\, \overline{C}_{s_{i+1}} \exp \frac{\alpha_i \mathbf{F}\epsilon_o}{RT} = k_{2i-1}\, \overline{C}_{s_i} \exp -\frac{(1-\alpha_i)\mathbf{F}\epsilon_o}{RT} \quad [8]$$

Equation [7] reduces to

$$\frac{i}{n} = i_{o,i}\left[\frac{C_{s_{i+1}}}{\overline{C}_{s_{i+1}}} \exp \frac{\alpha_i \mathbf{F}\eta}{RT} - \frac{C_{s_i}}{\overline{C}_{s_i}} \exp -\frac{(1-\alpha_i)\mathbf{F}\eta}{RT}\right] \quad [9]$$

The barred concentrations are the equilibrium concentrations (at the reversible potential) of the intermediate substances; the unbarred concentrations are those at the electrode surface during current flow. In the absence of concentration polarization, the ratios $C_{s_1}/\overline{C}_{s_1}$ and $C_{s_{n+1}}/\overline{C}_{s_{n+1}}$ are unity. Therefore $n-1$ variables exist besides i and η in the n equations. These $n-1$ variables can be eliminated by simple determinantal solution. To simplify expression of the determinant, let

$$F_1 \equiv n \exp \frac{\alpha_i \mathbf{F}\eta}{RT} \quad [10]$$

$$G_2 \equiv -n \exp -\frac{(1-\alpha_i)\mathbf{F}\eta}{RT} \quad [10']$$

$$X_i = C_{s_i}/\overline{C}_{s_i} \quad [11]$$

Equation [9] then forms a system of n linear equations with i and X_i as unknowns. The general solution for i can be written as

$$i = N/D$$

where

$$D = \begin{vmatrix} \frac{1}{i_{o,1}} & -F_1 & 0 & 0 & \cdots & 0 \\ \frac{1}{i_{o,2}} & -G_2 & -F_2 & 0 & \cdots & 0 \\ \frac{1}{i_{o,3}} & 0 & -G_3 & -F_3 & \cdots & 0 \\ \vdots & & & & & \\ \frac{1}{i_{o,n-1}} & & & & -G_{n-1} & -F_{n-1} \\ \frac{1}{i_{o,n}} & & & & 0 & -G_n \end{vmatrix}$$

AND

$$N = \begin{vmatrix} G_1 & -F_1 & 0 & \cdots & 0 \\ 0 & -G_2 & -F_2 & \cdots & 0 \\ 0 & 0 & -G_3 & \cdots & 0 \\ \vdots & & & & \\ 0 & & & -G_{n-1} & -F_{n-1} \\ F_n & 0 & & 0 & -G_n \end{vmatrix}$$

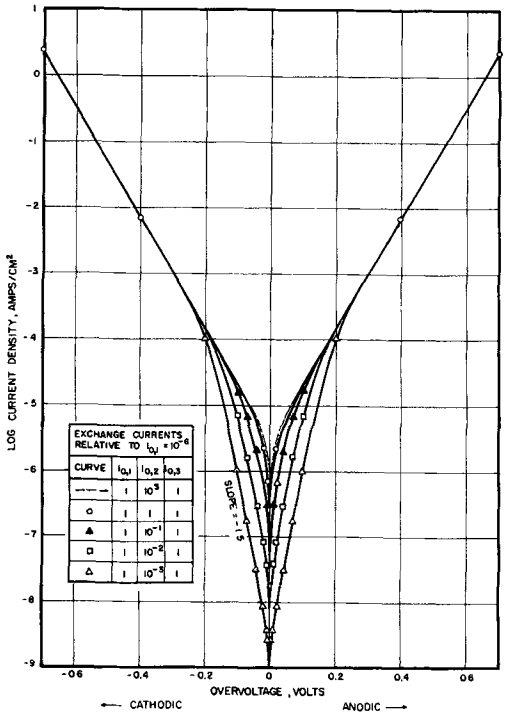

Fig. 6. Theoretical polarization curves—three consecutive electron transfer steps, $i_{o,2}$ varying.

Evaluating the indicated determinant and substituting back for F_i and G_i from Eq. [10] and [10′] gives the resulting general expression:

$$\frac{i}{n} = \frac{\exp\left(\sum_{j=1}^{n} \alpha_j\right)\frac{\mathbf{F}\eta}{RT} - \exp\left[-\left(n - \sum_{j=1}^{n}\alpha_j\right)\frac{\mathbf{F}\eta}{RT}\right]}{\sum_{k=1}^{n}\frac{1}{i_{o,k}}\exp\left[-\left\{(n-k) - \sum_{\substack{j=1\\ j\neq k}}^{n'}\alpha_j\right\}\frac{\mathbf{F}\eta}{RT}\right]} \qquad [12]$$

This equation can be put into many different forms, some of which are more convenient for examination of limiting cases and/or computation, by simply multiplying both numerator and denominator by appropriate exponential terms. One of these forms, which was used for the computer solutions of the three electron case is

$$\frac{i}{ni_{o,1}} = \frac{\left[1 - \exp -\frac{n\mathbf{F}\eta}{RT}\right]}{\sum_{j=1}^{n}\gamma_{o,j}\exp\left\{-\left[(n-j) + \alpha_j\right]\frac{\mathbf{F}\eta}{RT}\right\}} \qquad [13]$$

where $\gamma_{o,j} = \frac{i_{o1}}{i_{o,j}}$ with $\gamma_{o,1} \equiv 1$. This represents a normalization with respect to $i_{o,1}$, and eliminates many operations by introducing exchange current ratios directly.

Equation [13] was solved for $n = 3$, $\alpha_1 = \alpha_2 = \alpha_3 = 0.5$, and both $\gamma_{o,2}$ and $\gamma_{o,3}$ varying from 1 to 1000. The number of possible combinations of α values and exchange current ratios for $n = 3$ is so large as to make it impractical to examine the situation in detail, although again the limiting factor is the mere plotting of the data. However, examination of only a few of the more interesting cases reveals that much the same situation prevails here as with the two electron case, *i.e.*, the appearance of pseudo-Tafel regions at intermediate ratios of exchange currents, the slopes of which approach limiting values which sum to three when a single exchange current controls. This is illustrated by Fig. 6 in which the terminal exchange currents are fixed and equal while the center exchange current ranges from 10^3 to 10^{-3} of the terminal values. Essentially no effect is noted on the curves while the center reaction is faster or even of equal speed, but as it becomes slower the pseudo-Tafel regions appear and approach a slope of 1.5 on each branch. Further illustration is given by Fig. 7 in which $i_{o,2}$ and $i_{o,3}$ are increased until $i_{o,1}$ controls and by Fig. 8 in which $i_{o,3}$ is made progressively smaller until it alone controls. Note that in each of these last two figures one branch of the curve exhibits a true Tafel slope of ± 0.5, while the pseudo-Tafel slope approaches ± 2.5, so that in all three figures the limiting slopes sum to 3, although in different manners. Note also that in each limiting case, extrapolation of both the true and pseudo-Tafel regions yields the value of the smallest exchange current. Still it is entirely plausible that both linear-logarithmic regions may be observable in some experimental systems, thereby yielding sufficient information to solve the reaction parameters completely.

There are, of course, other interesting combinations of transfer coefficients and exchange currents for the three electron case, as well as for the higher n values, but those given are sufficient for the present paper. For those who desire to examine other cases, it need be noted only that the equations are

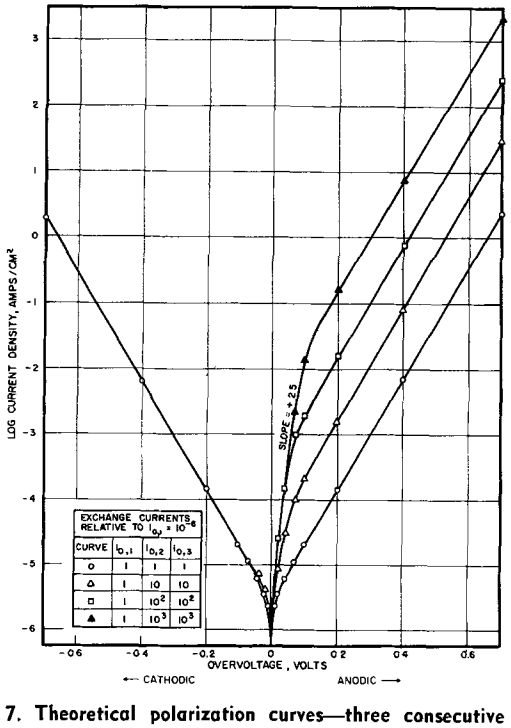

Fig. 7. Theoretical polarization curves—three consecutive electron transfer steps, $i_{o,2}$ and $i_{o,3}$ varying.

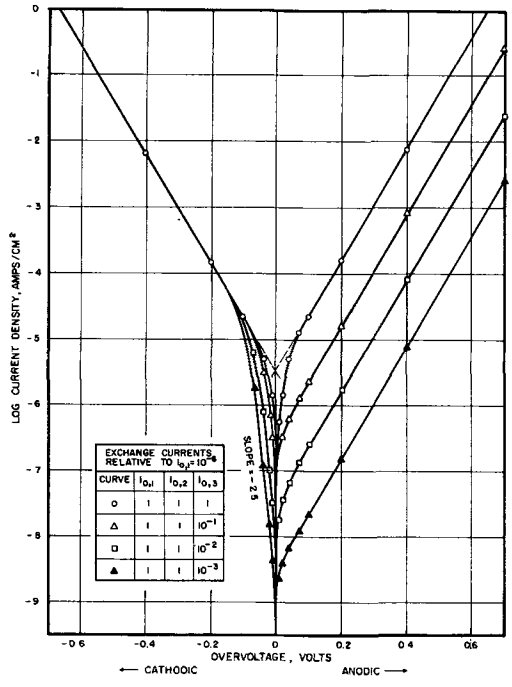

Fig. 8. Theoretical polarization curves—three consecutive electron transfer steps, $i_{0,3}$ varying.

solved readily in a matter of seconds on almost any modern computer, once a satisfactory program is established.

Conclusion

The use of complete solutions of equations describing the particular process of consecutive electron transfers can improve materially the interpretation of experimental data over the previously used methods of approximation and limiting cases. Certainly this is true in the majority of practical systems, where intermediate values of the kinetic parameters will be prevalent, and limiting cases not often encountered. The biggest drawback to the use of such complete solutions for interpretation lies in the fact that the experimental data need to be considerably more accurate to obtain full value from comparison with the theoretical curves. As a matter of fact, it is easy to see how one can be led to a false conclusion by data which are only a few per cent in error. Nevertheless, one can also be led (and probably more often) to a false conclusion by very accurate data if it is *not* realized that perfectly sound theoretical curves describing the data exist. As the procedures for obtaining data in electrode kinetics improve in accuracy, then, it is desirable to extend the use of computers and complete solutions of the kinetic equations into those areas where only approximations and limiting cases have been used previously.

Acknowledgment

The author wishes to acknowledge the invaluable help of Dr. A. F. Wittenborn of Texas Research Associates, who not only extended the equations to the general case of n consecutive steps, but also pointed out the various forms the equations could take, and selected the one for numerical computations.

This work was carried out under a research contract with Union Carbide Consumer Products Company as a part of their fundamental research program in organic electrochemistry.

Manuscript received July 31, 1961; revised manuscript received January 9, 1962. This paper was prepared for presentation at the Indianapolis Meeting, April 30-May 3, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

Cathodic Oxygen-Evolution Reaction of the Peroxo Cobalt Complex $[(NH_3)_5CoO_2Co(NH_3)_5]^{5+}$

S. Barnartt and R. G. Charles

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

ABSTRACT

At a bright platinum cathode in H_2SO_4 solutions, the complex ion $[(NH_3)_5CoO_2Co(NH_3)_5]^{5+}$ is reduced quantitatively to $2Co^{2+}$ in a one-electron reaction, with evolution of one molecule of oxygen gas. The same products also are produced by chemical reduction with silver powder. A probable mechanism for the cathodic reduction is outlined and its applicability to chemical reduction described. A cell containing an acid solution of this cobalt complex and platinum electrodes evolves 1.25 O_2/F, and may be used as an oxygen generator or as a sensitive gas coulometer.

In the course of cathodic current efficiency measurements for the oxygen-dissolution reaction, some measurements were made using sulfuric acid solutions containing the pentavalent decammino-μ-peroxo dicobalt ion I.

$$[(NH_3)_5CoO_2Co(NH_3)_5](SO_4)_2(HSO_4)\cdot 3H_2O$$

II

There has been considerable interest in this ion in the past due to the supposed tetravalency of one of the two cobalt atoms. Recent work has shown, however, that the single unpaired electron present in I is delocalized over the grouping CoO_2Co and that the two cobalt atoms are equivalent (1).

Solutions made by dissolving the corresponding sulfate, compound II, in molar sulfuric acid are relatively stable at ordinary temperatures. We have found that oxygen did not dissolve at a platinum cathode in these solutions, but instead oxygen was evolved. Preliminary experiments indicated that one mole of oxygen was liberated per Faraday. Since cathodic oxygen-evolution reactions are virtually unknown, we have investigated this reaction in some detail.

Experimental Procedures

Materials.—The preparation of $[(NH_3)_5CoO_2Co(NH_3)_5](SO_4)_2\cdot(HSO_4)\cdot 3H_2O$ was carried out by the method of Gleu and Rehm (2). The compound was recrystallized from 1M H_2SO_4 and air-dried at room temperature. Cobalt analysis gave a value of 17.8% (theoretical 17.77%).

Acid solutions containing II were moderately stable, but detectable changes in the visible and ultraviolet spectra occurred after long standing at room temperature (> 24 hr). Hence the solutions were prepared, without heating, immediately before use. Solid compound II was stored in a refrigerator and appeared to be stable indefinitely.

Measurements of current efficiency for oxygen evolution.—Figure 1 presents a diagram of the Pyrex glass electrolytic cell, which was designed for measurements of gas-evolution or gas-dissolution efficiency. For cathodic efficiencies the vertical plate a was made anode and the horizontal screen c was cathode. Both electrodes were of bright platinum. The former was suspended by a thin platinum wire; the latter, a screen of total geometrical area 10 cm^2, was held in place by means of a gold-plated clip and rod b, the latter being sealed through the cap of the cell. The cap was joined to the body of the cell with a standard taper rubber o-ring joint.

The catholyte was separated from the anolyte by a coarse fritted glass disk d, and was stirred magnetically by means of a Teflon-covered stirrer. Stopcocks e and f, attached to the cell with o-ring joints g, permitted the gas phase above the catholyte to be flushed and pressurized with oxygen or other gas.

A glass tube of uniform cross section was used for a 13 cm length of the anode compartment at and above the reference line, ref. Changes in the height h of anolyte level above catholyte level were restricted

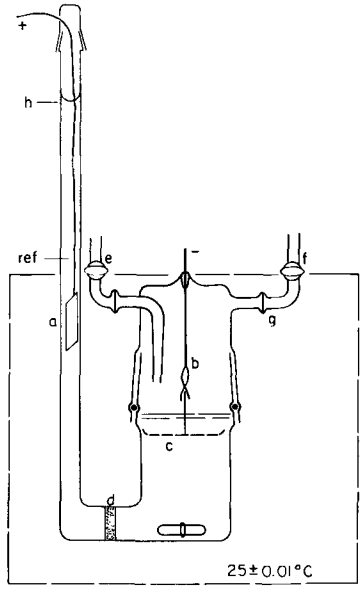

Fig. 1. Diagram of cell for measurement of gas-evolution or gas-dissolution efficiency.

to this region during a current efficiency measurement. The total volume of the cell up to the reference line was determined by filling the cell with water and weighing. In each experiment the volume of electrolyte was fixed at 50.0 ml, so that the gas volume in the cathode compartment was known for any value of h.

The cell was calibrated with 1M H_2SO_4 in an atmosphere of pure oxygen, with a current of 3.60 ma (0.36 ma/cm^2). A 1-hr period of cathodic pre-electrolysis was used to remove reducible impurities, after which the oxygen pressure was adjusted so that the solution level h was near the top of the uniform bore tube. The level was allowed to stabilize; then the screen electrode was made cathode again and the change of level Δh, for passage of a measured number of coulombs, was determined with a traveling microscope.

The number of moles Δn of gas dissolved or evolved is related to Δh through the relationship (see Appendix)

$$\Delta n = \frac{\Delta h}{RT}[A(P_i - P_s) + V_f d/13.5] \qquad [1]$$

Here A is the internal cross-sectional area of the anolyte tube. P_i is the initial pressure and V_f the final volume of the gas in the cathode compartment. P_s is the vapor pressure of the solution and d its density; for dilute solutions the corresponding values for the solvent may be used. When the atmospheric pressure changes during the determination, a correction to Δh is applied by use of Eq. [2], Appendix. Calibration of the cell involved determining A from an experimental measurement of Δh and the corresponding value of Δn, the latter derived from the number of Faradays passed. The value of A thus obtained for cathodic oxygen dissolution agreed with that similarly obtained from anodic oxygen evolution measurements within 1%.

For measurements on solutions of compound II, the cathode compartment was flushed and filled with pure argon. Otherwise the procedure used followed that of the calibration experiments, using the same current (3.60 ma) and the same pre-electrolysis period (1 hr) for each measurement.

Reduction of the μ-peroxo compound.—The number of moles of compound II reduced at the cathode per Faraday, as well as the reduction potential, were determined in a cell similar to that of Fig. 1 but with two modifications. (*A*) The cap of the cathode compartment contained an opening which permitted insertion of a saturated calomel electrode of the fiber-junction type. (*B*) The fritted disk was of very fine porosity; and the electrolyte level as well as the gas pressure (flowing argon above the catholyte, air above the anolyte) were the same on both sides. Thus diffusion of II between catholyte and anolyte was negligible.

The concentration of II in the catholyte was determined periodically by interrupting the current and removing a sample of the solution for analysis with a Cary recording spectrophotometer. The characteristic absorption peak at 6690Å (molar extinction coefficient = 880 for solutions in 1M H_2SO_4) was used for concentration measurements; none of the reduction products absorb significantly at this wavelength. Each sample was analyzed without dilution using an absorption cell of path length 0.20, 1.00, or 10.0 cm, as required The sample was returned as fully as possible to the electrolytic cell after measurement.

Cathode potential measurements, made with reference to the saturated calomel electrode, were converted to the hydrogen scale.

Determination of reduced cobalt-containing species.—Solutions which were analyzed for the quantity of II cathodically reduced also were subjected to cation-exchange chromatography to separate the cobalt-containing species. The ion-exchange column used (Bio-Rad AG 50W-X8 in the hydrogen form) and its effectiveness for acid solutions of some cobalt complexes have been described by the authors in a previous paper (3). The amount of eluted Co^{2+} was determined in acetate-buffered solutions by precipitation with 8-hydroxyquinoline (2). Since it was necessary to precipitate in the presence of a large amount of inert salts, which caused errors due to coprecipitation, simultaneous runs were carried out with standard $CoSO_4$ solutions containing similar salt concentrations. The latter results were used to apply corrections for coprecipitation.

Results and Discussion

Cathodic oxygen evolution.—A saturated solution of compound II in 1.00M H_2SO_4 was studied at 25.0°C (±0.01) in the cell of Fig. 1. An excess of II was added to the cell as a finely ground powder, and vigorous agitation was used. Hence the concentration of II remained close to the saturation value, 0.0035M, during cathodic reduction. Mass spectrometer analysis of the gas above the catholyte after electrolysis showed that only oxygen was evolved.

A typical curve showing the change in h (corrected for changes in atmospheric pressure) during reduction of II at constant current is presented in Fig. 2.

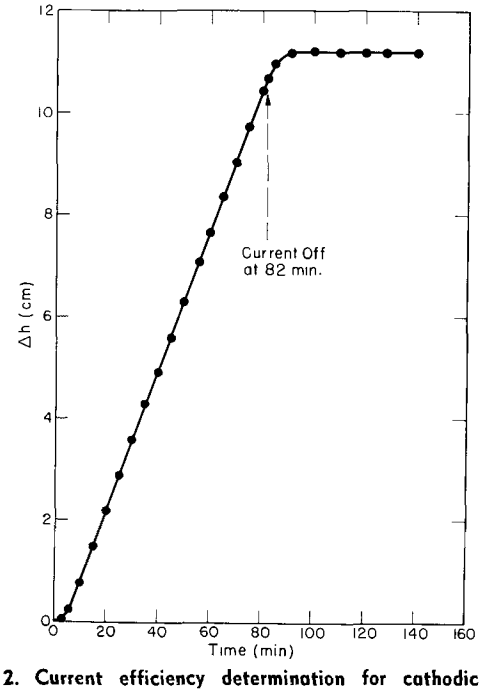

Fig. 2. Current efficiency determination for cathodic oxygen evolution from saturated solution of compound II in molar H_2SO_4, 25.00°C, 3.60 ma.

Table I. Experimental results for cathodic reduction of a saturated solution of $Co_2O_2(NH_3)_{10}(SO_4)_2HSO_4 \cdot 3H_2O$ in 1M H_2SO_4

	mole/Faraday	
$Co_2O_2(NH_3)_{10}(SO_4)_2HSO_4$ reacted	1.01,	1.00
O_2 evolved	0.99,	0.97
Co^{2+} produced	2.00,	1.99

The indicating level h exhibited an initial time lag, caused in part by the presence of the fritted disk in the cell. Cathodic oxygen evolution per Faraday calculated from the slope of the curve, however, was the same as that derived from the total Δh and total coulombs passed, within experimental error. It should be noted that oxygen also was evolved at the anode, but the rate of evolution and bubble size were sufficiently small that there was no difficulty in reading the meniscus level h with the traveling microscope.

The cathodic oxygen evolution from compound II was found to be one mole per Faraday, Table I.

Moles of compound II reduced per Faraday.—In the first type of experiment the current efficiency for reduction of II, as well as the cathode potential, were followed as a function of concentration, beginning with an unsaturated solution. The concentration of unreacted II was determined spectrophotometrically. The data, shown in Fig. 3, demonstrated that one mole of the compound was reduced per Faraday over the concentration range studied.

At concentrations below 0.3 mM the cathode potential was decreasing rapidly. Small amounts of a second cathodic reaction, such as oxygen reduction, could be expected in this region, but were not detectable within the accuracy of the data.

A more precise determination of the reduction efficiency was carried out in a second type of experiment in which the cathode compartment contained a saturated solution of II in 1M H_2SO_4, together with an excess of the powdered compound. After passage of 2.7×10^{-4} F, the contents of the cathode compartment (dissolved and undissolved) were removed. Sufficient 1M H_2SO_4 was added to effect complete solution and the resulting solution was analyzed spectrophotometrically to determine the quantity of II reduced. The results of duplicate experiments, included in Table I, show one electron per molecule of II reacted. There was evidently no simultaneous reduction of molecular oxygen (which would require 4 electrons per molecule) at the reduction potential, which was 0.82v in these experiments.

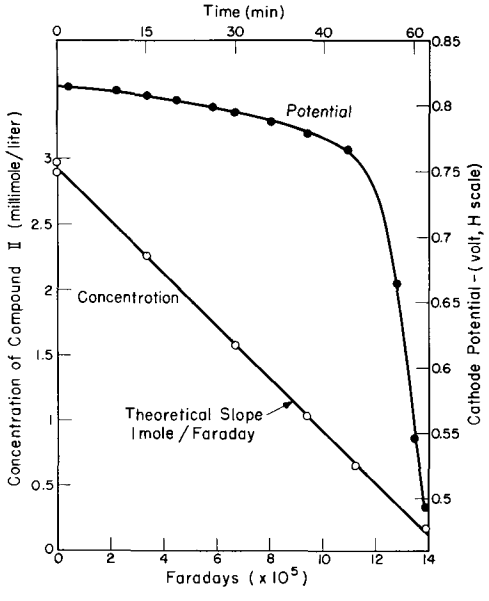

Fig. 3. Change in concentration and cathode potential during electrolysis of an unsaturated solution of compound II in 1M H_2SO_4, 3.60 ma, 22°C.

To test the possibility that a cathode surface of greater catalytic activity might give rise to a competing reaction, the latter type of experiment was repeated with a freshly platinized platinum screen in place of the bright platinum cathode. Results under these conditions were less reproducible but a lowered efficiency for reduction of II always resulted (moles II reacted per Faraday $\leqq 0.9$). Possibly the highly active platinized surface catalyzed the 5-electron reduction of II to Co^{2+} and water.

Cobalt-containing products.—Ion-exchange separation of cathodically reduced solutions of II in 1M H_2SO_4 yielded only one cobalt-containing product, Co^{2+} ion. Quantitative determination of Co^{2+} showed that two Co^{2+} ions were produced per electron (Table I). Under the conditions used, 8-hydroxyquinoline precipitates only Co^{2+} and does not interact with Co(III) species (2).

Reaction mechanism.—The above results establish unequivocally the over-all cathodic reaction

$$[(NH_3)_5CoO_2Co(NH_3)_5]^{5+} + 10H^+ + e \rightarrow O_2 + 2Co^{2+} + 10NH_4^+ \quad [3]$$

as well as the absence of side reactions.

The following reduction mechanism is proposed. The pentavalent ion is assumed to adsorb on the cathode with the peroxo group attached to the metal surface. Transfer of a single electron yields the adsorbed tetravalent ion III

$$M - - - \begin{bmatrix} & Co(NH_3)_5 & \\ O_2 & & \\ & Co(NH_3)_5 & \end{bmatrix}^{5+}$$

$$+ e \rightarrow M - - - \underset{\text{III}}{\begin{bmatrix} & Co(NH_3)_5 & \\ O_2 & & \\ & Co(NH_3)_5 & \end{bmatrix}^{4+}} \quad [4]$$

By means of the internal oxidation-reduction reaction [5], III decomposes to yield adsorbed molecular oxygen and an ammine complex of Co (II)

$$M - - - \begin{bmatrix} & Co(NH_3)_5 & \\ O_2 & & \\ & Co(NH_3)_5 & \end{bmatrix}^{4+}$$

$$\rightarrow M - - - O_2 + 2[Co(NH_3)_5]^{3+} \quad [5]$$

The latter is known to be unstable in acid solutions

$$[Co(NH_3)_5]^{2+} + 5H^+ \rightarrow Co^{2+} + 5NH_4^+ \quad [6]$$

Thus this simple mechanism is in complete accord with the observed over-all reaction [3].

Reaction [5] requires some justification in view of results reported previously (3) for decomposition of the ion $[(NH_3)_5CoO_2Co(NH_3)_5]^{4+}$ in H_2SO_4 solutions. This ion was found to decompose rapidly to yield at least eight cobalt-containing species. The data described in the previous paper (3) indicated that the first step in this decomposition involved attachment of a hydrogen ion to the peroxo group. From this it may be assumed that the attachment of the tetravalent ion III to the cathode surface prevents bonding of hydrogen ion and forces ion III to follow the simpler decomposition path of [5].

In a recent paper Vlcek (4), using a vibrating platinum cathode, showed that the reduction of $[(NH_3)_5CoO_2Co(NH_3)_5]^{5+}$ to $[(NH_3)_5CoO_2Co(NH_3)_5]^{4+}$ occurs reversibly in ammoniacal solutions. In ammonia, unlike acid, the tetravalent ion is relatively stable and can exist in the bulk of the solution in equilibrium with dissolved O_2 and Co (II) ammines. Thus the mechanism for cathodic reduction of I in ammonia differs from that in acid in that $[(NH_3)_5CoO_2Co(NH_3)_5]^{4+}$ can desorb from the cathode and accumulate in the ammoniacal solution.

The only other published investigation on reduction of I concerned chemical reduction with As_2O_3 in H_2SO_4 solutions, in the presence of OsO_4 as catalyst (2). A simple over-all reduction reaction was obtained. Oxygen was evolved, and Co^{2+} was the only cobalt-containing product. Incidental to the present work we studied a second, and more convenient, chemical reduction method. This involved merely shaking a mixture of powdered compound II and excess powdered silver metal with 1M H_2SO_4. The reaction proceeds quantitatively and relatively rapidly at room temperature in accordance with the over-all change

$$[(NH_3)_5CoO_2Co(NH_3)_5]^{5+} + Ag + 10H^+ \rightarrow O_2 + 2Co^{2+} + 10NH_4^+ + Ag^+ \quad [7]$$

Analytical results for Co^{2+}, O_2, and Ag^+ were all in good agreement with the theoretical values from [7].

That Co^{2+} is the only reduced cobalt species produced in acid by either chemical-reduction method is readily explained by generalizing the mechanism represented by [4] to [6]. For chemical reduction, the reductant [As(III) or Ag] becomes attached to the peroxo group of the pentavalent complex I. Following electron transfer the oxidized form of the reductant, which is still bonded to the peroxo group, prevents the hydrogen ion addition step which is needed to produce the more complex cobalt-containing products observed in our earlier work (3).

Possible applications.—The fact that oxygen is evolved at both cathode and anode in an acid solution containing II provides a novel and potentially useful method for electrolytically introducing known amounts of oxygen, uncontaminated by other gases, into closed systems. Electrolysis of solutions containing II also should find application in gas coulometers such as those described by Lingane (5). The sensitivity of the coulometer is increased by the use of II since 1.25 moles of gas (O_2) are evolved per Faraday, as compared with a total of 0.75 mole/**F** of hydrogen plus oxygen from the solutions commonly employed.

Conclusions

1. At a bright platinum cathode in H_2SO_4 solutions, the pentavalent complex $[(NH_3)_5CoO_2Co(NH_3)_5]^{5+}$ is reduced quantitatively to Co^{2+} in a one-electron reaction, with simultaneous release of the peroxo oxygen as oxygen gas.

2. Simple chemical reduction with silver powder was found to yield the same products quantitatively.

3. A probable reduction mechanism is outlined, based on the assumption that the reducing ion or metal surface atom becomes attached to the pentavalent complex at the peroxo group.

4. Electrolysis of an acid solution of the pentavalent complex between bright platinum electrodes provides a convenient electrolytic generator of pure oxygen. This system may also be used as a sensitive oxygen coulometer, yielding 1.25 O_2 per Faraday.

APPENDIX

Relationship between Δn and Δh for the current-efficiency cell

Evolution of Δn moles of gas increases the gas volume above the catholyte by $A(\Delta h)$. It increases the pressure of the gas by $(\Delta h)d/13.5$ and its water content by $\Delta n_w = A(\Delta h)P_s/RT$. From $\Delta n + \Delta n_w = (P_fV_f - P_iV_i)/RT$, one obtains

$$\Delta n = \frac{\Delta h}{RT}[A(P_i - P_s) + V_f d/13.5] \quad [1]$$

Dissolution of Δn moles of gas decreases the volume, pressure and water content of the gas by the same quantities as above. Since Δh is now negative, Eq. [1] still applies without any change of sign. A negative value of Δn refers to gas dissolution, a positive one to gas evolution.

If atmospheric pressure changes during the measurement, a correction δh must be applied to the observed value of Δh in Eq. [1]. An increase in atmospheric pressure, p_a, corresponds to an increase in gas volume of $A(\delta h)$ and a net increase in gas pressure of $[p_a + (\delta h)d/13.5]$. By applying the approximation $\Delta P/P_f = -\Delta V/V_f$, one obtains, with sufficient accuracy

$$\delta h = -p_a[A\,P_f/V_f + d/13.5]^{-1} \quad [2]$$

Thus $|\delta h|$ must be added to Δh_{obs} where atmospheric pressure has increased, and vice versa.

Technical Notes

Conditions for the Formation of α or β Lead Dioxide During the Anodic Oxidation of Lead

Richard A. Baker

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

The work of Kiseleva and Kabanov (1,2) concerning the behavior of the α and β modifications of lead dioxide in sulfuric acid has led them to propose that the formation of the β form is a consequence of H_2SO_4 chemisorption on the PbO_2 formed during anodic oxidation of lead. This explanation is open to challenge since it implies that sulfate or bisulfate anions perform, at least in part, a vital function in determining the lead dioxide modification formed. Recent work performed in this laboratory as well as other well-known facts support the contention that it is hydrogen ion concentration which influences the nature of the PbO_2 deposit.

Methods for the preparation of α- and β-PbO_2 in the laboratory are well known. In this laboratory, β-PbO_2 has been readily prepared by electrodeposition from acidic solutions of lead nitrate, lead sulfamate, lead fluoborate, and lead perchlorate as well as by the anodic oxidation of lead in strong sulfuric acid. On the other hand, α-PbO_2 has been electrodeposited from neutral solutions composed primarily of lead nitrate and lead acetate, and by the anodic oxidation of lead in alkaline solution at high current densities. Published descriptions of electrodeposition methods have been given by Rüetschi, Angstadt, and Cahan (3) and by Thomas (4). These conditions for electrodeposition suggest strongly that it is the pH which is the major factor controlling the modification of lead dioxide formed.

To test further the relative importance of H^+, $SO_4^=$, and HSO_4^- ions, a lead electrode was anodized and cycled in solutions of 2M Na_2SO_4, 2M $KHSO_4$, and 2M H_2SO_4 at room temperature and the lead dioxide modification produced was identified by means of x-ray diffraction powder patterns. The electrode was Doe-Run lead 99.998% pure which was first etched, washed, dried, and after immersion in electrolyte, made cathodic for a short time to reduce residual oxide.

The anodic current density was 1.5 ma/cm^2 of geometric area while cathodic current density was 0.75 ma/cm^2. Periods of charge were of the order of 10 times the capacity of the lead dioxide formed and discharges were carried to reversal of potential sign referred to a Hg/Hg_2SO_4 reference electrode. The results are presented in Table I.

Table I.

Electrolyte	pH	Electrode treatment	PbO_2 Modification
2M Na_2SO_4	7.6-8.0	Anodic only	100% α
		Anodic + 5 charge-discharge cycles	100% α
2M $KHSO_4$	0.7	Anodic only	100% α
		Anodic + 5 charge-discharge cycles	30% α — 70% β to 60% α — 40% β
2M H_2SO_4	<0	Anodic only	~50% α ~50% β
		Anodic + 3 charge-discharge cycles	<10% α >90% β

It is significant that only α-PbO_2 was formed in neutral Na_2SO_4 solution. Initial anodic oxidation of lead resulted in the formation of β-PbO_2 only in 2M H_2SO_4. In $KHSO_4$ solution, β-PbO_2 was produced only after charge-discharge cycling. It may be concluded, therefore, that the modification of lead dioxide formed on anodic oxidation of lead and even subsequent cycling depends primarily on the pH of the electrolyte. The only function of the sulfate species present other than electrical neutrality and conductivity of the electrolyte is the limit its concentration places on the solubility of lead II ions present in the solution.

Kiseleva and Kabanov have proposed that the formation of β-PbO_2 is retarded by the addition of Co^{++} in the cell because the Co^{++} displaces H_2SO_4 which is chemisorbed on the oxide. The formation of the α modification in turn is supposed to provide better protection against the anodic oxidation of the underlying lead. Our work as reported here together with the other facts previously described

indicate that it must be the protons which are displaced by cobalt ions and not H_2SO_4 as such.

The Effect of Electropolishing on the Codeposition of Hydrogen with Nickel

Thomas C. Franklin and Archie Blackburn

Chemistry Department, Baylor University, Waco, Texas

A number of investigations have been made of the advantages of electropolishing as a pretreatment of the electrode in electrodepositions. These have been surveyed by Faust (1). As a part of an investigation of the effect of organic additives on the hydrogen content of nickel deposits (2), a short study was made of the variation in the amount of hydrogen codeposited with nickel as a function of the pretreatment of the electrode.

Experimental Procedure

Nickel wires were used as the basis metal for nickel plating. They were 14 gauge and 1.5 cm in length. They were prepared for plating by two procedures. In one procedure the wire was polished mechanically by hand with number 2/0 emery cloth. In the other procedure the wire was polished mechanically in the same way and then electropolished at a current density of 60 ma/cm^2 in a bath containing 50 ml water, 370 ml 85% phosphoric and 80 ml 98% sulfuric acid. Nickel was plated from a standard Watts bath for a period of 12 min at a current density of 6.96 ma/cm^2.

The hydrogen content of the deposits and the current efficiencies were measured in the manner previously reported (2). The codeposited hydrogen was oxidized electrolytically, and the number of coulombs necessary for the oxidation was a measure of the amount of hydrogen. Current efficiency was measured by measuring the volume of hydrogen evolved during the deposition.

Table I. Effect of pretreatment of electrode on amount of codeposited hydrogen

	Number of millicoulombs necessary to oxidize codeposited hydrogen		
Electrode	Mechanically polished electrode	Electropolished electrode	Remarks
1	6.25 ± 0.086	Not measurable	Plated 12 min, electropolished 2 min
2	3.12 ± 0.51	Not measurable	Plated 12 min, electropolished 2 min
2		Not measurable	Plated 60 min, electropolished 2 min
3	3.26	Not measurable	Plated 12 min, electropolished 5 min

Results and Conclusions

Table I summarizes the results of the measurements of the amount of codeposited hydrogen. The table shows clearly that electropolishing the electrode before plating cuts the amount of hydrogen codeposited down to the point where it was not measurable by this technique.

There are two possible explanations for these results: (*a*) the difference in strain in the surface could change the current efficiency of the deposition process; (*b*) the difference in surface strain and roughness could change the ability of the hydrogen to adsorb to the surface.

Table II shows that there is essentially no difference between the current efficiency on the mechanically polished and electropolished electrodes.

Apparently the difference lies in the ability of the mechanically polished electrode to adsorb hydrogen. This is further shown by Table III, in which is tabulated the hydrogen retained by the nickel electrodes when only hydrogen is electrically generated on the electrodes.

Table II. Effect of pretreatment of the electrode on the current efficiency for the evolution of hydrogen

	Current efficiency for the evolution of hydrogen on:	
Electrode	Mechanically polished electrode, %	Electropolished electrode, %
4	1.69	2.00
5	1.83	1.64
6	2.42	2.80

Table III. Number of millicoulombs necessary to oxidize hydrogen adsorbed on and absorbed in nickel electrodes

Electrode	Mechanically polished	Electropolished
1	4.05 ± 0.23	0.04
2	4.38	0.02
3	3.62 ± 0.03	Not measurable
4	2.65 ± 0.02	Not measurable

Some Observations on Overpotential Variations During the Galvanostatic Electrodeposition of Copper

J. K. Prall and L. L. Shreir

Metallurgy Department, Corrosion Section, Battersea College of Technology, London, England

The variation in the activation overpotential with time, which has been observed by several workers during studies of the mechanism of electrode processes (1a-1h), is a factor which may result in irreproducibility of the value of the overpotential. During a study of the electrodeposition of copper from acid copper sulfate solutions it was observed that the conventional method of determining the activation overpotential (η_A), *i.e.*, allowing a predetermined time to elapse before recording the overpotential, did not always give reproducible results owing to the changing topography of the cathode surface during electrodeposition. As a result of these observations a reproducible substrate technique has been developed in which a platinum sheet is used as the cathode for each determination of η_A at each value of constant current. Removal of the copper deposit is effected by anodic dissolution before the next determination of η_A at another current. Full details of this apparatus and technique have been described in a previous publication (2).

Observations of the $\eta_A - t$ curves using this technique for a series of acid copper sulfate solutions (including some with addition agents) has led to the conclusion that these curves can be classified into three types. In the initial time interval, t_1, which may be a fraction of a second, the rapid rise in η_A is due principally to the establishment of the electrical double layer; t_1 is affected only slightly by variations in the substrate properties. If the surface topography of the substrate is unaffected by the electrode process, *e.g.*, a reduction of ions to a lower valency state or hydrogen evolution, the activation overpotential should remain constant with time. However, in the present study it was observed that during the next time interval t_2 (which could persist for several minutes), η_A could either increase or decrease immediately after the double layer was completely charged. The sign, magnitude, and duration of this change appeared to depend on the nature of the substrate (crystal orientation and size, crystal defects and thickness of deposit) and on the nature of the electrolyte (presence of co-depositable metallic impurities, active impurities such as chloride ions, concentration polarization, etc.). If the duration of t_2 is appreciable, then clearly the experimental time involved in obtaining $\eta_A - i$ plots will be unduly long and, in addition, other errors may be introduced by prolonged electrolysis.

A study has been made of the factors responsible for η_A changes during time t_2, and it has been established that the greater the amount of mechanical deformation applied to the platinum substrate (*e.g.*, by rolling or polishing) then the greater is the magnitude of $\Delta\eta_A$ and t_2. Figure 1 shows some $\eta_A - t$ curves which have been obtained using a platinum substrate, which had been subjected to different degrees of cold-rolling; before electrolysis the cathodes were lightly etched in boiling aqua regia for 10 sec.

It can be seen that the initial values of η_A differ according to the extent of cold-working of the platinum although the steady-state value is independent of any textural difference in the substrate which could have arisen during either cold-working or recrystallization. This indicates that the technique provides a sensitive method of detecting any effects caused by the structure of the substrate. It is relevant to observe that it has been previously postulated (3) that lattice building in electrocrystallization is accomplished by surface diffusion of transferred adions to edges, steps, or kinks; in the present study the number of these defects will be proportional to the degree of cold-work (4).

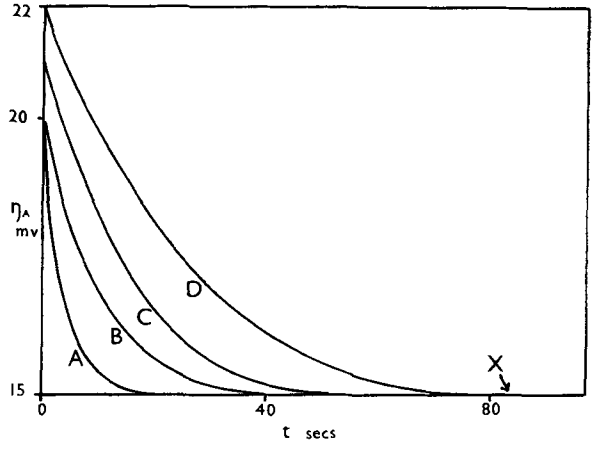

Fig. 1. Effect of metallurgical condition of the platinum substrate on the variation of η_A with time: electrolyte 0.5M $CuSO_4$ + 0.5M H_2SO_4, at 25°C and 0.25 amp/dm²: A,* V.P.N. 48, heat treatment continued to allow grain growth; B, V.P.N. 48; C, V.P.N. 72; D, V.P.N. 90. X, is the steady-state η_A.

* V.P.N. = Vickers Pyramid Hardness Number.

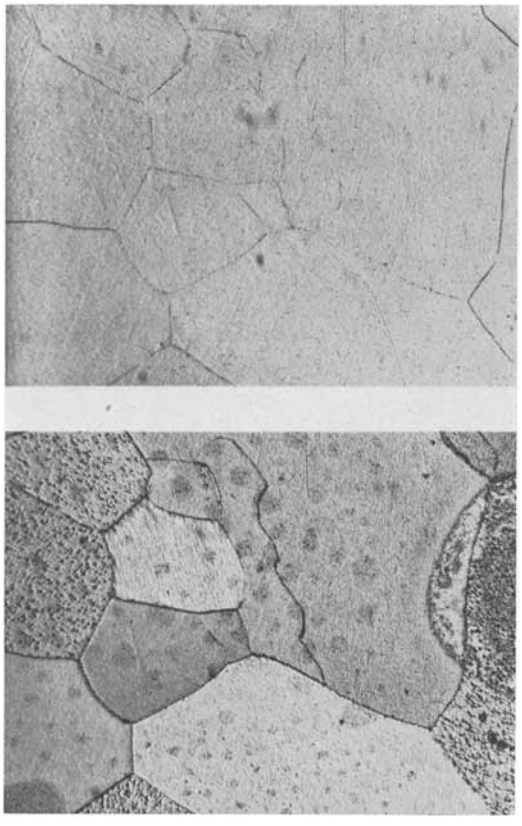

Fig. 2. A. (top) Platinum substrate surface, after light etching and prior to its being electroplated. Mag. 20X. B. (bottom) Localized growth of copper at the grain boundaries. Platinum substrate as described above, electroplated with copper and removed from plating solution when the steady η_A was reached.

Observations of the growth of thin layers of the deposits (Fig. 2A, 2B) show that deposition occurs preferentially at grain boundaries and in a direction which is perpendicular to the substrate. This would indicate that the more imperfect the substrate the greater will be localized deposition at imperfect sites (in this case crystal boundaries) and the greater the charge required to cover completely the platinum substrate. This is supported by the results shown in Fig. 1. In addition it has been observed that with any given substrate the $\eta_A - t$ curve can be reproduced after any time t (within the time t_2) without hysteresis during anodic and cathodic cycling. Further, it has been established that, irrespective of the current density, a constant charge is required to produce the same steady-state value of η_A.

The classical procedure (5) of allowing η_A to become constant at a given value of current is not always satisfactory owing to surface roughening of the deposit and other factors such as changes in concentration of active species in the electrolyte; such factors are insignificant in the reproducible substrate method owing to the very small charge used for each determination of η_A.

The present work has necessitated a study of the effect, and elimination, of adverse impurities in the electrolyte as it is well known that even trace amounts of impurities may have a very marked effect on η_A and the crystal form of the deposit (8). In particular, the effects of traces of chloride ions have been studied as, with normal reagents, this impurity is usually present in significant quantities and is difficult to remove by, for example, repeated recrystallization of $CuSO_4 \cdot 5H_2O$ (where 1-10 ppm Cl can still persist). Electrolytes, low in Cl^-, were prepared in solution by one of the following reactions, and in both cases the reagents can be prepared virtually free of chloride

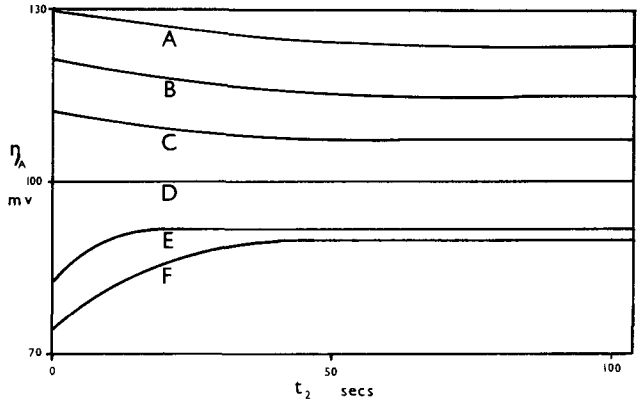

Fig. 3. Effect of chloride ions, added to a chloride-free electrolyte, on the variation of η_A with time: electrolyte 0.5M $CuSO_4$ + 0.5M H_2SO_4, at 25°C and 2.0 amp/dm^2: A, 0.00 ppm Cl^-; B, 0.08; C, 0.15; D, 0.60-5.00; E, 12.00; F, 40.00.

$$Ag_2SO_4 + Cu \rightarrow CuSO_4 \text{ aq.}$$

$$CuO + H_2SO_4 \rightarrow CuSO_4 \text{ aq.}$$

A further possibility of removing chlorides is by anodic oxidation at a platinum anode (6).

The effects of Cl^- on η_A are shown in Fig. 3, and it is evident that the amounts of chloride which are normally present, even in carefully prepared electrolytes, can markedly affect η_A.

The effect of Cl^-, on depolarization generally, has been attributed to their action in facilitating the transfer of electrons at the cathode surface (7). The reduction in t_2 with increasing chloride ion concentration may be explained on the basis that these ions encourage the electrodeposition of copper at otherwise unfavorable planar sites thereby resulting in a more rapid coverage of the platinum substrate.

It is considered from this preliminary study that the reproducible substrate technique may be of general application in studying the effect of the metallurgical condition of the substrate [providing that this is unaffected during electrolysis (2)] on electrocrystallization.

Chemical Etching of Germanium in HF-HNO_3-H_2O Solutions

Thomas E. Burgess

Research Laboratories, Sprague Electric Company, North Adams, Massachusetts

The kinetics of etching of germanium in HF-HNO_3-H_2O solutions have been reported by several authors and proposals of etching mechanisms have been made (1-4). Camp (5) has shown that both activation and diffusion control of the etching rate of germanium exist in solutions of HF-H_2O_2-H_2O and similar systems. The work reported here is concerned with the etching of germanium in HF-HNO_3-H_2O solutions under isothermal conditions and gives the chemical etch rates of germanium over a wide range of solution composition and temperatures of the etching medium. The results indicate that diffusion control of the etching rate appears when the nitric acid concentration in the etchant is high. An abrupt shift to activation control appears at lower nitric acid concentration and holds over a wide concentration range.

Experimental

The etch rates of germanium in the HF-HNO_3-H_2O solutions were determined by measuring the loss in weight of germanium pieces which had been etched for given periods of time in solutions maintained at constant temperatures during the etching process. Pieces of germanium measuring 0.64x0.64x0.25 cm were cut from single crystal material with the 0.64x0.64 faces lying in the crystal plane. These pieces were weighed and then supported in the etchant with all faces except one 0.64x0.64 cm face masked with polystyrene cement. The polystyrene cement effectively masked all surfaces during the etching reaction with only very slight lifting occurring around the edges of this mask leading to an insignificant etching error. The etchant was maintained at a constant temperature during the reaction by placing the polyethylene reaction beaker containing about 30 cc of solution inside a glass cooling cell through which water circulated from a controlled temperature bath. Vigorous agitation of the etchant was maintained during the reaction by a magnetic stirrer in order that the surface temperature of the etching germanium would remain at a constant value. It had been previously determined, by cementing a thermocouple to the etching surface, that the surface temperature rose 30°-40°C above the bath temperature when stirring was omitted. After etching for 3 min the germanium was removed from the etchant, washed with water, and the mask removed by peeling off the cement. Following this, the germanium piece was washed in toluene to remove traces of the cement, dried under a heat lamp, and weighed. The amount of germanium removed from the pieces during etching varied from 1 to 30 mg, depending on the composition and temperature of the etch.

The etchants were prepared from reagent grade nitric acid (70%) and hydrofluoric acid (49%) and water was added to all mixtures to adjust its concentration to 33M, the concentration of water in the reagent hydrofluoric acid. Thus, the etching rates were made in solutions having a constant water concentration with varying concentration ratios of nitric acid and hydrofluoric acid.

Results

Table I lists the data obtained in etching 1 ohm-cm n-type {111} germanium crystals. The etch rates are given for four temperatures and each point is an average of four values.

A plot of the log etch rates *vs.* $1/T$ appears in Fig. 1 for some of the data in Table I. The activation energies calculated from the slopes of these curves are around 6 kcal for the mole ratios of HNO_3/HF greater than 4.9. Below this ratio the energies range from 19 to 12 kcal. Figure 2 shows a plot of these activation energies *vs.* mole ratio HNO_3/HF for the ratio range between 0.06 to 1.3.

Table I. Etching rates of germanium in HF-HNO_3 solutions at various temperatures

Mole ratio HNO_3/HF	Etch rate, μ/min 15°C	25°C	35°C	40°C	Activation energy* ΔE kcal
0.06	0.76	1.5	3.1	4.2	12.3
0.14	0.94	2.8	4.9	7.4	12.7

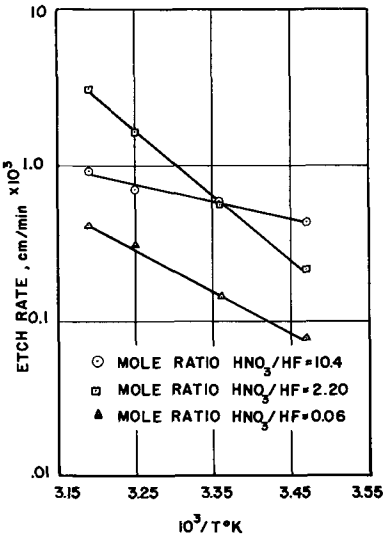

Fig. 1. Temperature dependence of the dissolution rate of germanium in HF-HNO_3-H_2O solutions.

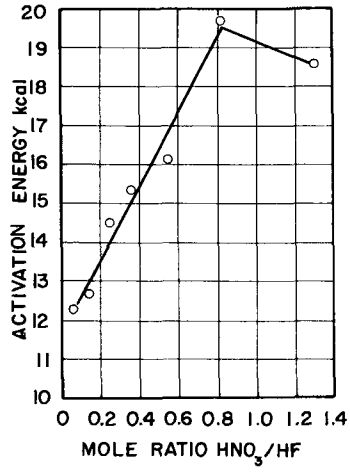

Fig. 2. Activation energy vs. mole ratio

Discussion

It is apparent from the activation energy curves shown in Fig. 1 that at higher concentrations of nitric acid the rate of etching is controlled by a transport process while at lower concentrations the controlling step is an activation process. This is to be expected since at high nitric acid concentrations the etch rate of germanium would be dependent on the ability of the hydrofluoric acid to diffuse to the oxide surface (probably the relatively insoluble GeO_2) where it would react with the oxide forming the soluble fluoride complex ion. As the concentration of hydrofluoric acid is increased there is a change to activation control and also an increase in the etching rate. At nitric acid concentrations below those reported there is probably again diffusion control, with the rate limited by transport of the oxidizing agent to the solid surface.

The region between these two extremes is complicated by the presence of a thin film found on the solid surface. This thin gold-colored film, which is visible on the etched surface when the molar ratio of HNO_3/HF is 0.36 or less (25°C), could possibly be caused by the formation of an amorphous germanium monoxide previously reported by Ellis (6) or by the formation of a polycrystalline germanium layer similar to that reported for silicon by Archer (7). The presence of this film accounts for the fairly low etch rate observed at the lower concentrations (Table I). It is interesting to note in the plot of activation energy *vs.* mole ratio (Fig. 2) that the activation energy increases linearly up to a mole ratio at about 0.8. This could possibly be an indication of the range of the film formation process.

If the film is amorphous germanium monoxide then it is conceivable that in this concentration range the dissolution of the germanium is a two-step reaction where the oxidation of germanium to the monoxide occurs at the surface with the subsequent solution and oxidation of this material to the tetravalent state followed by the function of the fluoride complex. The etch rate in this range would be dependent on the rate of solution of the monoxide. However, if the film is polycrystalline germanium then a mechanism similar to that proposed for silicon by Turner (8) may be involved where the divalent form of germanium would appear first, followed by disproportionation to polycrystalline germanium and germanium dioxide. The correct mechanism for the etching reaction could be determined possibly if an analysis of the reaction products including the film was made. Initial spectrographic analysis of a known weight of film removed from the germanium substrate by solution in 6*N* potassium hydroxide indicates that it is not pure germanium. This fact appears to support the germanium monoxide mechanism.

Brief Communications

Mechanism of Stress Corrosion Cracking in Stainless Steels

R. Stickler and S. Barnartt

Research Laboratories, Westinghouse Electric Corporation, Pittsburgh, Pennsylvania

Recently Forty (1) proposed a restricted-slip theory of stress corrosion cracking which may be used to predict the susceptibility or immunity of metals to this type of cracking. The theory presupposes cyclic chemical-mechanical propagation, as first clearly described by Keating (2). In this method of propagation a short period of relatively slow chemical attack, or electrochemical attack in the case of aqueous corrodents, leads to localized stress concentration and embrittlement. A microscopic crack results; then further chemical attack occurs at the tip of the crack, and the cycle repeats. Direct observations of periodic crack extension were made by Edeleanu (3) on the surface of an α-brass single crystal corroding in ammonia, and by Kirk, Beck, and Fontana (4) on commercial stainless steel surfaces in dilute NaCl solutions at 204°C. Hines (5), however, pointed out the need for other direct evidence, because it is possible for cracks growing smoothly in the bulk of the alloy to break through the surface periodically.

The chemical embrittlement process may be expected to vary with the type of corrodent and alloy involved. In studies on copper alloys, using the technique of electron transmission through thin films, Bassett and Edeleanu (6) and also Swann and Nutting (7) showed evidence for preferential chemical attack at or near stacking faults. They suggested that solute segregation at stacking faults may control the chemical embrittlement step, but as yet little is known of the embrittlement mechanism.

The restricted-slip theory refers to the mechanical-fracture step of the propagation cycle. According to this theory, when a crack is formed within the embrittled surface layer it will propagate into the underlying ductile metal only if dislocation movement is highly restricted. Propagation ceases when the crack enters a soft region, such as a preexisting slip band. Hence alloys which readily cross slip should be immune to this type of cracking.

Evidence that the restricted-slip theory may apply to copper alloys has been given by Swann (8). In the copper-zinc system, 3-37% Zn, it was shown that the stacking fault energy decreases with increasing zinc concentration, and a gradual change in dislocation distribution occurs. Pure copper has a high stacking fault energy, and the dislocation groups exhibit a cellular structure, which indicates that the dislocations can readily cross slip. As zinc is added the stacking fault energy decreases and cross slip becomes more difficult. The cell structure disappears and dislocations become confined to slip planes, indicating restricted slip. Alloys having 15-37% Zn, which are known to be highly susceptible to stress corrosion cracking, were found to have low stacking fault energy and exhibited highly restricted slip, in agreement with the theory.

Similarly with aluminum additions to copper, Swann showed that increasing aluminum content in the range 3.5-8% continuously lowered the stacking fault energy and restricted slip. Although no stress corrosion data were given for the particular alloys studied, others have reported Cu-4% Al to be apparently immune to stress corrosion cracking (9, 10) while alloys in the range 5 to 10% Al have cracked (10).

We have now tested the applicability of the restricted-slip theory to stainless steels. Both the stress corrosion behavior and the dislocation pattern have been determined in a pair of purified vacuum-melted 16 Cr-20 Ni steels. One of these was immune to stress corrosion cracking and the other susceptible. The immune alloy, E, has been shown in a previous paper (11) to remain uncracked in boiling 42% $MgCl_2$ under severe corrosion conditions. The susceptible alloy, K, has essentially the same composition except for the addition of 1.5% molybdenum, Table I. According to the theory, the molybdenum addition should have caused highly restricted

* Wires of 0.7 mm diameter, under constant tensile stress of 2800 kg cm^{-2} (40,000 psi), in 42% $MgCl_2$, 146°C.

dislocation movement. This was studied by electron transmission through thin films.

The thin films were prepared from annealed wire specimens (0.7 mm diameter) by first cold rolling the wires to 0.1 mm thick strips. The strips were annealed in vacuum (10^{-5} mm Hg) at 1065°C for 15 min and quenched by rapidly moving them to a cold section of the vacuum system. They were then deformed 15-20% by cold rolling; this amount of plastic deformation was approximately the same as that which occurred during initial loading of the wire specimens in stress corrosion cracking tests. An area 2 x 20 mm, the perimeter masked with lacquer, was electropolished under the following conditions until thin edges were produced: solution: H_3PO_4 (conc.)—60%, H_2SO_4 (conc.)—40% by vol; temperature: 60°C; anode current density: 2.5 amp cm^{-2}.

The thin areas thus produced, the order of 1000Å thick, were examined by transmission electron microscopy, and typical micrographs are shown in Fig. 1. In these micrographs dislocations appear as dark lines. Although the dislocation density is high, the general distribution is evident. In the purest alloy E (top micrograph) the dislocations form a "cell structure" consisting of light regions, which are relatively dislocation-free, and boundaries which contain high dislocation density. This distribution is characteristic of deformed face-centered cubic metals which allow easy cross-slip and which have high stacking fault energy (12). Alloy K (center micrograph) exhibits a dislocation distribution in which there is a definite tendency for the dislocations to be concentrated along parallel (slip) planes. This is characteristic of deformed face-centered cubic metals in which slip is restricted and the stacking fault energy is low (12). As shown in Table I the former alloy is not susceptible to stress corrosion cracking, while the latter with molybdenum added cracks readily. Thus the molybdenum addition has caused restricted slip in the metal and also made it susceptible to cracking, in agreement with Forty's theory.

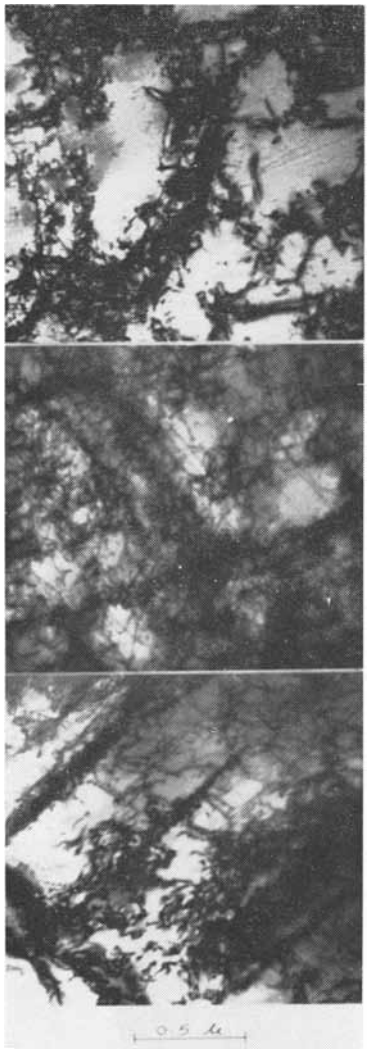

Fig. 1. Transmission electron micrographs of deformed 16 Cr-20 Ni stainless steels. Top, alloy E, no added element; center, alloy K, 1.5 Mo addition; bottom, alloy M, 5.06 Mo-1.44 Mn-0.45 Si-0.06 Al additions.

The only other data obtained with molybdenum addition to the 16-20 steel was for an air-melted alloy, M, containing 5% Mo plus smaller additions of Mn, Si, and Al (Table I). This alloy was susceptible to stress corrosion cracking, and the typical dislocation pattern found in the 20% cold-worked metal, Fig. 1 (bottom), again shows that restricted slip is associated with crack susceptibility.

The observations reported here all indicate that Forty's restricted-slip theory is applicable to these stainless steels. It is desirable to extend this work to include other single impurity additions to the purified 16-20 alloy, in order to isolate the effects of those which induce cracking and those which do not. In addition, direct measurements of stacking fault energy in stainless steels are needed for comparison with Swann's correlation of cracking in copper alloys having low stacking fault energy. These studies are now in progress.

Sealed Solid Method for Zone Melting Decomposable Compounds

F. K. Heumann

Research Laboratory, General Electric Company, Schenectady, New York

A number of procedures are used to crystallize materials containing or consisting of components volatile over the melt. Those in current use have limitations for achieving purification or for recovering material of uniform composition. Thus, the sealed tube Bridgman or directional freezing method results in general in ingots of varying composition along their length. Zone-melting in a boat or by floating zone requires that all of the sealed tube and hence the solid be heated by multiple furnaces at all times to control the partial pressures of the volatile components or impurities. With the solid always hot, movement of constituents in the solid either by diffusion in the solid or by a process of vapor transport and diffusion is possible. This can result in vitiating purification by zone melting or can result in inhomogeneous material if zone levelling is conducted. These problems can be overcome in a zone melting process in which there is no free volume for the movement of volatile constituents and in which the solid does not need to be maintained at an elevated temperature.

A schematic drawing of a sealed solid method of zone melting is shown in Fig. 1(b) in which the floating zone method is compared in (a). It has been found that many materials with volatile constituents can be weighed into a suitable tube, allowed to react, and cast without cracking the tube. Also, a narrow molten zone can be made to traverse the tube without causing cracking. If, as in Fig. 1(b), a molten zone is transported upward through the sealed cast ingot, the solid above and below the melt acts as the seal for vapor. Thus vapor transport does not occur. The last zone width to freeze is the only region that need lose volatile material. This amount may be kept small by keeping the volume above the casting small and/or by heating, and also by using a narrow zone. A narrow zone can be readily maintained because, without having to heat the solid, a sharp temperature gradient between melt and solid is realized. Since the solid cools rapidly toward room temperature after the passage of a molten zone, solid diffusion is kept to a minimum.

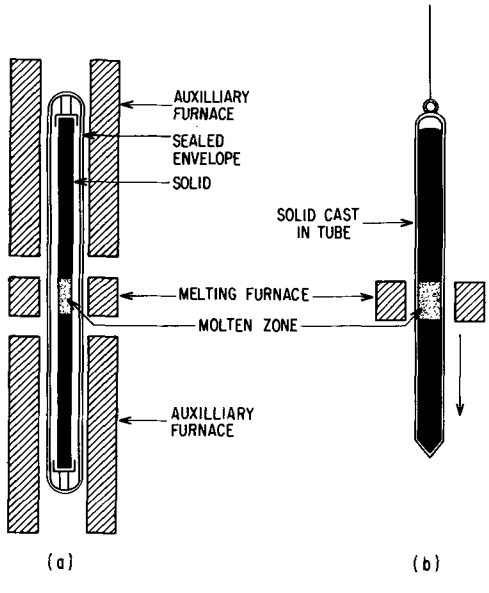

Fig. 1. Comparison of normal (a) and simple (b) zone melting of decomposable materials.

In the application of this method to the preparation of bismuth telluride alloys, for example, since material of uniform composition is desired, the process is conducted for zone levelling. The equipment used is simple. The melted zone is created by a narrow resistance furnace. The mechanism used to move the tube through the furnace can be simple as long as a constant rate can be maintained with the tube kept concentric with the furnace. A relatively rapid rate for the zone movement is used in order that the effective segregation coefficients of the constituents approach unity as nearly as possible. The limiting rate is that permitting good oriented crystal growth. Even in these materials with low thermal conductivity, rates of the order 6-8 cm/hr can be used since the thermal gradients can be kept large. Cracking of the tubes is not encountered when care is exercised to remove oxides from the materials. Ingots of 28 cm length have been made in quartz tubes using a single zone pass and a zone width of 1-2 cm. Typical electrical resistivity profiles for ingots of p- and n- type alloys were flat, with a deviation of less than 10% over 90% of the length. These profiles were used as one criterion of the homogeneity of the ingot. By comparison, ingots of the same alloys made by the Bridgman process showed variations in resistivity of a factor of almost two from one end to the other. The other thermoelectric parameters of the zoned ingots are similarly uniform, resulting in a variation for the figure of merit of less than $\pm 5\%$ of the average value obtained for a number of ingots.

A number of different materials, including I-VI, III-V, and V-VI compounds, have been successfully made by this process. Each compound may require a slightly different preparative technique in order to satisfy the requirement that the ingot be free to move in the tube before zoning. However, as long as the material does not react with

or stick to the crucible material, the method should work.

Electron Diffraction Study of the Ferrimagnetic Structure of Fe_3O_4

S. Yamaguchi

Institute of Physical and Chemical Research, Tokyo, Japan

It has been found possible to determine the orientation of magnetic induction in a magnetite crystal as described below.

A layer of a single crystal of magnetite (thickness about 5μ, area 2 x 1 mm^2) was prepared by mechanical polishing. This layer contained some pinholes with diameters of about 10μ. The specimen was magnetized in a thin and homogeneous field which was prepared at the sharp edges (thickness about 3μ) of two razor blades, whose remanence was about 2000 gauss. These two edges, separated by a narrow gap (ca. 1 mm), acted as magnetic poles (Fig. 1). A beam of electrons (diameter about 50μ) of well-defined wavelength was passed through, grazing one of the pinholes found in the specimen in order to give rise to a diffraction pattern. Here the incident electron beam runs nearly perpendicular to the face of the layer or to the lines of force (Fig. 1).

The diffraction pattern from the cold specimen, i.e., at 40°C, was first registered, and then that from the heated specimen at 300°C was superimposed. In this process, the positions of the specimen and of the photographic emulsion, and the well-defined wavelength of the incident electrons were kept fixed. The double diagram thus obtained is shown in Fig. 2. The incident electrons in Fig. 2 are parallel to the [$\bar{1}$10] zone axis of the Fe_3O_4 crystal. The temperature of the specimen was controlled by regulation of the electronic irradiation (1).

Figure 3 is a single diagram obtained from the specimen kept at the higher temperature, *i.e.*, at 300°C. It is noted in Fig. 2 that every diffraction spot is split, with a constant separation and in a definite direction, whereas such splitting is not found in Fig. 3. This phenomenon of splitting re-

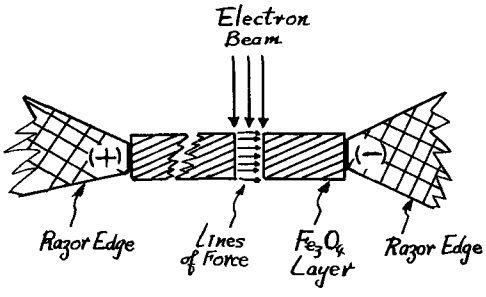

Fig. 1. Arrangement for the diffraction of electrons subjected to the magnetic lines of force in the Fe_3O_4 crystal. A photographic plate is situated perpendicular to the incident beam.

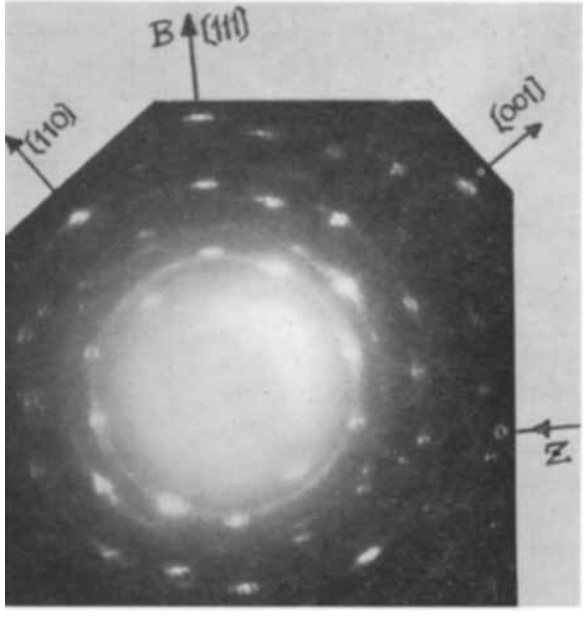

Fig. 2. Diffraction patterns of the cold specimen (40°C) and of the hot specimen (300°C) obtained by the double exposure process. The diffraction spots corresponding to these two temperatures are split as the result of the Lorentz effect. The direction of the splitting $\vec{Z}$ is perpendicular to the[111] axis, *i.e.*, to the induction $\vec{B}$. The incident beam is parallel to the[$\bar{1}$10] zone axis. Wavelength of the electrons: 0.0281Å; camera length: 495 mm. The positive enlarged 3.7 times.

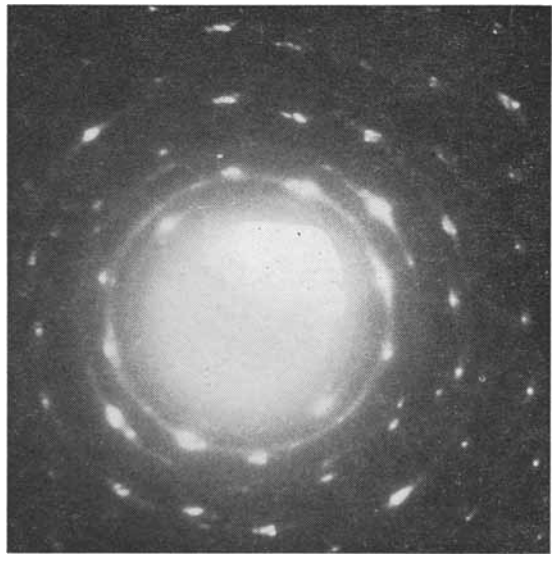

Fig. 3. A single diagram obtained from the specimen kept at 300°C.

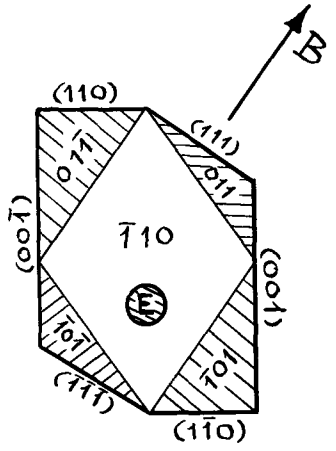

Fig. 4. Relations between the incident beam (E), the net planes of the Fe_3O_4 crystal and the induction (B). E and the (110), (111), and (001) planes are perpendicular to the paper face. B and the ($\bar{1}$10) plane are parallel to the paper face.

sults from the difference between the action of the Lorentz force of the specimen when hot and when cold, on the electron trajectories. The direction of the observed splitting $\vec{Z}$ is perpendicular to the crystallographic orientation of the magnetic induction found in the specimen, according to the Lorentz law. The direction of the induction $\vec{B}$ thus determined agrees with the [111] axis of the crystal of Fe_3O_4 (Fig. 2). It is concluded in this way that the ferrimagnetic electron spin planes are parallel to the (111) planes of the Fe_3O_4 crystal. This conclusion is in accordance with that reached by neutron diffraction (2). The relations between the incident beam (E), the orientation of the net planes, and the magnetic induction (B) are illustrated in Fig. 4.

Quantitative analysis of Fig. 2 results from a consideration of the Lorentz force F acting on an electron beam:

$$F = \frac{e}{c}[v\,B]$$

where e is the electron charge, c the velocity of light, v the velocity of the electrons, B the magnetic induction, and [ ] the vector product. From this expression we obtain a relation between the thermomagnetic splitting ΔZ of the diffraction spots in Fig. 2 and the induction change $\Delta I(\Delta B = 4\pi\,\Delta I)$ caused by the thermal perturbation under the experimental arrangement:

$$\Delta Z = \frac{eL\bar{l}}{mv} \cdot 4\pi\,\Delta I \qquad (L >> \bar{l})$$

$$= \frac{eL\lambda\bar{l}}{h} \cdot 4\pi\,\Delta I \qquad [1]$$

where m is the electron mass, v the velocity of the electrons, e the electron charge (1.6×10^{-20} emu), L the camera length (495 mm), λ the wavelength of the electrons (0.0281Å), h the Planck constant (6.6×10^{-27} erg-sec), and $\bar{l}$ the magnetic path of the electrons. We measure $\Delta Z = 0.348$ mm on Fig. 2. Therefore, we obtain according to Eq. [1], $\Delta I \cong 160$ gauss, if we assume $\bar{l}$ equal to the thickness of the specimen layer, 5μ (Fig 1). This ΔI value is plausible as the induction change of magnetite caused by the temperature change from 40° to 300°C.

Conclusion.—The present thermal perturbation procedure of electron diffraction is more to be recommended for the magnetic structure analysis of ferrites than neutron diffraction, especially when access to a nuclear reactor is not possible.

On the Polarization of the Manganese Dioxide Electrode

F. Kornfeil

U. S. Army Signal Research and Development Laboratory, Fort Monmouth, New Jersey

ABSTRACT

Experiments on the cathodic polarization and the potential recovery of γ-MnO_2 electrodeposited on platinum are described. It is shown that at low current densities and pH 7.5 the shape of the potential-time curves is in very good agreement with that predicted from the Coleman-Scott theory of concentration polarization involving the solid phase of the electrode.

The theoretical and experimental treatment of the discharge mechanism and the polarization of the manganese dioxide electrode has been of considerable interest to both theoretical electrochemists and battery engineers for some time (1-3). In 1946 Coleman (1) first advanced the idea that under certain conditions the overpotential associated with the cathodic polarization of the MnO_2 electrode and its subsequent decay after interruption of the polarizing current are determined by a diffusion process taking place in the solid phase of the electrode: At low current densities and in neutral or slightly alkaline electrolyte solutions the surface of the oxide is reduced to MnOOH ($Mn_2O_3 \cdot H_2O$ in the original publication)

$$MnO_2 + H^+ + e^- \rightarrow MnOOH \qquad [1]$$

The MnOOH remains part of the crystal structure, and the resulting "dilution" of the surface MnO_2 gives rise to a corresponding decrease of the electrode potential. Equalization of the concentrations of MnO_2 and MnOOH, and hence the recovery of the electrode potential, is effected by the diffusion of protons and electrons into the interior of the oxide particle. According to Coleman's theory we are therefore dealing with the phenomenon of concentration polarization involving the solid state. Mechanisms other than the diffusion of protons are possible, although less probable, *e.g.*, the diffusion of oxygen ions from the interior toward the surface, or the diffusion of Mn^{+++} ions from the surface into the interior of the oxide. These alternatives are of only minor concern here because the exact knowledge of the nature of the diffusing species is, fortunately, not required for a mathematical treatment of this problem.

To verify the correctness of Coleman's theory experiments were started in our laboratory to determine if the electrode potential observed during the periods of discharge and recovery is in agreement with the potential-time relation obtained from a quantitative treatment of the diffusion process as the rate-determining step of the electrode reaction.

It is quite obvious that an agreement between the observed and calculated values of the electrode potential, and indeed also the absence of such an agreement, can be meaningful only if certain experimental precautions are taken to insure the following conditions: (*a*) the reaction Eq. [1] is the only reaction occurring at the MnO_2 electrode at an appreciable rate. This was achieved by choosing a suitable electrolyte solution and by discharging the electrode at low current densities; in none of the experiments described below could Mn^{++} ions be detected in the electrolyte after discharge. (*b*) The sum of activation overpotential and concentration overpotential involving the electrolyte phase must be small compared to the total electrode polarization. Discharge at low current densities combined with vigorous stirring of the electrolyte alleviated this problem.

Preparation of Electrodes and Polarization Studies

Platinum electrodes (2 x 2 cm) were cut from Pt sheet, leaving in the center of one side an extension approximately 2 mm wide and 5 mm long which was then sealed into one end of a glass tube (10 cm long, 3 mm ID) so that only the square part of the electrode is exposed to the electrolyte. A copper wire and mercury provided the electrical contact with the platinum.

Manganese dioxide was deposited electrolytically onto these Pt electrodes from an aqueous solution of 50g $MnSO_4$ and 67g H_2SO_4 per liter, following essentially the procedure described by Ferrell and Vosburgh (5). Nickel sheet, arranged parallel to the surface of the platinum electrode, served as the cathode. The current density was maintained at 3.20 ma/cm^2 of platinum surface for 30 min. The electrolyte was mechanically stirred throughout the electrolysis and the bath temperature kept at 85°-90°C. After electrodeposition the electrodes were washed in running tap water for several days and then in frequently changed distilled water.

The manganese dioxide deposited in this manner is black in appearance and is formed as an extremely firmly adherent coating, particularly if the platinum electrodes are first given a dull finish by blasting with fine aluminum oxide. X-ray analysis, electron diffraction and electron microscopy characterized it as γ-MnO_2.

For the polarization experiments an MnO_2 electrode was positioned along the axis of a 400 ml cylindrical glass vessel, covered with a machined Teflon stopper through which holes had been drilled to accommodate the MnO_2 electrode, a saturated calomel electrode, a thermometer, stirrer, and a platinum lead connected to a platinum strip lining the inside of the vessel and serving as the anode. The electrolyte was a 1M aqueous solution of NH_4Cl

to which NH_3 had been added to raise the pH to 7.5. The electrolyte volume was sufficiently large (~ 350 ml) to render changes in the composition of the solution during discharge negligible. All experiments were made at 25° ± 0.5°C.

Each thoroughly washed electrode was allowed to stand in the electrolyte solution until its potential, measured against the calomel electrode, did not change by more than about 1 mv in 24 hr, two to three days normally being sufficient to attain this stability. To facilitate the uniformity among the electrodes necessary for a comparison of the potential-time curves with both polarizing current density and discharge time as the experimental variables, the MnO_2 was always deposited from the same solution simultaneously onto a pair of electrodes. The electrodes of each pair were then discharged at the same current density but for different lengths of time, and the potential recorded during the discharge and recovery periods. The current from a d-c power supply was regulated manually and the potential of the MnO_2 electrode measured with either a L&N K-3 potentiometer or with a Brown recording potentiometer.

Discussion

Knowledge of two factors is fundamental to the derivation of the potential-time relation. First, it is necessary to know the dependence of the MnO_2 electrode potential on the concentrations of MnOOH and MnO_2 at the electrode/electrolyte interface, and second, we must be able to calculate the change in these concentrations occurring during and after polarization at different current densities for different lengths of time.

Johnson and Vosburgh (6) found from measurements of the potential of electrodes of different compositions that the electrode potential ϵ, at 25°C and pH 7.5, is given by

$$\epsilon = \epsilon_o + k \log \frac{c_4}{c_3} \qquad [2]$$

where ϵ_o is a constant, c_3 and c_4 are the concentrations, in mole per cent, of MnOOH and MnO_2, respectively, and k equals 0.073v. The difference between the empirical factor k and the theoretical value of 0.059v is attributed to the use of concentrations rather than activities.

While our own polarization measurements were in progress, Scott (7) showed that a solution of the diffusion problem is possible, provided the following assumptions are made: (*a*) the effect of the gradient of the electrical potential on the migration of the ions through the solid is negligible compared to that of the concentration gradient (gradient of the chemical potential); (*b*) the diffusion coefficient D is constant; (*c*) the diffusion is linear and semi-infinite; (*d*) the MnOOH concentration $c_3 = 0$ at the start of the discharge ($t = 0$).

Scott realized that under these conditions the problem of the concentration changes occurring when the MnO_2 electrode is discharged at constant current density for a certain period of time, say τ, followed by recovery of the potential for a time t-τ, is mathematically identical with the problem of the temperature changes taking place when a flat heating element, immersed in an infinite medium of constant thermal conductivity, initially at zero temperature, is supplied with heat at a constant rate and then switched off. A solution of this heat transfer problem is available in the literature (8).

After making the necessary transformations from heat transfer to mass transfer, Scott obtained (in effect) the following expression for c_3 as a function of time t and distance x from the MnO_2 surface

$$c_3(x,t) = \frac{2\phi}{\sqrt{D}} \left(\sqrt{t}\ i\,\mathrm{erfc}\frac{x}{2\sqrt{Dt}} - \sqrt{t-\tau}\ i\,\mathrm{erfc}\frac{x}{2\sqrt{D(t-\tau)}} \right) \qquad [3]$$

where ϕ is the number of moles of MnOOH formed per unit area in unit time. At the surface Eq. [3] reduces to

$$c_3(0,t) = \frac{2\phi}{\sqrt{\pi D}} (\sqrt{t} - \sqrt{t-\tau}) \qquad [4]$$

Neglecting volume changes in the solid phase of the electrode, the sum of c_3 and c_4 is constant and the potential-time relation, therefore, is of the general form

$$\epsilon(t) = \epsilon_o + k \log \left(\frac{A}{\sqrt{t} - \sqrt{t-\tau}} - 1 \right) \qquad [5]$$

In Eq. [3] and [4] $\sqrt{t-\tau}$ is to be taken as zero for $t < \tau$, so that for the discharge period Eq. [5] is simply

$$\epsilon(t) = \epsilon_o + k \log \left(\frac{A}{\sqrt{t}} - 1 \right) \qquad [6]$$

The discharge and potential recovery curves for one representative pair of MnO_2 electrodes, discharged at 0.10 ma/cm² of apparent surface area, are shown in Fig. 1. One electrode was polarized for $\tau_A = 20$ min, the other for $\tau_B = 30$ min. A and B are the corresponding recovery branches of the potential-time curve. The solid lines in the diagram represent the observed values of the electrode potential.

A comparison of the experimental curves with the curves calculated from Eq. [5] can readily be made

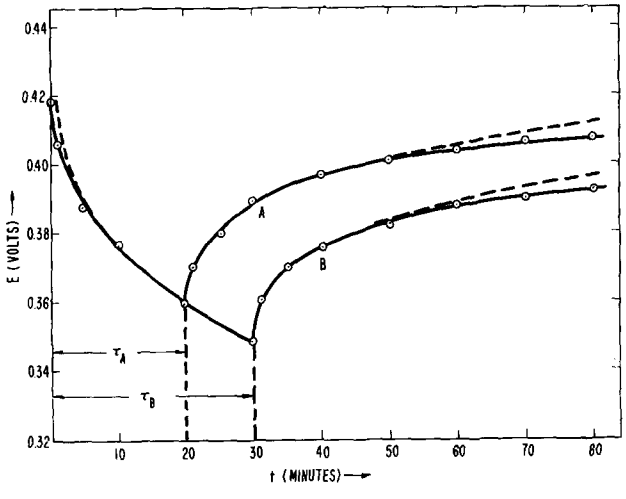

Fig. 1. Discharge and potential recovery curves for i = 0.10 ma/cm²; solid line observed; dashed line calculated.

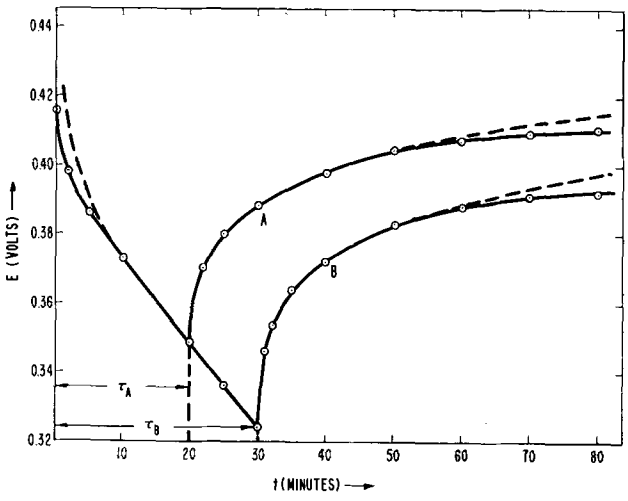

Fig. 2. Discharge and potential recovery curves for i = 0.15 ma/cm^2; solid line observed; dashed line calculated.

once the parameters ϵ_0, k, and A have been determined. These parameters can, in principle, be obtained from Eq. [6] and the values corresponding to three points on the discharge branch of the potential-time curve. However, because of the difficulties encountered in simultaneously solving three logarithmic equations with three unknowns, it is far more convenient to measure the slope of the discharge branch at two points.

Differentiation of Eq. [6] with respect to t gives the slope S

$$S = \frac{d\epsilon}{dt} = -0.434\, k \frac{A}{2t(A - \sqrt{t})} \qquad [7]$$

Having two corresponding values of S and t, it is easily seen that

$$A = \frac{\Delta(St\sqrt{t})}{\Delta(St)} \qquad [8]$$

ϵ_c and k can then be calculated by solving Eq. [6] and [7]. Using the foregoing method the parameters determined from Fig. 1 have the values: ϵ_0 = 0.352v, k = 0.068v, A = 10.25 min$^{1/2}$. Substitution of these figures in Eq. [5] yields the theoretical curves represented by the dashed lines in Fig. 1.

The same procedure was used to evaluate the parameters for the curves shown in Fig. 2. Here, the current density was 0.15 ma/cm^2, again for τ_A = 20 min., and τ_B = 30 min. Under these conditions the values of the parameters are: ϵ_0 = 0.370v, k = 0.068v, and A = 6.65 min$^{1/2}$. In both cases the agreement between the observed and calculated potentials is indeed very good, with deviations occurring only at the start of the polarization and after relatively extended periods of potential recovery. The deviations in the discharge branch are, of course, the result of the assumption of $c_s = 0$ at $t = 0$, making $\epsilon = \infty$ at the beginning of the discharge period. The deviations in the last part of the recovery branch are certainly due to the assumption of a semi-infinite diffusion, and are perhaps to some degree also the result of variations in D. The inconstancy of the diffusion coefficient can, however, be only small in view of the coincidence of the theoretical and experimental curves over such a wide range. It is therefore rather doubtful that the hypothesis of Scott (7) is correct, namely, that D should be proportional to the MnO_2 concentration. It seems quite conceivable that the mobilities of the protons and associated electrons are much the same in MnO_2 and MnOOH, the flux through a plane through the mixture being solely governed by the concentration gradient. It is interesting to note that the value of k = 0.068 is independent of the current density, as expected, and agrees well with k = 0.073, as determined by Johnson and Vosburgh (6) by an independent method. Since A is inversely proportional to ϕ, and therefore also to the current density, the ratio of A for i = 0.10 ma/cm^2 and i = 0.15 ma/cm^2 should be 1.50. The ratio of the two values of A presented in this paper is 1.54. There is little significance to the value of ϵ_0 since its only function is to shift the curves parallel to the ordinate.

Acknowledgment

The author wishes to express his appreciation to Mr. W. F. Nye for his help in the structural and morphological analyses of the MnO_2 deposits.

In the paper by A. C. Makrides "On the Mechanism of the Hydrogen Reaction" in the March 1962 issue of the *Journal*, the unnumbered equation in column 1, page 259 should read

$$\nu' = \nu \frac{(i_o)_{extr}}{i_o}$$

Investigation of the Electrochemical Characteristics of Organic Compounds

IX. Pyrimidine Compounds

R. Glicksman

Semiconductor and Materials Division, Radio Corporation of America, Somerville, New Jersey

ABSTRACT

A study of the electrochemical characteristics of nitropyrimidine compounds as cathodes in $MgBr_2$ electrolyte, and amino and hydroxypyrimidine compounds as anodes in NaOH electrolyte, shows that the potentials of these compounds are dependent on the aromaticity of the pyrimidine ring, as well as the type and position of substituted groups on the ring. The effect of these factors on the anode and cathode potentials of the various pyrimidine compounds is interpreted in terms of the electron density distribution in the molecule. Half-cell potential data for the alloxan-dialuric acid oxidation-reduction system is also presented.

As part of a general investigation of the electrochemical characteristics of organic compounds, a study has been made of the effect of the presence and molecular position of various group types on the cathode potential of aromatic nitro compounds (1) and the anode potential of aromatic hydroxy and amine compounds (2). Various heterocyclic nitro compounds such as the pyridine, thiophene, and furan nitro derivatives have also been investigated (3).

In this paper, the electrochemical characteristics of pyrimidine compounds are presented. These compounds are considered both as oxidizing agents (*e.g.*, nitro and nitrosopyrimidines) and as reducing agents (*e.g.*, amino and hydroxypyrimidine compounds.)

Apparatus and Technique

A technique, previously described (2), has been used to measure the operating potential of the various pyrimidine compounds during current flow. This technique consists in discharging a 0.5-g sample of the pyrimidine compound mixed with 0.05g of Shawinigan acetylene black, at a constant current drain of 0.005 amp/g, in a large volume of electrolyte. The change in anode or cathode potential with time was measured with a L&N type K potentiometer using a saturated calomel reference electrode. The measured potentials were corrected for the IR drop associated with the apparatus and electrolyte by means of an oscillographic technique.

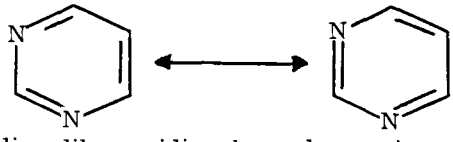
All half-cell potential data reported are referred to the normal hydrogen electrode and include a liquid junction potential. For most of the anode-potential measurements, an aqueous 1.44M NaOH solution ($a_{OH^-} = 1$)[1] was used as the electrolyte, and a manganese dioxide bobbin wrapped in cheesecloth served as the cathode. For the cathode half-cell potential studies, an aqueous magnesium bromide electrolyte was used with a magnesium anode.

[1] Calculated from the data given by Latimer (4).

Experimental Data and Discussion of Results

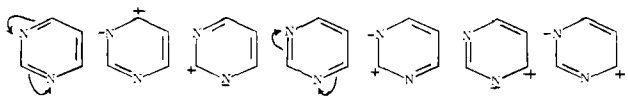
Nitropyrimidine compounds as oxidizing agents. —It has been shown previously that the cathode potential of aromatic nitro compounds increases with increasing ring aromaticity (3) in the order: 1-nitronaphthalene, nitrobenzene, and 2-nitropyridine. This order may be attributed to a lower electron density in the vicinity of the reducible nitro group of the more strongly aromatic pyridine compound.

Pyrimidine, a six membered ring containing two nitrogen atoms, can be represented by the usual Kekulé resonance possibilities.



Pyrimidine, like pyridine, has a lower ring electron density than benzene, and thus nitropyrimidine compounds would be expected to operate at higher cathode potentials than their corresponding nitrobenzene derivatives. However, because of the general reluctance of pyrimidine to react with electrophilic reagents, simple nitropyrimidine compounds are not readily available; therefore, a comparison of the cathode potentials of these compounds with nitrobenzene compounds is difficult.

Pyrimidine derivatives with electron donor groups such as the hydroxy and amino groups undergo electrophilic substitution reactions with a variety of reagents to introduce substituents in the 5-position, and a number of 5-nitropyrimidine derivatives are available. This type of behavior is consistent with the electronic effects operating in the pyrimidine ring which produce electon deficient centers at the 2-, 4-, and 6-positions (5).



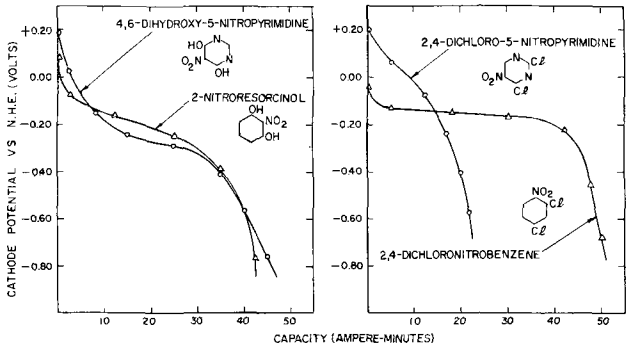


Fig. 1. Half-cell potential discharge curves of various nitropyrimidine and nitrobenzene compounds discharged at a rate of 0.005 amp/g in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte.

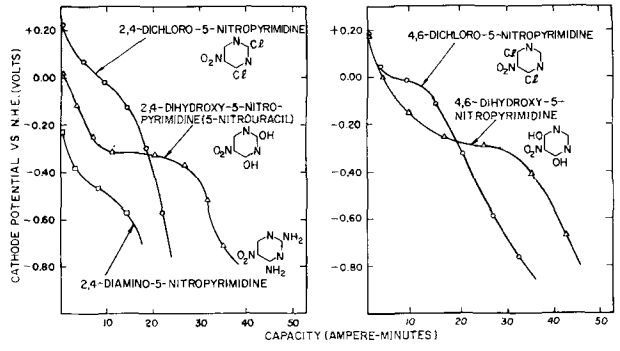

Fig. 2. Effect of substituted groups on the cathode potential of nitropyrimidine compounds discharged at a rate of 0.005 amp/g in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte.

Half-cell potential discharge curves of 4, 6-dihydroxy-5-nitropyrimidine and 2,4-dichloro-5- nitropyrimidine compared with their corresponding nitrobenzene derivatives, 2-nitroresorcinol and 2,4-dichloronitrobenzene are shown in Fig. 1. These curves were obtained by discharging the compounds at a rate of 0.005 amp/g in a 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte. In agreement with theory, the 5-nitropyrimidine derivatives initially operate at higher cathode potentials than the nitrobenzene derivatives. Additional compounds were not available to compare the two classes of nitro compounds further.

In Fig. 2, the higher cathode half-cell potentials of 2,4-dichloro- and 4,6-dichloro-5-nitropyrimidine as compared to 2,4-dihydroxy- and 4,6-dihydroxy-5-nitropyrimidine illustrate the effect of substituted groups on the cathode potential of nitropyrimidine. As with the nitrobenzene derivatives, compounds containing electron attracting chloro groups operate at higher cathode potentials than compounds containing electron-repelling hydroxyl groups. The more strongly electron repelling amino group is more effective in reducing the cathode potential than the hydroxyl group, as evidenced by the low cathode potential of 2,4-diamino-5-nitropyrimidine during discharge.

The effect of substituted electron attracting (*e.g.*, $-COOC_2H_5$) and of electron repelling (*e.g.*, —OH) groups on the cathode potential of nitropyrimidine compounds is further evidenced by the half-cell potential discharge curves for 5-nitrouracil, 5-nitrobarbituric acid, and 2,4-dihydroxy-5-nitro-6-carboxyethyl-pyrimidine shown in Fig. 3. The effect of these substituent groups on the cathode potential of nitropyrimidine compounds is similar to that observed with nitrobenzene derivatives and can be readily explained in terms of the electron-density distribution in the molecule (1).

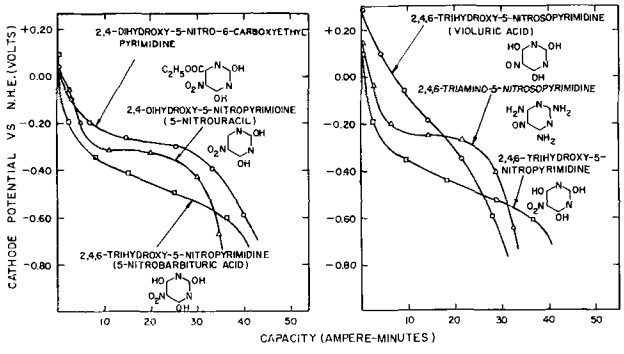

Fig. 3. Half-cell potential discharge curves of various 5-nitro and 5-nitrosopyrimidine derivatives discharged at a rate of 0.005 amp/g in 250 g/l $MgBr_2 \cdot 6H_2O$ electrolyte.

A comparison of the half-cell potential discharge curves of 2,4,6-trihydroxy-5-nitrosopyrimidine (violuric acid) and 2,4,6-trihydroxy-5-nitropyrimidine (5-nitrobarbituric acid) is also shown in Fig. 3. As with the benzene derivatives, the cathode potential of the nitrosopyrimidine compound is higher than that of the corresponding nitropyrimidine compound (6).

Theoretical capacity and electrode efficiency data for the nitro and nitrosopyrimidine compounds are given in Table I. The theoretical capacities were

Table I. Theoretical capacities and electrode efficiencies of various nitro and nitrosopyrimidine compounds

Compound	Theoretical capacity, amp-min/g	Experimental capacity,* amp-min/g	Electrode efficiency, %
2-nitroresorcinol	62.3	40.3	64.7
2,4-dichloronitrobenzene	50.3	46.8	93.0
2,4-dichloro-5-nitropyrimidine	49.8	19.9	40.0
4,6-dichloro-5-nitropyrimidine	49.8	27.3	54.8
4,6-dihydroxy-5-nitropyrimidine	61.4	41.9	68.2

2,4-dihydroxy-5-nitro-6-carboxypyrimidine ethyl ester	42.1	40.2	95.5
2,4,6-trihydroxy-5-nitropyrimidine	55.8	35.7	64.0
2,4,6-trihydroxy-5-nitrosopyrimidine	40.9	27.9	68.2
2,4,6-triamino-5-nitrosopyrimidine	41.8	31.8	76.1

* Capacity calculated on the basis of a −0.40v end potential.

computed by means of Faraday's law assuming a 6 and 4 electron change for the nitro and nitroso group, respectively. The electrode efficiencies were calculated from the data in Fig. 1-3. A —0.40v end potential was used to compute the capacities. In general, the electrode efficiencies of the nitropyrimidine and nitrosopyrimidine compounds are not as high as those of the nitrobenzene and nitrosobenzene compounds previously studied.

Aminopyrimidine and hydroxypyrimidine compounds as reducing agents.—Because of the more strongly aromatic nature of the pyrimidine ring as compared to the benzene nucleus, pyrimidine compounds have a lower ring electron density; thus, the electron affinities of amino and hydroxypyrimidine groups should be greater than those of amino and hydroxy groups on a benzene ring. As a consequence, the amino and hydroxypyrimidine compounds should be weaker reducing agents and have lower anode potentials than their corresponding benzene compounds.

These characteristics are consistent with the half-cell potential discharge data of various amino and hydroxypyrimidine and amino and hydroxybenzene compounds shown in Fig. 4 and 5. These data were obtained by discharging the compounds as anodes in 1.44M NaOH at a rate of 0.005 amp/g. In agreement with theory, o- and p-phenylenediamine operate at higher anode potentials than 4,5-diaminopyrimidine and 2,5-diaminopyrimidine, respectively (Fig. 4), whereas phloroglucinol and resorcinol are stronger reducing agents than barbituric acid and uracil (Fig. 5). The lower anode potential of cyanuric acid as compared to barbituric acid indicates that an additional nitrogen atom in the nucleus further increases the ring aromaticity. Similarly, additional half-cell potential data show that melamine, the triamide of cyanuric acid, has a lower anode potential than 2,4,6-triaminopyrimidine (Fig. 7).

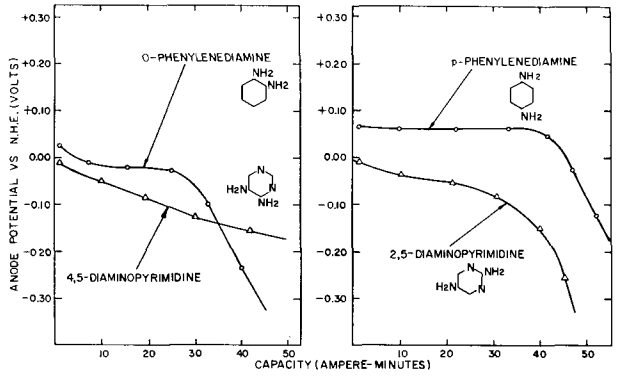

Fig. 4. Half-cell potential discharge curves of various diaminopyrimidine and diaminobenzene compounds discharged at a rate of 0.005 amp/g in 1.44M NaOH.

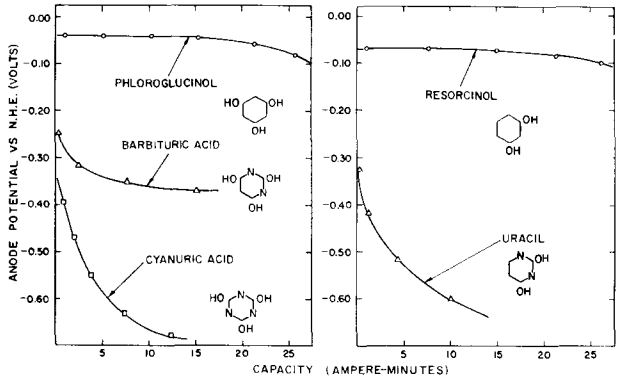

Fig. 5. Half-cell potential discharge curves of various hydroxypyrimidine and hydroxybenzene compounds discharged at a rate of 0.005 amp/g in 1.44M NaOH.

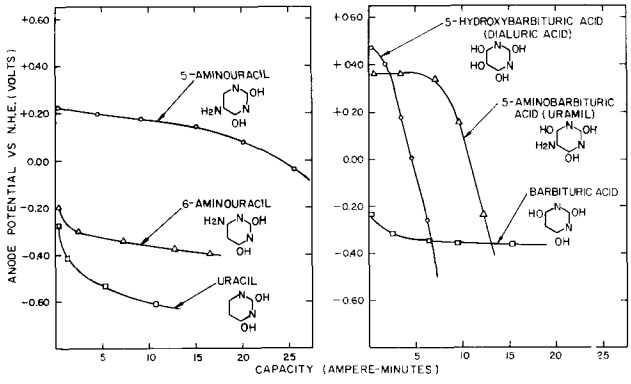

Fig. 6. Effect of substituted groups and their position on the anode potential of hydroxypyrimidine compounds discharged at a rate of 0.005 amp/g in 1.44M NaOH.

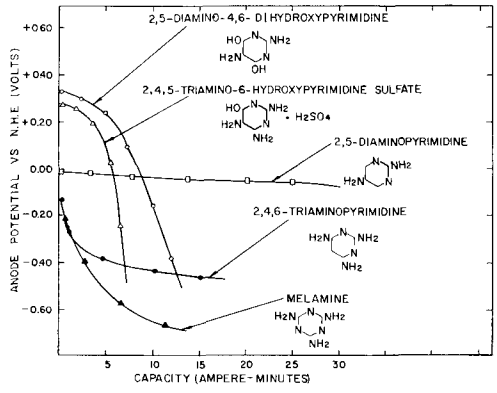

Fig. 7. Effect of substituted groups and their position on the anode potential of aminopyrimidine compounds discharged at a rate of 0.005 amp/g in 1.44M NaOH.

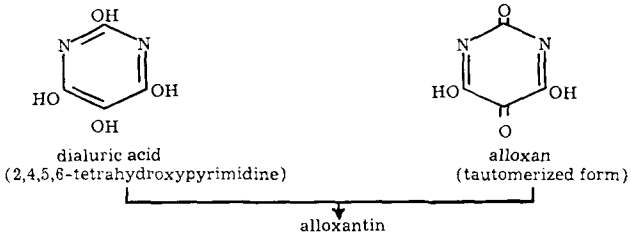
Figure 6 shows that the addition of substituted amino and hydroxy groups to uracil and barbituric acid results in compounds having higher anode potentials. This effect, which is in accord with previous results obtained with hydroxybenzene compounds (2), can be readily explained in terms of the effect of electron-repelling groups on the electron density in the vicinity of the oxidizable hydroxy groups. The higher potential of 5-aminouracil as compared to 6-aminouracil is believed to be due to the fact that, on oxidation, 5-aminouracil loses two hydrogen atoms and yields the corresponding quinoid compounds. Oxidation of this type is not possible for 6-aminouracil because no stable meta-quinoid structure can be written for this compound. The high anode potentials of uramil and dialuric acid can also be attributed to the same type of oxidation reaction.

Similarly, the 2,5-diaminopyrimidine compounds shown in Fig. 7, which have amino groups para to each other, operate at higher potentials than 2,4,6-triaminopyrimidine, which have the amino groups meta to each other. The higher anode potentials of 2,5-diamino-4,6-dihydroxypyrimidine and 2,4,5-

triamino-6-hydroxypyrimidine sulfate, as compared 2,5-diaminopyrimidine, are due to additional amino and hydroxy groups on the pyrimidine ring.

Alloxan-dialuric acid system.—The quinoid-benzenoid type of oxidation-reduction system in pyrimidine compounds is illustrated by the alloxan-dialuric acid system. Their structural formulas indicate that alloxan bears the same relationship to dialuric acid that quinone bears to hydroquinone.



Alloxantin is an intermediate product in the reduction of alloxan as well as the oxidation of dialuric acid and bears a relationship to dialuric acid and alloxan similar to that which quinhydrone bears to hydroquinone and quinone (7).

Figures 8 and 9 show comparisons of the cathode half-cell potential discharge curves of p-benzoquinone, alloxan, quinhydrone, and alloxantin discharged in different electrolytes. Table II compares the theoretical capacities and electrode efficiencies in the same electrolytes. The data were obtained by discharging these compounds as cathode materials

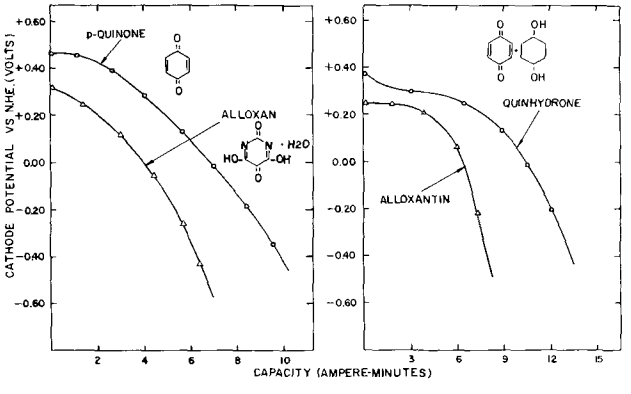


Fig. 8. Half-cell potential discharge curves of alloxan, alloxantin, and their corresponding quinone-type compounds discharged at a rate of 0.005 amp/g in 25% NH_4Cl—20% $ZnCl_2$—55% H_2O electrolyte.

in 25% NH_4Cl-20% $ZnCl_2$ (pH = 4.5) and 14% $MgBr_2$ (pH = 8.2) electrolytes at a rate of 0.005 amp/g. In acidic NH_4Cl-$ZnCl_2$ electrolyte, it is seen that p-quinone and quinhydrone operate at higher cathode potentials and yield greater capacities than alloxan and alloxantin, respectively. However, the reverse is true in weakly basic $MgBr_2$ electrolyte. The high cathode potential of alloxan in these electrolytes was to be expected on the basis of its ability to liberate iodine from iodides (7).

A comparison of the half-cell potential discharge curves of indophenol-sodium salt with that of a comparable pyrimidine compound, murexide, is also shown in Fig. 9. The pyrimidine compound is apparently more stable and less soluble than the indophenol salt, and it therefore operates at a much higher electrode efficiency in the magnesium bromide electrolyte.

The half-cell potential discharge data shown in Fig. 10 indicate the anodic characteristics of dialuric acid and alloxantin in 5.4% NaOH electrolyte in comparison to hydroquinone and quinhydrone. The high anode potential of dialuric acid as compared to hydroquinone is believed to be due to the additional hydroxyl groups on the pyrimidine nucleus, whereas

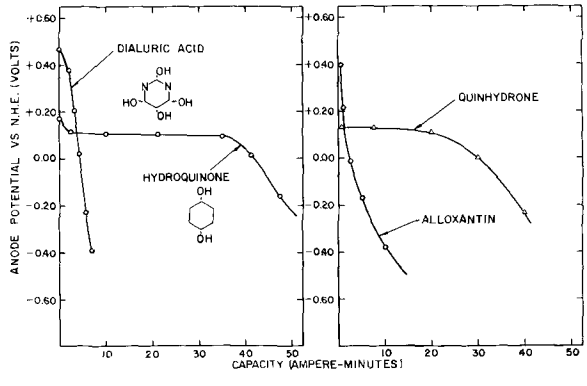

Fig. 10. Half-cell potential discharge curves of dialuric acid, alloxantin, and their corresponding hydroxybenzene compounds discharged at a rate of 0.005 amp/g in 1.44M NaOH.

its poor electrode efficiency is attributed to the fact that dialuric acid undergoes air oxidation readily. The high electrode efficiencies of hydroquinone and quinhydrone (in excess of 100%) have been shown to be due to a continued oxidation of the products of the initial oxidation reaction, *i.e.*, p-quinone itself is easily oxidized in alkaline electrolyte (2).

The electrochemical behavior of the alloxan-dialuric acid system, which has previously been studied polarographically (8), further emphasizes the aromatic nature of pyrimidine and the similarity of some of its derivatives to benzene compounds.

Nickel-Cadmium Cells

I. Thermodynamics and X-Ray Studies

Alvin J. Salkind[1] and Paul F. Bruins

Department of Chemical Engineering, Polytechnic Institute of Brooklyn, Brooklyn, New York

ABSTRACT

Voltage decays of electrodes in sintered type nickel-cadmium cells were measured in cells stored at temperatures between —18° and 52°C. The heat of reaction of the cell was calculated to be —64 kcal/g mole. The solid reaction products of the cell were studied, *in situ*, by x-ray techniques, in special cells designed to fit on an x-ray diffractometer.

Recently, several careful studies on the crystal structure and reaction mechanisms of the active materials of the nickel-cadmium cell have been reported (1-7). In some of these (6, 7), references have been made to the work discussed in this paper, which was available only by private communication (8). This research, initiated in 1955 and completed in February 1958, attempted to clarify some of the points concerning the oxide or hydroxide states of the electrodes and their potential decays. This present condensation is presented because later works have not duplicated the experimental methods and because of the unavailability of the private report to most of those who have expressed an interest in it.

Experimental X-Ray Studies

In all previous experiments reported in the literature, except those of Falk (6) which were carried out after this investigation was concluded, the x-ray studies were conducted with electrodes isolated from electrochemical cells. Thus, it appeared that some of the conflicting data could have arisen from changes in the nature of the active materials during washing and drying. Procedures were designed so the x-ray examinations of the electrodes were carried out while the electrodes were *in situ* in electrochemical cells in electrolyte. The electrodes were supplied by the Sonotone Corporation and were standard sintered plates, 0.625mm thick, made by impregnating sintered nickel plaques with nickel nitrate and cadmium nitrate salts and then converting to the hydroxides. The plates used for the x-ray studies were from the same batch as the test cells (nominal 5 A.H. Sandia type) used in the potential studies.

The first procedure used to avoid washing and drying plates was to charge sintered nickel plates in open plastic cells, and, after the completion of charge and partial or complete discharge, the wet plates were cut into quarters, sealed in polyethylene bags, and mounted on x-ray equipment. This method was abandoned since it was difficult to determine by film methods the comparative intensity of reflections of the active materials in different stages of charge. In addition, since 3-8 hr exposures were necessary to get sufficient blackening of the films, any possible products present only immediately after charge would not be detected. This was particularly important because the nickel electrode was known to have a fast initial self-discharge rate. A special cell was then designed and constructed which could be mounted on an x-ray diffractometer, so that selected reflections could be watched continuously as the active materials were charged and discharged, and of course, in addition, complete patterns could be recorded. This cell was made from polymethyl methacrylate (Lucite) and is shown in

Key: First numbers indicate "d" spacings in Angstrom units (Å). Numbers in brackets indicate comparative intensities of reflections. Reflections of nickel lines omitted from table.

Fig. 1. Small electrode plates were coated with polystyrene resin on all but the top surfaces so that the charge and discharge reactions had to take place on this surface, where they could be investigated with the diffractometer. Suitable electrical leads were potted in the plastic so that the cell could be charged or discharged, and the cell, with electrolyte, was covered with a polyester (Mylar) film during the x-ray examination. Twenty-one diffraction patterns were obtained on positive electrodes in various states of charge. The patterns were corrected using the reflections from nickel, and the reflections are listed in Tables 1A and 1B; reflections caused by nickel are omitted from this table. All intensities were corrected so that the value for the nickel 1.76Å reflection corresponded to 50. Few intensity corrections were necessary since almost all patterns were obtained with the same slit system on the x-ray machine and with the same amplification and recording constants in the electronic equipment. Duplicate patterns are not shown. The voltages of the electrodes were determined against mercury-mercuric oxide reference electrodes with a potentiometer, in many cases, immediately before the patterns were obtained. Diffractometer patterns A through G represent stages in the charge process for the same electrode. The uncharged active material gave a pattern which completely fitted the pattern

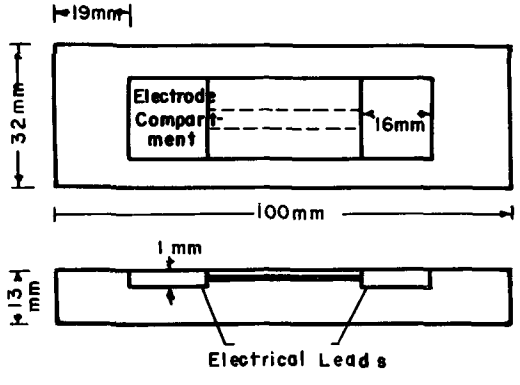

Fig. 1. Diagram of experimental nickel-cadmium cell used for x-ray studies.

for nickel hydroxide in the ASTM file. The charged active material gave patterns which fitted those associated by Glemser and Einerhand (8) with the structure of nickel III oxyhydroxide (β-NiOOH). Although several other of the higher nickel hydroxides have similar reflections, they may all be eliminated from consideration because they create additional strong reflections which were not present.

Early stages of charge were marked by the disappearance of lines in the patterns of $Ni(OH)_2$ rather than the creation of any new lines. In comparing patterns A through G it was seen that the 2.70, 1.56, 1.48, and 1.30Å lines gradually lost intensity as the charge progressed; the 4.60 and 2.33Å reflections shifted to larger d spacings. When the charge was nearly complete, the weak 1.40Å reflection of β-NiOOH appeared. Pattern H was obtained from an electrode which had been subjected to 5 charge-discharge cycles. The pattern obtained was similar to G, which was obtained on the first charge cycle. The failure of nickel hydroxide and β nickel hydroxide reflections to appear simultaneously, on charging, supports the conclusion that these materials are in a state of solid solution. This is confirmed by the evidence that the open-circuit electrode potential is a function of the state of charge. The sample prepared for pattern X, Table IB, was given a charge and severe overcharge at a high rate, the 1-hr rate, and then was dried free of electrolyte. In addition to the reflections attributed to β-NiOOH, the pattern obtained from this sample contained reflections of $Ni_2O_3 \cdot H_2O$. This material is stoichiometrically the same as NiOOH. The conditions used in the preparation of this sample would not normally be encountered in battery operation. Patterns O, I, J, K, P, L, and M represent decay and discharge states of nickel electrodes. As can be seen from patterns O, I, and J, no change in the pattern of NiOOH was obtained for the first 27 hr after charge when the electrodes were stored in the electrolyte at 24°C. After storing the nickel electrodes for 7 days at this temperature the 2.33Å line of $Ni(OH)_2$ appeared. When electrodes were stored for longer periods or were partially discharged the en-

tire $Ni(OH)_2$ pattern was obtained. Pattern E, obtained with a half-charged electrode, was almost identical with that of pattern L, obtained with a half-discharged electrode.

Cadmium electrodes were studied by rotating the previously prepared cells so that the negative electrode instead of the positive, was in the beam. The reflections from the nickel plaque were used to correct each pattern, as previously described. Patterns from partially charged plates included reflections from both cadmium and cadmium hydroxide. The peaks in these patterns were much sharper than those obtained with the nickel electrodes which indicates that the material was more crystalline. The charge process did not result in a gradual shift of reflections, but in the decrease in the intensity of the cadmium hydroxide reflections and the simultaneous increase in the intensity of the cadmium reflections. Reflections caused by cadmium hydroxides were found even in fully charged plates. Normal charge procedures were, therefore, not able to convert all the cadmium hydroxide to cadmium. The patterns were checked carefully for the reflections of cadmium oxide. The strongest reflection of cadmium oxide would be at 2.712Å, but this reflection was never observed on any of the patterns. The charge reaction of the cadmium electrode determined by x-ray examination is therefore cadmium hydroxide simply becoming cadmium. Thus, the data obtained by cycling electrodes *in situ* on x-ray apparatus confirms the earlier conclusion of Wynne-Jones and Briggs (2), obtained from washed and dried electrodes, and the later ones of Falk (6), obtained by a different *in situ* method. They are in agreement with the reaction mechanism later suggested by Kornfeil (4) in his very careful analysis of the charge-discharge process at the nickel electrode.

where the asterisks indicate hydration.

Experimental—Voltage Decay Studies

The electrode potentials in sintered plate nickel cadmium cells (97 Sandia cells) were measured with potentiometers using mercury-mercuric oxide reference electrodes containing electrolyte of the same concentration as the cells. The variables studied were temperature, plate spacing, electrolyte composition, and separator material. Only the effects of temperature and electrolyte composition are discussed in this paper. The cells were stored at temperatures of —17.8°, 34.4°, 43.3°, and 51.7°C and were originally filled with 20 and 31% potassium hydroxide electrolytes. Potential determinations were usually made at 30-min intervals for the first few hours after charge. Thereafter they were made daily for two weeks, and then weekly for several months. The initial voltage of the cadmium electrode at the end of charging at the ½-amp rate was approximately —1.00v with reference to the standard hydrogen electrode (acid). This dropped immediately on opening the circuit approximately to —0.96v and then decayed rapidly and linearly with the logarithm of time to approximately —0.88v. The voltages of the cadmium electrodes in all the cells tested at 34°C were in the range of —0.88v ± 0.01v after a thousand minutes from the end of charge. They then stayed in this range for the duration of the runs (about six months). Data on the potentials of the Cd-$Cd(OH)_2$ and Hg-HgO couples measured directly *vs.* hydrogen in KOH solutions were later obtained by Rüetschi, Ockerman, and Salkind (10) and are given in Table II. These data show that the equilibrium potential of the cadmium electrode is above the potential of hydrogen at all temperatures and concentrations of electrolyte, and therefore the electrode cannot self-decay through the evolution of hydrogen.

Potential measurements of nickel electrodes in nickel cadmium cells were made at the previously mentioned temperatures. It was possible to estimate the nickel potential of other cells where only

Table II. Potentials of Cd-Cd(OH)$_2$ and Hg-HgO electrodes vs. hydrogen in KOH solutions

Temp, °C		Cd-Cd(OH)$_2$	Hg-HgO
25		+0.022 ± 0.002	+0.929 ± 0.001
35	18.1% KOH	+0.0195 ± 0.001	+0.928 ± 0.001
45		+0.015 ± 0.001	+0.926 ± 0.001
25		+0.023 ± 0.002	+0.931 ± 0.001
35	26% KOH	+0.020 ± 0.002	+0.9295 ± 0.001
45		+0.014 ± 0.001	+0.927 ± 0.001
25		+0.023 ± 0.002	+0.936 ± 0.001
35	34.7% KOH	+0.016 ± 0.002	+0.933 ± 0.001
45		+0.008 ± 0.002	+0.930 ± 0.001

the total voltage was determined by subtracting the stable value of the cadmium electrode discussed in the previous paragraph. The potential of the nickel electrode decayed immediately on opening the charging circuit. This decay, after a few minutes, was linear with the logarithm of time. When the voltage level of the nickel electrode was approximately 0.40v with respect to hydrogen, a slower rate of decay began. The second decay period started 4 or 5 days after the end of charge. This is shown in Fig. 2. Not all points on these curves are shown, for simplicity in viewing. All points are for cells with 31% KOH electrolyte. Capacity determinations on cells, as well as data from the Sandia Corporation, indicated that very little cell capacity was lost in the first period of decay. Although there were some small differences in the half-cell potentials of the individual cells, the rate of voltage decay was essentially constant in all cells at a given temperature and electrolyte concentration. The voltage levels of the nickel electrodes in the secondary decay periods show the negative coefficient of $\partial E/\partial T$ for the electrodes. The values calculated were −0.0004 V/°C ± 0.0001 for the nickel electrode and −0.0005 ± 0.0001 for the cells. The voltage decay confirms the conclusions drawn from the x-ray data that the active materials of the nickel electrode are in solid-state solution. The two linear regions were also later observed by Conway and Bourgault (5) and were accounted for, by them, by a charge-transfer reaction.

The standard method of calculating heats of reaction is the direct use of cell or electrode potentials in the Gibbs-Helmholtz equation

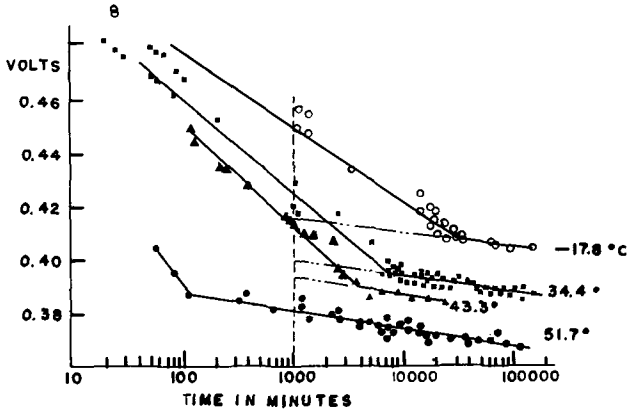

Fig. 2. Open-circuit voltage decay of nickel electrodes at different temperatures.

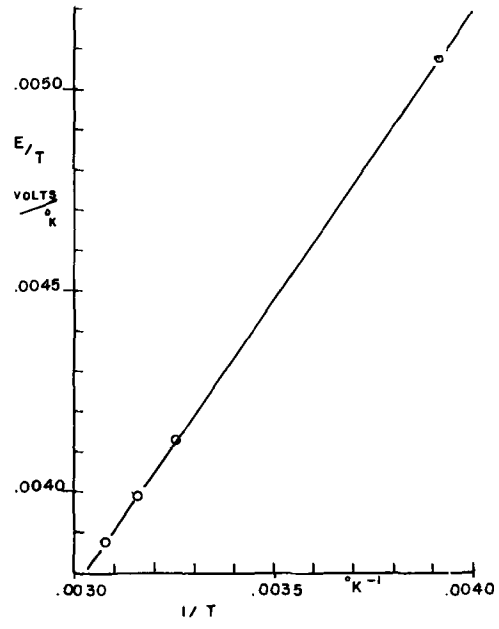

Fig. 3. Plot of E/T vs. $1/T$ for nickel-cadmium cells

$$\Delta H = -n\mathbf{F}E + n\mathbf{F}T\left(\frac{\partial E}{\partial T}\right)_p \qquad [2]$$

This can be rearranged to

$$\frac{E}{T} = -\frac{\Delta H}{n\mathbf{F}T} + \left(\frac{\partial E}{\partial T}\right)_p \qquad [3]$$

If we consider the coefficient of voltage change with temperature for nickel-cadmium cells to be constant over the range in question, then the slope of a plot of E/T vs. $1/T$ is $-\Delta H/n\mathbf{F}$. The ΔH thus obtained includes heat of hydration as well as heat of reaction. It is known, however, that the hydration energies of these particular electrodes are very low, as shown by the readiness with which CdO goes to Cd(OH)$_2$ and by the work of Rüetschi and Delahay (12).

The values used for electrode and cell voltages should be reversible electrode potentials. Since the nickel electrodes in the nickel-cadmium cells were never in thermodynamic equilibrium, an extrapolation method was used to obtain potentials which were approximately those of NiOOH at the beginning of the second decay period. The slopes of the decay curves in Fig. 2 were extrapolated or interpolated to a common time, 1000 min from the start of the open-circuit period. This represented close to the initial time in the experiment which ran six months. The potentials of cells and nickel electrodes given in Table III were used to prepare Fig. 3. From

Table III. Potentials of nickel electrodes and nickel-cadmium cells in the second decay period extrapolated to a common time (1000 min)

Temp, °K	Nickel electrode, in terms of S.H.E.	Ni-Cd cells, v
255.4	0.4112	1.295
307.6	0.3907	1.270
316.5	0.3861	1.203
324.9	0.3834	1.260

the slope of this line, the heat of reaction of nickel-cadmium cells was calculated to be −64 kcal/g mole. Another method of calculating heats of reaction, proposed by Othmer and Gilmont (9), gave a value of −62 kcal/g moles for this reaction.

A simplified reaction for the nickel-cadmium cell can be written as:

$$2\beta\,NiOOH + Cd + 2H_2O \rightleftharpoons 2Ni(OH)_2 + Cd(OH)_2 \quad [4]$$

The value −64 kcal/g mole, calculated for the heat of reaction, was used to estimate the approximate value for the heat of formation of β-NiOOH, since the values for all the other components in Eq. [4] were known (13). The value arrived at for the heat of formation of β-NiOOH was −164 kcal/g mole. This value was in close accord with the only value listed (13) for a valence three hydroxide of nickel, 162.1 kcal/g mole for $Ni(OH)_3$.

Acknowledgments

The authors would like to express their appreciation to Dr. G. Baumstark for his help in preparing the cells, to Mr. U. B. Thomas and Dr. R. Baker for their assistance and advice, especially in checking foreign references, to Dr. A. Fleischer, for his interest, and to Dr. E. Baars of Squire Signal Laboratories, Fort Monmouth, New Jersey, for the use of his laboratory in carrying out some low-temperature discharges. The authors are indebted to the Sandia Corporation for their support of this study and in particular to Dr. F. Thomas for his encouragement.

Manuscript received Jan. 11, 1960; revised manuscript received Nov. 25, 1961. This paper was prepared for delivery before the Columbus Meeting, Oct. 19-21, 1959. This paper was abstracted from the thesis of one of the authors (A.J.S.), submitted in partial fulfillment of the requirements for the Degree of D. Ch. E. at the Polytechnic Institute of Brooklyn.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

The Thermal Runaway Condition in Nickel-Cadmium Cells and Performance Characteristics of Sealed Light Weight Cells

Alvin J. Salkind and Joseph C. Duddy

The Carl F. Norberg Research Center, The Electric Storage Battery Company, Yardley, Pennsylvania

ABSTRACT

The thermal runaway condition, sometimes called the vicious cycle, can be caused in almost any type of cell under certain conditions. The underlying causes of the runaway condition are discussed with specific application to sealed nickel-cadmium cells on constant potential overcharge. The discharge and overcharge performance characteristics of sealed nickel-cadmium cells with plastic electrodes are presented. These cells operated at high energy density levels on both a weight and volume basis and were more difficult to put in the runaway condition.

The thermal runaway condition, sometimes referred to as the "vicious cycle," can occur in cells of all types. It is of particular importance in the case of sealed nickel-cadmium cells because it is a more dangerous phenomenon where sealed cells are involved, and nickel-cadmium cells are not only commonly charged and discharged at high rates but are also subjected to continuous overcharge. Literature references to this phenomenon are both few and brief; the most complete was that of Earwicker (1) concerning aircraft batteries of the lead-acid, silver-zinc, and nickel-cadmium types.

Description of the "Runaway Condition"

Since oxygen overpotential is due to a slow stage in the ionic discharge process, it is evident and well established (2) that an increase of temperature will decrease the overpotential. In the particular case of the nickel-cadmium cell, not only does the overpotential decrease with increasing temper-

Table I. Values of dE/dT for nickel electrodes and nickel-cadmium cells

ature, but the temperature coefficient of the open-circuit potential is negative. The coefficients have been reported by Falk (3) for sintered plate and pocket-type cells, by Salkind and Bruins (4) for sintered plate cells, and by Hosono and Watanabe (5) for tubular nickel electrodes. The coefficient is not completely independent of the state of charge, but, in the application to the overcharge problem, the coefficient of interest is the one representing a completely charged nickel electrode with a partially charged cadmium electrode.

In Table I, are presented the voltage temperature coefficients reported in the literature, as well as new data obtained with plastic electrodes prepared by the method described by Duddy and Salkind (6). Cell and electrode voltages were measured in cells, of the A type later described, stored at minus 18°, 26°, and 38°C. The voltage decays were plotted on open-circuit decay, and the stable voltages at a common time, approximately 1500 min from the end of charge, were used to calculate the voltage coefficient. The number shown is only an approximate one; experiments are still in progress to achieve a more exact value.

There is some variation in voltage and voltage coefficient with the state of charge of all the nickel electrode types listed, but all coefficients reported were negative. It can be seen that there is also a wide variance in the values reported. Since the nickel electrode is unstable, the magnitude of the coefficient obtained changes with the method of obtaining and plotting data. The inclusion of iron in the negatives of the pocket type and of cobalt or lithia and other additives in the Edison type also affect the magnitude of the coefficient for these cells. However, in every case, the over-all coefficient reported for the cell was negative.

The minimum emf necessary to charge a cell is the summation of the polarization at the nickel electrode, the equilibrium voltage, and the potential drops across electrolytic and electronic resistances. Glasstone (2) has given an approximate value for the change of overpotential with temperature of 2 mv/°C, and we can assume that the polarization change will be in this order. If we assume for the second item, a value of 0.5 mv/°C, and that for nickel cadmium cells, the temperature coefficients of last items are small, the total change of impedance with temperature in potential terms is approximately 2.5 mv/°C.

The Onset of Runaway

When a sealed cell is in the overcharge state, the oxygen cycling balances the electrochemical charge, so that the negative electrode stays in a constant state of partial charge and the energy of overcharge is dissipated as heat. (This is referred to by Earwicker as the parisitic current.) A temperature rise which can occur because of an environmental change or the inability of the cell to radiate or transfer heat at the generating rate causes a reduction in the cell impedance and increases the charge current, if the charge source is of the constant potential type. The increase in current increases the internal temperature, which reduces the impedance again, etc., and the runaway has begun. Where the capacity of the charger is large in proportion to the cell capacity, it is possible for the charging current to increase to the level where the oxygen re-adsorption rate at the negative plate is insufficient to prevent the full charging of the cadmium electrode. Then, one gets excess oxygen pressure and the possibility of hydrogen as well.

It may be advisable to remind ourselves, at this point, that other electrochemical systems can also be put in the runaway condition. In the case of the lead acid battery, the change in equilibrium emf with temperature has been reported by Vinal (7) to be about +0.25 mv/°C in battery concentration electrolyte. However, in this case the electrolytic resistance is appreciable and decreases with a temperature increase. Of course, the change in overpotential is the paramount item. Runaways in silver-zinc cells have also been reported, in particular by Chapman (8). At the same meeting, Earwicker (9) commented on runaways in several different battery systems.

Buffering Effect of Dehydration

Both the charged and discharged forms of the hydroxides of nickel are believed to contain either chemically combined or adsorbed waters of hydration. Kornfeil (10) has made some clarification of this in his work. In Fig. 1 are shown the dehydration curves for nickelous hydroxide at various temperatures. The material used was the green hydroxide precipitate employed in pocket electrodes. The loss of water was determined by weighing ceramic boats stored at the various temperatures after they had cooled in a dessicator. X-ray patterns of the dried materials were also obtained. It was observed that the water loss leveled out at the lower temperatures at a point equal to ¼-½ of a mole of water of hydration, and there was no change of crystal structure observed with the x-ray patterns under these conditions.

However, at the higher series of temperatures, above 175°C, the formation of NiO (Bunsenite) was

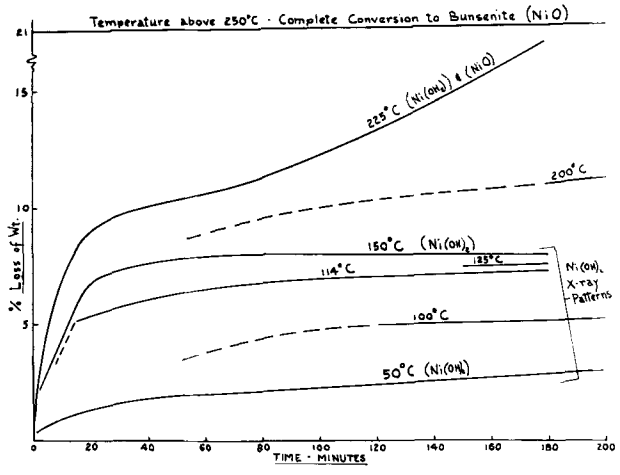

Fig. 1. Dehydration curves for nickelous hydroxide

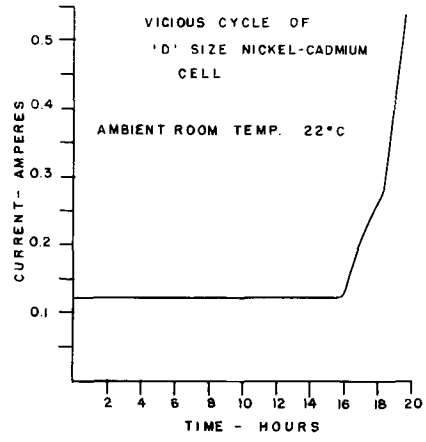

Fig. 2. Runaway charge of a 2.5 amp-hr cylindrical sealed nickel-cadmium cell with sintered electrodes.

observed with the loss of water and a blackening of the material; this was confirmed by x-ray analyses.

There are two buffering affects to the runaway condition which result from this dehydration. Under all temperature conditions the loss of water from the hydroxide crystal would dilute the electrolyte. The emf of nickel-cadmium cells is known to increase as the electrolyte concentration is decreased. The second buffering effect would take place when nickel oxide, Bunsenite, is formed. This material is an insulator, and its formation through dehydration increases the resistance of the nickel electrode on charge, because of the decrease in surface area as well as the straight-forward increase in electronic resistance. The exact amount of buffering that one obtains from these phenomena will depend on the geometry of the cell, but, in any case, will probably be quite small.

Aside from the peculiar usefulness of the conversion of nickel hydroxide to nickel oxide in this instance, in general it is a reaction very detrimental to cell performance. Our data indicate that it is irreversible, and that there is a permanent loss in cell capacity as well as the increase in electrode resistance. Probably it is mainly this reaction that precludes the high-temperature storage of nickel-cadmium cells. We believe that the conversion takes place at lower temperatures than those indicated in Fig. 1 over long periods of time, and experiments are in progress to determine this and the effect of storing in alkali.

Examples of Runaway Cells

Upstrom (11), Belove (12), and others in private communications have all reported observing runaway cells, and through their cooperation typical cycles are given. In Fig. 2 the charge of a 2.5 amp-hr cell at 1.40v and an ambient temperature of 22°C is shown. The cell was at an equilibrium current of 120 ma. The equilibrium was upset after 16 hr, and the charge current rose within 2 hr to over one-half an ampere, when the charge was interrupted. It has been suggested that this phenomenon will not occur if the charge voltage is below 1.40v, but no accurate data are available concerning the lower limit of potential which can cause the runaway condition.

In Fig. 3 another charge is shown; the battery in this case was a 24 cell unit, and the charge was at 36.0v. The rise in cell temperature was also recorded and is portrayed. The battery was cut off charge just after the charge current started to take a sharp rise.

General Performance Characteristics of Plastic Electrode Nickel-Cadmium Cells

Discharge and overcharge characteristics of some sealed cells constructed with high-energy density nickel and cadmium electrodes (6) were studied. The cells were designated as A, B, and C types. The A-type cell dimensions were 11 x 6 x 2.5 cm and were made with 11 positive and 10 negative plates. The types designated as B and C types had dimensions of 15 x 6.5 x 3 cm and 16 x 5.5 x 1.8 cm, respectively. The plates used in the latter two types were identical, with only the number of plates and the outer enclosure being varied The B type was made with 19 positive plates and 18 negative plates and had a nominal capacity of 18 amp-hr. The cell container used was extremely heavy and the energy density obtained was 28 whr/kg. The C type was made with 10 positive plates and 9 negative plates and delivered over 11.5 amp-hr to a 1.1v per cell cut-off. Since each cell weighed slightly over 400g, this corresponded to about 35 whr/kg. Most of the discrepancy in energy densities between the B and C types was attributable to the loss of positive

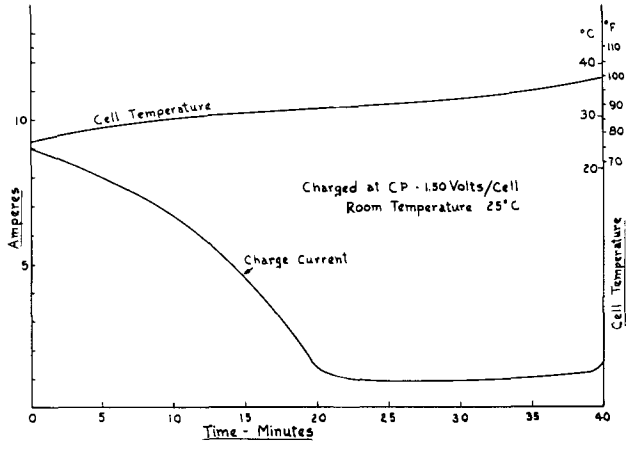

Fig. 3. Runaway charge of a 24-cell battery with sintered plate cells

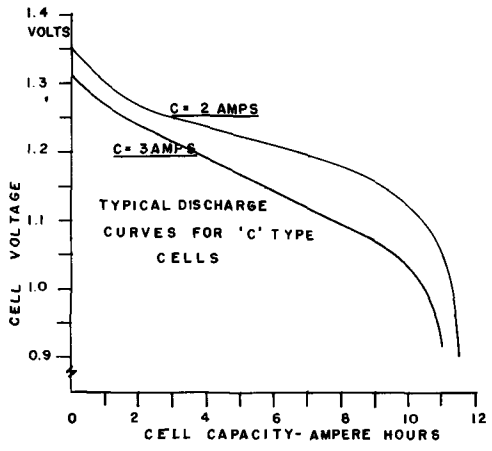

Fig. 4. Typical discharge curves for C-type cells at ambient room temperature, approximately 28°C.

electrode capacity in the B type because of prolonged heating during the case welding stage. Typical discharge curves for the C type cells are given in Fig. 4. The curves represent discharges at ambient room temperature, approximately 28°C. C-type cells were assembled into 4-cell batteries similar to those used for miner's lamps. The overcharge characteristics on constant current charging for such batteries are shown in Table II. These voltages are slightly higher than those reported for sintered plate cells; it has been shown (6) that these electrodes have Tafel curves with greater slopes than sintered electrodes.

In the C-type cells the most efficient charge was obtained by a two-stage constant-current charge. In the first stage, 75% of the capacity was replaced at the 5-hr rate, then the charge current was reduced and the cell kept on overcharge at the 20-hr rate.

Runaway of Nickel-Cadmium Cells with Plastic Electrodes

It has been possible to put the cells with plastic electrodes into the runaway condition with slightly more difficulty than conventional sintered plate cells. The ease with which a cell enters the runaway condition should depend on the total charging impedance, and the higher electronic resistance of the plastic nickel electrode acts as a buffer to cell runaway. Runaways in these cells were sometimes obtained at a charge voltage of about 1.44v or about 0.04v higher charge potential than that used to put some of the sintered plate cells into the runaway

condition. In Fig. 5 the runaway condition in a B-type cell is shown.

Discussion

We are entering an era where the use of sealed cells is likely to increase markedly. Many of the applications will be in space, but as Schulman (13) has pointed out, thermal runaways are unlikely in space applications because of the current limitations in the primary energy sources. However, many new applications are unfolding in portable appliances and tools. Although constant potential charging had been accepted in the past as one of the optimum methods of charging vented nickel-cadmium cells, it offers some hazards for sealed cells. It still provides a rapid method of charging, for most of the electrochemical capacity is restored before the nickel electrode begins to gas and, under normal conditions, the charge voltage can be set to restrict the charge current to a level the negative can accept for oxygen recombination.

However, where the danger of thermal runaways is likely, other provisions will have to be made. Lapuyade (15) and others have proposed voltage controls for the charger, based on the thermal condition of the battery. Earwicker (2) suggested polarized thermal relays, but cautioned that their use might lead to undercharging in warm conditions. Another solution is to match the maximum output of the charger to the current which the cell can accept in recombination.

A convenient limiter in laboratory applications is a common light bulb, for its resistance rises with both current and temperature. Modern design of batteries has resulted in a large increase in capacity with a reduction in internal resistance. This has been discussed by both Barak (14) and Earwicker (9). It may be possible to increase the heat dissipation of cells and therefore alleviate the runaway condition with better cell design. Since negative plates are usually much better electrical and thermal conductors than positive plates, future designs may ground the negatives to metallic outer cans in order to better dissipate the heat from the core, which is the hottest part of the cell stackup. In such designs, a series of parallel plates should dissipate heat faster than the common coiled cell design.

Manuscript received Oct. 25, 1961; revised manuscript received Jan. 17, 1962. This paper was prepared for delivery before the Detroit Meeting, Oct. 1-5, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

The "Vicious Cycle" in Secondary Batteries—A Mathematical Approach

W. G. Eicke, Jr.

National Bureau of Standards, Washington, D. C.

ABSTRACT

Equations relating voltage, temperature, heat capacity, time, and current have been derived for a cell on constant-potential charge. Assuming the cell to be fully charged and thermally isolated from its surroundings, thereby retaining all of the electrical energy supplied to it, the equations derived are

$$1/i = \frac{1}{i_o} - \left(\frac{(V_a - V_{\Delta H})(\Delta H^* - \alpha \mathbf{F} \eta)}{2RT_o^2 C_p} \right) t$$

and

$$1/T = \frac{1}{T_o} + \left(\frac{2R}{\Delta H^* - \alpha \mathbf{F} \eta} \left[\ln \frac{i_o}{i} \right] \right) t$$

where i is the current, t the time, T the absolute temperature, V_a the applied voltage, $V_{\Delta H}$ the voltage corresponding to the fraction of the electrical energy converted into chemical energy, ΔH^* the activation energy for the electrode reaction, α the transfer coefficient, η the activation overpotential, i_o and T_o the initial current and temperature, respectively, and C_p the heat capacity of the cell. The equations have been verified experimentally. The case where cooling occurs is also considered.

One problem that is encountered in secondary batteries is the tendency for them to go into a "vicious cycle" or "runaway" condition when they are charged at a constant potential especially at elevated temperatures. These terms apply to the phenomenon in which the charging current through a fully or nearly fully charged battery reaches destructive proportions because of the increase in battery temperature. Since the increase in battery temperature is caused by the charging current, the above terms are quite apt.

Whether a particular battery will go into a "vicious cycle" depends on the manner in which the temperature will vary with charging voltage, ambient temperature, rate of heat removal, the nature of the reactions taking place, and the physical construction of the cells and battery. In general, any of the present types of secondary batteries in use today can be made to go into a "vicious cycle" under the proper conditions.

It is the purpose of this paper to analyze mathematically the conditions that cause the "vicious cycle." However, before doing so, it will be desirable to review qualitatively the constant-potential charge.

Constant-Potential Charging

A constant-potential charge at normal and high temperature is characterized by a very high initial current which decays more or less exponentially with time as the cell becomes charged. Under ideal conditions the battery should become fully charged in 3-4 hr after which the current will be constant at a relatively low value. The charging potential is usually selected so that the cell can be fully charged in the minimum safe time. To accomplish this the charging potential is well above the re-

versible potential of the electrochemical reaction taking place. Woodbridge (1) reported that the variation of current with time could be approximated by the empirical equation,

$$i(t) = A \exp(-t) \quad [1]$$

where $i(t)$ is the instantaneous current at time t, and A is a constant. The above equation, however, does not adequately describe a normal constant-potential charge because it neither provides for a finite final charging current nor will one adjustable parameter satisfy all cases. A better approximation is

$$i(t) = i_f + A \exp(-kt) \quad [2]$$

where i_f is the final current after the cell is fully charged; A and k are adjustable parameters. At a constant temperature i_f would be constant and represents the current driving the overcharge reaction. The exponential term of Eq. [2] describes the current variation of the charging reaction. Equations [1] and [2] are represented graphically in Fig. 1 for the condition where a cell is held at a constant temperature.

If on the other hand the temperature of the cell is allowed to vary, as it normally does in service, the charging curve may be approximated by that shown in Fig. 2. It is assumed here that the cell does not lose any heat to the surroundings. If the charge is continued for sufficient time, the final current i_f will rise until it reaches destructive proportions as is shown by the dashed portion of the curve. This latter part of the curve is the region of "vicious cycle." If a typical curve were to be integrated, it would be found that the current will not begin to rise until the cell is either fully charged or nearly so. Since the "vicious cycle" does not normally occur until the cell is charged, the value of the second term in Eq. [2] will be zero or very nearly so. Therefore, any increase in current must be due to

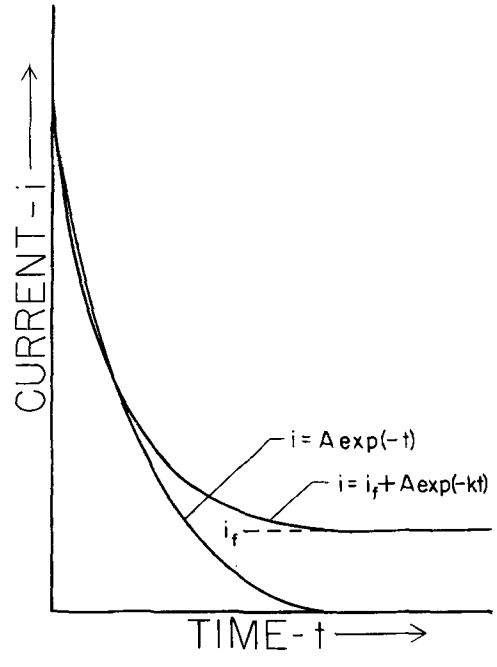

Fig. 1. Ideal constant-potential charging curves at constant temperature.

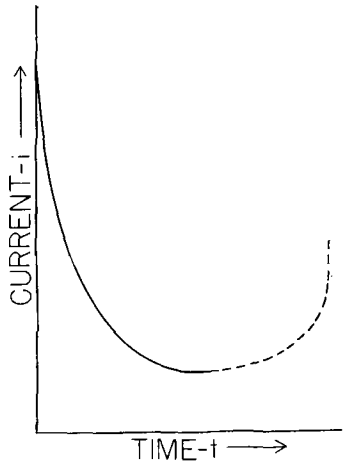

Fig. 2. Constant-potential charging curve for a cell that heats during the charge.

the effect of temperature on i_f, and it is this term that will be considered herein in some detail. An excellent discussion of the performance of several types of batteries on constant-potential charge is is given by Earwicker (2).

Assumptions and Idealized Model

As was stated earlier, the final charging current depends on a number of parameters which are often difficult to isolate and identify. To avoid the difficulty that would arise if an attempt were made to take them all into account in a mathematical analysis a simplified model will be used. This model is a cell, on charge at a constant potential, thermally isolated from its surroundings so that the only energy entering or leaving the system is the electrical energy being supplied by the charging current. It is also assumed that the cell is fully charged and all of the current is used to decompose water because in most open battery systems when fully charged most of the current is utilized to decompose water.

Mathematical Derivation

In general, the net rate at which the energy content of any system is changing is the difference between the rates at which energy enters and leaves the system. In the model just described no energy leaves the system, and the only energy being supplied the cell is the electrical energy. Therefore, the rate at which the energy content of the cell is increasing is

$$dU(t)/dt = V_a i(t) \quad [3]$$

where $dU(t)/dt$ is the rate at which energy being supplied at any time t, V_a the applied potential, and $i(t)$ the current at any time t.

The electrical energy is consumed in two ways. One is the electrochemical reaction and the other is the production of heat. As a result of the electrochemical reaction (the decomposition of water) the products of the reaction are in a higher energy state than the reactants by an amount of energy $-\Delta H/n\mathbf{F}$ energy units per coulomb. Assuming ΔH to be independent of temperature and hence time, the rate at which the electrical energy is converted to chemical energy $[dH(t)/dt]$ is

$$dH(t)/dt = (\Delta H/{}_{\eta}\mathbf{F})i(t) \quad [4]$$

where n is the number of equivalents for the electrochemical reaction and $\mathbf{F}$ the faraday. Defining $V_{\Delta H} = -\Delta H/n\mathbf{F}$ Eq. [4] can be rewritten as

$$dH(t)/dt = V_{\Delta H} i(t) \quad [5]$$

Since the rate at which the total energy supplied to the system is given by Eq. [3] and the rate at which electrical energy is converted to chemical energy is given by Eq. [5], the difference of these two equations gives the rate at which heat is being produced; hence

$$dQ(t)/dt = (V_a - V_{\Delta H}) i(t) \quad [6]$$

where $dQ(t)/dt$ is the instantaneous rate at which heat is being added to the cell at any time t. The heating of the cell can further be defined in terms of the temperature change of the cell, $dT(t)$, and its heat capacity, C_p. Assuming the latter is independent of temperature

$$dQ(t) = C_p dT(t) \quad [7]$$

Substituting Eq. [7] into Eq. [6] and rearranging

$$dT(t)/dt = (V_a - V_{\Delta H}) i(t)/C_p \quad [8]$$

In order to solve Eq. [8] it is necessary to establish a relationship between the current and the temperature. Such a relationship can be developed by considering the applied potential, V_a, which is made up of four components: the reversible potential (E), which is the potential of the H_2, O_2 couple, the activation overpotential (η), the ohmic overpotential (η_r) and the concentration overpotential (η_c). Hence

$$V_a = E(T) + \eta(T) + \eta_c + \eta_r = \text{constant}. \quad [9]$$

Both concentration and ohmic overpotential are small compared to the activation overpotential and can therefore be neglected. Furthermore the effect of temperature on $E(T)$ is negligible. Thus, for a constant-potential charge the activation overpotential will be constant, and in conjunction with the temperature it will control the current. The approximation that the current is determined by activation overpotential has been verified experimentally for the lead acid system by Vinal (3) and for the nickel-cadmium system by Duddy and Salkind (5). For both of these systems it was found that, on overcharge, plots of cell voltage, *vs.* log i are linear.

For any electrochemical reaction taking place at a single electrode the activation overpotential is given by

$$\eta = (RT/\alpha\mathbf{F}) \ln (i/i_e) \quad [10]$$

where α is the transfer coefficient and i_e the exchange current, which is given approximately by

$$i_e = K \exp -(\Delta H^*/RT) \quad [11]$$

where K is a constant whose value depends on the cell under consideration and ΔH^* is the activation energy for the electrode reaction. Since there are two reactions (one at each electrode) taking place, the total activation overpotential is the sum of the individual reaction overpotentials or

$$\eta = \eta_+ + \eta_- \quad [12]$$

where η_+ and η_- are given by

$$\eta_+ = (RT/\alpha_+ \mathbf{F}) \ln i - (RT/\alpha_+ \mathbf{F}) \ln [K_+ \exp - (\Delta H^*_+/RT)] \quad [13]$$

and

$$\eta_- = (RT/\alpha_- \mathbf{F}) \ln i - (RT/\alpha_- \mathbf{F}) \ln [K_- \exp - (\Delta H^*_-/RT)] \quad [14]$$

adding Eq. [13] and [14] and solving for i

$$i = \sqrt{K} \exp - [(\Delta H^* - \alpha\mathbf{F}\eta)/2RT] \quad [15]$$

where $K = K_+K_-$, $\Delta H^* = \Delta H^*_+ + \Delta H^*_-$, and α_+ and α_- are both approximately 0.5 for the decomposition of water.

For temperature changes that are small compared to the absolute temperature (as would be the case for room temperature and above) the current at any temperature (T) is given approximately by

$$i(T) = i_o \exp [(\Delta H^* - \alpha\mathbf{F}\eta)\Delta T/2RT_o^2] \quad [16]$$

where i_o and T_o are the initial current and temperature, respectively, and $\Delta T = T - T_o$. Differentiating Eq. [16]

$$di/dT = (\Delta H^* - \alpha\mathbf{F}\eta) i/2RT_o^2 \quad [17]$$

Solving Eq. [17] for dT and substituting in Eq. [8]

$$di(t)/i(t)^2 = \frac{(V_a - V_{\Delta H})(\Delta H^* - \alpha\mathbf{F}\eta)}{2RT_o^2 C_p} dt \quad [18]$$

Integrating Eq. [18] between the limits $t = 0$, $i = i_o$ and $t = t$, $i = i$,

$$1/i = 1/i_o - \left(\frac{(V_a - V_{\Delta H})(\Delta H^* - \alpha\mathbf{F}\eta)}{2RT_o^2 C_p}\right) t. \quad [19]$$

The variation of temperature with time can be evaluated using Eq. [19] and [16], thus

$$\frac{1}{T} = \frac{1}{T_o} + \left(\frac{2R}{\Delta H^* - \alpha\mathbf{F}\eta} \ln \frac{i_o}{i}\right) t \quad [20]$$

The last two equations have the empirical forms

$$1/i = A - Bt \quad [21]$$

and

$$1/T = C + D \ln(A - Bt) \quad [22]$$

Equations [19] and [20] define the variation of current and temperature with time for the ideal case in terms of measurable physical quantities, *i.e.*, the case where the only energy exchange between the cell and its surrounding is the electrical energy supplied for charging. These equations have certain limitations because of the simplifying assumptions made in their derivation and, therefore, should be considered only as limiting cases. The current or temperature predicted by the equations will be somewhat greater than would be realized in practice.

The Case Where Cooling Occurs

Above it was assumed that there was no heat exchange between cell and surroundings. It is also desirable to consider the case where the cell can lose heat to its surroundings since this situation is the one most frequently encountered in normal service.

When cooling occurs, the rate at which the heat leaves the cell is

$$dQ'(t)/dt = -k(T_c - T_a) \quad [23]$$

where $[dQ'(t)/dt]$ is the rate at which heat is being transferred from the cell to the ambient surround-

ings at any time t, T_c the cell temperature, T_a the ambient temperature, and k the heat transfer coefficient. Since the total rate at which heat is added to the cell is given by Eq. [6], the net rate of change of the heat content of the cell is the sum of Eq. [6] and [23] or

$$dQ_\eta(t)/dt = (V_a - V_{\Delta H})i(t) - k[T_c(t) - T_a] \quad [24]$$

Making use of Eq. [8] the net rate of temperature change of the cell is

$$C_p dT(t)/dt = (V_a - V_{\Delta H})i(t) - k[T_c(t) - T_a] \quad [25]$$

Setting $dT(t)/dt = 0$ Eq. [25] after rearranging becomes

$$(V_a - V_{\Delta H})\ i_{max} = k(T_{c_{max}} - T_a) \quad [26]$$

Since the current and cell temperature are related by means of Eq. [15], it is possible to solve Eq. [26] for either i_{max} or T_{max} in terms of the other parameters. Likewise, if i_{max} or $T_{c_{max}}$ are specified, it is possible to solve for either V_a, k, or T_a provided the other two are given.

Experimental Verification

Equations [19] and [20] were verified experimentally for a small lead acid cell and a nickel-cadmium cell. The charged test cell was placed in a Dewar flask at room temperature. To insure that it was fully charged the cell was charged at a low constant current for several hours before the experiment was started. The cell was then charged at a constant potential and the results recorded. The cell temperature was measured by a thermometer in the electrolyte and the current by an ammeter in series with the cell. The charging potential was held constant manually. Because of the heat loss through the electrical leads entering the Dewar and from the flask itself, it was necessary to use charging potentials greater than is considered normal in order to minimize these effects. The lead acid and nickel-cadmium cells were charged, respectively, at 2.60 and 1.60v. The results of these experiments are summarized in Fig. 3 through 6 in which the reciprocal of current and temperature are plotted as a function of time and log $(A - Bt)$, respectively. It can be seen that for both the lead acid and the nickel-cadmium the experimental data obey the empirical Eq. [21] and [22] except for longer times. As the

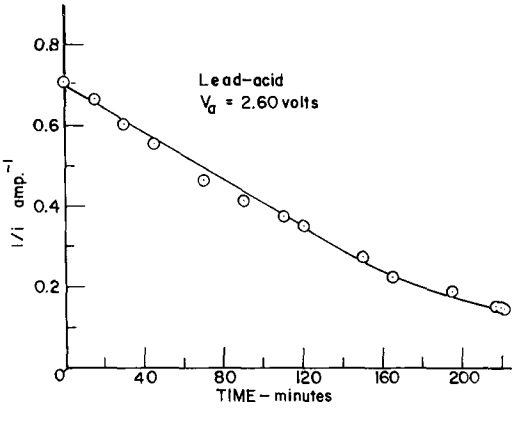

Fig. 3. Variation of current with time for a lead-acid cell on constant-potential charge.

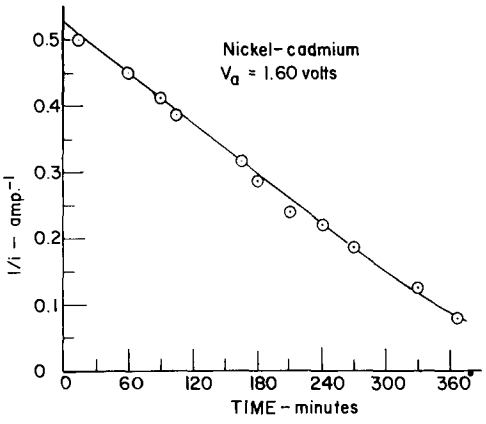

Fig. 4. Variation of current with time for a nickel-cadmium cell on constant-potential charge.

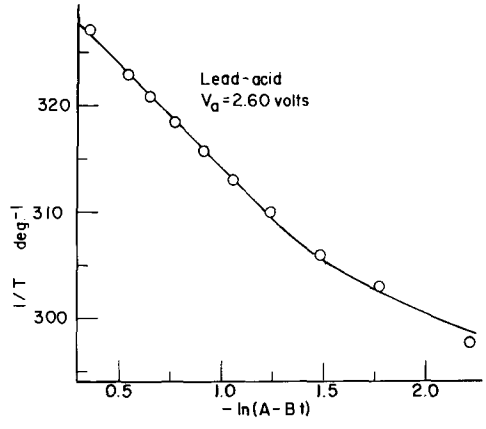

Fig. 5. Variation of temperature for the cell of Fig. 3

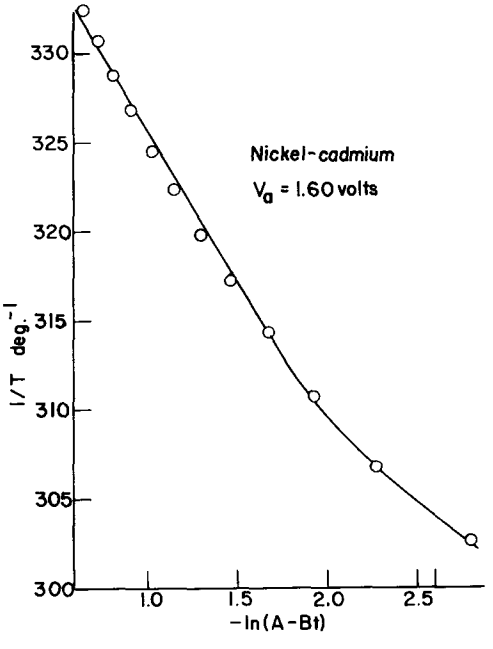

Fig. 6. Variation of temperature for the cell of Fig. 4

time increased, so did the temperature and consequently the heat loss. The deviations from expected behavior are in the correct direction to be accounted for by heat loss. For both types of cell the constants for the empirical equations were calculated from the figures and are summarized in Table I.

As a further verification of the derivation the activation energy, ΔH^* was calculated for the lead

Table I. Calculated constants for equations [21] and [22]

Cell	V_a, v	Constants A, amp^{-1}	$B \times 10^3$, amp^{-1} min^{-1}	$C \times 10^5$, deg^{-1}	$D \times 10^5$, deg^{-1}
Lead acid	2.60	0.700	2.95	330.4	17.8
Nickel-cadmium	1.60	0.523	1.40	343.2	16.6

acid cell. Using an estimated heat capacity of 233 cal/deg and the heat of formation of water to calculate $V_{\Delta H}$, ΔH^* was calculated to be 31.6 kcal/mole for the evolution of hydrogen and oxygen. This value agrees very well with that obtained from Glasstone and Bockris (4) and with the value calculated from Vinal's data (3). From these sources ΔH^* was found respectively to be 29 kcal/mole and 26.2 kcal/mole. The mean of the three is 28.9/kcal. This agreement adds confidence to the validity of Eq. [19] and [20]. Unfortunately, the heat capacity of the nickel-cadmium could not be estimated; however, from (4) ΔH^* was found to be 32 kcal/mole.

Tarnishing Reaction of Copper with Solutions of Thiourea and Derivatives. Study by Radiotracers

J. Llopis, J. M. Gamboa, L. Arizmendi, and F. Alonso

Instituto de Química Física "Rocasolano," Consejo Superior de Investigaciones Cientificas, Madrid, Spain

ABSTRACT

A tarnishing reaction takes place at the surface of copper when this metal reacts with thiourea or its derivatives, both in aqueous solutions and in organic solvents. In all cases coherent films of copper sulfide showing interference colors are formed. The kinetics of the film growth may be expressed by a quadratic equation, which leads to linear and parabolic laws as limiting cases. The kinetics will be linear with time if any of the interface reactions is the rate-determining step. This is the case for the reactions of dimethyl and diphenylthiourea in organic solvents, such as the hydrocarbon liquids. The remarkable influence of the dissolved O_2 has been widely studied. In aerated aqueous solutions of low concentration the reactivity decreases in the order thiourea > methylthiourea > dimethylthiourea, and the energy of activation amounts to 10 kcal/mole. In the case of dimethylthiourea the reactivity is smaller when anisole is used as solvent. Diphenylthiourea in xylene also shows a lower reactivity. In these cases the smaller reactivities lead to higher activation energy (14-20 kcal/mole). The research work has been carried out using radioactive tracers. In general, the compounds have been labeled with ^{35}S, but in the case of thiourea we also used ^{14}C, which permits the estimation of the proportion of molecules adsorbed at or occluded in the tarnishing film.

The study of the formation of sulfides on metallic surfaces by radiotracer methods, using ^{35}S labeled compounds, both in gaseous phase and organic solutions has been the subject matter of numerous publications during the last few years. This method is rapid, very sensitive, and accurate. A previous calibration permits the establishment of the activity-thickness ratio, according to which it is sufficient to measure the activity of a sample to know the sulfur content of the deposit formed.

Earlier results (1) suggested that a tarnishing reaction takes place at the surface of Cu, when this metal reacts with aqueous solutions of thiourea, forming a film of Cu_2S. This reaction yields coherent films showing interference colors. The kinetics of the film growth might be expressed by a quadratic relation such as

$$\frac{\Delta^2}{k_a} + \frac{\Delta}{k_r} = t \qquad [1]$$

where Δ is the deposit formed per unit area, usually expressed in μg of S per cm^2, t is the reaction time, and k_a and k_r are rate constants.

The research was extended to study the surface reaction of Cu with solutions of diphenylthiourea in xylene (2) and aqueous solutions of methylthiourea

(3). These reactions also give coherent films, and the remarkable influence of O_2 on their kinetics was established. If the O_2 is eliminated from the solution of methylthiourea, by passing pure N_2 before and during the reaction, the reactivity of this compound against Cu is very small.

Discussion of the results led us to conclude that molecules of thiourea, or its derivatives, are chemisorbed at the surface of the metal or at the outer interface of the tarnishing film. The access of O_2 to this interface seems to be essential for the splitting of the chemisorbed molecules, to form $S^=$ ions and cationic vacancies, which migrate toward the inner metal/sulfide interface. In this sense, the reaction involving the formation of surface sulfides will not proceed in the absence of O_2, and the following steps might be distinguished.

(*A*) The sulfide ions are formed at the outer ininterface (Cu_2S/H_2O + thiourea) through the action of O_2, which diffuses from the solution. Positive holes ($e\,\square$) and cationic vacancies ($Cu^+\square$) are formed, and they migrate from the outer interface to the metal. The reaction at the outer interface has been postulated as follows

$$\frac{1}{2}O_2 + \begin{matrix}RHN\\ \diagdown\\ \quad CS\\ \diagup\\ RHN\end{matrix} \longrightarrow \begin{matrix}RHN\\ \diagdown\\ \quad CO\\ \diagup\\ RHN\end{matrix} + S^= + 2Cu^+\square + 2e\square \qquad [2]$$

(*B*) Penetration of the metal in the Cu_2S film. This compound is deficient in metal, and therefore it has cationic vacancies which act as centers of effective negative charges. The electrical neutrality is preserved by the existence of positive holes near the lattice defects. The reaction taking place at the inner interface will then be:

$$Cu + Cu^+\square + e\,\square \longrightarrow Cu^+ \qquad [3]$$

according to which a Cu atom penetrates as Cu^+ ion into the Cu_2S lattice, filling a cationic vacancy and giving out an electron to a positive hole $e\,\square$ in the valence band of the sulfide.

(*C*) Transport of material through the tarnishing film. If this film is coherent, the transport takes place, for high temperatures and great thickness, by diffusion of Cu^+ ions through a concentration gradient of $Cu^+\square$ vacancies (Wagner's mechanism). For lower temperatures and small thicknesses, as may be the case for the processes here considered, the action of electrical fields, due to reactions [2] and [3], must be considered (Hauffe's boundary layers and mechanism of Mott and Cabrera). However, frequently, the films formed are no longer coherent, and the transport of matter is made easier, through pores, cracks, grain boundaries, etc., present in the film.

When none of the above processes (A, B, C) is the rate-determining step, it can be said that the "slowness" of the reaction (defined as the reciprocal of the reaction rate) is the sum of those corresponding to each of the partial processes (4, 5). These ideas lead to Eq. [1], where the term Δ/k_r accounts for the "slowness" due to the inner and outer interface reactions, being

$$\frac{1}{k_r} = \frac{1}{k_e} + \frac{1}{k_i} \qquad [4]$$

and the term Δ^2/k_d corresponds to that of the matter transport process.

The kinetic relation [1] leads as limiting cases to linear and parabolic kinetic laws. The kinetics will be linear ($\Delta = k_r\,t$) if any of the interface reactions is the rate-determining step. This implies that the transport of matter is rapid. For this transport it is essential to have a lattice with defects and high electrical conductivity. This is the case at the beginning of the formation of the surface films we are considering and especially in the case when Cu is attacked by thiourea derivatives in organic solvents. The parabolic term Δ^2/k_d appears as a curvature in the plot Δ *vs.* t. This curvature depends clearly on the experimental conditions.

All these considerations suggest a restudy in greater detail of the reaction of Cu with aqueous solutions of thiourea. The possibility of using this compound labeled alternatively with ^{35}S or ^{14}C permits the estimation of the proportion of thiourea molecules occluded as such in the deposit formed. On the other hand, since the dimethylthiourea is soluble in water and in anisole, the study of the reaction of Cu with this compound makes it possible to obtain information about the influence of the solvent. This paper describes results not yet published which we considered more relevant to our present discussion. Also, a general picture of the kinetics of this sulfuration process will be given especially regarding the influence of the various alkyl and aryl substituents of thiourea, the presence of O_2, and the nature of the solvent.

Experimental Technique

Preparation of labeled compounds.—In some cases labeled compounds of high specific activities have been obtained from radioisotope distribution centers (thiourea). In other cases the radioactive compounds have been prepared in our laboratory, either by an exchange reaction with high specific activity ^{35}S (diphenylthiourea) or by synthesis from other more simple compounds (methylthiourea and dimethylthiourea). In general, the compounds used were labeled with ^{35}S, but in some cases with ^{14}C. In both cases the activity is due to weak β radiation.

Counting equipment.—A Geiger-Müller tube was used for counting, and the necessary corrections were applied to the results. The uniformity of the deposits was checked by autoradiography. The samples were usually counted for a time long enough to have a statistical error of 1%.

Calculations of the specific activity of the labeled compounds.—Determination of counting efficiency.—To determine the efficiency of our counting system a thiourea reference source was used. It was supplied by the Radiochemical Center, Amersham, with a specific activity of 222 millicurie/g. With this source a solution was prepared containing 9.3 microcurie/ml and on the other hand another solution of inactive thiourea containing 100 mg/ml was

prepared. With these two solutions we could prepare solutions of varying concentration and varying specific activity.

The efficiency for solid samples was measured with circular Cu disks, identical with those used in the sulfuration experiments, of 2.5 cm diameter and 0.4 mm thickness, previously submitted to mechanical and electrochemical polishing. The efficiency for liquid samples was measured with flat bottom glass ashing dishes, 2.2 cm internal diameter and 7 mm deep.

Efficiency measurements for solid samples have been carried out by two procedures, denoted as evaporation and depletion method, respectively. In the first case solid samples were obtained by evaporation of thiourea solutions, containing known amounts of ^{35}S and distributed so that they occupy centered circles of increasing radius on the copper disks. The solutions are prepared so that both the sulfur content of the deposit expressed as μg of S per cm^2 and the total activity of the samples are kept constant. Therefore the specific activity of the deposit (microcurie/cm^2) will decrease with increasing radius. Countings corrected for coincidence, background, standard, and decay, are plotted *vs.* the radius of the samples, and the extrapolation to $r = 12.5$ mm of the graphically adjusted curve allows us to calculate the counting that would be obtained, should the deposit be uniformly distributed over the whole area of the disks.

Table I shows the results of experiments 1 to 4 carried out by evaporation procedure. In column 2 the deposits of S in $\mu g/cm^2$ are given; column 3 shows the absolute radioactivity of the samples; column 4 the activity measured in our equipment and column 5 the efficiency in percentage; column 6 shows the statistical weight given to the determinations.

In the depletion method the same experimental procedure as in the sulfuration experiments is used. Polished disks of copper are made to react with thiourea solutions until these are completely depleted; the concentration of each thiourea solution is such that a sulfide deposit of a certain thickness is obtained. The solution will be depleted when another disk, in the same conditions, does not show any reaction and its counting equals that of background. Table I shows the results of experiments 5 to 10 carried out by this procedure.

It can be seen in Table I that the counting efficiency is constant for the whole range of thicknesses of sulfide (Δ) studied, except for the experiments corresponding to negligible thickness carried out using the active thiourea solutions only. The value of the efficiency is higher in this case (9.5%), probably due to nonuniform distribution of the deposit which tends to accumulate at the center of the disks, during evaporation. The autoradiographs confirm this assumption. This result has been rejected in calculating the weighted mean value of the efficiency which is 7.0%.

For liquid samples the efficiency decreases with increasing density, due to a greater absorption of β particles. With aqueous solutions of thiourea, whose concentrations vary between 12 mg/l and 3 g/l (densities very nearly unity), an excellent proportionality between the disintegration rate and the counting rate is observed. The slope of the straight line thus obtained corresponds to an efficiency of 0.082%. Hence the ratio of efficiencies for solid and liquid samples is 85. This ratio is useful, because the higher precision of liquid sample counting avoids preparation of solid samples, where small variations in the uniformity of the deposit gives place to considerable errors.

Preparation of reacting solutions.—In each case the preparation of solutions with desired characteristics has been carried out by admixture, in appropriate proportion of the two stock solutions, one active and the other inactive.

Preparation of copper disks.—The disks were first mechanically polished, then degreased with benzene in a Soxhlet apparatus, followed by washing with acetone and distilled water. After further washing and electrochemical polishing in 60% H_3PO_4 solution, the disks were rapidly washed in distilled water. The polishing and subsequent washing were carried out immediately before the reaction experiments and, to minimize oxidation, the disks were introduced while still moist into the reactant solution.

When hydrocarbons or similar compounds are to be used as solvents the treatment of the copper disks was slightly modified. After electrochemical polishing the disks were washed again with distilled water and acetone and immediately submerged in dry benzene, xylene, etc. These manipulations were always carried out quickly and under the same conditions.

Performance of the experiments.—The experimental method consists in introducing the polished copper disks into the solution (30 ml) in such a

way that, by means of a slow rotating motor (60 rpm), they are moved up and down with simultaneous rotation, to obtain an efficient removal of the solution at the interface. During each experiment the temperature is kept constant. After a time the disk is rapidly removed, washed repeatedly either with distilled water or the solvent used in the experiment, then with acetone, and finally it is allowed to dry before counting.

Counting and calculation of film thicknesses.—Calculation by radioactivity measurements.—The radioactivity of the dried disk was then measured, taking into account corrections for coincidence, background, reference to standard, and decay of the nuclide. If the specific activity of the solution used is expressed as cts. $min^{-1}/\mu g\ cm^{-2}$, the original countings can be translated into amounts of sulfur in $\mu g\ cm^{-2}$ deposited at the surface. The thickness of the surface film can be calculated easily assuming a certain value for the density of the compound formed. Table II shows an instance of corrections and calculations performed for two experiments done with Cu and aqueous solutions of thiourea.

In Table II, column 5 shows the activities corrected for a paralysis time of 400 μ sec, fixed in our system of counting. In column 9 the activities are referred to a certain standard, while in column 10 account is taken of the correction for decay of nuclide. Column 12 gives the weights of sulfur per unit area, estimated from the activities given in column 10 and taking account of the specific activity given in column 11. If it is assumed that the product formed is Cu_2S, the thickness of the film can be estimated from its density 5.783 g/cm^3, whence 1 $\mu g\ cm^{-2}$ of sulfur deposited corresponds to a thickness of 85.9Å.

Thickness scale by visual observation of interference colors.—In the course of our experiments, it has been verified that the reaction of Cu with diphenylthiourea (2) leads to the formation of coherent sulfide films, showing suitable interference colors for establishing a scale relating colors with weights of deposited sulfur. This scale provides a convenient visual method of estimating the thicknesses of the surface films formed.

Dyess and Miley (6) determined by the coulometric method the thicknesses of sulfide films on Cu, corresponding to several interference colors in the first two orders. The success of a quantitative coulometric reduction of Cu_2S has been studied later on by Hoar and Stockbridge (7). Weighings of cathode and colorimetric determination of Cu in solution indicated that reduction was complete. Comparison of sulfur contents of films showing similar interference colors evidences satisfactory agreement between coulometric, colorimetric, and radiotracer estimation. This allows a greater reliability for estimating the thicknesses by visual observation of the disks during sulfuration.

Experimental Results with Aqueous Solutions of Thiourea

The reaction of Cu with aqueous solutions of thiourea is studied below in greater detail. The electrochemical behavior of this compound makes this study advisable. On the other hand, the availability of thiourea labeled with ^{35}S or ^{14}C allows one to draw new conclusions about the mechanism of this reaction.

Experiments with thiourea-^{35}S.—Experiments with aerated solutions.—In these solutions the O_2 concentration is determined by the partial pressure of this element in the air. Thus, the conditions prevailing in these experiments can be assumed to be similar to the actual conditions of corrosion phenomena.

With a constant O_2 concentration, the variables to be studied are the temperature and the concentration of thiourea. Figure 1 shows the results obtained for Δ *vs.* reaction time t, for a concentration 1.32 x 10^{-3} M and temperatures shown in the figure. It can be seen that the kinetic reaction law is quadratic [1], and plotting t/Δ *vs.* Δ the rate constants, k_d and k_r, for each value of concentration and temperature may be determined. To carry out this determination of rate constants the method of least squares has been applied in most cases.

The values of these rate constants from the whole series of experiments are shown in Table III, in which they are given in laboratory units (μg, cm^{-2},

min^{-1}) and in practical units (g, cm^{-2}, sec^{-1}). Figure 2 shows the plot log k_r *vs.* $1/T$ for the concentration 1.32 x 10^{-3}M. In all cases this plot allows one to draw straight lines from which the parameters in the Arrhenius equation may be calculated

$$k = A \exp(-\Delta H^*/RT) \qquad [5]$$

Values of ΔH_r^* are also given in Table III. The value $\Delta H_r^* = 10.9$ kcal/mole reported for the above concentration agrees well with that found for the same conditions in ref (1), which due to miscalculation should read 10.4 kcal/mole.

Figure 3 is a plot of k_r and k_d *vs.* thiourea concentration for the temperatures 20°, 35°, and 50°C. With regard to k_r it can be observed that the interface reaction rate passes through a maximum for a concentration 0.8 x 10^{-3}M. On the contrary, the values of k_d decrease at the beginning with increasing thiourea concentration, tending later to steady values nearly independent of the concentration. The study of the variations of both is discussed below.

Experiments carried out passing nitrogen and oxygen.—In order to check if the presence of dissolved O_2 is a decisive factor in the process of sulfuration

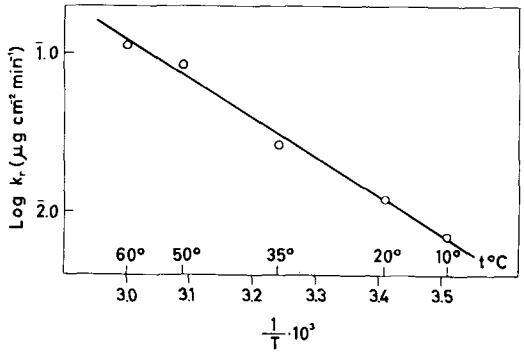

Fig. 2. Plot of log k_r vs. $1/T$ to determine the energy of activation. Concentration of thiourea 1.32 x 10^{-3}M.

of Cu by thiourea, a series of experiments were carried out, eliminating the dissolved air in the solution by passing N_2 at a rate of 20 cm^3/min. Figure 4 shows the results thus obtained for a concentration 1.32 x 10^{-3}M and 35°C. It shows also the results for experiments carried out passing O_2 in the same conditions and those obtained with aerated solutions. From this series of experiments we may conclude that the reactivity of thiourea against Cu increases notably by passing O_2, while the elimination of this element by passing N_2 decreases the reactivity. This effect is more evident as the elimination becomes complete.

Experiments carried out with thiourea-^{14}C.—Using thiourea-^{14}C we have been able to determine the content of thiourea molecules in the tarnishing films, due to adsorption at the solid/liquid interface or inclusion in the bulk of the sulfide film. The results so obtained are expressed, as before, as deposited S in $\mu g/cm^2$ so that they can be easily compared with those obtained with thiourea-^{35}S. The experimental procedure is the same as above, except that in this case the decay correction given in column 10, Table II, does not apply. The specific

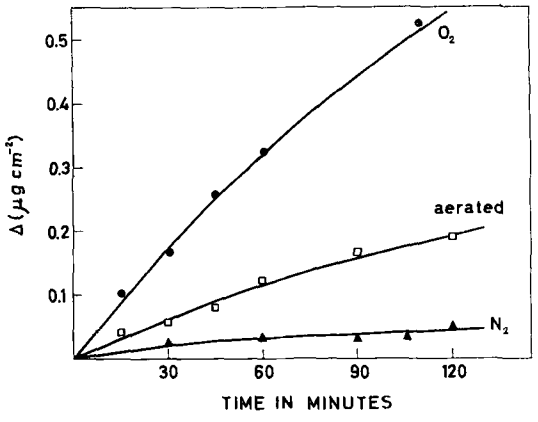

Fig. 5. Experiments carried out with aqueous solutions of thiourea—^{14}C. Concentration 1.32 x 10^{-3}M, 35°C.

activity to be given in column 11 is in this case 1.9 x 10^8 cts. $min^{-1}/\mu g\ cm^{-2}$.

The progress of the reaction is followed by observation of interference colors which should be identical, for the same experimental conditions, to those obtained with thiourea-^{35}S. The activity of the disks gives the contribution of thiourea molecules to the deposit formed. Figure 5 shows these contributions against time for a series of experiments carried out under similar conditions to those of Fig. 4. Comparing both figures it can be concluded that the contribution of thiourea molecules to the total thickness of the deposit considered as sulfide is approximately 14% in the experiments carried out passing O_2, 10% in those with aerated solution, and 6% when passing N_2. The influence of temperature has also been studied with aerated solutions of the above concentration, and the approximate contribution of thiourea molecules varied from 13% at 20°C to 10% at 35°C and 7% at 50°C.

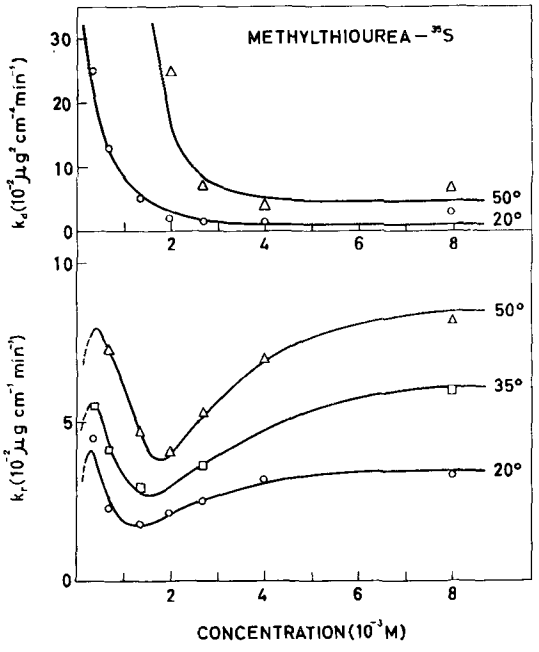

Fig. 6. Values of k_d and k_r vs. concentration of methylthiourea in aerated aqueous solutions.

Experimental Results with Aqueous Solutions of Methylthiourea

The surface reaction of Cu with aqueous solution of methylthiourea has been reported in another paper (3). However, a new consideration of those results obtained with aerated solutions of methylthiourea permits a more precise determination of the rate constants k_r and k_d. The results so obtained differ little from those published (3) and are summarized in Table IV, where in the last column the values of the activation energy for several concentrations are gathered.

Figure 6 shows the values of k_r and k_d *vs.* methylthiourea concentrations for three values of temperature (20°, 35°, and 50°C). The variation of k_r in the curve is similar to the one described for thiourea, but the maximum appears at lower concentrations, about 0.3 x 10^{-3}M. This fact is confirmed because of the presence of a minimum which is displaced to the left. The minimum reaches a lower level with methylthiourea. The value of k_d decreases rapidly at the beginning, tending later to steady values. In general lines the trend of these variations is similar to that observed in the case of thiourea.

Experimental Results with Aqueous Solutions of Dimethylthiourea

Dimethylthiourea presents the advantage of being soluble in water and in organic solvents; results obtained with aqueous solutions are described below. Radioactive dimethylthiourea was prepared from $^{35}S_2C$. The specific activity was determined by measurement of liquid samples and calculating the solid sample activities by the above mentioned ratio. Thus, we calculated for these experiments that 1 $\mu g/cm^2$ of S corresponds to 80.3 cts./min. The counting of the disks and the corresponding corrections are carried out in a form similar to that described for thiourea, except that in column 11 of

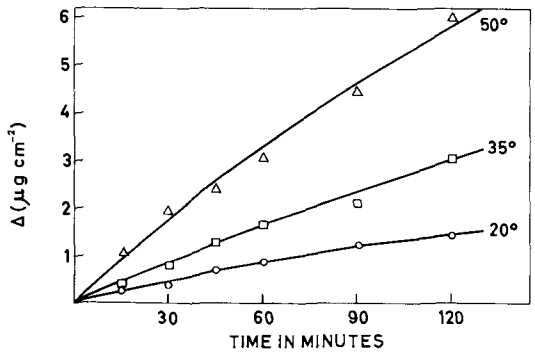

Fig. 7. Reaction curves for experiments carried out with aerated aqueous solutions of dimethylthiourea—^{35}S. Concentration 1.32 x 10^{-3}M.

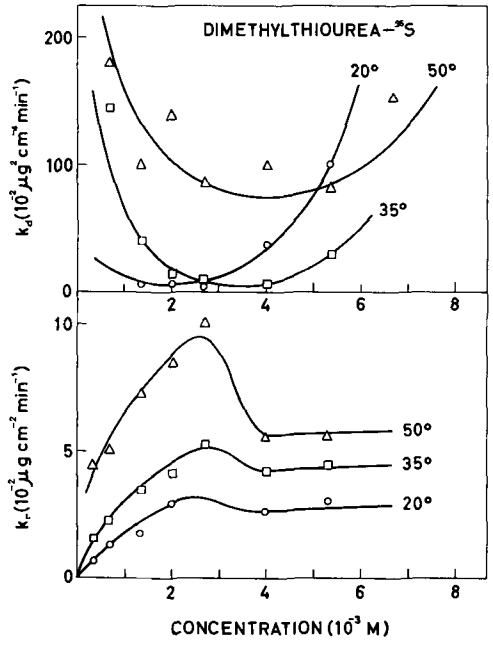

Fig. 8. Values of k_d and k_r vs. concentration of dimethylthiourea in aerated aqueous solutions.

Table II now appears the value 80.3 (cts. $min^{-1}/\mu g\ cm^{-2}$) for this activity-thickness ratio.

Experiments carried out with aqueous aerated solutions.—Figure 7 shows the reaction curves for three series of experiments carried out, respectively, at 20°, 35°, and 50°C and a concentration 1.32 x 10^{-3}M. As in the cases of thiourea and methylthiourea the results obtained in these experiments can be analyzed by the aforesaid quadratic law. The values of k_r, k_d, and ΔH_r^*, calculated in the same way as before for several concentrations and temperatures, are given in Table V.

In Fig. 8 the values of k_r and k_d are plotted against dimethylthiourea concentration for temperatures of 20°, 35°, and 50°C. The variation of k_r is similar to that observed for thiourea, except that the maximum lies displaced toward the concentration 2.5 x 10^{-3}M. The most noteworthy fact concerns in this case k_d, since this rate constant passes through a minimum with increasing concentration of dimethylthiourea. This minimum appears for smaller concentrations with decreasing temperature. Formally, this fact reflects itself in the plots of Δ *vs.* t, which, for a given temperature, tend to be again

Table V. Kinetic parameters for the whole series of experiments carried out with aerated aqueous solutions of dimethylthiourea—^{35}S

linear for higher concentration. The interpretation of these facts is given below in the Discussion.

Experiments carried out passing nitrogen.—In several series of experiments carried out at 20°, 35°, and 50°C, with different concentrations, and passing N_2 at a rate of 20 cm^3/min, the results show in all cases that there is a considerable decrease of reactivity against Cu, due to removal of dissolved air.

Experimental Results with Solutions of Dimethylthiourea in Anisole

Experimental conditions are similar to those used in aqueous solutions. The copper disks, after mechanical and electrochemical polishing, were washed with distilled water, with acetone, and finally with anisole. After reaction the disks were washed with anisole, acetone, and allowed to dry before counting. Figure 9 shows the results obtained for a concentration 1.32 x 10^{-3}M and temperatures of 60°, 75°, 80°, and 90°C. It follows from these results that the reactivity is lower than in aqueous solutions, and for most of the experiments the kinetic law of the film growth was linear with time. The results

obtained for different values of temperature and concentration of dimethylthiourea are given in Table VI. A set of experiments was also carried out passing pure N_2 before and during the reaction of sulfuration. They showed a decrease of reactivity to a minimum.

Experimental Results with Solutions of Diphenylthiourea in Xylene

Results obtained in the study of the surface reaction of Cu with solutions of diphenylthiourea in xylene have been published elsewhere (3); this reaction also yields coherent films, showing interference colors. The reactivity in this case is much lower than that of thiourea in aqueous solution, and the kinetic law of the film growth is linear with time. A value of $\Delta H_r^* = 14.2$ kcal/mole for the energy of activation is obtained. In the discussion below these results are considered again in trying to establish a comparison with all the results obtained with different compounds.

Discussion

From the results described above concerning the formation of surface films of sulfides on Cu by thiourea and derivatives we conclude that these compounds supply the $S^=$ ions at the outer interface, by the action of the O_2 dissolved in the solution. If the O_2 is eliminated, the reactivity with Cu decreases notably, and if the elimination should be complete, the reaction could be reduced to a chemisorption of a thiourea monolayer on the Cu surface, the molecules anchoring through the groups S=C.

Recent work by Trivich *et al.* (8), in which thiourea-^{35}S was used to study the effect of this compound on electrodeposition of Cu, showed how the adsorbed molecules interfere with the growth of the crystals. However, if aerated solutions of thiourea are used, the splitting of these molecules at the cathode surface may play also a role in the inhibiting effect. This splitting of the molecule may explain the occlusion of S in the electrodeposits (9, 1). Likewise, the results obtained in the experiments carried out with thiourea-^{14}C show the presence of molecules adsorbed and partly occluded in the sulfide film. This effect is greater when the sulfuration process is more intense. These results, besides the use of thiourea as collector in the flotation of sulfide minerals (10) and the possibility of complex and chelate formation with Cu, indorse the hypothesis that the thiourea molecules are chemisorbed both at the metal surface, in the initial stage of the reaction, and at the external surface of the sulfide film during its growth.

On the other hand, chemisorption of oxygen on a p-type semiconductor such as Cu_2S seems to be associated with adsorbed oxygen atoms and neutral pairs formed by O^- ions and positive holes trapped at the surface lattice cations (11). However, if the adsorption takes place at a thin sulfide film on a metal, it may be modified by electron transfer from the metal to the surface level in such a way that adsorption as O^- ions will exceed that on bulk sulfides. The electrical field thus established will contribute furthermore to the migration of Cu^+ ions through the tarnishing film (12, 13).

The high reactivity of the chemisorbed oxygen is readily understandable (14, 15) being ascribed to the O^- ions formed at the surface. In this way once the molecules of oxygen and thiourea are chemisorbed, the oxidation of the latter may take place, but the mechanism of the reaction cannot yet be elucidated. Freundlich and Fischer (16) studied the oxidation of thiourea solutions in the presence of activated carbon, and they supposed that sulfur and Hector base ($C_2H_4N_4S$) were formed in the reaction. However, the experiments described show that, in the presence of O_2, all the sulfur contained in the thiourea or its derivatives can react with Cu. This has led to the use of reaction [2] at least as a working hypothesis.

The observed variation of k_r, in the experiments carried out with aqueous solutions of thiourea, would show that there exists at the beginning an increasing reactivity with concentration, followed by an inhibiting effect due to the same thiourea. On the other hand, the variation of k_d leads to a greater curvature in the plot Δ *vs.* t for thiourea concentrations greater than 10^{-3}M. Now, if the physical meaning of this rate constant is related to the transport of matter, this would mean a greater hindrance for this transport when using solutions of increasing concentration. In principle, we can assume that this hindrance is due, in a great part, to the thiourea molecules occluded in the deposit formed and whose percentage has been determined in the experiments carried out with thiourea-^{14}C.

These results have been confirmed, in general, in the experiments carried out with aqueous solutions of methyl and dimethylthiourea. In the last case, constant k_d goes through a minimum when the concentration increases, and this minimum appears at lower concentration with increasing temperature. This means that, for a given temperature, the permeability of the films is greater when the concentration of dimethylthiourea increases above a certain value, perhaps due to CuS formation, which favored lowering the temperature (17).

If the rate of the interface reaction is smaller than that of the matter transport through the surface film and hence it becomes the rate determining step for the whole tarnishing process, it can be expected that the kinetic law of the film growth be linear. This might be the case with solutions of di-

methylthiourea in anisole and diphenylthiourea in xylene.

With all the experimental data, a comparative study regarding the rate constants k_r and the activation energies ΔH_r^* can be made, taking into account the several compounds, concentrations, and temperatures used. The results shown in Table VII lead to the following considerations.

In aerated aqueous solutions, the reactivity with Cu decreases in the order thiourea > methylthiourea > dimethylthiourea for very small concentrations. However, if the concentration is greater than 3 x 10^{-3}M the reactivities become of the same order or perhaps they increase in reverse direction. The activation energies ΔH_r^* are of the order of 10 kcal/mole. In general, if it is assumed that the prevailing factor for the reactivity of these compounds is the splitting of the C=S bond that depends on the negative electronic density of the S atom and the positive of the C atom, the substitution of H in the amine group by CH_3 will not alter essentially the conditions comparing with thiourea, because the CH_3 group is a weak electron donor.

In the case of dimethylthiourea, the reactivity is less when anisole is used as solvent. Diphenylthiourea in xylene shows a reactivity of the same order as that of dimethylthiourea in anisole. In many cases it is observed that weaker reactivity leads to greater activation energy, when the sulfuration reaction with thiourea derivatives takes place in non-aqueous solutions.

Finally, it is to be pointed out that, in all cases, the microscope observation of the surfaces after reaction reveals the presence of a color mosaic that follows the grain structure of metallic base. In general, the film is of uniform color for each grain. The observed colors can be due either to different thickness of the films formed on each grain, or differences in refraction index or to both factors. If the film formed is anisotropic the refraction index depends on the orientation. However, the experiments of Kruger (18) concerning the oxidation of a Cu monocrystal submerged in an aqueous O_2 solution and the gravimetric measurements of Benard and Talbot (19, 20), in the sense that certain crystallographic planes of Cu are oxidized more rapidly than others, seem to show that the variation in the thickness of the film and not that of the refraction index is the reason for the differences in color observed for different grains after the sulfuration reaction.

However, it is to be pointed out that this influence on the reaction rate, due to the orientation of the base lattice, will tend to decrease as the thickness of the tarnishing film increases, the reaction at the outer interface becoming finally the rate-determining step.

On the Oxidation of Zirconium

Karl A. Sense[1]

Research Department, Atomics International, A Division of North American Aviation, Inc., Canoga Park, California

ABSTRACT

The rate law for the oxidation of zirconium was found to be initially intermediate to linear and parabolic, then parabolic, and then nearly cubic over the first 10-min interval at both 400° and 500°C. At 400°C the oxidation rate became parabolic for an oxide thickness of about 300Å. At 500°C the oxidation rate became nearly cubic at about 3300Å, the transition from one rate to another being gradual rather than sharp. The activation energy for the parabolic region was 29.3 kcal/mole and for the nearly cubic region approximately 42 kcal/mole. The results obtained were independent of the shape of the specimen and its surface preparation. An analysis shows that the high solubility of oxygen in zirconium is not a sufficient condition to account for a cubic rate law of oxidation for a concentration-independent diffusion constant.

This work is a by-product of the primary objective, namely the study of the diffusion of hydrogen through thin films of ZrO_2 on zirconium metal. Since it was easier to obtain the desired oxide thickness at a lower temperature because of lower oxidation rates, the oxidation of zirconium was carried out at only two temperatures, 400° and 500°C. Also, since only thin films were desired, all of the runs with one exception were of a very short duration. The diffusion of hydrogen through ZrO_2 being the primary study, the kinetics of the oxidation of zirconium were not analyzed until after the experimental program was terminated, thus leaving the oxidation study incomplete from the standpoint of longer runs and greater temperature spread. Nevertheless, it is felt that the findings presented here are of sufficient interest to stimulate further work.

Experimental

Method.—The reaction rate between oxygen and zirconium was measured gravimetrically with an Electrona II balance which could detect weight changes of 1 μg. The reaction tube was attached directly to the balance. The furnace used was a 12-in. Hevi-duty type. Temperatures were measured with a platinum-platinum-rhodium couple located on the surface of the reaction tube. This couple was calibrated with respect to another couple located at the site normally occupied by the specimen. The temperature was controlled by a proportioning photocell-activated controller.

Two kinds of specimens were used, rectangular and spherical. The rectangular specimens had a surface area of about 13 cm^2 and a thickness which varied from 0.015-0.022 cm. The diameter of the spherical specimens varied from 0.51 to 0.52 cm. All of the specimens were prepared from reactor grade hafnium-free zirconium. All of the spherical and some of the rectangular specimens were abraded by being treated successively with 1, 2/0, and 3/0 abrasive paper and then polished with diamond dust to a mirror finish. They were then cleaned with a soap solution followed by water, acetone, ether, and absolute alcohol rinse. The rectangular specimens which were not abraded were chemically polished with a bath having the composition 45% HNO_3 (conc) 45% H_2O, and 10% HF (48%). The oxygen used was Matheson Company's research grade, maximum impurities in mole per cent being given by the manufacturer as follows: carbon dioxide 0.1, carbon monoxide 0.01, argon 0.01, nitrogen 0.05, hydrogen 0.01, and water 0.0002.

The following procedure was adhered to in making runs. The rectangular specimen was suspended from a thin hooked silica rod which was attached to either another silica rod or a three mil tungsten wire which was attached to the balance. The length of the system was so adjusted that the temperature gradient across the specimen in the hot zone was least, about 2°C. The spherical specimens were placed in a small silica basket. Because of the small diameter of the spheres the temperature gradient across the specimen was less than 1°C. At the start of a run the whole system was evacuated to a pressure of 7×10^{-5} mm Hg or less. Once the desired run temperature was obtained oxygen was admitted, the pressure being determined by a mercury manometer. Pure gold foil was placed between the manometer and the system to prevent mercury vapor from contaminating it. Balance readings were taken as soon as possible, usually 20 sec after oxygen was first admitted, and at 10-sec intervals thereafter except for the 2-hr run at 500°C when readings were taken at longer intervals after about 8 min.

Spheres were used in this work because we wanted to eliminate edge effects in the study of the diffusion of hydrogen through ZrO_2 films. Since the weighing capacity of the Electrona II balance used

was 1g we were limited to the use of small zirconium spheres so that the surface area of the spheres was only 0.81-0.86 cm^2. As a result, the magnitude of weight change for a 10-sec interval reading was only about one-fifteenth of that for a rectangular specimen. Since the most sensitive scale had to be used to measure weight changes for the spheres, the data showed more scatter than for the rectangular specimens.

Oxidation rates are expressed by the general law $w^n = kt$ where w is the weight gain, t the time, and k a constant. In making log-log plots of the weight gain *vs.* time from the data obtained in this work to get the value of the exponent, n, we found interestingly enough that every run made at 400°C obeyed at least two different rate laws of oxidation. This is shown very clearly in Fig. 1 for an abraded rectangular specimen. Table Ia summarizes the results for spherical and rectangular abraded specimens including one which was chemically polished. It is noted that the average of the results obtained for the rectangular specimens agrees quite well with that of the spherical specimens. Hence, the results obtained for the rectangular specimens are as valid as those obtained for the spheres. Also, the results for the chemically polished specimen are in good agreement with those of the abraded specimens. This contradicts the data of Gulbransen and Andrew (1) who found that the reaction rate for abraded specimens was 2-3 times as great as for chemically polished specimens in the 400°-500°C temperature region. Porte *et al.* (2) found that mechanically polished specimens reacted somewhat faster than did chemically polished specimens at 400° and 500°C, but that there was no significant difference at 600° and 700°C.

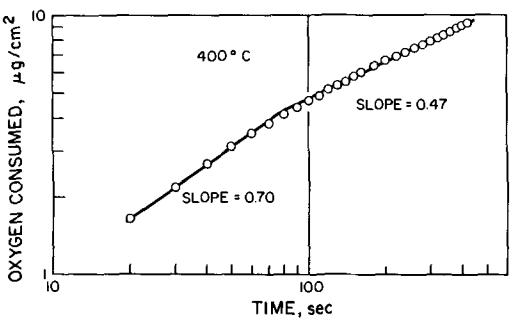

Fig. 1. Log-log plot of oxygen consumed *vs.* time at 400°C for a rectangular specimen.

Comparing the results of this work on the rate at which zirconium consumes oxygen with the results obtained by Pemsler (3) on the dissolution rate of anodically deposited ZrO_2 films we find that at 400°C the latter process is so much slower than the former that virtually all the oxygen consumed by zirconium can be considered to have gone into the formation of the ZrO_2 film. Hence, the critical film thickness at which the reaction rate becomes parabolic can be readily calculated. Using the conversion factor of 66.4Å/$\mu g/cm^2$ [2] this film thickness turns out to be about 307Å. One notes from Fig. 1 that the reaction rate changes gradually instead of sharply in the vicinity of the critical thickness. This behavior is true also for all the other runs and implies that one rate-controlling process takes over gradually from the other one as the oxide film gets thicker.

Of the runs made at 400°C only one had attained a sufficiently thick oxide film so that still another rate law could be observed. A plot of this run is shown in Fig. 2. We note that for a film thickness greater than about 730Å a new rate law prevails

[2] Obtained from an assumed density of 5.8 g/cm^3 for hafnium-free ZrO_2.

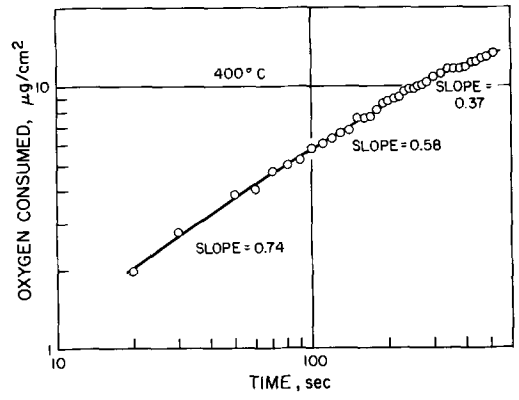

Fig. 2. Log-log plot of oxygen consumed vs. time at 400°C for a spherical specimen.

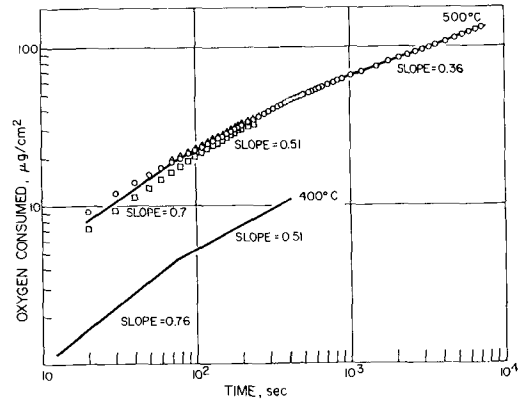

Fig. 3. Log-log plot of oxygen consumed vs. time at 400° and 500°C. Plot at 400°C represents composite of all runs made at that temperature up to 11 μg/cm² (see text).

which is nearly cubic, n having a value of 2.7. The scatter is greater here than in Fig. 1 because these data were obtained for a spherical specimen which has an unfavorable area-to-weight ratio, as pointed out above.

The results for the runs made at 500°C are summarized in Table Ib. A log-log plot of these runs is given in Fig. 3. This figure also shows a plot of the average of the results obtained from runs made at 400°C to a maximum oxide film thickness of 730Å. The change of slope occurring at 730Å as shown in Fig. 2 was not incorporated in this plot. The reason is that it occurs somewhat sooner in the one run shown than the average of all ten runs indicates (compare Fig. 2 and 3).

We note from Table Ib and from Fig. 3 that at 500°C the oxidation rate laws correspond to those observed at 400°C. The parabolic rate law starts when approximately 19 μg of oxygen have been consumed by 1 cm² of zirconium. This rate law continues until a weight gain of 51 μg/cm² has been attained after which the rate law becomes nearly cubic, n having a value of 2.81. From Pemsler's work (3) it is clear that in calculating the oxide thickness at 500°C correction must be made for the dissolution of the oxide film into the zirconium while the zirconium is being oxidized. Calculations then show that the parabolic rate law exists for an oxide thickness ranging very roughly from 1200Å to about 3300Å.

The rate law governing the initial oxidation of zirconium at 500°C is not nearly as well established as that at 400°C. We can only conclude that it is intermediate to linear and parabolic.

The reaction rate constants, k, for the parabolic portions of the 500° and 400°C curves were found to be 4.46 (μg/cm²)$^{1.86}$/sec and 0.261 (μg/cm²)$^{1.96}$/sec, respectively. Using these values the activation energy, ΔE, is determined from the equation $k = Ae^{-\Delta E/RT}$ where A is the frequency factor. ΔE turns out to be 29.3 kcal/mole, which is quite close to the value 28.6 kcal/mole obtained by Gulbransen and Andrew (1) who obtained a parabolic relationship for the temperature range of 525°-750°C using abraded rectangular specimens.

For the "cubic" region the reaction rate constants are 122.4 (μg/cm²)$^{2.8}$/sec and 2.16 (μg/cm²)$^{2.7}$/sec for 500° and 400°C, respectively. From these a ΔE value of 42 kcal/mole is obtained which is in agreement with the value of 42.7 kcal/mole found by Porte *et al.* (2) on the basis of a cubic relationship over the temperature range 400°-900°C. It must be pointed out that the data of this work in or near the "cubic" region show poorer agreement with those of Porte than might be assumed from the good agreement of the ΔE's. For example, at 500°C Porte shows weight gains of about 80 and 170 μg/cm² in 10 and 100 min, respectively. This is to be compared with weight gains of 55 and 123 μg/cm² found in this work for the same time intervals. At 400°C Porte shows a weight gain of about 28 μg/cm² after 5 min. For the corresponding time interval we obtain a value of 9.3 μg/cm² for the composite of all runs, or 11 μg/cm² for the single run (Fig. 2) for which a "cubic" rate law is observed.

Discussion

Whether the oxidation of zirconium obeys a parabolic or cubic rate law in the 400°-500°C temperature range has been disputed by various investigators (1, 2, 4-6). Gulbransen and Andrew (1) found furthermore that rectangular specimens such as used in this study obeyed the parabolic rate law when chemically polished and the cubic rate law when mechanically polished. The present study, on the other hand, finds that zirconium, regardless of the shape of the specimen or the manner of surface preparation, whether chemically polished or abraded, obeys both a parabolic and nearly cubic rate law depending on the thickness of the oxide coating. In fact, for about the first minute or so a nearly linear rate law seems to hold. It must be realized, of course, that the present investigation examines the initial oxidation critically, whereas other workers studied the oxidation rate over much longer times.

The formation of oxide films having a maximum thickness of several hundred Angstroms has been the subject of a theory by Mott (7) and Cabrera and Mott (8). The basis of their theory is that a contact potential difference exists between the chemisorbed oxygen and the metal resulting in the existence of an electric field across the oxide film. The cations move through this film under the influence of the electric field without much help from the temperature. For films of 50-100Å thickness Cabrera and Mott obtain a logarithmic law. In the case of an n-

type semiconductor Cabrera and Mott (8) obtain a parabolic law for films several hundred Angstroms thick. It turns out that ZrO_2 is an n-type semiconductor according to the work of Mallett and Albrecht (9) and should therefore obey the parabolic law.

Even at 400°C the rate of oxidation is sufficiently rapid that we cannot tell whether the logarithmic law is obeyed for a thickness of from 50-100Å. However, it is evident that the parabolic law is not obeyed until a thickness of about 300Å is attained. Hence, the theoretical results obtained by Cabrera and Mott (8) for thin films are not in agreement with the results obtained in this work.

The oxidation mechanism for film thicknesses greater than thin films but less than thick films (ca. 10,000Å) is imperfectly understood (8). For this intermediate range Wagner (10) states that an oxidation rate can be arrived at which is nearly logarithmic. Uhlig (11) finds that under certain circumstances a cubic equation can be obtained for oxide thicknesses up to several thousand Ångstroms. He bases his derivation on the consideration that the controlling step in the oxidation process is the electron flow from the metal. Still we find that in this work the rate law in the intermediate region is primarily parabolic.

The oxidation rate for thick films is found by Wagner (12) and Cabrera and Mott (8) to obey the parabolic law. However, Porte *et al.* (2) show that the oxidation of zirconium for thick oxide films follows the cubic law. The present work also shows that a nearly cubic rate law is obeyed for an oxide film about 8300Å thick (corrected for dissolution of the oxide film into zirconium). Until now there has been no satisfactory explanation as to why such thick films should obey a cubic oxidation rate law for n-type semiconductors. Kofstad and Hauffe (13) find that a cubic rate law exists also for the oxidation of titanium (TiO_2 also being an n-type semiconductor). They suggest that a cubic rate law could be the result of two factors, namely, the high solubility of oxygen in titanium and the dependence of the value of the diffusion "constant" on the oxygen concentration in titanium. The latter assumption is based on the work by Wasilewski and Kehl (14) who found indications that the value of the diffusion constant is concentration dependent. Since zirconium also has a high oxygen solubility (15), Kofstad and Hauffe assume that the cubic oxidation of zirconium can be explained in a similar manner.

Porte *et al.* (2) in attempting to follow Kofstad and Hauffe's explanation for the existence of a cubic rate law point out only the importance of the diffusion of oxygen through the layer of oxygen-enriched metal (having a high oxygen solubility). However, they fail to mention Kofstad and Hauffe's important hypothesis that, in addition, a concentration-dependent diffusion constant is necessary to arrive at a cubic rate law. The following analysis will show that high solubility of oxygen in metal is not a sufficient condition to account for a cubic rate law when the value of the diffusion constant is concentration-independent.

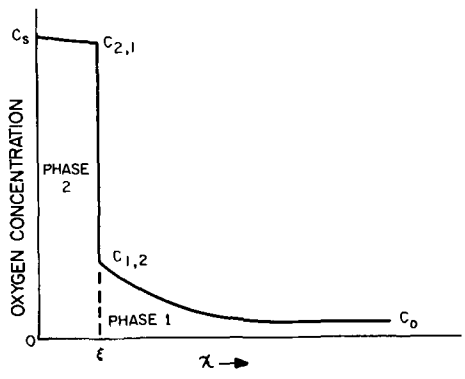

Fig. 4. Oxygen concentration as function of distance from the ZrO_2-oxygen interface ($x = 0$) as zirconium is reacting with oxygen (after Wagner).

Mallett and Albrecht (9) find that the oxidation of zirconium occurs by anion diffusion across the oxide layer to the zirconium-oxide interface to produce more ZrO_2. Hence, the problem falls under the general category of diffusion of oxygen into a homogeneous phase (oxygen dissolved in zirconium), a second phase (ZrO_2) developing from the surface.

Figure 4 is a plot of the oxygen concentration *vs.* distance from the oxide-oxygen interface at any time $t > 0$. C_s is the concentration of oxygen at the ZrO_2 surface. $C_{2,1}$ is the minimum oxygen concentration which can exist in the ZrO_2 phase. The difference between C_s and $C_{2,1}$ results from the presence of anion vacancies at $C_{2,1}$. $C_{1,2}$ is the maximum concentration of oxygen in zirconium metal at a given temperature. C_o is the initial concentration of oxygen in zirconium. The plane of discontinuity, ξ, is occasioned by the fact that a two-phase region separates phases 1 and 2.

For a concentration-independent diffusion constant, D, the diffusion processes are governed by Fick's second law.

$$\frac{\partial c}{\partial t} = D_1 \frac{\partial^2 c}{\partial x^2} \text{ for } \xi < x \qquad [1]$$

$$\frac{\partial c}{\partial t} = D_2 \frac{\partial^2 c}{\partial x^2} \text{ for } 0 < x < \xi \qquad [2]$$

The initial and boundary conditions are

$$c(x > 0, 0) = C_o \qquad c(0, t > 0) = C_s$$
$$c(\xi + \epsilon, t) = C_{1,2} \qquad c(\xi - \epsilon, t) = C_{2,1} \qquad [3]$$

Using these conditions one can follow Wagner's analysis as outlined by Jost (16) and obtain the following result

$$C_{2,1} - C_{1,2} = \frac{(C_s - C_{2,1}) \exp(-\gamma^2)}{\gamma\sqrt{\pi}\,\mathrm{erf}(\gamma)} - \frac{(C_{1,2} - C_o) \exp(-\phi\gamma^2)}{\gamma\sqrt{\pi\phi}\,[1 - \mathrm{erf}(\gamma\sqrt{\phi})]} \qquad [4]$$

where

$$\phi = \frac{D_2}{D_1} \quad \text{and} \quad \gamma = \frac{\xi}{2\sqrt{D_2 t}}$$

This result differs from that given in Jost's book only in the value of the exponent of the second term on the right side, the difference probably being due

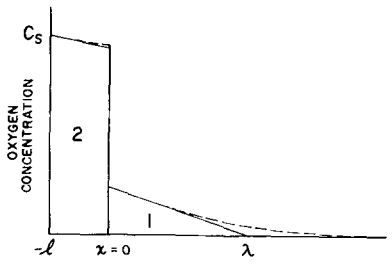

Fig. 5. Diffusion in two-phase system using "quasi-stationary state" approach. See text for explanation.

to a typographical error. Since it is not immediately obvious from Eq. [4] which rate law is being followed for a concentration-independent diffusion constant we shall try a different approach.

The diffusion processes resulting from the oxidation of zirconium can, to a good approximation, be considered to be in the "quasi-stationary state," and hence Eq. [1] and [2] can be set ≈ 0. For greater mathematical simplicity in this treatment the metal-oxide interface is considered to be the stationary boundary at $x = 0$ with the oxide-oxygen interface moving in the negative direction, and the initial oxygen concentration, C_o, in the metal taken to be zero. C_s is, as before, the concentration of oxygen at the ZrO_2 surface. Figure 5 shows the essentials. The dashed curves result from the exact solutions of Eq. [1] and [2] while the solid lines represent the solutions resulting from setting [1] and [2] equal to zero. The error involved by setting [1] and [2] equal to zero is given by the difference in the areas below the respective curves, the area below the straight line being about 90% of that below the error function curve in the case of phase 1.

Using this method we then have for

Phase 1:

$$\frac{\partial^2 c_1}{\partial x^2} \approx 0 \qquad [5]$$

Phase 2:

$$\frac{\partial^2 c_2}{\partial x^2} \approx 0 \qquad [6]$$

With solutions

$$c_1 = A_1 + B_1 x \qquad [7]$$

$$c_2 = A_2 + B_2 x \qquad [8]$$

and boundary conditions

$$c_1(\lambda) = 0 \qquad [9]$$

$$c_2(-l) = C_s \qquad [10]$$

The total amount of oxygen in phase 1 has come there by diffusion across the plane $x = 0$ during the time t. Hence, we have per unit cross section

$$\int_o^\lambda c_1 dx = \int_o^t J_1 dt = -\int_o^t D_1 B_1 dt \qquad [11]$$

where $J_1 = -D_1 B_1$ is the flux of oxygen across the interface $x = 0$, and D_1 the diffusion constant for phase 1. Similarly,

$$\int_{-l}^o c_2 dx = \int_o^t D_1 B_1 dt - \int_o^t D_2 B_2 dt \qquad [12]$$

First, we shall find a solution for λ. Using [7] and [9] we get

$$B_1 = -\frac{A_1}{\lambda} \qquad [13]$$

and

$$c_1 = A_1\left(1 - \frac{x}{\lambda}\right) \qquad [14]$$

Hence,

$$\int_o^\lambda c_1 dx = \int_o^\lambda A_1\left(1 - \frac{x}{\lambda}\right) dx = \frac{A_1\lambda}{2} \qquad [15]$$

From [11], [13], and [15] we also get

$$\int_o^t D_1 \frac{A_1}{\lambda} dt = \frac{A_1\lambda}{2} \qquad [16]$$

Differentiating [16] wih respect to t we get

$$\frac{D_1}{\lambda} = \frac{1}{2}\frac{d\lambda}{dt}$$

resulting in

$$\lambda = 2\sqrt{D_1 t} \qquad [17]$$

Next, we shall find a solution for l. From [8] and [10] we obtain

$$\int_{-l}^o c_2\, dx = \int_{-l}^o \left[A_2 + \left(\frac{A_2 - C_s}{l}\right)x\right] dx$$

$$= \frac{l}{2}(A_2 + C_s) \qquad [18]$$

Using [18] and [12] and differentiating with respect to t there results

$$\frac{A_2 + C_s}{2} \cdot \frac{dl}{dt} = D_1 B_1 - D_2 B_2$$

Using [8], [10], [13], and [17] we get

$$\frac{A_2 + C_s}{2} \cdot \frac{dl}{dt} = \frac{(C_s - A_2)D_2}{l} - \frac{A_1 D_1}{2\sqrt{D_1 t}}$$

Rearranging,

$$\frac{dl}{dt} - \frac{2(C_s - A_2)D_2}{(C_s + A_2)l} = -\frac{A_1\sqrt{D_1}}{(C_s + A_2)\sqrt{t}} \qquad [19]$$

Letting $l = \alpha\sqrt{t}$ we get

$$\frac{\alpha}{2\sqrt{t}} - \frac{2(C_s - A_2)D_2}{(C_s + A_2)\alpha\sqrt{t}} = -\frac{A_1\sqrt{D_1}}{(C_s + A_2)\sqrt{t}}$$

and

$$\alpha = -\frac{A_1\sqrt{D_1}}{C_s + A_2} + \sqrt{\left(\frac{A_1}{C_s + A_2}\right)^2 D_1 + \frac{4(C_s - A_2)D_2}{C_s + A_2}} \qquad [20]$$

From [20] it is noted that α is not a function of the time t. Therefore, since $l = \alpha\sqrt{t}$ we conclude that for a concentration-independent diffusion constant the parabolic law is observed for the growth of the oxide film as well as for the diffusion of oxygen into the metal and that this result is independent of the extent of oxygen solubility in the metal.

Acknowledgment

The assistance of Mr. Joseph Morreale in the laboratory and suggestions by Dr. Guy Ervin, Jr., who examined the manuscript in its final form are gratefully acknowledged. The author is particularly grateful to Dr. H. Reiss for the solution of the diffusion equations using the quasi-stationary approach. Work on this paper was performed under the auspices of the U. S. Atomic Energy Commission contract AT(11-1)-GEN-8.

Manuscript received May 12, 1961; revised manuscript received Jan. 9, 1962.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

Effect of Surface Roughness on the Oxidation Rate of Iron

A. G. Eubanks and D. G. Moore

National Bureau of Standards, Washington, D. C.

and W. A. Pennington

Department of Metallurgy, University of Maryland, College Park, Maryland

ABSTRACT

An investigation was made of the effect of surface roughness on the oxidation rate of iron in air at 800°C. Specimens of ingot iron were grit blasted to give surfaces of different textures. The roughened specimens were found to oxidize more slowly than as-rolled ones, the difference in rate becoming greater with increasing roughness. The as-rolled specimens oxidized parabolically with a certain rate constant at the beginning; however, with continued oxidation, roughness developed on the metal surface, and a change in the rate constant occurred. Specimens of high-purity iron with smooth surfaces, on the other hand, not only remained smooth throughout a 3-hr oxidation period, but they also oxidized parabolically with a single rate constant. It was found that the reduction in rate due to roughening was not caused by surface contamination or by surface cold work, but by voids that form in the scale layers on roughened surfaces. These voids apparently act as diffusion barriers for iron ions and, thereby, lower the rate at which roughened specimens oxidize.

In practically all studies of the oxidation of metals, the area of the specimen is computed from its macroscopic dimensions. For specimens that are optically flat and which remain flat throughout the oxidation, this procedure is acceptable. However, such surfaces are exceptions, and in most cases a certain amount of surface roughness is either present initially or develops as the oxidation progresses. The presence of this roughness increases surface area which, in turn, might be expected to increase the over-all oxidation rate of the specimen.

Several investigations have indicated, however, that when iron is oxidized the expected increase in rate with increased roughness does not always occur. Moore, Pitts, and Harrison (1), for example, found that grit blasting of both ingot iron and a titanium-bearing, low-carbon steel reduced the amount of oxidation occurring in air after 2 min at 840°C by a factor of about four. Bénard (2) observed that, although electrolytically polished iron, when heated in air at 850°C for various times, oxidized at a slightly lower rate than iron abraded with various grades of emery paper, the difference was less than would be expected from the differences in surface area. Winterbottom (3) found that iron surfaces polished with alumina had slower oxidation rates than bright annealed surfaces.

In the investigations cited, the observation that the oxidation rate of iron was reduced in certain cases by roughening was incidental to the main purpose of the study, and the effect was not investigated systematically. In the present investigation, a more

complete study of the roughness effect was undertaken. The goals were twofold: i, to determine by controlled oxidation tests in air at a single temperature (800°C) if the oxidation rate of iron specimens could, in fact, be reduced by roughening of the surface, and ii, if such a reduction was observed, to arrive at the most probable explanation for the reduction. The 800°C temperature was used because the study was a phase of an investigation concerned with ceramic-metal systems in which this particular temperature was of primary interest.

Materials and Test Equipment

Ingot iron in the form of sheet 0.7 mm thick was used for most of the experiments. The nominal composition of this material is C < 0.02, Mn < 0.02, P-0.005, S-0.02, and Si-trace.

Very high-purity iron was also used in a few of the experiments. This material, which was furnished by Dr. G. A. Moore of the Thermal Metallurgy Group of the National Bureau of Standards, was in the form of sheet 0.5 mm thick. It was prepared initially by J. G. Thompson and H. E. Cleaves (4) who were then of the Bureau staff. A chemical analysis made at the time of preparation showed it to be 99.990% Fe. Copper, silicon, sulfur, and oxygen were present as trace impurities.

The specimens were roughened by grit blasting their surfaces under closely controlled conditions. Different degrees of roughness were obtained by using different types of grit. The grits used are listed in Table I.

Oxidation tests were made in a wire-wound tube furnace that rested on a pneumatic lift. Three independent heating coils connected to separate variable transformers were used to heat the furnace. Each coil was adjusted so that the metal specimen would be heated as uniformly as possible. The temperature in the hot zone was measured with a Pt, Pt-10% Rh thermocouple that had been calibrated by the Temperature Physics Section of the National Bureau of Standards. At 800°C the temperature variation over the specimen was not more than 3°C.

The specimen to be oxidized was suspended in the furnace by a platinum wire attached to the beam of an automatic recording balance (5) mounted above the furnace. The balance is designed to sense any weight change that occurs and to record the change on a strip chart. The balance was found to be accurate to within 0.5% of the weight change indicated at any given instant.

Tests were begun by stabilizing the furnace at the desired temperature and then quickly raising the furnace around the specimen. Temperature measurements made with a small-wire thermocouple attached to a specimen showed that the specimen reached furnace temperature in approximately 2 min. At the end of a test the furnace was lowered, and the specimen was allowed to cool in air.

Table I. Grits used for roughening specimens

Grit No.	Grit Type	Particle size, μ
1	Silicon[a]	177-840
2	Silicon Carbide[a]	177-420
3	Fused Alumina[a]	177-420
4	Ottawa sand[b]	297-840
5	Ingot iron[c]	250-840

[a] Commercial grade.
[b] Well-rounded grains of quartz.
[c] Formed into tiny cubes from the same sheet stock as that used for the oxidation specimens by a semi-automatic shearing operation.

All experiments were performed in air at atmospheric pressure. The water vapor content of the air during the testing period varied over the range 0.0072-0.0093 g/g of dry air. The order in which the specimens were tested was selected so as to minimize any effect that the variation in water vapor content might have on differences in the oxidation rates of specimens having surfaces of different roughness. Air flow was controlled by natural convection through small vents at the top and bottom of the furnace. The measured flow rate was 3.6 liters/min. Based on this flow rate, the oxygen partial pressure in the furnace cavity during the first few minutes of testing, for specimens with the highest oxidation rate, was computed to be 155 mm Hg.

Experiments with Grit-blasted Ingot Iron

Ingot iron specimens, 25 by 75 mm in size, were cleaned in acetone, annealed in dry hydrogen for 2 hr at 950°C, and finally vacuum annealed for 1 hr at 730°C at a pressure of 2×10^{-5} mm Hg. The specimens were then divided into six groups of five specimens each. The specimens in groups one through five were roughened, in turn, by the five grits listed in Table I. After each blasting treatment, the specimens were cleaned ultrasonically in acetone to remove loosely adhering particles. The specimens in all six groups were then re-annealed in hydrogen and in vacuum in the manner just described.

Measurements of surface area were made on two specimens of each group. This was done by first shearing each of the two specimens into smaller pieces; three randomly selected pieces from each specimen were then plated with nickel by an electroless process (6) to preserve the surface contour, and mounted and polished. The "surface area index" and "true surface area" were determined from these polished sections by the procedure outlined in the Appendix. Figure 1 shows some of these surfaces.

Weight gain measurements were made on the remaining specimens of each group. The results of these measurements are shown in Fig. 2 in which the square of the weight gain per unit area is plotted against time. Each curve represents the average for three specimens. The data for the three were in good agreement in all cases; the maximum deviation observed was 3.4%.

Data plotted in Fig. 2 were computed on the basis of the true surface areas obtained by multiplying the macroscopic area of each specimen by the appropriate surface area index (see Appendix). It will be noted that in every case roughening reduced the oxidation rate. The treatment with silicon gave the greatest reduction, the weight gain after 90 min being lower than that of unroughened specimens by

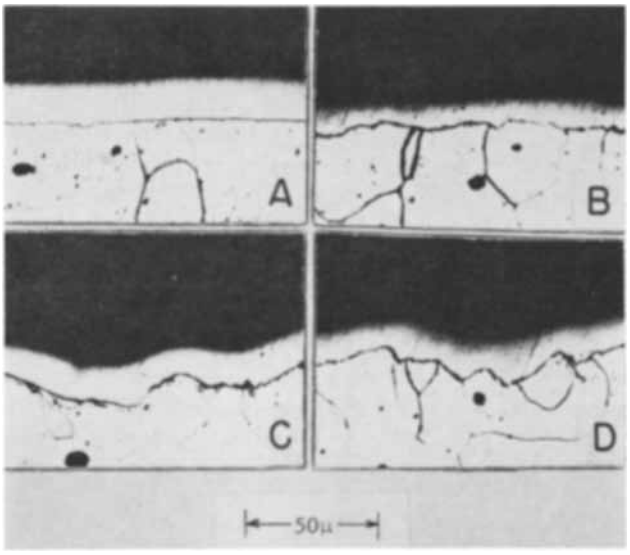

Fig. 1. Surface contours of specimens before oxidation; (A) as-rolled, (B) blasted with ingot iron grit, (C) blasted with silicon carbide and (D) blasted with fused alumina. White area above iron surface is nickel plate applied to preserve surface contour during polishing (2% nital etch).

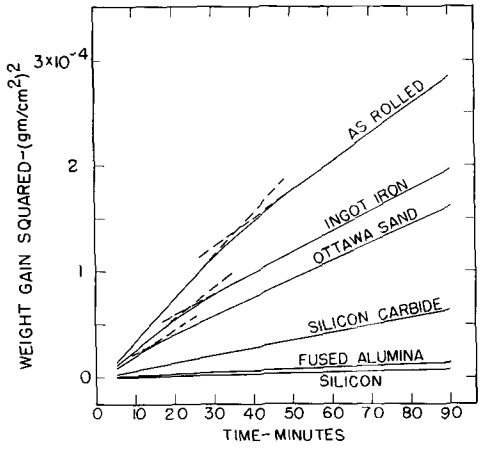

Fig. 2. Oxidation behavior at 800°C in air of ingot-iron specimens that had been grit blasted and then annealed. Weight gains are based on "true surface areas."

a factor of 6.2. The least reduction occurred when the specimens were roughened with ingot iron grit, the weight gain in this case being lower than that of the unroughened specimens by a factor of 1.2.[1]

In general the oxidation followed the parabolic rate law

$$w^2 = kt$$

where w is the weight gain per unit area, t the time, and k the rate constant.

The parabolic oxidation is indicated by the trend toward straight-line plots in Fig. 2. In the case of the specimens roughened with silicon carbide, fused alumina, and silicon, the plots are linear after the first few minutes. The curves for the as-rolled[2] specimens and for those roughened with Ottawa sand and ingot iron are more complex in that they consist of two linear portions rather than one.

[1] When these weight gains were computed on the basis of macroscopic area rather than true surface area the values differed by factors of 4.6 and 1.1, respectively.

[2] As-rolled refers to the surface that resulted from the final rolling operation in the steel mill.

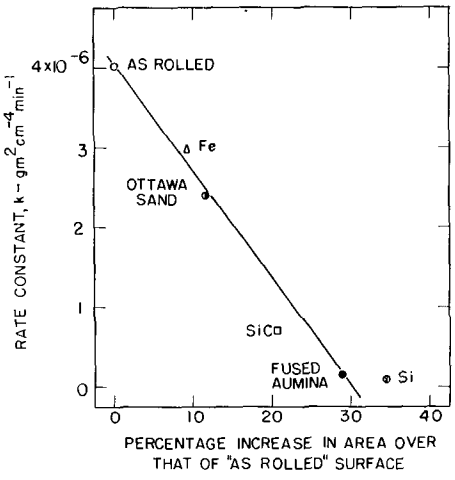

Fig. 3. Change in rate constant, k, with increase in computed surface area. Label for each point shows grit used for producing increased area of surface.

The rate constant, k, was obtained for each group of specimens by measuring the slopes of the straight lines in Fig. 2. For specimens that gave two different slopes, the rate constant assigned was that computed from the slope of the initial portion of the curve.

Figure 3 shows these rate constants plotted against the percentage increase in surface area produced by the various treatments. The points fall approximately on a straight line. This suggests that there is a direct relation between roughness, as measured by surface area, and the early stage oxidation rate. It also suggests that the reduction in rate is independent of the type of grit used for roughening.

That grit contamination was not a controlling factor in reducing the rate is shown by the results with ingot iron grit. In this particular case, the grit was made from the same material as the specimen; hence, it could not contaminate the specimen surface. Yet the point for the specimens roughened with ingot iron is below that for the as-rolled specimens.

Because the surface of the metal was cold worked during grit blasting, it was in a strained condition after the roughening treatments. If this strain were not relieved, it could conceivably affect the oxidation rate. However, since the temperature range in which iron recrystallizes is 200°-300°C the annealing treatments (2 hr in hydrogen at 950°C followed by 1 hr in vacuum at 730°C) that each specimen received after it was grit blasted very likely relieved any strain that was present. Even had the specimens not been annealed following the roughening procedure, the 800°C oxidation temperature is probably high enough to relieve the induced strain before it has any appreciable effect on the oxidation rate. In order to make certain that such was the case, however, the following experiment was carried out. Specimens were roughened by blasting with ingot-iron grit and oxidized without further treatment. These specimens were found to gain weight at the same rate as those that had been annealed after the grit-blasting. Such a result shows that any residual strain caused by cold working of the surface during the blasting had no influence on the oxidation behavior at 800°C. The same ex-

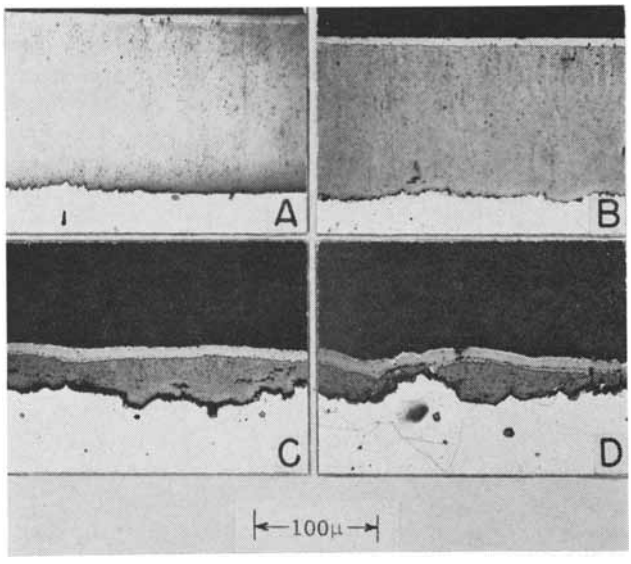

Fig. 4. Oxide layers formed on ingot iron after oxidation for 90 min in air at 800°C. Dark gray layer is wüstite (iron deficient FeO); lighter gray layer above it is magnetite (Fe_3O_4), while thin white layer at outer surface (visible in C and D only) is hematite (α-Fe_2O_3). Surface preparation was (A) as-rolled, (B) grit blasted with ingot iron, (C) grit blasted with alumina and (D) grit blasted with silicon. (2% nital etch).

periment also shows that any oxide that might have formed on the specimen surface during the blasting process had no effect on the subsequent oxidation rate.

Metallographic sections were prepared from many of the specimens after oxidation. The micrographs in Fig. 4 show the oxide scale and the interface between the oxide and the metal for four of these specimens. At temperatures above about 570°C the oxide scale on iron consists of three layers (7); the innermost layer is wüstite (iron deficient FeO), the center layer is magnetite (Fe_3O_4) and the outer layer is hematite (α-Fe_2O_3). The wüstite and magnetite layers are visible in Fig. 4; however, the outermost hematite layer is not clearly defined except in Fig. 4C and D.

Examinations of the sections showed that the over-all scale thickness decreased with increasing surface roughness. The examinations also showed that the relative thicknesses of the magnetite and hematite layers increased with increasing roughness while that of the wüstite layer decreased and that the relative thicknesses of the layers did not depend on the total scale thickness. The results of measurements of the relative thicknesses of the layers are listed in Table II.

Table II. Change of relative oxide layer thickness with increasing surface roughness after oxidation for 90 min in air at 800°C

Blasting medium	Surface area index	Rate constant, k[a] $gm^2\ cm^{-4}\ min^{-1}$	Relative thickness Wüstite %	Magnetite %	Hematite %
None	1.048	4.02×10^{-6}	95.5	3.5	1.0
Ingot iron	1.144	2.96	94.5	4.5	1.0
Ottawa sand	1.170	2.39	94.0	5.0	1.0
Silicon carbide	1.264	0.70	92.0	6.5	1.5
Fused alumina	1.350	0.15	65.0	32.0	3.0
Silicon	1.408	0.09	61.5	34.5	4.0

[a] Determined from the initial linear portion of the weight-gain squared curves for the as-rolled specimens and for the specimens roughened with ingot iron grit and Ottawa sand.

Another finding of interest was that the surface of the as-rolled specimens, and, to a lesser extent, the surfaces of specimens roughened with ingot-iron grit and Ottawa sand became rougher as oxidation proceeded. Also, voids began to appear in the wüstite layer quite close to the iron surface. Both the roughening effect and the void formation have previously been observed by Païdassi (8) on ingot iron that was electrolytically polished prior to oxidation. Micrographs of the oxide-metal interface of as-rolled specimens after various periods of oxidation are shown in Fig. 5. After 15 min of oxidation the surface was still relatively smooth. After 45 min the surface had become rougher, and voids were visible near the interface. In most instances these voids were not touching the metal. At 60 min the number of voids had increased considerably. From 60 to 90 min, however, the surface, although continuously changing, was found to have about the same degree of roughness, and the number and size of the voids remained fairly constant.

In the case of the specimens roughened with ingot-iron grit and Ottawa sand the oxidation time required to reach a condition of constant roughness was appreciably shorter. The oxide-metal interface of specimens that had been roughened by blasting with Ottawa sand are shown in Fig. 6. Voids are visible at the tips of asperities on the roughened surface after only 5 min at 800°C, and after 20 min numerous voids are visible in the oxide near the interface.

Experiments with Surfaces of Fixed Geometry

The experiments with grit-blasted ingot iron indicated that the geometry of the iron surface had an important influence on the subsequent oxidation rate. However, the grit blasting produced highly irregular interfaces (see Fig. 1), and it was believed that additional information could be obtained about the

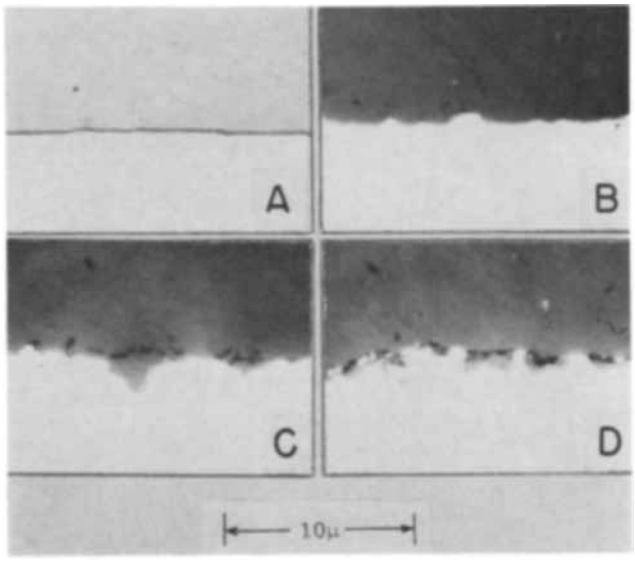

Fig. 5. Oxide-metal interface of as-rolled surface after oxidation at 800°C in air for (A) 0 min, (B) 15 min, (C) 45 min, and (D) 60 min. Gray area above iron surface in (A) is electroless nickel. Unetched.

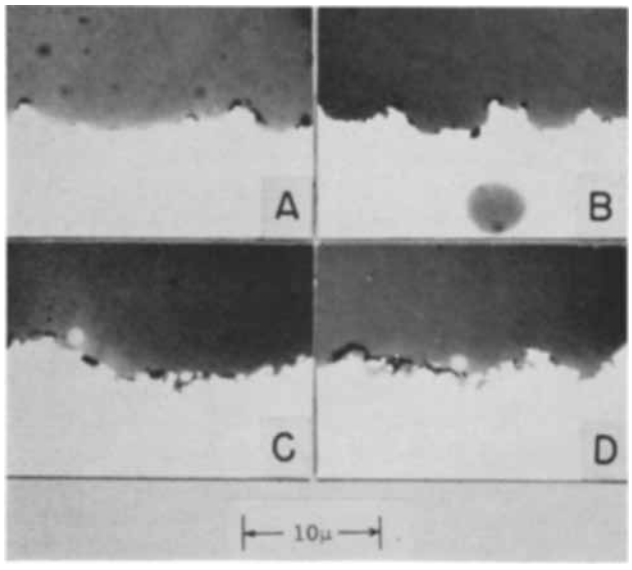

Fig. 6. Oxide-metal interface of surface roughened with Ottawa sand after oxidation in air at 800°C for (A) 5 min, (B) 10 min, (C) 20 min, and (D) 30 min.

oxidation-inhibiting mechanism, if tests were made with specimens that had surfaces of regular contour. Therefore, specimens were prepared by machining very small grooves into their surfaces. Some of the specimens had square grooves 0.004 in. deep and 0.006 in. wide spaced 0.003 in. apart. Others were prepared with V-shaped grooves approximately 0.004 in. deep and 0.008 in. wide. After being machined, the specimens were annealed in hydrogen and vacuum in the manner previously described and oxidized at 800°C in air.

Results of the tests with the grooved specimens are given in Fig. 7. Surface areas were computed from the dimensions of the grooves as determined from measurements made on polished cross sections. As seen in Fig. 7, the grooved specimens gained weight at a slower rate after the first 6-8 min than the as-rolled specimens. Here, as in the case of the specimens that were roughened by blasting, surface contamination is not considered to have played a significant role in the observed retardation of oxidation since the grooves were cut with a tool-steel saw on which no discernible wear was noted after the cutting operation.

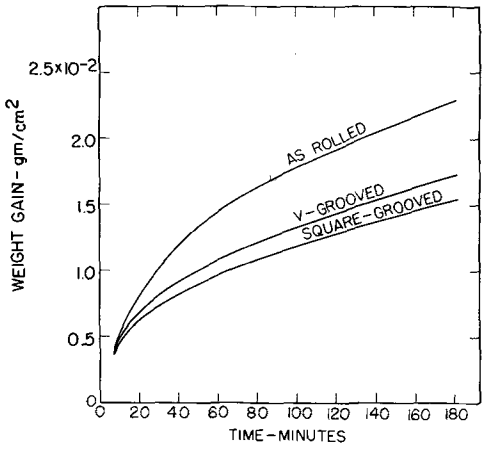

Fig. 7. Oxidation curves in air at 800°C for specimens with fixed surface geometry.

When grooved specimens that had been oxidized for various periods were mounted in cross section and examined microscopically they appeared as shown in Fig. 8. Separations between the oxide and metal were visible at the sharp corners of the square asperities and at the tips of the saw-toothed asperities after about 5 min. of oxidation at 800°C. The small voids which are concentrated above the asperities (some of which are indicated by arrows in Fig. 8) were first visible at high magnification on specimens that had been oxidized for about 15 min.

Experiments with High-purity Iron

In the tests with as-rolled ingot iron specimens, the oxidation rate was relatively high in the early stages. As oxidation progressed, however, the surface became roughened and the oxidation rate was lowered. This behavior suggested that, if the iron had remained smooth throughout the testing period, the specimens would have oxidized parabolically with only one rate constant. In this connection Collongues and Chaudron (9), while studying the high-temperature oxidation of iron in a mixture of hydrogen and water vapor, observed that the surface of ingot iron became rougher during the oxidation process while that of electrolytic iron did not. They attributed the roughening of the ingot iron to uneven oxidation of the surface as a result of localized variations in composition which did not exist in the case of the electrolytic iron.

It was believed that a high-purity iron might also oxidize without detectable roughening of the surface if the oxidation was done in air rather than in a mixture of hydrogen and water vapor. Consequently, specimens of the high-purity iron were cleaned by annealing in hydrogen and vacuum in

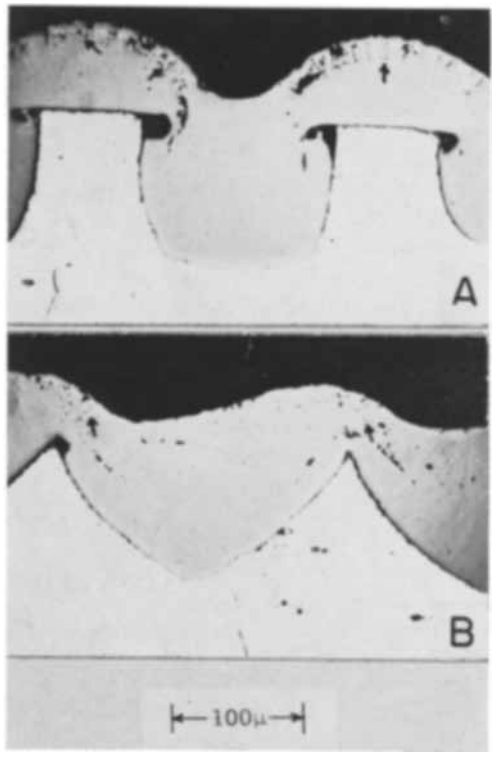

Fig. 8. Square-grooved and V-grooved specimens after oxidation in air at 800°C for 45 min.

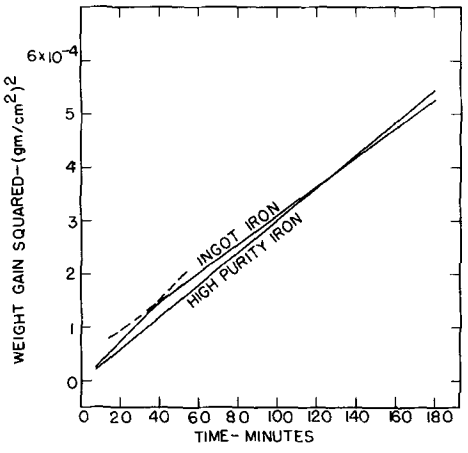

Fig. 9. Comparison of oxidation behavior in air at 800°C of high-purity (99.990 Fe) iron and ingot iron.

the manner previously described and oxidized for various periods at 800°C. The specimens were then mounted and polished for microscopic examination. The examination showed that the surface of the high-purity iron remained smooth even after 3 hr of oxidation and that no voids of any sort formed in the scale layer. Also, the weight-gain data, which is plotted against time in Fig. 9 along with similar data for ingot iron, showed that the high-purity iron oxidized with a single rate constant throughout the entire testing period.

Discussion of the Mechanism

The experiments described above show quite conclusively that the oxidation rate at 800°C in air of ingot-iron specimens with roughened surfaces was lower than that of specimens with smooth surfaces. That this reduction was not caused by surface contamination is indicated by the observation that the reduction in rate was a function of the roughness of the specimen surface and not of the type of grit that was used for the roughening treatment. Furthermore, the reduction occurred even when ingot-iron grit was used for the roughening operation. Other tests showed that strain in the surface layer caused by cold work had no measurable effect on the oxidation rate. Thus, some other but less obvious mechanism must be responsible.

In arriving at this mechanism, the decrease in the relative thickness of the wüstite layer which was observed on the grit-roughened specimens (see Table II) is considered to be especially significant. According to Païdassi (10) the oxide scale formed on iron in air at 800°C consists of approximately 95% wüstite, 4% magnetite, and 1% hematite. The relative thicknesses of the oxide layers on the as-rolled surface, as seen in Figure 4, and as listed in Table II, are in good agreement with these values. However, the relative amount of wüstite decreases markedly with increasing roughness.

It is of interest to consider how this change in the relative thicknesses of the layers could occur. Davies, Simnad, and Birchenall (11, 12) studied the mechanisms of growth of the three oxide layers and found that the growth of wüstite occurs nearly exclusively as a result of the outward diffusion of iron ions and that magnetite grows primarily, but not completely, by this same mechanism. The growth of hematite, however, was found to occur almost solely as a result of the inward diffusion of oxygen These investigators also concluded that above ; bout 620°C the rate of growth of the over-all layer s controlled by the growth of the wüstite. Taken to; ether, these results imply that the rate-controllin; process in the oxidation of iron at 800°C is the r :e at which iron ions diffuse through the wüstite la er. Thus, if this diffusion could be retarded in som- way, such as by creating separations between the iron and wüstite or by placing diffusion barriers of some sort in the layer, the growth rate of the over-all scale would be expected to decrease. Moreover, since the growth of the hematite is due almost solely to the inward diffusion of oxygen and the growth of the magnetite at least partially to the same mechanism, a decrease in the outward iron diffusion rate would bring about an increase in the relative amounts of these two outer layers at the expense of the wüstite. Table II shows that such an increase occurred for the roughened specimens.

Microscopic examinations showed that voids were present in the scale over rough iron surfaces, and it is believed that these voids act as barriers which partially block the diffusion of iron ions. The voids probably begin as tiny discontinuities in the iron oxide lattice and at the oxide-metal interface and eventually grow large enough to become visible under the microscope. The voids are found at three different places in the scale layer, and it is quite likely that they form at different times during the oxidation process. The places where the voids are found are (i) between the oxide and the metal at the tips of asperities (see Fig. 6A, 6B, and 8), (ii) in the wüstite layer close to the wüstite-metal interface over regions of the iron surface that are being, or have been, roughened by the oxidation process (see Fig. 5), and (iii) in the wüstite and magnetite layers above an asperity (examples are indicated by arrows in Fig. 8), but much further from the iron surface than (ii). For purposes of the discussion to follow the voids will be designated as type 1, type 2, and type 3.

Type 1 voids.—The voids that separate the iron from the scale layer at the tips of asperities (Fig. 6A, 6B, and 8) are similar to those observed by other investigators (13-15) at the corners of iron sheet specimens, and the explanation given in two of these studies (14, 15) for a corner separation applies in all essentials to one which forms at the tip of an asperity on a rough iron surface. Engell and Wever (15) demonstrated indirectly and MacKenzie and Birchenall (16) showed by actual experiment that wüstite will deform plastically at elevated temperature under a relatively low stress. Juenker, Meussner, and Birchenall (14) and Engell and Wever (15) concluded independently that on a flat surface this plasticity enables the wüstite layer to follow the iron surface as it recedes during oxidation, but that at a corner or an edge the mutual supporting effect of the oxide layers meeting at an angle hinders the flow, and eventually the receding iron breaks away from the oxide. Iron ions cannot dif-

fuse across this break, and as a result oxidation is retarded.

Type 2 voids.—The second type of void, which is observed in the wüstite layer near the ingot-iron surface over areas which have become roughened during the oxidation process, is probably formed by a mechanism somewhat similar to the one just described. The oxidation time which elapses before this type of void begins to form, however, is greater. It is possible that the voids are formed in the following way: At the beginning of the oxidation, the first thin layer of oxide has the same area as the ingot-iron surface. As oxidation proceeds the iron surface becomes roughened, and, as a consequence, its area increases. Since the wüstite layer grows at its upper surface, because outward iron ion diffusion is its growth mechanism, the portion near the oxide-iron interface cannot increase in volume to compensate for the increasing area of the iron surface. Therefore, plastic deformation must occur in such a way as to allow oxide from above to flow into the stressed regions, or, as an alternative, the wüstite must become porous near the iron surface. The ability of the wüstite to deform plastically at first permits it to maintain contact with the metal and still remain compact and continuous. Eventually, however, the plastic flow cannot keep pace and porosity occurs. It is this sort of porosity which is shown in Fig. 5.

Type 3 voids.—The third type of void is that found in both the wüstite and magnetite layers at some distance above asperities on the iron surface. In some cases, voids of this type tended to form radial patterns in the scale layer (Fig. 8) with no break in the pattern at the wüstite-magnetite interface. Similar voids have been observed in the oxidation of wires by Juenker, Meussner, and Birchenall (14), but no explanation was given as to their cause. These authors found that the time required for voids of this type to appear increased with increasing wire diameter. This is in agreement with the findings of the present investigation in which it was observed that in the oxidation of a surface with relatively large rounded protuberances the oxidation period required before the formation of voids began was greater than in the case of surfaces where the asperities were sharp.

Knowing that these three types of voids exist it is possible to explain the oxidation curves for the ingot-iron specimens as plotted in Fig. 2. In the case of specimens with smooth surfaces oxidation would occur parabolically until roughening developed and the type 2 voids began to form. The oxidation rate would then decrease continuously as the iron surface became rougher and more voids were formed until such time as a relatively stable degree of roughness had been reached and the number and size of the voids became constant. At this point a new and lower rate constant would prevail. As seen in Fig. 2 the behavior just described was followed by the as-rolled ingot-iron specimens.

In the case of surfaces that have been roughened prior to oxidation, type 1 voids would form very soon after oxidation began. The number and size of these voids, and consequently their effect on the oxidation rate, would depend to a large degree on the number and shape of the asperities present on the metal surface, the "rougher" the surface, the greater the number of voids. A short time later type 3 voids would also begin to form, contributing to the retardation of iron ion diffusion. The time at which the formation of type 3 voids began and the extent to which their formation occurred would also, as in the case of the type 1 voids, depend on the nature of the roughened surface.

The presence of type 1 voids on a roughened surface reduces the area of intimate contact between the iron surface and the wüstite layer. Since the interfacial area across which ion diffusion can occur is thus lessened, while the volume of oxide into which the diffusion occurs does not change appreciably, the ion flux across the contact areas between oxide and metal will be increased, and the metal surface in these areas will roughen more rapidly. As a consequence, the degree of roughness necessary for the formation of type 2 voids will be attained more quickly, and the time required for the surface to reach a stable roughness condition will be shorter, resulting in a shorter oxidation rate transition period which begins sooner. This type of behavior is seen to occur for the specimens roughened with the ingot-iron grit with the Ottawa sand.

In the case of severely roughened specimens such as those blasted with silicon carbide, fused alumina and silicon, such an abundance of type 1 and type 3 voids form at or near the oxide-metal interface that the area of metal surface which is suitable for the formation of type 2 voids is very small. Type 2 voids thus have a negligible effect on the oxidation rate, and as a consequence no transition region is detectable for these specimens.

Conclusions

The following conclusions appear to be justified from the results of an investigation of the effect of surface roughness on the oxidation behavior of iron specimens in air at 800°C.

1. Specimens that had been grit blasted oxidized at a slower rate than those with smooth surfaces. The reduction in rate was a function of the degree of roughening.

2. Specimens roughened by machining small grooves into their surfaces also oxidized at lower rates than those with smooth surfaces.

3. Experimental evidence indicated that the reduced oxidation rates on rough surfaces were not caused by (*a*) surface contamination during roughening, (*b*) residual strains due to cold work, or (*c*) formation of an oxide film during the blasting process.

4. Ingot iron specimens with smooth or mildly roughened surfaces oxidized parabolically in the early stages. However, with continued oxidation, roughness developed on the metal, and the rate constant began to change. After a transition period, the oxidation again became parabolic, but with a lower rate constant. High-purity iron, however, remained smooth throughout a 3-hr oxidation period. Also it oxidized parabolically with a single rate constant.

5. The relative thickness of the wüstite layer in the oxide scale decreased as the roughness of the iron surface increased. This behavior showed that there was a lowered diffusion rate of iron ions through the wüstite layer that formed on a rough surface.

6. The most likely reason for the lowered iron ion diffusion rate is the blocking of the diffusion path by small voids in the oxide scale that forms over rough surfaces. These voids, which were detected in the oxide layers on all roughened specimens, but not on smooth ones, act as barriers to ion diffusion and thereby lower the rate at which a roughened specimen oxidizes.

APPENDIX

Determination of Surface Area

In making the surface area measurements, randomly selected interfaces of specimens that had been nickel plated, mounted, and polished (see Fig. 1) were projected at a magnification of 4000X on the ground-glass screen of a Bauch and Lomb model ILS metallograph. The contour of each projected interface was then traced on a clear sheet of plastic (see Fig. 10) from which a quantity termed the "surface area index," S_i, was computed.

The length of the contour line BB in Fig. 10 was determined with a map measurer; the straight line distance AA with a rule.

The surface area index was then taken as:

$$S_i = \left(\frac{BB}{AA}\right)^2$$

The average index for each roughening treatment was computed from 20 fields selected at random. With this number of fields it was found that the true mean was within 3% of the calculated mean on the 95% confidence level. The true surface area was obtained by multiplying the macroscopic area of the specimen by this index.

The procedure just described does not give the exact surface area of the specimens for two reasons. First, the highest magnifications obtainable by optical methods probably do not resolve the smallest surface deviations. For example, if useful magnifications of 50,000 or 100,000 diameters were possible, the measured surface areas would undoubtedly be different from those obtained at the magnifications selected for the present measurements.

Second, the method used for calculating the surface area is not mathematically rigorous. The surface contours are highly irregular and because of this irregularity, it is difficult, if not impossible, to apply an exact analysis. The selected method is believed, however, to give the best indication of surface area that is possible from measurements made with a microscope on polished sections.

The Effect of Pressure on the Electroless Deposition Process

J. S. Sallo, J. I. Swenson, and J. M. Carr

Minneapolis-Honeywell Research Center, Hopkins, Minnesota

ABSTRACT

The effect of changes in hydrostatic pressure on the electroless deposition system has been investigated. The results indicate that some of these systems are controlled by a diffusion process while others are controlled by the area of active catalytic surface which is hydrogen free. The effect of hydrostatic pressure is attributed to an effect on the volume of the hydrogen bubbles formed at the active surface.

Since the initial development of the electroless deposition process by Brenner and Riddell in 1946 (1), a large quantity of data has become available on this and related systems. Conflicting data have been reported on acid baths of this type. Brenner (2) reports the rate of deposition to be independent of the hypophosphite ion concentration. Gutzeit (3), utilizing a different type of acid bath, reports the reaction to be first order[1] in hypophosphite ion provided the area of the substrate is small relative

[1] It seems likely that the data really indicate a pseudo-first order reaction. The pH is known to alter the rate of the reaction, and pH was held constant during these kinetic studies.

to the volume of the solution. In addition, Brenner reports that the efficiency of the process (moles nickel reduced/mole hypophosphite consumed) varies with the ratio of the area of the catalytic surface to the volume of the solution. Gutzeit presents data to refute the importance of this factor (4). It appears that, although the two systems are similar in composition, the mechanisms of these reactions may be different.

Brenner has suggested (5) previously that the rate in the acid bath may be controlled by diffusion of hydrogen ion from the catalytic surface. This hypothesis explains the independence of the rate on the concentrations of the primary reactants and the increase in rate which is observed when the substrate is moved during deposition. If this is the case, it seems likely that the rate of hydrogen gas leaving the substrate will control the diffusion (or transport) rate due to the agitation effect. In order to determine which, if any, of these reactions are transport controlled, the reactions were studied under various pressures. The change in pressure may alter the volume of the evolved hydrogen and alter the rate of the transport controlled reaction.

Experimental

The following systems were studied: Bath 1: [Brenner (2)] $NiCl_2 \cdot 6H_2O$, 30 g/l; $NaH_2PO_2 \cdot H_2O$, 10 g/l; sodium acetate, 3 g/l; bath 2: [Gutzeit (3)] $NiSO_4 \cdot 6H_2O$, 17 g/l; $NaH_2PO_2 \cdot H_2O$, 24 g/l; sodium acetate, 41 g/l; acetic acid, 30 g/l.

All electrodes were flash-coated on both sides with nickel from a Watts bath and weighed. Prior to insertion in the bath, the electrode was given a quick dip in 1:1 HCl followed by a water rinse. This was necessary to insure reproducible initiation of nickel reduction. When this procedure was followed, hydrogen evolution always began within 5 sec of the insertion of the sample. The sample was entirely immersed in the solution. Deposition time was 20 min in all cases.

An all-glass system (system A) was used for runs between 740 mm Hg and 1140 mm Hg. Higher pressures could not be attained in this system. It consisted of a one-liter reaction kettle fitted through ground glass joints with a plug for holding the sample, a thermometer well, a water-cooled condenser, and an open end mercury manometer. For runs under pressure all fittings were held by clamps and pressure was introduced through the condenser opening. The system was thermostated at 85° ± 0.2°C in a constant temperature oil bath. Electrodes were 51.5 cm^2 sheets of phosphor bronze.

For some of the reactions, and particularly where higher pressures were desired, a glass pressure bottle was used (system B). The sample, prepared as before, was allowed to stand on the bottom of the cell. In this case, the volume of the solution was 300 cc, and the electrode had an active area of 12.9 $cm.^2$

The sonic unit was a 2000w (average) generator driving a magnetostrictive transducer at 15 kc. The entire apparatus (system A) including the oil bath, was placed in the sonic cell. The cell was filled with water to insure transmittal of the sound waves, and the presence of cavitation inside the reaction vessel was confirmed both with and without applied pressure through the use of a ceramic lead zirconate titanate transducer.

All results reported are the average of several runs.

Results

The results obtained when a series of plates were prepared from fresh baths at various pressures of either nitrogen or hydrogen in system A are shown in Fig. 1. The application of pressure to bath 1 caused a decrease in rate of nickel deposition (Fig. 1A). Experiments with pressure in the case of bath 2 (Fig. 1B) showed an increase in the rate with applied pressure. If the decrease in rate observed in bath 1 is due to diffusion control, the application of a sonic field should destroy the diffusion control. When the pressure experiment on bath 1 is performed in a sonic field, the results are similar to those observed in bath 2; an increase in rate with pressure is observed. The results are shown in Fig. 1C.

A series of runs were made from bath 1 at higher pressures using system B. In this case a plot of Ni

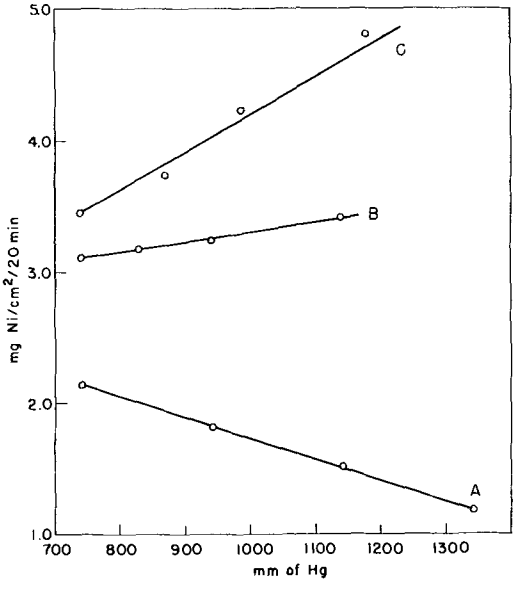

Fig. 1(A). Plot of mg $Ni/cm^2/20$ min vs. pressure for bath 1, system A; (B) Plot of mg $Ni/cm^2/20$ min vs. pressure for bath 2, system A; (C) plot of mg $Ni/cm^2/20$ min vs. pressure for bath 1 in the presence of ultrasonic cavitation, system A.

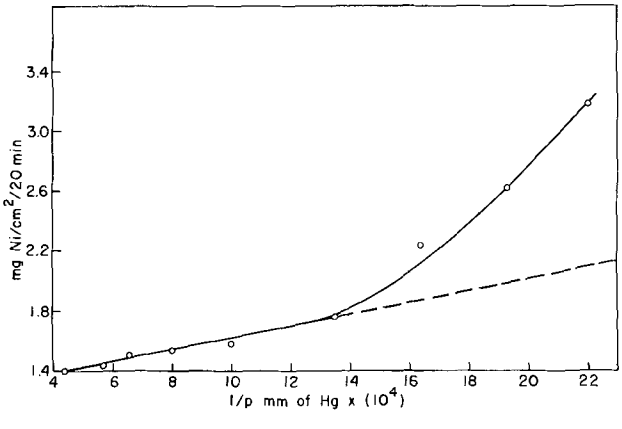

Fig. 2. Plot of mg $Ni/cm^2/20$ min vs. 1/pressure for bath 1, system B.

formed *vs.* pressure does not produce a linear relationship. A plot of Ni formed *vs.* I/P does produce a linear relationship. This is seen in the portion of Fig. 2 between 13.6 x 10^{-4}/mm Hg (atmospheric pressure) and 4.2 x 10^{-4}/*mm* Hg. As a further check, experiments were run in system B at less than atmospheric pressure. As expected, an increase in rate resulted. As is shown in Fig. 2, this increase is greater than is predicted by the I/P relationship (dashed line). This is probably due to an increase in the agitation effect caused by boiling of the solution at the lower pressures.

Discussion

Since nitrogen and hydrogen produce the same effect, it appears that the results are due to a true pressure effect rather than to a chemical effect. If the results were due to a chemical retardation of hydrogen formation, the results would be independent of nitrogen pressure. This limits any interpretation to purely physical effects independent of the chemistry of the process.

No rigorous interpretation of these results has been made; however, an explanation can be offered which fits the available data. This explanation is based on the decrease in the volume of the bubbles of hydrogen gas formed at the catalytic surface. When the system is under hydrostatic pressure, the hydrogen bubbles will be evolved at a lesser volume. Consequently, a less vigorous agitation effect will result. If the rate of nickel deposition is diffusion controlled, and if the diffusion rate is determined by the rate of agitation produced by hydrogen evolution, a decrease in rate is predicted as the result of hydrostatic presure. This is the case in Bath 1.

If this analysis is correct, the rate of deposition in a transport controlled system should vary with the volume of hydrogen evolved rather than with the applied pressure. Consequently the rate of nickel deposition should vary as I/P. Figure 2 shows this to be the case for pressures above atmospheric pressure. In Fig. 1A, due to the upper pressure limit of system A, a short segment of the I/P curve is seen and the apparent linear relationship with P results.

The rate of nickel deposition from bath 2 is increased by the application of hydrostatic pressure. In this case, the rate of nickel deposition must be controlled by factors other than diffusion control. As a check on this point, a series of deposits were prepared on rod substrates which could be rotated. Rotation of the rod served to double the rate of deposition from bath 1. Rotation of the rod caused only a very slight change in the rate of deposition from bath 2. This result further indicates that the rate of deposition from bath 1 is controlled by transport processes while the rate of deposition from bath 2 is controlled by other factors.

Under hydrostatic pressure the same quantity of hydrogen gas at the catalytic surface occupies less volume. Thus, in the case of a nontransport controlled system, the rate of nickel reduction may be increased because a larger area of active (hydrogen gas free) surface is available. If this conclusion is correct, the rate of nickel reduction is dependent on the area of the catalytic surface which is not covered by hydrogen. This result does not conflict with Gutzeit's claim that the rate is first order in hypophosphite since the active area probably remained constant during his work.

In the case of the experiments in the sonic field, the diffusion control in bath 1 is eliminated. It is then expected that the rate of deposition should be the same as that from bath 2 and that the application of pressure should lead to an increase in rate. In fact, the rate of deposition is greater than that observed in bath 2, and the increase of rate with pressure is greater than expected as seen from the slope of the curve in Fig. 1C.

The increase in over-all rate caused by sonics at atmospheric pressure and the increased effect of pressure on the rate in a sonic field are not surprising. Brenner (2) indicates that the rate of electroless deposition from alkaline solutions is not increased by agitation and that the rate is first order in hypophosphite. It therefore can be concluded that this system is not subject to transport control. Rich (6) has reported a large increase in the rate of electroless deposition from the alkaline system when ultrasonics are used. Ultrasonics must cause effects other than the elimination of diffusion control, and the increase in rate at atmopsheric pressure and the augmented effect of pressure in the presence of sonics must at present be attributed to unknown causes. The important conclusion is that ultrasonics reverses the effect of pressure in bath 1, leading to an increase in rate with increased pressure. This result is attributed to the elimination of transport control of the process.

It appears that increased hydrostatic pressure has the effect of decreasing the volume of evolved hydrogen. In the case where the system is transport controlled (bath 1), this results in a decrease in agitation which is proportional to the decrease in volume of evolved gas. The rate dependency on I/P results. In the case where the system is not transport controlled (bath 2 or bath 1 with sonics) the volume of evolved gas has no effect on the rate. In this case the rate is increased by the increase in hydrostatic pressure because the reduced volume of hydrogen gas at the surface leaves a greater area of exposed catalytic surface. In this case, no quantitative relationship between pressure and rate can be deduced from the available data.

The discrepancy over the area to volume ratio cannot be rigorously explained; however, when it is understood that the systems are different, this further difference is not unlikely. It is probable that the main difference between the systems studied in this work is that bath 2 is highly buffered and bath 1 is not. The buffer in bath 1 may be consumed in a local region of high hydrogen ion concentration. Thus, the rate of removal of hydrogen ion from the electrode region becomes rate controlling. In a system with a small area to volume ratio the entire system will not be agitated and a high hydrogen ion concentration will still exist near the electrode. This may explain the lower efficiency observed in this system.

Conclusions

It is concluded that the rate of nickel deposition from the Brenner bath is controlled by a transport

process. The rate of deposition from the Gutzeit bath is not transport controlled; however, the area of hydrogen free catalytic surface is rate controlling. If this area does not vary, other factors control the rate. Other factors also may control the rate if they control the active area. Hydrostatic pressure may control the rate in this way by an effect on the size of hydrogen bubbles or the quantity of gas contained by a bubble.

The Diffusion of Phosphorus in Silicon

I. M. Mackintosh*

Bell Telephone Laboratories, Murray Hill, New Jersey

ABSTRACT

A new process is described for the diffusion of phosphorus into silicon. The diffusions are carried out in a closed system, using as the diffusant source a glass consisting of phosphorus pentoxide and calcium oxide. This glass is shown to satisfy the various criteria which apply to such a source. The process is shown to be highly controlled. Sheet resistance values between 0.3 (±2%) and ~10,000 (±20%) ohms/□ can be obtained, and the junction depths are reproducible to about ±4%. Surface concentrations as low as about 10^{19} cm^{-3} and as high as 10^{21} cm^{-3} can be obtained with good reproducibility. The process is compatible with the oxide masking of layers with surface concentrations as high as 10^{21} cm^{-3}.

The high degree of process control, combined with the relative precision with which the measurable diffusion parameters have been determined, has revealed anomalies in the shape of the diffused impurity distributions. The general characteristics of these anomalous distributions are inferred and various mechanisms through which such effects might arise are discussed.

Data are presented for the effective diffusion coefficient and the effective activation energy for phosphorus in silicon as a function of temperature, surface concentration, and sample resistivity.

This paper describes a new process for the diffusion of phosphorus into silicon. The need for a new process has increased as the various older processes have become less able to meet the demand for ever-increasing reproducibility over wider and wider ranges of diffused distributions.

Various methods have been described for diffusing phosphorus into silicon.[1] One which has been used widely is the open-tube system (1), in which the diffusant molecules are carried from a P_2O_5 source to the silicon through the use of a moving gas. Such open-tube systems, however, suffer from a variety of disadvantages which tend to limit the reproducibility of the process. The principal problems are the necessity for controlling two temperatures, one for the silicon and one for the diffusant source, and the sensitivity of the process to the system geometry and to the rate of carrier gas flow. These problems largely could be avoided, however, by diffusing in a closed system, in which the silicon and diffusant source sit inside a closed box at a uniform temperature. Such a system has been used for boron diffusions (2) and has exhibited good process control. The efforts to improve the phosphorus diffusion situation were, therefore, focused on the development of a closed system, and it is such a process which is described below.

In the development of this process the philosophy of two-stage diffusion has been retained, as first suggested by C. J. Frosch and first described in detail by Howard (1). In the first (prediffusion) stage the silicon is heated in a saturated vapor pressure of the diffusant so that the surface concentration N_o depends only on the effective solid solubility of the impurity in the semiconductor. The junction depth x_j depends on both the temperature and time of prediffusion, but will, in general, be quite shallow. In the second (diffusion) stage the silicon is heated alone in order to redistribute the total number of prediffused impurity atoms $\bar{N}$ to the required final distribution.

The work is presented in the same general order: first, the prediffusion results, and then the diffusion results. The reproducibility of the process and the precision of the results has led to a further insight

into the nature of the diffused profiles, and this is discussed in detail in the last section.

Prediffusion Stage

Diffusant source.—Prediffusions in a closed system impose certain severe restrictions on the diffusant source. The essential properties of such a source can be stated as follows: (i) A source which is chemically complex must be molten over the desired range of prediffusion temperatures so that the diffusant vapor pressure is not affected by depletion effects at the surface of the source; (ii) the diffusant vapor pressure over a wide range of temperatures must be high enough so that the surface concentration is a function only of the solid solubility of the diffusant in silicon and is not limited by the rate of arrival of diffusant molecules at the silicon surface. In addition, the vapor pressure must not be so high as to cause deleterious effects (such as local alloying) on the silicon surface, nor to exhaust the source too rapidly; (iii) the source must evolve nothing which could impair the surface or the bulk properties of the silicon.

A phosphorus source which fulfills all of these requirements is the glass formed between phosphorus pentoxide and calcium oxide. A detailed phase diagram of this glass has been published (3) and a simplified portion of this is shown in Fig. 1. The solid section is composed of the compounds shown in the various proportions k, l, *etc.* It may be seen that the melting point of the glass can be made as low as about 500°C by suitably adjusting the proportions of the CaO and P_2O_5.

Other properties of this glass, plus evidence that the glass fulfills all of the above requirements are presented later. It should be mentioned, however, that none of the calcium phosphates (nor, indeed, any of the phosphorus compounds which have been considered) is suitable as a diffusant source. Their principal disadvantages are either a high melting point (thereby limiting the process to high temperatures) or decomposition at relatively low temperatures.

Manufacture of the glass is extremely simple. In this work the glass has been made by mixing together appropriate weights of P_2O_5 and CaO and firing these at about 900°C in dry nitrogen. The result is a clear, hard glass. The proportions of P_2O_5 and CaO used depend to some extent on the prediffusion temperature to be used, although it is shown later that the process is not sensitive to variations in these proportions.

Prediffusion equipment and procedure.—The prediffusion assembly used in the development of this process was the small platinum box depicted in Fig. 2. The glass was contained in the small tray and the silicon samples were laid on the ceramic-lined bridge. A close-fitting platinum lid is not shown in this figure. This assembly was inserted into the furnace on a quartz rod; the temperatures were monitored throughout every run by means of a standardized thermocouple and were controlled to ±1°C. A gas flow of about 1 liter/min was used throughout.

All the prediffusion runs were for 60 min, this being the time between insertion and withdrawal of the box. The average warm-up time for this system was about 11 min so that the assembly was at the actual prediffusion temperature for about 49 min. Prediffusion temperatures from 650° to 1300°C were used, with most emphasis on the range 700° to 1200°C. The material used was p-type silicon, polished on one side and lapped on the other; the diffusions were through the polished surface. The slices were in the form of ¼ in. x ¼ in. squares, approximately 0.012 in. thick, and four such slices were used in each run. Two resistivities were used; ~0.3 ohm-cm, corresponding to a background acceptor concentration N_B of about 10^{17} cm^{-3}, and ~25 ohm-cm, corresponding to about 5 x 10^{14} cm^{-3}. At least four different silicon ingots of each resistivity were used.

The silicon surfaces after prediffusion were almost invariably very good throughout the entire range of prediffusion temperatures used. There was no observable glass on the silicon, and a brief rinse in HF gave clean, polished surfaces.

Prediffusion results.—In order to assess the control limits of the process at least four runs were prediffused at 100° intervals throughout the range 700° to 1300°C. After each run the prediffusion sheet resistance r_p of all four samples was measured on an accurate four-point probe. To ensure precise knowledge of the geometrical factor used in computing r_p, the unknown diffused layer on the back of each slice was etched off prior to measurement. The values then were analyzed by standard

quality control techniques to determine the median value and the percentage control limits. One slice from each of these "control" runs was angle-lapped to determine the prediffusion junction depth x_{jp}, and an average value obtained from the four determinations. The measurement was made by means of a standard interference fringe technique. A few "single" runs (*i.e.*, one run of four samples) were made at various temperatures, but were not used to assess the process control. Their agreement with the control data, however, is a measure of the reproducibility of the process.

Figure 3 is a plot of r_p *vs.* the reciprocal of the prediffusion temperature T_p in degrees Kelvin. Points representing control runs and single runs, for both sample dopings used, are shown. Associated with each control point are the percentage control limits at that temperature. All the points lie satisfactorily on a smooth curve, the gradient of which increases with decreasing temperature, and no dependence of r_p on sample doping can be distinguished. The control limits increase from about 2% at high temperatures, to about 25% at 700°C. Prediffusions at 650°C do not appear on this figure because r_p was too high ($> 10^4$ ohm/□) to be meas-

The junction depth x_{jp} is plotted *vs.* $1/T_p$ in Fig. 4. The points represent the average of four determinations, one sample from each of the four control runs. In all cases the spread in the values was less than the measurement uncertainty, which was estimated to be a maximum of ± 0.005 mil and which is represented by the lines on the left of the figure. No values are available below 900°C because of the difficulty of measuring extremely thin layers.

In spite of the relatively large measurement uncertainty below about 0.2 mil the results clearly fall into separate straight lines according to sample doping, as expected. The precise location of the lines is uncertain; those shown represent the best

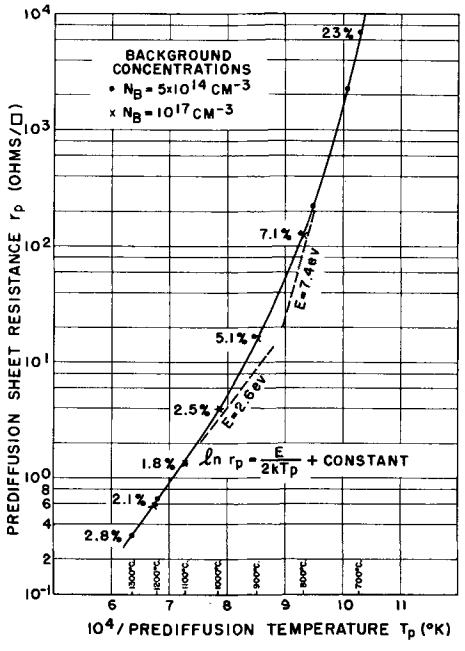

Fig. 3. Prediffusion sheet resistance *vs.* reciprocal prediffusion temperature.

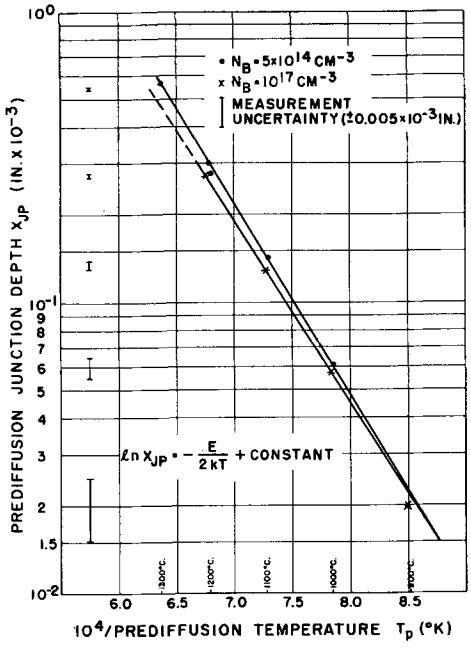

Fig. 4. Prediffusion junction depth *vs.* reciprocal prediffusion temperature.

fit. Note, however, that the separation of these lines is appreciably less than would be expected theoretically. The junctions were invariably flat and parallel to the surface.

From the experimental measurements of r_p and x_{jp}, the prediffusion surface concentration N_{op} can be inferred, assuming that the impurity distributions are complementary error function (erfc).[2] Values of N_{op} obtained in this way are shown plotted against T_p in Fig. 5, for temperatures ranging from 900° to 1300°C. It can be seen that N_{op} tends to saturate in the region 1100° to 1200°C at a value close to 10^{21} cm^{-3}. The apparent dependence of N_{op} on sample doping is not a real effect and is discussed in a later section.

Process criteria.—At this stage it is worthwhile considering how well the process satisfies the various criteria by which the usefulness of a diffusion

[2] These values of N_{op} were computed from diffusion curves calculated by I. M. Mackintosh and A. J. Siuta. Their curves are in agreement with the extensive diffusion data of Irvin (4)

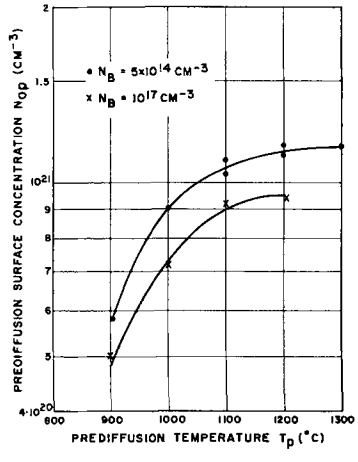

Fig. 5. Prediffusion surface concentration *vs* prediffusion temperature.

Table I. Oxide masking capabilities

All runs ~ 1200°C 60/min. All samples ~ 0.3 ohm-cm ($N_B \sim 10^{17}$ cm^{-3}).

process may be judged. These criteria, and the performance of the present process, are described below in some detail.

Process control.—In view of the capabilities of other known phosphorus diffusion processes the performance of this new process is very satisfactory. There is a general improvement in control, relative to other known processes, throughout the entire temperature range. In particular, control limits of better than 10% on sheet resistances of several hundred ohms significantly increase the range of phosphorus as a useful n-type impurity in silicon. The 1.8% limits on r_p at 1100°C effectively represent a temperature uncertainty of less than 1°C.

Compatibility with other device and process requirements.—No incompatibility with other processes or with specific device requirements has been exhibited by this process. Good alloy contacts have been made to silicon surfaces which had been diffused by this means. Lifetime-dependent devices have been made using the present process as one of the fabricating steps, and no unusual or adverse effects have been experienced.

It is pertinent to consider, however, the role of the calcium oxide in this process. After very long diffusion times at high temperatures the diffusant glass tends to disappear completely. This is strong evidence that the CaO is evaporating at a rate similar to that of the P_2O_5. No information is available, however, on the electrical behavior of calcium in silicon. This is apparently due to the fact that the solid solubility is extremely low (5). Moreover, the great stability of the CaO molecule inhibits its reduction and the subsequent diffusion into the silicon of metallic calcium (5). Thus the calcium, although present during the prediffusion treatment, is either electrically inactive in silicon or cannot get into the silicon in significant amounts.

Oxide masking capabilities.—Present-day device requirements demand from any silicon diffusion process with a claim to universality the ability to inhibit diffusion by the use of silicon dioxide layers on the silicon surface. By such masking techniques localized diffused regions of any desired shape can be obtained with ease.

The oxide masking capabilities of this process were investigated by prediffusing for 60 min at approximately 1200°C a number of slices (background concentration 10^{17} cm^{-3}) having different oxide thicknesses. Each run consisted of one completely oxidized slice (to determine the sheet resistance of the impurity layer, if any, which had been able to penetrate the oxide), and one control slice completely free of oxide (to ensure, through its sheet resistance, that the process was performing properly).

The results are shown in Table I. It can be seen that a layer of sheet resistance about 0.7 ohm/□ ($N_{op} \sim 10^{21}$ cm^{-3}) can be successfully masked by about 9000Å of SiO_2, a thickness which is compatible with photoresist etching techniques. Higher sheet resistance layers presumably can be masked by thinner oxides, although no data are available at this time.

Process simplicity.—Difficulties arise in any process involving the use of weighed quantities of a hydroscopic substance such as P_2O_5. For example, how can the water content be kept reproducibly low and, having weighed the powder, what fraction of the weight is due to the water content? If the process depends critically on these factors, it would probably be unsuitable for use in large-scale diffusion operations.

The sensitivity of the process to the method of manufacture of the glass was investigated in the following way. Without taking any special precautions, two samples of diffusant glass were made in ostensibly the same manner, but at different times. In each case the proportions of the weighed powders were approximately 15 parts P_2O_5 to 1 part CaO, by weight. These are described as 15:1 glasses. After being fired in identical ways (900°C for 30 min) the glasses were analyzed for P_2O_5 content and their approximate melting points were measured. The results are given in Table II. It can be seen that within the accuracy of the determinations the two glasses are essentially identical. It therefore is assumed that no major problem exists in the manufacture of the glass.

The sensitivity of the process to the glass proportions is also of great importance. To investigate this, glasses of widely differing proportions were

Table II. Reproducibility of diffusant glass

Glass sample	Weight ratio (P_2O_5:CaO)	Weight percentage of P_2O_5	Melting point, °C
A	15:1	87 ± 2	650 ± 50
B	15:1	89 ± 2	700 ± 50

Table III. Dependence of r_p on glass ratio

Temperature/time	No. of runs	Glass ratio	$\tilde{r}_p$
805°C/60 min	1	50:1	130
805°C/60 min	4	6:1	131
1000°C/60 min	2	50:1	4.04
1000°C/60 min	2	10:1	4.03

used for prediffusions at various temperatures. The results are shown in Table III, and it can be seen that there is no significant variation of the sheet resistance values with the glass ratio. Further confirmation of this propitious insensitivity is given by Fig. 3, in which the various points were obtained using a wide variety of glasses (6:1 to 50:1) without any noticeable effect. It is a safe assumption, therefore, that variations in the glass proportions will have an insignificant effect on the process, providing the ratio is high enough for the glass to be molten at the temperature of prediffusion.

Process simplicity is further improved if the necessity for frequent renewals of the loading or "charge" of the diffusant glass is avoided. In other words, the process is simpler the longer a given charge remains "active" and gives the correct results. The results of various investigations during the course of this work show that at 1200°C an average charge (~ 2g) will last at least 12 hr. At temperatures below 1000°C no charge renewal was found to be necessary.

Diffusion Stage

Diffusion equipment and procedure.—The diffusion of previously prediffused samples was carried out in the same general furnace system used for the prediffusion process, but using a clean furnace tube. The quartz push-rod was simply a long hollow rod with a flat platform at one end, on which the samples were laid. A standardized thermocouple was inserted into the rod so that it lay close to the samples, and the temperature was accurately measured and controlled during every diffusion run. A gas flow of 1000 cc/min of dry oxygen was used in all the diffusions.

In an attempt to obtain accurate information on the process (and on the value of the diffusion coefficient) at more than one temperature, each group of identically prediffused samples was divided into two subgroups, one being diffused for 16 hr at 1200°C, the other for 3 hr at 1300°C. These times were chosen so that the diffusion lengths for the two subgroups were approximately equal, thus permitting comparisons between the two sets of results.

Diffusion results.—No deterioration in the sample surfaces was observed after diffusion. A quick rinse in HF removed the oxide grown during diffusion and gave clean, bright surfaces. After each diffusion run measurements were made of the sheet resistance r_d and the junction depth x_{jd} of every sample, using the same techniques as used for the prediffusion measurements.

Figure 6 is a plot of r_d *vs.* the reciprocal prediffusion temperature, $1/T_p$. As with most of the diffusion results four point-symbols are used, representing the combination of sample resistivities and diffusion temperatures used. In this figure the symbols are separated from the actual points in order to avoid confusion. The points all lie satisfactorily close to a smooth curve and no systematic variation in r_d can be distinguished for either diffusion temperature or sample resistivity.

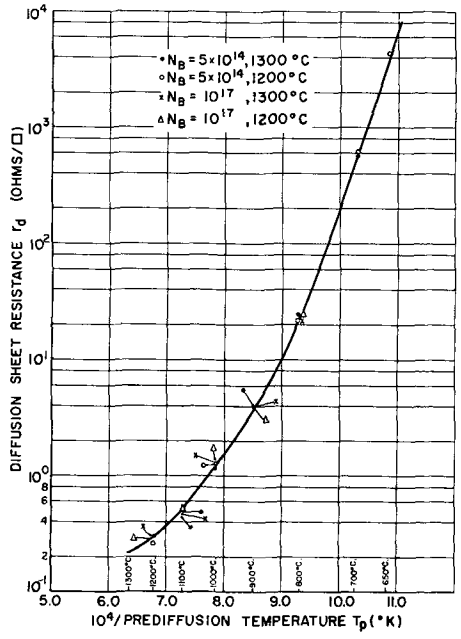

Fig. 6. Diffusion sheet resistance *vs.* reciprocal prediffusion temperature.

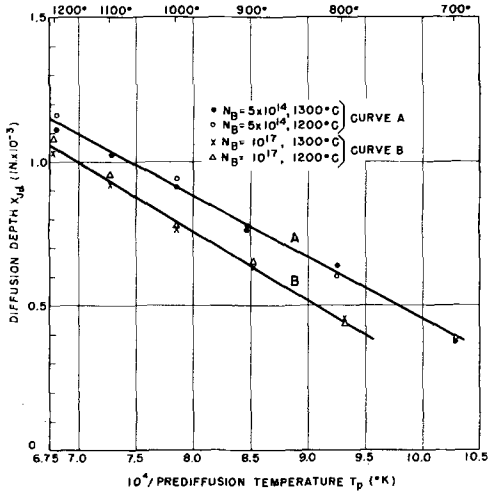

Fig. 7. Diffusion junction depth *vs.* reciprocal prediffusion temperature.

Precise information on the control of the diffusion process was difficult to obtain because of the small number of samples. This arose from the separation into two subgroups of the available prediffused samples. Roughly, however, the control limits seemed to be somewhat worse after diffusion; for example, ±3% after prediffusion, and about ±4% after diffusion. This is expected and reflects additional small randomizing effects during the diffusion runs.

The diffusion depth x_{jd} is plotted against T_p in Fig. 7. Here, as expected, the results separate according to sample resistivity. No further observable separation occurs since the diffusion lengths of the 1200° and 1300° runs are nearly equal. Measurement uncertainty in these values is quite small. The points represent average values and the spread was invariably less than ±4%. As with the prediffusion results, the separation of the two lines in Fig. 7 is

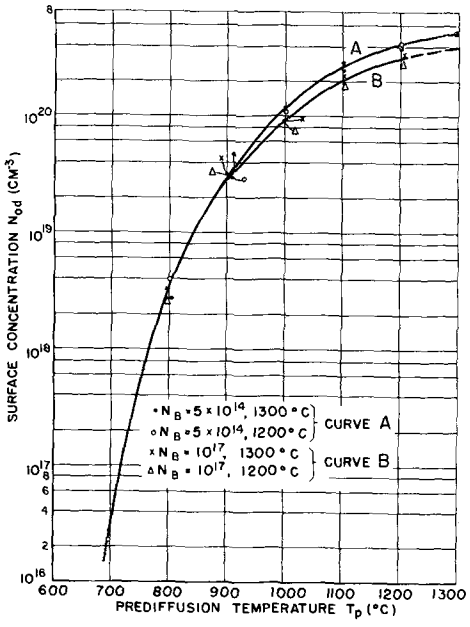

Fig. 8. Diffusion surface concentration *vs.* prediffusion temperature.

appreciably less than would be expected theoretically.

From the experimental measurements of r_d and x_{jd}, the diffused surface concentration N_{od} can again be inferred, assuming that the impurities have a purely Gaussian distribution.[3] Figure 8 shows a plot of N_{od} *vs.* T_p. The results separate into two curves above 900°C and, as for the prediffusion results, N_{od} is apparently higher for lower sample doping. The implications of this are discussed in the following section. It should be noted that surface concentrations as low as about 10^{16} cm^{-3} can be achieved with reproducibilities of about 20%.

Over-all process.—The successful use of two-stage processes necessitates good control in both stages of the process. For example, samples of identical r_p values, when identically diffused, should have the same values of r_d within close limits. That the present process fulfills this condition is established by Fig. 6.

[3] As for the prediffusion results, these values of N_{od} were computed from diffusion curves calculated by I. M. Mackintosh and A. J. Siuta, which are in agreement with the computed data recently obtained by Irvin (4).

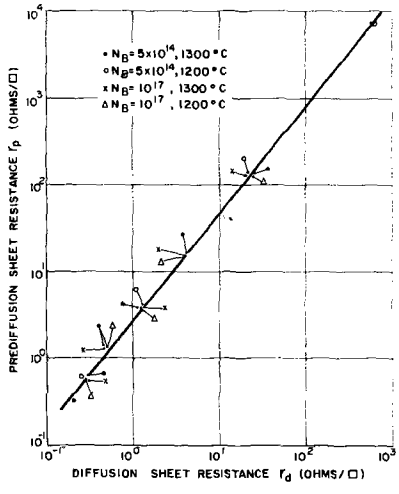

Fig. 9. Prediffusion sheet resistance *vs.* diffusion sheet resistance

In addition, it is very desirable to be able to predict with reasonable accuracy the prediffusion conditions necessary to give specific final distributions. An example of how well the present process achieves this desirable feature is shown in the plot of r_p *vs.* r_d in Fig. 9. A linear dependence of $\ln(r_d)$ on $\ln(r_p)$ is exhibited over at least five decades, and no dependence on sample resistivity or diffusion temperature is observed (a significantly different diffusion length, however, would change the shape of the plot). Thus, a required final value of r_d can be associated accurately with a required value of r_p; Fig. 3 then gives the necessary prediffusion temperature.

This pronounced linearity (on logarithmic scales) is somewhat surprising, but can be justified qualitatively on theoretical grounds.[4] The line can be represented by the equation

$$r_p = a\, r_d^{\,b} \qquad [1]$$

where $a = 2.8$ and $b = 1.3$. Now, by the use of several simplifying assumptions (see appendix) it can easily be shown that

$$r_p \approx r_d \frac{\bar{\mu}_d}{\bar{\mu}_p} \qquad [2]$$

where $\bar{\mu}_d$ and $\bar{\mu}_p$ are the effective average (constant) mobilities for the diffusion and prediffusion distributions, respectively. It also has been established (4) that over considerable ranges of impurity concentrations the mobility exhibits a dependence of the form

$$\mu = cN^{-d} \qquad [3]$$

where c and d are constants. Combination of Eq. [2] and [3] then can be shown to lead to a general relation between r_p and r_d of the form of Eq. [1]. The experimental values of the constants a and b are shown in this way to be theoretically reasonable but to depend (in a complicated manner) on the diffusion length L_d.

General Discussion

Shape of impurity distributions.—The results already presented have shown that this process performs in a controlled and reproducible manner over several orders of magnitude of sheet resistance. This reproducibility, and the relative precision with which the parameters r and x_j have been measured, raises the possibility of using these data to further the understanding of the diffusion process itself. Such an attempt is made in this section.

The curves shown in Fig. 5 and 8 suggest that the surface concentration N_o is a function of the background concentration N_B. Under the conditions imposed during these diffusions, however, there is no feasible mechanism by which such an effect could occur, particularly when N_o is many orders of magnitude greater than N_B. This is the primary anomaly through which an understanding of the true nature of the impurity profiles may be sought.

It is convenient at this stage to focus attention on the prediffusion results. The values of N_{op} were computed on the assumption that the impurity profiles were truly erfc distributions and, of course,

[4] A brief discussion of the appropriate diffusion theory is given in the appendix.

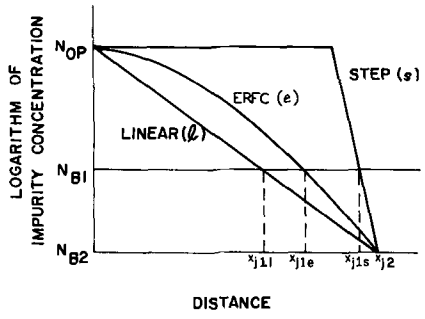

Fig. 10. Schematic of anomalous distributions

any departure from this theoretical distribution would lead to anomalous values for N_{op}. Departures from such a distribution can take two general forms, more convex or less convex on a logarithmic concentration plot.[5] In Fig. 10 these are represented in exaggerated form as step function (s) and linear gradient (1) distributions, respectively, on a plot of log (concentration) *vs.* distance. All three profiles have the same surface concentration and the same junction depth at the lower concentration N_{B2}.

Now it is well known that the sheet resistance of a diffused layer is primarily a function of the surface concentration, so that r_{pl}, r_{pe}, and r_{ps} (denoting the linear, erfc, and step profiles, respectively) will not be sensitive to changes in N_B. However, the form of the profile certainly affects the sheet resistance and it can be seen readily that $r_{pl} > r_{pe} > r_{ps}$. If the junction depths and sheet resistance values are now used to compute the apparent surface concentrations, assuming that each profile is an erfc distribution, then it is found that: (*i*) the linear gradient distribution gives apparent N_{op} values which lie below the true erfc values, and which increase with increasing N_B: (*ii*) the step function distribution gives apparent N_{op} values which lie above the true erfc values, and which decrease with increasing N_B. Since it is the latter trend which is observed experimentally (Fig. 5) then the actual profiles can be assumed to be more convex than the true erfc distribution. And, therefore, the true surface concentrations must lie on or below the lower curve shown in Fig. 5. This result gains additional support from the fact that the plots of x_{jp} *vs.* $1/T_p$ in Fig. 4 have a smaller separation than expected theoretically.

Diffused profiles which also exhibit this type of step function distribution have been observed (6) for zinc diffusion in gallium arsenide. One proposed explanation (6) is the increase in ionic radius of the Zn acceptor as it changes from an un-ionized state at heavy concentrations (Fermi level below the acceptor levels) to an ionized state at low concentrations, leading to a decrease in diffusion coefficient at these concentrations. This proposed mechanism cannot account for the present results because phosphorus is a donor in silicon and its decrease in ionic radius at low concentrations would lead to an increase in the diffusion coefficient.

Another proposal (7) to explain the anomalous Zn diffusion profiles in GaAs is based on the assumption that Zn can diffuse both substitutionally and interstitially with high and low diffusion coefficients, respectively. If most of the vacancies are surface-created (by the evaporation of As?) and themselves diffuse slowly, then it is readily seen that a step-function distribution would be obtained, the step occurring at the depth to which the surface-created vacancies have diffused. It is difficult, however, to envisage such an effect in silicon since the diffusion of vacancies in this material is commonly assumed (8) to be much faster than the diffusion of phosphorus.

Several other mechanisms can be postulated to account for this anomalous kind of impurity profile. Prominent among these are: (*i*) the presence of a strained surface layer (in which the diffusion coefficient might be abnormally high) due to mechanical polishing or other surface preparations; (*ii*) the simultaneous diffusion into or out of the silicon of a different species of impurity, chemical or electrical (*e.g.*, vacancy).

The first mechanism has been investigated experimentally by simultaneously prediffusing both mechanically and chemically polished samples which were otherwise identical. No significant difference in values of r_p and x_{jp} was observed between these samples thus suggesting that surface strain is not a cause of the observed anomalies.

The second mechanism is difficult to investigate experimentally. However, any impurity which could cause this effect must have a diffusion coefficient significantly less than that for phosphorus. This eliminates vacancies, oxygen, iron, gold, etc. from consideration. The fact that most of the crystals used in this experiment were boron-doped might be significant. Further work would be necessary before the importance of this could be checked.

The general conclusion that the prediffused impurity profiles[6] are more convex (on a logarithmic plot) than a true complementary error function distribution is confirmed by a recent detailed analysis of phosphorus-diffused layers in silicon (9). This method involves repeated room-temperature anodization of the silicon and measurement of the sheet resistance of the residual diffused layer, and is capable of yielding precise information about the distribution of ionized impurities.[6] The analysis indicates the existence of an upper limit to the concentration of electrically active phosphorus in silicon which is below the apparent surface concentrations shown in Fig. 5. Such a concentration limit would, of course, lead to a region close to the surface where the concentration of electrically active phosphorus was essentially constant, thus giving an impurity profile which was more convex than the error function complement.

The diffusion profiles, as considered through the curves of N_{od} in Fig. 8, exhibit similar anomalies for prediffusion temperatures above 900°C. In other words, the separation of the curves according to sample doping again leads to the conclusion that the diffusion profiles are more convex (on a logarithmic

[5] The terms "convex," "linear," etc., as used in this discussion refer to the shape of the distribution when plotted on semilog paper.

[6] Obviously, the measurement of sheet resistance will yield information on the density of electrically active impurities, not on the total density. Such limitation is implied during all of this discussion.

concentration plot) than the true Gaussian distribution. For prediffusion temperatures below 900°C there is no evidence (within experimental error) of a dependence of N_{od} on N_B, and it is therefore possible to assume the existence of Gaussian distributions for these cases. These conclusions are confirmed partially by the plots of x_{jd} in Fig. 7, since the separation of the two lines is quite close to the theoretical value at low values of T_p, but is considerably less than the theoretical separation at high values of T_p.

The situation therefore can be summarized as follows. Using only the measurement of sheet resistance and junction depth it has been established that, with the exception of samples having low-temperature prediffusions and relatively long diffusions, both the prediffused and diffused impurity profiles are more convex (on a logarithmic plot) than the theoretical error function and Gaussian distributions. The reason for this effect cannot be established with any certainty using these data, although it is possible to rule out some of the more likely causes. The precise nature of the impurity profiles can be investigated more easily using the anodization technique (9) mentioned previously, and it is from this work that a fuller understanding of the phenomenon can be expected to emerge.[7]

Evaluation of the diffusion coefficients.—In view of the existence of these anomalous distributions it is obvious that the value of the diffusion coefficient obtained from these results is not necessarily the true value. What emerges from the calculations is an effective value which represents the value the diffusion coefficient would have for a theoretically correct profile having the same sheet resistance, junction depth, etc. This effective diffusion coefficient is nevertheless of considerable interest since it represents the value which must be used in any practical diffusion experiment. For this reason various plots of the diffusion coefficient are presented in this section.

Figure 11 shows the value of the diffusion coefficient D, as calculated from the prediffusion results, plotted *vs.* $1/T_p$. The equations describing the prediffusion and diffusion conditions, and the methods for calculating the effective diffusion coefficients and activation energies are shown in the appendix. The points fall into two straight lines, according to sample doping, and have slightly different activation energies.

In calculating the diffusion coefficient from the diffusion results two additional complications arise. In the first place, the distributions can be truly Gaussian only when the prediffused layer can be regarded as a sheet source at the surface. This is certainly not a valid assumption for prediffusions above 900°C (where $x_{jp} = 0.02 \cdot 10^{-3}$ in.), but deviations from the true distributions already have been taken into account by calling the calculated value of D an "effective" coefficient. Second, the effective surface from which the diffusion depth should be measured lies inside the true surface by an amount which depends on the prediffusion conditions. In this work the penetration x'_{jp} of this effective surface is defined as that distance which, when multiplied by N_{op}, gives a total density of impurities equal to $\bar{N}_p$. In other words, the prediffusion profile is assumed to be a step function, the concentration falling from N_{op} to zero at a distance x'_{jp} from the surface such that

$$N_{op}\, x'_{jp} = \bar{N}_p = \frac{2L_p N_{op}}{\sqrt{\pi}} \qquad [4]$$

For the computation of the effective diffusivity, therefore, the depths shown in Fig. 7 have been corrected by their respective x'_{jp} value. This correction is a maximum of about 5% of the measured

[7] During the preparation of this paper for publication, a new study of phosphorus diffusion profiles by radioactive tracer techniques was published (10). The results of this recent study confirm the existence of anomalous impurity distributions of the kind described above.

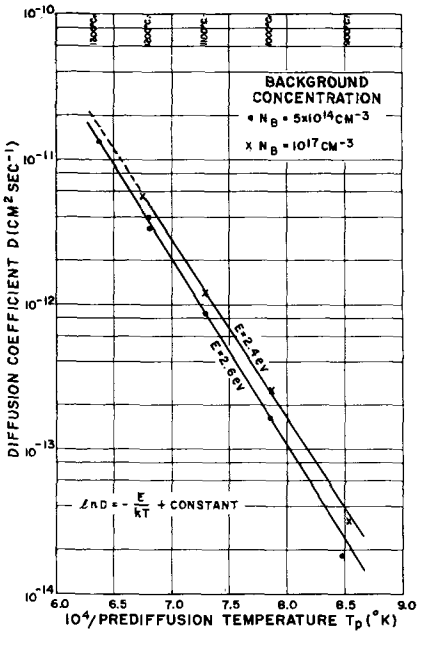

Fig. 11. Diffusion coefficient *vs.* reciprocal prediffusion temperature.

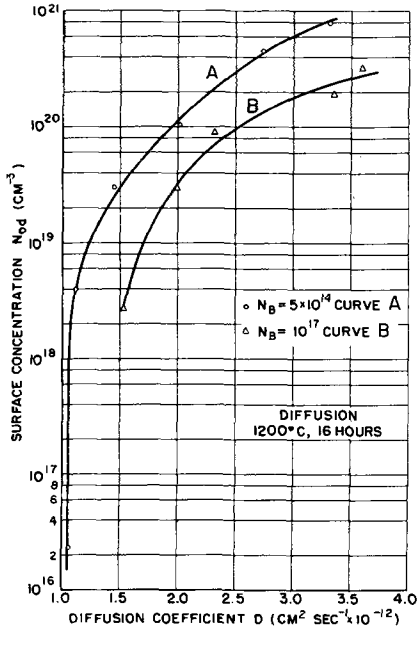

Fig. 12. Diffusion surface concentration *vs.* 1200°C diffusion coefficient.

diffusion depth for the high-temperature prediffusions.

Figure 12 shows a plot of N_{od} *vs.* D, calculated in the manner described above from the 1200°C diffusion results. D is a function of concentration because of the field-acceleration effect which occurs when N_o exceeds the intrinsic concentration n_i at the temperature of diffusion. It has been shown (11) that this effect can lead to a factor of two increase in D and that the effect in silicon first should be observed at some value of N_o less than about 10^{19} cm^{-3}. The figure confirms the latter aspect, but the fact that these results exhibit much more than a factor of two increase in D can be explained only by the presence of some other mechanism, as yet unknown.

Figure 13 shows the same kind of plot of N_{od} *vs.* D, but for the 1300°C diffusion runs. It serves to confirm that the effects observed in Fig. 12 are not special to 1200°C. Both of these figures demonstrate the dependence of this effective diffusivity on sample doping. This is not understood for samples prediffused below 900°C since Fig. 8 appears to confirm the existence of true Gaussian distributions (or very close to it) for these samples. Apparently it is not arising because of any peculiarity in the silicon samples since, as stated earlier, at least four different ingots of each resistivity range have been used in this work. No adequate explanation for this apparent effect has yet been found.

Values of D at 1200° and 1300°C for any specified N_{od} can be obtained from Fig. 12 and 13. By this means plots of D *vs.* $1/T$ have been obtained for three representative surface concentrations and are shown in Fig. 14. Also shown (dotted) are the values obtained from the prediffusion results (Fig. 11), corresponding to even higher surface concentrations. Figure 14 thus summarizes all of the present data on the effective diffusion coefficient as a function of temperature, surface concentration, and sample doping and may serve as a useful working chart.

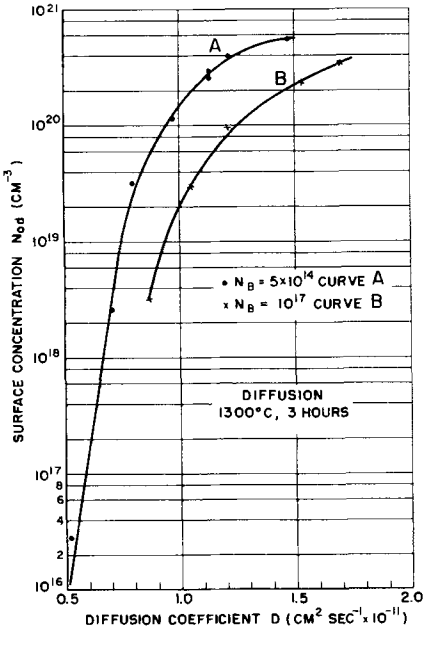

Fig. 13. Diffusion surface concentration *vs.* 1300°C diffusion coefficient.

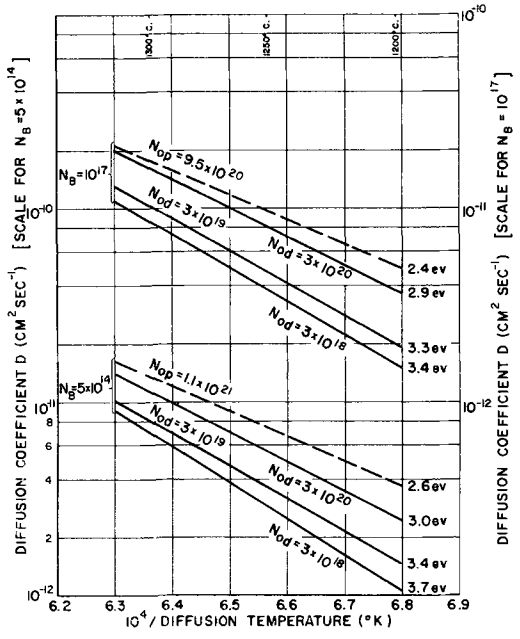

Fig. 14. Effective diffusion coefficient *vs.* reciprocal temperature

The dependence of the effective activation energy E on both N_{od} and N_B clearly emerges from this figure (14). Table IV summarizes all of the present data on E and a satisfactory degree of self-consistency is seen clearly. It should be noted, however, that these effective activation energies are significantly out of agreement with the results of earlier workers (1, 12).

Summary and Conclusions

A new process for the diffusion of phosphorus into silicon has been described which utilizes the inherent advantages of the closed system. The process is highly controlled and is capable of producing prediffused layers over at least five decades of sheet resistance. After diffusion, surface concentrations in the range 10^{16} to 5 x 10^{20} cm^{-3} can be obtained with good reproducibility. The various aspects of the process have been described in detail, and the diffusant glass has been shown to satisfy the several criteria which apply to such a source.

The high degree of process control, combined with the relative precision with which the measurable diffusion parameters (sheet resistance and junction depth) have been determined, has revealed an apparent dependence of surface concentration and diffusion coefficient on the background doping of the silicon samples. This effect has been shown to arise because of discrepancies between the actual impurity profiles and the distributions expected theoretically. Various possible causes of this effect have been discussed, but no satisfactory explanation has yet been found. Plots of the effective diffusion coefficient as a function of temperature, surface concentration, and sample doping have been presented. These represent the values which should be used in a practical diffusion experiment.

APPENDIX

Simplified Diffusion Theory

Prediffusion.—Theoretically the prediffusion impurity profiles are described by the equation

$$N_B = N_{op} \operatorname{erfc} (x_{jp}/2\sqrt{Dt_p}) \qquad [A\text{-}1]$$

from which

$$x_{jp} = 2\sqrt{Dt_p} \operatorname{erfc}^{-1} (N_B/N_{op}) \qquad [A\text{-}2]$$

The diffusion coefficient is given by

$$D = D_o \exp (-E/kT) \qquad [A\text{-}3]$$

where E is the activation energy and k is Boltzmann's constant. Hence, over the range of temperatures in which (N_B/N_{op}) is effectively constant we get

$$\ln (x_{jp}) = -\frac{E}{2kT_p} + \text{constant} \qquad [A\text{-}4]$$

This is the equation represented in Fig. 4.

The expression for the prediffusion sheet resistance can be simplified in the present work to

$$r_p \simeq \sqrt{\pi}/q\bar{\mu}_p \, 2N_{op} \sqrt{Dt_p} \qquad [A\text{-}5]$$

where q is the electronic charge. Hence,

$$\ln r_p = \frac{E}{2kT_p} + \text{constant} \qquad [A\text{-}6]$$

which is the expression represented in Fig. 3.

The total concentration of impurities in the prediffused layers is given by

$$\bar{N}_p = \int_0^{x_{jp}} N(x)\, dx = \frac{2N_{op}\sqrt{Dt_p}}{\sqrt{\pi}} \qquad [A\text{-}7]$$

Diffusion.—Theoretically the diffusion impurity profiles are described by the Gaussian equation

$$N_B = N_{od} \exp (-x_{jd}^2/4Dt_d) \qquad [A\text{-}8]$$

from which

$$D = x_{jd}^2/4t \ln (N_{od}/N_B) \qquad [A\text{-}9]$$

This is the equation from which the values shown in Fig. 12 and 13 were calculated.

The expression for the diffusion sheet resistance can be simplified in the present work to

$$r_d \simeq 1/q\bar{\mu}_d \, N_{od} \sqrt{\pi Dt_d} \qquad [A\text{-}10]$$

from which

$$\ln r_d = \frac{E}{2kT_d} + f(t_d, N_{od}, \text{etc.}) \qquad [A\text{-}11]$$

This expression has not been used to obtain another estimate of the effective activation energy, however, because no experiments were made keeping t_d constant and varying only T_d.

The total concentration of impurities in the diffused layers is given by

$$\bar{N}_d = \int_0^{x_{jd}} N(x)\, dx = N_{od}\sqrt{\pi Dt_d} \qquad [A\text{-}12]$$

The expression shown in Eq. [2] (section on Over-all process) can easily be obtained from Eq. [A-5] and [A-10] using the assumption that $\bar{N}_p = \bar{N}_d$.

The Adsorption of Water Vapor by Porous Glass

Myron J. Rand

Bell Telephone Laboratories, Inc., Allentown, Pennsylvania

ABSTRACT

Porous glass is a good getter for water vapor in semiconductor devices. This article presents a fundamental study of the physical adsorption of water on multiform porous Vycor over the range 30°-150°C and 10^{-3} to 25 torr water vapor pressure, with surface coverages up to a third of a monolayer. The adsorption isotherms, for which a general equation is given, are of the Freundlich type. Differential heats and entropies of adsorption have been determined, and from the latter it is concluded that the film of adsorbed water is intermediate in nature between rigidly localized and completely mobile. Kinetic studies give the result that the amount adsorbed is proportional to $(\text{time})^{1/2}$. The effects of various drying procedures on the subsequent adsorptive capacity of the glass are considered in some detail and the mechanism of surface dehydration inferred.

The porous glass discussed in this paper is an intermediate in the manufacture of Vycor brand glassware by the Corning Glass Works, and is essentially a finely divided amorphous silica with a consolidated instead of loose powder structure. It may be precision-fabricated into a variety of shapes by multiforming techniques; typical properties are shown in Table I. As a moisture adsorbent in a semiconductor device enclosure such a material would have the paramount advantage of physical strength and attendant freedom from dusting, spalling, or particle-shedding. In this it is unique among high-surface-area adsorbents. There are in addition the advantages of cleanness, freedom from ionizing impurities and organic contaminants, and closely controlled and reproducible manufacture. As a consequence porous glass was tried by these Laboratories as a moisture getter for transistors before any fundamental data on its adsorptive behavior were known. The criterion for success, as usual, was the stability of certain electrical parameters during life-testing. The first public mention (1) of improved reliability of devices incorporating a porous glass getter was made in 1957, and subsequent work has provided abundant evidence of the superiority of gettered germanium transistors (2).

A fundamental investigation of the behavior of multiform porous glass (MPG) as a moisture adsorbent begins with the establishment of its adsorption isotherm for water vapor. The complete isotherm for 25°C is shown in Fig. 1, which is a synthesis of measurements from Bell Telephone Laboratories, Corning Glass Works (by T. H. Elmer), and published data (3). The ordinate is the weight of water adsorbed per unit weight of dry MPG (x/m), and the abscissa the relative humidity (r. h.). The large hysteresis loop beyond 60% r.h. is presumed due to capillary filling and has been reported for a large variety of adsorbents on porous glass.

Since the glass, the transistor unit, and the gas ambient (if any) are all carefully dried at the time of encapsulation, the region of interest for getter behavior is the extreme toe of the isotherm. The range above 5% r. h. is easy to study, using sulfuric acid solutions to control water vapor pressure, but there is no way to predict accurately the low humidity part of the curve by the shape of any other part. All the work reported here is in the range below 5% r.h., and measurements have been made down to $p/p_o = 10^{-4}$. Isotherms have been established at nominal temperatures of 30°, 60°, 100°, and 150°.

Table I. Properties of multiform porous glass (Corning 7930 glass)

Typical composition

Apparent specific gravity	1.5
Porosity	29%
Average pore diameter	30-40Å
Surface area	170-230 m^2/g

* Mostly Al_2O_3 and ZrO_2.

Apparatus and Materials

The apparatus used for the determination of the MPG adsorption isotherms is shown schematically

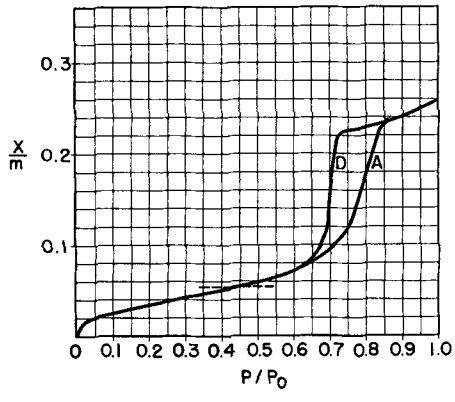

Fig. 1. Adsorption isotherm of porous glass at 25°C. D and A are desorption and adsorption branches. The dotted line indicates the monolayer.

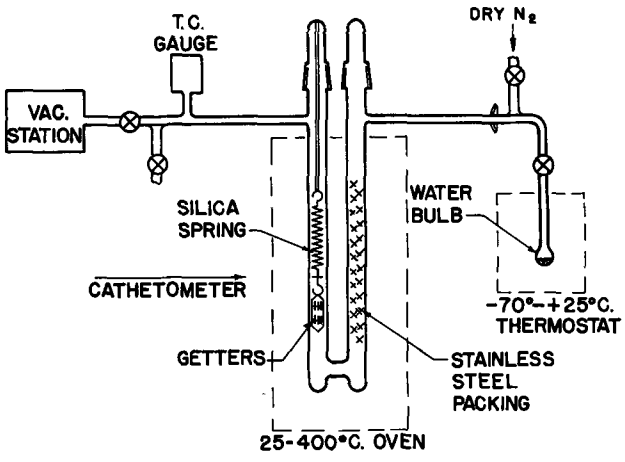

Fig. 2. Schematic diagram of sorption balance apparatus

in Fig. 2. This is a McBain-type sorption balance, with weight changes followed by observing the extension of a helical silica spring (4) with a cathetometer. The balance is designed for use in either vacuum or gas ambient, and the stainless steel packing in one arm of the adsorption cell aids in bringing flowing gas up to oven temperature before it reaches the sample suspended from the spring. The vacuum station includes a roughing pump, a three-stage oil diffusion pump, traps, and an ionization gauge. There is no trap between this gauge and the sorption balance. The thermocouple gauge continuously monitors the system pressure, but it is not relied on for accurate readings of the water vapor pressure. This is accomplished by maintaining a reservoir of pure water in the cryostat, whose temperature is controlled to ±0.1°C and read on a calibrated alcohol-filled thermometer. The water is degassed by several cycles of freezing, pumping, and melting.

The oven surrounding the adsorption cell is insulated heavily, with very narrow slots covered with plate glass serving as windows to follow the spring travel. Temperature is read on calibrated mercury thermometers. The elastic modulus of the spring is temperature-sensitive, and very close control is required: the temperature of the oven must be known to 0.1° to realize the ultimate sensitivity of the spring-cathetometer combination. The spring extension for a given weight change varies with the load also, and the spring must be calibrated accordingly. This was carried out over the range 30°-300° with gold weights placed in a silica bucket hung on the end of the spring. The micrometer-slide cathetometer, with a 20X eyepiece, read to 0.001 mm. With a spring of one-gram capacity and 10-cm stretch, the detection limit was a weight change fraction of 2×10^{-5}, corresponding to a sample surface coverage of 3×10^{-4} monolayer.

The MPG samples were from a standard production lot and are representative of those currently used as device getters. They are annular wafers about 8 mm OD x 0.8 mm thick, with a 2 mm diameter hole through the center; each weighs about 50 mg. Before use they were heated 16 hr at 150° in room air to drive off loosely held water. The "dry weight" (m of x/m) was taken on this basis; it does not differ from the activated weight, as determined below, by as much as 1%, and provides an invariant reference point. Fourteen getters were hung on the rods of a silica rack suspended from the spring.

In typical operation the spring and sample assembly are lowered into the adsorption cell with the oven already at the temperature chosen for activation of the MPG. After the ground joint is seated the apparatus is evacuated and the MPG pumped, most commonly at 200° for 12 hr. The pressure is read on the ionization gauge and weight changes may be observed if desired. At the end of the activation period the oven is cooled to the temperature at which the isotherm is to be measured, and the pumping station is closed off. The pressure at this point is below 10^{-5} torr; the apparatus can stand for several days with no change in the reading of the t.c. gauge, which is sensitive to 10^{-3} torr.

As soon as the balance reading for the activated condition is obtained, the water vapor source (which has been evacuated earlier) is opened to the cell and the weight gain followed. Equilibrium takes 2-12 hr, depending on conditions, and is considered attained when no detectable weight gain takes place in 1 hr. Equilibria could be approached also from the desorption side, but were reached more slowly.

The MPG had a surface area of 215 m^2/g by conventional B.E.T. methods (5). Assuming an adsorbed water molecule to occupy 10.8Å^2, the monolayer corresponds to $x/m = 0.06$, *i.e.*, a 6% weight gain. The range of x/m investigated here is from 5×10^{-4} to 2×10^{-2}, or $\theta = 0.01$ to 0.33.

Adsorption Isotherms

The moisture adsorption isotherms follow quite closely the Freundlich adsorption isotherm

$$x/m = k\, p^{1/n} \quad (n > 1)$$

This equation gives a straight line on a log-log plot, and the results are so presented in Fig. 3. Plotted as Langmuir isotherms ($p/(x/m)$ *vs.* p) the curves are concave toward the pressure axis; Temkin isotherms (x/m *vs.* log p) have opposite curvature (6).

A different group of samples was used for each isotherm. On several occasions a group used to establish one isotherm was used to fill in a point on a

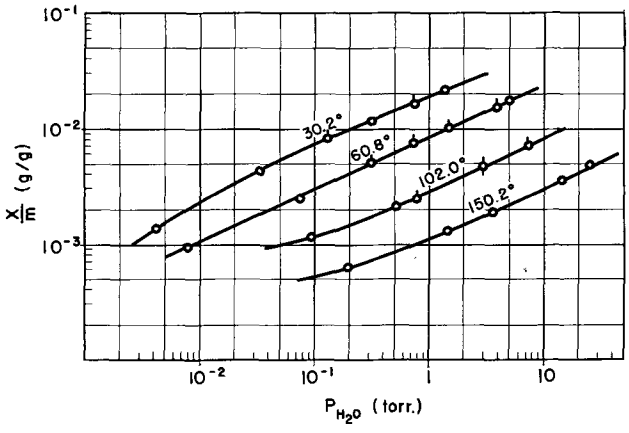

Fig. 3. Adsorption isotherms of water vapor on MPG. Activation 200°, 12 hr pump. Ó—second activation Ó third activation.

different isotherm. Often the samples were reactivated (particularly after standing over a weekend), and one group was reactivated twice; such points are indicated on Fig. 3. It is evident that the homogeneity of the MPG is good, and also that the adsorption is physical, at least in the sense that it is reversible, since weight gains were the same after reactivation. Sample surface areas and dry weights were found substantially unchanged after the measurements.

All the data of Fig. 3 are referred to initial activation conditions of 12-hr pumping at 200°. It is necessary to specify some standard activation since there is no readily definable zero point at which the glass may be said to be perfectly dry. At any temperature MPG *in vacuo* continues to release water for many hours. The 200° 12-hr activation was selected because these conditions should remove physically held water without appreciably dehydrating the silanol (SiOH) groups of the surface. This activation is hardly economical for device manufacture, however, and a study of the effect of various activation conditions is reported in the last section.

The isotherms have not been corrected for thermal transpiration (7) between the adsorption cell and the low-temperature water source. The correction can be calculated only rather empirically; the most generally useful discussion is that of Bennett and Tompkins (8). The thermal transpiration pressure ratio R has been calculated for a variety of temperature and pressure conditions; largely because the tubing connecting the points of temperature difference is 10 mm ID or more, the correction was so small as to be invisible on Fig. 3 except for the lowest pressure points of the 30° and 60° isotherms.

The exponent $1/n$ of the Freundlich isotherm equation appears as the slope of the log-log plots (Fig. 3). The value for the straight-line portions is 0.44, independent of temperature. The factor k is determined simply by reading it off the isotherm plot at $p = 1$, since here $k = x/m$. It happens that log k *vs.* $1/T$ is linear, and $k = 7.60 \times 10^{-7} \exp(3090/T)$. A general equation for the isotherms may now be written

$$x/m = [7.60 \times 10^{-7} \exp(3090/T)]\, p^{0.44}$$

where T is the absolute temperature and p the equilibrium pressure in torr. This equation describes a large range of behavior of MPG with an error not exceeding a few per cent, which is probably as good as the agreement among various manufacturing lots.

It should be remarked that over a 120° temperature range it is unusual for $1/n$ to be independent of temperature, and equally unusual to find a simple relationship between k and T. As an investigation of physical adsorption the work reported here is perhaps out of the ordinary in two respects: the surface coverages are low throughout, minimizing interactions between adsorbate molecules; and the adsorption is comparatively strong, probably involving forces beyond the usual van der Waals attractions.

Adsorption Thermodynamics

With equilibrium water vapor pressures over the MPG known at several temperatures, the isosteric differential heat of adsorption may be calculated from the Clausius-Clapeyron equation

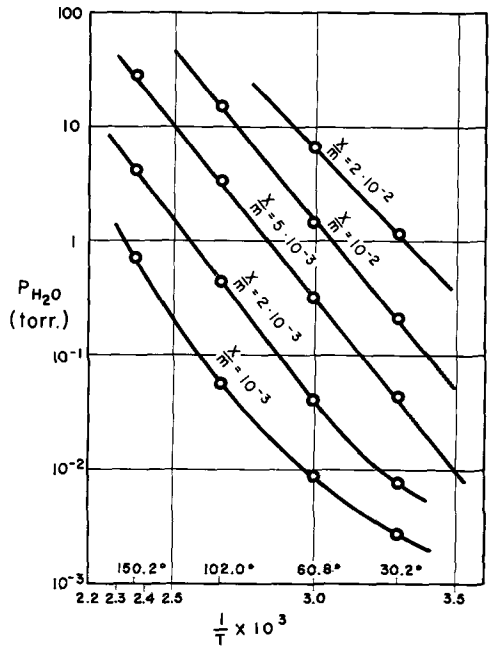

Fig. 4. Isosteres for water vapor adsorption on MPG

$$\left(\frac{\partial \ln p}{\partial T}\right)_\theta = \frac{\overline{\Delta H_a}}{RT^2} \qquad [1]$$

Figure 4 shows isosteres at θ's ranging from 0.017 to 0.33, plotted as log p *vs.* $1/T$. According to Eq. [1], assuming $\overline{\Delta H_a}$ independent of temperature, these should be linear, with slopes of $\overline{\Delta H_a}/2.303R$.

The isotherms also may be used to calculate an even more fundamental property, the entropy of adsorption, from which, by comparison with idealized models, some indication of the degree of mobility of the adsorbed film may be obtained. For this calculation it is necessary to choose a standard reference state; this is water vapor (ideal) at 1 atm throughout the discussion which follows. The free energy difference between this reference gas and the adsorbed molecules in equilibrium with water vapor pressure p is

$$\Delta G = RT \ln p \qquad [2]$$

with p in atmospheres. Experimental differential entropies then are calculated from

$$\Delta \bar{S}_a = \frac{\overline{\Delta H_a} - \Delta G}{T} \qquad [3]$$

It must be emphasized that $\Delta \bar{S}_a$ differs from ΔS_a, the change in entropy content of the system on adsorption of the gas. $\Delta \bar{S}_a$ is $(\partial S_a/\partial n)_{p,T,N}$ where n and N are amounts of adsorbate and adsorbent: the entropy change per mole accompanying infinitesimal adsorption at constant coverage, pressure and temperature, referred to the chosen standard state. The number of adsorption sites also is assumed constant. ΔS_a is always negative but $\Delta \bar{S}_a$ may take either sign.

Results for $\Delta \bar{H}_a$ and $\Delta \bar{S}_a$ are given in Table II. Since $\Delta \bar{H}_a$ is of the order of magnitude of the latent heat of liquefaction, the adsorption is physical. However, the

result is close to the limit of $\Delta H_L + 5.5RT$ (= 13.8 kcal/mole) which Trapnell (9) will allow for pure physical adsorption. At $\theta < 0.01$ there may well be some chemisorption; the difficulty of removing the last traces of water during activation supports this belief.

To interpret $\Delta\bar{S}_a$, models of the two extremes of the adsorbate, perfectly mobile and rigidly localized, will be considered, and the differential entropy changes calculated for each. Because of numerous assumptions in both the models and the conventional entropy equations for various kinds of motion, such an approach cannot be pushed too far. Agreement to perhaps 3-5 e.u. between theory and experiment is all that may be expected.

In the gas phase at ordinary temperatures the significant contributions to the entropy are the translational and rotational motions. In the perfect gas the entropy is an extensive quantity and $(\partial S/\partial n)_{p,T}$ and $S(p,T)/n$ are identical. The conventional entropy equations thus give the differential entropy directly. The three-dimensional translational entropy is given by the Sackur-Tetrode equation, which after inserting all the constants, is

$$_3S_{tr} = 11.44 \log T + 6.33 \qquad [4]$$

for one mole of ideal water vapor at 1 atm. The results range from 34.7 to 36.4 e.u. The three-dimensional rotational entropy is given by

$$_3S_{rot} = \frac{3}{2}R + R \ln \frac{8\pi^2}{\sigma h^3} (8\pi^3 ABC)^{1/2} (kT)^{3/2}$$

where A, B, C are the moments of inertia and σ the symmetry number. For a water molecule $\sigma = 2$ and A, B, C are (10) 1.024, 1.920, and 2.947 x 10^{-40}g cm^2. After inserting all the constants the result is

$$_3S_{rot} = 6.86 \log T - 6.59 \qquad [5]$$

giving 10.4 to 11.4 e.u.

The model of the adsorbed film must be less exact. If it is perfectly mobile its rotational freedom remains essentially unrestricted; in place of three-dimensional translation there will be a restricted two-dimensional translation plus a weak vibration. For the differential entropy of the former Law (11) gives an equation which is equivalent to

$$_2\bar{S}_{tr} = R \ln \left[\frac{2\pi mkTa_o e}{h^2} \left(\frac{1-\theta}{\theta} \right) + 1 \right]$$

where a_o is the area occupied by an adsorbed molecule, here taken as 10.8 x 10^{-16} cm^2 for water. The expression reduces to

$$_2\bar{S}_{tr} = 4.58 \log \left[1.73T \left(\frac{1-\theta}{\theta} \right) + 1 \right] \qquad [6]$$

giving values ranging from 13.8 to 21.2 e.u. over the coverages and temperatures used.

The molar vibrational entropy per mode is given by

$$S_{vib} = \frac{Rx}{e^x - 1} - R \ln (1 - e^{-x}) \qquad [7]$$

where $x = hc\omega/kT = 1.439\ \omega/T$, with ω the vibration frequency in cm^{-1}. For ordinary chemical bonds with vibration frequencies in the infrared, say 1000-5000 cm^{-1}, x is of such size that S_{vib} is negligible. Unfortunately this is not true of the weak bond of a mobile film and the entropy can only be estimated roughly. On rather tenuous evidence (12) 3 e.u. will be assigned to $_2\bar{S}_{vib}$.

With a completely localized adsorbate all the entropy associated with the 3-dimensional translation will disappear. Most of $_3S_{rot}$ of 10-11 e.u. also will disappear, but there will remain the rotation of the hydrogen atoms around the axis passing through the oxygen atom and the center of mass, since it is probably the oxygen which is most closely bonded to the silica surface. The value of 2-3 e.u., depending on temperature, will be assigned to $_0\bar{S}_{rot}$.

For localized adsorption $_3\bar{S}_{vib}$ can be neglected. If the bond is like an OH bond ($\omega \sim 3500$ cm^{-1}) Eq. [7] gives $S_{vib} << 0.01$ e.u. If attachment is by an Si-O bond ($\omega \sim 1100$ cm^{-1}) the associated entropy is 0.2 e.u.

Finally there remains a configurational entropy term arising out of the fact that on a partially covered surface there are many ways to distribute the adsorbate molecules among the available surface sites. $\bar{S}_{config.}$ may be readily derived statistically by considering a system composed of n molecules and m sites (m a constant) so that $n/m = \theta$. The number of ways in which the m sites may be arranged into two groups of n occupied sites and $(m\text{-}n)$ empty sites is $m!/(m\text{-}n)!n!$ and the molecular entropy is $S = k \ln \dfrac{m!}{(m\text{-}n)!n!}$. The use of the Stirling approximation, followed by differentiation with respect to n, leads to

$$\bar{S}_{config} = 4.58 \log \left(\frac{1-\theta}{\theta} \right) \qquad [8]$$

with values of 8.1-1.4 e.u. over the coverages studied.

Thus for the localized adsorption model

$$-\Delta\bar{S}_a = {}_3S_{tr} + {}_3S_{rot} - {}_0\bar{S}_{rot} - \bar{S}_{config} \qquad [9]$$

whereas for mobile adsorption

$$-\Delta\bar{S}_a = {}_3S_{tr} - {}_2\bar{S}_{tr} - {}_2\bar{S}_{vib} \qquad [10]$$

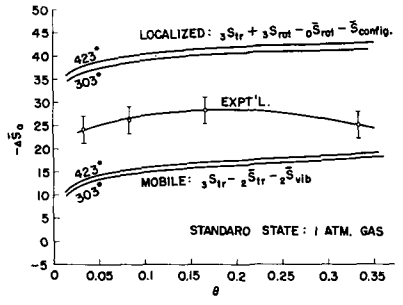

Fig. 5. Comparison of experimental values of $\Delta\bar{S}_a$ with those computed for extreme cases of fixed and mobile adsorbed film.

Values thus computed are nearly independent of temperature, so Eq. [9] and [10] are plotted *vs.* θ in Fig. 5, together with the experimentally determined $\Delta\bar{S}_a$ from Table II. It is evident that at coverages of 2-30% the adsorbed water on MPG is intermediate in nature between the two extreme models. The water molecules execute many vibrations in place, but presently they do hop to a neighboring site. There is some indication of greater mobility at coverages > 25%.

Law (11) found $\Delta\bar{H}_a = -14$ kcal mole^{-1} for the first layer of water on GeO_2 at ~300°K, and from entropy considerations he concluded that the adsorption was localized. For the multilayer region, however, the $\Delta\bar{H}_a$ fell toward −10 and the film, as expected, became mobile. At 30°C a monolayer of water on GeO_2 is completed at about 4 torr, at which MPG is only half covered. It is reasonable to conclude that dry MPG enclosed in a container with a GeO_2 surface cannot prevent the adsorption of some water vapor by the GeO_2 but definitely should prevent the formation of a film of water in which the molecules are mobile. Very probably a porous glass getter cannot hold surface recombination velocity at the optimum, nor can it prevent channel formation; but it should not permit any ionic conduction across the surface. This alone may be sufficient explanation for the improved performance of MPG-gettered devices, since without such a getter multilayer adsorption is easily possible.

Kinetics

In establishing the adsorption isotherms frequent readings of the weight change with time were made to study the approach to equilibrium, with the combination of low temperature (30°) and low pressure (~0.005 torr) being the slowest. Half the ultimate adsorption is reached in the order of ten per cent of equilibrium time. With gases other than water vapor present, *e.g.*, as in a device encapsulated in nitrogen, oxygen, etc., equilibrium will be reached much more slowly. In air at 1 atm, 25°C with p_{H_2O} = 1.2 torr (5% r.h.), MPG reaches equilibrium $x/m \sim 0.025$ in a week, with half the pickup occurring the first day.

Figure 6 presents typical data on the approach to equilibrium. Here the curves have been normalized by plotting θ/θ_{eq}, the fraction of the equilibrium coverage reached in time t. The curves are linear up to $\theta/\theta_{eq} = 0.75$. It is evident that the rate of approach to equilibrium is more sensitive to ambient

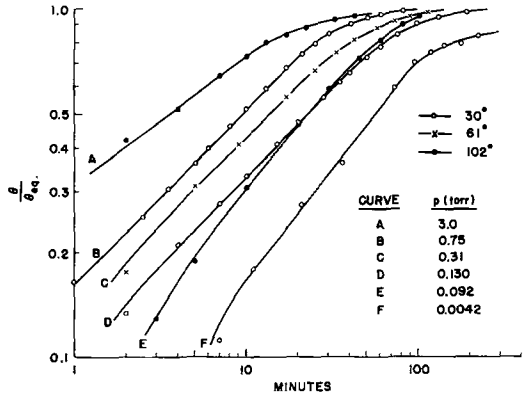

Fig. 6. Rate of approach to equilibrium during adsorption

pressure than to temperature; for example, curves D and E, which nearly coincide, are from runs 72° apart but with nearly the same pressure. Adsorption at higher temperatures does reach equilibrium somewhat sooner, but this is due almost entirely to more rapid approach above $\theta/\theta_{eq} = 0.8$.

There is some deviation from linearity in Fig. 6 at low coverages and low pressures. This probably reflects the heating effect of the initial rapid adsorption; heat transfer to the surroundings would be delayed not only by the low pressure but by the low thermal conductivity of MPG. For a typical case it was calculated that the heat liberated during the first minute of adsorption was sufficient to raise the entire adsorbent 3°, and doubtless even higher at the gross surface where the initial adsorption occurs.

It has been possible to find a general equation for the approach to equilibrium in much the same way as for the equilibrium isotherms. The slopes of the straight portions of the log-log plots are close to 0.5. If

$$\log \frac{\theta}{\theta_{eq}} = 0.5 \log t + \log k \qquad [11]$$

k may be determined for each run by observing t at some suitable θ/θ_{eq}. A temperature-independent relationship between k and pressure is shown in Fig. 7, where

$$1/k = 5.60 - 3.85 \log p$$

Then $\theta/\theta_{eq} = (x/m)/(x/m)_{eq} = t^{0.5}/(5.60 - 3.85 \log p)$, with t in minutes, p in torr, with no other gas present.

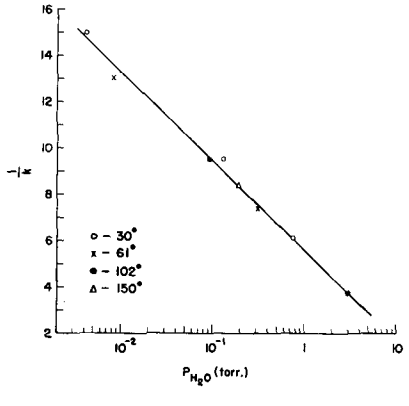

Fig. 7. Relation between k of Eq. [11] and pressure

Finally $(x/m)_{eq}$ from the general isotherm equation may be substituted, resulting in an equation of the form

$$\frac{x}{m} = \frac{Ae^{B/T}p^{C}t^{0.5}}{D - E\log p}, \quad 0.8 > \theta/\theta_{eq} > 0.1$$

with A, B, C, D, E all known constants. (D and E may change with getter geometry.) The equation states that at given conditions of pressure and temperature the cumulative weight gain $x/m = k_1\sqrt{t}$ and the rate of moisture pickup $\dfrac{d(x/m)}{dt} = k_2/\sqrt{t}$.

The treatment outlined above is not so successful for desorption. While the curves do have linear portions with similar slopes, the range of such correlation is limited not only in θ/θ_{eq} but in temperature also. Equilibrium is approached more slowly during desorption, probably because the activation energy for desorption is higher than that for adsorption.

Effect of Activation Conditions

When MPG which has been standing in room atmosphere is put into an oven a large part of the adsorbed water comes off in a rush during the first minute or two. Desorption continues, at a slower and slower rate, over a long period; the process may be accelerated by pumping. Desorption by vacuum bakeout has been followed up to 24 hr with the silica spring balance, but weight loss continues. There is no clearly definable point where it may be said that the MPG is "completely dry" or that it has been activated to a degree where no further treatment will improve its adsorptive capacity. It is generally believed that water can be liberated from silica surfaces in two ways: by desorption of physically adsorbed molecules and by interaction of adjacent silanol groups; but with MPG the two kinds of desorption apparently cannot be distinguished by weight changes.

The progress of vacuum desorption from the end of the first hour onward is shown in Fig. 8. An Elovich-type equation is followed: the weight loss is linear with log time (13). Such behavior usually is considered characteristic of chemisorption. Doubtless much of the water removed above 200° is chemically bound, *i.e.*, from SiOH groups, and largely irreversible, as will be shown; but it is still believed

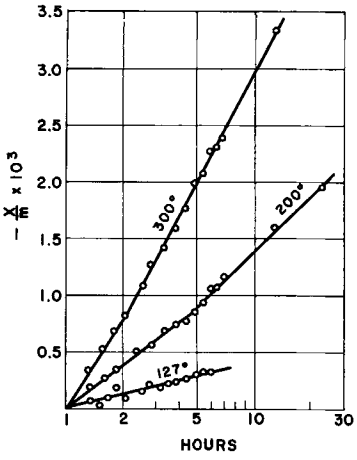

Fig. 8. Vacuum activation rates

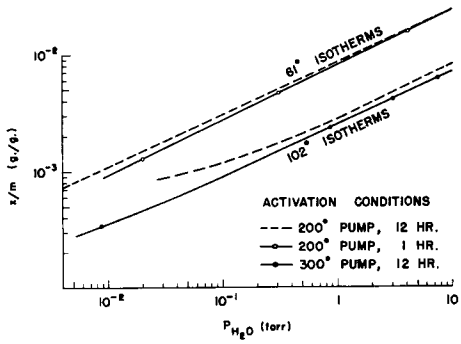

Fig. 9. Effect of vacuum bakeout conditions

that in MPG the rates are diffusion-controlled, and that the curves of Fig. 8 are more of practical rather than theoretical interest.

All the studies up to this point have employed 200° 12-hr vacuum activation. It remains to justify this choice, and also to investigate the effect of other activation conditions. The criterion is again the adsorption isotherm.

Two sets of experiments on pumping temperatures and times are summarized in Fig. 9. The dashed lines for the standard activation are taken from Fig. 3. When the pumping time is cut from 12 hr to 1 hr the 60.8° isotherm falls short of the standard one by a small and constant amount of $x/m = 0.3 \times 10^{-3}$. (On the log scale the isotherms appear to converge.) This is interpreted to mean that at 200° one hour is not sufficient to remove all the physically adsorbed (reversible) water. A few tenacious sites are still occupied, and the moisture pickup at a given pressure is then this much less.

Since the question now arises whether even the 12-hr activation is the optimum, a 300° 12-hr pump was next tested. Under these conditions removal of some chemically bound water is likely, but the literature is in conflict on the conditions and time required to reverse this reaction. To allow more opportunity for any rehydration to occur the 102° isotherm was determined for this activation. It is seen in Fig. 9 that a definite decrease in adsorptive capacity has occurred, and this time it is a constant proportion instead of a constant amount. The difference is about 12% and increases at $\theta < 0.02$. Here the inference is that some of the adsorption sites, and a disproportionate number of the more energetic ones, have been permanently removed. With this activation there was an irreversible 0.6% weight loss, [exactly the amount predicted (14) for amorphous silica from aquasols] whereas with 200° activation the getters showed essentially no dry basis weight change. While 300° activation is clearly deleterious, in all probability it could be tolerated if the time is restricted to an hour or less.

Experiments on the effect of dry nitrogen activation are summarized in Fig. 10. The dashed line is again the standard 60.8° isotherm from Fig. 3. The gas contained 8 ppm H_2O, at which the equilibrium adsorption at 61° is 0.87×10^{-3}. If this amount is subtracted from the isotherm over the entire range the dotted line results. This is the isotherm which would be predicted if (*a*) the gas flush activation is as effective as the standard one, and (*b*) after the activa-

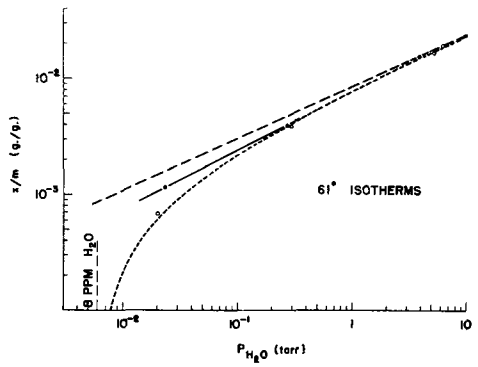

Fig. 10. Effect of hot gas activation. —— —— standard 200° 12 hr vacuum activation; -------- same, minus equilibrium adsorption at 61° from 8 ppm flushing gas; ○, *N* flush, 8 ppm H_2O, 200°, 12 hr, equilibrated with flushing gas at 61°; ●, *N* flush, 8 ppm H_2O, 300°, 30 min, incompletely equilibrated with flushing gas.

tion the MPG is permitted to come to equilibrium with the gas at the temperature at which the isotherm is determined. With the 200° 12-hr flush this latter requirement was met by allowing the getters to stand overnight in the gas before measurement. The resulting isotherm follows the predicted one closely. Thus condition (*a*) above is presumed true; nevertheless, a substantial loss in capacity at low pressures has resulted. This shows the folly of storing activated MPG at room temperature in dryboxes, which are usually far above 8 ppm moisture.

The 300° 30-min gas flush activation, shown also in Fig. 10, is a practical semiconductor device processing step. Here readsorption of moisture from the flushing gas was prevented as far as possible; the oven surrounding the sorption balance was cooled from 300° to 61° in 1½ hr and the isotherm measurements begun immediately. There is again a constant, but smaller, difference in the adsorptive capacity, since some readsorption cannot be avoided. However, in apparatus where the getters can be removed quickly from the activation chamber into sealed containers, or encapsulated immediately in devices, the 300° 30-min dry gas flush should be a quite satisfactory activation.

In all the gas flush experiments, the velocity of the nitrogen past the getters was about 20 cm/min. A higher velocity is desirable for the first few minutes if exposed getters are introduced into an oven already at temperature, to carry off the large initial burst of water vapor. Wet MPG should first be dried in a 150° air oven before any activation procedure.

The relative insensitivity of the 61° adsorption isotherm to the duration of 200° activation is significant. The adsorption is perfectly reproducible whether the sample has had one activation or three, even though the weight change continues in accord with the curve in Fig. 8. Between the end of the first and the twelfth hours of pumping a weight loss of 1.6×10^{-3} g/g occurs; yet the difference in the adsorption isotherms is only 0.3×10^{-3}. Water of constitution, *i.e.*, within the solid phase, cannot be removed at 200°; neither can the weight loss be due entirely to physically adsorbed water persisting past the first hour, since these tenacious sites would be the first to readsorb and the weight loss would be reversible. The 0.3×10^{-3} difference is ascribed to this kind of water, but the remainder can only represent silanol dehydration. A weight loss of 1.3×10^{-3} g/g represents removal of one hydroxyl in twenty, and if these hydroxyls were sites of physical adsorption of water molecules (by hydrogen bonding) the effect on the adsorption isotherm should be quite detectable at higher pressures. The absence of such an effect shows that the first hydroxyls to be removed are not adsorption sites, and indeed other work in these Laboratories has indicated that the MPG surface must be almost half dehydrated before moisture adsorption is significantly lower.

The futility of prolonged vacuum activation is thus demonstrated. The same is true of 200° dry gas activation, where both the weight loss over the second through twelfth hours (1.5×10^{-3} g/g) and the adsorptive capacity are virtually identical to those for vacuum activation. It is evident that the 200° 12-hr pump is the most effective activation procedure of all those tried, but any of the others can approach it with proper handling. Careless exposure first degrades the adsorption capacity at low equilibrium pressures, where device behavior may be very sensitive to moisture level. By and large there is no reason to believe, either from work reported here or from life-testing, that activation conditions are critical in the application of MPG to moisture gettering in devices.

Manuscript received Nov. 21, 1961; revised manuscript received Jan. 18, 1962. This paper was prepared for presentation before the Detroit Meeting, Oct. 1-5, 1961.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1962 JOURNAL.

Etching of Abraded Germanium Surfaces with CP-4 Reagent

E. N. Pugh and L. E. Samuels

Department of Supply, Australian Defence Scientific Service,
Defence Standards Laboratories, Sydney, New South Wales, Australia

ABSTRACT

The dissolution of the damaged layer has been investigated by a metallographic taper-sectioning technique and by direct microscopical examination of the etched surfaces. It is shown that the reagent penetrated the damage cracks in abraded surfaces opening them into deep crevices. At the same time, the surface begins to be smoothed out, a characteristic cellular pattern being produced. A completely flat surface is not achieved until well after the damaged layer is removed. A critical comparison of certain methods of estimating the depth of the damaged layer is made in the light of these observations. It is concluded that metallographic methods are the most reliable.

A recent metallographic study established that the damaged layer in abraded germanium surfaces contains numerous cracks and that these cracks in fact constitute the damage; it also established that high densities of dislocations are not present (1). In practice, the damaged layer in semiconductor devices is removed by chemical etching, so that it was considered of interest to investigate the effects of the cracks on this dissolution process. Such a study is also desirable to investigate further the discrepancy found in the earlier work between the metallographic measurements of the depth of damage and values obtained by the photomagnetoelectric (PME) method developed by Buck and McKim (2).

Experimental Methods

The investigations were carried out on {111} surfaces of n-type germanium abraded unidirectionally, by hand, with silicon carbide abrasives. Most of the work was carried out with 220-grade abrasive, but experiments with other grades confirmed that the results had general application. The abrasives were used both in papers, using flowing water as lubricant, and in a water slurry on a glass plate. The abraded specimens were etched for various times with CP-4 reagent,[1] the etching being confined to rectangular areas, 1.0 x 0.5 cm, by protecting the remainder of the abraded surface with a suitable lacquer coating. In each case, an estimation of the depth removed was made by the standard weight-loss method.

After preliminary examination under the microscope, the surfaces were taper sectioned at a nominal angle of 5° 43′ (taper ratio 10 : 1), the section line being made approximately perpendicular to the direction of abrasion. During sectioning, the surface was protected by means of electrodeposited nickel coatings. The sectioned surfaces were polished metallographically and examined under the microscope. The sections showed two regions corresponding to the unetched abraded surface and the etched surface, respectively. The depth removed by etching could therefore also be estimated from the displacement of the section line between the two regions, measured by means of a travelling microscope. These measurements were made from the crests of the surface irregularities in both the unetched and etched regions, the preferentially attacked area immediately adjacent to the unetched portion of the surface being ignored.

[1] 50 ml nitric acid (69%), 30 ml acetic acid (100%), 30 ml hydrofluoric acid (48%), and 0.6 ml bromine.

Metallographic Observations

Examination of the taper sections.—The taper sections of lightly etched surfaces indicated that the CP-4 reagent penetrated rapidly along the cracks in the damaged layer. Etching was uniform over the contact area resulting in widening of the cracks and rounding of their tips (Fig. 1). Once the most severely shattered portions of the damaged layer had been removed, the surface irregularities began to smooth out. A typical sequence for a surface treated with abrasive papers is shown in Fig. 2-5; allowing for the initial difference in the distribution of the

damage cracks (1), the behavior of surfaces abraded with a slurry was similar. The surface is still not completely smoothed even when the damaged layer has been removed completely (Fig. 5).

Direct examination of the etched surfaces.—Three distinct features were observed when successively etched surfaces were examined directly by optical microscopy, namely, cracks, a cellular structure, and etch pits.

Cracks.—In the early stages of etching, the cracks appeared as dark markings which mostly lay in directions consistent with their being {111} cleavage traces (Fig. 6 and 7). As expected from the earlier work (1), the cracks in surfaces abraded with abrasive papers formed regular patterns in the abrasion direction (Fig. 6-8). Those in surfaces abraded with an abrasive slurry were randomly arranged (Fig. 10-12). Further etching caused the cracks to broaden (cf. Fig 6 and 7), but they were still recognizable immediately before complete removal (Fig. 8 and 12).

The identification of the cracks at the early stages of etching was difficult because they tended to be obscured by the background structure. Indeed, Faust (3) was unable to distinguish them in a similar type of experiment. Their identification here was greatly assisted by the prior knowledge obtained from the examination of taper sections of the surfaces. Their presence was also confirmed by metallographically polishing the abraded surfaces until all the surface chipping had been removed, the surface subsequently being etched with CP-4 reagent as before. The confusing background did not then develop and the broadened cracks stood out clearly.
